
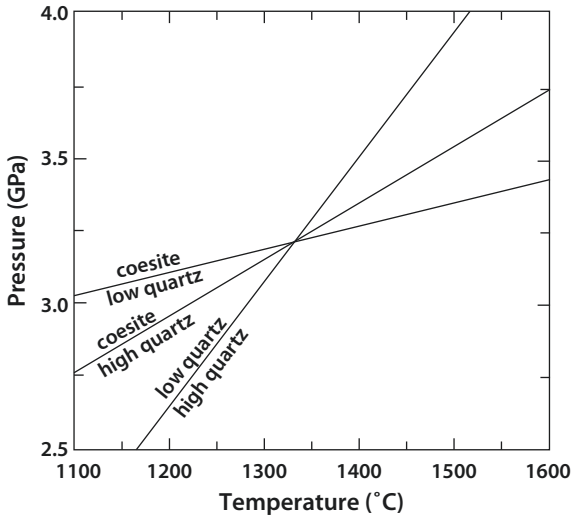
Phase Equilibria, Fig. 15 Example of the arrangement of univariant curves about an invariant point in a ternary system with a degeneracy wherein three phases are colinear in composition space



Phase Equilibria, Fig. 16 Phase relationships calculated with TWQ program of Berman, using database of Berman (1988)

Calculation of Phase Equilibria

With the recent progress in establishing internally consistent thermodynamic databases (Helgeson et al. 1978; Berman 1988; Holland and Powell 1990), it has become feasible to calculate phase equilibria with (often) good precision. There are two approaches to this problem. The first is to minimize the free energy of the entire system, exploring all possible phases. The second, more relevant to calculation of phase equilibria specifically, is to calculate $\overline{G}$ as a function of P and T for each phase or the ΔG for the reaction of interest. For example, for the reaction):

$$\mathrm{SiO_2(low\ quartz)} = \mathrm{SiO_2(high\ quartz)}$$

the ΔG for the reaction is the difference between the free energies of the product and reactant. The derivative form of the relevant equation for a single component system is:

$$d\Delta G = \left(\frac{\delta \Delta G}{\delta T}\right)_P dT + \left(\frac{\delta \Delta G}{\delta P}\right)_T dP \qquad (2)$$

Substitution of -ΔS and ΔV for the two derivatives in eq (2) and integrating yields:

$$\Delta G(P,T) - \Delta G\left(P_{ref}, T_{ref}\right) = \int_{T_{ref}}^{T} -\Delta S dT + \int_{P_{ref}}^{P} \Delta V dP \qquad (3)$$

The first integral may be expressed in terms of heat capacities because of the relationship between heat capacity and entropy:

$$\frac{\Delta C_p}{T} = \left(\frac{\delta(\Delta S)}{\delta T}\right)_P \qquad (4)$$

Substitution of the integral form of eq (4) into eq (3) yields:

$$\Delta G(P,T) - \Delta G\left(P_{ref}, T_{ref}\right) = -\int_{T_{ref}}^{T} \left(\Delta S + \int_{T_{ref}}^{T} \frac{\Delta C_p}{T} dT\right) dT + \int_{P_{ref}}^{P} \Delta V dP \qquad (5)$$

These data are provided by the internally consistent thermodynamic databases now available. As an example, application of Berman's (1988) database to phase relationships in the SiO_2 system yields the results in Fig. 16. The point of intersection of the three curves corresponds to point C in Fig. 11, but all three curves proceed straight through this point, rather than terminating at it, because both stable and metastable equilibria have been calculated in Fig. 16. In order to determine the correct array of curves around the invariant point, we need to apply Schreinemakers' analysis to these calculated curves. Doing so, by the analysis outlined previously, yields the arrangement of curves illustrated schematically in Fig. 11.

Summary

The study of phase equilibria is essential to much of petrology and geochemistry. The ability to analyze phase stabilities graphically provides a powerful tool in constraining natural systems. The recent progress in formulating internally consistent thermodynamic databases has not eliminated the need

for the ability to analyze a phase diagram, differentiate between stable and metastable equilibria, and ensure that the phase diagram is thermodynamically valid.

Institute of Earth Sciences, University of Lausanne, Lausanne, Switzerland

Element Data
Atomic Symbol: P
Atomic Number: 15
Atomic Weight: 30.97 g/mol
Isotopes and Abundances: ^{31}P (stable, 100%), radioactive isotopes from ^{24}P to ^{46}P, with ^{32}P (short-lived; half-life = 14.3 days) and ^{33}P (short-lived; half-life = 25.4 days) being the longest-lived ones

(*continued*)

1 Atm Melting Point: 44.1 °C
1 Atm Boiling Point: 280 °C
Common Valences: +5, +3, +2, +1, −2, −3
Ionic Radii: 2.12 Å (−3) and 0.29 Å (+5)
Pauling Electronegativity: 2.19
First Ionization Energy: 1012 kJ/mol
Chondritic (CI) Abundance: 926 ppm
Silicate Earth Abundance: 90 ppm
Crustal Abundance: 1120 ppm
Seawater Abundance: 0.06 ppm
Core Abundance: 2000 ppm

Properties, Origin, and Behavior

Elemental phosphorus is known in four allotropic varieties – white or yellow, red, violet, and black P, with different specific densities (1.82 g/cm^3, 2.34 g/cm^3, 2.36 g/cm^3, and 2.69 g/cm^3, respectively). Elemental phosphorus is highly reactive in the presence of oxygen, ignites and starts to luminescence ("phosphorescence": white phosphorus), hence its name, which literally means "carrier of light." Phosphorus does not occur in elemental form under natural conditions and is always present in oxidized form as phosphate. Its cosmic origin is related to neutron capture on silicon in neon-burning shells within massive stars (>8 solar mass) and also in carbon- and neon-burning layers during supernova explosions (Koo et al. 2013). Within the solar nebula phosphorus represents a relatively volatile element and chondritic meteorites display different degrees of phosphorus depletion (Wolf and Palme 2001). As a lithophile element, phosphorus behaves in an incompatible way during the early crystallization of basaltic magmas, due to its high solubility in melts, the partition coefficient between phosphorus and melt being smaller than 1 (Toplis et al. 1994). Once apatite and other phosphate minerals have formed, phosphorus behaves in a compatible way. On the Earth's surface, under natural conditions, the weathering of phosphate-containing minerals and rocks is the prime source of phosphorus to the biosphere.

History and Use

In 1669, H. Brandt (Hamburg) extracted phosphorus from a mixture of sand and urine, in his search of the philosopher's stone. In 1777, A. Lavoisier classified phosphorus as an element. In 1838 or 1839, W. Buckland showed the sedimentary phosphate-rich deposits of southern England to J. Liebig, who advertised their use as a source of fertilizers. In 1842, J. Lawes dissolved sedimentary phosphate in H_2SO_4 in order to produce a soluble fertilizer (Föllmi 1996). In the following, igneous and

sedimentary phosphate-rich occurrences and guano deposits were and are still increasingly used as a source of phosphate in the production of fertilizers. Besides that, phosphorus is used in the production of food additives, detergents, pesticides, and steel alloys. ^{32}P is applied as a radionuclide tracer.

Geochemistry and Occurrence

Phosphorus occurs in the form of phosphate-bearing minerals in igneous, metamorphic, and sedimentary rocks, and sediments (Fig. 1). It is also part of organic complexes, which may be preserved in the sedimentary reservoirs. Phosphate minerals principally belong to the apatite group $Ca_5(PO_4)_3(OH, F, Cl, CO_3)$ (Filippelli 2008). Non-apatite phosphate-containing minerals such as Whitlockite are comparably rare. In igneous rocks, fluorapatite is concentrated in carbonatites and silica-poor alkali intrusions, which are actually exploited in Russia, Finland, Brazil, and South Africa (Pufahl and Groat 2017). The igneous deposits can be as old as Palaeoproterozoic but mainly date from the Phanerozoic. In sedimentary deposits, the principal phosphate-bearing mineral is francolite – a carbonate fluorapatite (Jarvis et al. 1994). The most important regions in which sedimentary phosphate deposits are presently mined are located in China, Morocco, the United States, Jordan, Egypt, Peru, Tunisia, and Israel, in decreasing order of importance. The sedimentary reservoirs were preferentially formed during the late Neoproterozoic and Early Cambrian, Ordovician, Permian, Jurassic and Late Cretaceous, Paleocene, Late Oligocene, and Miocene (Cook and McElhinny 1979). Ninety-five percent of all exploitable reserves are sedimentary in origin, whereas the igneous occurrences represent the remaining 5% (Pufahl and Groat 2017). World reserves are estimated at more than 300 Gt and world phosphate rock production is projected to increase from 223 Mt/year (2015) to 255 Mt/year (2019) (U.S. Geol. Survey 2016).

Phosphorus, Fig. 1 Example of a sedimentary phosphatic deposit: a nodular phosphatic layer is preserved in an open-marine, deeper-water micritic carbonate. The dark phosphatic particles and nodules partly consist of broken and transported remains of fossils, such as ammonites; Albian (Cretaceous), Helvetic thrust-and-fold zone, Interlaken, Switzerland

Biological Utilization and Toxicity

In the form of phosphate, phosphorus represents an element essential for life, which is considered to determine primary productivity rates on geological time scales (Tyrrell 1999: Filippelli 2008). As such, its cycle is directly linked to the cycles of other biophile elements, notably those of carbon and oxygen. This implies that one molecule of phosphate may drive the transformation of over 100 CO_2 molecules into organic matter in marine planktonic ecosystems (Redfield 1958). In terrestrial ecosystems, the C:P transformation ratio may exceed 500 (Berner et al. 1993). It is mainly in this capacity that phosphorus is exploited, and its use as constituent of fertilizers is an important factor in feeding the ever increasing human population (Childers et al. 2011). The obvious side effect is the human-induced increase in phosphorus flux rates and notably the transfer of phosphorus to the oceans has been more than doubled in the last 75 years (Harrison et al. 2005). Eutrophication related to phosphorus overloading affects terrestrial, lacustrine and marginal marine ecosystems (Föllmi 2011). This has also a considerable impact on the oxygen households of lacustrine and marginal marine waters, leading to their depletion and the installation of so-called dead zones (Diaz and Rosenberg 2008).

Summary

Phosphorus is an element with unique characteristics, which does not only allow to trace important processes during the formation of the solar nebula and within our Earth but also to link phosphorus to important processes in the biosphere. Through its capacity as an essential element for life, it interfaces directly with the cycles of other biophile elements, such as carbon and oxygen. This to a degree that primary productivity rates and the oxygenation of the atmosphere and hydrosphere are often held to be directly dependent on the amount of phosphorus available. The use of phosphorus in fertilizers is one of the building blocks behind the "green revolution," allowing to feed an ever increasing population, but has also induced eutrophication in terrestrial and marine environments, with a negative impact on life's diversity and aquatic oxygen households. Global phosphorus resources are limited and as a nonrenewable element, mitigation pathways are presently more and more investigated in order to promote the sustainable use of this element.

Definition

Atomic number 78 is a dense, refractory, precious metal with a bright silvery-white luster and high resistance to oxidation. First isolated in 1757, it is widely used in jewelry production and catalytic converters in automobiles.

History and Uses

The material referred to as "platina," derived from the Spanish for "little silver," was first described to the Royal Society of London by William Watson in 1750. These were samples likely derived from placer deposits of the Choco District of Columbia, which had been exploited by the pre-Hispanic natives to produce jewelry and useful objects (fishing hooks, sewing needles, awls, tweezers). Subsequent analysis by William Lewis determined this to be a new-found material and that ". . ..it follows, that platina is not, as some believe, gold naturally debased by the admixture of some other metallic body, but a metal of the peculiar kind, essentially different

from all others" (Lewis 1757). Platinum is a highly-valued metal due to its high melting point, resistance to oxidation, and catalytic properties. Most Pt is used to catalyze key reactions involved in hydrocarbon fuel production (reforming and isomerization to enhance octane rating) and in automobile catalytic converters for engine emission control. A nearly equivalent amount of Pt is also used for jewelry. High thermal stability and resistance to corrosion makes Pt an ideal material for laboratory ware (i.e., crucibles), thermocouples, and electrical contacts. Other important applications are in health care, owing to the biocompatibility of Pt, including applications in angioplasty and implanted medical devices. Cisplatin (cis-Diamminedichloroplatinum[II]; cis-[Pt(NH3)2Cl2]) and its derivatives are drugs used in the treatment of ovarian and testicular cancer. A detailed account of the history of platinum, including important discoveries and scientific work, can be found in the book "*History of Platinum and its Allied Metals*" by McDonald and Hunt (1982).

Elemental and Physical Properties

Platinum has an atomic weight of 195.084[9], ground state electronic configuration of $[Xe]4f^{14}5d^{9}6s$, with melting and boiling points at 0.1 MPa of 1768.2 °C and 3876 °C, respectively (Arblaster 2007). Platinum is amongst the most dense of the elements (21,090 kg/m^3), similar to gold (19,300 kg/m^3) and about twice that of lead (11,340 kg/m^3). Platinum is considered to be a refractory element with a 50% condensation temperature of 1135 °C (Lodders 2003). Platinum has five stable isotopes: 192 (0.782[24]%), 194 (32.864[410]%), 195 (33.775[240]%), 196 (25.211[340]%), 198 (7.356[130]%), as well as the radioactive ^{190}Pt (0.012[2]%), which undergoes alpha-decay to ^{186}Os, with a half-life of 1.4×10^{11} years (see entry for ▶ "Osmium Isotopes"). In addition to the neutral metal, the common oxidation states are 2+ and 4+. The radius of the neutral atom is 177 pm (Clementi et al. 1967), and Pt crystallizes in the cubic close-packed structure (space group Fm-3 m) with a metallic radius of 139 pm (Waseda et al. 1975). The size of the cation varies as follows (from Shannon 1976): 60 pm (+2, IV-fold, square planar), 80 pm (+2, VI-fold), 62.5 pm (+4, VI-fold), and 57 pm (+5, IV-fold). Useful texts that provide synopses of the chemical properties of Pt and allied elements can be found in Cotton (1997) and in a compendium of papers edited by Hartley (1991).

Geochemical Behavior and Reservoir Abundance

Platinum is both highly siderophile and strongly chalcophile and is grouped with other 5th and 6th row transition metals having similar chemical properties: Pd, Rh, Ru, Os, and Ir; see entries for ▶ "Platinum Group Elements" (PGE) and ▶ "Siderophile Elements". Experiments have shown that Pt does not readily dissolve into rock-forming minerals, such as olivine and chromite (Brenan et al. 2016), but instead concentrates in base metal sulfides or forms accessory platinum group minerals, such as platinum-bearing telluride ($PtTe_2$; moncheite) or arsenide ($PtAs_2$; sperrylite), native metal, or alloyed with iron (Pt_3Fe, PtFe; isoferro- and tetraferroplatinum, respectively) and other platinum group elements (PGE). An extensive compilation of platinum-bearing minerals is provided in Cabri (2002).

The abundance of Pt in the carbonaceous chondrite Orgueil is 866.8 ng/g (Horan et al. 2003), taken as similar to the bulk earth concentration, which has now been highly fractionated into the core (5700 ng/g; McDonough 2003), upper mantle (7.6[1.3] ng/g; Becker et al. 2006), and crust (continental: 1.5 ng/g; Rudnick and Gao 2003; oceanic: 2.072 ng/g; Peucker-Ehrenbrink et al. 2012). The relative proportions of the PGEs are close to chondritic in the upper mantle (Becker et al. 2006) as well as higher and relatively unfractionated than expected for equilibrium between metal and silicate (Mann et al. 2012). Many believe this is the result of late accretion of chondritic materials following core formation. The platinum content of seawater (0.2–1.5 pmol/kg) is similar to that of the heavy rare-earth elements (Bruland and Lohan 2003), although the crustal abundance of Pt is >100x lower. Calculations indicate that the dominant Pt species in seawater is $[PtCl_4]^{2-}$ at 25 °C, pH 8.2, 0.1 MPa (Byrne et al. 1988).

Coupled enrichments in ^{186}Os/^{188}Os (due to ^{190}Pt decay) and ^{187}Os/^{188}Os (due to ^{187}Re decay) are observed in lavas formed in mantle plumes, such as Hawaii. The origin of this variation is debated and variously interpreted as recording outer core "reflux" into the mantle (Brandon et al. 1998), contamination of the magma source by certain rare sediment types (Scherstén et al. 2004) or eclogite (Luguet et al. 2008), or the presence of residual accessory minerals with elevated Pt/Os and Re/Os (Luguet et al. 2008). Carlson (2005) provides a comprehensive review of the use of the Pt-Re-Os isotopic system in geochemistry and geochronology.

Economic concentrations of Pt require >10,000-fold enrichment relative to crustal background values. This can occur when mantle-derived magmas reach saturation in immiscible sulfide liquid, or by accumulation of Pt-rich accessory minerals, or through the action of hydrothermal fluids. The largest Pt deposits are found in the Bushveld Igneous Complex of South Africa, occurring in chromitite (UG2 and Platreef) and pegmatoidal norite (Merensky Reef) horizons. Other important resources include the Norilsk (Russia), Sudbury (Canada), and Stillwater (USA) deposits. Global production in 2015 was ~160,000 kg, at an average market price of ~ $40,000/kg. The reader is referred to Platinum Metals Review, which

provides a range of technical and historical information on the allied platinum group metals.

Summary

Platinum is a bright, silvery-white precious metal characterized by high density and melting temperature, resistance to oxidation, and unique surface catalytic properties. The principal uses for this metal are for jewelry, catalysis of industrial processes, such as hydrocarbon refining, as well as automobile engine emission control. Platinum is highly siderophile, as well as chalcophile, and is therefore concentrated in Earth's core, with complementary depletions in the silicate mantle, crust, and surface reservoirs. Anomalously elevated abundances of ^{186}Os, a product of ^{190}Pt decay, in hot-spot related magmas may reflect a contribution of core material to Earth's mantle, although more recent interpretations underscore the possible role of accessory phases with elevated Pt/Os, or contribution from unusual surface inputs to mantle reservoirs. Extreme concentration of Pt relative to crustal background values is needed to produce minable deposits, requiring the massive extraction capacity of immiscible sulfide melts that form in silicate magmas.

Platinum Group Elements

Igor S. Puchtel
Department of Geology, University of Maryland, College Park, MD, USA

Definition

The Platinum Group Elements (PGE: Osmium, Iridium, Ruthenium, Rhodium, Platinum, and Palladium), also known as *platinum group metals and platinoids*, are transition metals located in the d-block of the Periodic Table of Elements (Groups VIII, IX, and X, Periods 5 and 6). The atomic radii of the Os, Ir, and Pt subgroup, caused by the lanthanide contraction of the 4*f* group elements, are similar to those of the Ru, Rh, Pd subgroup of the PGE. The almost doubling of the number of nucleons with the same atomic radii makes Os, Ir, and Pt the densest elements on Earth. Based on their behavior in magmatic systems, the PGE are subdivided into the iridium-group PGE (Ir-PGE: Os, Ir, Ru, Rh) and the palladium-group PGE (Pd-PGE: Pt, Pd) (Barnes et al. 1985; Barnes 1999).

Introduction

The PGE were discovered in the eighteenth through early nineteenth centuries by Lewis (1753, 1757), Tennant (1804), and Wollaston (1805); a detailed account of the history of the PGE can be found in McDonald and Hunt (1982). Studies of PGE abundances, combined with three radiogenic isotope systems that contain the PGE, in terrestrial and extraterrestrial materials, afford a unique view of early Solar System evolution and planet formation and differentiation. Unique chronological applications include dating of formation of sulfides, gold, organic-rich sediments, ultramafic lava flows, and meteorites. Although analytical techniques for precise analysis of PGE have only recently become available, these elements are now an important part of the geochemical toolbox.

PGE Abundances in the Bulk Silicate Earth

PGE have strong affinity for liquid metal and sulfide relative to silicate melt, which determines their both highly siderophile and chalcophile nature (i.e., $D^{\text{metal, sulfide/silicate}} >> 10^4$: Borisov et al. 1994; Borisov and Palme 1995; Fleet et al. 1999; Brenan et al. 2016). The PGE provide unique insights into processes of planetary accretion, core formation, and mantle differentiation. During the initial planetary differentiation and core formation, ~99.8% of the terrestrial PGE budget was sequestered into the core, stripping the mantle almost entirely of PGE. However, the relative abundances of individual PGE in the Bulk Silicate Earth (BSE) are too close to those in chondritic meteorites, and the absolute abundances are two to three orders of magnitude too high, to be the result of the core segregation event. The PGE abundances in the BSE are best explained by addition of 0.3–0.8% of chondritic materials to Earth after the core formation was complete (Morgan 1986; Walker 2009), based on the concept of late accretion (Chou et al. 1983; Morgan 1985). Issues related to the late accretion hypothesis are highly debated, including the time frame within which the late accreted materials were delivered to Earth and homogenized within the mantle, as well as the compositions of late accreted materials (Walker et al. 2015). Other hypotheses that were proposed to account for PGE present in the BSE include inefficient core formation (Arculus and Delano 1981; Jones and Drake 1986) and lowered metal-silicate partition coefficients resulting from metal segregation at elevated temperatures and pressures, as may have occurred at the base of a deep magma ocean (Li and Agee 1996; Righter and Drake 1997). Hybrid models that include aspects of all three hypotheses may ultimately be necessary to account for all of the observed PGE characteristics of the BSE (Walker 2009).

The PGE abundances in the BSE have been determined via analysis of mantle xenoliths and orogenic peridotite samples worldwide (Becker et al. 2006; Fischer-Gödde et al. 2011) to be (ng/g): 3.9 ± 0.5 (Os), 3.5 ± 0.4 (Ir), 7.0 ± 0.9 (Ru), 1.2 ± 0.2 (Rh), 7.6 ± 1.3 (Pt), and 7.1 ± 1.3 (Pd). While Os, Ir, Rh, and Pt occur in broadly chondritic relative abundances in the BSE, the Ru/Ir and Pd/Ir ratios are 20 to 30% higher. The PGE pattern of the BSE is, thus, not exactly matched by any chondrite group. However, it compares well with the PGE compositions of some lunar impact melt rocks formed during the Late Heavy Bombardment event at 4.0 – 3.8 Ga. This may indicate that the composition of late accreted materials is somewhat different from that of the chondritic meteorites residing in our collections (Puchtel et al. 2008; Fischer-Gödde et al. 2011; Sharp et al. 2014; Walker et al. 2015). Great promise for providing genetic fingerprints of late-stage accretionary additions to Earth and Moon is shown by Ru isotopes (Walker et al. 2015). Mass-independent nucleosynthetic isotopic anomalies have been observed in Ru present in whole-rock meteorites and their components (Fujii et al. 2006; Chen et al. 2010; Fischer-Gödde et al. 2015); the nature and magnitude of these Ru anomalies can be used to investigate the stellar origins of matter in the Solar System, as well as nebular mixing processes.

More than 90% of the PGE budget of the BSE resides in two types of sulfides (Alard et al. 2000; Lorand and Alard

2001; Luguet et al. 2007). The high-temperature Os-Ir-Ru-Rh-rich Fe-Ni monosulfide solid solution (*mss*) forms rounded inclusions in olivine, whereas low-temperature irregular-shaped Cu-Ni sulfides occupy intergranular space. During partial melting of mantle peridotite, Cu-Ni sulfides enter the melt, whereas the *mss* remains trapped in the melting residue until the degree of melting reaches *ca.* 25% (Keays 1995), at which point all the sulfide in the residue gets consumed and, as the degree of melting continues to increase, the magma becomes sulfide-undersaturated. As a result, at low degrees of partial melting, the resulting basalts are generally PGE-poor and are strongly enriched in Pd-PGE relative to Ir-PGE. At higher degrees of partial melting, the resulting picrites and komatiites have higher PGE contents and are only slightly to moderately enriched in Pd-PGE relative to Ir-PGE. Therefore, during partial melting of the mantle, Ir-PGE are compatible with the melting residue, although to a different degree, and Pt and Pd are incompatible (e.g., Barnes et al. 1985; Rehkämper et al. 1999; Puchtel and Humayun 2000).

Olivine and chromite are two major liquidus phases controlling composition of mafic and ultramafic magmas during differentiation. At the mantle oxygen fugacities of the FMQ buffer, all PGE are incompatible, although to a different degree, in olivine, and Pt and Pd are also incompatible in chromite, whereas Os, Ir, Rh, and Ru are compatible (Puchtel and Humayun 2001; Brenan et al. 2003, 2012; Puchtel et al. 2004).

PGE-Based Chronometry

Three radiogenic isotope decay systems include the PGE as a parent element ($^{107}Pd \rightarrow {}^{107}Ag$), daughter element ($^{187}Re \rightarrow {}^{187}Os$), or both ($^{190}Pt \rightarrow {}^{186}Os$). A key feature of these systems is that they track the unique behavior of the PGE during planet formation and differentiation and thus, afford information on processes to which other isotope systems, such as lithophile-element based, are not sensitive. Unique chronological applications include dating the formation of mafic-ultramafic lavas and layered intrusions, ore deposits, organic-rich sediments, meteorites, and even inclusions in diamonds. These systems also serve as isotopic tracers for such processes, as crust-mantle differentiation, recycling of oceanic crust into the mantle, core-mantle exchange, deposition of extraterrestrial materials on Earth's surface, and volatile-element depletion of planetary bodies (Walker et al. 1997; Shirey and Walker 1998; Carlson 2005; Walker 2009). Because of the low content in the Earth's crust, PGE are sensitive indicators of presence of extraterrestrial materials in rocks derived from terrestrial impact craters, such as the Chicxulub crater buried underneath the Yucatán Peninsula in Mexico (Gelinas et al. 2004) or Chesapeake Bay impact structure in Virginia, USA (Lee et al. 2006).

PGE Measurements

Due to their high ionization potential, PGE are difficult to ionize. Currently, Os and Ru isotopic compositions and Os concentrations in a variety of terrestrial and extraterrestrial materials are most efficiently measured via negative thermal ionization mass-spectrometry (N-TIMS: Creaser et al. 1991; Völkening et al. 1991), whereas Ir, Ru, Rh, Pt, and Pd concentrations are commonly determined via the inductively coupled plasma mass-spectrometry (ICP-MS) technique (Greenfield 1994). For high-precision measurements of Os and Ru isotopic compositions, the latest generation of thermal ionization mass-spectrometers, *ThermoFisher Triton®*, is being utilized, which allows to attain external precision of analysis of 10–15 ppm for Os and 6–7 ppm for Ru (2SD), based on the long-term reproducibility of the laboratory standards (e.g., Brandon et al. 2006; Puchtel et al. 2009, 2014; Bermingham et al. 2016). High-precision measurements of Ru isotopic compositions are also currently performed by multi-collector ICP-MS with an external precision of ca. 13 ppm (Fischer-Gödde et al. 2015).

PGE Mineral Deposits

The Earth's mantle is the principal reservoir, from which PGE deposits in the crust are derived. PGE mineralization has been identified in various rock types and at various stratigraphic levels in layered intrusions of any age, size, and magmatic lineage, but the most important deposits occur as relatively narrow stratiform reefs in the lower to central ultramafic-mafic portions of large tholeiitic intrusions of late Archean to early Proterozoic age (Maier 2005). In order to form a PGE ore deposit, PGE concentrations need to be raised by more than four orders of magnitude relative to the typical crustal abundances. This level of enrichment can be reached as a result of sulfide saturation and relies principally on the high-extraction capacity of sulfide liquid that sequesters PGE from silicate magmas. The majority of the world's PGE reserves are held in a small number of large deposits, most of which occur within the unique 2.05 billion-year-old Bushveld Complex of South Africa; the latter hosts 75% of the world's resources of Pt, 54% of Pd resources, and 82% of Rh resources (Mungall and Naldrett 2008; Naldrett et al. 2008).

Health Aspects of the PGE

The PGE are used in a number of therapies to enhance public health and well-being. Platinum alloys are essential components of prosthetic teeth and heart implant devices. Anticancer drugs cis-platin, carboplatin, and oxaliplatin are used to treat certain types of malignant tumors.

Environmental Aspects of the PGE

A detailed review of the environmental aspects of PGE is provided by Rauch and Morrison (2008). The PGE are increasingly used in a growing number of applications and ever-increasing emissions result in elevated concentrations of these elements in the environment. Automobile catalytic converters, which use Pt, Pd, and Rh, are the main source of PGE that are emitted into urban and roadside environment. Transport of PGE by stormwater may results in contamination of aquatic environments, where PGE can be present in a bioavailable form. However, currently available data are insufficient for an accurate assessment of associated potential risks.

Summary

The Platinum Group Elements (PGE: Os, Ir, Ru, Rh, Pt, and Pd) are transition metals located in the d-block of the Periodic Table of Elements (Groups VIII, IX, and X, Periods 5 and 6). The PGE have strong affinity for liquid metal and sulfide relative to silicate melt, which determines their both highly siderophile and chalcophile nature; they provide unique insights into processes of planetary accretion, core formation, and mantle differentiation. The PGE abundances in the BSE have been determined via analysis of mantle xenoliths and orogenic peridotite samples worldwide. These abundances are best explained by addition of 0.3–0.8% of chondritic materials to Earth after the core formation was complete (the late accretion hypothesis). Based on their behavior in magmatic systems, the PGE are subdivided into the iridium-group PGE (Ir-PGE: Os, Ir, Ru, Rh) and the palladium-group PGE (Pd-PGE: Pt, Pd). During mantle melting, Ir-PGE are moderately to strongly compatible, whereas Pd-PGE are moderately to strongly incompatible with the melting residue. Three PGE-based radiogenic isotope decay systems track the unique behavior of the PGE during planet formation and differentiation. Unique chronological applications include dating the formation of mafic-ultramafic lavas and layered intrusions, ore deposits, organic-rich sediments, meteorites, and even inclusions in diamonds. These systems also serve as isotopic tracers for such processes as crust-mantle differentiation, recycling of oceanic crust into the mantle, core-mantle exchange, deposition of extraterrestrial materials on Earth's surface, and volatile-element depletion of planetary bodies. The majority of the world's PGE reserves are held in a small number of large deposits, most of which occur within the unique 2.05 billion-year-old Bushveld Complex of South Africa. The PGE are increasingly used in a growing number of applications and emissions result in elevated concentrations of these elements in the environment. However, currently available data are insufficient for an accurate assessment of associated potential risks.

Poisson-Boltzmann Equation

Joan E. Curry
Department of Soil, Water and Environmental Science, University of Arizona, Tucson, AZ, USA

Definition

The Poisson-Boltzmann equation relates the electrostatic potential to the charge density as a function of spatial position in a system of charges. It has broad applicability and is particularly important for understanding the distribution of ions in geochemical systems.

Essential Concepts

The Poisson-Boltzmann equation forms the basis for a continuum understanding of strong electrolyte solutions, electrical double layers at charged surfaces, clay swelling, and colloidal stability, all of which are important topics in geochemistry. Practically it links the charge density and the electrostatic potential (and electric field through the derivative of the electrostatic potential) in a system of charged particles and may include solid surfaces. It is based on the well-known work by Gouy and Chapman, is further developed by Debye and Hückel, and is the electrostatic component of the DLVO (Debye, Landau, Verwey, and Overbeek) theory of colloidal stability, all being foundational work in colloid chemistry in the early twentieth century (see Verwey and Overbeek 1948). Poisson's equation, one of Maxwell's equations, relates the electrostatic potential as a function of position, ψ, to the charge density, ρ, as

$$\nabla^2\psi = -\frac{\rho}{\varepsilon\varepsilon_0}$$

In one dimension:

$$\frac{d^2\psi(x)}{dx^2} = -\frac{\rho(x)}{\varepsilon\varepsilon_o}$$

where the charge density is a sum of the contributions of all ionic species, $\rho(x) = \sum_i z_i e n_i(x)$, and n_i(x) is the concentration of ionic species i. Together with the Boltzmann expression, for each ionic species, $n_i(x) = n_{i\infty}e^{-z_i e\psi(x)/kT}$, we have the Poisson-Boltzmann equation

$$\frac{d^2\psi(x)}{dx^2} = -\frac{\sum_i z_i e n_{i\infty} e^{-z_i e\psi(x)/kT}}{\varepsilon\varepsilon_o}$$

where z_i is the valence of species i, e is the charge on an electron, k is the usual Boltzmann constant, and T is the absolute temperature in degrees Kelvin. $n_{i\infty}$ is the bulk concentration of ions of species i, ε is the dielectric constant of the medium, and ε_o is the usual permittivity of a vacuum.

The Poisson-Boltzmann equation is used in geoscience applications to describe the electrostatic potential and charge distribution around a charged particle in aqueous solution.

For a symmetrical 1:1 electrolyte such as NaCl,

$$\frac{d^2\psi(x)}{dx^2} = -\left[\frac{en_\infty e^{-e\psi(x)/kT} - en_\infty e^{e\psi(x)/kT}}{\varepsilon\varepsilon_o}\right]$$

And with $\varphi(x) = \frac{e\psi(x)}{kT}$, the equation can be rearranged as

$$\frac{d^2\varphi(x)}{dx^2} = \frac{2e^2 n_\infty}{\varepsilon\varepsilon_o kT}\sinh\varphi(x) = \kappa^2\sinh\varphi(x)$$

where κ^{-1} is the characteristic decay length of the charge distribution and is known as the Debye length where κ is given by

$$\kappa = \left(\frac{2n_\infty e^2}{\varepsilon\varepsilon_o kT}\right)^{1/2} \quad (\mathrm{m}^{-1})$$

This equation requires numerical solution, but in the limit of low potentials (<25 mV), truncation of the linearized exponential terms yields

$$\frac{d^2\varphi(x)}{dx^2} = \kappa^2\varphi(x)$$

which has an analytical solution and is the starting point for the Debye-Hückel solution theory (see entry ▶ "Debye-Hückel Equation" in this encyclopedia).

Applications

Considering a charged mineral surface in an aqueous solution, the concept of the electrical double layer has found great usefulness in describing the distribution of ions in solution around the charged particle. A diffuse cloud of ions enriched in the ionic species with the opposite charge from the surface charge forms around the surface. The cloud forms in response to the competing forces on the ions due to surface charge and the entropic tendency to dilute the high concentration of ions near the surface. The result is a diffuse cloud of ions and a nonzero electrostatic potential relative to the bulk solution in the region of the cloud. Overlap of the clouds on two like

charged particles in solution gives rise to a repulsive interaction and nonzero electrostatic potential at the midpoint between the surfaces which is related to the force opposing the approach of the surfaces. This has been measured experimentally for smooth mica surfaces in aqueous salt solutions (Israelachvili and Adams 1978).

The distance dependence of the force is related to the extent to which the double-layer cloud extends from the surface and depends on the ionic strength through the inverse Debye length (κ^{-1}). When two surfaces approach, solution of the Poisson-Boltzmann equation with appropriate boundary conditions predicts the magnitude of the repulsive force. Together with the van der Waals attraction, these two additive energies comprise the original DLVO theory of colloidal stability (see Israelachvili (2011) 3rd edition for further info). As can be seen by an examination of the expression for the inverse Debye length (κ^{-1}), low ionic strength expands the diffuse counterion cloud, and for the case of two clay sheets in aqueous solution in KNO_3 at 10^{-4}M, the repulsive force is measurable at 10s of nanometers. The ionic strength can be increased by increasing the salt concentration or by replacing monovalent with divalent ions. The repulsive force between clay particles in 10^{-4} M $CaCl_2$ solution appears at a shorter range allowing closer approach of the particles. This can be the difference between a swelling clay and a collapsed clay. In fact, ion exchange of a sodic-based soil with calcium can decrease swelling in clay materials. If the particles approach close enough for the van der Waals force to compete with the electrostatic repulsion, due to the overlap of the diffuse ionic clouds, it is possible that the overall force between the particles will be attractive and the particles will reversibly or irreversibly adhere (see Israelachvili (2011) 3rd edition for further info).

Summary

In summary, the Poisson-Boltzmann equation forms the starting point for understanding the behavior of charged particles in natural and engineered aqueous solutions. It is a cornerstone for the DLVO theory of colloidal stability which remains a central concept in geochemistry.

Core Abundance:

Properties

Polonium is a reactive, silvery-gray, extremely rare radioactive semimetal (Emsley 1991, 2001). It dissolves in dilute acids but is only slightly soluble in alkaline solutions. The solution formed by dissolving polonium in acids has a pink color, the color of the Po^{2+} ion, and it rapidly turns yellow as α-radiation forms oxidizing species in aqueous solution that convert Po^{2+} to Po^{4+}. Polonium has a relatively high vapor pressure for a solid element as about half of a sample of polonium will evaporate within 3 days. Polonium has chemical properties similar to selenium and tellurium. Most of the interest in Po is due to its radioactivity. The half-life of ^{209}Po, which does not occur naturally, is 105 y. The half-lives of

^{210}Po, ^{211}Po, ^{216}Po, and ^{218}Po are 138.4 d, 0.52 s, 0.15 s, and 3.11 m, respectively. Thus, the common isotope ^{210}Po is only found in trace amounts in uranium ore as it is a daughter product from the decay of ^{238}U.

History and Use

After Becquerel's discovery in 1898 of radiation from the uranium ore pitchblende (uranium oxide, U_3O_8), Marie and Pierre Curie studied pitchblende to determine the source of the radiation. They knew that uranium was one source of the radiation, but the amount of radiation could not come only from the uranium. After months of work of purifying tons of pitchblende, they isolated a new element, and Marie Curie named it polonium in honor of her homeland, Poland. Polonium is hundreds of times more radioactive than uranium. The existence of polonium had been predicted by Mendeleev in 1891 on the basis of his periodic table. He realized that there should be an element following bismuth that would resemble tellurium and predicted that it would have an atomic weight of 212.

Polonium is an α-emitter and is usually used as a thin film on a stainless steel for antistatic devices. Polonium was used in textile mills to eliminate static charges and in brushes to remove the accumulated dust in the manufacture of photographic plates. One gram of polonium reaches a temperature of 500 °C as a result of α-radiation emission and is used as a source of heat for space equipment. Polonium can be mixed or alloyed with beryllium to provide a source of neutrons which normally only access to a nuclear reactor can provide.

Geochemical Behavior

Polonium occurs rarely in nature in uranium ores and has so few uses that it is extracted from natural ores only for research purposes. All of the commercially produced polonium in the world is from Russia. About 100 g/year of polonium is produced by bombarding bismuth with neutrons in a nuclear reactor.

The radioactive disequilibrium between ^{210}Po and ^{210}Pb has been used as a chronometer to date glassy eruption flows in mid-ocean ridges, which are difficult to access (Rubin et al. 1994). The short half-life of ^{210}Po of 138.4 d means that it can only be used to determine if an event has occurred very recently. The use of this chronometer is based on the volatilization of Po in volcanic emissions above 400 °C likely as halides and its return to its equilibrium values. This method was used to determine when and for how long the ridge at 9° 50′ N on the East Pacific Rise erupted in the early 1990s.

Biological Utilization and Toxicity

Polonium has no biological role and is extremely dangerous because of its intense radioactivity (α-emitter) which overrides the toxicity concerns of tellurium, the noxious element just above polonium in the periodic table. Polonium is considered to be more than 10^{11} times more dangerous than hydrogen cyanide. ^{210}Po was used to assassinate Alexander Litvinenko, a Russian dissident residing in London in 2006.

^{210}Po has recently been found in the tobacco used in cigarettes and other products. ^{210}Po is soluble and circulates through the body to every tissue and cell and has been detected in the blood and urine of smokers. The circulating ^{210}Po causes genetic damage and early death from liver and bladder cancers, stomach ulcers, leukemia, cirrhosis of liver, and cardiovascular diseases.

Polyoxometalates and Other Metal-Oxo Clusters in Nature

May Nyman

Department of Chemistry, Oregon State University, Corvallis, OR, USA

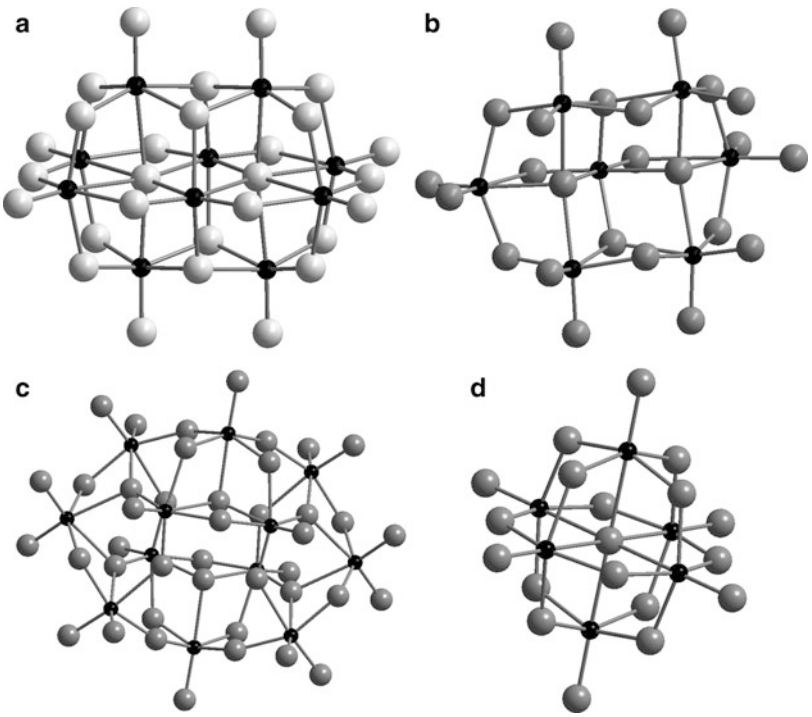
Definition

Metal-oxo clusters are broadly defined as polynuclear species (meaning containing two or more metal cations) with ligands of H_2O, OH^-, and O^{2-} and are molecular. Molecular means they have a distinct chemical formula. In the laboratory, they are ideally synthesized in water in a discrete form (meaning all clusters present in the aqueous synthesis solution have the exact same formula and geometry). Solubility of these

clusters in water necessitates a negative or positive charge; and the metal-oxo clusters are isolated by crystallization with counterions of the opposite charge. *Polyoxometalates*, commonly known as POMs, are one subset of metal-oxo clusters. These are discrete polynuclear metal-oxo clusters specifically composed of the early d^0 transition metals in their highest oxidation state with no valence electrons. These POM-forming metal cations include V^{5+}, Nb^{5+}, Ta^{5+}, Mo^{6+}, and W^{6+}. POMs are negatively charged and possess predominantly O^{2-} ligands. All metal-oxo clusters represent an important intermediate form between monomers and infinite solid lattices or surfaces in both the laboratory and in nature: they can be considered as soluble pieces of metal oxide. However, there are few metals that can form and be isolated as discrete metal-oxo clusters as defined here, with only the simple ligands derived from water (H_2O, OH^-, and O^{2-}). This is why POMs are uniquely important – this is readily accomplished with POMs.

Synthesis and Structure of POMs in the Laboratory

The synthesis of POMs of tungsten, molybdenum, and vanadium has been known for a long time. The first crystallographic solid-state structure obtained of a POM was that of silicotungstic acid, $H_3[SiW_{12}O_{40}]$ by J. F. Keggin (1933), and this common structural motif has since been dubbed the Keggin ion (more below). V^{5+}, Mo^{6+}, and W^{6+} exist in water, respectively, as oxoanions, VO_4^{3-}, MoO_4^{2-}, and WO_4^{2-}; and when salts of these are dissolved in water, the self-buffering pH is highly alkaline. Acidification of these solutions results in POM self-assembly, and predominance diagrams (Baes and Mesmer 1976) inform us the stability fields in water are in the acidic range (generally below 4); and the most common structural/compositional types include decavanadate $[V_{10}O_{28}]^{6-}$, heptamolybdate $[Mo_7O_{24}]^{6-}$, and dodecatungstate $[W_{12}O_{42}]^{12-}$ (Fig. 1a–c). On the other hand, POMs of Nb^{5+} and Ta^{5+} are formed by dissolution of the metal oxide in a highly alkaline solution, and the hexametalate, $[M_6O_{19}]^{8-}$ (M = Nb, Ta), dominates these solutions (Fig. 1d). These POMs are called isopolyanions, when only the aforementioned metals compose the cluster. Also note, these clusters dominate in the simplest of aqueous solutions. Many other cluster types can be obtained by varying the supporting electrolytes, performing synthesis in alternative media (i.e., organic solvents) or conditions (i.e., hydrothermal), or adding a "heterometal" to form a heteropolyanion. Heteropolyanions are known for all of the POM-forming metals except Ta, and the Keggin ion and derivatives thereof are the most common structural motif. The Keggin ion has five different polymorphs known as rotational isomers (α, β, γ, δ, ε), and α, δ, and ε (Fig. 2) are the most stable and common across the metal-oxo clusters described here. All the Keggin ions consist of four sets of three mutually edge-sharing MO_6 octahedra (M = metal), for a total of 12 octahedra. The linkage of the trimers define the rotational isomers: in the α-isomer, the trimers are all corner linked, and in the ε-isomer, they are all edge-sharing. In the δ-isomer, three are edge-linked and the fourth is corner linked. For the POMs, the



Polyoxometalates and Other Metal-Oxo Clusters in Nature, Fig. 1 Common isopolyanions of polyoxometalates that dominate speciation diagrams (Baes and Mesmer, 1976) (**a**) Vanadium: decavanadate, $[V_{10}O_{28}]^{6-}$. (**b**) Molybdenum: heptamolybdate, $[Mo_7O_{24}]^{6-}$. (**c**) Tungsten: dodecatungstate, $[W_{12}O_{42}]^{12-}$. (**d**) Hexametalate, $[M_6O_{19}]^{8-}$, M = Nb^{5+}, and Ta^{5+}. *Black spheres* are metals; *gray spheres* are oxygens

Gray* polyhedra are MO_4 tetrahedra (one per Keggin ion in the center) and MO_6 octahedra (12 per Keggin ion); M = the various metal cations discussed in this article

α-isomer is by far the most readily obtained. However, electrochemical reduction can result in conversion to the other isomers that are stabilized by localization of a pair of electrons at the metals that bridge the shared edge of two trimers, forming a metal-metal bond.

The reason the POM-forming metals can be easily isolated without ligation is their position on the periodic table, inside the "metal-oxo wall" (Winkler and Gray 2012). These metals in their highest oxidation state in water always exist as an "*yl*" species, meaning they have a doubly bonded oxo ligand that is relatively inert to hydrolysis and condensation reactions that would ultimately result in precipitation of an infinite metal oxide lattice. The strong double bond is achieved by overlap of the empty d_{xz} and d_{yz} orbitals of the metal with the filled p_x and p_y orbitals of the oxo; and this tendency is lessened in metals with partially filled d-orbitals, such as the later transition metals (Fe, Co, etc.). This inert *yl*-oxo acts as a ligand on the surface of the cluster, protecting it from further reactivity that leads to precipitation of a metal oxide. Uranyl POMS have been discovered more recently (Burns et al. 2005; Nyman and Burns 2012; Qiu and Burns 2013), and these self-assemble from the (UO_2^{2+}) species, also due to the inert *yl*-oxos. However, these POMs always exhibit capsule geometries because there are two oxos in a transconfiguration: the oxo is a protective shell on both the outside and inside of the capsule.

Importance of Metal-Oxo Clusters in Metal Oxide Dissolution and Precipitation in Nature

The POM-forming metals are not abundant in nature; however, POMs are found in rare mineral forms, which are discussed below. Nonetheless, the discrete molecular nature that POMs can be isolated in the solid-state and redissolved makes them valuable experimental and theoretical models for understanding reactivity at a metal oxide surface. Important reactions in the hydrosphere and geosphere include dissolution and precipitation of mineral phases (including weathering and biomineralization), adsorption of ions onto metal oxide surfaces, and contaminant transport in the environment. Dissolution and precipitation of clusters is intimately tied to the $O^{2-}/OH^{-}/H_2O$ ligand exchange and interconversion between these ligands via protonation/deprotonation as a function of pH and total solution composition. Recent experimental and theoretical studies showed that ligand exchange reactivity of clusters has amphoteric behavior, similar to solubility of minerals (Rustad and Casey 2012). This means the exchange of the $O^{2-}/OH^{-}/H_2O$ ligand can take place by initial association of a hydronium or a hydroxide. These studies are only possible experimentally and computationally with well-defined molecular species such as POMs.

Metal-oxo clusters have been considered as important pre-nucleation clusters to common minerals including calcium carbonate and ferrihydrite. More broadly, precipitation of metal oxides has been proposed recently to proceed via aggregation of pre-nucleation clusters, rather than atom-by-atom growth (Banfield et al. 2000; Gebauer et al. 2008; Baumgartner et al. 2013; Gebauer et al. 2014). Calcium carbonate grows by first formation of very uniformly sized particles, which when observed by small-angle X-ray scattering can be considered nearly molecular (Bolze et al. 2002); and this is true even at very low concentrations.

Iron Oxides

Arrangements of polyhedra within metal oxide lattices that closely resemble POMs and other molecular clusters have provoked hypotheses that these clusters may serve as pre-nucleation clusters to metal oxide phases, and therefore attempted synthesis and isolation of these clusters have taken some priority among chemists and geochemists. For example, the long-known structure of magnetite features the

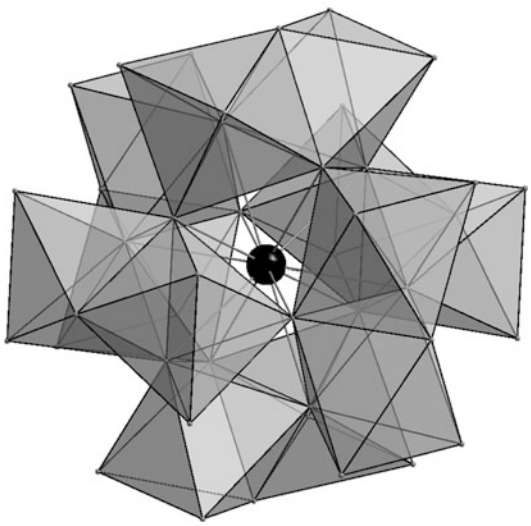
ε-polymorph of the Keggin ion, with Fe^{3+} occupying the tetrahedral lattice site and Fe^{2+} and Fe^{3+} occupying the octahedral lattice sites. More recently, a structural model for ferrihydrite was proposed from X-ray scattering data, revealing a δ-Keggin ion building block (Michel et al. 2007). This provoked more intense efforts to isolate a discrete iron-oxo Keggin ion cluster from water and was accomplished in 2015 (Sadeghi et al. 2015). In this very recent study, the authors showed that via removal of protecting ligands and counterions in water, ferrihydrite rapidly formed. While these studies suggested the possible importance of the Keggin ion molecular cluster in iron oxide mineral formation, there is still much to be understood. For instance, the ratio of octahedra to tetrahedra in the cluster is 12:1, while in the structural model of ferrihydrite, it is 4:1. Thus, rearrangement must occur for the conversion of the Keggin ion to ferrihydrite. Finally, in an even more recent study, it was suggested that no polynuclear species bigger than a dimer form prior to precipitation of ferrihydrite (Zhu et al. 2016). In summary the role of discrete molecular clusters in formation of ferrihydrite is not yet fully comprehended.

Aluminum Oxides

While iron is the third most abundant metal in the earth's crust, aluminum is the second most abundant. Unlike iron, discrete, molecular metal-oxo clusters of aluminum *can* be readily isolated; in particular the Keggin ion, ε-$[AlO_4Al_{12}(OH)_{24}(H_2O)_{12}]^{7+}$ (also referred to as Al_{13}), which is the same polymorph as the Keggin ion of magnetite. The ease of synthesizing and isolating Al_{13} lends to another reason geochemists have sought a synthetic analogue of the iron Keggin ion: Fe and Al are both trivalent with similar coordination geometries in minerals. On the other hand, Fe^{3+} is a much stronger Lewis and Bronsted acid than Al^{3+}, so hydrolysis reactions are difficult to control (pKa for Fe^{3+} and Al^{3+}, respectively, 2.19 and 4.97). Likewise, exchange of a water molecule bound to Fe^{3+} in a ligated cluster (Panasci et al. 2012) is ~3–5 orders of magnitude faster than that bound to Al^{3+} in a Keggin ion (Casey 2006). The mineral akdalaite (ICSD-28379), also the structural model for ferrihydrite, possesses the Al Keggin ion core. On the other hand, there has been considerable recent interest in another aluminum polycation that has been compared to the layered mineral brucite (Casey 2006). It is also a tridecamer and has 13 aluminum octahedra arranged in a plane, $[Al_{13}(OH)_{24}(H_2O)_6]^{15+}$, and is referred to as "flat Al_{13}" (Wang et al. 2011; Mensinger et al. 2012). Determining the relevance of this cluster as a pre-nucleation species in nature remains a challenge for the future. The Al_{13} Keggin cluster, however, has been identified in acidic mine drainage (Furrer et al. 2002), consistent with predominance diagrams showing the Al_{13} species dominate at pH 3–4 (Casey 2006).

Polyoxometalates and Other Clusters Found in Nature

Some metal-oxo clusters that can be synthesized in the lab are found in minerals formed in geological hydrothermal conditions. Numerous minerals containing decavanadate have been found and structurally characterized from the Uravan (uranium, vanadium) deposits in Colorado and Utah (Kampf et al. 2014a). This includes fully oxidized V^{5+} and mixed V^{4+}/V^{5+}. Countercations are predominantly common alkalis and alkaline earths, including magnesium, calcium, sodium, and potassium and also aluminum. Minerals featuring a dodecaniobate POM, $[Nb_{12}O_{42}]^{24-}$, have been found in São Paulo, Brazil, and Norway, respectively, named menezesite and aspedamite (Atencio et al. 2008; Cooper et al. 2012). Also found in Norway is the mineral peterandresenite that contains the common hexaniobate, $[Nb_6O_{19}]^{8-}$ (Friis et al. 2014). The dodecaniobate $[Nb_{12}O_{42}]^{24-}$ has never been synthesized in the laboratory, but the analogous $[M_{12}O_{42}]^{12-}$ (M = Mo, W) is readily made by oxidative dissolution of first-row transition metals in tungstic acid solution (Gunter et al. 1990). This structure type (Fig. 3) features unusual face-sharing octahedra of W or Nb. The cluster features six dimers of face-sharing octahedra, and the dimers are corner linked and create a central cavity with twelve oxo-binding sites. This cavity is occupied by Ba^{2+} in menezesite and Th^{4+} in aspedamite. Aspedamite has six additional Nb octahedra decorating the cluster by corner-sharing, and its 12 octahedral sites are occupied by nine Nb^{5+}, one Ti^{4+}, and two Fe^{3+}. Counterions are mainly



Polyoxometalates and Other Metal-Oxo Clusters in Nature, Fig. 3 Structure of $A[M_{12}O_{42}]$; synthesized in the laboratory with M = W, found in the mineral menezesite and aspedamite with M = Nb or Nb/Fe, respectively. *Gray* octahedra are the W/Nb/Fe MO_6; *black sphere* is a metal cation (i.e., Ba, Th, Mg, etc.) in the 12-coordinate cavity site

iron in aspedamite and mixed alkaline earth and Ti/Zr in menezesite. In the mineral ophirite(Kampf et al. 2014b), lacunary trivacant B-α-$[FeW_9O_{34}]^{9-}$ clusters sandwich a tetrad of Zn/Mn octahedra, a structural motif readily synthesized in the laboratory (Fe^{3+} occupies the central tetrahedral site) (Limanski et al. 2002). Lacunary POMs are defined as POMs with missing octahedra: from the tungstate Keggin ion, one, two, or three octahedra can be removed (via pH increase) to form these species, and they are commonly stabilized by binding other metals in the vacancies. In this sense, lacunary clusters behave as inorganic ligands to metal cations or small metal-oxo clusters.

Other metal-oxo clusters are represented in mineralogy, outside of POMs. In the rare mineral zunyite (Barclay-Kamb 1960), the Al_{13} Keggin ion is found, but it is the α-isomer with O^{2-} ligands instead of the common ε or δ isomers that are synthesized in the lab with H_2O and OH^- ligands, and the high negative charge $[Al_{13}O_{40}]^{41-}$ is counterbalanced by Si^{4+} cations that link the clusters into a three-dimensional network. Notably, the Al_{13} α-isomer has never been formed in the laboratory. Another cluster not prior observed in the laboratory is bouazzerite from Morocco, an Fe-Bi-arsenate polyanion (Brugger et al. 2007). Given that many of these cluster-containing minerals have been discovered and structurally characterized very recently, we anticipate additional discoveries in the future.

Conditions under which these minerals form in geological settings are vastly different than that in the laboratory. As an example, aspedamite forms in a granitic pegmatite, meaning saline, 400–700 °C, 3–4 kilobars of pressure, and a time scale up to millions of years (Cooper et al. 2012). pH of the geochemical fluids is most likely slightly alkaline. In comparison, in the laboratory, temperatures rarely exceed 200 °C, and pressure ranges from atmospheric pressure to the autogenous pressure of water (a few bars). Synthesis/crystallization times range from a few hours to several months, and the pH can be varied from highly acidic to highly basic. The instances in which clusters that grow in geological settings cannot be obtained under standard laboratory conditions (i.e., the α-Al_{13} Keggin ion) point toward these synthons as a challenge for the future for synthetic chemists.

Summary

Discrete, molecular metal-oxo cluster that can be synthesized in the lab or exist in nature have commonalities and differences. Both clusters in geochemistry and in synthesis are active fields of research. Therefore, the commonalities are becoming more abundant as new minerals, synthons, or reaction pathways are discovered. Rare minerals containing V, Nb, Ta, Mo, or W contain building block forms that resemble the polyoxometalates (POMs), which are readily synthesized and isolated in the laboratory. However, some differences are noted, due to the vast differences in geological time and settings compared to typical laboratory conditions. For example, the face-sharing Nb-polyhedron is a structural motif found in mineral forms but has not yet been synthesized in the lab. More common to geochemistry is clusters of earth-abundant aluminum and iron. Iron clusters that are recognized as building blocks in ferrihydrite have only been synthesized recently from water. However, unlike the POMs, these cannot exist with supporting ligands. Aluminum clusters are easily made in the laboratory in aqueous conditions and do not require supporting ligands. They generally do not exist in nature, as the acidic aqueous conditions in which they form are not common in the natural environment.

Porphyrins

J. William Louda
Department of Chemistry and Biochemistry and the Environmental Sciences Program, Florida Atlantic University, Boca Raton, FL, USA

Definition

Porphyrins are heterocyclic macrocycle organic molecules. These tetrapyrroles occur with (chlorophylls and bacteriochlorophylls) or without (hemes, cytochromes) the fifth so-called isocyclic (aka exocyclic or 13, 14-cycloethano) ring.

Introduction

Porphyrins are ubiquitous in all life forms. Figure 1 has the structures of the chlorophylls and protoheme as examples of these two main macrocyclic tetrapyrrole nuclei. While performing their function in cells, the vast majority of porphyrins contain a central chelated metal, magnesium or iron in the cases of the chlorophylls and the hemes, respectively. It is these biological dihydroporphyrins and porphyrins that form the precursors to a huge variety of geoporphyrins, also called "petroporphyrins" (Corwin 1960), for their occurrence in rocks, shales, and sediments.

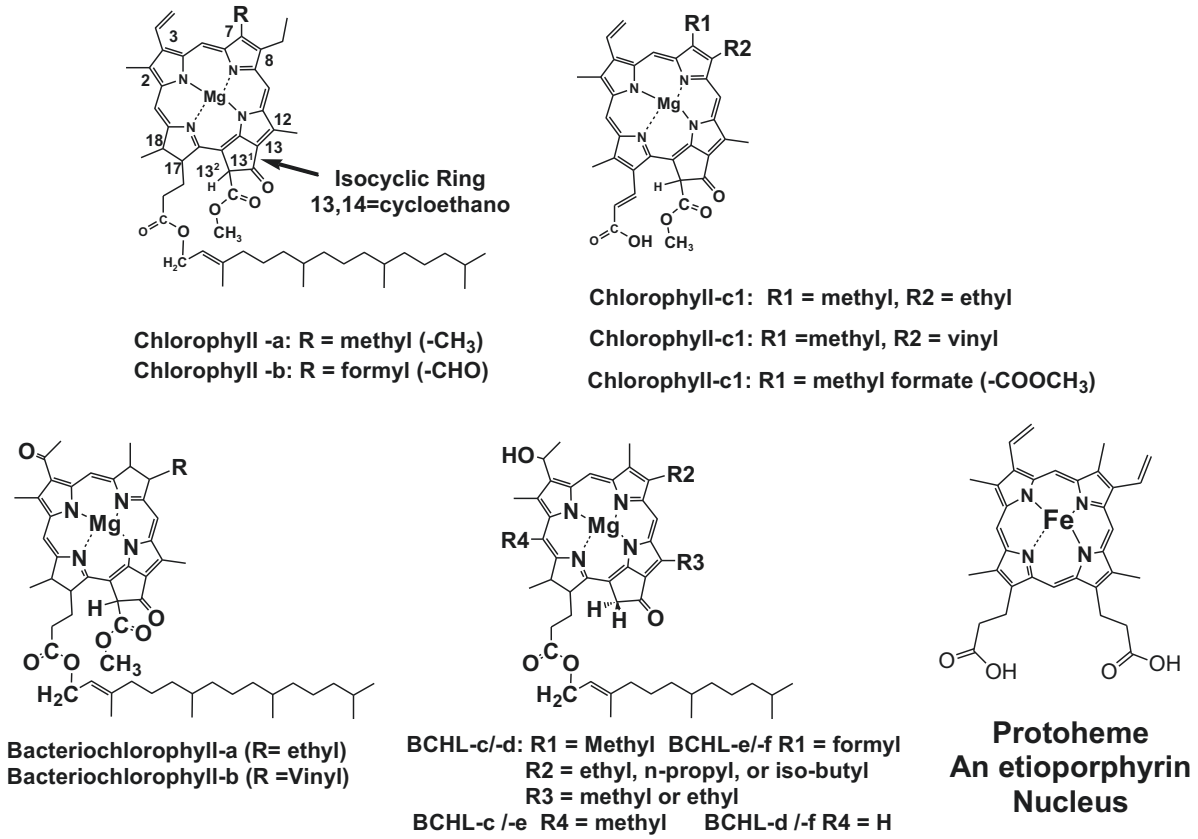
Geoporphyrin Precursors: Biological Pigments

There is a large number of chlorophylls, bacteriochlorophylls, and hemes (Fig. 1) that can serve as precursors to the geoporphyrins. A chapter by Hugo Scheer (2006) has a complete listing of these biotic pigments and several variations not depicted here.

Chlorophyll-a (CHLa Fig. 1) is distributed throughout all eukaryotic oxygenic photosynthetic organisms as well as the prokaryotic cyanobacteria. Chlorophyll-b (CHL-b) accompanies CHLa in green algae (chlorophytes) and higher plants. The chlorophylls-c (CHL-c: $\text{-}c_1/\text{-}c_2/\text{-}c_3$) accompanying CHLa are characteristic pigments in diatoms, dinoflagellates and a few other taxa (see Jeffrey et al. 2011; Scheer 2006). The bacteriochlorophylls (BCHLs) are present in the anoxygenic photosynthetic bacteria. BCHL-a and -b are characteristic of purple sulfur bacteria are tetrahydro (7,8 and 17,18) porphyrins and differ only by substitution on carbon #8, having an ethyl or vinyl respectively (Fig. 1). The BCHLs-c, -d, -e, and -g are in the green sulfur bacteria. One can easily imagine a wide C-number range of geoporphyrins arising from the BCHLs-c through -e, even without invoking alkylation reactions during diagenesis.

Geoporphyrins

The concept of "biological markers" or "chemical fossils" in the field of organic geochemistry is a direct outgrowth of Professor Alfred Treibs linkage of the structure of deoxophylloerythroetioporphyrin (DPEP), which was isolated from bitumen in shales and sediments, as well as a broad spectrum of petroleum samples, to the nucleus of CHL-a (Treibs 1936). Numerous references are covered elsewhere (Baker and Louda 1986, 2002; Callot 1991; Keely et al. 1990). The present treatise follows the contribution "Porphyrins" by Chris Boreham in the previous edition (Boreham 1999) of the Encyclopedia of Geochemistry. Space limitation here precludes large reference citations.

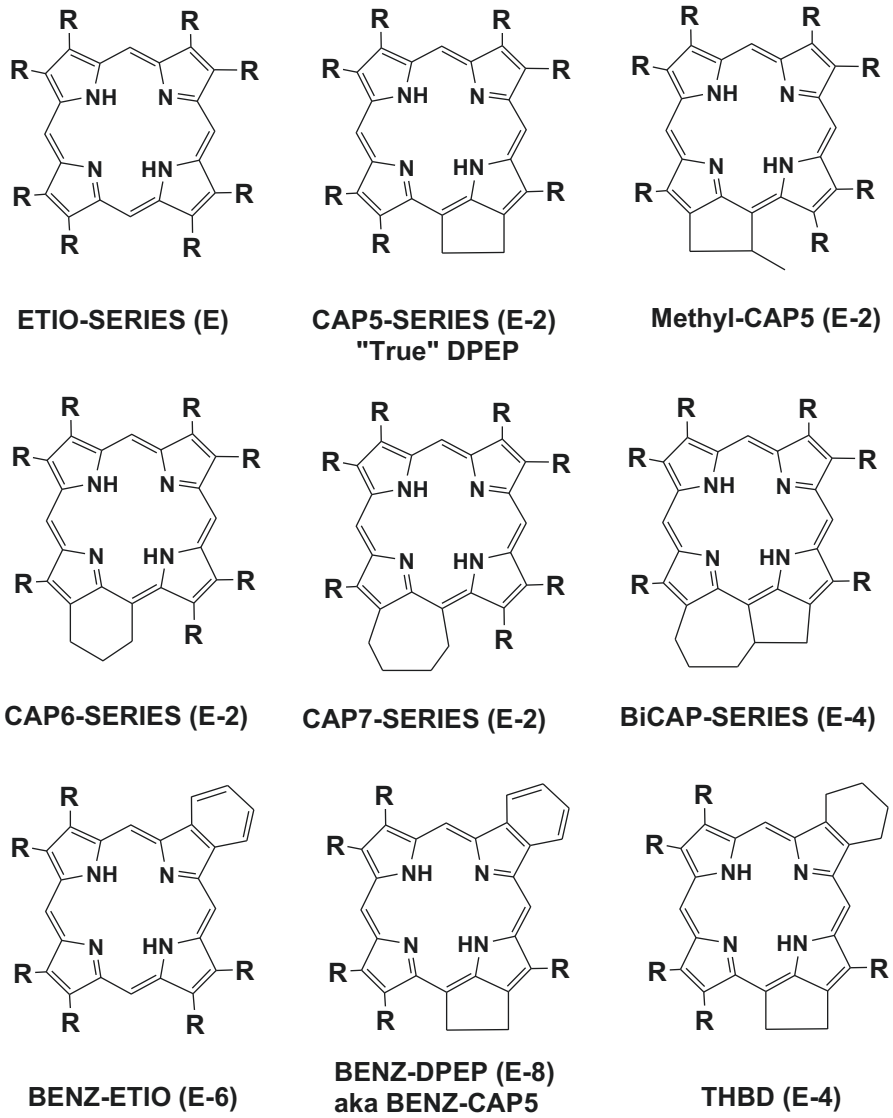


Porphyrins, Fig. 1 Structures of chlorophylls, bacteriochlorophylls, and protoheme

The most widely known types or nuclei of geoporphyrins are the DPEP and etioporphyrin (ETIO) series which differ by the presence or absence of the isocyclic ring (ring-V: Fig. 1) inherited from the chlorophylls. Carbon numbering of any peripheral substituents is shown in Fig. 1. The ETIO series is 2 amu (m/z) heavier than the corresponding DPEP series at each carbon number due to the lack of isocyclic ring. DPEP is a 32 carbon compound (C32-DPEP, 476 m/z). "Routine" analysis of geoporphyrins often involves determination of the molecular weight (carbon number) of each series present (Baker et al. 1967). As opposed to regular high voltage electron impact (70 eV) mass spectrometry (EI-MS), which gives small molecular ions and a plethora of overlapping methyl (M-15) and other fragmentation peaks. Low-voltage (e.g., 12–14 eV) EI-MS (Baker and Louda 1986) and many newer techniques have yielded a preponderance of molecular ions. For example, electrospray ionization (ESI-MS: Ramos et al. 2016), positive-ion electrospray ionization Fourier Transform Ion-Cyclotron Resonance MS (ESI-FT-ICR-MS: Liu et al. 2015), and HPLC-Orbitrap high resolution MS (Woltering et al. 2016) are just a few of the more advanced techniques used these days.

Geoporphyrin/Petroporphyrin Varieties

Geologic porphyrins and metalloporphyrins are known to exist with a wide variety of nuclei and exocyclic modifications (Fig. 2), derived from the interplay of specific biological precursors and postdepositional diagenetic/catagenetic modifications. Each series can be related to the ETIO-series (C32-E = 476 m/z) by hydrogen deficiencies due to exocyclic cyclizations, hydrogenations, and/or dehydrogenations. Thus, the DPEP series (C32 DPEP = 478 m/z) is E-2, resulting from the cycloethano group (aka isocyclic ring). The DPEP type porphyrins also fall into a larger group called the cycloalkanoporphyrins or CAPs. As true DPEP has a five membered exocyclic ring, consisting of a 13^2–15 cycloethano moiety, it becomes a CAP5. Beyond mass spectral typing of geoporphyrin distributions, the HPLC separation of individual porphyrins and their structural identification (e.g., NMR) then takes geoporphyrin analysis to be taken to the next level, allowing for a better understanding of the pigments present and an improvement on the estimation of their putative precursors (chlorophylls, bacteriochlorophylls, hemes, etc.).



Porphyrins, Fig. 2 *ETIO* etioporphyrin, *CAP* CycloAlkanoPorphyrin, *DPEP* deoxophyllo-erythroetioporphyrin, *Bi-CAP* Bi-CycloAlkanoPorphyrin, *Benz* benzene-like, *THBD* TetraHydroBenz-DPEP. Numbers modifying a CAP series refer to the numbers of carbon atoms forming the exocyclic ring structures. Parentheses refer to mass spectral differences, in nominal amu (m/z), relative to the ETIO-series

Only the DPEP (CAP-5) and certain ETIO-series geoporphyrins are believed to derive directly from their putative precursors, namely chlorophylls or hemes, respectively. ETIO-series porphyrins "may" also arise from the opening of the isocyclic ring (ring-V) of the DPEP series. The remaining geoporphyrin nuclei arise through diagenetic alterations including cyclizations, aromatizations and alkylation/dealkylation reactions. For example, the CAP-6 series having a cyclopropane (6-membered) ring can easily derive from reactions similar or identical to the mesorhodin reaction of mesoporphyrin-IX (see Fischer and Orth 1937 as detailed in Baker and Louda 2002). The benzoporphyrins (BENZ-ETIO and BENZ-DPEP; aka BENZ-CAP5) have been suggested as arising by a variety of possible reactions (see summary in Baker and Louda 2002). The CAP7 and BiCAP series likely derive from the cyclopheophorbide reactions detailed later herein.

Metallo-Geoporphyrins

Biological precursors to the geoporphyrins are mainly the Mg^{2+} and Fe^{2+}/Fe^{3+} chelates, the chlorophylls, and hemes, respectively. Fe^{3+} hemes also have an axial ligand such as Cl^{-}.

Sedimentary and petroleum geoporphyrins contain V^{4+}, as vanadyl (VO^{2+}), Ni^{2+} and to a lesser extent Cu^{2+} (Baker and Louda 1986, 2002; Callot 1991; Keely 2006). Coal (ETIO) porphyrins contain Fe^{3+}, Ga^{3+}, and Mn^{3+} (Bonnett and Czechowski 1981; Filby and Branthaver 1987). In general, Ni-PHs arise in the bitumen (solvent extractable portion) and VO-PHs within kerogen/sulfur complexes of the bulk organic matter (aka kerogen). The analyses of marine sediments provided by the Deep Sea Drilling Project (DSDP: Baker and Louda 1986, 2002) detailed the defunctionalization of phorbides, their aromatization to free base porphyrins and

the chelation of Ni^{2+}, as well as the "release" of VO-PHs with increasing thermal stress over time. Copper, highly dealkylated etioporphyrins porphyrins (Cu-PHs) have been reported in deep sea sediments (Baker and Palmer 1978; Baker and Louda 1984, 1986; Premovic et al. 2000) and are surmised to be redeposited terrestrial (coal) porphyrins, which underwent metal replacement by copper in acidic oxygenated river water.

Precursor-Product Considerations: Diagenesis and the ETIO Dilemma

The premier precursor-product alteration (diagenesis) scheme is the Treibs' hypothesis (Treibs 1936) wherein CHLa is processed into DPEP through a series of defunctionalizations (demetallation, ester hydrolysis, decarbomethoxylation, vinyl reduction, aromatization, and ketone loss).

Figure 3 is a representation of some of the known pathways of CHLa senescence/death alteration and organic diagenesis. The main (Treibs' Scheme) route flows down the center of this figure and involves the sequential defunctionalization and aromatization to yield C32 DPEP. The alteration of CHLa to pyropheophorbide-a (pPBIDa) occurs both during cellular senescence/death (Louda et al. 1998, 2002, 2011) and heterotrophic (e.g., zooplankton) grazing (Bianchi et al. 1998). Cyclization of pPBIDa yields cyclopheophorbide-a (CYCLO) which, through a series of oxidations (giving hydroxychlorophyllone, chlorophyllone) and ring-V opening (chlorophyllonic acid, chlorophyllactone: see Watanabe et al. 1993 and Baker and Louda 2002), yields a C33 BiCAP or CAP7 (see Fig. 3), respectively. CYCLO has been identified from deep sea sediments Baker and Louda 1986, 2002) and contemporaneous anoxic marls (Louda et al. 2000). Oxidative scission of the isocyclic ring (Ring-V) yields a few purpurins (-7, -18) and chlorins (-e4, -e6, -p6) (Baker and Louda 1986, 2002; Louda et al. 2011). As shown in Fig. 3, the transformation of CHLa to purpurin-18 and then chlorin-p6, via decarboxylation and aromatization, yields a C30 open-β etioporphyrin. All steps shown have been observed in the natural sediments and the microalgal incubation studies given above, except for the identification of C33BiCAP and C30 ETIO as those sequences were not "mature" enough.

All alternate Chlorophylls (CHLb, CHLs-c1/-c2/-c3, CHLd, and the BCHLs) can easily be envisioned and potentially shown to follow these or closely related routes, especially the route to DPEP (CAP5), with but a few minor adjustments. For example, reduction or removal of the 8-formyl moiety in CHLb, no need for aromatization step with the CHLs-c, and various hydroxyl, ketone and/or acetyl losses in the BCHLs. The BCHLs–c/–d would give a DPEP series with a C32 to C36 distribution due to their extended alkylation patterns.

Hendry et al. (1987) described the biological alterations of chlorophylls as being of two types. Type-I involves reactions that retain the pigment nature with a macrocyclic tetrapyrrole nucleus. Type-II reactions are those that destroy the pigment character and lead to open tetrapyrroles (bilins) and/or smaller remnants. Type-II reactions include those described by Matile et al. 1996) yielding the 19-formyl-1-oxo-bilanes and more fully degraded products. Type-I reactions have been divided (Baker and Louda 2002) into Types-IA and -IB for those that either (IA) retain the nucleus of the biological precursor (DPEP from chlorophyll and ETIO from hemes or (IB) have the isocyclic ring of the chlorophyll nucleus cleaved to ETIO precursor pigments (e.g., Puruprin-18) and/or novel exocyclic rings added, such as with the CAP6, CAP7, and, through cyclopheophorbide-a, BiCAP series (see Fig. 3).

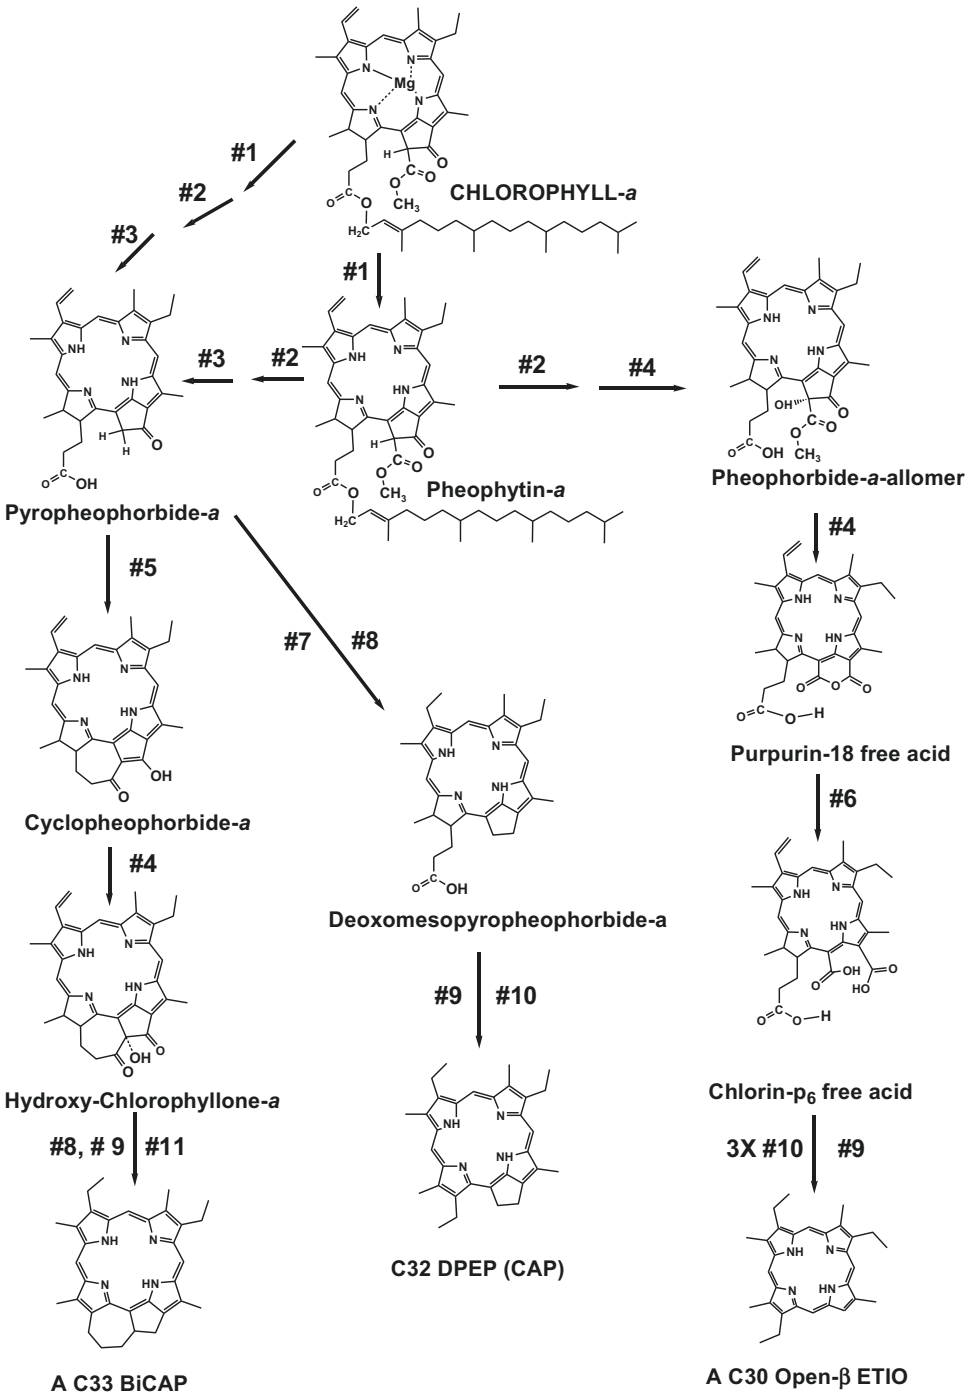
Geoporphyrins as Diagenetic/Catagenetic (Organic Maturation) Indicators

Except for coals, which contain a vast predominance of ETIO-series porphyrins, petroleum and their source rocks are found to contain both Ni and VO porphyrins as a mixture of DPEP and ETIO series, with DPEP dominating in "immature" (Baker and Louda 1986, 2002; Callot 1991; Keely et al. 1990; Ocampo et al. 1992 and others) samples.

The ETIO Dilemma: Is D Converted to E, is D Destroyed faster than E, or do both Occur?

The potential of a DPEP-to-ETIO crossover during organic maturation was popularized by the work of Didyk and others (Didyk et al. 1975). The DPEP-to-ETIO ratio has been used for decades as an indicator of thermal maturity, as modified by source input in certain cases (e.g., In Baker and Louda 1986, 2002; Callot 1991). A study of the con-familial petroleum crudes from the Big Horn Basin revealed a remarkable linear relationship ($r^2 = 0.9997$) between percent DPEP and vanadyl porphyrin (VO-PH) yields (Baker et al. 1987). This relationship argues strongly for a faster destruction of DPEP than the ETIO series porphyrins without a need for a D-to-E crossover by the thermocatalytic opening of the isocyclic ring. As maturity increases, higher carbon number porphyrins, mainly of the DPEP series, were observed to be released until dealkylation of the bitumen containing VO-PHs occurred with a concurrent lowering of the D-to-E ratio (aka %D).

Certain ETIO series precursors deriving from the chlorophylls were discussed above (Fig. 3 and text). As mentioned earlier, the putative or accepted ETIO series precursors are the hemes (see Fig. 1). However, many potential ETIO series porphyrins can indeed be derived from chlorophyll nuclei during senescence/death and early diagenetic processes. For



Porphyrins, Fig. 3 Biological-geological alteration of Chlorophyll-a. *Reactions involved* are: #1 (magnesium loss: -Mg^{2+}, +2 H^{+}), #2 (phytol loss: hydrolysis), #3 (decarbomethoxylation; hydrolysis of methyl formate moiety), #4 (oxidation), #5 (cyclization via dehydration), #6 (hydrolytic ring opening), #7 (reduction of vinyl to ethyl), #8 (ketone loss: reduction to alcohol→ dehydration→ reduction of 13^1–13^2 double bond {speculative?}), #9 (aromatization: 17,18-didehydrogenation), #10 (decarboxylation: -CO_2), #11 ("dehydration-reduction": loss of –OH)

example, following a 5.5 year incubation of the diatom *Navicula* sp., kept under dark, and anoxic and room temperature (25 °C) conditions, it was found that purpurin-18 aromatized to purpuroporphyin, in addition to the generation of chlorin-p_6 (Louda et al. 2011). Both of these pigments are theoretical direct precursors to a C30 beta-free etioporphyrin. Other oxidative ring opening reactions lead to many different chlorins, such as chlorin-e6 which is a potential precursor to a C31 etioporphyrin.

Still the question of whether or not geologic DPEP series porphyrins are converted to ETIO series by the thermal/thermocatalytic scission of the isocyclic ring remains for the future to answer.

Dealkylation of the geologic metalloporphyrins occurs during late diagenesis/catagenesis. In vitro dealkylation of ETIO-I at 450 °C was shown by Yen et al. (1969). Hydrous pyrolysis experiments at 350 °C for 48 h performed on an upper Miocene olive-gray claystone revealed both the release

of VO-PHs and the dealkylation of Ni- and VO-PHs (Baker and Louda 2002).

The change in dominance of DPEP to ETIO series and the lowering of the mean carbon number and range preceding the total demise of geoporphyrin in highly thermally mature sediments, shales, and bitumen (oil) signals the final stage of geoporphyrin maturation.

Summary

Porphyrins, in a geochemical context, are the products of the diagenesis and catagenesis of structures derived from their biological precursors, the chlorophylls, and hemes. These precursor compounds can and do undergo much alteration during the senescence/death of and predation on source biota. Geochemical maturation of the metallo-geoporphyrins (aka Ni and VO petroporophyrins) leads to both a DPEP (CAP)- to ETIO-series dominance change plus dealkylation reactions which lowers the average molecular weight and carbon number range. Geoporphyrins are useful in assessing the thermal maturity of samples and, in certain cases, source biota. When considering the history and origins of organic geochemistry, the porphyrins are clearly the premier biomarkers.

Potassium

Ricardo Arevalo Jr.
Planetary Environments Lab, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Element Data
Atomic Symbol: K
Atomic Number: 19
Atomic Weight: 39.098 amu
Isotopes and (Abundances): ^{39}K (93.258%), ^{40}K (0.012%), ^{41}K (6.730%)
1 Atm Melting Point: 63.5 °C (146.3 °F)
1 Atm Boiling Point: 759 °C (1398 °F)
Common Valences: 1+
Ionic Radii: fourfold: 151 pm, sixfold: 152 pm, eightfold: 165 pm, Pauling: 133 pm
Pauling Electronegativity: 0.82
First Ionization Potential: 418.8 kJ/mol
Chondritic (CI) Abundance[a]: 530 μg/g
Silicate Earth Abundance[b]: 240 μg/g
Crustal Abundance[c]: 1.49 wt%
Seawater Abundance[d]: 380 mg/L
Core Abundance: generally < 10 μg/g (estimates vary; see text for details)
[a](Lodders 2003)
(*continued*)

[c](Rudnick and Gao 2003)
[d](CRC 2001)

Properties

Potassium (K) is a member of Group IA of the periodic table and thus considered an alkali element. Native K manifests as a soft, silvery, and low-density (0.89 g/cm^3) metal that is malleable, ductile, and thermally and electrically conductive. Like other alkali metals, K is highly reactive under ambient atmospheric conditions. Elemental K tarnishes rapidly in the presence of oxygen gas (O_2), and in the presence of liquid water (H_2O), K reacts aggressively to form potassium hydroxide (KOH) and flammable hydrogen gas (H_2); this exothermic chemical reaction releases significant heat in the form of a characteristic lilac flame (www.rsc.org/periodic-table).

Along with the other elements located in Group IA, K belongs to the *s*-block of the periodic table. The specific electron configuration of K is often written as [*Ar*] *4 s*^{1}, comparable to that of the inert noble gas argon (Ar) but with the addition of a single, unpaired outer shell electron held in the *4 s* (*spherical*) orbital. Because *s* orbital electrons are only loosely bound (relative to electrons occupying *p*, *d*, and/or *f* orbitals), K and the other members of Group IA are easily ionized to form single-charged cations (i.e., 1+ valence state) (CRC 2001).

Of the three naturally occurring isotopes of K, ^{39}K (93.258%) and ^{41}K (6.730%) are stable, whereas ^{40}K (0.012%) is radioactive with a half-life ($t_{½}$) of 1.25 Gyr. As a radioisotope, ^{40}K decays through two pathways: 89.3% of ^{40}K decays to stable ^{40}Ca via beta decay, and the remaining 10.7% decays to stable ^{40}Ar via electron capture or positron emission. Because the average human body contains between 100 and 150 g of K, thousands of atoms of ^{40}K decay within our bodies each second, leading some communities to consider K as a "natural" cause of genetic mutation in humans and other animals and plants (Emsley 2001).

History and Use

The name *potassium* is derived from the English word "potash," meaning pot ashes (referring to plant ashes soaked in a pot of water). The origin of the symbol K comes from the Neo-Latin word "kalium," meaning alkali. On October 6th, 1807, a Cornish chemist/inventor named Humphry Davy became the first person to isolate native K. This feat was accomplished by splitting KOH into elemental K and molecular OH (which would further react into water and oxygen

gas) via electrolysis. In 1808, French chemists Louis-Josef Gay-Lussac and Louis Jacques Thenard built upon this discovery by isolating native K via heating of KOH and iron filings up to high temperatures (Emsley 2001).

In the realm of geology, K is the ninth most common element found in the continental crust (Rudnick and Gao 2003). Economically viable concentrations of K are found in variety of mined and manufactured salts (commonly referred to as "potash"), such as alkali-rich sylvite (KCl), langbeinite ($K_2Mg_2(SO_4)_3$), carnallite ($KMgCl_3$•$6(H_2O)$), and polyhalite ($K_2Ca_2Mg(SO_4)_4$•$2H_2O$). Estimated domestic potash resources total about seven billion metric tons; the USA extracted 850,000 marketable tons of K_2O equivalent alone in crop year 2014 (Jasinski 2016). Consumption of K in the commercial industry is controlled primarily by agricultural fertilizers (approximately 85% of US potash sales), with significantly smaller quantities used to manufacture potassium hydroxide (KOH), potassium chloride (KCl), and potassium carbonate (KCO_3), which are used in: industrial water treatments; soap manufacturing; metal treatment and recycling; fire extinguishers; textiles; and food products among other commercial applications (Searls 2001).

Chemistry/Geochemical Behavior

The homologous behavior of the elements in Group IA, resulting from the similar electronic structures of the constituent members, allows for reciprocal substitution for one another in geological materials. For example, because Na^+ and K^+ share identical valence states and similar ionic radii, they can substitute freely for one another in pyroxenes and feldspars with no charge balancing and only minimal strain imposed on the mineral lattice (Wood and Blundy 2003). In contrast, fitting a multivalent transition metal (such as manganese, Mn^{2+}) or high-field strength element (such as hafnium, Hf^{4+}) into the same site would require a coupled substitution to achieve electroneutrality, plus significantly more work to accommodate higher lattice strain energies.

Similar to the other alkali metals, K is categorized as a Large Ion Lithophile Element (LILE) due to its large atomic and ionic radii and its affinity for oxygen-rich geological phases (e.g., silicate rocks and minerals). Although a minimal amount of K (i.e., <10 μg/g) has been inferred to reside within the Earth's core (Oversby and Ringwood 1972; Chabot and Drake 1999; McDonough 2003; Corgne et al. 2007), some studies have challenged these conclusions (Lewis 1971; Lee and Jeanloz 2003; Murthy et al. 2003). Regardless, during silicate differentiation of the Earth and other planetary bodies, K behaves as an incompatible element, concentrating in melt phases rather than remaining behind during melting, or being forced into solidifying minerals during crystallization. Like the other LILE, K is also a fluid mobile element (Taylor and McLennan 1985) and thus commonly associated with metasomatism, hydrothermal alteration, and slab dehydration processes. As a result, the continental crust contains ten times more K than the modern mantle (Hofmann 1988; Sun and McDonough 1989; Arevalo et al. 2009), and significant quantities of K can be found in seafloor sediment (Plank and Langmuir 1998) and the dissolved loads of rivers (Meybeck 1987) due to continental weathering.

Geological Importance

Along with thorium (Th) and uranium (U), K is one of "the big three" long-lived radioactive elements driving the internal heat production within the Earth. The decay of ^{40}K through time also serves as a primary control on the abundance of ^{40}Ar in the atmosphere, as well as the foundation for K-Ar and ^{40}Ar-^{39}Ar radiometric dating techniques. As such, constraining the abundance of K in the Earth (and other rocky planets) has major ramifications for understanding the chemical evolution and dynamics of planetary interiors. However, K is moderately volatile during planetary accretion (Lodders 2003), challenging quantitative models of the composition of the Earth that hinge on chemical relationships between our planet and chondritic meteorites (McDonough and Sun 1995; Javoy 1999; Lyubetskaya and Korenaga 2007). Independent estimates of the abundance of K in the silicate portion of the Earth are disparate and range from as low as 130 μg/g up to 550 μg/g (Arevalo et al. 2009 and references therein). In order to account for the planet's volatile element depletion as well as the potential for nonzero K sequestration in the core, K/U and/or K/Th ratios are invoked frequently as proxies of the absolute abundance and spatial distribution of K in the Earth, other terrestrial planets, and meteorite parent bodies. Because K, Th, and U behave similarly during partial melting and fractional crystallization processes, K/U and K/Th ratios observed in mantle-derived materials may be inferred to represent the compositions of their respective sources.

Although variability in K/U ratios measured in localized suites of oceanic basalts has been observed, studies that have focused on characterizing the composition of a globally representative collection of mantle-derived materials agree on the representative K/U ratio of the modern mantle within the uncertainties of their respective models (Arevalo et al. 2009; Jenner and O'Neill 2012; Gale et al. 2013). Convergence on the quantity of K in the mantle (as extrapolated through the relationship between K and U), in conjunction with established models of K in the continental crust (Rudnick and Gao 2003), suggests that the silicate Earth contains on the order of 280 μg/g K (Arevalo et al. 2009). Because the quantity of Th (~80 ng/g) and U (~20 ng/g) in the silicate Earth are relatively well established due to their more

refractory behavior in the solar nebula and exclusion from the planet's core, approximately 20 TW (or 10^{12} W) of radiogenic heat must be produced from K, Th, and U alone (Arevalo et al. 2009), equating to some 43% of the planet's total surface heat flow of 46 TW (Jaupart et al. 2007). Due to the shorter half-life of ^{40}K relative to the absolute age of the Earth (approx. 4.5 Gyr), 12 times more ^{40}K was extant during the earliest stages of the planet's formation versus today. Interestingly, the shorter half-life of ^{40}K compared to those of ^{232}Th ($t_{½}$ ~ 14 Gyr) and ^{238}U ($t_{½}$ ~ 4.5 Gyr), and the higher absolute abundance of K relative to U in the silicate Earth (K/U ~ 10^4), implicates that K was the primary source of radiogenic heat (other than short-lived radionuclides) during differentiation of the early Earth (Fig. 1). Together, K, Th, and U generated five times more radiogenic heat in the geological past compared to today.

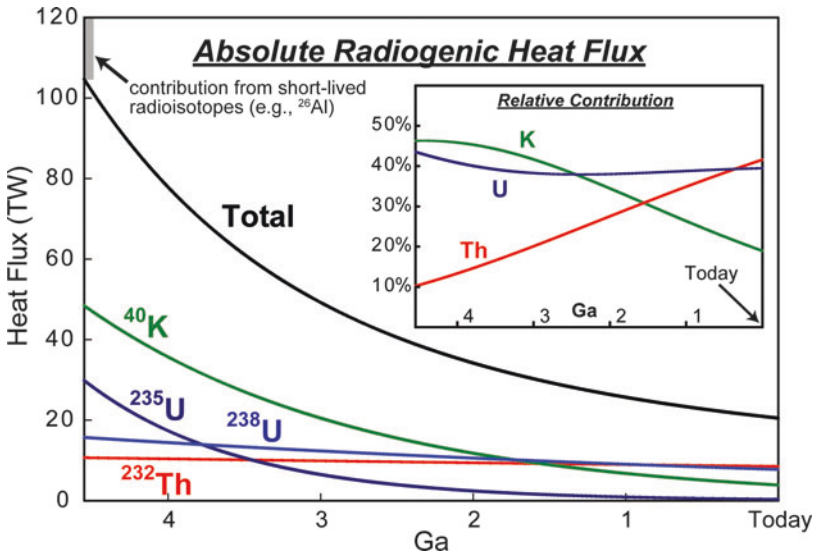
Despite varying proximities to the sun, neither Mercury (Peplowski et al. 2011) nor Venus (Vinogradov et al. 1973) nor Mars (Taylor et al. 2006) appear significantly depleted in K/Th relative to the Earth, as measured from orbit (Fig. 2); this is a surprising discovery due to the volatile behavior of K relative to the more refractory nature of Th. The moon (Prettyman et al. 2006) and the asteroid Vesta (Prettyman et al. 2015), on the other hand, are significantly depleted in volatile elements relative to the Earth based on their respective K/Th ratios.

Biological Utilization and Toxicity

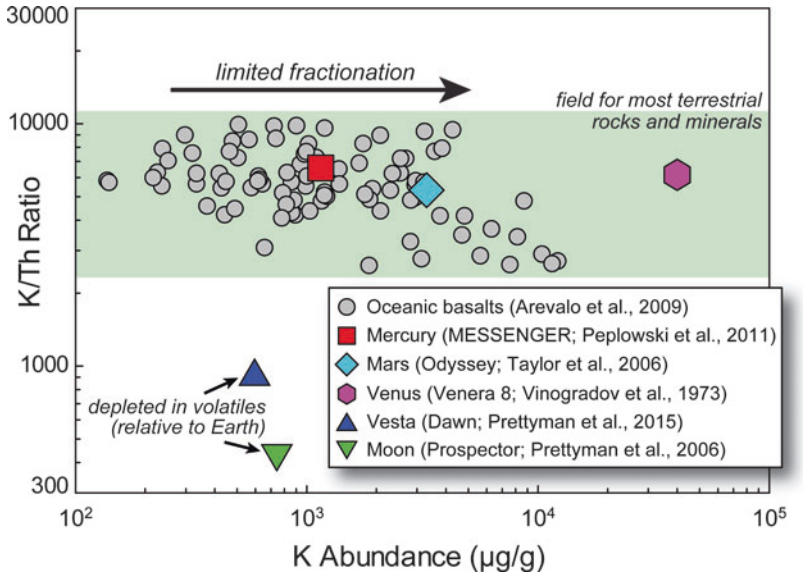
Along with ionic sodium (Na^+), chloride (Cl^-), magnesium (Mg^{2+}), and calcium (Ca^{2+}), K ions serve as electrolytes or substances that conduct electricity in the body. However, unlike other electrolytes K^+ ions are concentrated within cellular structures; in fact, 98% of the K in the human body is located within cells, with the remaining 2% found in extracellular fluids including blood. Cell membranes offer channels through which K^+ and Na^+ may be exchanged against a concentration gradient, termed "sodium-potassium pumps"; there are an estimated 10^{13} of these pumps in each square centimeter of the human body, supporting cellular health and operations (Emsley 2001).

Biologically speaking, K is critical to the proper function of cells, tissues, and organs in the human body. Specifically, K plays a key role in: skeletal and smooth muscle contraction, regulating intracellular fluids, solubilizing proteins, operating nerve impulses, maintaining healthy blood pH levels, and bone support. Dietary sources suggest that the average person should consume some 4.7 mg of K daily to support healthy bodily function, and over-the-counter supplements can be found in many forms, such as tablets, capsules, and liquids, to augment K intake as needed (http://umm.edu/health).

Potassium homeostasis is maintained by balancing consumption of K-containing foods/supplements along with the elimination of excess K through urine and to a lesser extent sweat. Kidney malfunction; laxatives; and diuretics, such as alcohol, coffee, and other caffeinated drinks, can contribute to excessive losses and lead to a deficiency of K in the body, a condition known as hypokalemia. Although mild hypokalemia may not generate any noticeable symptoms, more severe conditions may manifest as muscle weakness, fatigue, and/or cramps, as well as potentially dangerous heart arrhythmias (http://umm.edu/health). Hyperkalemia, or excess K in the body, can result in: gastrointestinal distress including stomach



Potassium, Fig. 1 Earth's radiogenic heat production from the decay of long-lived radionuclides, namely ^{40}K, ^{232}Th, ^{235}U, and ^{238}U, through geological time. For the first 2 Gyr following accretion, K acted as the planet's primary source of radiogenic heat (Figure modified from Arevalo et al., 2009)



Potassium, Fig. 2 Ratios of K/Th measured in terrestrial oceanic basalts compared to average values determined for the surfaces of other planetary bodies (based on remote observations from orbiting spacecraft); K/Th ratios provide a gauge of volatile element depletion. Surprisingly, K is not depleted in Mercury, Venus, nor Mars relative to the Earth, suggesting a decoupling between proximity to the sun and the loss of volatiles during planetary accretion. The moon and the asteroid Vesta, in contrast, are significantly depleted in K/Th

cramps, diarrhea, and vomiting; muscular weakness and ascending paralysis; and cardiovascular arrhythmia (Saxena 1989). The most common cause of hyperkalemia is kidney failure, though fatal injections of concentrated KCl have been applied as a means to murder, capital punishment, and euthanasia (Emsley 2001).

Summary

Potassium (K) is an alkali metal and member of Group IA; as a native element, K is unstable under atmospheric conditions. Like other members of Group IA, K is easily ionized (to K^+) and behaves as a fluid mobile and highly incompatible LILE. Commercially, K is used primarily as an agricultural fertilizer. In the human body, K serves as a vital electrolyte. In the realm of geology, K is concentrated in the continental crust relative to the modern mantle, with only a small fraction (if any) sequestered in the core (though estimates vary).

The decay of ^{40}K produces radiogenic heat, contributes to atmospheric levels of ^{40}Ar, and serves as the foundation for K-Ar and ^{40}Ar-^{39}Ar radiometric dating techniques. The silicate portion of the Earth contains approximately 280 µg/g K. Surprisingly, none of the other terrestrial planets (i.e., Mercury, Venus, and Mars) appear significantly depleted in K/Th relative to the Earth, as measured from orbit; in contrast, the moon and Vesta are measurably depleted in K/Th.

Praseodymium

Scott M. McLennan
Department of Geosciences, Stony Brook University, Stony Brook, NY, USA

Element Data
Atomic Symbol: Pr
Atomic Number: 59
Atomic Weight: 140.90766(2)
Isotopes and Abundances: ^{141}Pr, 100%
1 Atm Melting Point: 931°C
1 Atm Boiling Point: 3520 °C
Common Valences: +3
Ionic Radii: 99.0pm (CN6), 112.6 pm (CN8), and 128.6 pm (CN12)
Pauling Electronegativity: 1.13
First Ionization Energy: 528.1kJ mol^{-1}
Chondritic (CI) Abundance: 0.0964 ppm
Silicate Earth Abundance: 0.215 ppm
Crustal Abundance: 3.9 ppm
Seawater Abundance: 0.535 ppt
Core Abundance: ~0

Properties

Praseodymium (Pr), from the Greek *prasios* (green) and *didymos* (twin), is a soft, ductile, malleable, moderately dense (6.773 g cm^{-3}), silvery metal. Its electronic configuration is [Xe]4f^{3}6s^2. It is moderately stable at room temperature and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE). In geochemical terminology, it is grouped with light rare earth elements (LREE; La – Sm). Praseodymium has only one natural, stable isotope.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Pr as a major component are restricted to LREE varieties, including monazite [(Ce,La,Nd,Th)(PO$_4$)], bastnäsite [REE(CO$_3$)F], allanite [(REE,Ca,Y)$_2$(Al,Fe^{2+},Fe^{3+})$_3$(SiO$_4$)$_3$(OH)], and britholite [(REE,Ca)$_5$(SiO$_4$,PO$_4$)$_3$(OH,F)]. In addition, Pr may be enriched in ion adsorption lateritic kaolinite-halloysite clay deposits that are mined for REE.

Details of properties, mineralogy, history, and uses of Pr were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner (2016), Hammond (2016), and Meija et al. (2016a, b).

History and Use

Praseodymium was discovered in 1885 by Carl Auer von Welsbach, who separated the compound didymia (previously thought to be the oxide of a single element) into the salts of two rare earth elements, neodymia and praseodymia. Praseodymium metal was isolated in 1931. By far, the most important use of praseodymium is as an additive to neodymium magnets. It is also used to provide yellow coloration to ceramics, enamels, and glass. Additional uses include additives to various metals, batteries, lasers, and catalytic converters.

Geochemical Behavior

The fundamental importance of Pr in geochemistry is that it is one of the large trivalent rare earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction."

Praseodymium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element with a 50% $T_{condensation}$ of 1582 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Pr is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Pr normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Pr contents of clastic sediments typically reflect their average provenance abundances.

In seawater, Pr has very low concentrations (sub-ppt) and residence times (~240 year) with speciation dominated by Pr^{3+}, $PrCO_3^+$, and $Pr(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Pr can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration and residence time data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Pr, but in China REE have been added to fertilizers and to stock feed to promote growth. REE (including Pr^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Pr) in human tissues and fluids are very low (tens of ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Precambrian Geochemistry

Tsuyoshi Komiya
Department of Earth Science and Astronomy,
The University of Tokyo, Tokyo, Japan

Definition

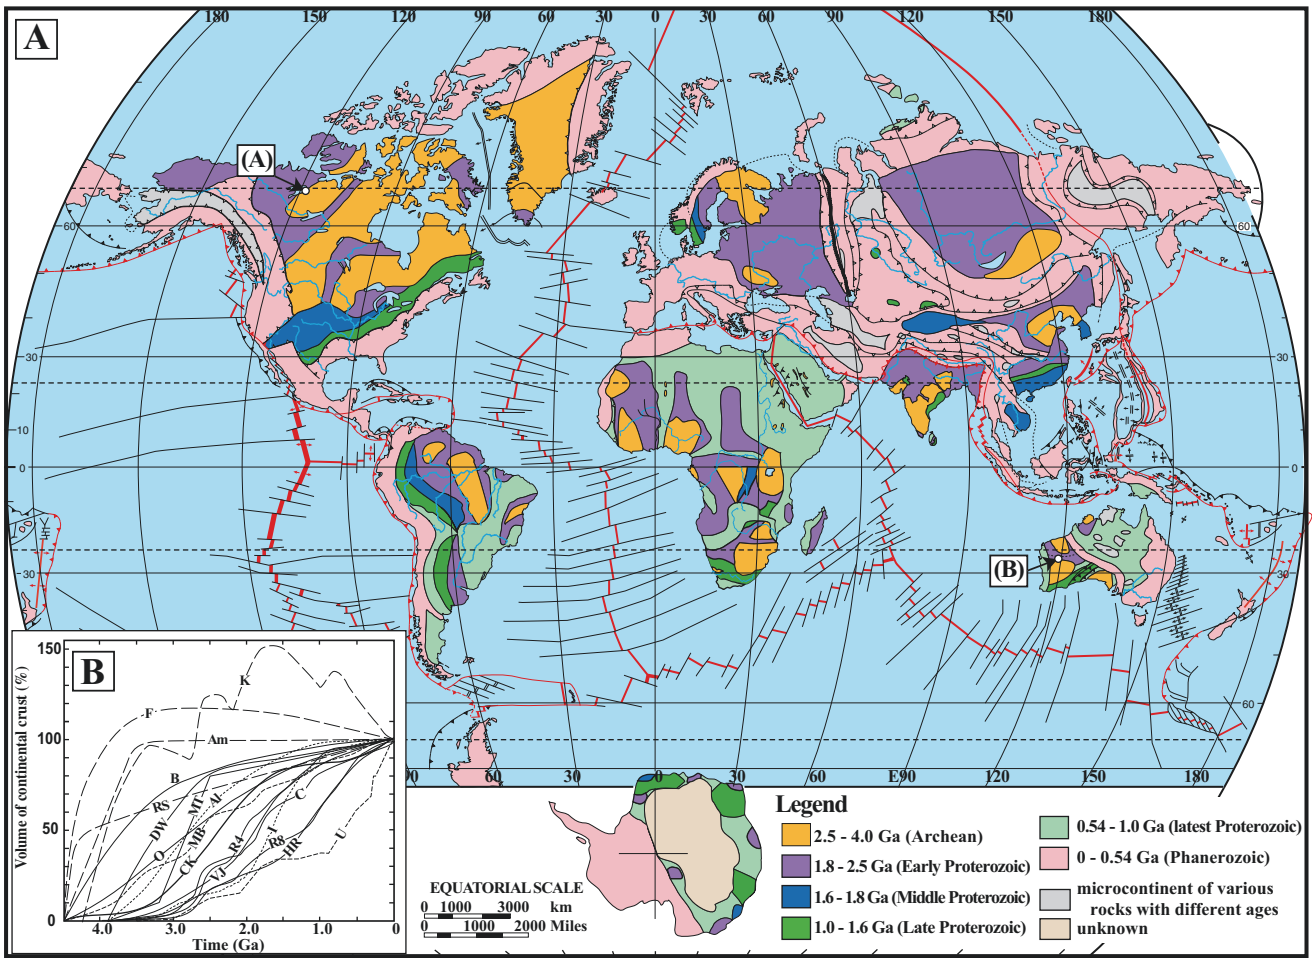
The Precambrian is divided into the Hadean (4567–4030 Ma), Archean (4030–2500 Ma), Proterozoic (2500–542 Ma) Eons. The Archean and Proterozoic are further subdivided into the Eoarchean (4030–3490 Ma), Paleoarchean

(3490–3240), Mesoarchean (3240–2780 Ma) and Neoarchean (2780–2430 Ma), and into the Eoproterozoic (2430–2060 Ma), Paleoproterozoic (2060–1600 Ma), Mesoproterozoic (1600–1000 Ma) and Neoproterozoic Eras (1000–542 Ma), respectively (Ogg et al. 2008).

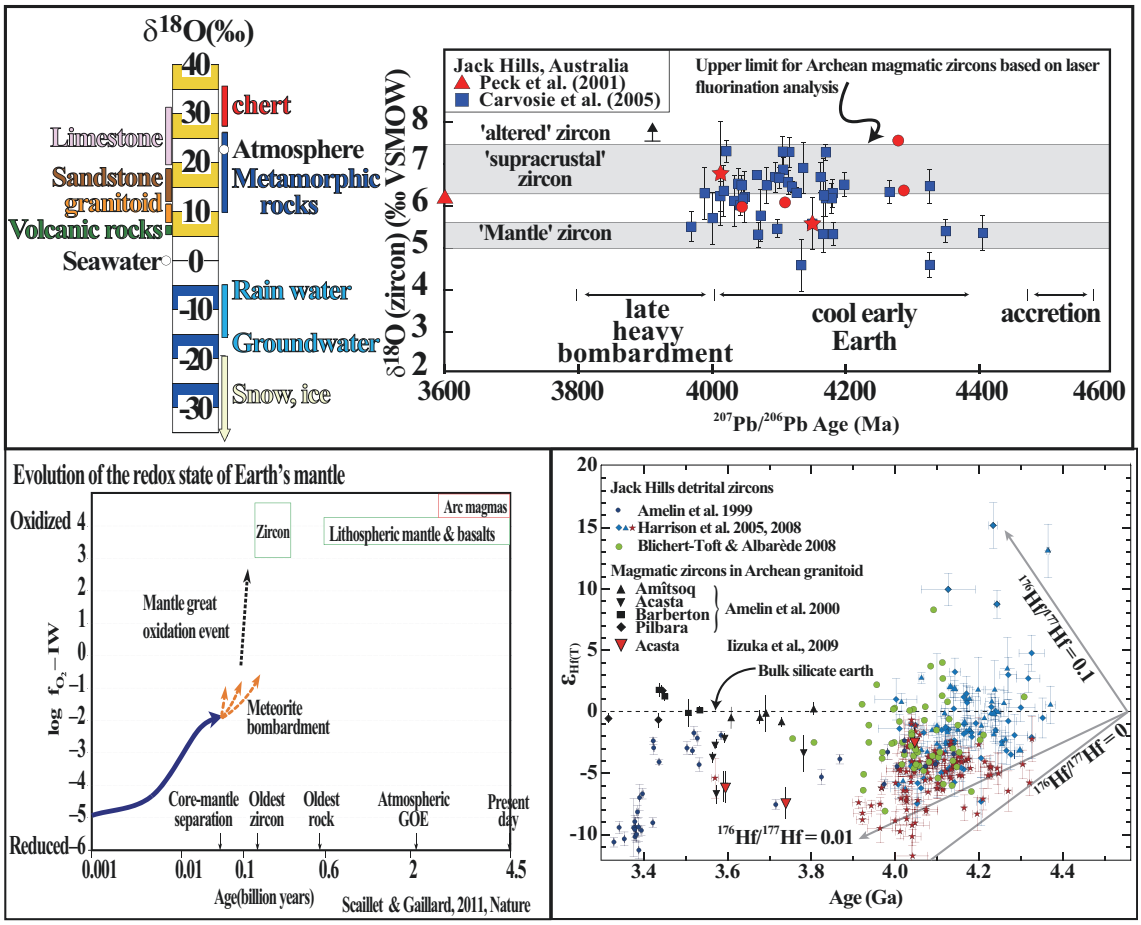
The boundary between the Hadean and Archean is defined by the oldest rock on the earth, the 4.03 Ga Acasta Gneiss Complex, which comprises orthogneisses of various ages and lithologies, and mafic to intermediate enclaves within the gneisses (Fig. 1, loc. A). On the other hand, the boundary between the Archean and Proterozoic is not defined by a specific event because of apparent diachronous and transitional changes of tectonics and sedimentation, and thermal, crustal, surface environmental, and biological evolutions during over 500 m.y. The so-called Proterozoic-style geology, characterized by platform and passive margin sedimentation of thick and coherent volcanosedimentary rocks on continental basements and rifts, started in the Mesoarchean in South Africa and Pilbara but became common in the Proterozoic. Atmospheric oxygen contents drastically increased from 2.5 to 2.2 Ga, known as the Great Oxidation Event.

The Hadean

No Hadean rocks or geologic bodies are preserved on the Earth, but the Hadean minerals are found from not only the Archean clastic sedimentary rocks and granitoids but also younger sedimentary rocks. The Paleoarchean conglomerate in Narryer Complex of the Yilgarn craton (Fig. 1, loc. B) contains many Hadean (up to *ca.* 4.4 Ga) zircons, whose geochemistry of rare earth element (REE) patterns, Ti contents and mineral inclusions indicate they crystallized from granitoid magmas. Moreover, their higher oxygen isotope values, Ce anomalies and large variation of Hf isotope ratios suggest that liquid water, oxidized mantle, and early mantle evolution with/without continental formation goes back to



Precambrian Geochemistry, Fig. 1 (**a**) Compilation map of orogenic belts worldwide (Modified after Utsunomiya et al. 2007). The alphabets mean localities, described in the text. (**b**) Summary of estimated continental growth curves, whose differences are mainly due to difference in estimate of recycling of continental materials and methods (Modified after from Komiya 2011)



Precambrian Geochemistry, Fig. 2 (**a**) Oxygen isotope values of the Hadean zircons from the Jack Hills, Western Australia (Cavosie et al. 2005). early earth (Fig. 2). All modern terrestrial rocks have excess of ^{142}Nd, which is a daughter isotope from an extinct isotope of ^{146}Sm ($\tau_{1/2} = 68$ myr), relative to chondrites (Fig. 3). The ^{142}Nd anomaly indicates early differentiation and/or crustal formation before *ca.* 4.2 Ga, and also suggests a hidden reservoir with a low ε^{142}Nd value within a deep mantle, escape of ^{146}Sm-poor early crusts during planetesimal accretion or accretion of nonchondritic materials. On the other hand, some of Archean materials have positive and negative anomalies of the ε^{142}Nd values relative to modern terrestrial materials, suggesting homogenization of the mantle after the early differentiation. All modern terrestrial rocks also have excess of ^{182}W, which is a daughter isotope from an extinct isotope of ^{182}Hf ($\tau_{1/2} = 8.9$ myr), relative to chondrites, and some of the Archean rocks are more enriched in ^{182}W than modern terrestrial rocks (Fig. 4). The anomaly indicates early core formation with/without early mantle differentiation. Ages of impact melt rocks on the Moon and lunar meteorites suggest the Late Heavy Bombardment event from *ca.* 4.1 to 3.8 Ga, when many asteroids collided with terrestrial planets.

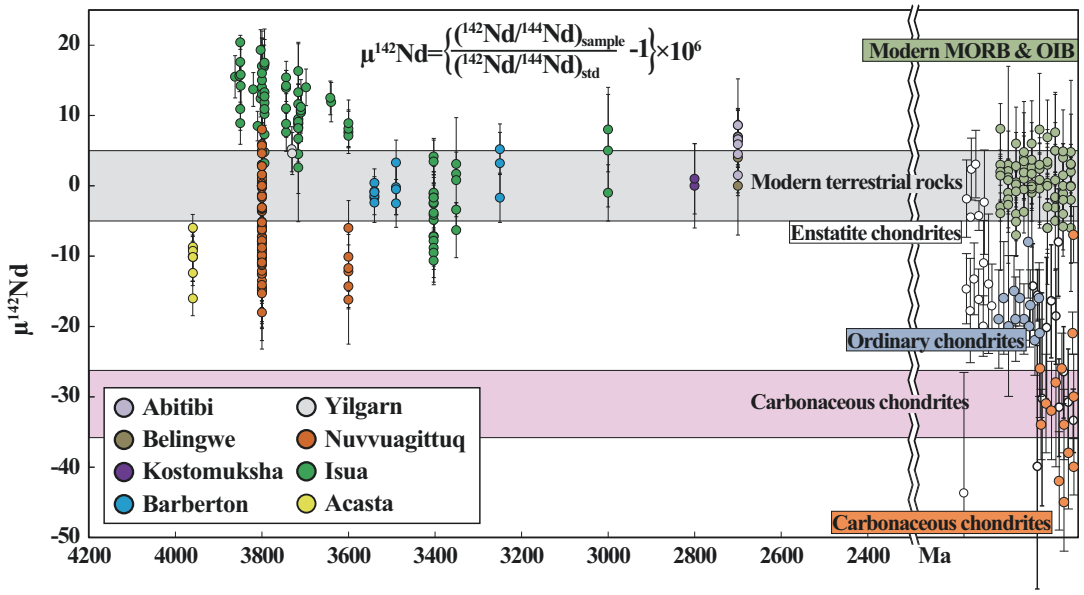
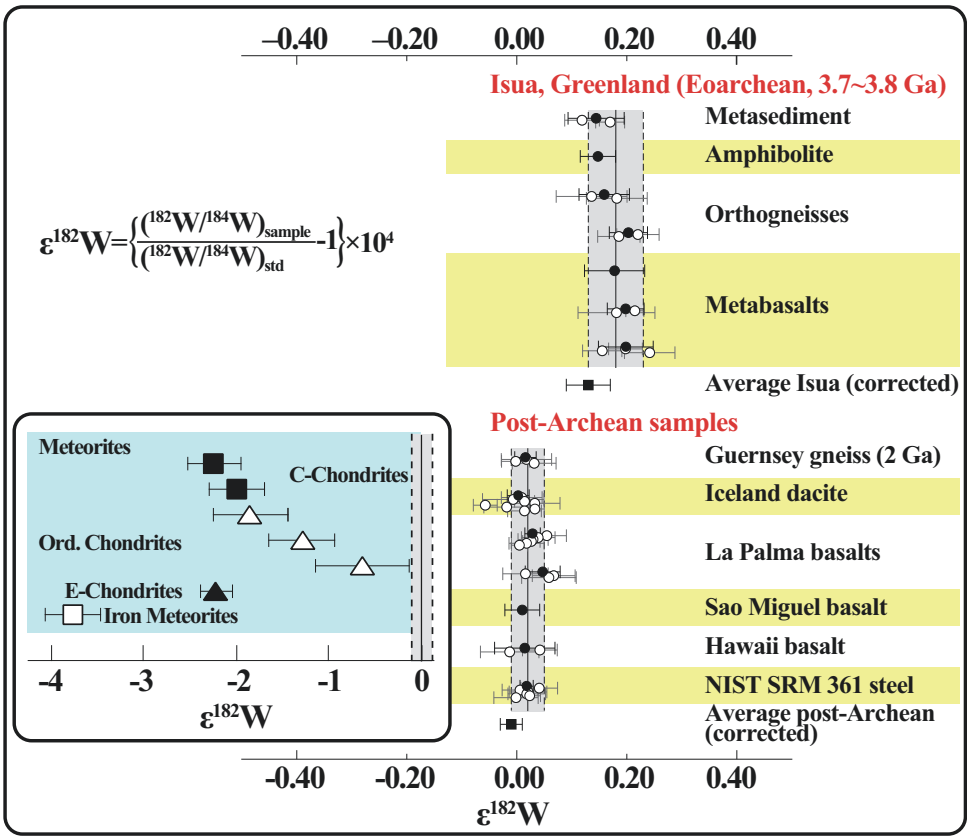
Solid Earth Evolution in the Precambrian

Estimates of continental growth are highly varied (Fig. 1) but can be divided into two major groups: (1) early crustal growth and subsequent recycling and (2) continuous or episodic crustal growth (see Komiya 2011). The estimates from the Earth's thermal history implied rapid growth of continental crusts (F, K in Fig. 1), whereas the estimates from their present distribution display slow growth (HR, U). The estimates from mantle and crustal compositions suggest moderate increase in the Proterozoic to Phanerozoic (CK, O, Al, MB, MT). Age distribution and Hf isotopes of detrital zircons showed significant continental recycling including intracontinental recycling, crustal reworking and crust–mantle recycling, and supported the early growth of continental crusts (C, I, R4, R8, Am, K, VJ).

The Archean continental crusts account for *ca.* 20% of present continental volumes (Fig. 1), and mainly comprise supracrustal rocks and intrusive granitoid batholiths, the so-called granite-greenstone belt terrains. The greenstone

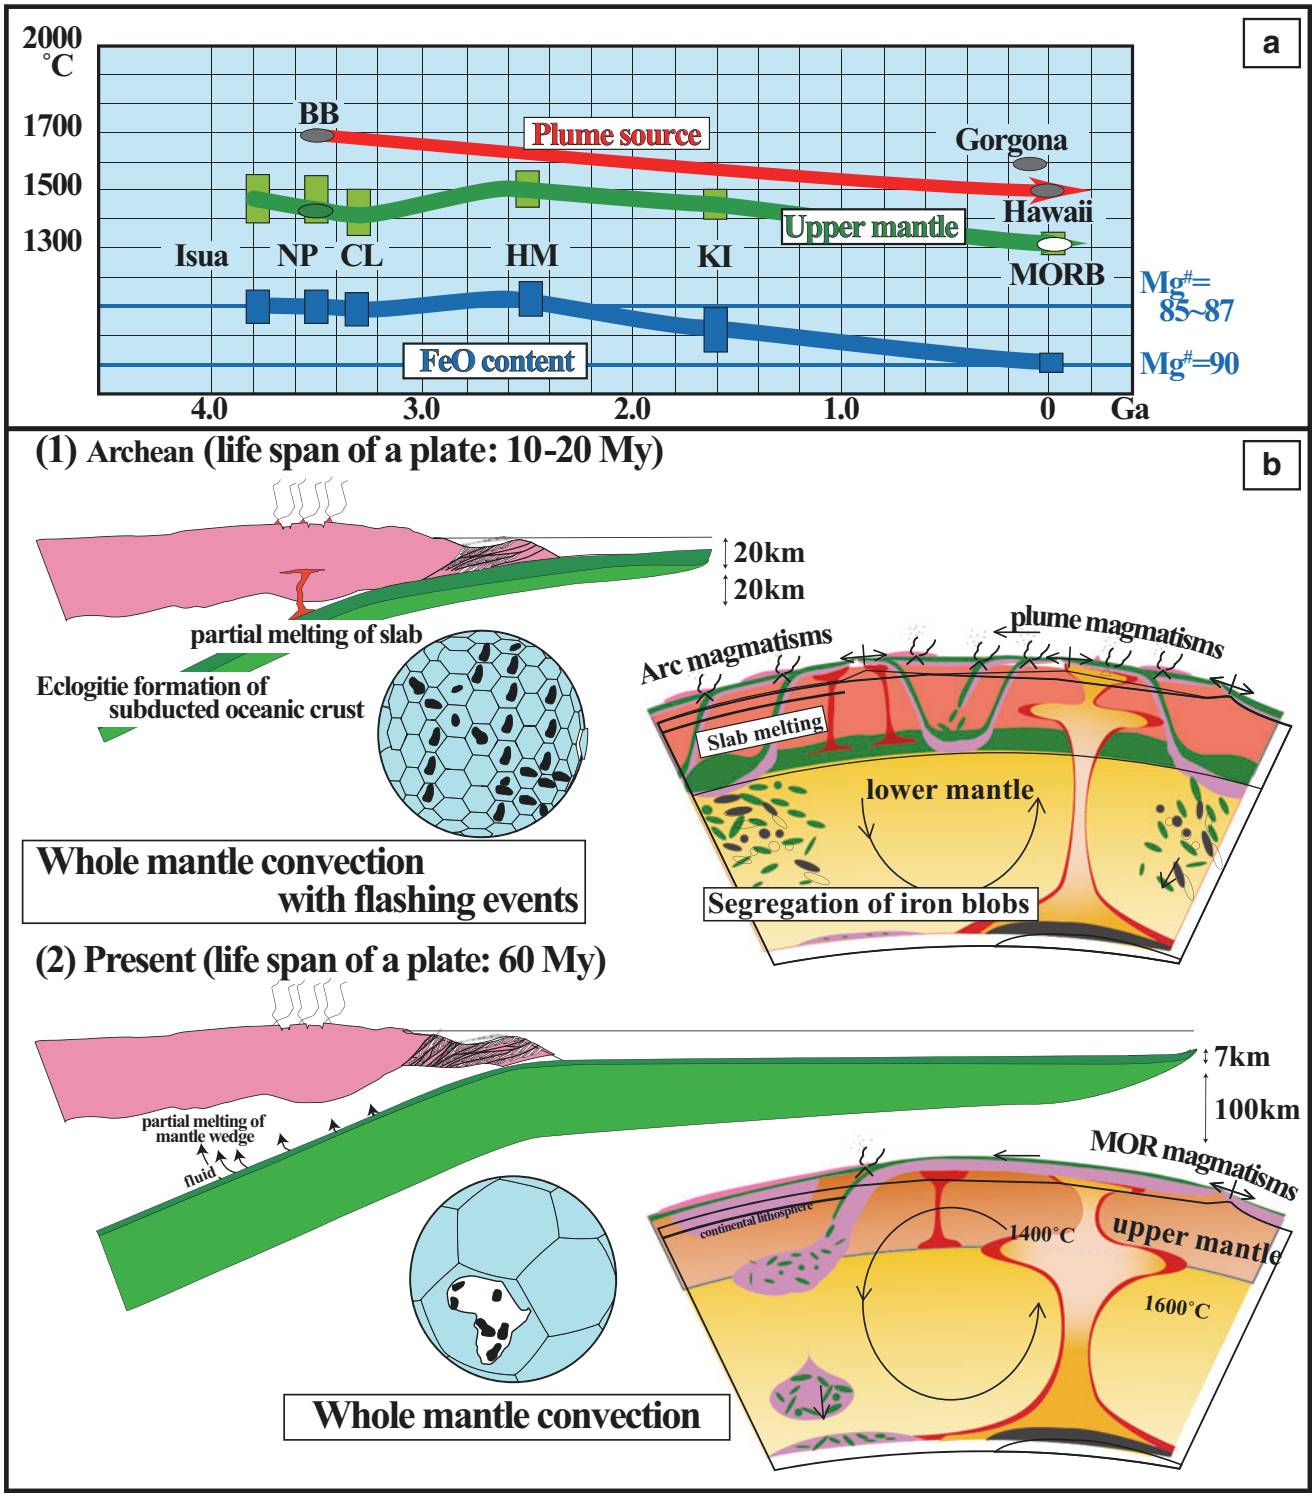


Precambrian Geochemistry, Fig. 3 Summary of $\mu^{142}Nd$ values of Precambrian rocks along with terrestrial modern rocks and carbonaceous, ordinary, and enstatite chondrites. The terrestrial rocks have excess of the $\mu^{142}Nd$ values compared with the carbonaceous chondrites, suggesting early differentiation before 4.2 Ga and hidden reservoirs or accretion of nonchondritic materials



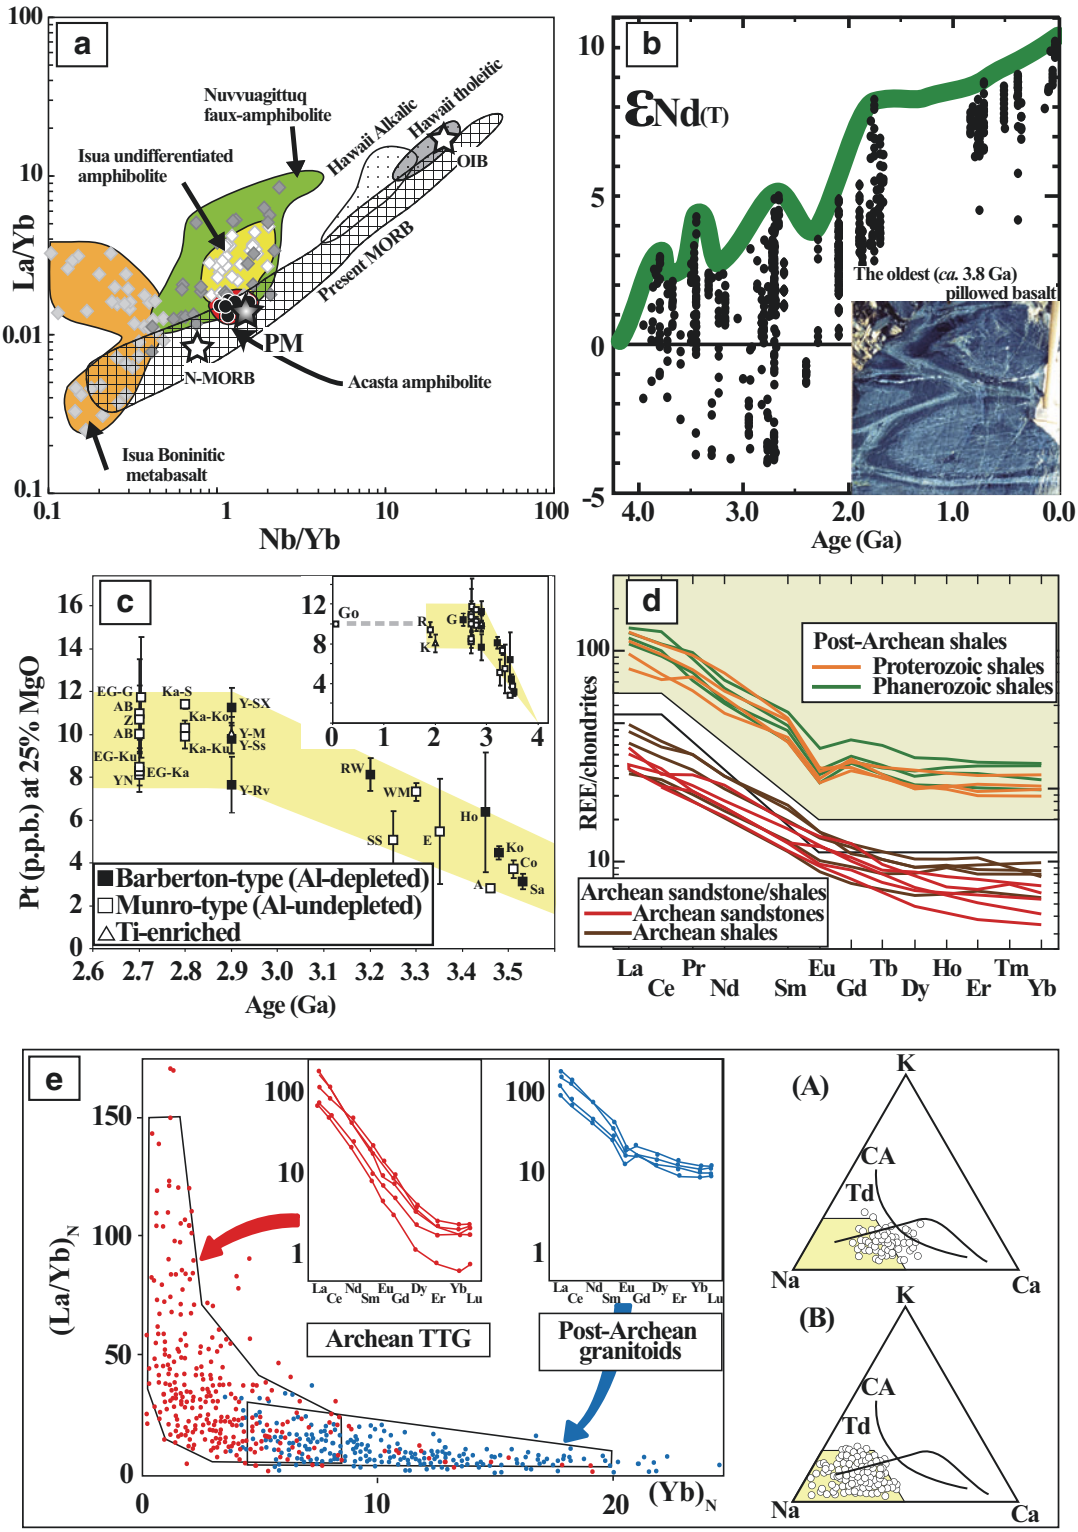
Precambrian Geochemistry, Fig. 4 Summary of $\varepsilon^{182}W$ values of the Eoarchean rocks along with terrestrial post-Archean rocks and meteorites. The terrestrial rocks have positive anomaly of the $\varepsilon^{182}W$ values, indicating the early core formation with/without early mantle differentiation

belts comprise a possible ophiolitic ultramafic body, ultramafic (komatiitic) and mafic volcanic rocks, chemical and minor clastic sedimentary rocks. Potential mantle temperatures of the Archean upper and plume-source mantles were estimated to be hotter by 150–200 °C than the modern equivalents from MgO, FeO, and SiO_2 contents of the mafic and komatiitic rocks, respectively (Fig. 5a). The higher mantle temperature results in thick oceanic crusts and thin, small, and

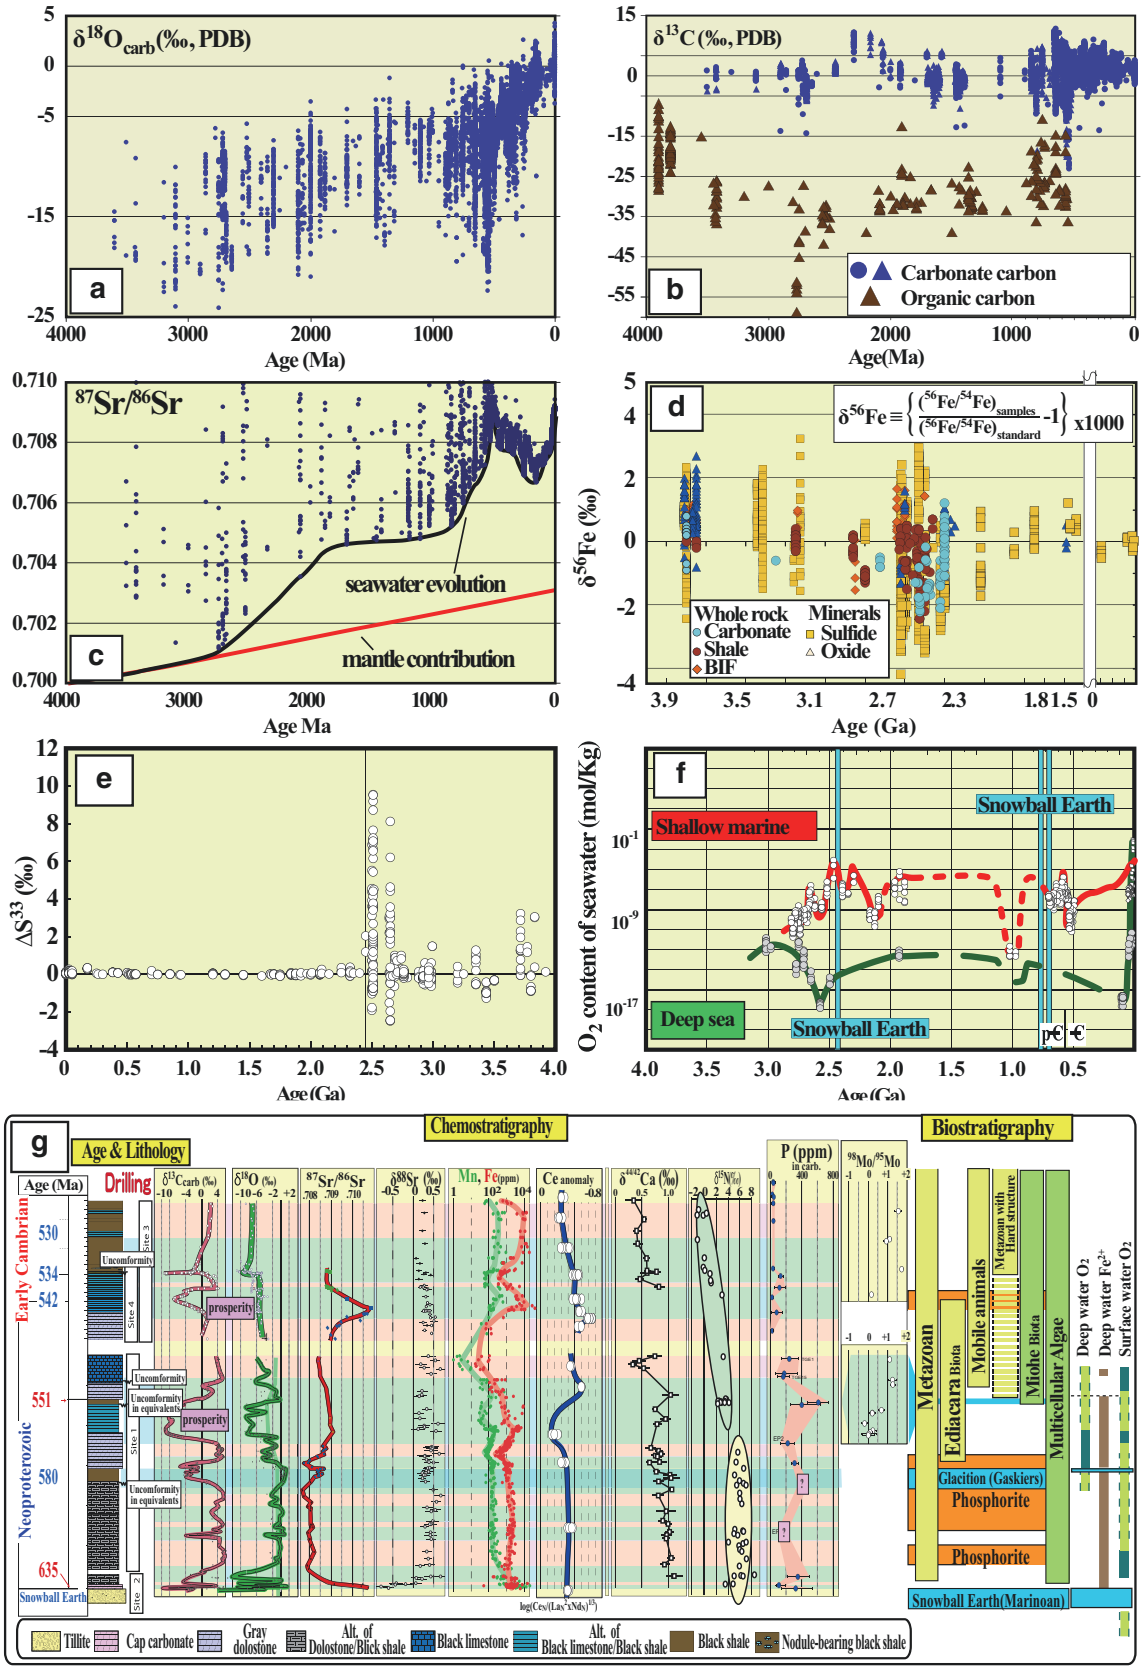


Precambrian Geochemistry, Fig. 5 (**a**) Secular variations of potential mantle temperatures of the upper and plume-source mantles and iron content of the upper mantle through the time. (**b**) Cartoons of modes of oceanic lithospheres and material circulation in whole mantles in Archean and Phanerozoic

young oceanic lithospheres (Fig. 5b). The Eoarchean mafic rocks are commonly depleted in Nb contents relative to modern MORB and OIB (Fig. 6a). The depletion is mainly due to crustal contamination with/without secondary alteration, but even if the secondary influence were corrected, they have lower Nb/Yb ratios (Fig. 6a). Their low Nb/Yb ratios suggest



Precambrian Geochemistry, Fig. 6 (**a**) A Nb/Yb vs. La/Yb diagram of the Eoarchean mafic rocks along with modern MORBs and OIBs. The mafic rocks are depleted in Nb contents relative to the modern basalts, suggesting the suprasubduction zone magmatism or deep mantle differentiation in the early earth. (**b**) Secular change of εNd values of mafic volcanic rocks through the time, showing the Nd isotopic evolution of the residual depleted mantle. (**c**) Secular change of platinum contents of komatiites at 25% in MgO contents, which shows that the Pt contents increased in the Archean possibly due to late meteorite impacts (Maier et al. 2009). (**d**) Comparison of REE patterns of the Archean and post-Archean shales. (**e**) Geochemical and petrological characteristics of the Archean and post-Archean granitoids (Martin 1999). The Archean granitoid has TTG compositions and is characterized by depletion of HREE and lack of Eu anomaly, evident for slab-melting



Precambrian Geochemistry, Fig. 7 (continued)

that they were formed in suprasubduction zones or from a Nb-poor source mantle, which underwent deep mantle differentiation in the early Earth. Figure 6b displays an Nd isotope evolution curve of a depleted (upper) mantle based on Nd isotope values of mafic rocks through the time and shows its progressive depletion with intermittent rejuvenation during the rapid continental growth. Figure 6c shows increase of platinum contents of komatiites at 25 wt% MgO contents, suggesting PGE contents, namely highly siderophile elements, increased through the time possibly due to late meteorite accretion. Figure 6d shows compositions of the Archean and post-Archean shales, and the post-Archean shales have distinct negative Eu anomalies. Figure 6e shows REE patterns of the Archean and post-Archean granitoids, and suggests that there has been no change in the composition of the upper crust after the Archean. Most Archean granitoid have tonalite-trondhjemite-granodiorite compositions and are characterized by depletion of the HREE and lack of Eu anomalies, suggesting that they were formed through partial melting of subducted oceanic crust (slab melting) in the garnet stability field.

Surface Environmental Evolution in the Precambrian

Oxygen isotope values of carbonate rocks and fossil carbonates increased through the time (Fig. 7a). Assuming that the $\delta^{18}O$ value of seawater was constant through the time and the primary $\delta^{18}O$ values are preserved, temperature of seawater is estimated to be *ca.* 70 °C in the Archean. But, the low $\delta^{18}O$ values are probably due to secondary alteration because the $\delta^{18}O$ values are susceptible to secondary alteration or due to secular change of $\delta^{18}O$ value of seawater. Figure 7b displays secular changes of carbonate and organic carbon isotope ratios through the time. The $\delta^{13}C_{carb}$ values show positive excursions in the Paleoproterozoic and Neoproterozoic, possibly due to increase of organic burial and atmospheric oxygen contents, and the large and frequent fluctuations since the Ediacaran. The low (<−25‰) $\delta^{13}C_{org}$ values in the Eoarchean suggest presence of early life, and quite low (<−40‰) $\delta^{13}C_{org}$ values in the Mesoarchean indicate aerobic or anaerobic methanotrophs. Sr isotope ratios of carbonate are a proxy of ratio of continental to hydrothermal influxes into seawater and the sudden increase in the Mesoarchean and Neoproterozoic suggest rapid growth of continental crusts (Fig. 7c). The presence of low (<−2‰) $\delta^{56}Fe$ values suggests bacterial-dissimilatory iron reduction since the Eoarchean whereas the high $\delta^{56}Fe$ values are indicate ferruginous ocean before the Paleoproterozoic and in the Ediacaran (Fig. 7d). The presence of mass-independent fractionation in sulfur isotopes indicates low atmospheric oxygen contents before the Paleoarchean (Fig. 7e). Figure 7f displays secular change of oxygen contents of shallow marine and deep seawater through the time based on REE contents of carbonate minerals and suggests oxygen contents of the shallow marine increased in the Neoarchean whereas deep-sea in the Phanerozoic. The drastic increase of atmospheric oxygen in the Neoarchean to Paleoproterozoic is named the Great Oxidation Event. After the Event, banded iron formations disappeared because the ocean changed from the ferruginous to sulfidic ocean.

The Ediacaran to Early Cambrian transition is a key period of the evolution of the earth: drastic changes of surface environments such as Snowball Earth and emergence of Metazoa (Fig. 7g). Chemostratigraphies of C, O, Sr, and Ca isotopes and Fe, Mn, REE, and P contents of carbonates, Mo isotopes of black shales and C and N of organic matter are proxies to estimate primary productivity, continental weathering influx, temperature, nutrient contents (P, N), and redox condition of seawater. The positive excursions of Sr isotopes indicate high continental influxes at *ca.* 580, 570–550, and 540 Ma, corresponding to timings of biological evolution. Phosphorus contents of carbonate rock were very high until *ca.* 550 Ma, and then decreased, suggesting the seawater was enriched in phosphate until then. High N and Ca isotope values indicate that seawater was depleted in nitrate and Ca contents until *ca.* 550 Ma, and then increased. Molybdenum isotopes of black shale, and Fe and Mn contents and REE patterns of carbonate rocks indicate that seawater became more oxic since *ca.* 550 Ma. The geochemical evidence suggests that the emergence of Metazoan in the Early Ediacaran was caused under a relatively less oxic and phosphate-rich condition, whereas their diversification occurred under an oxic, nitrate, and Ca-rich condition. Especially, the transition from phosphate to nitrate- and Ca-rich seawater possibly resulted in diversification of motile and Ca-biomineralizing animals.

Precambrian Geochemistry, Fig. 7 (**a**) Oxygen isotopic evolution of carbonate rocks and Phanerozoic calcitic fossils (Shields and Veizer 2002). Summary and Conclusions

It is widely considered that the Earth underwent some significant events such as planetesimal accretion, giant impact, magma ocean, core formation, early mantle differentiation, and Late Heavy Bombardment in the Hadean. But, the direct evidence is not preserved in the present Earth, and extinct radiogenic nuclides of ^{146}Sm-^{142}Nd and ^{182}Hf-^{182}W systems provide valuable insight into the early Earth. From the Archean to Proterozoic, thermal evolution and increase of atmospheric oxygen are important factors controlling the Earth's evolution. The decrease of mantle temperature resulted in the beginning of plate tectonics, continental formation, and mantle dynamics. The emergence of oxygen-producing organisms and the consequent expansion of oxidized surface environments led to the Great Oxidation Event, secular change of atmosphere and seawater compositions, and emergence of eukaryotes and metazoans. Many geochemical proxies to record the changes have been developed, especially after the recent establishment of stable isotope measurements of heavy transition metals so that the detailed pictures of secular changes of solid earth and surface environments through geologic time are being obtained.

Precambrian Organic Matter

Roger Summons
Earth, Atmospheric, and Planetary Sciences Department, Massachusetts Institute of Technology, Cambridge, MA, USA

Definition

Precambrian organic matter comprises all carbonaceous materials preserved in, and indigenous to, sedimentary rocks deposited during the Proterozoic and Archean Eons. These carbonaceous materials range in mass from small individual organic molecules such as simple hydrocarbons, through macromolecules and microscopic fossils, and extending all the way to massive accumulations of petroleum.

Historical Perspective

Organic matter, preserved in Precambrian sedimentary rocks, is an important repository for chemical data pertinent to the quest to understand the origins, evolution, and history of life on Earth (Eglinton 1969; Gaines et al. 2009; McKirdy 1974). As for the Phanerozoic, organic carbon and organic carbon compounds complement other sources of historical biogeochemical information derived from physical fossils, sedimentary fabrics, mineral deposits, sedimentary inorganic chemistry, and a numerous and growing collection of stable isotopic systems. A necessary underlying assumption is that any significant accumulation of sedimentary organic matter is the result of biological carbon assimilation, and this assumption is supported by the large carbon isotopic separation between the inorganic and organic carbon indicative of a biogeochemical carbon cycle operating since at least 3.45 billion years ago (Ga) (Schidlowski 2001). Sedimentary rocks older than this exist, but they are sparse and difficult to characterize, whereas after 3.45 Ga they become increasingly common, better understood in the sense of depositional settings, and afford evidence of both the antiquity of life and its influence on the development of the terrestrial environment through time.

Prevalence and Preservation

The prevalence of organic matter in Proterozoic sedimentary rocks is evidently not significantly different from that in Phanerozoic equivalents. However, the loss of sedimentary record through tectonic movements leading to erosion or to deep burial means that the chances of finding minimally

altered material decrease with increasing age. Archean sediments are particularly depleted for this reason. Systematic surveys of organic matter in Archean and Proterozoic rocks (Hayes et al. 1983; McKirdy 1974) used atomic hydrogen to carbon *(H/C)* ratios, X-ray patterns, visual analysis, and mineral assemblages to evaluate thermal alteration. It was found that despite the recognition of occasional Archean rocks with high organic carbon contents, they were invariably metamorphosed to the extent that remaining organic matter approached the composition of graphite with *HIC* ratios 0.0–0.5 (Hayes et al. 1983). Those Archean samples with higher than average *HIC* ratios were characterized by the presence of uranium or thorium bearing minerals (see below). Rocks of Proterozoic age also show evidence of significant thermal alteration, although they have a higher proportion of examples with moderate to good preservation (Hayes et al. 1983; McKirdy 1974). Subsequent detailed studies of some of those units (Brocks and Summons 2003; Crick et al. 1988; Hayes et al. 1992) have confirmed that for the Proterozoic, at least, there are numerous examples of abundant and very well-preserved organic matter as old as 1.64 Ga.

Kerogen

Kerogen is, by definition, insoluble, macromolecular, and immobile sedimentary organic matter. A specific example would be organic walled microfossils bearing strong morphological resemblances to their precursor organisms and which are composed of organic biopolymers. More often than not, however, kerogen is amorphous. Because it is immobile, kerogen is generally accepted as a form of organic matter that must be native to the host rock and formed by organisms living at the time of sedimentation. An exception to this generalization would be organic matter that encapsulates radioactive mineral grains. These are thucholites and are thought to have formed when migrating hydrocarbons became trapped and polymerized by the associated ionizing radiation (Rasmussen et al. 1993). A related process, possibly combined with natural biodegradation and thermal metamorphism, could have resulted in some more massive accumulations of poorly crystalline carbon such as the ~2 Ga Karelian shungite (Melezhik et al. 1999) which has the characteristics of migrated hydrocarbon and is the apparent remains of ancient, petrified oil fields (Melezhik et al. 2004). In the case of this material, spectroscopic studies show nanomolecular layers with similarities to natural and synthetic cokes. High-resolution transmission electron microscopy (HRTEM) images and nanodiffraction patterns of shungites suggest a material with partial shells of disordered carbon resembling bent stacks of graphene layers (Kovalevski et al. 2001). Thus, carbon in thucholites and shungites has experienced the combined and extreme effects of time, temperature, and/or radiolysis, and this has destroyed virtually all original and diagnostic chemical structure (Dahl et al. 1988; Kovalevski et al. 2001).

Carbon Cycle Reconstruction

Arguably, it has been the isotopic analyses of Precambrian kerogens and co-eval carbonates that has yielded most paleobiological knowledge including evidence for both the antiquity of life and the uniformity of fundamental biogeochemical processes through time (Des Marais 2001; Hayes and Waldbauer 2006; Schidlowski 1988; Schidlowski et al. 1983). Severe thermal alteration can disrupt or destroy the original C-isotopic signals of organic matter; screening for these effects is essential and has been useful for identifying and correcting for corrupted isotopic signals (Des Marais 2001). More recently, microRaman spectroscopy has been used to evaluate the H/C ratio of Precambrian kerogens and, if needed, make adjustments to C-isotopic data (Ferralis et al. 2016). Moreover, the isotopic composition of inorganic carbon, which is also used to evaluate secular change in the C-cycle, is complementary to that of organic carbon provided it has not been affected by diagenesis (Knoll et al. 1986). Studies, which have taken all these issues into account, now abound and indicate that sedimentary record of carbon isotopes is rich in informative detail. Thus, the C-isotopic data record a history of global secular change and offer the means to follow the evolution of the global carbon cycle (Des Marais 1997, 2001; Des Marais et al. 1992; Hayes and Waldbauer 2006; Rothman 2015; Rothman et al. 2003; Hayes et al. 1999) and concomitant change in the surface environment (Eigenbrode and Freeman 2006) and to conduct chemostratigraphic correlations in the Proterozoic (Derry et al. 1992; Halverson et al. 2005).

Precambrian organic matter also encodes other isotopic signals, organic nitrogen being a prime example. Nitrogen cycle reconstructions have been the primary target with considerable success despite the fact that most N in ancient sediments is preserved as ammonium with lower amounts of organic-N (Beaumont and Robert 1999; Godfrey and Falkowski 2009; Godfrey et al. 2013; Stüeken et al. 2015a, b; Thomazo et al. 2011). Data gathered so far indicate that a predominantly anaerobic N-cycle existed prior to the Great Oxidation Event (GOE) (Stüeken et al. 2016) after which emerged a pervasive aerobic marine nitrogen cycle (Zerkle et al. 2017). Although rarely reported, the isotope data for sulfur bound into organic matter can complement isotope data from pyrites in its capacity to reveal signals imparted by the Precambrian S-cycle (Bontognali et al. 2012). When coupled with ^{34}S data for co-eval sulfate and sulfide, the isotopic composition of organic sulfur compounds can be

informative about microbial sulfate reduction, sedimentary diagenesis (Amrani 2014; Meshoulam et al. 2016), as well as photochemical processes involving atmospheric sulfur species.

Morphologically Complex Organic Matter

In the Precambrian, there has long been a strong recognition of the ubiquity and distinctive appearance of organic-walled microscopic fossils and that they are informative about the progress of microbial evolution (Awramik and Barghoorn 1977; Barghoorn 1971; Barghoorn and Schopf 1965; Schopf and Walter 1983). Preservation in silica was generally seen offering the most favorable taphonomic window allowing a three-dimensional perspective on fossil morphologies (Schopf and Kudryavtsev 2009; Schopf et al. 2007; Wacey et al. 2011). This field is not without risk (Brasier et al. 2002), however, since it has been shown that abiogenic self-assembly of microscopic silica-carbonate structures can sometimes mimic microscopic fossils (García Ruiz et al. 2002, 2003; Hofmann 2004) requiring the application of multiple and complementary microscopic and microchemical approaches to distinguish genuine biotic remains (Brasier et al. 2006, 2015; Schopf and Kudryavtsev 2009; Wacey et al. 2012).

Shales have also been productive targets in the search for Precambrian organic-walled microscopic fossils. Objects with multiple eukaryote characteristics predominate (Javaux et al. 2001, 2003; Knoll 1992, 2014), especially in the Neoproterozoic, and are demonstrably providing a sharper picture of eukaryotic evolution (Agić et al. 2017; Butterfield 2000, 2015; Javaux and Knoll 2017; Knoll 2014) as well as being useful for biostratigraphy (Cohen and Macdonald 2015; Grey 2005; Grey and Willman 2009; Strauss et al. 2014). Some phosphorites have also been productive as a taphonomic medium (Xiao et al. 1998).

Techniques for microchemical analysis of amorphous Precambrian organic matter and individual organic microfossils have advanced significantly with secondary ion mass spectrometry (SIMS) methods able to precisely measure individual C-isotopic compositions (House et al. 2000, 2013; Williford et al. 2015), while scanning transmission X-ray microscopy (STXM) techniques and microRaman mapping can shed light on aspects of molecular preservation (Alleon et al. 2015, 2016, 2017) and chemical differences at the micron scale (Ferralis et al. 2016). Numerous additional-spectroscopy techniques including micro-Fourier transform infrared (micro-FTIR), X-ray photoelectron (XPS), electron probe microanalysis (EPMA), and fluorescence extend the array of ways to probe the chemistry and thermal histories of microscopic fossils (Hackley et al. 2017; Muirhead et al. 2017). Accordingly, and applying principles established through the chemical study of Phanerozoic organic matter, there clearly exists additional valuable isotopic and chemical signals encoded in optically recognizable microfossils and, logically, in the associated amorphous substances.

Bitumen: Solvent-Soluble Organic Matter

Early attempts to detect diagnostic organic molecules (biomarkers) in extractable organic matter (bitumen) offered considerable promise for learning more about early life on the Earth (e.g., Eglinton et al. 1964). However, some subsequent studies correctly pointed to inconsistencies between the chemical stabilities of some putative Precambrian molecular fossils (e.g., optically active amino acids) and the severe thermal histories to which the host rocks had been subjected (e.g., Hayes et al. 1983). This problem, and some apparently incongruous carbon isotopic relationships between Precambrian bitumens (Hoering 1965, 1966; Logan et al. 1995), which are mobile, and co-existing kerogens, which are not, led to a general cautionary approach to the potential of volatile or mobile organic compounds to yield credible information (e.g., Hoering 1965). However, given the nature, prevalence, and distribution of petroleum in sediments worldwide, it seemed that no method existed that could completely dispel concerns about migration of these mobile materials into the Precambrian from more recent strata.

Biomarkers are widely and confidently used in petroleum exploration and in studies of sedimentary geochemical processes. There is now a rich compendium of compounds for which chemical structure, biological origin, and diagenetic alteration pathways have been rigorously documented (Peters et al. 2005). Hydrocarbons, which are derived from and are diagnostic for bacteria, algae, and plants, have been described, and their occurrences determined with sufficient certainty that they are now routinely used to assign the thermal history, the lithology, and depositional settings of the sediments in which they were deposited. For example, heat-driven chemical reactions are known to convert molecules with original biological structures into thermodynamically more stable forms or "geo-isomers." The extent of conversion can be correlated with independent indices of temperature history such as kerogen elemental *H/C* ratio, reflectance, and fluorescence measurements or Rock-Eval pyrolysis parameters (Peters et al. 2005).

Studies of Precambrian hydrocarbons have been most informative and convincing when addressing the contents, compositions, and biological significance of biomarkers in the Neoproterozoic where deposits of petroleum and an abundance of low maturity petroleum source rocks were recognized in Oman (Grantham 1986; Grantham et al. 1988),

Eastern Siberia (Fowler and Douglas 1987), and Australia (Crick et al. 1988; Jackson et al. 1986; Summons et al. 1988). Detailed studies of these deposits confirmed the presence of eukaryotic steranes, bacterial triterpanes, carotenoids, porphyrins, acyclic isoprenoids, and mid-chain branched alkanes with unusual carbon number predominances that marked them as distinct from Phanerozoic counterparts (Bhattacharya et al. 2017; French et al. 2015b; Grosjean et al. 2009, 2012; Kelly et al. 2011; Klomp 1986). Hydropyrolysis experiments were able to show that many of these hydrocarbons were generated from co-eval kerogens (Love et al. 2008). The most abundant fossil steroids in these rocks, in particular, can be attributed to the Neoproterozoic rise to prominence of eukaryotic phytoplankton (Knoll et al. 2007). However, other steranes that are rare in, or absent from, younger sedimentary sequences were also detected (Bender et al. 2013, 2015; McCaffrey et al. 1994), some of which have been attributed to an origin from sponges (Brocks et al. 2016; Love et al. 2009).

In situ bitumens from older rock sequences have also been studied for their potential to reveal clues to the antiquity of particular microbial taxa and their biochemical pathways. Archean rocks from Australia and South Africa did yield assemblages of hydrocarbons of paleobiological interest (Brocks et al. 1999; Summons et al. 1999; Waldbauer et al. 2009), but these results subsequently became clouded in doubt. Manifold problems included the fact that the studied rocks, mostly from cores drilled for mineral exploration, had not been collected or archived with a view to conducting trace level organic analyses. The prevalence of potential sources of contamination (Brocks et al. 2008) as well as anomalous isotopic data and spatial distributions (Brocks 2011; Rasmussen et al. 2008) contributed further uncertainty. The inability to demonstrate that the reported Archean hydrocarbons, beyond all doubt, were indigenous and syngenetic to the host then led to an experiment where new cores were drilled into Archean sequences of the Pilbara Craton of Western Australia. Two sedimentary sequences that had previously yielded putative Archean biomarkers in drill core samples obtained for mineral exploration were re-drilled along with a third core through sequence of highly metamorphosed shales that served as a control. The cores were drilled, archived, sampled, and analyzed under stringently clean conditions and the results were unambiguous. Although non-diagnostic diamondoid and polyaromatic hydrocarbons were present, sterane, triterpane, and acyclic isoprenoid were undetectable in the fresh cores (French et al. 2015a). Further, the results showed that there were limits to the stability of saturated hydrocarbons and the degree of thermal metamorphism and age beyond which ancient sediments will not yield biologically recognizable biomarkers.

At the present time, the 1.64 Ga Barney Creek Formation, of the McArthur Basin in northeastern Australia, where present in wells that are at or below the maturity threshold for oil generation, is the oldest package of sediment that records the presence of a wide range of biomarker hydrocarbons including acyclic isoprenoids, tricyclic terpanes, pentacyclic hopanoid and gammacerane triterpanes, and C_{40} carotenoid-derived saturated and aromatic hydrocarbons (Brocks et al. 2005; Brocks and Schaeffer 2008). The only steroids identified comprise 4-methyl and desmethyl triaromatic steroids at ppm levels. These steroids lack the side-chain methylation that is characteristic of steroids produced by many eukaryotes and could be of bacterial origin. The most recent biomarker studies of Archean, Paleoproterozoic, and Mesoproterozoic sedimentary rocks, conducted in the era of heightened contamination awareness, reveal a similar picture of nondetection of eukaryote-specific 24-alkylated steranes (Blumenberg et al. 2012; Flannery and George 2014; Luo et al. 2015). In the Neoproterozoic, however, new data on secular trends in the distributions of steroidal biomarkers together with information derived from molecular clock analyses are revealing a surprisingly detailed and consistent picture about the emergence of algae and animals during the Cryogenian Period (Brocks et al. 2017; Erwin 2015; Gold et al. 2016; Hoshino et al. 2017; Love et al. 2005).

Future Potential

Precambrian organic matter, where sufficiently well preserved to reveal molecular detail, offers considerable further potential for detailed and productive study (Briggs and Summons 2014). Mistakes from the past have led to a deeper appreciation for the prevalence of contamination (Illing et al. 2014), and how to detect and avoid it (Jarrett et al. 2013) in rock sequences that have been altered through thermal metamorphism and radiolysis (Bruisten et al. 2013). Further discoveries of taxonomically informative organic-walled microscopic and macroscopic fossils (Cohen and Macdonald 2015; Cohen et al. 2015) and of indigenous and diagnostic molecular fossils (Schinteie and Brocks 2017) can be used to improve phylogenies derived from the DNA of contemporary organisms (Dacks et al. 2016), to calibrate and test molecular clocks (Gold et al. 2017), and overall, to provide further insight into the emergence and diversification of complex life on the Earth (Knoll and Nowak 2017). Last, but not least, the ability to measure the isotopic compositions of multiple elements in the same sample of organic matter, or even the same microscopic fossil, opens new windows into the microbial physiologies and the evolution of Precambrian biogeochemical cycles (Ader et al. 2016; Grotheer et al. 2017; House et al. 2000; Sessions 2016; Stüeken et al. 2016; Williford et al. 2015).

Presolar Grains

Peter Hoppe
Particle Chemistry Department, Max Planck Institute for Chemistry, Mainz, Germany

Definition

Presolar grains are nanometer- to micrometer-sized dust grains that are found in small quantities in primitive meteorites, interplanetary dust particles (IDPs), and in cometary matter. They are older than our Solar System and formed in the winds of evolved stars and in the ejecta of stellar explosions, as evidenced by large isotopic abundance anomalies.

Introduction

Our Solar System formed from the collapse of an interstellar gas and dust cloud some 4.57 billion years ago. Originally it was thought that all the matter that went into the making of our Solar System was completely mixed and isotopically homogenized. First hints about the presence of isotopically anomalous minerals in meteorites were found in the 1960s (Reynolds and Turner 1964; Black and Pepin 1969). It took another 20 years before Ed Anders and co-workers were able to isolate the first presolar minerals, silicon carbide (SiC), nanodiamonds, and (graphitic) carbon (in the following referred to as "graphite"), as carrier of isotopically anomalous noble gases from carbonaceous chondrites at the University of Chicago (Bernatowicz et al. 1987; Lewis et al. 1987; Amari et al. 1990). After their isolation it was found that SiC and graphite carry large isotopic anomalies also in their major elements and in many other minor/trace elements. It became quickly clear that these grains must have a presolar origin, i.e., they are older than our Solar System, and that they represent a sample of stardust that can be analyzed in the laboratory. In contrast, the origin of nanodiamonds is still a matter of debate today. The reason for this is their small size of only 2–3 nm, two to three orders of magnitude smaller than those of presolar SiC and graphite grains, which currently does not allow to measure isotopic compositions of individual nanodiamonds but only of ensembles of millions of grains. The major element carbon of these grain ensembles has approximately solar isotopic composition, which makes it difficult to decide which fraction of nanodiamonds is true stardust.

Following the discovery of carbonaceous presolar grains other types of presolar grains were identified in acid-resistant residues of meteorites in the 1990s, namely, silicon nitride (Si_3N_4) (Nittler et al. 1995) and refractory oxides (Hutcheon et al. 1994; Nittler et al. 1994). The most abundant presolar grain type, the silicates, remained undetected for a long time and was identified only at the beginning of this millennium (Messenger et al. 2003). The reason for this is that presolar silicates, other than carbonaceous presolar grains or refractory presolar oxides, cannot be separated by chemical treatments from meteorites. Only the development of new isotope measurement techniques (ion imaging) based on secondary ion mass spectrometry (SIMS) made the in situ discovery of presolar silicates possible.

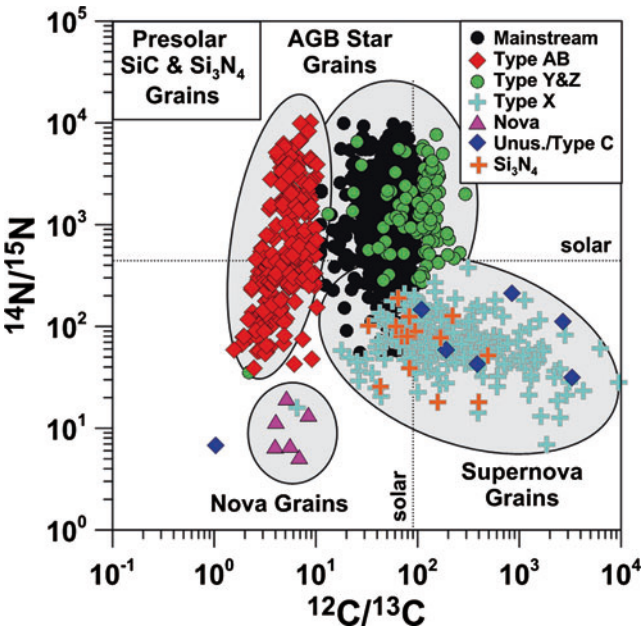
Especially presolar graphite grains, but also SiC, contain small subgrains, e.g., titanium carbide (TiC) and other refractory carbides (Bernatowicz et al. 1991).

Measurements of isotopic compositions, physical properties, and mineralogies of individual presolar grains can give detailed information on the parent stars and on all stages in the life cycle of presolar grains, from the formation in circumstellar environments to the incorporation into planetary bodies (asteroids, comets) in the Solar System. In the last three

decades laboratory studies of presolar grains have provided a wealth of astrophysical information, namely, on stellar nucleosynthesis and evolution, galactic chemical evolution (GCE), dust formation around stars, dust processing in the interstellar medium (ISM), the types of stars that contributed dust to the Solar System, and the early Solar System history. The following two sections describe the isotopic compositions, physical properties, and stellar sources of carbonaceous and oxygen-rich presolar grains. Detailed references can be found in recent review papers by Lodders and Amari (2005), Hoppe (2008), Meyer et al. (2008), and Zinner (2014).

Carbonaceous Presolar Grains

Silicon carbide is the best studied presolar mineral. Reasons for this are that (i) it is relatively abundant in primitive meteorites (up to 100 ppm), (ii) it can be separated by physical and chemical treatments in almost pure form from meteorites, (iii) many grains are larger than 1 μm, and (iv) it has high abundances of minor/trace elements. Based on the isotopic compositions of C, N (the most abundant minor element), and Si, presolar SiC is divided into distinct populations: mainstream (MS), and the minor grain types AB, C, X, Y, Z, and nova. The vast majority of presolar SiC (~90%) belongs to the MS group. These grains have $^{12}C/^{13}C$ ratios between 10 and 100 (Solar System: 89) and mostly higher than solar $^{14}N/^{15}N$ ratios (Fig. 1). Silicon isotopic abundance anomalies are smaller than those in C and N with typical enrichments in the heavy Si isotopes ^{29}Si and ^{30}Si of several percent. Other important characteristics of MS grains are enrichments in elements that are produced by the s-process (slow-neutron capture reactions) and isotopic patterns expected for the s-process. Based on a comparison with stellar models and astronomical observations, it is generally accepted that MS grains formed in the winds of low-mass (1–3 $M_\odot$) red giant stars of about solar metallicity (metallicity is the mass fraction of all elements heavier than He) on the asymptotic giant branch (AGB) of evolution. Also the Type Y and Z grains are likely from low-mass AGB stars, but from those with lower than solar metallicity, as indicated by specific Si-isotopic signatures. The origin of the Type AB grains is still a matter of debate. The most promising stellar sources are born-again AGB stars (AGB stars that experience a very late thermal pulse) and J-type carbon stars that can account for the very low $^{12}C/^{13}C$ ratios (<10) observed in AB grains (Fig. 1). Grains from supernova explosions (the final stage of stars heavier than about 8 $M_\odot$) are the Type X and C grains. X grains account for about 1% of all presolar SiC grains, and C grains for less than 0.1%. X and C grains have mostly higher than solar $^{12}C/^{13}C$ ratios and all have lower than solar $^{14}N/^{15}N$ ratios (Fig. 1). X grains often have very high N abundances (at the percent level), and they may be related to the very rare presolar



Presolar Grains, Fig. 1 Carbon- and N-isotopic systematics of presolar SiC and Si_3N_4. The solar isotopic ratios are shown by *dashed lines* for comparison. Data are taken from the Washington University Presolar Grain Data Base (http://presolar.wustl.edu/PGD/Presolar_Grain_Database.html; (Hynes and Gyngard 2009). Figure adapted from Hoppe (2011)

Si_3N_4 grains (found only at the ppb level) which share the isotopic characteristics of X grains (Fig. 1). Silicon-isotopic anomalies are much larger than those of grains from AGB stars; while X grains show strong depletions in the heavy Si isotopes (up to a factor of 5 relative to solar isotopic abundances), C grains are strongly enriched in these isotopes (up to a factor of 4). Other important signatures of supernova SiC grains are high abundances of ^{26}Mg from the decay of radioactive ^{26}Al (half-life 720,000 years) and evidence for incorporation of other radioactive nuclides, namely, ^{32}Si (half-life 153 years), ^{44}Ti (half-life 60 years), and ^{49}V (half-life 330 days) when the grains condensed. As the name implies the nova grains (<0.1% of SiC) are believed to come from nova explosions (triggered by mass-transfer from a companion star to a white dwarf) which are predicted to produce grains with very low $^{12}C/^{13}C$ and $^{14}N/^{15}N$ ratios (Fig. 1).

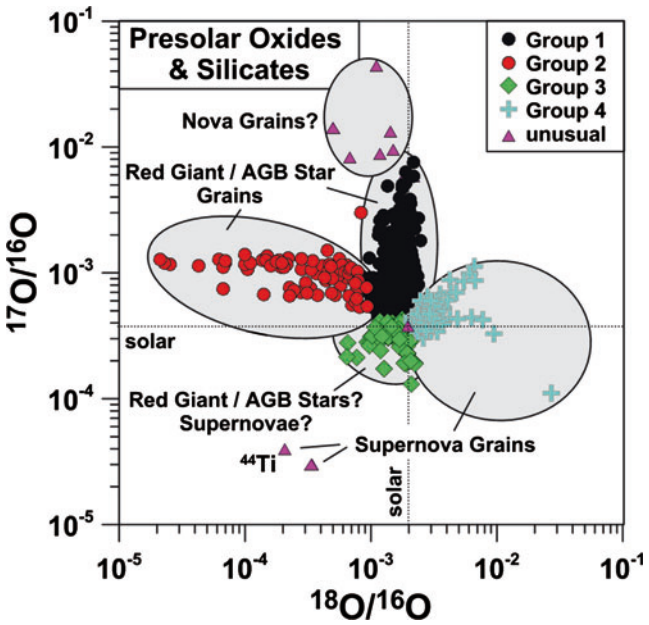
Presolar graphite grains are round and mostly larger than 1 μm. They are found at abundance levels up to ~10 ppm in primitive meteorites. Basically, two populations can be distinguished: low-denisty (LD) grains, which account for about 25% of all graphite grains, and high-density (HD) grains. Although the range of $^{12}C/^{13}C$ ratios (2–7000) is similar to that observed in presolar SiC (Fig. 1), the distribution of $^{12}C/^{13}C$ is different. Most HD grains show higher than solar $^{12}C/^{13}C$, with a peak in the distribution near $^{12}C/^{13}C = 500$. In contrast, most LD grains show lower than solar $^{12}C/^{13}C$ ratios. Based on inferred high ^{26}Al abundances, large

excesses in ^{15}N and ^{18}O, large excesses or deficits in the heavy Si isotopes, and evidence for the presence of radioactive ^{44}Ti and ^{41}Ca (half-life 105,000 years) at the time of grain formation, it is believed that the majority of LD grains formed in the ejecta of supernova explosions. The high $^{12}C/^{13}C$ ratios together with the chemical composition of subgrains and isotopic compositions of Si and heavy elements, on the other hand, suggest an origin from low-metallicity AGB stars for most HD grains. Extremely large isotope anomalies in Ca and Ti along with low $^{12}C/^{13}C$ ratios in some HD grains indicate small contributions from born-again AGB stars. Evidence for ^{22}Na decay (half-life 2.6 years) as source of so-called Ne-E(L) in presolar graphite together with low $^{12}C/^{13}C$ ratios suggests an origin of a small fraction (~1%) of presolar graphite grains from nova explosions.

Oxygen-Rich Presolar Grains

Abundances of presolar O-rich grains vary strongly among meteorites, apparently reflecting parent body processing. Presolar oxide abundances range up to ~50 ppm; presolar silicate abundances are higher, up to ~200 ppm in meteorites, ~375 ppm on average in so-called primitive IDPs, and up to the percent level in individual IDPs. Estimates for the abundance of O-rich presolar dust in matter from comet 81P/Wild 2 returned by NASA's STARDUST mission bear large uncertainties but are compatible with inferred abundances for IDPs. Presolar silicates have typical sizes of 200–300 nm. The same holds for presolar oxides identified in situ; chemically separated oxides, on the other hand, have sizes up to several μm. Most oxide grains are corundum and other forms of Al_2O_3, spinel, and hibonite; a few chromite, titanium oxide, and iron oxide grains were found as well. Presolar silicates show a range of chemical compositions. Most grains have nonstoichiometric compositions with (Mg + Fe)/Si ratios between 1 (pyroxene-like) and 2 (olivine-like). Multicomponent grains, consisting of oxide-silicates assemblages, were found as well. Information on the mineralogy is still limited because sample preparation (production of electron-transparent sections by focused ion beam lift-out) is very time-consuming. Crystalline grains (~25%), mostly olivine, amorphous to weakly nanocrystalline grains (~50%), and so-called GEMS (~25%), glass with embedded metal and sulfide, were identified.

Based on the O-isotopic compositions, O-rich presolar grains are divided into four distinct populations (Fig. 2). Most abundant (~70%) are Group 1 grains. These grains have higher than solar $^{17}O/^{16}O$ and close to solar $^{18}O/^{16}O$ ratios and silicates show Si-isotopic compositions similar to those observed in SiC MS grains. A comparison with stellar models and astronomical observations suggests that Group 1 grains originate from 1.2–2.2 $M_\odot$ red giant and AGB stars



Presolar Grains, Fig. 2 Oxygen-isotopic systematics of presolar oxides and silicates. The solar isotopic ratios are shown by *dashed lines* for comparison. Data are taken from the Washington University Presolar Grain Data Base (http://presolar.wustl.edu/PGD/Presolar_Grain_Database.html; (Hynes and Gyngard 2009). Figure adapted from Hoppe (2011)

of about solar metallicity. Group 2 grains have enhanced ^{17}O and large depletions in ^{18}O (Fig. 2). The proposed stellar sources are low-mass (<1.5 $M_\odot$) red giant and AGB stars that underwent so-called cool bottom processing. The origin of Group 3 grains, most of which show slight depletions in ^{17}O and ^{18}O (Fig. 2), is still not fully understood. Most Group 3 grains appear to originate from low-mass (<1.2 $M_\odot$) red giant and AGB stars of lower than solar metallicity and those with subsolar $^{17}O/^{18}O$ ratios might have a supernova origin. Group 4 grains exhibit enrichments in ^{18}O and a range of $^{17}O/^{16}O$ ratios (Fig. 2). Supernovae are considered the most likely stellar sources. Only two grains show strong enrichments in ^{16}O, the expected predominant signature of supernova grains. One of them carries now extinct ^{44}Ti, as observed in carbonaceous supernova grains. Recent studies indicate that supernova grains are more abundant among small (<150 nm) grains. Some grains have very high $^{17}O/^{16}O$ ratios (Fig. 2), higher than predicted for red giant and AGB stars, and these grains are possibly from nova explosions.

Summary

Primitive meteorites, IDPs, and cometary matter contain small quantities of nanometer- to micrometer-sized dust grains that carry large isotopic abundance anomalies. These

grains, called presolar grains, are older than our Solar System and formed in the winds of evolved stars and in the ejecta of stellar explosions. Laboratory studies have provided a wealth of astrophysical information, namely, on stellar nucleosynthesis and evolution, GCE, dust formation around stars, dust processing in the ISM, the types of stars that contributed dust to the Solar System, and the early Solar System history.

Definition

Programmed pyrolysis is a laboratory method commonly used to characterize organic matter in sedimentary rocks; it involves heating of a rock sample at progressively higher temperatures in the absence of oxygen in order to evaluate it as a petroleum source or reservoir rock or to determine kinetic parameters that describe the thermal decomposition of the organic matter to petroleum.

Introduction

This article focuses on the application of pyrolysis to petroleum resources. Pyrolysis at a programmed rate of increasing temperature is used to volatilize and crack organic matter from petroleum source-rock samples for characterization by various detectors. For example, programmed pyrolysis coupled with flame ionization and thermal conductivity detection monitors evolved hydrocarbons and other products and is suitable for screening large numbers of rock samples (Espitalié et al. 1977; Peters 1986). More detailed fingerprinting of these products can be obtained using other detectors, as in pyrolysis-gas chromatography or pyrolysis-mass spectrometry (Larter 1984). Other pyrolysis studies focus on polymers, biomass, and biology (e.g., Voorhees 1984). Many environmental studies include pyrolysis of air particulates and other pollutants, wastewater, soils, and sediments (Munson 2006). Pyrolysis has been used to study meteorites and search for evidence of life on Mars and other planets (Sephton 2017).

Open-system programmed temperature pyrolysis is used in exploration for conventional and unconventional petroleum resources to (1) rapidly and inexpensively measure properties of organic matter that can be used to evaluate the quantity, quality, and thermal maturity of large numbers of candidate source-rock samples from wellbores, (2) identify petroleum reservoir intervals and thermal maturity gradients with depth, and (3) provide kinetic parameters for source

Modified version from "Programmed Temperature Pyrolysis" published in Peters KE and Rodriguez LB (2017).

rocks that can be used in computerized basin and petroleum system modeling (BPSM) to simulate the transformation of organic matter to petroleum during burial in sedimentary basins. Commercial programmed pyrolysis instruments that address items 1 and 2, such as Rock-Eval® or SR Analyzer™, heat ~100 mg samples of drill cuttings or core from wells under an inert atmosphere using a single programmed ramp of increasing temperature, typically 25 °C/min (Espitalié et al. 1977; Peters 1986; Peters and Cassa 1994).

Specialized programmed pyrolysis instrumentation is used for item 3 to obtain accurate temperatures for the thermal decomposition of organic matter used in kinetic determinations. Early work summarized by Tissot and Espitalié (1975) showed that the laboratory maturation of organic matter in source-rock samples can be described by parallel series of independent first-order reactions. The recommended method for kinetic analysis of pyrolysis results generates a discrete activation energy distribution and corresponding frequency factor for thermally immature equivalents of the source rock and requires at least three pyrolysis temperature ramps on aliquots of each sample (~3–10 mg) that span a 20-fold variation of comparatively low rates, such as 1, 5, and 25 °C/min (Peters et al. 2015b). Instrument design, thermocouple orientation and size, and sample weight are key factors that influence the quality of the resulting kinetic parameters. Several commercial instruments that can be used to measure kinetic parameters include Pyromat II™, Hawk™, SR Analyzer™, and Rock-Eval 6®.

Although this paper focuses on pyrolysis and discrete sampling as described above, these data can be complemented by direct and indirect wireline measurements of total organic carbon (TOC; Peters et al. 2016a) and by downhole fluid analysis (DFA). For example, neutron-induced capture and inelastic gamma ray spectroscopy using a high-resolution scintillator differentiates complex lithologies and provides quantitative TOC values at typical well logging speeds (Gonzalez et al. 2013). DFA employs near-infrared, visible, and fluorescence spectroscopy for continuous measurements of fluid properties that are especially useful to evaluate reservoir fluid gradients and connectivity (Mullins et al. 2014, 2015).

Quality, Quantity, and Thermal Maturity of Rock Samples

Most petroleum industry or service laboratories use Rock-Eval pyroanalyzers, so the following discussion will emphasize the development and use of these systems. However, the methods and results obtained by other systems, such as the SR Analyzer, are similar. Various generations of Rock-Eval pyroanalyzers are currently used (Espitalié et al. 1977; Lafargue et al. 1998). Rock-Eval pyrograms and calculated parameters for large numbers of closely spaced samples in wells can be used to identify petroleum source rocks as well as petroleum reservoir rocks (Peters 1986; Peters and Cassa 1994). The method can be used as a screening tool to identify few key samples for further, more sophisticated geochemical analyses, such as gas chromatography-mass spectrometry (GCMS) of candidate petroleum source-rock extracts for biomarker (molecular fossil) composition (Peters et al. 2005).

Conventional and unconventional petroleum resources are fundamentally different and require different vertical sample spacing within wells for useful pyrolysis interpretations (Peters et al. 2015a, 2016a). As discussed below, conventional and unconventional exploration commonly require 10-m and 1-m or less sample spacing, respectively. Exploration for conventional resources aims to find petroleum that migrated from organic-rich, thermally mature source rock to reservoirs and traps. Unconventional rock or sediment units require stimulation, such as hydraulic fracturing, to produce the retained petroleum based on the balance between petroleum viscosity and rock matrix permeability. According to this definition, gas shales and gas hydrates are unconventional targets because very low permeability impedes the escape of hydrocarbon gases, such as methane, without stimulation. Shale oil in "tight" mudstones is an unconventional resource because the oil cannot readily pass through narrow pore throats in the rock. Oil sands are also unconventional resources because viscous biodegraded oil cannot readily escape from otherwise high-permeability sandstone without stimulation.

Petroleum Generation Kinetics for Rock Samples

Kinetic parameters for the transformation of organic matter to petroleum are required to compute petroleum yields and generation rates in basin and petroleum system modeling. Artificial maturation based on programmed pyrolysis of organic matter in source-rock samples can be used to generate independent first-order reactions that are constrained by a distribution of activation energies and a corresponding pre-exponential factor (Tissot and Espitalié 1975). These kinetic parameters were used in many early BPSM simulations (e.g., Sweeney et al. 1987; Espitalié et al. 1988; Ungerer 1990; Issler and Snowdon 1990). The method assumes that thermal alteration of organic matter can be described by independent, parallel first-order reactions that conform to the Arrhenius equation (e.g., Ungerer and Pelet 1987). This assumption may be oversimplified because petroleum generation comprises multiple cracking reactions, including initiation, propagation, and termination steps (Stainforth 2009) that involve free radicals, acid thermolysis, and carbonium ion reactions

with α-olefins (Kissin 1987). In addition, Stainforth (2009) infers that primary migration of petroleum through the source-rock network rather than kerogen cracking is the rate-limiting step in petroleum expulsion. Kerogen consists of particulate organic matter in sedimentary rocks that is insoluble in organic solvents. Despite these issues, most workers obtain source-rock kinetic parameters using programmed pyrolysis, partly because measured and predicted petroleum generation rate curves from open-system pyrolysis are similar to those observed in natural maturation series. These observations suggest that programmed pyrolysis experiments can be used to reliably predict maturation over geologic time (e.g., Schenk and Horsfield 1998). Predictions from BPSM that are based on laboratory kinetics agree with field data from exploration wells (e.g., Fig. 9 in Kuhn et al. 2012).

Some publications recommend open-system pyrolysis using a single temperature ramp and fixed frequency factor (e.g., Waples 2016 and references therein), but this is not recommended because one-ramp kinetics result in the potential for significant error (Peters et al. 2015b, 2016b). Several publications describe how to optimize kinetic parameters based on open-system programmed pyrolysis. Braun and Burnham (1987) showed that fitting to a single heating rate yields unreliable kinetic results for source rocks when both the activation energy (E_a, kcal/mol) distribution and pre-exponential factor (A, s^{-1}) are optimized. Model fitting based on single-ramp kinetics is deemed unacceptable by Vyazovkin and Wight (1999), and it is not recommended by the Kinetics Committee of the International Confederation for Thermal Analysis and Calorimetry (Vyazovkin et al. 2014). Sundararaman et al. (1992) and Dieckmann (2005) also showed that a single pyrolysis heating rate experiment gives unreliable discrete E_a distributions. Both authors concluded that reliable kinetic results require multiple pyrolysis experiments on aliquots of the source-rock sample at widely differing heating rates.

Other methods that differ from open-system programmed pyrolysis have been proposed to obtain kinetic parameters for the thermal decomposition of organic matter. These include closed-system isothermal pyrolysis, such as hydrous pyrolysis (e.g., Lewan et al. 1979; Lewan and Ruble 2002), microscale sealed vessel pyrolysis (MSSV, e.g., Horsfield et al. 1989), or gold tube reactors (e.g., Behar et al. 1992). Some papers discuss the reliability of kinetics determined using open- versus closed-system pyrolysis (e.g., Schenk and Horsfield 1993; Ritter et al. 1995; Barth et al. 1996; Lewan and Ruble 2002). In this paper, we focus on open-system programmed pyrolysis because it is the most commonly used and likely the most reliable method to obtain source-rock kinetic parameters.

Methods

Rock-Eval Pyrolysis

For Rock-Eval pyrolysis, samples of drill cuttings, sidewall core, or conventional core are first screened by binocular microscope and then crushed to fine sand particle size (0.125–0.25 mm), and ~100 mg of each dried (<50 °C) sample is loaded into pyrolysis crucibles. The samples are pyrolyzed under flowing helium at 100–300 °C for several min, followed by heating at 25 °C/min to 550–600 °C or 850 °C, depending on the pyroanalyzer model. Pyrolysis products from each sample, such as hydrocarbons (compounds that contain carbon and hydrogen) and generated by the pyrolysis, are measured in ~20–30 min. Programmed temperature pyrolysis also produces large quantities of nonhydrocarbons (compounds that contain nitrogen, sulfur, and oxygen, in addition to carbon and hydrogen). Both hydrocarbons and nonhydrocarbons are measured by a flame ionization detector (FID).

Programmed temperature pyrolysis and TOC data from wells are best interpreted using large numbers of samples taken at closely spaced intervals from each well. For conventional exploration, 10-m spacing is recommended, regardless of lithology (Peters and Cassa 1994). For unconventional exploration, increased resolution of 1-m spacing or less may be needed to optimize the best zone to position horizontal wells within source-rock units prior to hydraulic fracturing. Wireline tools offer the advantage of continuous rather than discrete measurements of TOC but cannot be used to interpret kerogen quality or thermal maturity (e.g., compare Figs. 3.3 and 3.7 in Peters et al. 2016a).

A "sweet spot" is that portion of unconventional source rock having more favorable porosity, permeability, water saturation, fluid properties, and/or rock stress that is likely to produce more petroleum than adjacent rock (Peters et al. 2016a). Identification of sweet spots requires properly scaled geochemical measurements. Multiple geochemical logs (see below) can be used to create maps to identify the lateral and vertical distributions of sweet spots. For critical samples that define source rock, reservoir rock, or potential productive zones for horizontal wells, interpretations from the pyrolysis results should be verified by other analyses, such as organic petrography, vitrinite reflectance, gas chromatography of extracts, and petrophysical measurements. This paper does not describe geomechanical properties of the rock, such as Young's modulus, Poisson's ratio, or preexisting fracture orientation, which must also be considered for positioning of horizontal wells within source-rock intervals (Peters et al. 2016a).

Kinetic Measurements

For kinetic measurements, the ideal sample consists ~3–10 mg of organic-rich, unweathered source rock that has

undergone diagenesis but has not yet generated appreciable petroleum (vitrinite reflectance equivalent $\leq$0.5%). Whole rock samples typically yield kinetic parameters similar to isolated kerogen (Tegelaar and Noble 1994; Reynolds and Burnham 1995). The organofacies in the sample must be representative of that within the effective source rock in the study area because the rate of thermal decomposition of organic matter to petroleum can differ for different source rocks (Tegelaar and Noble 1994) and even vertically or laterally within the same source rock (Peters et al. 2006).

Continuous temperatures are measured during each programmed pyrolysis experiment using a calibrated thermocouple in close contact with the sample. Performance and accuracy of temperature measurements for each pyrolysis system need to be evaluated independently. Products volatilized during decomposition of the kerogen are transferred to a flame ionization detector, typically by helium flow at 50 ml/min. Pyrolyzate peaks for kerogen decomposition can be processed by using various types of software, such as Kinetics05 or Kinetics2015, using methods originally described by Burnham and Braun (1999). Kinetic parameters are determined by iterative linear–nonlinear regression, where energy weighting factors are determined by constrained linear regression for a given frequency factor and the logarithm of the frequency factor is varied under Levenberg–Marquardt nonlinear regression (Levenberg 1944) until the root mean square deviation between measured and calculated generation rates of pyrolyzate yields a minimum.

Samples of thermally immature source rock that are age equivalent with the effective source rock in a basin are commonly unavailable. In such cases, a common but flawed practice in BPSM is to use default kinetic parameters available in the software for other source rocks that are assumed to contain organic matter similar to that in the study area based on kerogen type (e.g., Waples et al. 1992) or depositional environment and stratigraphic age (e.g., Pepper and Corvi 1995). We do not recommend this assumption because kerogen type as defined by Rock-Eval pyrolysis hydrogen index (HI, mg hydrocarbon/g TOC) is not systematically linked to kinetic response and it is risky to infer kerogen type or kinetics based on source-rock depositional environment (Peters et al. 2006). Thus, default kinetics for source rock from one basin may not apply to that in other basins, even when the HI for immature equivalents of each source rock is identical.

Interpreting Rock-Eval Pyrograms

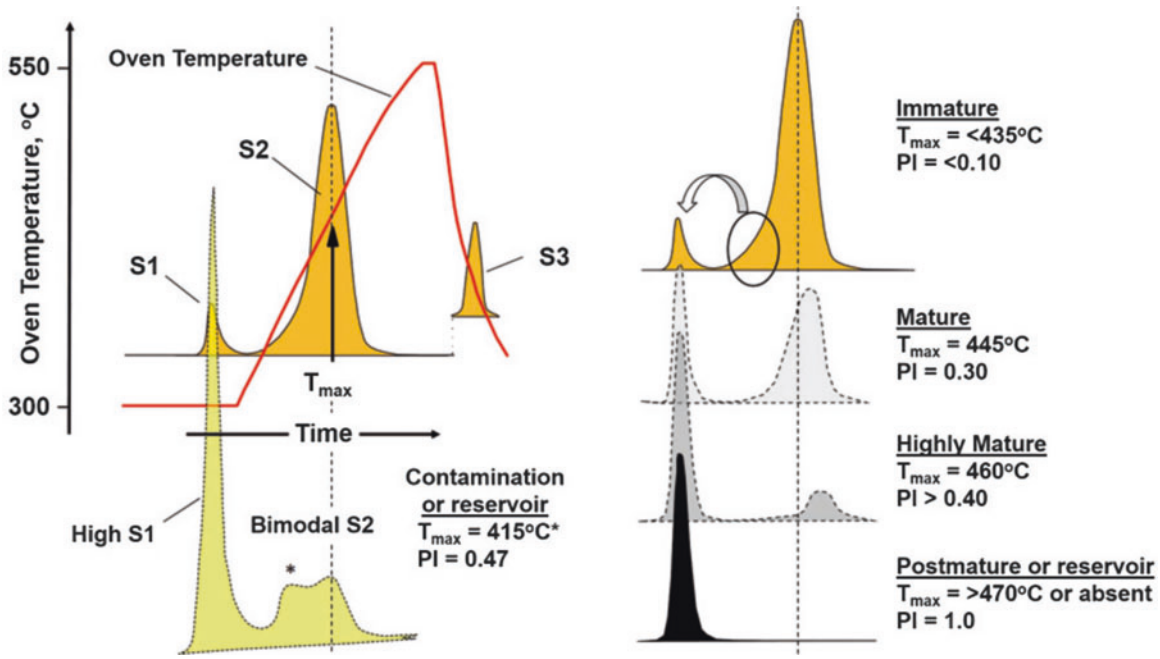
An example of a programmed temperature pyrogram shows products generated from low-maturity source rock that has not yet reached the oil-generative window (Fig. 1, upper left). The thick red line shows oven temperature through time. The shaded peaks represent S1 (volatile hydrocarbon yield at 300 °C), S2 (hydrocarbons cracked from kerogen in the range 300–550 °C), and S3 (carbon dioxide generated up to 390 °C). S1 generally increases at the expense of S2 during thermal maturation of source rocks (Fig. 1, right column), although loss of some S1 due to expulsion can occur. S1 is high in active source rocks and reservoir rocks that contain petroleum. S2 is a better indicator of generative potential (quality) than TOC (quantity), which does not differentiate between oil-prone, gas-prone, or inert carbon. S2 is high in potential and active source rocks but low in postmature (spent) source rocks, non-source rocks, and many reservoir rocks. Ideally, S3 indicates carbon dioxide cracked from the kerogen. However, some carbonate-rich rocks that contain clays generate carbon dioxide below the 390 °C trap temperature (Peters 1986). Oxidation of organic matter in weathered outcrop samples and over-grinding during sample preparation can also elevate S3. S1 and S2 are measured by FID, while S3 is measured by thermal conductivity detection (TCD). FID measures hydrocarbons and nonhydrocarbons (e.g., sulfur-, nitrogen-, or oxygen-containing compounds) provided that the latter contain carbon atoms.

Rock-Eval T_{max} is a measure of thermal maturity based on programmed pyrolysis oven temperature that should not be confused with geologic temperature. In the absence of fluid or particulate contamination (discussed below), T_{max} commonly correlates with other thermal maturity parameters, such as vitrinite reflectance (R_o). For example, Jarvie et al. (2001) recommend the following formula to convert Rock-Eval pyrolysis T_{max} to R_o:

$$R_o(\text{calculated}) = (0.0180)(T_{max}) - 7.16 \quad (1)$$

The formula was derived from a collection of shale samples containing low-sulfur type II and type III kerogen (Jarvie et al. 2001) but can be inaccurate for type I kerogens. Kerogen type is defined by Rock-Eval HI in Table 1. Use of the formula is not recommended for very low- or high-maturity samples (where T_{max} is <420 °C or >500 °C) or when S2 is less than 0.5 mg HC/g rock. However, these correlations are best determined on a case-by-case basis (Wüst et al. 2013). T_{max} determined on very small S2 peaks (<0.2 mg HC/g rock) can be inaccurate. HI can be low, while T_{max} is high compared to isolated kerogen from organic-lean (<1 wt.% TOC) clay-rich rocks due to adsorption of pyrolyzate on clays (Peters 1986).

The production index [PI = S1/(S1 + S2)] increases with depth in fine-grained rocks because thermally reactive components in the kerogen (S2) are gradually converted to volatile hydrocarbons (S1). Coarse-grained conventional reservoir rocks stained with oil show anomalously high S1 and PI values that deviate from the depth trend in the adjacent fine-grained rocks. In some cases, T_{max} may be suppressed due to carry-over of heavy ends in the oil from S1 to S2 (Fig. 1, lower left). Oil-based drilling mud additives can



Programmed Temperature Pyrolysis, Fig. 1 Schematic programmed temperature pyrogram *(upper left)* shows S1 (volatile petroleum) and S2 (kerogen pyrolyzate, mg hydrocarbons (HC)/g rock), S3 (organic carbon dioxide, mg CO_2/g rock), and T_{max} (oven temperature in °C at the maximum of the S2 peak). Calculated parameters include hydrogen index (HI = 100 × S2/TOC, mg HC/g TOC), oxygen index (OI = 100 × S3/TOC, mg CO2/g TOC), and production index [PI = S1/(S1 + S2)]. Crude oil or contamination by oil-based drilling mud can yield anomalously high S1, high PI, and low T_{max} (*asterisk* at lower left, S3 not shown). Column at *right* shows typical evolution of S1, S2, T_{max}, and PI due to increasing thermal maturation of source rock. Pyrograms that show high S1 and PI with a very low or no S2 peak could represent postmature source rock or petroleum reservoir rock

Programmed Temperature Pyrolysis, Table 1 Programmed pyrolysis and vitrinite reflectance (R_o) parameters used to determine quantity, quality, and thermal maturity of rock samples. The three segments of the table must be interpreted separately. Thickness of the rock unit is also important for volumetric considerations

Quantity[a]			Quality[b]				Thermal maturity[c]		
Amount	TOC_o, wt. %	TOC_m, wt. %	Type	HI_o, mg HC/g TOC	Product	Stage	Ro, wt.%	Tmax (°C)	PI, [S1/(S1 + S2)]
Poor	<1	<1	I	>600	Oil	Immature	0.20–0.60	<435	<0.10
Fair	1–2	1.0–1.5	II	300–600	Oil	Early mature	0.60–0.65	435–445	0.10–0.15
Good	2–3	1.5–2.0	II–III	200–300	Oil/ gas	Peak mature	0.65–0.90	445–450	0.25–0.40
Very good	3–4	2.0–2.5	III	50–200	Gas	Late mature	0.90–1.35	450–470	>0.40
Excellent	>4	>2.5	IV	<50	None	Postmature	>1.35	>470	–

[a]TOC_o = original total organic carbon content for thermally immature source rock, TOC_m = measured total organic carbon for thermally mature or postmature source rock (unconventional target). Approximate values determined using data for nine top shale gas plays (Data from Jarvie 2012a)
[b]Type = kerogen type based on pyrolysis hydrogen index, HI_o (= 100 × S2/TOC for thermally immature source rock)
[c]R_o = oil-immersion vitrinite reflectance, T_{max} = pyrolysis oven temperature at maximum of S2 peak; for onset of oil generation: type I ~445 °C, type II ~435 °C, type III ~440 °C; PI = production index, where S1 = petroleum volatilized at 300 °C and S2 = petroleum cracked from the kerogen in the range 300–550 °C during pyrolysis at 25 °C/min

also interfere with pyrolysis measurements, especially S1 and PI. Oil-based contamination of cutting samples commonly yields a large S1 peak, a low-temperature shoulder that interferes with the S2 peak and represents heavy ends of the oil rather than kerogen, and a corresponding anomalously low T_{max} value (Fig. 1, lower left). S1 values >1 mg HC/g rock and anomalously high PI may indicate contamination of cutting samples by migrated oil or oil-based contamination. Such samples are routinely extracted with organic solvent (e.g., *n*-heptane) and reanalyzed in order to derive more accurate

measures of HI and T_{max} (Peters 1986; Peters and Cassa 1994). Provided that their presence is recognized, particulate additives, such as walnut hulls or polyethylene, can be removed under a binocular microscope.

Hydrogen index [HI = 100(S2)/TOC] and oxygen index [OI = 100(S3)/TOC) are based on combined pyrolysis and TOC parameters. Modified Van Krevelen plots of OI versus HI or plots of T_{max} versus HI must be used with caution to infer kerogen type and approximate level of thermal maturity (Espitalié et al. 1977; Peters 1986). Because kerogen consists of mixtures of macerals, plot locations on the modified Van Krevelen diagram can be deceptive (Dembicki 2009). Macerals are microscopically recognizable particles of kerogen that show distinct physicochemical properties. The three main maceral groups include liptinite, vitrinite, and inertinite. For example, a mixture of oil-prone type II (liptinite macerals) and inert type IV (inertinite macerals) might plot near the type III pathway on the Van Krevelen diagram, which could be incorrectly interpreted to indicate kerogen dominated by vitrinite macerals with the potential to generate only hydrocarbon gases. Pyrolysis-gas chromatography of such a sample could be used to reveal significant oil-generative potential (e.g., Peters et al. 1983; Pepper and Corvi 1995).

Jarvie (2012a) derived original hydrogen indices (HI_o) for thermally immature samples of the ten top North American shale gas plays: Barnett, Bossier, Eagle Ford, Fayetteville, Haynesville, Marcellus, Montney, Muskwa, Utica, and Woodford formations. He determined the average present-day TOC (TOC_m) on collections of samples from those plays showing mostly gas window thermal maturity. The equation below excludes data from the Haynesville Shale, which began with an unusually high HI_o, (722 mg HC/g TOC), resulting in a point far off the correlation line. The remaining nine data points show a linear correlation between TOC_o and TOC_m with a high correlation coefficient (>0.98):

$$TOC_m = 0.5468(TOC_o) + 0.3261 \quad (2)$$

This relationship was used to calculate the approximate cutoff values for poor, fair, good, very good, and excellent TOC_m for unconventional targets in Table 1. These TOC values represent quantity (not quality), and they are based on an average HI_o of ~438 ± 62 mg HC/g TOC. Peters et al. (2005, pp. 97–100) provide mass balance calculations to determine TOC_o from TOC_m.

Historical Development of Rock-Eval Pyroanalyzers

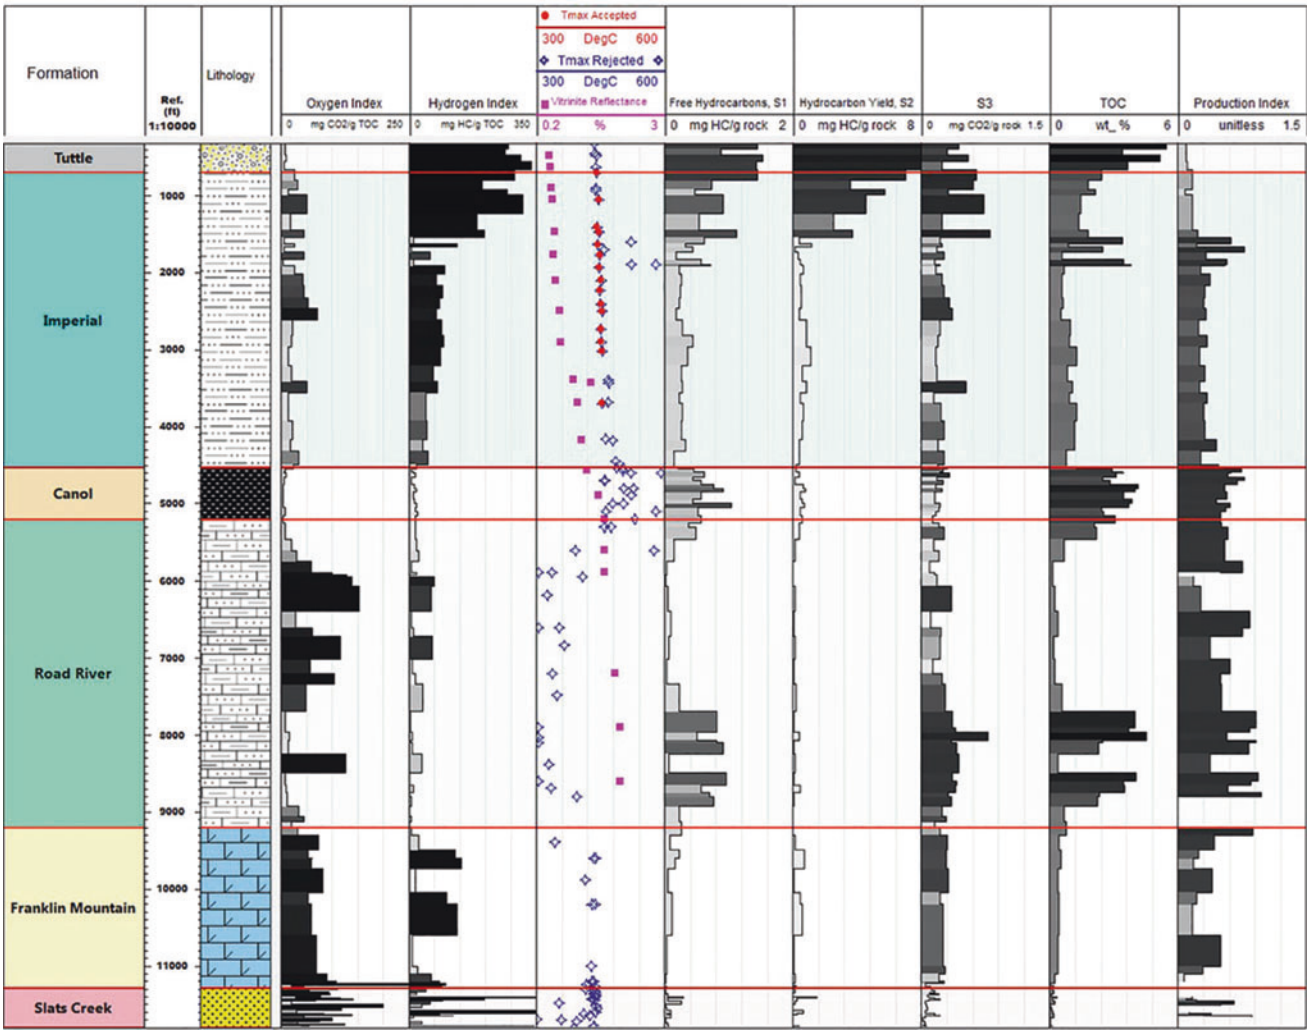
Since the 1970s, various Rock-Eval pyroanalyzers were developed to characterize rock samples from wellbores and outcrops, and these have become the most popular programmed pyrolysis instruments used by the petroleum industry. Many commercial laboratories still use Rock-Eval 2 instruments (Espitalié et al. 1977), which include automatic sampling and microprocessor control not available in Rock-Eval 1. In Rock-Eval 2, the S1 peak includes all hydrocarbons volatilized at 300 °C over a 3-min isothermal heating. TOC is determined separately on splits of the same sample by combustion. Rock-Eval 3 (oil show analyzer) effectively separates the volatile components into two peaks, S0 and S1. S0 includes light gas or condensate hydrocarbons in the range C_1–C_8 that are volatilized during a 90 °C isothermal heating for 1–5 min, while S1 includes hydrocarbons volatilized at 300 °C during a 3-min isothermal heating. Contamination of samples during drilling or evaporative loss during sample handling can seriously affect S0 values. Rock-Eval 3 combusts the residue from the pyrolysis, which allows determination of TOC without the need to split rock samples for separate pyrolysis and TOC analyses. Since the combustion in Rock-Eval 3 occurs at the same maximum temperature as the original pyrolysis (550–600 °C), TOC values for highly mature rock samples are commonly lower than conventional combustion results (>1,000 °C) because they may contain organic matter that is not readily oxidized.

The Rock-Eval 6 pyroanalyzer improves on earlier versions by providing S1, S2, S3, as well as carbonate carbon and TOC. Similar results can be obtained using the SR Analyzer TPH/TOC™. Combustion in the Rock-Eval 6 oven occurs at 850 °C, resulting in more efficient oxidation for TOC determination.

Data Interpretation Using Geochemical Logs

Geochemical logs simplify data interpretation by showing large amounts of pyrolysis, TOC, and other data, such as vitrinite reflectance, versus depth in wells (Fig. 2). Multiple geochemical logs can be used to create maps (Demaison 1984; Dahl and Yukler 1991) to identify the lateral and vertical distributions of sweet spots. Trends and anomalous data are readily apparent on geochemical logs and can be validated by examination of pyrograms, inquiries about well conditions or sampling methods, and, if necessary, repeat or additional analyses.

Geochemical logs that include carbonate content and the oil saturation index (OSI = 100 × S1/TOC) provide information on both geomechanics and geochemistry that is useful to evaluate unconventional resources. OSI can be used to indicate zones within unconventional strata that are likely to be productive, provided that significant amounts of brittle carbonate or silicate minerals are present to effectively receive proppant upon hydraulic fracturing. The injected proppant keeps fractures open, thereby increasing surface area in the target rock and increasing fluid flow into the well. Proppant



Programmed Temperature Pyrolysis, Fig. 2 Typical geochemical log of programmed pyrolysis, TOC, and vitrinite reflectance data for the Caribou N-25 well, Mackenzie Corridor, Canada. Accepted and rejected T_{max} data are indicated using *solid* and *open* symbols, respectively (Raw data are from Allen et al. 2008)

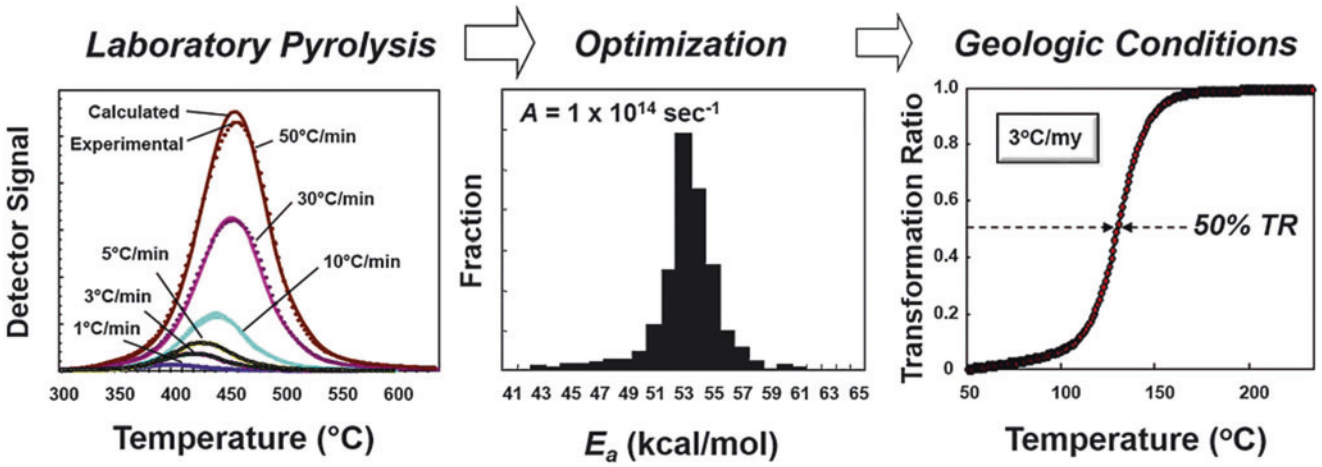
consists of sand or man-made ceramic particles injected during hydraulic fracturing in order to increase exposed surface area in the rock and enhance gas and oil production. Zones that readily fracture and have OSI values >100 mg oil/g TOC are favorable for unconventional oil recovery (Jarvie 2012b).

Interpretation of geochemical logs can be facilitated using automated software. For example, AGEL (automated geochemical log interpretation) is proprietary Schlumberger software that interprets large amounts of pyrolysis, TOC, and vitrinite reflectance data using a set of interactive and heuristic rules. Figure 2 shows an AGEL geochemical log with accepted and rejected data for the Caribou N-25 well from the Mackenzie Corridor, Canada. Interpretation of raw data and the log would have been difficult without the use of heuristic rules to screen anomalous results. Note that the correlation between R_o and T_{max} differs from that in Eq. 1 as follows ($R = 0.96$):

$$R_o(\text{measured}) = (0.0132)(T_{max}) - 5.25 \quad (3)$$

Although programmed pyrolysis and TOC data represent a valuable screening tool to evaluate hundreds or thousands of measurements, some pitfalls must be acknowledged (for more details, see Peters 1986; Peters and Cassa 1994; Dembicki 2009):

1. Pyrolysis sample size should be uniformly near 100 mg.
2. There is no simple relation between TOC and S1 or S2 (quantity versus quality).
3. Bitumen, migrated oil, and oil-based drilling additives can interfere with parameters, particularly S1, S2, PI, HI, and T_{max}. Extraction to remove these fluids results in loss of S1 during evaporation of the solvent and may not improve measurements of S2, HI, and T_{max}.



Programmed Temperature Pyrolysis, Fig. 3 *Left:* pyrograms for six programmed pyrolysis experiments on aliquots of the same thermally immature source-rock sample *(dotted curves)* fit using Kinetics05 software *(solid curves).* Extremely slow (<1 °C/min) or fast (>30 °C/min) heating rates are not recommended due to volatilization or thermal lag effects (Peters et al. 2016b). *Center:* calculated E_a distribution versus fraction (i.e., transformation ratio) and A value. *Right:* Extrapolation to geologic conditions assuming a constant heating rate of 3 °C/my. Fraction = transformation ratio or extent of conversion of kerogen to petroleum. This plot is useful to compare the response of different source-rock kerogens. In BPSM, the burial history and paleo-heat flow would be used to calculate extent of conversion

Lithology and mineral/organic matter ratio can influence response (Espitalie et al. 1980; Katz 1983; Dahl et al. 2004).

4. T_{max} is inaccurate for small peaks (<0.2 mg HC/g rock).
5. Some carbonate-rich rocks can contribute to S3 and OI.
6. Some coals (>50 wt.% TOC) show anomalously high HI values.
7. Pyrograms should be examined, especially when contamination or migrated oil is suspected.
8. Geochemical logs simplify interpretation and should be constructed using data that have been evaluated using heuristic rules to control data quality.

Extrapolation of Kinetic Measurements to Geologic Time

Discrete activation energy (DAE) modeling requires optimization of both E_a and A to determine the rate of kerogen decomposition at any laboratory temperature. The "compensation law" shows that a wide range of E_a and A combinations can satisfy the Arrhenius equation for the laboratory rate constant, but extrapolation of incorrect E_a and A to geologic time can result in incorrect temperature predictions (Peters et al. 2016b). DAE uses a single frequency factor for all possible activation energies associated with the discrete distribution. The value of A can be optimized by the software (e.g., Kinetics05, Kinetics2015; http://geoisochem.com/software/kinetics2015/index.html) or it can be an assumed, universal value (not recommended). Use of a universal value for A (e.g., 1×10^{14} s^{-1}; Waples 2016 and references therein) can lead to erroneous results (Peters et al. 2016b). For robust solutions, the pyrolysis experiments must include three or more widely differing heating rates using an energy spacing of 1 kcal/mol or less (Fig. 3).

Summary

Programmed temperature pyrolysis, TOC, and vitrinite reflectance are rapid and inexpensive tools that are commonly combined in geochemical logs to evaluate the quantity, quality, and thermal maturity of source-rock organic matter and the presence of petroleum in conventional or unconventional rock units. Pyrolysis and TOC measurements are most effective when based on large numbers of closely spaced samples in wellbores: typically 10-m or <1-m spacing in conventional or unconventional resources, respectively.

Good, very good, and excellent quantities of organic carbon are in the ranges 2–3, 3–4, and >4 wt.% TOC for thermally immature equivalents of conventional source rocks and 1.5–2.0, 2.0–2.5, and >2.5% for thermally mature unconventional source rocks. Four measured and three calculated parameters from Rock-Eval programmed temperature pyrolysis are as follows:

1. S1 represents free hydrocarbons (gas and oil) in the sample (mg HC/g rock). S1 > 1 mg/g rock may indicate an oil show. Crude oil and oil-based drilling mud can interfere with S1 and other pyrolysis parameters.
2. S2 represents hydrocarbons cracked from the kerogen (mg HC/g rock), which indicates the remaining

potential of the rock to generate oil and gas if buried further. Particulate additives, such as walnut hulls or polyethylene, can interfere with HI, T_{max}, and other pyrolysis parameters.

3. S3 is the amount of carbon dioxide generated from the kerogen (mg CO_2/g rock). Some carbonate minerals decompose below 390 °C and can interfere with S3. Oxidation due to weathering of outcrop samples or overgrinding during sample preparation can also contribute to S3.
4. T_{max} is the oven temperature at the maximum yield of S2, which gives an indication of the level of thermal maturity of the kerogen. T_{max} is sensitive to the type of organic matter, e.g., the onset of oil generation can occur at slightly different T_{max} values.
5. Calculated parameters include hydrogen index (HI = 100 × S2/TOC), oxygen index (OI = 100 × S3/TOC), and production index [S1/(S1 + S2)]. HI in thermally immature rock identifies oil-prone type I (>600 mg HC/g TOC) and type II (300–600 mg HC/g TOC) kerogen, whereas type III (50–200 mg HC/g TOC) yields mostly hydrocarbon gas. The relative thermal maturity of organic matter in samples can be estimated by (1) location on the modified Van Krevelen diagram of OI versus HI and (2) approximate T_{max}, where immature <435 °C, mature = 435–470 °C, and postmature >470 °C.

Open-system programmed pyrolysis of source-rock samples can be used to generate kinetic parameters for petroleum generation assuming independent first-order reactions that are constrained by a distribution of activation energies and a corresponding frequency factor. The method assumes that thermal alteration of organic matter can be described by first-order reactions that conform to the Arrhenius law. Most workers obtain source-rock kinetic parameters using programmed pyrolysis rather than other methods, such as hydrous pyrolysis, because measured and predicted petroleum generation rate curves from open-system pyrolysis are similar to those of natural maturation series. Predictions from BPSM that are based on laboratory kinetics agree with field data from exploration wells.

Promethium

Scott M. McLennan
Department of Geosciences, Stony Brook University, Stony Brook, NY, USA

Element Data
Atomic Symbol: Pm
Atomic Number: 61
Atomic Weight: ~145
Isotopes and Abundances: -
1 Atm Melting Point: 1042 °C
1 Atm Boiling Point: ~3000 °C
Common Valences: +3
Ionic Radii: 97 pm (CN6), 110 pm (CN8), and 127 pm (CN12)
Pauling Electronegativity: —~1.2
First Ionization Energy: 538.6 kJ mol^{-1}
Chondritic (CI) Abundance: 0 ppm
Silicate Earth Abundance 0 ppm
Crustal Abundance: 0 ppm
Seawater Abundance: 0 ppt
Core Abundance: 0 ppm

Properties

Promethium (Pm), originally called prometheum and named after *Prometheus*, one of the Titans of classical mythology, is a moderately dense (7.264 g cm^{-3}) silvery-white metal with an electronic configuration of $[Xe]4f^5 6s^2$. It is a group 3 or IIIB inner transition element and is one of the lanthanide rare earth elements (REE). Promethium does not exist in nature apart from negligible abundances of short-lived isotopes that form as decay products. Promethium has no natural stable or long-lived radioactive isotopes but does possess at least 38 short-lived isotopes with half-lives ranging from <1 μs to 17.7 years (^{145}Pm). Since Pm essentially does not occur in nature, there are no minerals that contain it as a significant component. Details of properties, history, and uses of Pm were compiled from Zaimes et al. (2015), Gschneidner (2016), and Hammond (2016).

History and Use

The existence of promethium was predicted in 1902 by Bohuslav Brauner and, after several mistaken and inconclusive identifications, was first produced in 1945 by Marinsky, Glendenin, and Coryell at Oak Ridge National Laboratory by separating it from the fission products of irradiated uranium. Although not found in nature, ^{147}Pm ($t_{1/2}$ = 2.62 years) is relatively easy to produce and used as a radioactive source in nuclear batteries, phosphor-based light sources, fluorescent light starters, and thickness gauges.

Geochemical Behavior

Promethium has been identified in the emission spectra of rare Ap stars (Cowley et al. 2004), an observation that provides supportive evidence for the theory of stellar nucleosynthesis of heavy elements.

Biological Utilization and Toxicity

There are no known biological uses for Pm. ^{147}Pm emits X-rays during decay and as such is theoretically dangerous if exposed in sufficient concentration. Under most circumstances, however, Pm is in such low concentrations that it is not hazardous, but concentrated Pm requires the same precautions as any low- to medium-level radioactive material.

Protactinium

Julie Prytulak
Department of Earth Science and Engineering, Imperial College London, London, UK

Element Data
Atomic Symbol: **Pa**
Atomic Number: **91**
Atomic Weight: 231.0359 g mol^{-1}
Isotopes and Abundances: ^{231}Pa ($t_{1/2}$ 32,760 year) ~100% ^{234}Pa ($t_{1/2}$ 70 s)
1 Atm Melting Point: 1569 °C
1 Atm Boiling Point: 4000 °C
Common Valences: 5+, 4+, 6+
Ionic Radii: Pa^{5+} VI-fold: 78 pm, VIII-fold 91 pm
Pauling Electronegativity: 1.5
First Ionization Energy: 568 kJ mol^{-1}
Chondritic (CI) Abundance: 2.7 fg/g
Silicate Earth Abundance: 7.5 fg/g
Crustal Abundance: 880 fg/g
Seawater Abundance: 1 fg/g
Core Abundance: ~0

Properties

The element protactinium (Pa) is a short-lived nuclide belonging to the decay chain of 235-Uranium and the third element in the actinide series (Z = 91) with an atomic mass of 231.0359. At room temperature it is a tetragonal solid gray metal, with a calculated density of 15.37 g/cm^3 and an atomic radius of 1.63 pm when XII-fold coordinated in its metallic state (Elson 1954). The electron configuration of Pa is [Rn] $5f^2$ $6d^1$ 7 s^2. It has been suggested that Pa most closely resembles Nb and Ta in terms of its chemical behavior, and theoretical considerations of its mineral-melt partitioning have used Nb and Ta as proxy elements (e.g., Blundy and Wood 2003).

History and Use

The name "protactinium" was officially adopted in 1949 by the IUPAC and derives its meaning from the Greek "*protos*" (first) and actinium, since it is parental or "before" ^{227}Ac. Protactinium was little known outside its nuclear applications during its rather fascinating history through the scientific prediction of its existence, the trial and error of its isolation, and the debate over its official designation. All of which largely took place under the backdrop of WWI and II and rising government interest in nuclear research. Today, although its combined toxicity and rarity limits commercial application, it has been successfully employed to geochemically investigate strikingly disparate topics such as high-temperature investigations of mantle melting and low-temperature investigation of water masses through time.

Protactinium has a rather riveting history of discovery as it was actively sought by competing research groups. The search for Pa can be traced back to Mendeleev's 1871 periodic table, where a vacancy between Th and U in Group V was postulated to contain a hypothetical element "eka-tantalum." In 1900, William Crookes isolated protactinium, but did not recognize it as a new element, instead calling it uranium-X. It transpired that uranium-X was in fact the minor ^{234}Pa isotope, which was named "brevium" by Fajans and Gohring (1913) due to its 1.17 min half-life. The discovery of the more abundant ^{231}Pa in 1917 is generally credited to independent work in 1917 of both Lise Meitner and Otto Hahn in Germany (Hahn and Meitner 1918) and Frederick Soddy and John Cranston (Soddy and Cranston 1918) in Glasgow, UK.

Soddy and others devised the displacement rule for decay series in 1913. The radioactive displacement principle has two simple tenents: (1) if a radioelement emits an alpha particle, its position in the table shifts two places to the left, (2) if it emits a beta particle, it shifts once place to the right. Uranium-X was an obvious discrepancy: a beta emitter with the chemistry of Th and in Group IV. The existence of such an element was required to complete uranium decay chains. Thus the search for the "mother of actinium" began in earnest. It was a painstaking process, as months of decay were required to accumulate enough material to be measured and demonstrate the existence of a new element. Given the position of the unknown element on the periodic table, its chemistry was thought to be similar to Ta. Thus the approach adopted by Meitner and Hahn was to separate large amounts of Ta from pitchblende and wait to see if it produced measurable actinium.

There are many reviews on the historical discovery of protactinium including factual accounts (e.g., Myasoedov et al. 2006) and recent synopses (Wilson 2012). Sime (1986) presents a particularly engrossing account, which incorporates WWI correspondence during the discovery of Pa, translated from German, between Meitner and Hahn.

Natural Occurrence

Protactinium is extremely rare. The global stock of the element is 125 g of 99.9% pure Pa which was extracted from

60 tonnes of spent uranium fuel by the UK Atomic Energy Authority in 1961 (Emsley 2001). In natural settings, as part of a U-series decay chain, the abundance of ^{231}Pa is dictated by its half-life and the concentration of ^{235}U with which it attains secular equilibrium. The decay constant of ^{231}Pa is 2.116×10^{-5} (Robert et al. 1969). Thus the abundance of ^{231}Pa can be calculated from U for terrestrial reservoirs of interest including the continental crust (U = 2.7 ug/g; Rudnick and Gao 2012), the mantle (U = 0.0229 ug/g; Palme and O'Neill 2012), CI chondrites (U = 0.0081 ug/g; Palme and O'Neill 2012), and seawater (U = 0.003 ug/g; Emsley 2001).

It is very difficult to directly determine mineral-melt partition coefficients for Pa, and it is assumed to be highly incompatible in most phases (see discussion in Blundy and Wood 2003). The exception is zircon, where directly determined partition coefficients (D) are available ($D_{Pa}^{zircon} = 0.9$ to 2.2 (Schmitt 2007)). Irrespective of some compatibility in zircon, Pa concentrations increase with magmatic evolution in magmatic products. Mid-ocean ridge basalts with MgO abundances >6 wt% generally contain on the order of 10s up to a few hundred fg/g (e.g., Goldstein et al. 1993; Elkins et al. 2014) while ocean island basalts and arc lavas with MgO >6 wt% generally display greater concentrations on the order of several hundred fg/g (e.g., Bourdon et al. 2006; Avanzinelli et al. 2012), reflecting the higher abundance of U in these rock types. The highest concentrations of Pa are found in materials such as uranium ores, which can contain on the order of 0.3 ug/g (Elson 1954).

Measurement and Applications

The minute abundances of naturally occurring Pa, combined with its high radioactivity (and thus toxicity), currently restrict applications to scientific research.

Isolation and Measurement

A key issue with the measurement of Pa by radiometric techniques such as alpha counting is the interference of vastly more abundant radioactive elements in the sample (e.g., Th, Ra). To avoid these complications, much effort was made to chemically isolate Pa from matrix elements. Many initial separation protocols were prompted by the nuclear industry in the 1930s to 1960s. A useful compilation of research conducted during the Manhattan project forms much of the background for present-day separation protocols (Hyde 1954). Perhaps the most vexing problem with protactinium isolation is its refusal to stay in solution. Protactinium has extremely low solubility even in concentrated percholoric, hydrochloric, and nitric acids. This is due to polymerization processes, the particle reactivity of Pa, and the extreme ease with which it undergoes hydrolysis. Current analytical protocols typically use hydrofluoric acid to achieve Pa solubility. Thus chemical separation of Pa is not for the faint hearted, as extremely dangerous acids must be employed to separate this highly toxic, radioactive element (e.g., Pickett et al. 1994; Regelous et al. 2004).

Once a purified Pa fraction is obtained, alpha counting requires weeks for a single measurement with precisions on the order of 5–10%. A significant step forward was the first thermal ionization mass spectrometry (TIMS) measurements of protactinium (Pickett et al. 1994). The technique does not have the complications of interfering radioactivity, as it is a mass measurement, but does require the addition of an artificial spike isotope (^{233}Pa) for precise and accurate measurement. The half life of ^{233}Pa is 26.967 days (Usman and MacMahon 2000), thus spike preparation, isolation of Pa from sample matrix, and measurement must all take place in the space of a few months to ensure that enough ^{233}Pa remains to be measured.

Preparation of ^{233}Pa is generally undertaken by "milking" a solution of ^{237}Np, with which ^{233}Pa will be in secular equilibrium (e.g., Pickett et al. 1994; Regelous et al. 2004). The process is time consuming and the spike must be continually and carefully recalibrated (e.g., Prytulak et al. 2008). An alternative procedure involves neutron activation of ^{232}Th in a nuclear reactor (e.g., Bourdon et al. 1999). The procedure has the advantages of rapid production of ^{233}Pa and removal of the need to recalibrate the spike with time. The requirement of frequent access to a nuclear reactor, however, can curtail the number of researchers able to employ this approach.

Although TIMS measurements were a significant improvement on the days to weeks that alpha counting methods require for Pa analysis, the ionization efficiency of Pa is low (<0.7%) and a single measurement requires 50–100 fg of Pa and several hours (Pickett et al. 1994). More recent protocols using multicollector inductively coupled plasma mass spectrometry (MC-ICPMS) with improved ionization efficiency (~0.9%) drastically reduce collection time to minutes and sample requirements to as low as 20 fg/g (e.g., Regelous et al. 2004). Thus MC-ICPMS protocols are currently the method of choice for analyzing Pa abundances in natural samples. Finally, Christl et al. (2007) have explored the measurement of Pa by accelerator mass spectrometry (AMS). This technique may have the advantage of even faster sample throughput, which is attractive for research requiring high sample density such as paleoceanography (see below).

Applications

A comprehensive review of both high- and low-temperature U-series decay applications are given in Bourdon et al. (2003). Below some common examples are highlighted with inclusion of more recent literature.

High-Temperature Igneous Processes

Uranium, Pa, and Th have different valences, partition coefficients, and chemical affinities. Thus, they are easily fractionated from one another and the return to secular equilibrium of the disturbed decay chain yields time information. An analytical rule of thumb is that the precision with which Pa and Th can be measured in silicate materials means that useful time information can be obtained for up to five times the half-life of the daughter in question. Therefore ^{231}Pa can be used to resolve magmatic processes on the order of 160kyr and ^{230}Th on the order of 350kyr. Employing both systems is more robust than one alone and can provide useful tests for concordance and secondary disturbances (e.g., Cheng et al. 1998; Condomines et al. 2003; Sims et al. 2008).

Measurement of combined ^{235}U-^{231}Pa and ^{238}U-^{230}Th disequilibria in volcanic materials have been used, for example, to model rates of mantle upwelling and magma transport beneath ocean islands and mid-ocean ridges (e.g., Bourdon et al. 2006; Elkins et al. 2014), magma generation in arcs (e.g., Turner et al. 2006; Avanzinelli et al. 2012), and the melt productivity of the mantle (e.g., Prytulak and Elliott 2009). In all of these approaches the greatest sources of ambiguity lie not in the precision of measurement, but in the range of range of mantle porosity values and for the mineral-melt partition coefficients of each nuclide.

Low-Temperature Paleoceanography

The contrasting half-lives of the U-series decay chain nuclides have been exploited in paleoceanography. Specific to protactinium, the ^{231}Pa/^{230}Th ratio of water masses and deep marine sediments has been investigated as a tool for past ocean circulation, with the greatest focus on the rate of Atlantic Meridional Overturning Circulation, and its causal link to abrupt climate change (e.g., McManus et al. 2004; Lippold et al. 2009; Bradtmiller et al. 2014).

The Earth's oceans are in steady state with respect to uranium, which has a residence time of 450,000 years. The production rate of Pa and Th from U-decay yields a constant oceanic ^{231}Pa/^{230}Th activity ratio of 0.093. However, due to their high particle reactivity and low solubility, both Pa and Th are scavenged from the water column by suspended particles (e.g., Anderson et al. 1983). The scavenging of ^{231}Pa and ^{230}Th results in excesses in marine sediments. Thorium and Pa excesses in this context are defined as the unsupported ^{230}Th and ^{231}Pa resulting from the decay of U in the water column and must be calculated taking into account ^{230}Th and ^{231}Pa produced from detrital U. Thorium is more easily adhered to sinking particles than Pa and thus has a very short residence time of tens of years compared to Pa, which is on the order of a couple hundred years (e.g., Henderson and Anderson 2003). The residence time of Pa is similar to the timescale of deep water transport in the Atlantic Ocean. Thus, all else being equal, approximately half of the Pa budget may be transported from the Atlantic without corresponding transport of Th. The resulting variation in ^{231}Pa/^{230}Th of marine sediments can be modeled to infer changes in water mass circulation (e.g., Burke et al. 2011). There are, however, important caveats to the application of ^{231}Pa/^{230}Th as an ocean circulation tracer, which complicate its interpretation. These include changes in scavenging rates and documented preferential scavenging of Pa by opal and the observation that Pa contents vary greatly vertically in a single water column (e.g., Thomas et al. 2006).

Biological Utilization and Toxicity

Protactinium plays no known biological role. The rarity of the element minimizes its risk to the general population. The dominant toxicological risk is from radioactive decay as part of the ^{238}U and ^{235}U decay chains.

Summary

Analytical advances in the measurement of the vanishingly small natural abundances of protactinium have heralded a surprising breadth of scientific applications in the past 15 years. Although the ^{235}U-^{231}Pa decay system is not as established as the related ^{238}U-^{230}Th decay system, the measurement of Pa provides an invaluable cross check on both geochronological applications and "tracer" studies employing the better studied ^{238}U decay chain. Other model parameters in paleoceanography or uncertainties in partition coefficients are now the limiting factor in geochemical interpretation of ^{235}U-^{231}Pa disequilibria, rather than any analytical hindrance.

Q

Quantum Numbers

David A. Dixon
Department of Chemistry, University of Alabama, Tuscaloosa, AL, USA

Definition

One of the results of quantum mechanics is that at the atomic level, energy is discrete. This was first observed experimentally in atomic spectra. The solution of the Schrödinger equation gives eigenfunctions and eigenvalues. The numerical solutions of this equation have constants in them which turn out to be integers or half-integers, the latter in the case of spin. These integer or half-integer constants are generally referred to as quantum numbers.

Overview

The Schrödinger wave equation was developed to provide a mathematical description of DeBroglie's matter waves. DeBroglie showed that every particle has a wavelength λ related to its momentum p by the equation $p\lambda = h$ where h is Planck's constant. The kinetic energy operator in the Schrödinger equation is a second derivative (gradient), and the form of the equation means that sines and cosines (e^{ix}) or exponentials are possible solutions. A general set of references for quantum mechanics with a focus on quantum chemistry is provided (Karplus and Porter 1970; Pauling and Wilson 1985; Szabo and Ostlund 1996; Messiah 1999; Pilar 2001; Schatz and Ratner 2002; Lowe and Peterson 2006; McQuarrie 2008; Atkins and Friedman 2011; Engel and Reid 2013; Levine 2014).

Particle in a Box

A simple problem is the particle in a box with infinite walls. The solution of the Schrödinger equation for the motion in this simple box is subject to the conditions that the wave function be everywhere continuous and the first derivative be continuous. The boundary conditions for the particle in the box with infinite walls mean that the wave function has to go to zero at the boundaries so that one can only fit a discrete integer or half-integer number of waves for any energy level. The energy solution for a mass m and box length a is

$$E_n = h^2n^2/8ma^2 \quad (1)$$

where n is the integer quantum number and h is Planck's constant. Clearly the energy is discrete. The particle in a box solution is not just a simple example but can be used to explain the results of the UV-visible spectra of conjugated polyenes as an example. If one has a three-dimensional box, then there are three quantum numbers, one for each dimension. Classically, there are six constants of the motion in three dimensions, the momentum in each direction (p_x, p_y, p_z) and the particles position (x, y, z). However, in quantum mechanics, there are only three quantum numbers (one per dimension) because of the Heisenberg uncertainty principle. This principle relates canonical conjugate variables as $\Delta px \Delta x \geq h/4\pi$. In one dimension, if one precisely knows the energy ($KE = p^2/2\ m$), then one cannot precisely know the position x so x is now represented by a wave. An example of this is the zero-point energy of a system. A second example is the 1 s orbital for the electron in the H atom with a precise energy of 13.6 eV, the ionization potential. The 1 s orbital is a probability distribution where one is expected to have a certain probability of finding the electron in a region of space, but one cannot define precisely where it is due to the energy and hence the momentum being known exactly.

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

Harmonic Oscillator

As another example, consider the quantum mechanical solution for the harmonic oscillator in one dimension. The solution of this equation yields a single quantum number of the vibrational motion in one dimension. The energy is

$$E = \tfrac{1}{2}(h/2\pi)\omega(n + \tfrac{1}{2}) \quad (2)$$

where h is Planck's constant, ω is the frequency given by $\sqrt{}(k/m)$ where k is the force constant and m is the appropriate reduced mass, and the quantum number n is an integer. The corresponding eigenfunctions are the Hermite polynomials. The quantum number arises because the wave function is everywhere finite, and the series solution of the differential equation does not converge unless it is truncated giving an integer quantum number. Notice that the lowest energy is not zero. There is always a zero-point energy for the harmonic oscillator.

Rigid Rotor

The next set of quantum numbers to consider is that for the solution of the rigid rotor in two dimensions. Here we transform from Cartesian x, y, and z coordinates to spherical polar coordinates. If the distance between the two atoms in a simple diatomic molecule, as an example, is fixed, then there are two degrees of freedom so there are two quantum numbers. The quantum number of the projection onto the x,y plane is the φ quantum number m_l and is an integer ranging from $-l$ to $+ l$. This is the quantum number of the L_z angular momentum operator and arises from φ being single valued over the range 0 to 2π. The other quantum number is l which arises from the solution of the equation for θ and is again due to truncation of a power series to keep the wave function finite. The differential equation for l does depend on m_l. The l quantum number is a positive integer and is $l = 0, 1, 2, \ldots$. This is the quantum number of the L^2 angular momentum operator. The complete solution to the rigid rotor are spherical harmonics with the associated Legendre polynomials for θ and the $e^{im\varphi}$ for φ. The energy is

$$E = l(l+1)(h/2\pi)^2/2I$$

where I is the moment if inertia. In this case, the energy of the lowest state is zero. The two good quantum numbers are l and m_l arising from the L_z and L^2 operators which commute.

Atoms

For atoms and molecules, one makes the Born-Oppenheimer approximation to separate the nuclear and electronic motion. The solution for the one-electron H atom is essentially that for the rigid rotor plus the inclusion of the distance of the electron from the proton. The solutions are products of the associated Legendre polynomials for the angular component and the associated Laguerre polynomials for r. The resulting quantum numbers are

$$m_l = -l, -(l-1), \ldots 0, 1, 2, \ldots l$$
$$l = 0, 1, 2\ldots$$
$$n = 1, 2, \ldots.$$

The angular parts have been discussed above. The radial equation solution depends on the value of l, and the quantum number n again arises because of the need to keep the power series finite. In the one-electron atom, the energy depends only on the value of n

$$E = 2.18 \times 10^{-18}\mathrm{J}\left(Z^2/n^2\right)$$

where Z is the atomic number and 2.18×10^{-18} J is a constant known as the Rydberg energy.

The final quantum number needed to describe an atom is $m_s = \pm \tfrac{1}{2}$, the spin, which arises from the solution of the relativistic Schrödinger equation for the electron.

The quantum numbers for the H atom give rise to the normal orbital labels as follows:

Orbital	n	l	m_l
1s	1	0	0
2s	2	0	0
2p	2	1	−1,0,1
3s	3	0	0
3p	3	1	−1,0,1
3d	3	2	−2,−1,0,1,2
4s	4	0	0
4p	4	1	−1,0,1
4d	4	2	−2,−1,0,1,2
4f	4	3	−3,−2,−1,0,1,2,3

For a polyelectronic atom, the energy is far more complex than for H, and there is a splitting of the orbital energies such that the degeneracy of n is split and one obtains:

$$1s < 2s < 2p < 3s < 3p < 4s < 3d < 4p < 5s < 4d < 5p < 6s < 4f < 5d < 6p\ldots.$$

The periodic table is generated by using the Pauli exclusion principle that no two electrons can have the same quantum numbers as they are fermions and the Aufbau principle (two electrons per orbital and filling the orbitals from the lowest energy ones). We then use the approximation for atoms that L (total orbital angular momentum quantum number) and S (total spin angular momentum quantum number)

are good quantum numbers as is their sum J = L + S. This is good for values of Z < 40 for a qualitative approach. For larger Z, the effects of relativity need to be considered, and this leads to a spin-orbit LS terms in the Hamiltonian so that L and S are no longer good quantum numbers, and only J = L + S is a good quantum number. This gives rise to the term symbols for the atom, $^{2S+1}L_J$. The values for L and S are obtained by vector sums of the individual angular momentum components. The values of L are labeled as S(L = 0), P(L = 1), D(L = 2), F(L = 3), G(L = 4), H(L = 5)... . The values of 2S + 1 are labeled as follows: singlet(S = 0), doublet (S = ½), triplet (S =1), quartet (S = 3/2), quintet (S = 2).... The ordering of the states is given by Hund's rules:

1. The lowest energy term has the greatest spin multiplicity.
2. For the same spin multiplicity, the term with the greatest orbital angular momentum has the lowest energy.
3. If the unfilled subshell is exactly or more than half full, the level with the maximum value of J has the lowest energy. If the unfilled subshell is less than half full, the level with the lowest J value has the lowest energy.

Conclusions

Quantum numbers arise in the solution of the Schrödinger equation due to the presence of boundary conditions and the properties of a well-behaved wave function solution. The quantum numbers are used to describe the discrete energy levels of a system at small scales. The periodic Table of the elements can be readily explained with the use of four quantum numbers, the Pauli exclusion principle, and the Aufbau principle. Three of these four quantum numbers arise from the solution of the equation describing the solution of the electron in the hydrogen atom, and the fourth is due to the ±½ spin of the electron. Quantum numbers are also important in rotational spectroscopy as well as in vibrational spectroscopy, with the latter quantum numbers being important for isotope fractionation factors.

Radioactivity

Don Porcelli
Department of Earth Sciences, Oxford University, Oxford, UK

Definition

Radioactivity is the process of spontaneous decay of atomic nuclei, releasing energy and atomic particles. The main types of radioactive decay involve nuclear transmutations from a radioactive parent isotope to a stable daughter isotope either directly or through a series of decays of progressively smaller unstable nuclei. A radioactive isotope is an atomic species that has insufficient nuclear binding energy to overcome instability due to an excess of either protons or neutrons. There are many naturally occurring radioactive isotopes of a wide range of elements that are present in the environment, although many more, highly unstable isotopes also have been created in the laboratory.

There are three main effects of radiation to the natural environment: decay produces the emission of high energy radiation that can interact with the environment and can lead to radiation exposure; the release of decay energy results in the production of heat within the Earth; and the generation of daughter nuclides can be used for geochronology.

The Radioactive Decay Law

Radioactive decay is a statistical process that depends upon the instability of the isotope and is completely unpredictable for any individual nucleus. The rate of radioactive decay of an isotope N follows the well-known radioactive decay law, where the fraction of atoms, λ (the decay constant), that decay over a period of time is fixed and is an intrinsic characteristic of the isotope:

$$dN/dt = -\lambda N \quad (1)$$

This can be integrated to describe the resulting isotope abundance with time;

$$N = N_0 e^{-\lambda t} \quad (2)$$

and the amount of daughter isotope atoms produced is equal to $D = N_o - N$. The half-life of N ($t_{1/2}$) is the time required for half of the atoms of N to decay. It is related to the decay constant by

$$t_{1/2} = \ln 2/\lambda \quad (3)$$

Therefore, the greater the decay constant, the faster the decay and the shorter the half-life. The infrequently used mean lifetime of an atom is $\tau = 1/\lambda$.

The rate of decay is reported in the SI unit the Becquerel (Bq), equal to one decay per second. The Curie (Ci) is equal to 3.7×10^{10} decays per second, the approximate radioactivity of 1 g of ^{226}Ra. The abundance of a short-lived nuclide can be reported as an activity (N), which is equal to the decay rate (dN/dt).

Radiometric geochronology methods are based on the constant decay rate of isotopes in the environment and involve either determining how much of a radioactive element has decayed away from a known abundance or how much of a radiogenic daughter has accumulated compared to the amount of radioactive parent remains.

Modes of Decay

There are three main types of decay in the natural environment.

Beta Decay

Beta decay releases a beta particle (a high energy electron or positron), resulting in no change in the total number of

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

nucleons (A, the number of neutrons plus protons), but there is a change in atomic number (Z, the number of protons), resulting in a daughter nucleus of a different element than that of the parent. In β-decay, within the nucleus of a neutron-rich (relative to stable isotopes of the element) isotope, a neutron is converted into a proton, which releases a high energy electron (β^-) along with a neutrino, e.g., $^{14}C \rightarrow {}^{14}N + \beta^- + \nu + Q$, where Q is the energy released as kinetic energy of the decay products and as electromagnetic, very high-frequency gamma (γ) radiation. In β^+ decay, within the nucleus of a proton-rich isotope, a proton is converted into a neutron, a positron (β^+), and a neutrino, e.g., $^{26}Al \rightarrow {}^{26}Mg + \beta^+ + \nu + Q$. A less common decay mechanism is electron capture, where the nucleus of a proton-rich isotope incorporates one of the orbiting electrons and emits a neutrino, while a proton is converted into a neutron, e.g., $^{40}K + e \rightarrow {}^{40}Ar + \nu + Q$.

Beta radiation is moderately ionizing and can be blocked with a few millimeters of aluminum. Electromagnetic energy is highly ionizing and requires considerable shielding (e.g., 1 cm of lead will absorb 50% of a γ flux).

Alpha Decay

During alpha decay, there is emission from the parent nuclide of an alpha (α) particle composed of two protons and two neutrons (i.e., a ^{4}He nucleus). The result is a change in both A and Z. An example is $^{238}U \rightarrow {}^{234}Th + \alpha + Q$, where energy Q is released both as kinetic energy of the α-particle and the daughter nuclide and as gamma radiation. The charged α-particles do not travel far (a few cm in air, 10^{-3} times that in water, and readily blocked) due to interactions between the charged particle and bound electrons, and so is the type of radiation with the least penetrating power. Where α-particles are retained within a solid as ^{4}He atoms, their accumulation can be used like other stable daughter isotopes for geochronology.

Fission Decay

Spontaneous fission involves the decay of the nucleus into larger fragments, typically two subequal atoms, releasing substantial energy along with neutrons and gamma radiation. This occurs as an alternative decay mode, e.g., ^{238}U spontaneously fissons 5×10^{-7} times the rate of alpha decay, with a fixed spectrum of isotopes of Xe, Mo, and other elements. The fragments are ejected into the surrounding medium and in minerals leave a track of damage. The accumulation of these tracks is equivalent to the accumulation of stable daughter isotopes and is the basis of fission track dating.

Induced fission occurs when a nucleus interacts with a neutron and becomes unstable. This requires a neutron flux and generally occurs in nuclear reactors. There has been one reported natural occurrence, in Oklo, Gabon 2Ga ago when there was a higher proportion of ^{235}U in U, where sufficient ^{238}U was concentrated to provide a high neutron source by spontaneous fission and where there was water to moderate neutron energies to optimize reaction with ^{235}U. This left production of telltale isotopes, e.g., U, Nd, Xe, and Ru (de Laeter and Hidaka 2007) in the deposit.

Some isotopes are subject to more than one mode of decay, e.g., ^{238}U decays by both α-decay (to ^{234}Th) and spontaneous fission, and ^{40}K decays by both electron capture (to ^{40}Ar) and β^-decay (to ^{40}Ca) according to well-defined branching ratios.

Determination of Decay Constants

The decay constant for each separate isotope is determined by direct measurement of either decay radiation or the accumulation of daughter isotopes from a measured abundance of the radioisotope. For very long-lived isotopes, a comparison can be made between the age determined using a decay scheme involving a radioactive parent with a well-constrained decay constant (generally ^{238}U) and decay schemes of other radioactive elements (Blum 1995).

There is consistent evidence that the value for λ for each isotope is a constant, especially on the scale needed for geochronology and environmental studies, through comparison between different schemes over a range of time scales, direct measurements, and limitations on the variation in the underlying controlling fundamental constants that affect nucleus decay (Uzan 2003).

An exception to this is for decay by electron capture, which by involving an electron orbiting in an inner shell, may be subtly affected by environmental conditions. The only major isotope of environmental relevance subject to electron capture is ^{40}K; the value for λ has been calculated to only increase by 0.025% at a pressure of 25GPa (equivalent to a depth of 700 km) (Lee and Steinle-Neumann 2008) and experimentally found to not be significantly affected (to within 1%) in the chemical environment (Norman et al. 2001).

Sources of Radioactive Isotopes

There are various reasons why naturally unstable isotopes with a wide range of half-lives (shown in parentheses below) are found in the environment.

Long-lived isotopes were produced during nucleosynthesis in stars or supernovae along with stable isotopes and were then incorporated into the Earth during formation. These isotopes have not fully decayed away and form the basis for the various decay schemes used for geochronology over Earth history. The primary sources of natural radioactivity, as well as of heat production within the Earth, are the long-lived isotopes ^{238}U (4.47×10^9a), ^{235}U (7.04×10^8a), ^{232}Th

(1.41×10^{10}a), and ^{40}K (1.40×10^{9}a). Other long-lived isotopes include ^{147}Sm (1.06×10^{11}a), ^{87}Rb (4.88×10^{10}a), ^{187}Re (4.6×10^{10}a), and ^{176}Lu (3.71×10^{10}a).

Short-lived isotope daughters are continually produced as intermediate isotopes within the ^{238}U, ^{235}U, and ^{232}Th decay series that ultimately produce stable Pb isotopes. These include isotopes of a range of different elements that can become separated in the environment due to chemical or physical processes, for example, ^{222}Rn escapes from rocks and soils to the atmosphere, where it decays and produces other radioactive daughters.

Short-lived isotopes in the early solar system were also produced in stellar environments and have half-lives long enough to be incorporated into the early Earth but not to survive to the present day. Their earlier presence in some meteorite minerals formed early in solar system history is inferred from enrichments in the stable daughter isotopes. This includes ^{53}Mn (3.7 Ma) ^{107}Pd (6.5 Ma), ^{182}Hf (9 Ma), ^{129}I (16 Ma), ^{244}Pu (82 Ma), and ^{146}Sm (103 Ma), as well as ^{26}Al (0.7×10^{6}a), which was also an important heat source in the early solar system and may have caused melting of very early-formed small bodies (Lee et al. 1977).

Cosmogenic nuclides. The Earth is continuously bombarded by cosmic rays largely from beyond the solar system and composed of high energy particles, primarily protons, that interact with the nuclei of atoms in the atmosphere and exposed surfaces, producing various radioactive isotopes through a series of nuclear reactions. The concentrations are generated in very low but detectable concentrations and can be used to quantify processes occurring over very short time scales [using, e.g., ^{7}Be (53 days), ^{32}P (14.3 days), and ^{35}S (87.5 days)] or to date environmental processes over longer periods [using, e.g., ^{3}H (12.3a), ^{10}Be (1.4 Ma), ^{14}C (5730a), ^{36}Cl (0.3 Ma), ^{39}Ar (269 a), and ^{129}I (80 Ma)].

Anthropogenic isotopes are produced within nuclear reactors and by reactions related to nuclear explosions. While there are many very short-lived isotopes, there are some that are sufficiently long-lived to disperse in the environment. This includes ^{3}H, ^{14}C, ^{90}Sr (29a), ^{99}Tc (0.21 Ma), ^{129}I, ^{137}Cs (30a), ^{237}Np (2.1 Ma), ^{241}Am (430a), and several U and Pu isotopes (Hu et al. 2010).

Measurement Methods for Radiation and Radioactive Isotope Concentrations

Various detectors can be used to quantify the emission rates of different types of radiation, and the abundances of the radioactive isotopes can be measured by quantifying the radiation resulting from decay (L'Annunziata 2012). In some circumstances, an isotope will decay to another short-lived isotope that can be more readily measured and can then be related to the abundance of the parent.

Alpha spectrometry can be used to detect and count emitted alpha particles, where the contributions from the decay of different isotopes can be distinguished by their distinctive α-particle energies. Since α-particles can readily interact with surrounding atoms, and so escape detection, good chemical separation, and purification from other elements are critical.

Beta spectrometry, for counting emitted beta particles, uses the ionizing or excitation effects of the charged β-particles for detection and is commonly done with a Geiger-Müller counter, which employs a gas-filled tube where ions are ionized by each intercepted β-particle, and this is converted into an electrical pulse. These counters do not distinguish between beta particles by energy and so require chemical separation to quantify the contributions from different isotopes rather than total radiation. The isotopes ^{3}H and ^{14}C emit low-energy electrons and require an alternative method such as liquid scintillation counting, in which a sample is dissolved in a solvent solution containing compounds that convert energy received from each β-particle into light, and the resulting pulses are counted.

In gamma spectrometry, emitted gamma rays are detected when they ionize target atoms, and the resulting charge is measured. Gamma rays can penetrate a considerable distance in solid material, so that isotopes of interest do not need to be separated from sample material before counting. Gamma energy spectra can be used to measure various radioactive isotopes simultaneously. The detection limit is typically several orders of magnitude higher than for beta and alpha counting.

As an alternative to determining radioactive isotope abundances by radiation measurements, the atoms present can be measured directly by mass spectrometry. In general, short-lived nuclides, with high radiation fluxes due to high values of λ and despite low atomic abundances, can be more readily measured by counting. The abundances of long-lived nuclides are more precisely measured by mass spectrometry. However, the optimal method for each isotope depends upon the available amount and nature of the sample, the element involved, and specific analytical considerations.

Radioactivity Exposure and Hazards

The natural terrestrial background of radioactivity is largely due to the decay the radioactive isotopes in the ^{238}U, ^{235}U, and ^{232}Th decay chains, along with ^{40}K, and so is controlled by the distribution of K, U, and Th in rocks and soils. Bioaccumulation of these elements can enrich radioactive isotopes and increase exposure. For example, there is ^{40}K (as well as ^{14}C) in food and in the body, ^{210}Po in tobacco, and ^{210}Pb in aquatic biota. The use of natural materials for construction, such as granites and shales that are enriched in

U and Th, can increase radiation within buildings. However, the greatest exposure is from ^{222}Rn in the ^{238}U decay series, which is mobile as an inert gas and can escape from rocks and soils and accumulate within buildings. It has a short half-life (3.8 days) and then decays to a series of other short-lived isotopes that together can account for a substantial fraction of natural exposure.

The radioactivity of naturally occurring radioactive materials (NORM) can be concentrated through industrial activities (IAEA 2003). Combustion of coal concentrates U and Th in fly ash and processing of phosphate rocks for fertilizer leaves similarly enriched residual waste. Similarly, U and Th can be found in waste from metal mining and tailings and in mineral sands that are processed for Zr, Ti, and REE. During oil and gas production, formation wastewaters can accompany extraction and are enriched in Ra isotopes that are then concentrated in sulfate precipitates within pipelines.

Artificially produced radionuclides produced from nuclear explosions or released from waste discharges or nuclear accidents are widely distributed due to dispersion by atmospheric transport or ocean circulation. This includes isotopes of a wide range of elements and with very different half-lives. A clear of example of the global impact of nuclear explosions is ^{14}C, which is naturally produced in the atmosphere due to neutrons from cosmic ray reactions; the atmospheric concentration of ^{14}C almost doubled by the early 1960s due to additional neutron fluxes from aboveground nuclear testing and subsequently dropped only after such testing was banned. Similar peaks occurred for ^{3}H and ^{36}Cl as well. Exposure hazards due to nuclear accidents and discharges depend upon the transport properties and exposure pathways involved for each isotope. The radioactive isotopes most responsible for radiation exposure by the general population after the Fukushima (2011) and Chernobyl (1986) reactor incidents were ^{131}I, ^{134}Cs, and ^{137}Cs, which were dispersed through the atmosphere (Steinhauser et al. 2014). The impact of intentional and accidental discharges can be seen even in remote areas. Discharges into the ocean from the Sellafield nuclear reprocessing plant in the UK have led to a plume of low-level ^{137}Cs and ^{129}I and ^{236}U that can be traced into the Arctic Ocean. Similarly, low levels of ^{238}Pu (88 a),^{239}Pu (24 ka), ^{240}Pu (6.6 ka), ^{137}Cs, and ^{241}Am are found in soils even in remote Arctic regions (AMAP 2016).

Element Data

Atomic Symbol: Ra
Atomic Number: 88
Atomic Weight: 226.03
Isotopes and Abundances: ^{226}Ra ($t_{1/2}$ = 1599 y) ~100%, ^{228}Ra ($t_{1/2}$ = 5.76 y), ^{223}Ra ($t_{1/2}$ = 11.4 d), ^{224}Ra ($t_{1/2}$ = 3.6 d)
1 Atm Melting Point: 696 °C
1 Atm Boiling Point: 1500 °C
Common Valences: 2+
Ionic Radii: 148 pm

(*continued*)

Pauling Electronegativity: 0.9
First Ionization Energy: 509.29 kJ/mol
Chondritic (CI) Abundance: 4.6×10^{-3} ppt (0.17 Bq/kg; Girault et al. 2017)
Silicate Earth Abundance: 7.9×10^{-3} ppt
Crustal Abundance: 0.47 ppt
Seawater Abundance: 0.14–0.83 fmol/L
Core Abundance: ~0

Properties

Radium has no stable or long-lived isotopes and exists in nature only because it is continually produced by radioactive decay, ultimately of U and Th. Its longest-lived and consequently most abundance isotope, ^{226}Ra, is part of the ^{238}U decay series chain and the daughter of ^{230}Th. Concentrations in the silicate Earth and crust listed here assume ^{226}Ra is in secular radioactive equilibrium with ^{238}U; other isotopes are orders of magnitude less abundant. ^{228}Ra and ^{224}Ra are part of the ^{232}Th decay chain; ^{223}Ra is part of the ^{235}U decay chain. Pure Ra is a soft silvery-white metal with a density of 5500 kg/m^3, but rapidly reacts with air to form radium nitride. Radium is highly radioactive; the Curie (Ci) unit of radioactivity was defined as the activity of 1 g of Ra and is equal to 3.7×10^{10} decays per second or becquerels (Bq), which is the SI unit of radioactive decay. ^{223}Ra, ^{224}Ra, and ^{226}Ra decay by emission of α particles; ^{228}Ra decays by emission of a β^- particle.

As the heaviest alkaline earth element, Ra behaves as an lithophile element and most Ra salts are soluble in water ($RaSO_4$ being the most notable exception), although less so than salts of the lighter alkaline earths. In many respects, its chemistry is similar to that of the next heaviest alkaline earth, barium.

History and Use

Radium was first isolated and identified as a new element spectroscopically by Marie and Pierre Curie in 1898; the pure metal was isolated 10 years later (Emsley 2001). In the early twentieth century, Ra was used to produce luminous paints for watch dials, etc., by mixing radium bromide with zinc sulfide, with the α-particles stimulating fluorescence of ZnS. It was also used in health treatments, generally very much to the detriment of the patients involved, before the hazards of radioactivity were fully realized.

Today, use of Ra is limited to treatment of some metastasized cancers and as a radiation source for some types of industrial radiography.

Radium Geochemistry

Radium's large ionic radius makes it incompatible in most common minerals and it behaves similarly to other large ion lithophile elements in magmatic systems. Owing to the short half-lives of Ra isotopes, the distribution of Ra in crystalline rocks will closely follow that of its parents, U and Th. However, as a consequence of alpha-recoil during its production by one (in the case of ^{228}Ra) or more α-decays, some Ra atoms will be ejected from crystals and the remainder will occupy damaged crystal sites, making it susceptible to leaching during weathering. Nevertheless, Michel (1984) found that ^{226}Ra was present in excess over ^{238}U in weathered granite and was concentrated in the leachable fraction, suggesting Ra lost from primary minerals is quickly incorporated into secondary ones. At low temperature, Ra is most compatible in sulfates such as anhydrite and barite and, to a lesser extent, carbonates such as aragonite (Langmuir and Riese 1985).

In soils, ^{226}Ra/^{238}U activity ratios averaged over entire soil profiles are close to radioactive equilibrium, but Ra is generally enriched in surface soil and in the exchangeable and organic fractions. Conversely, soil minerals are typically Ra-depleted relative to U. This likely reflects the effects of vegetation, in which Ra is strongly concentrated over U. The result of this vegetative uptake is to move Ra upward in the soil and concentrate it in the organic fraction (Greeman et al. 1999).

In low ionic strength stream and groundwaters, Ra is mainly present as uncomplexed Ra^{2+} ion. Its behavior, however, is dominated by its rapid absorption onto solid surfaces in low ionic strength solution (Krishnaswami et al. 1982). Its transport in groundwater is consequently strongly retarded. The very different half-lives of the four Ra isotopes can be used to distinguish processes occurring at different rates and time scales, making them particularly useful in groundwater migration studies (Porcelli and Swarzenski 2003). The discovery of high concentrations of ^{226}Ra in coastal waters of South Carolina led to the recognition of the importance of submarine groundwater discharge (Moore 1996), and subsequent Ra studies have helped to quantify submarine groundwater discharge elsewhere (Moore 2010).

Decay of Th in sediments rather than riverine input is the principal source of Ra in seawater. Within the ocean, Ra distribution closely follows that of Ba, with a nearly constant Ba/Ra ratio of about 4.5×10^{-9} mol/mol (Ku and Luo 1994; Foster et al. 2004). Both elements are depleted in surface waters due to particle scavenging but are mostly regenerated within the upper 250–1000 m. Both elements have seawater residence times of the order of 10^4 years and behave quasi-conservatively in the deep ocean. As its residence time is longer than its half-life, Ra largely decays within the ocean

rather than being removed. Because of its conservative behavior and the differing half-lives of its four isotopes, Ra is used as a tracer of ocean circulation and mixing (e.g., Ku and Luo 1994; Charette et al. 2015).

Based on the extent of radioactive disequilibrium between parent and daughter nuclides, Ra isotopes, like other nuclides in the U-series decay chain, can be useful geochronological tools. The short half-life of ^{226}Ra makes it useful mainly on times scales of thousands of years, making it particularly useful in studies of magmatic processes (e.g., Hawkesworth et al. 2004). For example, excesses of the activity of ^{226}Ra over its parent ^{230}Th have revealed surprisingly short time scales between melt segregation in the mantle and eruption at the surface in island arc volcanoes (e.g., Gill and Williams 1990; Turner et al. 2001). Radium isotopes have also been used to date travertine deposits (e.g., Sturchio 1990; Soligo and Tuccimei 2008) and the residence times of water hydrothermal systems at mid-ocean ridges (e.g., Kadko and Butterfield 1998). Radium can be present at concentrations orders of magnitude above levels considered safe for drinking in saline formation waters pumped to the surface in petroleum production and in barite precipitated on equipment. ^{228}Ra/^{226}Ra ratios can be used to establish the age of these precipitates and distinguish between sources of contaminated soils (Zielinski et al. 2001).

Biological Utilization and Toxicity

Radium has no biological function; its toxicity derives from its radioactivity. As an alpha-emitter, it is particularly damaging to tissue when inhaled or ingested. The U.S. Environmental Protection Agency considers levels in drinking water above 5 pCi/L (0.185 Bq/L) to be unsafe. An additional hazard associated with Ra is its decay to radon (Rn), which as a noble gas is particularly mobile and easily inhaled.

Summary

Radium is present in the Earth only as a consequence of its continued production through decay of U and Th; because of the short half-lives of its isotopes, its concentration is extremely low. Despite this, and despite its very limited practical use, Ra has proved valuable to geochemists in a wide variety of ways, ranging from studying groundwater to magma migration and ocean mixing. In addition, studies of naturally occurring Ra inform understanding of the behavior of Ra in radioactive nuclear waste.

Seawater Abundance: ~0.6–6 Bq m^{-3}

Properties

Radon is a noble gas (with a filled outer electron shell), with three naturally occurring isotopes, all of them radioactive. Each is produced by decay of a radium isotope parent within one of the ^{238}U, ^{235}U, and ^{232}Th decay series. Rn is colorless, odorless, and generally unreactive in the natural environment. The longest-lived isotope, ^{222}Rn, is the most abundant, although ^{220}Rn contributes a significant fraction of the total Rn radioactivity very close to where it is being continuously produced by parent ^{224}Ra decay. Rn does not readily form chemical compounds or interact with most natural materials but has been found to adsorb onto activated charcoal, zeolites, and silica gel in the laboratory. The solubility of Rn in water, at 1 atmosphere pressure and 20 °C, is 230 cm^3/kg.

Radon, Table 1 Data for Naturally-Occurring Radon Isotopes

	^{222}Rn	^{220}Rn	^{219}Rn
Half-life $t_{1/2}$	3.83 days	55.6 s	3.96 s
Decay constant λ	2.09×10^{-6} s^{-1}	0.0127 s^{-1}	0.175 s^{-1}
Decay series	^{238}U	^{232}Th	^{235}U
Immediate parent	^{226}Ra	^{224}Ra	^{223}Ra
Immediate daughter	^{218}Po	^{216}Po	^{215}Po
Relative abundance[a]	99.98%	0.02%	0.00006%
Relative activity[a]	1	1.2	0.05
Conversion: 1 Bq=	4.8×10^5atoms	80 atoms	5.7 atoms

[a]Assuming the average crustal values of (Th/U)wt = 3.8 and (^{238}U/^{235}U) molar = 138

Since Rn is present in very low concentrations and decays rapidly, it is measured through decay counting, usually either by alpha counting of Rn decay or gamma counting of the decay of its daughter products. The abundance of each isotope (atoms, N) is typically reported as the activity, or rate at which the atoms decay (in Bq, decays per second), where the activity $dN/dt = \lambda N$ for each isotope with decay constant λ (Table 1).

History and Use

Radon was discovered through a series of experiments, starting in 1899, investigating the properties of radioactive substances by the Curies, Rutherford, and Dorn. Radioactive gaseous emanations from thorium (^{220}Rn) and radium (^{222}Rn) were finally identified as constituting a new element by Rutherford (Marshall and Marshall 2003) and used to determine the short half-lives, atomic masses, and chemical properties.

There are no significant direct uses of Rn. Although there are some claims that exposure to natural environments enriched in ^{222}Rn has therapeutic effects, these are not accepted by health organizations.

Geochemical Behavior

The distribution of Rn in rocks reflects the distribution of U and Th. In closed systems within minerals and rocks where decay series nuclides cannot readily escape, a state of secular equilibrium is maintained where the decay rate of each Rn isotope is equal to the production rate through decay by the corresponding parent Ra isotope, which in turn is equal to the decay rate of the U or Th isotope at the top of the decay series. Radon concentrations are highest in rocks with U mineralization, and high in granites and organic-rich shales, but are low in sandstones. The average concentration of

^{226}Ra in soils is ~25 Bq/kg (and so ~1.2 × 10^7 atoms ^{222}Rn/kg) (UNSCEAR 1982).

Radon can escape from minerals through alpha recoil, when the decay of the parent Ra atom imparts sufficient energy on the resulting Rn atom to propel it ~10 nm through mineral structures in a random direction. The Rn atom may cross the mineral surface and come to rest in water-filled pore space or fracture, or be implanted into an adjacent mineral from which it can migrate out through the damaged mineral lattice of the recoil track. The proportion of Rn produced that is released this way depends upon the size and shape of U- and Th-bearing minerals as well as the distribution of Ra in secondary phases and adsorption sites. This can be up to ~10% in groundwaters and may be substantially greater in soils. Subsequent migration of Rn in unsaturated soil profiles upwards depends upon the diffusive path in vapor-filled pores and fractures, advective vapor migration, and partitioning with any pore water present. In aquifers, Rn transport is dominated by groundwater advection.

The diffusive and advective fluxes of Rn can be used to quantify various short-term transport processes (Baskaran 2016). In the hydrosphere, the recoil flux of ^{222}Rn out of solids provides a measure of the recoil fluxes of the short-lived isotopes of U, Th, Pa, Ra, and Po and can be used to calculate transport rates of these elements in groundwaters (Porcelli 2008). The concentrations of ^{222}Rn in groundwaters is high due to the high ratio of U-bearing rock to water in aquifers, and so groundwater discharge into surface waters, which have low ^{222}Rn due to a lower supply and loss to the atmosphere, can be identified in rivers, lakes, and oceanic shelves. In the deep oceans, ^{222}Rn is in secular equilibrium with dissolved ^{226}Ra except in the upper ~100 m, where ^{222}Rn is partially lost to the atmosphere, and near the seafloor, where ^{222}Rn is enriched due to a diffusive flux from the underlying sediments. The variations near the sediment-water and water-air interfaces have been used to study vertical transport processes in these zones and mixing between water masses (Smith et al. 2011).

There have been reports of increased ^{222}Rn fluxes preceding or accompanying tectonic activity and so providing an indicator of an upcoming earthquake. However, such occurrences have not been uniform between sites or even spatially and temporally at a single site. Moreover, the mechanisms for release and transport of ^{222}Rn, and the conditions under which there is unambiguous association with tectonic activity, have not been clearly established (Woith 2015).

High fluxes of radon may be used to identify U deposits, although this is expected to be limited to identifying occurrences within ~100 m of the surface due to the short half-life of ^{222}Rn, unless it is carried advectively to the surface. High ^{222}Rn fluxes may also reflect preferential transport to the surface through the presence of subsurface faults. Naturally occurring radioactive materials (NORM) such as residues from resource extraction activities (e.g., oil, gas, and coal industries; mineral sands processing for Th) also can be local sources of ^{220}Rn and ^{222}Rn (Ishimori et al. 2013).

In the atmosphere, the concentration of ^{222}Rn decreases with elevation in the atmosphere due to a changing balance between upward transport and decay and can be used to determine rates of atmospheric advection. The mean world-wide flux of ^{222}Rn from soils is 16 mBq m^{-2} s^{-1} (UNSCEAR 2000) though this can vary considerably and can be substantially higher in areas with underlying soils with high U concentrations. Atmospheric concentrations decrease with altitude and reflect vertical advective transport and mixing processes.

Biological Utilization and Toxicity

About 60% of the total natural radiation dose is from Rn and its decay products (Appleton 2012). The hazards of Rn were established through epidemiological studies that found increased incidences of lung cancer in uranium miners. For the general population, most of the exposure is due to increased concentrations in dwellings, and it has been estimated that ~10% of total death rate by lung cancer is attributable to Rn. The incidence rate is greater for smokers (WHO 2009).

^{222}Rn is unreactive and does not accumulate in the body. However, it decays to the sequence of very short-lived ^{218}Po (3.04 min half-life), ^{214}Pb (26.8 min), ^{214}Bi (19.9 min), and ^{214}Po (164 μs) isotopes, which attach to natural aerosols that may be inhaled and become lodged to lung epithelial cells. The alpha radiation from decay of ^{218}Po and ^{214}Po damage DNA both directly and through the generation of free radicals. Since major genetic damage can be caused by even a single alpha particle, health organizations generally consider any level of exposure potentially harmful (WHO 2009). Similarly, ^{220}Rn decays to a series of particle-reactive short-lived nuclides, including those subject to alpha decay.

Most Rn enters buildings by air advection from above the soil surface and through openings in the structure (Nazaroff 1992) and so is dependent upon atmospheric conditions. Building materials generally only contribute a small fraction of indoor Rn but may be important in areas with low soil fluxes or when concrete or blocks are used that are made using natural materials that are high in U, such as granites or alum shale (Appleton 2012). The flux from soils is almost entirely ^{222}Rn due to the long transport times relative to the half-life of ^{220}Rn, although building materials may provide a significant flux of ^{220}Rn.

Maps of the level of potential hazard due to Rn are often used to assess local risk and may be based on indoor Rn levels and dwelling construction features, geochemical characteristics and lithology of underlying rocks and soils, Rn transport

data such as soil permeability and moisture levels, and Rn soil gas concentrations (Appleton 2012).

Indoor ^{222}Rn concentrations are the result of the balance between the influxes and the rate of removal by ventilation and decay. Therefore, maintaining low Rn concentrations in high-risk locations involves limiting the flux of Rn from soils into buildings using barriers and sealing openings and enhanced ventilation below and within structures.

Summary

Radon has unique characteristics as a short-lived noble gas that is present throughout the environment. Rn can accumulate in dwellings and be a significant source of natural radiation. Rn also provides a unique geochemical tracer for very short-term environmental processes.

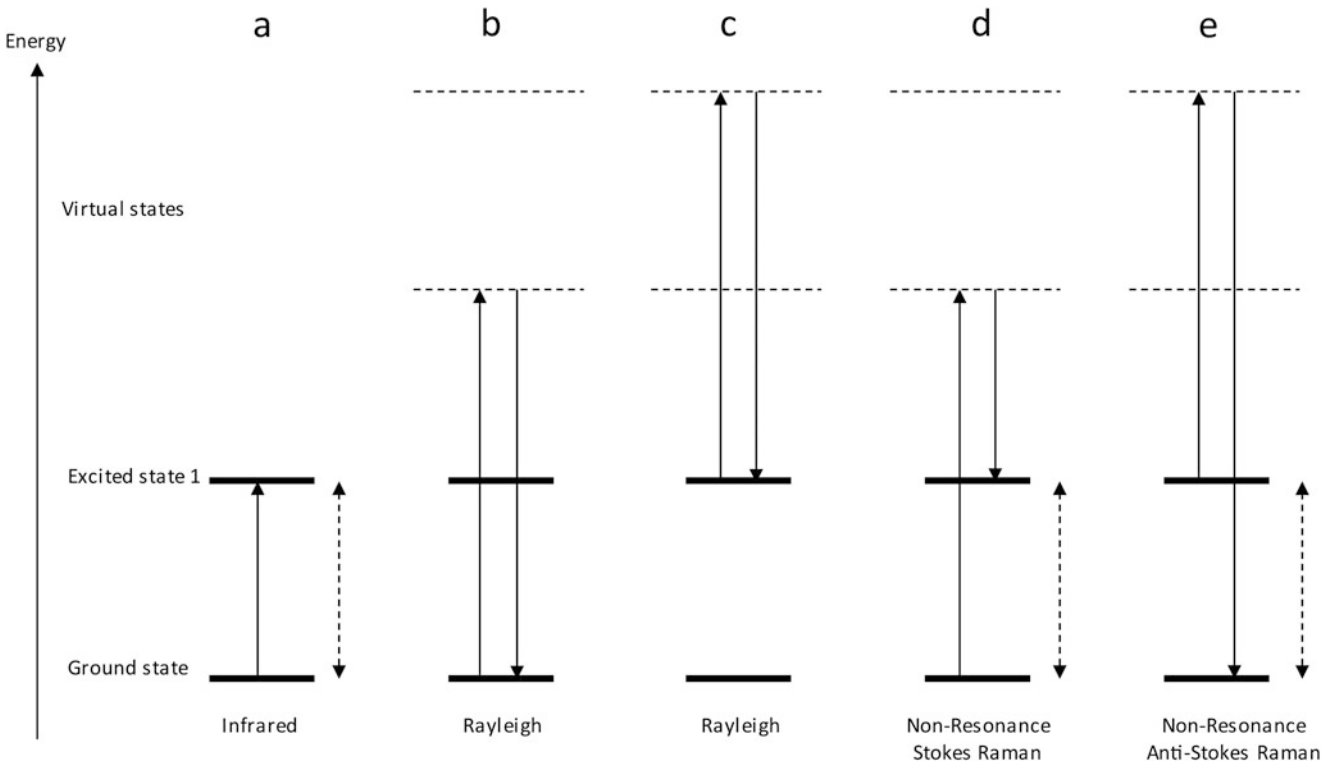
Hyperspectral Raman imaging; Micro-Raman spectroscopy; Raman imaging; Raman mapping; Raman microscopy

Definition

Raman spectroscopy is a spectroscopic technique based on the inelastic scattering of photons (the Raman effect), resulting in a shift of the frequency of the monochromatic light used for irradiating the sample, based on molecular vibrations and rotations (or other low frequency movement modes in a system). Microspectroscopy refers to spectroscopy performed in a spatially resolved manner.

Basic Principles and History

The inelastic scattering of photons has been postulated on theoretical grounds at the area of quantum mechanics (Smekal 1923) and was experimentally demonstrated shortly after in liquids (Raman and Krishnan 1928) and in crystals (Landsberg and Mandelstam 1928). This inelastic scattering (the Raman effect) is the basis of Raman spectroscopic methods that study molecular vibrations and rotations. In many senses, Raman spectroscopy is complementary to infrared spectroscopy, as both are probing molecular motions and symmetries that correspond to essentially the same energy level differences, although approached by different routes (Fig. 1), as Raman spectroscopy is based on the above mentioned scattering and not on absorption as is the case for infrared spectroscopy. Since only a fraction of the photons undergo inelastic scattering (Fig. 1), the Raman effect and consequently Raman spectroscopic signals are frequently weak. Most importantly for spectroscopic applications, the inelastic scattering results in a shift of the incoming light frequency (i.e., energy is either lost or gained upon interacting with the molecules of the sample), and this shift is characteristic of the molecules of the sample but independent from (although related to) the original monochromatic light frequency. Thus, conclusions regarding the presence of certain functional groups, conformations, and symmetry of the molecules in the sample can be drawn from the Raman spectrum in much the same way as from an infrared spectrum. The complementary nature of vibrational spectroscopic



Raman Microspectroscopy, Fig. 1 Energy diagram with schematics illustrating the Raman effect. The vibrational states are marked with *bold horizontal lines* and labeled as ground or excited states (the rotational states in each vibrational state are excluded for simplicity). Virtual states are shown in *dashed horizontal lines*. The transitions are marked with *single-headed arrows*, and the energy difference is marked with *dashed double-headed arrows*. (**a**) Absorption of mid-infrared light results in a transition from the ground vibrational state to the first excited vibrational state; (**b** and **c**) Rayleigh scattering does not result in energy exchange, whether the molecules were in the ground state or the excited state originally; (**d**) during Stokes Raman scattering, the atom or molecule gains energy, the transition corresponding to that of the infrared absorption case (in **a**) but achieved differently; (**e**) a fraction of the atoms/molecules was already in an excited state (according to the Boltzmann distribution) and will lose energy during the anti-Stokes Raman scattering to return to the ground state. The energy difference is the same as in (**a**) and (**d**), but its sign is opposite (due to energy loss instead of gain). It has to be noted that only a small proportion of light is scattered, and the vast majority of the scattered photons undergo Rayleigh scattering (10^3–10^5 as much as Stokes scattering). Thus, the Stokes lines represent ca. 10^{-6}–10^{-9} of the light intensity. Since there are considerably fewer molecules in the excited state at start (Boltzmann distribution), and most of them will undergo Rayleigh scattering (according to **c**), the anti-Stokes lines have even lower intensity than the Stokes lines

techniques can be further illustrated by the fact that molecular vibrations can be either Raman active (if they involve a change in the polarization potential), infrared active (if the polarization is altered), both Raman and infrared active, or none (which can be particularly beneficial in the case of diatomic gases, such as N_2 and O_2, as it means that dry air usually does not disturb measurements).

Instrumentation

For a modern dispersive Raman spectrometers, the essential components include a light source, a sample compartment (with a possibility to focus the laser light), collection optical elements (often including filters to remove the strong Rayleigh signal, Fig. 1), a dispersing optical element (most commonly gratings) and a detection system (usually charge coupled devices, to convert photons to electric signal), and a computer to handle the system. Raman spectrometers can be equipped with a microscope attachment at the sample compartment site, allowing for spatially resolved measurements. The lateral (xy) resolution depends on the ability to focus the laser spot and is commonly in the micron range. Microscopes are often manufactured to enable the setting of a confocal pinhole, considerably improving resolution in the z-direction (and slightly in the xy direction) at the price of potentially weakened signals. Microscope accessories enable the collection of hyperspectral data, that is, generating chemical maps over 2D or 3D (especially with confocal settings) sample areas. This is usually achieved by point scanning, although array detectors have become more common recently, allowing for simultaneous scanning of a defined area (often a line) at the cost of spatial resolution limitations (based on detector size instead of laser focusing capacity).

Raman (micro)spectroscopy instruments are generally versatile and can be equipped with fiber optic probes and a set of different lasers to enable workarounds for (auto)fluorescence problems of certain materials. Raman spectrometers can also be equipped with other accessories (such as temperature and humidity control chambers, polarizers, autosamplers, immersion setups, etc.) and combined with other instruments (such as atomic force microscopes, in which case the AFM needle head serves as the Raman laser exit and entry point, allowing for generating a chemical map overlay as the topography is probed).

As a final note, Fourier-transform (FT) Raman spectrometers also exist, particularly for lasers in the near infrared range of the spectrum, where fluorescence problems are avoided. These setups often have more limited lateral resolution and employ different detectors than the corresponding dispersive setups with lower wavelength lasers.

Sample Preparation, Measurement, and Data Analysis

Preparing samples for Raman microspectroscopy is often very simple. When only the surfaces of larger objects (mm size) need to be investigated, the sample often requires no preparation specifically for the measurement and can be used as is. For smaller samples or investigating deeper layers of nontransparent heterogeneous materials, the sample may need to be prepared to provide the best signal in the shortest time. This preparation can involve sectioning or depositing (a layer of) the sample on a carrier (either standard microscopy slides or special Raman transparent carriers, made of, e.g., CaF_2 or BaF_2).

Finding the ideal measurement conditions is usually done iteratively, starting by selecting the appropriate laser (to provide the best signal with the least disturbances, such as fluorescence, heat generation, power and focusing possibilities, etc.) and the required lens (based on magnification and other properties such as medium immersion or long-working distance objectives). Exposure time, focus settings (including focus levels, focus tracking, and confocal settings), and spectral range selection follows, often interdependently. Finally, the measurement area needs to be defined, together with the step sizes, which determines the number of points (pixels or voxels) that are recorded. Together with the exposure time and the mode of spectrum acquisition, this determines the time each measurement takes. The length of measurement can be of particular importance if the sample can change over time (e.g., due to being sensitive to laser exposure or unstable or because processes with comparable time spans are monitored, etc.)

Data analysis can be extremely simple as well, in case diagnostic bands exist and can be monitored accurately. Evaluating their intensity (or checking for the presence/absence) can be performed using univariate methods (integrals or simple spectral intensity readouts) but often require preprocessing, such as the removing of cosmic rays, baseline correction, and optionally smoothing/noise filtering and intensity normalization (to compensate for out-of-focus intensity fluctuations, for instance). These preprocessing steps are often necessary before multivariate analyses as well, although some of them can be "filtered" by the multivariate methods. Multivariate analyses are more time-consuming especially for large hyperspectral datasets and frequently require some level of chemometrics knowledge from the user.

Selected Advantages and Disadvantages of Raman Microspectroscopy

General and common advantages:

1. Cost and time effectiveness. Raman microspectroscopy is generally fast and inexpensive, especially considering the high information content of the resulting spectra(l maps).
2. Minimal to no sample preparation may be required, and most phases of materials can be measured with relative ease (gases, liquids, solids).
3. A complete chemical profile of the sample is gained without the need for labelling/staining/marking or extraction (i.e., in situ, with no a priori knowledge or bias for tracking). This includes not only chemical composition but also structure (e.g., protein conformational changes, crystallinity measures, etc.)
4. Directional activity: since the laser is polarized, anisotropy, chirality, and polymer orientations can be determined together with chemical compositional and structural information.
5. High specificity, since each Raman active molecule provides a unique Raman spectral fingerprint.
6. Potentially high sensitivity (certain Raman techniques are capable of detecting single molecules of chemicals. Generally, however, concentrations down to micromolar ranges are investigated).
7. (Semi)quantitative analysis, as the intensity of the Raman signal should be proportional to the concentration of the scattering species, if other (optophysical) factors are eliminated.
8. Complementary to infrared spectroscopy: water does not disturb (except for near infrared lasers, e.g., FT-Raman), and bands are often narrower (better resolved) than in the corresponding infrared spectra.
9. High spatial resolution. Unlike in FTIR microspectroscopy, the resolution is not diffraction limited. Often, the maximum achievable resolution depends on the focus of the laser (set by the numerical aperture of the lens and the optical setup of the spectrometer as well as by

the wavelength of the laser) and the step movement accuracy of the microscope stage. Normal Raman microspectroscopy can operate in 0.1 μm spatial resolution, but coupled to AFM nanometer spatial resolution is achievable.

General and common disadvantages:

1. Since the Raman signal is inherently weak, long exposure times and high laser powers may be required (especially for samples with low concentrations or otherwise weak Raman activity). Samples may not stay intact during this time.
2. Fluorescence. Strong fluorescence can completely swamp Raman signals and is hard to circumvent, especially if inherent to the sample (e.g., autofluorescing materials) and not caused by contamination. Quenching the fluorescence by long laser exposure may work in certain cases, but frequently selecting a different laser line (often in the near infrared range) is the only solution.
3. Sample sensitivity to heat/light. Especially in the case of colored samples and high power near infrared lasers, the absorbed light may result in an extreme heat locally where the laser is focused. This, in turn, may damage the sample. Similarly, samples sensitive to light may be altered due to the high photon flux in the laser focus area.
4. Specificity may be compromised in mixtures, as overlaps may render bands nondiagnostic.

Selected Earth Science Applications of Raman Microspectroscopy

Raman (and infrared) microspectroscopy is widely used to characterize geological materials, either "as is" or sectioned/polished, in fields as broad as mineralogy, petrology, paleontology, geochemistry, and even cosmochemistry (Gillet 2002). Due to the extreme versatility and customization possibilities of the technique, even non-laboratory conditions can be studied (e.g., extreme pressures and temperatures to study mineralogy in the Earth's mantle and core, or conditions mimicking those on the surface of Mars, to study ice formation, surface reactions, etc.)

One particular area is to study minerals, as Raman microspectroscopy can provide complementary information to X-ray-based techniques regarding crystal structures and phase transitions. (It has to be noted here that materials with noncrystalline structures, such as melts or glasses, feature broad Raman bands which are harder to assign and quantify.) Reference spectra for common minerals are often compiled into searchable databases which enables quick identification even in mixtures. Spectral features have been identified and listed for the major classes of minerals, ranging from silicates to different oxides (iron, aluminum, etc.), carbonates, phosphates, and sulfates/sulfides (Gillet 2002 and references therein).

Additional Raman Spectroscopic Techniques

Resonance Raman Spectroscopy (RRS): utilizes resonance effects to increase Raman signal intensity by up to a millionfold. Frequently used for transition metal containing large biomolecules.

Coherent Anti-Stokes Raman Spectroscopy (CARS): using two very intense lasers pulsed (fixed and variable). Often used in biological imaging.

Raman Optical Activity (ROA): utilizes oppositely circularly polarized lasers. Frequently used for determining conformations and absolute configurations of chiral molecules.

Optical Tweezers Raman Spectroscopy (OTRS): used for measuring single cells or individual particles.

Tip-Enhanced Raman Spectroscopy (TERS), using AFM or STM metallic tips, allows for nanometer resolution and single-molecule sensitivity.

Surface-Enhanced Raman Spectroscopy (SERS): adsorbates on metals (often Cu, Au or Ag) of the right dimensions (or colloidal), greatly increases the intensity of the signal (by $10^{8–11}$), and is frequently used in various fields, ranging from solar cells to biology.

Summary

Raman microspectroscopy is a fast, inexpensive, nondestructive and noninvasive, label-free technique to assess the chemical composition of a broad range of materials in situ (i.e., without extractions or processing). Common setups achieve spatial resolutions in the micrometer range, and sensitivities are generally in the micromolar concentration range, although special techniques and setups allow for nanometer spatial resolutions and single-molecule detection. The technique is very versatile and can be easily tailored to specific needs.

Refractory Inclusions in Chondritic Meteorites

Alexander N. Krot[1] and Glenn J. MacPherson[2]
[1]Hawai'i Institute of Geophysics and Planetology, University of Hawai'i at Mānoa, Honolulu, HI, USA
[2]Smithsonian Institution, Washington, DC, USA

Definition

Refractory inclusions are submillimeter-to-centimeter-sized objects with mineralogy similar to that predicted by thermodynamic calculations to condense out of a gas of solar composition at total pressure $<10^{-3}$ bar and temperatures above ~1300 K (Fig. 1). Refractory inclusions are a minor component (<5 vol%) in all groups of chondritic meteorites (chondrites); they were also found in a comet dust returned to Earth by NASA's *Stardust* mission from the Jupiter Family Comet 81P/Wild 2. Refractory inclusions comprise two kinds of objects – Ca,Al-rich inclusions (CAIs) and amoeboid olivine aggregates (AOAs). CAIs formed by aggregation of solids that resulted from evaporation (often incomplete) and condensation in a protoplanetary disk region with high ambient temperature (at or above condensation temperature of forsterite) and approximately solar redox conditions (i.e., highly reduced). Subsequently some CAIs experienced melting, evaporation, and condensation during transient heating events, most likely in the same disk region. AOAs are aggregates of igneous and nonigneous CAIs and forsterite condensates. Most inclusions we now study clearly experienced significant and extended reprocessing during transient heating events, including solid-state recrystallization, melting, and some degree of lower-temperature back-reaction with the nebular gas. Few, if any, of the primary condensates are actually preserved among the objects we now see.

Classification of Refractory Inclusions

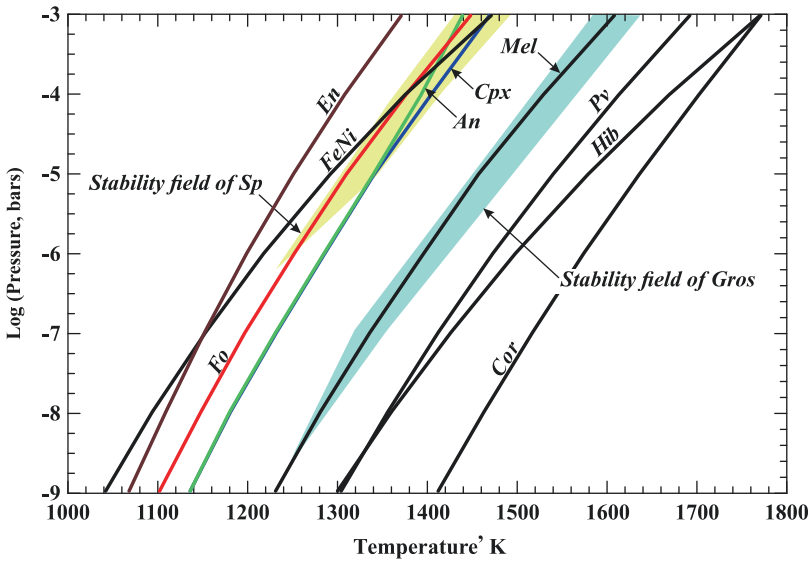
CAIs can be classified in terms of major minerals (listed here in order of decreasing condensation temperature, not abundance): corundum (Al_2O_3), hibonite ($CaAl_{12}O_{19}$), grossite ($CaAl_4O_7$), perovskite ($CaTiO_3$), melilite [gehlenite ($Ca_2Al_2SiO_7$) – åkermanite ($Ca_2Mg_2Si_2O_7$) solid solution], spinel ($MgAl_2O_4$), Ca-pyroxene [diopside ($CaMgSi_2O_6$) – kushiroite ($CaAl_2SiO_6$) – grossmanite ($CaTi^{4+}Al_2O_6$-$CaTi^{3+}AlSiO_6$) – davisite ($CaScAlSiO_6$) solid solution], anorthite ($CaAl_2Si_2O_8$), and forsterite (Mg_2SiO_4). Large CAIs, commonly present only in CV (Vigarano-type) chondrites, are divided into four types – Type A (dominated by melilite + spinel), Type B (made mostly of melilite + Ca-pyroxene + anorthite + spinel), Type C (composed mainly of anorthite + Ca-pyroxene + spinel), and forsterite-bearing Type B.

Both igneous and nonigneous CAIs are typically surrounded by a thin (<50 μm) sequence of nearly monomineralic layers of a similar thickness, referred to collectively as Wark-Lovering rim (Fig. 2). A complete rim sequence, observed around some CAIs, consists of an innermost spinel ± perovskite ± hibonite layer, a layer of melilite often replaced by anorthite, a layer of Ca-pyroxene, and a layer of forsterite. These rims are thought to have formed in the CAI-forming region by flash melting of outermost portion of the host CAIs, followed by evaporation, condensation, diffusion-controlled metasomatic reactions, and prolonged thermal annealing.

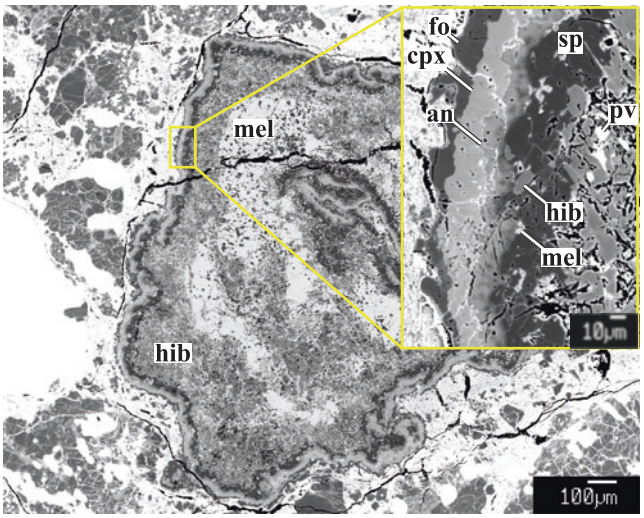
Bulk Chemical Compositions of Refractory Inclusions

The bulk major element chemical compositions of refractory inclusions follow approximately an equilibrium condensation path from a gas of solar composition (Fig. 3). The deviations from this path have been interpreted in terms of (1) non-equilibrium evaporation of Mg and SiO that the CAI melts have experienced during transient heating events (Grossman et al. 2000), (2) condensation of SiO into the CAI melts (Krot et al. 2007), and (3) condensation of fine-grained spinel-melilite-anorthite-rich CAIs at low total pressure, $<10^{-5}$ bar (MacPherson et al. 2004).

The bulk rare earth element (REE) compositions of CAIs are volatility controlled and divided into six groups (Fig. 4). Most CAIs have essentially unfractionated (except Eu and Yb) REE patterns (groups I, III, V, and VI), which



Refractory Inclusions in Chondritic Meteorites, Fig. 1 Equilibrium condensation sequence of a gas of solar composition at total pressure of 10^{-3} to 10^{-9} bar (after Petaev and Wood 2005). Mineral abbreviations: *An* anorthite, *Cor* corundum, *Cpx* Ca-pyroxene, *En* enstatite ($MgSiO_3$), *Fo* forsterite, *Gros* grossite, *Hib* hibonite, *Mel* melilite, *Pv* perovskite



Refractory Inclusions in Chondritic Meteorites, Fig. 2 Back-scattered electron image of a CAI from a CR (Renazzo-type) carbonaceous chondrite. The CAI consists of melilite, hibonite, spinel, and perovskite. It is surrounded by a Wark-Lovering rim (see inset) composed of an innermost spinel-hibonite layer, a layer of anorthite replacing melilite, a layer of Ca-pyroxene, and a layer of forsterite. Mineral abbreviations are the same as in Fig. 1

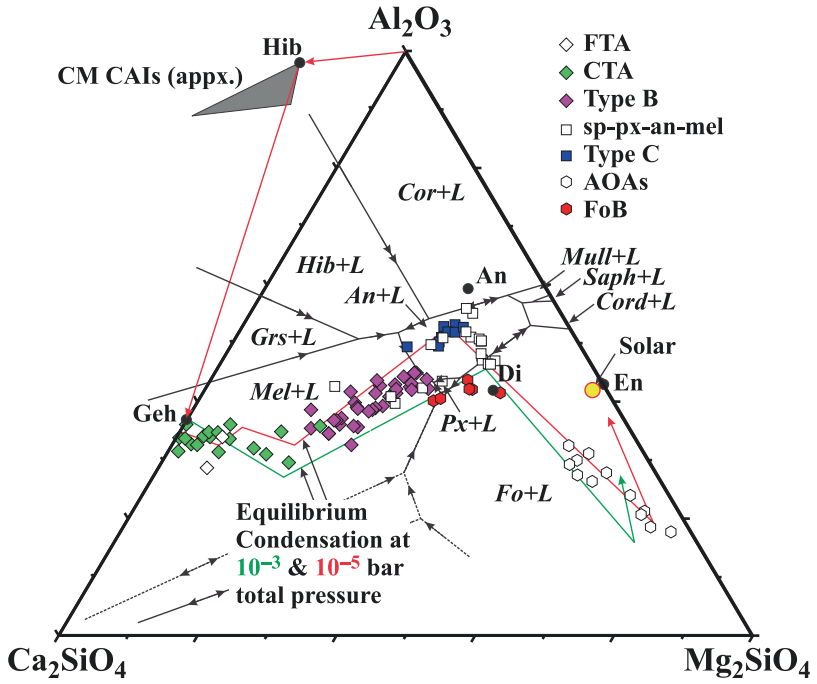
have been interpreted in terms of complete condensation from a solar gas (Boynton 1975; Davis and Grossman 1979). Group II pattern is depleted in both the most refractory (Gd, Tb, Dy, Ho, Er, and Lu) and the most volatile REEs (Eu and Yb), and resulted from fractional condensation from a gaseous reservoir in which a component containing the most refractory REEs was removed either by condensation or by incomplete evaporation. The nature of this ultrarefractory (UR) component is still unknown, but can be potentially identified in rare CAIs having UR REE patterns, which are roughly complementary to group II (Fig. 4). The UR CAIs contain a number of μm-sized minerals highly enriched in very refractory elements (Zr, Sc, Y) such as allendeite ($Sc_4Zr_3O_{12}$), Sc-rich anosovite [$(Ti,Mg,Sc,Al)_3O_5$], davisite ($CaScAlSiO_6$), kangite [$(Sc,Ti,Al,Zr,Mg,Ca)_2O_3$], lakargite ($CaZrO_3$), panguite [$(Ti,Sc,Al,Mg)_{1.8}O_3$], tazheranite [$(Zr,Ti,Ca,Y)O_{1.75}$], thortveitite ($Sc_2Si_2O_7$), zirconolite ($CaZrTi_2O_7$), warkite ($Ca_2Sc_6Al_6O_{20}$), and eringaite [$Ca_3(Sc,Y,Ti)_2Si_3O_{12}$]. The REE patterns of these UR minerals have yet to be studied.

Formation Age of Refractory Inclusions

CAIs are the oldest solar system solids dated using ^{207}Pb-^{206}Pb absolute chronology. CAIs show significant variations in $^{235}U/^{238}U$ ratio (Brennecka et al. 2010). The U-corrected Pb-Pb age of the only four CV CAIs measured so far, 4567.3 ± 0.16 Ma (Connelly et al. 2012), is considered to represent the beginning of the solar system formation – t_0, in cosmochemical rather than astrophysical sense.

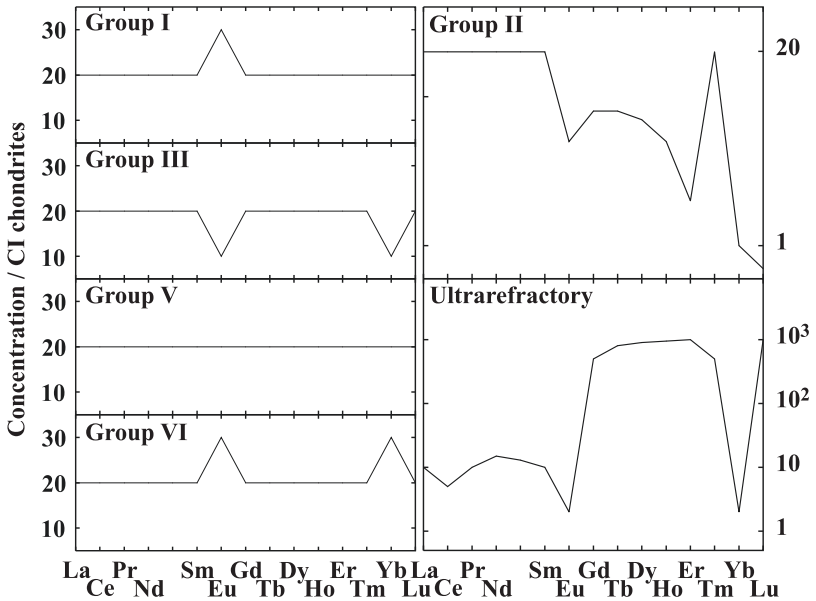
Short-Lived Radionuclides in Refractory Inclusions

Because of their antiquity, CAIs preserve evidence for short-lived (half-lives, $t_{1/2} < 10$ Myr), now extinct, radionuclides in the early solar system, including ^{10}Be (decays to ^{10}B with $t_{1/2} \sim 1.4$ Myr), ^{26}Al (decays to ^{26}Mg with $t_{1/2} \sim 0.7$ Myr), and ^{182}Hf (decays to ^{182}W with $t_{1/2} \sim 8.9$ Myr). ^{10}Be is inferred to have formed by solar energetic particle irradiation of nebular gas from which CAIs or their precursors condensed, most likely near the Sun (McKeegan et al. 2000). ^{26}Al and ^{182}Hf have an external stellar origin. ^{182}Hf was inherited from the protosolar molecular cloud and appears to be uniformly distributed in the protoplanetary disk, making it an important



Refractory Inclusions in Chondritic Meteorites, Fig. 3 Bulk chemical compositions of AOAs and major CAI types, igneous [Compact Type A (CTA), Type B, Type C, and forsterite-bearing Type B (FoB)] and nonigneous [Fluffy Type A (FTA) and fine-grained spinel-pyroxene-anorthite-melilite (sp-px-an-mel)], in CV chondrites projected from spinel on forsterite (Mg_2SiO_4) – corundum (Al_2O_3) – larnite (Ca_2SiO_4) plane (MacPherson and Huss 2005). The *shaded* field labeled CM CAIs (appx.) indicates the general region where silicate-poor CAIs from CM (Mighei type) chondrites plot. Equilibrium condensation paths from a gas of solar composition at a total pressure of 10^{-3} (Yoneda and Grossman 1995) and 10^{-5} (MacPherson et al. 2004) bar are indicated by *green* and *red* lines, respectively. Data from Wark (1987), Grossman et al. (2000), Krot et al. (2004), and Bullock et al. (2012). Abbreviations: *Cord* cordierite, *Di* diopside, *En* enstatite, *Geh* gehlenite, *L* liquid, *Mull* mullite, *Saph* saphirine. Other abbreviations are the same as in Fig. 1

Refractory Inclusions in Chondritic Meteorites, Fig. 4 Schematic illustration of bulk rare element patterns in CAIs (from MacPherson et al. 1988)



relative chronometer of disk processes (Kruijer et al. 2014). In contrast, the initial $^{26}Al/^{27}Al$ ratios [$(^{26}Al/^{27}Al)_0$] among individual CAIs from weakly metamorphosed chondrites show large variations, from $<5 \times 10^{-6}$ to $\sim 5 \times 10^{-5}$; $(^{26}Al/^{27}Al)_0$ in most CAIs, however, is $\sim 5 \times 10^{-5}$, and called the "canonical" value (MacPherson 2014). The observed variations in $(^{26}Al/^{27}Al)_0$ among CAIs have been interpreted to reflect several processes, including (i) recent addition of

^{26}Al from a neighboring massive star (supernova, Wolf-Rayet, or asymptotic giant branch stars) prior to collapse of the protosolar molecular cloud, (ii) homogenization of ^{26}Al in the disk at about the canonical level, and (iii) subsequent thermal processing of CAIs (e.g., Krot et al. 2012; Kita et al. 2013). Although there are multiple generations of CAIs (e.g., Krot et al. 2008), the heterogeneous distribution of ^{26}Al among them prevents use of ^{26}Al-^{26}Mg systematics for defining the entire duration of CAI formation. At the same time, the existence of the canonical $(^{26}Al/^{27}Al)_0$ in CAIs from different chondrite groups may suggest a homogeneous distribution of ^{26}Al in the disk by the time most CAIs formed. If this is the case, ^{26}Al has an important chronological significance for dating early solar system processes that postdate homogenization of ^{26}Al in the disk.

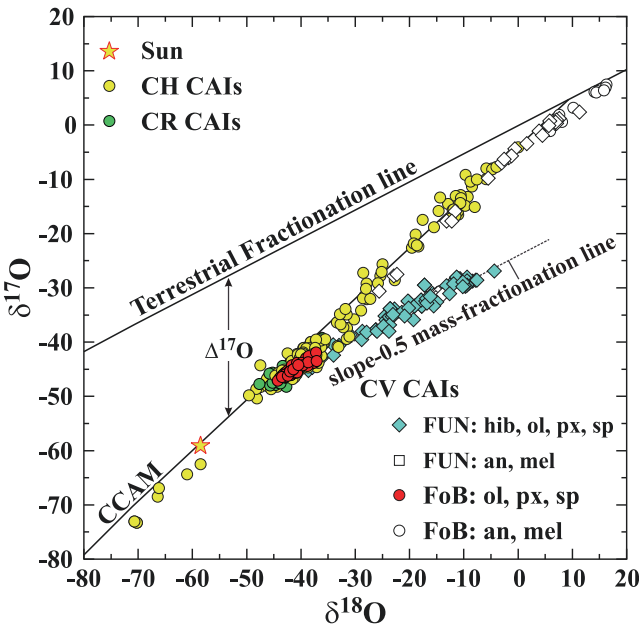
Nucleosynthetic Isotopic Anomalies in Refractory Inclusions

CAIs preserved nucleosynthetic isotope anomalies in many elements (W, Ba, Nd, Sm, Sr, Ca, Ti, Mg, etc.), reflecting incomplete evaporation of presolar dust and the lack of isotopic homogenization in the solar system. These anomalies are much smaller than in presolar grains formed around dying stars. The largest isotope anomalies are found in CAIs with low $(^{26}Al/^{27}Al)_0$, platy hibonite crystals (PLACs), and FUN CAIs (mass-dependent fractionation and "unknown" nuclear effects), consistent with their early formation, prior to homogenization of ^{26}Al in the disk.

Oxygen Isotopic Compositions of Refractory Inclusions

On a three-isotope oxygen diagram ($\delta^{17}O$ versus $\delta^{18}O$, where $\delta^{17,18}O = (^{17,18}O_{sample}/^{17,18}O_{SMOW} - 1) \times 1000$, and SMOW is Standard Mean Ocean Water), the terrestrial samples define a mass-dependent fractionation line with a slope of 0.52, called the terrestrial fractionation (TF) line (Fig. 5). In contrast, most extraterrestrial solids (meteorites, Moon, and Mars) deviate from the TF line (e.g., Yurimoto et al. 2008). Refractory inclusions are enriched in ^{16}O compared to other solar system solids. The majority of refractory inclusions in unmetamorphosed chondrites are isotopically uniform and have $\Delta^{17}O$ values (deviation from the TF line $= \delta^{17}O - 0.52 \times \delta^{18}O$) of about −24‰, close to the composition of the Sun inferred from measurements of the solar wind ($\Delta^{17}O = -28 \pm 2$‰) returned by the NASA's *Genesis* spacecraft (McKeegan et al. 2011). Relative to this solar value, some CAIs are ^{16}O-enriched ($\Delta^{17}O$ up to −37‰) or ^{16}O-depleted ($\Delta^{17}O$ up to −5‰). On a three-isotope oxygen diagram, most CAIs plot along carbonaceous chondrite anhydrous mineral (CCAM) line with a slope of about 1 (Fig. 5), interpreted to be a mixing line between the coexisting ^{16}O-rich and ^{16}O-poor reservoirs inherited from the protosolar molecular cloud and/or generated in the disk. Some igneous CAIs, including FUN CAIs, plot significantly to the right from the CCAM line, along mass-dependent fractionation line that deviates from the TF line by about −24‰. Mass-dependent fractionation effects are also observed in these CAIs for silicon and magnesium (Grossman et al. 2000). These effects were reproduced experimentally by melt evaporation under nearly vacuum conditions (Mendybaev et al. 2013).

CAIs and their Wark-Lovering rims in CV chondrites are often isotopically heterogeneous, with spinel, hibonite, forsterite, and pyroxenes being ^{16}O-rich relative to melilite and anorthite (Fig. 5). These observations have been interpreted as evidence for rapid fluctuations of oxygen-isotope composition of nebular gas in the CAI-forming region (Simon et al. 2011). The nature of oxygen-isotope heterogeneity in CV CAIs remains poorly



Refractory Inclusions in Chondritic Meteorites, Fig. 5 Three-isotope oxygen diagram of the inferred composition of the Sun and individual minerals in CAIs from CR, CH, and CV chondrites measured by secondary ion mass-spectrometry. Carbonaceous chondrite anhydrous mineral (CCAM) line with a slope of ~1 and the terrestrial fractionation (TF) line with a slope of 0.52 are shown for reference. Most CAIs plot along the CCAM line. Some igneous CAIs plot along slope-0.52 line that deviates from the TF line by about −24‰. Mineral abbreviations are the same as in Fig. 1. Data from McKeegan et al. (2011), Bullock et al. (2012), and Krot et al. (2008, 2014). *FoB* forsterite-bearing Type B CAIs

understood; the proposed mechanisms include gas-melt or gas-solid exchange, and condensation from nebula gas of variable composition (Yurimoto et al. 2008 and references therein). It has been also hypothesized that anorthite and melilite in CV CAIs experienced some oxygen-isotope exchange during fluid-rock interaction on the CV parent asteroid. This hypothesis has yet to be evaluated experimentally.

Radial Transport and Residence Time of Refractory Inclusions in the Protoplanetary Disk

The presence of multiple generations of CAIs in all chondrite groups indicates that refractory inclusions were episodically removed from the CAI-forming region and dispersed throughout the disk. A mechanism of this radial transport remains poorly understood; turbulent diffusion along the disk mid-plane and stellar wind above the disk are being discussed (Shu et al. 1996; Ciesla 2010). Subsequently, some refractory inclusions experienced various degrees of melting during chondrule formation 1–3 Myr after t_0, suggesting their long residence time in the disk prior to accretion into chondrite parent bodies (MacPherson et al. 2012). In thermally metamorphosed chondrites, refractory inclusions experienced various degrees of aqueous and metasomatic alteration which modified their primary nebular records (Brearley and Krot 2013).

Summary and Conclusions

Refractory inclusions are the oldest objects known to have formed in the solar system. They preserve clear evidence for the existence of the short-lived radionuclides in the early solar system, the isotopic signatures of presolar stellar nucleosynthesis, and the oxygen isotopic composition of the gaseous and possibly solid reservoirs in the early solar system. The petrologic and isotopic characteristics of refractory inclusions recorded several hundred thousand years of very high-temperature processes (evaporation, condensation, aggregation, and melting) in the inner solar system. They formed in the protoplanetary disk near the Sun, and were subsequently transported radially away and accreted into chondritic and cometary parent bodies over several Myr.

Seawater Abundance: 40 pmol/kg
Core Abundance: 230 ng/g

Definition

Atomic number 75 is a dense, highly refractory, transition metal with a bright silvery-white luster. Discovered in 1925, it is widely employed in the production of Ni-based superalloys and as a catalyst for gasoline production. ^{187}Re decay to ^{187}Os is used for radiometric age determinations and isotopic tracing.

History and Uses

The discovery of rhenium (atomic number 75) is attributed to W. Noddack, I. Tacke, and O. Berg, who in 1925 detected the element spectroscopically in platinum ores and in the minerals columbite, gadolinite, and molybdenite. Rhenium is the last discovered of the elements with a stable isotope. The name is derived from Rhenus, latin for Rhine.

Most Re (>80%) is consumed in the production of Ni-based superalloys, which are employed in the manufacture of aircraft engines and gas turbine fan blades. A second important application is as a component in Pt-Re alloys, utilized to catalyze key reactions to enhance the octane rating during gasoline production. Other important uses are for crucibles and electronic components. ^{186}Re and ^{188}Re are short-lived ($t_{1/2}$ = 89.3 and 17 h, respectively) isotopes produced for the treatment of bone and liver cancer.

Elemental and Physical Properties

Rhenium has an atomic weight of 186.207[1], ground state electronic configuration of $[Xe]4f^{14}5d^{5}6s^{2}$, with melting and boiling points at 0.1 MPa of 3185 °C and 5551 °C, respectively (Arblaster 1996). Rhenium is amongst the most dense of the elements (21,090 kg/m^3), similar to gold (19,300 kg/m^3) and about twice that of lead (11,340 kg/m^3). Rhenium is considered to be a highly refractory element, with a 50% condensation temperature of 1544 °C (Lodders 2003). Rhenium has one stable isotope, 185 (37.40[5]%), as well as the radioactive ^{187}Re (62.60[5]%), which undergoes beta decay to ^{187}Os, with a half-life of 4.16×10^{10} years. In addition to the neutral metal, the common oxidation states are −1, +2, +4, +6, and +7. The radius of the neutral atom is

188 pm (Clementi et al. 1967), and Re crystallizes in the hexagonal close-packed structure (space group P63/mmc) with a metallic radius of 137.5 nm (Wyckoff 1963). The size of the cation varies as follows (from Shannon 1976): 63 pm (+4, VI-fold), 58 pm (+5, VI-fold), 55 pm (+6, VI-fold), 38 pm (+7, IV-fold), and 53 pm (+7, VI-fold).

Geochemical Behavior and Reservoir Abundance

Rhenium is both highly siderophile (see entry for ▶ "Siderophile Elements") and strongly chalcophile (see entry for ▶ "Chalcophile Elements") and is grouped with other 5th and 6th row transition metals having similar chemical properties: Ru, Rh, Pd, Os, Ir, and Pt; the so-called platinum group elements (PGE; see entry for ▶ "Platinum Group Elements"). In rare cases, such as volcanic sublimates, Re occurs as ReS_2, rheniite, but more commonly dissolves as a component in molybdenite (MoS_2), owing to the geochemical similarity of Re and Mo. Re can also substitute into base metal sulfides (pyrrhotite, chalcopyrite, pentlandite), and experiments have shown that Re can readily dissolve into rock-forming minerals, such as olivine, pyroxene, and garnet, but this is highly dependent on the oxygen fugacity (summary in Brenan et al. 2016). The abundance of Re in the carbonaceous chondrite Orgueil is 39.5 ng/g (Horan et al. 2003), taken as being similar to the bulk earth concentration, which has now been highly fractionated into the core (230 ng/g; McDonough 2003), upper mantle (0.35[0.06] ng/g; Becker et al. 2006), and crust (continental: 0.188 ng/g; Rudnick and Gao 2003; oceanic: 0.736 ng/g; Peucker-Ehrenbrink et al. 2012). The relative proportions of both Re and the PGEs, as well as (age-corrected) radiogenic ^{187}Os (see below), are close to chondritic in the estimates for the primitive upper mantle (Becker et al. 2006). Abundances of these elements are higher than expected for equilibrium between metal and silicate (Mann et al. 2012) and relative abundances are unfractionated. Many believe this is the result of late accretion of chondritic materials following core formation. The rhenium content of seawater (40 pmol/kg) is >10x higher than the heavy rare-earth elements (Bruland and Lohan 2003), although the crustal abundance of Re is similar. Calculations indicate that the dominant Re species in seawater is $[ReO_4]^{2-}$ at 25 °C, pH 8.2, 0.1 MPa (Byrne et al. 1988).

Re-Os Isotopic System

Whereas most other long-lived isotopic systems used in geochronology involve lithophile elements as parent and daughter, the siderophile/chalcophile nature of the ^{187}Re-^{187}Os system is unique. Re and Os partition differently into various sulfide minerals, which allows for the dating of massive sulfide and porphyry copper ore deposits, as well as sulfide mineral inclusions in diamonds. Rhenium is incompatible and osmium is compatible during mantle melting, resulting in large differences in the Os-isotopic compositions of crust and mantle reservoirs. This allows a distinction to be made between crustal and mantle inputs to magmatic sulfide ores. Rhenium is also fractionated from osmium during the solidification of planetary cores, so this isotopic system has been used to date the formation of iron meteorite parent bodies (e.g., Walker et al. 2008). Under reducing conditions, rhenium is concentrated in organic-rich sediments, and hydrocarbons, which has been useful for dating sediment deposition, as well as tracking the source and migration of oil (Selby and Creaser 2005). Carlson (2005) and Stein et al. (2001) provide comprehensive reviews of the use of the Pt-Re-Os isotopic system in a wide range of applications.

Economic Geology

Economic concentrations of Re require >1,000-fold enrichment relative to crustal background values. Essentially all of the global Re supply is a by-product of copper mining. Re is volatile in oxidized form, so is removed from the Cu ore concentrate during smelting and captured in the flue gas. The largest supplies of Re are from magmatic porphyry ores (80%), hosted in molybdenite, with other sources found in sediment hosted stratabound deposits. Global production in 2014 was ~50,000 kg, with approximately half from Chilean copper deposits, at an average market price of ~$3,000/kg.

Summary

Rhenium is a bright, silvery-white transition metal characterized by high density and high melting temperature. The principal uses of rhenium are in the manufacturing of Ni-based superalloys and as catalysts for gasoline production. Rhenium is highly siderophile, as well as chalcophile, and is therefore concentrated in Earth's core, with complementary depletions in the silicate mantle, crust, and surface reservoirs. Rhenium has one radioactive isotope, ^{187}Re, that decays to ^{187}Os ($t_{1/2} = 4.16 \times 10^{10}$ years). Unique aspects of this isotopic system are that both parent and daughter are siderophile/chalcophile, and rhenium is concentrated in organic-rich sediments. These attributes have led to a number of novel geochemical applications, such as dating and tracing the source of magmatic sulfide ores, establishing the timing of core formation on iron meteorite parent bodies, dating sediment deposition and tracing oil migration. Extreme enrichment of rhenium relative to crustal background values is needed to produce minable ores, with significant concentrations in the mineral molybdenite, formed in porphyry copper deposits.

Properties

Rhodium ($_{45}$Rh) is one of the platinum group elements (PGE) and as such is a member of the transition metals. Together with Cobalt, Iridium, and Meitnerium it is also part of the Cobalt group.

As the energy difference between the outer *s* and *d* shell is relatively small, one electron is transferred to the *d* orbitals resulting in an electron configuration of [Kr] $4d^8$ 5 s^1. The small energy difference between the valence shells allows a high number of possible oxidation states (−1, 0, +1, +2, +3, +4, +5, +6) with +3 as the principal oxidation states besides

the neutral metal. As a monoisotopic element, the atomic weight is very well determined, with a value of 102.905 50(2) g/mol. The melting point is 1964 °C, with a density of 12.4 g/cm^3 (Predel 2006), both of which are lower than those for Ru, but higher than those for Pd. The metal has cubic symmetry (fcc). The atomic radius of 1.345 Å is also in between that of Ru and Pd, but similar to Ir. Rhodium shares many properties with neighbors of the same row, Ru and Pd, and also some with the same column, Ir (e.g., similar refractory acid digestion behavior). Unlike any other PGE, Rh can be dissolved in boiling HBr/Br_2. The metal can also be dissolved by melting with potassium or sodium hydrogensulfate, while Pt, Ir, and Ru remain unaffected (Renner et al. 2001). Rhodium is the only monoisotopic PGE, making it inaccessible for isotope dilution mass spectrometry. Though accessible via neutron activation, the most common procedure for Rh analysis is NiS fire assay in combination with ICP-MS, although this method has limitations due to the impurity of reagents (Meisel and Horan 2016). Hence, little published Rh data of low-concentration samples is available for geochemical samples, in particular for basalts and sediments.

History and Use

Wollaston discovered Rh in 1803, along with Pd, through chemical experiments on large quantities of crude alluvial platinum ore with aqua regia and alkali salts. Rose-red colored precipitates that formed during the isolation process lent the name Rhodium from Greek *rhodon* (ῥόδον) or *rhodeos* (ῥόδεος) meaning "rose" or "rose-red," respectively.

The hardness, mechanical and chemical stability, and reflectivity make Rh coatings superior to all other PGE metals. With the ideal properties of a homogeneous catalyst, more than 80% of the Rh metal production is used for three-way catalytic converters in gasoline engines with currently no appropriate substitute except for Pt and Pd (Loferski 2015). The production of many important chemicals relies on the use of Pt-Rh catalysts. For example, the catalytic conversion of ammonia to nitric oxide is important for the production of nitric acid, fertilizers, and explosives.

Natural Occurrence

The Bushveld Complex (South Africa) contains more than 80% of the world's exploited resources of Rh metal. The most common Rh-bearing minerals are pentlandite, Pt–Rh–Cu sulfide, and several sulfarsenides (e.g., Hollingworthite [(Rh,Pt,Pd)AsS]), and native Rh has also been observed (O'Driscoll and González-Jiménez 2016).

The estimated mean concentration in CI chondrites is 133 μg/kg (Fischer-Gödde et al. 2010). Rhodium shows highly siderophile geochemical behavior with a metal/silicate partition coefficient of $>10^4$ (Day et al. 2016). It is highly enriched in the Earth's core and occurs, though highly depleted in the Earth's mantle, among all other PGEs and Re, in chondritic relative abundances (Day et al. 2016). This fact is remarkable, as this behavior cannot be predicted based on partitioning experiments between silicates and metals. One of the hypothesis that can explain this remarkable observation is addition of material with chondritic relative abundances to the Earth's mantle after core formation, so-called late accretion (Kimura et al. 1974; Day et al. 2016). The highly siderophile-chalcophile geochemical property of Rh makes it one of the rarest nonradioactive elements, with an estimate of 0.018 μg/kg in the Earth's crust. The current estimate for the Earth's mantle is 1.2 ± 0.2 ng/g (Fischer-Gödde et al. 2011). Previously, it had been unclear as whether rhodium belonged to the IPGE [Ir, Os, and Ru (Barnes et al. 1985)] or PPGE [Pt, Pd (Barnes et al. 1985)] group of platinum group elements. However, based on more recent Rh data, it became clear that Rh should be classified as more compatible PGE and there as a member of the Ir-PGE or IPGE group (Barnes 1999).

Biological Utilization and Toxicity

Rhodium and rhodium compounds have no biological function. Very little is known about the aqueous behavior, the mobility, and toxicity of rhodium compounds because of its rareness and low abundance in the environment. However, $Rh(OH)_3^{3-n}$ and $RhCl_3^{3-n}$ with an range of 0.4 to 1 pmol/kg and an estimated mean abundance of 0.8 pmol/kg have been described (Bruland and Lohan 2003).

Summary

The highly siderophile geochemical behavior made rhodium to be one of the rarest nonradioactive elements in the Earth's crust. Compared to the other PGE very little concentration data for geochemical is available. The chemical and mechanical stability makes Rh an ideal for metal coatings and catalytic converters. The common use as catalytic converter in automobiles has increased the interest in environmental monitoring and environmental-geochemical behavior.

Atomic Number: 37
Atomic Weight: 85.4678
Isotopes and Abundances:
Rb-85, 72.17%
Rb-87, 27.83%
1 Atm Melting Point: 39 °C
1 Atm Boiling Point: 688 °C
Common Valences: 1+
Ionic Radii: 1.72 Å
Pauling Electronegativity: 0.82
First Ionization Energy: 403.0 kJ/mol
Chondritic (CI) Abundance: 2.32 μg/g
Silicate Earth Abundance: 0.464 μg/g
Crustal Abundance: 49 μg/g
Seawater Abundance: 0.12 μg/g
Core Abundance: nil

Properties

Rubidium is an alkali metal of Group Ia of the periodic table with the atomic number of 37 and an average atomic mass of 85.4678, an electron configuration of [Kr] 5s1, and a valance state of +1. In elemental form, it is a very soft (0.3 Mohs scale), silvery-white metal that is extremely reactive, that is, it reacts violently with water and spontaneously ignites in air. It melts at ca. 39 °C and boils at ca. 688 °C. The element has two naturally occurring stable isotopes, Rb-85 and Rb-87, and 27 synthetic isotopes with half-lifes of ca. 86 days or less. From its two naturally occurring isotopes, Rb-87 is radioactive with a β^- decay and a half-life of ca. 49 billion years. This corresponds to a Rb decay constant of $\lambda^{87}\mathrm{Rb} = 1.393 \times 10^{-11}$ (Nebel et al. 2011a), determined by age comparison against the U-Pb system, $\lambda^{87}\mathrm{Rb} = 1.395 \times 10^{-11}$ through ingrowth experiments (Rotenberg et al. 2012), $\lambda^{87}\mathrm{Rb} = 1.396 \times 10^{-11}$ by physical counting (Kossert 2003), and a IUPAC recommended average of $\lambda^{87}\mathrm{Rb} = 1.394 \times 10^{-11}$ (Villa et al. 2015). The ratio of natural Rb isotopes can be precisely measured by plasma source mass spectrometry to ±0.05% on $^{87}\mathrm{Rb}/^{85}\mathrm{Rb}$ (Waight et al. 2002; Nebel et al. 2005). The natural

ratio appears constant in terrestrial rocks (Nebel et al. 2005) but shows small variations in chondritic meteorites (Nebel et al. 2011b).

Rubidium has a relatively low first ionization energy and the large difference between the first and second ionization potential (4.18 vs. 27.3 eV) results in its +1 atomic charge. Rubidium has an ionic radius of 1.72 Å, which is similar to that of K, Cs, and Tl.

History

The element rubidium (Rb, Latin – *rubidius*, "deepest red") was discovered by Robert Bunsen and Gustav Kirchhoff in 1861 through the extraction of rubidium salt analyses from lepidolite, a mica-group mineral. Bunsen purified Rb within 2 years of its discovery. Campbell and Wood were the first to report its natural radioactivity in 1906.

Minerals

Rubidium forms no silicate mineral of its own but can occur in some in quantities of up to a few per cent but no more than five. Following the Goldschmidt rules, it substitutes best for potassium and thus occurs predominantly in K-rich minerals such as orthoclase or mica. In felsic rocks, especially highly differentiated intrusives, such as pegmatites, it can be enriched to $\gg$1000 ppm. The residence time in oceans is ca. 800 ka. With an average Rb concentration in seawater of 0.12 ppm, it is substantially enriched compared to variable but substantially lower concentrations in surface waters, depending on ambient country rocks.

Geochemistry

Rubidium is a lithophile element and is thus hosted by the silicate portion of the Earth, with no Rb in the Earth's core. Combined with its large ionic radius, it is considered a large ion lithophile element (LILE) and mobile in aqueous solutions. The CI chondrite abundance of Rb is 2.32 ppm but highly variable due to its volatile nature, and with a half condensation temperature of 727 K, it is depleted in most early solar system materials. Hence, Rb concentrations in the bulk silicate Earth (BSE) are estimated and based on Rb/Sr and Sr abundances. In a chondritic Earth model, the $[Rb]_{BSE}$ is 0.605 ppm (Palme and O'Neill 2014). However, in a nonchondritic Earth model, and assuming $^{87}Sr/^{86}Sr_{BSE} \sim 0.71$ and a $^{87}Rb/^{86}Sr_{BSE} \sim 0.61$ (Caro and Bourdon 2010), the resultant $[Rb]_{BSE} = 0.464$. During mantle melting, it is incompatible in almost all common mantle minerals and is therefore highly enriched in the crust. The only significant host of Rb in the mantle is metasomatic phengite. Estimations for Rb concentrations in the lower, middle, and upper continental crust vary considerably and increase from 11 ppm over 65 ppm to 84 ppm, respectively, reflecting the incompatible nature of Rb. Average continental crust contains ~49 ppm Rb (Rudnick and Gao 2014).

In sedimentary systems, Rb abundances are controlled by detrital mica and Rb^+ absorption out of solutions to clay-size minerals, resulting in a threefold increase in Rb abundances in clay over silt-size fractions. Carbonates do not contain significant amounts of Rb. In metamorphic reactions, Rb is controlled by the stability phyllosilicates. It is easily redistributed into newly formed mica and due to its mobility in aqueous solutions can be easily transported, which accounts for the low Rb abundance in high-grade, dehydrated granulite facies rocks.

Utilization and Toxicity

Rubidium has only a limited commercial use in fireworks and modern laser technology and plays no critical role in biologic systems with a relatively low toxicity.

Summary

The high mobility of Rb in aqueous fluids is useful for tracing water-rock interactions and the mobility of LILE in low temperature environments. In high temperature processes, the incompatible nature of Rb during mantle melting, and igneous differentiation of primitive melts can be useful in understanding rock-forming processes. In combination with Sr, however, Rb is most useful as a geochronometer.

Core Abundance: 4 mg/kg (McDonough 2014)

Properties

The transition metal $_{44}$Ru is one of the six platinum group elements (PGE) and a member of the iron group (iron, ruthenium, osmium, and hassium).

Ruthenium has the electron structure [Kr] $4d^7$ 5 s^1. As for Rh, only one electron can be found in the *s*-shell due to the small energy difference between the *s*- and *d*-shell. The atomic radius of 1.325 Å is the lowest value within the "light" platinum group elements (PGE group) (Ru, Rh, and Pd) but has the highest melting point, 2334 °C, and density, 12.2 g/cm^3 (Predel 2006). As for osmium, the crystal structure is hexagonal close packed (hcp). Ruthenium not only shares many properties with its horizontal neighbors but also with Os, which is a member of the "heavy" PGE (Os, Ir, Pt). Unlike all the other PGE, both Ru and Os react with KOH, NaOH, and Na_2O_2 melts. Under oxidizing conditions, Ru and Os form tetraoxides, as only these two PGE can reach the oxidation state of +8. Ruthenium can also reach the following known oxidation states: −2, 0, +2, +3, +4, +5, +6, +7, +8 with +4 as the most common. Ruthenium has an atomic weight of 101.07(2) g/mol with seven stable isotopes. Isotope dilution mass spectrometry (IDMS), combined with inductively coupled mass spectrometry (ICP-MS) after acid digestion at high temperatures or after nickel sulfide fire assay, is the most common method of analysis (Meisel and Horan 2016).

History and Use

The name ruthenium is derived from Ruthenia, the Latin word for Rus', a Urals mountain region from where the samples from which ruthenium was first isolated, were derived. Ruthenium was probably discovered also in the residues after platinum extraction in aqua regia together with the other platinum group elements in the beginning of the nineteenth century but was only until 1844 when its isolation procedure, described by the Baltic German chemist Karl Ernst Claus (Карл Ка́рлович Кла́ус in Russian), was verified.

Ruthenium metal absorbs light throughout the visible spectrum making it attractive for solar energy technologies. The largest portion of the metal production goes into the electronics industry. As a versatile catalyst, Ru and ruthenium compounds have important applications in organic and pharmaceutical chemistry.

Physical, Chemical, and Geochemical Properties

Natural Occurrence

In nature, ruthenium occurs as rare native metal, as sulfides (e.g., laurite RuS_2), arsenides (e.g., ruthenarsenite [(Ru,Ni)As]), sulfarsenides (e.g., ruarsite, RuAsS), and Os–Ir–Ru alloys (O'Driscoll and González-Jiménez 2016). Ruthenium minerals are mined as by-product by the mineral processing of platinum and palladium ores (e.g., Bushveld, South Africa). A major source of Ru is anode slime created by the electro-refining process of nickel.

The estimated mean concentration of Ru in CI chondrites is 688 μg/kg (Fischer-Gödde et al. 2010). Estimates of the Earth's mantle and crust are 7.2 and 0.03 μg/kg, respectively (Becker et al. 2006; Park et al. 2012). The highly siderophile–chalcophile geochemical behavior and compatibility during mantle melting result in Ru as being one of the rarest elements in the Earth's crust. This geochemical behavior is shared with Ir and Os (thus Ru is also member of the Ir-PGE group).

Biological Utilization and Toxicity

Ruthenium and ruthenium compounds have no known biological function. Very little is known about the aqueous behavior, the mobility, and toxicity of ruthenium compounds because of its rareness and low abundance in the environment. However, $Ru(OH)_n^{4-n}$ species have been described with an abundance of less than 50 fmol/kg (Bruland and Lohan 2003). The only well-known toxic molecule is RuO_4. ^{106}Ru, as short-lived fission product formed from uranium in nuclear reactors and explosions, has been observed in the environment, possibly released as volatile RuO_4.

Summary

Ruthenium is one of the rarest PGE in the Earth's crust with a highly siderophile–chalcophile geochemical behavior similar to Ir and Os. Ruthenium shares similar resistance toward acids and solubility in alkali melts as Os and also forms volatile tetraoxide species.

History and Use

Samarium was first discovered by Swiss chemist Marc Delafontaine in 1878 who named it "decipium," later proven to be a mixture of samarium and other rare earths. French chemist Paul-Emile Lecoq de Boisbaudran isolated samarium in 1879. It was purified from the mineral samarskite named for Colonel Vasili von Samarsky, a Russian mine official (Holden 2001). Commercial applications of Sm include samarium-cobalt magnets, which have a permanent magnetization second only to neodymium magnets, though Sm magnets can withstand higher temperatures before losing magnetization. Radioactive ^{153}Sm is used in a drug (^{153}Sm lexidronam) to treat painful bone metastases (Serafini et al. 1998) and to kill cancer cells in the lung, prostate, and breast. The isotope ^{149}Sm has a large neutron adsorption cross section and is used in the manufacture of control rods for use in nuclear reactors. Sm is typically concentrated along with other light rare-earth elements in late differentiated melts and typically found in commercially viable concentrations in the minerals bastnaesite and monazite associated with carbonatites or phosphate deposits (USGS 2015).

Geochemical Behavior

Samarium is a refractory, lithophile element following the Goldschmidt classification and belongs to the lanthanide rare-earth element group. It is thought to partition wholly in the silicate earth with practically no Sm in the core. Due to its relatively large ionic radius and 3+ charge, it is moderately to highly incompatible in most major rock-forming minerals and in the Earth's mantle, approaching a partition coefficient of 1 only in some garnets (Salters et al. 2002). As a consequence,

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

Sm has lower concentration in the depleted upper mantle (0.27–0.239 ppm, Salters and Stracke 2004; Workman and Hart 2005), and higher concentration in the continental crust (3.9 ppm; Rudnick and Gao 2003) and mid-oceanic ridge basalts (3.8 ppm; Gale et al. 2013) than primitive mantle.

The most important usefulness of Sm in geochemistry is through its role in the neodymium (Nd) isotope system. ^{147}Sm decays to ^{143}Nd by α-decay and a half-life of 1.06×10^{11} years and a decay constant ($\lambda_{Sm}{}^{147}$) of 6.54×10^{-12} year^{-1}. ^{146}Sm decays to ^{142}Nd by α-decay and a short half-life estimated between 68×10^6 (Kinoshita et al. 2012) and 103×10^6 years (Marks et al. 2014). Samarium is generally more compatible than Nd in most petrogenetically significant minerals, which leads to fractionation of Sm from Nd during melting and crystallization processes. This fractionation leads, over time, to variable enrichment of ^{143}Nd over the stable ^{144}Nd in different minerals, forming the basis of ^{147}Sm/^{144}Nd geochronology and the use of Nd isotopes as key tracers of mantle processes. Due to its short half-life, ^{146}Sm is practically extinct at present. Nevertheless fractionation of the Sm/Nd system within the first 300–400 My of the Earth's history resulted in measurable fractionation of the ^{142}Nd/^{144}Nd isotope system which has been used to constrain early differentiation of the Earth and the chronology of the solar system (e.g., Marks et al. 2014; see also "▶ Neodymium Isotopes" for details).

As an intermediate rare-earth element, the comparison of samarium concentrations to that of the larger and highly incompatible light rare-earth element lanthanum (La) through the La/Sm ratio is a useful proxy for the fractionation of rare-earth element patterns, where La/Sm ratios lower than chondrite meteorites are a clear indication of a melt-depleted reservoir.

Samarium, as the other rare-earth elements, is highly insoluble in fluids at neutral pH, and its solubility increases with decreasing pH. In typical seawater composition and at pH = 8.2, Sm exists primarily as the carbonate ion species $Sm(CO_3)_2^-$ (Schijf et al. 2015). In the absence of strong organic complexing ligands, like humic acids (Sonke and Salters 2006), Sm is highly particle reactive and readily adsorbed in hydrated Fe and Mn oxide phases and particulate surfaces (Schijf et al. 2015), resulting in very low concentrations in seawater of less than 20 pmol/kg, typically around 3–5 pmol/kg (Alibo and Nozaki 1999; Tachikawa et al. 1999).

Biological Utilization and Toxicity

There is no known biological usage of Sm, likely due to its low concentration in waters that discouraged organisms for developing a use for it. Specific data for toxicity of Sm is lacking.

Element Data
Atomic Symbol: **Sc**
Atomic Number: **21**
Atomic Weight: 44.95591
Isotopes and Abundances: ^{45}Sc 100%
1 Atm Melting Point: 1541 °C
1 Atm Boiling Point: 2836 °C
Common Valences: 3+
Ionic Radii: 6-fold, 74.5 pm, 8-fold, 87 pm
Pauling Electronegativity: 1.36
First Ionization Energy: 633.1 kJ/mol
Chondritic (CI) Abundance: 5.81 ppm
Silicate Earth Abundance: 16.4 ppm
Crustal Abundance: 21.9
Seawater Abundance: 2–20 pmol/L
Core Abundance: ~0

Properties

Scandium is the lightest group 3 (IIIB) element and is the lightest of the transition metals. Its atomic number (proton number) is 21, has only one long-lived isotope, and has an atomic mass of 44.95591 u. Scandium's electronic configuration is [Ar]$4s^2 3d^1$ and only occurs in the trivalent state (Sc^{3+}) in nature. Thus, unlike most other period 4 transition metals, the geochemical behavior of scandium is not affected by redox conditions and shows lithophile behavior. The effective ionic radii in six- and eightfold coordination are 74.5 and 87 pm, respectively (Shannon 1976), and its Pauling electronegativity is 1.36. Pure scandium metal has a melting point of 1541 °C at 1 atm. The International Union of Pure and Applied Chemistry considers Sc to be a rare earth element (REE) (Damhus et al. 2005); however, the ionic radius and electronic configuration of Sc are sufficiently different from yttrium and the lanthanides that it is generally excluded from discussions of the REE.

History and Use

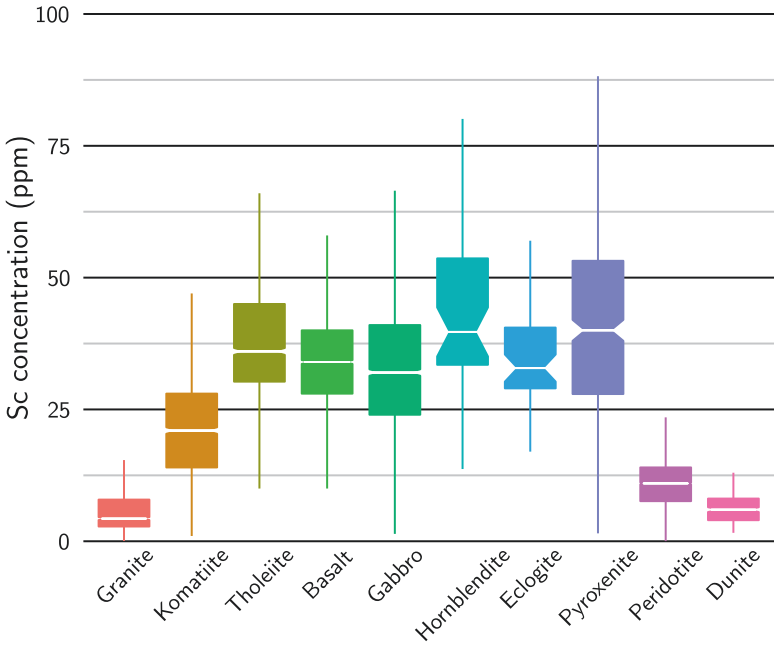
Scandium was "discovered" by Lars Fredrik Nilson in 1879 by separation from rare earth mixtures from euxenite and gadolinite and is named for Scandinavia.

Global production of Sc is small (~10 tonnes per year) as a by-product from mining of ores of titanium, rare earths, apatite, and uranium. Bauxites are another potential source of Sc, as it gets concentrated, along with other elements, in the "red mud" residue that results from Al processing (Deady et al. 2016). The principal uses of Sc are in Sc-Al alloys and in solid oxide fuel cells. Minor amounts of Sc are also used in a variety of other applications including electronics, lasers, and lighting.

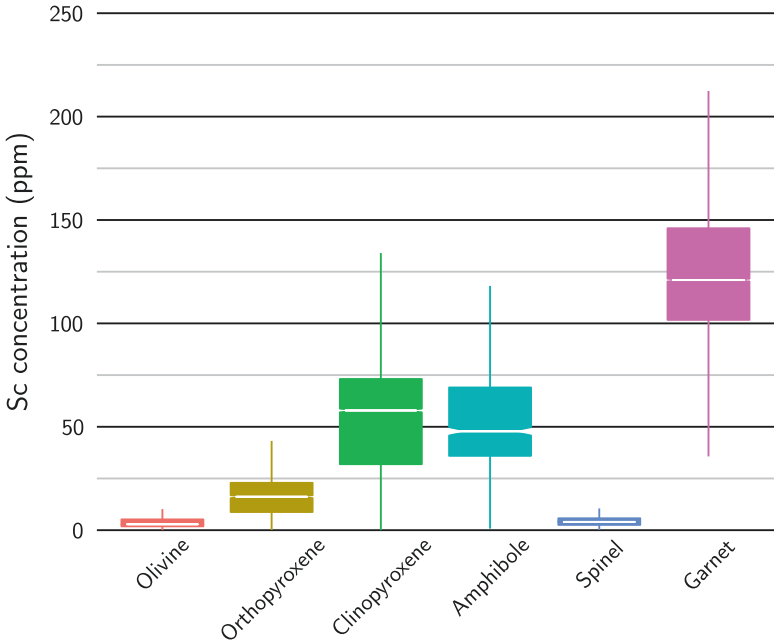
Natural Abundances

The abundance of Sc in the solar system, as estimated from chondritic meteorites, is ca. 5.81 ppm (McDonough and Sun 1995). The refractory behavior of this element in the solar nebula as well as its lithophile behavior led to the relative concentration of this element in the silicate Earth, with an estimated abundance of about 16 ppm, which is also the estimated abundance of the primitive mantle (Palme and O'Neill 2014). The abundance of Sc in the Earth's continental crust is higher, with average values of 31, 19, and 14 ppm for the lower, middle, and upper crust, respectively, and an average continental crust value of 21.9 ppm (Rudnick and Gao 2014). It occurs in higher concentrations in oceanic crust as reflected in values in MORB of between 34 and 48 ppm (Klein 2003). Thus, as with the rare earth elements, scandium is not particularly rare, and is found in similar concentrations in the crust to Pb, and is orders of magnitude more abundant than most of the precious metals in the Earth's crust.

The relatively large ionic radius to charge ratio (ionic potential) of Sc^{3+} means that it is incompatible in the structures of many of the common rock-forming minerals, such that it is generally present in low concentrations, ranging from a few ppm to a few tens of ppm. The concentration of Sc in different rock types is shown in Fig. 1. Scandium is generally incompatible in mantle rocks (Davis et al. 2013), which explains the lower Sc concentration in komatiites compared to basalts and the low Sc content of peridotites and dunites. The latter reflects low concentrations and mineral/melt partition coefficients for olivine and spinel compared to garnet, clinopyroxene, and amphibole (Davis et al. 2013; Bédard 2014; Fig. 2). The very similar ionic radii (74.5 and 72 pm in sixfold coordination) and electronegativities (1.36 and 1.31) of Sc and Mg, respectively, explain the substitution of Sc for Mg in the M1 octahedral site of clinopyroxene and M octahedral sites of amphibole. Scandium also substitutes



Scandium, Fig. 1 Box-and-whisker plot of Sc concentrations in some common lithologies. (Data from the GEOROC database, Sarbas and Nohl (2008); 11,846 analyses.) "Tholeiite" stands for tholeiitic basalt, whereas "basalt" includes a wide range of other basalt types. The boxes represent the first and third quartiles of the data distribution. The horizontal line represents the median, and the width of the adjacent notches provides the 95% confidence interval about the median. The "whiskers" represent the last value before 1.5 × midrange (arithmetic mean of maximum and minimum values) beyond the first or third quartile



Scandium, Fig. 2 Box-and-whisker plot of Sc concentrations in various mantle-related minerals. (Data from the GEOROC database, Sarbas and Nohl (2008); 21,475 analyses.) The minerals mostly come from xenoliths of various mafic and ultramafic lithologies

for Mg due to similar ionic radii in the cubic X site of pyrope garnets (Oberti et al. 2006). Felsic rocks, such as granites, are depleted in Sc, as quartz and feldspars cannot accommodate significant amounts of Sc. Because vanadium (V) has comparable behavior to Sc, but also variable valence, V/Sc ratios are sensitive to fO_2 and have been used to provide information on the redox conditions in the mantle (Li and Lee 2004).

Scandium is residually concentrated in soils and typically reaches concentrations between about 1 and 10 ppm (e.g., Jeske and Gworek 2013). Coal can contain significant Sc. Average Sc concentrations in a wide variety of coals from Asia range from 0.85 to 16.0 ppm, with an overall average of 4.3 ppm and a maximum value of 230 ppm (Arbuzov et al. 2014). Consequently, coal fly ash can also contain significant Sc, generally several tens of ppm (e.g., Bettinelli et al 1987; Franus et al. 2015).

Although Sc generally occurs in low concentrations in common minerals and rocks, it can achieve higher concentrations in restricted environments, most notably alkaline igneous rocks, including carbonatites, in granitic pegmatites, in hydrothermal veins, and in some meteorites. It is in these environments that Sc-rich minerals occur.

Scandium Mineralogy

Minerals that contain Sc at concentrations greater than a few tens of ppm include Sc-rich varieties of minerals such as columbite, rutile, perrierite, euxenite, ixiolite, and pyrochlore (e.g., Åmli 1977; Bergstøl and Juve 1988; Wise et al. 1998), as well as minerals in which Sc is an essential element. There are relatively few minerals known that contain Sc as an essential element, and only seventeen IMA-approved minerals exist, comprising silicates, phosphates, and oxides. Silicates belong to the inosilicate (e.g., cascandite [$Ca(Sc,Fe^{2+})Si_3O_8(OH)$]), cyclosilicate (e.g., bazzite [$Be_3(Sc,Al)_2Si_6O_{18}$]), sorosilicate (e.g., thortveitite [$(Sc,Y)_2Si_2O_7$]), and orthosilicate (eringaite [$Ca_3Sc_2(SiO_4)_3$]) subclasses. Phosphates include anhydrous and hydrous species, such as pretulite [$ScPO_4$] and kolbeckite [$ScPO_4 \cdot 2H_2O$]. A number of scandium-bearing oxides have been recognized, and most of these occur in meteorites, such as allendeite [$Sc_4Zr_3O_{12}$], named for its type locality, the Allende meteorite. These minerals are rare, and, as described above, most scandium on Earth occurs as a trace component of other minerals.

Aqueous Geochemistry

Scandium concentrations in surface waters are invariably very low, generally in the parts per trillion (ppt) range. The limited data available on Sc concentrations in seawater indicate an average concentration of around 13 pmol L^{-1} (~0.6 ppt) (Horovitz 1999). This is consistent with a profile through the Pacific Ocean that shows a gradual increase from 2 pmol L^{-1} (0.09 ppt) at the surface to 20 pmol L^{-1} (2 ppt) at the ocean floor, which is considered to be a nutrient-like profile (Amakawa et al. 2007). Concentrations in river water are also very low, in the range of 1–16 ppt (Silker 1964; Tanizaki et al. 1992; Cerutti et al. 2003); however, concentrations can be higher (ppb levels) in acid mine drainage (e.g., Jerez et al. 2014).

The relatively small radius of Sc^{3+} and its trivalent nature make it a "hard" acid in the sense of Pearson (1963) and, in aqueous solutions, will preferentially bond to hard bases, including OH^- and F^-, and certain organic ligands, such as acetate. This is confirmed by available thermodynamic and experimental data which indicate that in most low-temperature environments (pH ~ 4–10), the aqueous complexes $Sc(OH)^{2+}$, $Sc(OH)_2^+$, and $Sc(OH)_3^0$ will predominate. At low pH, Sc^{3+} will predominate. With increasing temperature, the hydroxy complexes with higher ligand numbers are predicted to become increasingly important. Scandium fluoride complexes are relatively stable and could be important in fluorine-rich environments, particularly at low pH. There are few data on the aqueous solubility of the Sc minerals described above. Calculated solubilities for the phase ScOOH at 25 °C indicate low solubilities (~9 ppb) and a solubility minimum between pH ~ 6 and 10, but that under acidic conditions, solubilities can reach several hundred ppm (Wood and Samson 2006). In low-temperature phosphate-rich environments, the phase $ScPO_4$ is calculated to have even lower solubilities and would severely limit the mobility of Sc (Wood and Samson 2006), for example, in some soil environments where REE phosphates are known to occur (Aide and Aide 2012).

Biological Utilization and Toxicity

Scandium does not bioaccumulate readily in plants (Alloway 2013) and, given the concentrations found in biomaterials, is generally not considered a toxic element, except at higher than normal doses, but can have some beneficial effects on organisms (Bordean et al. 2013). Scandium chloride ($ScCl_3$) is, however, more toxic (Horovitz 2000).

Summary

Scandium, a lithophile element, is the lightest of the transition elements and has crustal abundances that generally range between 15 and 50 ppm. Scandium can occur in higher concentrations, generally in alkaline rocks, where it can form Sc minerals, but is mostly present as a trace component in a wide range of rock-forming minerals, most easily substituting for Mg. It occurs in very low concentrations in natural waters and does not easily bioaccumulate.

Core Abundance: 8 ppm

Properties

Selenium (Emsley 1991, 2001; Anthoni 2006; Anders and Grevesse 1989; McDonough 2005) is a semi-metal that exists in two allotropic forms as a silvery metal and as a red amorphous powder; the former is produced from the latter by heat. The metal consists of spirals of linked selenium atoms and the red form has stacked rings each made up of eight selenium atoms. The importance of the eight ring structure is also found for sulfur. The metal form conducts electricity better in the light than in the dark, and it is used in photocells. Selenium burns in air and it is not affected by water, but it dissolves in concentrated nitric acid and alkaline solutions.

Selenium resembles sulfur and tellurium which lie above it and below it, respectively, in the Periodic Table, in terms of its chemical activity and physical properties.

History and Use

Selenium was discovered by Jöns Jacob Berzelius in 1817 in Stockholm. He was preparing sulfuric acid and found a red-brown sediment at the bottom of the chambers in which the acid was made. When heated, it had a strong smell of radishes and Berzelius thought at first that the element was tellurium, but, eventually, he realized that it was a new element, chemically similar to tellurium. He named it selenium from the Greek "selene" which means Moon to match the name tellurium from the Latin "tellus" meaning Earth. He observed that the new element was like sulfur because it vaporized on heating and can be redeposited on a cold surface as beautiful crystals known as "flowers," with bright yellow "flowers" for sulfur and red "flowers" for selenium in its nonmetallic form. Berzelius found that selenium was also present in samples of tellurium and that selenium gave tellurium the smell of radishes. Berzelius was personally affected by selenium as it can be absorbed through the skin and caused him to experience bad breath. Within a few years of its discovery, selenium was found in many minerals. Sometimes, the metallic form of selenium was refined and cast into medallions carrying pictures of its founder Berzelius.

The biggest use of selenium is as an additive to glass. There are selenium compounds that decolorize glass and others that give it a deep red color. Selenium is used to reduce the transmission of sunlight in architectural glass by giving it a bronze tint. Also it is used to make pigments for ceramics, paints, and plastics. Selenium has both photovoltaic and photoconductive properties. Thus, it is useful in photocells, solar cells, and photocopiers and in rectifiers (converting AC current to DC current). Selenium is also used as an additive to make stainless steel and to improve the abrasion resistance in vulcanized rubbers. Selenium, as sodium selenite, is used in animal feeds and food supplements. Some selenium compounds are added to antidandruff shampoos because selenium is toxic to the scalp fungus that causes dandruff.

Geochemical Behavior

Selenium is a rare element on the surface of earth and is present in the atmosphere as its methyl derivatives. Uncombined selenium is occasionally found, and there are about 40 known selenium-containing minerals, some of which can have up to 30% selenium. These minerals are rare and generally occur together with sulfides of metals such as copper, zinc, and lead. The main producing countries are Canada, the USA, Bolivia, and Russia.

Selenium occurs naturally in the environment being released through both natural processes and human activities. Selenium is present in phosphate fertilizers, and it is often added as a trace nutrient. Selenium settles from air and thus its levels in soils and waters increase. Selenium pollutes the environment around certain facilities, for example, coal-burning power stations, metal smelters which use sulfide ores, and municipal incinerators burning paper, cardboard, and tires, which contain small amounts of selenium.

Selenium in soils does not always react with oxygen and it remains fairly immobile. Selenium that is immobile and will not dissolve in water is less of a risk for organisms. Factors such as the oxygen level in the soil, soil temperature, moisture, the season, and the acidity of the soil will increase mobile forms of selenium.

Biological Utilization and Toxicity

Selenium is an essential trace element for some species, including humans. Selenium is part of the antioxidant enzyme

glutathione peroxidase, which eliminates peroxides before they form dangerous free radicals. Human bodies contain about 14 mg of selenium, and every cell in a human body contains more than a million selenium atoms. The recommended maximum daily intake is 450 micrograms. Too little selenium can cause health problems and in the same time too much can be dangerous. In excess, selenium is carcinogenic and teratogenic. Excess amounts can be readily detected as a garlic odor to the breath.

Siderophile Elements

James M. D. Day
Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA, USA

Definition

Siderophile elements preferentially partition into metal phases during cosmochemical and geochemical processes. The siderophile elements include the highly siderophile elements (HSE; Re, Os, Ir, Ru, Pt, Rh, Au, Pd), which are characterized by low-pressure metal–silicate distribution coefficients of more than 10^4; the moderately siderophile elements (MSE; including Mo, W, Fe, Co, Ni, P, Cu, Ga, Ge, As, Ag, Sb, Sn, Tl, Bi), with low-pressure metal–silicate partition coefficients that are typically more than 10, but less than 10^4; and the slightly siderophile elements (SSE; Mn, Cr, and V) (Table 1). The SSE, along with the highly chalcophile elements (HCE: S, Se, Te, Pb), and elements that otherwise exhibit atmophile, lithophile, or chalcophile affinity, can become siderophiles at specific temperatures (T), pressures (P), compositions (x), or oxygen fugacity (fO_2). An example of this phenomenon is the composition of Earth's core which, from seismological constraints, requires an alloy of FeNi metal and light elements. The nature of the light alloying element(s) remains uncertain, with Si, O, S, H, and C all considered as potential candidates, implying potential siderophile behavior of these elements at high pressures and temperatures.

Properties of the Siderophile Elements

The siderophile elements have both long-lived and short-lived radioactive isotope decay schemes and important novel stable isotope systems (e.g., Fe isotopes) embedded within them (Table 1). Of the radiogenic isotope systems, ^{182}W is the decay product of the extinct radionuclide ^{182}Hf and can be used to date core formation due to Hf partitioning into silicate portions of planets, relative to W, which partitions preferentially into metallic cores. The ^{187}Re-^{187}Os is a long-lived isotope chronometer and has found wide application, from geochronology to studies of mantle isotopic heterogeneity or the record of continental weathering from seawater $^{187}Os/^{188}Os$ composition (Shirey and Walker 1998; Harvey and Day 2016).

During condensation of elements at the formation of the solar nebula, siderophile elements sequestered in refractory metallic alloys, or into iron sulfides, depending on volatility, leading to some fractionation of the siderophile elements. Early differentiation of Earth led to siderophile elements being extracted into a metallic iron core and corresponding depletion of these elements in Earth's silicate mantle and crust. Application of low-pressure metal–silicate partition coefficients shows that the predicted abundances of some siderophile elements, especially the HSE, are higher than expected from metal–silicate partitioning in the bulk silicate Earth. The overabundance of siderophile elements in Earth's mantle has been attributed to "late accretion" of materials with generally chondritic bulk composition after core formation ceased, to account for the generally flat, chondrite-relative abundances of the HSE (Fig. 1).

Experimental partitioning studies have found that some siderophile elements have decreasing metal–silicate partitioning coefficients at high pressures. Thus, the possibility of high pressure core-mantle equilibration to account for the siderophile element – and specifically HSE – abundances in the bulk silicate Earth cannot be ruled out, but we have to account for both the abundances of these elements and the long-term ratios of Re/Os and Pt/Os that are within 5–10% of chondritic values deduced from $^{187}Os/^{188}Os$ and $^{186}Os/^{188}Os$ in terrestrial mantle rocks (e.g., Day et al. 2016). Asteroidal parent bodies, which underwent metal–silicate partitioning at low pressures, also show enrichments of siderophile elements in broadly chondritic proportions, indicating that late accretion was ubiquitous to planetary bodies. Late accretion is a natural consequence of planetary growth, whereby the end of

Magmas

Definition

Produced at depth by partial melting of mantle or crustal rocks, silicate melts form as small droplets at mineral-grain boundaries. By coalescing and concentrating volatiles present at depth – primarily water and CO_2 – these droplets constitute the liquid phase that is the main component of magma. Owing to a density lower than that of the surrounding rock, the magma begins its rise to the Earth's surface, undergoing along the way complex processes known as fractional crystallization and assimilation and often carrying solid enclaves. At depths of a few tens of km, lower pressures cause volatiles to become oversaturated and to exsolve as bubbles, enhancing

the buoyancy. The process results in volcanism during which the lava emitted cools down quickly. Depending on factors such as melt viscosity and compressive or extensive geological contexts, however, all magmas do not reach the Earth's surface. Cooling then is very slow and melt crytallization eventually results in solidification of plutonic intrusions.

The Discovery of Silicate Melts

Magma owes its geochemical importance to the efficient way it transports energy and matter, at all scales, in response to pressure and temperature gradients. Ever since its formation 4.5 billion years ago, the Earth has thus primarily been shaped by magmatic processes. The discovery of this activity is rather recent, however, because from antiquity until the end of the eighteenth century it was believed that rocks were melted by subterranean combustion of matters such as sulfur, coal, or bitumen. Volcanism thus was perceived as an accidental process of very limited extent. The situation abruptly changed when de Dolomieu (1797) concluded from smart geological observations that magmas were originating instead from a region located below the then-thought primordial granite, which was itself lying on an older material from which lavas were issued. Announcing the concepts of isostasy and asthenosphere, Dolomieu concluded that this region upon which the solid crust rested all over the world was "pasty and viscous." At a given place, he noted, this source could produce large amounts of lava for very long times without leaving empty spaces collapsing under the weight of growing volcanoes, and without needing continuous supplies of combustible and of the then-known oxygen. With a source that was extending all over the Earth, magmas had at last become a major geological agent.

The Peculiarity of *Liquids*

The importance of silicate melts stems from the fact that these are *liquids*, i.e., phases characterized by a lack of long-range order and a high atomic mobility. Here the concept of unit cell thus is completely irrelevant, but not that of short-range order as oxygen coordination polyhedra similar to those of crystals can still be defined. Interatomic distances and bond angles do not take on fixed values, however, but follow instead more or less broad distributions that vary continuously with composition. Like in crystals, increasing SiO_2 contents cause an increasing polymerization of the structure. In olivines, pyroxenes, and SiO_2 polymorphs, all SiO_4 units are, for instance, connected to 0, 2, and 4 other tetrahedra by *bridging* oxygens (BO), respectively, whereas 4, 2, and 0 oxygens are left *nonbridging* (NBO). In glasses and melts, polymerization in contrast proceeds progressively through the coexistence of SiO_4 units having different numbers of bridging oxygens. This is why much attention is paid to the distribution of the so-called Q^n species, where n is the number of bridging oxygens per TO_4 polyhedra: here T designates not only Si^{4+} but also cations such as Al^{3+} and Fe^{3+} that can also be part of the silicate framework provided that they are associated with other cations (mostly alkalis and alkaline earths) to bring the overall formal charge to 4+. To describe polymerization/depolymerization, it is then useful to distinguish between network-former (T) and network-modifier (M) cations whose roles are summarized by the reaction

$$M_2O + T{-}BO{-}T = 2\ Si{-}NBO{-}M \qquad (1)$$

in the case of a monovalent M cation.

Contrary to solids where atomic positions are fixed and strongly constrained by long-range symmetry, liquids are in addition characterized by dynamic disorder, that is, by unceasing atomic rearrangements made possible by the excess thermal energy, with respect to solids, that they acquire on melting. Part of the thermal energy gained upon heating actually induces structural changes without causing temperature rises, which is the reason why melts have higher heat capacities than their crystalline counterparts. Such *configurational contributions* originating in structural changes are also found for the compressibility and thermal expansion coefficient. As a rule, they represent from 10% to more than 30% of these second-order thermodynamic properties, increasing with decreasing SiO_2 contents (cf. Mysen and Richet 2005).

From a geochemical standpoint, several important consequences follow. First, the disordered structure of melts generally allows a wide range of elements or oxides to coexist in a single phase, as illustrated by the fact that only one liquid forms upon melting of a rock made up of a number of distinct mineral phases. Second, water, CO_2, and other volatile species brought at depth by subduction zone processes can be incorporated at rather large concentrations in the newly formed magma; upon decompression their solubility is exceeded only under subsurface conditions where volatile exsolution causes sharp buoyancy increases and, thus, triggers volcanic eruptions. Third, atomic arrangements are generally more compact if ordered rather than disordered so that melts are less dense than their isochemical crystalline assemblages and, therefore, buoyant with respect to them, and the effect is enhanced not only by the dissolution of light volatiles such as water, but also by fractional crystallization since precipitation of dense ferromagnesian minerals causes the density of residual melts to decrease. Fourth, whereas crystalline phases are stable in limited pressure and temperature ranges, where changes in bond angles and distances must remain consistent with their long-range symmetry, liquids do not experience discontinuous phase transitions since

their structure keeps constantly adjusting to varying temperatures and pressures. Their lack of long-range order makes in particular possible a wide diversity of densification mechanisms, such as continuous pressure-induced changes of Si and Al from four to higher coordination by oxygen (e.g., Ghiorso 2004).

Besides, a major consequence of the progressive enrichment in SiO_2 and alkali oxides of the residual melts in all petrogenetic series is the aforementioned increasing polymerization of the structure, from the isolated SiO_4 tetrahedra and Si_2O_6 chains of olivine- and pyroxene-like units, respectively, to the three-dimensional network of SiO_4 and AlO_4 tetrahedra when the aluminosilicate compositions of rhyolites are reached. Correlatively very strong viscosity increases take place, which affect markedly rates of magma ascent and, therefore, eruption temperatures and eruptive styles. To quote a single example, rapidly rising basalts typically erupt at temperatures of about 1200 °C, which are 300 °C higher than for andesites. The viscosity difference between these melts thus increases from two orders of magnitude at 1200 °C to six at their eruption temperatures (Fig. 1): this feature accounts very simply for the difference between their effusive and explosive eruptive styles, respectively, and for the resulting morphology contrast between shield and stratovolcanoes.

Contrary to what has long been assumed, however, viscosity does not increase upon melt polymerization because of increasing entanglement of the silicate units when their average size increases. As alluded to above about mobility, the average lifetime of bonds tremendously decreases with rising temperatures so that the relative motion of silicate units involved in viscous flow must thus be pictured as a mutual interpenetration that takes place through bond exchange (Fig. 2). This is the reason why viscosity scales as the rate of bond rearrangement between oxygen and the network-forming cations Si and Al (Farnan and Stebbins 1994). All elements are involved, however, because the network-modifying cations have to move away for the activated complex to form. As a result (Richet 2009), viscosity can be expressed in terms of a constant enthalpic factor, *Be* (reflecting the average strength of the rearranging bonds) and an entropy term, *Sconf* (markedly increasing with temperature, accounting for the greater size of the units that can rearrange):

$$\log\eta = Ae + Be/TSconf, \tag{2}$$

where *Ae* is a pre-exponential factor.

The Silica Paradox

The very strong increase of viscosity with SiO_2 content reflects the much greater strength of Si—O compared to other metal–oxygen bonds. But since fusion temperatures also increase with bond strengths, one would expect SiO_2 polymorphs to melt at much higher temperatures than minerals such as lime (CaO), periclase (MgO), or forsterite (Mg_2SiO_4). And since the most refractory crystals precipitate first upon fractional crystallization, magma differentiation should cause residual melts to become progressivly poorer in SiO_2. These two statements are, of course, blatantly contradicted by experience.

The paradox lies in the fact that bond strengths are usually considered within the framework of ionic forces, which are by definition nondirectional. Now, directionality is an inherent feature of Si—O bonding in view of its markedly covalent character. Because electron delocalization through polymerization and creation of Si—O—Si linkages is not large enough to constrain geometrically the arrangements of the SiO_4 tetrahedra, the same energy variations are, for instance, caused in $H_6Si_2O_7$ clusters by a 0.02 Å change of the Si—O bond length and by a 20° modification of the O—Si—O intertetrahedral angles (Fig. 3). Bending thus is so easy that configurational rearrangements take place without involving much energy, as most simply illustrated by the transitions of α-quartz or α-cristobalite (the high-temperature SO_2 polymorph), near 573 °C and 250 °C, respectively, to their dynamically disordered β-forms. Hence, fusion of such minerals does not require the breaking of bonds needed in ionic crystals. Magma differentiation thus is eventually a quantum-chemical effect mainly driven by the sp^3 hybridization of silicon orbitals (Richet and Ottonello 2014), which causes highly polymerized crystals to melt at temperatures much lower than would be expected from their Si—O or Al—O bond strengths. But much work, of course, remains to be done to account quantitatively for the petrogenetic series themselves in terms of such first-principles calculations.

Summary

Silicate melts owe their fundamental importance to a high atomic mobility prevailing in disordered structures. Whereas the former factor makes viscous flow possible, the latter causes buoyancy with respect to surrounding rocks and make continuous adjustments of the structure and physical properties in response to pressure, temperature, and composition changes.

Silicate Minerals

Ritsuro Miyawaki
Department of Geology, National Museum of Nature and Science, Tokyo, Japan

Definition

A silicate mineral is a salt of silicate anions and cations formed by geological processes. Silica minerals [SiO_2], such as quartz, cristobalite, and tridymite, and the hydrous phases [$SiO_2 \bullet nH_2O$], opal and mogánite, are often grouped with the silicate minerals. A silicate anion is an oxo acid of silicon, and commonly consists of one centered Si and four O atoms forming a SiO_4 tetrahedron, or rarely of one centered Si with six O atoms forming a SiO_6 octahedron.

Classification

Tetrahedral $(SiO_4)^{4-}$ anions are isolated in the crystal structures of nesosilicates. Forsterite [Mg_2SiO_4] of the olivine group and almandine [$Fe^{2+}{}_3Al_2(SiO_4)_3$] of the garnet super group are typical examples of nesosilicate. In the other silicates, tetrahedral $(SiO_4)^{4-}$ anions are polymerized by means of sharing the apical oxygen atom(s) to form dimers, trimers, or polymers. Solosilicates consist of the dimer $(Si_2O_7)^{6-}$ and/or trimer $(Si_3O_{10})^{8-}$, e. g., epidote [$Ca_2Fe^{3+}Al_2(Si_2O_7)(SiO_4)O(OH)$] of the epidote super group and thalénite-(Y) [$Y_3Si_3O_{10}F$]. Cyclosilicates have three- four- six- or rarely eight- or 12-membered rings of SiO_4 tetrahedra as the structural pieces. Benitoite [$BaTiSi_3O_9$] and nagashimalite [$Ba_4(V^{3+},Ti)_4(O,OH)_2[(B_2O_3)(Si_2O_{12})_2]Cl$] are examples for cyclosilicates with three- and four-membered rings, respectively. The six-membered rings are in the crystal structures of schorl [$NaFe^{2+}_3Al_6(Si_6O_{18})(BO_3)_3(OH)_4$] (Fig. 1) of the tourmaline super group and beryl [$Be_3Al_2Si_6O_{18}$]. Different type rings are sometimes combined in a crystal structure of cyclosilicate, such as hexagonal double rings, in other words, the combination of six- and four-membered rings, in osumilite [$KFe^{2+}_2Al_3(Al_2Si_{10})O_{30}$]. Inosilicates are characterized by the chain structures of silicate polymers. Single chains (pyroxenes such as augite [$(Ca,Mg,Fe)_2Si_2O_6$] (Fig. 2), and wollastonite[$CaSiO_3$]), double chains (amphiboles as actinolite [$Ca_2(Mg,Fe^{2+})_5Si_8O_{22}(OH)_2$], xonotlite [$Ca_6Si_6O_{17}(OH)_2$], and others), and triple chains (e.g., jimthompsonite[$Mg_5(Si_6O_{16})(OH)_2$]) have been known. A part of Si is sometimes replaced with Al (aluminosilicate). Micas, e.g., muscovite [$KAl_2(Si_3Al)O_{10}(OH)_2$], and most of clay minerals, e.g., serpentine group [$(Mg,Fe)_3Si_2O_5(OH)_4$)], are phyllosilicates. They are characterized by the layered structures of combined octahedral and tetrahedral sheets in a ratio of 1:1 or 2:1, and, sometimes, interlayer ions and molecules. The feature on configuration of SiO_4 tetrahedra, which share the individual three of four apical oxygen atoms with neighboring three SiO_4 tetrahedra, is hexagonal in the network. The centered Si is often replaced with Al and/or, rarely, with Fe. In the crystal structures of tectosilicate, the SiO_4 tetrahedra share all four apical O atoms to build up a three-dimensional framework. Quartz [SiO_2] is one of the typical

Silicate Minerals, Fig. 3 A VESTA illustration of the edge-sharing columns of SiO_6 octahedra (*blue* in color) in stishovite. The columns are connected with the others by the corner-sharing linkages. The structure data are from AMCSD

tectosilicates. Lots of aluminosilicates, e.g., microcline [$KAlSi_3O_8$] in feldspar family, nepheline[$NaAlSiO_4$] in feldspathoid family, and analcime[$NaAlSi_2O_6 \cdot H_2O$] in zeolite family, are included in this subclass.

Atomic Coordination

Octahedral SiO_6 can be observed in the crystal structures of some high-pressure phases, e.g., stishovite [SiO_2] (Fig. 3), bridgmanite [$MgSiO_3$] having the perovskite structure, and majorite [$Mg_3(MgSi)(SiO_4)_3$], a member of garnet super group consisting of SiO_6 octahedron and SiO_4 tetrahedron. These silicate minerals crystalized in the lower mantle of the Earth, or by shock during meteorite impacts. Thaumasite [$Ca_3Si(OH)_6(SO_4)(CO_3) \cdot 12H_2O$] is an unique mineral of alterations products having octahedral $Si(OH)_6$ in the crystal structure.

The coordination of O atoms around a Si in a silicate can be examined by the high resolution nuclear magnetic resonance (NMR) spectroscopy for ^{29}Si, in addition to the crystallographic data based on diffraction of X-ray and/or neutrons. The ^{29}Si-NMR spectra show a correlation between chemical shift and polymerization, Q^n notation presenting the number of bridging O atoms per a Si atom in a SiO_4 tetrahedron: Q^0 (monosilicate), Q^1 (disilicate or chain end), Q^2 (middle in a chain), Q^3 (chain branching site or middle in tetrahedral sheet), and Q^4 (sharing all O atoms in three-dimensional cross-linked framework).

Chemical and Physical Properties

Silicates are weakly soluble in pure water or acidic solutions, except for hydrofluoric acid (HF) solution, under the ambient temperature and pressure. However, groundwater and seawater contain small but measurable amounts (ppm order) of solute orthosilicate ion $(SiO_4)^{4-}$ to form extremely weak silicic acid (H_4SiO_4, in other formula, $Si(OH)_4$). High pH basic aqueous solutions (e.g., NaOH solution) and alkaline fusions (e.g., Na_2CO_3 melt) can dissolve silicate minerals. Silicates are remarkably soluble in hydrothermal waters, especially supercritical ones.

Some silicate minerals crystallize from melts, but the others from solutions such as hydrothermal solutions and hot spring water. Some are secondary minerals or weathering products after rock-forming minerals. Quartz in chert and amorphous silica in diatomite are major examples of biogenic silicates.

Most of silicate minerals have a vitreous luster. Their hardness varies over a wide range in Mohs scale; from 1 [talk: $Mg_3Si_4O_{10}(OH)_2$] to 8 [topaz: $Al_2SiO_4F_2$].

Summary

Silicate minerals constitute the majority of Earth's crust and mantle. Approximate 1500 species of silicate minerals have been described among ca 5000 mineral species approved by the Commission of New Minerals, Nomenclature, and Classification of the International Mineralogical Association (CNMNC-IMA).

Properties

Silicon (Emsley 1991, 2001; Anthoni 2006; Anders and Grevesse 1989; McDonough 2005), classified as a member of metalloids, is the eighth most abundant element in the universe and the second most abundant in the Earth's crust after oxygen. Silicon rarely occurs as the pure free element on Earth's crust, but it is found as oxides (silica) and as silicates. The oxides include sand, quartz, rock crystal, amethyst, agate, flint, and opal. The silicate form includes asbestos, granite, hornblende, feldspar, clay, and mica.

Silicon is a solid at room temperature and has a greater density in the liquid state than in the solid state, and, similar to water, it expands when it freezes. Silicon is a good heat conductor. In its crystalline form, pure silicon is strong, very brittle, and prone to chipping and has a gray color and metallic luster. Silicon is a semiconductor in its pure form with semiconductivity increasing by introducing small amounts of impurity. Silicon is similar to metals in its chemical behavior.

History and Use

Silicon, as silica (SiO_2) in the form of sharp flints, was among the first tools made by humans. Ancient civilizations used other forms of silica such as rock crystal and knew how to turn sand into glass. Considering silicon's abundance, it is somewhat surprising that it received very little attention from early chemists. Even though a number of chemists were close to isolating silicon, the credit for its discovery goes to the Swedish chemist Jöns Jacob Berzelius who, in 1824, obtained silicon by heating potassium fluorosilicate with potassium. The product was contaminated with potassium silicide, but he removed this by stirring it with water, with which it reacts, and thereby obtained relatively pure silicon powder which is a noncrystalline form (amorphous silicon). Berzelius called this new element silicium, but in 1831 T. Thomson named it silicon because of its nonmetallic character. Crystalline silicon, the other form of silicon, was actually discovered years later, by mistake, in 1854, by Henri Deville.

Elemental silicon is produced commercially by reducing sand with carbon in an electric furnace. High-purity silicon, for the electronics industry, is prepared by the thermal decomposition of ultrapure trichlorosilane, followed by recrystallization. These crystals can be doped with boron, gallium, germanium, phosphorus, or arsenic and are used in the manufacture of solid-state electronic devices, such as transistors, solar cells, rectifiers, and microchips. Silicon is the basis of the semiconductor industry, and silicon-based chips have been following Moore's Law for almost 50 years. Silicon dioxide (SiO_2) is the most common compound containing silicon and mostly takes the form of ordinary sand, but also exists as quartz, rock crystal, amethyst, agate, flint, jasper, and opal. Silicon is extensively used in the manufacture of glass and bricks. Silica gel, a colloidal form of silicon dioxide, easily absorbs moisture and is used as a desiccant.

Silicon forms other useful compounds: silicon carbide (SiC) is nearly as hard as diamond and is used as an abrasive; sodium silicate (Na_2SiO_3), also known as water glass, is used in the production of soaps, adhesives, and as an egg preservative; and silicon tetrachloride ($SiCl_4$) is used to create smoke screens. Silicon is also an important ingredient in silicone, a class of material that is used as lubricants, polishing agents, electrical insulators, and medical implants.

Geochemical Behavior

Silicon dioxide is found in all three types of rocks. Silicates weather leading to dissolution and erosion when exposed at the surface of the continents to water and wind. Besides bicarbonate, dissolved silica (undissociated silicic acid $Si(OH)_4$) represents a dominant species in river water at higher concentration than in seawater. The suspended silicates are only slightly affected during their transport by rivers. On a geological time scale, the input of dissolved silica by rivers to the sea must be compensated by a removal process which is only possible in the sediments. The silica cycle is closely tied to the carbon and sulfur cycle due to metamorphic processes. Of particular importance is the reaction between carbonates and silicates. Accumulation of silicates at geological time scales leads to an increase of CO_2 levels in the atmosphere, and the reverse occurs when there is preferential accumulation of carbonates in the sediments.

Biological Utilization and Toxicity

Silicon is not in particular toxic, but fine particles of silicates or silica (e.g., asbestos) can cause damage to lungs, silicosis, and different health agencies have different legal limits. People are exposed to silicon by breathing it in, swallowing it, skin contact, and eye contact. Silicon supplements are used as medicine. Silicon in various forms is used to treat weak bones (osteoporosis), heart disease and stroke (cardiovascular disease), Alzheimer's disease, hair loss, for improving hair and nail quality, improving skin healing, treating sprains and strains, and digestive system disorders. Silicone (a group of materials resembling plastic that contain silicon, oxygen, and other chemicals) is used to make breast implants, medical tubing, and a variety of other medical devices. There is some evidence that silicon might have a role in bone and collagen formation, but the clear biological role of silicon in humans is not really known.

Silicon Isotopes

Anat Shahar
Geophysical Laboratory, Carnegie Institution for Science, Washington, DC, USA

Definition

Silicon, atomic number 14, has 24 known isotopes with mass numbers ranging from 22 to 45. Silicon has three stable isotopes: ^{28}Si with 92.23% abundance, ^{29}Si with 4.67% abundance, and ^{30}Si with 3.1% abundance.

Introduction

As the second most abundant element on Earth, silicon has been used to trace processes from as far back as 4.5 billion years ago to today. The added benefit of having three stable isotopes (^{28}Si, ^{29}Si, and ^{30}Si) that can be used to further our understanding of the silicon cycle and processes occurring on Earth and in the solar system makes silicon an increasingly powerful tool for geochemistry. Since the 1950s there have been studies aimed at analyzing silicon isotope ratios, mostly in low-temperature environments, using gas source mass spectrometry. In the early 2000s, the development and application of multiple collector inductively coupled plasma mass spectrometry was applied to Si isotopes, and the field of high-temperature silicon isotope geochemistry flourished. In this entry we focus on what has been learned from silicon isotope geochemistry to date. All isotope values are written in traditional delta notation as defined below:

$$\delta^{30/28}\mathrm{Si} = \left(\frac{\left(^{30/28}\mathrm{Si}_{\mathrm{sample}}\right)}{\left(^{30/28}\mathrm{Si}_{\mathrm{standard}}\right)} - 1 \right) * 1000 \qquad (1)$$

Low Temperature

Silicon isotopes have been used extensively to study continental weathering, oceanic primary production, and as a tool for understanding the silicon cycle today and throughout Earth's history. The silica sources to the oceans include hydrothermal fluids, seafloor (basalt) weathering, and aerosol deposition, but are dominated by riverine input, derived from weathering of the continents (e.g., Georg et al. 2009; Treguer and De La Rocha 2013). Diatoms and other silica-secreting organisms require the dissolved silicic acid (H_4SiO_4) for growth and provide the major sink for the dissolved silica in the modern ocean. These organisms and their predecessors have played a dominant role in the marine silica cycle through geologic time. Silicon isotopes have been shown to fractionate during the utilization of silicic acid by diatoms (e.g., De La Rocha et al. 1997; Hendry and Brzezinski 2014) and during continental weathering, whereby the seawater is left enriched in the heavy isotopes. The δ^{30}Si of modern seawater is ~1.1 ‰ (De La Rocha et al. 2000) which is more enriched than both the continental and hydrothermal inputs due to the light isotopes partitioning into the organisms in the ocean. The Si isotope fractionation ranges from −1.1 ‰ for diatoms to −3.5 ‰ for marine sponges (De La Rocha et al. 1997; De La Rocha 2003; Hendry and Robinson 2012). Using the δ^{30}Si of diatom silica from sediments can trace the percent removal of the nutrient dissolved silicon from surface waters in the past.

In terms of continental weathering, Georg et al. 2006 show that in order to understand the δ^{30}Si of river waters, the important parameters are the discharge of the rivers, the resulting weathering fluxes, and the concentration of dissolved silicon. Less is known about the effect of hydrothermal alteration on Si isotopes (e.g., Frings et al. 2016). On the other hand, clays, which are the products of chemically

weathered silicates, are on average lighter than igneous rocks and about 0.4 ‰ lighter than coexisting feldspars and 0.6 ‰ lighter than groundwater (Georg et al. 2009). This implies that the heavier isotopes are enriched in the fluid, which has a weaker bonding environment, antithetical to equilibrium isotope geochemistry theory.

Another fascinating use of silicon isotopes is understanding cherts (deposits of amorphous silica) which can document the evolution of the silica cycle through time and possibly be used as a paleothermometer of the ocean. Chert formation (by evaporation) also leads to an enrichment of silicon isotopes in seawater and can provide crucial insights into the sources and sinks of marine silica before the evolution of the silica-secreting organisms such as sponges and diatoms. Robert and Chaussidon (2006) reported the use of combined O and Si isotope data to argue that past seawater temperatures were close to 70 °C. It is important to note however that chert precipitation can be complicated and one needs to know the source of silica, the mechanisms of silica precipitation, and the depositional setting in order to interpret the analyses (e.g., Oelze et al. 2014). But as more models and laboratory experiments become available, the possibility exists to use these isotope ratios as a paleothermometer and as a tool for reconstructing the silicon cycle through time. Further, more laboratory measurements and geochemical markers can be used to constrain a possible paleo-proxy. A recent study (Delvigne et al. 2016) looked at combining the Si isotope record with Ge/Si ratios in order to constrain desilication in the Archean. For a more in-depth review of low-temperature Si isotope fractionation, see the review of Frings et al. 2016.

High Temperature

Early (gas source) measurements of the Si isotope compositions of high-temperature materials such as meteorites and terrestrial igneous rocks (Douthitt 1982; Molini-Velsko et al. 1986; Ding et al. 1996) found no resolvable fractionation among different reservoirs. Following the application of MC-ICPMS and HF-free sample preparation techniques (Georg et al. 2006), accurate Si isotope measurement of all types of planetary material is now reliably attainable, and small but important isotope variations have been reported.

With the intention of learning about the building blocks of the terrestrial planets, much work has gone into constraining the silicon isotope composition of chondritic meteorites. The average compositions of ordinary and carbonaceous chondrites are indistinguishable and are used as a chondritic reference frame, estimated to be $\delta^{30}Si_{chondrite} = -0.46 \pm 0.09$ ‰ (2sd) by Savage et al. (2014). On the other hand, enstatite chondrites have a distinctly light Si isotope composition which has been explained as being due to either lithophile element fractionation in the solar nebula (Fitoussi and Bourdon 2012) or inclusion of isotopically light Si in the metal phase during condensation (Savage and Moynier 2013). The bulk silicate Earth (BSE) has a $\delta^{30}Si_{BSE} = -0.29 \pm 0.07$ ‰ (2sd) which is significantly heavier than the chondritic value (Fitoussi et al. 2009; Savage et al. 2010; Armytage et al. 2011; Zambardi et al. 2013). This difference was interpreted to reflect that isotopically light Si entered the core during the Earth's differentiation. Georg et al. (2007) used first-principles calculations to test whether there would be a silicon isotope fractionation between metal and silicate and found that even at high temperature (2000 K), the silicate is enriched in the heavier Si isotopes on the order of $\Delta^{30}Si_{silicate\text{-}metal}$ ($\delta^{30}Si_{silicate} - \delta^{30}Si_{metal}$) ≈ 1.5 – 1.7 ‰.

Shahar et al. (2009, 2011) then experimentally constrained the metal-silicate Si isotope partitioning, using piston-cylinder and multi-anvil setups, the latter allowing pressures up to 7 GPa and temperatures up to 2200 °C. As with the ab initio calculations of Georg et al. (2007), the experiments consistently found the silicate enriched in the heavier isotopes and more specifically found the following temperature dependence:

$$\Delta^{30}Si_{silicate-metal} = \frac{7.45(\pm 0.41) \times 10^6}{T^2} \quad (2)$$

However, a more recent experimental study by Hin et al. (2014) investigated $\Delta^{30}Si_{silicate\text{-}metal}$ between basalt and metal and found ~40% lower degrees of isotope fractionation at a given temperature compared to the work of Georg et al. (2007), Shahar et al. (2009, 2011), and Ziegler et al. (2010) but in the same direction. It is unclear why the results differ but the composition of the experiments was quite different (Young et al. 2015).

Analyses of meteorites from Mars, Vesta, the Moon, and aubrite and angrite achondrites have all helped in our understanding of how these planetary bodies formed. For example, samples from Mars show no resolvable variation between the different meteorite groups: $\delta^{30}Si_{Shergottite} = -0.47 \pm 0.06$, $\delta^{30}Si_{Nahklite} = -0.51 \pm 0.04$, and $\delta^{30}Si_{Chassigny} = -0.47 \pm 0.06$, with an overall average of $\delta^{30}Si_{MARS} = -0.48 \pm 0.06$ (Armytage et al. 2011; Pringle et al. 2013; Zambardi et al. 2013). This value is identical to ordinary and carbonaceous chondrites suggesting that no processes have altered the silicon isotope composition of bulk Mars since its formation. On the other hand, basaltic samples from the moon show an identical value to the Earth's mantle (Armytage et al. 2012; Fitoussi and Bourdon 2012; Zambardi et al. 2013; Poitrasson and Zambardi 2015) adding further evidence that the Moon is genetically linked to the Earth.

Arguably, the most interesting meteorites analyzed to date are the angrites, an oxidized basaltic achondritic meteorite group. Two groups (Pringle et al. 2014; Dauphas et al. 2015) have measured these samples and found that the angrite

parent body mantle had a composition of $\sim -0.21 \pm 0.03$ (2sd) which is significantly heavier than all the achondrites measured and very similar to the bulk silicate Earth's value. However, unlike the Earth these meteorites are too oxidized for enough silicon to partition into their parent body's core, and thus this cannot be the explanation for the value. Therefore, new mechanisms are needed in order to explain these data. Pringle et al. (2014) suggested that the Si isotope composition of the angrites is related to volatile depletion on the parent body, whereby there is preferential loss of isotopically light Si due to impact-related kinetic isotope fractionation. However, Dauphas et al. (2015) argue that the heavy Si isotope composition of angrites is not due to planetary processes, but instead is inherited from nebula fractionation of Si isotopes (similar to the theory of Fitoussi and Bourdon 2012). These are very different hypotheses with very different ramifications; however, as is the case with high-temperature stable isotope ratios, there are many physical and chemical ways to achieve such small deviations. For a more in-depth look at high-temperature silicon isotope, see Savage et al. 2014 and Shahar et al. 2016.

Summary

In sum, while silicon isotopes have been studied for decades, there is a lot more potential in using silicon isotopes as tracers for both high- and low-temperature environments due to recent technological advances. This will be a fascinating area of research to follow.

Silver

Helen Mango
Department of Natural Sciences, Castleton University, Castleton, VT, USA

Element Data
Atomic Symbol: **Ag**
Atomic Number: **47**
Atomic Weight: 107.8682 g/mol
Isotopes and Abundances: ^{107}Ag 51.839%, ^{109}Ag 48.161%
1 Atm Melting Point: 961.8 °C
1 Atm Boiling Point: 2162 °C
Common Valences: 2+, **1**+, 0
Ionic Radii: 129 pm (1+); 108 pm (2+)
Pauling Electronegativity: 1.93
First Ionization Energy: 731.0 kJ/mol
Chondritic (CI) Abundance: 0.201 ppm
Silicate Earth Abundance: ~0.05 ppm
Crustal Abundance: ~0.056 ppm
Seawater Abundance: <0.003 ppm
Core Abundance: ~0.15 ppm

Properties

Silver (symbol Ag) has atomic number 47 and atomic mass 107.8682 ± 2 (Haynes et al. 2014). Silver has two naturally occurring isotopes: ^{107}Ag and ^{109}Ag, with abundances of 51.839% and 48.161%, respectively (IUPAC 2015). The metallic radius of the silver atom is 144 pm (Greenwood and Earnshaw 1997). Because its outer electron configuration is $5s^1 4d^{10}$, the univalent ion (Ag^+, ionic radius = 129 pm) is more common than the divalent ion (Ag^{2+}, ionic radius 108 pm) (Shannon 1976). Pure silver has a specific gravity of 10.50 (20 °C) and a hardness of 2.5–3, with a melting point of 961.78 °C (1 atm) and a boiling point of 2162 °C (1 atm); it has a brilliant white metallic luster, a cubic crystal structure, is very ductile and malleable, has a heat capacity of 0.235 J/gK, and the highest electrical and thermal conductivities and lowest contact resistance of all the metals (Haynes et al. 2014).

History and Use

Silver has been known since ancient times. For thousands of years it has been used for jewelry, utensils, and coinage. It is currently also used in photography and the production of mirrors, solders, brazing alloys, bearings, electrical contacts, photovoltaics, dental alloys, high-capacity Ag-Zn and Ag-Cd batteries, and printed circuits (Goonan 2014; Haynes et al. 2014; USGS 2015). Photography is the largest end use, accounting for 30% of silver consumption in the United States; the increase in digital photography is reducing the use of silver in this application but has increased it in medical and industrial X-rays (Goonan 2014; Haynes et al. 2014) and as a metal ink for printing semiconductors (Yung et al. 2014). Silver is used as a catalyst in oxidation reactions, such as in the production of formaldehyde and ethylene oxide (Goonan 2014; USGS 2015). Silver iodide is used for seeding clouds (Haynes, 2014). Nanosilver has germicidal properties and is used for purifying water, sterilizing equipment, and for treating wounds (Goonan 2014).

Abundance

Table 1 gives the abundances of silver in different geologic materials.

Geochemical Behavior

Silver is found in the native state and in combination with other elements, primarily S, Sb, Se, Pb, As, Bi, Cu, and Au. It is strongly chalcophile in geologic processes, although in

Silver, Table 1 Silver abundances in geologic materials

Material	Average abundance/range
Iron meteorites	20 ppb
Chondrites	200 ppb
Lunar rocks	10 ppb
Average Earth	50 ppb
Continental crust	80 ppb
Upper crust	53 ppb
Middle crust	48 ppb
Lower crust	65 ppb
Mantle	6 ppb
Ultramafic igneous rocks	50 ppb
Mafic igneous rocks	100 ppb
Intermediate igneous rocks	70 ppb
Felsic igneous rocks	50 ppb
Metamorphic rocks	10^2–10^3 ppb
Carbonates	100–170 ppb
Sandstones	200–250 ppb
Evaporites	<100 ppb
Phosphoric/black shales	10^2–10^3 ppb
Manganese nodules	3 ppm
Abyssal clays	10 ppb
Coal/peat	<10 ppm
Petroleum	10 ppm
Soils	0.01–5 ppm
Fresh water	0.2–0.3 ppb
Ocean water	<3 ppb
Metalliferous brines	<2 ppm
Geothermal fluids	10^1–10^3 ppb
Fluid inclusions	10^1–10^3 ppm

Silver abundances in geologic materials. Data from Seward et al. (2014), Lodders (2010), Rudnick and Gao (2014), Palme and O'Neill (2014), McLean and Bledsoe (1992), Henderson (1986), Aubert and Pinta (1977), Parker (1967), McDonough (2014)

cosmochemical reactions it is moderately volatile and can exhibit both siderophile and chalcophile behavior (Woodland et al. 2005). Native silver is rarely pure; it is usually alloyed with measurable quantities of one or more of the following elements: Au, Hg, As, Sb, Bi, Te, Cu, Fe, Sn, Pb, Co, Ni, Pt, and Ir.

Silver's transport in hydrothermal solutions in ore-forming processes is greatly dependent on the presence of complexing ligands. Within the range of temperatures (<350 °C) and pH (acidic) of most hydrothermal systems, chlorosilver (I) complexes appear to be the most important transporters of silver. Figure 1 shows silver solubility in the presence of aqueous sulfur species. Silver deposition from soluble complexes can occur if pH rises or the oxidation potential of the system decreases. Although the complexes $AgCl^0$, $AgCl_2^-$, $AgCl_3^{2-}$, and $AgCl_4^{3-}$ and the silver ion Ag^+ may all exist in hydrothermal solutions, complexes of low coordination number are favored, especially $AgCl_2^-$ (Seward 1976). While fluid salinities tend to be less than 3 M in many hydrothermal systems, silver-rich magmatic brines may be responsible for high-grade ore formation (Wilkinson et al. 2013).

For the univalent silver ion in aqueous solution, at 25 °C and 1 atm, the Ag^+ ion is coordinated by four inner-sphere water ligands with an average Ag-O distance of 2.32 Å, while at 350 °C, the coordination number decreases to approximately 3, and the Ag-O bond decreases by about 0.10 Å (Seward et al. 1996). Silver is a type-B metal cation, and so has a great affinity for sulfur; Ag^+ forms strong bonds with organic ligands such as thiols and mercaptans, which allows for rapid exchange of Ag^+ onto and off the cells of organisms (Bell and Kramer, 1999).

The highest concentrations of silver in soils are found overlying Ag-bearing bedrock; the silver tends to occur in the surface A_0 horizon, suggesting that chelated complexes of humic material are important for binding silver (Levinson 1974). Soil pH appears to control the mobility of silver; Ag is more soluble in acidic conditions and fairly immobile in more alkaline conditions (pH > 4). Silver mobility is also controlled by the availability of ligands in the soil, such as SO_4^{2-}, NO_3^-, $S_2O_3^{2-}$, HCO_3^-, and organic acids (McLean and Bledsoe 1992).

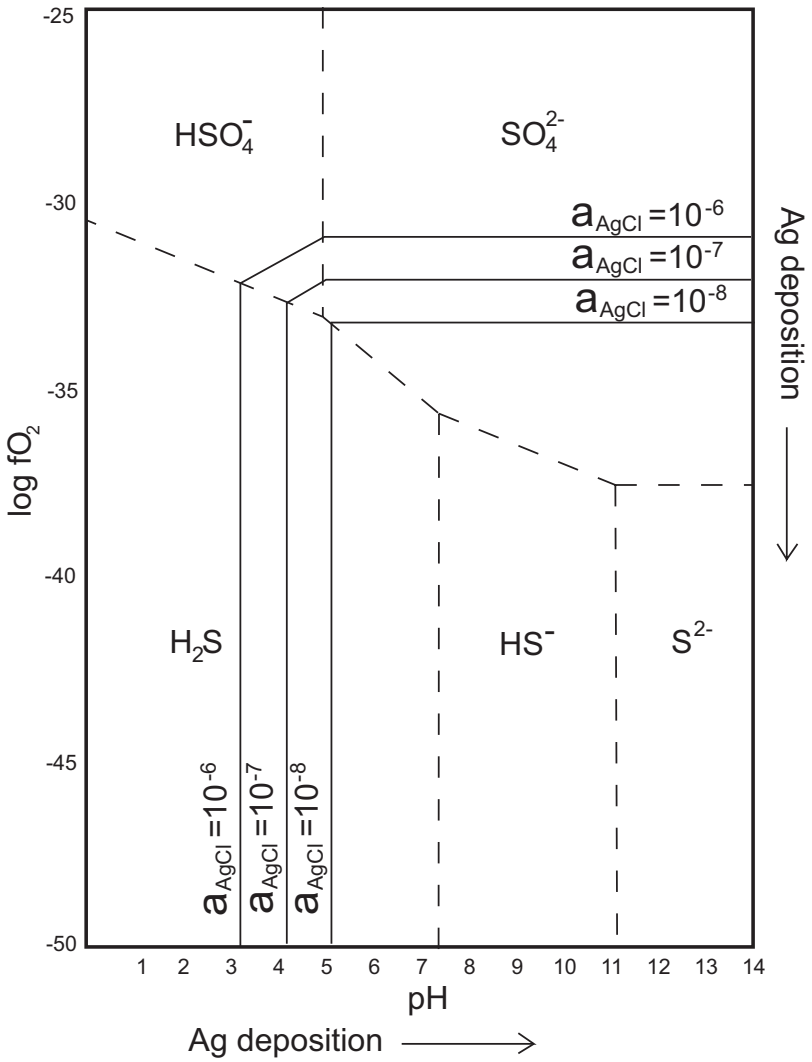
Silver Minerals

Table 2 lists the most common silver-bearing minerals.

Ore Deposits

In 2014, the ten top producers of silver were Mexico, Peru, China, Australia, Chile, Bolivia, Russia, Poland, the United States, and Argentina (Silver Institute 2015). Ore deposits that are related to igneous activity account for 60% of all silver discovered, and of these, a significant amount of silver is found in clearly defined veins (Singer 1995).

Epithermal vein deposits account for approximately 17% of the silver mined in the world (Singer 1995) and have very high silver grades (500–2000 g/t Ag; Wilkinson et al. 2013). Deposits of this type are concentrated in convergent tectonic zones, associated with calc-alkaline to alkaline magmatism (Simmons et al. 2005). These deposits are mostly young (<65 million years) and shallow (<1.5 km) and are characterized by the presence of fractures, fissures, zones of leaching, and other open spaces in which ore precipitated from hydrothermal solutions (Kissin and Mango 2014). Epithermal deposits are divided into low-sulfidation (adularia-sericite) and high sulfidation (acid-sulfate) types (Heald et al. 1987). Low-sulfidation deposits are more silver-rich, with silver occurring in sulfides, sulfosalts, selenides, and tellurides, with associated electrum and base-metal sulfides such as galena, chalcopyrite, sphalerite, pyrite, stibnite, and cinnabar.



Silver, Fig. 1 pH-fO_2 diagram showing silver solubility (as activity of AgCl) superimposed on the stability fields of aqueous sulfur species (separated by *dashed lines*) at 250 °C and total sulfur activity of 10^{-1}. Silver solubility decreases as a function of increasing pH and/or decreasing oxygen fugacity (Modified from Mango et al. (2014))

Silver, Table 2 Names, mineral families, and chemical formulae of the most common Ag-bearing minerals (Carmichael, 1989)

Mineral name	Mineral family	Chemical formula
Native silver	Native element	Ag
Electrum	Native element	Ag-Au alloy
Acanthite[a]	Sulfide	Ag_2S
Argentite[a]	Sulfide	Ag_2S
Proustite	Sulfosalt	Ag_3AsS_3
Pyrargyrite	Sulfosalt	Ag_3SbS_3
Polybasite	Sulfosalt	$(Ag,Cu)_{16}Sb_2S_{11}$
Pearcite	Sulfosalt	$Ag_{16}As_2S_{11}$
Stephanite	Sulfosalt	Ag_5SbS_4
Aguilarite	Sulfosalt	Ag_4SeS
Hessite	Telluride	Ag_2Te

[a]Argentite inverts to acanthite below 179 °C

Ore minerals often grade downward from a silver- and gold-rich zone at the top to a base-metal-rich zone below. They form from near-neutral pH, reduced, gas-rich, meteoric/magmatic hydrothermal fluids (Albinson et al. 2001; John 2001; Leavitt et al. 2004; Mango et al. 2014). Examples are Guanajuato, Fresnillo, Pachuca, and Tayoltita in Mexico, and Tonopah, Round Mountain, Midas, Comstock, and Creede in the United States.

Silver-bearing epithermal veins are found in late-stage mineralization above porphyry copper deposits; the silver occurs in sulfosalts and in solid solution in sphalerite and galena (Hurtig and Williams-Jones, 2015; Sillitoe 2010).

Silver-lead-zinc veins form a major class of silver deposits (Kissin and Mango 2014). Cordilleran vein type deposits are formed from magmatic-hydrothermal solutions. Silver is found in sulfosalts such as the tetrahedrite-tennantite series and form in the temperature range of 280–320 °C. Associated minerals include pyrite, chalcopyrite, sphalerite, galena, bornite, pyrrhotite, magnetite, arsenopyrite, and chalcocite, sometimes with uranium and tungsten minerals. Cordilleran-type veins hosted in clastic metasedimentary rocks appear to lack an igneous source for the ore solutions. Silver occurs in sulfosalt minerals associated with galena, sphalerite, pyrite, pyrrhotite, magnetite, and chalcopyrite (Kissin and Mango

Silver, Fig. 2 Sample of native silver for the Kongsberg district, Norway. Sample dimensions: 3.7 × 2.5 × 1.8 cm (Photo credit: www.irocks.com)

2014). Solution temperatures average 250–300 °C. Magma, Tintic, and Coeur d'Alene in the United States and Casapalca and Cerro de Pasco, Peru, are examples of this type of ore deposit.

Five-element (Ag-Ni-Co-As-Be) veins include the Kongsberg district of Norway, from which many fine specimens of native silver have been recovered (Fig. 2). Silver is found as the native element and in sulfosalts such as pyrargyrite, proustite, and stephanite. Uranium can be a significant coproduct, and some deposits are arsenic-rich. Silver deposition occurs in the temperature range 150–250 °C, although a much wider fluctuation in temperature, as well as fluid mixing, appears to have caused mineral deposition (Kissin and Mango 2014). Deposits of this type include the Cobalt-Gowganda, Thunder Bay, and Great Bear Lake districts in Canada.

Silver veins are also found related to granite-hosted tin mineralization, such as in Cerro Rico de Potosí in Bolivia (considered to be the largest silver deposit in the world). Here, silver-rich veins are associated with hydrothermal alteration above an igneous dome (Simmons et al. 2005). In the Cornwall deposits in England, silver occurs as argentiferous galena in veins that cross-cut earlier-formed tin mineralization and appear to be associated with faulting (Jackson et al. 1989).

Silver is associated with skarn mineralization, occurring as Ag-sulfosalts in polymetallic veins within the skarn and in distal Au-Ag veins (Einaudi et al. 1981; Jackson et al. 1989; Meinert et al. 2005).

Because silver is relatively soluble when combined with common anions existing in the oxidized zone of an ore deposit, but is very insoluble in the reduced sulfide form or as a native metal, it is frequently found in supergene enrichment zones associated with hydrothermal systems (Guilbert and Park 1986; Sillitoe 2009). Silver halides found in the oxidized zone of supergene enrichment are particularly insoluble and immobile (Sillitoe 2009).

Annual silver metal production worldwide (2014) was 20,300 tons, with a reserve base of 570,000 tons (USGS 2015).

Application to Cosmochemistry

The Pd-Ag chronometer is used to set constraints on the timing of early planetesimal formation. ^{107}Pd decays to ^{107}Ag, with a half-life of 6.5 million years (Chen and Wasserberg 1996). ^{107}Pd is now extinct in meteorites, but Pd/Ag ratios can be measured; in particular, Fe-Ni metal usually has much higher Pd/Ag ratios than cogenetic sulfides, reflecting fractionation (Woodland et al. 2005). Pd/Ag fractionation processes during condensation, early accretion, and metal segregation in the solar nebula allow construction of isochrons from which accretion models of Earth formation can be constructed (Chen and Wasserberg 1996; Woodland et al. 2005).

Toxicity

Argyria is a nontoxic tissue build-up of silver that causes blue-gray skin discoloration (Goonan 2014). Most silver salts are poisonous: exposure to dust containing silver nitrate or silver oxide may cause respiratory problems, lung, throat and skin irritation, and stomach pain (ATSDR 2015). Strong bioaccumulation of Ag^{+} has been observed in benthic organisms to the point of toxicity (Bell and Kramer 1999; Eisler 1996).

Sodium

Jérôme Gaillardet
Institut de Physique du Globe de Paris, Paris, France

Element Data
Atomic Symbol: Na
Atomic Number: 11

(*continued*)

Atomic Weight: 22.98977 u
Isotopes and Abundances: ^{23}Na 100%
1 Atm Melting Point: 97.7 °C
1 Atm Boiling Point: 883 °C
Common Valences: 1+
Ionic Radii: 110 pm
Pauling Electronegativity: 0.93
First Ionization Energy: 496 kJ.mol^{-1}
Chondritic (CI) Abundance: 4962 ppm
Silicate Earth Abundance: 2590 ppm
Crustal Abundance: 2.3%
Seawater Abundance: 0.47 mol/kg
Core Abundance: ~0

Properties

Sodium (Na) is an alkali metal belonging to the first column of the periodic table. Like the other alkali metals (Li, K, Rb, Cs, Fr), it is a highly reactive element that does not exist in a metallic form on Earth. It easily loses an electron and combines mostly with oxygen and halogens. Its electronic configuration is [Ne] $3s^1$ and its ionic radius is 1.1 Angstrom making Na^+ one of the largest cations.

It is mainly found in silicates, chlorides, or as the free ion Na^+ in surface fluids. It is particularly enriched in seawater as a result of its mobile behavior during fluid-rock interactions. It has an important biological role in cell homeostasis and nerve impulse circulation.

History and Use

Sodium was first isolated in 1807 by Humphrey Davy in England from the electrolysis of melted soda. The symbol has been adopted from the Latin name Natrium by the German chemist Berzelius in 1813.

Table salt has long been a very precious good for humans, often used as a food preservative agent. The word "salary" is derived from the Latin word "salarium" denoting the salt ration received monthly by the Roman soldiers.

Na is an element widely used by humans for different purposes: food (i.e., table salt), paper, glass, soap, textile, petroleum, and metal industries. NaCl is used as road salt for deicing. It is extracted essentially from seawater, rock salts (evaporites), or salt lakes. Sodium hydroxide and sodium carbonate, widely used in chemical industry, are derived from NaCl by industrial processes. The global production of NaCl is approximately 250–400 $\times$ 10^6 t/year, representing an anthropogenic Na flux of 100–160 $\times$ 10^6 t/year on the same order of magnitude than the global flux of Na to the ocean (200 $\times$ 10^6 t/year). China and the USA are the main NaCl producers.

Geochemical Behavior and Distribution

Na is about the 14th most abundant chemical element in the universe as deduced from the standard cosmic abundances. Na is 17 times less abundant in the solar photosphere that is silicon and 158 times less abundant that is carbon (Palme et al. 2014). On our planet, Na is mostly concentrated in the mantle (90–95%), the rest being in the continental and oceanic crust and in the ocean. The concentration of Na varies a lot in different Earth materials. While Na is a minor element in the mantle, it is a major element in the oceanic and continental crusts where it contributes to the stoichiometry of the major rock forming minerals.

The condensation temperature of Na is approximately 970 K at 10^{-4} bar. The concentration of Na in chondrites varies between 3300 and 6800 ppm (Li 2000). CI chondrites have mean Na concentration of 4982 ppm while the bulk silicate earth is about 2590 ppm (Palme and O'Neill 2014). This illustrates the volatile character of sodium. During the accretion of the Earth, the planet probably lost part of its initial Na. The concentration of Na in the core is not known and is usually assumed to be negligible.

Na in Magmatic Processes

According to the Goldschmidt classification, Na can be classified as a lithophile element with regard to its affinity for silicates. The estimated Na concentration in the bulk continental crust is 2.3% or 3.1% Na_2O (Rudnick and Gao 2014). Na is more concentrated in the upper part of the continental crust (2.4%). Na in crustal rocks is mainly hosted in plagioclase (e.g., albite $NaAlSi_30_8$) and alkali feldspars. It usually enters into the octahedral sites of aluminosilicates in association with Ca.

The behavior of sodium during partial melting and fractional crystallization is that of a moderately incompatible element, which means that Na will preferentially be enriched in silicate melts and rocks formed by their crystallization. Among alkali elements, Na has the highest partition coefficient between melt and solid (concentration in the solid over that in the liquid) and is thus the least incompatible of the alkalis. The bulk partition coefficient of Na between the mantle and the crust was estimated to be 0.1 by Hofmann (1988) using a simple crust-mantle differentiation model, much higher than the partition coefficient of heavier alkalis. In mid-oceanic ridge basalts (MORB), a correlation is observed between Na concentration varying between 1.3% and 2.5% (1.7–3.4% Na_2O) and axial depth (Klein and

Langmuir 1987), a feature interpreted by variations in the extent of mantle melting linked to temperature variations in the mantle.

Na in Fluid-Rock Interactions

Na is one of the most soluble elements (at least among cations) at the surface of the Earth. It mostly occurs in fluids as free Na^+ except in high temperature concentrated fluids where it can be found as complexes (e.g., with aluminum). This mobile character of Na during water-rock interaction is mainly attributed to its large ionic radius and +1 valence state (or in other words, to its low ionic potential), precluding Na from entering into precipitating minerals as dictated by Goldschmidt's rules. There are very few clay minerals containing significant amounts of Na (e.g., smectites). Na will thus be particularly enriched in fluids formed by weathering and metamorphic processes.

With chloride, sodium is the most concentrated element in seawater (0.47 mol/kg or 10.8 g/kg) suggesting that Na has accumulated over geological time in the ocean. The residence time of Na in the ocean is very long (on the order of 100 Myrs), confirming its lack of reactivity at Earth's surface conditions.

The dissolution of sea salt atmospheric aerosols produced by bubble bursting over the ocean allows Na to be one of the most abundant elements in rainwater, its concentration decreasing sharply with distance from the coast.

Sodium is also concentrated in rivers, particularly those draining igneous rocks. The mean Na concentration carried by large rivers to the ocean is 240 µmol/kg (5.5 mg/kg). About 40% of Na added each year to the ocean by rivers is derived from the chemical weathering of silicate rocks; the remaining Na originates from rain (leaching atmospheric sea salts) and evaporite dissolution (Gaillardet et al. 1999).

Accordingly, the secondary weathering products (clays and oxides) accumulating in soils or transported by rivers to the ocean are depleted in Na compared to the source rock, confirming its soluble behavior at the surface of the Earth (Viers et al. 2009). On a global scale, modern large river sediments are between 2 and 10 times depleted in Na compared to upper continental crustal rocks, with Na concentrations ranging from 2000 ppm to 15,000 ppm, on average (respectively, 0.25–2 Na_2O weight%). River sands transported as bed load are usually richer in Na due to the presence of detrital feldspars. In continental weathering studies, Na (soil profiles, modern and ancient sediments) is often used as the most mobile element to which other metal mobilities are compared.

Na in hydrothermal mid-oceanic ridge vents is slightly more concentrated (0.3–0.6 mol/kg) than seawater, indicating that Na is leached out of the oceanic lithosphere when seawater and seafloor interact at high temperature. Less is known about the off-axis low-temperature interaction between seawater and oceanic floor, but Na concentrations in fluids tend to indicate that Na is retained in the secondary minerals formed (Na zeolites, phillipsite smectite, palagonite minerals). This is corroborated by the comparison between fresh and weathered oceanic crust that shows a net gain of Na in the oceanic crust (Staudigel 2014).

In continental hydrothermal settings, Na is generally the most abundant cation in the aqueous phase, also confirming that Na is not significantly controlled by the precipitation of secondary phases.

During the evaporation of seawater in confined conditions, it is possible to precipitate Na in halite (NaCl) when Na reaches a typical concentration of 360 g/L. Halite precipitation is rare on modern Earth. It happens in modern salt marshes but happened massively in the Earth's history during particular periods (e.g., at middle and late Permian in Europe). Rare evaporitic minerals, such as natron (Na_2CO_3, $10H_20$), are also known to precipitate Na from brines in arid settings.

Joly's Sodium Age of the Earth

In a brilliant paper published in 1899, John Joly, an Irish scientist, proposed a method relying on sodium to estimate the age of the ocean and thus of the Earth. By assuming the rate of Na discharged to the ocean has remained constant throughout Earth's history, Joly used the amount of Na in the ocean and its modern delivery yield to the ocean (corrected from cyclic rain salts and evaporite dissolution) to show that the Earth should be 90–100 Myrs (Jackson 2001). We now know that Joly's estimate was not the age of the Earth but rather the residence time of Na in the ocean. He assumed that Na was not reactive in the ocean and was simply accumulating over time. This hypothesis is erroneous and several mechanisms can be invoked to recycle Na from the ocean to either crustal or mantle rocks. The enrichment of Na in the oceanic crust during its interaction with seawater, the episodic formation of saline rocks or its incorporation in authigenic phases ("reverse weathering") and carbonates, or, ultimately, the subduction of Na in the mantle are the main plausible mechanisms explaining the fate of Na in the ocean. There is, finally, a last process able to scavenge oceanic Na, which is the ion exchange with Ca onto clay surfaces occurring when Ca-rich river particles enter into the Na-rich ocean:

$$S - Ca + 2Na^+ = S - Na + Ca^{2+}$$

This mechanism is invoked to ultimately lead to the precipitation of carbonate in the ocean following the continental weathering of Na silicates.

We still lack precise knowledge of the processes scavenging Na from seawater, but it is clear that compared to K and Li, Na is less prone to be reincorporated into secondary phases.

Biological Utilization and Toxicity

Sodium has an important biological role in cell homeostasis and nerve impulse circulation.

Na is an element essential to life. Na is found in the biosphere at concentrations ranging between 10^3 and 10^4 ppm. Human blood contains 1800 ppm of Na (about 1.8 mg/L; Li 2000). It plays an important (together with potassium) role in maintaining the ionic balance in biological tissue and in not only compensating the negative charges of major biopolymers but also in maintaining osmotic pressure and electrical potentials. Very precise mechanisms of Na homeostatic behavior been developed by life, in particular for maintaining the electrical and concentration gradients necessary to produce highly energetic polymers (e.g., ATP). Active specific Na^+ (and K^+) pumps coupled to enzyme ATPase have been discovered that help to maintain the gradients across biological membranes. The circulation of messages in nerve cells of animals also implies the opening of Na^+ (and K^+) channels (Da Silva and Williams 2001).

Summary

Na is a chemical element that has been concentrated in the surface layers of the Earth, due to its affinity for the fluid phase during meting and weathering processes. The ocean is salty, because Na (together with Cl) accumulated over Earth's history which also reflects its very long residence time (80 Myrs). As a consequence of this oceanic abundance, marine and then terrestrial life took advantage of Na and used it as an essential electolyte. The high Na concentration in the interior fluids of terrestrial vertebrates is probably a legacy of the early times of oceanic life.

Soils

Johannes Lehmann
Soil and Crop Science, School of Integrative Plant Science, Cornell University, Ithaca, NY, USA

Definition

Soils constitute the uppermost layer of the Earth. They exhibit pedogenic horizons as a result of physical, chemical, and biological weathering, growth of plants, transformation of minerals, accumulation of organic matter, and microbial and faunal activity.

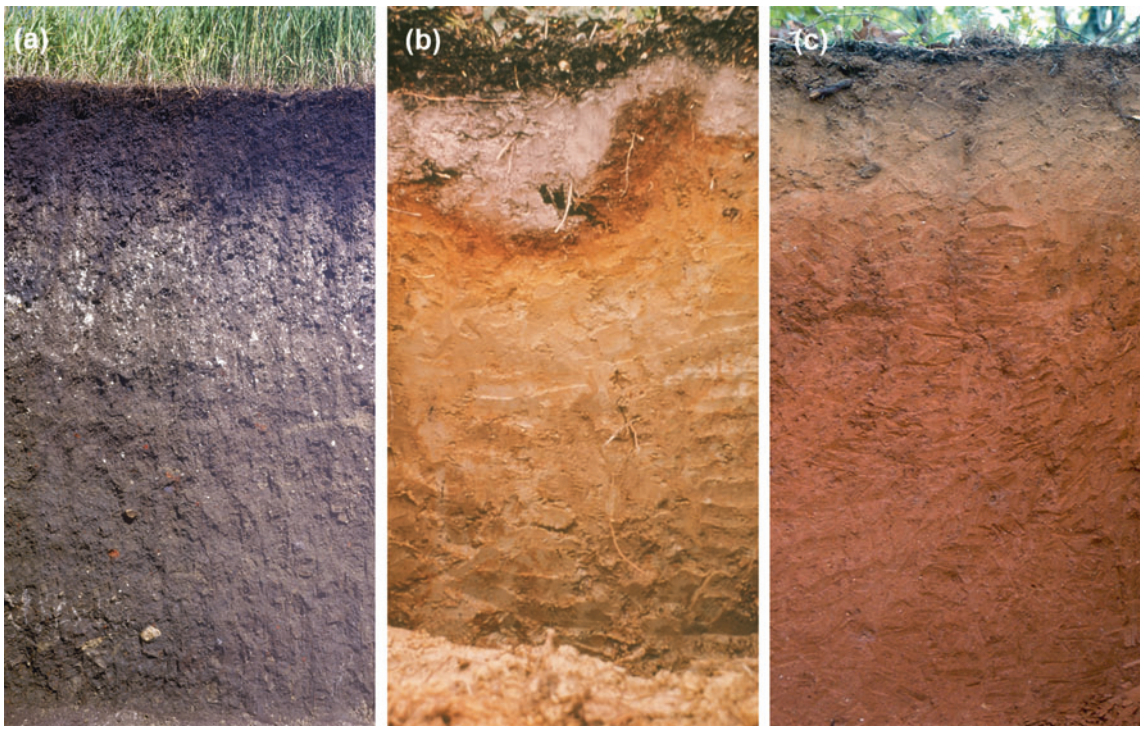
Introduction

Soils are at the nexus of the lithosphere, atmosphere, biosphere, and hydrosphere and therefore a product of a plethora of influences that determine their genesis and properties (Jenny 1941). Soils distinguish themselves from rock by chemical, physical, and biological transformations that lead to the accumulation of organic matter and the activity of microbiota (Weil and Brady 2016). They are distinct from sediments morphologically by the presence of horizons that are formed in situ (Fig. 1), in contrast to layers present in sediments. On the one hand, temporarily or permanently submerged soils exist, for example, in mangrove ecosystems where one would normally expect ocean sediments; on the other hand, soils can develop on sediments, generating transitions between sediments and soils. In comparison, paleosols are not soils but remains of soils in the geological record (Retallack 1988).

Soil horizons are typically divided into organic or O horizons (conventionally abbreviated by letters) overlaying the mineral soil; mineral A horizons with an accumulation of organic carbon or a depletion of minerals (Fig. 1); mineral B horizons with an accumulation of minerals, clay, or organic matter from the A horizon or transformation in situ; and mineral C horizons that are weakly transformed, often only by weathering, and overlay the parent rock material (Weil and Brady 2016). Different classification systems exist (such as the "World Reference Base of Soil Resources," Food and Agriculture Organization of the United Nations and the "Keys to Soil Taxonomy," United States Department of Agriculture) that establish different criteria to distinguish soil types and horizons, either based on how the soil was formed (e.g., the German soil classification system) or what chemical and physical properties it possesses (e.g., the USDA Soil Taxonomy). Soil properties depend on the nature of the rock they develop on, deposition or erosion, climate, vegetation, and time and can vary widely.

Soil Development

Depending on climate, the development to highly weathered soils can take millions of years even in contemporary tropical environments and is best described as an evolution of soils due to inconsistency of soil-forming factors over long periods of time (Huggett 1998). During such evolution, the mineralogy changes from a domination of primary minerals that are a reflection of the underlying bedrock to the formation of phyllosilicates with a stoichiometry of silicon to aluminum of 2:1 such as illites and smectites and of iron oxides such as goethite (Weil and Brady 2016). During further soil development, silicon is predominantly lost, leading to preferential



Soils, Fig. 1 Soil profiles of (**a**) a Mollisol, (**b**) a Spodosol, and (**c**) an Ultisol. Clearly visible are soil horizons with mainly organic matter accumulation in upper A horizons, a depleted E horizon in the Spodosol, and horizons with iron oxide accumulation in B horizons (Photos courtesy of USDA, Natural Resources Conservation Service)

formation of phyllosilicates with a stoichiometry of silicon to aluminum of 1:1 such as kaolinite and of aluminum oxides, until the secondary soil minerals are rich in aluminum and iron oxides. These profound changes in soil mineralogy also affect soil solution chemistry in many different ways. At early stages of soil development, weatherable cations are released, and the soil pH is determined by the parent material ranging from slightly acidic on granitic rock to slightly alkaline on limestone, and soil minerals contain little negative charge that retains cations. In contrast, successively developing 2:1 phyllosilicates such as smectites have large permanent negative charge due to isomorphic replacement of silicon by aluminum, and aluminum by iron, as well as large inner surface areas exposed during expansion of the aluminosilicate layers. The pH is still largely influenced by the parent material, while pH in turn strongly influences ion retention due to variable charge increasing negative charge with higher pH and positive charge with lower pH. Further soil development decreases the pH, increases the sensitivity of surface charge to changes in pH, and reduces the net negative charge. This proceeds until the mineral phase in oxide-rich soils develops net positive charge that does not retain any cations but can retain anions especially in subsoils that are low in organic matter.

As soil mineralogy changes over long periods of time, the release of elements such as phosphorus or calcium declines (Chadwick et al. 1999; Vitousek and Farrington 1997). Atmospheric input can then under some conditions be significant, such as in the proximity of oceans through input by sea spray (Chadwick et al. 1999) or through input of dust even by long-distance transport (Prospero et al. 2002). In addition to changes in mass balances, the interaction between solutes and mineral surfaces changes significantly with soil development and concomitant changes in mineralogy. For example, phosphorus sorption and fixation increases with an increase in iron and aluminum oxides (Vitousek and Farrington 1997), thereby decreasing ecosystem phosphorus availability.

Nitrogen is not to any appreciable extent released by weathering of primary rock. Since nitrogen is an essential nutrient for both flora and fauna and typically needed in large quantities, any soil development requires input of nitrogen from the atmosphere (Vitousek and Howarth 1991). To a great extent, this input is delivered by free-living or symbiotic microorganisms that have the capability to fix atmospheric nitrogen. During initial periods of soil development, plant productivity is primarily limited by nitrogen, whereas it may be more constrained by phosphorus availability in weathered soil. Similarly, sulfur availability is low at initial stages of soil development, but in contrast to phosphorus after these initial changes does not change greatly thereafter (Turner et al. 2016). However, atmospheric inputs from oceans (Turner et al. 2016) and anthropogenic emissions from coal (Lehmann et al. 2008c) can significantly affect isotopic composition, and in the case of coal emissions, organic sulfur forms also on the long term.

Soils and Civilizations

Soils' use and degradation are on many levels intimately connected to the development and decline of human civilizations. The word "human" itself has linguistic roots in the Latin word "humus" for soil, and many religions use imagery of mankind being born out of the Earth and becoming part of it in a cycle of life. In a more practical sense, soil fertility is the foundation for land-based food production. Early civilizations starting at 10,500 years BC began exploring crop and soil management to increase food production as an alternative to hunter-and-gatherer societies (Zeder 2008). The overexploitation of soils leading, for example, to salt accumulation in ancient Babylonia (Jacobsen and Adams 1958) also led to declines in food production and disappearance of what were once large and complex societies. Soil management did not significantly evolve further until the late eighteenth to the mid-nineteenth century when growing scientific insights provided the basis for the concept of nutrient fertilization. It took until the early twentieth century to develop the technology that enabled nitrogen fertilizer production from atmospheric dinitrogen through the Haber-Bosch process when its use started having Earth system impacts on soil productivity. Apart from food production, soils can be credited to have been the source of antibiotics such as streptomycin isolated by Selman Waksman and Albert Schatz in 1943 and of many other substances.

Soil Biota

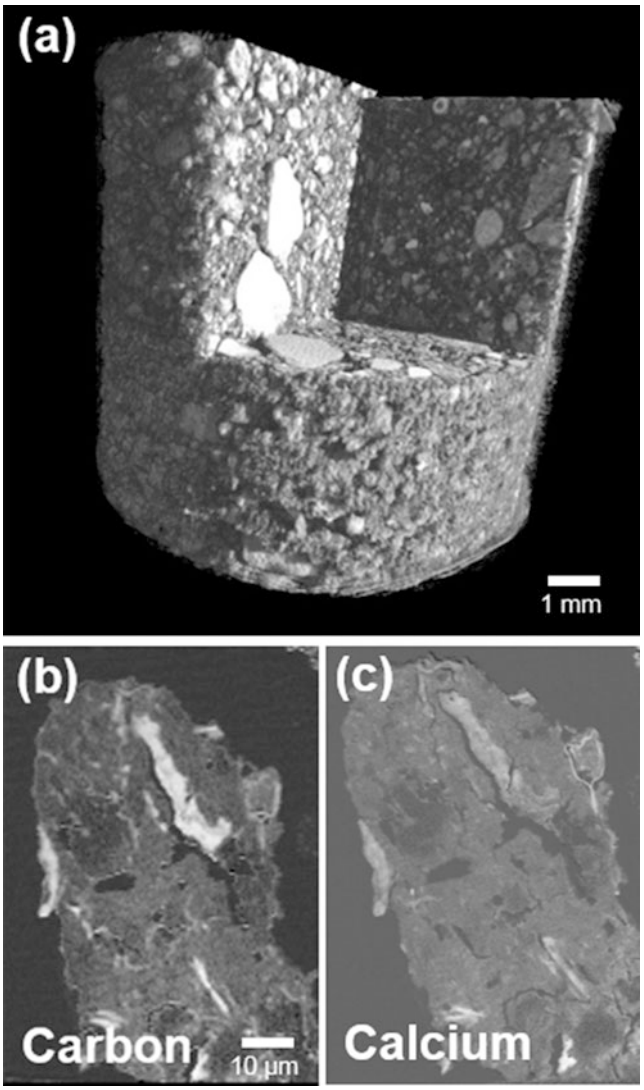
Soils contain a tremendous amount of organisms, including both fauna and flora that build complex food webs with implications for both ecosystem diversity (Bardgett and van der Putten 2014), crop production and food quality (Lakshmanan et al. 2014), and human health (Wall et al. 2015). One gram of a given soil harbors millions of species of microorganisms, and billions of living organisms, mainly bacteria and fungi. Knowledge of soil biodiversity and resultant biogeochemistry is limited, but it is clear that biodiversity varies globally as a function of pH, climate, vegetation, and soil management (Fierer and Jackson 2006). However, clear biogeographical patterns across biomes do not seem to exist as for aboveground plant and animal composition which also implies a certain degree of de-coupling between above- and belowground biodiversity at a global scale (Bardgett and van der Putten 2014). On the scale of an individual soil, biota composition varies widely between topsoil and subsoil or over the course of a year. On an even smaller scale of

millimeters, soils are very heterogeneously populated by microorganisms as a function of soil architecture (Fig. 2a; Young and Crawford 2004), despite the large amounts of organisms per unit mass.

Soil Organic Matter

An even greater heterogeneity can be observed for soil organic matter at the relevant scale where biogeochemical processes occur (Fig. 2b and c; Lehmann et al. 2008a). Organic matter properties vary greatly between different locations in microaggregates (Milne et al. 2011), and the average organic matter composition of a soil sample does not represent the properties observed at the scale of nanometers (Lehmann et al. 2008a) as a result of different biotic and abiotic processes dependent on micro-location. Therefore, bulk soil properties of organic matter are irrelevant for evaluating soil organic matter cycling that is controlled by access of microorganisms and their enzymes to organic matter adsorbed to mineral surfaces or entrapped in aggregates and small pores (Kleber et al. 2015). On a global scale, both climate and soil mineralogy appear to be important determinants of soil carbon storage (Doetterl et al. 2015).

Soils are important for key functions of terrestrial ecosystems such as the provision of clean water and regulation of climate in addition to many other biogeochemical cycles. Soils contain three times more organic carbon than is present in the world's plants and as carbon dioxide in the atmosphere combined. The organic matter in soils is therefore a globally important ecosystem property for food security, water quality, and the climate. Soil organic matter is progressively decomposed and can be seen as a continuum ranging from large biomolecules of plant and animal origin to small decomposition products to carbon dioxide (Lehmann and Kleber 2015). The residence time of an organic molecule is less a function of its intrinsic chemical composition than a result of its solubility, adsorption to soil minerals, encapsulation in soil aggregates, the decomposer community, other energy (e.g., additions of organic matter) and electron donor/acceptors, moisture content, and temperature, among others.



Soils, Fig. 2 High spatial heterogeneity in soil shown for (**a**) the soil physical assemblage (Young and Crawford 2004), (**b**) soil carbon (Lehmann et al. 2008a), and (**c**) soil calcium (Solomon et al. 2012) (*white areas* in (**b**) and (**c**) indicate higher amounts of the target element) (With permission from the publishers)

Fire and Soil

Vegetation fires are part of the Earth's system that are both natural and anthropogenic and have profound direct and indirect effects on soil properties and processes. Direct heat oxidizes organic matter, destroys soil biota, and changes soil mineralogy (Certini 2005). Indirectly, combustion residues such as ash increase soil pH as well as constitute an input in base cations and phosphorus. Thermally decomposed organic matter, called pyrogenic organic matter, augments persistent organic matter in soils (Lehmann et al. 2008b), increases cation retention (Liang et al. 2006), and may change cycling of biologically transformed organic matter in a process often referred to as "priming" (Woolf and Lehmann 2012).

Soil Erosion

Erosion of soil is both a natural landscape process and influenced by human activity (Amundson et al. 2015). Erosion typically removes topsoil on upper and middle slope positions and deposits it at foot slopes or exports it to streams where it may form stream or lake sediments or enter the oceans. Erosion is mainly seen as a loss of organic matter and soil fertility

(Montgomery 2007) but also as a sink of organic matter through its eventual burial (Van Oost et al. 2007) and as an input of nutrient-rich runoff (Nixon 2003). Subsoils have also only recently been recognized as containing important sources of nutrients (Lehmann 2003) and serving as an important sink of atmospheric carbon dioxide (Marin-Spiotta et al. 2014).

Soil Contamination

Anthropogenic contamination of soil is a relatively recent phenomenon in the Earth's history. Agrochemicals such as pesticides and herbicides, but also atmospheric emissions of polycyclic aromatic hydrocarbons (PAH), lead, sulfates, and nitrates, as well as direct input of dioxins, petroleum, pathogens, heavy metals, arsenic, polychlorinated biphenyls (PCB), endocrine disruptors, nanoparticles, and others may cause various human and ecosystem health issues. In some cases, however, contamination can also have natural sources, such as with arsenic originating from weathering of arsenic-rich rock, transport with ground water, and uptake into crops (Smith et al. 2000). Both the uptake into food crops and the transport to ground and surface waters are of concern and depend on retention by various adsorption mechanisms to the soil matrix as well as in the case of organic contaminants the metabolization by microorganisms. Decontamination is often difficult to achieve and may involve phytoremediation (Lasat 2002), leaching with or without added solutes, remediation using microbial additives, and mechanical barriers (Mulligan et al. 2001a, b).

Future Soil Management

Managing the diverse ecosystem services that soils provide poses a challenge in a world with greater population, greater demand on food production, and more diverse expectations such as for soils to contribute to climate change mitigation and water quality (Keesstra et al. 2016). Balancing these demands requires all stakeholders to be involved and appropriate market incentives to be developed (Tilman et al. 2002). The current renewed recognition of the importance of soil will only be successful in addressing global change challenges if the vast variability of its properties will be recognized at spatial scales from an individual molecule to the global scale and temporal scales from minutes to millions of years. Modern information technology is required to implement site- and time-specific management built on the best available science.

Summary

Soils form the upper layer of the Earth' crust and develop different properties over time depending on parent geological material, climate, vegetation, and management. On small scales where microbial or abiotic processes occur, soils are highly variable and constitute a highly dynamic system for organic matter stabilization and nutrient availability. Historically, soils provided the foundation for the development of human civilization and continue to provide key ecosystem services to sustain food production, water quality, and climate stability.

Definition

By analogy with aqueous solution, a solid solution, sometimes called mixed crystal, is defined as an homogeneous solid-state solution of one or more solutes in a solvent. Its composition may vary in a more or less wide range of compositions, between extreme values which correspond to pure solids, known as its end-members. At variance with a mechanical mixture in which the components are mixed but not chemically bonded, mixing in a solid solution occurs at the atomic level, generally by substitution of one type of atoms by another on the same lattice. Many metal alloys, oxides, and silicates are substitutional solid solutions, but solid solutions may also be formed by insertion of foreign atoms at interstitial sites in the host crystal (interstitial solid solutions) or by loss of atoms in nonstoichiometric compounds (omissional solid solutions). The importance of solid solutions comes from the synergistic properties that they may display compared to their end-members and to their ubiquity in the natural environment.

In some cases, an homogeneous SS may become unstable with respect to its components, and phase separation, also called demixing or exsolution, may occur. More precisely, exsolution is the processes of separation of an initially homogeneous solution phase (liquid or solid) into two compositionally different immiscible phases. This process may be triggered by pressure, temperature, or composition changes but mostly by the two former for solid phases which show little volume change upon pressure.

Introduction

Solid solutions (SSs) are often encountered in chemistry, in metallurgy, as well as in the earth sciences: mineralogy, petrology, or geochemistry. In metallurgy, alloying elements are added to metals to improve their strength and their hardness or their resistance to corrosion. In the natural environment, compared to pure minerals, mixed minerals are the generality rather than the exception. Indeed, the formation of SSs is often thermodynamically preferred over the separate formation of their end-members, as can be judged by the frequent incorporation of trace elements in minerals; the ubiquity of complex oxides, silicates, or carbonates; and the scarcity of pure minerals (see Trace Elements, Clay Minerals, Oxide Minerals, Silicate Minerals, Carbonate Minerals). Two main processes lead to the formation of SSs: condensation from a melt or precipitation from a supersaturated aqueous fluid. Understanding SS formation conditions may bring insight into global element cycles, composition of natural waters, and diffusion of elements in contaminated soils and may be useful to try reconstructing past conditions.

In substitutional SSs, the process of mixing relies on the existence of local interactions between substituent (solute) and host atoms. In order that mixing takes place at the atomic level, several conditions have to be fulfilled:

- The crystal structure of the solvent should remain unchanged upon addition of the solute. End-members should thus have the same atomic structure.
- The substituting and host ions should have ionic radii differing by less than ≈15% (Hume Rothery rule) (see Ionic Radii).
- For single substitutions, the substitution has to be isoelectronic (replacing ion of the same valence as host ion). For multiple substitutions, global electric neutrality requires a coupling between charges and molar fractions. For example, substitution of Si by Al in the tetrahedral sites of phyllosilicate minerals requires a correlated charge compensation in the interlayer space or in the octahedral sites.
- The chemical affinity of host and solute atoms should be low; otherwise defined compounds are formed rather than solid solutions.

If these conditions are not fulfilled, SSs are restricted to a composition range of a few percents. Conversely, SSs which exist in a large composition range are usually made from elements which are close to each other in the periodic table.

Depending on the sign and strength of the interatomic interactions, fully disordered SSs, SSs with short-range order or defined compounds with long-range order, may form. In some instances, phase separation may take place, for example, leading to exsolution upon cooling. Simple models of mixing account for all these possibilities and allow deriving generic phase diagrams as a function of the thermodynamic conditions (temperature, pressure, composition, contact with an aqueous solution) and discussing out-of-equilibrium processes.

Mixing Properties of Substitutional Solid Solutions

The thermodynamic state (molar volume V, entropy S, enthalpy H, Gibbs free energy G) of a SS of the $A_{1-x}B_xC$ type is conveniently characterized with respect to the thermodynamic functions of its pure end-members AC and BC (McGlashan 1979) (see Geochemical Thermodynamics). When no chemical interaction takes place at the atomic level, which is the case of a *mechanical mixture*, these quantities are obtained by simple linear interpolation between those of the end-members, weighted by their respective mole fractions $X_{AC} = 1 - x$ and $X_{BC} = x$. For example, the molar volume of a mechanical mixture is equal to $V_{M\,M} = X_{AC}\,V_{AC} + X_{BC}\,V_{BC}$, which is the expression of Vegard's rule, and its Gibbs free energy is equal to $G_{M\,M} = X_{AC}\,G_{AC} + X_{BC}\,G_{BC}$.

When solution takes place, the linear relationship between the SS thermodynamic functions and those of its end-members no longer holds. Mixing quantities (ΔV_M, ΔS_M, ΔH_M, ΔG_M) are then defined by difference between V, S, H, and G and those of the mechanical mixture, e.g., $\Delta G_M = G - X_{AC}\,G_{AC} - X_{BC}\,G_{BC}$.

A first contribution to ΔG_M, of entropic origin, arises due to the disorder induced by the substitution. In the case of full randomness, it expressed as (R the gas constant):

$$\Delta S_M^{id} = -R(X_{AC}\ln X_{AC} + X_{BC}\ln X_{BC}) \qquad (1)$$

ΔS_M^{id} is a positive quantity, which lowers $\Delta G_M = \Delta H_M - T\,\Delta S_M$ (T the temperature) and thus stabilizes the SS with respect to the mechanical mixture in the whole compositional range. When ΔG_M has no other contribution than ΔS_M^{id}, the SS is said to be *ideal* (hence the superscript *id*).

However, very few SSs are ideal, as shown by numerous results of advanced calorimetric and diffraction methods (Geiger 2001; Navrotsky 2014) (see Calorimetry). This stems from so-called *excess* mixing terms, including entropy as well as enthalpy contributions. The excess mixing entropy includes the vibrational entropy and a contribution due to the decrease in the number of accessible configurations with respect to perfect randomness when short-range order exists (Benisek and Dachs 2012). The excess mixing enthalpy involves elastic and chemical terms. The elastic one, always positive, results from the lattice distortions associated to mixing which increases the internal energy of both end-members. The chemical term is associated with effective

interactions between substituent and host atoms. They are both accounted for in the following polynomial expansion of ΔH_M proposed by Guggenheim (1937) for *non-ideal* SSs:

$$\Delta H_M = X_{AC}X_{BC}A_0 + X_{AC}X_{BC}(X_{AC} - X_{BC})[A_1 + A_2(X_{AC} - X_{BC}) + \ldots] \quad (2)$$

The first term relies on the number and strength of each type of nearest-neighbor bond. Its constant A_0 depends on the energy difference between chemical bonds connecting identical or distinct species $A_0 \propto 2W_{A-B} - W_{A-A} - W_{B-B}$. Usually, the largest contribution comes from the nearest neighbors, but longer-range interactions can also be included in this term. Multi-body interactions (triplet, quadruplet, etc.) are accounted for in the higher-order terms A_1, A_2, and so on. ΔH_M varies with temperature but usually more weakly than ΔS_M^{id}.

Aside from experimental methods to determine mixing properties, the huge development of numerical simulations in the last decades has allowed calculations of alloy thermodynamic properties such as short-range order in SSs and composition-temperature phase diagrams. A methodology, known as the cluster expansion method (Kikuchi 1951; Ducastelle 1991; Vinograd and Winkler 2010), consists in parametrizing the energy of an alloy under the form:

$$E = \sum_i g_i J_i (\Pi_j p_j) \quad (3)$$

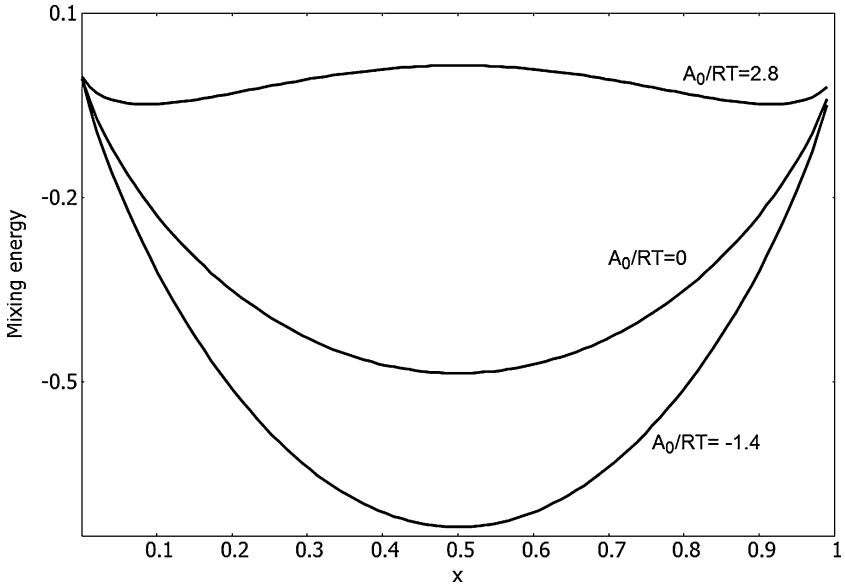
in which the index i scans all existing pairs (in which case, j takes two values), triplets (j takes three values), etc., of degeneracy g_i associated to occupation numbers $p_j = \pm 1$ in the configuration upon consideration. The coefficients J_i of the cluster expansion are determined by fitting them to the energy of a relatively small number of configurations obtained through first-principle computations (see Density Functional Theory). The convergence of the expansion is usually rapid. Only a few terms representing pairs and small triplets are necessary to obtain good accuracy on thermodynamic properties.

The cluster expansion method gives a rationale for the Guggenheim expansion. However, the latter is a mean field approximation in which the probability of finding an AB pair is replaced by the (uncorrelated) product of site probabilities X_{AC} or X_{BC}. Going beyond such an approximation, for example, by using Monte Carlo approaches, based on the cluster expansion Hamiltonian, Eq. 3, is necessary to account for fluctuations of probabilities around their mean values and for possible ordered phases (van de Walle and Asta 2002).

When only the first term in the Guggenheim expansion is important, i.e., when the strength of the interactions is independent on composition, the SS is said to be *regular*, and ΔG_M is symmetric with respect to $x = 0.5$. Depending on the sign and the value of A_0, ΔG_M displays a single minimum ($A_0/RT < 2$) or two minima ($A_0/RT > 2$), as shown in Fig. 1.

SSs which require two terms in the polynomial expansion of ΔH_M (so-called two-parameter Margules model) are called *sub-regular* SSs. The A_1 term accounts for a linear dependence of the interactions on composition. It yields an asymmetry of ΔG_M with respect to $x = 0.5$. In the infinite dilution limits, $A_0 + A_1$ and $A_0 - A_1$ represent the solubilities of B in pure AC and A in pure BC, respectively (see Solubility).

The chemical potentials μ_i of the end-members (i = AC or BC) in the SS are derived from the knowledge of the molar Gibbs free energy $G = \Sigma_i \mu_i X_i$, as:



Solid Solution/Exsolution, Fig. 1 Composition dependence of the mixing Gibbs free energy of a regular SS for three values of $A_0/RT = -1.4$, 0 and +2.8

$$\mu_i = G + (1 - X_i)\left(\frac{\partial G}{\partial X_i}\right)_{P,T} \quad (4)$$

and this allows determining their activities a_i (see Activity and Activity Coefficients) through the relationship $\mu_i = G_i + RT$ Ln a_i (Neperian logarithm). For a given composition of the SS, μ_{AC} and μ_{BC} can be graphically read at the intersections of the tangent to the G curve at $x = 0$ and $x = 1$, respectively (Fig. 2, left panel). The activity coefficients $\gamma_i = a_i/X_i$ of the end-members in the SS are equal to 1 in ideal SSs, and their deviation from 1 evidences the existence of excess terms of mixing in the Gibbs free energy. Following Redlich-Kister, they read (Glynn 1991):

$$\begin{aligned} RT\ln\gamma_{AC} &= X_{BC}^2(A_0 + A_1(3X_{AC} - X_{BC}) + \ldots) \\ RT\ln\gamma_{BC} &= X_{AC}^2(A_0 - A_1(3X_{BC} - X_{AC}) + \ldots) \end{aligned} \quad (5)$$

These concepts may be generalized to the case of multiple substitutions. For example, when the two substitutions occur on different sites and are uncoupled, the solid solution, of generic chemical formula $A_{(1-x)(1-y)}B_{x(1-y)}C_{y(1-x)}D_{xy}$, has four end-members (A, B, C, D), associated to molar fractions $X_A = (1 - x)(1 - y)$, $X_B = x(1 - y)$, $X_C = y(1 - x)$, and $X_D = xy$. The molar fractions are linked not only by the usual relationship $X_A + X_B + X_C + X_D = 1$ but also by the cross product equality $X_A X_D = X_B X_C$, which results from the fact that there are only two independent composition parameters (x and y). Such solid solutions are referred to as *reciprocal* solid solutions. Contrary to the case of a single substitution, they are non-ideal with end-member activity coefficients different from 1 (Ganguly 2001), even when the mixing in each site is ideal, i.e., when ΔG_M only involves the ideal mixing entropy term:

$$\Delta S_M^{id} = -R(x\ln x + (1-x)\ln(1-x) + y\ln y + (1-y)\ln(1-y)) \quad (6)$$

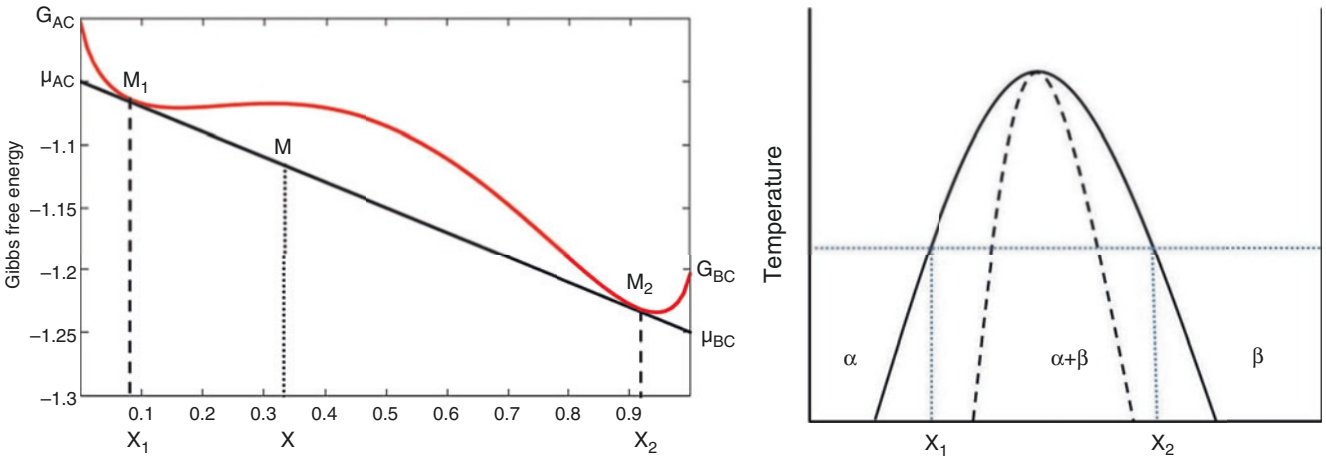
Temperature-Composition Phase Diagram

Igneous rocks are formed when a magma or a lava cools and solidifies. Metamorphic rocks, for their part, result from the transformation of existing rocks when they are subject to heat and/or pressure. SSs are often encountered in these cases. The phases in presence, once thermodynamic equilibrium has been reached, can be read on a temperature-composition $T - x$ phase diagram, directly derived from the canonical ensemble expression of G discussed previously (see Phase Equilibria).

Thermodynamic Equilibrium

When the mixing Gibbs energy is negative and displays a single minimum as a function of composition, as in the case of ideal or weakly non-ideal SSs, an homogeneous mixing is energetically favorable over a mechanical mixture, and a SS exists in the whole composition range.

When ΔG_M displays two minima, as in the case of strongly non-ideal mixing, there exists a composition range $x_1 < x < x_2$, called the *miscibility gap*, in which an homogeneous SS is unstable with respect to the coexistence of two immiscible SSs α and β of compositions x_1 and x_2. Phase separation thus takes place. For such a process to be thermodynamically stable, the chemical potentials of the end-members μ_i (i = AC or BC) have to be equal in the two phases: $\mu_i^\alpha = \mu_i^\beta$. This requirement



Solid Solution/Exsolution, Fig. 2 Left panel: Composition dependence of the Gibbs free energy of a strongly non-ideal regular SS at fixed temperature T ($A_0/RT = +2.8$). The plain straight line is the common tangent to ΔG_M, marking the limits of the miscibility gap $x_1 < x < x_2$. Right panel: Typical phase diagram of a strongly non-ideal SS. The region of the miscibility gap is delineated by the solvus (plain line). The spinodal line is represented by a dashed line

graphically defines the compositions x_1 and x_2 of the α and β SSs as the abscissa of the points of common tangent to the G curve (Fig. 2, left panel). The locus of these points when temperature varies is called the *solvus* (Fig. 2, right panel). For a given average composition x of the solid phase, the proportions Q_α and Q_β of the α and β phases are given by the ratios MM_2/M_1M_2 and MM_1/M_1M_2 of the tangent segments represented in Fig. 2, respectively (lever rule). When T increases at fixed pressure, the miscibility gap generally becomes narrower, because the negative contribution to G coming from the ideal entropy term increases (in absolute value) much more rapidly than the positive enthalpic contribution. Beyond a critical temperature T_M, called the *upper consolute temperature*, the region of phase coexistence vanishes, and the components of the mixture are soluble in all proportions.

The generic phase diagram displayed in Fig. 2 is highly simplistic, since only two ordered phases are considered (the end-members). The phase diagrams of metallic alloys, for example, often involve several ordered phases and several regions of miscibility gaps between them and SS phases with various compositions. Mixed carbonate minerals may also display more complex phase diagrams, the most famous example being the calcite-magnesite system with the ordered dolomite phase at 50% composition. Several numerical codes allow calculation of the phase diagrams of binary systems, e.g., the ATAT code (van de Walle 2017) and the OpenCalphad code (Fries 2013).

Exsolution Process

When a SS which is homogeneous in the temperature range $T > T_M$ enters the region of a miscibility gap, phase separation, also called demixing or exsolution, occurs. Exsolution begins at the atomic scale, but as it continues, the exsolved phase usually forms irregular patterns (lamellae, films or patches), depending on the region of the miscibility gap in which it takes place. A special curve, called *spinodal* (Fig. 2 right panel), which connects the inflection points of G inside the miscibility gap (condition $\partial^2 G/\partial x^2 = 0$), separates the latter in two regions in which the early composition fluctuations leading to exsolution are either periodic or exponentially decaying in space.

Most minerals exsolve upon appropriate conditions of temperature, pressure, and composition, e.g., feldspars, pyroxenes, amphiboles, micas, oxides, carbonates, and sulfides (e.g., Schumacher 2007). For example, the important group of feldspars, to which belong the most abundant phases of igneous rocks, can be described in the ternary solid solution system: albite $NaAlSi_3O_8$, microcline $KAlSi_3O_8$, and anorthite $CaAl_2Si_2O_8$. Albite-microcline SSs, called alkali feldspars, which are formed at high temperature, easily exsolve at low temperature, each end-member being only able to substitute a small amount of the other alkali ion. At variance, plagioclases, which are also formed at high temperature, do not exsolve. All intermediate compositions are known between their end-members albite and anorthite. These feldspar SSs play an important role as components of granitic rocks and major contributors to hydrothermal alteration or weathering processes at lower temperature.

The process of exsolution of a SS may be used in solvus geothermobarometry (see Geothermometry and Geobarometry), due to the sensitivity of the exsolved phase composition to temperature and pressure. Data on geothermometers are derived from both laboratory studies on artificial mineral assemblages, where minerals are grown at known temperatures and pressures and the chemical equilibrium measured directly, and from calibration using natural systems. They also require a theoretical thermodynamic understanding of the components and phases involved. The measurements and interpretation are not straightforward and may lead to noticeable uncertainties, because it is difficult to assess if a system has truly reached thermodynamic equilibrium. Moreover, the synthesized minerals are difficult to characterize due to their often poor crystallinity and their submicrometer sizes.

Solid Solutions Formed by Precipitation from a Supersaturated Aqueous Fluid

Another important class of SS formation processes concerns the precipitation from a supersaturated aqueous solution (AS) (see Aqueous Solutions). At variance with results obtained in the canonical ensemble (fixed P, T, and composition), the mean composition of a SS in equilibrium with a multicomponent aqueous medium is not a priori fixed but depends on the composition of the AS, which may change if external conditions do so (Glynn and Reardon 1990; Prieto 2009). In natural solutions, a large number of chemical elements are usually present which may participate to the formation of secondary minerals, either as major constituents or as trace elements in solid solutions. Clay minerals which are very commonly produced in geochemical systems (weathering sequences, hydrothermal alterations, diagenetic transformations) are striking examples of SS phases formed in the presence of an AS. They display large composition variability, by substitution in their skeleton (tetrahedral and octahedral sites) and/or cation exchange in their interlayer space (see Fluid-Rock Interactions, Hydrothermal Alteration, Weathering: Chemical). Clays as well as other SSs share the major property of being able to adapt their composition to the evolution of the fluid composition as a function of time (Tardy and Fritz 1981).

Thermodynamic Equilibrium

As a general statement, a solid of fixed composition is in equilibrium with an AS when their chemical potentials are

equal. The chemical potential of the relevant ions in the AS is equal to $\mu_{\text{ions}} = RT\ln(IAP)$, with IAP the ion activity product, and the chemical potential of the solid phase is equal to its Gibbs energy per mole, which defines its solubility product K: $\mu_{\text{solid}} = RT\ln K$ (See Solubility). Equilibrium is thus reached when $K = IAP$, or equivalently, when the saturation state of the AS with respect to the solid $I = IAP/K = 1$.

The generalization of this condition to a binary SS $A_{1-x}B_xC$ in equilibrium with an AS involves two conditions, one for each end-member i (i = AC or BC), stating that their chemical potentials are equal to the chemical potential of their corresponding ions in the AS. Using the expression $\mu_i = G_i + RT\ln X_i\gamma_i$ and introducing the solubility products K_i of the end-members and the saturation states I_i of the AS with respect to them, the conditions for thermodynamic equilibrium are:

$$\begin{aligned} I_{AC} &= (1-x_0)\gamma_{AC}(x_0) \\ I_{BC} &= x_0\gamma_{BC}(x_0) \end{aligned} \tag{7}$$

Numerical codes, like KINDIS (Madé et al. 1994) or PHREEQC (Parkhurst and Appello 2013), allow the determination of the SS characteristics in equilibrium with an aqueous solution.

Equation 7 shows that, while a BC compound would not form as a pure phase in a highly undersaturated AS ($I_{BC} \ll 1$), B ions may easily be incorporated as trace elements in the substitutional sites of an AC compound, if the AS is nearly saturated with respect to the latter ($I_{AC} \simeq 1$). This illustrates why most mineral phases produced in natural systems are not pure end-members. Conversely, quasi pure phases are strong indicators of the composition of the fluids that produced them and may be an indicator of paleo-conditions.

Stoichiometric Saturation State

Thermodynamic equilibrium conditions (Eq. 7) are equivalent to saying that the stoichiometric saturation state $I(x)$ of the AS with respect to the SS of composition x is simultaneously equal to 1 and maximum with respect to x. This can be proved by considering the stoichiometric solubility product $K(x)$ of the SS, equal to:

$$K(x) = K_{AC}^{1-x}K_{BC}^{x}\exp\left(\frac{\Delta G_M}{RT}\right) \tag{8}$$

and writing $I(x) = IAP/K(x)$, i.e.:

$$I(x) = \left[\frac{I_{AC}}{(1-x)\gamma_{AC}(x)}\right]^{1-x}\left[\frac{I_{BC}}{x\gamma_{BC}(x)}\right]^{x} \tag{9}$$

When only the condition that $I(x)$ is maximum with respect to x is fulfilled, one speaks of the *stoichiometric saturation state*. It amounts to considering the SS with respect to which the AS is the most supersaturated (Prieto 2009). Its composition x_{st} obeys the implicit equation:

$$\frac{I_{AC}}{(1-x_{st})\gamma_{AC}(x_{st})} = \frac{I_{BC}}{x_{st}\gamma_{BC}(x_{st})} \tag{10}$$

It obviously only depends on the composition of the AS through the quantity $W = I_{BC}/I_{AC} = [B]K_{AC}/[A]K_{BC}$, proportional to the ratio of activities of the exchangeable ions. Equation 10 has no analytic solution. However, it can be solved numerically quite easily for regular and sub-regular SSs (Noguera et al. 2016). It has a single root whenever ΔG_M displays a single minimum and three roots if ΔG_M has two minima. The number of solutions of Eq. 10 thus only depends on the values of the coefficients A_0 and A_1 in the Guggenheim expansion of ΔH_M.

When Eq. 10 has three roots, two correspond to a minimum of $I(x)$ and one to a maximum. Of the two minima, the one which is relevant is associated to the lowest Gibbs free energy of the system (lowest value of $-\ln I(x)$). Because the $I(x)$ curves associated to the three roots cross each other, a discontinuity in x_{st} between two values x_1 and x_2, characterized by the same Gibbs free energy, takes place for some specific value of W, as shown in Fig. 3. The discontinuity $x_2 - x_1$ marks the existence of a miscibility gap, which increases as the SS becomes more and more non-ideal. In this representation, W combines the information on the AS composition and on the solubility products of the end-members, in a more compact way than the (equivalent) classical Roozeboom plot (Mullin 1993) which displays x_{st} as a function of $[B]/([A]+[B])$ but requires one curve for each K_{BC}/K_{AC} ratio.

Out-of-Equilibrium Processes

The stoichiometric saturation state does not fully characterize thermodynamic equilibrium, but its characteristics are useful to approach nucleation and growth processes (see Crystal Growth).

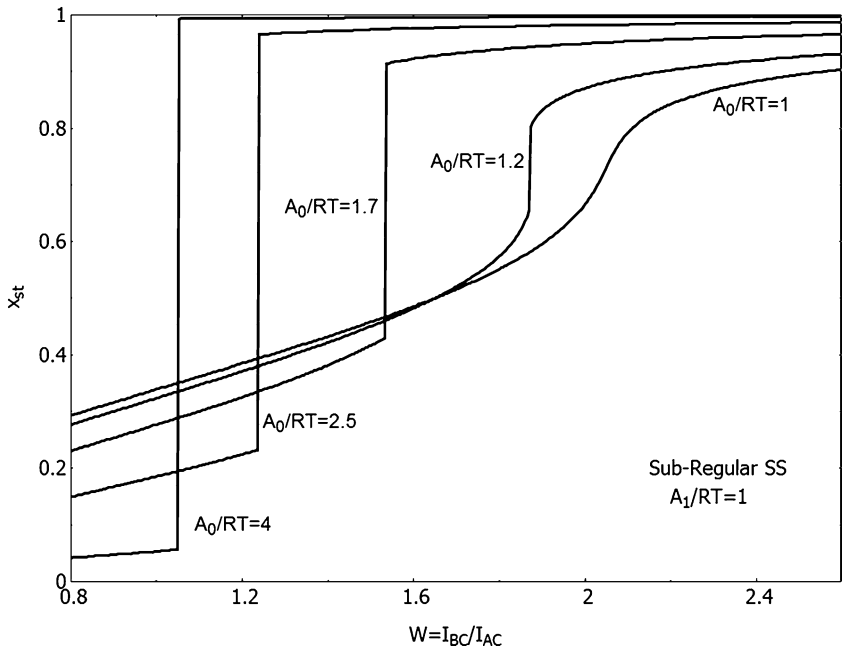
Within the classical nucleation theory, assuming that the SS surface energy σ and molar volume v are weakly dependent on composition, the change in Gibbs free energy in the formation of a SS nucleus of composition x and containing n formula units reads (k_B the Boltzmann constant and X a shape factor) (Markov 1995; Noguera et al. 2016):

$$\Delta G(n,x) = -nk_BT\ln I(x) + n^{2/3}v^{2/3}X\sigma \tag{11}$$

When $I(x) > 1$, $\Delta G(n,x)$ displays a maximum as a function of n, which defines the nucleus size and the barrier $\Delta G_m(x)$ to overcome for its nucleation:

$$\Delta G_m(x) = \frac{4X^3\sigma^3v^2}{27(k_BT\ln I(x))^2} \tag{12}$$

S



Solid Solution/Exsolution, Fig. 3 Representation of the relationship between a sub-regular SS composition x_{st} and $W = ([B]K_{AC})/([A]K_{BC})$, which characterizes the AS composition, for $A_1/RT = 1$ and various values of the Guggenheim parameters A_0/RT. When $A_0/RT \gtrsim 1.15$, the x_{st} curve displays a discontinuity

The composition x^* of the critical nuclei is then determined by the condition that the nucleation barrier is minimum with respect to x, leading to a maximum of the nucleation frequency. Since, according to Eq. 12, this amounts to finding the maximum of $\ln I(x)$, the composition of the critical nuclei is equal to x_{st}. A similar reasoning can be applied to the composition of the incremental growth layers, when growth is limited by surface reactions.

Since the composition of an AS may vary with time, either because external conditions change (temperature or seasonal cycles) or in a closed system due to the precipitation process itself, x_{st} is also due to depend on time. Time variations of the particle composition thus usually occur, which leads either to a change in the average composition (if solid-state diffusion is efficient) or to composition inhomogeneities inside the particles (composition profiles) when solid-state diffusion does not occur. Considering the typical evolution of x_{st} as a function of the AS composition W as shown in Fig. 3, the composition profiles are smooth in ideal or weakly non-ideal SSs, while they display a discontinuity for strongly non-ideal SSs. Except under very specific conditions, W does not remain fixed at the critical value of the discontinuity during the precipitation process so that demixing is much less likely than in processes at constant T, P, and x conditions. Numerical codes like KINDIS (Madé et al. 1994) or NANOKIN (Noguera et al. 2010) account for the kinetics of precipitation of SSs under various approximations.

The specificity of SS dissolution kinetics has not been considered in details so far. In dissolution processes, SSs are generally assumed to be defined compounds with a fixed composition inherited from their formation conditions. This assumption overlooks the existence of a distribution of compositions inside the particle population and the existence of composition profiles inside each particle. Moreover, when equilibrium is approached, the activity ratio of the ions released in the AS is likely closer to that in the solid phase than to the one required in the AS for thermodynamic equilibrium. The way equilibrium can be reached thus remains an open question.

Summary

Solid solutions are ubiquitous in the natural environment, due to the existence of multicomponent fluids (aqueous solutions or melts) from which they form. Their major property is their ability to continuously adapt their composition as the fluid composition evolves in time. Their phase diagrams may involve homogeneous phases in part or in the whole concentration range and regions of phase separation. Incorporation of trace elements is often thermodynamically easy, which explains the scarcity of pure minerals, particularly those formed at low temperature and pressure. While the description of their mixing properties and their equilibrium properties has greatly improved in the last decades, both experimentally and theoretically, much remains to be done to account for the kinetics of their formation and dissolution.

Solubility

Jean-François Boily
Department of Chemistry, Umeå University, Umeå, SE, Sweden

Definition

Solubility is the maximal quantity that a substance can dissolve as a solute in a host solvent, forming a saturated solution. Any additional quantity occurs as a precipitate and results in a suspension of particles. Solubility is expressed in terms of concentration units for a given temperature and pressure.

Introduction

Solubility is an essential concept needed in many areas of geochemistry to describe the ability of gases (g), liquids (l), or solids (s) to dissolve in substances. The resulting solutions are homogeneous mixtures of two or more substances, where the solvent is typically, although not necessarily, one of high mole fraction and the solute of lower mole fractions. Examples include the dissolution of sodium chloride (halite) in water, or of water in magmas. In contrast to miscibility where

substances can mix in all proportions (e.g., water and ethanol), solubility pertains to the maximal quantity that can be accomodated by the host solvent. This quantity is predominantly one determined by laboratory experiments, explained by molecular details of solute–solvent interactions, and predicted by thermodynamics.

The concept of solubility is essential for understanding and predicting numerous forms of mass transport processes in fluids of Earth's surface and subsurface. Examples include fluid flow in geothermal systems and ore deposits, diagenesis, secondary porosity generation in sedimentary basins, contaminant transport in aquifers, as well as injection of supercritical CO_2 in geological storage sites and remediation of contaminated sites. The concept is also needed in experimental simulations of geochemical reactions, such as in the study of mineral growth, nucleation and dissolution, as well as in laboratory (e.g., preparation, purification) procedures and analytical determination of natural samples. This concept is even needed in molecular simulations of geological fluids for determining the maximal number of ions that can be realistically inserted into a box of solvent molecules.

Solubility is expressed as a concentration for a given temperature and pressure. The mass fraction (w_i) of solute *i* in solvent *solv* is given by:

$$w_i = \frac{s_i}{s_i + s_{\text{sol}}} \tag{1}$$

where s_i and s_{solv} are respectively the masses of the solute and of the solvent. Other concentration units relate to w_i through:

$$[i] = 1000\,\rho_{\text{solv}}\,\frac{w_i}{M_i} \quad \text{for Molarity} \tag{2}$$

$$m_i = 1000\frac{w_i}{M_i(1-w_i)} \quad \text{for Molality} \tag{3}$$

$$x_2 = \frac{w_i}{M_i}\left(\frac{w_i}{M_i} + \frac{1-w_i}{M_{\text{solv}}}\right)^{-1} \quad \text{for mole fraction} \tag{4}$$

$$r_i = 100\frac{w_i}{1-w_i} \quad \text{for mass of solute per 100 g water} \tag{5}$$

and where ρ_{solv} is the density of the solvent and M is molecular weight.

A conventional rule of thumb for rationalizing aqueous solubility involves the concept of polarity. A polar solute is soluble in a polar solvent, like water, but insoluble in a nonpolar solvent, like benzene. Likewise, the solubility of an organic molecule in water can be largely controlled by the population and distribution of polar groups (e.g., carboxyls) on a molecule. On the molecular front, solubilization can be explained by the differences between solute/solvent interaction energies with those of solute/solute and solvent/solvent interactions. Intermolecular, ion-dipole, ion- and dipole-induced dipole as well as (London) dispersion forces govern the ability of a solvent to host solutes. Hydrogen bonding in water is notably a well-known form of interaction solubilizing hydrophilic substances. Solubility can be strongly affected by temperature due to changes in the hydrogen-bonding capability of water, explained through changes in its dipole moment (dielectric constant) and self hydrogen bonding populations and structure.

In this article, thermodynamic expressions describing solubility are presented alongside several key examples also detailing the molecular-level details of solute–solvent interactions.

Thermodynamics of Solubility

The Gibbs free energy of formation of solutes generated by the dissolution of a substance into a solvent at a given temperature (T) relates to, just as all in chemical processes, the enthalpy (H) and entropy (S) of the reaction, $\Delta G = \Delta H - T\Delta S$. The enthalpy change resulting from this reaction is accounted for by Hess' law:

$$\Delta H_{\text{soln}} = \Delta H_{\text{solute}} + \Delta H_{\text{solvent}} + \Delta H_{\text{solute-solvent}} \tag{6}$$

where ΔH_{soln} is the total heat of solution, ΔH_{solute} is the (endothermic) heat involved in separating the solute particles against intermolecular forces of the original substance (e.g., lattice energy of solids), $\Delta H_{\text{solvent}}$ is the (endothermic) heat involved in separating the solvent molecules to accomodate the solute, and $\Delta H_{\text{solute–solvent}}$ is the (exothermic) heat resulting from solute–solvent interactions. For the specific case of the dissolution of a solid in water, hydration energy (ΔH_{hydr}) is the sum of the $\Delta H_{\text{solvent}}$ and $\Delta H_{\text{solute–solvent}}$ terms and is exothermic when ion–water dipole interactions are stronger than the sum of water–water hydrogen bonds broken to accomodate the ion.

The entropic contribution to these reactions pertains to the dispersion of solutes from a solid to the solvent. In a system of *r* components, the entropy of mixing is:

$$\Delta S_{\text{mix}} = -Nk_{\text{B}}\sum_{i=1}^{r} x_i \ln x_i \tag{7}$$

where N is the number of molecules, k_B Boltzmann's constant, x_i is a mole *fraction* (also, probability of finding a component in a given site). As such, there is always a gain in entropy during as substances randomly mix in a solution. Entropy is the driving force for dissolution when no heat is exchanged, such as in the mixing of organic liquids. However, when heat is exchanged, dissolution will be favored by

reactions that are strongly exothermic to mildly endothermic. These reactions proceed until saturation is achieved, namely, at solubility, the point beyond which no additional solute can be accomodated by the solvent.

A thermodynamic description of solubility in non-ideal (real) solutions begins with the chemical potential $\left(\mu_i = (\delta G/\delta N_i)_{T,P,N_j}\right)$ of solute species i at temperature T and pressure P:

$$\mu_i = \mu_i^*(T,P) + \mathrm{RT}\gamma_i x_i = \mu_i^*(T,P) + \mathrm{RT}a_i \tag{8}$$

where μ_i^* is the chemical potential of the ideal species, γ_i is the activity coefficient, x_i the mole fraction, and the activity is given by $a_i = \gamma_i\, m_i$. When, say, a gas (g; μ_i^θ) is in equilibrium with a liquid solution (l), the chemical potential of species i will be identical in both phases:

$$\begin{aligned}\mu_i(g) = \mu_i(l) &= \mu_i^*(T,P) + \mathrm{RT}\ln\gamma_i x_i \\ &= \mu_i^\theta(T) + \mathrm{RT}\ln P_i\end{aligned} \tag{9}$$

From this equation:

$$P_i = \gamma_i x_i k_i \tag{10}$$

with

$$k_i = \exp\left(\frac{\mu_i^*(T,P) - \mu_i^\theta(T)}{\mathrm{RT}}\right) \tag{11}$$

Thus, if the mole fraction x_i is 1, we have Raoult's law (Convention I) where k_i relates to the vapor pressure of the solvent of dilute solutions or mixtures of similar types of liquids.

As many solutions cannot form high mole fractions of each substance, the main species present at high mole fractions is referred as the solvent and the minor species the solute. As stated above, *solubility* is the composition of a solution containing the *maximal* quantity of a solute that can be incorporated by a solvent. In this case, Convention II for activity coefficients (γ) stipulates distinct thermodynamic treatments for the solvent and the solutes. Thus, as in Raoult's law, the chemical potential of the solvent is expressed through:

$$\mu_{\mathrm{solv}} = \mu_{\mathrm{solv}}^*(T,P) + \mathrm{RT}\ln\left(\gamma_{\mathrm{solv}} \cdot x_{\mathrm{solv}}\right) \tag{12}$$

with $\gamma_{\mathrm{solv}} \to 1$ when the mole fraction $x_{\mathrm{solv}} \to 1$. For the solute, the chemical potential also becomes:

$$\mu_{\mathrm{solute}} = \mu_{\mathrm{solute}}^*(T,P) + \mathrm{RT}\ln\left(\gamma_{\mathrm{solute}} \cdot x_{\mathrm{solute}}\right) \tag{13}$$

except that $\gamma_{\mathrm{solute}} \to 1$ when $x_{\mathrm{solute}} \to 0$. The chemical potential of the solute (μ_{solute}^*) is that of the ideal ($\gamma_{\mathrm{solute}} = 1$) pure solute at $x_{\mathrm{solute}} = 1$ for a given T and P. Under dilute conditions solute–solute interactions are negligible, and μ_{solute} is dominated by solute–solvent interactions, and Eq. 10 is then Henry's law with the constant $k_{Hi} = k_i$. In this case, the chemical potential of the solute is one behaving as an ideal liquid under infinite dilution ($\gamma_{\mathrm{solute}} \to 1$). Stated otherwise, at equilibrium, the mass of gas dissolved in the solvent is proportional to its partial pressure in the adjacent gas phase. The temperature dependence of k_{Hi} can be expressed via the van't Hoff equation (e.g., $k_{H_i} = k_{H_i}{}^{\mathrm{ref}}\exp\left[C\left(\frac{1}{T} - \frac{1}{T^{\mathrm{ref}}}\right)\right]$, where ref denotes a reference (e.g., standard state) value and C a constant in Kelvin related to the enthalpy of the solution.

When working within solutions only and the mole fraction of the solute i is sufficiently low, the chemical potential ($\mu_{m,i}$) of species i is more conveniently expressed on a molality (m_i; moles per kg solvent) scale, such that

$$\mu_{m,i} = \mu_{m,i}^*(T,P) + \mathrm{RT}\ln\left(\gamma_{m,i} m_i\right) \tag{14}$$

and where the activity of i is $a_{m,i} = \gamma_{m,i} m_i$. In this case, the standard state is a fictious 1 molal (or molar) solution where $\gamma_{m,i} = 1$. This is a widely used convention in the realms of low temperature aqueous and hydrothermal geochemistry. Activity coefficients can be neglected for solutions containing a constant ionic strength or predicted using extended Debye-Hückel (I < 0.1 m), Güntelberg (I < 0.1 m), or Davies (I < 0.5 m) theories. The (semiempirical) Pitzer ion interaction model can alternatively be used for a wider range of ionic strengths, as, for instance, simultaneously applied for various minerals of eight component Na-K-Mg-Ca-H-Cl-SO_4-OH-HCO_3-CO_3-CO_2-H_2O system (Harvie et al. 1984).

Building upon this framework, the dissolution of, say, the binary A_xC_y solid, with the soluble anion A^{z-} and cation C^{z+}

$$A_xC_y(s) \rightleftharpoons xA^{z-}(aq) + yC^{z+}(aq) \tag{15}$$

is predicted with the equilibrium constant

$$K = \frac{a_A{}^x a_C{}^y}{a_{\mathrm{AC}}} = \gamma_A{}^x \gamma_C{}^y \cdot m_A{}^x m_C{}^y \tag{16}$$

Taking the activity of A_xC_y to 1 ($a_{\mathrm{AC}} = 1$), the *solubility product* is defined as

$$K = K_{\mathrm{sp}} = a_A{}^x a_C{}^y \tag{17}$$

where the activities of A^{z-} and C^{z+} at saturation are used to obtain K_{sp}. As such, when the ion activity product (IAP) product exceeds the solubility product (IAP > K_{sp}) precipitation occurs, but when it is below this value (IAP < K_{sp}),

dissolution occurs. Concrete examples include the solubility of silica:

$$SiO_2(s) + 2H_2O \rightleftharpoons H_4SiO_4 \quad (18)$$

with $K_{sp} = a_{H_4SiO_4}$ because $a_{SiO_2} = 1$ and $a_{H_2O} = 1$ and that of calcite with

$$CaCO_3(s) + H^+ \rightleftharpoons Ca^{2+} + HCO_3^- \quad (19)$$

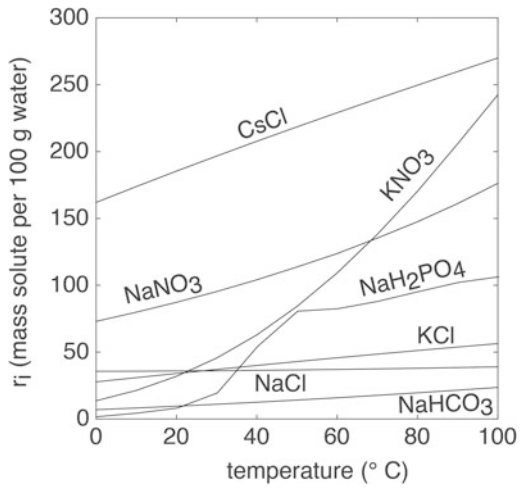
with $K_{sp} = a_{Ca^{2+}} a_{HCO_3^-} a_{H^+}^{-1}$ because $a_{CaCO_3} = 1$.

As solubility is affected by the ability of the solvent to overcome the attractive forces of the solute molecules of the incipient substance, temperature increases the kinetic energy of the solvent molecules and therefore generally favors solubility. This can be generally observed in inorganic salts (Fig. 1). Still, retrograde (or reverse) solubility occurs for solids whose dissolution is exothermic, such as cerium sulfate, calcium carbonate, calcium sulfate, calcium phosphate, and magnesium silicate.

The pressure (P) dependence, in turn, is given by the differences in the partial molal volumes (ΔV) of the solids involved

$$\log\left(\frac{K_{sp,P}}{K_{sp,P_{ref}}}\right) = \frac{-\Delta V(P - P_{ref})}{2.303\ RT} \quad (20)$$

While this dependence is typically negligible for Earth surface processes, it becomes essential for predictions of deeper Earth and deep sea processes. Examples include pressure dissolution phenomena within solutions at grain boundaries under where pressure (cf. stylolites), or the enhanced solubility of calcite in oceanic bottoms (cf. carbonate compensation depth).



Solubility, Fig. 1 Solubility of common inorganic salts in water

Prediction of solubility can be made using thermodynamic parameters derived by experimentation and with values tabulated in comprehensive reviews on the subject (e.g., IUPAC-NIST Solubility Database). As a note of caution, databases of solubility constants can contain large variations for the same substances, such as minerals. These disprepancies can arise from numerous factors including (1) variations in crystallinity, (2) impurities or trace elements hindering congruent dissolution, (3) unaccounted complexing agents (e.g., pH buffers such as potassium hydrogen phthalate), (4) differences in equilibration criteria, (5) variations in ionic strength, and (6) heterogeneous particle size distributions. Ideally, solubility constants of solids ought to pertain to highly crystalline, pure, large monocrystalline particles of low specific surface area. Still, even for pure samples, particles of high specific surface area (cf. submicrometer-sized particles) may have shifted reaction energies. This shift can be expressed through and apparent (*app*) solubility constant with:

$$\log K_{s,app} = \log K_s + \frac{\gamma A}{3.454\ RT} \quad (21)$$

where γ is surface tension, A is the molar surface area of the solute. Tightly bound water molecules on small (e.g., nanometer-sized) particles can impact surface tension and therefore reaction energies. The impact of particle size on the thermodynamics of deydroxylation reactions of iron oxyhydroxides to iron oxides was notably demonstrated by (Navrotsky et al. 2008).

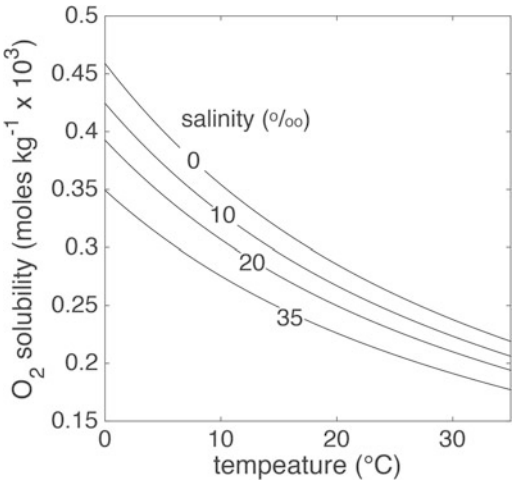
Examples of Solubility

Gases in Water

Dissolution of gases in liquids require the accommodation of the host solvent for the gaseous molecules. Those reacting with the solvent will have greater solubilities than those that are relatively inert. For example, the solubility of common gases in geochemistry is greater in the order $He < N_2 < O_2 < CH_4 < CO_2 < NH_3$. Generally, the solubilization of a nonpolar gas in a solvent first involves an endothermic component to make space for the molecule. An exothermic component then results from the formation of a hydrophobic hydration shell via van der Waals dispersion interactions (e.g., H_2O gas), forming a clathrate-like environment. Reactions are generally more endothermic in organic solvents than in water because the energy required to accomodate space for the solute is larger, and less energy is released via organic solvent–solute interactions. Thus, following Le Châtelier's principle, the solubility of gases in water is generally smaller at larger temperatures where heat is added to the system. Additionally, as dissolved salts effectively compete for hydration waters, gas solubility is

generally lowered by salinity, as, for example, shown in the case of O_2 solubility in aqueous solutions of NaCl (Fig. 2) (Benson and Krause 1984).

Gases undergoing reactions with water, such as CO_2 and NH_3 are, on the other hand, more soluble. The case of CO_2 solubility in water



Solubility, Fig. 2 Impact of salinity (NaCl) on solubility of oxygen in water

$$CO_2(g) \rightleftharpoons CO_2(aq) \tag{22}$$

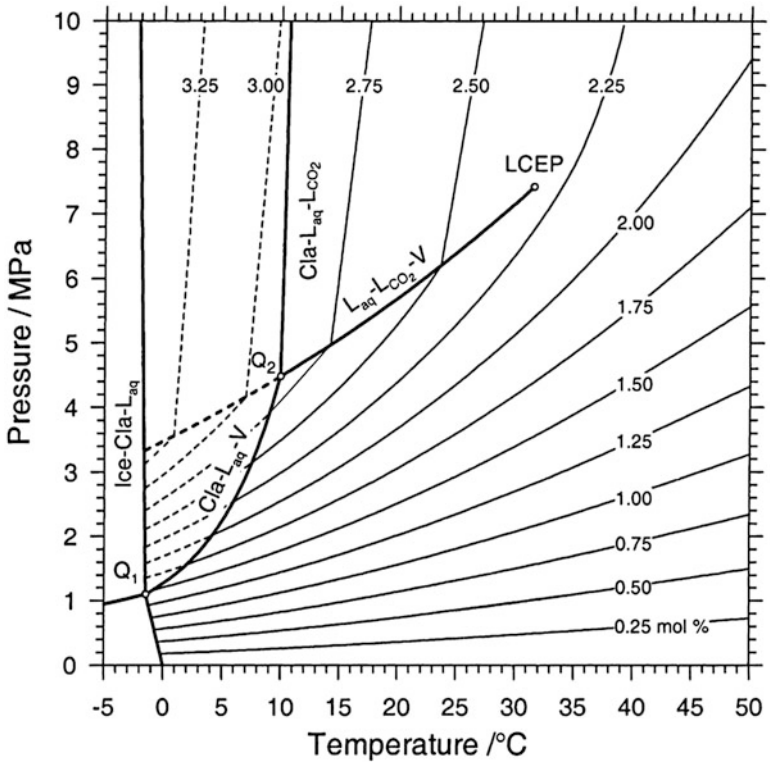
is a pivotal process to many geochemical processes and can be predicted through Henry's constant (K_H) with:

$$[CO_2(aq)] = K_H P_{CO_2} \tag{23}$$

where K_H relates to Dalton's law of partial pressure ($K_D = [CO_2(aq)]/[CO_2(g)]$ with $[CO_2(g)] = P_{CO_2}/RT$ and ($K_H = K_D/RT$). CO_2 solubility in water over a wide range of pressures and temperatures can be accurately predicted using equations of states, such as the virial-like formulation of Henry's law by (Diamond and Akinfiev 2003) (Fig. 3):

$$\ln(k_H) = (1-\xi)\ln f^0_{H_2O} + \xi \ln\left(\frac{RT}{M_W}\rho^0_{H_2O}\right) + 2\rho^0_{H_2O}\left[a + b\left(\frac{1000}{T}\right)^{0.5}\right] \tag{24}$$

where ξ is a scaling factor (-0.088) for predicting standard partial molar volume of CO_2, $f^0_{H_2O}$ is the fugacity (MPa), $\rho^0_{H_2O}$ the density ($g \cdot cm^{-3}$) of pure water, and a and b are empirial fit parameters predicting solubility over -1.5–100 °C and 0.1–100 MPa.



Solubility, Fig. 3 P-T diagram of solubility isopleths of CO_2. Reproduced with permission from Elsevier. Diamond LW, Akinfiev NN (2003) Solubility of CO2 in water from -1.5 to 100 degrees C and from 0.1 to 100 MPa: evaluation of literature data and thermodynamic modelling. Fluid Phase Equilib 208 (1-2):265-290. https://doi.org/10.1016/s0378-3812(03)00041-4

Soluble CO_2 (aq) can be regarded as a hydrophobe (e.g., 0.56 hydrogen bond per molecule in water (Lam et al. 2015; Kumar et al. 2007)) embedded in a cylindrical void forcing a local ordering of water. Carbonic acid (H_2CO_3), which results from the association of CO_2(aq) and H_2O, represents however about 1% of the total soluble CO_2 and has a short lifetime of ~300 ns. This lifetime was recently suggested to arise from deprotonation to bicarbonate (Adamczyk et al. 2009) and thus not to the backdissociation as often stated in textbooks. The total analytical concentration of dissolved CO_2 is expressed as $[H_2CO_3^*] = [CO_2(aq)] + [H_2CO_3]$. When accounting for the deprotonation to bicarbonate and carbonate, the total concentration ($[CO_2]_T$)of CO_2 in a solution is given by $[CO_2]_T = [H_2CO_3^*] + [HCO_3^-] + [CO_3^{2-}]$. Moreover, the pH-dependent total concentration of CO_2 in a solution exposed to an open atmosphere relates to Henry's law via:

$$[CO_2]_T = \left(K_H + \frac{K_H K_1}{[H^+]} + \frac{K_H K_1 K_2}{[H^+]^2}\right) p_{CO_2} \quad (25)$$

where K_1 and K_2 are the first and second deprotonation constants of carbonic acid, respectively. As a result, CO_2 solubility increases strongly at *pH* values exceeding the first deprotonation step from carbonic acid to bicarbonate.

Gases in Melts

The solubility of volatiles in melts can, in principle, be calculated via thermodynamic properties of a given decomposition reaction (e.g., biotite → feldspar + magnetite + water) involving a rock of a given mineralogical composition at the time of crystallization. The study of fluid inclusions also supplies estimates for the pressure during fluid entrapment. At the same time, experimental studies provided direct means at assessing the ability of melts at solubilizing gases. For instance, water solubilizes in silicate melts as OH- and molecular (H_2O_m) species. A representative H_2O dissolution reaction for melts can be written as (Zhang et al. 2007):

$$H_2O(g) \rightleftharpoons H_2O_m(\text{melt})\ K_1 \quad (26)$$

$$H_2O(\text{melt}) + O(\text{melt}) \rightleftharpoons 2OH(\text{melt})K_2 \quad (27)$$

The pressure dependence of the total solubility H_2O (H_2O_T) does not follow Henry's law as it follows the expression of the type:

$$[H_2O_T] = \frac{1}{2}[OH] + [H_2O_m] = k_1 p_{H_2O}^{1/2} + k_2 p_{H_2O} \quad (28)$$

The temperature-dependent equilibrium constant of reaction *n* is represented by

$$K_n = \frac{X_{H_2O_m}}{f^0_{H_2O}} = A_n \exp\left(-\frac{\Delta H^0_n}{RT}\right) \quad (29)$$

where X is the mole fraction of H_2O in the melt, f_{H2O} is the fugacity of water vapor, *A* is a preexponential factor, and ΔH^0 is the standard state reaction enthalpy. Improved, yet semi-empirical, expressions have been formulated to better account for composition of Fe-free silicate melts such as (Zhang et al. 2007):

$$C_w = \left(-0.231 + \frac{651.1}{T}\right)\sqrt{P} + \left(0.03424 - \frac{32.57}{T} + 0.02447 \cdot AI\right) \quad (30)$$

where C_w is the total solubility of water (weight %), *P* is pressure (MPa) and AI is a compositional parameter given by AI = Na + K − Al given in mole fractions. Predictions of mixed volatile solubility (e.g., H_2O-CO_2) can be more readily achieved via computer codes (Newman and Lowenstern 2002).

Solids in Liquids

Dissolution of an ionic solid compound, such as NaCl, produced hydrated Na^+ and Cl^- species each surrounded by a number of hydration shells. The molar enthalpy of the resulting solution corresponds to the dissolution of one mole of a molecule, such that

$$NaCl(s) = Na^+(aq) + Cl^-(aq)\ \Delta H = 3.9 kJ/mol \quad (31)$$

for pure NaCl(s), with a solubility of 35.9 g per 100 g of water at 298 K. A saturated aqueous solution of NaCl thus contains an average of ~9 H_2O per NaCl molecule. It therefore not only consists of hydrated Na^+ and Cl^- species but also of solvent-shared and contact ion pairs (e.g., $[Na(H_2O)_n Cl]^0$). Molecular simulations of NaCl aqueous solutions at elevated temperatures also suggest the possible presence of polyatomic complexes of the type $Na_xCl_y^{x-y}$, whose formation could be induced by the decrease in the dipole moment (cf. dielectric constant) of water (Driesner et al. 1998).

Dissolution of solid compounds into water and whose components undergo aqueous speciation reactions can display strongly pH- and complexation-dependent solubilities. For instance, the dissolution of gibbsite (α-$Al(OH)_3$) to Al^{3+}:

$$\alpha\text{-}Al(OH)_3 + 3H^+ \rightleftharpoons Al^{3+} + H_2O \quad (32)$$

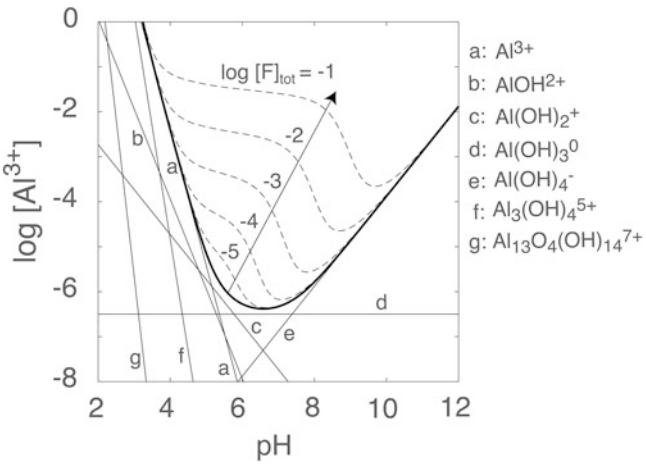
involves the pH-dependent hydrolysis of this ion via:

$$qAl^{3+} + pH_2O + rL^{z-} \rightleftharpoons Al_q(OH)_pL_r^{3q-p-rz} + pH^+ \quad (33)$$

In the absence of a foreign ligand (L^{z-}), common species $AlOH^{2+}$ ($p,q = -1,1$), $Al(OH)_2^+$ ($p,q = -2,1$), $Al(OH)_3^+$ ($p,q = -3,1$), $Al_3(OH)_4^{5+}$ ($p,q = -4,3$), and $Al_{13}O_4(OH)_{24}^{7+}$ ($p,q = -32,13$) control gibbsite solubility. The pH-dependent concentration of aluminum is then given by the sum of the concentrations of its aqueous species ($q = 0$):

$$[Al]_{tot} = \sum_0^p \sum_0^q \sum_0^r q\left[Al_q(OH)_pL_r^{3q-p-rz}\right] \quad (34)$$

and forms the characteristic U-shaped solubility curve of many metal (oxy)(hydr)oxide minerals in water and with the solubility minimum controlled by the crystallinity of the minerals involved (Fig. 4). The slopes (s) of the solubility curves on a log (base 10) $[Al^{3+}]$ vs. pH plot are the result of the pH-dependent speciation of the aqueous species, with $s = -(3q\text{-}p)/q$ when a single species dominates the speciation (e.g., $s = -3$ for Al^+ but 0 for $Al(OH)_3^0$). Increased salt (e.g., NaCl) can favor more highly charged ions and therefore enhance solubility. Addition of metal-complexing ligands can considerably enhance solubility, such as in the case of fluoride forming various mixed aluminum-hydroxo-fluoro complexes (Fig. 4). Formation of (nano- to micro-meter thick) surface coatings can, in turn, block dissolution reactions and therefore suppress solubility. One example includes aluminum hydroxo fluoride precipitates when gibbsite is exposed to concentrated fluoride solutions. The fluoridation of apatite surfaces, forming a non-stoichiometric coating of low solubility, is another example of how passivation of mineral surfaces leads to important changes in solubility.



Solubility, Fig. 4 Solubility of gibbsite (α-$Al(OH)_3$) in water at 25 °C with and without NaF

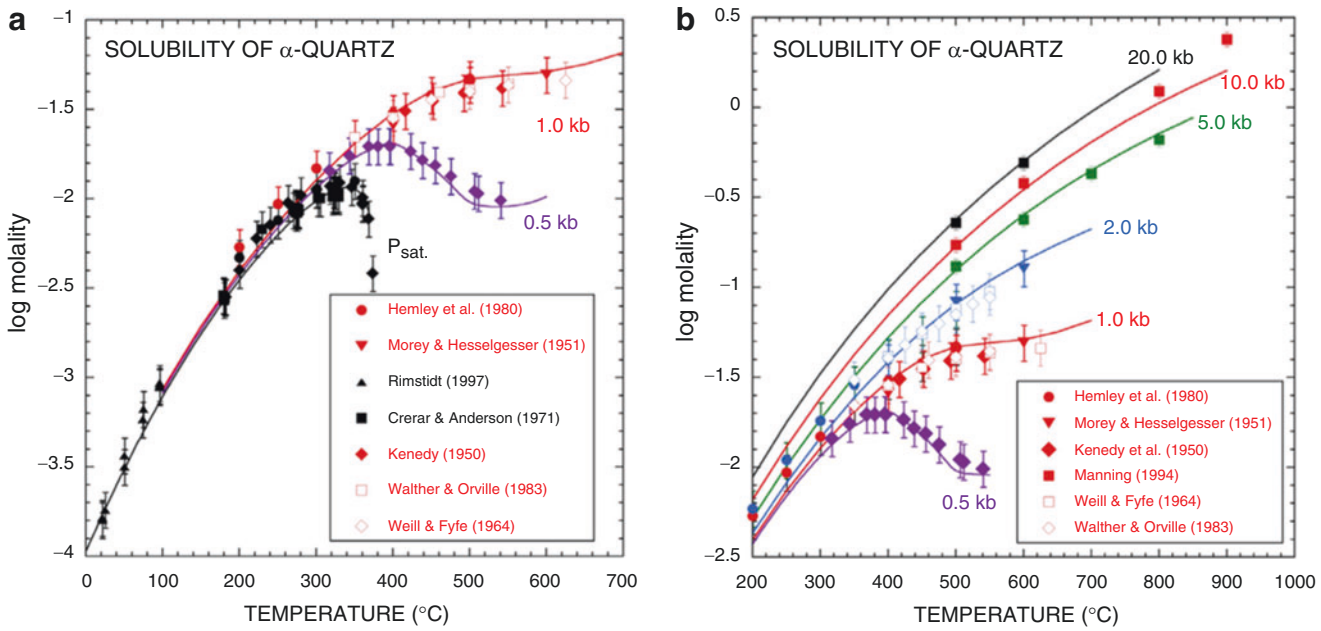
Temperature and pressure effects on solubility are strongly affected by changes in aqueous speciation. This directly arises from changes in the ability of water to hydrate ions. For example, changes seen in metal (oxy)(hydr)oxides include shifts in the solubility minima to more acidic conditions with temperature and to the increase in the concentration of species of lower charge due to the decreased dielectric constant (static permittivity) of water. Born theory can be used to predict the thermodynamics of solvation of ion i:

$$\Delta G_{solv} = \omega_i\left(\frac{1}{\epsilon_r} - 1\right) \quad (35)$$

where ω is a species-dependent Born interaction parameter and ϵ_r is the relative permittivity of the solvent. Knowledge of the latter value for water (Pan et al. 2013; Sverjensky et al. 2014) enables use of Equations of State (e.g., Helgeson-Kirkham-Flowers model; (Helgeson et al. 1981) to predict thermodynamic properties of aqueous species at elevated temperatures and pressures. For example, the solubility of quartz to several kb and hundreds of °C (Sverjensky et al. 2014) can be effectively described in this fashion (Fig. 5). An alternative approach stems upon the log-log relationship of equilibriums constants with the density of water and with relative permittivity (Dolejs and Manning 2010; Marshall and Franck 1981). Accounting for variations in the solvent density (Dolejs and Manning 2010) provides advantages for rationalizing changes in solubility with temperature and pressure. This view accounts for the energetic contributions of the compression of the hydration shell (electrostriction) on the solute – which are smaller in neutrally charged and larger in highly charged aqueous species. As such, the solubility of minerals generating highly-charged species (e.g., Ca-bearing calcite, apatite, fluorite, and portlandite of Dolejs and Manning (2010)) undergo important hikes in solubility in solvents of greater density (at constant temperature). This dependence is weaker in minerals generating neutrally charged species (e.g., $Si(OH)_4^0$, $Al(OH)_3^0$ at circumneutral pH). Likewise, the retrograde solubility of minerals generating charged species tends to occur under conditions of lower solvent density (e.g., high temperature, low pressure).

Solids in Gases

Although many solid phases of interest for geochemistry are of low volatility, gaseous reactants can act as transport agent. For example, boiling of hydrothermal fluids can produce species CO_2, H_2S, HCl, SiO_2 as well as low molecular weight metals complexes (e.g., $AgCl{\cdot}(H_3O)_3(g)$; (Migdisov et al. 1999)) in high temperature steam. Transport of such species along a temperature gradient can drive crystallization reactions which can, for example, account for epithermal transport and deposition of ore deposits, such as those of gold (Hurtig



Solubility, Fig. 5 Solubility of quartz (α-SiO_2) as a function of temperature and pressure, and thermodynamic predictions. Reproduced with permission from Elsevier. Sverjensky DA, Harrison B, Azzolini D (2014) Water in the deep Earth: The dielectric constant and the solubilities of quartz and corundum to 60 kb and 1200 degrees C. Geochim Cosmochim Acta 129:125-145. https://doi.org/10.1016/j.gca.2013.12.019

and Williams-Jones 2014). Chemical vapor deposition methods are also used in the production of solid materials for technological uses.

R. Bunsen (Biot et al. 1852) first invoked vapor-driven transport to describe the formation of crystalline Fe_2O_3 by HCl-bearing volcanic gases. In the absence of a transport agent, solid/gas transfers include direct sublimation (e.g., $AlCl_6(s) \rightleftharpoons Al_2Cl_6(g)$) and decomposition sublimation (e.g., $CuCl_2(s) \rightleftharpoons CuCl(s) + ½\ Cl_2(g)$, followed by $CuCl(s) \rightleftharpoons CuCl(g)$) reactions. In contrast, a transport agent, such as HCl (g), facilitates solid/gas conversion via a reaction of the type:

$$Fe_2O_3(s) + 6HCl(g) \rightleftharpoons Fe_2Cl_6(g) + 3H_2O(g) \qquad (36)$$

The transport direction can be understood by the sign of the reaction enthalpy, in the sense that Le Châtelier's principle will stipulate that endothermic transport proceeds toward cooler while exothermic reactions to warmer reaction. As the reaction of Eq. 36 is endothermic, transport of $Fe_2Cl_6(g)$ along a thermal gradient favors deposition of hematites in colder regions, such as vents of volcanoes.

In the presence of water vapor, species can be stabilized via solubilization in small molecular clusters of water (e.g., $H_3O^+ \ldots (H_2O)_m$, with $m = 1 \leq 5$) (e.g. Lemke and Seward 2008). Gas-phase solubility metals (*or* metal fugacity) and speciation can therefore be strongly affected by steam composition and properties. For example, Hurtig and Williams-Jones (2014) show that gold solubility in steam increases with water density, such as along the water vapor saturation curve.

Summary

The concept of solubility is essential in geochemistry for describing the maximal quantity of a substance that can be dissolved in solutions. It often becomes a starting talking point for understanding whether solutions are homogeneous or prone to bear particular matter. Preditions of solubility often require a distinct thermodynamic treatment of the solute and the solvent that can be built in different modeling frameworks. Equations of states or more empirical sets of equations can be used to effectively predict solubility over a range of conditions relevant to the solvent. Examples include salinity and pH of water, partial pressures of gases, as well as pressure and temperature of water and melts. The concept of solubility thus applies to diverse aspects of Earth Sciences and enables a means for formulating predictive models on mass transport in nature.

Stable Isotope Geochemistry

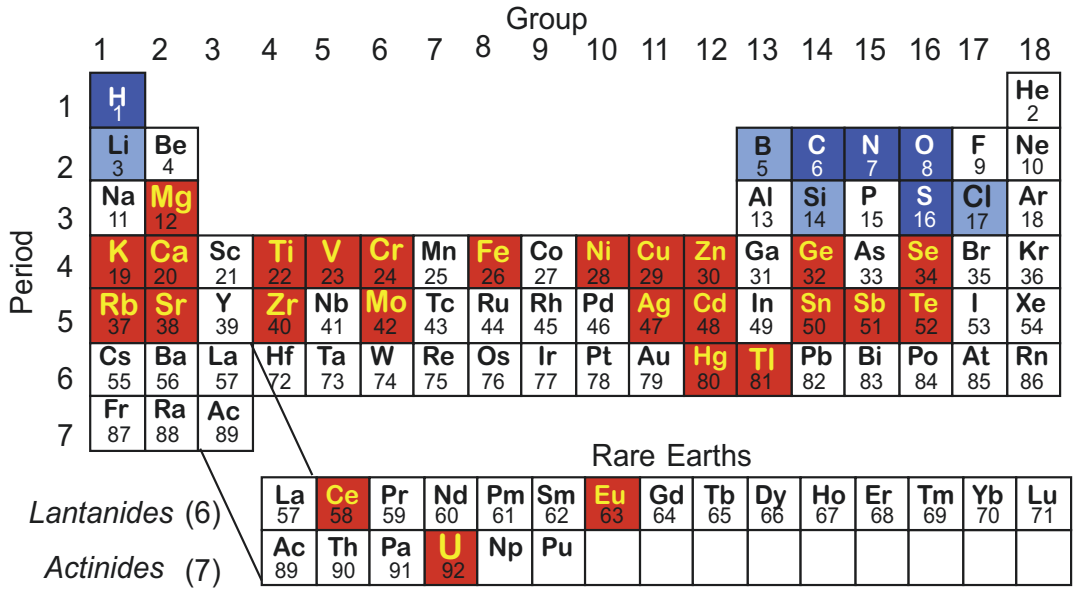
William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Definition

Stable isotope geochemistry is the study of natural variations in the isotopic composition of elements that occur as a consequence of chemical and physical processes other than radioactive decay in the Earth and Solar System.

Introduction

Although chemical processes involve only the electrons of atoms, atomic mass does play a role in the chemical and physical behavior of atoms. This leads to slightly different behavior of the various isotopes of an element, which in turn leads to variations in the ratios of isotopes within the Earth and the Solar System. Stable isotope geochemistry began with the study of a few of the lightest and most abundant elements, H, C, N, O, and S, that exhibited large variations in isotopic composition. The field began with early work of Alfred Nier of the University of Minnesota, who measured the



Stable Isotope Geochemistry, Fig. 1 The traditional stable isotopes are shown in *dark blue*; elements for which some work was done in the 1970s and 1980s are shown in *light blue*. Nontraditional isotopes are shown in *red*

isotopic compositions of many elements and noted variations, and of Harold Urey and his colleagues at the University of Chicago, who laid the theoretical foundations of stable isotope geochemistry (Bigeleisen and Mayer 1947; Urey 1947). Over the past decade or two, stable isotope geochemistry has expanded to include most of the multi-isotopic chemical elements, driven in part by advances in analytical techniques, most notably the development of multi-collector–inductively coupled plasma–mass spectrometers (Fig. 1). Increasing sensitivity and accuracy of other types of mass spectrometers, the development of high-resolution gas source multi-collector mass spectrometers, improvements in ion microprobes enabling in situ, micron-scale measurements of isotope ratios in solids, and advances in absorption spectroscopy and nuclear magnetic resonance spectroscopy are also contributing to this advancement. Many of these techniques are described in separate entries. This entry will review the main principles of the field: the isotope geochemistry of many specific elements is described in dedicated entries in this encyclopedia or in the entry on the element itself. In addition, the book edited by Teng et al. (2017) provides more details on many of the nontraditional stable isotopes.

Terminology

Because variations in isotope ratios are usually small, they are reported in parts per thousand or *per mil* variations, denoted ‰, from a standard. This is the delta notation, which for the $^{18}O/^{16}O$ ratio is:

$$\delta^{18}O = \left[\frac{\left(^{18}O/^{16}O\right)_{\text{sample}} - \left(^{18}O/^{16}O\right)_{\text{std}}}{\left(^{18}O/^{16}O\right)_{\text{std}}}\right] \times 1000 \quad (1)$$

The standard may be a naturally occurring substance such as air, the standard for $^{15}N/^{14}N$ ratio, or an artificially prepared laboratory standard. In some cases, more than one standard is used, in which case the standard used is denoted as a subscript, e.g., $\delta^{18}O_{\text{SMOW}}$. Many early defined natural standards, such as Standard Mean Ocean Water (SMOW), the standard for oxygen and hydrogen isotopes, have been replaced by artificial standards, most notably ones distributed by the International Atomic Energy Commission in Vienna. These are designated with a V, e.g., V-SMOW. It should also be noted that the isotopic composition of hydrogen is expressed as δD, where D designates deuterium, ^{2}H. As analytical precision has improved and the smaller variations in nontraditional stable isotopes (Fig. 1) have been explored, several analogous notations have emerged, epsilon (ε) and mu (μ), which are the relative deviations from standards in parts in 10,000 and parts per million, respectively.

When a process results in a change in the isotopic distribution of an element between phases, isotopes are said to be fractionated. The *fractionation factor*, α, is the ratio of isotope ratios in two phases, *a* and *b*, that will occur as a consequence of a process or reaction:

$$\alpha_{a-b} = \frac{\left(^{18}O/^{16}O\right)_a}{\left(^{18}O/^{16}O\right)_b} \quad (2)$$

The fractionation of isotopes between two phases is also often reported as

$$\Delta_{A-B} = \delta_A - \delta_B \tag{3}$$

Because isotope fractionations are almost always small, Δ and α can be related as:

$$\Delta \approx (\alpha - 1) \times 10^3 \tag{4}$$

or

$$\Delta \approx 10^3 \, ln \, \alpha \tag{5}$$

The upper-case delta (sometimes spoken as cap-delta) has two other uses in stable isotope geochemistry which will be described in subsequent sections.

Fractionation factors can be determined either observationally (e.g., measuring the isotope ratios of two minerals at equilibrium in a rock), experimentally (e.g., precipitating a mineral from solution), or theoretically from a knowledge of crystal/molecular bonding and quantum mechanics. When theoretical calculations are involved, isotope fractionation is also often expressed in terms of a β-factor defined as the ratio at equilibrium of the isotope ratio of the substance of interest to the isotope ratio of dissociated atoms, for example:

$$\beta_{H_2O}^{\left({}^{18}O/{}^{16}O\right)} = \frac{\left({}^{18}O/{}^{16}O\right)_{H_2O}}{\left({}^{18}O/{}^{16}O\right)_O} \tag{6}$$

The denominator is the isotope ratio in a gas of monatomic oxygen and the numerator is the isotope ratio in water in equilibrium with it. The fractionation factor can then be calculated from the ratio of β factors. For example, in the exchange of oxygen between CO_2 and water, a similar β factor for CO_2 can be written and denominators would cancel in the ratio of β factors can so that the fractionation factor may be calculated as:

$$\alpha_{CO_2-H_2O} = \frac{\beta_{CO_2}}{\beta_{H_2O}} \tag{7}$$

The advantage of this expression is that β values are closely related to the partition function of statistical mechanics.

Causes of Isotope Fractionations

Isotope fractionation can originate from both *kinetic* effects and *equilibrium* effects. Equilibrium isotope fractionations arise from the *translational, rotational, and vibrational motions* of molecules in gases and liquids and atoms in crystals because the energies associated with these motions are mass-dependent. Systems tend to adjust themselves so as to minimize energy. Thus, isotopes will be distributed so as to minimize the vibrational, rotational, and translational energy of a system. Of the three types of energies, vibrations, the only mode of motion available to atoms in a solid, make by far the most important contribution to isotopic fractionation.

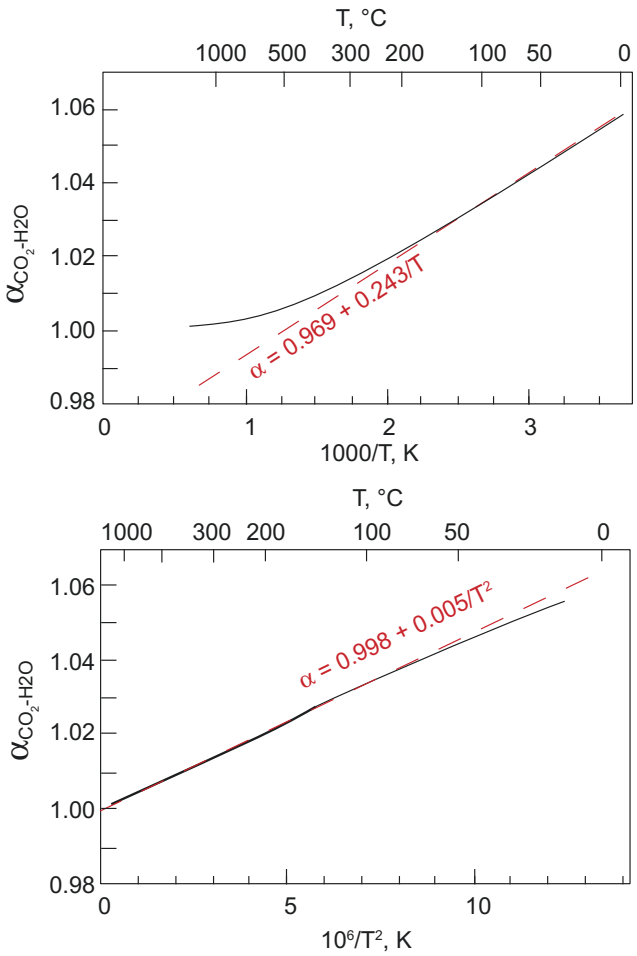
All atomic motions are quantized and, as Urey (1947) and Bigeleisen and Mayer (1947) demonstrated, equilibrium fractionations can be predicted from quantum statistical mechanics. The reader can find detailed explanations elsewhere (O'Neil 1968; Sharp 2007; Hoefs 2015; White 2015; Blanchard et al. 2017). Equilibrium constants of chemical reactions, K, can be calculated from the ratio of *partition functions, Q* (which is the denominator of the Boltzmann Distribution Function), of products and reactants:

$$\mathrm{K} = \prod_i Q^{v_i} \tag{8}$$

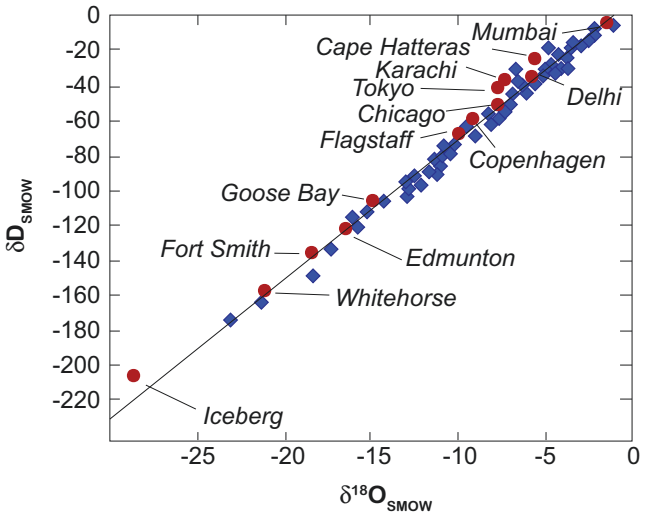
Where v_i is the stoichiometric constant of phase i and is negative for reactants. Consequently, equilibrium fractionation factors may be predicted if the available energy states of products and reactants are known.

This approach reveals that the vibrational frequency will be lower for a bond involving a heavier isotope of an element, which in turn lowers the vibrational energy of the molecule or crystal, thus bonds involving heavier isotopes will be stronger. In a system consists of two phases with different bond energies available, the energy of the system is lowered when the heavy isotope occupies the site with the stronger bond. Thus, at equilibrium, *the heavy isotope of an element will tend partition into the phase with the stronger bond.* A second important result of the statistical mechanical approach is that isotope fractionations will be temperature dependent. The temperature dependence can be complex as mass occurs in the partition functions in several forms, but at low temperatures (up to approximately Earth's surface temperatures), equilibrium fractionation factors are generally proportional to the inverse of temperature (Fig. 2). At higher temperatures, equilibrium fractionation factors vary approximately with the inverse square of temperature. This temperature dependence is the basis of stable isotope geothermometry. It is primarily useful at low to moderate (i.e., metamorphic) temperatures. As igneous temperatures are approached, fractionations become too small to provide useful geothermometers.

Isotope fractionations may also occur due to the kinetics associated with fast, incomplete, or unidirectional processes like evaporation, diffusion, dissociation reactions, and biologically mediated reactions. Kinetic fractionations arise because molecules and ions of lighter isotopes diffuse faster (a consequence of equipartition of energy: if a lighter molecule has the same energy as a heavier one, it must be moving



Stable Isotope Geochemistry, Fig. 2 Temperature dependence of the oxygen water-CO_2 fractionation factor. α is approximately proportional to 1/T a low temperature and $1/T^2$ at high temperature (From White (2015))



Stable Isotope Geochemistry, Fig. 3 Correlated variations in hydrogen and oxygen isotopes in precipitation define a global meteoritic water line

faster). The weaker bonds formed by lighter isotopes are more readily broken, hence light isotopes will react more rapidly. Consequently, where reactions do not achieve equilibrium, the lighter isotope will usually be preferentially concentrated in the reaction products, but where reactions attain equilibrium the equilibrium fractionations will dominate.

Kinetic fractionations often work in tandem with equilibrium ones. This is the case in the hydrologic cycle. At equilibrium, water vapor is isotopically light (low δD and δ^{18}O) relative to the liquid, but isotopically light water also evaporates more readily. Once it evaporates, the opportunity for atmospheric water vapor to equilibrate with the oceans is limited; hence, water vapor is more depleted in D and ^{18}O than predicted from equilibrium. When water vapor condenses as precipitation, an equilibrium fractionation again occurs and the rain or snow will be enriched in the heavier isotopes with limited opportunity to equilibrate with the vapor. As water vapor is carried away from its source region, precipitation will progressively deplete the remaining vapor in the heavier isotopes. Further, as the air mass moves toward the poles it cools, so that fractionations become greater. As a result of this Rayleigh condensation process, δD and δ^{18}O in polar ice can be as low as −450‰ and −50‰, respectively, and there is a strong correlation between the isotopic composition of precipitation and mean annual temperature. As this process affects both hydrogen and oxygen isotopic composition and the ocean is effectively an infinite reservoir of water, the two are strongly correlated such that $\delta D_{SMOW} \cong 8\delta^{18}O + 10$ in meteoric water something known as the *Meteoric Water Line* (Fig. 3). Deviations from this line are observed locally, for example, water that has evaporated or has mixed with evaporated water typically defines a trend of lower slope than the global meteoric water line. Hydrogen and oxygen isotopes are thus important tools in hydrology, ecology, and paleoclimate (e.g., Bowen 2010).

Mass Dependent Verses Mass Independent Fractionations

Where an element has three or more isotopes, for example, ^{16}O, ^{17}O, and ^{18}O, the variation in the ratio of any pair of isotopes will usually be strongly correlated with that of any other pair, with the extent of fractionation depending on mass difference. For example, the mass difference between ^{17}O and ^{16}O is half the difference between ^{18}O and ^{16}O and theoretically we expect the fractionation between ^{17}O and ^{16}O to be about half that between ^{18}O and ^{16}O. Specifically, fractionation factors calculated from partition functions show that the ratio of fractionation factors $\Delta^{17}O^{16}O/\Delta^{18}O/^{16}O$ should be ≈ 0.53 over the range of temperatures near the surface of the

Earth (or Mars). The empirically observed ratio for terrestrial fractionations (and also within classes of meteorites) is $\Delta^{17}O^{16}O/\Delta^{18}O/^{16}O \approx 0.52$. This relationship is known as *mass dependent fractionation* (MDF). Because of this simple and predictable relationship of fractionation between ^{18}O, ^{17}O, and ^{16}O, the $^{17}O/^{16}O$ ratio is rarely measured. In some cases, however, the variations in isotope ratios of multi-isotopic elements do not bear this simple relationship to mass difference. This is known as *mass independent fractionation* (MIF). It was first observed in oxygen isotope ratios in meteorites by Clayton et al. (1973) and interpreted as a nucleosynthetic effect; however, Thiemens and Heidenreich (1983) subsequently demonstrated mass independent fractionation of oxygen isotopes during ozone production in laboratory experiments. Recognition of these mass independent effects led to the introduction of another use of Δ in stable isotope geochemistry: it is the deviation of an isotope ratio from the expected mass dependent fractionation. For example:

$$\Delta^{17}O = \delta^{17}O - 0.52\delta^{18}O \tag{9}$$

Subsequently, mass independently fractionated O isotopes were observed in stratospheric ozone (Mauersberger et al. 1993) as well as other atmospheric gases. Mass independent fractionation of sulfur was also found in sulfides and sulfates older than the early Paleoproterozic as a consequence of the early Earth's ozone-free atmosphere (Farquhar et al. 2000) and in mercury isotopes of compounds produced by photochemical reactions (Bergquist and Blum 2007).

To date, essentially all examples of mass independent fractionations appear to involve photochemical reactions. The causes are not completely understood and likely varied. One likely cause is self-shielding, which may explain the MIF oxygen isotopes in meteorites (Clayton 2002; Yurimoto et al. 2007). This occurs when radiation with energy to photodissociate the dominant isotopic species, such as $^{12}C^{16}O$, is completely absorbed at some distance and hence not capable of initiating chemical reactions while that of a minor one such as $^{12}C^{18}O$ is not. A second factor may be the ability of excited asymmetric molecules such as $^{17}O^{16}O^{16}O$ and $^{18}O^{16}O^{16}O$ to repartition energy more readily than symmetric ones such as $^{17}O^{16}O^{16}O$ (Hiedenreich and Thiemens 1986). In heavy nuclides, differences in nuclear sizes and shapes of isotopes shift the ground electronic energy of an atom or molecule, which is known as the nuclear field effect (Bigeleisen 1996) and the extent of this effect differs for nuclei with odd and even numbers of neutrons. Finally, nuclei with odd numbers of nucleons have an intrinsic nuclear spin or nuclear magnetic moment, which gives rise to the nuclear spin effect (Buchachenko 2001). In such nuclei, nuclear magnetic moments can interact with the magnetic moments of electrons and affect the reaction rates of reactions involving excited reaction intermediates, such as those in photochemical reactions. This effect is strictly kinetic and does not affect equilibrium isotope distributions.

Further information on mass independent fractionations maybe found in the review by Thiemens (2006) as well as the entries on oxygen isotopes, sulfur isotopes, and mercury isotopes in this Encyclopedia.

Isotope Clumping

The term isotope clumping refers to the tendency of the heavy isotopes of a pair of elements, for example, ^{13}C and ^{18}O, to occur together in molecules or species with more frequency than a purely random distribution.

Molecules of the same chemical but different isotopic composition, for example, $^{12}C^{16}O_2$, $^{12}C^{16}O^{18}O$, and $^{13}C^{16}O^{18}O$, are known as *isotopologues*. Statistical mechanics predicts that the distribution of isotopes in a chemical species will not be random but rather that some of these isotopologues will be thermodynamically favored, in particular the heavier isotopes of elements (^{13}C and ^{18}O) are more likely to be "clumped" together in a single molecule than to be randomly distributed among all molecules. The reason for this is that double heavy isotope substitution generally leads to a reduction in vibrational frequency and energy greater than twice that of single substitution. Thus, clumping lowers the energy of the system as a whole compared to a merely random distribution of isotopes. The extent to which this clumping occurs is described by yet another use of the upper-case delta

$$\Delta_i = \left(\frac{R_{i-e}}{R_{i-r}} - 1\right) \times 1000 \tag{10}$$

where $R_{i\text{-}e}$ is that ratio of the observed or calculated equilibrium abundance of isotopologue i to the isotopologue containing no rare isotopes and $R_{i\text{-}r}$ is that same ratio if isotopes were distributed among isotopologues randomly. Thus, in the example of CO_2:

$$\Delta_{47} = \left(\frac{\left(\left[^{13}C^{18}O^{16}O\right]/\left[^{12}C^{16}O^{16}O\right]\right)_e}{\left(\left[^{13}C^{18}O^{16}O\right]/\left[^{12}C^{16}O^{16}O\right]\right)_r} - 1\right) \times 1000 \tag{11}$$

The subscript 47 refers to the molecular mass of $^{13}C^{18}O^{16}O$. The random distribution can be calculated directly as the probability of choosing isotopes randomly to form species. The equilibrium distribution can be calculated from partition function ratios. Ghosh et al. (2006) demonstrated that Δ_{47} could be measured in coral carbonates and that measured values variated as a function of temperature as predicted from theoretical calculations, thus demonstrating its value as a geothermometer. It has the advantage over

S

conventional isotope geothermometers that temperature can be determined from analysis of a single phase. Clumped isotope analysis has found wide application in paleoclimatology and diagenesis. One of the most interesting applications was demonstrating that dinosaurs could regulate their body temperature (Eagle et al. 2010).

Isotope clumping has also been studied in methane. Stolper et al. (2014) showed that clumping of ^{13}C and ^{2}H in methane (Δ_{18}) could be used to reliably determine its formation temperatures (and hence distinguish biogenic and thermogenic methane). In addition, kinetic effects leading to nonequilibrium distribution of isotopologues of biogenic methane (Wang et al. 2015) and methane oxidation processes (Whitehill et al. 2017), leading to new insights into them. Additional details on isotope clumping can be found in reviews of Eiler (2011, 2013), and Douglas et al. (2017).

Applications

Stable isotope geochemistry has had an enormous impact on our understanding of the Earth and the Solar System. One of its first and still greatest successes has been determining paleotemperatures, work initiated by Harold Urey and his students and associates at the University of Chicago, including Casare Emiliani (1955), who published the first $\delta^{18}O$ time series of Pleistocene carbonates in deep sea sediments and concluded the "Ice Ages" were driven by Milankovitch cycles. Records of $\delta^{18}O$ and δD in Antarctic and Greenland ice cores (Jouzel et al. 2007) have provided more detailed and accurate records of climate variability while substantiating Emiliani's original conclusions. Stable isotopes have also been invaluable in other paleoclimate and paleoenvironmental studies as well as atmospheric evolution as described in entries on those topics in this encyclopedia.

The temperature dependence of isotope fractionations has led to widespread application of isotope geothermometers, particularly in metamorphic rocks and hydrothermal systems (e.g., Valley 1986). Rocks of the crust, particularly the continental crust, have usually interacted with water and as a result have widely varying O isotope compositions. At mantle temperatures, isotope fractionations become extremely small in most cases, so that most fresh mantle rocks comprise a quite narrow range of stable isotopic compositions. As Taylor and Sheppard (1986) stated "igneous rocks whose oxygen isotopic compositions show significant variations from the primordial value (+6) must either have been affected by low temperature processes, or must contain a component that was at one time at the surface of the Earth." Cavosie et al. (2005) observed elevated $\delta^{18}O$ in zircons as old as 4325 Ma and argued that liquid water was present on the Earth by this time. Taylor and Sheppard's statement can be generalized to other stable isotopes as well, and consequently they have become useful tools in recognizing crustal assimilation by magmas (e.g., Bezard et al. 2014) and in the generation of ore deposits (e.g., Ripley et al. 2017). Stable isotopes have also proved useful in identifying recycled crustal material in the Earth's mantle (e.g., Eiler 2001; Delavault et al. 2016; Pringle et al. 2016). Meteorites and comets show considerable variation in stable isotope composition as a consequence both of fractionations and incomplete mixing of material from various nucleosynthetic sources. Stable isotopes therefore provide strong constraints on the Earth's formation and early differentiation (e.g., Fitoussi and Bourdon 2012; Halliday 2014; Huang and Jacobsen 2017).

$\delta^{13}C$ is fractionated by up to about −30‰ when inorganic carbon is fixed in organic molecules in photo- and chemosynthesis. Metabolic processes produce relatively small fractionations, so isotopically light carbon is a characteristic of all biologically produced organic matter, including petroleum, coal, and natural gas. Isotopically, light carbon in Eoarchean rocks from the Isua Belt of Greenland and the Nuvvuagittuq Belt of Canada thus provide evidence (albeit somewhat controversial) for the very early appearance of life on Earth (Rosing 1999; Dodd et al. 2017). Nitrogen is also isotopically fractionated during assimilation, but because most autotrophs can utilize only reduced (e.g., NH_3) or oxidized (NO_3^-) nitrogen and availability of this reactive nitrogen is limited and its isotopic composition varies more than inorganic carbon. The $\delta^{15}N$ of autotrophs reflects this variability as well as fractionations during assimilation. Legumes, which form a symbiotic relationship with nitrogen-fixing bacteria, contain less fractionated N than other terrestrial plants. Unlike carbon, however, other cellular processes significantly fractionate $\delta^{15}N$, particularly amino acid production, so that nitrogen tends to become isotopically heavier at each trophic level. Oxygen and hydrogen are taken up by biota as water and there is little isotopic fractionation in this process (although some fractionation occurs as a consequence of transpiration); hence, the O and H isotopic composition of biomolecules generally reflects that of the local water. Determination of the isotopic composition of carbon and other elements in specific biomolecules such as biomarkers through compound-specific isotope analysis has become important tool in biogeochemistry and organic geochemistry. Studies on H, C, O, N, and S isotopes as well as on nontraditional stable isotopes have become important tools in ecology (Peterson and Fry 1987; Fry 2006), forensics (Cerling et al. 2016), paleontology and archeology (e.g., Lee-Thorp 2008), atmospheric evolution (Pufahl and Hiatt 2012), and medicine (Albarède et al. 2017).

Summary and Outlook

Stable isotope geochemistry has had an enormous impact on geochemistry and more broadly earth and planetary sciences

generally. The impact ranges from formation of the Earth and its neighbors and mantle evolution to paleoclimate, mineral exploration, petroleum exploration, and hydrology. Following the lead of geoscientists, archeologists, forensic scientists, and biologists have also found widespread use for stable isotopes in fields ranging from paleontology and ecology to medicine.

Future impacts are likely to be greater as stable isotope geochemistry is presently experiencing a particularly rapid development. Part of this relates to exploring isotopic variations of nontraditional stable isotopes (Fig. 1): in many instances these fields are still in their infancy with yet much to be discovered. Part of it reflects exploring new directions such as mass independent fractionation and isotopic clumping. Progress is also driven by continued innovation in analytical techniques enabling smaller sample volumes, greater precision, and the analysis of specific molecules and, in the future, determine the isotopic composition of atoms at specific sites in molecules. Eiler et al. (2014) provide a more detailed review of the frontiers of stable isotope geochemistry.

Standard States

William H. Casey[1] and Peter A. Rock[2]
[1]Department of Chemistry and Department of Earth and Planetary Sciences, University of California, Davis, CA, USA
[2]College of Math and Physical Sciences, Department of Chemistry, University of California, Davis, CA, USA

Definition

Energy states, and thermodynamic activities, are calculated relative to a chosen condition called a standard state that is required as an integration limit. For pure substances these states are usually defined at a fixed temperature and pressure. For solutions, these states are usually defined at a fixed temperature, a pressure, and a composition that has an ideal behavior for a solvent or a solute, meaning that the behavior satisfied Raoult's law or Henry's Law, respectively.

Elaboration

The concept of standard states arises from the definition of the activity function that was created by G.N. Lewis, one of the most revered American physical chemists in the early twentieth century. Lewis invented the activity function in order to preserve the simple algebraic form of the law of concentration (mass) action first enunciated by the Norwegian chemists Gulberg and Waage (Lewis and Randall 1961; Laidler 1993). If μ_i is the chemical potential of component i in a multicomponent system at temperature T and pressure, P, then the activity, a_i is defined as follows:

$$d\mu_i = -\overline{S}_i dT + \overline{V}_i dP = RTd\ \ln(a_i) \qquad (1)$$

where $\overline{S}_i$ and $\overline{V}_i$ are the partial molar entropy and partial molar volume, respectively, of component i. Note that Eq. 1 is an *incomplete* definition of the activity as there is an integration constant that is yet unspecified.

Peter A. Rock: Deceased.

We now integrate Eq. 1 at fixed temperature from a standard, or reference, state that is denoted by the superscript "o" to another (nonstandard) state:

$$\int_{\mu_i=\mu^o}^{\mu_i} d\mu_i = \int_{a_i=a^o}^{a_i} RT \ d\ln(a_i) \tag{2}$$

or

$$\mu_i - \mu_i^o = RT \ \ln\left(\frac{a_i}{a_i^o}\right) \tag{3}$$

The integration constant is required by the limit and is referred to as the "standard state."

The choice of a standard state is purely arbitrary, but the most common choice is a state for which the activity can be set equal to unity, $a_j = 1$ (exactly), which has obvious mathematical utility in that the logarithm is zero. The activity is a unitless ratio of conditions (see "▶ Fugacity"). For gases, the ratio is the fugacity relative to that of a standard state fugacity that can be derived from statistical mechanics (see Dill and Bromberg 2010, pp. 211, 242) or measured.

The standard state can be a real state that is accessible to laboratory measurement, or it can be a hypothetical state. If component i exists as a pure substance in the same type of phase (solid, liquid, or gas) as the solution (e.g., liquid water at $T <$ I00 °C, 1 atm, for an aqueous solution at $T <$ 100 °C, 1 atm), then we choose the *pure* substance at 1 atm and the temperature of the solution as the standard state for which we set $a_i = 1$ (exactly). Thus for an aqueous solution at 25 °C and 1 atm totals pressure, we choose the standard state of water as the pure liquid at 25 °C and 1 atm, for which a_i^o is equal to unity. This type of standard state is referred to as a Raoult's law (or solvent) standard state. The Raoult's law description of a solvent means that one has chosen the mole fraction concentration scale. The pure solvent has unit mole fraction; $X_i = 1$ or logarithm$(X_i) = 0$.

For nonvolatile solutes, but which are soluble in the solvent of interest (e.g., liquid water), yet which do not exist as pure liquids at the temperature of the liquid solution, we are forced to choose a hypothetical standard state. By convention we choose aqueous solutes to have a *Henryan* state of a hypothetical one molal solution with the properties of infinite dilution. The wording seems obscure but is not difficult to parse in light of the equations above. A 1 m standard state is used because the $\log(m_i = 1.0) = 0$ (whereas the solvent has a $X = 1$ standard state). Reference to the *properties of infinite dilution* means that a finite slope exists between activity and concentration that is rarely true for real one molal solutions. For this Henry's law and hypothetical solute standard state, $a_i^o = 1.0$ (exactly), where $a_i^o = m_i^o \cdot \gamma_i^o$; $m_i^o = 1.0$ and γ_i^o is the activity coefficient of component i in the standard state ($\gamma_i^o = 1.0$).

In order to establish a Henry's law standard state, experiments must be carried out on solutions of decreasing concentration ($m_i \to 0$) to establish the dilute limit where $\gamma_i \to 1.0$. Practically, the activity coefficients are estimated using a theory, with the ones based upon the Debye-Hückel theory for electrolytes being the most common. When we attain the Henryan region, $a_i = m_i$. Note that other concentration scales can also express Henryan behavior – we emphasize electrolytes and the molality scale here only as the most familiar examples. In the Henry's law region, we have for an aqueous electrolyte:

$$\mu_i = \mu_i^o + RT\ln(m_i) \tag{4}$$

Because they often work at high temperatures and pressures, the arbitrary nature of choosing solute (Henryan) or solvent (Raoultian) standard states is particularly evident to geochemists. For example, the concentration of dissolved carbonate in equilibrium with the atmosphere ($pCO_2 = 10^{-3.5}$ atm) is on the order of 10^{-5} m, which is so small that a Henryan standard state is obvious. A given volume of some metamorphic or hydrothermal fluid, however, can contain amounts of dissolved CO_2 or dissolved SiO_2 that exceed the concentration of water. For these cases it may be more convenient to employ a Raoult's law standard state (see Rock 1983) and the mole fraction concentration scales for both components in the mixture. It is hard in those cases to decide if it is silica dissolved in water or water dissolved in silica.

To elaborate further, one generally chooses a fixed-pressure standard state to describe solutions near the Earth surface, but any fixed pressure could be used as a standard state. The activities of states that differ only in pressure are related by the equations:

$$\int_1^2 d\ln(a_i) = \frac{1}{RT}\int_{P_1}^{P_2} \overline{V}_i \ dP \tag{5}$$

or

$$\ln\left(\frac{a_{i,2}}{a_{i,1}}\right) = \frac{1}{RT}\int_{P_1}^{P_2} \overline{V}_i \ dP \tag{6}$$

where in general, $\overline{V}_i$ depends on both P and T. The activity for a fixed-composition substance at pressure, P, relative to a 1 bar (10^5 Pa) standard state for that temperature, where: $a_{i,1}^0 = 1$ is:

$$\ln(a_{i,2}) = \frac{1}{RT}\int_1^{P_2} \overline{V}_i(P) \ dP \tag{7}$$

We can set $a_{i,1} = 1$ for any convenient value of P and refer all $a_{i,2}$ values to that standard state. Alternative standard states are described in Anderson and Crerar (1993).

S

Conclusions

Well-defined standard states are explicit in thermodynamic calculations and derive from the need for an integration limit. Choice of standard states, however, is purely a matter of convenience. In biological systems, for example, the standard state for H_3O^+ is not the 1.0 m solution described above, but a 10^{-7} M solution, which is closer to a physiological media like blood (see Alberty and Silbey 1992, pp. 280–282). Geochemists also move the standard states to elevated temperatures and pressures to better match the environmental conditions (see Anderson and Crerar 1993; Nordstrom and Munoz 1994) that are often far different from conditions at the Earth surface.

Stoichiometry

Anna F. Oliveri

Department of Chemistry, Department of Earth and Planetary Sciences, University of California, Davis, CA, USA

Definition

The stoichiometry of a chemical reaction is the molecular ratio of individual reactants and products, typically represented as whole numbers. When the relative quantities of molecules are calculated correctly, the number of each type of atom should be equal in the reactants and products.

In a given chemical reaction, the numbers that come before each reactant and product represent the quantities, or stoichiometry, of each substance. In Eq. 1, two quantities (usually expressed in moles) of AX_3 react with three quantities of BY_2 to produce two and three quantities of AY_3 and BX_2, respectively. One mole is 6.022×10^{23} particles of a given substance. This unit is similar to a dozen and is used to organize gigantic numbers of items (molecules, atoms, etc.) into practicable proportions. The law of conservation of mass dictates that no mass (or energy) can be created or destroyed; therefore, using moles, you can see that the reaction starts and ends with 6 mol of X^-.

$$\mathbf{2AX_3 + 3BY_2 \rightarrow 2AY_3 + 3BX_2} \quad (1)$$

To determine the proper stoichiometry for a chemical equation, you must simply balance the specific types of atoms. Take the simple reaction of hydrogen peroxide decomposing into water and oxygen gas (Eq. 2). Without stoichiometry, the chemical equation indicates that each individual reaction begins with two oxygen atoms and spontaneously produces a new one, resulting in three oxygen atoms.

$$\mathbf{H_2O_2 \rightarrow H_2O + O_2} \quad (2)$$

This cannot be true, due to the law of conservation of mass. By indicating that two hydrogen peroxide molecules must react to form two water molecules and one oxygen molecules, the reaction is balanced, and mass is conserved (Eq. 3).

$$\mathbf{2H_2O_2 \rightarrow 2H_2O + O_2} \quad (3)$$

Stoichiometry is extremely useful for determining experimental concentrations, limiting reagents and molar proportions, predicting yield, and calculating percent yield. Stoichiometric ratios allow for easy mathematical conversion from one type of substance to another. If 1.0 g of H_2O_2 is allowed to decompose, how many g of H_2O will be created after complete O_2 gas evolution? Having a balanced chemical equation makes this an extremely simple question to answer; no experimental data is needed (Fig. 1).

The stoichiometric ratio, provided by the balanced chemical reaction, allows for the type of molecular conversion shown in Fig. 1. By comparing the calculated value (the predicted yield) to experimental data, the percent yield of a reaction can be determined. Conversely, if a specific quantity of product is desired, the stoichiometric ratio can be used to ascertain the needed quantities of reactants.

^{87}Sr*, 7.00%
^{88}Sr, 85.58%
1 Atm Melting Point: 769 °C
1 Atm Boiling Point: 1348 °C
Common Valences: 2+
Ionic Radii: 126 pm
Pauling Electronegativity: 0.95
First Ionization Energy: 549.47 kJ/mol
Chondritic (CI) Abundance: 7.79 ppm
Silicate Earth Abundance: 22 ppm
Crustal Abundance: 320 ppm
Seawater Abundance: 8 ppm
Core Abundance: nil

Properties

Strontium (Sr) is an alkaline Earth element of group IIa of the periodic table. In its low temperature polymorph (transition into high temperature polymorphs at 235 °C and 540 °C), it is a soft, silvery metal (Mohs scale 1.8). It rapidly reacts to a yellowish colored oxide in air and decomposes vigorously in water. Strontium has an average atomic weight of 87.62, an electron configuration of [Kr]$5s^2$, and occurs in a 2+ valence state in natural systems.

Strontium has four naturally occurring, stable isotopes: Sr-84, Sr-86, Sr-87, and Sr-88, of which Sr-87 is subject to radiogenic ingrowth by Rb-87 beta decay. The range in $^{87}Sr/^{86}Sr$ in natural terrestrial material prevents a more precise standard atomic weight and the isotopic composition of Sr can vary substantially in rocks and minerals, depending on age and Rb content. With a half-life of ca. 49 billion years, the related ^{87}Rb-^{87}Sr isotope system is a widely applied dating tool and isotope tracer (Nebel et al. 2011). Twenty-four additional, short-lived isotopes of Sr are known, of which Sr-90 has the longest half-life with ca. 28 years.

History and Use

Strontium is named after the village Strontian, located in Sunart in the Scottish highlands. The element was first identified in 1787 from the mineral strontianite ($SrCO_3$) by Adair Crawford, which was recovered from a local lead mine and identified as a new element by Thomas Hope in 1791. It was first isolated by electrolysis by Humphrey Davy in 1808. Strontium also forms a sulfate mineral of its own (celestite, $SrSO_4$). In all other naturally occurring minerals, Sr is only present in trace amounts. In industry, Sr is frequently used in pyrotechnics for red coloring, such as fireworks and warning flares. Strontium can further be used as a compound in ferrite magnets and as chloride hexahydrate in toothpaste for sensitive teeth.

In Earth sciences, Sr is frequently used as an indicator mineral for the fractionation of plagioclase in igneous petrogenesis. In combination with Rb, it is one of the most important dating tools for igneous rocks. Radiogenic and stable isotopes of Sr are often employed as geochemical tracers in both high-temperature rocks and low-temperature chemical sediments and waters.

Geochemical Behavior

Strontium is lithophile and moderately incompatible in mantle phases. It is thus enriched in the crust compared to primitive or depleted mantle. The Earth's core contains no Sr. Accordingly, an estimation of the abundance of Sr in the bulk silicate Earth (BSE) is 22 ppm, based on a chondritic refractory element budget for Earth and a chondritic abundance of 7.79 ppm (Palme and O'Neill 2014). Strontium abundance in continental crust is estimated to average 320 ppm (Rudnick and Gao 2014). Values for Sr abundances in upper, middle, and lower continental crust vary only marginally with values of 320, 348, and 320 ppm, respectively (Rudnick and Gao 2014). These reflect the relative equal distribution of Sr in all crustal assemblages. This equates to an average D(Sr) during crust-mantle differentiation of 0.69. In magmatic systems, Sr is a trace element with abundances $\ll$1% in most rocks, except for highly alkaline or carbonatitic rocks and anorthositic rocks. Strontium readily substitutes for and partitions into the site of Ca^{2+} due to their similar charge and ionic radii (Sr^{2+} = 1.26 Å, Ca^{2+} = 1.12 Å). It preferentially partitions into anorthite and to a lesser extent into the smaller octahedral site of clinopyroxene or, if present, into clino-amphibole. Because of its incompatible nature in most igneous minerals (except plagioclase), Sr concentration increases in the melt until the onset of feldspar fractionation, often indicated by co-variations with Eu* (Eu/[Gd + Sm]). In more felsic systems, Sr is mainly hosted by plagioclase but also in Ca-bearing accessory phases, for example, apatite. In highly alkaline rocks, such as carbonatites, Sr can occur to up to lower wt% abundances. Strontium is a large ion lithophile element and considered mobile during fluid transport. In aqueous solutions, it has an effective diameter of 500 pm, similar to Ba but smaller than Ca (600 pm). Owing to its high solubility in water, Sr is relatively concentrated in the oceans (ca. 7.6 ppm) and surface waters (2 orders of magnitude lower than in oceans, depending on bed-rock geology). Subsurface brines can contain thousands of ppm Sr. There is a generally good co-variation of Sr concentration and its radiogenic isotope composition in waters, which indicates that Sr is an excellent tracer for fluid-rock interactions, mixing of aquifers and recharge areas, and fluid migration during diagenetic processes. Consequently, Sr is often re-distributed during hydrous metamorphic reactions and low-temperature fracture fills.

Strontium in seawater has a long ocean residence time between 1 and 20 Myrs (Vollstaedt et al. 2014) and reflects a mix between continental run-off and Sr exchange between oceanic crust and seawater at oceanic ridges. A high continental run-off into the oceans and relatively fast ocean mixing times result in a relatively constant global Sr concentration and isotope composition in seawater. Over geologic timescales, the Sr isotope composition of the oceans can vary in response to changes in the isotopic composition of continental run-off during fluctuations in the tectonic and erosional regimes.

Strontium has a high affinity for chemical sediments and cement. Whereas carbonates are the most abundant Sr hosts (up to 0.1 wt%) with aragonite > calcite > dolomite, phosphorites can also contain significant amounts. Strontium is further incorporated into biogenic carbonates and phosphates. Absolute concentrations and Sr/Ca in corals or other marine skeletons can serve as proxies for present and past sea surface temperature reconstructions (Devilliers et al. 1995; Corrège 2006).

Biological Utilization and Toxicity

Strontium is considered nonhazardous for organisms. The only known health risk is associated with Sr-90, which is a hazardous radioactive isotope produced by nuclear fission. Injected or consumed Sr is almost instantly cleared from blood and is readily incorporated into bone and marrow (ca. 99% of the human Sr budget). Strontium deficiency or high concentrations (up to 0.5% uptake) have no reported effect on man or farm animals (Nielsen 2004). In low quantities, Sr can be used as a medical tracer or in radiotherapy as a cancer treatment. Strontium borate is being tested as a future material for bone substitute material.

Definition

Strontium (Sr) isotopes are widely applied tracers in geoscientific applications. One of the four stable isotopes (^{87}Sr) is subject to long-term radiogenic ingrowth by radioactive decay of rubidium (^{87}Rb). Resultant isotope variations in $^{87}Sr/^{86}Sr$, but also other stable isotope variations, can be employed to trace mixing of global reservoirs, ranging from high-temperature-pressure processes preserved in solid rock to low-temperature, environmental conditions in surface waters, oceans, chemical sediments, or biogeochemistry. A second, frequent application is the dating of rock-forming processes using the Rb-Sr decay scheme, ranging in age from the infant stages of the solar system to most recent geologic events.

Introduction to Rb-Sr Systematics

Rb-Sr systematics are based on the radioactive decay of the isotope ^{87}Rb (that today accounts for ~27% of all rubidium) to ^{87}Sr (~9% of all strontium) by beta decay with a half-life of approximately 49 billion years, corresponding to a Rb decay constant (λ^{87}Rb) of 1.394×10^{-11}/a (Nebel et al. 2011b). A prime application of the decay scheme is tracing geochemical processes using the radiogenic Sr isotope signature in rocks and minerals. As a dating technique Rb-Sr is, in principle, suitable for samples from the early stages of the solar system to a few million years before present. Modern Rb-Sr geochronology of multiple phases can achieve precisions similar to Ar-Ar dating or conventional U-Pb dating, in the order ca. ±0.2% (Nebel and Mezger 2008; Willigers et al. 2004). The thermal threshold, or closure temperature T_C, for Rb-Sr reset is between 300 °C and 400 °C, dependent on mineralogy. This renders Rb-Sr one of the most susceptible systems to thermal overprint among the long-lived lithophile element isotope systems.

Isochron relationships can further be used to test initial isotope equilibrium of phases. For this, in an isochron diagram, isotope equilibrium at t_0 is marked by the ordinate intercept of the regression line (Fig. 1) or can be calculated as initial $^{87}Sr/^{86}Sr$. The related decay equation is (with t in millions of years):

$$^{87}Sr/^{86}Sr_{present} = {}^{87}Sr/^{86}Sr_{initial} + {}^{87}Rb/^{86}Sr \times \left(e^{(\lambda \times t)} - 1\right)$$

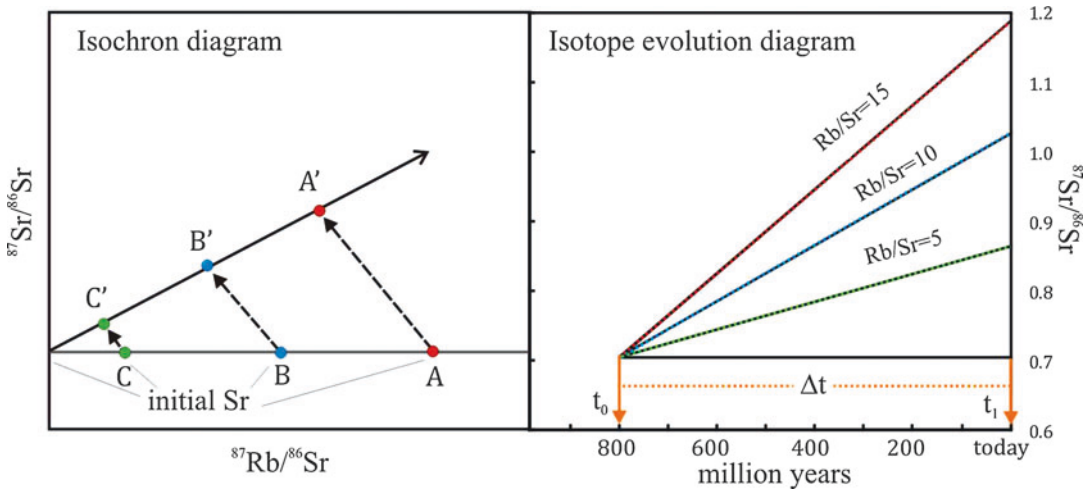
Strontium Isotope Analyses

Strontium isotope compositions vary from subtle variations among whole rocks or mineral phases in the 5th decimal place (i.e., 0.00005) to large variations, especially in older samples. The $^{87}Sr/^{86}Sr$ can be routinely analyzed in > 50 ng Sr of purified sample material by thermal ionization mass spectrometry (TIMS). Precisions are typically ±40 ppm but can be as good as ±5 ppm with modern TIMS instruments. An alternative method is the use of multicollector inductively coupled plasma source mass spectrometry (MC-ICP-MS). This technique allows a high sample throughput and *in situ* analyses via laser ablation, but yields less precise data no better than ±100 ppm (Vroon et al. 2008) and is restricted to samples with low Rb/Sr. Collision-cell, triple-quadrupole ICP mass spectrometers, however, can be used for *in situ* Rb-Sr dating with precisions <1.5% of the sample age (Zack and Hogmalm 2016). Mass fractionation in the mass spectrometer during isotope analyses is corrected for by using a $^{86}Sr/^{88}Sr = 0.1194$ by convention, or in the case of stable isotope analyses, by correction relative to the NBS-987 isotope standards.

Radiogenic Sr Isotopes in Early Solar System Material and Bulk Silicate Earth

The initial $^{87}Sr/^{86}Sr$ composition of the solar system ($^{87}Sr/^{86}Sr_{SS}$) is best estimated by analyses of calcium-aluminum-rich inclusions (CAI) in primitive chondrites. These inclusions, composed of predominantly refractory elements, are believed to be the first solids condensed from the solar nebular. Their initial $^{87}Sr/^{86}Sr$ has recently been determined to 0.698975 ± 0.000008 (Hans et al. 2013).

Previous determination of $^{87}Sr/^{86}Sr_{SS}$ also employed initial $^{87}Sr/^{86}Sr$ of achondrites (best achondrite basaltic initial - BABI), including the pyroxene-rich angrite Angra Dos Reis (ADOR). These older analyses revealed $^{87}Sr/^{86}Sr$ isotope heterogeneity among the earliest solar system bodies. However, Hans and co-workers found variations in the stable $^{84}Sr/^{86}Sr$ in these meteorites, which they ascribe to



Strontium Isotopes, Fig. 1 (**a**) Rb-Sr isochron diagram showing the time-dependent evolution of three different phases, (A-C) with variable Rb/Sr that formed in isotopic equilibrium and thus have the same initial $^{87}Sr/^{86}Sr$ isotope composition. Points A'-C' reflect the present day isotope composition of phases A-C, respectively. (**b**) $^{87}Sr/^{86}Sr$ isotope evolution versus time plot (with t_0 defining the onset of radiogenic ingrowth and t_1 the time of sampling) with the respective ^{87}Sr ingrowth of three different phases as a consequence of their variable Rb/Sr

incomplete mixing of *r*-process nuclides in the solar nebula. Upon correction for these isotope variations in $^{84}Sr/^{86}Sr$ compositions (and thus also affecting $^{87}Sr/^{86}Sr$ prior to radiogenic ingrowth), the resultant $^{87}Sr/^{86}Sr_{SS}$ in angrites is identical to those in CAI. Considering the very similar formation age of angrites, within ca. two million years after CAI formation, this indicates a homogeneous initial $^{87}Sr/^{86}Sr$ of the early solar system.

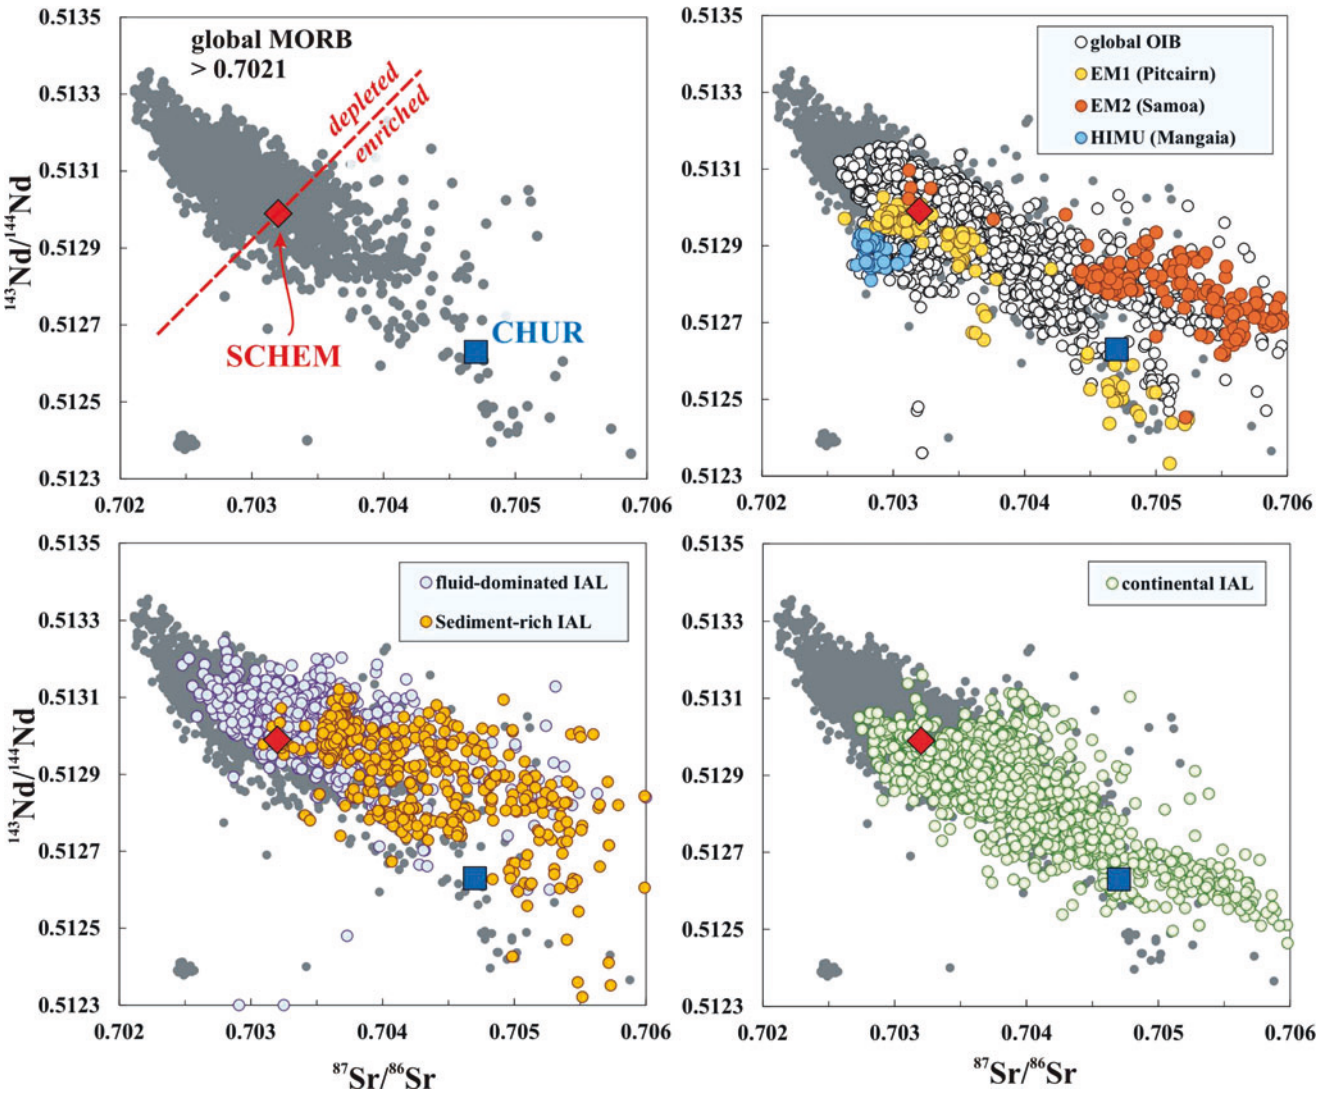
A key problem in determining the $^{87}Sr/^{86}Sr$ evolution of the bulk silicate Earth (BSE) is that its average Rb/Sr is unknown, and no representative sample is available for analysis. The reason for this is two-fold: One major obstacle is that although the Sr isotope compositions of primitive chondrites can be precisely measured, the Rb/Sr of these terrestrial building blocks are highly variable due to the volatility of Rb (half-condensation temperature of ~800 K). Loss of volatile elements, including Rb, during early solar system body collisions or depletion into the early sun or the outer solar system has likely altered the chondritic Rb/Sr (Nebel et al. 2011a). Using terrestrial Sr-Nd isotope covariations in mantle-derived rocks (Fig. 2a) as a substitute yields a Sr isotope composition of $^{87}Sr/^{86}Sr_{CHUR} \sim 0.705$ in a chondritic Earth model (CHUR), or $^{87}Sr/^{86}Sr_{SCHEM} \sim 0.703 \pm 0.004$ in a subchondritic Earth model (SCHEM, (Caro and Bourdon 2010).

Radiogenic Sr Isotopes in the Crust–Mantle System

Continental crust has formed with time mainly by partial melting of the upper mantle at convergent plate margins or in plumes. During melting processes in the mantle, Rb is less compatible than Sr, which leads to a time-integrated high Rb/Sr in the crust compared to the mantle and a correspondingly high $^{87}Sr/^{86}Sr$ in crustal rocks. A sample or entire terrane separated from the mantle at one point in Earth's history will therefore diverge from the mantle's Sr isotope evolution. However, due to substantial Rb/Sr fractionation during igneous differentiation processes, the continental crust is highly heterogeneous in its $^{87}Sr/^{86}Sr$ with an average present day isotope composition of $^{87}Sr/^{86}Sr \sim 0.715$, based on loess samples (e.g., Yokoo et al., 2004).

The present day depleted mantle is also heterogeneous in its Sr isotope composition, owing to melt extraction and re-fertilization by recycled crust. Due to elevated $^{87}Sr/^{86}Sr$ and high Sr abundances in crustal rocks and their sedimentary products, crustal recycling has a strong effect on the Sr isotope composition of mantle rocks with less radiogenic $^{87}Sr/^{86}Sr$ (Armstrong 1968; DePaolo 1981). On average, global mid-ocean ridge basalts (MORB), considered representative of the upper mantle, show a depleted Sr isotope signature with the lowest reported present day value of $^{87}Sr/^{86}Sr = 0.7021$ (Fig. 2a). A key difference between the actively discussed chondritic versus subchondritic Earth models is the degree of mantle depletion. About one-third of ocean floor lavas at oceanic ridges is isotopically enriched through crustal components in a SCHEM model, opposing a nearly complete depletion in a CHUR model.

Oceanic island lavas (OIB), considered by most to be sourced by thermo-chemical anomalies from the lower mantle (plumes), also show elevated radiogenic isotope signatures associated with crustal recycling. The common model explains these signatures with a recycling process of



Strontium Isotopes, Fig. 2 Comparison of Sr and Nd isotope ratios in global ocean floor lavas following the rational of DePaolo and Wasserburg (1977). (**a**) Mid-ocean ridge basalts (MORB) show a clear co-variation (*gray dots*). In a subchondritic Earth model (SCHEM), 1/3 of al data are isotopically enriched, tending towards the *top-left* corner in the diagram. (**b**) Ocean Island basalts (OIB) with the three isotope end members enriched-mantle 1 and 2 (EM1, EM2) and high-μ (HIMU). (**c, d**) Subduction zone data for global island arc lavas (IAL) in comparison with MORB; MORB and OIB/IAL data taken from www.earthchem.org/petdb and http://georoc.mpch-mainz.gwdg.de, respectively. SCHEM and CHUR values as listed in Caro and Bourdon (2010)

S

subducted, crustal components into the lower mantle and their return to the surface in upwelling plumes (Hofmann and White 1982). Even though the calculated amount of crust in these rocks appears small, in the order of <5%, the radiogenic isotope character of Sr is still sufficiently indicative for the presence of crustal components in the source of these lavas. Mantle-residence times of crustal components vary substantially from <650 Myrs in some so-called enriched mantle 1 (EM1) components (Sobolev et al. 2011), based on $^{87}Sr/^{86}Sr$ in Hawaiian lavas, to >2.3 Ga in the most extreme HIMU lavas with remarkably low $^{87}Sr/^{86}Sr$. Samoan OIB show the most extreme Sr isotope values among OIB, which represent the so-called enriched mantle 2 (EM2) component. (Jackson et al. 2007).

The major sites for crust-mantle interaction is and Sr pollution of the mantle occurs at convergent margins, that is, in subduction zones. However, recycling into the mantle is incomplete, evidenced by elevated $^{87}Sr/^{86}Sr$ in most erupting island arc lavas (IAL) when compared to average MORB. The Sr isotope composition in IAL is broadly correlated to the amount of sediment that is being subducted in the subduction zone. Fig. 2c shows a plot of arcs associated with large amounts of subducted sediment (Banda and Lesser Antilles arc) with a clear offset from MORB due to partial sediment

melting. In contrast, IAL from so-called fluid-dominated arcs (Marianna, Izu-Bonin, Kermadec, and Aleutian) show intermediate signatures, often related to overprint with Sr-bearing fluids. In continental arcs (Fig. 2d, Cascades, Central American and Mexican Volcanic arc), crustal assimilation plays an important role, illustrated by lower Sr isotopes for a given Nd isotope signature when compared to intraoceanic arcs.

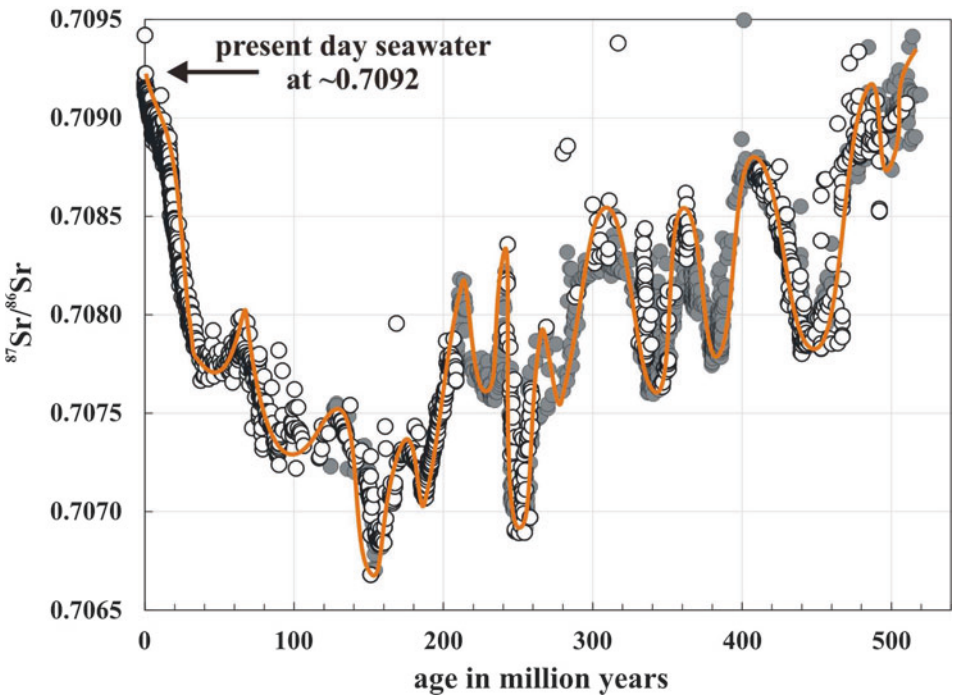
Stable Sr Isotopes in Geochemistry

Within the current analytical limits of ±0.02 δ^{88}Sr units (the delta notation is the deviation in $^{88}Sr/^{86}Sr$ from the NBS-987 standard times 1000), early solar system materials, including Martian rocks, are identical. In contrast, terrestrial rocks show lighter values in relation to igneous differentiation, tentatively linked to plagioclase fractionation and associated substitution of Sr^{2+} for Ca^{2+} with a preference for the heavier isotope (Charlier et al. 2012). In the low temperature environment, stable Sr isotopes show fractionation during weathering of crustal rocks and in associated soils and waters (Stevenson et al. 2016). Experimental work on biological carbonate material suggests a dependence between ambient temperature and δ^{88}Sr (Fietzke and Eisenhauer 2006). In marine carbonates sampled throughout the Phanerozoic, however, stable Sr isotope compositions show little or no dependence with temperature. Instead, the variations in δ^{88}Sr, decoupled from $^{87}Sr/^{86}Sr$, can be used to constrain the flux of Sr run-off into the oceans and associated ocean residence times (Vollstaedt et al. 2014).

Radiogenic Sr Isotopes in Surface and Ocean Water

Strontium is a large ion lithophile element (LILE) and therefore considered mobile in aqueous solutions. It has a high solubility and is readily transported in surface waters and hydrothermal fluids. In ground water, dissolution of Sr^{2+} through reaction with aquifer lithology leads to highly variable $^{87}Sr/^{86}Sr$, which can be used to trace water pathways (Jacobson and Wasserburg 2005). Because of the radiogenic nature of the continental crust, crustal weathering results in radiogenic isotope signatures in most surface waters and open oceans with an average, present day seawater $^{87}Sr/^{86}Sr \sim 0.712$ (Palmer and Edmond 1989). Continental run-off of Sr into the ocean is related to continental weathering rates, and the related ocean residence time is in the order of 1 Myr to as long as 20 Myrs in the Phanerozoic Oceans (Vollstaedt et al. 2014). Consequently, enhanced weathering due to erosion of crustal terranes with associated radiogenic $^{87}Sr/^{86}Sr$, for example, during times of peak orogenesis, results in more radiogenic Sr isotope signatures in seawater. Similarly, the contribution of juvenile $^{87}Sr/^{86}Sr$ to the ocean in times of extensive seafloor spreading, for example, during continental reorganization following the break-up of supercontinents, can alter seawater Sr isotopic composition.

Strontium is easily incorporated into Ca-bearing chemical sediments (e.g., carbonates or phosphates) or biogenic carbonate-phosphate skeletons (e.g., shells, corals). Hence, with a detailed knowledge of the $^{87}Sr/^{86}Sr$ signatures of seawater through time, the isotope signatures of Ca-bearing



Strontium Isotopes, Fig. 3 Strontium isotope evolution of Phanerozoic seawater after Veizer et al. (1999). Filled symbols represent coherent data reported in Veizer et al. (1999); open symbols are additional literature data. The *orange line* is a moving average drawn by eye to highlight the sharp changes in $^{87}Sr/^{86}Sr$. marine sediments, for example carbonates, may be used to place them into a broader stratigraphic context. This process is known as Sr chronostratigraphy. Careful analyses of limestones and/or biogenic calcite with known age revealed a detailed Sr isotope evolution of seawater throughout the Phanerozoic (Burke et al. 1982; Veizer and Compston 1974). Subsequent refinements of the seawater evolution curve revealed a cyclic evolution with de- and increasing isotope signatures (Fig. 3). Notable is a constant decline in average Sr isotope composition from the Cambrian to the late Jurassic. A steady increase since then has led to a present day $^{87}Sr/^{86}Sr = 0.7092$, broadly matching Cambrian seawater isotope composition.

Sr Isotopes in Forensic Sciences

Strontium readily substitutes for Ca^{2+} in biogenic phosphates and with this also locks in the $^{87}Sr/^{86}Sr$ isotope code of the environment in which the organism grows. With this, Sr isotope compositions of bones and teeth are a valuable tracer in forensic sciences for provenances studies or to track migration routes. Application range in identifying historic human remains and their provenance using teeth, for example, the iceman discovered in Austria (Muller et al. 2003), or tracking human or bird migration through hair or feather analyses, respectively (Font et al. 2007; Font et al. 2012). Analyses in human bone, however, reflect only the last ca. 6 years of life (Price et al. 2000).

Subduction Zone Geochemistry

Terry Plank
Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA

Definition

The exchange of chemical components between the Earth's interior and exterior driven by plate subduction.

Introduction

Subduction zones are not just sites of plate convergence but regions where the interior and exterior of the Earth chemically exchange (Fig. 1). Like a factory, raw material from the Earth's exterior is fed into the subduction zone and transformed in a series of chemical reactions driven by increasing pressure (P) and temperature (T) in the sinking plate. Some of the products are buoyant and so rise, drive melting in the mantle, and return back to the Earth's crust via intrusion and volcanism. Dense waste products continue to sink into the deep mantle, perhaps to the boundary with the core. This subduction factory is ultimately responsible for generating continental crust, re-enriching the mantle, and redistributing water and carbon dioxide in the planet. The processes that occur inside the factory are hidden from view, inferred from comparison of oceanic input and volcanic output chemical fluxes, laboratory experiments that simulate high P-T reactions, thermodynamic calculations, and exhumed high-pressure rocks.

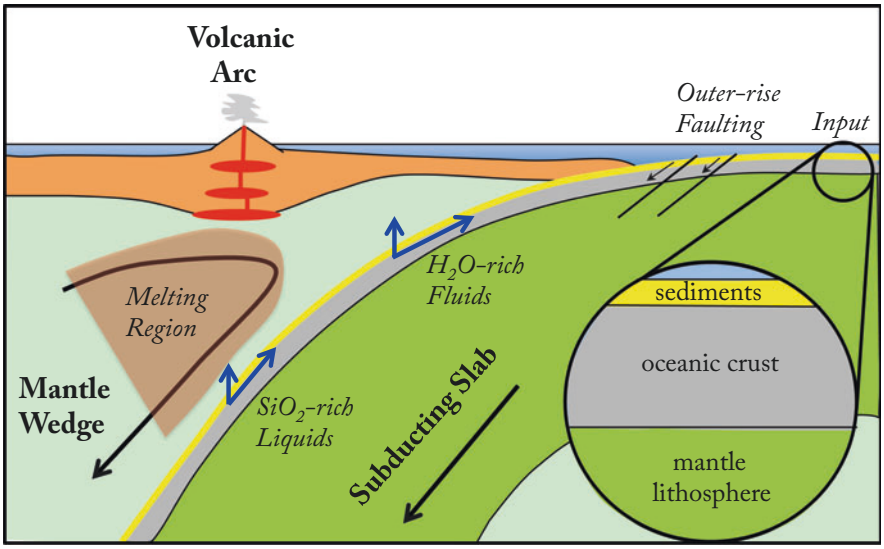
Input Materials

The input to the subduction zone is the incoming plate, which consists of three layers of fundamentally different chemical compositions: the basaltic oceanic crust created at mid-ocean ridges, its mantle residuum substrate that moves with the plate, and marine sediments that deposit on top (Fig. 1). Each of these layers interacts differently with the ocean as the plate travels from mid-ocean ridge to deep sea trench. Most information on the chemical composition of the subducting plate has come from the international scientific ocean drilling programs through direct sampling and borehole observatories.

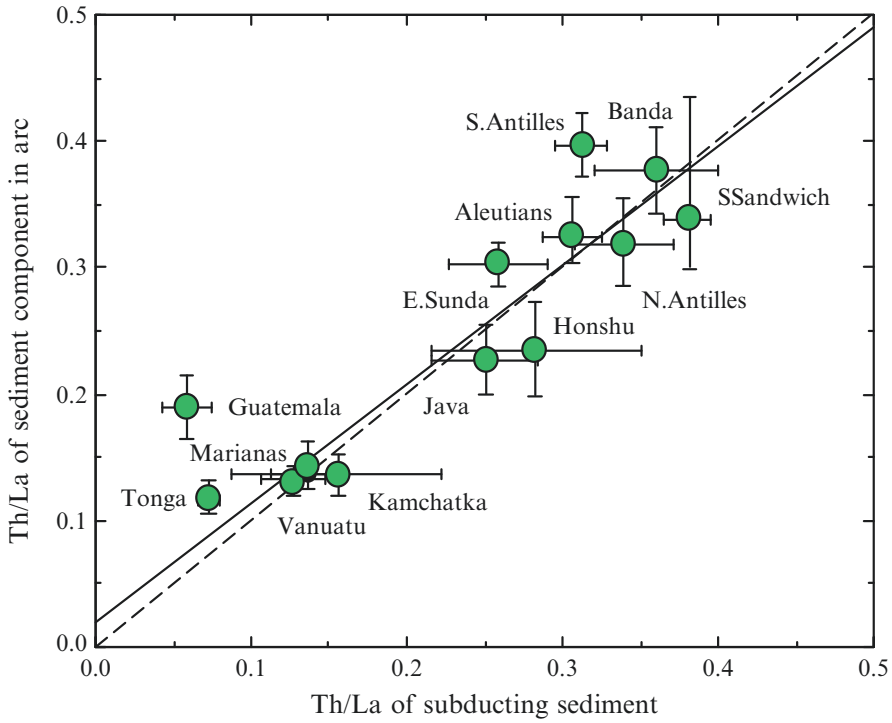
The basaltic oceanic crust represents the melt layer segregated from the melting mantle at mid-ocean ridges, and its initial chemical composition reflects the degree of melting and history of the upper mantle source region. Hydrothermal circulation near the active spreading center then decorates the oceanic crust with secondary minerals such as smectite and Fe oxides and introduces chemical components such as H_2O, S, U, Li, B, and alkalis (Kelley et al. 2003). Carbonate veins precipitate at lower temperatures as the plate moves off the ridge axis (Alt and Teagle 1999). Near the trench, plate bending opens new fractures that hydrate the oceanic crust. The sum of these chemical interactions produces an altered basaltic crust with very different parent-daughter isotope ratios, such as high $^{238}U/^{206}Pb$ and $^{87}Rb/^{87}Sr$, which initiate distinct isotopic evolutionary paths (Kelley et al. 2005; Porter and White 2009).

The extent to which the mantle peridotite substrate reacts with the ocean is debated, but critical to the fate of water at the surface of our planet. The primary mineral in peridotite is olivine, which may undergo rapid and extensive hydration, even at ambient temperatures, to the mineral serpentine (a hydrous mineral with an abundance of H_2O, ~12–13 wt%). The peridotite section of the oceanic plate is thus a sponge to water if it can be delivered to depth. The primary evidence for serpentinization of the oceanic plate comes from a reduction in seismic velocity toward the trench, observed at the Central American, Andean, and Aleutian margins (Shillington et al. 2015). As little as 2% serpentinization of the top few km of incoming peridotite holds enough water to subduct the entire ocean every billion years (Hacker 2008). Although H_2O is the dominant chemical component attending serpentinization, other diagnostic features include elevated Cl and $\partial^{11}B$ (Vils et al. 2009; Debret et al. 2014).

Sediments deposited on the seafloor constitute the greatest chemical heterogeneity injected into the subduction zone, from pure silica chert to nearly pure calcium carbonate chalks and metal-rich red clays (Plank 2014). Marine sediments are physical mixtures of variable amounts of continental detritus, delivered by wind, rivers, and/or volcanic eruption, biogenic accumulations of primarily carbonate, opal and apatite organism hard parts, and hydrothermal particulates as the complements to seafloor alteration. All of these phases may be seeds for adsorption of chemical complexes from seawater itself, a hydrogenetic component. Globally, marine sediments are dominated by continental detritus and so have a composition very similar to that of average shales and the upper continental crust. Biogenic phases are largely diluents to most chemical species in the detritus, except for Sr, Ba, and U in carbonates, rare earth element (REE) in phosphates, and Ba associated with biogenic opal. In regions of the oceans far from wind or river inputs, sediments are dominated by



Subduction Zone Geochemistry, Fig. 1 Cartoon of subduction zone depicting some key sources and processes that affect geochemistry

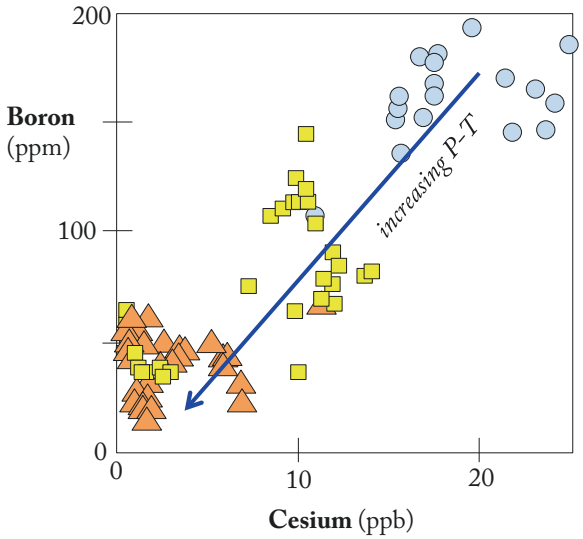


Subduction Zone Geochemistry, Fig. 2 One-to-one correlation between the Th/La of bulk sediment subducting into different trenches and Th/La measured in the corresponding arc volcanoes. This relationship demonstrates the geochemical connection between sediment input and volcanic output at subduction zones. The sediment component in each arc is calculated by linear regression of Th/La-Sm/La in basaltic samples (Plank 2005)

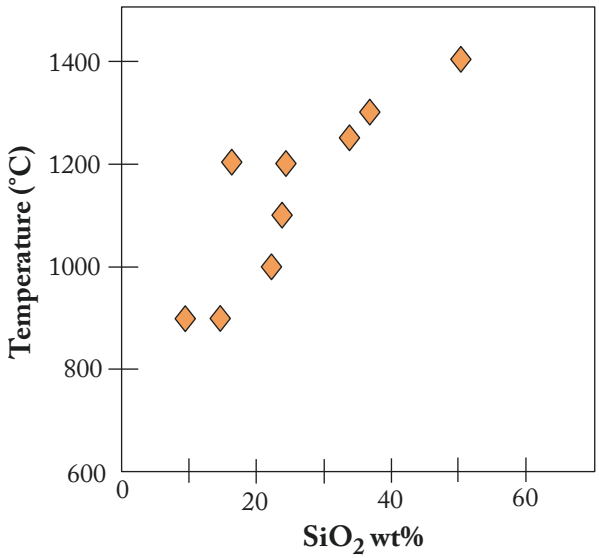
hydrogenetic or hydrothermal components, rich in Fe-Mn oxides, REE, Th, Pb, Co, and other metals. Unlike most planetary reservoirs, marine sediments may have distinctive Nd-Hf isotopic compositions due to the strong enrichment of REE in some phases and the lack of the heavy mineral zircon in sediments far from land (Vervoort et al. 2011). The oceanic realm also may lead to the distinctive fractionation of Ce (which is highly particle reactive when 4+) from the other dominantly trivalent REE. The sedimentary input to different subduction zones is widely variable, depending on the paleogeography and paleoceanography of each site. The unique geochemical characteristics of each sedimentary section is shared by its adjacent volcanic arc (Fig. 2), providing strong evidence for cycling through the subduction zone.

On the Way Down

As oceanic material enters the subduction zone, it begins a path of increasing T and P that drives mineral transformations,



Subduction Zone Geochemistry, Fig. 3 The loss of boron and cesium during subduction, as recorded in micas from metasedimentary rocks of the Catalina Schist during increasing P (pressure) – T (temperature) grade from ~200 °C to 600 °C. *Circles* are lowest grade lawsonite-albite schists; *squares* medium grade blueschists; *triangles* higher-grade amphibolites (From Bebout (2014))



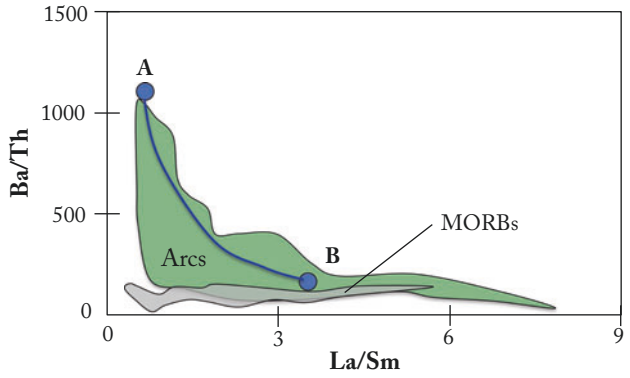
Subduction Zone Geochemistry, Fig. 4 SiO2 concentration of high P-T fluids generated in the laboratory (equilibrated with basalt at 6 GPa). Fluids evolve continuously from low-SiO2 aqueous fluids at low T to high-SiO2 melt-like supercritical fluids at high T (Figure from Kessel et al. (2005))

devolatilization reactions, fluid evolution from aqueous to solute rich, and an increase in the solubility of many trace-element-bearing minerals. Mineral reaction and fluid production in turn accompany a spectrum of fault slip behavior in the subduction zone, from slow and silent slip to the world's largest intraplate earthquakes.

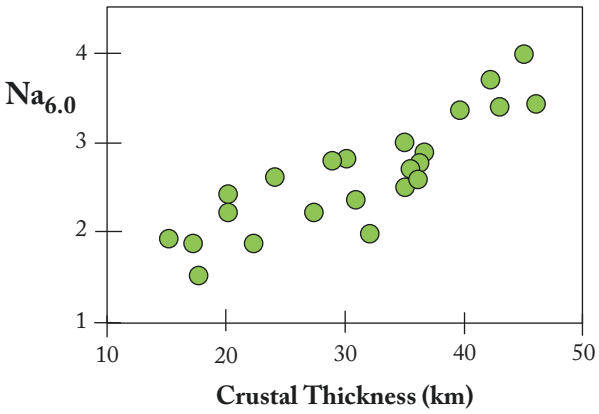
The lowest P-T conditions involve compaction and dehydration of the sedimentary section as the clay mineral smectite transforms to illite and the light elements Li and B as well as alkalis Cs and Rb are liberated into a water-rich fluid (Ishikawa et al. 2008; Bebout 2014; Fig. 3). At higher P-T, the dominant minerals in the basaltic crust become lawsonite, garnet, and clinopyroxene (Klimm et al. 2008), while quartz and mica also form in sediments. A plethora of accessory mineral phases and their T-dependent solubility control the behavior of key tracers, such as REE, Th, and U in monazite and allanite, Nb and Ta in rutile, and Zr, Hf, U, and HREE in zircon (Hermann and Rubatto 2009; Skora and Blundy 2010). Serpentine minerals have a maximum stability of 600–700 °C (Schmidt and Poli 1998), but may persist to >200 km depth in the peridotite section because the slab interior heats up more slowly (Hacker 2008). Deformation within the subduction zone may create mélange (Marschall and Schumacher 2012), a mechanical mixture of sediment-basalt-peridotite that may favor the formation of distinctive minerals such as chlorite.

At higher temperatures, fluids evolved during the breakdown of lawsonite, amphibole, and mica are more solute rich, containing Si, Al, and alkalis (Manning 2004). If flushed with water-rich fluids, the top of the plate may melt at T $\geq$ 700 °C and P $\geq$ 3 GPa (Mann and Schmidt 2015). At pressures higher than 5 GPa, sediments no longer melt at a discrete solidus but instead evolve "supercritical" liquids that span a continuum of compositions (Kessel et al. 2005; Fig. 4) from dilute aqueous liquids with little dissolved silicate to melt-like silicate-rich liquids with dissolved water (Hermann et al. 2006).

The workings within the subduction zone beneath volcanic arcs are of particular interest because they prime the source of arc magmatism. The tracers of the slab include large ion lithophile elements (e.g., alkalis, Ba, Pb) that are thought to be mobile in lower T fluids and high-field strength elements (e.g., Nb, Ta, REE, Th) which are thought to be mobile only in higher T fluids/melts/supercritical liquids (Elliott 2003; Fig. 5). A range of fluid and solid compositions will exist for different subduction zone P-T paths. Young slabs (e.g., Cascadia) follow higher T/P paths than old, fast subducting slabs (e.g., Tonga; Syracuse et al. 2010). Different thermal regimes will lead to different slab fluid compositions that supply different arcs, for example, REE-poor and high Ba/La, U/Th, and B/Be at Tonga and low H_2O/Ce and high Sr/Y at Cascadia (Ruscitto et al. 2012). Sedimentary versus basaltic slab material supply different $^{143}Nd/^{144}Nd$, $^{10}Be/^{9}Be$, and $^{205}Tl/^{203}Tl$ compositions, reflecting greater mean age, cosmogenic contribution, and seawater interaction, respectively (White and Patchett 1984; Morris et al. 2002; Prytulak et al. 2013). Volcanic arcs often inherit the local subducted sedimentary fingerprints in their Th/La (Plank 2005) and $^{207}Pb/^{204}Pb$ ratios.



Subduction Zone Geochemistry, Fig. 5 Subduction zones produce arc basalts (*green field*) that are significantly enriched in Ba/Th compared to mid-ocean ridge basalts (*gray field*). *Line* shows expected mixing between low-temperature/altered oceanic crust fluid (1) and high-temperature/sediment melt (2) from the subduction zone (Mixing calculation and figure from Elliott (2003))



Subduction Zone Geochemistry, Fig. 6 Correlation between the thickness of the crust and the sodium concentration of basaltic magmas, averaged for different volcanic arc segments globally. This relationship is interpreted to reflect lower extents of mantle melting beneath arcs with thick crust, due to the displacement of the hot mantle wedge core to greater depths. Na6.0 is the average Na2O concentration (wt%) of volcanic rock samples with 5.5 > MgO < 6.5 wt% (Data compilation, figure, and interpretation from Turner and Langmuir (2015a))

One Man's Trash Is Another Man's. . .

The progressive removal of water, fluids, melts, supercritical liquids, and buoyant solids leaves behind a dense slab that sinks deeper into the upper mantle, the transition zone, the lower mantle, and potentially as far as the core-mantle boundary. Such processed slab material contributes to mantle heterogeneity. Carbonate and organic carbon are stubborn substances in subduction zones, some destined to become diamonds in the mantle (Walter et al. 2011; Sverjensky et al. 2014). Particularly cold P-T paths can ferry water into the lower mantle in a series of dense hydrous magnesium silicates, leading to a loss of water from the surface hydrosphere (Nishi et al. 2014). The transition zone is capable of containing oceans of water in the mineral ringwoodite, recently discovered as inclusions in high-pressure diamonds (Pearson et al. 2014). The subduction zone can deliver to the deep mantle stable isotope tracers in $^{18}O/^{16}O$, $^{7}Li/^{6}Li$, and $^{34}S/^{32}S$ that bear vestiges of their origin in the biosphere, hydrosphere, and atmosphere at Earth's surface (Eiler 2001; Farquhar et al. 2002; Elliott et al. 2006; Sleep et al. 2012). Other radiogenic isotope tracers such as $^{206}Pb/^{204}Pb$, $^{187}Hf/^{186}Hf$, and $^{87}Sr/^{86}Sr$ evolve to anomalous values due to extreme fractionation of parent from daughter isotope in subducting slabs (Chauvel et al. 2008). Such distinctive slab material is thought to surface again in rising mantle plumes, producing volcanism on ocean islands like Hawaii, Galapagos, and Samoa (Blichert-Toft et al. 1999; Jackson et al. 2007; Hofmann 2014).

Or, What Goes Down Must Come Up

Fluids evolved from the subducting plate may rise up the slab interface or into the overlying mantle (Wilson et al. 2014). The exact path of fluid flow from slab to hot core of the mantle wedge and the extent of reaction along the way are poorly known (Pirard and Hermann 2015). Weak, low-density sediment or mélange may become gravitationally unstable and rise as diapirs into the overlying mantle (Behn et al. 2011). These materials may interact with and/or drive melting in the overlying mantle wedge, the source of magmas that feed arc volcanoes.

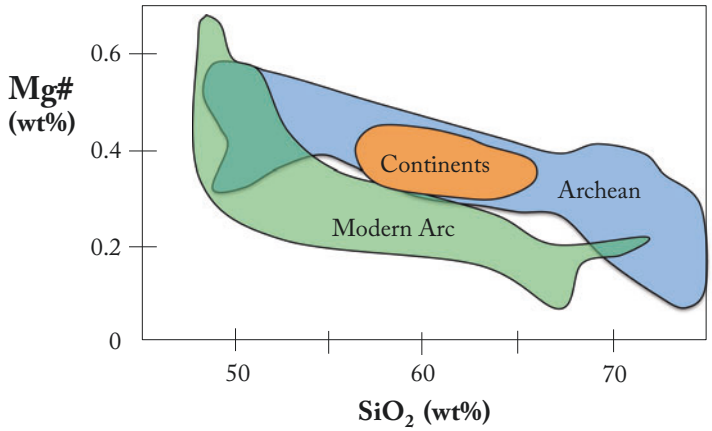
The mantle wedged between the upper and downgoing plates may melt in two ways: (1) by the addition of slab fluid (s.l.) that lowers the mantle melting temperature or (2) by adiabatic decompression due to an upward component of plate-driven circulation, primarily in the back-arc region (Grove et al. 2002). It has also been proposed that the removal of ice loads during deglaciations may lead to enhanced decompression melting (Huybers and Langmuir 2009). Slab diapirs may also melt as they rise through the mantle wedge and heat up (Castro and Gerya 2008). This sum of processes leads to zonation in the concentration of H_2O and other slab tracers in volcanism at different distances from the trench (Pearce et al. 2005; Kelley et al. 2006; Portnyagin et al. 2007). The mantle melting signal is thought to be best recorded in elements which do not derive primarily from the downgoing plate, such as the high-field strength elements (HFSE: Nb, Ta, Hf, Zr, Ti, and Y) and Na. These elements, in turn, vary with both H_2O (Plank et al. 2013) and crustal thickness (Turner and Langmuir 2015a; Fig. 6), leading to competing models whereby slab H_2O on the one hand and wedge depth on the other control mantle melting (Turner and Langmuir 2015b). Some volcanoes erupt magmas with similar geochemical heritage (e.g., U/Th, Ba/La) for 100,000's year (Wade et al. 2005; Jicha and Singer 2006), while others

erupt an enormous diversity of primary compositions (Patino et al. 2000). The primary melts that rise out of the mantle are thought to be basalts in most cases but in some regions are high Mg/(Mg + Fe) andesites and dacites (Kelemen 1995). Such magmas appear to have been more common in the early Earth (Fig. 7).

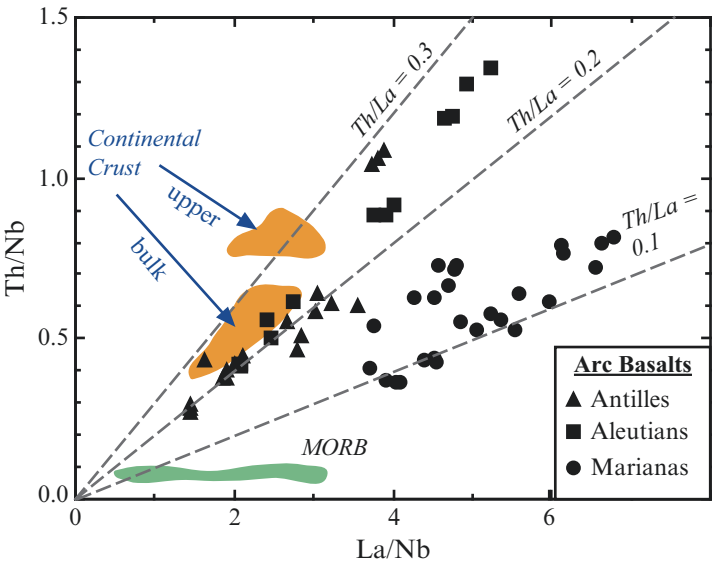
Building Volcanoes and Continents

Magmas continue to be buoyant in the crust, particularly once they begin to exsolve volatile species (e.g., H_2O, CO_2, SO_2, halogens) to vapor. Some of the magmas born in the subduction zone will erupt out a volcano, while some will meet their "viscous death" and crystallize in the crust to become a plutonic body (Annen et al. 2006). The magma flux through the crust will affect the extent of cooling, crystallization, and final composition of the erupted or intruded magma. Magmas with short residence time in the crust will remain basaltic (with high MgO, Ni, Cr), and those with the longest residence time and/or interaction with the crust will evolve to become rhyolites (with high SiO_2 and alkalis). As magmas evolve, they may enrich in Fe (the tholeiitic trend) or deplete in Fe (calc-alkaline). Calc-alkaline trends, predominant at subduction zones and distinctive to Earth, are created from high initial water and oxygen fugacity (Sisson and Grove 1993; Zimmer et al. 2010). Trace elements that are essential constituents to accessory minerals, such as P in apatite and Zr in zircon, will show kinks along crystal fractionation paths as these minerals saturate. Magmas will variably interact, digest, and disrupt the crust they intrude, leading to decreases in $^{143}Nd/^{144}Nd$ as magmas evolve to higher SiO_2 (Sisson et al. 2014), isotopic heterogeneity within individual crystals (Davidson et al. 2001), and/or a cargo of foreign crystals (Dungan and Davidson 2004).

The continental crust and arc magmas share geochemical fingerprints, such as low La/Nb and Th/Nb (Fig. 8), which have long provided strong evidence for continent formation at



Subduction Zone Geochemistry, Fig. 7 SiO2 and Mg# (Mg/[Mg + Fe]) in Archean igneous rocks (dots), bulk continental crust (*orange field*) and typical modern Aleutian arc lavas (*green field*). Most modern subduction lavas are not compositionally similar to the continental crust (From Kelemen (1995))



Subduction Zone Geochemistry, Fig. 8 Th/Nb vs. La/Nb in arc basalts f rom subduction zones, compared to average continental crust (orange field) and mid-ocean ridge and oceanic island basalts (green field). The high Th/Nb (depletion in Nb) is a feature shared by both the continental crust and subduction magmatism. Figure after Plank (2005)

subduction zones (Rudnick 1995; Plank 2005). Few modern arcs, however, provide a good match to the full continental fingerprint (Gazel et al. 2015), and most arc crust is significantly less silicic than bulk continental crust (Rudnick and Gao 2014). This "silica problem" has several proposed solutions (Tatsumi et al. 2008), generally falling into two categories: (a) predominance of high-silica primary magmas in the early Earth or plutonic record (Kelemen 1995; Fig. 7) and (b) subtraction of low-silica crystals by sinking of dense lower crust into the mantle (Jull and Kelemen 2001).

Timescales of Subduction Geochemistry

Radioactive isotopes and diffusion chronometry constrain the timescales of subduction geochemistry, from millions of years to minutes. Geochemical variations and U-Pb zircon geochronology track the evolution and construction of convergent margins over tens of millions of years (Lee et al. 2007). The presence of the cosmogenic and radioactive isotope ^{10}Be in arc volcanic crystals requires Be to travel from shallow sediments on the seafloor down the subduction zone and back to the surface in less than a few Ma (Morris et al. 2002). Disequilibrium in the activity of U-chain isotopes clocks transport from the slab to the surface in less than a few 100,000 years and perhaps as rapidly as a few 1000 years (Turner et al. 2003). Ar-Ar geochronology establishes the lifetime of individual volcanoes to 100–600 ka (Carr et al. 2007). Crystals erupted from volcanoes can endure several freeze-thaw cycles in magma storage regions (Cooper and Kent 2014), recorded in ^{238}U–^{230}Th crystallization ages on the order of 10,000 years. Diffusion profiles of transition metals (Ni, Fe, Mg, Cr) in primary olivine crystals are speedometers of rapid magma supply from the mantle to some volcanoes in months to years (Ruprecht and Plank 2013). The eruptive process itself may occur in minutes, fueled by the rapid loss of volatiles from melt to vapor and recorded in H_2O diffusion profiles in glass and crystals (Lloyd et al. 2014).

Mass Balances Across the Subduction Zone

Developing meaningful mass balances of different tracers across subduction zones remains an outstanding challenge. An example comes from the rare earth element Nd. The concentration and isotope ratios of Nd in sediments and basaltic crust entering subduction zones are fairly well constrained by drilling. The Nd abundance in subducting peridotite is minor, and Nd is not widely mobilized during the first 700°C of heating in the subduction zone. Its release into slab fluids/melts will be governed largely by the T-dependent solubility of the REE-rich minerals allanite and monazite. A few percent of sediment is generally sufficient to reproduce the ^{143}Nd/^{144}Nd composition of arc magmas, but the balance from subducting basaltic crust versus mantle is not currently well constrained. Other unknowns are the contributions of Nd from the preexisting arc crust, especially if it is made of young arc volcanics with similar ^{143}Nd/^{144}Nd to the intruding magma. The Nd concentrations in arc volcanics are reasonably well known for many volcanoes, but large uncertainties in the magma flux rate at arcs (volcanic and plutonic) lead to minimum uncertainties of a factor of two in the output flux of any magmaphile element. By comparing the volcanic output to the subducted input, it is clear that the Nd contributed from the slab is widely variable from arc to arc. From 0% to 60% of the Nd in volcanic arcs is derived from the slab (Porter and White 2009). Still, the net effect of subduction on the slab is relatively minor for Nd, with 100–70% of the initial slab Nd continuing into the deep mantle.

Even greater uncertainties exist for the mass balance of other chemical species, such as carbon, where current estimates are anywhere from ~0% to 80% C entering subduction zones continuing into the deep mantle (Kelemen and Manning 2015). A similar situation exists for H_2O, although the presence of the surface ocean over most of geological time places maximum constraints on the amount of water that can disappear into the mantle (Parai and Mukhopadhyay 2012). The slow subduction process adds up over geological time; an ocean of water and a mass equivalent to the entire surface pool of organic C have disappeared down subduction zones every few billion years. Variable and inefficient return may have contributed to the unusually high H/C of our planet's surface (Hirschmann and Dasgupta 2009).

Most mass balance estimates to date are like balancing a checking account that has large uncertainties on the deposits and withdrawals – this leads to an uncomfortable situation! A fundamentally different approach is gaining accuracy. Given a P-T path for a slab, it is possible to calculate where and how much departing fluid is evolved and its elemental composition using thermodynamic and partitioning data from laboratory experiments. With enough accuracy of the underlying chemical reactions, the future will see subduction mass balances predicted from calculation. Such an approach is underway with the arc basalt simulator (Kimura et al. 2009), and geochemical-thermomechanical models (Hebert et al. 2009; Baitsch-Ghirardello et al. 2014).

Summary and Conclusions

Subduction geochemistry is a rich topic, spanning from marine geology to igneous petrology, geodynamics to thermodynamics. Accordingly, diverse and multidisciplinary observations and measurements are needed to understand the full subduction cycle for any geochemical tracer. These

include the study of sediments and serpentinite from the seafloor, study of metamorphic rocks and high-pressure simulations in the laboratory, modeling of magma and mantle movement, and study of plutonic and volcanic rocks, glasses, gases, and crystals. For this reason, subduction geochemistry has generally advanced through coordinated, international programs involving hundreds of scientists, with efforts crossing the shoreline and spanning from megascale drilling to nanoscale chemical analysis. The challenges to our understanding are wide and deep, and the stakes are high – subduction has built the continents, stirred the mantle, and developed our hydrosphere and carbosphere over Earth history.

Sulfate Minerals

Andrew G. Christy
School of Earth and Environmental Sciences, University of Queensland, St Lucia, QLD, Australia
Geosciences, Queensland Museum, Hendra, QLD, Australia

Definition

Sulfate minerals are mineral species in which the dominant anionic entity is the sulfate anion, $[SO_4]^{2-}$ (Chang et al. 1996; Alpers et al. 2000). About 380 valid species of sulfate minerals had been described by early 2017 (cf. www.mindat.org), which are often grouped into a broader "sulfate" anion class along with the much small number (ca. 50) of chromates, molybdates, and tungstates. Even rarer related complex anions are the sulfite ion $[S^{4+}O_3]^{2-}$ in scotlandite ($PbSO_3$), fluorsulfonate ion $[SO_3F]^-$ in reederite-(Y) ($Na_{15}Y_2(CO_3)_9(SO_3F)Cl$), and thiosulfate ($[SO_3S]^{2-}$ or $[S_2O_3]^{2-}$) in sidpietersite ($Pb_4(S_2O_3)O_2(OH)_2$).

Introduction

Sulfur is the commonest element in the Earth that occurs in both negative (S^{2-}) and positive (S^{4+}, S^{6+}) oxidation states. Hexavalent sulfur usually occurs bonded to four oxygen atoms in a tetrahedral arrangement, forming the sulfate anion $[SO_4]^{2-}$. The complex anion is held together internally by rather strong, covalent S-O bonds (bond valence = 1.5 valence units), but are bound to other cations to form a mineral structure through links that are usually lower in bond valence and more ionic in character. The formation of sulfate anion requires conditions that are oxidizing relative to those found in the deep Earth, so sulfate minerals are characteristic of near-surface environments that are oxygenated, particularly the oxidized zones of sulfide ore bodies, oxidized hydrothermal and fumarole systems and since sulfate is a common anion in the ocean and many other water bodies, in evaporites. Oxidation of sulfides to form sulfuric acid and hence sulfate minerals is frequently catalyzed by acidophile lithoautotrophic bacteria such as *Thiobacillus* and *Sulfobacillus* in cooperation with iron-oxidizing species (Nordstrom and Southam 1997; Pósfai and Dunin-Borkowski 2006). This process may be exploited for ore processing by bioleaching, and it should be noted that other species utilize the converse reaction of sulfate reduction (Southam 2012). Anhydrite ($CaSO_4$) may also crystallize as a primary mineral from oxidized, sulfur-rich magmas, although it is may not always be preserved in the geological record since it is sparingly water soluble.

Examples

Sulfate minerals may be simple, anhydrous salts of one or more cations. However, most are more complex, containing additional water, hydroxide anion, or other anionic species such as chloride or carbonate. Sulfate is also an essential but subordinate constituent in some minerals such as nosean ($Na_8[Al_6Si_6O_{24}](SO_4)\cdot H_2O$) which do not fall into the sulfate anion class (nosean is a tectosilicate of the sodalite group). Most of the anhydrous sulfate minerals are uncommon, highly water soluble, ephemeral species of fumaroles, and arid environments. However, baryte ($BaSO_4$) and celestine ($SrSO_4$) are extremely insoluble in water and are common hydrothermal gangue minerals of ore deposits, as well as occurring as evaporites. The names of these minerals are as included in the Mineral List of the International Mineralogical Association (2017); the spellings "barite" and "celestite" remain common in American usage. They have an orthorhombic crystal structure in which the large Ba and Sr cations are in 12-fold coordination by oxygen. Anglesite ($PbSO_4$), which shares the same crystal structure, is a frequent oxidation product of lead sulfide ore minerals such as galena.

Calcium sulfate occurs primarily as orthorhombic anhydrite and also as the common monoclinic dihydrate gypsum ($CaSO_4\cdot 2H_2O$), as well as the rare, metastable hemihydrate bassanite ($CaSO_4\cdot \frac{1}{2}H_2O$), which is a natural analog of synthetic "plaster of Paris." Gypsum predominates at the Earth's surface, but it is readily dehydrated to anhydrite through the increase in pressure and temperature associated with burial, with 21% volume decrease of the solid phase. Conversely, anhydrite crystallizes directly from water above 55 °C, but is readily hydrated to gypsum by the action of water at low temperature and pressure. Gypsum formed some of the largest single crystals known of any mineral (up to 12 m long), discovered in 2000 in the "Cave of Crystals" at Naica, Chihuahua, Mexico (García-Ruiz et al. 2007). Also in Mexico, the abundance of these calcium sulfate minerals in evaporitic sediments at the 65-million-year-old Chicxulub impact site is believed to have filled the atmosphere with sulfate aerosol that caused a prolonged global cooling,

exacerbating the Cretaceous-Paleogene mass extinction event (Pope et al. 1997).

While gypsum is by far the commonest hydrated sulfate mineral, this group also includes epsomite ($MgSO_4{\cdot}7H_2O$), melanterite ($FeSO_4{\cdot}7H_2O$), goslarite ($ZnSO_4{\cdot}7H_2O$), and chalcanthite ($CuSO_4{\cdot}5H_2O$), all of which are highly water soluble and are found as efflorescences resulting from sulfide oxidation, often as postmining products.

Hydroxyl-bearing sulfates tend to be less soluble in water. This group includes the green copper sulfates antlerite ($Cu_3[SO_4](OH)_4$) and brochantite ($Cu_4[SO_4](OH)_6$), which are often found in the supergene zones of copper sulfide deposits, along with carbonates such as azurite ($Cu_3[CO_3](OH)_4$) and malachite ($Cu_2[CO_3](OH)_2$) and the amorphous copper silicate chrysocolla.

Economic and Environmental Importance

The large alunite supergroup of minerals, including sixteen sulfate minerals and another nine sulfate-phosphates or sulfate-arsenates as of 2017, shares the rhombohedral structure of alunite $KAl_3[SO_4]_2(OH)_6$ and jarosite, $KFe^{3+}{}_3[SO_4]_2(OH)_6$. Alunite is formed through alteration of feldspars by acid sulfate waters, while jarosite is a widespread oxidation product of iron sulfides such as pyrite at near-surface conditions and is a common component of limonitic gossans and mine waste. It is also a characteristic mineral of formerly sulfidic soils of wetlands that have oxidized on draining to become acid-sulfate soils (Dent and Pons 1995). Jarosite is only stable under acidic conditions and liberates sulfuric acid on its decomposition to goethite at higher pH. It accumulates toxic heavy metals such as Pb and As and releases them upon decomposition (cf. Murray et al. 2014), complicating attempts to remediate such environments. Synthetic jarosite is precipitated as a low-cost and efficient means of removing iron during processing of zinc ore (cf. Dutrizac and Monhemius 1986), but its disposal presents an environmental problem because of the link to acidity. Jarosite has been detected on the surface of Mars by the NASA Mars Rover "Opportunity" using Mössbauer Spectrometry (Klingelhöfer et al. 2004); the mineral is important evidence for the former presence of liquid water on Mars.

Celestine is the principal source of strontium metal and its compounds and baryte of barium. However, the majority of baryte mined commercially is used in fine powder form as a component of drilling muds in hydrocarbon exploration. This is due to its lack of chemical reactivity, magnetism, or abrasiveness, while possessing a high density (ideally 4.48 g/cm^3). It is also used as a dense, inert white filler in paints and plastics. High absorption due to the presence of the heavy barium ion combined with its insoluble, nontoxic nature leads to it being used as a contrast agent for medical X-rays of the digestive system. Gypsum, very soft at 2 on the Mohs scale, has been used in massive form since ancient times as the easily carved sculptural medium "alabaster." It is also used for blackboard "chalk," as a fertilizer and, when partially dehydrated to bassanite, as plaster. Bassanite powder in water forms a viscous paste, which may then be shaped before gradual rehydration of the solid phase turns it back into a rigid mass of interlocking gypsum crystals (cf. Van Driessche et al. 2012).

Formation of sulfate minerals is also important in the corrosion and degradation of concrete and cement products. Sulfate-bearing waters and atmospheric sulfur dioxide attack the calcium silicates, carbonates, and hydroxides of such structural materials to produce minerals such as gypsum, ettringite, $Ca_6Al_2[SO_4]_3(OH)_{12}{\cdot}26H_2O$, and thaumasite, $Ca_3[Si(OH)_6][SO_4][CO_3]{\cdot}12H_2O$, with associated softening and volume expansion (Winter 2012).

Summary

The sulfate anion is widespread under near-surface conditions on Earth, with the result that about 7% of all known mineral species are members of the "sulfate" anion class. Most of these are rare secondary minerals produced by oxidation of sulfide-rich ore bodies, but a small number are important and sometimes rock-forming minerals. Out of these, baryte and celestine are major sources for the elements barium and strontium, respectively, while the extremely common calcium sulfate minerals have found a wide range of industrial uses since Classical times. Volume changes due to sulfate mineral formation can play a major role in degradation and erosion of engineered structures, while redox cycling between sulfide and sulfate species, usually mediated by microbes, produces minerals such as jarosite which play an important role in controlling acidity in environments such as mine waste and drained wetlands.

Sulfide Minerals

Andrew G. Tomkins[1] and Bree Morgan[2]

[1]School of Earth, Atmosphere and Environment, Monash University, Melbourne, VIC, Australia

[2]School of Geosciences, The University of Sydney, Camperdown, NSW, Australia

Synonyms

Sulfosalt minerals (Sulphosalt); Sulphide minerals

Definition

Reduced sulfur bonds as an anion with a significant range of metals (M) to form sulfide minerals of the general form M_aS_b, although two or more metals exist in many sulfide minerals. Sulfosalt minerals are a more complex subset of sulfide minerals of the general form $M_aX_bS_c$, where X is typically one or more of the semimetals (As, Sb, Bi). Metals typically found as major cations in sulfide minerals on Earth include Fe, Co, Ni, Cu, Zn, Mo, Ag, Cd, Hg, Tl, and Pb. Metals that can be found as, sometimes important, trace substitutions in sulfide minerals include the Platinum Group Elements (PGE: Pt, Pd, Rh, Ru, Ir, Os), Au, Ga, Ge, In, and Sn. Together, this large group of metal and semimetal cations, are referred to as chalcophile elements (meaning sulfur-loving). However, the PGE and Au behave as siderophile elements when metallic FeNi metal is present (Hayden et al. 2011). Selenium and Te are chalcogens, which substitute for, or replace S in many minerals (forming selenides and tellurides, respectively), and the semimetals As and Sb act as anions in place of S in subgroups of minerals known as arsenides and antinomides, respectively; these elements and S are important constituents of many platinum group minerals. This large range of minerals is grouped under the heading of Sulfides in the Nickel-Strunz classification system (version 10), which contains nearly 700 minerals.

Given this large number of sulfide minerals, the range of crystal structures is great (Makovicky 2006). The most abundant sulfide minerals in the accessible Earth, in estimated order of abundance, include pyrrhotite ($Fe_{1-x}S$, monoclinic with hexagonal polytypes), pyrite (FeS_2, isometric diploidal, typically cubic habit), pentlandite ($[Fe,Ni]_9S_8$, isometric hexoctahedral), chalcopyrite ($CuFeS_2$, tetragonal scalenohedral), sphalerite (ZnS, isometric hextetrahedral), and galena (PbS, cubic hexoctohedral). At the temperatures and pressures of the upper mantle, monosulfide solid solution (MSS) is the dominant sulfide phase, which exsolves upon cooling to pyrrhotite (dominant), pentlandite and chalcopyrite. Pyrite is the dominant sulfide in the upper crust but tends to break down to pyrrhotite in the mid to lower crust (e.g., Pitcairn et al. 2006; Tomkins 2010; Finch and Tomkins 2017).

Introduction

Sulfur (S) is the tenth most abundant element in the Universe, and the fifth most abundant in the Earth, so the minerals and compounds it forms play, and have played, key roles in the evolution of the Earth and its life. Sulfide minerals are the most abundant form of sulfur in the solid Earth, and contain important metal resources that are essential to modern societies, so understanding their formation and stability is fundamental to many subdisciplines of geosciences.

Sulfide Ore Deposits

Sulfide minerals are the key metal-bearing constituents of many of our most important ore deposit types. There is a wide range of ore deposit types because S is highly mobile in aqueous fluids and magmas. Various sulfide ore deposit types fall under the broad headings of magmatic, magmatic-hydrothermal, and hydrothermal ore deposits.

Our most important resources of Ni and PGE form as magmatic sulfide deposits (Cu is an important constituent of some), where mafic to ultramafic magmas become saturated in S, promoting exsolution of immiscible sulfide liquid droplets, which are able to gravitationally accumulate and sequester chalcophile elements from the silicate magma (Mungall 2014). The most important Cu and Mo deposits (Au is commonly an important constituent) form when felsic to intermediate magmas crystallize in the upper crust, releasing saline and S-bearing hydrothermal fluid, which scavenges metals from the magma and transports them to a range of structurally controlled locations where sulfide minerals form (Cooke et al. 2014). Most of the world's gold deposits formed when metamorphism in orogenic belts promoted release of fluids containing H_2O, CO_2, and H_2S from mid to lower levels of the crust, which transported Au (and Ag) into structurally controlled sites in the mid to upper crust (Tomkins 2013), where Au was deposited in close association with typically pyrite and arsenopyrite (FeAsS); a range of other sulfide minerals are also sometimes present. The most important Zn and Pb resources formed in deep sea floor settings (so-called volcanogenic massive sulfide (Hannington 2014) and sedimentary exhalative sulfide deposits (Wilkinson 2014)), involving deep circulation of warm saline fluid through igneous and/or sedimentary rocks before expulsion of metal-bearing fluids through vents on the sea floor where sulfide minerals are precipitated due to distinct temperature and fluid chemistry changes. Many of the chalcophile elements are primarily extracted as byproducts from these main sulfide ore deposit groups, including As, Bi, Co, Ga, Ge, Hg, In, Sb, Se, Te, and Tl. However, there is a wide range of other settings where sulfide-rich ore deposits form.

Sulfide Minerals in Biogeochemical Systems

Sulfide mineral precipitation in low temperature anoxic conditions is largely driven by the global biogeochemical cycling of S, Fe, and organic C and can be limited by availability of each of these components depending on system conditions. Because sulfate is abundant in modern oceans, dissimilatory sulfate reduction is the dominant process fueling microbial break down of organic matter in marine systems (Rickard and Luther 2007). Furthermore, some of the earliest life forms are thought to have gained energy by oxidizing molecular hydrogen (H_2), or methane (CH_4), while reducing sulfate (SO_4^{2-}) to sulfide, existing in an early Earth environment that lacked free oxygen (~3.9–2.4 billion years ago). In both cases, these sulfate reducing prokaryotes produce dissolved sulfide (H_2S, S^{2-} or HS^-), which then reacts with reduced divalent metal ions (M^{2+}), to be immobilized in sulfide minerals. Fe-sulfide minerals are most commonly precipitated during this process due to the high abundance of reactive iron at the Earth's surface, with reduction of Fe^{3+} to Fe^{2+} being thermodynamically favored (and thus preceding) over the reduction of sulfate (Burdige 2006).

Pyrite is the most abundant Fe-sulfide mineral produced by biologically mediated sulfate reduction (Rickard and Luther 2007). The formation of sedimentary pyrite is a complex process, generally involving the initial precipitation of metastable monosulfide precursors, including poorly crystalline mackinawite (tetragonal FeS) and greigite (cubic Fe_3S_4; Hunger and Benning 2007). The "hydrogen sulfide pathway" and the "polysulfide pathway" are widely thought to promote pyrite formation from an iron monosulfide precursor, and involve the reaction of FeS with hydrogen sulfide or polysulfide (S_n^{2-}), respectively (Schoonen 2004; Rickard and Luther 2007). The transformation of Fe-monosulfides to thermodynamically stable pyrite requires the availability of an oxidant (other than dissolved sulfide) to proceed, such as O_2, S^0 , and other S intermediates (Schoonen and Barnes 1991; Benning et al. 2000).

Sulfide Minerals and the Global Sulfur Cycle

To biogeochemists, the term sulfur cycle refers to the cycling of sulfur through organic processes in the surface environment and upper crust, as discussed above. However, there is a larger-scale, longer-term cycle whereby S is cycled through the atmosphere and hydrosphere, often via the biosphere, into the deep Earth, and eventually back into the atmosphere. This cycle can be viewed as starting with sulfur in volcanic gases, and sulfur released into rivers by weathering of sulfide minerals (mainly pyrite) in rocks exposed in mountain belts. Sulfur from these sources is introduced into the oceans, where SO_4^{2-} is the second most abundant anion. This sulfate is circulated into the oceanic crust at volcanic mid-ocean ridges and other areas of extensional faulting, where seawater promotes alteration of the rock and formation of pyrite, pyrrhotite and anhydrite ($CaSO_4$), storing S in the oceanic crust (Alt 1995). The layer of sediments sitting on top of the basaltic crust typically contains biogenic pyrite. This oceanic crust is eventually subducted into the mantle, where the pyrite and anhydrite break down during blueschist and eclogite facies metamorphism, releasing S into fluids that migrate upwards into the overlying mantle (Tomkins and Evans 2015). These fluids promote metasomatism of the mantle,

forming mainly disseminated grains of monosulfide solid solution, and making the mantle more susceptible to melting (Rielli et al. 2017). These sulfide mineral grains are partially dissolved into the magmas that develop, and these eventually make their way up to magma chambers beneath the numerous volcanoes that populate magmatic arcs. Some sulfide mineral rich ore deposits form in this environment (and are eventually eroded), and some magmas erupt through the volcanoes releasing gaseous sulfur back into the atmosphere. Because the sulfate in the oceans is thought to have become more abundant due to the evolution on the biosphere, it has been postulated that this global sulfur cycle may have driven changes in the chemistry of the deep Earth over billions of years (Evans and Tomkins 2011).

Extraterrestrial Sulfide Minerals

Sulfide minerals are common in meteorites, which represent approximately 110 asteroids, as well as Mars and the Moon. Most meteorites contain the mineral troilite (stoichiometric FeS). A small proportion of oxidized meteorites, and most of those from Mars, contain pyrrhotite ($Fe_{1-x}S$) and pentlandite ($[FeNi]_9S_8$). Pyrite (FeS_2) is found in very few meteorites but is notably abundant in an important regolith breccia from Mars (NWA 7034 and pairs). Given that S is a volatile element, rocky and rock-ice bodies that formed further from the Sun are expected to have greater abundances of sulfide minerals, and this appears to be the case for Mars compared to the Earth.

The most reduced meteorites, the enstatite chondrites and achondrites, have such little oxygen that elements such as Ca, Mg, and Mn partly combine with S to form sulfide minerals such as oldhamite (CaS), niningerite (MgS), and alabandite (MnS) and their solid solutions involving Fe. Sulfide minerals in these ultrareduced meteorites also contain elevated lathanides and actinides (Barrat et al. 2016).

Summary

Because sulfur is relatively abundant in the Earth's crust and mantle and can exist in multiple valence states in many geochemical domains, sulfide minerals have been a cornerstone of several important geochemical processes. They are the products of the anaerobic respiration utilized by some of the earliest life forms on Earth (sulfate reducing prokaryotes), which persist today in anoxic subaqueous environments. They are part of the global sulfur cycle, which transfers sulfur from the surface through subduction zones into the deep Earth and back through volcanoes. And, they are the hosts to many of our most important metal resources.

Sulfur is the tenth most common element in the solar system with an abundance about half that of silicon and a little less than one tenth that of oxygen (Lodders 2003). While there are a number of nucleosynthetic pathways for production of this element, the principal nucleosynthetic pathway for production of its three lightest isotopes (^{32}S, ^{33}S, ^{34}S) is related to explosive burning of oxygen (Woosley et al. 1973) and the pathway of its rare isotope is principally via neutron rich silicon burning (Cameron 1979; McDonough 2014; Meija et al. 2016a, b; Meyer 1976; Palme et al. 2014; Rudnick and Gao 2014; Steudel 2003; Steudel and Eckert 2003; Wang and Becker 2013; Whittaker and Muntus 1970).

Properties

Sulfur in its elemental form is a yellow crystalline solid. When broken, it has a sulfurous smell. Elemental sulfur sublimates at ambient temperatures, is insoluble in water, but soluble in organic solvents such as carbon disulfide, benzene, toluene, xylenes, and chloroform, and carbon tetrachloride. The electronic structure of sulfur ([Ne] $3s^2$ $3p^4$) determines its accessible oxidation states, which range from −2 to +6, leading to a wide range of sulfur-bearing compounds in nature.

History and Use

Sulfur has had a variety of uses, including as a component in black powder, to harden (vulcanize) rubber by creating cross-linkages, in the form of mercaptan (SCH_3) as an odorant in natural gas, and as a pesticide. In nature, sulfur compounds act as cryoprotectants in cells and as natural deterrents to predation. Sulfur in various forms is also used as a fertilizer. Sulfur as sulfate is used for sulfuric acid, a component in batteries.

Geochemical Behavior

Sulfur in nature occurs in gas, liquid, and solid phase organosulfur as well as inorganic sulfur compounds. This rich chemistry, in combination with the moderately high abundance of sulfur creates a role for sulfur chemistry in the atmosphere, ocean, and solid Earth.

Sulfur is introduced to the atmosphere from a variety of natural and anthropogenic sources. Biological sources of sulfur include hydrogen sulfide, a byproduct of sulfate reduction by prokaryotes, as well as various volatile organosulfur compounds (carbonyl sulfide and methylated sulfur compounds). Atmospheric sulfur is also supplied as hydrogen sulfide and sulfur dioxide released from volcanic edifices. These include large explosive eruptions that can influence climate by injecting sulfur into the stratosphere where it is oxidized to sulfate which forms reflective aerosols, and quiescent degassing such as is observed in hydrothermal regions like Yellowstone. Anthropogenic sources of sulfur include various industrial sources such as coal burning, hydrocarbons, smelting of steel, as well as from waste treatment.

Once in the atmosphere, sulfur compounds participated in complex chemical reaction networks that produce numerous oxidized intermediates and products. Some of these products are hygroscopic and contribute to cloud formation. Other sulfur products contribute to particulate aerosols that can have consequences for air quality and also serve as loci for further chemical transformations of atmospheric compounds. The oxidation of sulfur compounds in the atmosphere also generates species that react with water to form strong acids, making them one of the key contributors to acidification of

rain, snow, and even surface waters when they occur in regions with low buffering capacity.

In the oceans, sulfur is present in both organic matter and as dissolved sulfate. Dissolved sulfate is the second most abundant anion in seawater and its catabolic reduction by microbial metabolisms in marine environments is the second most important pathway for organic carbon mineralization on geological timescales. Sulfate reduction contributes on the order of 30% of the total to organic carbon mineralization and through burial of pyrite provides a long-term geological sink for electrons that contributes significantly to the net oxidation state of Earth's surface environments.

In the solid Earth, sulfur partitions chalcophile elements and is responsible for concentration of metals in the silicate Earth. Earth's mantle is significantly depleted in sulfur relative to that seen for the solar system because of partitioning of sulfur into Earth's core (Savage et al. 2015).

Biological Utilization and Toxicity

Sulfur is an essential element for life, being a key component in the amino acids methionine and cysteine. Sulfur cross-linkages are essential for formation of proteins, and sulfur is present in keratin, a compound found in finger nails and hair. More complex organic sulfur compounds are key components for plants and microbes that are used to deter predation, for signaling and communication, and also for freezing point depression as cryoprotectants. Compounds familiar to humans through experiential, even if not explicitly recognized, include glucosinolates such as sinigrin which is a component of mustard and wasabi (horse radish), allicin which is a component of garlic that adds to its characteristic flavors and has antibiotic and anticancer properties. Antibiotic and anticancer properties have also been identified for a variety of other organosulfur compounds such as glucoraphanin and glutathione which are components of cruciferous vegetables such as broccoli and cabbage. Biological sulfur compounds often smell, sometimes pleasant, as in the low level methyl sulfides that bring the characteristic smell of the ocean, and sometimes unpleasant as in the smell of a skunk, or of rotten eggs, vegetables, or meat.

Summary

The diverse oxidation states of sulfur contribute to a rich chemistry in Geobiology and Geochemistry. In biology, sulfur cross-links proteins, is part of essential amino acids, and provides key properties for biologically relevant chemicals. In Earth's atmosphere, redox transformations contribute to aerosol formation and acidification of rain. In the oceans, the reactivity of microbially produced sulfide with iron and oxygen has made it one of the key elements for controlling whether the oceans, in part or in whole, have been oxic, ferruginous, or sulfidic. In Earth's crust and mantle, sulfide chemistry of chalcophile elements plays an important part in their concentration and distribution. In the solid Earth and its precursors, sulfur is thought to have been strongly partitioned into the metallic liquids during planetary differentiation and thus is considered a strong candidate light element for the core.

Sulfur Cycle

Martin A. Schoonen
Brookhaven National Laboratory, Upton, NY, USA
Department of Geosciences, Stony Brook University, Stony Brook, NY, USA

Definition

The global sulfur cycle refers to the transfer of sulfur between the upper lithosphere, hydrosphere, pedosphere, biosphere, and atmosphere as a result of geological, biological, and anthropogenic processes. Sulfur passing through the cycle is subject to redox reactions with oxygen, carbon, and iron as major reactants, which lead to a tight coupling of the global cycles for these elements.

The Major Sulfur Reservoirs on Earth

Most sulfur on Earth involved in the global sulfur cycle is retained in the upper lithosphere and marine sediments (Table 1). A large unknown amount of sulfur residing in the Earth's core and mantle is effectively sequestered and excluded from the global sulfur cycle. The oceans contain most of the sulfur residing in the hydrosphere, dwarfing the amount of sulfur in lakes and rivers (Table 1). The amount of sulfur contained in soils and biomass is roughly four orders of magnitude smaller than the amount of sulfur in the oceans, while the atmosphere represents the smallest reservoir of sulfur on Earth (Table 1). Table 1 not only summarizes estimates of the amount of sulfur contained in the major reservoirs; it also indicates the most abundant forms of sulfur in each reservoir.

Sulfur Cycle, Table 1 Major sulfur reservoirs on Earth[a]

Reservoir	Major forms of sulfur	Mass (Tg S)[b]
Atmosphere	Gas: H_2S, SO_2, DMS, OCS Aerosols: H_2SO_4, $(NH_4)_2SO_4$	4.8
Pedosphere and biosphere	Sulfates, organic S, pyrite	3×10^5
Rivers and lakes	SO_4^{2-}	300
Oceans	SO_4^{2-}	1.3×10^9
Marine sediments	Pyrite, gypsum, anhydrite	3×10^8
Lithosphere	Gypsum, anhydrite, metal sulfides, sulfur	2×10^{10}

[a]Based on Brimblecombe (2014) and Jones et al. (2016)

The Modern Natural Global Sulfur Cycle

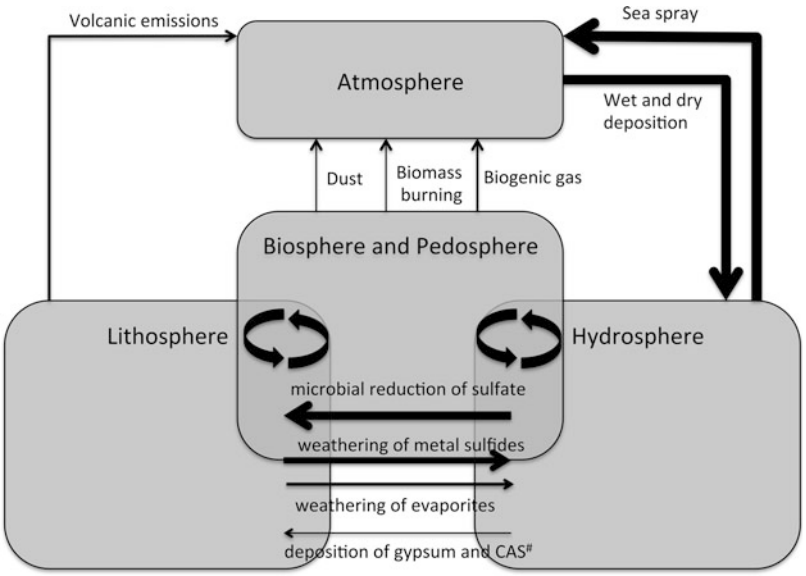
The modern natural global sulfur cycle is dominated by processes involving transfer of sulfur in and out of the oceans (Sievert et al. 2007). A significant amount of sulfur is lofted into the air in the form of small sulfate-containing salt crystals; see Fig. 1. Most of the particles settle rapidly back into the ocean, but some are transported over land and are removed from the air mass through precipitation or by settlings as dry deposition. Removal of sulfate through microbial reduction in marine sediments to sulfide, followed by the formation of pyrite, is a major process that removes sulfate from the ocean (Schoonen 2004). Some sulfate is also removed from the oceans in the form of evaporate minerals and as a trace constituent of sedimentary carbonates (Staudt and Schoonen 1995). Microbial conversion of sulfate into volatile organo-sulfur compounds in marine environments also contributes to a transfer of sulfur from the ocean reservoir through the biosphere into the atmosphere (Sievert et al. 2007).

Inputs to the ocean reservoir in the natural sulfur cycle are dominated by weathering of sulfate-containing evaporative deposits and weathering of pyrite-containing sediments. Removal of volcanogenic sulfur emissions via precipitation or dry deposition into the oceans constitutes a small input, although the magnitude of this flux varies with volcanic activity (Jones et al. 2016).

The magnitudes of all the fluxes in the modern natural global sulfur cycle are difficult to reconstruct because contributions from human activity are difficult to separate from natural contributions. New approaches relying on the study of multiple S isotope systematics are promising (Tostevin et al. 2014), but it remains difficult to close the natural sulfur budget.

Sulfur Cycle Through the Earth's History

As the Earth evolved, so did the sulfur cycle (Rickard 2012; Brimblecombe 2014). Microbial processes play a significant role in the modern natural sulfur cycle (Fig. 1). Hence, on a prebiotic Earth, the sulfur cycle would have been dominated by emissions of volcanic sulfur gases – predominantly SO_2, with minor H_2S – into the atmosphere and removal of sulfur from the atmosphere through photochemical reactions. There was likely very little subaerial crust, all but eliminating gypsum deposition and dissolution as major processes at this early time. Dissolved reduced iron (Fe(II)), leached from crustal rock interacting with ocean waters, would have limited the amount of hydrogen sulfide in solution through iron sulfide precipitation. A higher heat flow on the early Earth would have promoted widespread hydrothermal circulation of ocean water through the crust. The net



Sulfur Cycle, Fig. 1 Simplified modern natural sulfur cycle. The weight of the *arrow* indicates the relative importance of a given flux. There is considerable cycling of sulfur that involves uptake and release of sulfur within the overlaps of hydrosphere, lithosphere, and biosphere as indicated by the *curved arrows*. Anthropogenic activities have a significant effect on the natural sulfur cycle; see Fig. 2, which makes it difficult to determine the absolute magnitude of the modern natural fluxes. #*CAS* carbonate associated sulfur

effect would have been sequestration of sulfate as metal sulfide as ocean water interacted with the crust at elevated temperatures.

The emergence of life triggered significant changes in the sulfur cycle (Rickard 2012). The most profound change to the sulfur cycle occurred at the time of the transition from an anoxic atmosphere to an oxic atmosphere around 2.3 Ga as a result of the emergence of photosynthetic bacteria producing oxygen as a waste product. Detailed studies exploiting multi-S-isotope systematics point to a sulfur cycle that is largely dominated by inorganic processes up to this point in the Earth's history (Johnston 2011). Once the atmosphere contained molecular oxygen, volcanogenic sulfur emitted into the atmosphere was readily oxidized to sulfate. Besides the accumulation of oxygen in the atmosphere, the growth of continents enabled chemical weathering of sulfide-containing rocks through oxidation, resulting in the enhanced transport of sulfate to the ocean. This sets the stage for sulfate-reducing bacteria – possibly long present in the ocean but limited by the availability of sulfate – to flourish and produce sedimentary pyrite in abundance. The emergence of continents also provided settings for the formation of evaporite deposits that removed sulfate from the oceans in the form of gypsum and barite.

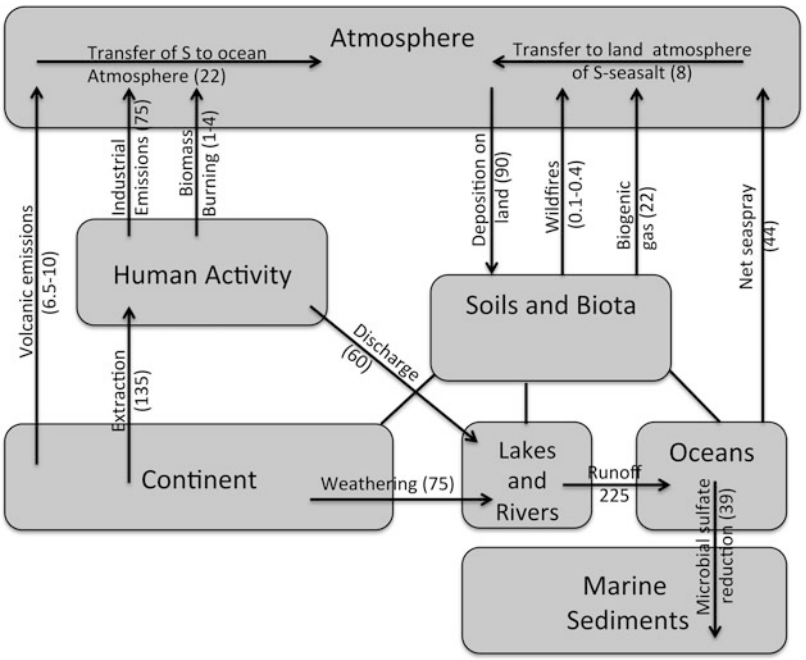
With microbial life established and continents forming and reforming, the sulfur cycle saw additional perturbation as a result of changes in the rate of primary production, evaporite deposition, and weathering (Brimblecombe 2014). Geological, geochemical, and isotopic studies have allowed for detailed reconstructions of these excursions. However, one of the single largest excursions in the sulfur cycle has been induced by human activity over the last two centuries.

Anthropogenic Influence on the Sulfur Cycle

Anthropogenic activities transfer a significant amount of additional sulfur into the atmosphere and hydrosphere. Most pronounced is the burning of S-containing fossil fuel, such as coal. Sulfur in coal is predominantly present as small pyrite crystals (FeS_2), which converts to gaseous SO_2 upon burning and contributes to acidification of rain. Modern scrubbing technologies remove much of the SO_2 from flue gas, but the technology is not widely implemented in China and India, which have emerged as major contributors to the atmospheric SO_2 burden (Klimont et al. 2013). In addition, mining of coal or metal sulfides creates sulfur-containing dust as well as sulfide-containing mine waste that often reacts with water and air to form acid mine drainage. Oxidation of mine waste contributes significantly to the riverine flux of sulfate out to the sea. Roasting of metal sulfide ores, a necessary step to provide society with metals such as zinc and copper, releases a significant amount of SO_2. International shipping, which relies on burning of S-rich bunker fuel, amounts to about 10% of the global anthropogenic SO_2 emissions (Klimont et al. 2013).

The magnitude of the anthropogenic perturbation of the sulfur cycle is illustrated in Fig. 2. For example, it is estimated that more than half of the sulfur transported to the oceans by rivers and 75% of the sulfur emissions to the atmosphere are anthropogenic in origin (Berner and Berner 1996).

On a global scale, the emissions of SO_2 have dropped recently (Klimont et al. 2013). Changes in economic activity



Sulfur Cycle, Fig. 2 Annual fluxes of sulfur (Tg/a). Fluxes based on Brimblecombe (2014) and Berner and Berner (1996) The flux associated with wildfires is estimated to be a factor of ten smaller than biomass burning associated with crop waste burning and land-clearing activities

have a profound effect on the demand for fossil fuel, metals, and transportation of goods via international shipping, and the recent (2005–2011) drop likely reflects the impact of a global recession. However, it is projected that economic growth in India, an expansion of international shipping, and growth of emerging economies in Africa will add to the atmospheric SO_2 burden. At the same time, stricter environmental regulations are expected to lead to a broader application of technologies to scrub SO_2 from flue gas in China, Europe, and North America. While this will lead to a long-term, sustained decrease in SO_2 emissions, it only addresses one of the anthropogenic processes that contributes to the imbalance of the global sulfur cycle (Klimont et al. 2013; Brimblecombe 2014).

Conclusions

The modern global sulfur cycle is out of balance as a result of anthropogenic activity. The sulfur cycle has changed as the Earth evolved. On the prebiotic Earth, volcanic emissions played a key role in the sulfur cycle. This cycle may have remained largely unchanged, until free oxygen accumulated in the atmosphere as photosynthetic microbes emerged. The presence of oxygen and the growth of continents fundamentally changed the sulfur cycle, with evaporate deposition, oxidative weathering of pyrite-containing rocks, and dissolution of evaporites becoming important processes. One of the outcomes was a built up of sulfate in the oceans that allowed microbial sulfate reduction to emerge as an important process. It is thought that the flux of sulfate removal from the ocean through microbial sulfate reduction has grown with the increased atmospheric sulfur deposited in the ocean as a result of human activity. Adoption of new mitigation technologies is likely to reduce the anthropogenic emissions of sulfur.

Introduction

Sulfur has one relatively long-lived cosmogenic isotope ^{35}S and four stable isotopes ^{32}S (95.018%), ^{33}S (0.75%), ^{34}S (4.215%), and ^{36}S (0.017%) that have proven valuable for geochemistry. The cosmogenic isotope, ^{35}S, has a half-life of 87 days and is used as an atmospheric tracer, principally of stratospheric air masses and as a radiolabel for studies of sulfate reduction rates (Howarth and Jørgensen 1984). The four stable isotopes are used to study a wide variety of geochemical processes that extend from the atmosphere to the solid Earth, and from the present-day to time when Earth formed.

Notation

Several types of notation are used to describe variation of S isotope ratios (R): ^{34}R ($^{34}S/^{32}S$), ^{33}R ($^{33}S/^{32}S$), and ^{36}R ($^{36}S/^{32}S$). The most commonly used notation is the lower case delta notation for $^{34}S/^{32}S$:

$$\delta^{34}S = \left(^{34}R_a/^{34}R_{ref} - 1\right) \times 1000$$

which describes the deviation of a ratio of sample (a) relative to a reference (ref), and is expressed at the level of permille (‰) and normalization on the V-CDT scale using IAEA reference materials. V-CDT (Vienna Canyon Diablo Troilite) is an inferred composition for meteoritic sulfur (originally calibrated using a single troilite nodule of the Canyon Diablo meteorite) that is calibrated relative to International Atomic Energy Agency standards.

The second type of notation is the upper case delta notation to describe deviations of the $^{33}S/^{32}S$:

$$\Delta^{33}S = {}^{33}R_a/^{33}R_{ref} - \left(^{34}R_a/^{34}R_{ref}\right)^{0.515},$$

and $^{36}S/^{32}S$:

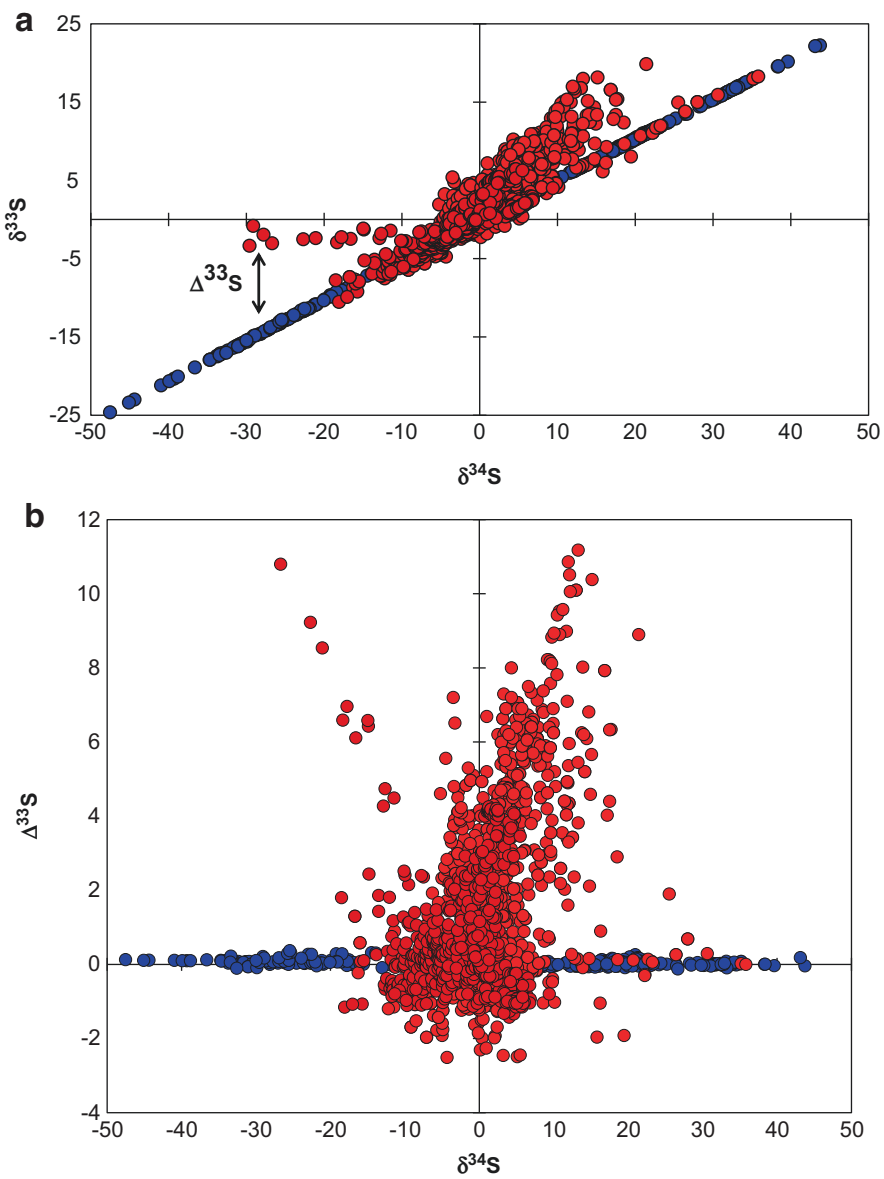
$$\Delta^{36}S = {}^{36}R_a/^{36}R_{ref} - \left(^{34}R_a/^{34}R_{ref}\right)^{1.90},$$

ratios from a composition on a reference mass fractionation array with the same $\delta^{34}S$. The exponents (0.515 and 1.90) are an approximation of low temperature chemically produced, mass-dependent isotopic fractionations. Thus the upper case delta values quantify mass-independent fractionations. Figure 1 presents mass-independent data (red) and mass-dependent data (blue) on plots of $\delta^{34}S$ versus $\delta^{34}S$ (lower case delta) and $\Delta^{34}S$ versus $\delta^{34}S$ (upper case delta).

Using the delta and capital delta notation ($\delta^{34}S$, $\Delta^{33}S$, and $\Delta^{36}S$), geochemists have been able to gain important insights into processes associated with temperature-dependent equilibrium isotope fractionations, kinetic isotope fractionation (all described below) that occur with ground state and excited state species, and to trace material transferred between different geochemical and mineralogic reservoirs.

Standards

Various standards have been used for measurement of sulfur isotopes. The original standard material was a single troilite nodule from the Canyon Diablo IAB iron meteorite (see entry on ▶ Iron Meteorites) that is archived at the USNM (museum of Natural History of the Smithsonian Institution). Because this material is limited and because of concerns about its



Sulfur Isotopes, Fig. 1 Plots illustrating mass-dependent data (blue) and mass-independent data (red) for lower case delta (top) and upper case delta (bottom)

homogeneity, a secondary scale was devised (the V-CDT scale) that calibrated a composition of the troilite relative to a prepared reference material IAEA S-1 (silver sulfide) that was demonstrated to be homogeneous (Robinson 1995). These standards have also been used to normalize $\Delta^{33}S$ and $\Delta^{36}S$, but further work is still needed to refine and anchor these calibrations relative to CDT and other meteoritic reference frames.

Methods of Measurement

Various strategies have been employed for measurement of sulfur isotopes, gas source isotope ratio mass spectrometry (GS-MS), ICP-MCMS (inductively coupled plasma source, multicollection mass spectrometry), TIMS (thermal ionization mass spectrometry), SIMS (Secondary Ionization Mass Spectrometry), and spectroscopic techniques.

The most commonly used approach is gas source isotope ratio mass spectrometry with either sulfur dioxide or sulfur hexafluoride as the analyte gas (Mayer and Krouse 2004; Böttcher and Schnetger 2004). The advantage of sulfur dioxide techniques is the rapidity with which the samples can be analyzed in when produced and carried by a helium carrier. The advantage of sulfur hexafluoride techniques is the lack of isobaric interferences which allow for measurements of all four stable sulfur isotopes at high precision.

ICPMS techniques have recently shown considerable promise for measurement of three of the four isotopes ^{32}S, ^{33}S, and ^{36}S for samples in solution and gas at very low abundance levels (Paris et al. 2013).

TIMS techniques also allow for $\delta^{34}S$ of small samples to be analyzed at high precision using double spike techniques. Secondary Ion Mass Spectrometry allows for in situ measurements to be undertaken on all four sulfur isotopes at a resolution of several 10s to less than 0.1 micron at lower precision.

Spectroscopic techniques have been used for remote monitoring of atmospheric and telescopic determination of isotope ratios, and methods based on spectroscopy (e.g., Christensen et al. 2007) are likely to become part of the standard tool kit for isotope geochemists as methods based on laser spectroscopy techniques are developed and refined. Since sulfur is not usually present in the form that is used for analysis, various extraction techniques are required for its extraction, purification, and chemical preparation for analysis by most of these techniques.

Mass Dependence: A distinguishing feature of isotope effects that occur for ground state species and for equilibrium isotope exchange is strong dependence of the magnitude of the produced isotope fractionation (the isotope effect) on the mass difference between isotopes being exchanged. Thus, if there is a fractionation of 50 permille for $\delta^{34}S$, which arises because of the partition coefficients for isotopic species containing ^{34}S and ^{32}S, the fractionations for species containing ^{33}S and ^{36}S will have associated shifts approximately half and twice this magnitude because the mass difference between ^{33}S and ^{32}S is approximately half that between ^{34}S and ^{32}S, and the mass difference between ^{36}S and ^{32}S is approximately twice that between ^{34}S and ^{32}S. The exact relationship is very close to that described by the reference array used to in the $\Delta^{33}S$ and $\Delta^{36}S$, and the $\Delta^{33}S$ and $\Delta^{36}S$ will both have values very close to zero. Small deviations in these values can be produced by mixing and fractionation of sulfur with different $\delta^{34}S$, and this is seen in many metabolic and biogeochemical reaction networks.

Equilibrium isotope partitioning of sulfur isotopes among mineral phases and/or aqueous phase and gas phase species is related to the way that vibrational and in the cases of gases translational and rotational energy is partitioned among various isotopic sulfur-containing substances and are determined using experimental techniques to directly measure isotope fractionations, or more recently, using theoretical (ab initio) techniques to calculate partition functions for substances (e.g., Eldridge et al. 2016). Finally, constraints can be obtained by making inferences from observations (empirical calibrations).

Ab initio calculations also allow for determinations of the isotopic partitioning characteristics of species that are not physically separable, but that need to be considered to interpret isotopic fractionations in systems at equilibrium. An example of this is given by Eldridge et al. (2016) for the bisulfite system. In this study, the isotopic partition coefficients of inseparable two bisulfite isomers were determined using ab initio techniques and then weighted using independent constraints on their isomerization coefficients to explain the partitioning of bulk bisulfite in solution as well as its unusual temperature dependence.

Chemical kinetic isotope effects (KIE) involving ground state and transition states also produce mass-dependent isotope effects. These KIE are elementary effects that are produced by unidirectional reactions and result from differences in the rates of reaction for different isotopic species. In cases where this partitioning is the primary determinant of reaction rate, the KIE for systems with more than two isotopes will yield rates that scale with mass, and thus with the mass difference (Δm) between the substituted isotopes in the reacting species. Thus the effect will reflect how the transition state (TS) is populated, and this is mass dependent.

While reaction rates and KIE are relevant for understanding the total sulfur isotopic fractionation produced by a single organism metabolizing sulfur, which has been referred to by geochemists as "vital" effects, the two constructs, KIE and vital effects, are distinct. Such vital isotope effects for sulfur can be produced by a combination of EIE and KIE that are part of the total metabolism, but KIE refer to a distinctly chemical isotope effect that is produced by differences in the rates of reaction for isotopic species. There are also differences in energy for the different sulfur isotope species involved in KIE because part of the basis for the rate control is population of the TS, which depends on quantized energy levels in the TS and the reactant state.

Mass Independence: Larger variations for $\Delta^{33}S$ and $\Delta^{36}S$ can be seen when factors in addition to the mass difference between the isotopes of sulfur contribute to the isotope of fact. The most common situation where these factors come into play is for excited state reaction kinetics, where selection factors can depend on factors other than mass, or on factors that do not scale linearly with mass.

These mass-independent isotope effects are thus most common in gas phase reactions such as those seen in photochemistry and are thus relevant for distinguishing geochemical signatures produced by atmospheric processes from those produced in condensed phase where ground state chemistry prevails.

In some kinetic isotope reactions other factors that come into play and exert an additional control on reaction rates for different isotopic sulfur species yield relationships that deviate considerably from the Δm relationships. In these cases, the effects are often referred to as mass-independent and significant nonzero $\Delta^{33}S$ and $\Delta^{36}S$ can be produced. Such additional factors can include resonance coupling between electron and nuclear spin that permit different rates of reaction (Magnetic Isotope effects – MIE) (Oduro et al. 2011), differences in the density of states that are related to the symmetry of isotopic molecules, and differences in coupling between states (Franck-Condon Factors) for isotopic molecules (Zmolek et al. 1999).

In addition to the possibility of equilibrium isotope effects, kinetic isotope effects, and various physical processes that can cause isotopic fractionation, there are also characteristic signatures relevant to interpretation of sulfur isotopes that are produced when sulfur with two different compositions is mixed or when sulfur isotopes are involved in a process that preferentially removed from a mixture (isotopic distillation).

When mixing involves pools with very different isotopic compositions, the change in isotopic composition for all four isotopes reflects the proportions of material added (or removed) and these changes scale linearly with the amount of material transferred.

In cases where the mixing is associated with a mass-dependent process (equilibrium isotope effects or KIE) the isotopic compositions of the endmembers are related by an exponential relationship, so a small deviation for mixing is seen for $\Delta^{33}S$ and $\Delta^{36}S$. This has been referred to as a mass conservation effect and has been used as a tool to study biological and biogeochemical systems (Ono et al. 2006). Mixing of isotopic pools also provides opportunities for using sulfur isotopes to trace addition of unrelated materials because of the significant magnitude of sulfur isotope compositions that is observed among different types of geological materials.

Thus, processes that mix sulfur of different isotopic compositions ($\delta^{34}S$, $\Delta^{33}S$, and $\Delta^{36}S$) can be unraveled with information about compositions or amounts of materials mixed. These different responses of $\delta^{34}S$, $\Delta^{33}S$, and $\Delta^{36}S$ to different types of processes provide a variety of different types of ways to apply sulfur isotopes in geochemistry. In the following, a few of the key applications and findings made using sulfur isotopes are described.

Geochemical Records

Atmospheric: Studies of sulfur isotopes in the atmosphere indicate that sulfur is introduced to the atmosphere by geological processes associated for the most part with volcanism, by biological activity of microbial and higher forms of life, and from anthropogenic sources such as coal and hydrocarbon combustion, steel smelting and mineral processing, as well as waste treatment.

While the amount of sulfur in the atmosphere is minor compared to that of oxygen or nitrogen, its chemistry allows it to play potentially important roles as a factor controlling rainwater pH, with aerosols that may act as cloud condensation nuclei and influence Earth's radiation balance and climate, and compounds that can be toxic and in some cases have negative health impacts. For these reasons, isotopic techniques that can be used to track its origin have been of widespread interest.

The contribution of sulfur as sulfur dioxide (SO_2) via combustion can be monitored by the isotopic composition of sulfur from combustion sources which can span a wide range of $\delta^{34}S$ values, but commonly centers on $\delta^{34}S$ values of 0–5‰. Mukai et al. (2001) demonstrated that the isotopic composition of atmospheric sulfate aerosols in China are closely correlated with the isotopic compositions of regional coal indicating a strong connection. Understanding these contributions is important because of the role played in acidification of rain resulting from the atmospheric oxidation product S(VI) [S^{6+}] reacting with atmospheric water to form sulfuric acid by reactions like

$$SO_3 + H_2O = H_2SO_4.$$

Studies of isotopic signatures of rainwater and lake water sulfate led to the suggestion that acid rain led to significant lowering of pH in lakes in the coal burning regions of North America in the late twentieth century (e.g., Caron et al. 1986). These isotope studies and others combined with other geochemical data provided critical information into a process that negatively impacted agriculture as well as higher animals including fish like trout, leading to key regulations in North America and Europe that have significantly addressed the problem.

While regulations that reduce emissions of sulfur dioxide by burning of low sulfur coal and scrubbing sulfur gases from power plant emissions in North America and Europe have had a profound effect and reversed the damages that were being seen, in other parts of the world (e.g., parts of Asia) acid rain and snow are still seen downwind of industrial activity that generate sulfur-bearing gases like sulfur dioxide. Isotopic studies continue to be used to trace the origin of this sulfur (Mukai et al. 2001).

Formation of atmospheric sulfate via natural processes from oxidation of volatile biogenic sulfur species such as dimethylsulfide (DMS – CH_3-S-CH_3) carries a more ^{34}S enriched composition with $\delta^{34}S$ values of ~18–20‰ (Patris et al. 2000; Oduro et al. 2012; Amrani et al. 2013). DMS and other methylated sulfur compounds are present at trace levels in oceanic air and contribute to the "smell" we perceive when near the ocean. The biological origin of DMS makes it potentially a forcing agent for climate that also responds to prevailing climate conditions. It has been suggested that DMS production and chemistry also play a role in climate regulation as cloud condensation nuclei, and participate in a feedback loop known as the CLAW hypothesis (Charlson et al. 1987) where biogenic oceanic DMS emission fluxes respond to, and indirectly control, insolation that is in turn controlled by cloud cover and cloud condensation nuclei (CCN) that are produced as a result of chemistry involving DMS and its oxidation products.

Other types of climate impacts of sulfur have been documented using sulfur isotopes both $\delta^{34}S$ and $\Delta^{33}S$

(Savarino et al. 2003; Baroni et al. 2007) for injections of sulfur dioxide (SO_2) by large volcanic eruptions into the stratosphere where it is oxidized to form a high-altitude layer of sulfate aerosols. These high-altitude aerosols impact Earth's radiation balance and lead to cooling such as in the year following the Pinatubo eruption or for the year without summer in 1816 which is attributed to eruption of the Indonesian volcano Tambora. The unique chemistry of photochemical oxidation to form sulfate in the stratosphere produces an anomalous signature for sulfur isotopes that evolves over the course of the deposition cycle to the ice, leaving behind a clear signal that can be used to identify evidence of these events in ice core records.

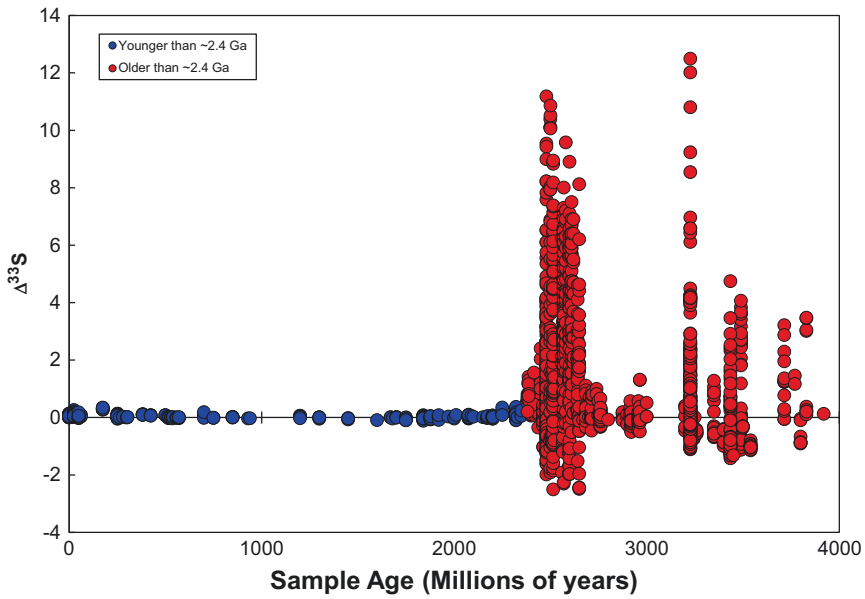
A challenge of atmospheric applications of sulfur isotopes is partitioning the contributions from various sources. Other information used for source partitioning can include additional constraints from other isotopic systems ($\Delta^{33}S$, $\Delta^{36}S$, and ^{35}S for sulfur and $\delta^{18}O$ and $\Delta^{17}O$ for oxygen in sulfate) as well as the amount (concentration) of aerosols. Constraints from $\Delta^{33}S$, $\Delta^{36}S$, ^{35}S, and $\Delta^{17}O$ are used to track atmospheric chemistry as well as contributions from stratospheric air. $\Delta^{33}S$ and $\Delta^{36}S$ provide insight into photochemical oxidation and $\Delta^{17}O$ provides constraints on the oxidation pathways. So far, isotopic compositions (principally $\delta^{34}S$ and $\delta^{18}O$) of atmospheric aerosols, of sulfate in rainwater, and of sulfate in ice cores and snow have been used to evaluate the relative importance of various biogenic, anthropogenic, and geological sources of atmospheric sulfur. The present, understanding of atmospheric chemistry and dynamics is informing understanding of isotopic measurements of $\Delta^{33}S$, $\Delta^{36}S$, $\Delta^{35}S$, and $\Delta^{17}O$. The challenge for future sulfur isotope studies will be to reverse this flow of information by developing ways to use this isotopic information to inform chemical and dynamical aspects of the atmosphere.

The deep time geological and meteorite records also preserve information about atmospheric sulfur. Signatures are seen for both $\Delta^{33}S$ and $\Delta^{36}S$ in the Archean and earliest Proterozoic (Farquhar et al. 2000). These signatures are attributed to photochemical reactions involving atmospheric sulfur compounds in a low oxygen, low ozone atmosphere that was largely transparent to the ultraviolet wavelengths needed to drive mass-independent reactions and conducive for the transfer of this signature to the rock record (Ono 2017).

A record of mass-independent sulfur is widespread in sedimentary successions from prior to about 2.4 billion years ago and the disappearance of a mass-independent signature from the sedimentary record is taken as indicative of the onset of an oxygenated atmosphere. Figure 2 illustrates this striking transition from a geological regime characterized by mass-independent sulfur preserved in the rock record prior to ~2.4 Ga, to a regime characterized by mass-dependent sulfur since ~2.4 Ga.

Oceanic: Studies of the isotopic composition of sulfur in sedimentary and water column environments have been used to reconstruct biological and abiological processes involved in the reduction and oxidation of sulfur compounds in the present-day as well as in ancient oceans.

The isotope fractionation imparted by bacteria and archaea that reduce sulfate to sulfide is enriched in light isotopes and imparts a complementary positive $\delta^{34}S$ (light isotope depletion) to oceanic sulfate. This sulfate, due to its long residence time, has a relatively homogeneous composition at $\delta^{34}S \approx 21‰$. Because the residence time of this sulfate is longer than the residence time of seawater, leading to a homogenous $\delta^{34}S$ value and an enhancement of sulfate



Sulfur Isotopes, Fig. 2 Plot of $\Delta^{33}S$ versus sample age, illustrating the change from a period prior to 2.4 Ga. (red symbols) when mass-independent sulfur was preserved in the geologic record to a period since 2.4 Ga (blue symbols), when mass independent signatures are not seen

concentrations over that of its sources, this has provided a tool to study the sulfur cycle in Earth's ancient oceans.

The principal source of sulfate to the oceans is and has been from the continents and includes a combination of remobilized evaporite sulfate and sulfate produced by oxidation of sulfide minerals. A secondary source is from mid-ocean ridge and back arc hydrothermal activity. These sources, in combination with sulfide sinks, maintain oceanic sulfate concentrations near 28 millimolar and with compositions that are stable over long periods of time.

The isotopic composition of oceanic sulfate has been shown using highly precise marine barite records to have possessed $\delta^{34}S$ values of ~20–21‰ through much of the Cenozoic (Paytan et al. 1998). Work by Claypool et al. (1980) had previously demonstrated swings of oceanic $\delta^{34}S$ to more positive and negative values in earlier parts of the Phanerozoic reflecting different proportions of sulfide burial and possibly variations in the magnitude of the isotope fractionation associated with buried pyrite.

The primary sulfide sink is sedimentary sulfide (iron sulfides like pyrite and organic sulfur compounds). Reduction of sulfate to sulfide that leads to the sedimentary sulfide sink is carried out by prokaryotic sulfate reducing bacteria that use S (VI) from sulfate as an electron acceptor and organic carbon as an electron donor. A significant amount of this sulfide is reoxidized, returning sulfate to the oceans and allowing these organisms to oxidize a significant amount of organic matter while producing a sink of mineralized sulfide that maintains a high sulfate concentration.

The proportion of sulfide reoxidized is intricately linked to the isotopic fractionation that is expressed between buried pyrite and oceanic sulfate. Wu et al. (2010) have shown that the $\Delta^{33}S$ of Phanerozoic sulfate also varies with time, but at a much lower level than that seen for mass-independent signatures of the early Proterozoic and Archean. These low level variations have been used in combination with a model to constrain the $\delta^{34}S$ evolution of buried pyrite and the role of sulfide oxidation (but see Leavitt et al. 2013, for an interpretation that also invokes a concomitant biological response). The work by Wu et al. (2010) suggests that larger fractionations (variation of $\delta^{34}S$ of about 40‰) prevailed for the past 250 million years and smaller fractionations ($\Delta^{34}S$ of about 30‰) for the earlier Phanerozoic.

Sulfide can also play a role in local environments. In some atypical cases where sulfide accumulates in the water column, such as in the Black Sea or in basins like the Cariaco Basin, its isotopic composition usually varies with depth and has very negative $\delta^{34}S$, sometimes as negative as −40‰. In sediments, the situation is different; as sulfate in porewater is consumed, the isotopic composition of porewater sulfate evolves to more positive $\delta^{34}S$. The ^{34}S enrichment typically increases deeper in the sediment. Likewise the isotopic composition of sulfide changes with depth from a more negative $\delta^{34}S$ higher closer to the sediment-water interface and a less negative $\delta^{34}S$ deeper in the sediment.

Factors that influence the isotopic profiles of porewater sulfate and sedimentary sulfide include the rate of porewater-seawater exchange, the role of secondary reactions (oxidation (sulfide to sulfur intermediate or sulfate) or disproportionation, a fermentative metabolism where sulfur intermediates are decomposed into sulfide and sulfate), and mass transfer of sulfate and sulfide in the system.

Sulfur isotope studies have also been conducted on water-column organic sulfur compounds like dimethylsulfide which exhibits a positive $\delta^{34}S$ in the range of 18–21‰ (Amrani et al. 2013) which is similar to oceanic sulfate and points to a connection between oceanic sulfate and the metabolic pathways responsible for production of DMS precursors.

DMS is relevant as a biogenic sulfur-bearing gas that is emitted to the atmosphere and knowledge of its isotopic composition and variability of the isotopic composition is used as one of the knowns in reconstruction of atmospheric sources (source partitioning).

Solid Earth: Sulfur is present in Earth's crust, mantle, and core. In Earth's crust, the affinity of sulfur and metals for each other makes sulfide deposits such as Volcanogenic Massive Sulfide (VMS) deposits sources of elements such as copper, zinc, lead, gold, and silver.

Sulfides are also found in high abundance in some sedimentary rocks like black shales and some coals. The characteristic positive $\delta^{34}S$ of oceanic sulfate and negative $\delta^{34}S$ of sedimentary sulfide compared to the near zero $\delta^{34}S$ of juvenile terrestrial sulfur has made it possible to track sources of sulfur in the solid Earth.

Likewise, the occurrence of mass-independent sulfur Isotopic signatures in Earth's earliest sediments provides a way to trace their contributions to solid-Earth reservoirs. Labidi et al. (2013) demonstrate evidence for such recycling, and for a more subtle sulfur isotope fractionation effect associated with core formation (^{34}S depletion in mantle sulfur) using relationships between Sr isotopes and $\delta^{34}S$ of mid-ocean ridge sulfur.

Similarly, Cabral et al. (2013) and Delavault et al. (2016) report anomalies for $\Delta^{33}S$ in oceanic island basalts that implicate recycling of ancient crustal sulfur to reservoirs in the deep mantle that are sourced by ocean island basalts. They suggest that the observation of isotopic signatures for $\Delta^{33}S$ in some ocean island basalts and diamonds has been interpreted to indicate recycling of ancient surface-derived sulfur with mass-independent characteristics (Cabral et al. 2013).

Another place where anomalous $\Delta^{33}S$ has been observed is in Martian meteorites. These meteorites preserve evidence of weathering on Mars, and the signatures have been interpreted to indicate that the sulfur present in these meteorites possesses a component indicative of atmospheric (photochemical)

oxidation. Like for terrestrial samples, this signature has also been traced to sulfide phases and indicates uptake of a sulfur-bearing component on emplacement or assimilated by the parent melts on their way to the place where they were emplaced (Franz et al. 2014).

Equilibrium isotope fractionations for sulfur isotopes are large because of significant differences in the bonding environments for sulfate minerals compared to sulfide minerals. It is possible to extract information about temperature from isotopic fractionations between sulfur-bearing minerals because partitioning of isotopes is temperature dependent and in some cases this is done. Complexity in the application of isotopic thermometers arises when minerals do not attain isotopic equilibrium or when the isotopic composition of one or more mineral used to obtain a temperature is disturbed.

It is also not uncommon for sulfide minerals and sulfate to exhibit disequilibrium because of different temperatures of formation and slow exchange of sulfur between sulfate and sulfide; it is, however, possible to extract information about disequilibrium and to gain insight into the histories different mineral phases.

The significant range of observed variation for $\delta^{34}S$ and $\Delta^{33}S$ observed in the rock record has thus made it a valuable tracer of sulfur sources, leading to a wide variety of applications of sulfur isotopes in the study of crustal rocks, and particularly in hydrothermal and ore-bearing systems.

Summary

Sulfur has four stable isotopes and is standardized relative to the V-CDT scale and measured by a number of different geochemical techniques, but predominantly by Isotope Ratio Mass Spectrometry. Sulfur isotope variations include both mass-dependent and mass-independent isotopic signatures. Mass-dependent isotopic signatures are produced by equilibrium processes and a host of processes that occur in gas, liquid, and gas phase. Mass-independent isotopic signatures are principally produced by gas phase chemistry involving excited state species and are used to trace atmospheric processes. One of the significant atmospheric signals that sulfur isotopes have been used to trace is related to the evolution of Earth's atmosphere and marks the appearance of oxygen in Earth's atmosphere. In this case, mass-independent signatures were produced and transferred to the rock record when the atmosphere had low (sub ppm) levels of oxygen and then was not transferred when oxygen levels rose above this threshold. The rich isotopic chemistry of sulfur also makes its isotopic characterization useful for study of other systems such as (i) to trace biological activity of sulfate reducers in Earth's oceans and in other environments where these organisms live, (ii) in solid earth systems where sulfur isotopes are fractionated between sulfur-bearing phases, and (iii) in cases where isotopic signatures are used as tracers of subducted surface materials.

Supergene

Martin Reich
Department of Geology and Andean Geothermal Center of Excellence (CEGA), FCFM, Universidad de Chile, Santiago, Chile

Definition

The term *supergene* is used to describe processes and products that are the result of near-surface alteration and modification of originally deeply formed rocks. It is in the *critical zone* – the Earth's contact zone where air, water, biota, organic matter, and minerals interact – where combinations of geological, chemical, physical, and biological processes operate together on preexisting minerals so as to adjust to the new environmental conditions (average $T_{atm} \sim 15$ °C, $P_{atm} \sim 1$ bar, and $pO_2 \sim 0.2$ bar) (Reich and Vasconcelos 2015).

Supergene Processes and Enrichment

Supergene processes are controlled by three basic factors. The first and most important factor is the parent rock (e.g., limestone vs. andesite) and its mineral constituents (e.g., silicates vs. sulfides). The second factor is landscape, which is shaped by hydrological and pedological processes coupled with the geodynamic evolution of the crustal section under consideration. The third factor is climate, reflecting ambient temperature, availability of liquid water (i.e., rainfall intensity and seasonality), evapotranspiration rates, and biological and microbiological activity (Vasconcelos et al. 2015).

Supergene deposits form when recurrent chemical weathering promotes the dissolution, remobilization, and reprecipitation of elements at or near the Earth's surface, creating a chemically stratified weathering profile, which may extend down from a few meters to ~1000 m below the surface. Although the term *supergene* can be used to describe any process or alteration product formed by descending or ascending water at low temperature and pressure (Reich et al. 2009), its most common use relates to supergene oxidation

and enrichment of deeply buried primary (or hypogene) ore bodies that are exposed at or near the Earth's surface.

The phenomenon known as supergene enrichment refers to the secondary, in situ, accumulation of metals as a result of three essential processes: (1) the electrochemical oxidation of primary sulfides, oxides, or native metals (e.g., native copper Cu(0) to Cu(II)), (2) the transport of the released metals as soluble metal species (e.g., $CuSO_4^0$, $AuCl_4^-$), and (3) the reprecipitation of the metals by reduction (e.g., Cu(II) to native copper Cu(0)), by supersaturation (e.g., Mg^{2+} in magnesite deposits), or by cation exchange (e.g., Ni^{2+} exchange for Mg^{2+} in smectite- or serpentine-group minerals) (Reich and Vasconcelos 2015). The resultant highly enriched supergene zone or "blanket" that forms above ore deposits is usually accessible during the early stages of surface mining and contributes significantly to the overall viability of the mine.

The process of supergene enrichment of metals is commonly exemplified by copper (Sillitoe 2005). In most copper ore bodies, the stepwise hydrolysis and oxidation of primary pyrite- and chalcopyrite-bearing assemblages leads to a decrease in the pH of descending groundwaters and the liberation of soluble Cu^{2+} ions and oxidized sulfur as SO_4^{2-} anions. These dissolved species encounter progressively greater reducing conditions deep into the profile. This process is accompanied by "capping," the precipitation of iron oxyhydroxides in the leached zone from which copper is removed. The thickness of the leached cap is highly variable but can reach several hundred meters in porphyry copper deposits, particularly when the water table was deep enough during the supergene oxidation and enrichment phase (Taylor 2011).

Summary

Supergene enrichment may result in a two- to tenfold increase in metal grades for commodities such as Cu, Al, Fe, Ni, Mn, U, Au, and Zn. Supergene deposits, apart from these major metal components, can contain economic or near-economic concentrations of *critical metals* including the rare earth elements (REE), platinum group elements (PGE), Co, Be, V, Ga, In, Ge, Li, and I, making these deposits attractive targets for exploration and exploitation.

Interfacial geochemistry

Definition

The chemistry that occurs at the interface between two phases of matter.

Introduction

> Das Volumen des Festkörpers schuf Gott,
> ihre Oberfläche wurde vom Teufel gemacht. (W. Pauli)

The subject of surface chemistry extends across virtually all fields of the Earth sciences, although most research concerns the surface of a mineral in aqueous solutions because of the recognized importance of soil minerals to environmental

chemistry. One could equally argue that interface chemistry is just as essential to atmospheric chemistry or even oceanography, however, or the myriad other fields within Earth science that don't prominently state an interest in surface chemistry.

The term "surface" is poorly defined. It can refer to the region that is within a single-bond distance from material interface, or can extend over hundreds of nanometers, although one can encounter more restrictive definitions. The chemistry in this region is unique and exerts fundamental control over many geochemical transformations, including phase transformations, rates of diagenesis, and the metal enrichments in ore formation. This chemistry is most commonly approached by coupling simple experiments with sophisticated methods of surface analysis, such as X-ray photoelectron spectroscopy, surface-probe microscopy, and synchrotron methods. X-ray free electron laser (XFEL) methods now allow spectroscopic investigations of ultrafast surface reactions. In addition, some methods that are inherently for bulk analysis, such as XAFS or NMR spectroscopy, can be adapted to study surface processes by clever choice of the experimental conditions, such as the use of unique isotopes.

The Gibbs-Thompson Equation

The incremental energy change to create area from bulk solid is described as a partial derivative of Gibbs energy with respect to surface area:

$$\left[\frac{\partial G}{\partial A}\right]_{T,P,N_i} = \gamma \quad (1)$$

at fixed temperature *(T),* pressure *(P)* and composition *(N)* with a coefficient of proportionality *(γ)* known as the interfacial surface energy (or surface tension). Values of this energy for liquids in contact with their vapors range from 0.01–0.06 J/m^2 for condensed gases to 2 J/m^2 for liquid metals (Adamson 1982). The coefficients depend, of course, on which two phases are in contact at the interface. The change in interfacial energies with composition relate to the surface *excess* concentrations of each component and the chemical potentials of those components via the Gibbs isotherm equation.

For geologists, the surface energy presents a formidable activation barrier to phase changes. New area is created as bubbles or crystals nucleate from a melt and as etches form on a dissolving crystal. Furthermore, the energy derived by reducing the exposed surface area is large relative to changes in bulk energy if the particles are small. Therefore, large mineral particles grow at the expense of small ones and small soap bubbles coalesce in a bath of suds in a process referred to as "Ostwald ripening." Description of the surface chemistry at this scale requires no knowledge of molecular configuration or reaction mechanisms. The opposing contributions of bulk energy and surface energy make the formation of new phases an activated process, with a barrier energy that prevents reaction and must be surmounted. These subjects are treated using classical theories called "BCF" theory after the major authors in the mid-twentieth century (Burton et al. 1949, 1951).

Adsorption/Desorption at Hydrolyzed Surfaces

Description of mineral surfaces in water using Eq. 1 is unwieldy. The interfacial tensions are difficult to measure and sensitive to small changes in solution composition. They also provide no molecular insights.

Molecular interactions control much of the conspicuous surface chemistry of minerals and solid oxides. For example, oxide solids, like many ions, exhibit an amphoteric chemistry and the Brønsted acid-base chemistry of a particular mineral surface is characteristic of its composition and structure. Just as silicic acid ($H_4SiO_4^o$(aq)) is not expected to have an acid-base chemistry that is similar to aluminum ion ($[Al(H_2O)]_6^{3+}$(aq)), so too is the acid base chemistry of solid silica (SiO_2(s)) different than that of corundum (α-Al_2O_3(s)). Silica has a near-neutral surface at near-neutral pH and acidic conditions. At these conditions corundum has a positive charge on its surface from the uptake of protons. Corundum surfaces are neutral at pH $\sim$ 9, meaning that at this pH there is an equal concentration of positively and negatively charged surface sites.

Surface-complexation models emphasize reaction at ionizable functional groups (Boehm 1966). In aqueous solutions these are most commonly hydroxyls, which are abbreviated as: >Me-OH, where Me stands for the surface cation ("Metal") of the mineral surface (Schindler and Stumm 1987). For example, Brønsted reactions can be portrayed:

$$>Si-OH(s) + H_2O(l) = >Si-O^-(s) + H_3O^+(aq) \quad (2)$$

or:

$$>Al-OH(s) + H_2O(l) = >Al-OH_2^+(s) + OH^-(aq) \quad (3)$$

in a similar fashion as solutes. Although it is possible to assign the equilibrium constants to actual coordinated oxygens at the surface, as is done for acids and bases in homogeneous solution, more common for surface chemistry is the assignment of equilibrium constants to a generic site at the surface, as above. These surface-complexation models link surface

chemistry to the broader fields of coordination chemistry for metals in solution (Schindler 1991).

Besides these Brønsted reactions, surface charge can arise from substitutions of unequally charged ions in the lattice of the solid, such as Al(III) substitution into a Si(IV) site or vice versa. Surface charge attracts counterions, forming an electrostatic double layer of charged adsorbates, co-ions and counterions. The distribution of ions in this double layer, which is analogous to the counterion swarm of Debye-Hückel theory, is usually calculated by solving the Poisson-Boltzmann equations that relate electrostatic potential to the net distributions of attracted counterions and repelled co-ions. The same approach for ions in solution yields Debye-Hückel theory and solute activity coefficients. If instead of an ion sphere, a charged plate is used in the equations, one arrives at Guoy-Chapman theory of the interface and the electric double layer, which is important to colloid stabilities. Diminution of the electric field with distance from the charged surface relates to the ionic strength because aqueous ions shield one another and diminish the electrostatic force.

The contribution of electrostatic energy is commonly treated separately in surface-complexation models. This separation leads to an equilibrium expression that varies with the concentration of charge on the surface, or more correctly, with the interfacial potential, which is not equivalent. It is easy to see the origin of these electrostatic contributions – it takes less energy to protonate a negatively charged surface than a positively charged one. Thus, the electrochemical potential (μ_i) of an ion, i, has a Coulombic term and is given as:

$$\mu_i = \mu_i^o + z_i F\psi + \mathrm{RTln}(a_i) \tag{4}$$

where μ_i^o is the standard-state chemical potential of the ion, z_i is the charge of the ion, ψ is then the electrostatic potential, R is the gas constant, T is temperature in Kelvins, a_i is the thermodynamic activity (see e.g., Schindler 1991; Sverjensky and Sahai 1994) and F is the Faraday constant. Although here we emphasize oxide surfaces with charges that arise from ionization of functional groups, uncharged phases could also rise to an electrical potential if they were in contact with one another and had different dielectric constants. Electrical work would be performed in moving the ion from one phase to the other.

For ions at the mineral-water interface, the net result is that one typically observes an exponential term in models of surface equilibria that varies with a Coulombic surface potential:

$$K = K_{\mathrm{int}} e^{z_i F\psi_o/\mathrm{RT}} \tag{5}$$

where K_{int} is the *intrinsic* equilibrium constant in the reference state of no surface charge. The subscript "*int*", and the word "intrinsic", expresses the idea that K_{int} represents a chemical stability constant that is free of influence by surface charges (see Schindler 1991). Details of how these electrostatic energies are treated depends upon the model chosen to describe the surface potential and charge (e.g., the "Constant Capacitance Model," the "Triple-Layer Model" etc.; see Sposito 2004). The key result, however, is that conditional equilibrium constants for complexation reactions at an interface commonly vary by factors of 10–100 with surface charge concentration (see Sposito 1984).

Practical benefits are most important. The different models to describe surface complexation are now implemented into computer software (e.g., Westall 1980, 1987) so that adsorption onto surfaces, and competition between metals and ligands, is solved simultaneously with aqueous speciation. Coupling of aqueous speciation to surface speciation has advanced understanding of environmental toxicity. One such application is the "Biotic Ligand Model" (e.g., Di Toro et al. 2001) that couples toxicity to surface complexation on biological materials. Assessing ecological toxicity depends upon the health of indicator organisms, such as trout minnows or water fleas in various chemical settings. The surface-complexation models allow the effect of a toxicant on these indicator organisms to be related to the concentration actually adsorbed at key biological membranes (e.g., gills for fish), and allows for full competition between metals and ligands. Previously the toxicity would be inferred from the total analytical concentration of toxicant in the stream or lake, which was incomplete because of competition with other constituents for the key biologic functional groups.

Colloid stability also reflects surface chemistry in results in geographic features that are so large as to be identifiable from satellites. When the electrostatic forces are coupled to Van der Waal's forces, one gets the DLVO theories (from: ***D***erjagian, ***L***andau, ***V***erbey and ***O***verbeek) of colloid stabilities and interactions (see Bunker and Casey 2016). The essence of colloid stability is that surface charges repel one another, but Van der Waal's forces attract and these two opposing forces vary in importance depending on solution composition. The net result is a colloid stability that depends sensitively on ionic strength. Thus in the dilute waters of the Mississippi River, clays are stable as separated colloids because the electrostatic forces prevent collisions and bonding. However, when those waters mix with seawater in the New Orleans estuary, the ionic strength increases and the distance of electrostatic repulsion diminishes so much that the clay particles collide. The colloids bond to one another by Van der Waal's forces, flocculate and settle out of the water column to form the Mississippi River Delta, identifiable from space.

The links between homogeneous and interfacial chemistry cannot be overestimated. The same variables that affect classes of reactions for solutes in water also affect those reactions at mineral surfaces, and often quantitatively so. The broad classes are ligand exchange, electron exchange and chelation.

A similarity between ligand exchanges affecting metal ions in water and those metals at dissolving mineral surfaces are shown in Fig. 1.

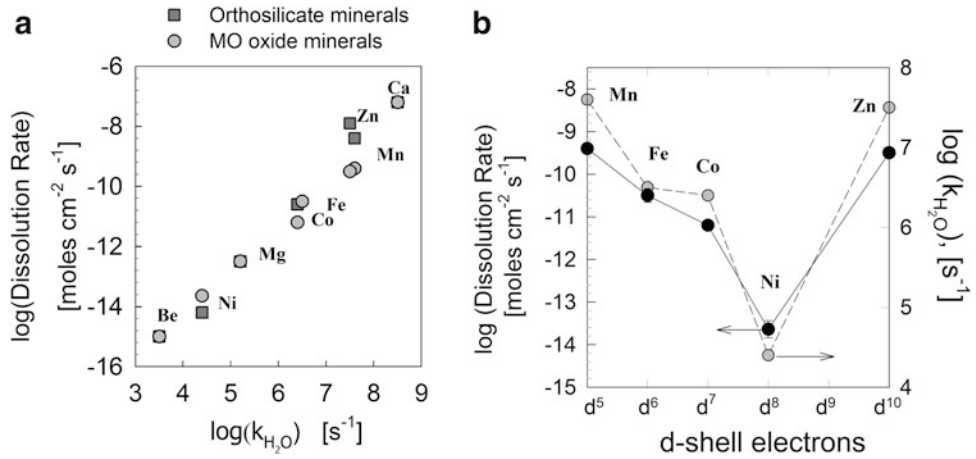
In Fig. 1 the dissolution of a mineral with an unpolymerized fabric (e.g., MgO, periclase) is shown to resemble the exchange of waters from the solvation sphere of $[Mg(OH_2)_6]^{2+}$(aq) in water. This similarity in reactivity trends (Fig. 1) should not be surprising since one can view surface reactions like dissolution as a series of ligand exchange reactions. Instead of ligands like bound waters being replaced, it is the bridging oxygens that link the metal to the mineral (Casey and Ludwig 1995). Dissolution of an unpolymerized oxide like periclase (MgO(s)), for example, involves stepwise replacement of bridging oxygens with non-bridging oxygens until a solute like $[Mg(OH_2)_6]^{2+}$(aq) is released. Thus the same variables that affect ligand-exchange rates for ions is also commonly manifested at mineral surfaces (see Casey 1991).

The similarity arises in part because many metals have similar coordination geometries in the mineral structure and in the solute released by dissolution. The Mg(II) metal, for example, is hexacoordinated to oxygens in both the periclase structure, at the periclase-water interface, and in the $[Mg(OH_2)_6]^{2+}$(aq) ion. What differs considerably is the coordination number of the exposed oxygens. These numbers range from six-coordination to single coordination at a typical surface kink site, whereas the Mg(II) metal remains six-coordinated throughout the process. Exceptions can be found where the coordination number of the metal differs between the mineral structure and aqueous species (e.g., B (III), Al(III)), but these are relatively uncommon. None of these changes in coordination are captured by the abbreviated equations, above.

These surface reactions are important to the health of the planet as marine and lacustrine particles scavenge trace metals and organic matter. Many toxicants are removed from natural waters as the particles aggregate and settle. Similarly the reactions at interfaces are key to atmospheric chemistry as the interfaces can catalyze otherwise slow processes and can themselves generate reactive species, such as free radicals. Finally, just as injection of an electron into a multimeric aqueous complex can labilize rates of ligand exchange by weakening the bond strengths, so too can injection of an electron into an oxide surface labilize the reactions at the interface. The details differ enormously, but the general reaction trends are preserved.

Organic Molecules and Aqueous Surface Films

Non-polar molecules, such as lipids, hydrocarbons and carbohydrates, have a larger affinity for other non-polar molecules than for solvation with waters. They tend to become segregated out of an aqueous phase onto mineral surfaces, or to the air-water interface. For example, a monolayer exists at the air/water surface of marine and fresh waters that is 2–500 nm thick and considerably enriched in non-polar molecules. Likewise, chlorinated hydrocarbons and non-polar pesticides accumulate at the microlayer because of their "hydrophobic" tendencies. The extent to which these molecules are enriched at mineral surfaces varies with aqueous solubility and the molecular weight of the organic molecule.



Surface Geochemistry, Fig. 1 Here the dissolution rates of sets of metal-oxide minerals having the stoichiometry: "MO" and the orthosilicate minerals having the stoichiometry "M_2SiO_4" are plotted against the logarithm of the rates of water exchange around the corresponding ion in solution (k_{H_2O} on the abscissa). In both (**a**) and (**b**) figures, "Mg," for example, indicates the dissolution rates of MgO(s) and Mg_2SiO_4 as well as the rates of ligand exchange around $[Mg(OH_2)_6]^{2+}$(aq), expressed as the logarithm of the k_{H_2O} value. In the *right-most* figure, (**b**) the rates are plotted against the number of d electrons in the metal, showing that the same crystal-field effects that control ligand exchange in solution also control reaction at the mineral interface (Adapted from Casey and Westrich 1992)

Addition of each -CH_i- group to a hydrocarbon chain increases the partitioning of the non-polar organic to mineral surfaces. Stated simply – just as our bodies can accumulate hydrophobic substances in our fatty lipid-rich organs, so too can lipid-rich parts of soil or natural waters accumulate hydrophobic molecules and these are usually at interfaces.

Life itself exists through these hydrophobic forces because they maintain integrity in the lipid bilayers of cell membranes. Likewise, the hydrophobicity of hydrocarbons in water leads to petroleum accumulation in discrete bodies. The attraction of these hydrocarbon molecules to mineral surfaces via Eq. 1 controls the wetting of pores in a reservoir and the migration of liquid hydrocarbons in strata.

Metal-ion adsorption is sometimes significantly changed in the presence of dissolved organic ligands. There are many causes but two are particularly important: competition between dissolved and surface ligands for the metal, and the formation of ternary surface complexes, as both the metal ions and the dissolved ligands coadsorb to surfaces of minerals, and these are usually oxides in the shallow Earth. This proximity can lead to a catalytic property.

Surface Catalysis

The catalytic properties of minerals were known well before Fritz Haber sampled different iron-oxide ores to develop a path for nitrogen fixation. These experiments led to the Nobel Prize (1918) and one of the most important single set of experiments in the twentieth century (with the development of cheap fertilizer, which now allows half of the people on the planet to feed themselves). The importance of this surface catalysis cannot be overstated – it staved off mass starvation in the twentieth century.

The catalytic properties of minerals fall into several categories. Some reactions relate to the electronic properties of a metal or metal oxide mineral. The semiconducting properties of minerals such as MnO_2 and TiO_2 make them particularly useful for photodegrading organic molecules (see Hocking et al. 2011). In acid-mine drainage, oxidation of pyrite to sulfuric acid involves autocatalysis by adsorbed Fe^{3+} (aq). Likewise, reactions that are catalyzed by configuration to protons commonly proceed more rapidly as adsorbates than in homogeneous systems. Protons are particularly reactive at mineral surfaces – the Brønsted acidity of water at the surface of nearly dry kaolinite has acidity comparable to concentrated sulfuric acid. The micropores of zeolites combine this high surface acidity with a confining space that keeps reactants in close proximity. Minerals such as hydrotalcite (also called layered-double hydroxides) can combine surface ionization reactions with changes in layer charge that lead to industrially useful catalysts (e.g., Gerken et al. 2011).

Enzymes function by adsorbing and stabilizing the critical molecules in a biochemical reaction and therefore are key to understanding the evolution of life on this planet. These enzymes must have initially developed abiotically, perhaps by reconfiguration of amino acids on mineral surfaces in a particularly reactive geologic setting, such as a hot spring. Thus, the core of the photosynthetic enzyme, Photosystem-II, resembles a fragment of one of the manganese-oxide minerals (e.g., Sauer and Yachandra 2002). The structural links are not accidental.

The Future

Scientists are comparing the structures of adsorbates calculated via quantum-chemical models with those determined via the spectroscopies that allow for *in situ* measurements (scanning probe microscopy, SPM; extended X-ray absorption fine structure analysis, EXAFS). The goal of this work is a set of rules analogous to Pauling's rules for solids, that predicts the structural chemistry and reactivities of adsorbates. Those interested in a more extensive discussion are referred to references in Bunker and Casey (2016) and particularly to Israelachvili (1992), Yariv and Cross (1970) and Stumm (1992).

Synchrotron X-Ray Fluorescence Analysis

Juan S. Lezama Pacheco[1] and Scott E. Fendorf[2]
[1]School of Earth, Energy, and Environmental Sciences, Stanford University, Menlo Park, CA, USA
[2]Department of Geology, Stanford University, Menlo Park, CA, USA

Definition

Synchrotron X-ray fluorescence refers to the emission of fluorescent X-ray resulting from a sample being bombarded with monochromatic X-rays generated from a synchrotron particle accelerator.

Introduction

X-ray fluorescence spectrometry is a technique based on the analysis of secondary emission of photons with an X-ray frequency (known as X-ray fluorescence) from a given sample. As a result of a primary interaction with an X-ray excitation source, inner shell electrons are ejected from the atom leaving a "hole" (or vacant orbital) in the inner orbitals. The electrons ionized in this manner are therefore referred to as photoelectrons, and the vacant orbital left by this interaction is referred as core hole. Electrons from higher orbitals decay, filling the core hole so that the atom is brought back to its lowest energy state. In order to balance the energy given by the electron decay, a photon is produced having a frequency in the X-ray range. The frequency (or energy) of this photon is *unique* to each element, changing as a function of the core hole *energy level, the atomic number*, *and electronic configuration*. Each photon given by this electronic decay is therefore unique for each type of atom in the periodic table, making the fluorescent X-ray a unique signature for each element (Elam et al. 2002). The secondary photon emission produced through a photoionization process by X-rays is referred to as **X-ray fluorescence (XRF)**. After a sample is illuminated by a primary X-ray source, the analysis of XRF lines directly fingerprints the atomic species in a sample. Moreover, as the intensity of the fluorescence emission is related to the relative amounts of each element in a given sample, direct quantification of the sample composition is possible.

Early Stages

Since its discovery by Moseley in the early 1912, the potential of XRF was recognized for its nondestructive and reliable attributes in identifying elemental composition of samples ranging from metal alloys to rocks to biological materials. Although many advances have been made, the typical layout of an X-ray spectrometer has remained relatively unchanged. Three components are needed to perform an XRF measurement: (1) X-ray source, (2) sample stage, and (3) X-ray detector. X-ray tubes are the most commonly used source in "bench-top" and other commercial systems. These sources have a spectrum dependent on the anode and the voltage. Therefore, the excitation energies are intrinsically limited, shortening the range of elements that can be studied with conventional XRF. In addition, the non-monochromatic nature of X-ray sources makes the differentiation between elements and emission lines hard to deconvolute – as the samples are excited with a continuous X-ray spectra, the

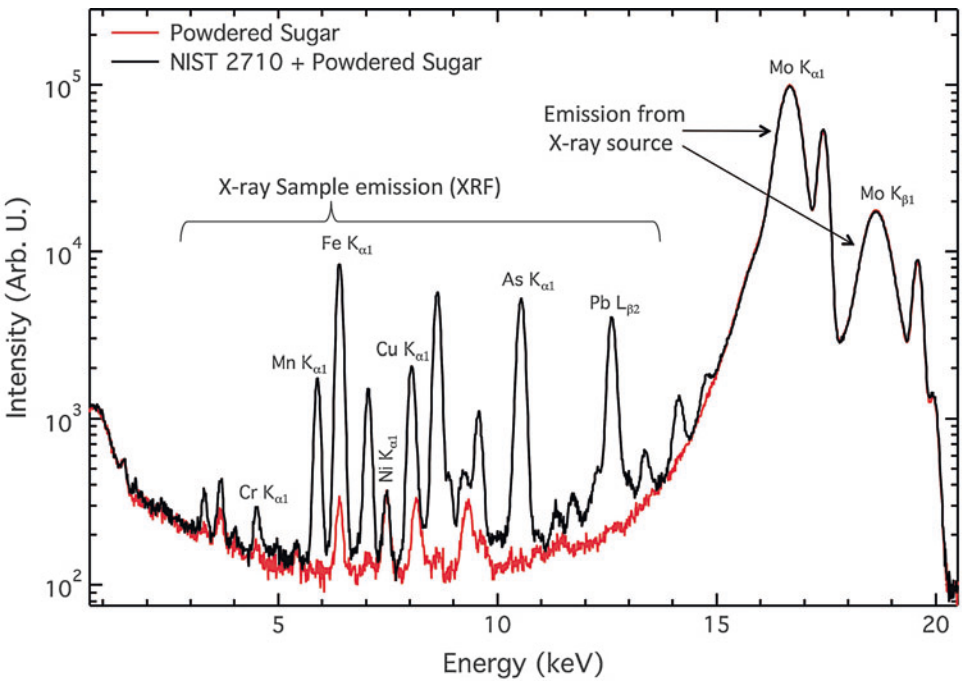
overlap between the different fluorescence lines is increased. Finally, with a few exceptions and some recent developments, XRF spectrometry has been regarded as a bulk technique. This is mainly due to the limited X-ray optics and the divergent nature of X-ray beams by typical X-ray sources, limiting the study of microscopic samples and missing the possible element correlations that could occur in the micrometer scale.

Synchrotron-XRF

Synchrotron radiation is emitted by charged particles undergoing acceleration; the particles are maintained at a velocity near the speed of light but undergo a change in direction (and thus an acceleration) while navigating a (near) circular pathway. As charged particles are accelerated through these trajectories, a "fan" of white (a collection of frequencies from UV to gamma rays) light is emitted. The white light is captured in specially aligned pipes that bring the radiation to a spectrometer. After passing though different sets of optics and mirrors, a monochromatic beam of light is obtained. The light beam can be "tuned" to different energies by passing it through a monochromator; most monochromators are a set of crystals that allow light of a specific energy or wavelength to pass based on the incidence angle of incidence, which can then be adjusted to give different energies. Additionally, secondary focusing optics allow for the control of the beam size from tens of millimeters to micron size beams. The intensity of such energy beams is approximately 10^8 times the intensity of the emitted spectra by an X-ray tube, reducing the measurement time from hours to a few seconds. All of these capabilities make synchrotron radiation the perfect X-ray source for XRF spectrometry. From here on, we will refer to XRF spectrometry using synchrotron radiation as *S*-XRF.

Instrumentation and Analysis

Just as its bench-top counterpart, S-XRF requires a detector and a sample positioning system. With the development of semiconductor technology in the 1970s, materials like Ge and Si have been used as energy-dispersive (i.e., detection of several X-ray energy intensities at once) detectors for S-XRF. As a sample is excited with an X-ray beam at a given energy, each of component elements emits its corresponding fluorescence lines. These fluorescence lines are nothing more than a discrete set of X-ray energies. Each time one of these X-rays hits the detector material (Ge or Si), it creates distinct set of electron–hole pairs. The intensity and frequency of these pulses are binned and translated into a more meaningful energy scale and intensity scale; plotting the intensity of emitted lines against their energy (Fig. 1) represents the elemental composition of the sample. Integrating the relative intensities and locating its position in an absolute energy scale allows a quantitative estimation of the relative abundances of the elements composing a sample. The absolute intensity scale can be calibrated using reference foil



Synchrotron X-Ray Fluorescence Analysis, Fig. 1 Typical X-ray fluorescence spectra from powdered sugar and a 1:1 dilution with NIST 2710 soil standard (Montana Soil). Each emission line energy represents an element present in the sample, and the amplitude is related to the concentration of that element in the sample. Note the emission lines from the elements in the soil standard sitting *on top* of the powdered sugar matrix used in the dilution (background emission)

standards, which contain definite amounts of a set of elements. The final component of S-XRF is the positioning system. Briefly, these systems usually consist of a motorized x-y-z stage with micrometer resolution movements, including frequently 2–3 rotation angle movements. Coupled to current state of the art X-ray focusing optics, it transforms S-XRF from a bulk to a technique with microscopic resolution. 2-D and 3-D maps can be generated by synchronizing the sample stage movements and the acquisition electronics and detectors. This provides a full rendering not only of the elemental composition and concentrations but the actual spatial distribution of the different elements composing a sample (Fig. 2).

The elemental mapping capability has opened S-XRF spectrometry to a more broad audience, from environmental sciences to archeology. Moreover, because the optics for synchrotron X-ray sources allows incident X-ray energies to be selected, element sensitivity is dramatically improved potential overlaps in fluorescent lines to be mitigated. By simply selecting energies below and above the X-ray ionization potential (or absorption edge) of a given element, a difference map can be generated, isolating the signal of an element and revealing potential correlations that otherwise would be hard to deconvolute.

As with many other analytical techniques, S-XRF is subject to matrix effects (i.e., changes in signal based on the composition of the material). Some of these effects are countered by either working with pictographic thin sections or by mathematically correcting for matrix effects. Matrix effects range from self-absorption (or auto-absorption) of the fluorescence by the matrix (leading to nonlinear X-ray emission), X-ray penetration depth effects (irregular sampling if excitation energies are changed), and other effects. If the overall composition of the sample is known to a certain degree, a correction can be applied. Thin sectioning helps reduce those artifacts in a less artificial manner. Lighter matrix materials (organic materials like plants and root and low Z elements) provide ideal matrices, as the background absorption is minimal.

Conclusion and Perspectives

Despite its noted uses, S-XRF is still advancing. Current developments in X-ray optics are capable of generating more intense X-ray beams in the submicron scales, allowing greater spatial resolution. Also, more intense X-rays imply greater sensitivities. Coupled with faster detection systems, not only the sensitivity but also the measurement time is decreased (from minutes to a few milliseconds).

S-XRF can be applied to dozens of systems, from plant roots to archeological materials, making an extremely versatile and powerful technique for identification and the spatial distribution of elements in a sample.

Element Data
Atomic Symbol: **Ta**
Atomic Number: **73**
Atomic Weight: 180.94788 ± 2
Isotopes and Abundances (CIAAW): ^{180}Ta 99.988%, ^{181}Ta, 0.01198%
1 Atm Melting Point: 3017 °C
1 Atm Boiling Point: 5458 °C.
Common Valences: 5+
Ionic Radii: 6-fold: 64 pm
Pauling Electronegativity: 1.5
First Ionization Potential: 761 kJ/mol
Chondritic (CI) Abundance: 15 ppb
Silicate Earth Abundance: 43 ppb
Crustal Abundance: 0.7 ppm
Seawater Abundance: 0.01 to 0.3 pmol/g
Core Abundance: ~0

Properties

Tantalum is a transition metal of low toxicity with the atomic number of 73. Its melting point is 3017 °C, and its boiling point is 5458 °C. Tantalum has two stable isotopes, ^{180}Ta and ^{181}Ta, with an atomic mass of 180.94788 ± 2 (CIAAW 2015). The small isotope ^{180}Ta only has an abundance of ca. 0.012% (Berglund and Wieser 2011), making it the rarest stable isotope in the solar system. A more precise measurement of natural ^{180}Ta/^{181}Ta (Weyer et al. 2002) yielded isotope abundances of 0.0001198 ± 6 for ^{180}Ta and of 0.9998802 ± 6 for ^{181}Ta. By better taking into account tailing effects during mass spectrometry, Pfeifer et al. (2017) revised the natural ^{180}Ta/^{181}Ta to 0.00011705 ± 41, yielding a revised atomic weight of 180.9478787 ± 38. Notably, ^{180}Ta is only stable in nature in its excited isomeric state, whereas in its ground state, it would decay rapidly with a half-life of ca. 8 h. In nature, Ta occurs in +5 valence state, although +4 valence is known from synthetic systems. Its atomic radius is 146 pm, and its ionic radius in +5 valence state and sixfold coordination is 64 pm, virtually identical to its geochemical twin Nb (Shannon 1976). Due to its high ratio of charge to ionic radius, Ta is classified in geochemistry as *high field strength element*.

History and Use

Tantalum was first discovered in 1802 by the Swedish chemist A. Ekeberg (Ekeberg 1803), following the discovery of the chemically similar *Niobium* 1 year earlier (named *Columbium* at the time, Hatchett 1802). The element was named after Tantalus, a Greek mythological figure, reflecting the extreme chemical inertness of Ta. It was not until 1845 that the German chemist Heinrich Rose (Rose 1845) could clearly demonstrate *Tantalum* and *Niobium* are two different elements.

Economically important Ta deposits are always bound to Nb deposits and are typically hosted by pegmatitic granites or carbonatites. The most important economical grade Ta mineral is tantalite (Ta-rich variety of columbite), and this type of mineralization is often referred to as COLTAN. Countries with the world's largest Ta deposits have traditionally included Australia and Brazil, but in Africa, Eastern Congo, Ruanda, and Burundi became increasingly important in the last years, now covering more than 50% of Ta world production (USGS 2015), despite being conflict areas. Technically, Ta is mainly used as materials for capacitors in automotive electronics, personal computers, and mobile phones. Other

industrial uses include alloys for nuclear reactors, chemical equipment, and jet engines.

Geochemical Behavior

Tantalum is a highly refractory element with a 50% condensation temperature of 1573K (Lodders 2003) and has behaved lithophile during the Earth's differentiation. Ratios of Ta and similarly refractory elements like rare earth elements, Zr or Nb, are nearly constant in most groups of chondrites, and only CV chondrites rich in refractory components are depleted in Nb relative to Ta (Münker et al. 2003). The solar system abundance of Ta as estimated from CI chondrites is 15 ppb; the estimated abundance in the bulk silicate Earth is 43 ppb (Palme and O'Neill 2014). As Ta is not known to be significantly depleted in the silicate Earth relative to other refractory lithophile trace elements, it is assumed that the Earth's core contains no Ta, in line with experimental evidence (Wade and Wood 2001; Mann et al. 2009).

During silicate melting on Earth, Ta behaves highly incompatible in mantle minerals and is therefore depleted in the mantle and enriched in the crust. In the continental crust, the Ta content is estimated to 0.7 ppm with a content of 0.9 ppm and a Nb/Ta between 12 and 13 in the upper crust (Barth et al. 2000; Rudnick and Gao 2014). Relative to similarly incompatible elements like La or U-Th, however, Ta and its geochemical twin Nb are markedly depleted in the continental crust, mirroring their selective depletion in subduction zone magmas that contributed to the bulk of the continental crust. The selective depletion of Ta (and Nb) in subduction-related lavas and the continental crust is caused by their lower solubility in subduction zone fluids and by their retention in Ti-rich phases like rutile in subducting oceanic crust and possibly in subducting sediments (e.g., Zack et al. 2002; Hermann and Rubatto 2009). Together with its geochemical twin Nb, Ta is therefore a viable tracer for elemental mass balances in subduction zone systems, and employing Nb/Ta ratios in igneous and metamorphic rocks has now become an important tool to better understand silicate melting processes. Although the ionic radii reported for Ta and Nb are similar (Shannon 1976), experimental studies simulating mantle melting have shown that Ta behaves slightly less incompatible than its geochemical twin Nb (e.g., Blundy et al. 1998, Mc Dade et al. 2003). This observation argues for a slightly smaller ionic radius of Ta compared to Nb.

Due to its high valence state, Ta tends to hydrolize easily and is not very soluble in seawater, with an estimated concentration range between 0.01 and 0.3 pmol/kg, where 0.1 pmol/kg marks a typical value (Firdaus et al. 2011; Bruland et al. 2014). Compared to silicate rocks, Ta is less abundant in seawater than its geochemical twin Nb, as indicated by elevated Nb/Ta in seawater that are as high as 85 (Firdaus et al. 2011). Once more data will become available for aqueous systems, combined Nb and Ta studies may therefore have great potential to better understand weathering processes and ocean circulation.

Biological Utilization and Toxicity

Tantalum has no known biological role. Due to its inertness, it is used on bio-implants, but Ta dust can be a skin, eye, and lung irritant at high concentrations (US Centers for Disease Control and Protection 2015).

Summary

Tantalum is a highly refractory incompatible element and one of the high field strength elements. Unlike its geochemical twin, Nb, it is strictly lithophile. It has low solubility and is generally considered immobile. Compared to elements of similar incompatibility, it is depleted in the Earth's crust and in subduction zone magmas.

Core Abundance: ~0

Properties

Technetium (Tc), with atomic number of 43, is an element between molybdenum (Mo) and ruthenium (Ru). Tc is the lightest element which has no stable isotopes. The isotopes known for this element are all radioactive. The isotopes with a half-life ($T_{1/2}$) of more than 1 h are ^{93}Tc ($T_{1/2} = 2.8$ h; decay mode, EC + β^+), ^{94}Tc ($T_{1/2} = 4.9$ h; EC + β^+), ^{95}Tc ($T_{1/2} = 20.0$ h; EC + β^+), ^{95m}Tc ($T_{1/2} = 61.0$ days; EC + β^+ or IT), ^{96}Tc ($T_{1/2} = 4.3$ days; EC + β^+), ^{97}Tc ($T_{1/2} = 2.6 \times 10^6$ years; EC), ^{97m}Tc ($T_{1/2} = 90.1$ days; EC, IT), ^{98}Tc ($T_{1/2} = 4.2 \times 10^6$ years; β^-), ^{99}Tc ($T_{1/2} = 2.1 \times 10^5$ years; β^-), and ^{99m}Tc ($T_{1/2} = 6.0$ h; β^-, IT). Even the longest $T_{1/2}$ of 4.2×10^6 years for ^{98}Tc is not long enough to be present from the time of the nucleosynthesis of elements that constitute the solar system. Thus, Tc found in the Earth is only produced naturally by the decay of other radionuclides or as fission products and artificially by nuclear reactions, such as in nuclear reactors and nuclear weapons. In particular, ^{99}Tc comprises 6% of the total fission products of ^{235}U and ^{239}Pu, and its long $T_{1/2}$ makes it accumulate gradually in the environment through the use of nuclear energy. As a result, knowledge on the environmental chemistry of Tc has accumulated.

Technetium is located at the center of the transition metals in the periodic table. The electron configuration of Tc is [Kr] $4d^5 5s^2$, which ensures a variety of applications in chemistry. The oxidation states known for this element are −1, 0, +1, +2, +3, +4, +5, +6, and +7 but are mainly found as Tc(VII) and Tc(IV) species. The chemical structure of Tc was investigated using a long-lived isotope, ^{99}Tc ($T_{1/2} = 2.13 \times 10^5$ years), which is readily produced by milking of ^{99}Mo produced by fission of enriched U or neutron activation of ^{98}Mo. A stable oxide of Tc is TcO_2, and a Tc species soluble in aqueous

solution is TcO_4^- under oxic conditions. Technetium becomes Tc(IV) and insoluble as $Tc(OH)_4$ or TcO_2 under reducing conditions and is only soluble as TcO^{2+} or $TcOOH^+$ under acidic conditions (Icenhower et al. 2010).

History and Use

It was thought that the discovery of this element could not be difficult, because the position of Tc was already predicted as "ekamanganese (Em)" immediately below manganese in the periodic table by Dmitri Mendeleev. Before the discovery of Tc, all stable elements were already found (the final stable element was rhenium (Re), which is below Tc in the periodic table), and two positions among the elements lighter than lead (Pb, which is the heaviest element with stable isotopes) were unoccupied, which corresponded to Tc and promethium (Pm). In 1937, Perrier and Segrè successfully isolated Tc from a molybdenum foil that had been used as a target of a deuteron beam in a cyclotron in the Lawrence Berkeley National Laboratory in California (Perrier and Segrè 1937). The element was named after the Greek word "technetos," meaning "artificial."

Geochemical Behavior

Observation of Tc in natural systems was first reported by Merrill (1952), who observed spectra from relatively young stars outside the solar system. Afterward, Tc in terrestrial environment was found as fission products of uranium (U) in pitchblende, a uranium-bearing ore (Kenna and Kuroda 1961). Natural ^{99}Tc was also detected in uranium ores from the Cigar Lake uranium deposit in Canada (Curtis et al. 1999). Migration of ^{99}Tc in Cigar Lake was observed in a limited area possibly because of the absence of pertechnetate (TcO_4^-), the mobile form of Tc, under reducing condition of the system.

Isotope ratio anomalies of Ru induced by the decay of Tc have been investigated in several systems. Excess ^{100}Ru compared with the normal isotopic ratio of Ru produced by neutron capture of ^{99}Tc was used to trace the migration of Tc in Oklo and Bangombé natural fission reactors in Gabon (Hidaka et al. 1999). An anomaly in ^{99}Ru was detected in individual presolar silicon carbide (SiC) stardust grains, which was explained by the in situ decay of ^{99}Tc in the grains. The anomalous Ru isotopes caused by the extinct Tc were used to identify the origin of presolar SiC grains (Savina et al. 2004). This study also indicated that detection of ^{99}Ru due to the decay of ^{99}Tc in early solar system materials cannot be estimated based on the amount of ^{99}Tc produced in such stars.

As mentioned previously, determination and speciation of Tc in the environment has been investigated in particular for safety assessment of radioactivity in the environment and nuclear waste management (Shi et al. 2012). Emission from nuclear reprocessing plants is primarily important (>1,874 $\times$ 10^{12} Bq), followed by global weapon fallout (140 $\times$ 10^{12} Bq) and nuclear accidents (Chernobyl and Fukushima; about 1 $\times$ 10^{12} Bq). The concentration of ^{99}Tc in the normal environment is 1–10 μBq/L (= 1.6 $\times$ 10^{-15} to 1.6 $\times$ 10^{-14} ^{99}Tc g/L) and 4–88 mBq/kg (= 6.4 $\times$ 10^{-15} to 1.41 $\times$ 10^{-13} ^{99}Tc g/g) in seawater (Japan Sea) and soil in Japan, respectively. The low concentration at this level must be measured with the appropriate pre-concentration and separation methods. Detection is mostly conducted by β counting or ICP-MS. The β counting method, a radiometric method using a low-level GM counter, is commonly used, but needs a long measurement time. The ICP-MS method is sensitive and fast, but is subject to mass interference from ^{99}Ru, which needs to be removed before analysis.

The environmental behavior of Tc has been investigated in various systems, such as the soil–plant systems on land and the marine environment (Icenhower et al. 2010). Chemical processes, including redox reactions, sorption reactions, colloid formation, and interaction with humid substances, have been investigated. Generally, Tc is enriched in solid phases, such as soil and sediment, under reducing conditions because of the formation of insoluble Tc(IV) species. By contrast, Tc is highly soluble as TcO_4^- under oxic conditions, such as in normal seawater.

Biological Utilization and Toxicity

Technetium has no known biological role. It is toxic due to its radioactivity. Technetium has a high complex-forming ability ability, which allows the synthesis of various labeled compounds of ^{99m}Tc. The short lifetime of ^{99m}Tc is appropriate for using the Tc compound for medical diagnosis and medical research. ^{99m}Tc is exclusively supplied by ^{99}Mo–^{99m}Tc generators. Although the medical application of ^{99m}Tc prevails widely the amount of ^{99}Tc released from medical use is less than 0.02 $\times$ 10^{12} Bq, which is negligible compared with those from other sources, such as reprocessing and nuclear testing (Shi et al. 2012).

Summary

Technetium (Tc) is an element without any stable isotopes but has been used as various labeled compounds in medical diagnosis. Environmental study of Tc is important, which has been developed based on the advanced high-sensitive analytical methods.

Properties

Tellurium (Te) is one of the chalcophile elements that belong to group 16 in the periodic table and has an electronic configuration of $[Kr]4d^{10}5s^25p^4$. There are eight stable isotopes from ^{120}Te to ^{130}Te. It is expected that ^{126}Te is enriched relative to other isotopes because of the decay of the short-lived nuclide tin 126 (half-life: 2.345×10^5 year) in certain phases with high Sn/Te ratio in primordial materials in the solar system, such as chondrite meteorites (Yokoyama and Walker 2016). However, clear evidence of this anomaly has not been obtained yet. Tellurium stable isotope fractionation has been found mainly as a consequence of abiotic and biotic redox reactions of Te in nature (Smithers and Krouse 1968; Baesman et al. 2007).

Te exhibits variable oxidation states of −2, 0, +2, +4, and +6, similar to selenium (Se). Although the chemical characteristics of Te are generally regarded as similar to those of sulfur (S) and selenium (Se), they are substantially different in various aspects. The ionic radii (^{CN}r; CN is the coordination number) of Te at various oxidation states are larger than those of S and Se (e.g., $^6r(S^{4+}) = 0.37$ Å; $^6r(Se^{4+}) = 0.50$ Å; $^6r(Te^{4+}) = 0.97$ Å). Consequently, isomorphic replacement of S in various compounds is more frequently observed for Se than for Te. Te has a large number of independent minerals, as shown below. Te compounds generally show more covalent or metallic bonding compared with S and Se compounds.

History and Use

Tellurium was discovered in gold telluride by Franz-Joseph Müller von Reichenstein in 1782 and named after the Latin word *tellus*, which means the Earth by Martin Heinrich Klaproth in 1798.

From an economical point of view, Au–Ag–Te minerals are unimportant because of their rarity. Instead, more ubiquitous deposits of pyrite, pyrrhotite, and chalcopyrite with smaller concentrations of Te (and Se) than in Au–Ag–Te ores are the main source of Te. The recovery of these elements

from pyrite, pyrrhotite, or chalcopyrite is relatively easy, since Te effectively accumulates in dust or anodic slugs in electrolytic copper refinery plants. Te production is approximately 220 tons per year in the USA, Russia, Sweden, Japan, Peru, and Canada (Brown et al. 2015). Te is primarily utilized in metallurgy and chemical industries as additives to (i) copper alloys and stainless steel to make processing and milling easy and to (ii) lead (Pb) to increase strength. Te has been also utilized in electrotechnical and electronics industries and photonic glasses. In particular, its use in solar cells in photovoltaics has been greatly expanding, which poses concern about the supply of Te, one of rare metals due to its low crustal abundance (Zweibel 2010; Green 2013).

Geochemical Abundances and Behavior

The abundance of Te in the solar system (4.81 atoms per 10^6 Si) is the highest among all elements with atomic number >40. However, Te is only about the 80th most abundant element in the crust, since Te is one of highly volatile elements that was not incorporated into solid planetary materials during condensation. The abundances of calcogen elements in silicate rocks and various types of chondrites have been studied to unveil the "late veneer" hypothesis that chondritic materials with volatiles were accreted to the Earth after core formation (Wang and Becker 2013).

The abundance of Te in silicate rocks is in the range of 0.4–12 ppb. Similarly, background Te concentrations in soils and sediments are at the low ppb level. Its concentration in seawater is usually less than 2 ng/L (about 16 pM), whereas the concentration is approximately one order of magnitude higher in freshwater (Belzie and Chen 2015).

Native Te exists in crystalline and amorphous forms. The specific gravity of the two at 18 °C are 6.24 and 6.0–6.2, respectively. Their melting and boiling points are 450 °C and 990 °C, respectively.

The most notable feature of Te in terms of mineralogy is the formation of Au–Ag–Te species, such as calaverite ($AuTe_2$), krennerite ($AuAgTe_2$), sylvanite ($AuAgTe_4$), and hessite (Ag_2Te) in epithermal, orogenic, and intrusion-related hydrothermal ore deposits. During the formation of these minerals, Te can be transported as gaseous species, such as H_2Te and Te_2, under reducing conditions (Grundler et al. 2013). The transport by the gaseous Te species is also important during its emission from volcanoes.

Under Earth's surface conditions, Te forms tellurite (TeO_3^{2-}) or tellurate (TeO_4^{2-}) depending on the redox condition. These ions can be fixed to the solid phase through the adsorption on Fe (hydr)oxides, such as ferrihydrite and goethite (Harada and Takahashi 2008). The adsorbed species form an inner-sphere complex on the surface of metal oxides. Meanwhile, selenate forms an outer-sphere complex. The difference in the adsorbed species results in the insoluble nature of Te compared with Se in soils or sediments under ambient conditions. Tellurite or tellurate can be fixed to the solid phase through the formation of native Te under reducing conditions. Te is highly enriched in ferromanganese nodules or crusts at the seafloor. The degree of enrichment in ferromanganese oxides relative to shale is the largest for Te compared with any other elements (Hein et al. 2003) possibly due to the isomorphous substitution of Te(VI) to Fe^{3+} or Mn^{4+} ions in ferromanganese oxides (Kashiwabara et al. 2014).

Biological Utilization and Toxicity

The environmental behavior of Te is of great importance because of its high toxicity. Specifically, tellurite is more toxic than tellurate. No biological role is known for Te. In humans, Te is exhaled in the breath of victims of Te toxicity as dimethyl telluride, $(CH_3)_2Te$, a gas with a garlic-like odor.

The size distribution of Te in aerosols shows that Te is mainly found in submicron particles, which suggests that Te is emitted as a gaseous species through its preferential emission from combustion processes and then converted into fine particles by condensation as the fumes cool or by chemical reactions in air (Chiou and Manuel 1986). Similarly, the vapor transport of radioactive Te is also important in commercial nuclear power plants related to its occurrence as a short-lived fission product. Te radioisotopes (e.g., ^{132}Te) decay to radioiodine (^{132}I), which is a hazardous radioisotope because of the accumulation of iodine into the thyroid. Te can be released with other volatile elements, such as Cs and I, nuclear reactor accidents such as at Chernobyl (1986) and Fukushima Daiichi (2011) nuclear power plants (Jantunen et al. 1991; Yoshida and Takahashi 2012).

Silicate Earth Abundance: 0.084 ppm
Crustal Abundance: 0.60 ppm
Seawater Abundance: 0.175 ppt
Core Abundance: ~0

Properties

Terbium (Tb), named after the Swedish village of Ytterby, is a soft, ductile, malleable, dense (8.230 g cm^{-3}), bright silvery-gray metal. Its electronic configuration is [Xe]4f^{9}6s^{2}. It is relatively stable at room temperature and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE). In geochemical terminology, it is grouped with heavy rare earth elements (HREE; Gd-Lu). Terbium has one stable isotope.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Tb as a significant component are restricted to Y and HREE varieties, such as xenotime [$Y(PO_4)$], gadolinite-Y [$Y_2FeBe_2(Si_2O_{10})$], bastnäsite [$REE(CO_3)F$], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+},Fe^{3+})_3(SiO_4)_3(OH)$], and britholite [$(REE,Ca)_5(SiO_4,PO_4)_3(OH,F)$].

Details of properties, mineralogy, history, and uses of Tb were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner (2016), Hammond (2016), and Meija et al. (2016a, b).

History and Use

Terbium was discovered in 1843 by Carl Gustaf Mosander; early naming is somewhat confused as the names erbium and terbium were switched in 1864. The most important use of terbium is in green phosphors used in visual displays, tubes, and fluorescent lights. Secondary uses include as additives in neodymium magnets, lasers, and phosphors and in alloys used in a variety of electronic and magnetic devices.

Geochemical Behavior

The fundamental importance of Tb in geochemistry is that it is one of the small trivalent rare earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction."

Terbium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element, with a 50% $T_{condensation}$ of 1659 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Tb is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Tb normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Tb contents of clastic sediments typically reflect their average provenance.

In seawater, Tb has very low concentrations (sub-ppt) and residence times (~570 year) with speciation dominated by Tb^{3+}, $TbCO_3^+$, and $Tb(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Tb can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration and residence time data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Tb. REE (including Tb^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Tb) in human tissues and fluids are very low (~ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Introduction

Thallium (Tl) is a soft blue-grey metal that is present in trace quantities in the Earth's crust and is highly toxic either as a metal or as one of many compounds. It was first discovered in 1861 by William Crookes, and Tl metal was first isolated in 1862 by both Crookes and Claude-August Lamy (Peter and Viraraghavan 2005). Thallium has an atomic number of 81, atomic weight of 204.37, and is in group 13 of the periodic table. It has two oxidation states, with a 3+ state similar to other elements in group 13 (e.g., boron and aluminum) and a 1+ state. The relatively common Tl + ion is similar in charge and radius to group I elements K, Na, and Rb. It is dense (11.85 g/cm^3 at room temperature) and considered highly volatile, with a melting point of 577 K and a boiling point of 1746 K. There are two stable isotopes of Tl; ^{203}Tl (29.524%) and ^{205}Tl (70.476%). There are also several short lived radioisotopes of Tl including ^{204}Tl ($t_{0.5}$ 3.78 years), ^{202}Tl ($t_{0.5}$ 12.2 days), and ^{201}Tl ($t_{0.5}$ 73 h).

Thallium in the Earth's Crust

Thallium is widely distributed throughout the Earth's continental crust with an average concentration of ~0.5 ppm (Wedepohl 1995). In detail, there is approximately 3 times more Tl in the upper continental crust than in the lower crust, and orders of magnitude more Tl in the continental crust than is present in either the oceanic crust or mantle (Wedepohl 1995; Peter and Viraraghavan 2005; Nielsen and Rehkamper 2012). The reason for this enrichment of Tl in crustal rocks is that the isotopes of Tl have a relatively large ionic radius (Tl^+ 1.49A, Tl^{3+} 1A) that is too large to incorporate into the crystal lattice of mantle minerals olivine and pyroxene (Heinrichs et al. 1980; Shaw 1952). Thus, Tl behaves as an incompatible element during partial melting of the mantle, i.e., instead of remaining in mantle minerals Tl is preferentially incorporated into the melt. Because the Earth's crust is ultimately derived from this melt fraction, the crust becomes relatively enriched in Tl and the mantle becomes relatively depleted. The prevalence of the reduced form of Tl (+1 valence state) and similarity of its ionic radius and charge with group I elements means that, in the silicate Earth, the behavior of Tl closely corresponds to the alkali metals K^+, Rb^+, and Cs^+ (Rehkamper and Nielsen 2004). In terms of the most common rock forming minerals, Tl is usually concentrated in K^+ rich minerals such as K-feldspar and biotite, where Tl concentrations are commonly between 1 and 10 ppm (Shaw 1952; Heinrichs et al. 1980). In contrast, mantle minerals such as pyroxenes and olivine have Tl concentrations ~20–50 ppb.

As well as being a lithophile element, Tl is also chalcophile (readily combines with sulfur) so Tl readily partitions into sulfide melts (Rehkamper and Nielsen 2004). Significant quantities of Tl (Wt% levels) have been found in a small number of very rare sulfide minerals including lorandite ($Tl_2S.As_2S_3$) and huthinsonite ($PbS.(Ag,Tl)_2S.As_2S_3$). For economic purposes, the Tl-rich sulfide minerals are usually too scarce and the concentration of Tl in major rock-forming minerals too low for large-scale extraction. An example of a mining operation in which Tl is the primary target is the Xiangquan mine in China. Here the Tl is mostly present in pyrite but some lorandite and huthinsonite is also present (Zhou et al. 2005). Typically, the main source for commercial extraction of thallium is other heavy metal sulphide ores such as galena, sphalerite, and chalcopyrite. In these ores Tl can be present in the ppm level up to Wt% levels in chalcopyrite (Peter and Viraraghavan 2005). In addition, significant quantities of Tl (up to 1000 mg/kg) have been found in organic-rich shales and coal measures (Kazantzis 2000), and in deep sea sediments and manganese nodules (Peter and Viraraghavan 2005).

Thallium Behavior During Weathering

The concentration of Tl in river and seawater is typically between 10 and 20 ng/l (Flegal and Patterson 1985), though higher concentrations are observed in waters close to auriferous ore bodies and in polluted streams (Peter and Viraraghavan 2005). Thallium concentrations in soil typically range between 0.1 and 1 ppm, although values as low as 0.01 ppm and as high as 55 ppm have been observed (Kazantzis 2000; Jakubowska et al. 2007; Tremel et al. 1997). Such high concentrations in soil can be naturally derived; for example Tremel and coauthors (1997) observed 55 ppm Tl in soil derived from calcareous parent rocks that contain abundant sulphide minerals. Adsorption of Tl from solution onto oxide and phyllosilicate minerals plays an important role in controlling the Tl distribution in surface waters, soils, and crustal sediments. In particular, ferric oxides are important; adsorption of Tl+ does not take place at pH $<$ 3, but readily occurs at pH ~6.5 (Karlsson 2006). The readiness with which Tl can be adsorbed onto oxides, clay

minerals, and organic matter means that Tl will persist in soils rich in these minerals. In general the oxidation state of Tl plays a crucial role in controlling Tl uptake (Karlsson 2006). For example, in seawater Tl+ preferentially adsorbs to negatively charged Mn oxides, while Tl^{3+} adsorbs to neutrally charged FeOOH.

Anthropogenic Thallium and Toxicity

Although global production of Tl is low (around 15 t per year), it is estimated that annually between 2000 and 5000 t of Tl are released into the environment (Kazantzis 2000). The majority of this Tl is released by emissions from coal burning power plants and smelting of lead, copper, and zinc ores (Kazantzis 2000). Other significant sources of Tl include cement production and refining of nonferrous metals. Because Tl is very volatile, it is vaporized and then recondensed onto fine ash and dust particles which pass through conventional filtering systems in power plants.

In river and stream waters, the highest Tl concentrations measured are in industrial wastewaters; concentrations between 1 and 88 ppm have been observed in wastewaters from metal mines (Peter and Viraraghavan 2005). Similarly, the highest concentrations of Tl in soils are also reported in close proximity to mining areas. Close to the Silesian-Cracowian lead-zinc ore deposit, Tl concentrations of 150 ppm have been measured (Jakubowska et al. 2007). Other areas in which the concentration of Tl in soil ranges from 5 to 120 ppm include pyrite processing plants and near sulphide ores of heavy metals such as Hg, Au, and As. These high concentrations of Tl are usually confined to the topsoil, around 0–0.2 m from the surface (Jakubowska et al. 2007).

High concentrations of Tl in soil can be taken up into plants, depending on the plant type, solubility of the Tl compound, and acidity of the soil (Tl being more mobile in higher acidity waters). Concentrations of 25–50 mg/kg (dry weight) have been measured in some green cabbage, rape seed, and kale (LaCoste et al. 2001). These concentrations can exceed the concentration of Tl present in the soil and approach levels that are major potential risks for human consumption. Thallium poisoning involves inhibition of certain potassium dependent biological processes due to similarities between the ionic radius and charge of K+ and Tl+ ions. This affects the action of certain enzymes, coenzymes, and proteins and can result in gastrointestinal disturbances and central nervous system disorders (Galvan-Arzate and Santamaria 1998).

Summary

Thallium is typically present in trace quantities (sub-ppm) in the Earth's crust and mantle. Because it is a chalcophile element, relatively high concentrations up to the Wt% level can be found in sulphide minerals and ore bodies. Though the concentration of Tl in natural waters and soils is low, local to ore bodies and near to industrial ore processing plants the concentration of Tl in streams and soils can be orders of magnitude above background levels and have implications for human health if contaminated material is ingested or inhaled. Because of its extreme toxicity, it is important to understand its mobility and distribution during both natural weathering processes and anthropogenic processing.

Thallium Isotopes

Sune G. Nielsen
Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Definition

The element thallium (Tl) has two isotopes; ^{203}Tl and ^{205}Tl. Thallium isotope measurements have been conducted since the 1960s due to the hypothesized presence of the radioactive isotope ^{205}Pb (which decays to ^{205}Tl with a half-life of ~15 million years) when the solar system formed. However, it was only with the development of high precision measurements of Tl isotope ratios by multiple collector inductively coupled mass spectrometry (MC-ICP-MS) in the late 1990s that variation in ^{205}Tl/^{203}Tl was detected. In addition to significant Tl isotope variation in meteorites from the decay of ^{205}Pb, studies of terrestrial samples have revealed that Tl isotopes, despite their heavy masses, can fractionate substantially, especially in the marine environment. The most fractionated reservoirs identified are ferromanganese sediments and low temperature altered oceanic crust. These display a total isotope variation of about 35 ε^{205}Tl-units, which is more than 70 times the current analytical reproducibility. The isotopic variation can be explained by invoking a combination of conventional mass dependent equilibrium isotope effects and the nuclear field shift isotope fractionation, but the specific mechanisms are still largely unaccounted for.

Thallium isotopes have been applied to investigate paleoceanographic processes in the Cenozoic, the magnitude of hydrothermal fluid circulation through ocean crust, subduction zone and mantle recycling processes, and anthropogenic contamination of soil.

Historical Context

Thallium has two isotopes with atomic masses 203 and 205 (Table 1). This equates to a relative mass difference of <1%. Considering that conventional stable isotope fractionation theory states that the magnitude of isotope fractionation should scale with the relative mass difference of the isotopes (Urey 1947) one would not expect large stable isotope effects for Tl. The main reason behind the first Tl isotope studies was the search for radiogenic isotope variations due to decay of the now-extinct radioactive isotope ^{205}Pb (Anders and Stevens 1960; Ostic et al. 1969). Lead-205 decays to ^{205}Tl with a half-life of 15.1 Myrs (Pengra et al. 1978), whereas ^{203}Tl is stable and has no radioactive precursor. Therefore, it was believed that variable ^{205}Tl/^{203}Tl ratios would reveal the former presence of ^{205}Pb when the solar system formed. A number of studies between 1960 and 1994 all failed to register any resolvable Tl isotope variation for some selected terrestrial and a large number of extraterrestrial materials (Anders and Stevens 1960; Ostic et al. 1969; Huey and Kohman 1972; Chen and Wasserburg 1987, 1994). The failure to detect any Tl isotope variation was due to the relatively large errors (>0.2%) associated with the thermal ionization mass spectrometry (TIMS) measurements used at that time. The breakthrough came in 1999 when the first high precision Tl isotope measurements by MC-ICP-MS were published (Rehkämper and Halliday 1999). This technique provided a reduction in the uncertainty of more than an order of magnitude with errors reported at about 0.01–0.02% (Rehkämper and Halliday 1999). As with the previous Tl isotope investigations, Rehkämper and Halliday (1999) were ultimately motivated by the search for ^{205}Pb. However, analyses of a number of terrestrial samples that were meant to define the Tl isotope composition of Earth, which could then be compared to extraterrestrial findings, revealed large Tl isotope variation in excess of 15 times the analytical reproducibility. In principle, it is not possible to distinguish between ^{205}Tl/^{203}Tl variation caused by decay of ^{205}Pb and stable isotope fractionation because Tl has only two isotopes. However, the observed variation was clearly unrelated to radioactive ^{205}Pb and thus was inferred to be the result of stable isotope fractionation. Subsequent studies have confirmed that stable Tl isotope variation is common on Earth as well as in meteorites.

Thallium Isotopes, Table 1 Physical properties of thallium (Nriagu, 1998)

Melting point	577 K	
Molar weight	204.38 g	
Density	11.85 g/cm^3	
Valence states	Tl^+	Tl^{3+}
Redox potentials (V)		
$Tl_{(s)} \rightarrow Tl^+ + e^-$	+0.336	
$Tl^+ \rightarrow Tl^{3+} + 2e^-$	−1.28	
Ionic radius (Tl^+)	1.50 Å	
Ionic radius (Tl^{3+})	0.89 Å	
Isotopes	^{203}Tl	^{205}Tl

Thallium Isotope Measurements

The reason that MC-ICP-MS produces Tl isotope data far superior to TIMS is that instrumental isotope fractionation can be monitored during MC-ICP-MS measurements. Samples of Tl are introduced into the mass spectrometer as a solution (or a desolvated aerosol) into which the NIST SRM 981 Pb standard is admixed. By measuring all isotopes of Tl and Pb simultaneously and assuming that the isotope

fractionation incurred for the two elements is proportional, isotope ratios can be determined very accurately and precisely (Rehkämper and Halliday 1999; Nielsen et al. 2004) with the most recent studies reporting uncertainties of ~0.003–0.005% (Nielsen et al. 2015). Thallium isotope compositions are determined relative to the NIST SRM 997 Tl isotope standard and isotope compositions are reported as:

$$\varepsilon^{205}\mathrm{Tl} = 10^4 \times \left(\left({}^{205}\mathrm{Tl}/{}^{203}\mathrm{Tl}_{\mathrm{sample}} - {}^{205}\mathrm{Tl}/{}^{203}\mathrm{Tl}_{\mathrm{NIST\ 997}}\right) \times / \left({}^{205}\mathrm{Tl}/{}^{203}\mathrm{Tl}_{\mathrm{NIST\ 997}}\right)\right)$$

The terminology used for Tl isotope ratios is slightly different to standard stable isotope ratio conventions, which generally use the δ-notation (variations in parts per 1000). The reason for this is that the Tl isotope system was originally developed as a cosmochemical radiogenic isotope system, which by convention mostly is reported using the ε-notation (variations in parts per 10,000). Hence, the original notation was retained in order to make comparisons between cosmochemical and terrestrial data easier. In addition, the analytical uncertainty on and overall variability of stable Tl isotope ratios make the ε-notation very convenient as most data are thereby shown in whole digits with only a single figure behind the decimal point.

In order to measure Tl isotope ratios precisely and accurately it is necessary to completely separate Tl from the sample matrix (Rehkämper and Halliday 1999; Nielsen et al. 2004). The chemical separation technique relies on the fact that the trivalent Tl ion produces anionic complexes with the halogens (the technique uses either Cl^- or Br^-) in acidic solutions that partition very strongly to anion exchange resins. Conversely univalent Tl does not form strong anionic complexes and thus does not partition at all to anion exchange resins. Therefore, samples are prepared in oxidizing media by adding small amounts of water saturated in Br_2 to the samples already digested and dissolved in hydrochloric acid. This process ensures that all Tl is in the trivalent state, which will adsorb onto the anion exchange resin prepared in a quartz or teflon column. The sample matrix can then be eluted in various acidic media as long as Br_2 is present. Lastly, Tl is stripped from the resin by elution with a reducing solution that converts Tl to the univalent state. The reducing solution used is 0.1 M hydrochloric acid in which 5% by weight of SO_2 gas has been dissolved.

Applications of Thallium Isotopes

Evidence for ^{205}Pb in Meteorites

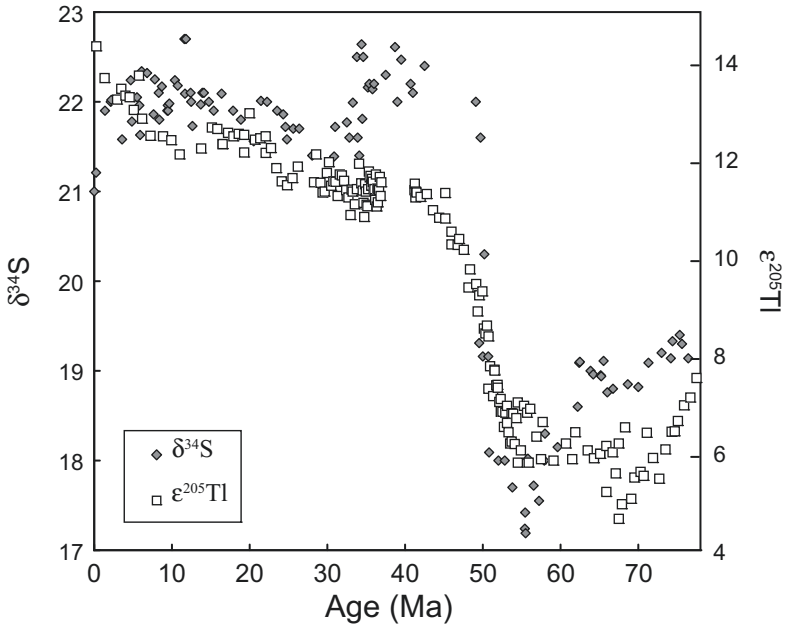
Two studies have found evidence for the presence of ^{205}Pb in the early solar system. The first study investigated Tl isotope systematics in several iron meteorites and found overall variation of ~50 ε^{205}Tl-units (Nielsen et al. 2006a). This variation was concluded to originate from both stable isotope fractionation and decay of ^{205}Pb. Measurements of multiple metal fragments of the IAB iron meteorite Toluca was found to form an isochron with $^{205}Pb/^{204}Pb \sim 7.4 \times 10^{-5}$ at the time of metal crystallization. The solar system initial $^{205}Pb/^{204}Pb$ depends on the age of Toluca metal crystallization, which is highly uncertain. The second study of Tl isotopes in meteorites investigated primarily carbonaceous chondrites and found an overall Tl isotope variation of only ~5 ε^{205}Tl-units (Baker et al. 2010). However, the majority of the carbonaceous chondrite data formed an isochron with $^{205}Pb/^{204}Pb \sim 1 \times 10^{-3}$ at the time of carbonaceous chondrite formation. Given that carbonaceous chondrites likely formed only a few million years after the start of the solar system (Kleine et al. 2005) it was concluded that the carbonaceous chondrite $^{205}Pb/^{204}Pb$ was essentially the initial of the solar system (Baker et al. 2010).

Studies of Tl Isotopes in Fe-Mn Crusts

Three studies have determined Tl isotope depth profiles for several hydrogenetic Fe-Mn crusts, which identified large systematic changes in Tl isotope compositions (Rehkämper et al. 2004; Nielsen et al. 2009, 2011). Modern surfaces of Fe-Mn crusts are characterized by $\varepsilon^{205}\mathrm{Tl} \sim 13$ (Rehkämper et al. 2002) whereas seawater is uniform with $\varepsilon^{205}\mathrm{Tl} \sim -6$ (Rehkämper et al. 2002; Nielsen et al. 2006c). Application of a constant Tl isotope fractionation factor between seawater and old Fe-Mn crust layers implied that the Tl isotope composition of seawater has experienced a single large shift in Tl isotope composition, which occured between ~55 and ~45 Ma (Fig. 1). It was proposed that the large shift in the ε^{205}Tl value of seawater in the early Cenozoic reflects a decrease in the amount of authigenic Mn oxides that were deposited with pelagic sediments in the early Eocene (Nielsen et al. 2009). Therefore, archives of the marine Tl isotope record are potentially a robust monitor of the oxidation state of seawater because the precipitation of Mn oxides requires oxygen at the sediment-water interface.

Calculation of Hyrothermal Fluid Fluxes Using Tl Isotopes in the Ocean Crust

Hydrothermal fluids are expelled from the seafloor (i) at high temperature on mid ocean ridge axes, as fueled by the magmatic energy from the crystallization and cooling of fresh ocean crust to ~300–400 °C and (ii) at lower temperatures on the ridge flanks, as the ocean crust cools slowly over millions of years. These hydrothermal fluxes play pivotal roles in controlling seawater chemistry, but the magnitude of the high temperature water flux at mid-ocean ridge axes remains widely disputed, whilst the volume of low temperature vent fluids expelled at ridge flanks is virtually unconstrained.



Thallium Isotopes, Fig. 1 Thallium isotope data for a Fe-Mn crust from the Pacific Ocean plotted for the last 75Myrs. The chronology of the Tl isotope curve was determined based on Os isotope data (Burton 2006) (Figure modified from Nielsen et al. (2009))

Thallium displays distinct behavior during high and low temperature hydrothermal alteration of the oceanic crust. High-T fluids effectively leach Tl from the cooling rocks with no isotope fractionation between fluid and rock, whereas low-T fluids deposit Tl into the upper part of the oceanic crust with deposition of light Tl isotopes into alteration minerals (Nielsen et al. 2006c; Coggon et al. 2014).

The high-T hydrothermal fluid flux was calculated using a mass balance between Tl in fluids and Tl available in the oceanic crust (Nielsen et al. 2006c), which yielded a range of fluid fluxes from 0.2 to 2.9 $\times$ 10^{13} kg/year. Low-T hydrothermal fluid fluxes were calculated using a similar mass balance equation between Tl supplied by seawater and the average Tl enrichment of oceanic crust altered by low-T hydrothermal fluids. It was found that 0.2–5.4 $\times$ 10^{17} kg/year of seawater is cycled through the upper 600 m of oceanic crust with an average temperature increase over ambient seawater of only 0.1–3.6 °C.

Thallium Isotopes as a Tracer for Ocean Crust Recycling in the Mantle

Thallium isotopes can be used to trace material recycled deep into the mantle because specific processes such as ocean crust alteration and marine Mn oxide precipitation causes substantial Tl isotope fractionation. Since Tl isotopes are not substantially fractionated during magmatic processes (Nielsen et al. 2016), subduction of these materials into the deep mantle should produce Tl isotope heterogeneity in regions of the mantle dominated by recycled oceanic crust and sediments.

To date, basalt samples from the Azores, Iceland and Hawaii have been investigated (Nielsen et al. 2006b, 2007). As it is unclear whether the Azores basalts were affected by post-eruptional alteration (Nielsen et al. 2007), these data will not be discussed here. Samples from Hawaii exhibit the most convincing Tl isotope evidence for presence of sediments in the mantle source (Nielsen et al. 2006b). About 10 ppm by weight of pure Fe-Mn sediment would be sufficient to explain the heavy isotope compositions recorded in these rocks.

Additional Tl isotope data for a suite of Icelandic basalts, on the other hand, did not show any significant Tl isotope variation and it could not be ascertained based on Tl isotopes if any sediment or altered oceanic crust is present in the mantle beneath Iceland (Nielsen et al. 2007).

Causes of Thallium Isotope Fractionation

In general, Tl isotope variations on Earth are fairly limited, with only a few select environments displaying significant deviations from the bulk Earth value of $\varepsilon^{205}Tl = -2$ (Nielsen et al. 2005, Nielsen et al. 2006b, Nielsen et al. 2006c, 2007). However, the overall magnitude of Tl isotope variation in natural environments on Earth now exceeds 35 ε^{205}Tl-units (Rehkämper et al. 2002, 2004; Nielsen et al. 2006c). This variability is comparable to the extent of fractionation observed for $^{56}Fe/^{54}Fe$ (Anbar 2004), which has a relative mass difference almost four times that of Tl. The larger-than-expected Tl isotope variation was shown to likely originate partially from equilibrium reactions in which so-called nuclear field shift isotope fractionation takes place (Bigeleisen 1996). Nuclear field shift isotope fractionation is not mass dependent but scales positively with the electron density close to the atom nucleus, which is generally largest

for the heavy elements due to relativistic contraction of s-orbitals for high-mass elements (Knyazev and Myasoedov 2001; Schauble 2007). The calculations that were carried out for Tl predict that an equilibrium system featuring Tl^{+} and Tl^{3+} will produce both regular mass dependent and nuclear field shift isotope effects, with isotope fractionation factors that act in the same direction (Schauble 2007).

Three experimental studies have investigated the Tl redox and isotopic effects during sorption of Tl to Mn oxide (Peacock and Moon 2012; Nielsen et al. 2013), which is the primary host of Tl in Fe-Mn rich sediments (Koschinsky and Hein 2003; Peacock and Moon 2012). These studies revealed that the MnO_2 phase hexagonal birnessite has the capacity to oxidize Tl^{+} to Tl^{3+}, following adsorption as a univalent ion (Bidoglio et al. 1993; Peacock and Moon 2012). In addition, it was found that this oxidation reaction was associated with significant Tl isotope fractionation in which the heavy Tl isotope was concentrated on the birnessite (Nielsen et al. 2013). The direction and magnitude of the isotope fractionation was consistent with that observed for natural Fe-Mn crusts (Rehkämper et al. 2002). Furthermore it was shown that natural Fe-Mn crusts are dominated by trivalent Tl (Peacock and Moon 2012) despite seawater almost exclusively contains univalent Tl (Nielsen et al. 2009). The experimental results are, therefore, consistent with the theoretical predictions in which ^{205}Tl is preferentially associated with trivalent Tl (Schauble 2007).

The Tl isotope fractionation found in low-T altered ocean crust is more poorly understood, which is in part because the host mineral for Tl in the altered oceanic crust is yet to be directly identified. Different studies have suggested that either sulfides or alkali-rich minerals contain most of the Tl added through low-T alteration (McGoldrick et al. 1979; Jochum and Verma 1996; Nielsen et al. 2006c; Coggon et al. 2014).

Summary

High precision measurements of Tl isotope ratios have only been possible since 1999, but this isotope system has already found a number of novel applications. To date, studies have revealed that Tl isotopes fractionate substantially in the marine realm with ferromanganese sediments and low temperature hydrothermal alteration displaying a total isotope variation of about 35 $\varepsilon^{205}Tl$-units. The isotopic variation can most likely be accounted for by invoking a combination of conventional mass dependent equilibrium isotope fractionation and nuclear field shift isotope effects (Bigeleisen 1996; Schauble 2007). It has been suggested that preferential oxidative sorption of ^{205}Tl onto the Mn oxide hexagonal birnesite is one of the primary mechanisms causing Tl isotope variation in the ocean and sediments (Peacock and Moon 2012; Nielsen et al. 2013).

Thallium isotopes have thus far mainly been applied to investigate past and present marine environments where Tl isotopes may be utilized as a monitor of the Mn supply rate or Mn oxide deposition rate over million year time scales (Rehkämper et al. 2004; Baker et al. 2009; Nielsen et al. 2009). Thallium isotopes can also be used to calculate the magnitude of hydrothermal fluid circulation through ocean crust. Such calculations can be performed both for high and low temperature fluids (Nielsen et al. 2006c).

Lastly, it has been shown that marine ferromanganese sediments can be detected in mantle-derived basalts (Nielsen et al. 2006b), which confirms that marine sediments subducted at convergent plate margins can be recycled to the surface via mantle plumes (e.g., Hofmann and White 1982).

Thermal Ionization Mass Spectrometry

John C. Lassiter
Department of Geological Sciences, Jackson School of Geosciences, University of Texas at Austin, Austin, TX, USA

Definition

Thermal ionization mass spectrometers are used for high-precision measurement of isotope ratios. Ions are produced by heating the element of interest under vacuum, focused and accelerated by applying an electrostatic potential, and then sorted by momentum (mass) using an electromagnet.

Introduction

Thermal ionization mass spectrometry (TIMS) is one of the primary methods available for high-precision isotope analysis and is used for many applications in the geological sciences and nuclear industry. A thermal ionization mass spectrometer consists of four main components: an ion source, a series of electrically charged plates used to focus and accelerate ions generated from the source, an electromagnet surrounding a "flight tube" through which the accelerated ions travel, and a detector system for measuring the intensity of ion beams after they have passed through the magnetic field.

Ion Source and Mass Analyzer

The ion source consists of one or more metal filaments. The element to be analyzed is loaded onto a filament that is heated under high vacuum by passing an electric current through the filament. The element must first be chemically purified, most commonly by ion exchange chromatography, in order to avoid potential interferences (e.g., a mass spectrometer cannot distinguish ^{87}Rb and ^{87}Sr ions because they have nearly identical mass). Typically, high-purity metals with high work functions such as tungsten, tantalum, or platinum are used for

the filament material. Heating of the filament causes the element loaded onto the filament to desorb or volatilize, and a portion of the desorbed atoms are ionized, as described by the Saha-Langmuir equation (Dresser 1968). Elements with low first ionization potentials are most susceptible to thermal ionization, producing +1 ions (e.g., Rb, Sr). However, some elements with high ionization potentials (e.g., Hf) are not easily ionized in this manner, and other elements (e.g., Os) are best measured as negative rather positive ions (as OsO_3^-).

Ions are then focused into a collimated beam and accelerated by applying controlled voltages to a series of horizontally and vertically aligned plates that contain slits through which the ions pass. The total electric potential gradient typically used is 8–10,000 V for acceleration of positive ions. Because ions desorbed from the filament possess much lower thermal energies and a narrow energy spread, ions accelerated in this manner exit the source lens array in a tightly focused beam, all having nearly identical kinetic energies. However, because the kinetic energy of an ion is described by the equation:

$$KE = \frac{1}{2}mv^2 \tag{1}$$

but the momentum of a particle is defined as:

$$M = mv \tag{2}$$

where m is the mass and v is the velocity, this acceleration results in two ions with the same charge but different mass exiting the source lens having different velocities and therefore different momenta. An ion's kinetic energy after being accelerated by the imposed electric potential is given as:

$$KE = Vq \tag{3}$$

where V is the applied accelerating voltage and q is the ion charge. After exiting the electrostatic lens, the ions pass though a magnetic field whose strength is controlled by varying the current applied to an electromagnet. The electromagnet is oriented such that the magnetic field lines are perpendicular to the path of the charged ions. Interaction with the magnetic field causes the ion paths to curve, with the radius of curvature controlled by the momentum of the charged particles, because the force exerted by the magnetic field is balanced by the centripetal force. Thus:

$$F_{\text{mag}} = qvB \tag{4}$$

where q is ion charge, v is the particle velocity, and B is the magnetic force vector. This is exactly balanced by:

$$F_{\text{cent}} = \frac{mv^2}{r} \tag{5}$$

where m is particle mass, v is again velocity, and r is the radius of curvature of the particle path. Combining the above equations, we find:

$$r = \frac{\sqrt{2mV/q}}{B} \tag{6}$$

Thus, all ions with the same charge/mass ratio follow the same curved path. Different isotopes of the same element have the same charge but different mass and therefore follow distinct, diverging paths. Ions with greater mass and therefore greater momentum follow circular paths with larger radii than lower-mass particles, and upon exiting the magnetic field, these different ions will travel along diverging paths to the detector assembly. The curvature of the ion paths can be adjusted by increasing or decreasing the strength of the applied magnetic field.

Detectors

Finally, one or more detectors are positioned at the back of the instrument to collect the different ion beams. Several detectors may be used, each positioned to collect the ions associated with each of the momentum-sorted ion beams. Alternatively, a single collector is used, with the magnetic field varied over time to sequentially position each ion beam of interest into the detector. To first order, the isotopic composition of the sample being analyzed is equal to the relative intensities of the ion beams associated with the different isotopic masses.

Several different types of detectors are commonly used to measure the intensity of the ion beams generated in a TIMS analysis. The most common type of detector is a Faraday detector. Ions enter a "cup" commonly composed of machined graphite or graphite-coated ceramic. The ions impart a small charge to the cup, which is then dissipated by applying a current equal to the number of ions impacting the cup per unit time. Thus, a 10^{-11} A current would correspond to an ion beam of equal intensity. For a beam of ions with a +1 charge, this corresponds to ~62 million ions entering the detector cup per second. Measurement of such small currents is achieved by use of high-resistance amplifiers, which convert the current into a voltage difference. Commercially available resistors used in modern mass spectrometers have resistances ranging from 10^{10} to 10^{12} Ω, and 10^{13} Ω resistors are in development (Koornneef et al. 2014). Higher resistance produces greater magnification of the signal to be measured and generally improves signal/noise ratio. However, amplifiers with very high resistance have a number of potential drawbacks, including a limited signal range where they have linear response and slower response time. Therefore, the most suitable type of amplifier to be used varies with application.

For ion beams greater than a few million ions per second, Faraday collectors provide excellent linearity and stability

and are the detector of choice for high-precision (<0.01%) isotopic measurements. However, measurement of small signals using high-resistance amplifiers is compromised by amplifier Johnson-Nyquist noise, the spurious voltage recorded by an amplifier in the absence of any real applied current due to the random thermal motion of electrons within the amplifier itself (Nyquist 1928). This noise is unavoidable and the signal/noise ratio places a limit on measurement precision at low beam intensities. Other methods of measuring small ion beams include electron multipliers and Daley detectors. These detectors work by converting ion collisions with the detector into either an electron cascade or light pulses that are then measured. Electron multipliers and Daley detectors are very effective at low-noise measurement of very small ion beams. However, they are in general less linear and less stable than Faraday collectors and have a more limited dynamic range. In addition, all measurements include uncertainty associated with counting statistics, so that the maximum possible precision of an isotopic measurement is to first order roughly equal to $1/N^{0.5}$, where N is the number of ions measured of the least-abundant isotope.

Mass Fractionation

Instrumental mass fractionation during measurement is also significant and varies systematically over time, and so must be corrected for in order to generate precise measurements. Mass fractionation occurs because lighter isotopes preferentially desorb from the filament relative to heavier isotopes. At the same time, because the sample loaded onto a filament represents a finite reservoir, the isotopic composition of this reservoir, and therefore of the desorbed species, typically becomes progressively heavier as an analysis proceeds. This Raleigh-Taylor fractionation can be corrected for by normalizing the measured isotopic ratio of two non-radiogenic isotopes to a fixed "natural" value and then applying this same correction to the ratios of other isotopes. For example, in Sr-isotope measurements, the isotopic ratio of interest is usually $^{87}Sr/^{86}Sr$, because the isotope ^{87}Sr is generated by the radioactive decay of ^{87}Rb. To correct for mass fractionation, the $^{86}Sr/^{88}Sr$ ratio is also measured and corrected to a fixed, accepted value using one of several mass fractionation laws (e.g., Wasserburg et al. 1981), and the derived correction factor is then applied to the measured $^{87}Sr/^{86}Sr$ as well to derive a value that is corrected for mass fractionation. Some elements do not have a pair of non-radiogenic stable isotopes that can be used for internal normalization (e.g., Pb-isotopes), and for some applications, it is the natural variation in stable isotope ratios that is the signal of interest (e.g., Ca-isotopes). In these cases, mass fractionation correction can in principle be achieved either through standard-sample bracketing or by adding an isotopically enriched spike to the sample. However, these methods are labor-intensive and can limit final analytical precision. For many such applications and for elements with higher first ionization potentials (e.g., Hf), isotopic measurement via MC-ICP-MS may be preferable.

Summary

Thermal ionization mass spectrometry is a highly precise method of measuring the isotopic compositions of target elements, with wide applications in geochemistry, cosmochemistry, and the nuclear industry. Although many elements previously analyzed by TIMS can also be analyzed via multi-collector inductively coupled plasma mass spectrometry quickly and precisely, TIMS is preferable for some applications, particularly where sample size is limited, due to better overall ion yield often capable by TIMS relative to other analytical methods.

Thermogravimetric analysis (TGA)

Definition

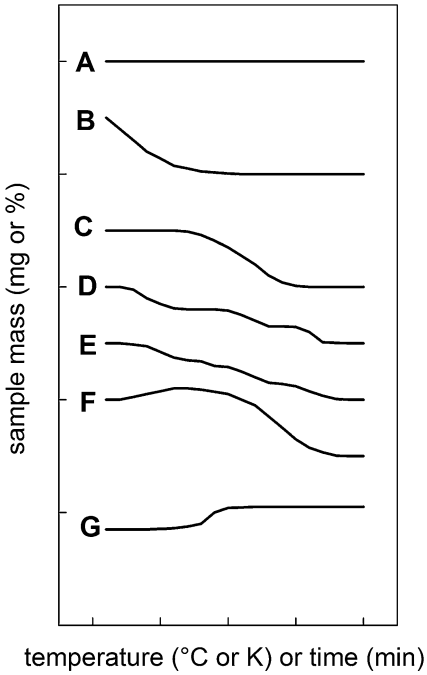
A technique in which the mass of a substance (and/or its reaction product(s)) is measured as a function of temperature, while the substance is subjected to a controlled temperature program (IUPAC 1997).

Background

Thermogravimetry (TG) is one of the mostly used methods of thermal analysis. Its principle is relatively simple. A crucible with a sample is placed onto the balance and subjected to a programmed temperature regime, during which sample mass is continuously monitored. The mass can stay either constant or it can change. Indeed, many thermally initiated processes accompanied by a change in sample mass can occur. A decrease can be caused due to sublimation and evaporation of volatile constituents, desorption of gasses, loss of crystalline water, oxidative degradation (if the experiment is conducted in air or oxygen), thermal decomposition (if the experiment is conducted in inert atmosphere), and reaction in which a gaseous product is evolved (e.g., decarboxylation). An increase in sample mass can be caused by an adsorption of gases, oxidation of metals, and pre-oxidation of some organic materials or heterogeneous materials in which a reactant is part of used atmosphere.

The result of TG measurement is a TG curve, which is a dependence of sample mass on either temperature or time. Figure 1 summarizes the most frequent TG curves obtained under either isothermal (time scale) or non-isothermal (temperature scale) conditions: A, sample is stable over used temperature interval; B, desorption or drying; C, single-step process (decomposition, evaporation); D, multistep processes (i.e., decomposition); E, the same as D, but sample was heated too fast; F, reaction with atmosphere (e.g., pre-oxidation) followed by decomposition; and G, reaction with atmosphere, but with a stable product.

To separate the overlapping processes (e.g., curve E), it is beneficial to express the TG records as derivative (DTG) or second derivative (DDTG) records. The thermobalances (as are TG instruments called) are often equipped so that they can also record simultaneously other signals such as differential scanning calorimetry (DSC) or differential thermal analysis (DTA). The combination of TG with these techniques allows observing also the thermal effects that are not connected with mass loss, and for this reason, it is beneficial for understanding the transitions (e.g., melting) that sample undergoes before or during changing its mass. The magnetic susceptibility of samples can be measured by thermomagnetometry, which is a hybrid TG technique based on the change of the attraction between a sample and superimposed magnetic field. TG can also be hyphenated with other



Thermogravimetry, Fig. 1 Most typical pattern of thermogravimetry curves

instruments such as Fourier transform Infrared spectroscopy (FTIR), mass spectrometry (MS), gas chromatography mass spectrometry (GSMS), or ultrahigh-resolution Fourier transform ion cyclotron resonance mass spectrometer (UHR FTICR MS) in order to analyze the composition of gases evolved during sample heating (evolved gas analysis (EGA)). This coupling is beneficial for compositional and stability analyses of complex materials.

Methodology

The TG experiments serve mostly for quantitative analysis. To a lesser extent, TG is also used for qualitative analyses or for the determination of kinetic parameters of studied processes. The purpose of the experiment is decisive for the designing of experimental conditions, and also the resulting TG curves reflect chosen experimental conditions. The most important parameters in TG analysis are heating program, type of dynamic atmosphere and pressure.

Typically, the temperature program involves linear heating and cooling ramps or periods of isothermal segments. The heating and cooling ramp rates are mostly used within the range of 1–50 °C min^{-1}, though the commercially available devices allow large spam (linear heating from 0.1 °C min^{-1} to at least 500 °C min^{-1} and ballistic heating > 2000 °C min^{-1}). Nevertheless, one should always be aware that very slow ramps require longer time for analysis, and very fast ramps cause a deviation between programmed and real temperature

of sample. The latter is caused by thermal resistance that is low for metals and high for organic and some mineral samples. In addition, fast ramps decrease the resolution of TG curve (curve E in Fig. 1), thus several processes can overlap in one "broad" process. This is undesirable for quantitative analysis that is based on an exact definition of onset and endset temperatures of investigated process. For this reason, the controlled rate thermal analysis (CRTA) known also as high-resolution TG was developed. In the CRTA method, the ramp rate is continuously adjusted (using a mathematic function) according to the instantaneous sample mass change.

A second important parameter influencing the TG curve is the type of purge gas that controls the sample environment. The flow of nitrogen, helium, or argon is used as an inert atmosphere and either air or oxygen as an oxidative atmosphere. In special cases, experimental conditions may require specific atmosphere of carbon dioxide, ammonia, or air enriched by water vapors. Conducting of experiments in air or oxygen leads to thermo-oxidative degradation, while choosing inert gases prevents samples against oxidation, and (organic) samples can be transformed by pyrolysis. If the gas produced during sample's heating is the same as purging gas, the flow rate influences the equilibrium of the investigated process, especially if the process is reversible.

Third, the TG curve is also influenced by the pressure around the sample. Usually, the pressure in a thermobalance is constant, and its influence is neglected. However, gases are frequently evolved during TG experiments, and pressure can significantly influence their dynamics. Specialized instruments allow to modulate pressure from vacuum to overpressure, because pressure-controlled TG is beneficial to study sorption/desorption processes or gasification. In addition, also the shape of sample holder (a crucible) influences the solid-gas interfaces. Therefore, it is desirable to choose such a type of holder that allows the reactive gas to diffuse into the solid material and at the same time enables the evolved gas to escape. This can also be improved by reducing the packing of material in crucible and increasing the solid-gas interface. Frequently, the interface is increased by sample grinding. However, this should be done with care because due to friction, grinding can significantly increase the temperature and change the investigated material. Last but not the least, change in density of used gases with temperature causes buoyancy affecting the balance signal. The correction of buoyancy is either a part of calibration or it is recommended to conduct a correction run under the same conditions with empty crucibles and subtract it from the measurement.

The derivative TG curve, indicating mass changes in temperature intervals, serves directly for quantitative analysis of sample's components or conversion of studied processes. The determination of kinetics of those processes can be conducted either under non-isothermal or isothermal conditions. Under non-isothermal conditions are measured mass losses in dependency on time employing several heating rates. Under isothermal conditions the masses are measured in dependency on time at several temperatures. The kinetic analysis is usually carried out to obtain activation energy, pre-exponential factor and reaction model. This kinetic triplet allows the prediction of stability of investigated material. As a rule, the degradation processes are complex; therefore, the so-called model-free methods have been introduced to facilitate the process analysis and modeling (Vyazovkin et al. 2011).

TG could be also used for qualitative analysis, but it requires strictly reproducible conditions of analysis. Obtained temperature and shape of the TG curve serve as a fingerprint. The most typical qualitative analyses are decomposition, evaporation, and sublimation or identification of metals according to the change in their magnetic properties.

Instrumentation

The instrument used in TG is a thermobalance. Currently, three main balance/furnace designs are used. First system is a vertical overhead thermobalance system with top loading. An extended version of this system is a parallel guide differential top pan balance mechanism, which enables simultaneous measurement of temperature and mass changes between an inert reference and sample. Second arrangement is also vertical, but with a sample holder hanging on a thin hangdown wire into the furnace below the balance. A reference pan may be placed on another balance in a separate chamber. Third system is a horizontal arrangement of balance, in which balance arms with thermocouples on pan carriers hold the sample and reference.

Most of the TG measurements start at room temperature, although some instruments allow to measure mass changes also at subambient temperatures (from ~ −196 °C). The highest temperature of measurement is furnace and sample limited. Most of organic materials are degraded below 1000 °C; for inorganic materials the temperatures up to ~2500 °C can be used. The accuracy of sample mass determination in TG measurements depends on the type of analysis. Modern instruments have the sensitivity <0.1 μg, but for most analyses, it is recommended to use several to tens milligrams of sample. However, in specific cases, e.g., in trace analyses, when the mass loss is expected to be extremely small, sample mass can be even in grams (if the instrument enables it). Prior to running TG experiments, the instrument requires calibration of both temperature and balance under the same conditions as the experiment. To calibrate balance, inorganic salts with known stoichiometry of decomposition are used (e.g., calcium oxalate monohydrate, calcium carbonate etc.). When simultaneous DTA and DSC are available, they can be used for calibration of furnace temperature. If not, the most frequent way is to determine Curie temperature by measuring

the metallic standards (e.g., alumel, nickel, Perkalloy, iron) in magnetic field. The detailed information on thermogravimetry and other methods of thermal analysis can be found, e.g., in Brown (1988).

Applications in Geochemistry

TG is widely used for the analysis of geological materials, but only several examples will be mentioned here. TG provides large opportunities to analyze fossil fuels such as coals or oil shales. However, the interpretation of the obtained records is not straightforward due to the complexity of processes taking part during heating of organic materials. The analysis of coals and other fossil fuels under inert conditions results in mass loss steps that correspond to contents of moisture and volatile compounds. TG is also used to monitor coking and cracking process. Under oxidative conditions, the mass losses correspond to contents of moisture and combustible part, while the residual mass represents the ash content. The change in atmosphere from inert to oxidative in the course of analysis allows the determination of fixed carbon (Ottaway 1982; Kok 2008). Using hydrogen atmosphere, the iron pyrite in residual ash can be reduced into metallic iron and consequently quantitatively detected using thermomagnetometry (Gallagher 1997).

TG is also frequently used in soil science (Plante et al. 2009). Heating of soil to 200 °C causes mainly the loss of soil moisture. Soil organic matter decomposes in two or three steps. First, there is a decomposition (up to the 400 °C) of stable part consisting of fresh residues, followed by decay of a humified part together with organo-clay complexes (up to 550 °C). The mass loss above 550 °C is due to the decomposition of soil carbonates. The loss on ignition (LOI) between 105 °C and 550 °C corresponds to the total organic matter content mainly in organic soils. In mineral soils, LOI is enhanced by intercrystalline water, decay of hydroxy groups in sesquioxides, destruction of charcoal, and the decay of some carbonates. Similarly as for other organic substrates, the interpretation of TG records of soils is complex due to a large number of simultaneous chemical and physicochemical processes. An alternative approach is the extraction of mass losses from 10 °C intervals. For a wide range of mineral soils, these intervals can be used for the determination of total soil organic carbon and nitrogen and clay contents (Siewert 2004) or modeling of soil microbiological activity represented by CO_2 production (Kucerik and Siewert 2014).

Frequently, TG is used to study the composition of minerals, which are thermally active. Their activity is determined by the conditions of rock formation. For example, igneous rocks formed under high temperatures and are thermally inert and do not provide any mass change up to 1000–1500 °C. On the contrary, igneous mineral associations formed at lower temperatures and pressures, or those that were transformed under low temperatures, are less stable. As a result, for most of the rocks, only part of their minerals can be analyzed using TG. An important part of these minerals represent water. Mass loss in particular temperature intervals allows the classification of mineral water according to the binding mechanisms. The mineral water can be divided into weakly bound water fraction adsorbed on external surfaces, in open and closed internal spaces and strongly bond water mostly in cation hydrate sheets, crystal water, and structural water. TG is useful for the interpretation of stoichiometric ratios in many minerals including oxides, hydroxides, carbonates, chalcogenides, silicates, sulfates, etc. A large collection of the TG records of various minerals and some examples of atypical applications of TG in geoscience were summarized by Földvári (2011). Additional applications in geoscience can be found in ASTM collection edited by Earnest (1988).

Summary

TG is a simple but very robust and mature technique that requires expenditure of very little sample. The analysis is quick, low cost, and provides precise and reproducible data. The thermobalances and the consumables are relatively inexpensive, and the maintenance is easy. For this reason, the technique is affordable by most laboratories and useful for both routine analyses and research purposes.

National High Magnetic Field Laboratory and Department of Earth, Ocean and Atmospheric Sciences, Florida State University, Tallahassee, FL, USA

Element Data
Atomic Symbol: **Th**
Atomic Number: **90**
Atomic Weight: 232.038
Isotopes and Abundances: ^{232}Th, ~100%, ^{230}Th, ^{234}Th, ^{228}Th, ^{227}Th
1 Atm Melting Point: 1750 °C
1 Atm Boiling Point: 4790 °C
Common Valences: 4+
Ionic Radii: 6-fold, 108 pm; 4-fold, 112 pm
Pauling Electronegativity: 1.3
First Ionization Energy: 724 kJ/mol
Chondritic (CI) Abundance: 29.4 ppb
Silicate Earth Abundance: 79.5 ppb
Crustal Abundance: 5.6 ppm
Seawater Abundance: 0.12 ppt
Core Abundance: ~0

Properties

Thorium, Th, with an atomic number of 90, has an atomic weight of 232.038. Its melting point is 2023 K and its boiling point is in excess of 5000 K. The density of the pure metal form is 11.72 g/cm^3. Thorium is a white silvery metal that is stable at surface conditions but over months' time will oxidize and at the surface will turn gray and subsequently black. The metal is very ductile and can be rolled. Its properties are governed by its purity with the most common contaminant its oxide, which makes the material more brittle. Thorium's crystal structure changes from a cubic to a body-centered cubic structure at 1673 K.

History and Use

Berzelius first identified thorium in 1828 in the mineral thorite discovered by Esmark on the island of Lauvöya, northern Norway. The name thorium is derived from the Scandinavian god of war, Thor. Powdered Th is pyrophoric and burns brilliantly white in air. Mantles of portable gas lights take advantage of this property and are the main use of Th. Its further uses are for manufacturing of alloys (with Mg), high-quality lenses, and coating of filaments (W) for electronic tubes. ^{232}Th has further use as a nuclear fuel for the production of fissionable ^{233}U by neutron capture and followed by two electron emissions.

Isotopes and Applications

Th has five naturally occurring isotopes of which ^{232}Th has the longest half-life (14.01 Gyr; see Table 1) and is the only primordial isotope of Th that has survived on Earth. Th with U and K is the Earth's main heat-producing element. The other isotopes are part of the uranium decay series. The longest lived of these is ^{230}Th and the ^{230}Th/^{232}Th in the Earth is $\sim 5 \times 10^{-6}$; the natural abundances of the remaining isotopes are negligible. Th isotopes are used to investigate processes in which it is significantly fractionated from its parent. In aquatic systems Th isotopes are an important tool in sediment dating and determining particle fluxes in the oceans (Henderson and Anderson 2003). The ingrowth of ^{230}Th in marine corals has allowed for precise dating and calibration of the ^{14}C timescale (Bard et al. 1990). The high U/Th ratio of seawater is reflected by the coral which contains very low levels of common Th.

Thorium, Table 1 Half-lives of Th isotopes and their use in geosciences

Isotope	Half-life	Decay	Parent	Application
^{234}Th	24.1 days	β	^{238}U	Elemental scavenging, particle/carbon fluxes in the oceans, particle mixing
^{232}Th	14.01 Gyr	β	na	Trace element, Pb isotope
^{230}Th	75,584 (±110) year[1]	β	^{234}U	Elemental scavenging, sediment dating, coral growth dating, magma chamber dynamics, melt transport
^{228}Th	1.912 (±0.002) year	β	^{228}Ac	Particle/carbon flux in the oceans
^{227}Th	18.72 days	β	^{227}Ac	Particle/carbon flux in the oceans

[1]Cheng et al. (2013)

Th isotopes are also utilized for dating of volcanic rocks and mineral residence times in magmatic systems. More details are in the U series entry.

Chemistry

Thorium is an actinide element with an electronic structure (Rn)$6d^2 7s^2$. The outer electronic structure and bond characteristics resemble those of Zr and Hf which contribute to similarities in their chemical properties. Thorium is electropositive, has only one oxidation state, and in solution is tetravalent. However, the ionic radius of Th results in a quite different behavior as a trace metal in solids than Zr or Hf. The Th metal can be dissolved easily in concentrated hydrochloric acid or in aqua regia. Th(IV) easily complexed with anions in solution, and fluoride, oxalate, iodate, and phosphate salts with Th have very low solubility products making Th insoluble even under acidic solutions. This property of Th was used early on for quantitative separation and gravimetric determination from a large range of samples.

Ores and Distribution in Rocks

Thorium is a trace element in all rocks with concentrations ranging from sub-ppb to ppm levels. The tetravalent thorium ion has a high charge over radius which strongly limits its substitution for major ions and makes it a member of the high-field strength elements. Therefore, Th does not partition into most rock-forming minerals and concentrates in the melt during most melting and crystallization events. Typical partition coefficients for mineral phases during melting and crystallization are less than 10^{-3} (GERM database, https://earthref.org/GERM/).

Because of its incompatible behavior, high concentrations of Th are found in rocks that represent a small melt fraction either due to the low degree of melting or the high degree of fractional crystallization, granitic rocks and pegmatites, and differentiated alkaline magmas and epigenetic veins associated with alkaline magmas. Carbonatites can have as high as 200 ppm Th (Bizimis et al. 2003). Monazite (REE, Th)PO_4 is the most commonly occurring Th-bearing mineral and contains about 10 wt% of Th. These high concentrations of Th combined with low Pb concentrations allow the determination of monazite ages by electron or ion microprobe. Monazite is a heavy mineral (density of 4.7–5.6 g/cm^3) and can concentrate in placer deposits that can be easily mined. Such placer deposits occur among others in coastal India and Brazil and the Carolinas and north Florida coast in the USA (Van Gosen et al. 2009).

High-Temperature Geochemistry

The insolubility of Th in fluid caries through to high temperatures and metamorphic fluids also have low Th content compared to elements with similar partitioning coefficients in anhydrous mantle melt systems. The ratio of fluid-mobile elements, like Ba or La, and fluid-immobile elements, like Th or Nb, can be used in subduction environments to constrain slab contributions from fluids and melts. Ba, Th, and U behave very similar as highly incompatible elements during melting, but Ba/Th and U/Th are fractionated during fluid extraction. Fluid contributions in variably depleted mantle source composition can be assessed through La/Th versus La/Sm ratios whereby La/Sm indicates source enrichment and La/Th is an indicator for fluid addition (Plank 2005). Island arc volcanics have significant ^{230}Th deficiencies (U excesses). These disequilibria are the result of fluid addition to source of the volcanics. *More details are in the uranium decay series entry.*

Although the behavior of U and Th is similar during most magmatic processes, these elements do fractionate with Th, in general, being more incompatible. Magmatic processes lead to disequilibrium between ^{238}U and ^{230}Th. The half-life of ^{230}Th allows investigation of timescales up to 500 ka. During melting, especially mantle melting under dry conditions, Th is slightly more incompatible than U and consequently the melt will carry ^{230}Th excesses. Under mantle conditions garnet is better able to fractionate Th from U. Significant ^{230}Th excesses observed in zero-age mid-ocean ridge basalts require that melting starts in the garnet stability field. This requires that melting starts at a depth where garnet is stable and strongly constrains melting rate and melt transfer rates. In most models melting is fractional or dynamic, and the parameters that are varied are mantle and melt ascent velocity and residual porosity (McKenzie 1985). *More details are in the uranium decay series entry.*

Low-Temperature Geochemistry

At the Earth's surface, tetravalent Th has very low solubility and is particle reactive. Therefore Th concentrations in natural waters are very low. During weathering Th, which resides mostly in resistant accessory minerals, stays either in the regolith or is transported in the particulate fraction or colloidal fraction (Chabaux et al. 2003). If transported in the aqueous phase, Th complexes very strongly with humic acid (Stern et al. 2014). The retention of Th in soils can be used to date soil-forming processes by measuring ^{230}Th-^{238}U disequilibria, but studies have shown that these processes are more complex that simple U-leaching or precipitation while Th is immobile (Chabaux et al. 2003).

Biological Utilization and Toxicity

Thorium is not used by living organisms as micronutrient and there is no selective uptake in organisms. Th toxicity stems from its radioactivity only. For example, there is no drinking water maximum contaminant level for Th.

Summary

Th is incorporated in few minerals and behaves like an incompatible element during melting and crystallization. In aquatic systems Th is particle reactive and dissolved concentrations are extremely low. Its radioactivity makes it useful for age dating a variety of processes.

Thulium

Scott M. McLennan
Department of Geosciences, Stony Brook University, Stony Brook, NY, USA

Element Data
Atomic Symbol: Tm
Atomic Number: 69
Atomic Weight: 168.93422(2)
Isotopes and Abundances: ^{169}Tm, 100%
1 Atm Melting Point: 1545 °C
1 Atm Boiling Point: 1950 °C
Common Valences: +3
Ionic Radii: 88.0 pm (CN6), 99.4 pm (CN8), and 120.7 pm (CN12)
Pauling Electronegativity: 1.25
First Ionization Energy: 596.695 kJ mol^{-1}
Chondritic (CI) Abundance: 0.0256 ppm
Silicate Earth Abundance: 0.057 ppm
Crustal Abundance: 0.32 ppm
Seawater Abundance: 0.169 ppt
Core Abundance: ~0

Properties

Thulium (Tm), named after *Thule*, the original name for Scandinavia, is a soft, malleable, dense (9.321 g cm^{-3}), bright silvery-gray metal. Its electronic configuration is $[Xe]4f^{13}6s^2$. It is stable at room temperature and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE).

In geochemical terminology, it is grouped with heavy rare earth elements (HREE; Gd-Lu). Thulium has one stable isotope.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Tm as a significant component are restricted to Y and HREE varieties, such as xenotime [$Y(PO_4)$], gadolinite-Y [$Y_2FeBe_2(Si_2O_{10})$], bastnäsite [$REE(CO_3)F$], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+},Fe^{3+})_3(SiO_4)_3(OH)$], and britholite [$(REE,Ca)_5(SiO_4,PO_4)_3(OH,F)$].

Details of properties, mineralogy, history, and uses of Tm were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner (2016), Hammond (2016), and Meija et al. (2016a, b).

History and Use

Thulium was discovered in 1879 by Per Theodor Cleve, who separated the oxide and named it *thulia*. Reasonably pure thulium metal was first isolated in 1911. Due to its very low crustal abundances, thulium is very expensive and accordingly has relatively few applications. Minor uses include as a component in radiation sources of portable, X-ray equipment, YAG lasers, and high-temperature superconductors.

Geochemical Behavior

The fundamental importance of Tm in geochemistry is that it is one of the small trivalent rare earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction."

Thulium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element, with a 50% $T_{condensation}$ of 1,659 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Tm is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Tm normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Tm contents of clastic sediments typically reflect their average provenance.

In seawater, Tm has very low concentrations (sub-ppt) and residence times (~2430 year) with speciation dominated by Tm^{3+}, $TmCO_3^+$, and $Tm(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Tm can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration and residence time data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Tm. REE (including Tm^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Tm) in human tissues and fluids are very low (~ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Tin

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Element Data
Atomic Symbol: **Sn**
Atomic Number: **50**
Atomic Weight: 118.81 g/mol
Isotopes and Abundances: ^{112}Sn 0.97%, ^{114} Sn 0.66%, ^{115}Sn 0.34%, ^{116}Sn 14.54%, ^{117}Sn 7.68%, ^{118}Sn 24.22%, ^{119}Sn 8.54%, ^{120}Sn 32.58%, ^{122}Sn 4.63%, ^{124}Sn 5.79% ($t_{1/2} > 10^{17}$years)
1 Atm Melting Point: 232 °C
1 Atm Boiling Point: 2875 °C
Common Valences: 4+, 2+
Ionic Radii: 4+: 69 pm, 2+: 118 pm
Pauling Electronegativity: 1.96
First Ionization Potential: 708.4 kJ/mol
Chondritic (CI) Abundance: 1.63 ppm
Silicate Earth Abundance: 0.14 ppm
Crustal Abundance: 1.7 ppm
Seawater Abundance: 0.1–0.2 ppb
Core Abundance: ~0.5 ppm

Properties

Because it has a "magic number" of protons (50), the tin nucleus is particularly stable and Sn has greatest number of stable isotopes (10) of any element. The common valence states of Sn in nature are +4 and +2. Pure Sn exists in two forms: β-tin or white tin, stable at and above room temperature, is a silvery white, malleable, low-melting point metal forming a body-centered tetragonal lattice, while α-tin, or gray tin, stable below 13 °C, forms a diamond cubic structure. Bonding is covalent in the latter, and hence it is brittle and lacks typical metallic properties. This transformation severely degrades tin objects and is known as "tin pest."

History and Use

Tin is one of the most anciently known metals whose discovery is lost to history. Its chemical symbol derives from the Latin name for the metal, *stannum*. Alloying of Cu with 10–15% Sn produces bronze, a much stronger metal than Cu. The development of bronze metallurgy and consequent replacement of stone tools and weapons with bronze ones marks the end of the Neolithic Period in many parts of the world. Since Sn and Cu rarely occur together in the same deposits, bronze metallurgy also spurred the development of extensive new trade networks. Although some older bronze objects are known, widespread bronze metallurgy began around 3200–3000 BCE in the Middle East, Europe, and India and around 2000 BCE in East Asia. Some bronze was also produced by South and Central American cultures after about 200 BCE, but was used for ornamental rather than utilitarian purposes.

Pliny the Younger mentioned the use of Sn in solder in 79 BCE and solder remains one of the primary uses of Sn. Tin-plated steel cans for food storage and beverage storage has been an important use since the early nineteenth century. Tin continues to be used as an alloying metal, most notably in bronze and pewter (>90% tin and lesser amounts of Cu and Sb). Nb_3Sn is used for superconducting magnets, and zirconium-tin alloy is used for cladding nuclear fuel cells. Because of its low-melting point, liquid tin is used to "float" glass as it solidifies. Stannous fluoride (SnF_2) is a common additive to toothpastes used to promote fluoridation of tooth enamel (Greenwood and Earnshaw 1984).

Cassiterite, SnO_2, is the most common Sn mineral and primary ore of Sn and occurs primarily in pegmatites and hydrothermal veins and stockworks associated with granitic intrusions. Tin ores include both these rocks and weathering products and placers derived from them. Tin-bearing complex sulfides containing other metals, such as stannite (Cu_2FeSnS_4), occur in some of these deposits. Britain, Cornwall in particular, was a primary supplier of Sn to Europe from preclassical to recent times. As of 2015, the principal producers were China, followed by Indonesia, Burma, Peru, Bolivia, and Brazil.

Geochemical Behavior

Tin is moderately volatile with a 50% nebular condensation temperature of 704 K (Lodders 2003). It is also moderately siderophile, and consequently much of the Earth's inventory is thought to reside in its core (McDonough 2014). Within the silicate Earth, Sn behaves as a moderately incompatible lithophile element, but understanding of its behavior is limited. Sn/Sm ratios are roughly constant at ~0.32 in the mantle and mantle-derived rocks, with concentrations ranging from ~1 ppm in MORB to as high as 20 ppm in some OIB (Jochum et al. 1993; Yi et al. 1995). The Sn/Sm ratio of the bulk continental crust appears to be slightly higher (0.44; Rudnick and Gao 2014). Sn is compatible in ilmenite (Klemme et al. 2006) as well as biotite in highly evolved granites and pegmatites (Tischendorf et al. 2001).

The valence state of tin depends on oxygen fugacity and the crossover between Sn^{2+} and Sn^{4+} dominance in magmas appears to occur at oxygen fugacities near the fayalite-magnetite-quartz (FMQ) buffer (Durasova et al. 1986). The standard electrode potential for reduction of Sn^{4+} to Sn^{2+} is 0.384 ± 0.02 V (Gajda et al. 2009), implying that the 4+ form (stannic) is predominant in systems in contact with the atmosphere. The solubility of cassiterite depends on the f_{O_2}: it is more soluble at low f_{O2} where the +2 (stannous) form dominates. It also depends on temperature and melt or fluid composition, including factors such as the ratio of aluminum to alkalis, H_2O, F, and Cl content (e.g., Bhalla et al. 2005).

Tin appears to be a highly immobile element during weathering and is consequently strongly enriched in highly weathered and flushed lateritic soils and bauxites (Kronberg et al. 1982; Romer and Kroner 2014) and very impoverished in seawater (Sun and Li 2015). Marine sediments have Sn contents approximately the same to those of upper continental crust, 2–4 ppm (Li and Schoonmaker 2014).

Tin is likely present in seawater as stannic hydroxide complexes (Bruland et al. 2014), but Sn^{2+} forms strong carbonate, chloride, fluoride, and sulfate complexes (Cigala et al. 2012). These may be important in hydrothermal solutions and development of Sn ores (Müller and Seward 2001).

Tin mineralization is associated with highly evolved granites concentrated in discontinuous "tin belts," which are often associated with continental margins but not necessarily with subduction-related magmatism (Romer and Kroner 2016), and Sn is apparently not enriched in subducting lithosphere-derived fluids (Noll et al. 1996). Extreme fractional crystallization under conditions of low f_{O_2} (enhancing the solubility of Sn in the melt) is an important precondition for tin mineralization (Lehmann 1982), but high concentrations in the magma source appear to be critical as well. Essentially all Sn-rich granites are the products of crustal anatexis or have assimilated large quantities of crustal material. Romer and Kroner (2016) argue that melting or assimilation of sediments derived from intensely weathered crustal precursors is an essential precondition for development of Sn mineralization (Romer and Kroner 2016).

Tin Isotopes

Relatively few studies have been carried out on isotopic variations of Sn in nature, most of these with the objective of distinguishing tin sources in ancient bronze and other artifacts. As yet, there is no consensus on which isotope ratios are measured or on standards. Moynier et al. (2009) demonstrated mass independent fractionation in the laboratory of Sn isotopes bearing the odd-even signature of the nuclear field shift effect, but mass independent fractionations have not yet been identified in nature. Haustein et al. (2010) analyzed Sn isotope ratios in cassiterites from Sn deposits in Germany and England and found a range in isotopic composition of 0.55‰/u, with deposits isotopically homogeneous. Yamazaki et al. (2013) found a range of isotopic composition of 0.19‰/u in Asian Sn deposits. While these variations are archeologically useful, Yamazki et al. concluded that "the cause of Sn isotopic variation is yet to be established." Because Sn consists of nuclides formed in s-, r-, and p-process nucleosynthesis, isotopic variations in meteorites are expected, but studies with sufficient precision to identify them have not yet been carried out (Yokoyama and Walker 2016).

Biological Utilization and Toxicity

Tin has no known biological use. In its inorganic form, it is nontoxic, as its widespread use in food containers and toothpaste attests. Some organic tin compounds, however, are toxic. Tributyl-tin was used for a time in paints for the hulls of ships as an antifouling agent, but it proved to be an environmental toxin and is no longer used (Emsley 2001).

Summary

Tin metallurgy played a key role in the development of civilization, and Sn remains widely used today. Much of the Earth's tin is sequestered in the core, and it behaves as a moderately incompatible and highly immobile element with the highest concentrations occurring in highly evolved granites and associated hydrothermal veins. Its geochemical behavior nonetheless remains poorly understood.

Seawater Abundance: 6–250 pmol/kg
Core Abundance: ~0

Properties

Titanium is the second element in the first transition series and is a silver, lightweight metal in pure form. It has a density of 4.506 g/cm^3 at standard conditions. In nature, Ti behaves as a refractory lithophile element.

History and Use

Titanium oxide was first discovered in 1791 by mineralogist and chemist Reverend William Gregor while studying minerals in Cornwall, England (Russell 1955). In his modest laboratory in the town of Creed, Gregor analyzed the mineral ilmenite (now known to be $FeTiO_3$) collected from a stream at

Tregonwell Mill in the nearby village of Manaccan. Gregor determined that the ilmenite contained iron and the oxide of a new metallic substance he proposed be named menaccanite (originally called menachanite, menacanite, or menakanite). Later in 1791 Franz Joseph Muller also produced an unidentified substance from ilmenite. In 1795 chemist M. H. Klaproth concluded that the mineral rutile (TiO_2) contained a new element he proposed be called titankalk or titanium in reference to the strong giants of Greek mythology.

Rutile-, ilmenite-, and apatite-rich rocks called nelsonites associated with anorthosites in Nelson County, Virginia, were the primary source of Ti worldwide through the 1940s (Watson 1915; Herz et al. 1970). Anorthosite-related rocks continue to be valuable sources of Ti (Woodruff et al. 2013). The most economically important Ti resources are heavy mineral sands in which rutile, ilmenite, and leucoxene are concentrated along with other heavy minerals in alluvial, marine, and eolian placer deposits (e.g., Philander and Rozendaal 2015). Approximately 95% of Ti ore is refined to produce white-colored TiO_2 pigment, and the remainder is used to produce Ti metal (Bedinger 2015).

Titanium metal was first purified from TiO_2 by chemist M. A. Hunter at Rensselaer Polytechnic Institute (Troy, NY) in 1910 by reacting $TiCl_4$ with sodium metal in a high temperature "bomb"-type pressure vessel using a method now known as the Hunter process (Hunter 1910). In 1937 V. W. Kroll developed a similar process (Kroll 1937) in which rutile and ilmenite mineral concentrates were reacted to form metal chlorides (e.g., $TiCl_4$, $FeCl_2$) followed by reduction with magnesium metal to form $MgCl_2$ and Ti metal. The Kroll process is currently the most widely used method to produce Ti metal. Titanium metal is widely used for aerospace and nautical applications because it has a high strength to weight ratio and resists corrosion. Prosthetic implants are commonly fabricated from Ti metal because it is biocompatible and strong.

Geochemistry

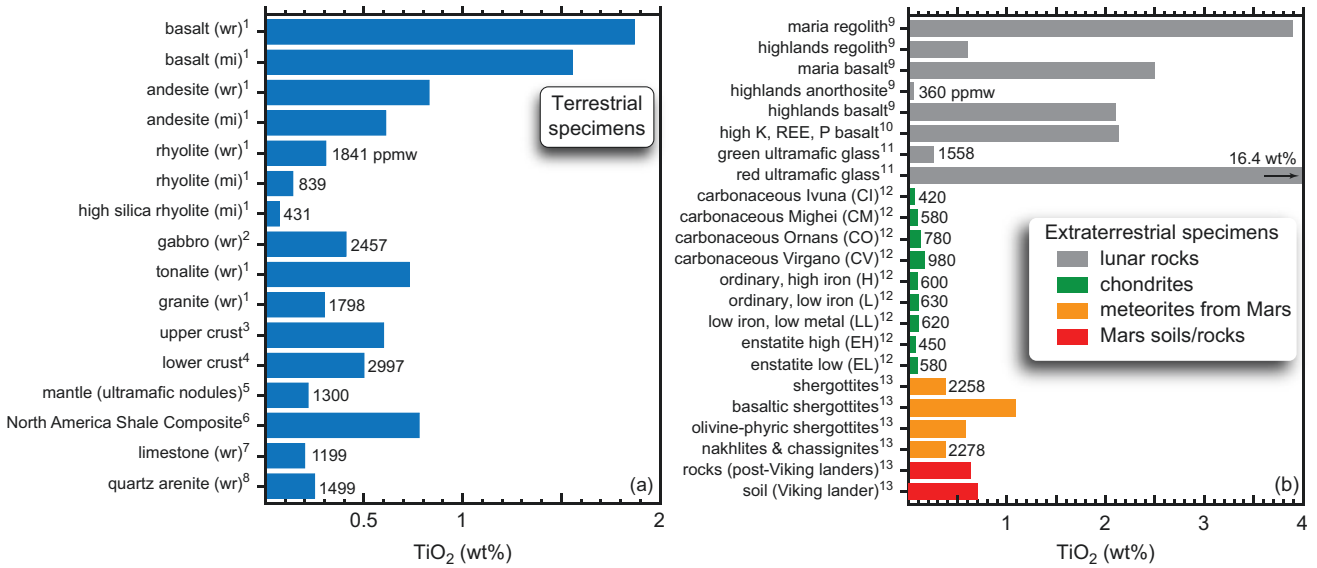
Titanium does not commonly occur as a native element (Chen et al. 2000); it is usually bonded to oxygen. The electronic properties and ionic radii of Ti (element data table) strongly influence the solubility of Ti in fluids, melts, and minerals. Titanium may occur as Ti^{3+} or Ti^{4+} in minerals and melts. The blue color of some Ti-bearing minerals has been attributed to incorporation of Ti^{3+} (Johnson and Weyl 1949; Ihinger and Stolper 1986). Trivalent Ti occurs in lunar and meteoritic minerals, but it is exceptionally rare in terrestrial systems. It was believed that very low oxygen partial pressures (i.e., oxygen fugacity; fO_2) are required to stabilize Ti^{3+} (Anderson et al. 1970; Papike 2005; Borisov 2012). It is conceivable that fO_2 values in extraterrestrial systems are sufficiently low to produce melts with Ti^{3+}/Ti^{4+} higher than in melts observed on Earth; however, measurements of natural lunar basaltic composition melts and experimental analogs formed at fO_2 characteristic of the Moon (i.e., fO_2 lower than the iron-wustite oxygen buffer) show that most Ti occurs as Ti^{4+} (Krawczynski et al. 2010; Borisov 2012). This observation is supported by recent experiments which showed that Ti^{3+}/Ti^{4+} in minerals may vary widely at a fixed fO_2 because crystal chemistry can stabilize oxidation states independent of fO_2 (Doyle et al. 2014).

The accessory minerals (<1% of the rock) rutile, ilmenite, and titanite ($CaTiSiO_5$) host the majority of Ti in most crustal rocks. There are also numerous less abundant minerals that contain Ti as an essential structural constituent (i.e., their chemical formula and crystal structure are defined in part by the presence of Ti; http://rruff.info/chem=Ti/display=default/). Beyond these, many common terrestrial minerals can contain Ti in major element concentrations, including spinels, garnets, pyroxenes, amphiboles, and micas (Deer et al. 2013). Meteorites and lunar specimens commonly have the minerals hibonite, armalcolite, and grossmanite that contain major element concentrations of Ti (Sheng et al. 1991; Ma and Rossman 2009; Doyle et al. 2014). Titanium is a cathodoluminescence activator in some silicate minerals (e.g., Leeman et al. 2012, and references therein).

A wide range of Ti concentrations are observed in terrestrial and extraterrestrial rocks (Fig. 1). In terrestrial rocks the highest Ti concentrations are in mafic rocks (e.g., basalts), intermediate composition rocks (e.g., andesite, tonalite) have intermediate Ti concentrations, and the lowest Ti concentrations are observed in evolved felsic rocks (e.g., high-SiO_2 rhyolites). Sedimentary rocks contain Ti concentrations similar to intermediate composition igneous rocks (Fig. 1a).

Most extraterrestrial specimens contain Ti concentrations similar to rocks on Earth (Fig. 1b). One exception is the lunar high-Ti ultramafic glasses collected during the Apollo Moon landings (Delano 1986). The glasses are among the most unusual composition igneous materials observed in the solar system. The high-Ti ultramafic glasses have colors that range from green to yellow to orange to red and corresponding TiO_2 concentrations that range from 0.26 to 16.4 wt% TiO_2. Chondrites have lower Ti concentrations than most rocks from the Earth, Moon, and Mars (Fig. 1b).

Large Ti isotopic variations observed in solar system materials (e.g., presolar grains, hibonite grains, calcium-aluminum inclusions, chondrules, etc.) are used in cosmochemistry to study origins of the solar system (e.g., see references in Zhang 2012; Steele and Boehnke 2015). Processes such as equilibrium partitioning between phases, diffusion, and evaporation/



Titanium, Fig. 1 Average Ti concentrations measured in (**a**) terrestrial and (**b**) extraterrestrial specimens. Notations in parentheses for terrestrial specimens are *wr* whole rock, *mi* melt inclusion. For specimens with <0.5 wt% TiO_2, the concentrations are listed in parts per million by weight (ppm). *1*, http://georoc.mpch-mainz.gwdg.de/georoc/; *2*, Natland and Dick (2002); *3*, Taylor et al. condensation produced mass-dependent isotopic fractionations during early solar system assembly. Nucleosynthetic processes, radioactive decay, and cosmic-ray-induced transmutations produced mass-independent fractionations of Ti isotopes. Early solar system solids formed in different parts of the proto-solar nebula at different times; thus, Ti isotopes can be used to study physical and chemical processes that accompanied early solar system formation. Distribution of ^{46}Ti and ^{50}Ti in early solar system solids has been used to evaluate the efficiency of mixing processes in stellar-derived gas and dust in the proto-solar system. Additionally, similarity of $^{50}Ti/^{47}Ti$ ratios of earth and lunar materials supports derivation of the Moon from the Earth by impactor processes (Zhang et al. 2012).

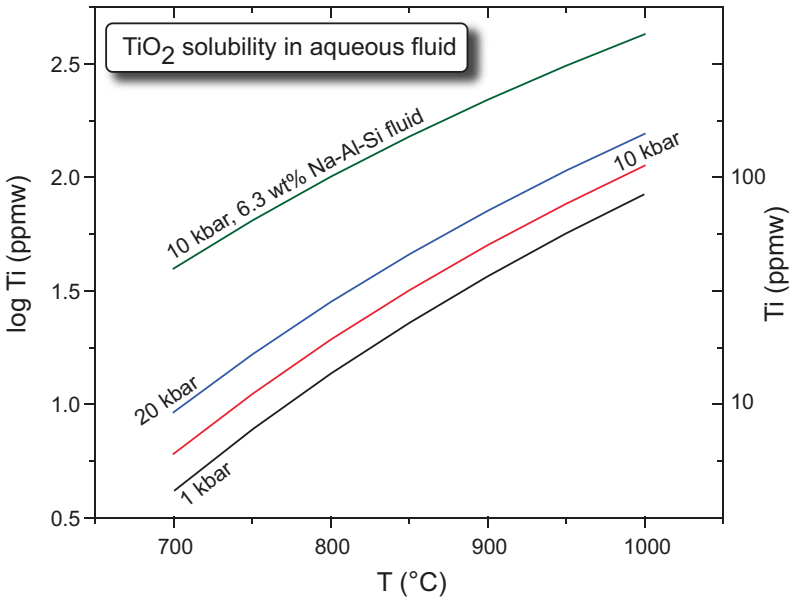
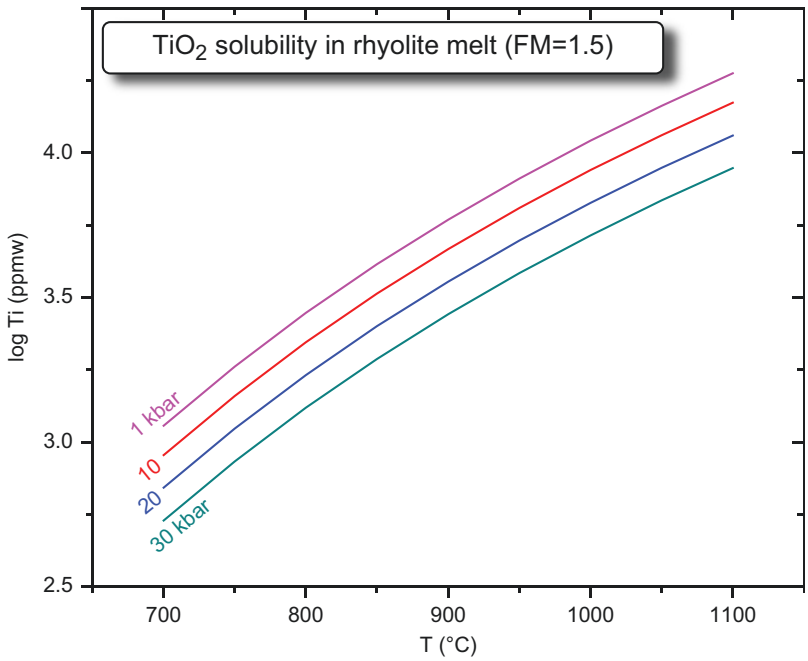
Titanium Solubility in Fluids, Melts, and Minerals

Pressure, temperature, and system composition strongly affect the solubility of Ti in aqueous fluids, melts, and minerals. Because rutile commonly coexists with a free fluid phase in the Earth, the solubility of TiO_2 in fluids is important to equilibrium and kinetic processes that control Ti uptake and transport in earth materials. Experimental studies of rutile solubility in aqueous fluids at crustal and upper mantle conditions show that rutile is sparingly soluble in pure H_2O (Fig. 2; Antignano and Manning 2008). Rutile solubility in pure H_2O increases with pressure and temperature. Addition of Na-Al components (e.g., albite) to the fluid substantially increases solubility of TiO_2 in the fluid (Fig. 2; Antignano and Manning 2008; Hayden and Manning 2011). At 10 kbar and 700 °C, approximately 6 ppm Ti dissolves into pure water, whereas ~40 ppm Ti dissolves into an aqueous solution containing 6.3 wt% Na-Al silicate.

The solubility of TiO_2 in silicate melts is strongly affected by pressure, temperature, and composition. TiO_2 solubility in melts can be used to calculate titania activity in rutile-free magmatic systems for application of thermobarometers that involve TiO_2 equilibria (Hayden and Watson 2007; Ghiorso and Gualda 2012). Additionally, the P–T–X dependencies of rutile solubility in melts can be used to determine the extent to which rutile in magmatic source regions controls high field strength element variations (e.g., Ti, Nb, Ta) in many igneous rocks. Rutile saturation in melts was investigated by crystallizing rutile from TiO_2-saturated melts ranging in composition from rhyolite to basalt in experiments conducted from 1 bar to 35 kbar and 1000 to 1300 °C (Ryerson and Watson 1987; Gaetani et al. 2008). Rutile solubility in silicate melts increases considerably with increasing temperature and decreasing pressure (Fig. 3). The Ryerson and Watson (1987) rutile saturation model predicts that 1138 ppm Ti will dissolve into rhyolitic composition melt at 1 kbar and 700 °C, and 8855 ppm Ti will dissolve into the melt at 1100 °C and 30 kbar. Recent studies showed that TiO_2 solubility increases markedly with increasing water content in the melt (Gaetani et al. 2008).



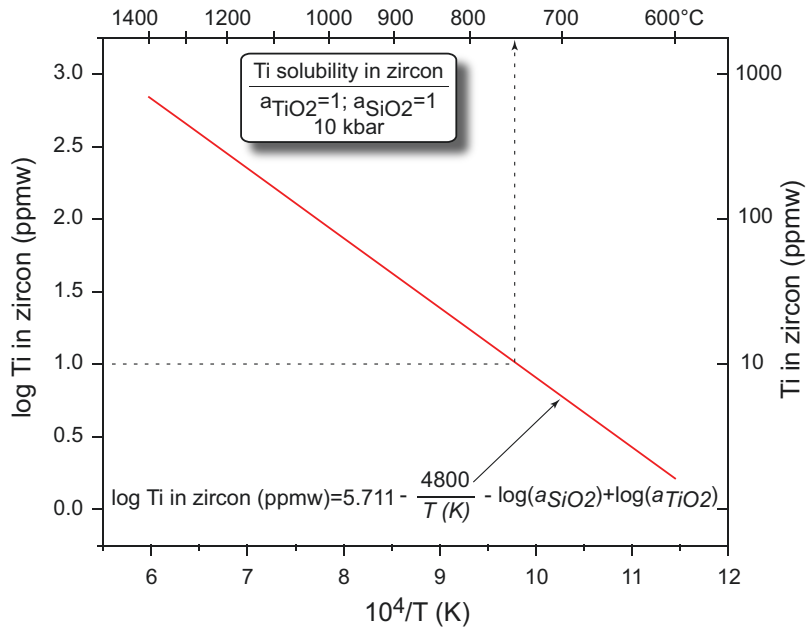
Titanium, Fig. 2 Rutile solubility in aqueous fluids (Antignano and Manning 2008). The lower three curves show the solubility of Ti in pure H_2O. The *upper red curve* shows the solubility of Ti in a fluid with 6.3 wt% silicate solution produced from dissolved albite ($NaAlSi_3O_8$) (Source: Jay Thomas)



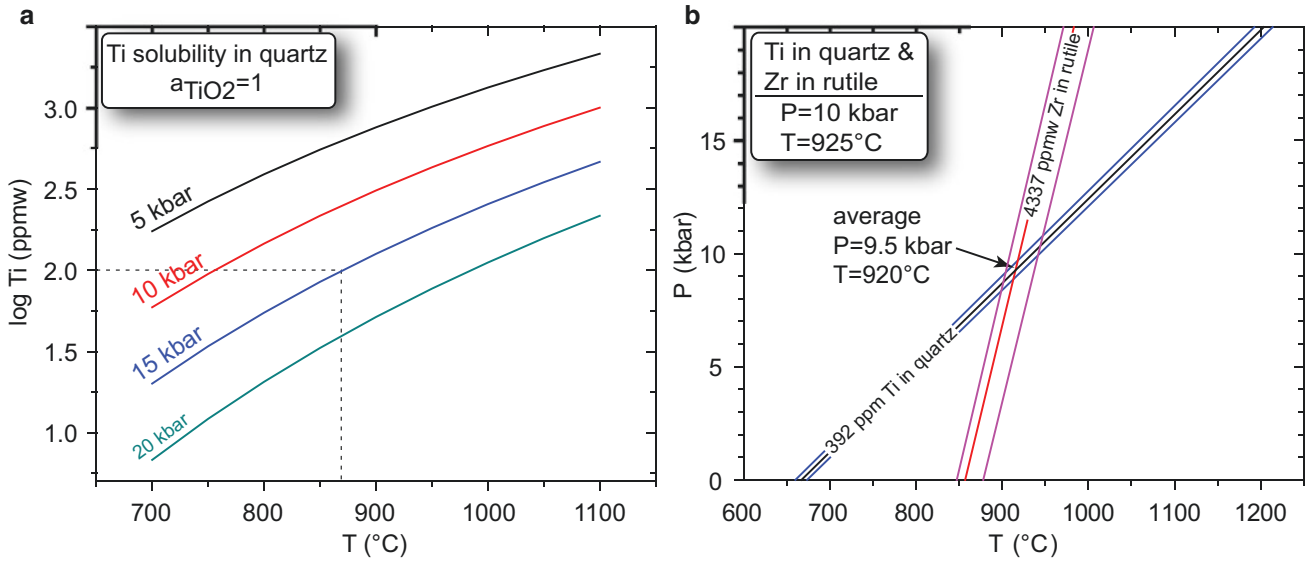
Titanium, Fig. 3 TiO_2 solubility in rhyolite composition melt (Ryerson and Watson 1987). FM is a compositional parameter (Source: Jay Thomas)

Using Ti in Zircon and Quartz to Determine Crystallization Pressure and Temperature

The minor to major element Ti content and the presence of near-pure rutile in many natural systems makes Ti an ideal candidate for thermodynamically based experimental calibrations to estimate crystallization temperature and/or pressure. Experimental studies in the ZrO_2-SiO_2-TiO_2 system showed that Ti solubility in zircon systematically increases with increasing temperature (Fig. 4; Watson et al. 2006; Ferry and Watson 2007). Zircon was co-crystallized along with rutile and quartz from SiO_2-, TiO_2-, and $ZrSiO_4$-saturated fluids and melts. The temperature dependence of Ti solubility in zircon was presented as a geothermometer "calibration" that can be used to estimate the temperature of zircon crystallization. For example, the Ti-in-zircon solubility model predicts that a zircon with 10 ppm Ti that grew in the presence of rutile and quartz crystallized at 746 °C (Fig. 4). Magma compositions that commonly crystallize zircon are not typically rutile saturated, which means that titania activity must be estimated for applications to most igneous systems (Hayden and Watson 2007; Ghiorso and Gualda 2012).



Titanium, Fig. 4 Calibration of the Ti-in-zircon thermometer (Watson et al. 2006; Ferry and Watson 2007). Activities of titania and silica in the system, $a_{TiO_2}^{\text{liquid}-\text{rutile}}$ and $a_{SiO_2}^{\text{liquid}-\text{quartz}}$, are referenced to rutile and quartz saturation, respectively (Source: Jay Thomas)



Titanium, Fig. 5 (**a**) Ti-in-quartz solubility model; isobars calculated from $\log \text{Ti in quartz (ppmw)} = -26530 + 50 \cdot T(\text{K}) - 760 \cdot P(\text{kbar}) + RT \log a_{TiO_2}^{\text{liquid}-\text{rutile}}/RT(\text{K})$, where R is the gas constant 8.3145 J/K, T is temperature in Kelvin, and $a_{TiO_2}^{\text{liquid}-\text{rutile}}$ is titania activity in the system referenced to rutile saturation (Thomas et al. 2010). (**b**) Application of the Ti-in-quartz solubility model to an experiment of Thomas et al. (2015). The average Ti-in-quartz isopleth calculated from the calibration of Thomas et al. (2010) and the average Zr-in-rutile isopleth calculated from the calibration of Tomkins et al. (2007) cross at 9.5 kbar and 920 °C, which is in excellent agreement with the P–T conditions of the crystallization experiment at 10 kbar and 925 °C (Source: Jay Thomas)

The pressure and temperature dependencies of Ti-in-quartz solubility have been quantified from experimental studies in the SiO_2-$TiO_2 \pm ZrO_2$ system (Thomas et al. 2015, and references therein). Titanium solubility in quartz systematically increases with increasing temperature and decreasing pressure (Fig. 5a). For example, the Ti-in-quartz solubility model predicts that quartz with 100 ppm Ti that grew at 15 kbar in the presence of rutile crystallized at 869 °C (Fig. 5a). The P–T dependencies of Ti-in-quartz solubility can be used as a thermobarometer when used in combination with another thermobarometer in a coexisting mineral, an independent P or T estimate of quartz crystallization, or well-constrained phase equilibria (Fig. 5b; Thomas et al. 2010; Thomas and Watson 2012; Thomas et al. 2015).

Biological Utilization and Toxicity

Titanium is not biologically utilized and is not toxic.

Summary

Terrestrial and extraterrestrial rocks have a wide range of Ti concentrations. The majority Ti in rocks is contained in accessory minerals rutile, ilmenite, and titanite. Heavy mineral sands are the most economically important Ti sources. Large variations of Ti isotopes are used in cosmochemistry to study processes that produced mass-dependent and mass-independent fractionations. In terrestrial systems there is a well-defined geochemical framework to use Ti-in-quartz and Ti-in-zircon solubilities and lattice diffusion parameters (Cherniak and Watson 2007; Cherniak et al. 2007) to develop petrogenetic models that include the pressure and temperature of crystallization (e.g., Wark et al. 2007; Thomas and Watson 2012; Breiter et al. 2014), temperature of deformation (Nachlas et al. 2014, and references therein), the time scales of thermobarometric events (Spear et al. 2012), and the provenance of quartz crystals (Ackerson et al. 2015).

Trace Elements

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Definition

A trace element is one present at very low abundance in a particular system such that it obeys Henry's Law in that system.

Which Elements Are Trace Elements?

The answer depends on the system of interest; a trace element in one system may be a major element in another. Oxygen, magnesium, silicon, iron, aluminum, calcium, nickel, and calcium make up ~99% of the Earth, so all other elements could be considered trace elements. Nevertheless, for example, potassium constitutes ~1.5% of the Earth's continental

crust, where it is considered a "major element." Manganese and phosphorus are also conventionally reported along with the major oxides in rocks, even though their concentrations rarely exceed a few tenths of a percent.

One possible definition of a trace element or trace component is that it does not significantly affect the chemical or physical properties of the system as a whole. Yet trace elements can determine the color of a mineral, CO_2 profoundly affects the atmosphere's transparency to infrared radiation, and consequently Earth's climate, even in concentrations of 100's of ppmv and hydrogen dramatically affects mantle viscosity even at concentrations below 100 ppm. So this definition is not satisfactory either.

This leads to what may be the best definition of a trace element: *an element whose activity obeys Henry's Law in the system of interest*. This implies sufficiently dilute concentrations that interactions between atoms of that element are sufficiently rare that its behavior is independent of its concentration.

Geochemical and Biochemical Importance of Trace Elements

Although trace elements constitute only a small fraction of a system of interest, they provide geochemical information out of proportion to their abundance. There are several reasons for this. First, variations in the concentrations of many trace elements are much larger than those of major components, often by many orders of magnitude. Second, in any system the number of trace elements far exceeds the number of major elements. Third, the range in behavior of trace elements is large, and collectively they are sensitive to processes to which major elements are insensitive. One example is the depth of partial melting. When the mantle melts, the major element composition of those melts depends only weakly on pressure. The heavy rare earths, however, are highly sensitive to the depth of melting because they partition into garnet, which is only present at high pressure (e.g., Kay and Gast 1973). Another example is cadmium in the fossil shells of microorganisms, which has provided information about the biological productivity and circulation patterns of ancient oceans (e.g., Boyle 1988). Finally, many elements that are present only in trace quantities in the environment are biologically essential. For example, zinc, present in soils at the parts per million (ppm) level and in seawater at the parts per billion (ppb) level, is a component of many essential proteins and enzymes.

Concentration Units

Trace element concentrations are often reported in weight units as parts per million (ppm), parts per billion (ppb), or parts per trillion (ppt), which correspond to milli-, micro-, and nanograms per kilogram. Commonly used molarity units are milli-, micro-, or nano-moles per liter abbreviated as mM, μM, and pM. For atmospheric gases, volume units are more commonly used, for example, parts per million by volume (ppmv).

Transition Elements

Dante Canil
School of Earth and Ocean Sciences, University of Victoria, Victoria, BC, Canada

Definition

The transition elements are defined as having an electronic configuration of partially filled d- or f-orbitals. As a group they have a range of valence states and are responsible for the variety of colors and magnetic properties in many natural minerals and glasses. The multivalent nature of transition elements makes their distribution in fluids, gases, and minerals in natural geologic systems especially sensitive to temperature and redox state.

Abundance and Distribution

Only transition metals with unfilled d-shells are considered in this chapter. There are 29 such metals, subdivided by their

position in the rows of the periodic table as first row (Sc – Zn), second row (Y to Cd), and third row (Hf – Hg) transition elements. The first row transition elements are the most abundant in the Sun, chondrites, and the bulk Earth compared to the other two groups. Iron is the most abundant transition element in the bulk Earth, maximized in concentration by nucleosynthetic processes that formed all elements (Table 1).

The transition metals can be classified as siderophile (affinity for metal), lithophile (combine readily with oxygen), or chalcophile (pairing with sulfide). The classification of transition metals as chalco-, sidero-, or lithophile, however, varies substantially with oxidation state. For example, Fe is siderophile at conditions of the core, lithophile in most of the mantle and crust, and yet is a common constituent of many sulfide minerals and melts. Some transition metals (Cd, Hg) are even atmophile given their volatility at certain conditions.

Behavior

The valence states of transition metal ions control their substitution into crystal structures and their solubility in solutions. Chemical fractionation during formation of the early Earth segregated metallic Fe to the core. Partial melting to form magmas has sequestered some of the transition elements (Cr, Ni, Fe, Co) that are more compatible in silicates or oxides of the mantle, or the crust (Sc, Ti). Exsolution of sulfides from magmas or hydrothermal fluids has focused anomalously high concentrations of other transition elements into ore deposits of the crust (Cu, Zn, Ni).

Valence State and Crystal Chemistry

The valence states for transition metal ions can vary from 1^+ to 8^+, though 2^+ and 3^+ are the most common valence states in

Transition Elements, Table 1 Properties of transition metal ions in terrestrial rocks

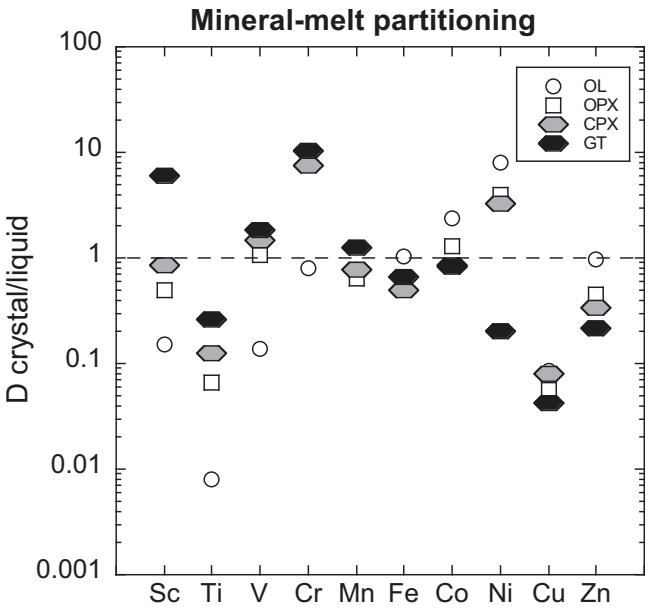
minerals at terrestrial conditions. In common rock-forming minerals of the crust and mantle, the first row transition elements substitute mostly on octahedrally coordinated sites, less so on cubic sites (Shannon 1976). Substitution on tetrahedral sites is rare. With the exception of Fe, no common rock-forming minerals are dominated by the concentration of any given transition element. Some accessory minerals are dominated by transition elements: Ti in perovskite ($CaTiO_3$), rutile (TiO_2), and ilmenite ($FeTiO_3$); Fe and Cr in spinel group minerals; Mn in oxides; and Cu-Zn-Ni in sulfides.

Crystal-Melt Partitioning

A number of attributes of the transition metals in earth materials can inform about conditions in the Earth both now and in the past. The ratio of Fe^{3+}/Fe^{2+} in magmas is sensitive to temperature, composition, and oxygen fugacity. The change in Fe^{3+}/Fe^{2+} ratio in melts with these variables reveals the redox states for the formation of terrestrial magmas, and its changes during differentiation or melting. The range in Fe^{3+}/Fe^{2+} in magmas spans several orders of oxygen fugacity, possibly related to that of their mantle source region (Carmichael 1991).

The partitioning of Fe, Mn, Zn, Sc, and V between mantle minerals and melts varies considerably (Fig. 1) and is useful to deduce the redox state or major element and mineralogical heterogeneity of the mantle source region of basaltic magmas (Canil 1999; Le Roux et al. 2011). The element pairs Fe-Zn and Sc-V generally have the same compatibility in mantle minerals olivine and pyroxene relative to melts, except that the partition of Fe or V is redox sensitive (Mallmann and O'Neill 2009). The V/Sc or Zn/Fe in basalts from mid-ocean ridges and volcanic arcs are nearly the same, requiring their redox state during melting to be nearly equal, contrary to that inferred by their different Fe^{3+}/Fe^{2+} (Lee et al. 2005; Lee et al. 2010). This leaves a dichotomy for the high Fe^{3+}/Fe^{2+} and oxygen fugacity of many arc magmas.

The Fe/Mn and Fe/Zn is very uniform in terrestrial oceanic basalts, except for those from ocean islands (Qin and Humayun 2008). When compared to olivine or orthopyroxene, both garnet and clinopyroxene partition less Zn and more Mn relative to Fe (Le Roux et al. 2010). Thus, lithologies rich in garnet and clinopyroxene (eclogite, pyroxenite) must be significantly more abundant and mixed in with peridotite in the mantle sources of ocean island basalts relative to those of arcs and mid-ocean ridges (Davis et al. 2013).



Transition Elements, Fig. 1 Plot of partition coefficients D crystal/liquid = [element concentration in crystal]/[element concentration in melt] for first row transition elements measured between mantle melts and olivine (OL), orthopyroxene (OPX), clinopyroxene (CPX), and garnet (GT) (Data from: Canil (1999), Le Roux et al. (2011), Davis et al. (2013), and Liu et al. (2014))

High–Low Spin Transition in Fe

The d-orbitals of transition metals ions can split in energy level, proportional to the charge on the ion and its coordination state. The splitting is described by crystal field theory and can affect the absorption of light (to produce color). In addition, for first row transition metals in octahedral coordination, the splitting of electrons can affect their spin state to be either high or low (Burns 1993). The spin state of a coordination complex affects its ionic radius, thus the density or molar volume of a mineral, or its magnetic properties.

The high spin state of Fe is the normal configuration, where a single electron occupies each d-orbital, whereas in the low spin state, the orbitals are paired as much as possible. High-low spin transitions in Fe predicted to occur at high pressures in Earth's lower mantle (Badro et al. 2003) have been borne out by direct experiments (Catalli et al. 2011). The two most abundant transition metal ions, Fe^{2+} or Fe^{3+}, can undergo high – low spin transitions in the lower mantle minerals ferropericlase ($Fe_{1-x}O$) and bridgmanite ($(Mg,Fe)(Fe,Al)O_3$ – perovskite). The high-low spin state transitions may be sharp or smooth throughout the temperature-pressure range of the lower mantle, depending on its composition and oxidation state (Catalli et al. 2011). Such transitions can produce anomalies in the seismic wave speed, magnetic properties, or heat transfer in the deep mantle (Lin et al. 2007).

Hydrothermal Fluids

The solubility and speciation of transition metals in fluids are affected by pH, pressure, temperature, and composition (Crerar et al. 1985). In certain pressure-temperature regimes in the upper crust and seafloor, boiling of hydrothermal fluid may occur, leading to exsolution of vapor from liquid. Transition metals such as Fe, Mn, Zn, Cu, and Au can be fractionated from one another due to complexation with specific ligands in fluids and vapors. The complexation tends to follow Pearson's (1963) rules – hard acids pair with hard bases and vice versa. For example, Cu^{+} is soft and binds with S^{-} complexes (H_2S) and HS^{-}, whereas Zn^{2+} is hard and pairs with hard bases (Cl^{-} or HCl) as ZnCl species (Pokrovski et al. 2005; Nagaseki and Hayashi 2008). In this way, transition metals such Cu and Au will concentrate in ores produced by vapor transport such as porphyry and epithermal settings, whereas as Zn, Mn, or Fe prefer the liquid/brine phase (Heinrich et al. 1999).

Tungsten

George R. Helz
Departments of Geology and Chemistry, University of Maryland, College Park, MD, USA

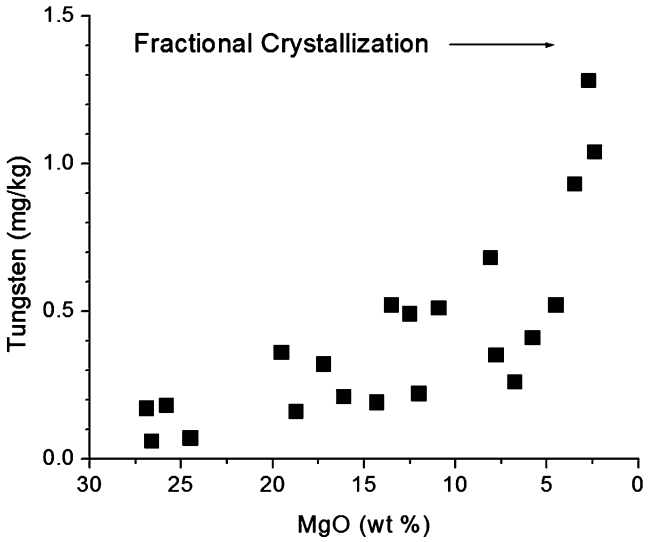
Element Data

Atomic Symbol: W
Atomic Number: 74
Atomic Weight: 183.84
Isotopes and Abundances: ^{180}W (0.12%, $t_{½}$ 1.8x10^{18} y), ^{182}W (26.50%), ^{183}W (14.31%), ^{184}W (30.64%), ^{186}W (28.43%) (additionally 27 artificial isotopes)
1 Atm Melting Point: 3695 K
1 Atm Boiling Point: 6203 K
Common Valences: W^0, W^{3+}, W^{4+}, W^{5+}, W^{6+} (other valences not important in nature)
Ionic Radii: (Coord. No.): W^{6+}(6-fold) 76 pm, W^{6+}(4-fold) 56 pm, W^{4+}(6-fold) 80 pm
Pauling Electronegativity: 2.36
First Ionization Potential: 7.864 eV
Chondritic (CI) Abundance: 0.093 ppm
Silicate Earth Abundance: 0.013 ± 0.010 ppm
Crustal Abundance: 1.4–2.0 ppm
Seawater Abundance: 0.0092 ppb
Core Abundance: 0.50 ± 0.12 ppm

Properties

Notable properties of tungsten include its melting point (highest of any metal) and its density (exceeding all stable elements except gold and platinum group elements). Combined in tungsten carbide, it forms an abrasive with extraordinary hardness, like that of corundum. Tungsten is also the heaviest element that is essential to some prokaryotes, though not to eukaryotes (including humans). Tungsten shares Group 6 of the Periodic Table with Cr and Mo. Oxidation states below +6 are much less common for W than for Cr and Mo owing to relativistic destabilization of 5d electrons in W (Holm et al. 2011).

Tungsten's principal minerals are scheelite, $CaWO_4$, and wolframite, (Fe, Mn)WO_4. In these, W is respectively fourfold and sixfold coordinated by oxygen. Tungsten sulfides, such as tungstenite (WS_2), catamarcaite (Cu_6GeWS_8), and kiddcreekite (Cu_6SnWS_8), are rare. A few complex silicate minerals are known.



Tungsten, Fig. 1 Tungsten's incompatability during fractional crystallization illustrated in Kilauea Iki lava lake (data of Greaney et al. 2017)

History and Use

Discovery of tungsten is often attributed to Scheele, who obtained tungstic acid in 1781. Its first isolation as an element was accomplished by the brothers Elhuyar in 1783.

In 2016, China was the world's largest producer (82% of world production, 71,000 metric tons) and Vietnam the second largest (7%, 6,000 metric tons).

Tungsten's principal use is in tungsten carbide abrasives. It also finds use in wear-resistant and high-temperature alloys and in munitions, where its density is advantageous for armor-penetrating projectiles. Owing to its high melting point, it has long been favored for filaments in light bulbs and other electrical devices.

Geochemical Behavior

Tungsten is a moderate siderophile, and in consequence, more than nine-tenths of Earth's W budget resides in the core. On the other hand, in the silicate earth, W is an incompatible element, similar to U, so fractional melting and crystallization processes concentrate it in the crust, leaving a depleted mantle containing 0.008 ± 0.007 μg/g (Arevalo and McDonough 2008) (Fig. 1).

Tungsten does not display the borderline chalcophile tendencies of its Group 6 neighbor, Mo. In skarn and porphyry ore deposits, W is most often found as $CaWO_4$ or (Fe, Mn)WO_4 whereas in the same rocks Mo is found as its sulfide, MoS_2 (Hsu 1977; Wood and Samson 2000). In sulfidic pore waters from estuarine and continental shelf sediments, W is mobilized whereas Mo is precipitated (Mohajerin et al. 2016). Likewise, W is mobilized and Mo precipitated during circulation of sulfidic hydrothermal waters through the seafloor near spreading centers (Kishida et al. 2004). Experiments show that aqueous WO_4^{2-} can be thiolated to WS_4^{2-}, but only at much higher sulfide concentrations than needed to thiolate MoO_4^{2-} (Mohajerin et al. 2014).

Traditionally, five stable W isotopes have been recognized. The lightest, ^{180}W, is now known to be a low-activity α emitter ($t_{½}$ 1.8 × 10^{18} y; Cozzini 2004). Cosmochemists and geochemists have devoted most attention to ^{182}W, the daughter of radioactive ^{182}Hf ($t_{½}$ 8.9 × 10^6 y). Planetary core formation separates lithophile Hf from siderophile W, so the abundance of ^{182}W relative to other W isotopes in silicate and metal reservoirs yields information about timing of core formation and late accretion (Kleine et al. 2002).

Chemical fractionation among W stable isotopes is anticipated, but this subject largely remains to be developed. Tungstate adsorbed to Fe and Mn oxyhydroxides is isotopically lighter than aqueous tungstate, hinting at similarity in W and Mo stable isotope behavior. The fractionation mechanism involves tungsten's transfer from tetrahedral coordination in water to distorted octahedral coordination on oxyhydroxide surfaces (Kashiwabara et al. 2017).

Acidification causes dilute aqueous WO_4^{2-} to become diprotonated near pH 4. This process initiates hydration, producing octahedrally coordinated $W(OH)_6^0$. At dissolved W concentrations exceeding10^{-5} M and at pH below 5, WO_4^{2-} forms polyoxyanion oligomers (e.g., $W_6O_{20}(OH)^{5-}$; Baes and Mesmer 1976). In most natural waters, W concentrations are far too low to stabilize such species.

Even where W concentrations exceed 10^{-5} M in nature, such as in mine drainage or in rivers and lakes subject to evaporative concentration (Petrunic and Al 2005; Johannesson et al. 2000), pH is usually too high for oligomerization. Nonetheless, polyoxyanions are proposed to form in some soils, possibly stabilized by low water activity (i.e., relative humidity) in soil pore spaces, and could explain anomalous W mobility (Sun and Bostick 2015). Once formed, polyoxotungstates react sluggishly.

Present as WO_4^{2-} at about 0.05 nmol/kg, tungsten is a conservative component of seawater with a mean residence time of about 14,000 y (Firdaus et al. 2008). In river waters, its concentration is much higher and quite variable, averaging about 0.54 nmol/kg (Gaillardet et al. 2005). High dissolved (i.e., filter passing) W concentrations in rivers are due partly to colloidal transport (Pokrovsky and Schott 2002).

Shales and sandstones are similar to continental crust in their W content, but carbonate sediments are mildly depleted. In organic-rich black shales, the median W concentration is 2.9 μg/g, which is only narrowly enriched relative to crust (Ketris and Yudovich 2009). In contrast, Mo is highly enriched.

On the other hand, W is considerably enriched in marine ferromanganese nodules and crusts (50–100 μg/g; Hein et al. 2013). The principal host phases appear to be Mn oxyhydroxides rather than Fe oxyhydroxides (Kashiwabara et al. 2013).

Biological Utilization and Toxicity

Until about 30 years ago, tungsten's role in biology was viewed as solely injurious owing to interference in Mo-dependent processes (Andreesen and Makdessi 2008). Since then, beneficial utilization in a number of W-dependent enzymes has been recognized, especially in hyperthermophilic prokaryotes. Redox potentials in W enzymes are lower than in comparable Mo enzymes (Bevers et al. 2009; Holm et al. 2011). In some cases, structures of active sites in W and Mo enzymes are almost identical, yet these enzymes catalyze quite different reactions. In other cases, as in Mo nitrogenase (a N_2 reduction catalyst), the W form is inactive.

Genetic evidence shows that hyperthermophiles were among the earliest organisms. It has been proposed that W enzymes evolved before Mo enzymes, at a time when hydrothermal vents were the main source of W and Mo to the ocean (Williams and Frausto da Silva 2002).

Recognition of a cluster of leukemia cases near tungsten mines in Nevada gave rise to a hypothesis that W is an environmental carcinogen (Koutsospyros et al. 2006). So far, this hypothesis lacks firm support (Lemus and Venezia 2015). The US Occupational Safety and Health Administration has set 8-h threshold limits for air of 1 and 5 mg/m^3 for water-soluble and water-insoluble tungsten, respectively. Currently, W is not regulated in drinking water by the World Health Organization or by the US Environmental Protection Agency, but Russia has set a standard of 50 μg/L.

Summary

Tungsten and molybdenum have been described as twins due to their similar ionic radii and electronegativity. Their crustal abundances are nearly the same despite tungsten's much lower cosmic abundance. In natural waters, both are found as tetrahedral oxyanions and are conservative components of seawater. Both sorb readily to ferromanganese oxide minerals with the lighter isotopes preferentially depleted in solution. They form structurally similar minerals in the earth and enzymes in living organisms. On the other hand, key differences include tungsten's greater siderophilicity and lower chalcophilicity as well as tungsten's lower redox potential. Neither is currently regarded as problematic in the environment, although this could change as more information becomes available.

Tungsten Isotopes

Thorsten Kleine
Institut für Planetologie, University of Münster, Münster, Germany

Introduction

Tungsten consists of the five stable isotopes ^{180}W (0.12%), ^{182}W (26.50%), ^{183}W (14.31%), ^{184}W (30.64%), and ^{186}W (28.43%), which are produced by three different nucleosynthetic processes: the *p*- (proton capture), *s*- (slow neutron capture), and *r*- (rapid neutron capture) processes. Of the stable W isotopes, ^{180}W is produced in the *p*-process, whereas the four major W isotopes are produced by both the *s*- and *r*-processes. In addition, ^{182}W is produced by β^--decay of now-extinct ^{182}Hf with a half-life of 8.9 ± 0.1 Ma (Vockenhuber et al. 2004), leading to variable ^{182}W abundances in terrestrial and extraterrestrial samples. The short-lived ^{182}Hf-^{182} W system has been widely used as a chronometer for meteorites and the large-scale chemical differentiation of asteroids and terrestrial planets.

Origin of W Isotope Variations

Tungsten isotope variations have several distinct origins, including radiogenic, cosmogenic, and nucleosynthetic processes, as well as mass-dependent fractionation. *Radiogenic* ^{182}W variations result from the decay of ^{182}Hf and form the basis of the Hf-W system (e.g., Kleine et al. 2009). *Cosmogenic* W isotope variations predominantly affect ^{182}W in lunar samples and iron meteorites, and arise from secondary neutron capture reactions induced by the interaction with galactic cosmic rays (GCR) (Leya et al. 2003). *Nucleosynthetic* W isotope variations result from the heterogeneous distribution of presolar material. They have been observed in several components of primitive chondrites (e.g., Budde et al. 2016b; Burkhardt et al. 2012; Kruijer et al. 2014a) and in some bulk meteorites (Kruijer et al. 2017a; Qin et al. 2008). Nucleosynthetic W isotope anomalies serve as tracers of genetic relationships and have been used to demonstrate a genetic link between chondrules and matrix (Budde et al. 2016b), and between some iron meteorites and carbonaceous chondrites (Kruijer et al. 2017a). Both nucleosynthetic and cosmogenic W isotope variation must be quantified for chronological applications of the Hf-W system.

Mass-dependent W isotope fractionations during high-temperature processes seem to be limited, but small variations may occur during magmatic differentiation (Krabbe et al.

2017). More significant W isotope fractionations have been observed for low-temperature processes, such as the precipitation of W onto surfaces of Fe and Mn oxides (Abraham et al. 2015; Kashiwabara et al. 2017).

The ^{182}Hf-^{182}W System

Because Hf is lithophile (silicate-loving) and W is siderophile (iron-loving), metal-silicate fractionation results in a large fractionation of the Hf/W ratio, making the Hf-W system uniquely useful as a chronometer of planetary core formation (e.g., Harper et al. 1991). Additional Hf/W fractionation likely occurred in the mantle of planetary bodies, because W is more incompatible than Hf (Righter and Shearer 2003). Processes such as magma ocean crystallization or partial melting can therefore also be dated using the Hf-W system. Finally, the Hf-W system is a versatile chronometer for meteorites and meteorite components, because there is sufficient spread in Hf/W ratios among the constituent minerals of these rocks.

A Hf-W model age of core formation is usually determined by assuming that core formation occurred in a single instant from a reservoir that previously evolved with chondritic Hf/W. As both Hf and W are refractory elements, the assumption of chondritic Hf/W for bulk planets is reasonable. The assumption of single-stage core formation is more problematic and is only appropriate for meteorite parent bodies. By contrast, for larger bodies such as the Earth and Mars, core formation occurred by several distinct events during planetary growth. One common model is to assume that accretion and concomitant core formation occurred at an exponentially decreasing rate. This model provides a mean age of accretion as the time necessary to reach 63% of a planet's mass (Harper and Jacobsen 1996). However, the Earth's core likely formed episodically by a few giant impacts, meaning that the exponential growth model may not be appropriate (Nimmo and Agnor 2006). Moreover, the extent to which the metal cores of giant impactors equilibrated with Earth's mantle has a strong influence on the calculated model ages for core formation (Halliday 2004).

^{182}W Compositions of Meteorites and Terrestrial Planets

Tungsten isotope ratios are either normalized to ^{184}W or ^{183}W and are corrected for instrumental and natural mass-dependent isotope fractionation using either ^{186}W/^{184}W or ^{186}W/^{183}W. It is common practice to report results for both normalizations, which allows a reliable quantification of nucleosynthetic contributions to observed ^{182}W variations. This also allows quantification of small analytical artefacts on ^{183}W induced during sample preparation, where the nuclear field shift effect leads to small apparent ^{183}W deficits (Cook and Schönbächler 2016).

Tungsten isotopic data are typically expressed as the parts-per-10,000 deviation from terrestrial standard values (Alfa Aesar or NIST W 3163) as follows:

$$\varepsilon^{182}\mathrm{W} = \left(\frac{^{182}\mathrm{W}/^{184}\mathrm{W}_{\mathrm{sample}}}{^{182}\mathrm{W}/^{184}\mathrm{W}_{\mathrm{standard}}} - 1 \right) \times 10^4.$$

More recently, W isotopic data have also been reported as μ^{182}W values (=100 ε^{182}W). The ^{182}W compositions of meteorites and samples from the Earth, Moon, and Mars are summarized in Table 1 and plotted on Fig. 1.

Rapid Accretion of Protoplanets

Compared to chondrites, iron meteorites show ^{182}W deficits, whereas angrites and eucrites have ^{182}W excesses (Table 1, Fig. 1). These ^{182}W variations indicate that core formation in meteorite parent bodies occurred well within the first ~3 Ma of the Solar System. Such early differentiation is consistent with ^{26}Al-decay as the major heat source driving melting of small planetary bodies, and indicates that differentiated protoplanets accreted within ~1 Ma of Solar System history (Kruijer et al. 2017a; Kruijer et al. 2014b). A key constraint from the ^{182}W data is that the accretion of iron meteorite parent bodies predated those of the more primitive chondrite parent bodies.

Iron meteorites that are genetically linked to carbonaceous meteorites have younger core formation ages (~2.2–2.8 Ma) than noncarbonaceous iron meteorites (~0.3–1.8 Ma) (Kruijer et al. 2017a). This difference has been interpreted to indicate a later accretion at greater heliocentric distance of the carbonaceous irons (Budde et al. 2016a; Kruijer et al. 2017a), and has been used to argue that Jupiter's solid core formed within ~1 Ma of Solar System formation, leading to the spatial separation of the carbonaceous and noncarbonaceous meteorite reservoirs (Kruijer et al. 2017a).

Timescales for Mantle Differentiation

Variations in ε^{182}W values among eucrites and angrites (Fig. 1) provide evidence for magmatic activity on their parent bodies for at least until ~20 Ma and ~10 Ma after Solar System formation, respectively (Kleine et al. 2012; Touboul et al. 2015b). ^{182}W variations among Martian meteorites have been interpreted to indicate magma ocean crystallization within the first 20–25 Ma, followed by crust

Tungsten Isotopes, Table 1 Hf-W isotopic systematics of meteorites and terrestrial planets

Planetary body	$^{180}Hf/^{184}W$	$\varepsilon^{182}W$	Model age	Accretion timescale
Chondrites[a]	1.35 ± 0.11	−1.9 ± 0.1

[f]Assumes distinct Hf/W ratios of Moon and Earth's mantle

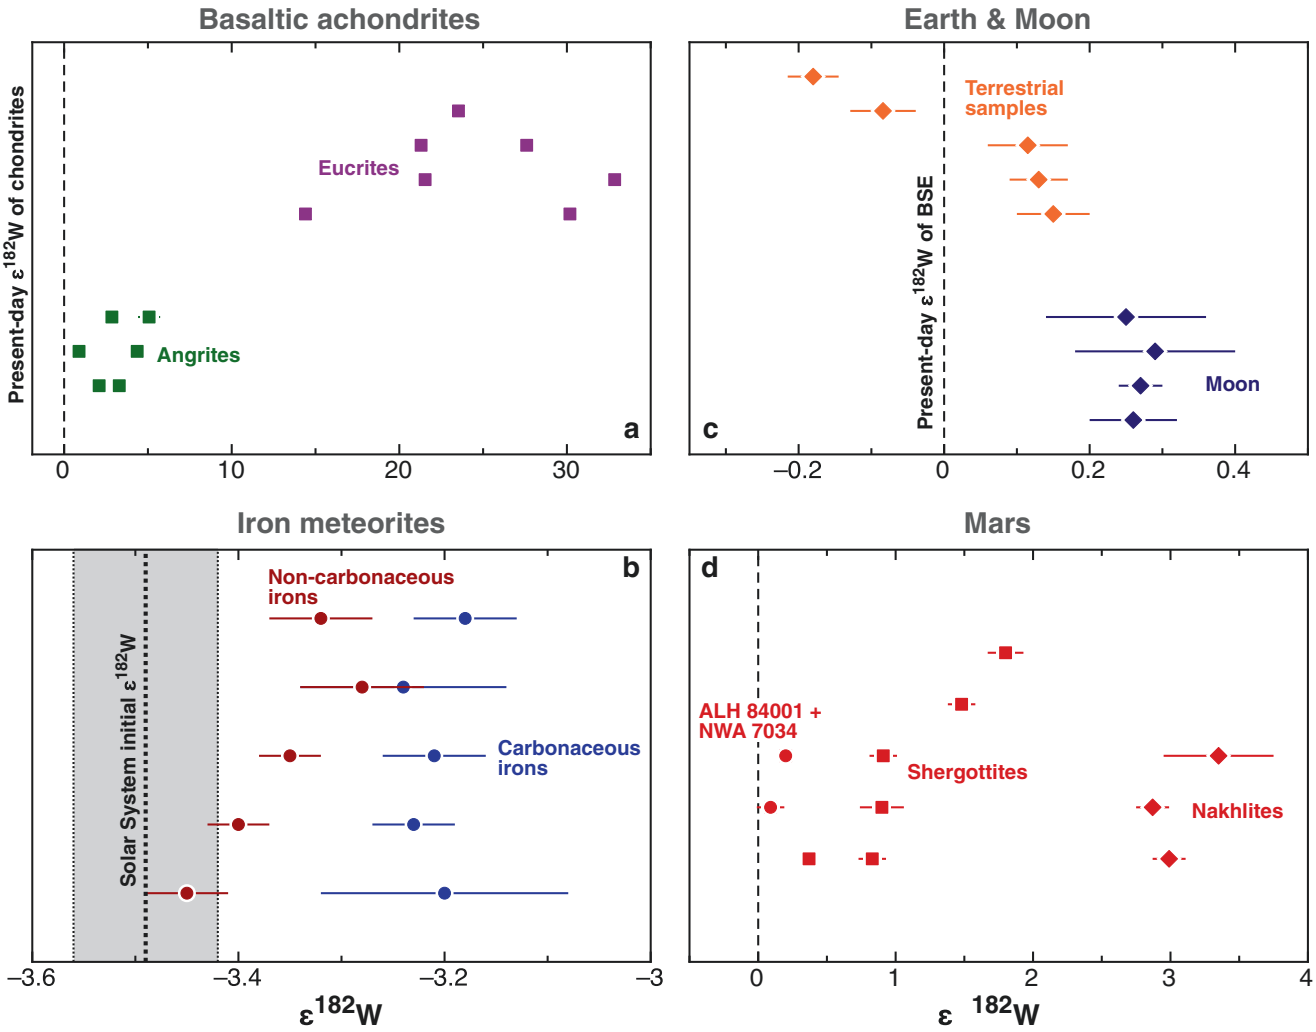
formation until at least ~40 Ma after Solar System formation (Foley et al. 2005; Kruijer et al. 2017b).

There are no radiogenic ^{182}W variations among different lunar rock types (Fig. 1), indicating that differentiation of the Moon occurred later than ~70 Ma after Solar System formation (Touboul et al. 2007; Kruijer and Kleine 2017). By contrast, small ^{182}W variations exist among terrestrial samples (Fig. 1) (see summary in Kleine and Walker 2017). Whereas the ^{182}W excesses in some Archaean samples may reflect derivation from sources that lack some portion of the late veneer (e.g., Willbold et al. 2011), the small ^{182}W deficits observed for some ocean island basalts (Mundl et al. 2017) cannot be explained in this manner. These ^{182}W deficits were interpreted as vestiges of an early differentiation of Earth's mantle within the first 60 Ma of the Solar System. Such early differentiation processes could have also produced the ^{182}W excesses observed in Archaean samples (Touboul et al. 2012). Thus, as for Mars but unlike for the Moon, ^{182}W heterogeneities from Earth's earliest formative period have been preserved until the present-day.

Accretion Timescales for the Earth, Moon, and Mars

The mantles of the Earth and Mars have higher $\varepsilon^{182}W$ compared to chondrites, indicating that core formation at least partly occurred during the lifetime of ^{182}Hf. Although the Earth's and Mars' mantles have similar $\varepsilon^{182}W$, their Hf/W ratios are very different (Table 1), leading to distinct Hf-W ages. For Mars, the two-stage model for core formation is 4 ± 3 Ma after Solar System formation, with a mean age of accretion of ~2 Ma (Dauphas and Pourmand 2011). For the Earth, the two-stage model age is 34 ± 3 Ma, while the mean age is ~11 Ma (Kleine et al. 2002; Schoenberg et al. 2002; Yin et al. 2002). As noted above, the assumption of single stage core formation is not appropriate for large bodies, meaning that accretion probably took longer than given by the two-stage model ages. As such, Mars was probably fully formed by ~10 Ma after Solar System formation (Kruijer et al. 2017b). For the Earth the end of accretion is poorly defined, mainly because the extent of equilibration of metal and silicate during giant impacts is not known. Incomplete equilibration leads to younger calculated Hf-W ages. For instance, assuming only ~40–50% equilibration would change the Hf-W age to ~100–150 Ma, which would be consistent with the Pb-Pb age of the Earth (Rudge et al. 2010).

The Moon exhibits a small ^{182}W excess of ~25 ppm over the present-day bulk silicate Earth (Kruijer et al. 2015; Touboul et al. 2015a). This ^{182}W difference likely results from late accretion following the Moon-forming impact, which lowered the ^{182}W composition of Earth's mantle by about 10–30 ppm, but left the lunar ^{182}W composition essentially unchanged. Prior to late accretion the $\varepsilon^{182}W$ of the Moon and Earth's mantle were, therefore, indistinguishable. The lack of a resolvable radiogenic ^{182}W difference between the Moon and Earth's mantle implies formation of the Moon after extinction of ^{182}Hf, more than ~60 Ma after Solar System formation (Touboul et al. 2007). This conclusion is valid



Tungsten Isotopes, Fig. 1 $\varepsilon^{182}W$ variations among extraterrestrial and terrestrial samples. Note the different scales for each panel. *Dashed line* in **a**, **c**, and **d** represents W isotopic composition of the present-day bulk silicate Earth (BSE). Note the much larger $\varepsilon^{182}W$ variations in basaltic achondrites (**a**) and Mars (**d**) compared to the Earth and Moon (**c**). (**c**) For terrestrial samples, only data for selected localities are shown, but these cover the entire range of ^{182}W variations reported to date

only if the Hf/W ratios of the lunar and terrestrial mantles are sufficiently different.

Summary

Tungsten isotope studies are widely applied to determine the timescales of planetary accretion and differentiation and have demonstrated that differentiated protoplanets accreted within ~1 Ma, Mars accreted within the first ~10 Ma, and Earth's accretion was completed no earlier than ~30 Ma after Solar System formation. The Hf-W system also serves as an important chronometer for meteorites and meteorite components, and as a tracer of late accretion. In addition, nucleosynthetic W isotope anomalies have important applications for establishing genetic links among early Solar System materials.

U

Unified Atomic Mass Unit, Avogadro Constant, and Mole

Norman E. Holden
National Nuclear Data Center, Brookhaven National Laboratory, Upton, New York, USA

Definition

The unified atomic mass unit, u, is defined as 1/12th of the rest mass of a neutral atom of ^{12}C in its nuclear and electronic ground state. Avogadro's constant, N_A, is the number of atoms in a mole of substance, where mole, denoted *mol*, is defined as the amount of substance that contains as many elementary entities as there are atoms in 0.012 kg of carbon-12.

Unified Atomic Mass Unit

The nineteenth-century chemists had two different standards for atomic weight values: hydrogen = 1, as chosen and quoted by John Dalton (1805), and oxygen = 16, as suggested by Brauner (1889) and the German Atomic Weights' Committee (Ostwald 1903) because oxygen was a primary measurement standard. At the start of the twentieth century, chemists (Landolt et al. 1900) voted for oxygen =16. The physicist, Francis Aston, who was using a mass spectrometer to determine mass ratios of isotopes (nuclides), used the stable isotope $^{16}O = 16$ as a standard. With the discovery (Giaugue and Johnson 1929a; Giaugue and Johnson 1929b) of the oxygen isotopes, ^{17}O and ^{18}O in 1929, there was a slight difference in the two standards. The physical scale was 0.27% smaller than the chemical scale. Initially, this factor was used to convert measurements between the two different scales. However, with Dole's discovery (Dole 1935) of different atomic weight values for oxygen in air and in water, this became a variable difference between the chemical and physical standards for atomic weights that persisted for three decades. When IUPAP and IUPAC agreed to change the atomic mass scale from oxygen to carbon in 1960/1961, the physicist's definition of the atomic mass unit, *amu*, as equal to 1/16th of the mass of an atom of ^{16}O would become a unified atomic mass unit, u, defined as 1/12th of the rest mass of a neutral atom of ^{12}C in its nuclear and electronic ground state (Holden 1984). When the unification of scales was proposed, the name aston (symbol An) was proposed for the unit (Cohen, Private communication, 8 July 1981). More recently, the biochemical suggestion of the Dalton was proposed, which a number of international bodies have adopted. When the atomic weight value of a chemical element is used with the International System of Units (SI) unit of grams, the result is the gram-atomic weight or a mass of a mole of that element, i.e., the mass of Avogadro constant of atoms of that element.

Avogadro Constant and Mole

Avogadro's constant, N_A, the number of entities in the amount of substance of one mole, is a scaling factor between the microscopic (atomic scale) and the macroscopic properties of matter. It has a unit of a reciprocal mol. It is named after the Italian scientist, Amedeo Avogadro, who proposed that the volume of a gas (at a given pressure and temperature) is proportional to the number of atoms or molecules regardless of the nature of the gas (Avogadro 1811). The latest recommended value of N_A is $6.022140857\ (74) \times 10^{23}\ mol^{-1}$ in the SI, where the number in parentheses (74) is the uncertainty in the two trailing digits, "57", in the value. It is based on the 2014 adjustment of the CODATA (International Council for Science's Committee on Data for Science and Technology) recommended values of the fundamental constants of physics and chemistry. N_A expresses the ^{12}C mass in kilograms according to the expression:

$M(^{12}C) = N_A \bullet m(^{12}C)$, where $M(^{12}C) = 0.012$ kg/mol is the molar mass and $m(^{12}C)$ is the atomic mass of ^{12}C.

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

The mole is defined as the amount of substance of a system, which contains as many elementary entities as there are atoms in 0.012 kg of carbon-12. Its symbol is "mol." When the mole is used, the elementary entities must be specified, and they may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles.

It has been suggested that "amount of substance" should be replaced by the term "chemical amount." However, "chemical amount" is not a well-understood term. No conclusion has been reached in this regard.

There is a proposed new definition of the mole, which sets the magnitude of the mole by fixing the numerical value of the Avogadro constant. However, the definition of the Avogadro constant is the number of atoms in a "mole."

The effect of the new definition of the mole would reverse the situation of the Avogadro constant and the atomic mass of ^{12}C. At present, the atomic mass of ^{12}C is equal to 12 with no uncertainty, while the value and the uncertainty of the Avogadro constant is determined by measurement. With the new definition, the value of the Avogadro constant would be fixed with no uncertainty, while the value and uncertainty of the atomic mass of ^{12}C would become variable and be set by measurement. At the present time, measurements of the Avogadro constant continue and the exact value and uncertainty of the Avogadro constant has not been finalized.

Summary

The unified atomic mass unit (or Dalton) is equal to 1/12th of the rest mass of a neutral atom of ^{12}C in its nuclear and electronic ground state.

The Avogadro constant is the scaling factor between the microscopic and the macroscopic properties of matter, whose value is the number of ^{12}C atoms in their nuclear and electronic ground states in 0.012 kg of ^{12}C (designated as 1 mol).

The mole is the amount of substance (or chemical amount) of a system which contains as many elementary entities as there are atoms in 12 g of ^{12}C.

Uranium

Vincent J. M. Salters
National High Magnetic Field Laboratory and Department of Earth, Ocean and Atmospheric Sciences, Florida State University, Tallahassee, FL, USA

Element Data
Atomic Symbol: **U**
Atomic Number: **92**
Atomic Weight: 238.029
Isotopes and Abundances: ^{238}U, 99.2745%, ^{235}U 0.7255%, ^{234}U, ^{223}U
1 Atm Melting Point: 1,132 °C
1 Atm Boiling Point: 4,131 °C
Common Valences: 4+, 6+
Ionic Radii Tetravalent U: sixfold, 108 pm; fourfold, 112 pm
Pauling Electronegativity: 1.38
First Ionization Energy: 597.6 kJ/mol
Chondritic (CI) Abundance: 8.1 ppb
Silicate Earth Abundance: 20.3 ppb
Crustal Abundance: 1.3 ppm
Seawater Abundance: 3.2 ppb
Core Abundance: ~0

Properties

The element is named after the planet Uranus. Its symbol is U, its atomic number is 92, and its atomic weight is 238.0289. Its melting point is 1,408 K and its boiling point is 4,404 K and is considered a refractory lithophile element, with a 50%

nebular condensation temperature of 1,010 K (Lodders 2003). The specific gravity of U is 18.95 g/cm^3, which makes it the fourth in line with respect to density after Pt, Au, and W. Uranium is a white silvery metal which is pyrophoric when finely divided. It is malleable, ductile, and slightly paramagnetic. Its metal has three forms α (ορτηορομβιχ), β (tetragonal), and γ (cubic) with transition temperatures of 961 K and 1,049 K.

History and Use

Uranium was first recognized as an unknown element by Klaproth in 1789, and the metal was first isolated by Peligot in 1841. Uranium is used for inertial guidance devices, gyrocompasses, and ballast for missile reentry vehicles. Depleted uranium (depleted in ^{235}U) is used for shielding for tanks as well as armor-piercing bullets. Its metal is also used for X-ray target to produce high-energy X-rays. Enriched uranium has higher than natural abundance of ^{235}U and is used as fuel for nuclear reactors.

Chemistry

Uranium is an actinide and can be di-, tri-, tetra-, penta-, and hexavalent. Its ground-state electronic configuration is [Rn] $5f^3 6d^1 7s^2$. In nature, the two common valence states are tetravalent under reducing and hexavalent under oxidizing conditions as in the oceans. In its tetravalent state, it behaves much like Th and is particle reactive and insoluble in water. Under oxidizing conditions, it is soluble in water resulting in relatively high concentrations in surface and ocean waters. In solution, the dominant form of U is the uranyl ion, UO_2^{2+}, but U is also complexed by F^-, OH^-, SO_4^{2-}, NO_3^-, and carboxylates. In most minerals, it is tetravalent with an ionic radius 8.9 nm in sixfold coordination and 10 nm in eightfold coordination.

Concentrations of U in bulk samples are generally low, in the ppm to ppb range, and are mostly measured by inductively coupled plasma mass spectrometry (ICP-MS) or by isotope dilution. Its first ionization potential is relatively high, 6.3 eV, making it more difficult to analyze by flame photometry. Before the era of ICP-MS, U concentrations were analyzed by neutron activation or by XRF. ^{234}U abundance (activity) is also measured by alpha counting or by thermal ionization mass spectrometry (Chen et al. 1992).

Isotopes and Applications

Natural occurring uranium isotopes are ^{238}U (99.2745%), ^{235}U (0.720%), and ^{234}U (0.0055%). The present-day ^{238}U/^{235}U isotope abundance ratio is 137.88; at secular equilibrium, the ^{238}U/^{234}U isotope abundance ratio is 18236. All three natural occurring isotopes are unstable and have half-lives of 245,250 ± 490 years (^{234}U), 0.70381 ± 0.00096 G years (^{235}U), and 4.468 ± 0.0048 G years (^{238}U). The stable daughter isotope in the ^{238}U-series is ^{206}Pb; during this decay scheme, eight alpha particles are released. The ^{235}U decay series ends at ^{207}Pb and seven alpha particles are released. At the start of the solar system, the ^{238}U/^{235}U was 3.3. Any significant variations in ^{206}Pb/^{207}Pb have to be produced early in Earth's history as for the last 2Ga ^{207}Pb/^{204}Pb has changed little due to the now low abundance of ^{235}U.

Except for at the Oklo nuclear reactor (Bros et al. 1993), the present-day ^{235}U/^{238}U was long thought to be constant. Natural fractionation of uranium isotopes was first exploited by Stirling et al. (2007) and Weyer et al. (2008). Isotopic compositions are reported as δ^{238}U, which is the relative deviation, reported in per mil, of the ^{238}U/^{235}U of the sample compared to that of a standard. For most analyses, samples are spiked with ^{233}U–^{236}U for mass bias correction. The natural variation in δ^{238}U is approximately 3 ‰. These natural variations occur through low-temperature processes, and the largest differences are between oxidizing and reducing environments. Black shales are approximately 0.4 ‰ heavier than seawater. These fractionations are thought to be related to volume-dependent equilibrium fractionation where U in seawater is reduced and the ^{238}U is preferentially concentrated in the reduced U(IV) and concentrates in the sediment. During microbial reduction, the heavy isotope is also concentrated in the reduced fraction (Bopp et al. 2010). The magnitude and direction of the fractionation is consistent with theoretical prediction of the fractionations being related to differences in nuclear volume (Schauble 2007). Kinetic isotope fractionations would predict enrichments in the light isotope in the reduced phase, which is opposite to the observations. Except for near the basalt-seawater interface, altered oceanic crust also shows heavy isotope enrichment which is attributed to the penetration of seawater to deeper levels, reduction of U(VI), and addition of U to the crust (Andersen et al. 2015).

Absorption of U to Fe-Mn hydroxides also results in an isotope fractionation whereby the absorbed fraction is lighter (Weyer et al. 2008). The absorption, as observed with Mn nodules, is not associated with a change in valence state (Brennecka et al. 2011), and kinetic fractionation is expected and consistent with the sense of the observed mass fractionation.

Ores and Distribution in Rocks

Uranium is a trace element in all rocks and is mostly present in tetravalent state. Due to its large ionic radius and high charge,

uranium is not easily incorporated in crystal structures of common rock-forming minerals. Therefore, during melting, uranium enters the melt very early, and mineral melt partition coefficient is typically less than 10^{-3}. U is a large ion lithophile element as well as a high field strength element. It enters the melt easily and during crystallization is concentrated in the residual melt and is incorporated in late-stage crystallizing trace phases like zircon, apatite, xenotime, or sphene. The tendency for U to substitute in zircon makes it the premier geochronometer because, as well as being U-rich, it typically contains little or no Ph initially, it is a common accessory mineral in many rocks, and it extremely chemically and mechanically stabile. Although there are significant uncertainties, approximately 16% of the Earth's U is sequestered in the continental crust, which comprises only 0.2% of Earth's mass.

Uranium concentrations in igneous rocks are low in most mafic and ultramafic rocks, but have higher concentrations in alkaline and silica-undersaturated magmas, but can be as high as 50 ppm in carbonatites and up to 100 ppm in syenites. Marine phosphorites are the highest in U concentration (100 ppm) of sedimentary rocks. High silica granites can have 10–20 ppm of U. In most other natural materials, the concentration of uranium is low. For example, mid-ocean ridge basalts have U concentrations generally below 1 ppm.

Concentrations of U in ultramafic rocks are very low, often less than 10 ppb. It is, however, unclear where the U resides. The sum of the uranium content of the individual mineral phases is often less than the bulk rock content, indicating U is probably residing along grain boundaries or in fluid inclusions.

Uranium ores can be formed under a wide variety of conditions with uraninite (UO_2) or pitchblende as the main mineral. Ores can be formed by concentration in late-stage melts or in sedimentary rocks by being transported by fluids and precipitated at a reaction front due to more reducing conditions resulting in UO_2 precipitation.

Uranium together with Th and K are presently the three elements responsible for almost all the radiogenic heat production in the Earth, therefore knowing its concentration in the mantle because the heat production in the mantle contributes to convection, plate motion, and magmatism. A novel and expensive way to measure U concentration in the Earth is with the placement of giant liquid scintillators-based detectors deep in the crust to measure geoneutrinos (McDonough and Šrámek 2014), but this will ultimately provide a better estimate of the U content of Earth.

High-Temperature Geochemistry

In subduction zones, U is mobilized by dehydration of the slab and enriches the overlying mantle wedge with U. This conclusion is supported by the low Th/U ratios and $^{230}Th/^{238}U$ showing U excesses in island arc magmas (Turner et al. 2003). Mass balance calculations and the variations in U/Th ratios indicate that the addition of slab components is a two-step process: first bulk addition of sediment or sediment melt with unfractionated U/Th followed by a fluid addition from the altered oceanic crust more enriched in U than Th resulting in U excesses in the magmas (Turner et al. 2003).

During melting, U concentrates in the melt phase together with other highly incompatible elements. The Nb/U is constant in mid-ocean ridge basalts over a wide range of concentrations indication that their behavior is very similar during melting of a peridotite and subsequent crystallization at lower pressures. Its behavior under these conditions is also very similar to Th. One of the major shallow mantle minerals able to fractionate U from Th is garnet in which $D_{Th} < D_U$.

The cycling of Th and U in the Earth through time is constrained by the Pb isotope variations of the different Earth reservoirs. An example is that Th/U of the upper mantle is lower that what is expected based its Pb-isotopic composition measured in mid-ocean ridge basalts (Elliott et al. 1999). It has been argued that a change in behavior of U is the cause of this in that the early Earth had an anoxic atmosphere and U behaved very much like Th. With the increase in oxygen of the atmosphere, U behavior on the Earth's surface changed, and presently U is preferentially lost over Th from the slab, while in the early Earth when the ocean was anoxic, U in the altered subducted slab was tetravalent. Thus, on the early Earth, there was no low Th/U flux in to the upper mantle, like there is nowadays. The recent discovery of U isotope fractionation, including on the ocean floor (Stirling et al. 2007; Weyer et al. 2008), provides a tracer for U that has been in an oxygenated environment and allows for testing the U/Th cycle (Andersen et al. 2015). Present-day MORB are heavy in $\delta^{238}U$ (-0.268 ± 0.005 ‰) versus ocean island basalts (-0.308 ± 0.005 ‰) and island arcs (~-0.4 ‰), while altered oceanic crust $\delta^{238}U$ is -0.17 ‰ with Th/U = 0.44. This is explained as preferential loss of light, mostly sediment-derived U, to the island arc while at greater depth heavier U from the altered oceanic crust which also has low Th/U. Although there is much evidence for sediment and oceanic crust recycling in OIB sources, it is argued these sources are established before the oceans were oxygenated and therefore do not have fractionated $^{235}U/^{238}U$ (Andersen et al. 2015).

Low-Temperature Geochemistry

Under oxygenated conditions, U is hexavalent and is relatively soluble in concentrations in freshwater and in the oceans is relatively high. Seawater has over 3 ppb of

U which is high compared to elements with similar behavior in magmatic systems. Groundwaters have high ^{234}U as β-decay of ^{238}U results in recoil of the daughter product ^{234}Th in the groundwater which subsequently decays with a 24.1 day half-life through ^{234}Pa to ^{234}U. This results in an excess of ^{234}U. The exact amount of excess is dependent on the nature of the aquifer, the degree of interaction between the dissolved fraction and the aquifer matrix, as well as the colloidal fraction (Porcelli and Swarzenski 2003). ^{234}U excesses in the oceans are about 15% (Chen et al. 1986). Rivers can have larger excesses, and the excess ^{234}U in groundwaters can be extreme with ($^{234}U/^{238}U$) up to 11 (Porcelli and Swarzenski 2003). In groundwater, the ^{234}U excesses have been useful in tracing flow through subsurface conduits. In marine sediment, the $^{234}U/^{238}U$ is often measured as a check on the age disequilibria involving shorter-lived U-series radionuclides. ^{234}U has the longest half-life of the daughter isotopes in the U-series decay scheme, and thus if the disequilibrium dates the time at which it is separated from seawater, then the ^{234}U should still be present.

Biological Utilization and Toxicity

In the subsurface, a large variety of bacteria, dissimilatory metal-reducing and sulfur-reducing bacteria, have the ability to reduce hexavalent uranium. These uranium reducers seem to have in common that they thrive in anaerobic conditions where the redox potential is low enough for the reduction of U (VI) to take place (Wall and Krumholz 2006). The bacterial reduction to U(IV) renders U immobile, and stimulating bacteria in the subsurface to immobilize U have been experimented with (Anderson et al. 2003) and have shown to be effective in bioremediation by containing U contamination in the subsurface.

Uranium is toxic at intake levels of 20–40 mg and can result in kidney damage and failure. Radiological toxicity is due to the U decay that produces alpha particles. Due to the limited penetration depth of alpha particles ingestion or inhalation of uranium are the main hazards.

Summary

The geochemical behavior of uranium is strongly dependent on its valence state: hexavalent U goes in solution, while tetravalent is near insoluble. Presently U is in the hexavalent state at the oxygen-rich Earth's surface. But, before the Earth's surface was oxygenated, its behavior was markedly different. U is the parent in the U-series that ultimately lead to stable lead isotopes. This provides the opportunity for dating processes over a large range of time scales. Because of its large ionic radius, U is not easily accommodated in most crystal lattices and is incompatible, concentrates in trace phases like zircon, and enters a melt early and crystallizes out late in a sequence.

Definition

Uranium decay series are the products of radioactive decay of uranium isotopes (^{235}U and ^{238}U). U decay series are an essential tool of modern geochronology for ages ranging between a few years to one million years. This is due both to the excellent temporal resolution afforded by U-series dating and the ability to measure low-level geological samples. In parallel, U-series are also powerful tracers of both low- and high-temperature processes in the Earth, providing key constraints on the rates and timescales of numerous geological processes.

Basic Principles in U-Series Geochemistry

^{238}U decays to stable ^{206}Pb via a series of α and β decays. If the decay chain is undisturbed, it reaches a steady state called secular equilibrium, and the abundance of short-lived intermediate nuclides is then controlled by their half-lives. However, this secular equilibrium can be perturbed by physical or chemical processes (e.g., crystallization, water-rock interaction, or nuclear properties) that lead to a fractionation between isotopes of the U decay series. This fractionation is the basis for U-series geochemistry. The basic equations that describe the evolution of the U-series decay chain can be written for the first nuclide (^{238}U, ^{235}U, or ^{232}Th) as follows:

$$\frac{dN_1}{dt} = -\lambda_1 N_1 \tag{1}$$

where N_1 is the number of atoms of the parent isotope (i.e., ^{238}U or ^{235}U) and λ_1 the decay constant. For the nuclides that are produced by successive decay of the parent isotope, the following equation should be used:

$$\frac{dN_{i+1}}{dt} = -\lambda_{i+1} N_{i+1} + \lambda_i N_i \tag{2}$$

Given some initial conditions, this system of ordinary differential equations can be solved analytically. The solution for the first nuclide can be integrated as:

$$N_1 = N_1^0 e^{-\lambda_1 t} \tag{3}$$

and for the second nuclide:

$$N_2 = \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1^0 \left(e^{-\lambda_1 t} - e^{-\lambda_2 t}\right) + N_2^0 e^{-\lambda_2 t} \tag{4}$$

where N_1^0 and N_2^0 are the number of atoms of nuclides 1 and 2 at t = 0. In the case of a long-lived nuclide such as ^{238}U or ^{235}U, the term $e^{-\lambda_1 t}$ is almost equal to 1. In this case, it can be shown that if the system is undisturbed, N_2 reaches a steady-state value:

$$N_2 = \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1 \tag{5}$$

Since λ_1 is small compared to λ_2, the equation can be further simplified to $\lambda_1 N_1 = \lambda_2 N_2$. This corresponds to an equality of the activity of nuclides N_i where the activity is defined as $\lambda_i N_i$. This equation can be generalized to the whole decay chain:

$$\lambda_1 N_1 \approx \lambda_2 N_2 \approx \ldots \approx \lambda_n N_n \tag{6}$$

where the subscript 1 indicates the parent nuclide (^{238}U or ^{235}U), λ_i is the decay constant for nuclide i, and N_i is the number of nuclides of i. The return to secular equilibrium is a function of time and this property can be used for age determination. Following a fractionation event between two given nuclides, the dating method is operative if there is a resolvable difference between the value measured for the daughter nuclide and the value at secular equilibrium; this corresponds to a time of the order of six half lives. Radiometric dating with

U-series is possible when the processes causing fractionation are a discrete event. When the process itself is protracted relative to the half-life of the daughter product, then it is only possible to derive a timescale for this process or alternatively its rate. In what follows, the various methods and applications of U-series nuclides are described while highlighting the most recent advances.

^{238}U-^{234}U Dating

The main principle behind the ^{238}U-^{234}U dating method is that in low-temperature environments, ^{234}U can fractionate from ^{238}U due to nuclear effects. The first part of the ^{238}U decay chain can be written as follows:

$$^{238}U \xrightarrow{\alpha} {}^{234}Th \xrightarrow{\beta^-} {}^{234}Pa \xrightarrow{\beta^-} {}^{234}U \tag{7}$$

The half-lives of the intermediate nuclides ^{234}Th and ^{234}Pa are very short (24.1 days and 6.69 h, respectively) compared with geological processes. The ^{234}Th is ejected by recoil from the site where ^{238}U was residing, and this implies that the daughter nuclide can be more labile. If the ^{238}U resided near the boundary of a grain, the ^{234}Th can be directly ejected out of the grain. Alternatively, it can be more easily leached out of the grain during weathering reactions compared with ^{238}U because it no longer sits in an energetically stable lattice site. Collectively, these effects can lead to a fractionation between ^{238}U and ^{234}U. The experiments of Kigoshi (1971) have shown that a solution in contact with a zircon can be enriched in ^{234}U relative to its secular equilibrium abundance, due to its preferential release in the solution. Leaching experiments of granite also showed that dissolution leads to ^{234}U-^{238}U fractionation (Andersen et al. 2009). If a mineral forms in equilibrium with seawater or any water whose ^{234}U/^{238}U is known and subsequently behaves as a closed system, the following equation is used to calculate its isotopic composition as a function of time:

$$\left(\frac{^{234}U}{^{238}U}\right)_t - 1 = \left(\left(\frac{^{234}U}{^{238}U}\right)_{\text{initial}} - 1\right)_{\text{initial}} e^{-\lambda t} \tag{8}$$

This equation can be inverted to obtain the time since the mineral last equilibrated with water provided the initial ratio is known (Andersen et al. 2008).

Dating Based on ^{230}Th-^{238}U and ^{231}Pa-^{235}U Disequilibrium

These dating methods are based on the existence of chemical fractionation between ^{230}Th and ^{234}U or ^{231}Pa and ^{235}U. This fractionation arises because U and Th (and Pa) behave differently in geochemical processes. For the sake of illustration, we describe the dating of carbonates. When carbonates form by precipitation from seawater, the carbonate incorporates U (^{238}U, ^{234}U, and ^{235}U) but little ^{230}Th and ^{231}Pa which have a very low abundance in seawater but also a low partition coefficient in carbonates. As a result the initial ^{230}Th/^{234}U and ^{231}Pa/^{235}U activity ratios in carbonates are close to zero. If one assumes that the system is closed and solves (Eqs. 1 and 2), one obtains:

$$\left(\frac{^{230}Th}{^{238}U}\right) = 1 - e^{-\lambda_0 t} + \left(\left(\frac{^{234}U}{^{238}U}\right) - 1\right)\left(\frac{\lambda_0}{\lambda_0 - \lambda_4}\right)\left(1 - e^{-(\lambda_4 - \lambda_0)t}\right) \tag{9}$$

$$\left(\frac{^{231}Pa}{^{235}U}\right) = 1 - e^{-\lambda_5 t} \tag{10}$$

By measuring the activity ratios of ^{230}Th/^{238}U and ^{234}U/^{238}U, the only unknown in Eq. 9 is time t, while for Eq. 10, the measurement of ^{231}Pa/^{235}U is sufficient to derive an age. These methods have been used extensively to determine the age of corals for ages as old as 1 Ma or for dating speleothems (Hu et al. 2008). The great powers of these methods have been first the ability to determine ages precisely and second to use jointly the ^{230}Th-^{234}U-^{238}U and ^{231}Pa-^{235}U dating methods using concordia approach similar to the U-Pb technique. With this approach it is possible to ascertain that the ages have not been disturbed by a later event leading to open-system behavior. In some cases, open-system behavior has been identified and this can be due to recoil effects. Using the following equations, Thompson et al. (2003) were able to correct the ages while quantitatively estimating the effect of recoil:

$$\begin{aligned}
\frac{d^{238}U}{dt} &= -\lambda_8 {}^{238}U \\
\frac{d^{234}U}{dt} &= -\lambda_4 {}^{238}U + f_4\lambda_8 {}^{238}U \\
\frac{d^{230}Th}{dt} &= -\lambda_0 {}^{230}Th + f_0\lambda_4 {}^{234}U
\end{aligned} \tag{11}$$

where f_i represents the fraction of nuclides that are not lost from the system by recoil. An evaluation of such models is given in Scholz and Mangini (2007).

Dating Magmatic Event and Magma Storage

Upon eruption, a magma crystallizes relatively rapidly, and the difference in compatibility between U-series nuclides (in this case, U, Th, Pa, Ra) can be used for dating. By analyzing mineral phases in a volcanic rock, it is possible to use an isochron approach to obtain an age. There are two main methods: (1) dating mineral crystallization with ^{230}Th-^{238}U disequilibrium (2) dating recent events with ^{226}Ra-^{230}Th disequilibrium.

For the first method, one assumes that all mineral phases remain closed system after eruption. In this case, the following equation can be used to describe the time evolution of each mineral phase/matrix (Allègre 1968):

$$\left(\frac{^{230}Th}{^{232}Th}\right) = \left(\frac{^{230}Th}{^{232}Th}\right)_0 e^{-\lambda t} + \left(\frac{^{238}U}{^{232}Th}\right)\left(1 - e^{-\lambda t}\right) \quad (12)$$

This equation is similar to Eq. 4, except that it has been normalized by the activity of ^{232}Th, which is assumed constant over the timescale of interest. An additional assumption is that all the minerals formed in isotope equilibrium (i.e., with identical ^{230}Th/^{232}Th ratios) with the melt. In numerous cases, a comparison with eruption ages was possible and it was found that the U-Th age was older than the eruption age. These observations have enabled to develop a new range of applications where U-series are used for dating magma storage and for dating phenocryst growth (e.g., Cooper and Kent 2014).

The second method based on ^{226}Ra-^{230}Th disequilibrium makes the assumption that Ra and Ba are chemical analogues, and since there is no stable isotope of ^{226}Ra, the activity of Ra is normalized to Ba to yield an equation similar to Eq. 4. There has been criticism regarding this approach, and it was subsequently extended to a new method to take into account the difference in partitioning between Ra and Ba (Cooper et al. 2001).

Tracing Mantle Melting and Melt Migration

During partial melting of the mantle, chemical equilibrium between melt and mineral phases leads to a chemical fractionation between U-Th-Ra and U-Pa, which results in a disequilibrium of the decay chains. This disequilibrium can be used as a probe of melting processes in various geodynamic settings. First, U-series disequilibria can be used to infer the rate of melting and the porosity of the mantle during melting. Second, the ^{226}Ra-^{230}Th disequilibrium has been argued to be a tracer of the rate of melt migration.

The existence of ^{230}Th-^{238}U disequilibrium in mantle-derived magmas is surprising because Th-U fractionation should be small as mineral-melt partition coefficients of these elements are low ($D \sim 10^{-3}$). For a fractionation to take place, the mantle porosity should be of the same order of magnitude as D. In turn, this observation puts strong constraints on the porosity of the mantle (ϕ) during melting. Similarly, the observations of ^{226}Ra-^{230}Th disequilibria in mantle melts indicate that melt transport was sufficiently rapid to allow the extraction of magmas on timescales that are short relative to the half-life of ^{226}Ra (1600 years).

One important aspect of the U-series disequilibria measured in mid-ocean ridge basalts (MORB) is that they are responding to the pressure dependence of U-Th partitioning. U-Th fractionation is mostly sensitive to the first few percent of melting as both elements are highly incompatible (Blundy and Wood 2003). The mineral/melt partition coefficient of U is often greater than that of Th and Pa in most minerals (see exception below). During partial melting of the mantle beneath ridges and hotspots, if melting starts in the garnet lherzolite stability field, ^{230}Th, ^{231}Pa, and ^{226}Ra are enriched in the melt relative to U, which creates a fractionation that can be used for tracing magmatic processes (Beattie 1993). In the spinel lherzolite stability field, the budget of U is mostly in clinopyroxenes, and experiments by Landwehr et al. (2001) showed that in this case, the ratio of D^U/D^{Th} is less than 1 and decreases with decreasing pressure. Thus, melting at shallower pressure should yield ^{238}U excess in the melt. ^{238}U-^{230}Th systematics in MORB show that basalts produced from a greater depth of melting have ^{230}Th excesses larger than those produced at shallower depth (Bourdon et al. 1996; Elkins et al. 2014), thereby constraining the depth of melting for MORBs.

Another key parameter that controls the degree of U-Th-Pa fractionation is the rate of melting (McKenzie 1985). In the context of adiabatic melting beneath mid-ocean ridges and intraplate volcanism, the melting rate increases with the rate of mantle upwelling. It has been shown analytically that the U-Th or U-Pa fractionation is a direct function of the rate of mantle upwelling (Bourdon and Sims 2003). Thus, an increasing melting rate leads to a smaller ^{231}Pa/^{235}U and ^{230}Th/^{238}U in the melt. Sims et al. (1999) showed that the ^{231}Pa/^{235}U and ^{230}Th/^{238}U decreased toward the center of the hotspot which they attributed to increasing mantle upwelling rates. Hotspots with larger buoyancy fluxes and faster melting rates were shown to have smaller ^{231}Pa and ^{230}Th excesses (Bourdon et al. 2006). These observations were used to map mantle upwelling rates beneath hotspots and to infer mantle temperatures.

It is worth mentioning here that the presence of pyroxenites can affect U-series systematics during melting. Notably, the garnet mode in pyroxenite is much greater than in peridotites which means the U-Th and U-Pa fractionation is enhanced and their melting rates is much greater. Thus it is important to quantify the abundance of these lithologies to interpret U-series in mantle-derived rocks (e.g., Elkins et al. 2014).

U-Series as Tracer of Water-Rock Interaction

In the surface environment, U and Ra are more soluble than Th and Pa, which means that water-rock reactions lead to fractionation of U relative to Th and Pa. In the case of

^{234}U-^{238}U, water-rock interaction leads to preferential removal of ^{234}U in the water phase. The observed fractionation can then be used to trace the timescale of water interaction in waters, aquifers, soils, or sediments. There have been a number of applications to infer the rates of chemical weathering in soils or at the scale of a basin (e.g., Dosseto et al. 2008), the rates of dissolution in sediments (Maher et al. 2004), the ages of comminution of fine grained sediments (Lee et al. 2010), and the transport timescales of sediments (Dosseto et al. 2008).

In order to infer the timescale of chemical weathering, one needs to make assumptions about the kinetics of these reactions. Experimental work has shown that first-order reaction could be used to describe the release rate of U-series nuclides in soils (e.g., Andersen et al. 2009) in the case of silicate or carbonate rocks. One can describe this process by the following equation:

$$\frac{d^{238}U}{dt} = -k_8{}^{238}U_s \tag{14}$$

$$\frac{d^{234}U_s}{dt} = \lambda_8{}^{238}U_s - (k_4 + \lambda_4)^{234}U_s \tag{15}$$

By solving a series of coupled equations describing ^{238}U-^{230}Th-^{234}U measured in solids and dissolved form, it is possible to derive both the rate and timescale of weathering. This approach has been described in more detail in Vigier et al. (2001) and Dosseto et al. (2008). It was argued by Keech et al. (2013) that a two-stage model with first-order kinetics was a better representation of observations, and this results in differences in the calculated timescales. If one assumes as in DePaolo et al. (2006) that the dominant source of ^{238}U-^{234}U fractionation is due to recoil effect, the following equation can be written:

$$\frac{d^{234}U_s}{dt} = \lambda_8{}^{238}Us - \lambda_8 f_\alpha{}^{238}Us - \lambda_4{}^{234}U_s \tag{16}$$

where f_α represents the fraction of recoil nuclide that are ejected from the solid. By solving this equation, one can derive the age of "mineral comminution." Several studies have attempted to use this approach, and although a correct timescale can be obtained (Lee et al. 2010; Handley et al. 2013), there could be complications, owing to the fact that ^{234}U-^{238}U can be fractionated during leaching (Andersen et al. 2009) and not simply due to recoil.

Applications in the Field of Oceanography

The U-series nuclides (mainly ^{230}Th and ^{231}Pa) have become particularly powerful tools to study particle scavenging, ocean circulation, and paleoproductivity. The solubilities of Pa and Th in seawater are extremely low, and it is expected that the abundances of ^{230}Th and ^{231}Pa should be directly linked to their in situ production by decay of ^{238}U and ^{235}U. This ratio can be modified by adsorption of Th and Pa onto biogenic particles, and it has been found experimentally (e.g., Roberts et al. 2009) that the adsorption of Pa is smaller than that of Th. As a consequence, the residence time of Pa in the oceans is greater than that of Th, and this difference in adsorption properties yields variations in Pa/Th ratios in water masses relative to the production ratio. Variations in the biological productivity of the oceans are correlated with the flux of biogenic particles, and it has been found that the Pa/Th ratio increases with biogenic particle flux (Kumar et al. 1995). Therefore, this ratio measured on sediments can be used as a proxy for paleoproductivity. Most often, this proxy is not used in isolation and it is often coupled with models of paleocirculation (Siddall et al. 2005).

Another application of U-series in the oceans is the possibility to determine groundwater fluxes from continental margins to the oceans. During decay of ^{230}Th contained in solid particles, a fraction of ^{226}Ra can be ejected into the sediment pores which leads to an enhancement of this nuclide inside sediments. If freshwater circulates through the sediment, this ^{226}Ra can be fluxed out toward the oceans. This results in a local increases in ^{226}Ra concentration that can be directly scaled to the flux of groundwater, and by measuring gradients in ^{226}Ra along a shoreline, it is possible to quantify the submarine groundwater discharge (Moore 1996).

Summary

The radioactive decay chain of U and its daughters evolve to a state of secular equilibrium at a predictable rate. The extent of disequilibrium between members of the decay series can not only provide a geochronology tool for dating events such as crystallization of a magma but also provide insights into such diverse processes as mantle upwelling and melting, biological productivity, and groundwater flux to the oceans.

Van der Waals Force

Taku Tsuchiya
Geodynamics Research Center, Ehime University, Matsuyama, Ehime, Japan

Synonyms

London dispersion force

Definition

The van der Waals force is the term used to describe weak but general forces acting between neutral atoms or molecules. Forces due to covalent bonds or electrostatic interactions between ions or ionic groups with one another or with neutral molecules are not included.

Description

This force was first introduced by van der Waals in 1873 as an attractive force among neutral atoms to account for the equation of state of non-ideal actual gases. Although he did not provide its detailed mechanisms, three different types of interactions with different physical origins have later been proposed as van der Waals force: (1) the dipole-dipole interaction, (2) the dipole-induced dipole interaction, and (3) the instantaneous dipole-induced dipole interaction (London dispersion interaction) (van Oss et al. 1988).

Among these three, the first two are found with molecules that have permanent dipoles. Only the London interaction is universal, being present in non-polarized atom-atom interactions or molecule-molecule interactions as well, and is predominantly important between the macroscopic bodies in condensed systems. Thus, the London force is responsible for bonding in solid-state rare gases and organic molecules. It is also responsible for bonding between non-charged carbon layers in graphite and in electrically neutral silicate and oxide layers in clay minerals and micas. The London force is a force caused by the dipole moments between an instantaneous dipole on one atom or molecule and the induced dipole on the neighboring ones by the instantaneous dipole. The system experiences this as an attractive van der Waals force. London used a quantum-mechanical theory based on second-order perturbation theory with charge fluctuations in one part of an atomic system that are electrodynamically correlated with charge fluctuations in another (London 1937).

There are empirical and semiempirical accounts for the van der Waals or London dispersion forces that rely on the asymptotical form $-1/R^6$ for atoms or molecules, where R is the distance between the nuclear centers of mass (Kittel 1991). This asymptotical form has been widely used in molecular simulations using pairwise interatomic model potentials. However, the London dispersion interactions constitute a quantum-mechanical phenomenon, so that their correct values at important distances like the van der Waals bond lengths are substantially different from those predicted by the asymptotic forms. Since the van der Waals force at one point depends on the charge events at another region and is a truly nonlocal correlation effect, high-level (time-consuming) quantum-mechanical (wave function) approaches were required for its quantitative evaluations (e.g., Tsuzuki et al. 2002). Due to recent developments of a practical functional form for the nonlocal correlations between electrons, density-functional theory (DFT), which has long since proven successful for dense matter and is more efficient compared to wavefunction approaches, has been extended to sparse matter (atoms or molecules with large separations across marginal charge density regions) (Dion et al. 2004; Thonhauser et al. 2007) and applied to various relevant systems, including layered systems like graphite, dimers of benzene, polymer, and the structure of DNA with intercalators. Studies of

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

minerals with this modern technique remain limited so far and future applications are expected.

Summary

The van der Waals force is the term used to describe weak but general forces acting between neutral atoms or molecules. The London dispersion interaction in particular constitutes a quantum-mechanical phenomenon. Practical techniques to evaluate this interaction quantitatively have been developed recently, but applications to minerals are still limited so far.

Properties

Vanadium (chemical symbol, V) is a d-block transition metal, silver in color, appearing in the first long period of the periodic table between titanium and chromium. Vanadium has two stable isotopes: ^{50}V and ^{51}V, with atomic abundance of 0.25% and 99.75%, respectively. Vanadium has several oxidation forms (between 2+ and 5+). In the lithosphere, V occurs as reducing V(III) form, whereas in oxidizing conditions V prevails under V(IV) form. Vanadium(II) is particularly unstable in the environment. Vanadium(III) is more stable than V(II), but it is also gradually oxidized by the air or dissolved oxygen. Vanadium(V) is expected to be the prevailing form in waters exposed to atmospheric oxygen, whereas V(IV) may be present in reducing environments. Depending upon geometry and environment, V ionic radii vary between 36 pm and 79 pm. Vanadium has a high melting point of 1910 °C and is a mildly incompatible, refractory, lithophile (siderophile in the iron core and chondrites) element. Vanadium has an electronegativity of 1.63 on the Pauling scale and displays a first ionization potential of 6.74 eV. More details can be found in Richards (2006) and Haynes (2015).

History and Use

Vanadium was first discovered by del Rio in 1801 and was incorrectly considered as impure chromium. Vanadium was rediscovered and named by Sefström in 1830 after the Scandinavian goddess Vanadis. In 1867, Roscoe isolated V in nearly pure form by reducing V chloride with hydrogen. Vanadium of high purity (99.3–99.8%) was not produced until 1927. The V redox chemistry and its specific application

to renewable energy technologies (e.g., vanadium redox battery; a type of rechargeable flow battery using V in different oxidation states to store chemical potential energy) have already add to the demand for this element and will definitely continue to increase in the near future. Vanadium demand for construction materials is the greatest consumer of mined V - (Moskalyk and Alfantazi 2003). Indeed, vanadium is the most widely used alloying element for strengthening steels employed in buildings and bridges. Vanadium volume that is cycled through terrestrial and aquatic reservoirs can thus be expected to further growth. It results in uncontrolled V releases in the environment, and environmental issues appear in developing and developed countries (Imtiaz et al. 2015).

Geochemical Behavior

Widely and sparsely distributed, V is not found as the free metal in nature. It originates from primary sources such as ores (i.e., iron oxides deposits), metallurgical slags (i.e., processing of U and Ti ores), and petroleum residues. Other sources include vanadiferous sandstones, bauxite, coals, or oil shales.

Vanadium is widely distributed in igneous and sedimentary rocks and minerals. Among more than fifty minerals, carnotite [$K_2(UO_2)_2(VO_4)_2.3H_2O$], roscoelite [$KV^{3+}{}_2(Si_3Al)O_{10}(OH)_2$], vanadinite [$Pb_5(VO_4)_3Cl$], mottramite [$PbCu(VO_4)(OH)$], and patrónite ($VS_4$) are the most important V-carriers. It is also present in some crude oils as organic complexes. Its average content in the Earth's crust is approximately 138 ppm and is similar to that of Zn and Ni. It is, however, more dispersed in the crust than either of those elements, and concentrated mineral deposits are consequently rare. The average V contents of CI chondrites range from 54.6 ppm to 56.5 ppm. The silicate Earth has a V content of 86 ppm, the bulk Earth of 105 ppm, whereas its content in the metallic core is slightly higher (150 ppm). Vanadium contents in the bulk continental crust vary significantly from 96 ppm to 230 ppm. These aspects have been further reviewed by McDonough (2014), Palme et al. (2014), and Rudnick and Gao (2014).

Historically, geochemists' interest in vanadium has derived from the occurrence of variable redox states in Earth surface environments, +3, +4, +5, and as a consequence its application as a redox indicator (Huang et al. 2015). Indeed, V chemical speciation and solubility are strong functions of pH and Eh conditions. Incorporation of reduced V species (III, IV) in clays and other secondary minerals provides a useful redox indicator for past anoxic conditions. Moreover, V behaves as an incompatible element because V(III) is preferentially incorporated into crystals: V-bearing minerals which crystallized in equilibrium with a low fO_2 magma have a higher V content than crystals from the same magma with high fO_2 (Mallmann and O'Neill 2009). It results in an increasing interest in V partitioning during high temperature – high pressure magma differentiation processes. Studies on V partitioning among Earth's crustal reservoirs have provided critical insights into the interaction and evolution of these reservoirs. Vanadium depletion in the silicate Earth is explained by it preferential partitioning into the metallic core during "deep magma ocean" process (at high pressure and low fO_2; Wood et al. 2006). The core could contain half of the total V budget of the bulk Earth (McDonough 2014). Perspectives to exploit V stable isotope chemistry are considered: Wu et al. (2015) proposed first-principles calculations that predict V isotopes fractionation among V species with different valences in aqueous systems and during sorption of V(V) to goethite.

Vanadium is also a naturally occurring element in air, soil, plants, and water. The concentration of dissolved V in natural freshwater and seawater is generally several mg/L or lower (Bruland et al. 2014; Gaillardet et al. 2014). Vanadium concentrations in marine and nonmarine sediments are generally below 100 ppm, reflecting a net accumulation from the aqueous phase. Vanadium in trace amounts represents an essential element for normal cell growth, but it may cause adverse effects when its concentration is much greater than a few tenths of μg/L (Chatterjee 2009). Most data on the release of V into the environment have been related to industrial activities, especially from oil refineries and power plants using V-rich fuel oil, and coal crude oil is enriched in V with respect to many other trace elements, with concentrations occasionally exceeding 1 mg/L. Thus, the fraction of dissolved V in surface waters might be an environmental indicator of oil combustion or pollution (Hope 2008). Such pollution sources may be responsible for appreciable amounts of V into the environment, well above the natural background levels associated with rock weathering and sediment leaching. Fluvial dissolved V concentrations might also be indicative of the types of rocks being weathered or of the nature of the involved weathering processes. Weathering rate and source rock type, rather than solution chemistry or anthropogenic influences, appeared to be the important controlling factors on fluvial dissolved V concentrations (Hope 2008).

The oxidation rate of V(IV) to V(V) and the equilibrium between these two species in aqueous solution will regulate V prevalence in water (Pourret et al. 2012). It further depends on several factors, such as pH, V concentration, redox potential, ionic strength of the aqueous system, and biological activity. In water, V(IV) is commonly present as a vanadyl cation [VO^{2+}, $VO(OH)^{+}$], whereas V(V) exists as a vanadate oxyanion ($H_2VO_4{}^{-}$, $HVO_4{}^{2-}$). VO^{2+} is strongly adsorbed onto solid phases, including organic and oxyhydroxide phases. Adsorption of anionic V ($H_2VO_4{}^{-}$, $HVO_4{}^{2-}$) is much lower than the cations; however, VO^{2+} solubility may be greatly increased through complexation with organic matter. Whereas V(IV) is not thermodynamically stable at

pH > 7, complexation by various organic and inorganic species may considerably increase its stability. Eventually, V(V) oxidation state ion is more toxic than V(IV) ion one.

Biological Utilization and Toxicity

Whereas low concentrations of V are required for plants to positively influence chlorophyll synthesis, K consumption, or N assimilation, higher V concentrations are toxic as they cause chlorosis and limit growth. At trace amounts V is essential for normal cell growth, whereas possibly toxic at higher concentrations, especially when occurring as pentoxide (Rehder 2008). Chronic exposure may result in inflammation of bronchi and trachea, eyes and skin irritation, pulmonary edema, and systemic poisoning (Mukherjee et al. 2004).

Summary

Vanadium's occurrence receives more attention as the global demand for V increases. However, its prevalence in environment becomes a new critical issue. Vanadium has been suggested to be a potentially dangerous pollutant, and the United States Environmental Protection Agency classifies V in the priority list of environmental risk elements. Fixing the environmental issue of V is constrained by the limited understanding of V biogeochemistry relative to other d-block transition metals. A better understanding of V biogeochemical behavior may support to assess the risk to the environment and to human health and to assist in developing new remediation tools.

Definition

The term "volcanic gas" identifies the fluid gas phase released by active volcanoes, both during eruption and quiescence. Compositionally, volcanic gases are molecular combinations of four major elements (H, C, O, and S) but also include a variety of minor (Cl, F, N, He, Ne, and Ar) to trace components. Being generally water-dominated, volcanic gases show a spread of compositions, reflecting a

combination of source processes (magma and its geodynamic context) and interactions with local hydrothermal or hydrologic systems. Volcanic gases can be schematically distinguished among (i) "magmatic gases", being sourced by a relatively shallow magmatic source, are hot (>500 °C), and rich in SO_2 and halogens (HCl and HF), whereas (ii) "hydrothermal gases", being mostly contributed by magmatic gas-heated boiling aquifer(s), are cool, and richer in steam, CH_4, and H_2S (and virtually HCl- and HF-free). Finally, soil gases, dominated by CO_2, make the diffuse, low-temperature emissions occurring through the flanks and faults on active volcanoes.

In the Earth's interior, the volatiles species of the H-C-O-S system and the magma are intimately related since magma concentrates volatile species and volatiles trigger melting of rocks. The production of volcanic gases results from the decrease in the solubility of H-C-O-S species in melts as pressure decreases: as the magma rises from the mantle through the crust, volatile components are increasingly transferred from the melt into a vapor phase becoming volcanic gases at the surface.

Our understanding of the compositions and fluxes of volcanic gases arises from two approaches: (i) direct measurements involving in situ or remote sampling and (ii) calculations based on lava abundances in H, C, O, and S and equilibrium partition coefficients between melt and fluid. Geochemists using approaches (i) and (ii) broadly agree on the composition of volcanic gases and how it changes with temperature (magmatic vs. hydrothermal), with geodynamics (arcs, hotspots, ridges, and rifts), and with eruptive dynamics (submarine, subaerial, explosive, and effusive). The issue of gas fluxes is, however, more debated since (i) volcanoes emit gas during quiescent and eruptive periods, within their crater and on their flanks making a global and integrated assessment tentative and (ii) most of magma produced in the Earth does not erupt but remains at depth as intrusive solidifying body, whose contribution to degassing is difficult to quantify; finally, the dominant part of volcanism on Earth, which is produced at mid-ocean ridges, is submarine and ridge volcanic gases are inaccessible for sampling, implying that only indirect reconstructions allow us to estimate fluxes of volcanic gases at ridges.

Scientific Interests

Volcanic gases are studied for several reasons corresponding to several processes ranging from planetary to regional scales and occurring at various timescales. Integrated over geological times, the flux of volcanic gases is contributing to the regulation of surficial processes, including long-term climate, chemistry of surface waters, and biogeochemical processes including photosynthesis (Holland 2002; Halevy et al. 2010; Gaillard et al. 2011). Noteworthy, this regulating role has been perturbed through the ages of the Earth during the emplacement of several large magmatic provinces, producing over millions of years a tremendous amount of H, C, O, and S species with dramatic impacts on the environment recorded as mass extinctions (Iacono-Marziano et al. 2012; Self et al. 2014). At the timescale of single eruptive events, catastrophic eruptions are also able to emit large amounts of reactive gas species perturbing the chemistry of the atmosphere and stratosphere with immediate climatic effects (Robock 2000). At very short timescale, volcano monitoring constitutes a very active field on volcanic gas research. It involves using the chemical compositions of volcanic gases and their changes with time to probe the status of the magma stored at depth and to track potential changes of this status. If acquired at a sufficient temporal resolution, this chemical message can be deciphered in terms of eruptive dynamics with critical implications for mitigation of volcanic risk (Saccorotti et al. 2014). As a notable example, volcanic gas CO_2/SO_2 ratios and plume CO_2 flux emissions have recently been monitored in great details and have both shown clear precursory increases prior to eruption, reflecting pre-eruptive, deep degassing of bubble-rich magmas ascending in the crust (Aiuppa et al. 2007). Finally, volcanic gases provide key information on volatile abundances and behaviors in magmas, on the source mantle (Wallace et al. 2015), on the cycling and fate of volatiles during geodynamic processes (e.g., during subduction), and on magma-crust processes (Iacono-Marziano et al. 2012; Fischer and Chiodini 2015).

Chemical and Isotopic Composition

The composition of volcanic gases depends on (and yields insights onto) the processes that occur throughout the entire magma evolution path, from generation in the mantle, through ascent-storage in the crust, and eventually eruption.

High-temperature (>500 °C) volcanic gases have compositions that most strictly reflect conditions (volatile content and degassing history) of the source magmas. Compositionally, these so-called "magmatic" gases are typically water-dominated, with carbon dioxide (CO_2) and sulfur dioxide (SO_2) coming next in order of abundance. H_2O, CO_2, and SO_2, taken together, normally make >99 mol% of the magmatic gas phase, but the levels of H_2O enrichment vary from volcano to volcano and with geodynamic/tectonic setting. The "arc" magmatic gases that are degassed at convergent margin volcanoes, for example, are systematically more hydrous ($H_2O \gg 90$ mol%) than those seen at divergent/within plate volcanoes (where H_2O can be as low as 50 mol%) (Symonds et al. 1994; Giggenbach 1996; Oppenheimer et al. 2014). This compositional diversity is

commonly ascribed to the involvement of a recycled seawater component in arc volcanism, as isotopic (δD and $\delta^{18}O$) determinations on arc magmatic gases suggest (Taran et al. 1989; Giggenbach 1992). The contribution of recycled "sedimentary" fluids, issuing from the subducted slab, to the arc magmatic gas budget is also proved by the more HCl-rich (but HF-poor) nature of arc gases (relative to "multi-component nonarc" gases) and by their carbon (CO_2), sulfur (SO_2), and nitrogen (N_2) isotopic compositions that are intermediate between mantle and crustal sediment signatures (Fischer et al. 2002; Marty 2012; Kagoshima et al. 2015). Magmatic gases also contain appreciable amounts of H_2, CO, and N_2 (typically at 0.01 to <1 mol% level) and minor to trace amounts of noble gases (He, Ar) and heavy metals. Noble gas (He, in particular) isotopes, that are unaffected by degassing or gas-water reactions, have been particularly useful in constraining the relative contributions of the mantle, the crust, and slab fluids to arc magmatic gases (Hilton et al. 2002; Sano and Fischer 2013).

For volcanic systems in quiescent time (i.e., the majority of the Holocene volcanoes), the magma is stored at depth and the expelled magmatic gases cool and interact with crustal/meteoric fluids, so that the composition of the fluids finally reaching the surface is irremediably altered. The resulting "hydrothermal" gas discharges are compositionally distinct from "magmatic" gases, being more hydrous (H_2O often >98% mol%) and depleted in water-soluble compounds (e.g., HCl and HF) (Symonds et al. 2001). Hydrothermal gases are also typically SO_2-free, this species being converted into H_2S by gas-water-rock redox reactions taking place in the hydrothermal envelope. Gas/solutions/minerals reactions also affect carbon and hydrogen compounds, favoring the low-temperature species CH_4 and H_2O (Chiodini and Marini 1998). Hydrothermal gases keep memory of the isotopic composition of the source magma (particularly for noble gases and, partially, for carbon) but also record a larger contribution of crustal fluids and/or the impact of isotopic fractionations during low-temperature gas-water-rock interactions (Fischer and Chiodini 2015).

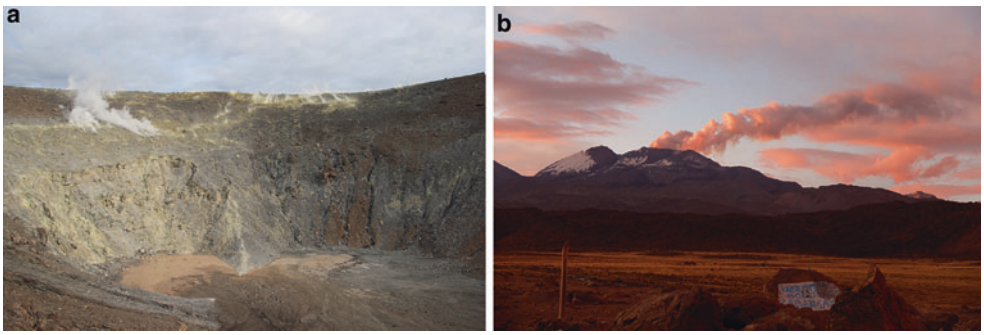
Techniques for Volcanic Gas Measurements and Volcano Monitoring

The multicomponent nature of volcanic gases, and their diversity of emission modes, requires that a combination of gas sampling/sensing techniques is used by geochemists.

Since the beginning of the nineteenth century, direct sampling techniques have been used to collect gas from fumaroles/vents (Fig. 1). A variety of sampling apparatus have been utilized, but the so-called "Giggenbach bottle" technique (pioneered by Werner Giggenbach in the 1970s) is the most common. This method employs evacuated glass flasks to collect acid components (CO_2, SO_2, H_2S, HCl, and HF) in a sodium hydroxide solution and noncondensable gases (N_2, O_2, H_2, CO, and noble gases) in the headspace of the bottle (Giggenbach and Gougel 1989; Symonds et al. 1994). Field collection is followed by analysis in a laboratory by standard wet chemical methods and gas chromatography.

Since the late 1960s, degassing associated to erupting volcanoes has been assessed by remote sensing observations (e.g., measurement from distal locations; Carn 2015). This has allowed the characterisation of large, open-vent gas emissions through volcanic plumes (Fig. 1b), and the quantification of volcanic gas fluxes (e.g., mass of gas released per unit time) by deriving integrated gas column amount along the cross section of a plume. All such remote sensing methods work basing upon the principles of spectroscopy, e.g., they rely upon the interaction of chemical bonds in volcanic gas species and a (natural or artificial) light source. Scattered ultraviolet (UV) sunlight, measured from ground or aircraft, has been used as the source for measuring SO_2 fluxes from volcanoes using COrrelation SPECtrometers (COSPEC). More recently, the advent of more compact and less power consuming scanning differential optical adsorption spectrometers (DOAS) has revolutionized our ability to make fully automated, continuous gas observations leading to unprecedented long SO_2 flux records of high spatial-time resolution (Galle et al. 2003; Carn 2015).

The recent introduction of Fourier-transform IR (FTIR) spectroscopy in volcanology has paved the way to real-time sensing of all major volcanic gas species (Allard et al. 2005;



Volcanic Gases, Fig. 1 The two main modes of volcanic gas release: (**a**) fumarolic vent emissions at a quiescent closed-vent volcanoes (Vulcano Island, Italy); (**b**) an example of open-vent crater plume degassing (Sabancaya volcano, Perù) (Photos: A. Aiuppa)

Burton et al. 2007), but its use is restricted to a relatively limited number of volcano observatories, due to the expense of the instrument and high level of expertise required to interpret the data. More compact, cheaper, rugged, and user-friendly sensor units, commonly termed Multi-GAS sensors (Shinohara 2005; Aiuppa et al. 2007), are increasingly used to monitor the actual mixing ratios of volatile species (H_2O, CO_2, SO_2, H_2S, HCl, H_2) in volcanic plumes with a temporal resolution of a few seconds. At many volcanoes worldwide, these crater rim installations are complemented by use of commercial soil degassing units (based upon the "accumulation chamber" principle; Chiodini et al. 1998), targeting the "diffuse" CO_2 flux emissions issuing from soils and steaming grounds along faulted volcanic flanks and/or solfataras.

In order to address volcanic gases at a planetary scale, future direction will require measuring gas from space. It was in the 1980s that a new era in volcanology opened when the Total Ozone Mapping Spectrometer (TOMS) contributed the first satellite-based measurements of SO_2 emitted by explosive volcanic eruptions (Krueger 1983). Space-borne UV spectrometers (e.g., the Ozone Monitoring Instrument, OMI, on NASA's Aura satellite) detects SO_2 emissions from large volcanic eruptions and effectively contribute to monitoring passively degassing volcanoes, particularly those located in remote or unexplored regions (Carn 2015). The major challenge of satellites remains to extend observations to detection/quantification of other relevant volcanic species that are less abundant (H_2S, CO) or more difficult to investigate (CO_2).

Summary

Volcanic degassing, transferring H-C-O-S species from the innermost planet to the atmosphere, is a key step in the geodynamic cycle of volatiles and governs a variety of processes determining the habitability of a planetary environment. Present-day fluxes remain difficult to precisely assess, and establishing the preindustrial baseline for fluxes of C and S remains critical for understanding the dynamic nature of our planet. Several recent technical progresses allow precise field analyses; but the variety of physical expression of volcanic gases (e.g., plumes during eruption, crater fumaroles during quiescent time and diffusive emission on the flanks of volcanoes) complicates the interpretation of this chemical message sent from magma at depth. Satellite-based observations will certainly provide a planetary view of volcanic degassing that is difficult to capture with regional field data collection. Finally, fundamental research on the fate and behavior of volatiles at depth is needed to establish a theoretical framework that can be tested by empirical field observations.

Volcanism

Nick Rogers
School of Environment, Earth and Ecosystem Sciences, The Open University, Milton Keynes, UK

Definition

Volcanism is the surface expression on any planetary body of the production, migration, and eruption of molten rock or magma from that body's interior.

Introduction

Magma comprises three phases – solid, vapor, and liquid – in the form of crystals and bubbles suspended in a liquid, usually molten silicate rock. The production of magma implies that any volcanically active planetary body has a source of internal energy. On Earth that source of internal energy is a combination of radiogenic heat from the long-lived radioisotopes ^{235}U, ^{238}U, ^{232}Th, and ^{40}K and residual primordial heat from the Earth's formation and core segregation. On other bodies, such as Io, one of the larger Jovian moons, the heat is derived from tidal distortions caused by its proximity to Jupiter. Other moons in the solar system show evidence of volcanism caused by the melting of thick layers of ice.

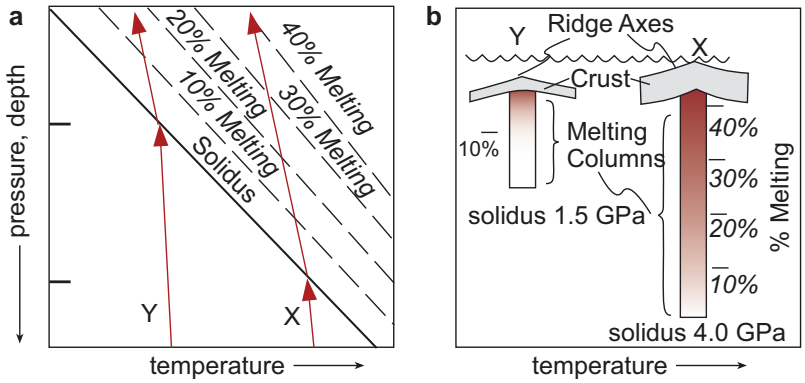
All four of the inner planets of the solar system and the Earth's moon show evidence of volcanic processes in the past, but only Earth has unequivocal evidence of current volcanic activity. It is known from a combination of remote sensing, direct observation, and meteorite samples that volcanic activity on these five planetary bodies is almost exclusively silicate based and is caused by the partial melting of their mantle and crustal layers.

Volcanism and Plate Tectonics

Modern day volcanism on Earth is intimately linked to plate tectonics and mantle convection. Volcanic rocks are found at both convergent and divergent plate margins, but the compositions of the volcanic rocks from these two tectonic environments show distinctive characteristics that reflect the processes of their generation and subsequent evolution. In addition volcanism is found away from plate margins, in so-called intraplate environments, and volcanic rocks from these locations form a third distinctive compositional group.

The dominant form of volcanic activity today is related to the eruption of basaltic magma, formed by partial melting of the mantle. Melting can be triggered by two dominant processes: decompression and the introduction of hydrous fluids. Once produced, melt migrates toward the surface as a result of matrix compaction and upward flow because the melt is less dense than the solid residue.

Decompression melting is the dominant process at divergent plate margins, where the separation of two lithospheric plates induces the underlying mantle to rise toward the surface. In so doing the mantle rises adiabatically and melts as soon as the pressure falls sufficiently, at a depth of around 75 km, and continues to the base of the newly formed oceanic crust at about 10 km (Fig. 1). The resulting magma is known as mid-ocean ridge basalt or MORB (Gale et al. 2014). The total volume of oceanic crust added by magmatic process at

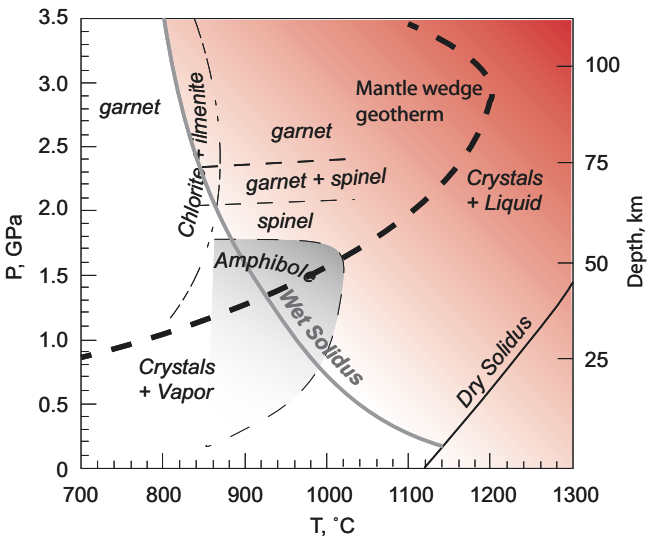


Volcanism, Fig. 1 (**a**) Pressure (depth) – temperature relationship for adiabatically upwelling mantle undergoing melting. The example Y represents the situation beneath ocean ridges where mantle of ambient temperature rises and intersects the P-T conditions on the mantle solidus at about 75 km depth. The case for hotter mantle, as in a mantle plume, is illustrated by curve X. This intersects the solidus at a higher pressure and temperature and can produce much greater volumes of melt. However, if the melting regime is overlain by oceanic lithosphere, then the top of the melting column occurs at a greater depth than shown, and the resulting melt fractions are smaller. (**b**) Illustrates the relationship between axial depth, crustal thickness, melting, and mantle temperature. Hotter mantle X produces more melt, and so a thicker crust and the ridge is maintained at a higher elevation by its buoyancy (Modified after Klein and Langmuir (1987) and White (2013))

constructive margins is between 10 and 20 km^3 per year, making ocean ridge volcanism the most widespread and extensive on Earth, yet much of this occurs unseen beneath the oceans.

Beneath ocean islands, which form on older, thicker lithosphere, the mantle temperature must be greater than that beneath mid-ocean ridges for melting to occur (Fig. 1). Such ocean island basalts (OIB) are poorer in silica than MORB but richer in incompatible elements, reflecting greater pressures and temperatures of melt generation and smaller melt fractions (Niu et al. 2011). These observations, together with the time progressive nature of volcanism along chains of ocean islands, have led to the concept of mantle plumes underlying many ocean islands.

Melting associated with convergent plate margins is related to the release of volatile components, especially water, from the subducted oceanic lithosphere, or slab, which percolate upward through the overlying mantle wedge. Water has the effect of dramatically reducing the solidus temperature of peridotite by as much as 300 °C so the introduction of water by itself is capable of inducing melting in ambient mantle (Katz et al. 2003) (Fig. 2). This can be further enhanced by decompression if tectonic activity causes the mantle to rise, for example, in a back-arc environment (Kelley et al. 2010).



Volcanism, Fig. 2 Phase diagram for the system peridotite – water (H_2O). The dry solidus represents the melting temperature of peridotite in the absence of water, whereas the wet solidus represents the conditions under which peridotite will melt in the presence of free water – which can be many hundreds of degrees cooler than dry mantle. Other curved lines represent the stabilities of critical phases, while the *bold-dashed line* labeled mantle wedge geotherm is an example of the temperature variation with depth in the mantle above a subducting slab. The drop to lower temperatures at high pressure illustrates the cooling effect of the slab. Note how, the wedge geotherm passes through the region of melt plus crystals for peridotite + H_2O (After Grove et al. (2006) and White (2013). Wedge geotherm taken from van Keken et al. (2002))

Magma Evolution and Volcanic Eruptions

As magma emerges from the melting regime and rises toward the surface, it changes in composition as a result of cooling and crystallization. This is envisaged to happen largely in magma chambers that form when magma encounters discontinuities in the surrounding geology (e.g., the crust-mantle boundary). During cooling mafic minerals crystallize and drive the liquid toward compositions with lower MgO, CaO, and FeO and higher SiO_2, Al_2O_3, and alkali elements. These changes reduce the density of the magma which can

then rise further toward the surface, possibly halting in higher level magma chambers en route to the surface where the magma is eventually erupted as a volcanic rock (see Cashman and Sparks 2013).

Magma composition has a profound influence on both the eruptive style of volcanic rocks and the morphology of volcanic structures. Basaltic magmas form at high temperatures and with low volatile and modest SiO_2 contents, resulting in a low viscosity. They therefore tend to erupt effusively, forming sheetlike lava flows from shield volcanoes with shallow slopes. Small-volume effusive eruptions, such as those on Iceland and Hawaii, can be observed from close proximity, although they are not without their own hazards. However, larger effusive eruptions, such as the Laki fissure eruption on Iceland in 1783–1784 lasted 8 months, had a final erupted volume of 14 km^3, and caused considerable environmental and societal effects both locally on Iceland and more distantly, especially in Northern Europe as a consequence of the large masses of sulfur dioxide (120 Mt) and other gases released (Thordarson and Self 2003).

Evolved magmas rich in silica and alumina, such as andesites and rhyolites, erupt at lower temperatures and tend to have higher viscosities because of the formation of molecular networks and polymerization of Si-O and Al-O bonds. Hence, andesitic lavas produce steeper-sided cones, so-called stratovolcanoes, such as Mt Fuji in Japan. The process of differentiation has the additional effect of increasing the volatile content of a magma so that on eruption volatiles are released explosively and fragment the magma. Thus, andesites, rhyolites, and other volatile-rich magmas often erupt explosively (Fig. 3), and the resultant deposit is unconsolidated and generally described as tephra. Tephra fragments are subdivided into ash, lapilli, and bombs according to their sizes, and if the deposit becomes lithified, as a result of heating and compaction, then it is termed a pyroclastic rock.

History is scattered with records of these violent, explosive eruptions of volatile-charged magmas. That of Vesuvius in 79 CE was observed by Pliny the Younger who is credited with producing the first written description of a major volcanic event and gave his name to that type of eruption – Plinian. Plinian eruptions inject volcanic ash and gases high into the atmosphere as the large magma chamber rapidly empties. They also produce density currents or surges that are turbulent mixtures of pumice and hot gases known as ignimbrites that move down the flanks of a volcano at remarkably high speeds. Plinian eruptions frequently remove large parts of the volcanic structure, leaving hollowed out circular depressions in the center of the residual volcano known as caldera.

Plinian eruptions are spectacular and often hit the news headlines, for example, Mt St Helens in the USA (1980) and Mt Pinatubo in the Philippines (1991) were both extensively covered by the media. Even though Mt Pinatubo was the second largest eruption of the twentieth century, the death toll was less than 1000, and while any death caused by a natural hazard is to be regretted, volcanoes rank far behind hurricanes, earthquakes, floods, and famine as a source of human casualties and misery. Pinatubo is dwarfed by the 1815 eruption of Tambora in Indonesia, which at 50 km^3 volume was the largest in recent history. It had a global reach, triggering the "year without a summer" in 1816 (Oppenheimer 2003).

Further back in time, prehistoric eruptions from so-called super-volcanoes (Miller and Wark 2008) are of much greater volume: Taupo in New Zealand erupted 530 km^3 of rhyolite 25.4 +/− 0.2 ka BP (Wilson 2008), and eruptions exceeding 1000 km^3 were associated with the Yellowstone Caldera at 2.1 Ma, 1.3 Ma, and 650 ka (Christiansen 2001). The eruption of Toba in Indonesia (69 ka BP) erupted an estimated 2800 km^3 of volcanic material, and its effects on global climate are considered by some to have influenced human

Volcanism, Fig. 3 The early stage of an eruption of Sarychev Peak, Matua Island, Kuril Islands, as photographed from the International Space Station on June 12, 2009. This is an example of a Plinian or sub-Plinian eruption showing the early stage of the development of the eruption column, already 3–5 km in height and capped by a developing mushroom head. The pale gray cloud at the base of the column represents a pyroclastic flow, moving rapidly down the flanks of the volcano (NASA) http://eoimages.gsfc.nasa.gov/images/imagerecords/38000/38985/ISS020-E-09048_lrg.jpg

evolution (Petraglia et al. 2012). The effects of such a super-eruption today would be global and probably catastrophic, potentially plunging the world into a "nuclear winter" and disrupting trade and communication for years (Self 2006).

The deeper geological record includes evidence of yet more voluminous eruptions of both basaltic and rhyolitic composition (Bryan and Ferrari 2013). The former are often termed flood basalts or large igneous provinces (LIP) and may have volumes in excess of 10^6 km^3 erupted over periods of less than 10^6 years. Examples include the Deccan traps of India and the Karoo flood basalts of Southern Africa, and within these provinces individual eruptions can have volumes of hundreds of km^3. LIP events closely coincide with major breaks in the stratigraphic and fossil record and have been implicated as the causes of significant global environmental change.

Volcanism for Geochemistry

Volcanism provides one of the most effective windows on the composition of the Earth's interior, particularly the use of basaltic volcanism to map variations in the composition of the upper mantle. From the earliest analyses of trace elements and radiogenic isotopes in oceanic basalts, it was apparent that there are significant differences in the composition of MORB and OIB. The depletion of the most incompatible elements in MORB relative to enrichments of the same elements in OIB is reflected in radiogenic isotope ratios which implies that the depletion of the MORB source is long-lived. These observations rapidly evolved into models in which the uppermost mantle has been depleted by the extraction of the continental crust over geological time.

Subsequently, subtle variations have been observed in both MORB and OIB that have allowed discrete areas of particular mantle compositions to be mapped out (e.g., the DUPAL anomaly in the Southern Indian Ocean). The variation in OIB compositions has been interpreted as resulting from the mixing of various putative end-member compositions in the mantle (EM1, EM2, HiMu, etc.) that are now thought to be the imprint of recycled sediment and oceanic crust (White 2015). Variations in titanium and compatible trace elements in OIB lead to similar conclusions (Prytulak and Elliott 2007; Sobolev et al. 2007). The identification of possibly primordial material in mantle plumes, characterized by enrichments of ^{3}He over radiogenic ^{4}He, testifies to the presence of a reservoir in the deep Earth, frequently referred to as PREMA, C, or FOZO, that has retained a fraction of the volatile material from the earliest Earth and may have a more primitive composition. Most recently, systematic zonation of key isotope ratios within single ocean island chains (e.g., Hawaii and Samoa) have been related to chemical heterogeneities inherited from the source regions of mantle plumes, arguably located on the boundaries of large seismic anomalies in the lower mantle. If so, this opens up the exciting possibility of using volcanic rocks to map lateral variations in the age and composition of the lower mantle.

The composition of magmas generated above subduction zones is distinct from both MORB and OIB in that they show an enrichment in large ion lithophile elements over high field strength elements, reflecting the incorporation of subducted sediments in arc magma sources and the effects of hydrous fluids on element mobility. Isotope and trace element studies have allowed the quantification of these effects and related magma composition to the compositions of the sediments being subducted. Confirmation of recycling of materials once at the surface was achieved by the detection of the cosmogenic nuclide ^{10}Be in arc volcanic rocks.

Volcanic rocks provide geochemists with samples of quenched melts in the form of melt inclusions in phenocrysts and other glasses such as submarine basaltic pillow rinds. These are particularly valuable in that they represent liquid compositions and preserve the original dissolved volatile inventory of the magma prior to eruption. They reveal high H_2O concentrations in arc-related magmas, as expected from trace element and other compositional variations, and much lower volatile abundances in MORB and OIB (e.g., Kent 2008; Plank et al. 2013).

Geochemistry for Volcanology and Petrology

The principles of physical chemistry and thermodynamics have provided the foundations of petrology for over a century, while the evolution of analytical geochemistry now permits the analysis of element abundances and isotope ratios in rocks and minerals to an unprecedented level of precision, accuracy, and spatial scale. Geochemical analysis is now a routine aspect of many investigations of volcanic and magmatic processes and provides the basis for volcanic rock classification independent of earlier mineralogical criteria. Starting with simple models of crystal fractionation and partial melting (e.g., Bowen 1928; Shaw 1970), our current understanding of the evolutionary processes operating within and beneath volcanoes has developed to a sophisticated level involving thermodynamic models of silicate melts and the partitioning of elements between different phases (e.g., melts http://melts.ofm-research.org/, also Bohrson et al. 2014). The combination of these approaches – analysis and modeling – to cogenetic suites of volcanic rocks has led to a quantification of the effects of fractional crystallization, partial melting, crustal contamination, magma mixing and hybridization, and the roles played by fluids, especially water, in all processes from magma source to eruption.

Geochemistry provides insights into the timescales of magmatic processes, especially into the evolution of super-

volcanoes such as Taupo. The application of U-Th-Ra disequilibria is critical in determining the rates of assembly of large magma chambers prior to major eruptions (e.g., Cooper 2015), and there is an active debate as to whether such chambers are long-lived features or whether they develop over a relatively short period of time (Annen et al. 2015), thus giving less advance warning of an impending eruption. Element diffusion between zones in crystals can also be used to determine the time between the development of the zonation and quenching on eruption. Different elements diffuse at different rates and so this method can be used to probe a range of time scales (minutes to millennia) and processes that produce crystal zonation, providing the diffusion coefficients of the relevant elements and minerals are known and the magmatic temperature can be determined with some precision. The two methods often complement each other in understanding magma chamber development, while diffusion chronometry is allowing the timing of pre-eruptive magmatic events to be compared with the timing of geophysical signals of pre-eruptive unrest (see papers in Putirka 2008).

Conclusions

The interplay of geochemistry, petrology, and volcanology has been one of the most remarkable areas of scientific expansion in the Earth sciences over the past 50 years and has led to a vastly increased knowledge of the composition and evolution of the upper mantle and continental crust, of the nature of magmas and their evolution, of the link between igneous processes and the timing and styles of volcanic eruption, and of the cycling of materials through the solid Earth. As analytical methods improve, our scientific understanding of volcanic rocks and volcanic processes will be further refined, and new ideas will develop, but the complexity of volcanic systems will always present a challenge to both chemical analysis and scientific interpretation.

Water

Carl O. Moses
Provost and Vice President for Academic Affairs, Grand View University, Des Moines, Iowa, USA

Definition

Water (H_2O), present in the geologic environment as solid, liquid, vapor, and supercritical fluid, is one of the most important components of Earth's fluid envelope. Without water and its special properties, Earth would be a vastly different planet in many ways. Water plays critical roles in atmospheric processes, including the absorption of radiant energy and the redistribution of energy through weather mechanisms, thus fundamentally influencing climate. In the lithosphere, water serves as an essential solvent and transport medium for many of the elements, a modifier of rock physical properties, and a lubricant for tectonic processes. The biosphere also depends on water for its very existence, for its solvent properties, and, in photosynthesis, as an electron-donating nutrient.

Properties of Water

Many of water's physical and chemical properties (Table 1) are anomalous, whether by comparison with other compounds generally; by comparison with the dihydride compounds of S, Se, and Te, with which O shares a column in the periodic table; or by comparison with isoelectronic hydrides like CH_4, NH_3, and HF. Perhaps the most notable property of water is the temperature dependence of its density. Unlike most materials, the solid phase of water is less dense than the liquid phase, and as a consequence, ice floats on liquid water. Water is even more unusual in that as T increases above the melting point, density continues to increase in the liquid phase up to 3.98 °C, above which it decreases. The temperature dependence of density ensures that bodies of water freeze from the top down rather than from the bottom up and causes inverse stratification of lakes during cold weather (water $T < 3.98$ °C overlying water with $T \geq 4$ °C), which has significant implications for life in aquatic habitats. Because density is a macroscopic manifestation of molecular structure, a structural model for water must account for the unusual temperature dependence of water's density.

Many of water's other properties also have geochemical significance. If water's melting and boiling points followed the trend of other Group VIB dihydrides (Fig. 1), only water vapor would exist in the surficial Earth system; the anomalously high melting and boiling points of water allow the existence of liquid water and ice. In addition, liquid water is stable over a remarkably wide range of temperature (the difference between T_{boil} and T_{melt}). The short bond length, tetrahedral bond angle, and great strength of the O–H bonds also indicate a very stable compound. The bonding characteristics of H_2O distinguish it from the dihydrides of S, Se, and Te, all of which have longer bonds, orthogonal bond angles, and weaker M–H bonds.

Water's enthalpy of vaporization is very high, which has great significance for the climate system. A mole of H_2O liquid extracts 44 kJ of energy from its surroundings as it evaporates, which is responsible for the cooling effect associated with evaporation. Furthermore, in the vapor, that energy is in a very mobile form that can be transported at great distances by the movement of air masses before it is released in the reverse process, condensation. This transfer of "latent heat" is an important mechanism by which energy is transported from low latitudes to high latitudes by the climate system, and it is a significant component of tropical storms and convective storms. During condensation, substantial energy releases take place that can result in significant warming of upper elevations of the troposphere that can, in turn, offset some of the adiabatic cooling that takes place during uplift of an air mass. When latent heat is combined with water's high heat capacity (proportionality constant for

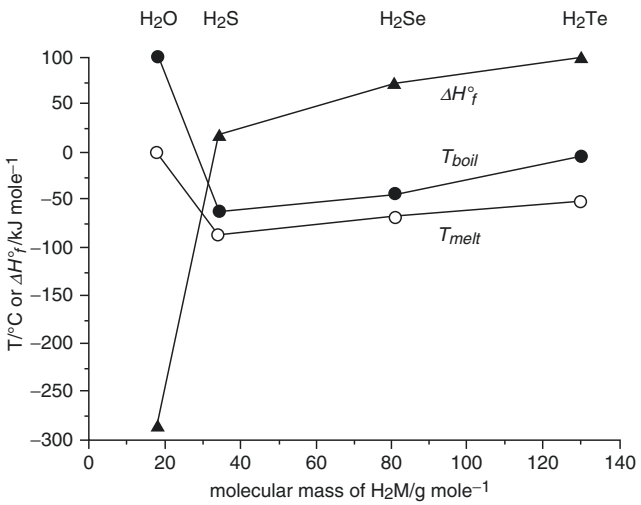
Water, Table 1 Selected properties of water (at $T = 298.15$ K, P = 0.1 MPa (1 bar) unless otherwise noted)

Property	Data	Comments
Density, ρ	$\rho_{solid} < \rho_{liquid}$ $T_{\rho max} = 3.98$ °C $\rho_{max} = 1.0$ g/cm^3	ρ_{max} is much less than that predicted by geometric argument; unusual for solid to float on liquid; unusual for ρ to increase with temperature
Melting point, T_{melt}	0.0 °C	Both T_{melt} and T_{boil} are anomalously high and the temperature span between T_{melt} and T_{boil}
Boiling point, T_{boil}	100.0 °C	Is anomalously large (Fig. 1)
O–H bond length	95.7 pm	Small; cf. H_2S (133.6), H_2Se (146), and H_2Te (169)
H-O-H bond angle	104.5° (gas phase)	Tetrahedral angle; cf. ~90° angle for H_2S, H_2Se, and H_2Te
Enthalpy of formation, $\Delta H°_f$	−285.85 kJ/mol	Highly exothermic; much stronger bonding than endothermic formation of H_2S, H_2Se, and H_2Te
Enthalpy of vaporization, $\Delta H°_{vap}$	44.02 kJ/mol	Very high ($\Delta S°_{vap} = 118.8$ J/K/mol is also high)
Heat capacity, $C° p$	75.19 J/K/mol	Unusually high
Dissociation constant, K $W = (a_{H}+)(a_{OH}-)$	10^{-14}	Very small; cf. H_2S ($\sim 10^{-7}$), H_2Se ($\sim 10^{-4}$), and H_2Te ($\sim 10^{-3}$)
Surface tension, γ	71.97×10^{-3} J/m^2	Large
Dielectric constant, $\in$	78.4 (unitless)	Very large



Water, Fig. 1 Comparison of melting point (T_{melt}), boiling point (T_{boil}), and $\Delta H° f$ for H_2O and other Group VIB dihydrides

the relationship between heat transfer and temperature change; see ▶ Geochemical Thermodynamics), one can appreciate the moderating effect that water has on weather patterns.

Water is a weaker acid than H_2S, H_2Se, and H_2Te, which, in part, reflects the greater M–H bond strength of water as well as the stabilizing role of H-bond formation. Water may also behave as a weak base, forming H_3O^+. This amphoteric nature of water (see ▶ Acid–Base Reactions) enhances water's influence on the solubility of rocks and gases, because water is able to react with both acids and bases.

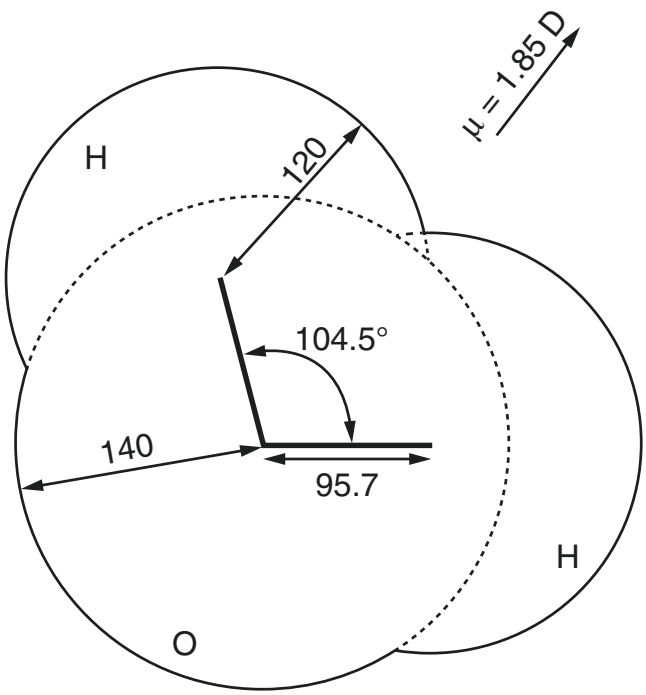
The high surface tension of water plays a vital role in climate through the regulation of water droplet size in clouds and precipitation. Surface tension also controls the relative wetting of mineral surfaces by water and nonpolar fluids (e.g., oil) and thus influences the relative mobility of water and other fluids in porous rocks.

The dielectric constant of water reflects the ability of water molecules to separate electrical charges. For example, ions in aqueous solution with opposite charge tend to attract one another, and if they combine, the result may be the formation of a precipitate; the aggregate effect of such processes would be diminished solubility. Water is very effective in separating such charges (shielding ions from interactions with one another), thus enhancing solubility. Water is over ten times as effective in this regard as mica or Teflon, substances that one readily recognizes as excellent dielectric media.

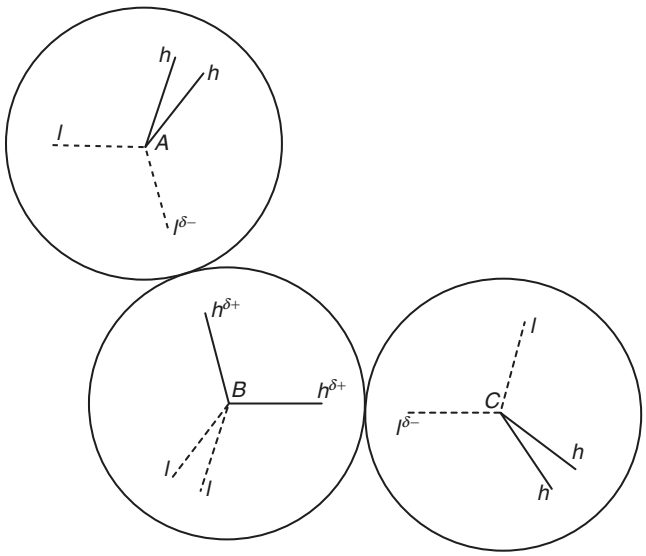
Structure of Water

The central O of a water molecule has the electronic configuration [He]$2s^2 2p^4$, and H has the ls^1 configuration. One might expect that the formation of H_2O involves the sharing of bonding electrons between the O 2p and H ls orbitals, and this does, indeed, appear to be the dominant bonding mechanism in H_2S, H_2Se, and H_2Te. In water, however, the combination of the small size of the O and the orthogonal configuration of the 2p orbitals would bring the two H atoms too closely together; the resulting repulsion destabilizes the system. Instead, the 2 s and 2p orbitals of O combine with the H ls orbitals to form four tetrahedrally oriented sp^3 hybrid molecular orbitals, two of which are occupied by lone-pair electrons and two of which are occupied by bonding electrons. The two lone pairs repel each other somewhat more strongly than the two H atoms repel each other, so the H atoms are separated by an angle (104.5°) slightly smaller than the ideal tetrahedral angle of 109.5° (Fig. 2), while the lone pairs are separated by a slightly larger angle (113°).

The tetrahedral orientation of the H_2O molecule lends itself to a highly symmetric interaction in which H_2O molecules are hydrogen bonded to one another (Fig. 3). An electrostatic bond forms between an $H^{\delta+}$ on one H_2O and a lone



Water, Fig. 2 Schematic illustration of a water molecule; length dimensions are pm. The molecule's center of mass is displaced from the center of the O atom by about 4.5 pm along the axis that bisects the H-O-H angle. Water molecules generally behave like spheres with a radius of 141 pm. The field-free dipole moment of the molecule, μ, is oriented as shown; 1 D (debye) = 3.33×10^{-30} C m



Water, Fig. 3 Relative orientation of three H-bonded water molecules; h = H atom and l = lone pair of electrons; δ indicates a fractional increment of charge (not all charges are shown). ∠H-O-H = ~105° in each molecule but ∠O-O-O (ABC) = ~109.5°, giving an extended structure of H-bonded molecules the ideal tetrahedral geometry. For clarity in illustration, the vectors of lone-pair orbitals are dashed and the water molecules are drawn as spheres

pair ($lp^{\delta-}$) on another H_2O (the δ represents a fractional charge of the indicated sign). The energy of H bonds depends somewhat on the local environment of the molecules but is on the order of 20 kJ/mol. Although small clusters of H-bonded H_2S, H_2Se, and H_2Te molecules may form, they do not grow large owing to steric hindrance resulting from the large size of the molecules and the orthogonal H-M-H and lp-M-H angles. In contrast, the evidence suggests that extensive three-dimensional networks of H-bonded water molecules dominate the structure of water.

At atmospheric pressure and $0° > T > \sim -130$ °C, ice forms a hexagonal framework structure, I_h, similar to tridymite (at lower T, an isometric polymorph like cristobalite exists, and other polymorphs are found at pressures > ~200 MPa). In the I_h structure, each H_2O is H bonded to four others in tetrahedral coordination, two via its lone pairs to H on other H_2O molecules and two via its H atoms to lone pairs on other H_2O molecules. The O-O-O angles have the ideal tetrahedral value of 109.5°, but the H-O-H angles are still ~105°, suggesting that H bonding does not fully relax the repulsive relationships among the lone pairs and H atoms on a given H_2O molecule. The I_h structure is not a close-packed structure. In fact, the observed density of ~1 g/cm^3 suggests that the four-fold coordination leaves ~62% of the volume of ice unfilled. The large open cavities, or interstices, in the ice structure are responsible for its low density.

As ice melts, large H-bonded clusters or polymers of water molecules remain intact in the liquid phase, retaining the open three-dimensional framework I h structure. H_2O monomers that are also released during melting slip inside the large interstices of the clusters. This interstice-filling process allows more H_2O molecules to fill a given volume of liquid water than the same volume of ice, hence the higher density of liquid water. Thermal agitation competes with interstice filling for control of the density of liquid H_2O. The temperature dependence of H_2O density suggests that interstice filling dominates at $0° < T \leq 3.98$ °C, and thermal processes dominate at $T > 3.98$ °C. Radial distribution function measurements indicate that, at T = 3.98 °C, ~82% of the H_2O molecules are in ice-like clusters and that, at 100 °C, ~73% are still in clusters. Clearly, H bonding yields a stable and robust configuration for H_2O molecules, but clusters have only fleeting existences, with a half-life of $\sim 10^{-10}$s (which is still ~1000 × longer than the vibrational period of an H bond and ~10 × longer than the time required for a H_2O molecule to diffuse through a distance equal to its own diameter). The interstitial model of water structure described here has been termed the "flickering cluster-monomer theory" to convey an image of the highly dynamic nature of the structure. Note that other structural models have been advanced for liquid water, but regardless of details, there is little doubt that tetrahedrally coordinated H bonds play a substantial role.

The stability of the unusual H-bonded structure of liquid water accounts for many of water's unusual properties. The high melting and boiling points, the wide range of stability for the liquid phase, the high enthalpy of vaporization, the high heat capacity, and the high surface tension are all manifestations of a very stable material. The tetrahedral coordination caused by the sp^3 hybrid molecular orbitals is responsible for the H-bonded framework structure; it is also responsible for the great stability of the O–H bonds in a given H_2O molecule, which is manifested in the strongly exothermic enthalpy of formation and the very weak acidity of H_2O in comparison with H_2S, H_2Se, and H_2Te.

Water's dielectric property is attributed to its dipole moment (Fig. 2) and the polarizability of water molecules. The dipole moment arises from the asymmetric distribution of charge, with the δ^+ of the H atoms on one "side" of the molecule and the δ^- of the lone pairs on the other side. Strictly speaking, a water molecule is a quadrupole, but the dipole treatment is sufficient for most purposes. Dipole moment is given by $2aq$, where $2a$ is the distance between the + and – charges and q is the amount of charge. If q is fixed, as in H_2O, the dipole moment may still change if $2a$ varies. In the absence of an electrical field, the dipole moments of a large population of H_2O molecules are randomly oriented, and the population generates no electrical field of its own. If an electrical field is imposed (e.g., by a solute ion or a charged mineral surface), the H_2O molecules will reorient themselves (subject to the usual constraints imposed by thermal agitation) so that their dipole moments are pointing against the external electrical field (by convention, electrical field strength vectors point from – to + charge, so the dipoles orient with their vectors pointing toward – charges). As a result, the population of oriented H_2O molecules generates a field that partly offsets the external field. The strength of the offsetting field is proportional to the dipole moment, the number of dipoles, and the degree of alignment the dipoles achieve with the external field. In a polarizable molecule, such as water, the response to the external field includes an increase in $2a$ (i.e., the molecule stretches), which increases the dipole moment and, thus, the strength of the offsetting field. Dielectric strength decreases with increasing T, reflecting the disruptive influence of thermal motion on the mutual orientation of the molecules generating the offsetting field.

The production of an offsetting electrical field by the oriented dipoles is the key characteristic of a dielectric medium and determines the extent to which the dielectric can separate opposite charges. In water, the significance of the offsetting electrical field lies in its ability to reduce electrostatic interactions among ionic solutes. A strong offsetting field "shields" an ion from others. As noted above, water is exceptionally effective in this regard.

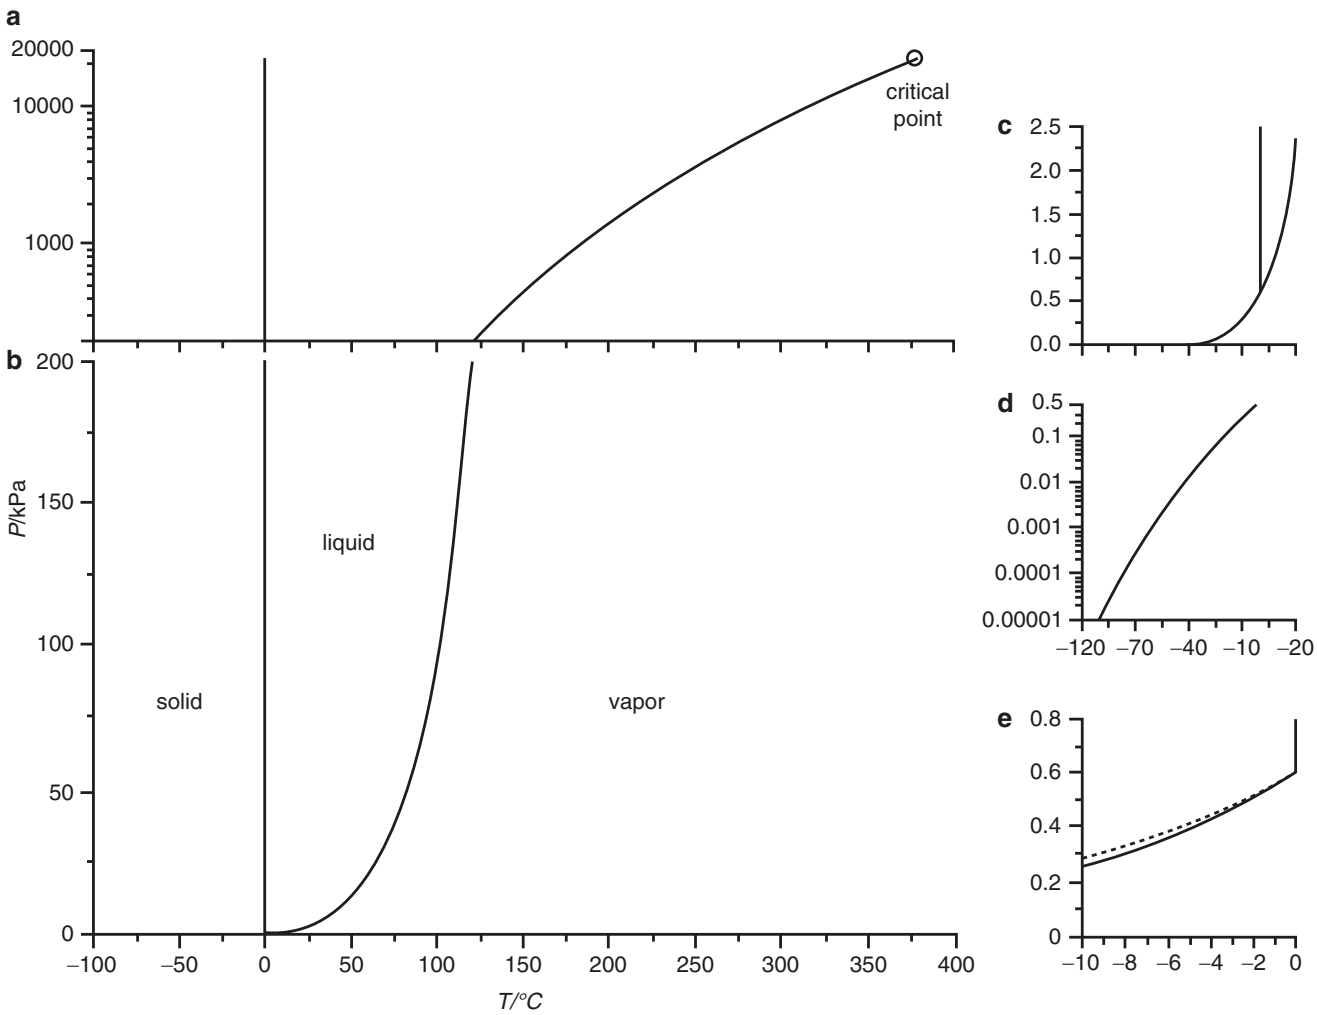
Phase Behavior of Water

Entropy always increases on melting ($\Delta S_{melt} > 0$), so the unusual density behavior of water ($\Delta V_{melt} < 0$) leads (by the Clapeyron equation; see ▶ Entropy) to a negative slope, $\Delta P/\Delta T < 0$, for the solid–liquid boundary on a P–T phase diagram of water (Fig. 4). This boundary marks the set of (T, P) conditions for which solid and liquid coexist at equilibrium. In fact, the slope of that boundary is so steep that it is almost imperceptibly different from − infinity and leads to a temperature decrease of only 0.01 K between the triple point ($T_t = 273.16$ K, $P_t = 611$ Pa) and T_{melt} at 10^5 Pa (273.15 K and 1 bar, $\Delta P/\Delta T < -9.9$ MPa/K).

In the absence of liquid water in the local environment at $T < T_t$, the presence of ice surfaces can lead to very dry conditions owing to the sublimation process (exchange of water between solid and vapor phases). The $\Delta P/\Delta T$ slope of the solid–vapor boundary, which marks the set of (T, P) conditions for which the solid and vapor coexist at equilibrium, is always positive (Fig. 4c, d), and the vapor pressure over ice decreases from 611 Pa at T_t to 260 Pa at −10 °C (263.15 K, $\Delta P/\Delta T \approx 35$ Pa/K). The magnitude of $\Delta P/\Delta T$ for the solid–vapor boundary diminishes with decreasing T. The liquid–vapor boundary is metastable at $T < T_{melt}$ at any pressure, but supercooled water can only slightly increase P_{H2O} from its equilibrium value with ice (~10% at 263.15 K, Fig. 4e).

The $\Delta P/\Delta T$ slope of the liquid–vapor boundary, which marks the set of (T, P) conditions for which liquid and vapor coexist at equilibrium, is also always positive (Fig. 4), and its magnitude increases with increasing T from ~1000 Pa/K in the 0–100 °C range to almost 0.2 MPa/K in the 300–370 °C range. The unusual stability of the liquid phase accounts for the considerable "length" of the liquid–vapor boundary (Fig. 4), which is limited by the critical temperature, T_c (647.14 K), and the critical pressure, P_c (22.06 MPa; critical data from Lide and Kehiaian 1995). Beyond (T_c, P_c), the liquid–vapor boundary ceases to exist. If one considers an isotherm (line of constant temperature, i.e., a vertical line on the P–T diagram) at $T < T_c$ and one at $T > T_c$, one might conclude that the critical point marks the temperature limit of stability for the liquid phase. On the other hand, if one considers an isobar (line of constant pressure, i.e., a horizontal line on the P–T diagram) at $P < P_c$ and one at $P > P_c$, one might conclude that the critical point marks the pressure limit of stability for the vapor phase. The fluid that exists beyond the critical point and is neither liquid nor vapor is termed a supercritical fluid. The critical molar volume of water, $\overline{V}_c$, is 56 cm^3/mol. It may be interesting to note that, even at the relatively extreme conditions of the critical point, water's density is 0.9970 g/cm^3, i.e., still very close to 1.

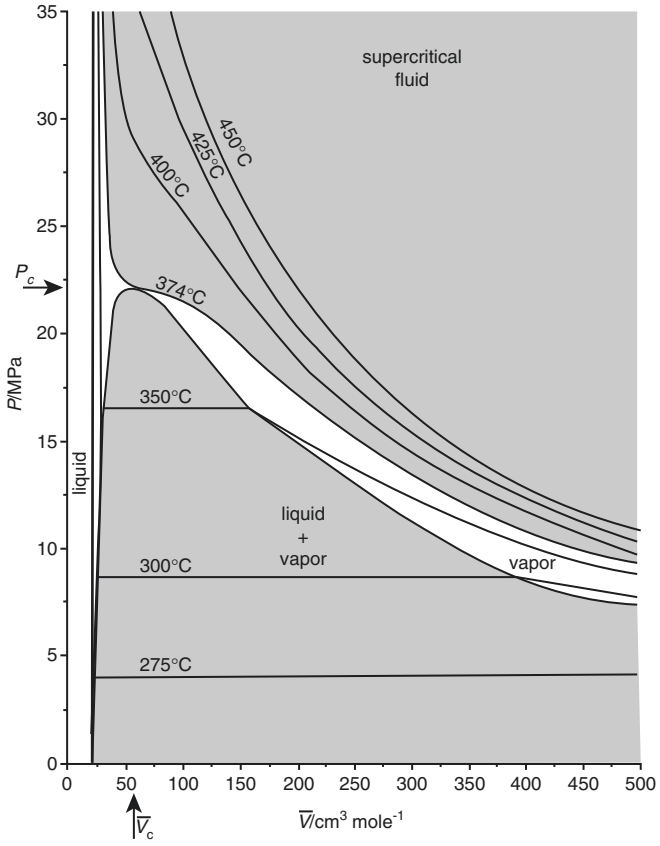
A phase diagram in P–V coordinates (Fig. 5) is useful in understanding the concept of a supercritical fluid. The lines in



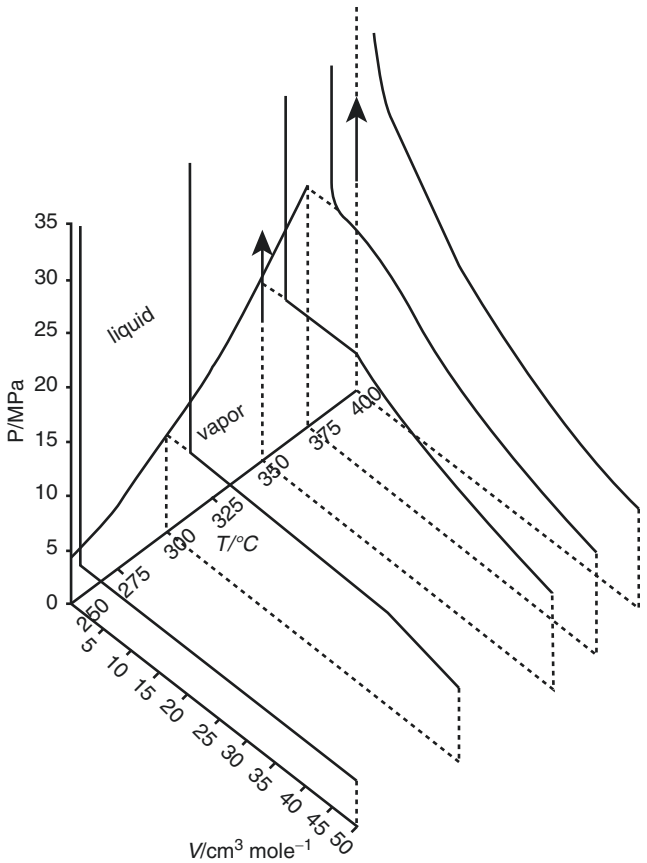
Water, Fig. 4 *P–T* phase diagram for water. (**a**, **b**) Relationship of solid, liquid, and vapor phases; note different pressure axis scales. (**c**, **d**) Region near the triple point; note change in pressure axis scales to display the solid–vapor boundary more clearly in (**d**). (**e**) Solid–vapor boundary (*solid line*) and metastable liquid–vapor boundary (*dashed line*) at $T < 0$ °C. 1 bar = 100 kPa

Fig. 5 labeled with temperatures are isotherms and represent the pressure changes that result from isothermal volume changes. Overall, each isotherm has a negative dP/dV slope, reflecting the fact that pressure increases as volume decreases and vice versa. Note that all of the isotherms steepen in slope (i.e., the magnitude of the slope increases) as volume decreases. In detail, however, some of the isotherms (those for $T < T_c$) also have an isobaric segment; this segment is longest at low temperatures and grows shorter, approaching zero length, as $T \rightarrow T_c$. In the high V, low P region of P–V space, vapor is the only stable phase for $T < T_c$, and pressure is free to vary with volume. When the pressure reaches the vapor pressure for a given temperature, liquid begins to condense. Now two phases, liquid and vapor, coexist, and the system loses a degree of freedom. Consequently, pressure remains fixed as long as both phases exist and temperature remains constant, but volume can continue to decrease (with no pressure change). When volume decreases to the point that only liquid exists and no vapor is left, the isotherm enters the low V, high P region of P–V space, liquid is the only stable phase for $T < T_c$, the system regains a degree of freedom, and pressure is free to vary with volume. Owing to the relative incompressibility of the liquid phase, the dP/dV slope is much steeper than for the vapor phase. In P–V–T coordinates (Fig. 6), the projection of the isobaric sections onto the P–T plane gives the familiar liquid–vapor boundary of Fig. 4 on which P is fixed by T (or vice versa) and liquid and vapor coexist.

With increasing temperature, the isobaric section of the isotherms (the volume range for which liquid and vapor coexist) becomes shorter until, at T_c, the isobaric section is infinitesimal. For $T > T_c$, there is no volume range for which liquid and vapor can coexist, so there is no phase transition. Note that, even in the supercritical fluid, dP/dV is shallower at



Water, Fig. 5 *P–V* phase diagram for water in the region of the critical point. The labeled lines are isotherms. Isotherms for $T > T_c$ (374 °C) pass through the liquid + vapor stability field (*the lower gray area*), in which $P \neq f(\overline{V})$. The liquid + vapor stability field does not exist for $T > T_c$. The upper gray area indicates the *P–V–T* domain for supercritical water



Water, Fig. 6 Constructing the liquid–vapor boundary in *P–T* coordinates (cf. Fig. 5) by projecting the isobaric segments representing liquid + vapor stability from planes of equal temperature in *P–V–T* coordinates onto the *P–T* plane. The heavy arrows represent isothermal compression paths in *P–T* coordinates at $T < T_c$ and $T > T_c$

high V and low P than it is at low V and high P. This behavior is consistent with the behavior of any fluid, including the vapor and liquid phases existing below (T_c, P_c). The key distinction of the supercritical fluid, then, is the absence of the first-order phase transition between vapor and liquid.

Supercritical water exists in many crustal settings and is geologically important for solute transport and mineral solubility relations in such problems as ore deposits, metamorphic fluids, and magmatic crystallization. Aside from temperature and pressure considerations, one of the most important properties of supercritical water is its greatly reduced dielectric strength, which enhances the formation of solute complexes. Depending on fluid composition, those complexes may increase or decrease the solubility of the solutes. Free radical reaction mechanisms are greatly hindered in the liquid phase of water but occur much more readily in supercritical water. Accordingly, supercritical water may also prove to be a useful medium for decomposing certain nonpolar organic contaminants.

The Hydrologic Cycle

In the environment, water is highly abundant and mobile. The exchanges of water among different parts of the environment are summarized in the hydrologic cycle (Table 2). The data from Berner and Berner (1987) were compiled mostly in the 1960s and 1970s, while the Trenberth et al. (2007) data were compiled between the late 1980s and early 2000s. The more recent data may be somewhat more accurate, but global estimates of the smaller reservoirs are imprecise. Berner and Berner (1987) include the biosphere as a reservoir containing 0.6×10^6 km^3 water. About 99% of Earth's modern inventory of water is in the oceans or in ice. During periods of extensive glaciation, some of the oceanic inventory is shifted to ice. Most of the remaining global inventory is in groundwater. The water content of the crust diminishes with depth, but evidence from metamorphic rocks indicates that liquid water exists at depths of at least 20 km in the crust.

Most marine precipitation is derived from marine evaporation, and most continental evaporation is returned to the

Water, Table 2 Reservoirs and fluxes in the hydrologic cycle, comparing data from Trenberth et al. (2007) and Berner and Berner (1987). Reservoirs, 10^6 km^3; fluxes, 10^6 km^3 y^{-1}

Reservoirs	Trenberth et al. (2007)		Berner and Berner (1987)	
Oceans	1335.0400 (96.95%)		1370.0000 (97.25%)	
Ice (ice sheets, sea ice, glaciers)	26.3500 (1.91%)		29.0000 (2.06%)	
Groundwater	15.5300 (1.11%)		9.5000 (0.67%)	
Surface water (lakes, rivers)	0.1780 (0.01%)		0.1267 (0.01%)	
Soil water	0.1220 (0.01%)		0.0650 (<0.01%)	
Permafrost	0.0220 (<0.01%)		n/a	
Atmosphere (liquid equivalent)	0.0127 (<0.01%)		0.0130 (<0.01%)	
Total	1377.0247		1408.7047	
Fluxes	Evaporation	Precipitation	Evaporation	Precipitation
Over oceans	0.413	0.373	0.4231	0.3857
Over land	0.073	0.113	0.0729	0.1103
Continental drainage	0.040		0.0374	

continents as precipitation. On the other hand, marine evaporation exceeds marine precipitation, while continental precipitation exceeds continental evaporation. The system is balanced by transport of water vapor from the oceans to the continents and the drainage of liquid water from the continents to the oceans. Aside from its effect on the global water budget, the net transport of water vapor to the continents is a significant part of the climatic moderating influence associated with marine air masses (as noted above, vapor transport = latent heat transport).

Water in the Lithosphere

The most familiar action of water in relation to rocks is to dissolve (chemically weather) mineral components. Minerals are soluble to varying degrees, so one would not expect the elements to be partitioned into the hydrosphere in the same relative abundances observed in the lithosphere. Excluding oxygen, the seven most abundant elements of the lithosphere, in decreasing order of abundance, are Si, Al, Fe, Ca, Na, K, and Mg. In the hydrosphere, the sequence of abundance is Cl, Na, S (as SO^{2-}_4), Mg, Ca, K, and C (as HCO^{-}_3). The differences result from differences in solubility controls, which are a combination of thermodynamic (equilibrium) and kinetic effects, ion exchange processes, and biological utilization. For example, the low abundance of aluminum in the hydrosphere chiefly reflects its low equilibrium solubility; chemical weathering processes generally transfer little Al from the solid phase to the aqueous phase. An example of the effect of ion exchange processes is the enhanced mobility of Na in the hydrosphere compared to K, which is about equal in crustal abundance to Na but has roughly 10% of the abundance of Na in the hydrosphere. An example of the effect of biota is carbon, which is not abundant in igneous rocks or, indeed, in the total solid Earth inventory. Sedimentary rocks, however, contain large quantities of carbon, which chiefly reflect interactions among the biosphere, atmosphere, and lithosphere, mediated by the hydrosphere.

Water also contributes to the physical alteration of the lithosphere. Because water expands when it freezes, rocks exposed at Earth's surface that are intruded by liquid water may experience repeated cycles of freezing and thawing with consequent decrepitation. Moving water is able to transport particles of decrepitated rock in suspension, and in many rivers, the transport of suspended solids greatly exceeds that of dissolved solids. Continental denudation makes an important contribution to marine sediments and nutrient availability in near-shore marine ecosystems. In addition, rapid continental denudation, occurring in regions of high rainfall and significant topographic relief, has recently received attention as a mechanism for tectonically "unloading" areas of continental crust and allowing substantial rates of uplift (Ruddiman and Kutzbach 1989; Kutzbach et al. 1993).

Aside from the familiar interactions between water and the rocks of the lithosphere, other significant geologic processes are influenced by water. Two examples come from structural geology and petroleum geology. The transport of large (km thick) thrust blocks over great distances along faults with low dip angles cannot be explained when realistic coefficients of friction for rock surfaces are combined with the strength of rocks; horizontal forces necessary to overcome the friction are far in excess of the forces necessary to fracture the blocks. Hubbert and Rubey (1959) recognized that fluid pressure in the fault plane would reduce the shear stress required to move block by reducing the normal component of stress on the fault. The relative incompressibility of water permits the development of sufficient hydrostatic pressures to lubricate major overthrust faults, thus allowing dramatic tectonic displacements. In petroleum geology, Hubbert (1954) recognized the important role that hydrodynamic processes play in trapping oil (or any immiscible fluid with a lower density than water's) under dipping surfaces of low permeability. Even when the flow of formation water is more or less parallel

to the low permeability surface, the buoyancy of the low-density fluid gives it a significant upward component of motion, leading to the development of a trapped stationary lens overlying the flowing water.

Water in the Atmosphere

Although the atmosphere has one of the lowest inventories of water in the hydrosphere, the dynamics of water in the atmosphere are vital to weather (and climate) and to many geochemical processes. The discussion above has already alluded to the role of evaporation and condensation in the transport of energy as latent heat through the environment by atmospheric processes. The water content of the atmosphere is highly variable in both time and space, but generally, most atmospheric water is in the troposphere, water content diminishes with altitude, air masses at tropical and temperate latitudes have a higher atmospheric water content than at sub-tropical or polar latitudes, and marine air masses have a higher water content than continental air masses.

Most of the water in the atmosphere is present as vapor; clouds consist of liquid water droplets or ice crystals. In the gas phase, atmospheric water content is expressed as the mixing ratio, $w = m_v/m_d$, where m_v is the mass of water vapor (g) and m_d is the mass of dry air (kg). The relationship between w and the partial pressure of water P_{H2O} depends on the total atmospheric pressure, P_{tot} (Eq. 1; $\varepsilon = M_w/M_d = 0.622$, where M_w and M_d are the molecular masses of water and dry air, respectively).

$$P_{H_2O} = \left(\frac{w}{w+\varepsilon}\right) P_{tot} \qquad \text{(W2)} \qquad (1)$$

The saturation vapor pressure, $P^0{}_{H_2O}$, corresponds to the vapor pressure given by the Clapeyron equation for the liquid–vapor equilibrium. To a first approximation ($\Delta H^0_{evap} \neq f(T)$ at normal environmental temperatures), $\log P^{0,\,liquid}{}_{H_2O} = 9.4 - (2354/T)$, where T is in K and $P^{0,\,liquid}{}_{H_2O}$ is in mb (1 mb = 100 Pa). The solid–vapor (sublimation) boundary gives a saturation vapor pressure with respect to ice, for which $\log P^{0,\,ice}{}_{H_2O} = 10.55 - (2667/T)$.

There is a saturation mixing ratio that corresponds to the saturation vapor pressure, $w_s = m_{v,s}/m_d$, where $m_{v,s}$ is the mass of water vapor in saturated air of the given temperature. As with the relationship in Eq. 1, the relationship between w_s and $P^0{}_{H_2O}$ depends on P_{tot} (Eq. 2; an approximation depending on the fact that $P_{tot} > P^0{}_{H_2O}$).

$$w_s = \frac{\varepsilon P^0_{H_2O}}{P_{tot}} \text{(W2)} \qquad (2)$$

Because $P^0{}_{H_2O} = f(T)$ and, therefore, $w_s = f(P, T)$, the saturation mixing ratio is a function of state in the atmosphere. Relative humidity is the ratio of the observed vapor content and the saturation vapor content, expressed as a percentage: $h = w/w_s \times 100\%$. The dew point is the temperature to which the air must be cooled (at constant pressure) to reach $h = 100\%$ (i.e., the temperature at which $w = w_s$; cooling air at constant pressure causes w_s to decrease while w is conservative). Usually, w_s is defined with respect to liquid water, but it can also be defined with respect to ice.

Clouds form when droplets of liquid water (or crystals of ice) can nucleate and grow. Condensation nuclei in the form of, for example, dust, sea salt, or biogenic aerosols are sufficiently abundant in the atmosphere for condensation to proceed by heterogeneous mechanisms at $h \approx 100\%$; homogeneous nucleation, which would require $h > 100\%$, apparently never occurs in the environment. With reference to the P–T diagram (Fig. 4), P–T conditions for water in the atmosphere are either in the vapor-phase stability field or, uncommonly, on the liquid–vapor or solid–vapor boundary; conditions in the atmosphere never enter the liquid or solid stability fields. Cloud particles have dimensions generally <20 μm and are easily kept aloft by slight updrafts. In order for precipitation to take place, the particles must grow large enough (≥1 mm, depending on vertical wind velocity) to fall. Furthermore, the particles must reach the ground surface before evaporating. Small particles (sufficiently large to fall) can reach the ground under conditions of high humidity, but if the humidity is low, very large particles may be required.

In addition to the phase transitions associated with weather and climate, water's interactions with solar and terrestrial radiation are important. Water vapor is, in fact, a "greenhouse" gas, so called because it absorbs radiant energy passing through the atmosphere. Water vapor's heat capacity is greater than that of most gases (about twice that of dry air), so water vapor is very effective at retaining the energy it absorbs. Liquid and solid water have even higher heat capacities, enhancing the ability of atmospheric water to retain energy. The more rapid cooling of the environment under low humidity conditions than under high humidity conditions is a familiar manifestation of energy absorption and retention by water vapor. The nonuniform spatial and temporal distribution of water vapor in the atmosphere is thus an important determinant of regional climate patterns.

Atomic Symbol: Xe
Atomic Number: 54
Atomic Weight: 131.293 AMU
Isotopes and Abundances: ^{124}Xe, ^{126}Xe, ^{128}Xe, ^{129}Xe, ^{130}Xe, ^{131}Xe, ^{132}Xe, ^{134}Xe, and ^{136}Xe with the relative abundances of these isotopes in air being 0.095%, 0.089%, 1.910%, 26.4%, 4.017%, 21.23%, 26.91%, 10.44%, and 8.86%, respectively
Atm Melting Point: 161.4 K
1 Atm Boiling Point: 165.1 K
Common Valences: 0
Atomic Radii: 2.16 Å (van der Waals radius)
Pauling Electronegativity: 2.6
First Ionization Energy: 1170.35 kJ/mol
Chondritic (CI) Abundance: 0.17 ppb
Silicate Earth Abundance: 30–500 ppq
Atmospheric Abundance: 87 ppb
Seawater Abundance: 65 ppt
Core Abundance: Not known

Properties

Physical Properties

At standard temperature and pressure of 273.15 K and 1 atmosphere, Xe is a gas. In the Earth's interior, at pressures >8 gigapascal (GPa), Xe that is not hosted within a mineral would be present as a pure solid phase (Jephcoat 1998). Since the Xe abundance in the mantle is very low, whether pure solid Xe phases exist in the Earth's interior is not clear.

Among the stable noble gases (i.e., He, Ne, Ar, Kr, Xe), Xe can be the most easily polarized, which makes it the most soluble of the noble gases in water. Furthermore, Xe exhibits the strongest temperature dependence of solubility in water, a property that can be exploited to obtain paleotemperature from water bodies. The solubility of Xe can be expressed by Henry's Law

$$C = H \times P_i$$

where C is the dissolved concentration, P_i is the partial pressure, and H is the Henry's constant, a function of pressure, temperature, and salinity. In water, Xe solubility decreases as temperature and salinity increase (Ozima and Podosek 2002).

Xe usually has the lowest solubility of the noble gases in silicate melts and usually the highest solubility in silicate minerals (Ozima and Podosek 2002). However, in bridgmanite, the primary lower mantle mineral, Xe solubility is observed to be lower than Ar and Kr (Shcheck and Keppler 2012). In melts, Xe solubility decreases with decreasing silica content and increasing concentrations of network modifiers; i.e., solubility decreases as the melt becomes depolymerized (Lux 1987; Shibata et al. 1996, 1998). The dissolution of Xe in silicate melts appears to be controlled by its coupling to the bridging oxygen atom in the silicate melt.

Crystal-melt partitioning data for Xe, which is effectively the ratio of the solubility of Xe in the crystal to the solubility in melt, exists between basaltic liquid and the major upper mantle minerals, olivine and clinopyroxene. Earlier partitioning studies sometimes indicated partition coefficients close to 1, although these experiments might have been affected by melt contamination of crystals or adsorbed gases (Broadhurst et al. 1992; Hiyagon and Ozima 1986). Recent advances with microanalytical techniques, such as UV laser ablation, appear to largely avoid these issues with crystal-melt partition coefficients for Xe converging to values of 2×10^{-4} to 1×10^{-3} (Brooker et al. 2003; Heber et al. 2007).

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

Diffusion data for Xe in geologic materials is limited to basaltic liquids (Lux 1987) and glasses of silica, albitic, and jadeitic compositions (Roselieb et al. 1992, 1995). In silica, albite, and jadeite glasses, the activation energy of diffusion and diffusivities increase as Si is substituted by Na and Al, possibly as a result of structural relaxation of the melt (Roselieb et al. 1995). In basaltic melt, the diffusion coefficient at 1350 °C is 3×10^{-5} cm^2/s, which is several orders of magnitude higher than expected from extrapolated values of diffusivities in silicate glasses, suggesting diffusivities cannot be extrapolated through the glass transition temperature for silicates (Lux 1987). The only available data for minerals are some step-heating experiments in Ba-rich silicates, from which the activation energy of diffusion can be estimated but not diffusivities (Hetherington and Villa 2007).

Chemical Properties

Xenon interactions with solids are often described by adsorption. Adsorption can either be in the form of physisorption or chemisorption. Physisorption usually involves interactions associated with the weak van der Waals, while chemisorption involves electron sharing or even electron transfer. Since Xe has the largest atomic radii and lowest ionization energy of the noble gases, compared to the other noble gases, it has the strongest interactions with concentrations of Xe in a wide variety of materials are often described as resulting from adsorption, such as in charcoal, clay minerals, sedimentary rocks, igneous rocks, and meteorites.

In 1962, Neil Bartlett at the University of British Columbia demonstrated that Xe was reactive enough to form chemical bonds. He produced the first noble gas compound, xenon hexafluoroplatinate, by reacting Xe gas with platinum hexafluoride. Subsequently a large number of Xe compounds have been synthesized, including halides (XeF_2, XeF_4, XeF_6, $XeCl_2$), oxides (XeO_3, XeO_4), and oxohalides ($XeOF_2$,). Additionally, bonds between Xe and C in organic compounds have been observed. Xenon also forms clathrates with a number of hosts, such as water, nitrogen, and methane ice, and formation of Xe clathrates might be a particularly relevant process in the outer solar system (Lunine and Stevenson 1985; Swindle et al. 2009; Thomas et al. 2007; Mousis et al. 2013).

Biological Properties

Xe has been developed for use in humans as an inhalation anesthetic. Its anesthetic and neuroprotective function are achieved by binding to the glycine site glutamatergic N-methyl-D-aspartate (NMDA) receptor competitively and blocking it (Franks et al. 1998). A significant advantage of Xe as an anesthetic and neuroprotector appears to be its lack of toxicity and, because of its low blood-gas coefficient, fast recovery times for patients (Goto et al. 1997). The high costs associated with Xe production, however, have so far limited its widespread usage as an anesthetic.

More recently, Xe has been tested as a treatment for post-traumatic stress disorder (PTSD) (Meloni et al. 2014). Xe inhibits NMDA receptors, which are important in memory functions and affect the synaptic plasticity in two key brain areas, the amygdala and hippocampus. In animal trials using mice, Xe was found to substantially and persistently inhibit memory reconsolidation, opening a potential new path for treating people with PTSD and other memory disorders (Meloni et al. 2014).

History and Xenon Applications in Earth Science Research

The element xenon, whose name comes from a Greek word meaning *the stranger*, was discovered by chemists Sir William Ramsay and Morris Travers in 1898. Sir Ramsay was awarded the Nobel Prize in 1904 for the discovery of xenon.

The strong temperature dependence of Xe solubility in water has been utilized in numerous groundwater studies to reconstruct continental paleotemperatures. The relative abundance of Xe with respect to the other stable noble gases in groundwaters from tropical and temperature northern latitudes suggests a 5–10 °C increase in temperatures between the last glacial maximum and the Holocene. A complication in the paleotemperature reconstructions is the presence of excess air, which leads to noble gas concentrations in excess of their predicted equilibrium solubility in water. Numerous models have been developed to account for the excess noble gases in groundwater, although it is not clear which of the models best describe the physical process responsible for the phenomenon (e.g., Aeschbach-Hertiz and Solomon 2013). However, the models do suggest that while the absolute temperatures may be sensitive to the model chosen to account for excess air, the relative changes in paleotemperature reconstructions are more robust.

Over the past decade, the relative abundance of Xe with respect to the other noble gases has been used with some success to reconstruct continental temperatures from fluid inclusions trapped in speleothems (Kluge et al. 2008; Vogel et al. 2013). These studies are often plagued by noble gas budgets in speleothems being dominated by trapped air and/or gases trapped in the calcite lattice. However, techniques have been developed to reduce the non-fluid inclusion gases, such as pre-crushing samples in a He atmosphere or combined vacuum crushing and sieving (Scheidegger et al. 2010, 2011; Vogel et al. 2013). These techniques may allow for temperature reconstructions from speleothems with an uncertainty in the range of 1–2 °C (Vogel et al. 2013).

Xe measurements in seawater, combined with measurements of the noble gases, have been used to constrain air-sea gas exchange, a process that is critical to tracing the cycle of gases that play an important role in ocean biogeochemistry (such as CO_2, N_2O, dimethyl sulfide) (Stanley et al. 2009; Hamme and Severinghaus 2007). Recently, Xe measurements, in concert with measurements of other noble gases, were used to trace the addition of glacial meltwater from Antarctica to the southern ocean (Loose and Jenkins 2014).

Xe has been a particularly useful element with which to understand the early degassing and long-term degassing associated with plate tectonics. While a significant fraction of the mantle Xe inventory was degassed into the atmosphere within a hundred million years of Earth's history (Allegre et al. 1987; Kunz et al. 1998; Moreira 2013; Mukhopadhyay 2012), recent work also indicates that subduction is regassing the mantle Xe content (e.g., Holland and Ballentine 2006; Kendrick et al. 2011; Parai and Mukhopadhyay 2015).

A particularly vexing problem associated with terrestrial Xe research is the issue of missing Xe on Earth. Briefly, while Xe, along with the heavier noble gases, is believed to have a chondritic affinity, Xe is depleted in the Earth more than Ar and Kr when compared to chondritic abundances. The depletion was recognized since the 1960s (e.g., Canalas et al. 1968) and is particularly difficult to understand, as any loss processes on Earth should preferentially deplete lighter noble gases compared to Xe. This is known as the missing Xe paradox. Two significant advances in addressing the missing Xe paradox have been made recently. The first is the discovery that the initial atmospheric composition that was mass fractionated to produce the modern atmosphere of the Earth can be successfully explained by a mix of cometary xenon measured in the short-period comet 67P/Churyumov-Gerasimenko (Marty et al. 2017) and chondritic/solar Xe (Marty 2012; Marty et al. 2017). The second discovery was made by Pujol et al. in 2011 who realized from measurements of trapped gases in 3.5–3.0 Ga barites and cherts that, in preference to the other noble gases, Xe was being lost from the atmosphere during the Hadean and Archean. While the exact mechanism driving Xe loss is unclear, the process might be related to the fact that Xe is the easiest of the noble gases to ionize with solar UV and, importantly, is the only noble gas that is more easily ionized than hydrogen. Therefore, Xe can be ionized by UV photons, whereas Kr and lighter noble gases would be more difficult to ionize, as hydrogen would absorb the photons that could ionize the lighter noble gases (Zahnle et al. 2007, 2015). Subsequently, the Xe^+ ions may get dragged away by escaping hydrogen ions along open magnetic field lines (Zahnle 2015). The missing Xe problem, which still requires a quantitative understanding, is a key component to explaining the origin and subsequent evolution of Earth's atmosphere.

Summary

Xenon is a member of the group VIIIA gases, usually referred to as noble or rare gases. While Xe is usually considered to be an inert gas, it does chemically interact with other elements. Although it primarily interacts with matter via physi- and chemisorption, it also participates in chemical bonds, and a number of Xe compounds have been synthesized with Xe oxidation states of +2 to +8. Xe is particularly effectively as an anesthetic given its low blood toxicity and is potentially a new way of treating PTSD. Xe has been used in a number of applications in earth science research including paleotemperature estimates from studies of groundwater and speleothem, air-sea gas exchange, mantle degassing, loss of terrestrial volatiles, and the origin and evolution of the atmosphere. Two significant recent advances in the study of Xe in earth sciences have been the realization that comets must have contributed Xe to Earth's early atmosphere and the missing Xe paradox was not a result of Earth's accretion, but rather due to protracted Xe loss from the atmosphere during the Hadean and Archean.

Xenon Isotopes

Sujoy Mukhopadhyay
Department of Earth and Planetary Sciences, University of California Davis, Davis, CA, USA

Definition

Xenon is an inert gas and belongs to group VIIIA of the periodic table. Xenon has nine stable isotopes, second only to tin. The nine xenon isotopes are ^{124}Xe, ^{126}Xe, ^{128}Xe, ^{129}Xe, ^{130}Xe, ^{131}Xe, ^{132}Xe, ^{134}Xe, and ^{136}Xe. Of these isotopes, ^{124,126,128,130}Xe are nonradiogenic, ^{129}Xe is radiogenic and ^{131,132,134,136}Xe are fissiogenic. The relative abundances of these isotopes in the atmosphere are 0.095%, 0.089%, 1.910%, 26.4%, 4.017%, 21.23%, 26.91%, 10.44%, and 8.86%, respectively. The isotopic abundances in other reservoirs, such as crust, mantle, or groundwater, differ from the atmospheric abundances due to fractionation of I-Xe, U-Xe, and Pu-Xe and subsequent radioactive decay. This contribution will focus on the Xe isotopes in the solid Earth and atmosphere.

Introduction

Measurements of xenon isotopes in mantle-derived basalts provide information on processes as varied as volatile accretion, mantle degassing history, styles of mantle convection, and volatile exchange between the deep Earth and the atmosphere. The nonradiogenic isotopes ^{124}Xe, ^{126}Xe, ^{128}Xe, and ^{130}Xe are primordial with terrestrial inventories established by the balance between volatile delivery during accretion and atmospheric loss processes. The radiogenic Xe isotopes can be divided into two categories: ^{129}Xe produced by β-decay of ^{129}I and ^{131,132,134,136}Xe produced by fission from extinct ^{244}Pu and extant ^{238}U. Radiogenic ^{129}Xe was produced only during the first ~90 Myr of solar system history by β-decay of the extinct nuclide, ^{129}I ($t_{1/2}$ = 15.7 Ma). ^{129}I was the first extinct radionuclide detected in our solar system through the measurements of ^{129}Xe in meteorites (Reynolds 1963). Fissiogenic ^{131}Xe, ^{132}Xe, ^{134}Xe, and ^{136}Xe were produced from extinct short-lived ^{244}Pu ($t_{1/2}$ = 80.0 Myr) for the first ~500 million years of solar system history and continues to be produced from extant ^{238}U ($t_{1/2}$ = 4.468 Gyr). Pu and U fission, however, produce the fissiogenic Xe isotopes in distinct, characteristic proportions. Xe isotopic measurements in mantle-derived samples can, therefore, be used to deconvolve the fraction of Xe derived from Pu-fission versus U-fission. Thus, the radiogenic Xe isotopic compositions can be used to investigate the evolution of mantle volatile budgets on a variety of timescales. Here, I first provide some background on how Xe isotopes have been used to obtain information on accretion and mantle degassing timescales, and then focus on four major discoveries associated with Xe isotopes during the past decade: (1) regassing of mantle xenon, (2) preservation of heterogeneities created during Earth's accretion, (3) heterogeneous volatile accretion, and (4) loss of Xe from the atmosphere during the Hadean and Archean.

Background and Prior Work

Decay of ^{129}I on the Earth would produce ^{129}Xe, and I-Xe fractionation would induce differences in the ratio of radiogenic ^{129}Xe to nonradiogenic ^{130}Xe (^{129}Xe/^{130}Xe). Variations in ^{129}Xe/^{130}Xe ratios between different reservoirs can only be generated within the first 90 million years of solar system history. The first excess of ^{129}Xe in the solid Earth, relative to Earth's atmosphere, was detected by Butler et al. (1963) in Harding County CO_2 well gas and attributed to ^{129}I decay in the early Earth. Staudacher and Allegre (1982) measured excesses in ^{129}Xe in mid-ocean ridge basalts (MORBs) and modeled the measured ^{129}Xe excess in the Earth's mantle to suggest that Earth formed 50–75 Myrs after the formation of meteorites. In ocean island basalts (OIBs), derived from partial melting of mantle plumes, ^{129}Xe excesses were first detected in Hawaiian xenoliths (Hennecke and Manuel 1975; Kaneoka and Takaoka 1978) and later in Samoa (Poreda and Farley 1992), Iceland (Harrison et al. 1999; Trieloff et al. 2000), Shona, and Discovery seamounts (Sarda et al. 2000). These measured excesses were attributed to both early degassing as well as mixing between upper mantle Xe and atmospheric Xe (e.g., Poreda and Farley 1992; Trieloff et al. 2000).

The ^{244}Pu- and ^{238}U-produced fission isotopes of Xe (^{131,132,134,136}Xe) provide information about mantle degassing rates, particularly during the early history of the Earth (e.g., Allegre et al. 1987; Coltice et al. 2009; Kunz et al. 1998; Ozima et al. 1985; Staudacher and Allegre 1982; Yokochi and Marty 2005). ^{244}Pu and ^{238}U produce the four fission isotopes in different proportions and fission Xe yields from Pu are significantly larger than from U. A reservoir that remains completely closed to volatile loss over Earth's history has a $^{136}Xe_{Pu244}$*/$^{136}Xe_{U238}$* of ~27, where "*" refers to fissiogenic Xe (Azbel and Tolstikhin 1990; Tolstikhin et al. 2006; Tolstikhin and O'Nions 1996). ^{244}Pu became extinct at ~4 Ga. Thus, reservoirs that underwent extensive degassing over the past 4 Gyrs have lost a significant fraction of the Pu-produced fission Xe and consequently have a large proportion of ^{238}U-derived fission Xe. Importantly, $^{136}Xe_{Pu244}$*/$^{136}Xe_{U238}$* in degassed reservoirs is $\ll$27. Hence, if the Pu and U yields of the different Xe isotopes are known precisely, measurements of Xe isotopes in mantle-derived rocks can yield the fraction of Xe derived from ^{244}Pu versus ^{238}U, which in turn constrains the timing and degree of outgassing of the mantle reservoir.

The terrestrial fission Xe excesses relative to air were first detected by Boulos and Manuel (1972) in the Harding County well gases. They noted the measured compositions were consistent with a ~1:3 mixture of Pu-fission Xe and U-fission Xe. However, due to the large uncertainties, the Xe isotopic measurements by Boulos and Manuel (1972) were also consistent with pure Pu- fission or pure U-fission. Subsequent measurements with increased precision (Phinney et al. 1978; Caffee et al. 1999) put a limit of 20% for Pu-derived fission Xe in the well gases. Kunz et al. (1998) presented more precise isotopic measurements to constrain 32 ± 10% of the fission Xe to be ^{244}Pu-derived assuming that the terrestrial mantle had the same initial composition as atmospheric Xe. Assuming an initial solar composition of the mantle, Pepin and Porcelli (2006) assigned 60% of the fission Xe to ^{244}Pu. The ratio of Pu to U-derived Xe in all of these estimates suggests extensive degassing of the Earth's mantle.

Combining the I-Xe and Pu-Xe system is a particularly powerful approach to understanding volatile accretion timescales, the timing of mantle degassing and the formation of the atmosphere. The I-Pu-Xe system is interrogated from the measured ^{129}Xe/^{136}Xe ratio and using the fraction of ^{136}Xe derived from ^{244}Pu (calculated from measurements of

^{131,132,134,136}Xe) to compute the ^{129}Xe*/^{136}Xe$_{Pu244}$* ratio. Wetherill (1975) used the I-Pu-Xe and data from the Harding County well gases (Butler et al. 1963; Boulos and Manuel 1972) to estimate that the formation interval of the Earth was 127 Myr after the formation of the ordinary chondrite Bjurböle. Based on MORBs measurements, Staudacher and Allegre (1982) used the I-Pu-Xe system to compute a formation interval of 40–60 Myrs for the Earth and a mean age of 70–80 Myrs for the Earth's atmosphere. These estimates were largely confirmed through more precise measurements by Kunz et al. (1998).

Pepin and Phinney (1976) combined the I-Pu-Xe system to formulate a closure age (T) of a reservoir given by:

$$T = \frac{1}{\lambda_{244} - \lambda_{238}} \times \ln\left[\frac{\left(^{129}\mathrm{Xe} * / ^{136}\mathrm{Xe}_{Pu244*}\right)\left(^{238}\mathrm{U}/^{127}\mathrm{I}\right)_o \left(^{244}\mathrm{Pu}/^{238}\mathrm{U}\right)_o {}^{136}\mathrm{Y}_{244}}{\left(^{129}\mathrm{I}/^{127}\mathrm{I}\right)_o}\right] \ldots \quad (1)$$

where λ is the decay constant, $^{136}Y_{244}$ is the fission yield of ^{136}Xe from Pu fission, ^{129}Xe* is the radiogenic ^{129}Xe produced from ^{129}I decay, ^{136}Xe$_{Pu244}$* is the fissiogenic ^{136}Xe produced from ^{244}Pu fission and the subscript "o" refers to the initial value. The formulation yields the age when a reservoir (e.g., solid Earth, Earth atmosphere) transitions from quantitatively Xe loss to closed system retention of Xe. Using this formulation, Pepin and Phinney (1976) calculated an atmospheric closure age of ~80 Myrs after the start of the solar system, while Pepin and Porcelli (2006) calculated closure ages of ~100 Myr for both the atmosphere and the MORB source.

The ratio of ^{129}Xe*/^{136}Xe$_{Pu244}$* also provides insights into the relation between mantle Xe and atmospheric Xe. For example, the ^{129}Xe*/^{136}Xe$_{Pu244}$* ratio in the MORB source suggests that atmospheric Xe must be from a late accretionary source and not degassed from the mantle (Caffee et al. 1999; Marty 1989; Ozima et al. 1985; Yokochi and Marty 2005). The argument follows from the fact that as the half-life of ^{129}I is significantly shorter than the half-life of ^{244}Pu, at the time of atmosphere formation, a larger proportion of ^{244}Pu would not have undergone radioactive decay compared to ^{129}I. Consequently, if the atmosphere were derived from degassing of the MORB mantle, the ^{129}Xe*/^{136}Xe$_{Pu244}$* ratio in the MORB mantle source must have evolved to a lower value than the atmosphere. However, the MORB mantle has a higher ratio than the atmosphere. Consequently, Xe in the MORB source is not consistent with the composition of a reservoir that is residual to outgassing of Xe into the atmospheric. This argument was recently challenged (Boehnke et al. 2015) on the ground that ^{129}Xe*/^{136}Xe$_{Pu244}$* in MORBs may have been overestimated due to improper accounting of uncertainties in Pu fission yields when computing the value of ^{136}Xe$_{Pu244}$*.

Regassing of Mantle Xenon

Early models on the noble gas evolution of the mantle required subduction zones to be a barrier towards the transport of atmospheric noble gases into the mantle (e.g., Staudacher and Allegre 1988). Thus, while volatile elements like H, C, N, and S were supposed to be recycled back into the mantle, noble gases were supposed to have a unidirectional transport out of the mantle. As a result, differences in MORB and OIB Xe isotopic compositions were modeled to indicate differences in the degree of mantle outgassing. That is, variations in Xe isotopes in the mantle could result only from I-Xe fractionation or Pu-U-Xe fractionations associated with partial melting or magmatic degassing. In these models, the plume source was thought to be sampling a more primitive less degassed mantle source compared to the MORB source. In mantle steady state models (Porcelli and Wasserburg 1995), recycling of atmospheric Xe could occur into the MORB source, but depended on an assumed composition of the OIB source.

The subduction zone barrier was challenged in 2006 by Holland and Ballentine based on the full suite of noble gas measurements (He, Ne, Ar, Kr, and Xe) in CO_2 gases from the Bravo Dome gas field in New Mexico, USA. Holland and Ballentine (2006) demonstrated that the relative abundances of Ar, Kr, and Xe in the CO_2 gas was similar to that of the gas-rich "popping-rock" sample from the North Atlantic mid-ocean ridge (Moreira et al. 1998), and the relative abundance patterns in both samples were similar to that of seawater. This observation suggested the subduction of noble gases dissolved in seawater into the convective mantle. The non-radiogenic Xe in the mantle was modeled as a mixture of 80% recycled atmospheric Xe and 20% primordial Xe. The recycling of Xe back into the mantle is an important paradigm shift since it introduces a fundamentally different way to interpret variations in observed Xe isotopic ratios. For example, differences in ^{129}Xe/^{130}Xe ratios in mantle-derived samples do not need to arise from preservation of mantle domains with difference melt and gas extraction histories. Instead, ^{129}Xe/^{130}Xe variations could arise from differences in the amount of recycled atmospheric Xe in the mantle. Holland and Ballentine (2006) suggested that the Xe isotopic composition of OIBs were closer to atmospheric values compared to MORBs because of preferential recycling of atmospheric Xe dissolved in seawater into the OIB source.

Subsequent work by Sumino et al. (2010) and Kendrick et al. (2011) in exhumed metamorphic terranes at subduction zones confirm deep recycling of Xe. At the Higashi-akaishi peridotite body in the Sanbagawa metamorphic belt in Japan, Sumino et al. (2010) found fluid inclusion trapped in olivine crystals at a depth of 100 km. Xenon and the other noble gases in these fluid inclusions have a striking resemblance to those in marine pore fluids. Sumino et al. (2010) suggested that the marine fluids were liberated from either sediments, or the

oceanic crust, or from lithospheric mantle hydrated at the outer rise of the subduction zone. These fluids were subsequently trapped in the mantle wedge peridotite and exhumed as the Higashi-akaishi peridotite body. While the observation directly links recycling of atmospheric-derived Xe down to depths of 100 km, it is likely that the atmospheric component is being subducted deeper as not all of the subducted water is liberated and returned to the surface at subduction zones (Van Keken et al. 2011; Parai and Mukhopadhyay 2012).

Kendrick et al. (2011) further investigated the subduction of atmospheric noble gases, including Xe, through measurements of halogens and noble gases in antigorite schists from Ligurian Alps, Italy, and in olivine–enstatite rocks from Betic Cordillera, Spain. These rock assemblages sample increasingly higher pressure-temperature environments in subduction zones, reflecting the progressive breakdown of serpentine (antigorite schists) to produce olivine and enstatite residues. Kendrick et al. (2011) observed fluid inclusions in olivine–enstatite veins in the antigorite schists and interpreted them to reflect fluids generated from serpentine breakdown. These fluid inclusions had $^{130}Xe/^{36}Ar$ ratios similar to sea water, or seawater–marine sediment mixtures, although the ^{130}Xe concentrations in the fluid inclusions were higher than in seawater. Fluid inclusions trapped in the olivine–enstatite rocks were interpreted as higher pressure fluids generated by the final breakdown of serpentine, and these inclusions had $^{130}Xe/^{36}Ar$ ratios that were similar to values observed in the OIBs. Overall, the range of $^{130}Xe/^{36}Ar$ ratios seen in the fluid inclusions is broadly similar to that seen in different mantle reservoirs, with the inclusions having concentrations that are one to three orders of magnitude higher than the mantle concentrations (Kendrick et al. 2011).

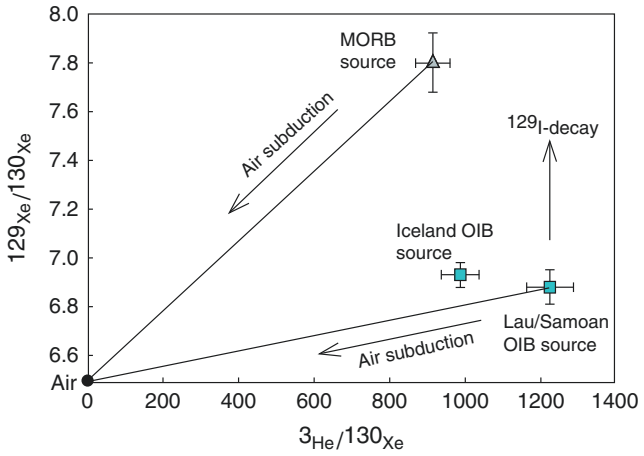
While Holland and Ballentine (2006) and Sumino et al. (2010) suggested that the transport of Xe back into the mantle is associated with unbound pore fluids, Kendrick et al. (2011, 2013) argued that seawater-derived noble gases are directly incorporated into hydrous phases, like serpentine, during hydration of the lithospheric mantle. Breakdown of serpentine in subduction zones releases fluids carrying the seawater-derived noble gases, which are subsequently trapped in the breakdown products of olivine–enstatite. These fluid inclusions could be released into the shallow mantle during deformation and recrystallization of the olivine-enstatite rocks associated with downward transport of the plate. Alternatively, the fluids could be incorporated into olivine polymorphs (wadsleyite) and transported into the deep mantle (Kendrick et al. 2011).

The recycling of substantial atmospheric Xe into the mantle was also confirmed using a completely different approach from measurements of MORBs and OIBs that represent a different repository of mantle-derived material than exhumed high pressure-temperature metamorphic rocks (Mukhopadhyay 2012; Parai et al. 2012; Parai and Mukhopadhyay 2015; Tucker et al. 2012; Pető et al. 2013). From combined $^{20}Ne/^{22}Ne$-$^{40}Ar/^{36}Ar$-$^{129}Xe/^{132}Xe$ isotope mixing systematics, these authors corrected for shallow-level air contamination to determine the mantle Xe isotopic compositions. The mantle Xe isotopic compositions were then modeled as a mixture of primordial Xe, recycled atmospheric Xe, radiogenic (^{129}Xe) and fissiogenic Xe ($^{131,132,134,136}Xe$) using a least squares fitting routine. For both MORBs and OIBs, between 80% and 90% of the Xe budget was determined to be atmospheric Xe returned to the mantle via subduction. Thus, numerous lines of evidence suggest that the Xe budget of the mantle is dominated by recycled atmospheric Xe. Consequently, Xe transport into the mantle has been regassing the mantle. Furthermore, the recycling of Xe appears to be tied to recycling of water itself (Holland and Ballentine 2006; Sumino et al. 2010; Kendrick et al. 2011, 2013).

Preservation of Heterogeneities Created During Terrestrial Accretion

While differences in measured Xe isotopic composition between MORBs and OIBs have long been recognized (Hennecke and Manuel 1975; Kaneoka and Takaoka 1978; Poreda and Farley 1992; Harrison et al. 1999; Trieloff et al. 2000), the interpretation of the isotopic differences remained unclear until recently. In general, $^{129}Xe/^{130}Xe$ ratios in OIB ratios are lower than MORBs, with the highest values reaching values of 6.8–7.0 compared to MORB values of 7.8–7.9 (Holland and Ballentine 2006; Poreda and Farley 1992; Mukhopadhyay 2012; Moreira et al. 1998; Sarda et al. 2000; Tucker et al. 2012; Parai et al. 2012; Pető et al. 2013; Staudacher and Allegre 1982; Kunz et al. 1998; Trieloff et al. 2002). Since the atmospheric $^{129}Xe/^{130}Xe$ ratio (6.49) is lower than the OIB values, the differences between OIB and MORB lavas could result from a higher degree of syn- to posteruptive atmospheric contamination of OIB lavas, mixing between subducted atmospheric Xe and MORB Xe (Holland and Ballentine 2006; Poreda and Farley 1992; Trieloff and Kunz 2005), or different I/Xe ratios for the OIB and MORB sources (Allegre et al. 1987; Poreda and Farley 1992).

High precision Xe isotopic data from an Icelandic basalt, which samples the OIB source, demonstrated that the differences in $^{129}Xe/^{130}Xe$ ratios between MORBs and OIBs must result from different I/Xe ratios for the two sources (Mukhopadhyay 2012; Fig. 1). The Iceland and MORB sources, along with the atmospheric composition, are plotted in $^{129}Xe/^{130}Xe$-$^{3}He/^{130}Xe$ space (Fig. 1). Two-component mixing in this space is linear. Since the MORB and Iceland source compositions are not colinear with the atmospheric composition, adding subducted air, or a shallow-level air contaminant to a MORB source cannot produce the lower



Xenon Isotopes, Fig. 1 Correlation of ^{129}Xe, produced from the decay of extinct ^{129}I, with ^{3}He for the MORB and OIB source composition. The MORB source data are from Moreira et al. (1998) while the Iceland and Lau/Samoa source data are from Mukhopadhyay (2012) and Pető et al. (2013), respectively. Two-component mixing in this space is linear and the observations demonstrate that adding recycled atmospheric Xe to the MORB source cannot generate the OIB composition

^{129}Xe/^{130}Xe ratios in OIBs. Consequently, the OIB sample from Iceland must have evolved with a different I/Xe ratio than the MORB source, and the two mantle sources must have differentiated by 4.45 Ga. Subsequent mixing between the MORB and OIB reservoirs must also have been limited, otherwise the differences in Xe isotopic composition would have been destroyed (Mukhopadhyay 2012). These first order conclusions were confirmed by Pető et al. (2013) from the northern Lau Basin, which samples the Samoan OIB source, (Fig. 1) and by Caracausi et al. (2016) from magmatic gas samples derived from the deep mantle in the Eifel volcanic area of Germany.

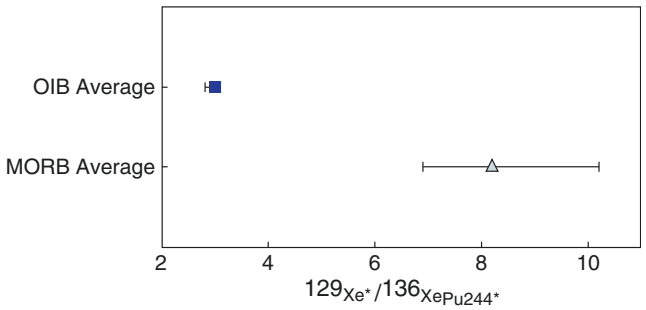
The observation that differences in isotopic composition produced by extinct radionuclides persist within the mantle to the present day has several important implications for understanding Earth accretion, mantle evolution, and volatile fluxes between Earth reservoirs. The lifetime of ^{129}I is concurrent with Earth's accretional timescale (e.g., Jacobsen et al. 2014). Therefore, the differences between OIB and MORB ^{129}Xe/^{130}Xe were setup during Earth's accretion. The preservation of heterogeneities created during Earth's accretion then requires that the Earth's mantle was not chemically homogenized by giant impacts and magma oceans. Likewise, the preservation of ancient heterogeneities indicate that differences between the OIB and MORB sources cannot be generated solely through processes associated with plate subduction, mantle convection or crust-mantle differentiation occurring during the past 4.4 Gyrs of Earth's history.

Differences in noble gas compositions between MORBs and OIBs have often been interpreted in the context of steady-state mantle models that require primordial noble gases in the volatile depleted MORB source to be derived from a primitive volatile-rich OIB source (e.g., Porcelli and Wasserburg 1995; Tolstikhin and Hoffmann 2005). Admixtures of the OIB-derived primordial noble gases, radiogenic noble gases produced in the MORB source, and subducted atmospheric noble gases lead to the noble gas isotopic compositions observed in MORBs. However, the steady-state model is fundamentally at odds with the observed Xe isotopic variations between MORBs and OIBs. This is because the OIB source cannot supply Xe to the MORB source unless augmented with ^{129}I-derived ^{129}Xe (Fig. 1). However, ^{129}I went extinct at 4.45 Ga. As a result, Xe and other noble gases in MORBs must primarily be indigenous to the MORB source. Consequently, the present day budget of primordial noble gases in the MORB source was set by the initial budget after the Moon-forming giant impact, 4.5 Ga of outgassing via mantle convection, and regassing of the mantle associated with recycling. Regassing is, however, not important for all the noble gases, but relevant for Ar, Kr, and Xe (e.g., Holland and Ballentine 2006; Kendrick et al. 2011, 2013).

Heterogeneous Volatile Accretion

The isotopes of Xe provide powerful constraints on Earth's accretion, particularly on the history of volatile delivery. The constraints are provided by the parent radionuclides, ^{129}I and ^{244}P. While I is a volatile element, Pu is a refractory lithophile element. Hence, the ratio of I/Pu in different reservoirs can be used to trace volatile accretion rate. The I/Pu ratio of the Earth can be interrogated through the ^{129}X*/136Xe$_{Pu244}$* ratio (e.g., Mukhopadhyay 2012). Traditionally, the ^{129}Xe*/^{136}Xe$_{Pu244}$* ratio has been used to constrain the closure time for volatile loss of a mantle reservoir (Eq. 1; Pepin 1991; Pepin and Porcelli 2006; Avice and Marty 2014). Since ^{129}I has a shorter half-life than ^{244}Pu, for reservoirs with the same initial I/Pu ratio, higher ^{129}Xe*/^{136}Xe$_{Pu244}$* ratios are indicative of earlier closure to volatile loss.

With the advent of better mass spectrometric techniques, more precise measurements of Xe isotopic ratios were made in mantle-derived material. These measurements allowed the deconvolution of Xe into radiogenic (^{129}Xe), plutogenic, uranogenic, recycled atmospheric Xe and primordial Xe, which indicated lower ^{129}Xe*/^{136}Xe$_{Pu244}$* ratios for the OIB source and higher values for the MORB source (Mukhopadhyay 2012; Tucker et al. 2012; Pető et al. 2013; Parai and Mukhopadhyay 2015; Caracausi et al. 2016). Depending on whether the primordial Xe component in the mantle was solar or chondritic, the ^{129}Xe*/^{136}Xe$_{Pu244}$* of the OIB source mantle was determined to vary between 2.1 ± 1.6 and $2.9^{+0.4}_{-0.1}$, with the corresponding range for MORBs being $7.8^{+3.1}_{-1.8}$ and $9.4^{+5.5}_{-2.7}$ (Mukhopadhyay 2012; Pető et al. 2013; Parai and Mukhopadhyay 2015). The discovery that the



Xenon Isotopes, Fig. 2 Ratios of I- to Pu-derived Xe in OIB and MORB sources assuming a chondritic starting composition for Xe isotopes in the mantle (Caracausi et al. 2016). The OIB average was compiled from data presented in Mukhopadhyay (2012), Pető et al. (2013), and Caracausi et al. (2016). The MORB average is from Parai and Mukhopadhyay (2015) based on data presented by Tucker et al. (2012) and Parai and Mukhopadhyay (2015)

primordial Xe component in the mantle was chondritic (Caracausi et al. 2016), enabled the $^{129}Xe^*/^{136}Xe_{Pu244}^*$ ratio to be further restricted to $3^{+0.1}_{-0.2}$ for OIBs and $8.2^{+2.0}_{-1.3}$ for MORBs (Fig. 2; Schlichting and Mukhopadhyay 2017).

If the whole mantle had a homogenous I/Pu ratio, then based on Eq. (1), the higher $^{129}Xe^*/^{136}Xe_{Pu244}^*$ ratio in the MORB source would imply that the shallower MORB mantle source became closed to significant volatile loss earlier than the deeper OIB mantle source; i.e., the shallow stopped losing volatiles while volatile loss in the deeper mantle kept ongoing. Such a scenario is physically unrealistic as mantle outgassing and volatile loss occurs at the Earth's surface. A simpler and more plausible interpretation of the lower $^{129}Xe^*/^{136}Xe_{Pu244}^*$ ratio in OIBs is that it reflects a lower initial I/Pu ratio for the deeper OIB source compared to the shallower MORB source. Since I is a highly volatile element, the $^{129}Xe^*/^{136}Xe_{Pu244}^*$ provides direct confirmation of heterogeneous volatile accretion with the initial phase of Earth's accretion being volatile poor compared to the later stages of accretion. Importantly, because the signature of varying volatile accretion rate associated with Earth's formation is still preserved in the present day mantle, magma oceans and giant impacts that characterized Earth's growth from an embryo to its current size (Agnor et al. 1999; Jacobsen et al. 2014; Melosh 1990; Tonks and Melosh 1993; Tucker and Mukhopadhyay 2014) did not ever homogenize the planet; chemical signatures acquired during the embryo stage are still present in the deepest part of the Earth's mantle.

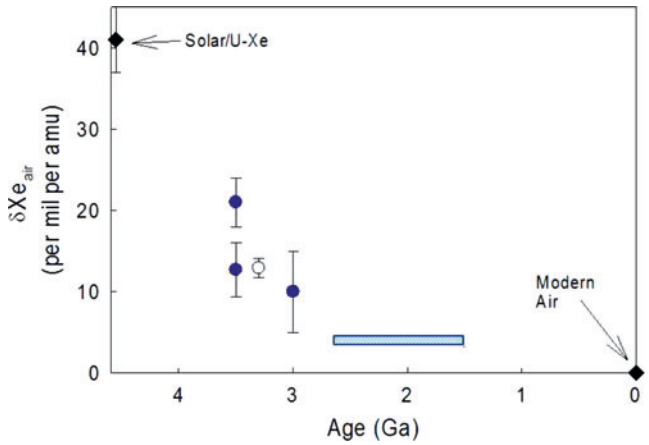
Loss of Xe from the Atmosphere During the Hadean and Archean

Atmospheric Xe is mass fractionated and enriched in the heavier isotopes by ~4%/amu compared to both solar and chondritic Xe. The mass fractionation of Xe is usually taken as a telltale sign of atmospheric Xe loss from the Earth, or in the precursor bodies that accreted to form the Earth (Pepin 1991, 2000; Pepin and Porcelli 2002; Zahnle et al. 1990a, b). The magnitude of the Xe mass fractionation is, however, quite puzzling as the isotopic composition of Kr is mass fractionated from solar by only ~0.4%/amu. A second puzzling observation with atmospheric Xe is that simple mass dependent fractionation of solar or chondritic xenon cannot produce the observed isotopic abundances in the atmosphere; the mass fractionation produces an overabundance of the heaviest isotopes ($^{134,136}Xe$) without even adding any Pu- or U-derived fission Xe that would have been produced on the Earth.

Both of these puzzling aspects of terrestrial atmospheric Xe have been written about extensively (e.g., Pepin 1991, 1992, 2000; Pepin and Porcelli 2002, 2006) and only a brief summary is given below. To solve the initial atmospheric composition, nebular Xe was supposed to have the composition of U-Xe (Pepin 1991), a mathematically constructed composition that when mass fractionated, and added to Pu-derived fission Xe, yields the atmospheric composition. While the existence of U-Xe has been long speculated, only recently has the progenitor of U-Xe been potentially identified in the comet ^{67}P/Churyumov–Gerasimenko (Marty et al. 2017). Analysis of the Xe isotopes in the coma of the comet by the Rosetta Orbiter Spectrometer show significant deficits in heavy Xe isotopes, similar to that in U-Xe. These measurements suggest that the Earth's atmosphere could be made of mixture of 22 ± 5% cometary Xe with chondritic/solar Xe (Marty et al. 2017).

The Xe isotopic fractionation observed in the present day atmosphere was modeled to result from loss of a primary solar nebular atmosphere associated with hydrodynamic escape during Earth's accretion (e.g., Pepin 1991). Hydrodynamic escape of the atmosphere would mass fractionate the light gases more than the heavier gases, leading to a higher degree of mass fractionation for Kr isotopes compared to Xe isotopes. The lower extent of mass fractionation for Kr isotopes is achieved by outgassing of mantle Kr enriched in the lighter isotopes. However, recent work indicates that mantle Kr is enriched in *heavier* isotopes compared to the atmosphere (Holland et al. 2009). Therefore, hydrodynamic escape of a primary nebular atmosphere followed by mantle outgassing cannot explain the differences in the extent of mass fractionation for Xe and Kr isotopes in the modern atmosphere.

Xenon isotopic measurements in Archean rocks also challenge the notion that Xe mass fractionation was produced by hydrodynamic escape during Earth's accretion. Srinivasan (1976) detected nonradiogenic Xe in a 3.5 Ga Archean barite that was mass fractionated compared to modern day atmosphere. Based on additional measurements in 3.5 Ga barite and 3.0 Ga cherts from the Pilbara craton in Australia, Pujol et al. (2009, 2011) documented an increase in the extent of Xe isotopic fractionation from primordial values towards modern air (Fig. 3). They suggested that this signature of evolving Xe



Xenon Isotopes, Fig. 3 Change in atmospheric Xe mass fractionation through time. The solid circles are data from Pujol et al. (2009, 2011) and Srinivasan (1976) from barite and chert samples from the Pilbara craton in Australia. The open circle is from quartz samples from the Barbeton Greenstone belt in South Africa (Avice et al. 2017). The hatched rectangle is based on data from deep fluids in Precambrian rocks from Timmins, Ontario, Canada (Holland et al. 2013)

isotopic fractionation from 3.5 to 3.0 Ga in the rock record was a signature of the evolving atmospheric Xe composition driven by Xe escaping from the atmosphere during the Hadean and Archean. The observation that ancient atmosphere was less fractionated then modern air has now been reproduced in other localities, including macrocrystalline quartz samples from the Barbeton Greenstone belt in South Africa (Avice et al. 2017) and deep fracture fluids in Precambrian basement rocks in Timmins, Ontario, Canada (Holland et al. 2013). These data appear to suggest a monotonic increase in mass fractionation through the Archean into the Proterozoic (Fig. 3; Pujol et al. 2009, 2011; Avice et al. 2017). Thus, significant Xe loss from the atmosphere appears to have been protracted over at least the Hadean and Archean.

A physical process that drives protracted Xe loss has not yet been conclusively identified. A key observation in the Archean rock record is that the Kr isotopes are not mass fractionated compared to modern air (Pujol et al. 2011; Avice et al. 2017). Hence, the process must only drive Xe loss and not loss of the lighter elements. Since the ionization potential of H_2 is higher than Xe but lower than Kr, Zahnle (2015) suggest that solar UV could readily ionize Xe while ionizing Kr would be considerably harder. Moreover, the ionized Kr would be readily lost through reaction with H_2 (Zahnle 2015). The ionized Xe could then get dragged away by H^+ ions along open magnetic field lines. Such a process would require a substantial flux of escaping H_2, which could be derived from oxidation of H_2O. The escaping H_2 would ultimately lead to oxidation of the Earth's surface and the rise of O_2 in the atmosphere (Zahnle 2015). The atmospheric Xe record is thus important, as it might provide the observational basis for substantial hydrogen escape in the Archean.

Summary

Measurements of Xe isotopes were utilized in the first detection of an extinct radionuclide in the solar system, ^{129}I. Xe isotopes have been used to constrain the atmospheric closure age, the formation interval of the Earth, and timescales for mantle degassing. In the past decade, several important advances in Earth Science have been made through studies involving Xe isotopes. These include convincing evidence for the transport of atmospheric noble gases associated with hydrous phases back into the mantle, key new insights into the preservation of deep mantle heterogeneities dating back to Earth's accretion, evidence of heterogeneous volatile accretion with early accretion being volatile poor, mass fractionating Xe loss from the atmosphere during the Hadean and Archean, and the discovery of the progenitor of U-Xe in comets. Looking ahead, key areas for improvement in Xe isotopes studies include measurement precision, techniques to reduce shallow level air-contamination in terrestrial samples, and a better determination of the isotopic composition of Xe generated from Pu versus U fission.

X-Ray Diffraction

Tori Z. Forbes
Department of Chemistry, University of Iowa, Iowa City, IA, USA

Definition

X-ray diffraction is the result of coherent scattering of an X-ray beam through a solid-state crystalline phase. Single-crystal X-ray diffraction can provide information about the arrangement of atoms and overall chemical composition of mineral phases by determining the angle and intensity of the diffracted beam. Powder samples can also be analyzed using this method to identify unknown phases or mixtures, provide unit cell parameters, and determine particle sizes.

Introduction to X-rays

X-rays were first discovered by Wilhelm Conrad Roentgen in 1985 during experiments with a cathode ray tube (Bertin 1975; Reventos et al. 2012). This device consists of a specialized vacuum tube in which images can be created when electrons are accelerated or deflected onto a phosphorescent screen. During his experiments, he observed that a fluorescent screen located on a table six feet away from his experiments glowed when he activated the tube. Since these rays were previously undescribed, he named them X-rays.

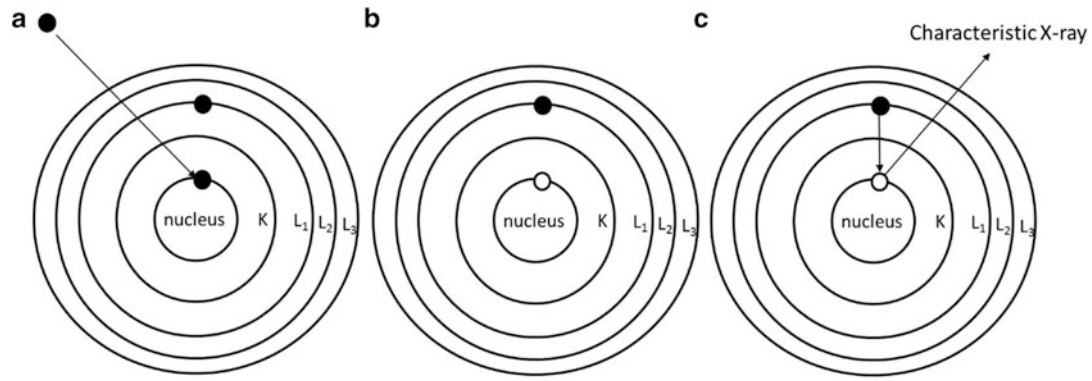
We now know that X-rays are a subset of the electromagnetic spectrum that has wavelengths from 0.1 to 100 Å (10^{-10} m) (Bertin 1975). X-rays are produced in a cathode ray tube by shooting a high velocity stream of electrons at a target. The electrons in the stream collide with electrons in the target and if the oncoming electrons have the right velocity, the target electrons are knocked into a higher energy orbital. When the electrons fall back down into the lower energy orbital, X-rays are produced. Bohr's model of the atom can be used to describe this phenomenon (Fig. 1). In this diagram, an electron is knocked out of the K shell and then an electron from the L-shell then drops down to the lower energy state, releasing a photon in the process. This photon, or X-ray, has a very specific wavelength that is related to the energy difference between the two shells and referred to characteristic X-rays. If the electron does not strike a target electron, but instead interacts with the positively charged nucleus, the velocity can change and result in the formation of an X-ray, which is referred to as Bremsstrahlung radiation. Characteristic X-rays have defined energies, but Bremsstrahlung radiation has a wide range of energies based upon the wide range of kinetic energy for this reaction.

X-rays are described based upon their photon energy with soft X-rays having energies below 5 keV and hard X-rays having photon energies above 5 keV. Hard X-rays are used for diffraction techniques because of their ability to penetrate solid materials and interact with the electron clouds of the atoms present in the crystalline lattice. The wavelength (<2.5 Å) of hard X-rays is also similar to the size of atoms, providing the ability to determine their arrangement within the solid-state material.

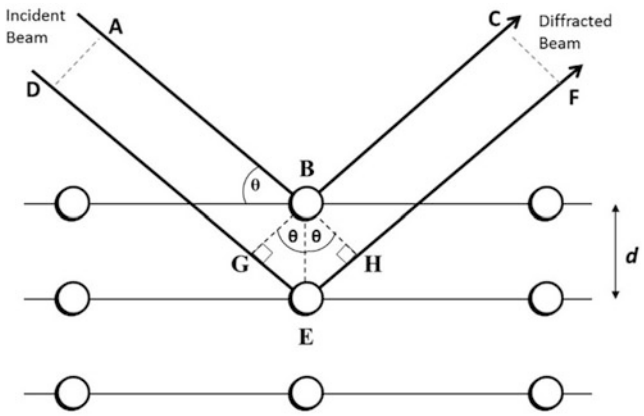
Principles of X-ray Diffraction

When X-rays photons propagate through a substance, they can be scattered or absorbed, but it is the analysis of the coherently scattered X-rays that is utilized in diffraction techniques. For coherent scattering to take place, the X-ray beam will interact with the electrons surrounding the nucleus, creating an oscillation with the same frequency as the electric field component of the electromagnetic wave. The radiation created from this process is emitted in all directions and has the same wavelength as the incoming wave. In a crystalline solid, such as a mineral phase, millions of atoms are arranged in ordered arrays and the monochromatic X-ray beam can interact with a multitude of electrons associated with these atoms. The coherently scattered waves can interact either destructively (canceling out the amplitude of the wave) or constructively (increasing the magnitude of the wave). Constructive interaction of the X-ray beam produces wave fronts that are in phase, and this cooperative scattering effect is known as diffraction.

When an X-ray beam penetrates a crystal, the diffraction can occur as a "reflection," where the incident beam reflects back out of the crystal from these parallel planes. However, for the diffraction effect to be of measurable intensity, reflections from the individual planes must be in phase with each other to lead to constructive enhancements. The necessary



X-Ray Diffraction, Fig. 1 Characteristic X-rays are produced when (**a**) an incoming electron removes an electron from a core shell and (**b**) creates a hole. (**c**) An electron from a higher energy orbital moves to the hole and releases a photon with a specific energy or wavelength, resulting in characteristic X-ray



X-Ray Diffraction, Fig. 2 Diffraction of the incident X-ray beam by atomic planes in a crystalline solid can result in enhanced signals if all the waves are in phase. This can be accomplished if there is an integral wave value, as determined by Bragg's law

conditions for in-phase diffraction or "reflection" by the parallel atomic planes can be expressed using Bragg's equation. William Lawrence Bragg was a British physicist who was considered one of the first X-ray crystallographer (Reventos et al. 2012). He and his father (William Henry Bragg) determined that an integer value of the wavelength is related to the distance between the parallel atomic planes and the angle of the diffracted beam. Within the crystalline lattice, a set of parallel atomic planes can be described that are separated by a distance (d) (Fig. 2). X-rays hitting the first plane are reflected at the incident angle, θ, and must be reinforced by in-phase reflection (integral values) of the other atomic planes (e.g., second, third, fourth) for diffraction to be measurable. Therefore, the wave path along first atomic plane (ABC) is shorter than the second plane (DEF), and this value must be a whole number of the wavelength (nλ) for diffraction conditions to be satisfied. In Fig. 2, lines BG and BH are drawn perpendicular to AB and BC so that AB = DG and BC = HF. To satisfy the in-phase condition, GE + EH = nλ. The line drawn between B and E is perpendicular to the atomic planes and is equal to the interplanar spacing (d). This creates two right triangles where d sin θ = GE and d sin θ = EH. Thus, Bragg's equation states:

$$\mathbf{2d\ sin\theta = n\lambda}$$

When a single crystal ($\sim 1 \times 10^{-4}$ m) is placed into the incoming X-ray beam, then the resulting diffraction from a specific plane of diffraction results in a single reflection and rotation of the crystal is required to observe coherent scattering from all possible Bragg angles. Integration of the diffraction data allows complete characterization of the sample including the crystal system, space group, atom locations, bond lengths and angles, and chemical content of the solid (Massa 2004). It is often difficult to obtain or collect highly ordered single crystals with the correct dimensions for analysis with single-crystal X-ray diffraction. Polycrystalline material can also be analyzed using power X-ray diffraction and the large number of randomly ordered crystallites gives rise to lines of diffraction (Bish and Post 1989). The positions of these lines are related to the atomic position and thus the resulting powder X-ray diffractogram can be used as a "fingerprint" to identify mineral phases.

Instrumentation

An X-ray diffractometer is used to collect information regarding the placement and the intensity of the diffracted beam and consists of three major components: (1) X-ray source, (2) sample stage, and (3) detector. The X-ray tube consists of a tungsten filament cathode to provide the source of electrons and a target metal to produce the characteristic X-ray. Most laboratory-based systems contain molybdenum (Mo), copper (Cu), or cobalt (Co) targets that result in $K\alpha_1$ wavelengths of

0.70932, 1.5418, and 1.7902 Å, respectively (Pecharsky and Zavalij 2005). The sample stage consists of a goniometer that allows the sample to be moved through a wide range of diffraction conditions. Specialized sample cells have been designed to handle high pressure and variable temperatures to explore structural changes in mineral phases under geologically relevant conditions (Toulemonde et al. 2014). The detector converts the individual X-ray photons into voltage pulses that can be transformed into information regarding the intensity and position of the diffracted beam. Traditionally, photographic film was used to collect information on the diffracted beam, but current methods use solid-state semiconductors within one- and two-dimensional position sensitive detectors (Pecharsky and Zavalij 2005).

Uses in Geochemistry

Single-crystal X-ray diffraction has been utilized extensively in mineralogy and geochemistry to determine the structural feature of geologic media. Halite (NaCl) was the first atomic resolution structure to be determined by X-ray diffraction in 1913, and other minerals analyzed the following year include fluorite, calcite, and pyrite (Reventos et al. 2012). Since the early years, thousands of minerals have been structurally characterized, leading to an advanced understanding of the chemical and physical properties of these materials. An example of the latest structural characterization include mineral species collected from meteorites (Xie et al. 2015), high temperature and pressure phases (Golubkova et al. 2015; Merlini et al. 2015), and unusual quasicrystals (Bindi et al. 2015). While thousands of mineral phases are known, it is possible that there is still 25% of unknown mineral phases with undescribed structural features (Hazen et al. 2015).

Given the polycrystalline nature of a significant portion of geologic media, powder X-ray diffraction is a very important technique and is used for identification, evidence of chemical changes in the material, and size determination of nanoparticle samples. Structural determination of solid-state materials can also be performed using Rietveld analysis on the collected diffractogram (Bish and Post 1989). Powder X-ray diffraction has been used to investigate biomineralization processes (Pokroy et al. 2004; Villalobos et al. 2006; Cam et al. 2015) and identify clay minerals on the surface of Mars (Bristow et al. 2015), meteorite mineralogy (King et al. 2015), and composition of Mn-nodules from the Pacific Ocean (Wegorzewski et al. 2015). Advancements in powder X-ray diffraction and related techniques are currently pushing the limits on detection of crystalline ordering to investigate poorly crystalline and amorphous systems (Mikutta et al. 2014; Dideriksen et al. 2015).

Summary

X-ray diffraction techniques are used to determine the structural features of a solid material. Single-crystal methods provide the atomic arrangement and elemental composition of highly ordered mineral phases. Powder X-ray diffraction is used to identify unknown samples and mixtures (soils or sediments), determine structural parameters, and ascertain particle sizes.

X-Ray Fluorescence Analysis

Izumi Nakai
Department of Applied Chemistry, Tokyo University of Science, Tokyo, Japan

Definition

X-ray fluorescence (XRF) analysis is one of the best analytical techniques to perform nondestructive elemental analysis of solid or liquid samples for major and minor components. A sample is excited by bombarding with X-rays causing ejection of inner electrons with subsequent emission of the characteristic (fluorescence) X-rays of the sample. The energy of the fluorescence X-rays is a characteristic of an element, and their intensities are proportional to the number of excited atoms and thus can be used for qualitative and quantitative analysis of the sample.

Introduction

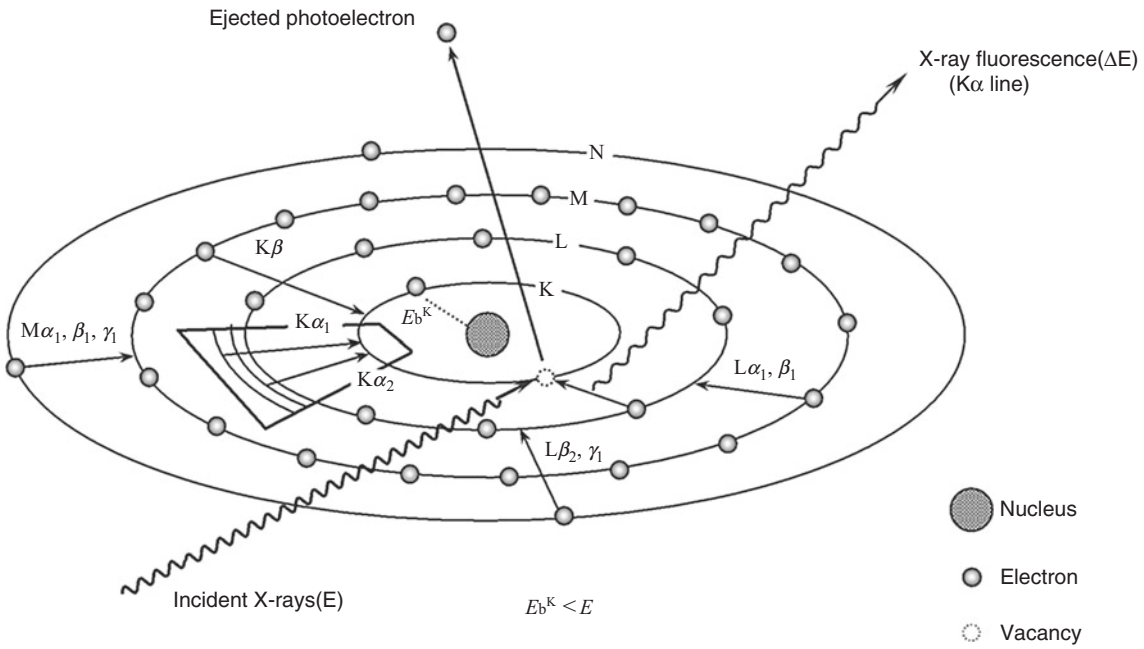
Since discovery of X-rays by Rontgen in 1895, interaction of X-rays with an atom became a target of eager study in physics research, and X-ray spectroscopy was developed (Bertin 1978). At early stage of X-ray spectroscopy development, Moseley (1913) showed that the chemical composition of a substance can be determined with the aid of X-ray spectroscopy. However, introduction of modern X-ray spectrometer for XRF analysis must wait until 1948, when Friedman and Birks built the prototype of the first modern commercial X-ray secondary-emission spectrometer with a sealed-off X-ray tube (Bertin 1978). Nowadays, XRF analysis is a well-established analytical method that is one of the fundamental techniques of element analysis and is widely used in various fields such as geochemistry, geology, archaeology, material sciences and industry (Muller 1972).

Principle of X-ray Fluorescence Analysis

The principle of X-ray fluorescence emission is well explained by Bohr's model as shown in Fig. 1: a positively charged nucleus is surrounded by electrons that travel in circular orbits (defined by their energy levels E_i) around the center and are bound to the nucleus by the Coulomb forces. These electron shells (orbits) are denoted by K, L, M, N, etc., shells in the order of increasing shell diameter (Fig. 1). The energy of an electron depends on the size of the orbit and is lower for smaller orbits. Therefore, K shell is the smallest, and E_K is the lowest.

When an X-ray photon with energy E is impinged on a K shell electron, which is bound to a nucleus with a binding energy E_b^K, the electron may be knocked out of the shell as a photoelectron if $E > E_b^K$. Then, this atom becomes an excited state with an electron vacancy in the K shell. The vacancy is filled by an electron from a neighboring outer shell (e.g., L shell), and the excess energy ($\Delta E = E_K \sim E_L$) is emitted in the form of X-rays, which is called the X-ray fluorescence K line (if from L shell, it is called the Kα line). E_b is the minimum energy necessary for the excitation of the electron in the shell. This threshold energy is called the absorption edge energy. ΔE is characteristic of an emitting element; therefore, we can accurately identify the element, qualitative analysis, by measuring ΔE, which is the energy of the emitted X-ray fluorescence line. On the other hands, since the intensity of the emitted X-ray (I) is basically proportional to the amount of the element, quantitative analysis can be performed by measuring I. These are basic principles of X-ray fluorescence analysis (Muller 1972).

The XRF spectrometer measures the energy (ΔE) and intensity (I) of the X-ray fluorescence signal emitted from a sample by irradiation of X-rays, and, thus, an XRF spectrum is obtained. The XRF spectrometer is composed of an X-ray source, sample chamber, X-ray detector, and electronic devices for signal processing, amplification, counting, and computing. There are two types of instruments to measure the XRF energy: wavelength dispersive (WD) and energy dispersive (ED) analyses (Grieken and Markowicz 2001). In ED analysis, a solid-state detector is used to measure the XRF spectrum, and the X-ray energy and intensity can be simultaneously measured with the detector. In WD analysis, the XRF signals emitted from a sample are directed into analyzing



X-Ray Fluorescence Analysis, Fig. 1 Principle of X-ray fluorescence analysis. A Bohr atom showing the first four inner shells and the origin of the X-ray spectra; intraatom electron transitions are responsible for the principal X-ray spectral lines of analytical interest

crystals, diffraction grating monochromators with known d spacing. By varying the angle (θ) of incidence and the take-off on the analyzing crystal, the X-ray wavelength (λ) is selected by X-ray diffraction based on the Bragg equation of $n\lambda = 2d\sin\theta$. ED analysis has the advantage of simple components of the instruments, i.e., an X-ray source and a detector are two basic essential components, which allow miniaturization of the instrument. The weak point of ED analysis is that the energy resolution is not good, ca. 120 eV as that of WD (~30 eV). This causes the peak overlap of the neighboring elements in the spectrum. However, WD analysis requires a moving mechanism of the monochromator, which requires a large instrumental volume with a long beam pass and a strong intensity of X-ray irradiation, which may cause damage to the sample.

The XRF technique is suitable for nondestructive multielemental analysis of solid, liquid, and gas samples. Conventional instruments allow analysis of Na and heavier elements in air and in vacuum analysis of lighter elements down to Be, which can be detected with high-performance instruments. The sensitivity of quantitative XRF analysis of heavy elements is in the order of sub-ppm and somewhat worse than that of ICP-AES. The great advantage of the method is nondestructive nature, suitable for analysis of precious samples. Another advantage is that the sample preparation is easy, without the necessity of dissolving a solid sample into acid or alkali which requires chemical laboratory. XRF analysis is a type of surface analysis with an information depth of 1 μm to a few millimeters depending on the X-ray energy and the mean atomic number of samples. For quantitative analysis, a sample should be sufficiently thick (infinite thickness) and homogeneous. For quantitative analysis, a calibration curve is prepared using a standard sample of known compositions with similar matrix components to the sample. The FP (Fundamental Parameter) method is a theoretical method widely used in quantitative XRF analysis, and the X-ray intensity is theoretically calculated based on the physical parameters such as absorption factor, X-ray intensity. The least-square analysis is used to refine the concentration parameters, such that the difference between the observed and calculated intensities becomes minimum.

Recent Innovation in XRF Analysis

Hand-Held XRF Analyzer

In recent years, two big innovations emerged in XRF analysis. One is the development of a hand-held XRF analyzer (Fig. 2). The weight of the instrument is around 1 kg and can be held by one hand. With this handy instrument equipped with a battery, anyone can feel free to analyze a sample without specialized knowledge at anytime and anywhere. Examples of applications include analysis of soils with GPS data, analysis of huge rocks, ore mineral, environmental samples, etc., and can be used on location for immediate results.

Synchrotron Radiation Application

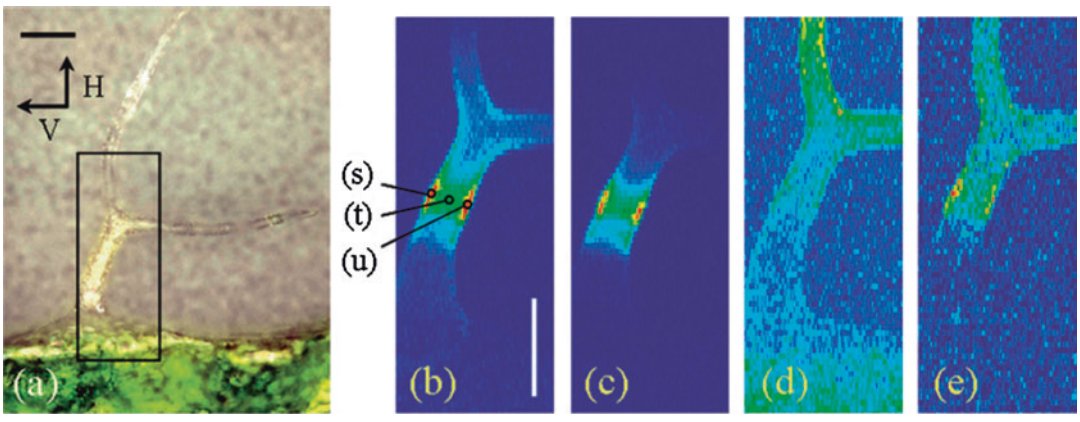
Another innovation is the fact that synchrotron radiation (SR)-XRF analysis becomes more or less a routine technique. A large number of SR facilities have been constructed

globally, and the SR-XRF technique becomes not specialized to limited number of users. SR X-rays are brilliant light source and are energy-tunable: the users can select the energy required for their experiments. The use of monochromatic X-rays in XRF analysis with a suitable X-ray excitation energy drastically increases the sensitivity of the analysis by selective excitation of a specific element of interest. SR X-rays are ideal as an excitation source in XRF analysis, and their characteristic applications were illustrated in the following example.

SR is a parallel beam, and a microbeam with 1 μmϕ focused by a total reflection mirror is practically available. The champion data of the smallest beam size are on the order of ten nanometers (Mimura et al. 2010). This micro (nano)-beam is suitable for two-dimensional analysis of geological and biological samples. Figure 3 shows an example of μ-XRF imaging of a plant, *Arabidopsis halleri*, a hyper accumulator of Cd (Fukuda et al. 2008). It is interesting to reveal where this plant accumulates a toxic Cd ion. Figure 3 (a) shows the photograph of the measured sample showing the imaging area, and the distribution of (b) Cd, (c) Zn, (d) Ca, and (e) Mn are expressed using red (the highest intensity) to blue (the lowest intensity) colors corresponding to the XRF intensities of each element. It is found that Cd was highly accumulated in a part of trichome, epidermal hairs existing on the surface of the leaves. Figure 3b, c shows a significant correlation between the XRF intensity distributions of Cd and Zn. The results showed that Cd and Zn behave in a similar way. Thus, in vivo analysis of plant and animal samples with the cellular resolution in air is possible by SR-μ-XRF analysis. A similar spatial resolution can be obtained using scanning electron microscopy–energy dispersive spectoscopy (SEM-EDS) analysis; however, analysis of living samples in air is not possible with SEM-EDS analysis. SEM-EDS analysis involves electron beam excitation, which tends to cause damage to the sample. SEM-EDS analysis is suitable for analyzing light elements, such as C, N, O, and F, but the sensitivity of heavy element analysis is relatively low at 0.1% level. In contrast, SR-μ-XRF analysis shows a ppm–ppb sensitivity for heavy elements, though the sensitivity of the analysis of light elements is low. Instead of SR application, X-ray microbeam produced by capillary optics became popular in XRF analysis in a laboratory, and an XRF microscope with a spatial resolution of 10 μm is commercially available.

The use of high-energy 116 keV X-rays in XRF analysis allows excitation of K-shell electrons of uranium ($E_b^K = 115.6$ keV), the heaviest element in nature, and the U K line spectra can be measured (Nakai 2004). The K line region of the XRF spectra of heavy elements do not overlap with any light element lines. Thus, high-sensitive analysis of geochemically important heavy elements, such as lanthanide, is possible by using high-energy XRF analysis with 116 keV X-rays.

X-Ray Fluorescence Analysis, Fig. 2 Handheld X-ray fluorescence analyzer

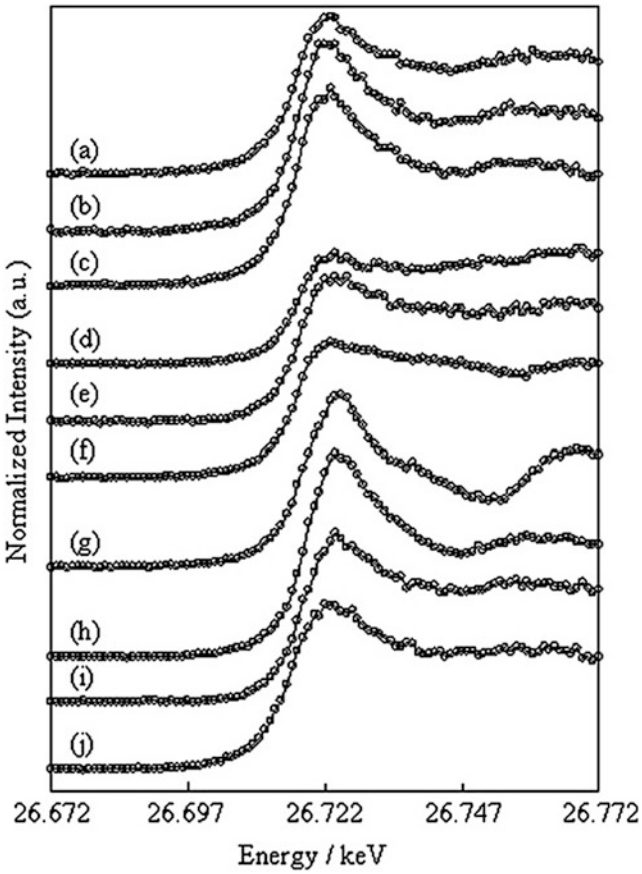


X-Ray Fluorescence Analysis, Fig. 3 μ-XRF imaging of trichome; the X-ray energy is 37 keV, the beam size is 3.8 μm (H) × 1.3 μm (V). (**a**) Photographs of the measured samples showing the imaging area. The elemental distribution maps of (**b**) Cd, (**c**) Zn, (**d**) Ca, and (**e**) Mn are shown as a color scale from *red* (the highest XRF intensity) to *blue* (the lowest XRF intensity). (Fukuda et al. 2008; Fig. 2)

Chemical State Analysis

Another characteristic application of SR-XRF analysis is chemical state analysis using fluorescence-X-ray adsorption fine structure (XAFS) spectra. A fluorescence-XAFS spectrum can be obtained by measuring the X-ray fluorescence intensity of an element from a sample as a function of the excitation energy from ca. 50 eV below the X-ray absorption edge energy (E_b) of the element to 1 keV above E_b. The fine structure of the XAFS spectrum below and above E_b is called the X-ray absorption near edge structure (XANES) spectrum, and the oscillation structure from 50 eV to 1 keV above the edge is called the extended X-ray absorption fine structure (EXAFS). The energy of E_b increases when the oxidation state of the absorber atom increases, which is called the chemical shift. With this principle, chemical state analysis of the absorber element in the microregion is possible with SR X-rays. This method is applicable to any form of the sample, solid, liquid, gas. Moreover, the analysis of EXAFS oscillation provides information about the local structure around the absorber atom (bond distance, coordination number, etc.) even from an amorphous sample without knowing any structural information. Therefore, fluorescence XAFS is very useful technique for geochemists. At early stage of SR application, XAFS was independent of XRF analysis. However, more than 30 years have passed since XAFS became a popular analytical tool, and fluorescence-XAFS measurement combined with micro-XRF analysis became a routine technique of the XRF beamline at an SR facility. Especially, a micro-X-ray absorption near edge structure (XANES) spectrum measurement with a microbeam is a powerful technique to determine the chemical form of an element in geochemical samples.

Figure 4 shows an example of the Cd-K edge XANES spectra of trichome of *A. halleri* (see Fig. 3) and the reference compounds (Fukuda et al. 2008). The Cd Kedge XANES spectra of points (s), (t), and (u) in Fig. 3b in trichome are shown in Fig. 4 as (a), (b), and (c), respectively. The comparison of the XANES spectra of the reference materials shown in Fig. 4 suggests that there is a characteristic difference in the shapes between the spectrum of Cd with S ligands: (f) CdS, (d) phytochelatin (PC)-Cd, and (e) metallothionein (Mt)-Cd, and that of Cd with O ligands: (g) CdO, (h) $Cd(NO_3)_2$aq, (i) cadmium acetate (AcCd) or N ligand, (j) hexakis(imidazole) cadmium(II) nitrate $(Im)_6Cd(NO_3)$. The covalent nature is high in the Cd–S bond, while the ionic nature is high in the Cd–O (N) bonds yielding a very flat feature for the XANES spectra of the former type. The spectra from Fig. 4a–c are similar in shape to those of compounds containing Cd with O or N ligands. Consequently, it was found that a majority of Cd in *A. halleri* was divalent and bound to O or N ligands, not to S ligands.



X-Ray Fluorescence Analysis, Fig. 4 Cd K-edge μ-XANES spectra of trichome of *A. halleri* and reference compounds (*a*) point s, (*b*) point t, and (*c*) point u of the trichome sample in Fig. 2b, (*d*) PC-Cd, (*e*) Mt-Cd, (*f*) CdS, (*g*) CdO, (*h*) $Cd(NO_3)_2$aq, (*i*) AcCd, (*j*) $(Im)_6Cd(NO_3)_2$. (Fukuda et al. 2008; Fig. 4)

Conclusion

XRF analysis is not an insensitive analytical method any longer. A combination of a secondary target and three-dimensional polarizing optical geometry of a spectrometer greatly reduced the background of the XRF spectrum, and analysis of heavy elements at ppb level becomes possible in a laboratory. Handheld XRF analyzers provide fast, easy, and nondestructive elemental analysis by anyone at any place, which will open a new field of XRF applications. The utilization of SR X-rays expands application fields of XRF analysis into chemical state analysis. Two-dimensional analysis with a spatial resolution of 1 μm is practically possible. With these innovations, it could be said that XRF analysis has now entered a new stage of application.

Crustal Abundance: 1.9 ppm
Seawater Abundance: ~0.17–1.2 ng/kg
Core Abundance: ~0

Properties

Ytterbium is a silvery-white metal, with a slight yellowish tinge (see Fig. 1). Ytterbium is a lithophile element (McDonough and Sun 1995). It is soft, malleable, and quite ductile. It is slowly oxidized by air. However, this oxide layer forms a protective layer on the surface, preventing complete oxidation (Emsley 2011; Hammond 2016).

The element reacts slowly with water, and dissolves readily in dilute acids. The +3 oxidation state is predominant. In solution ytterbium exists as Yb^{3+}, associated with nine molecules of H_2O. Both Yb solutions and salts are colorless (Emsley 2011).

History and Use

Ytterbium was first discovered in 1878 by Swiss chemist Jean Charles Galissard de Marignac, 1817–1894, (Marignac 1878). He separated an Earth which he called ytterbia from erbium nitrate. About the same time, Carl Auer (1858–1929) discovered the same oxide and named it aldebaranium (Emsley 2011). Ytterbium metal was made first in 1937, but it was not pure enough for the properties to be reliably measured (Hammond 2016). In 1953, a pure sample was finally obtained (Emsley 2011).

The artificial isotope ^{169}Yb is used as a source of gamma rays for non-destructive testing and radiomedicine (Hammond 2016). Ytterbium is also used in atomic clocks (NIST 2013), and in catalysis (Emsley 2011; Mori and Kobayashi 2012). Applications are also found in alloys (Hammond 2016). The total amount of applications of Yb is, however, limited (Hammond 2016).

Geochemical Behavior

Ytterbium is a moderately incompatible trace element, and behaves as a lithophile element. As are the other lanthanides, it is highly insoluble in natural aqueous solutions and considered immobile. Because it, along with Eu and Ce, has lower nebular condensation temperatures than the other lanthanides, both chondrites and their refractory inclusions

sometimes exhibit Yb anomalies (Boynton 1975). Ytterbium is found mostly in the mineral monazite (Ce, La, Th) PO_4, but also in euxenite (Y,Ca,Ce,U,Th)(Nb,Ta,Ti)$_2O_6$ and xenotime (YPO_4). It also partitions strongly into garnet. It can be extracted by ion exchange and solvent extraction (Emsley 2011).

Biological Utilization and Toxicity

Ytterbium has no known biological function and has a low acute toxicity rating (Hammond 2016).

Properties

Yttrium is a transition metal with a silvery-white color. It has strong chemical similarities with the lanthanides, especially with the heavier ones (Gd–Lu). Therefore it is usually classified as a (heavy) rare earth metal. It is also always found combined with rare earth metals. The most prominent ore mineral is xenotime (YPO_4). Yttrium's only stable isotope, ^{89}Y, is also its only naturally occurring isotope. The metal is readily oxidized by air, which however forms a resistant oxide film on the surface of the metal, preventing full oxidation. It is attacked by water, where it causes decomposition with the release of hydrogen gas (Emsley 2011), (Fig. 1).

History and Use

Yttria, which is an earth containing yttrium, was discovered by Finish chemist Johan Gadolin (1760–1852) in 1794 (Gadolin 1794, 1796). The material from which yttria was prepared was found in a quarry near the Swedish town of Ytterby (Hammond 2016).

Yttrium, Fig. 1 Yttrium, sublimed-dendritic, high purity 99.99%, as well as an argon arc remelted 1 cm^3 yttrium cube for comparison. Purity 99.9% (Source: Wikipedia.en (Yttrium). (https://en.wikipedia.org/wiki/Yttrium) Photograph by H. Pniok. No changes made. Link to the license: https://commons.wikimedia.org/wiki/Commons:Reusing_content_outside_Wikimedia. Used with Permission)

Friedrich Wöhler (1800–1883) obtained the impure element in 1828 (Wikipedia 2016a). Highly pure yttrium was first prepared in 1953 by Frank Spedding (1902–1984) at Ames Laboratory, Iowa (Wikipedia 2016b).

Yttrium oxide is one of the most important compounds of yttrium and accounts for the largest use. Yttrium is widely used to produce YVO_4 and Y_2O_3, which, doped with europium are widely used as a red phosphor in color televisions. Also yttrium oxide sulphide $Y_2O_2S{:}Eu_{3+}$ doped with europium is used as such (Emsley 2011; Hammond 2016).

Yttrium is also used for the production of $Y_3Fe_5O_{12}$ (yttrium iron garnet, or YIG), which is an effective microwave filter. Yttrium iron garnet is also exceptionally efficient as both a transmitter and transducer of acoustic energy.

Yttrium iron, aluminium, and gadolinium garnets (e.g., $Y_3Al_5O_{12}$) have interesting magnetic properties. Yttrium aluminium garnet, with a hardness of 8.5, is also finding use as simulated diamond. YAG (Yttrium Aluminium Garnet) doped with a variety of elements, such as Nd, Ho, Er, Yb, Ce, etc. are used as lasers (Emsley 2011; Hammond 2016).

In metallurgy, small amounts of yttrium (0.1–0.2%) are used to reduce grain size in chromium, molybdenum, zirconium, and titanium. Such amounts are also used to dope aluminium and magnesium alloys, where yttrium increases strength. There are several other alloy applications, among them an aluminium-nickel-yttrium alloy, which is used in aircraft manufacture (Hammond 2016).

In catalysis, yttrium is used as a catalyst for ethylene polymerization (Emsley 2011). Ceramic superconductors of the type $YBa_2Cu_3O_7$ ("123 superconductors," Wu et al. 1987) also rely on yttrium.

Geochemical Behavior

Like all other REE, yttrium behaves as a moderately incompatible lithophile ("rock-loving") element in igneous systems. Yttrium concentrates in magmatic liquids and late crystallizing mineral phases and is thought to have an incompatibility similar to that of rare earths Dy and Ho. Like the lanthanides, Y is highly insoluble in natural aqueous solutions and considered immobile. Yttrium favorably concentrates in xenotime, YPO_4 (Emsley 2011).

Biological Utilization and Toxicity

Yttrium has no known biological function. Some soluble yttrium salts may be mildly toxic and yttrium may be carcinogenic in some animals and may cause lung disease in humans (Emsley 2011; Occupational Safety and Health Guideline for Yttrium and Compounds (2016)).

Element Data
Atomic Symbol: **Zn**
Atomic Number: **30**
Atomic Weight: 65.38(2) g/mol
Isotopes and Abundances: Five stable isotopes: ^{64}Zn, 49.17(75)%; ^{66}Zn, 27.73(98)%; ^{67}Zn, 4.04(16)%; ^{68}Zn, 18.45(63)%; ^{70}Zn, 0.61(10)%
1 Atm Melting Point: 419.6 °C
1 Atm Boiling Point: 907 °C
Common Valences: +2
Ionic Radii: 60 pm (4-fold) and 0.74 pm (6-fold)
Pauling Electronegativity: 1.65
First Ionization Energy: 906.4 kJ mol^{-1}
Chondritic (CI) Abundance: 312 ppm
Silicate Earth Abundance: 55 ppm
Crustal Abundance: 70 ppm
Seawater Abundance: 35 ppb
Core Abundance: <5 ppm (?)

Properties

Zinc is a bluish-white, rather soft metal. Zinc has atomic number 30 and is the first of the group IIB elements in the periodic table. It has atomic mass 65.38(2) g/mol, density 7.14 g/cm^3; its melting point of 419.6 °C is the lowest melting point of any transition metal aside from the other group IIB elements, Hg and Cd.

History and Use

Isolated examples of the use of impure zinc in ancient times have been discovered. Zinc–copper alloys ("brass") were in use as early as the fourteenth–to the tenth century BC, with isolated discoveries of other alloys dating to the twenty-fifth century BC. The naming of zinc is attributed to Swiss alchemist Paracelsus (1493–1541) after the German "Zinke," "pointy object, fork tooth, comb tooth," in allusion to its pointy habit in melting ovens. German chemist Andreas Marggraf is usually credited with the discovery of Zn as an element in 1746.

With an annual production of about 13 million tons (2013 and 2014), zinc is the fourth most commonly used metal, following iron, aluminum, and copper. The most important use of zinc is as an anticorrosion coating (>50%), followed by alloys and batteries. In the USA, other industrial uses account for about 8% of total use, including zinc oxide as a white pigment in paints and a catalyst in the manufacture of rubber; zinc chloride as a fire retardant or wood preservative; or various compounds used in organic synthesis. Zinc oxide absorbs UV light, and nanoparticulate ZnO is a common active ingredient in sunscreen.

Cosmochemistry

Zinc is the 22nd most abundant element in the solar system (1260 Zn atom per 10^6 Si atoms; 312 ppm; Anders and Grevesse 1989). The average concentration of zinc in Earth's crust is about 70 ppm (approximately as abundant as rubidium (78 ppm) and copper (68 ppm), and 53.5 ppm in the Mantle (Palme and O'Neill 2005). A Silicate-Earth value of 55 ppm is well established (McDonough and Sun 1995). Seawater contains 35 ppb Zn. Zn can behave both as a lithophile (e.g., Zn is dominantly concentrated in oxides and silicates within chondritic meteorites; Nishimura and Sandell 1964) or as

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

a chalcophile element. Zinc concentrations are generally very low (<5 ppm) in fractionally crystallized iron meteorites, suggesting lithophile behavior during planetary differentiation. Consequently, models of Earth's chemical composition assert that Zn is present in only negligible quantities in the Earth's core (McDonough and Sun 1995). The discrepancy between solar system abundance and bulk Earth could be related to Zn volatility during large impacts or partitioning into S-rich metallic melts.

Mineralogy

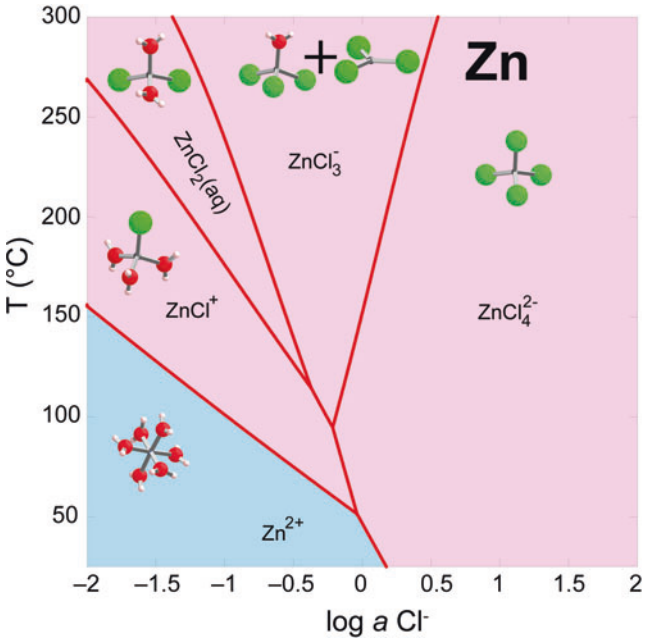
Metallic zinc (Hexagonal, $P6_3/mmc$) is a very rare mineral occurring mostly in the cementation zone of polymetallic ore deposits and in volcanic sublimates (Boyle 1961; Karpov and Mokhov 2010). The divalent oxidation state is the only significant oxidation state of Zn in Nature. Zinc(II) has ionic radii of 0.60 Å (tetrahedral coordination) and 0.74 Å (octahedral coordination).

Zinc is an essential constituent of more than 200 minerals and occurs at minor to trace levels in many more. The most common Zn minerals include sphalerite and its polymorph wurtzite (ZnS), smithsonite ($ZnCO_3$), and hemimorphite ($Zn_4Si_2O_7(OH)_2 \cdot 2H_2O$). Since the ionic radius of Zn(II) is similar to that of Mg(II) and Ca(II), Zn can substitute in the crystal lattice of many common rock-forming minerals (e.g., staurolite – zincostaurolite endmember; chlorite – baileychlore endmember; calcite/dolomite – smithsonite/minrecordite endmembers).

Aqueous and Hydrothermal Geochemistry

In aqueous solutions, Zn(II) complexes with a variety of inorganic and organic ligands, including chloride, bromide, hydroxide, bisulfide, carbonate, acetate, cyanide, or amine. Zinc chloride, sulfate, and nitrate salts are readily soluble in water, whereas Zn oxides, carbonates, phosphates, and silicates are poorly soluble in water at ambient temperature. Zinc sulfide (sphalerite) is highly insoluble in reduced sulfur-bearing solutions at room temperature. The corrosion resistance of metallic Zn and its alloys is due to the formation of insoluble, thermodynamically stable Zn oxide or Zn carbonates on their surface. Zinc(II) chloride complexes are responsible for Zn transport in most crustal fluids, although thermodynamic calculations suggest that Zn bisulfide complexes (e.g., $Zn(HS)_2(aq)$) may become important at high temperatures (>500 °C) (Zhong et al. 2015).

At room temperature, the Zn(II) aquo complex displays an octahedral geometry, being coordinated to six water molecules. This octahedral $Zn(H_2O)_6^{2+}$ complex is destabilized by the addition of chloride ions in favor of tetrahedral



Zinc, Fig. 1 Speciation of zinc in natural fluids as a function of temperature and activity of chloride (Data from Mei et al. (2015))

complexes such as $ZnCl(H_2O)_3^+$. Similarly, the $Zn(H_2O)_6^{2+}$ complex is unstable at high temperature relative to tetrahedral $Zn(H_2O)_4^{2+}$. Tetrahedral $ZnCl_4^{2-}$ is stable in saline solutions up to high temperature; however, with increasing temperature, $ZnCl_3^-$ and $ZnCl_2(aq)$ become increasingly stable. This is especially true for $ZnCl_3^-$, which also shows a change in geometry, from predominantly tetrahedral $[ZnCl_3(H_2O)]^-$ at lower temperature to predominantly trigonal planar $[ZnCl_3]^-$ at 600 °C (Fig. 1).

Biological Utilization

Zinc is an essential trace element for humans, other animals, plants, and microorganisms alike. Zinc is an efficient Lewis acid and can therefore act as a catalyst for hydroxylation and other enzymatic reactions. In addition, the flexible coordination chemistry of Zn allows proteins using it to rapidly shift conformations to perform biological reactions. A human body contains 2–4 g Zn, and Zn is "*typically the second most abundant transition metal in organisms*" after iron (Broadley et al. 2007). For example, the protein hormone insulin contains Zn, and the metal is essential for growth, development, and reproduction in humans. Zinc deficiency results in stunted growth and in male sexual immaturity. Because of the ubiquitous and varied role of zinc in biochemical processes, its 18 synthetic radioactive isotopes are commonly used as tracers in biological studies (e.g., ^{65}Zn, $t_{1/2} = 245$ days; ^{69}Zn, $t_{1/2} = 55$ min).

Some plants are able to hyperaccumulate Zn, e.g., up to 4.0 g kg^{-1} in *Thlaspi caerulescens*.

Environmental Geochemistry and Toxicity

Since Zn plays an important role as an essential trace metal in all organisms from bacteria to humans, the metal has low toxicity compared to other elements such as cadmium, mercury, and lead. Consequently, Zn shortage in soils around the world is an important problem, although levels of Zn in excess of 500 ppm (e.g., via contamination around zinc smelters or where zinc-containing sludge is used as fertilizer) interfere with the ability of plants to absorb other essential metals such as Fe and Mn. About 2000 years ago, Zn emissions from mining and smelting totalled 10,000 tons a year. Zinc emissions peaked at 3.4 million tons per year in the 1980s and declined to 2.7 million tons in the 1990s. Anthropogenic and natural emissions occur at a ratio of 20–1 (Broadley et al. 2007).

The forms of Zn in soils may include:

- Constituents of the lattice of primary and secondary minerals, either as an essential element or in substitution for Ca, Mg (mainly)
- Adsorbed on the surface of clay minerals, Fe, Mn, Al oxy-hydroxides, and organic matter
- Immobilized in living organisms and biological residues

The Zn concentrations in weathering solutions are controlled by adsorption rather than by solubility of secondary Zn carbonates, hydroxides, and phosphates. The Zn contents in soils range mostly from 10 to 300 ppm. Several soil profile studies show that the extractable Zn contents generally decrease with depth, while total Zn is uniformly distributed throughout the profile. The content of extractable Zn usually correlates positively with that of total Zn, content of organic matter, clay content, and cation exchange capacity. An inverse correlation between the amount of extractable Zn and free $CaCO_3$, soil pH, and base saturation was also observed.

In surface waters, Zn occurs mainly bound to suspended matter (clays, Al, Fe, Mn, Si hydrous oxides). Acid mine water can locally accumulate Zn up to a high concentrations. Zinc occurs in the atmosphere mainly as fine particles (<2 μm). Atmospheric Zn results from the production and processing of Zn, nonferrous smelters, fossil fuel combustion, and car emissions.

Ore Deposits and Mineral Processing

Although Zn can become enriched via extreme magmatic differentiation in some pegmatites and agpaitic rocks, all economic Zn ore deposits share a hydrothermal origin. By far the most common economic Zn ore minerals are the cubic Zn sulfide sphalerite (ZnS) and its hexagonal polymorph, wurtzite. The most common impurities in sphalerite and wurtzite (sometimes recovered as a by-product of zinc mining) are Fe, Cd, Pb, In, Cu, and Ag; high concentrations of Ge (to 3000 ppm) and Sn occur in some localities.

The three major producing countries in 2014 were China (38%), Australia (11%), and Peru (10%). More than half of the World's Zn is produced from sedimentary exhalative (SEDEX) Zn-Pb-(±Ag,Cu,Au) massive sulfide deposits (e.g., Red Dog Mine, Alaska, USA; Mount Isa Mine, Queensland, Australia) and their putative metamorphosed equivalents (e.g., Rampura-Agucha mine, India; Broken Hill, New South Wales, Australia). Another important class of Zn deposits are carbonate-hosted "Mississippi Valley Type" Pb-Zn deposits. Their name reflects their historic occurrences along the Mississippi River in the USA, but large provinces exist in Ireland, Canada, and Australia. Some vein-type and skarn deposits (e.g., El Toqui zinc-gold mine in Chile) are also mined for Zn.

In "nonsulfide Zn deposits," sulfide-free minerals such as smithsonite ($ZnCO_3$), hemimorphite ($Zn_4Si_2O_7(OH)_2 \cdot 2H_2O$), willemite ($Zn_2SiO_4$), or the smectite sauconite ($Na_{0.3}Zn_3[(Si,Al)_4O_{10}](OH)_2 \cdot 4H_2O$) are the Zn carriers. This genetically varied class of deposits accounts for less than 10% of total Zn production, but these deposits are attractive as they have high Zn grades and less environmental impact than sulfide ore (e.g., no sulfur emissions or waste, little or no acid drainage). These deposits can form from the weathering of sulfide Zn deposits (e.g., Skorpion Mine, Karas Region, Namibia), direct hydrothermal precipitation of willemite (e.g., Beltana, South Australia; Vazante, Brazil), or high-grade metamorphism of preexisting Zn mineralization (e.g., Franklin, New Jersey, USA).

Zinc metal is produced using extractive metallurgy, typically involving: (i) grinding the ore; (ii) froth flotation to separate sphalerite/wurtzite from gangue by taking advantage of differences in the hydrophobicity of the various minerals; this results in a concentrate that contains ~50% Zn; (iii) roasting to convert the Zn sulfide to Zn oxide; the produced sulfur dioxide is used to produce sulphuric acid, which is used in the leaching process; (iv) reduction of ZnO to metallic Zn via either pyrometallurgy or electrowinning. Pyrometallurgy processing reduces ZnO with carbon or carbon monoxide at 950 °C into the metal. The metal is distilled as Zn vapor, during which metallic impurities that are not volatile are eliminated. In electrowinning, Zn is leached from the ore concentrate by sulphuric acid, and aqueous Zn is reduced by electrolysis.

Summary

Zinc (atomic number 30) is the 22nd most abundant element in the solar system (312 ppm; 70 ppm in the Earth's crust). Zinc can behave both as a lithophile or as a chalcophile element and occurs in the divalent oxidation state in Nature. Zinc is the fourth most commonly used metal, following iron, aluminum, and copper. All economic Zn ore deposits share a hydrothermal origin, with sphalerite (ZnS) as the most common Zn mineral. Zinc(II) chloride complexes are responsible for Zn transport in most crustal fluids, with Zn bisulfide complexes possibly becoming important at high temperatures. "Non-sulfide Zn deposits" (containing Zn carbonates or silicates minerals) account for less than 10% of Zn production. Zinc plays an important role as an essential trace metal in all organisms from bacteria to humans. Consequently, the metal has low toxicity compared to other elements such as Cd, Hg, and Pb, and Zn shortage in soils around the world is an important problem.

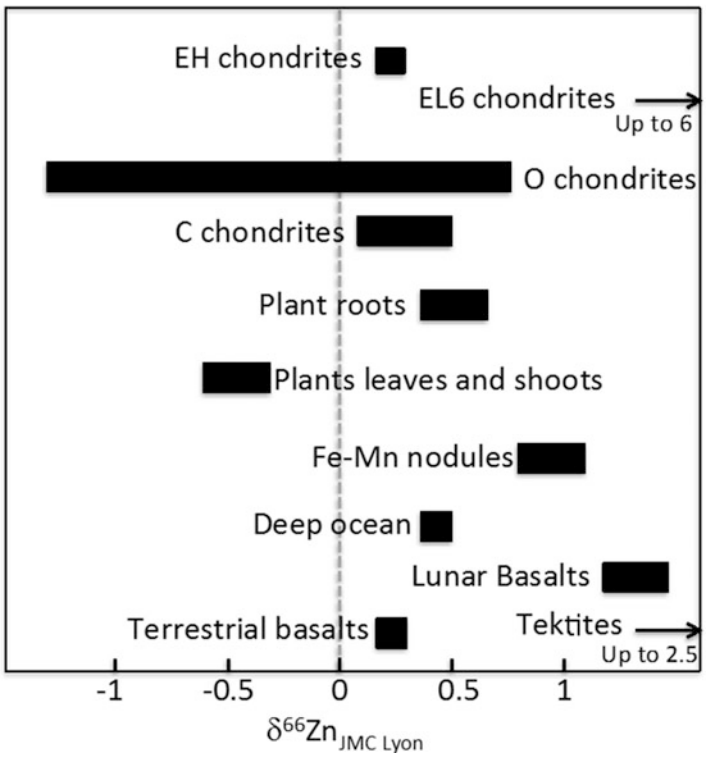
Introduction and Definitions

Zinc is comprised of five natural stable isotopes, ^{64}Zn (48.6%), ^{66}Zn (27.9%), ^{67}Zn (4.1%), ^{68}Zn (18.8%), and ^{70}Zn (0.6%). Due to its relatively high first ionization potential (9.4 eV), the measurement of Zn isotope ratios is very difficult by thermal ionization mass spectrometry (TIMS). This explains the very limited Zn isotope data produced before the advent of multi-collection inductively coupled plasma mass spectrometry (MC-ICP-MS). Since the first commercialized MC-ICP-MS in the late 1990s and the first high precision Zn isotope ratio measurements (Maréchal et al. 1999), more than 1000 papers have been published (source ISI Web of Science) on various geochemistry topics associated with Zn isotopes (e.g., oceanography, cosmochemistry, environmental sciences, medical sciences). Generally, the isotopic data are acquired by MC-ICP-MS by either standard bracketing (e.g., Maréchal et al. 1999; Weiss et al. 2005; Viers et al. 2007; Balistrieri et al. 2008) and only rarely by the double spike method (e.g., Bermin et al. 2006; Arnold et al. 2010). Most of the isotopic variations measured in natural samples are mass dependent (Moynier et al. 2009a) and are represented as the per mil deviation of the ^{66}Zn/^{64}Zn ratio from the JMC-Lyon standard as (Fig. 1)

$$\delta^{66}Zn = \left[\frac{\left(^{66}Zn/^{64}Zn\right)_{sample}}{\left(^{66}Zn/^{64}Zn\right)_{JMC-Lyon}} - 1\right] \times 1000$$

Zinc in Igneous Rocks and Extraterrestrial Samples

Zinc is a moderately volatile element with a 50% condensation temperature of 660 K (Lodders 2003), and the main sources of isotopic variation at high temperature are related to volatile events. Since Fe^{2+} and Zn^{2+} share similar ionic radii, the Fe/Zn ratio is not fractionated during partial melting of peridotites, and primitive basalts preserve the Fe/Zn ratio of the parental magma and therefore Zn (Le Roux et al. 2011). The Zn isotopic compositions of terrestrial igneous rocks are clustered within $0.2 < \delta^{66}Zn < 0.4$ with an estimated value for the bulk Earth of 0.28 ± 0.05 (Chen et al. 2013); the only exceptions are tektites (Moynier et al. 2009b). Tektites are terrestrial natural



Zinc Isotopes, Fig. 1 $\delta^{66}Zn$ normalized to JMC-Lyon of different planetary reservoirs. *EH* enstatite chondrites H, *EL6* enstatite chondrites L of high metamorphic grade, *O Chondrites* ordinary chondrites, *C Chondrites* carbonaceous chondrites. Lunar basalts are enriched in the heavier isotopes of Zn compared to terrestrial basalts. Planetary samples with high volatile depletions (tektites and EL6) are highly enriched in the heavier isotopes of Zn

glasses produced during a hypervelocity impact of an extraterrestrial projectile onto the Earth's surface. They are extremely depleted in volatile elements, and they are among the driest terrestrial samples (<0.02% of water). Tektites are extremely enriched in the heavier isotopes of Zn, with $\delta^{66}Zn$ up to 2.5 per mil. This enrichment was attributed to kinetic isotopic fractionation during evaporation. Therefore, since Zn is not fractionated to a large extent during igneous processes and fractionated during evaporation, it is an ideal tracer to investigate the origin of Zn abundance variations in planetary bodies.

Zinc isotopes have been used to understand the origin of the volatile element abundance variations between chondrites (Luck et al. 2005; Albarede 2009). The negative correlation between $\delta^{66}Zn$ and 1/Zn is robust evidence against evaporation as the origin of the variability of Zn abundance between chondrite groups; rather, this suggests that the variation in the volatile element content of chondrite parent bodies was caused by nebular processes (Luck et al. 2005). This argument was later developed by Albarede (2009) to suggest that the volatile element abundances in chondrites were inherited from nebular conditions during accretion, and the Earth must have accreted "dry" and acquired its volatile elements later via impact. Following this work, Zn isotopes have been used to study the origin of the volatile element depletion of the Moon compared to the Earth (Moynier et al. 2006; Herzog et al. 2009; Paniello et al. 2012; Kato et al. 2015). The Moon is isotopically heavier than the Earth with $\delta^{66}Zn$ ~1.3. This suggests that the Moon has lost its volatile elements by evaporation either during the giant impact or during the magma ocean phase early in the Moon's history (Day and Moynier 2014). Zinc isotopes have also been used to understand the relative depletion of volatile elements in the enstatite meteorites and the depletion of volatile elements in the EL enstatite chondrites compared to the EH ones (~ factor 5). The EL6 chondrites are highly enriched in the heavier isotopes of Zn ($\delta^{66}Zn$ up to 6 per mil), suggesting that the EL parent body has lost its volatile elements during evaporation (Moynier et al. 2011). Ureilite meteorites are residues of partial melting. The Zn isotopic composition of samples with different shock degrees and volatile element abundances is positively correlated with 1/Zn, whereby samples with the lowest Zn content showed the heaviest Zn isotopic compositions. This suggests that the variations in the abundance of Zn isotopes between ureilite samples were controlled by evaporation processes (Moynier et al. 2010). In addition, the more depleted samples also exhibit a higher shock state, suggesting impacts have been responsible for the heating event.

Zn Isotopes in Surface Environments

In terrestrial environments, some of the largest isotope fractionations occur during the exchange of Zn isotopes between chemical species (e.g., carbonates, sulfides, phosphates, citrates), and changes in speciation control the isotopic

composition of aqueous solutions (e.g., Fujii et al. 2011). The same is true for the Zn isotopic fractionation in biological materials, where Zn isotopes are fractionated between the different enzymes in which Zn is bound (Moynier et al. 2013; Fujii et al. 2014). Because of the control of chemical speciation on isotopic fractionation, Zn isotopes represent a tracer for the physical and chemical conditions (e.g., pH, temperature) under which Zn isotopes were fractionated (Pons et al. 2011), the mechanisms of Zn transport in soils and plants (Weiss et al. 2005; Viers et al. 2007; Bigalke et al. 2010), biological productivity (Pichat et al. 2003; Andersen et al. 2011), and the possible changes of the metabolism associated with pathologies (Albarede 2015). In addition, Zn is a vital micronutrient that is involved in many biological processes. Zinc isotopes are fractionated during the uptake of Zn by microorganisms; the organic cellular material is enriched in the lighter isotopes (John et al. 2007), while adsorption enriches the cell's surfaces in the heavier isotopes (Gelabert et al. 2006; John et al. 2007; Balistrieri et al. 2008; Jouvin et al. 2009; Andersen et al. 2011). The Zn isotopic composition of seawater is globally heavier than the input to the ocean by ~0.2 per mil which requires an isotopically light sink of Zn incorporated into sediments (Little et al. 2014; Zhao et al. 2014) similarly to what is observed for Li and B (Paris et al. 2010; Misra and Froelich 2012).

Zinc isotopes are fractionated during the transport of Zn in plants from the roots to the aerial parts (e.g., Weiss et al. 2005; Viers et al. 2007; Moynier et al. 2009c; Aucourt et al. 2011). This fractionation has been explained by the difference of speciation of Zn between the root system (isotopically heavy Zn phosphates) and the aerial parts, rich in isotopically light malates (Fujii and Albarede 2012). Zinc isotopic fractionation between organs of sheep and mice has been observed (Balter et al. 2010; Balter et al. 2013; Moynier et al. 2013). In mice, red blood cells (RBC) and bones are enriched by 1 per mil compared to the brain and the liver (Moynier et al. 2013). These isotopic fractionations are well explained by the equilibrium distribution of isotopes between different bonding environments of Zn in different organs. In the RBC, Zn is bounded to isotopically light histidine-rich proteins, while in the brain and the liver, Zn is principally bounded to isotopically heavy cysteine-rich proteins (Moynier et al. 2013). Differences in gender and genetic background do not appear to affect the isotopic distribution of Zn, which show the potential use of Zn isotopes as a tracer for dietary Zn, and for detecting disturbances in Zn metabolism due to pathological conditions.

Zinc isotopes in 3.8 Ga serpentinites from Isua are depleted in heavy isotopes compared to the bulk silicate Earth (BSE), while serpentinites from modern mid-ocean ridge ophiolites are isotopically similar to the BSE (Pons et al. 2011). Theoretical calculation shows that the incorporation of isotopically light Zn in serpentinites requires that the serpentinization reactions occurred at high pH, with a fluid rich in carbonate at medium temperature (100–300 °C). These are the conditions that are found in modern mud volcano environments such as the Mariana forearc, where the serpentinites are also isotopically light. Therefore, Zn isotopes can be used as a pH proxy for ancient environments (Pons et al. 2011).

Summary

Evaporation/condensation processes mainly fractionate Zn isotopes in high-temperature systems and by changes in speciation at lower temperature. Zinc isotopes are little fractionated by igneous differentiation, and isotopic variations of Zn in meteorites and lunar samples have been used to constrain the origin of the variation of the volatile element abundances between solar system planetary bodies. The fractionation of Zn isotopes between different chemical species suggests that Zn isotopes could be used as pH proxy for high-pH range. The difference in the isotopic composition between the Zn uptakes in living organisms, the Zn adsorbed at the surface of the cells, and between the different species present in the ocean water makes Zn isotopes good proxy to study biochemical cycling of Zn in the ocean and changes of biological productivity with time. Finally, due to its importance in biological reactions, and the different bounding environment in the different organs, Zn isotopes have a strong potential in medical geochemistry in order to trace changes in metabolism due to medical pathologies.

Zirconium

Carsten Münker
Institut für Geologie und Mineralogie, Universität zu Köln, Köln, Germany

Element Data
Atomic Symbol: **Zr**
Atomic Number: **40**
Atomic Weight: 91.224
Isotopes and Abundances: ^{90}Zr, 51.45% ^{91}Zr, 11.22%, ^{92}Zr, 17.15%, ^{94}Zr, 17.38%, ^{96}Zr, 2.80%
1 Atm Melting Point: 1855 °C
1 Atm Boiling Point: 4371 °C
Common Valences: 4+
Ionic Radii: sixfold: 72 pm
Pauling Electronegativity: 1.33
First Ionization Potential: 640 kJ/mol
Chondritic (CI) Abundance: 3.63 ppm
Silicate Earth Abundance: 10.3 ppm
Crustal Abundance: 132 ppm
Seawater Abundance: 9–300 pmol/kg
Core Abundance: n/a

Properties

Zirconium is a transition metal of low toxicity with the atomic number of 41. Zirconium has five stable isotopes (90, 91, 92, 94, 96) with an atomic mass of 91.224(2) (CIAAW 2015). The isotope ^{92}Zr is the decay product of the now extinct ^{92}Nb with a half-life of 34.7 Ma (e.g., Münker et al. 2000; Schönbächler et al. 2002; Iizuka et al. 2016). In some chondrites and CAIs, the neutron-rich isotope ^{96}Zr is slightly enriched relative to other Zr isotopes, reflecting variable contributions from AGB stars and supernova material to early solar system matter (e.g., Akram et al. 2015).

In nature, Zr occurs in +4 valence state, although a lower valence state of +2 is known from synthetic systems. Its atomic radius is 155 pm, and its ionic radius in +6 valence state and sixfold coordination is 72 pm (Shannon 1976). Due to its high ratio of charge to ionic radius, Zr is classified in geochemistry as *high field strength element*.

History and Use

Zirconium was first discovered in 1789 by the German chemist M.H. Klaproth, who named it after the mineral *zircon*. In 1824, it was for the first time synthesized by the Swedish chemist J.J. Berzelius, although the atomic mass estimated at the time was too high due to the presence of small amounts of Hf that exhibits an extreme geochemical similarity to Zr.

Economically important Zr deposits are hosted by placer deposits, granitic rocks, or coastal sand deposits that in most cases exhibit a paired enrichment of both Zr and its geochemical twin Hf in heavy minerals. Such important economical grade heavy minerals include zircon and baddeleyite. Countries with the world's largest Zr deposits include Australia, the USA, South Africa, and Brazil, with Australia and South Africa presently supplying most of the industrially used Nb (USGS 2014). Technically, Zr is mainly used as high-temperature ceramic material, as opacifier, for laboratory crucibles and for heat-resisting equipment including space vehicle parts, turbines, and jet engines. There is also some minor use in nuclear industry.

Geochemical Behavior

Zirconium is one of the most refractory elements with a 50% condensation temperature of 1764°K (Lodders 2003), and it has traditionally been regarded as behaving lithophile during Earth's differentiation. Ratios of Zr and similarly refractory elements like Hf, Nb, or Ta are nearly constant in most groups of chondrites (Münker et al. 2003). The solar system abundance of Zr as estimated from CI chondrites is 3.63 ppm; the estimated abundance in the bulk silicate Earth is 10.3 ppm (Palme & O'Neill 2014). Because of its strongly lithophile behavior, the concentration of Zr in the core is negligibly low. Due to its virtually identical geochemical and cosmochemical properties, Zr behaves very similar to Hf, leading to a virtually constant Zr/Hf ratio in chondrites and the silicate Earth (34.3 ± 0.3; Münker et al. 2003).

During silicate melting on Earth, Zr behaves as a mildly incompatible element in mantle minerals and is therefore depleted in the mantle and enriched in the crust. In the continental crust, the Zr content is estimated to 132 ppm with a content of 193 ppm and a near chondritic Zr/Hf in the upper crust (Barth et al. 2000; Rudnick and Gao 2014). Relative to similarly incompatible elements like Nd or Sm, however, Zr (and Hf) is slightly depleted in the continental crust, mirroring its selective depletion in many subduction zone magmas that contributed to the bulk of the continental crust. The selective depletion of Zr in subduction-related lavas and the continental crust is caused by its lower solubility in subduction zone fluids and by its retention in HFSE-rich phases like zircon or rutile in subducting crust (e.g., Zack et al. 2002; Hermann and Rubatto 2009). Together with its geochemical twin Hf, Zr is therefore a viable tracer for elemental mass balances in subduction zone systems, belonging

to some of the most insoluble elements in subduction zone fluids (e.g., Pearce and Peate 1995).

Employing Zr/Hf and Zr/Sm ratios in igneous rocks has now become an important tool to better understand melting processes and the role of residual phases such as zircon, rutile, or amphibole during silicate melting. Although behaving broadly similar, Zr is slightly more incompatible during mantle melting than Hf (e.g., McDade et al. 2003), leading to higher Zr/Hf ratios in basalts if compared to depleted mantle rocks (e.g., David et al. 2000; Münker et al. 2003). Moreover, Zr/Hf ratios can serve as viable tracers for carbonatite metasomatism and for recycled eclogitic components in the mantle (e.g., Pfänder et al. 2007, 2012; Klemme et al. 2002). Ratios of Zr/Sm are important tracers for the presence of amphibole during continental crust formation (e.g., Foley et al. 2002).

Due to its high valence state, Zr tends to hydrolize easily and is not very soluble in seawater, with an estimated concentration between 9 and 300 pmol/kg (Firdaus et al. 2011; Bruland et al. 2014). Notably, Zr/Hf are elevated in seawater if compared to silicate rocks (Godfrey et al. 1996; Firdaus et al. 2011), indicating that Zr can be highly fractionated from its geochemical twin Hf in aqueous systems due to their different complexing behavior. This observation was also made for chemical sediments, as well as for high-temperature fluids and their deposits, where strong Zr/Hf fractionation was also observed (e.g., Bau 1996; Schmidt et al. 2014). Collectively, Zr/Hf ratios are therefore valuable tracers for aqueous processes in silicate rocks.

Biological Utilization and Toxicity

Zirconium has no known biological role, and most Zr compounds have been shown to have low toxicity, largely due to their low solubility.

Summary

Zirconium is a highly refractory lithophile element and one of the high field strength elements and forms the highly stable and common accessory mineral zircon. It has low solubility and is generally considered immobile. Compared to elements of similar incompatibility, it is depleted in the Earth's crust and in subduction zone magmas.
