Lithium

Jeffrey G. Ryan
School of Geosciences, University of South Florida, Tampa, FL, USA

Element Data
Atomic Symbol: Li
Atomic Number: 3
Atomic Weight: 6.941
Isotopes and Abundances: ^{6}Li, 7.5%; ^{7}Li, 92.5%
1 Atm Melting Point: 180.5 °C
(*continued*)

1 Atm Boiling Point: 1342 °C
Common Valences: +1
Ionic Radii: 0.76 Å
Pauling Electronegativity: 0.98
First Ionization Energy: 520.2 kJ/mol
Chondritic (CI) Abundance: 1.49 ppm
Silicate Earth Abundance: 1.6 ppm
Crustal Abundance: 17 ppm
Seawater Abundance: 0.18 ppm
Core Abundance: ~0

Properties

Lithium is a low-density (0.5 × H_2O), silvery-white metal, which, while somewhat less reactive in water than sodium or other alkali metals, is nonetheless highly reactive and found in nature only in compounds or as a trace-level constituent in rocks.

History and Use

Johan August Arfvedson isolated lithium from the mineral petalite in 1817 and subsequently identified Li in both lepidolite and spodumene. Today lithium is extracted from brines (from LiCl) and is as well mined from large spodumene-bearing pegmatites. Lithium forms a range of silicate and evaporitic minerals, including Li-variants on micas and sheet silicates (lepidolite, zinnwaldite), inosilicates (spodumene), and tectosilicates (petalite), and a number of lithium-bearing phosphates (amblygdonite, triphilite, lithiophilite). Lithium has a wide range of industrial uses: as the key electrochemical agent in Li-ion batteries, in lubricants, and in medicine (Trujillo et al. 2011). Hiddenite, a green variant of the Li-mineral spodumene, and kunzite, a pink/lavender variant, are sought as gemstones.

Geochemical Behavior

In terms of nucleosynthesis, a portion of available ^{7}Li is thought to have been formed during the Big Bang (Stegman and Walker 1992), but Li is unstable in stellar interiors. Most Li (and nearly all ^{6}Li) forms at low abundances via spallation processes on CNO nuclei in interstellar medium (Stegman and Walker 1992; Vangione-Flam et al. 1999). Cosmochemically lithium is a moderately depleted element that largely follows Mg during nebular condensation (Dreibus et al. 1976). Li abundances in chondritic meteorites range from 1 to 2 ppm (Nichiporuk and Moore 1970, 1974), while

eucrites and lunar basalts range from 2 to 20 ppm Li (Dreibus et al. 1976; Shearer et al. 1994).

The ionic radius of Li^{1+}, at 0.76 Å, is close to that of Mg^{2+} (Shannon 1976), and as such the element substitutes at a $D^{mineral/melt}$ value of 0.1–0.3 into the M1 cation sites in many mafic minerals, in particular olivine, pyroxenes, and amphiboles; into alkali sites in plagioclase; and strongly ($D^{mineral/melt} \approx 0.3 -> 1.0$) into sheet silicate minerals, including micas and (in particular) Mg-bearing sheet silicates like serpentine (e.g., Brenan et al. 1998; Earthref.org 2016; Tomascak et al. 2016). Lithium concentrations are comparatively high in mantle rocks, with abundances in peridotites ranging from 1 to 4 ppm Li (Ryan and Langmuir 1987; Seitz and Woodland 2000). Lithium abundances are consistently low in mafic volcanic rocks, with basalts from all tectonic settings ranging between 2 and 10 ppm Li (Ryan and Langmuir 1987; Ryan and Kyle 2004). Li/Yb ratios are essentially constant in ocean-ridge basalts at ≈1.8, while Li/Dy ratios are constant in ocean island and intraplate lavas (Ryan and Langmuir 1987). This apparent tectonic setting-related difference in Li behavior results from the distinctive pattern of Li mineral-melt partitioning, in that Li, unlike all other commonly studied lithophile elements, substitutes into nearly all mafic silicate mineral phases with $D^{mineral/melt}$ values of similar magnitude.

Differentiated lavas and granitic rocks are higher in Li and can reach values of over 100 ppm, though most are in the range of 10–50 ppm Li, consistent with overall estimates for the continental crust (Teng et al. 2004, 2006; Rudnick and Gao 2014). Li is a conservative species in the oceans at 0.18 ppm, varying with Cl content, while seafloor hydrothermal fluids can have Li contents up to 50 times seawater values (Von Damm et al. 1985). Li is adsorbed by clays during marine alteration, and marine sediments typically contain 30–50 ppm Li (Plank 2014), while altered oceanic basalts can locally reach very high contents but overall are probably around 10 ppm (Donnelly et al. 1980).

During hydrothermal fluid-rock exchanges, Li tends to be mobilized to only a limited degree, even at temperatures as high as 375 °C (Seyfried et al. 1984). During metamorphism, Li concentrations increase slightly with grade (implying Li retention while fluids and other species are lost) until reaching the highest grade (granulite) conditions, where Li shows depletions suggestive of metasomatic removal (Sighinolfi and Gorgoni 1978). Metasediments from greenschist/blueschist to amphibolite facies metamorphic conditions thus largely preserve their original lithium contents, albeit with extensive isotopic re-equilibration (Sighinolfi and Gorgoni 1978; Penniston-Dorland et al. 2012).

With its high charge-to-mass ratio, lithium has the highest chemical diffusivity of any non-gaseous element, with diffusion coefficients several orders of magnitude higher than other alkalies and nearly all other lithophile trace elements (Cunningham et al. 1983; Lundstrom et al. 2005). This unique chemical characteristic of Li can result in comparatively rapid Li isotopic and abundance homogenization of mantle domains, and in the development of marked isotopic heterogeneities across interfaces with strong Li abundance gradients (Richter et al. 2003; Lundstrom et al. 2005).

Biological Utilization and Toxicity

Lithium is not biologically utilized in humans, though it seems to afford some benefit in plant growth. Natural human intake of Li in foods ranges between 0.6 and 3 mg/day, though in areas with high natural Li abundances these values may be >3 times higher without apparent negative effects (Aral and Vecchio-Sadus 2008). Li metal is toxic in high doses, as it can negatively impact neurological function. Li_2CO_3, to a serum level of up to 10 mg/l (close to its toxity level), is a traditional pharmacological treatment for bipolar disorder, though the specifics of how it impacts mood and mental state are still not clearly understood (Aral and Vecchio-Sadus 2008).

Lithium Isotopes

Jeffrey G. Ryan
School of Geosciences, University of South Florida, Tampa, FL, USA

Definition

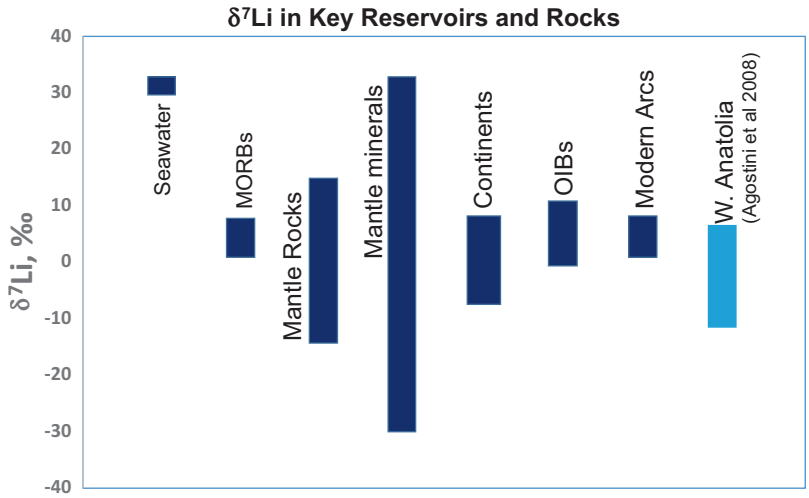
The large relative mass difference between the lithium isotopes (^{7}Li (~92.5%) and ^{6}Li (~7.5%)) leads to isotopic fractionations of Li during equilibrium and kinetic reactions in Earth systems. Substantial (20–30‰) δ^7Li differences exist between natural waters and rocks. Mafic igneous rocks from all tectonic settings range in δ^7Li from +2‰ to +6‰, suggesting a uniform mantle reservoir, though mantle-derived samples may show variable δ^7Li due to its high chemical diffusivity. Weathering processes lower δ^7Li in surface rocks, with continental δ^7Li at ~0‰. While subduction processes do not usually lead to strong Li isotope shifts, in places where subduction is ceasing, large δ^7Li variations have been observed in lavas.

Introduction

Lithium has two naturally occurring stable isotopes which occur in the Earth at approximately the ^{7}Li/^{6}Li ratio of ~12 encountered in primitive meteorites (Tomascak et al. 2016). The large relative mass difference between its isotopes makes lithium highly susceptible to chemically induced isotopic fractionation. Successful chemical separation of Li and thermal ionization mass spectrometric determinations of Li isotopes on geological samples was first reported by Chan (1987) and Chan and Edmond (1988). Tomascak et al. (1999) presented results using solution multicollector ICP-MS analysis with sample-standard bracketing, and this advance has led to a wealth of new Li isotopic data on a wide range of geological materials and a better understanding of the Li isotopic system overall.

Natural Waters

In aqueous solutions, Li generally exists as an $Li([H_2O]_N)+$ complex coordinated with four oxygens (Jahn and Wunder 2009; Kowalski and Jahn 2011), while in minerals, it can coordinate both octahedrally and tetrahedrally, largely substituting for Mg in silicate phases. ^{7}Li is preferentially concentrated in hydrous fluids, and as such δ^7Li $((({}^7Li/{}^6Li_{sample} - {}^7Li/{}^6Li_{L\text{-}SVEC})/({}^7Li/{}^6Li_{L\text{-}SVEC}))\times 1000$, where L-SVEC is the NIST Li_2CO_3 isotopic reference material) values in the oceans and natural freshwater bodies are 20–30‰ higher than in minerals and rocks. δ^7Li in modern



Lithium Isotopes, Fig. 1 δ^7Li variation in key rocks and reservoirs. *Dark bars* based on data compiled in Tomascak et al. (2016); Western Anatolia is from Agostini et al. (2008)

seawater is ~+31‰ (Fig. 1), though evidence from foraminiferal tests suggests a secular variation in the seawater reservoir in the Cenozoic that likely relates to changes in continental Li inputs (Misra and Froelich 2012; Pogge von Strandmann et al. 2013). River water δ^7Li signatures in the dissolved load are elevated, while suspended and bed load signatures verge closer to the value of entrained sediments (Huh et al. 2001). Hydrothermal fluids are typically closer in their δ^7Li to the rocks they interact with, largely ranging between 2‰ and 15‰ in the oceans (Chan et al. 1993, 1994).

Mafic Rocks and the Mantle

Basaltic igneous rocks have largely uniform δ^7Li signatures, with MORBs ranging between +2‰ to +6‰ (Tomascak et al. 2008). Oceanic intraplate basalts show evidence for somewhat greater δ^7Li variability (e.g., higher δ^7Li in HIMU and South Pacific lavas: Ryan and Kyle 2004; Nishio et al. 2005; see also Tomascak et al. 2016). The comparatively limited δ^7Li range in mafic lavas contrasts with the large range in ultramafic samples (−12‰ to +12‰: Brooker et al. 2004; Rudnick and Ionov 2007; Ackerman et al. 2013) and an even larger range in minerals from mantle-derived samples (+30‰ to −28‰: Tomascak et al. 2016). The high overall chemical diffusivity of Li, specifically the substantial relative diffusivity difference between the Li isotopes, is responsible for much of the Li isotopic variability observed in mantle samples, as strong Li isotopic gradients can develop, even in subsolidus conditions, across any boundary where there is a Li abundance gradient (Richter et al. 2003, 2014; Lundstrom et al. 2005). Li diffusivity is likely also responsible for the apparent isotopic homogeneity of mantle sources as sampled by basaltic magmas, as solid-state diffusive homogenization of Li isotopic anomalies in the mantle is possible on a ~10^7–10^8 year scale (Richter et al. 2003). Under low temperature conditions, Li isotopic heterogeneities can develop during the alteration of mafic and ultramafic lithologies by progressive fluid-rock exchanges where Li is taken up in Mg-rich phyllosilicate phases, such as serpentine, in which it is compatible (Decitre et al. 2002; Benton et al. 2004).

Sediments, Metamorphic Rocks and the Continents

Rudnick et al. (2004) and subsequent workers have documented that surficial weathering and alteration processes reduce Li contents and the δ^7Li in soils and sediments. Marine sedimentary sections as well show an overall shift to lower δ^7Li, although both on land and in the oceans, some materials recording very high δ^7Li are preserved. Sediment δ^7Li signatures are reflected in both sedimentary rocks and in metamorphic and granitic igneous rocks formed from sedimentary protoliths (Teng et al. 2004; Chan et al. 2006; Penniston-Dorland et al. 2012; see also Tomascak et al. 2016). Teng et al. (2004) estimated that the δ^7Li of the upper continental crust is 0 ± 2‰, reflecting the influence of weathering-related Li isotopic fractionations. High-pressure metamorphic rocks often record δ^7Li < than 0‰, based on which, some have suggested substantial subduction-related Li isotopic fractionations, though experimental results have argued against this (Zack et al. 2003; Marschall et al. 2007: see below). Current thinking is that fluid-rock diffusive and chemical exchanges associated with the uplift and unroofing of high-P rock suites may be primarily responsible for anomalously low δ^7Li in some samples (Tomascak et al. 2016).

Subduction Cycling of the Li Isotopes

While some early studies of volcanic arc lavas and subduction-related metamorphic rocks have been suggestive of large Li isotopic fractionations during subduction zone processes (e.g., Moriguti and Nakamura 1998; Zack et al. 2003), broader-based studies have not turned up clear evidence for such systematics: Tomascak et al. (2002) and Chan et al. (2002) found that mafic volcanic arc lavas have δ^7Li similar to MORBs, and Marschall et al. (2007) showed both

analytically and experimentally that the potential change in δ^7Li during subduction zone fluid-rock exchanges is likely not more than ±3‰. Benton et al. (2004) found that under forearc P-T conditions, eruptive serpentinites from the Mariana forearc preserve a δ^7Li of only +6‰ to + 7‰, pointing to comparatively modest slab-related increases in δ^7Li, as compared to large increases in δ^{11}B (up to +18‰; Benton et al. 2001). Given that the upper mantle has Li abundances of 1–2 ppm and (thanks to Li diffusivity) a relatively uniform δ^7Li value, slab-derived Li additions may not be sufficient to produce a Li isotopic anomaly in arc source regions, even though Li shows enrichments in arc lavas (Ryan and Langmuir 1987). Interestingly, Agostini et al. (2008), in a time series study of volcanic rocks spanning the transition from subduction to extension in Western Anatolia, found strong, paired Li and B isotopic declines as subduction shut down, followed by a rapid recovery to prevalent mantle values with the onset of extension. They hypothesized that the shutdown of mantle wedge convection and extreme distillation of a slowing downgoing plate permitted the ephemeral development of a highly fractionated δ^7Li reservoir, which quickly became homogenized with the onset of extension.

Conclusions

Thanks in equal parts to high Li solubility in fluids at low temperatures and its high chemical diffusivity at higher temperatures, δ^7Li signatures are relatively uniform at the scales of melting in the mantle and crust but can be highly diverse on a finer scale. Many of the more promising applications of the Li isotopes (deep Earth fluid-rock exchanges, secular variation in the oceans) leverage this finer scale diversity.

Definition

Lithophile is a term used to refer to elements that are preferentially partitioned into silicate minerals as opposed to sulfides or metals.

The Goldschmidt Classification of the Elements

Goldschmidt (1929; 1937) used various chemical considerations to classify elements as *lithophile* (coined from the Greek for "rock-loving," indicating it is found in silicates), *siderophile* ("iron-loving," therefore partitioning into the Fe-rich metal of planetary cores), *chalcophile* ("copper-loving," meaning it is found in sulfides, like Cu), and *atmophile* (gas-loving). The *Goldschmidt classification* of the elements derived predominantly from the distribution of elements between the various mineral phases that make up *meteorites*, but it can be predicted to a large extent from the standard-state Gibbs free energies of formation of the oxide ($\Delta_f G^\circ_{(Ox)}$) and sulfide ($\Delta_f G^\circ_{(sulf)}$) of the element in its lowest commonly encountered nonzero valence state. These quantities reflect the element's fundamental chemical properties in the chemical environment relevant to most geological processes. For metals (i.e., electropositive elements, meaning elements whose common valence state is positive), a large negative $\Delta_f G^\circ_{(Ox)}$ indicates lithophile tendencies, a positive or small negative difference ($\Delta_f G^\circ_{(Ox)} - \Delta_f G^\circ_{(sulf)}$) indicates chalcophile tendencies, and elements having neither $\Delta_f G^\circ_{(Ox)}$ nor $\Delta_f G^\circ_{(sulf)}$ very negative are likely to be siderophile. The behavior of Fe as summarized in the Gibbs free energies of formation of FeO and FeS can be taken as the benchmark. Electronegative elements are either lithophile or atmophile. The distinction between siderophile and chalcophile elements is not as clear-cut as that between lithophiles on one hand and siderophiles plus chalcophiles on the other, since sulfides are miscible in molten Fe-rich metal. So in the context of core-forming processes in planets, the term "siderophile" is often used to cover both siderophile and chalcophile elements.

The lithophile elements are typically subdivided according to their cosmochemical volatility, a property that is quantified using a theoretical concept, the element's "condensation temperature," Tc, defined as the calculated temperature at which 50% of the element would be condensed out of a cooling gas of solar composition, assuming a constant pressure (traditionally, 10^{-4} bars) and chemical equilibrium (Lodders 2003). With this classification:

Refractory lithophile elements (T_c = 1850–1355 K): a group of 28 elements with Tc greater than the condensation temperatures of the main planet-forming elements Mg, Si, and Fe. The group consists of Be, Al, Ca, Sc, Ti, Sr, Y, Zr, Nb, Ba, the 14 *lanthanide rare earth elements* (REE), Hf, Ta, Th, and U. In the past, V often used to be included, but this element is now usually classified as *siderophile*. Two of these elements, Ca and Al, are major elements in rocky planets and, together with Ti, are essential for forming refractory phases such as hibonite (ideally, $CaAl_{12}O_{19}$) and perovskite ($CaTiO_3$) that host the other refractory lithophile elements in Ca-Al-rich inclusions (CAIs) in unmetamorphosed, hence texturally primitive chondritic meteorites. The relative proportions of the refractory lithophile elements are approximately the same in nearly all groups of *chondrites*, and these proportions match those of the solar composition, as deduced from spectroscopic measurements of the solar photosphere, within uncertainty. Until recently it was widely assumed that the

refractory lithophile elements occur in the bulk silicate Earth in the solar proportions (e.g., Palme and O'Neill 2014), but this assumption is now being questioned (e.g., O'Neill and Palme 2008).

Main group lithophile elements (T_c = 1355–1250 K): Mg and Si. These elements are calculated to condense out of the solar nebular (initially as forsterite, Mg_2SiO_4) at a similar temperature to the most abundant *siderophile* elements, Fe, Ni, and Co. Mg and Si with their associated *oxygen* plus Fe are the main constituents of the rocky planets.

Moderately volatile lithophile elements (T_c = ≥1250 K): *alkali earth metals* (Li, Na, K, Rb, and Cs), *halogens* (F, Cl, Br, and I), and B. These elements are depleted relative to Mg and their solar proportions in all chondritic *meteorites*, except for the CI carbonaceous *chondrites*. They are also depleted in the bulk silicate Earth composition, but with a quite different pattern of depletion compared to any of the depletion patterns recorded in the chondrites (O'Neill and Palme 2008).

Summary and Conclusion

The Goldschmidt classification scheme should be viewed as a guide rather than a definitive classification scheme, because the chemical affiliation of elements is sensitive to differences in temperature, pressure, redox conditions, and sulfur contents. For example, in aubrites (enstatite achondrites), the REEs are almost entirely chalcophile, being held in oldhamite (CaS). Similarly some Si occurs in the metal phase of enstatite chondrites, and it is commonly supposed that the low Si/Mg of the bulk silicate Earth is due to some Si partitioning into **Earth's core** (Palme and O'Neill 2014). There may also be a small deficit of Nb in the bulk silicate Earth, which could be similarly explained (e.g., Wood et al. 2008), as Nb is the refractory lithophile element with the greatest **siderophile** tendency. Hence, whether an element is classified as "lithophile" or not depends on the geochemical process that is being documented.

Environmental Geochemistry

Definition

Low-temperature or environmental geochemistry is the study of chemical processes that occur in the earth's surficial environments. While basic aqueous chemistry principles, including acid-base equilibrium, reduction-oxidation reactions, and solubility, are the driving force behind most phenomena, interconnections between geology, hydrology, biology, and atmospheric science require an interdisciplinary approach to investigating these systems. Low-temperature geochemistry is a broad field, but major areas of study include mineral precipitation, chemical weathering, soil chemistry, sedimentary processes and diagenesis, biogeochemical cycles, and contaminant transport.

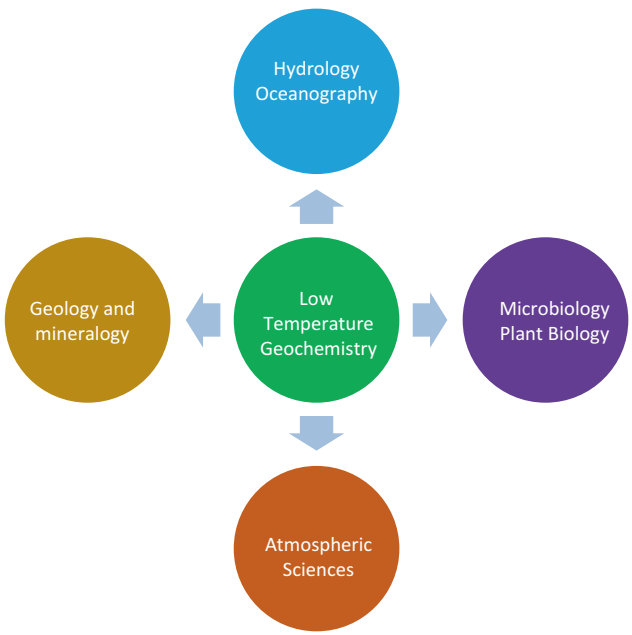
Introduction to Low-Temperature Geochemistry

In general, geochemistry can be defined as the study of the chemical composition and changes of the earth and other celestial bodies. We further define the subject based upon the overall geologic environment, pressure, or temperature. While the delineations in temperature are somewhat vague, the most

accepted definition for low-temperature geochemistry describes the chemistry of minerals, rocks, solid, water, and atmosphere when the temperature is below 200 °C (Guangzhi 1996). This temperature range typically occurs on the earth's surface or within the first few km of the lithosphere. Surface water, soils, exposed rock formations, groundwater, aquifers, and hydrothermal vents can all be considered systems that are regulated by low-temperature geochemical processes.

Due to the relationship between geochemistry and natural processes that occur within the environment, low-temperature geochemistry is often presented within the context of environmental geochemistry (Ryan 2014). No region on the surface of the earth can be considered a closed system so there are continuous interactions taking place between the various components. Understanding complex environmental systems requires thinking about phenomenon on molecular, regional, and global scales. In addition, it requires using an interdisciplinary approach due to the deep and complex relationship between atmospheric, hydrologic, biotic, and geologic systems (Fig. 1).

Low-temperature geochemistry is also intimately tied to human society because our activities have significant impacts on the processes that are happening on the earth's surface. Sometimes these activities are direct, such as the release of chemical waste form a mine and milling piles. Other times, the connections are less direct, such as the release of small amounts of a compound that undergo chemical transformations that result in a new compound that has much greater detrimental effects on the ecosystem. Thus a major thrust of low-temperature geochemistry is to understand the impact of humans on these processes on the molecular, regional, and global scales.

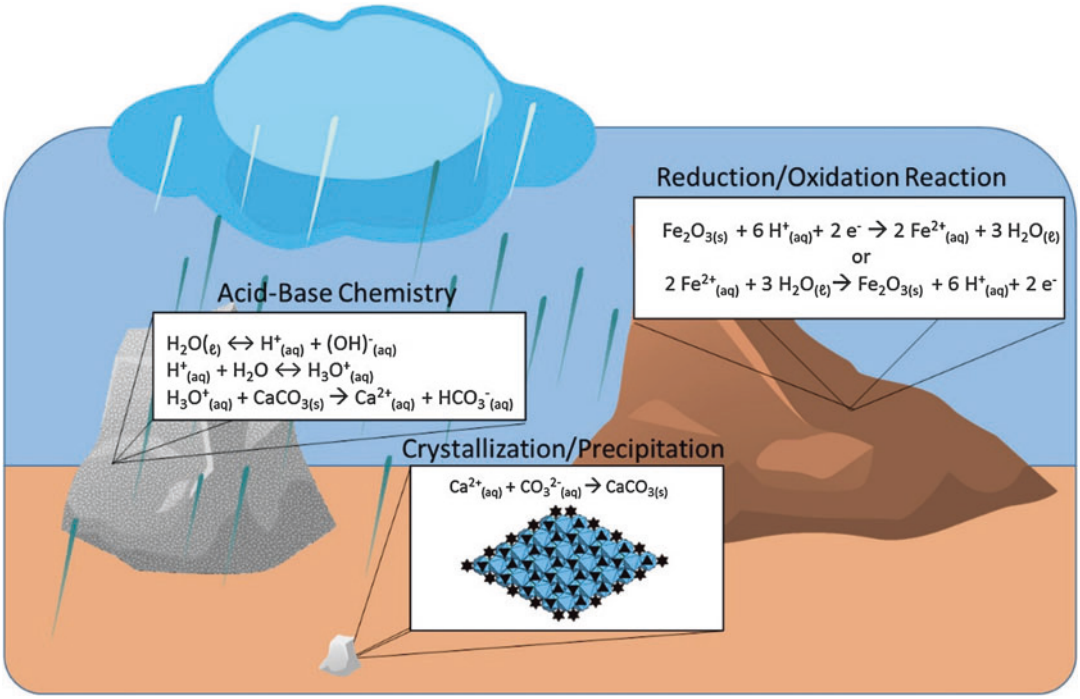


Low-Temperature Geochemistry, Fig. 1 Low-temperature geochemistry requires interdisciplinary thinking due to the interconnections between geology, biology, hydrology, and atmospheric sciences

History and Basic Principles

Low-temperature geochemistry is a relatively new subdiscipline of geology, developing from the molecular scale before encompassing global phenomena. The Norwegian scientist, Victor M. Goldschmidt is often considered to be the founder of geochemistry with his important contributions to mineral reactivity and his guiding principles on elemental substitutions in crystalline phases (Reinhardt 2001). The idea of geochemistry was broadened by the work of Vladimir I. Vernadsky, who determined that chemical reactions resulted in the formation of minerals and more specifically that living organisms could reshape geological systems or even planets (Ryan 2014). Investigations regarding the consequences of anthropogenic activities on environmental and geochemical systems began in the 1960s with concerns regarding contamination of the air, water, and soil. Seminal work during this period found that pesticides were a significant threat to ecosystem health (Carson 1962), acid rain was caused by industrial emissions (Likens and Bormann 1974), and humans were impacting the global climate through emissions of greenhouse gasses (Hansen et al. 1981). Current investigations in low-temperature geochemistry span the range of topics and scale that was laid down by the leaders in this area.

At the most basic level, low-temperature geochemical processes are controlled by fundamental chemical principles that control reactions in aqueous systems (Fig. 2). A major factor in the formation and dissolution of minerals and rocks is acid-base equilibrium and hydrogen ion activity (pH). In water, the hydrogen ion activity (pH) is the driver for many geochemical properties including dissolution, precipitation, crystallization, gas solubilities, and biochemical reactions. The pH of the solution can also be influenced by inorganic constituents, most notably the equilibrium between dissolved carbon dioxide and the carbonate anion (Drever 1997). Reduction and oxidation (redox) reactions are also of importance for elements that can access multiple oxidation states. Hydrogen, nitrogen, oxygen, sulfur, iron, and manganese are abundant and important redox active elements in geochemical systems (Drever 1997). These elements typically control the redox conditions within aqueous solutions, which in turn can determine the speciation, mobility, and toxicity of trace metals and organic compounds. Organisms, such as microbes and fungi, also play an important role in harnessing the chemical energy within geochemical systems to control the redox conditions, molecular speciation, and precipitation of mineral phases. Equilibria between the various inorganic and organic components and their overall energetics and stability (thermodynamics) ultimately determine the overall chemical



Low-Temperature Geochemistry, Fig. 2 Fundamental chemical reactions, such as acid-base, reduction-oxidation, and crystallization/precipitation, control low-temperature geochemical processes

reactions and products within the environment (Drever 1997). These basic chemical principles can be applied to a wide range of geologic media, environments, and processes, and the broad categories of low-temperature geochemistry will be described in the following sections.

Major Topics in Low-Temperature Geochemistry

Mineral Precipitation/Crystallization and Chemical Weathering

A wide range of common mineral phases is formed under low-temperature geochemical conditions by precipitation and crystallization reactions. Precipitation is the direct result of reaching the solubility limit of an aqueous species that leads to the formation of a solid phase (Jarvinen 2009). Crystallization can be considered a precipitation reaction, but more specifically, one that has long-range ordering of the chemical constituents within the crystalline lattice. Amorphous phases may form from precipitation reactions, but minerals must have some degree of crystallinity (Jarvinen 2009). Table 1 provides a summary of common mineral classes and phases that form under low-temperature geochemical environments, although there are a number of less abundant minerals that form under similar conditions. The major mineral types that typically form in surficial or hydrothermal environments include hydroxides, borates, carbonates, halides, sulfides, and clays (Klein 2002).

Changes in chemical equilibria related to pH or redox conditions or through the evaporation of water can result in the precipitation of aqueous species into a solid mineral. Acidic waters can dissolve metal cations, such as Fe(III) and Al(III) and upon mixing with more neutral freshwater, causes the formation of hydrolysis products. These hydrolysis products have low solubility in water and cause the precipitation of hydroxide phases (Stumm and Morgan 1981). In some cases, the metal cation is present in the reduced form, and initial oxidation is required for the precipitation reaction to occur. Such is the case for dissolved Fe (II) oxidizing in the presence of O_2 to form Fe(III), which is then followed by the hydrolysis and precipitation reaction (Stumm and Morgan 1981; Cornell and Schwertmann 2004). Evaporite minerals are formed when saline lakes or restricted sea bodies evaporate, creating extensive deposits in arid regions (Schreiber and Tabakh 2000; Klein 2002). Halides and sulfates are the most common evaporite mineral classes, with gypsum and halite deposits constituting the most common mineral species within the natural deposits (Spencer 2000; Screiber and Tabakh 2000). Carbonates can be marine in origin, and over the history of the earth there has been a shift from low-temperature chemical precipitation to biogenic sources, such as benthic and pelagic organisms (Morse et al. 2007). Calcium carbonate is also a major constituent in freshwater systems and is widely observed in sedimentary rocks and as the building blocks of cave formations (Drever 1997; Klein 2002; Kotz et al. 2006; James and Jones 2015). Borate mineral deposits can be found in marine basins, but the largest known deposits originated as chemical precipitates from thermal springs or hydrothermal solutions associated with volcanic activities (Kistler and Smith 1975; Argust 1998).

Chemical weathering is the change in the composition of the original geologic media, often in the presences of water that occur because of oxidation, hydrolysis, and dissolution of the elements present in the parent rock (Carroll 1962). Some hydroxide phases, like bauxite, form in surficial or low-temperature supergene environments by leaching of silica from aluminum-bearing rocks (Schellmann 1994). The leaching process occurs through initial dissolution of the mineral lattice by the slightly acidic rainwater, followed by hydrolysis and precipitation of the insoluble hydroxide phase upon an increase in the pH of the pore water (Whittington and Muir 2000). Hydrolysis reactions occur when anhydrous mineral absorbs water and water dissociates to H^+ and OH^- ions, which interact with the cations present in the solid and result in structural changes to the solid-state material (Reaction Scheme 1). Overall the reaction causes the formation of a secondary mineral phase from the parent rock, plus soluble species that are removed as the water flows over the surface. Other hydroxide phases, such as goethite and ferrihydrite, can form from an initial oxidation step, such as the oxidation both sulfur and iron in pyrite, followed by hydrolysis and precipitation (Lowson 1982; Nordstrom 1982). Dissolution reactions result in the breakdown of the solid-state mineral into soluble aqueous species. One of the most common mechanisms for dissolution occurs when CO_2 in the atmosphere is dissolved in rainwater to form carbonic acid, which is also referred to as carbonation reactions (Reaction Scheme 3) (Ryan 2014).

Reaction Scheme 1 (Hydrolysis)

$$2\,KAlSi_3O_8(s) + 2\,H^+(aq) + 9\,H_2O_{(\ell)} \rightarrow H_4Al_2Si_2O_{9(s)} + 4\,H_4SiO_{4(aq)} + 2\,K^+{}_{(aq)}$$

Reaction Scheme 2 (Oxidation)

$$FeS_{2(s)} + 15/4\,O_{2(aq)} + 7/2\,H_2O_{(\ell)} \rightarrow Fe(OH)_{3(s)} + 2\,H_2SO_{4(aq)}$$

Reaction Scheme 3 (Dissolution/Carbonation)

$$CO_{2(aq)} + H_2O_{(\ell)} \rightarrow H_2CO_{3(aq)}$$

$$CaCO_{3(s)} + H_2CO_{3(aq)} \rightarrow Ca^{2+}{}_{(aq)} + 2\,H_2CO_{3(aq)}$$

Sedimentary Processes and Diagenesis

Chemical weathering results in the breakdown of rocks and formation of soils, but sedimentation processes utilize geochemical reactions to create new geologic deposits. Sedimentary rocks are formed by the accumulation of sediments (small particles of gravel, sand, silts, and clays) that are held together through lithification (West 1995). Early diagenesis or lithification is the process by which unconsolidated sediments are converted into solid rock and can occur via mechanical (compaction), geochemical (cementing or crystallization), or a combination of both processes. Cementation involves filling the pore space between the individual sediment grains with a binding agent. Under low-temperature regimes, calcium carbonate or iron hydroxides can precipitate from water seeping through the sediments, resulting cementation and lithification to occur (West 1995). Crystallization processes typically focus on the transformation of amorphous or colloidal substances into crystalline mineral phases and generally occur after deposition and even in some cases after lithification of the sedimentary rock.

Changes in the sedimentary rocks at temperatures and pressures lower than the formation of metamorphic rocks is considered late diagenesis (Teodorovich 1961). It is important to point out that late diagenensis is a different process than chemical weathering described above. Recrystallization processes can occur during later diagenesis, most notably in limestones, where aragonite in contact with freshwater can convert into calcite crystals within the solid sedimentary rock. Burial of organic matter within sedimentary rocks results in the chemical transformations of lipids, proteins, carbohydrates, and lignin-humic compounds into hydrocarbons,

which are the major constituents of methane, petroleum, and coal deposits (Singer and Muller 1983).

Chemistry of Soils

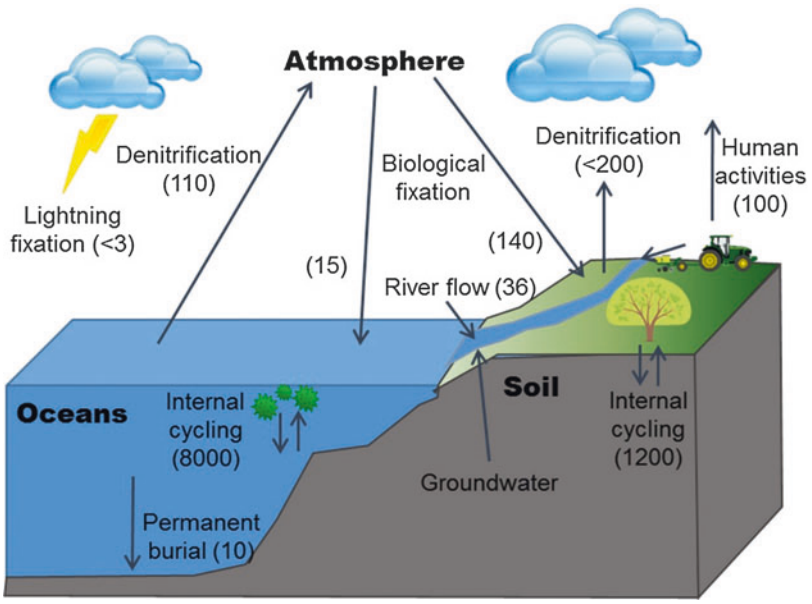
Low-temperature geochemical processes are the driving force for the formation and evolution of soils in the surficial environments. Soils are porous media created at the surface by weathering processes and differ from weather rocks because they show a vertical stratification (Sposito 1989). Mechanical weathering processes can result in the breakdown of bulk rock into smaller particles and is combined with chemical weathering processes to form the inorganic components of soils (Sposito 1989). Given the presence of water and dissolved chemical components, soils are excellent environments for microbes and fungi that can control redox reactions and breakdown organic matter (Ehlrich and Newman 2009). This leads to a complex mixture of organic components that are hospitable to plants and larger organisms and a rich and diverse biogeochemical system.

Soils are in continuous flux and exchange both matter and energy with the surrounding air, water, and biome (Sposito 1989). Meteoric water is continually percolating through soils, dissolving soluble chemical species, and transporting it through the soil column. Atmospheric gasses can easily penetrate this porous media, resulting in additional weathering and oxidation reactions (Sposito 1989). Microbial communities can continuously evolve through changes in the chemical and physical conditions of the soil (Ehlrich and Newman 2009). Humans can also influence the soil environment, either directly (intensive agricultural efforts) or indirectly (acid rain), and in turn the soil quality has impacts on overall health of the population (Locke and Zablotowicz 2004; Singh and Agrawal 2008; Brevik and Sauer 2015).

Biogeochemical Cycling

The surficial environment can be considered an open system with continual chemical fluxes between the various components; thus there is continuous movement of elements throughout the global system (Schlesinger 1997). As discussed in the previous sections, meteoric water moves through soils and porous rocks, picking up various chemical components through weathering processes. Some of the chemical constituents in the water can undergo precipitation reactions within the soil or porous rock, resulting in a sink or removal of that particular element from the solution. Interactions with plants and organisms can also cause elements to either remain in the soil or biome or be transported with the hydrologic flux. Other elements can remain dissolved in the water, where it is transferred through the subsurface system and can then be recharged into surface water through seeps and springs. Additional precipitation or redox reactions can occur within the surface water either resulting in precipitation or dissolution of the chemical component, where there can again be interactions with biological systems or dispersion into the atmosphere. Once in the atmosphere, additional chemical reactions can occur that result in addition global dispersion or wet/dry deposition. The impact of human activities must also be accounted for when considering the flux of elements between the biological, geological, hydrological, and atmospheric systems. It is the chemical reactions that occur within these systems combined with the flow and mass balance of elements of interest within these different domains that constitutes the study of biogeochemistry (Schlesinger 1997).

A well-known biogeochemical cycle as illustrated in Fig. 3, which describes the different chemical processes that control the flux of nitrogen throughout the soil, ocean, and atmosphere (Schlesinger 1997). A portion of the nitrogen is



Low-Temperature Geochemistry, Fig. 3 The biogeochemical cycle for nitrogen. Values are provided by Schlesinger (1997) and are in units of 10^{12} g N per year

stored as a reservoir within the organic matter of the soil that can undergo chemical reactions, such as mineralization (Reaction Scheme 4) and nitrification (Reaction Scheme 5). Within the soil column, nitrogen is also involved with an internal cycle of uptake and release within terrestrial plants and additional mass is added to the soil through biological fixation (Reaction Scheme 6). Removal of nitrogen from the soil can occur through denitrification (Reaction Scheme 7) and release to the atmosphere. A second pathway for release is the dissolution of the nitrogen in the form of $NO_3^-{}_{(aq)}$ or $NH_4^+{}_{(aq)}$ that can be transported either by the subsurface groundwater or as run-off into freshwater streams, rivers, and lakes. Eventually the water from the surface and subsurface sources flow into the ocean where there is a large reservoir of dissolved nitrogen species. An internal cycle also occurs in the ocean with the uptake and release of nitrogen by phytoplankton and marine organisms and burial in the ocean sediments. Flux to the ocean can also occur through nitrogenase-catalyzed biological fixation, and removal of nitrogen to the atmosphere occurs through denitrification processes (Kim and Reese 1994). Within the atmosphere, nitrogen can be converted to different forms through fixation by lightning or photocatalyzed redox reactions. Humans can also add to the global nitrogen cycle through release of NO_x gasses or through the overfertilization of agricultural lands (Fields 2004). Changes in the amount of nitrogen in the air or freshwater systems that is the result of human activity can cause significant changes in the nitrogen reservoirs for these systems. This has impacts on the state of these systems as evidenced by the production of acid rain or the eutrophication of the coastal regions, particularly the Gulf of Mexico (Schlesinger 1997; Fields 2004).

Reaction Scheme 4 (mineralization)

$$R - NH_2 + H_2O \rightarrow NH_3 + R - OH$$

Reaction Scheme 5 (nitrification)

$$NH_3 + \frac{1}{2}O_2 + 2e^- \rightarrow NH_2OH + H_2O \rightarrow NO_2^- + 5\,H^+ + 2\,e^-$$

Reaction Scheme 6 (nitrogen fixation)

$$N_2 + 8H^+ + 6e^- \rightarrow 2NH_4^+$$

Reaction Scheme 7 (denitrification)

$$2\,NO_3^- + 12H^+ + 10\,e^- \rightarrow N_2 + 6H_2O$$

Changes that human activity has on global biogeochemical cycles for a wide range of elements are a major area of current scientific investigations. Global warming is the direct result of changes in the carbon cycle, and understanding the details of the chemical reactions that result in fluxes between the different systems is important for more accurate climate models and means for combating climate change (Hansen et al. 1981). As described above, overfertilization of agricultural lands causes an influx of elements that are then washed into freshwater rivers in lakes. While excess nitrogen causes problems in marine environment, the high influx of phosphorus results in the eutrophication of freshwater systems (Correll 1998). Human activity can also influence the global cycling of trace metals due to their use in industrial applications or modern living and then release through improper disposal. Lead (Pb) is an example a trace metal that was impacted by anthropogenic effects when it was added as a fuel additive in the 1970s (Shotyk and Le Roux 2005). During the combustion process, lead was released into the atmosphere through exhaust systems that resulted in dry and wet deposition into surface waters and land. Increased concentrations of lead were observed in soils and the human population until polices were adopted that minimized the use of lead as an additive and in industrial processes (Shotyk and Le Roux 2005).

Contaminant Transport

Low-temperature geochemical processes control the oxidation state and speciation of elements that are harmful to human and ecosystem health, which in turn determines the mobility and fate of contaminants in the environment. Release of contaminants into the environment can be through natural processes or through human activities that catalyze the release of toxic elements and compounds into the environment (McCarthy and Zachara 1989; Brown and Calas 2011). For example, weathering and dissolution of host rocks can occur either through natural ore deposits that are exposed to the atmosphere or groundwater or the leaching from mine and milling tailings. Typically this process is controlled both by the acid-base chemistry of the meteoric water and redox reactions when the rocks are exposed to oxygen present in the atmosphere. Mobility of the contaminant phases in surface or subsurface waters depends on the aqueous speciation and water-rock interactions. Surface interactions typically involve adsorption and binding of the contaminant to mineral phases, which can limit its mobility in the environment (McCarthy and Zachara 1989; Brown and Parks 2001). Contaminant adsorption on mineral surfaces can be reversible and again controlled by the low-temperature geochemical parameters. Interactions with the microbial community can also impact the fate of contaminants in soils and sediments, typically by control of redox parameters and precipitation reactions (McCarthy and Zachara 1989; Ehrilich and Newman 2006). Ultimately the chemical speciation controls the mobility of the contaminant in water, uptake by biological organisms, and the overall public health risk.

Inorganic elements that are of concern for public and ecosystem health include heavy metals, radioactive isotopes, and problematic main group elements. Heavy metals, such as mercury, are naturally occurring elements that become contaminants in the environment due to natural processes (redox, microbial activity) but can also be caused by human activities,

such as mining, release from industrial processes, or accidental dispersion. Speciation of mercury is a major factor in determining health risk, with methylation by bacterial communities resulting in increased uptake and bioaccumulation (Boening 2000). Arsenic is an example of a problematic main group element that occurs naturally and becomes soluble when in the reduce form (arsenite, AsO_3^{3-}) (Bowell et al. 2015). Countries such as Bangladesh, India, China, Mexico, and Argentina have significant arsenic contamination in water sources due to formation of strongly reducing aquifers or closed basins in arid or semiarid climates (Smedley and Kinniburg 2002). Uranium is a naturally occurring radioactive element that has health risks when ingested through drinking water or food sources due to its chemical and radiological toxicity (Brugge et al. 2005). Redox conditions also drive the mobility of uranium in environmental systems, with the oxidize uranyl (UO_2^{2+}) moiety forming soluble complexes over a range of environmentally relevant pH values (Maher et al. 2013).

Organic contaminants are typically the result of human activities and can be controlled by natural geochemical processes that are often utilized by environmental remediation. Volatile organic compounds, plasticizers, pesticides, and chlorinated compounds are the most common organic pollutants in drinking waters (Olson 2003). Due to concerns over the presence of hormones and endocrine disruptors, the USGS comprehensive survey conducted in 2002 also that found steroids (coprostanol, cholesterol), insect repellant (*N*,*N*-diethyltoluamide), caffeine, antimicrobial agents (triclosan), fire retardant (tri(2-chloroehtyl)phosphate), and detergent residues (4-nonylpentol) can be detected in surface waters and are now considered emerging contaminants (Kolpin et al. 2002; Lapworth et al. 2012). Sunlight can cause photochemical reactions that transform natural organic matter into other compounds, such as halogenated species (Mendez-Diaz et al. 2014). Some of these transformations can yield degradation products that are less harmful than the initial material, but some of these reactions were reported to be reversible. An endocrine disruptor, 17α-trembolone has been shown to degrade in the presence of light but then reform in the dark (Qu et al. 2013). Chemical spills of hydrocarbons or chlorinated compounds present in groundwater can be remediated through microbial degradation processes that utilize these compounds as an energy source. For example, tetrachloroethane and trichloroethane are common contaminants in water, but under anerobic conditions microbial communities can be transformed to less chlorinated dichloroethane and vinyl ethane for natural attenuation (Bradley et al. 2005).

Summary

Low-temperature geochemistry is the study of chemical processes that occur in a complex and ever changing environment. It requires understanding fundamental chemical principles applied to geology, hydrology, biology, and atmospheric systems to understand some of the most important processes on the surface of the earth. Mineral precipitation, chemical weathering, sedimentation, diagenesis, soil science, biogeochemical cycling, and contaminant transport impact natural ecosystems and human society. Low-temperature geochemistry also provides a means to understand how interconnected we are with natural processes and our actions can cause significant impacts on global processes.

Beginning with fundamental elemental processes that occur within solid-state minerals and branching out into global topic, low-temperature geochemistry continues to be an important area of scientific study. Continued interest in combating climate change requires advanced understanding of how rocks, soils, natural bodies of water, and the atmosphere are connected through chemical, physical, and biological processes. As we continue to change the landscape and release new chemicals into the environment, there is increased efforts to determine the impact of these emerging contaminants on the ecosystem. Given our relationship and reliance on the natural world, understanding the geochemical processes that occur in low-temperature, surficial environments will continue to be a key research focus for human and global health.

Luminescence

Tori Z. Forbes
Department of Chemistry, University of Iowa, Iowa City, IA, USA

Definition

Luminescence is the creation of light by chemical or physical processes that does not involve heat. Photoluminescence, which uses light as the excitation source, can be observed in minerals and provides information regarding the presence of trace metals, formation of defect sites, growth conditions, and sample age. Spectroscopic methods can be utilized to determine chemical and physical properties of the mineral specimen, and dating of geologic media can be achieved through thermoluminescence techniques.

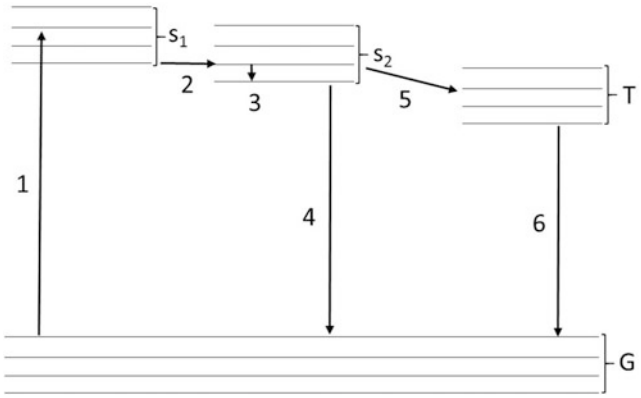
Basics of Luminescence

When an electron within a molecule or solid compound is promoted to an excited state through the absorption of energy, there are two possible processes that will return the electron to the ground state. Non-radiative transfer mechanism allows the energy to dissipate through translation, rotational, or vibrational motion of the atoms and occurs on the order of 10^{-11} to 10^{-10} s. Radiation processes release energy through the emission of a photon and are generally classified as luminescence (Ingle and Crouch 1988).

The process of luminescence can be further classified as either fluorescence or phosphorescence depending on the transfer of the electron within the excited state. After energy absorption and promotion, the electron can move between excited singlet states (where the spin of the electrons is still paired) through internal conversion and undergo vibrational relaxation until it reaches the lowest energy excited singlet state. Fluorescence occurs when a radiational transition between the excited singlet state and the ground singlet state results in the release of a photon and occurs on time scales of 10^{-10} to 10^{-6} s. When an electron absorbs energy, it can only be promoted to singlet states, but intersystem crossing can result in the formation of triplet states (where the spin of the electrons is not paired). Additional vibrational relaxation transfers the electron to the lowest energy triplet excited state, followed by radiational deactivation that occurs through the release of a photon. This process is called phosphorescence and takes place on slower time scales (10^{-4} to 10^{4} s) because of the need for intersystem crossing. Different categories of luminescence are distinguished through the excitation energy source (Fig. 1).

Photoluminescence is the most common category of luminescence and describes emission of photons after excitation by electromagnetic radiation. It often occurs through the absorption of ultraviolet or visible light, but some materials may absorb X-rays (X-ray excited luminescence). For both fluorescence and phosphorescence, resulting wavelength of released photon is longer than the absorbed light because the electron is promoted to higher energy excited states (Ingle and Crouch 1988). Energy of the photon released through photoluminescence is typically in the visible range but can also occur in the ultraviolet or infrared regions (Geake and Walker 1975; Rakovan and Waychunas 1996).

Luminescence can also occur when the electron is excited or released by other mechanisms. Cathodoluminescence is caused by promotion of the electron to the excited state with an electron beam (Gotze 2012). If a mechanical action (crushing, tricking, scratching, or rubbing) triggers an electrical excitation, then it can cause phosphorescence and is referred to as triboluminescence, mechanoluminescence, piezoluminescence, or fractoluminescence (Zink 1978; Sweeting 2001). In thermoluminescence, the electron was originally promoted by electromagnetic radiation or some other energy source and then trapped in the excited state (Wintle and Huntley 1982; Forman 1989). The trapping centers are generally defect sites caused by radioactive or stacking faults, but they can also be caused by ion substitution. Upon exposure to heat, the trapped electrons are released and fall back to the ground state, releasing a photon in the process (Wintle and Huntley 1982; Forman 1989).



Luminescence, Fig. 1 Diagram of the luminescence process. (*1*) An electron is promoted from the ground state (*G*) to a singlet excited state (S_1) and can (*2*) transfer to a different singlet excited state (S_2). (*3*) Vibrational relaxation lowers the energy until (*4*) the electron moves to the ground state and releases a photon to create fluorescence. Alternatively, intersystem crossing (*5*) results in movement of the electron into an excited triplet state (*T*). (*6*) Phosphorescence occurs with electron transfer from the excited triplet state back to the ground state, which results in the release of a photon

Luminescence in Minerals

In most mineral phases that exhibit photoluminescence, there are atoms present with the correct separation of the energy levels to emit a photon in the visible or ultraviolet region (Rakovan and Waychunas 1996). These atoms are called activators and can be present in either bulk compositions or trace levels. A related process involves absorption of electromagnetic radiation or an electron beam by one atom (the sensitizer) which can then be transferred to the excited state of a second atom (the activator) before the release of a photon (Rakovan and Waychunas 1996). Common activators and sensitizers are manganese (II), chromium (III), tungstates, titanates, molybdates, zirconates, sulfide, uranyl, some hydrocarbons, and rare earth elements (Rakovan and Waychunas 1996; Gaft et al. 2005).

A less common mechanism for photoluminescence occurs through defect centers within the solid-state crystalline lattice. The luminescence mechanisms for defect sites are not

completely understood; however, a well-known type is the Frenkel defect or F-center (Rakovan and Waychunas 1996). This type of defect can occur in halite where the displacement of the Cl^- anion will leave a vacancy and an electron will inhabit the site as a means for overall charge balancing (Rodriguez-Lazcano et al. 2012). Within the vacancy, the electron can be present in an excited state, and photoluminescence occurs when transitions result in the release of a photon in the visible region.

In 1989, Dr. Gerhard Henkel published an exhaustive list of minerals that undergo luminescence and includes 566 mineral species and 59 related substances (Henkel 1989). Only a handful of minerals undergo fluorescence when pure phase, including scheelite ($CaWO_4$) and secondary hexavalent uranium minerals (autinite ($Ca(UO_2)_2(PO_4)_2 \cdot 10–12\ H_2O$)) (Gorobets and Sidorenko 1974; Nikl et al. 2000). Other common minerals such as calcite, fluorite, and apatite will fluoresce when trace amounts of activators (generally Mn^{2+} or UO_2^{2+}) are present in the solid-state materials (Machel et al. 1991; Calderon et al. 1992; Waychunas 2002). The Franklin mine (New Jersey, USA) is home to the largest number of fluorescent mineral specimens observed from one site, including some spectacular specimens that contain bright fluorescence and unusual crystal habits (Wilkerson 1962).

Other types of luminescence are rarer, but can be observed in a handful of mineral species. Thermoluminescence has been observed in apatite, calcite, fluorite, quartz, zircon, lepidolite, and some feldspars (McKeever 1985). In each of these cases, there must be activators present and the luminescence of the specimen is removed after heating. Triboluminescence has been reported in some minerals, but is generally not consistent between specimens. This is the case for calcite, feldspars, sphalerite fluorite, micas, and quartz (Walton 1977; Chapman and Walton 1983). Sphalerite samples are typically the most consistent, and the light associated with the triboluminescence can be observed in the dark.

Luminescence Zoning

Luminescence can be used as a tool for identifying different minerals within a specimen. Intercrystalline luminescence describes the difference in fluorescence for different mineral phases within the same host rock (Rakovan and Waychunas 1996). Typically this will be observed through difference in the color of the resulting fluorescence when the sample is placed underneath ultraviolet radiation. This type of luminescence can be used to distinguish minerals that may look similar in visible light or aid in the isolation of individual crystallites within the matrix. It is important to point out that luminescence may aid in identification, but cannot be used as the only method because certain mineral from the same species may fluoresce different colors from different locations due to difference in the trace element chemistry. Once a mineral has been identified, the specific fluorescent wavelength that it emits can sometimes be helpful to identify its place of origin (Rakovan and Waychunas 1996).

Intracrystalline zoning is defined as variations that occur within individual crystallites. Zoning within minerals occurs when there is a spatial difference in a particular chemical or physical property and provides information regarding the morphological history of the crystal, changes in the deposition environment, growth mechanism, and atomic-level structure. Zoning of the luminescence signal is caused by changes in the activator concentration and is usually the result of the growth process (Rakovan and Waychunas 1996). Zoning can occur as concentric rings or as defects on specific crystal phases (sectoral and intrasectoral zoning) and provides wealth of information regarding the deposition environment and growth of the mineral sample.

Luminescence Spectroscopy

Photoluminescent properties of a mineral specimen can be measured using a spectrometer and can provide information regarding the chemical and physical properties that result in the release of a photon (Waychunas 2014). The energy levels of the ground and excited states are dependent on the identity of the element, oxidation state, coordination geometry, and local site symmetry. Thus, luminescence spectroscopy can determine the presence and identity of the activator, even at trace levels within the sample.

The absorption, excitation, and emission processes can all be probed using this technique. Absorption spectra measure the amount of light absorbed or transmitted by a sample, while the wavelength of the incident radiation is varied to provide information on the energy of the electronic transmission in the ground states to multiple excited states of the activator or luminescence center. Excitation spectroscopy scans the wavelength of the incident beam while monitoring emitted light to impart information regarding the energies that produce luminescence when they are absorbed by the sample. By comparing the absorption and excitation spectra, the exact wavelengths required for luminescence can be determined. The emission spectra are collected by fixing the incident wavelength and scanning through the emitted energy, which shows the transition from that specific excited state that releases the photon (Waychunas 2014). This can provide details regarding the identity of the activator because those specific energy levels can be probed by scanning through the emission spectra. The spectra of both absorption and emission

spectroscopy of unknown activators can be compared to standards to provide identification of the elements in the sample.

Cathodoluminescence spectra can also be collected using an electron-beam instrument like a scanning electron microscopy or an electron microprobe (MacRae et al. 2005; Gotze 2012). The energy from the electron beam can promote electrons from the ground state to the excited state for most activators, so identification of the element responsible for luminescence can be difficult to identify using this technique. However, high-resolution spatial mapping can be obtained for mineral specimens and provide information regarding growth, zoning, impurities, and the crystallization environment (Waychunas 2014).

Luminescence Dating

Soils and sediment may contain thermoluminescence minerals which can be used to determine the geologic age of the sample (Singhvi and Mejdahl 1982; Wintle and Huntley 1982). Minerals, such as calcite, quartz, or zircon, present within the sample matrix, are heated under an inert atmosphere or vacuum, and the emitted light is recorded using a photon sensitive detector (Huntley et al. 1988; Rendell et al. 1993). Electrons are trapped at different depths, and thus, the variation in temperature is related to the irradiation history of the sample, which occurs due to exposure to naturally occurring radioactivity. The spectra of the mineral will change as a result of crystal purity, radiation dose, dose rate, and thermal history. The age is determined by dividing the equivalent dose determined through thermoluminescence by the overall dose rate of the sample (obtained through gamma spectrometry) (Wintle and Huntley 1982; Duller 2004). This technique is particularly useful when dating samples from the quaternary period, but given that the thermal history or impurities may impact the overall emission, thermoluminescence dating is often combined with other methods, such as U-series dating or stratigraphy (Forman 1989; Duller 2004).

Summary

Luminescence in geologic samples can occur through a variety of pathways, but photoluminescence is the most commonly observed form. Luminescence signals can provide information on the presence of trace elements in the sample, crystallite growth, and deposition environment. Spectroscopic techniques can be used to understand the chemical characteristics of the mineral phase, and thermoluminescence is utilized in geochronological studies of soils and sediments.

Element Data
Atomic Symbol: Lu
Atomic Number: 71
Atomic Weight: 174.9668(1)
Isotopes and Abundances: ^{175}Lu, 97.401(13)% and ^{176}Lu, 2.599(13)%
1 Atm Melting Point: 1663 °C
1 Atm Boiling Point: 3402 °C
Common Valences: +3
Ionic Radii: 86.1 pm (CN6), 97.7 pm (CN8), and 119.4 pm (CN12)
Pauling Electronegativity: 1.27
First Ionization Energy: 523.52 kJ mol^{-1}
Chondritic (CI) Abundance: 0.0254 ppm
Silicate Earth Abundance: 0.057 ppm
Crustal Abundance: 0.30 ppm
Seawater Abundance: 0.227 ppt
Core Abundance: ~0

Properties

Lutetium (Lu), named after *Lutetia*, the Latin name for Paris, is a soft, malleable, ductile, dense (9.841 g cm^{-3}), bright silvery metal. Its electronic configuration is [Xe]4f^{14}5d^{1}6s^{2}. It is relatively stable in air and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE). In geochemical terminology, it is grouped with heavy rare earth elements (HREE; Gd-Lu). Lutetium has one natural, stable isotope and one long-lived radioisotope (^{176}Lu; $t_{1/2} = 3.713 \times 10^{10}$ year; beta decaying to ^{176}Hf) occurring in nature, listed above with their abundances.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Lu as a significant component are restricted to minerals such as gadolinite-Y [$Y_2FeBe_2(Si_2O_{10})$], xenotime [$Y(PO_4)$], bastnäsite [REE(CO_3)F], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+},Fe^{3+})_3(SiO_4)_3(OH)$], and britholite [$(REE,Ca)_5(SiO_4,PO_4)_3(OH,F)$].

Details of properties, mineralogy, history, and uses of Lu were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner (2016), Hammond (2016), and Meija et al. (2016a, b).

History and Use

The early history of Lu was controversial, being identified independently by three workers (Urbain, von Weisbach, James) in 1907, with final attribution of discovery (and naming) going to Georges Urbain in 1909. Lutetium metal was first produced in 1953. Being the rarest of the naturally occurring REE in the Earth, Lu is also the most valuable but has limited commercial use. It has been used as a catalyst in petroleum cracking, and due to its very high density, $LuTaO_4$ has been used in X-ray phosphors. Lu is also used in Tm:LuYAG lasers, PET medical imaging detectors, and LED lights.

Geochemical Behavior

The fundamental importance of Lu in geochemistry is that it is one of the small trivalent rare earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction." The ^{176}Lu/^{176}Hf decay system is an important geochronometer and isotope tracer in a wide variety of geological settings (e.g., Wu et al. 2007).

Lutetium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element, with a 50% $T_{condensation}$ of 1659 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Lu is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Lu normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Lu contents of clastic sediments typically reflect their average provenance.

In seawater, Lu has very low concentrations (sub-ppt) and residence times (~2890 year) with speciation dominated by Lu^{3+}, $LuCO_3^+$, and $Lu(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Lu can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration and residence time data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Lu. REE (including Lu^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Lu) in human tissues and fluids are very low (~ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Chemical mass transfer; Computational thermodynamic modeling of magmatic systems; Equilibrium and fractional crystallization, assimilation, recharge of magmas; Magmatic evolution

Definition

Chemical and physical processes that influence the evolution of a magma body from one state to another, including crystal fractionation, equilibrium crystallization, assimilation, recharge, and heat transport, magmatic differentiation, magmatic evolution.

Introduction

Magmatic processes embody the transfer of energy and mass into or out of a body of magma and characterize the irreversible mechanisms driving the magmatic system towards an equilibrium state. They are the coupled, time-dependent, physiochemical phenomena that enable magmatic evolution. Crystallization, volatile degassing, immiscibility, and other aspects of phase change are manifestations of magmatic processes as are preserved rock textures, phase distributions, and chemical zonation. With the spectacular exception of volcanic eruption, magmatic processes are seldom directly observable. We do not witness fractional crystallization, crystal growth, degassing, assimilation, recharge, heat conduction, diffusion, or convection. Their nature is inferred from the cumulative chemical signature and spatial heterogeneity of that signature recorded in the rocks at the reflects nation of the sequence of events that drive magma evolution.

Magmatic geochemists and petrologists justify, by forward modeling, hypotheses concerning process sequences that result in the chemical signatures preserved in the rock record. They have been doing this exercise with greater and greater sophistication for well over a century and a half. But, despite the familiarity and acceptance of this approach, modeling magmatic processes is fraught with both difficulty and uncertainty. Not only is our knowledge of the underlying physiochemical constraints (thermodynamic properties of the phases involved and the kinetics of their interaction) incomplete and derived from sparse, inadequate, and often contradictory experimental data, but computational fluid dynamical tools available to forward model process scenarios are deficit due to deficiencies in theoretical formalism and lack of raw computational power. Accounting explicitly for the physics and chemistry of microscale processes simultaneously with the macrophysics of magma body evolution is not yet computationally feasible. For example, it is beyond our current ability to model crystal growth in a cooling magma body of realistic bulk composition and account for the crystal size distribution of phenocryst phases derived from the process, let alone the texture of the resulting rock, or the chemical signatures preserved in the phenocryst assemblage. Compounding the problem is the nonunique nature of process inversion. Chemical signatures preserved in the igneous rock record may be broadly consistent with a spectrum of process scenarios. In addition, this ambiguity of interpretation is often exacerbated by a myopic focus on a limited number of observables. For example, it is counterproductive to rely exclusively on a particular element or group of elements, a preferred isotopic signature, or a specific favorite mineral phase in trying to unravel the sequence of processes that result in the igneous rock record. An analysis based on this sort of reasoning is typically misleading and usually contradictory to ignored observables or to

https://doi.org/10.1007/978-3-319-39312-4

unappreciated but plausible physiochemical constraints on system evolution.

Given the complexities and pitfalls inherent to magmatic process modeling, the reader may wonder why it is attempted at all. The answer to this question derives largely from the regularity of the igneous rock record and implications of this regularity in illuminating the nature of the dominant constraints operative during magmatic evolution. If kinetic phenomena driven by far from equilibrium conditions were first-order determinants of source composition and crystallization history of a magma, then we would expect a diversity of magma compositions and crystallization products that were entirely dependent on localized heat flow and eruptive/cooling style; in particular, we would not expect the products of igneous activity to conform to experimentally determined equilibrium phase diagrams. But, of course, igneous rocks do so conform, and this conformation reveals that the first-order characteristic of igneous evolution is that it takes place via a series of states each approximating thermodynamic equilibrium. Approximating, since an equilibrium state cannot naturally progress, unless perturbed and allowed to recover. Modeling an overall irreversible process as a sequence of equilibrium steps is a well-established geochemical technique (Garrels and Mackenzie 1967; Helgeson 1968), but application of this technique demands that rates associated with the formation of reaction products far exceed those that modify magmatic intensive variables or bulk composition. Generally, this assumption is a reasonable one, and thus, magmatic processes are typically modeled as a sequence of equilibrium steps; this is why phase diagrams are applied to the interpretation of equilibrium and fractional crystallization; how trace element modeling is utilized in the analysis of crystallization, assimilation, and recharge events; and why constitutive phase relations are utilized in the context of fluid dynamical simulations.

Techniques Used for Modeling Magmatic Processes

Equilibrium phase diagram calculators are central to magmatic process modeling efforts. These calculators can take a variety of forms. Originally, graphical phase diagrams provided the basis for understanding magmatic evolution (Bowen 1915, 1919, 1922a). The advantage of the graphical phase diagram is that if it is correctly constructed, the diagram embodies thermodynamic principles governing phase relations that extend and interpret the raw experimental data. This filtering of experiments is important and is sometimes underappreciated. The disadvantage of graphical phase diagrams is that they limit the complexity of the chemical system being described due to our inability to visualize in higher dimensional spaces. The use of graphical phase diagrams as a basis for magmatic process modeling faded once computers became generally accessible, and numerical procedures gained acceptance for their novelty and perceived accuracy. The simplest of these numerical calculators are direct and empirical parameterizations of experimental phase relations, and the most complex rely on internally consistent thermochemical models of constituent phases from which reaction boundaries are calculated using the mathematical apparatus of computational thermodynamics. The former class of numerical models generally reproduces the experimental calibrants with higher fidelity. This ability derives from the flexibility of choosing a form for the interpolating functions that is not required to conform to theoretical relationships dictated by an underlying physical theory. By contrast, phase diagram calculators that do conform to the rules of thermodynamics must accommodate experimental constraints with mathematical expressions that guarantee the existence of energy functionals that prescribe specific geometrical relationships at equilibrium between energetic surfaces that characterize the phases. These theoretical constraints impose themselves on the experimental calibration and demand internal consistency between sets of experimental observations that might otherwise appear to be independent. There is nothing in theory that prevents thermodynamically based descriptions of phase relations from achieving the equivalent ability of empirical formulations to reproduce experimental observations, but because thermodynamic models depend on a global analysis of energetic relations in a chemical system, there may in practice be insufficient experimental data to parameterize such a model (or collection of models) in a unique and rigorous manner. The objectives of the two approaches are different: the empirical description is a local interpolation, meant only to be applied locally, whereas the thermodynamic description is a global analysis, capable of extrapolation and meant to reconcile sets of disparate experimental results.

Whether empirical or thermodynamically based phase diagram calculators are used in magmatic process modeling, depends on the objective of the exercise. If recovery of phase relations is all that is desired and if experimental coverage is complete, then empirical calculators are sufficient – such is often the case in fluid dynamical simulations that require estimates of phase proportions. However, if the magmatic process being considered is constrained in such a way that experimental data are inapplicable, then a thermodynamic approach is desirable. A simple example will suffice to illustrate this point.

Why Phase Equilibrium Experiments Are Not Enough

Suppose our modeling objective is to compute closed system equilibrium or fractional crystallization of a basaltic bulk composition magma body (for context, the MORB

Magmatic Process Modeling, Table 1 Bulk compositions used in examples

wt%	MORB	High-silica rhyolite

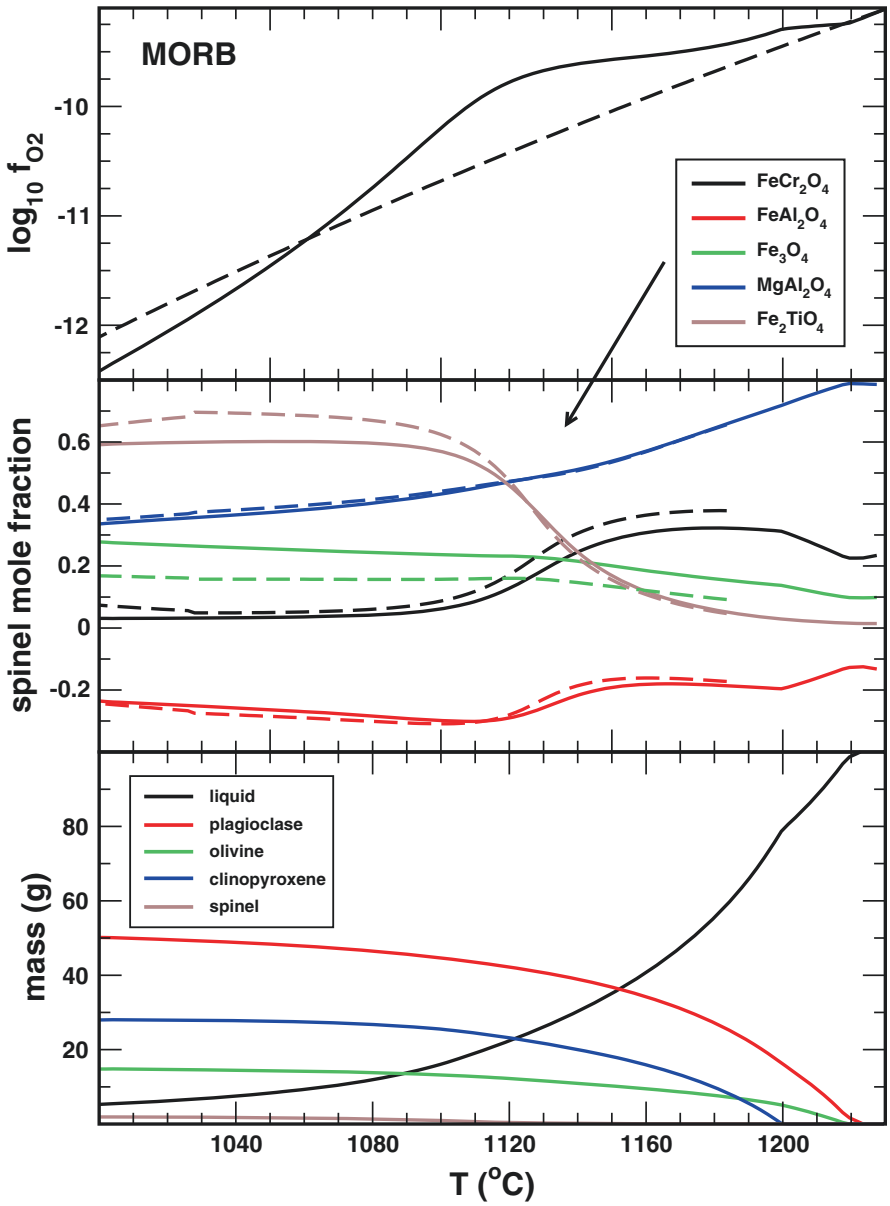
composition listed in Table 1). This is perhaps the simplest magmatic modeling process that can be envisioned and is often illustrated in one form or another in elementary textbooks. By specifying closed system crystallization, the magma is considered chemically isolated, but of course, the body is not thermally isolated from its surroundings, which permits heat to flow out into the surrounding rocks during cooling. If we choose to model this crystallization process empirically, we would need to find experimental data documenting closed system crystallization of this midocean ridge basalt (MORB) in order to parameterize the required functions (or interpolate the provided data). Unfortunately, the experimental data required to empirically parameterize this model are unavailable and are likely to remain unavailable. It is almost impossible to perform a sequence of crystallization experiments on a bulk composition involving elements that have variable oxidation states (e.g., iron), without the system *changing bulk composition* in the process of crystallization due to the loss or absorption of oxygen. In fact, most experimentally determined crystallization sequences on iron-bearing systems are oxygen buffered, meaning that bulk composition evolves with changing temperature to keep constant *the relative oxidation state and not the oxygen content* of the system. As practical as this redox constraint is for experimental configuration, nature, arguably, does not conform to this constraint. In nature, the oxidation state of a magma body is dictated by what phases are crystallizing and by homogeneous equilibria among redox-species in the liquid phase (Osborn 1959 1962; Ghiorso and Carmichael 1985). Consequently, modeling equilibrium or fractional crystallization of magma as a closed system cannot be accomplished by empirical parameterization of experimental data. Those data must be interpreted by deriving from them a thermodynamic model and calculating from that model a true closed system path. Such a path is illustrated for the MORB bulk composition of Table 1 in Fig. 1. Along with the closed system evolution, an equivalent open system crystallization process is illustrated that maintains the same redox state (relative to the Ni-NiO oxygen buffer). The thermodynamic calculator used to generate these results is described in Ghiorso and Sack (1995) and Gualda et al. (2012a). Details of how these calculations were performed are provided in the figure legend and the modeling infrastructure is summarized in an Appendix to this chapter.

The evolution path of the closed system model is calculated by minimization of the Gibbs free energy of the system at each temperature (e.g., Ghiorso 1985). The open system path is calculated by minimizing an alternative thermodynamic potential named after Dmitriĭ Sergeevich Korzhinskiĭ (Ghiorso and Kelemen 1987) who pioneered the field of geochemical analysis of equilibrium phase relations in open systems where the fugacity or chemical potential of a thermodynamic component is fixed by external constraints (e.g., the system is forced to follow an oxygen buffer). The profoundly different redox path followed by the closed system evolution is controlled by the partitioning of ferrous and ferric iron into the crystallizing solid phases. If that partitioning favors ferrous iron into the solid phase(s), then the liquid ferric/ferrous ratio increases and so too does the oxygen fugacity of the magma (Kress and Carmichael 1991). It is fortuitous that for this example, with the exception of the onset of crystallization of spinel, the proportions of phases are not markedly different between the two crystallization scenarios. Compositions of the crystallized ferromagnesian phases differ markedly between the buffered and closed system scenarios (*middle panel*, Fig. 1), and one would expect this difference to carry forward to partitioning of trace elements with variable redox states.

Why Thermodynamic Models of Phase Equilibria Provide Important Constraints on Magmatic Process Modeling

Another example of modeling the magmatic crystallization process is illustrated for a very different bulk composition in Fig. 2, which shows the redox-buffered solidification of a liquid of high-silica rhyolite composition (Table 1). In contrast to the results displayed in Fig. 1, for this bulk composition, crystallization traverses the temperature of the quartz-two-feldspar-fluid "invariant" point (Tuttle and Bowen 1958), and the magma essentially solidifies over a 1 °C interval. This "eutectic-like" behavior is perhaps the closest that nature ever comes to mimicking simple two and three component phase diagrams. The calculations reported were made using rhyolite-MELTS (v. 1.1.0, http://melts.ofm-research.org/) (Gualda et al. 2012).

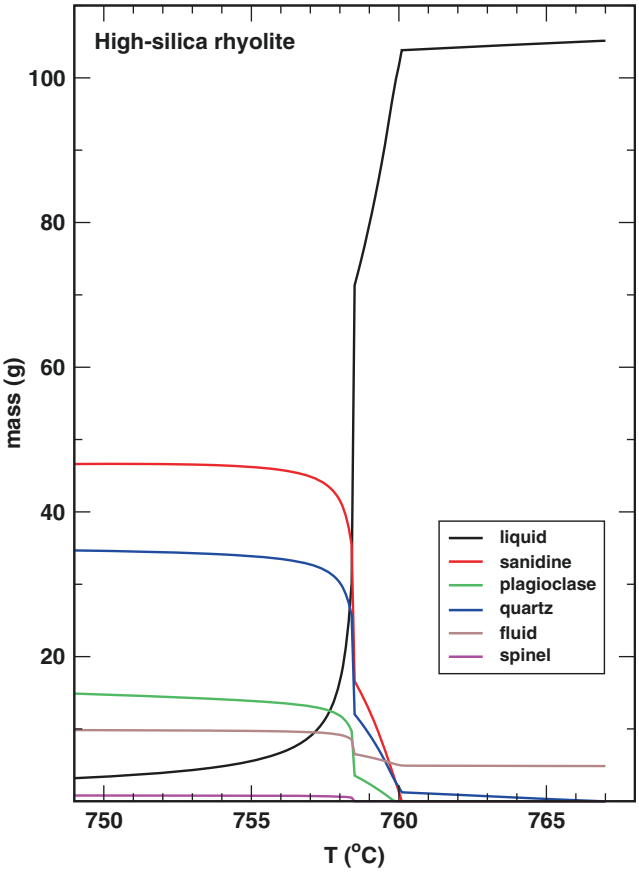
The crystallization process simulation presented in Fig. 2 provides a convenient reference point to discuss several



Magmatic Process Modeling, Fig. 1 Equilibrium crystallization of midocean ridge basalt (MORB, Table 1) modeled using the computational thermodynamics package rhyolite-MELTS (Gualda et al. 2012). *Upper panel* shows evolution of the system oxygen fugacity as a function of temperature for the closed system (*solid curve*) and open system (*dashed curve*) case, which parallels the Ni-NiO buffer (O'Neill and Pownceby 1993). The redox state of the closed system model is calculated using the experimental calibration of Kress and Carmichael (1991). *Middle panel* shows the composition of the spinel phase along the magma crystallization path. Note that the buffered path produces a less oxidized spinel that appears about 50 °C below the liquidus temperature of the closed system assemblage. *Lower panel* shows the mass of each phase in the system. Only the closed system path is shown as the open system phase proportions are virtually identical

aspects of modeling magmatic systems. Let us assume that there exists a magma body of high-silica rhyolite bulk composition that is present in the mid to shallow crust. This body may undergo a number of physical processes: crystallization, assimilation of country rocks, recharge of new magma, eruption, to name just a few. How the body arose in the first place is a reflection of additional processes, including perhaps fractional crystallization from a more mafic parent, partial melting, and/or melt extraction. All processes of melt generation require heat; all processes of melt crystallization require the loss of heat. The operative quantity that describes how magmas evolve is the heat content of the body. Heat content is a more natural descriptor than temperature because heat flows from sources to sinks, into and out of the system of interest.

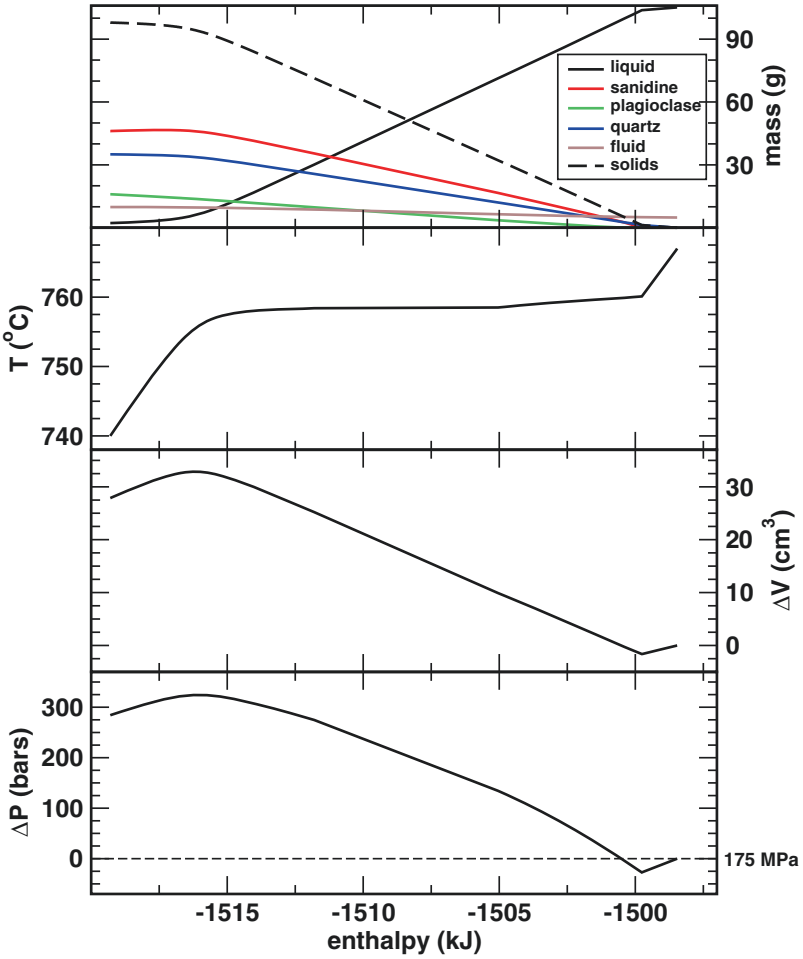
In the upper two panels of Fig. 3, some results from the open system crystallization of the high-silica rhyolite bulk composition reported in Fig. 2 are plotted as a function of the heat content of the system, or the system enthalpy. In a thermodynamic system at fixed pressure, a change in enthalpy is equivalent to a change in total heat content. If the system is in a variable pressure field, a reversible change in heat content is equivalent to a change in system entropy. Passing from more positive to more negative values of enthalpy, therefore represents withdrawal of heat from the magma body, and in the context of knowledge of the thermal regime in which the body resides in the crust, the flux of heat transfer can be related to time. For example, if heat flux out of the magma body is approximately constant, as might be the case if the thermal regime in the country rocks has reached an



Magmatic Process Modeling, Fig. 2 Equilibrium crystallization of a fluid-saturated high-silica rhyolite (Table 1) modeled using the computational thermodynamics package rhyolite-MELTS (Gualda et al. 2012). The simulation was performed by open system Korzhinski potential minimization (Ghiorso and Kelemen 1987) along the Ni-NiO buffer (O'Neill and Pownceby 1993). The mass of each phase in the system is shown, plotted as a function of temperature

approximate steady state, then the heat content change is linearly proportional to the change in time to withdraw that quantity of heat from the body; the proportionality of course being dependent on, among others things, the size of the reservoir. Consequently, the enthalpy abscissa can be viewed as a measure of the history of the body – a reverse time axis, and it is quite clear that in the case of this high-silica rhyolitic bulk composition, the vast majority of time under which this body crystallizes is spent at a single temperature (± 1 °C). This feature is due to the eutectic nature of crystallization and the fact that latent heat is generated as the liquid crystallizes into the solid assemblage. This heat of crystallization must be removed before the body may be cooled to a lower temperature; for this example, the latent heat completely overwhelms the sensible heat, which is the heat held by the phases themselves. Withdrawal of sensible heat lowers the temperature of the system.

In addition to the heat content of the magma body, which through the phase diagram determines the temperature of the system, it is the volume of the body that dictates the pressure under which crystallization takes place; volume and pressure, just as heat content and temperature, are complimentary thermodynamic descriptors of the equilibrium state of a thermodynamic system. When modeling magmatic processes, it is especially important to keep this in mind. The reason is that the volume of magma is strongly dependent on phase change. Crystallization of mineral phases from the liquid generally leads to a reduction in volume, typically on the order of 3%, while separation of a fluid phase generally involves generation of volume, the magnitude of which is strongly dependent on confining pressure. For the case of the high-silica-rhyolite bulk composition, the third panel of Fig. 3 displays the volume change associated with phase transformation and cooling. Note that the system volume initially decreases as heat is withdrawn, then increases across the interval of major crystallization, reaches a maximum, and subsequently decreases. The slopes of the initial and final segments of the volume curve are negative in these intervals for two reasons: (1) the decrease in volume associated with the crystallization of solids exceeds the increase association with fluid phase separation and (2) a volume decrease is associated with thermal contraction of the system. Just as a distinction is commonly made between sensible and latent heat, so too can volume change be ascribed to either cooling or to phase change. The volume change with cooling is generally negative unless some structural rearrangement of the material intervenes to counteract bond contraction due to diminished thermal motion. Therefore in a cooling magma body, unless a product phase is produced that has substantially higher volume (lower density) than the reactants, the overall trend will be contraction. But, the volume of a magma container cannot assume whatever value is dictated by the internal phase equilibria. The volume of the container is dictated by the physical state of the country rocks that enclose the magma. If those rocks can be deformed at a rate that is comparable to the rate of magma volume change, then the container can accommodate the perturbation. If not, the imposed container volume will result in a change in the internal pressure of magma body and consequently a differential pressure between the magma and surrounding country rocks. The sign of this differential pressure is always the same as that of the volume change and scales as the inverse of the magma compressibility. As an example, the lower most panel of Fig. 3 plots the pressure change that would result if the container holding the high-silica rhyolite was rigid during cooling. A better modeling scenario might be that the container itself contracts with cooling at a rate comparable to the thermal contraction of the magma, which would make the differential pressures plotted in the lower panel of Fig. 3, minimal values. At the onset of crystallization, the pressure differential decreases and then begins to rise, reflecting solid-phase crystallization followed by exsolution of a fluid phase of low density. This



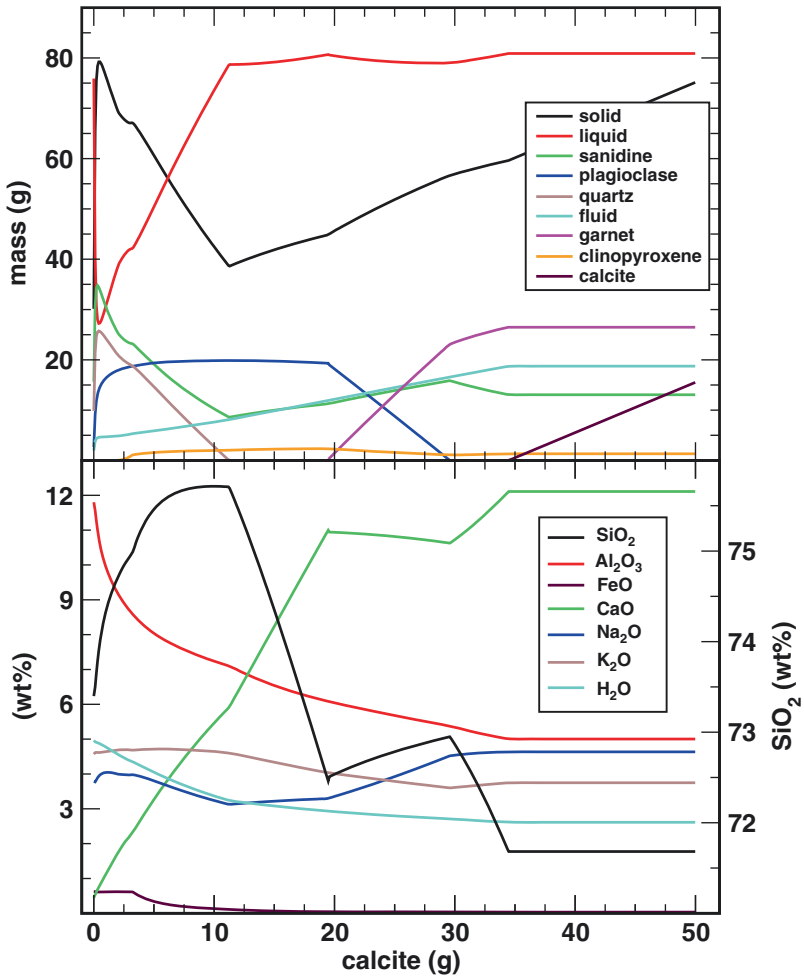
Magmatic Process Modeling, Fig. 3 Equilibrium crystallization of a fluid-saturated high-silica rhyolite (Table 1) modeled as in Fig. 2. *Top panel* shows phase abundances plotted against system enthalpy, which proxies for the total heat content of the magma body. *Second panel from top* shows the temperature of the magma and the *third panel* the volume of the magma. Note that the volume is an extensive quantity computed for the total mass of the system. *The lower 5-fold* ws the pressure relative to 175 MPa calculated on the assumption that the container holding the magma is rigid

partitioning of volatile components from the liquid to the fluid is not a consequence of diminished solubility in the melt, but rather, it is consequence of the change in mass of available liquid and therefore the capacity of the magma to hold these volatile components in solution. Crystallization is therefore driving the pressure increase. In this case, the overpressure developed is on the order of 150 bars when the magma is about 35% crystallized, which may be sufficient to cause fracturing or eruption of the system.

The point of the model developed in Fig. 3 is that a process as simple as crystallization of a magma body, when viewed in the context of a mass and energetically balanced coupled wall rock-magma system, can be profoundly informative. Importantly, the majority of information gleaned from such a model derives directly from the underlying thermodynamic treatment. Is the system chemically open or closed? How is heat transferred in or out of the body? To what extent is the magma container deformable? These questions are dynamic and process oriented. They cannot be answered without an underlying context that couples the chemistry and energetics of the system. In other words, answers to questions involving the evolution of a magma body cannot be provided from phase diagrams or experiments of phase equilibria without the benefit of interpretive theory, and that theory is the underlying thermodynamics of the process. Modeling a magmatic process is an exercise beyond simply understanding the chemical transfers from one phase to another or the physics of transport of material. It is an exercise in understanding how the chemistry and physics are coupled and feedback on one another. Nowhere is this more apparent than when trying to model the process of assimilation or recharge of new magma into an existing magma body. Let us next explore an example of assimilation to understand and illustrate this point further.

Assimilation Processes

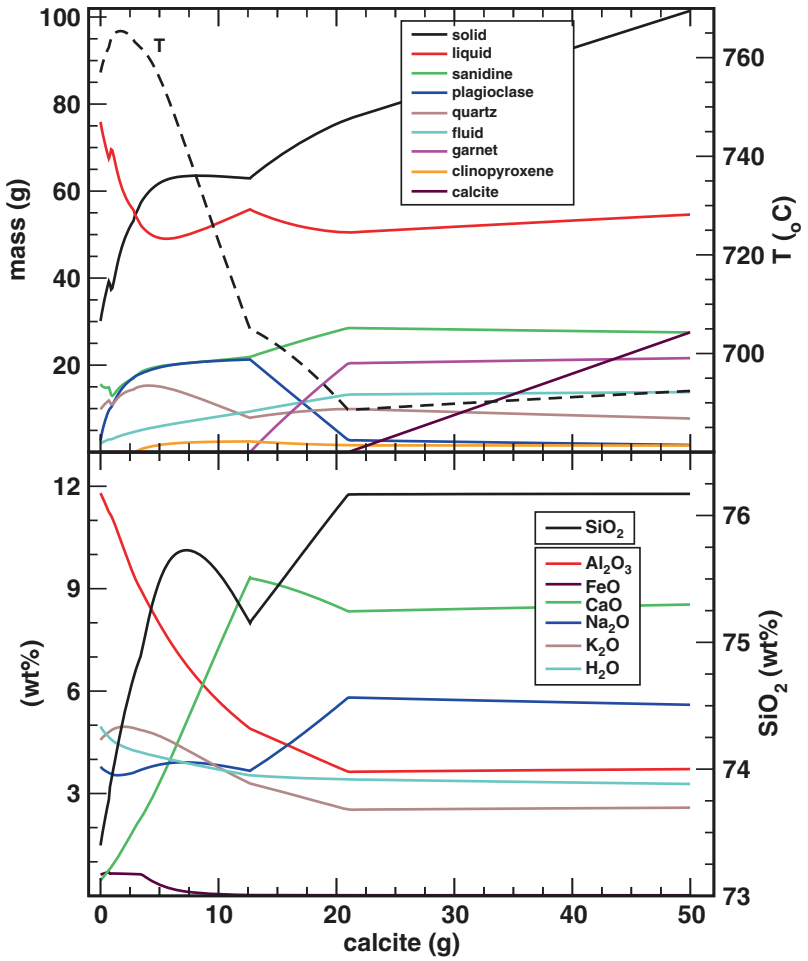
Continuing with the high-silica rhyolite magma composition, rhyolite-MELTS (Gualda et al. 2012 as extended by Ghiorso and Gualda (2015) to include mixed H_2O-CO_2 fluid saturation in the liquid phase) can be used to model the chemical reactions accompanying assimilation of calcite ($CaCO_3$) into this magma. Results are displayed in Fig. 4 for the case of the uncontaminated magma starting at a temperature of 759 °C



Magmatic Process Modeling, Fig. 4 Assimilation of the mineral calcite into a high-silica rhyolite bulk composition magma. Initial conditions of the magma are 759 °C and 175 MPa, with the assemblage quartz+sanidine +plagioclase stable under fluid saturation. The calcite is titrated into the magma in 0.1 g increments, and the system is maintained at constant temperature. The calculation is performed with rhyolite-MELTS (Gualda et al. 2012) as modified (v. 1.1.0) for the addition of a CO_2-bearing fluid phase (Ghiorso and Gualda 2015). *Upper panel* shows phase abundances plotted as a function of mass of assimilant. *Lower panel* shows composition of the liquid phase; note that the concentration of SiO_2 is read from the right-hand ordinate

and 175 MPa and at saturation with a fluid phase (99 mole% H_2O). These conditions correspond to the calculated onset of the two-feldspar-quartz-fluid saturated "eutectic" for this bulk composition (Fig. 2). Calcite is "titrated" into this system mimicking the physical process of interaction of country rocks with the magma reservoir. Figure 4 displays phase proportions (top panel) and changes in liquid composition (lower panel) accompanying calcite addition. Note that the magma does not saturate with calcite until about 35 g have been added to ~100 g of initial material. Also, note that the stoichiometry of the reaction process is extremely complex. This result is important and quite a general characteristic of the assimilation process in magmatic systems. Assimilation does not necessarily involve melting of the assimilant; the process of assimilation is one of the reactions of material that is out of equilibrium with the magmatic phase assemblage and that reaction may produce or consume solids or may balance product and reactant solid masses to maintain a constant liquid fraction. In the case displayed in Fig. 4, the initial addition (<1 g) of calcite induces solidification, provoking crystallization of sanidine, quartz, and plagioclase, but further addition lifts the bulk composition off of the "eutectic," so that quartz and sanidine are consumed along with the calcite, resulting in the production of plagioclase and liquid. Liquid proportion grows until, after 11 g of calcite have been consumed, the amount of liquid present is comparable to the initial quantity. At this point, all of the quartz in the system is eliminated, and the reaction stoichiometry changes abruptly as further addition of calcite transfers CO_2 to the fluid phase and consumes SiO_2 from the liquid phase to produce silicate mineral products. Eventually, the system saturates with grossular garnet, forming at the expense of plagioclase, and the SiO_2 reduction trend is reversed until the plagioclase is consumed. Ultimately, after ~35 g of calcite are added, the magma saturates in that phase, the coexisting fluid (*not the magmatic liquid*) becomes CO_2 rich, and the solid assemblage garnet, clinopyroxene (a diopside solid solution), sanidine, and calcite are stabilized, producing a skarn-like mineral assemblage. Remarkably, the liquid fraction remains at its initial proportion.

The results plotted in Fig. 4 demonstrate a fascinating record of a complex reaction progress history, but is this record petrologically relevant? More specifically, is the calculation petrologically relevant over and above any



Magmatic Process Modeling, Fig. 5 Assimilation of the mineral calcite into a high-silica rhyolite bulk composition magma. Initial conditions and calculation scheme as in Fig. 4. The calcite +magma system is maintained at constant enthalpy under the assumption that heat flow is negligible compared to reaction rates. It is assumed that the calcite is at the same initial temperature and pressure as the magma. The calculation is performed by maximizing the system entropy at each step, calculating as a consequence the phase proportions, phase compositions, and the temperature of the equilibrium assemblage. *Upper panel* shows phase abundances and temperature plotted as a function of mass of assimilant. Note that the value of temperature is read from the right-hand ordinate. *Lower panel* configured as in Fig. 4

inaccuracies or inadequacies associated with the underlying thermodynamic modeling tools? This is an important question, one that should be asked for every assimilation process modeling undertaken for a magmatic system. Can one simply and arbitrarily titrate any quantity of solid material into magma at some fixed temperature and pressure and expect the result of that calculation to be physically meaningful? Or, in other words, can one independently specify the ratio of the mass assimilated to the mass crystalliz when trying to tease out the chemical or isotopic consequences of an assimilation event? The answer is yes only if the volume and heat content of the magma are allowed to change in a manner consistent with the various heats of reaction associated with consumption of the assimilant and the production of secondary reaction products. But, this change in properties demands specific boundary constraints on the body, *which are generally not satisfied*. Further, the heat content and volume of the assimilant come into consideration in the inventory of sensible heat and sensible volume for the combined system. The proper way to model this process is to explicitly account for both the energy balance and volumetric changes associated with the assimilation process. As in modeling magmatic crystallization, the physics of heat flow through and deformation of the magma container must constrain the permissible reaction path that the system takes during its irreversible evolution. In this light, we examine this assimilation model again under more physical boundary constraints.

In Fig. 5 the evolution of a high-silica rhyolite magma is plotted, starting under the same initial conditions as in Fig. 4, but with the reaction path constrained to maintain energetic balance. Two assumptions are made: (1) that the calcite being assimilated is at the same initial temperature as the magma and (2) that there is no heat loss from the magma+assimilant system during the reaction process. The first assumption is made for convenience and can easily be relaxed. Making this assumption insures that the effects being modeled focus on heats of reaction and do not include the sensible heat contribution required to raise the assimilant to magmatic temperatures. The second assumption may also be relaxed if details are known about the relative rates of heat transfer compared to rates of reaction. As adopted, the rate of heat transfer is assumed to be negligible compared to the rate of the assimilation reaction. Therefore in practical terms, this assumption is equivalent to modeling the process as one where no net heat

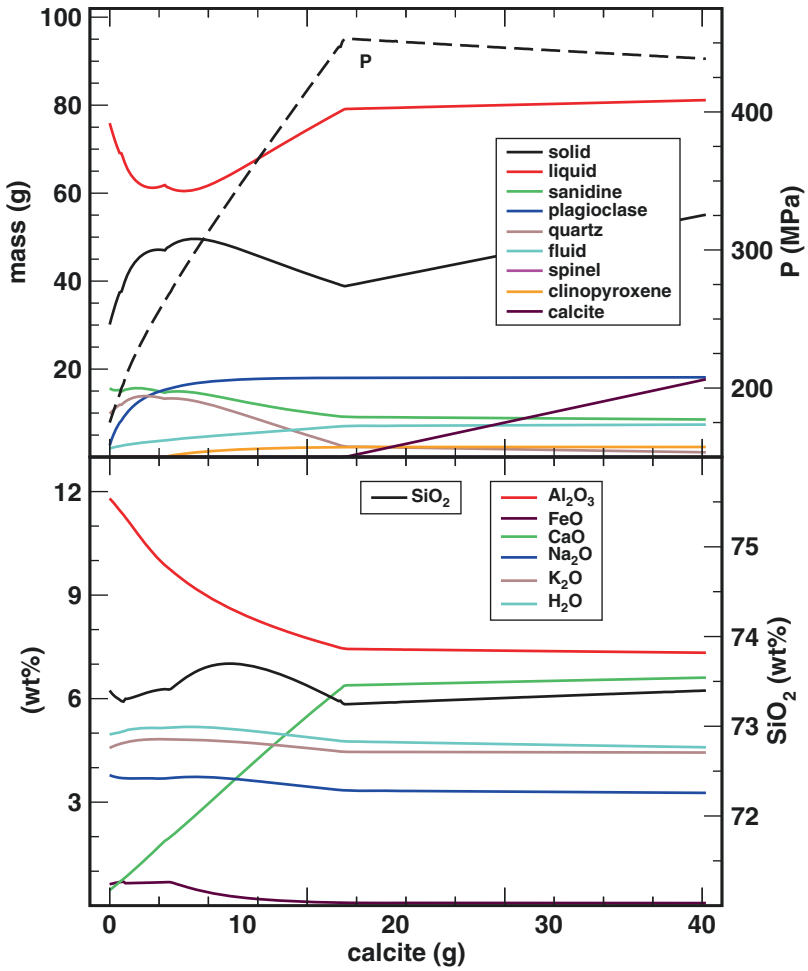
transfer occurs, that is the heat content of the magma +assimilant system is assumed to be constant; at constant pressure, for a reversible process, constant heat content is equivalent to constant enthalpy. The calculation is carried out by computing the enthalpy of the added calcite, adding this enthalpy plus the mass of that calcite to the magma, and computing the equilibrium phase assemblage for this new bulk composition at stipulated pressure and at a total enthalpy equal to that of the magma+calcite addition. Technically, this calculation is done by maximizing the total combined system entropy (Ghiorso and Kelemen 1987). While experiments could be configured to evaluate the outcome of the calcite titration scenario modeled in Fig. 4, it would be difficult, if not impossible, to construct an experiment that directly evaluates the energy constrained assimilation scenario modeled in Fig. 5. Yet, the energy-constrained case is more petrologically meaningful (Bohrson and Spera 2001; Spera and Bohrson 2001, 2002; Bohrson et al. 2014), just as the closed system crystallization calculation described above (Fig. 1) embodies the more realistic constraints on the magma crystallization process.

The energy-constrained assimilation scenario plotted in Fig. 5 produces very different results than those shown in Fig. 4. The first feature to note is that the temperature of the system is now a function of the extent of assimilation, which results from the enthalpy balance constraint; temperature is a dependent variable. As calcite is added to the magma, the system responds by reacting the calcite with existing phases to form products. Any heat of reaction must be balanced by a change in temperature in order to zero the total enthalpy change. The perhaps nonintuitive consequence of balancing the heat budget is that the temperature can rise or fall depending on the exact stoichiometry of the reaction. The first person to thoroughly discuss this phenomena from a thermodynamic perspective was Norman L. Bowen (1922b). In the case illustrated in Fig. 5, temperature initially rises, which should have the effect of moving the system away from the quartz-two-feldspar-fluid saturated cotectic. But instead, the rise in calcium content of the melt offsets this temperature increase, maintaining the magma +assimilant system on the eutectic, while crystalizing a higher proportion of plagioclase to sanidine+quartz. Simultaneously, the liquid fraction diminishes as in the isothermal titration case, but unlike that case does not reverse this trend until ~5 g of assimilant are added. The isenthalpic reaction path does not loose either quartz or plagioclase from the product assemblage, and the system saturates in both garnet and calcite at lower levels of added assimilant than under isothermal conditions. Another interesting consequence of the isenthalpic scenario is that the silica content of the residual liquid is much larger at the onset of crystallization of calcite. The final phase assemblage shown in Fig. 5 is liquid+sanidine+plagioclase+quartz+fluid +clinopyroxene+garnet+calcite.

Regardless of the details of these two assimilation scenarios, it is important to appreciate how different the outcomes are and that these differences arise not because of choice of initial magma bulk composition, temperature, and pressure or because of the nature of the assimilant. Modeling the process of assimilation in magmatic systems is entirely dependent on the constraints placed on the physics of the assimilation process, e.g., what is the relative difference in the rate of heat transport compared to the rate of reaction. Each case must be evaluated quantitatively by working out the full reaction-product stoichiometry. Focusing just on trace elements or isotopic signatures and ignoring the phase diagram or heat flow constraints cannot yield either a unique or a meaningful answer. And, importantly, the two illustrative models presented here are still abstract end-members of a continuum of realistic constraints, most of which would require modeling the process with a fully coupled dynamic-thermodynamic approach. To illustrate this point further, let us examine the volumetric consequences of this assimilation scenario and explore whether either the isothermal or isenthalpic end-member cases have verisimilitude.

In Fig. 6, the calcite assimilation scenario is evaluated again, this time under the constraint of fixed volume of the magma+assimilant assemblage; the internal pressure of the magma body is a dependent quantity under these constraints. The physical scenario underlying this case is one of reaction rates exceeding those of deformation of the magma+reactant container. The assumption is made that both the magma and the assimilant maintain a temperature of 759 °C; therefore, these results should be compared to the isobaric-isothermal calculations presented in Fig. 4. The net volume change of the assimilation reaction is positive, so, consequently, the expectation would be that to maintain a constant volume condition the internal pressure of the magma must increase. As discussed above, this is due to the fact that the compressibility of a substance is always positive, so that higher pressure is required to squeeze the product assemblage back down to the volume of the reactant assemblage. Because the solubility of CO_2 in rhyolitic magma is quite low, the assimilation of calcite generates a CO_2-rich fluid, which at these shallow crustal pressures is a low-density or high-volume phase. This fluid phase exsolution drives the pressure increase on assimilation (Fig. 4) to values approaching 500 MPa; the pressure increase trend is only checked once the magma saturates in calcite and fluid production ceases. The phase assemblage formed maintains the preassimilation assemblage quartz+sanidine+plagioclase+fluid, but unlike the isothermal case (Fig. 4), there is no production of garnet, most likely because calcite saturates sooner in the assimilation process, at a CaO concentration in the magma of only 6 wt%.

The pressure increase computed for this assimilation scenario indicates that the constant volume constraint leads to an unrealistically high differential between the magma and surrounding country rocks. Such a large pressure differential will either drive ductile deformation (violating the key assumption



Magmatic Process Modeling, Fig. 6 Assimilation of the mineral calcite into a high-silica rhyolite bulk composition magma. Initial conditions and calculation scheme as in Fig. 4. The calcite +magma system is maintained at constant volume under the assumption that deformation rate is negligible compared to reaction rates; temperature of the magma and the assimilant are held at 759 °C. The calculation is performed by minimizing the Helmholtz free energy at each step, calculating as a consequence the phase proportions, phase compositions, and the pressure of the equilibrium assemblage. *Upper panel* shows phase abundances and pressure plotted as a function of mass of assimilant. Note that the value of pressure is read from the right-hand ordinate. *Lower panel* configured as in Fig. 4

of constant volume) or at least initiate cracking, with expulsion of material to relieve the internal stress; a difference of 200 bars (20 MPa) is generated after addition of *only* ~1 g of assimilant. Perhaps, assimilation alone can initiate a perturbation in the pressure field sufficient to instigate eruption?

Manifesto

Analyzing this calcite assimilation problem within these three different reaction constraint contexts demonstrates something quite fundamental about modeling magmatic processes. The same geochemical scenario, in this case adding calcite to high-silica rhyolitic magma, can yield quite different outcomes, not all of which are easily testable from field observation and certainly not from geochemical data alone. Posing just one scenario, say isothermal-isobaric assimilation, and testing that scenario against observation might broadly reproduce some geochemical trend observed in the rocks, but it may make little physical sense in terms of heat sources or sinks, or the reaction may drive the system into a pressure regime where the assumed underlying phase diagram is no longer applicable. The most robust models of magmatic processes, like the best petrologic insight, are those that account not only for the observations made in the field and the laboratory, but those that also account for the dynamical contexts that constrain the reaction path. We routinely make simplifying assumptions about the state of a magmatic system that we have sampled – we use geothermometers, geobarometers, trace element distribution between phases, we apply phase diagrams, we compare one system to another – all of which are predicated on the implicit assumption that what we are looking at is approximated by an equilibrium state, but how those states are connected to one another in the sequence of events relating the evolution of the system in time and space is often treated as "not our concern." Well, it is our concern. Geochemists and petrologists should not legitimately pose a geochemical scenario that is nonsensical because it violates the physics of transport, nor should geophysicists and geodynamicists posit a physical mechanism of magma generation, transport, or eruption that does not account fully for geochemical observations. Energy (and all of its derivatives, volume, heat capacity, thermal expansion, compressibility, bulk modules, etc.) and composition are not independent

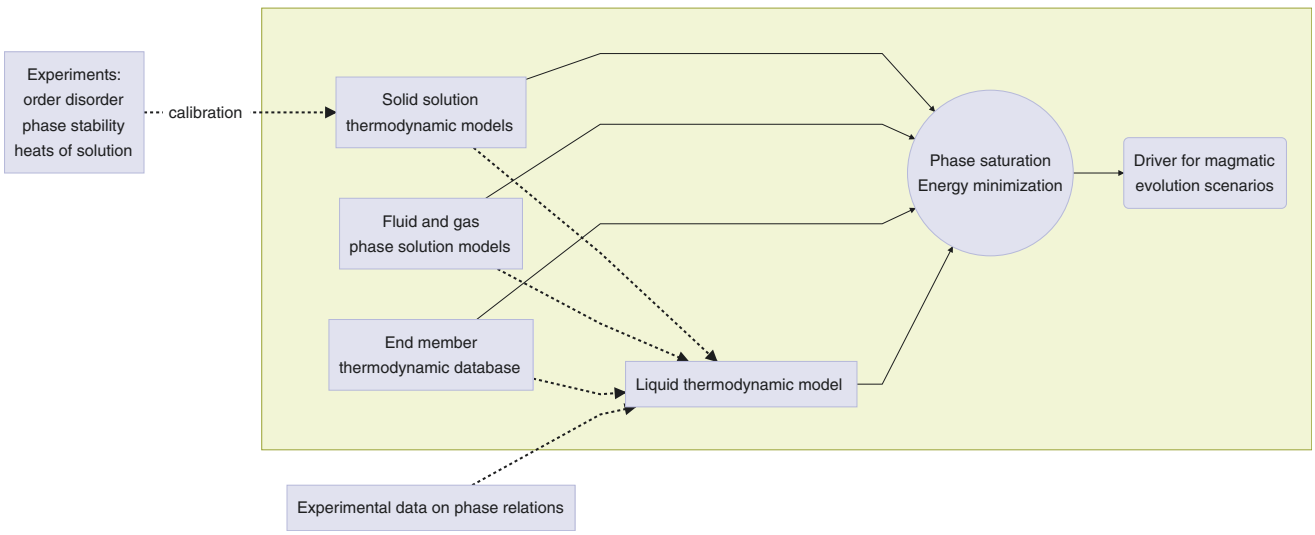
constructs. Acknowledging the interplay between the two is central to magmatic process modeling.

Conclusions and What About Kinetics

Throughout this article, the concept of an irreversible process being modeled as a sequence of local equilibrium states has been exploited. It has been argued that this is a reasonable assumption for understanding magmatic phenomena; indeed, it is an assumption that underlies the majority of the interpretation of igneous and metamorphic rocks and our understanding of water-rock interaction at elevated temperatures. However, this assumption of local reversibility is incorrect in detail. Igneous phenocrysts display chemical and isotopic zonation, and ample evidence exists documenting the existence of xenocrysts and antecrysts in magmatic systems. Crystal growth on syneruptive timescales (Gualda et al. 2012b) create textural features that are demonstrably not in spatial equilibrium. The preserved rock record provides ample evidence of disequilibrium and the importance of interpreting observations in terms of kinetic theory. In fact, one of the most exciting areas of modern petrological research is related to the timescales of magmatic processes (Cooper and Kent 2014; Pamukcu et al. 2015), and much of that information is gleaned from the interpretation of preserved disequilibrium phenomena. Nevertheless, the application of kinetics in magmatic process modeling is in its infancy, and there are many reasons for this. Firstly, disequilibrium phenomena must be modeled in reference to an equilibrium state in order to properly calculate growth rates and reference conditions, requiring either a thermodynamic model or appropriate experiments to characterize that state. Secondly, the length scales of crystal growth or diffusion are small compared to the typical size of a magma body. This scaling issue makes the process of coupling the regime of microphysics kinetics to the regime of large-scale flow of heat and mass computationally intractable. Thirdly, the fundamental data required in order to model kinetic phenomena associated with growth, diffusion, transport, and other disequilibrium features of magmatic systems is sufficiently inadequate that causal predictions of observable phenomena at the hand specimen or thin section scale cannot yet be made. Yet, there is hope that at least on the computational front progress will be forthcoming to produce a fully integrated thermodynamic-kinetic-dynamical modeling tool to explore magmatic processes. Until that time, appropriately constrained thermodynamic models that exploit the simplification of local equilibrium reaction paths still provide a rich and informative window on the geochemical evolution of magmatic systems.

Appendix: From Experiment to Model

Computational thermodynamics simulators (like rhyolite-MELTS (Gualda et al. 2012) and its predecessors) require a complex infrastructure of internally consistent thermodynamic models that work together in order to calculate the equilibrium state of a magmatic system. This complexity is illustrated in Fig. 7. Models are required to calculate properties of stoichiometric end-member minerals, fluids, and melt components and to estimate the thermodynamic properties of



Magmatic Process Modeling, Fig. 7 Illustration of the internal structure and model interdependencies of the MELTS family of magmatic process simulation software. The *yellow box* corresponds to the distributed modeling tool, which incorporates a number of thermodynamic models for mineral, fluid, and melt solutions as well as compact representations of end-member thermodynamic properties. Experimental data required to calibrate the thermodynamic models within MELTS are indicated by *boxes* external to the distributed module. Workflow pathways for calibrating the internal model collection are shown by *dashed lines*. Inputs for performing a model simulation are shown by *solid lines*

mineral, melt, and fluid solutions. What results is a collection of models all providing inputs in order to estimate the thermal and mechanical evolution of a magmatic system. Properties of stoichiometric compounds are often assembled into so-called thermodynamic "databases," although it is important to understand that all quantities contained in these databases are in reality numerical values of fitting parameters to models of heat capacity, third-law entropies, enthalpies of formation, and equation of state formulations. Thermodynamic databases rarely contain primary data; primary data such as heat of solution, heat capacity, or heat content measurements obtained from adiabatic, differential scanning, or drop calorimetry are adjusted in order to make the database predict outcomes that reflect experimentally determined or naturally observed phase relations. This procedure is known as rendering the database internally consistent. In the rhyolite-MELTS modeling hierarchy, the stoichiometric compound end-member "database" is but one component in a collection of models. In this hierarchy, thermodynamic models for minerals and fluids are obtained independently by calibrating against experimental data pertaining exclusively to those phases. Once calibrated and combined with the end-member database, they are utilized in conjunction with experimental data corresponding to heterogeneous phase equilibria determined for magmatic bulk compositions under high-temperature, pressure conditions, to establish an internally consistent collection of models by formulating and calibrating a thermodynamic model for the liquid (melt) state. Thus, the model parameters that describe thermodynamic properties of silicate liquids are *dependent* on (1) the end-member properties database adopted, (2) the solution models adopted for mineral and fluid solutions, and (3) the collection of experimental phase equilibrium data available for model calibration. Once all these calibrations are accomplished, the resulting thermodynamic models are referenced by a computational engine that computes phase saturation and heterogeneous phase equilibrium under specified bulk composition and ancillary thermodynamic constraints (e.g., T and P). Calculation of magmatic evolution scenarios (as described in this chapter) are computed by driving the phase saturation and energy minimization engine in a direction consistent with the petrologic scenario underlying the evolution.

Magnesium

Fang-Zhen Teng
Isotope Laboratory, Department of Earth and Space Sciences, University of Washington, Seattle, WA, USA

Element Data

Atomic Symbol: Mg
Atomic Number: 12
Atomic Weight: 24.305 amu
Isotopes and (Abundances):
^{24}Mg (78.99%)
^{25}Mg (10.00%)
^{26}Mg (11.01%)
1 Atm Melting Point: 650 °C (1202 °F)
1 Atm Boiling Point: 1090 °C (1994 °F)

(*continued*)

Common Valences: 2+
Ionic Radii: 72 pm
Pauling Electronegativity: 1.31
First Ionization Energy: 737.2 KJ/mol
Chondritic (CI) Abundance: 9.54 wt.%
Silicate Earth Abundance: 22.8 wt.%
Crustal Abundance: 2.81 wt.%
Seawater Abundance: 0.128 wt.%
Core Abundance: 0

Properties

Magnesium, with symbol Mg and atomic number 12, belongs to the alkaline Earth element (Group II) of the periodic table. The pure Mg is a silvery white metal. It has a melting point of 650 °C and boiling point of 1090 °C at 1 standard atmosphere, i.e., 101.325 kPa (Lide 1993–1994). The electronic configuration of Mg is $[Ne]3s^2$, with the first and second ionization energies of 737.2 and 1450 KJ/mol, respectively. The low ionization energies make Mg ionic in character with a common valance state of 2+ and a typical ionic radius of 0.72 Å or 72 pm for sixfold coordination (Shannon 1976).

Magnesium has three stable isotopes, with mass numbers of 24, 25, and 26, and typical abundances of 78.99%, 10.00%, and 11.01%, respectively (Berglund and Wieser 2011). It has a standard atomic weight of 24.305 (CIAAW 2015). The isotopic abundance varies ~7‰ in $^{26}Mg/^{24}Mg$ ratio in the Earth and can vary much larger in meteoritic materials due to the decay of ^{26}Al to ^{26}Mg, with a half-life of 0.73 Myr (Teng 2017).

History and Use

The name magnesium originates from the Greek word for a district in Thessaly called Magnesia, which itself is derived from the Greek tribal name Magnetes. Magnesium was discovered as an element in 1755 by Joseph Black in the oxide form via heating magnesite. In 1808, Humphry Davy isolated Mg metal through electrolysis of a mixture of magnesium oxide and mercury oxide (Davy 1808). In 1831, Antoine Bussy made a significant amount of Mg metal by reacting magnesium chloride with potassium and later examined its properties (Bussy 1831).

Magnesium metal is mainly obtained by silicothermic Pidgeon process or electrolysis of fused Mg chloride. It is commonly used in metal alloys, especially in Al-Mg alloys, to increase the strength and lower the density. Magnesium metal alloys are widely used in aircraft, automotive, electronics, and other industries. Magnesium compound is also used in fertilizer and medicine as Mg^{2+} ion is important for the synthesis of chlorophyll and photosynthesis in plants and is essential to cells and enzymes in the human body.

Natural Distribution

Magnesium is the seventh most abundant element by atom in the solar system and the fourth most abundant element by weight in the CI chondrites, with a mean solar abundance of 9.54 wt.% (Palme et al. 2014). It is a common element during condensation with a condensation temperature of 1081 °C, which is higher than the moderately volatile elements such as K and Na but lower than the refractory elements such as Al and Ca (Lodders 2003).

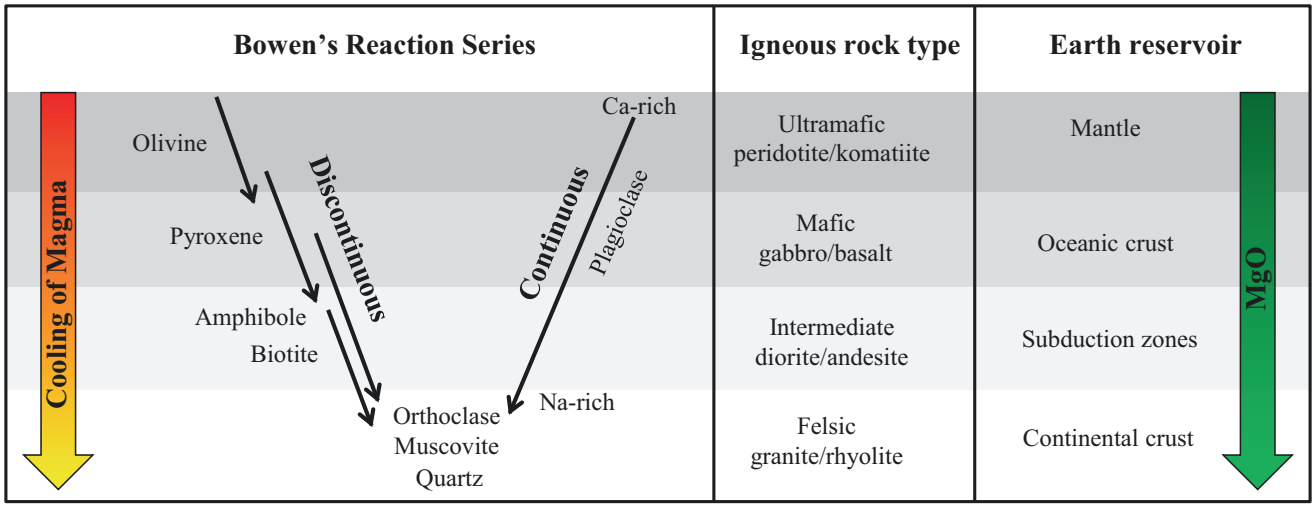
Magnesium is the fourth most abundant element by weight in the Earth (below O, Fe, Si) (McDonough and Sun 1995). As Mg is lithophile during core-mantle differentiation, all Mg resides in the silicate Earth. Magnesium is highly compatible during mantle melting and magmatic differentiation as Mg is a major constitute in typical mafic phases such as olivine and pyroxene. Hence, Mg is concentrated in the Earth's mantle than the crust with overall concentration in the silicate Earth increasing with depth (Fig. 1). Magnesium is the fifth most abundant element in the bulk continental crust with an average MgO concentration of 4.66 wt.% and increases from the upper (2.48 wt.%), middle (3.59 wt.%), to the lower continental crust (7.24 wt.%) (Rudnick and Gao 2003). The oceanic crust has an average MgO concentration of 10.3 wt.% (White and Klein 2014), and the mantle has the highest MgO concentration of 37.8 wt.% (McDonough and Sun 1995).

Magnesium is the second most abundant cation in seawater (after Na) with a concentration of 0.128 wt.% or 52.82 mmol/kg (Pilson 2013). It has a residence time of 14 Myr (Li 1982), which is much longer than the mixing time of the ocean. Therefore, Mg is thoroughly mixed in the ocean. Similarly, Mg is also a major cation in riverine water with an average concentration of 4 ppm and ranging from <1 to 50 ppm, mainly depending on the nature of the bedrocks (Holland 1978; Livingstone 1963).

The high abundance of Mg in the silicate Earth makes it a major constituent of many rock-forming minerals (e.g., olivine, garnet, pyroxene, amphibole, mica, spinel, carbonate, sulfate, chlorite, and clay minerals) in igneous, metamorphic, and sedimentary rocks. Of these minerals, Mg is coordinated with six oxygens except in garnet and spinel where Mg is coordinated with eight and four oxygens, respectively.

Geochemical Behaviors

The behavior of Mg during igneous differentiation is well studied and mainly controlled by mafic minerals, as shown



Magnesium, Fig. 1 Magnesium is compatible during mantle melting and magmatic differentiation as Mg is a major constitute in typical mafic phases such as olivine, pyroxene, amphibole, and biotite. Consequently, Mg is widely distributed in all major types of igneous and metamorphic rocks, as illustrated by the Bowen's reaction series, and MgO concentration decreases from the mantle, oceanic crust, lower, middle, to the upper continental crust

in the Bowen reaction series (Bowen 1928). MgO content in magma generally decreases with magmatic differentiation, e.g., from ~8 wt.% in basalt to <1 wt.% in granite due to the early crystallization of mafic minerals.

Though Mg is fluid mobile and expected to be removed from rocks during metamorphic dehydration, it is relatively conservative during prograde metamorphism, because of the continuous stability of Mg-rich minerals in both metapelites and metabasalts during progressive metamorphism. For example, Mg is continuously hosted in chlorite, amphibole, and pyroxene when metamorphic grade increases from blueschist facies to eclogite facies during oceanic crust subduction.

Magnesium is fluid mobile during continental weathering and seafloor alteration when Mg-rich minerals break down and secondary minerals are formed. During these low-temperature water-rock interactions, Mg is redistributed among the hydrosphere, continental crust, and oceanic crust. The most important Mg-rich minerals in igneous and metamorphic rocks that decompose during continental weathering are olivine, pyroxene, amphibole, biotite, and chlorite and in sediments are dolomite, Mg-calcite, and chlorite. During continental weathering, Mg in these minerals is liberated into the solution by hydrolysis reactions with dissolved CO_2 derived from the atmosphere and finally enters the oceans. Continental weathering of Mg-rich minerals thus helps to regulate CO_2 cycling. Magnesium is removed from the seawater to the oceanic crust through formation of Mg-rich silicates during high-temperature hydrothermal reactions at mid-ocean ridges, carbonate precipitation, and adsorption onto clays (Drever 1974; Elderfield and Schultz 1996). Eventually Mg in the oceans is recycled into the mantle by subduction of the oceanic slab.

Summary

Magnesium is a major element and widely distributed in the silicate Earth, hydrosphere and biosphere. Its unique chemical properties make Mg great tracers for high-T magmatic differentiation, low-T chemical weathering, and global elemental cycling, in addition to its wide applications in industry and medicine.

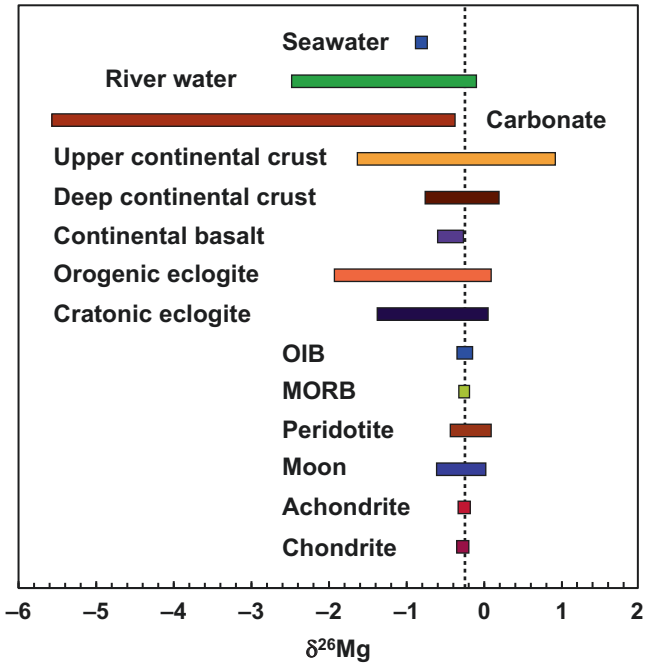
Magnesium Isotopes

Fang-Zhen Teng
Isotope Laboratory, Department of Earth and Space Sciences, University of Washington, Seattle, WA, USA

Introduction

Magnesium (Mg) is widely distributed in the silicate Earth, hydrosphere, and biosphere and has three stable isotopes, ^{24}Mg, ^{25}Mg, and ^{26}Mg, with the natural abundance of 78.99%, 10.00%, and 11.01%, respectively (Berglund and Wieser 2011). The large mass difference (>8% between ^{24}Mg and ^{26}Mg) has led to large mass-dependent Mg isotope fractionation. To date, >7‰ variation in ^{26}Mg/^{24}Mg has been observed, with carbonates at the light end (δ^{26}Mg = −5.6, Wombacher et al. 2011) and weathered residues at the heavy end (δ^{26}Mg = +1.8, Liu et al. 2014) (Fig. 1). Similar to other isotopes, Mg isotopes are fractionated less at high temperature and fractionated the greatest during low-temperature processes (Teng 2017).



Magnesium Isotopes, Fig. 1 Magnesium isotopic composition of major extraterrestrial and terrestrial reservoirs. The *vertical dotted line* represents the average Mg isotopic composition of the mantle (Teng et al. 2010a)

Magnesium Isotopic Distribution in Major Reservoirs

Chondrite, Achondrite, and the Moon

Magnesium isotopic composition is homogenous among different types of chondrites, with an average δ^{26}Mg = −0.28 ± 0.06 (Teng et al. 2010a). The identical Mg isotopic composition in all major types of chondrites suggests that the primary and secondary processes that affected the chemical and oxygen isotopic compositions of chondrites did not significantly fractionate Mg isotopes.

Magnesium isotopic compositions of most achondrites are similar to chondrites except some angrite and HEDs, which are slightly heavier. Their slightly heavier values likely resulted from impact-induced evaporation or high abundance of isotopically heavy clinopyroxene (Sedaghatpour and Teng 2016).

Magnesium isotopic compositions of lunar samples display a dichotomy between low- and high-Ti samples. Low-Ti basalts, together with lunar highland rocks, breccias, and soils, have similar Mg isotopic composition to chondrites. By contrast, high-Ti basalts have light isotopic composition, which may reflect the source heterogeneity produced

during differentiation of the lunar magma ocean (Sedaghatpour et al. 2013).

The Earth's Mantle

Magnesium isotopic composition of the mantle accounts for that of the bulk Earth as the mantle holds >99.9% of Mg in the Earth. Peridotite xenoliths, MORBs, and OIBs have similar Mg isotopic composition, with an average $\delta^{26}Mg = -0.25 \pm 0.07$ (Teng et al. 2010a; Pogge von Strandmann et al. 2011). This value represents Mg isotopic composition of the Earth, which is similar to that of chondrites and the Moon.

The Continental Crust

The upper continental crust, as represented by granite, shale, and loess, has very heterogeneous $\delta^{26}Mg$ values ranging from −1.64 to +0.92, which likely reflects large Mg isotope fractionation during continental weathering (Li et al. 2010; Huang et al. 2013; Wimpenny et al. 2014). The deep continental crust, as sampled by high-grade metamorphic terranes and granulite xenoliths, also displays a large range in $\delta^{26}Mg$ from −0.76 to +0.19. This large isotopic variation reflects source heterogeneity caused by incorporation of chemically weathered upper crustal materials and by deep-crustal fluid metasomatism (Teng et al. 2013; Wang et al. 2015a; Yang et al. 2016).

The Hydrosphere

The oceans control the Mg isotopic budget of the hydrosphere as it accounts for ~97% of water on the Earth's surface and has the highest Mg concentration in all reservoirs of the hydrosphere (Pilson 2013). Seawaters sampled at various depths and from global location have an identical $\delta^{26}Mg$ value of -0.83 ± 0.09 (2SD), indicating a homogenous Mg isotopic composition of the oceans (Ling et al. 2011, and references therein). By contrast, $\delta^{26}Mg$ values of rivers are highly variable, ranging from −2.5 to −0.1 (Fig. 1), reflecting both Mg isotopic variation in bedrock lithology and Mg isotope fractionation during water-rock interactions (Tipper et al. 2006). Overall, the flux-weighted $\delta^{26}Mg$ of global runoff is estimated to be −1.09 (Tipper et al. 2006), significantly lower than seawater. The isotopic difference between seawater and global runoff indicates the existence of additional heavy inputs or light outputs, which might result from carbonate precipitation, low-T seafloor alteration, and high-temperature hydrothermal alteration.

Behaviors of Magnesium Isotopes During Major Geological Processes

Continental Weathering

Continental weathering produces one of the largest Mg isotope fractionations in nature. Behaviors of Mg isotope fractionation during continental weathering have been extensively investigated, through studies of river waters (Brenot et al. 2008; Pogge von Strandmann et al. 2008; Tipper et al. 2008; Jacobson et al. 2010; Wimpenny et al. 2011); continental weathering profiles of basalt, diabase, and shale (Teng et al. 2010b; Huang et al. 2012; Liu et al. 2014; Ma et al. 2015); as well as laboratory leaching experiments (Wimpenny et al. 2010). These studies found large Mg isotope fractionation during weathering with light Mg isotopes generally preferring fluids to weathered residue, leading to the formation of an isotopically light hydrosphere and a heavy weathered upper continental crust.

Biological Processes

Magnesium isotopes, as an essential element in biosphere, are largely fractionated during biological processes. Large Mg isotope fractionation occurred during incorporation of Mg into chlorophyll (Black et al. 2006). Plants prefer heavy Mg isotopes to nutrient sources during growth, and light isotopes are enriched in leaves relative to roots (Bolou-Bi et al. 2010, 2012). Large Mg isotopic variation was also observed in marine biogenic carbonates, reflecting multiple processes such as kinetic and biogenic vital effect, temperature, precipitation rate, pH, etc. (Saenger and Wang 2014; Teng 2017).

Partial Melting and Magmatic Differentiation

The MgO content in magma generally decreases with magmatic differentiation as Mg is compatible in mafic minerals. Magnesium isotopic composition however does not change during partial melting and differentiation of mafic to felsic magmas (Teng et al. 2007, 2010a; Liu et al. 2010). Studies of coexisting pyroxene and olivine in peridotites and hornblende and biotite in granites found similar Mg isotopic composition. Hence partial melting and fractional crystallization of these minerals do not cause measurable isotopic shifts in the compositions of the melt (Yang et al. 2009; Liu et al. 2010; Xiao et al. 2013).

Metamorphic Dehydration

Magnesium isotope fractionation during metamorphic dehydration is limited as high-grade metamorphic rocks, e.g., granulite and eclogite, have similar Mg isotopic composition to their protoliths (Li et al. 2011; Teng et al. 2013). Studies of genetically related prograde metamorphosed basalts and pelites also show that metamorphic rocks formed at different temperature and pressure have similar Mg isotopic composition, suggesting that metamorphic rocks still preserve isotopic compositions of their protoliths (Li et al. 2014; Wang et al. 2014b, 2015b). The lack of isotope fractionation during prograde metamorphism mainly results from the conservative behavior of Mg as it is always hosted in major rock-forming minerals during metamorphic reactions, and little Mg was lost into fluids.

High-Temperature Equilibrium and Kinetic Isotope Fractionation

Large Mg isotopic variation has been found in Mg-rich minerals in igneous and metamorphic rocks, reflecting both equilibrium and kinetic isotope fractionation. Though Mg isotopes are not significantly fractionated among pyroxene, olivine, biotite, and hornblende (Yang et al. 2009; Liu et al. 2010; Xiao et al. 2013), large Mg isotope fractionation occurs between biotite, pyroxene, olivine, garnet, and spinel in some peridotite, eclogite, and granulite. Garnet is lighter and spinel is heavier than other coexisting minerals (Li et al. 2011; Liu et al. 2011; Xiao et al. 2013; Wang et al. 2012, 2015a, c). The large equilibrium, inter-mineral isotope fractionation reflects the difference in Mg coordination number (CN) as CN is 8 in garnet, 4 in spinel, and 6 in other minerals. In addition, large Mg isotopic variation is also observed in olivine fragments from the Kilauea Iki lava lake, which is negatively correlated with Fe isotopic variation. The coupled Mg and Fe isotope fractionation was produced by interdiffusion of Mg and Fe between olivine and melts (Teng et al. 2011). In situ analysis of zoned olivines by micro-mill, LA-MC-ICPMS, and SIMS confirms this and found remarkable Mg and Fe isotopic zoning, coupled with Mg and Fe elemental zoning in single olivine (Sio et al. 2013). Furthermore, disequilibrium Mg isotope fractionation is also observed among pyroxene, olivine, and spinel in pyroxene-rich peridotite, reflecting kinetic Mg isotope fractionation during mantle metasomatism (Xiao et al. 2013; Hu et al. 2016).

Applications of Magnesium Isotope Geochemistry

Magnesium isotope geochemistry is still in its infancy. Nonetheless, promising applications have emerged. The large equilibrium inter-mineral Mg isotope fractionation associated with garnet and spinel in igneous and metamorphic rocks could be developed as a high-precision geothermometry (e.g., Li et al. 2011; Liu et al. 2011). The large kinetic isotope fractionation induced by diffusion can be used to tell the nature of mineral zoning, i.e., crystal growth or diffusion, which lays the foundation for using mineral zoning as a geospeedometry (e.g., Teng et al. 2011; Sio et al. 2013). The large Mg isotopic variation produced during low-T processes (especially in carbonates) can survive during subduction, leads to form a distinct mantle end member, and is later recorded in mantle/mantle-derived rocks. Thus Mg isotopes can be used as a tracer of subducted carbonates (Yang et al. 2012; Wang et al. 2014a) and origins of cratonic eclogites (Wang et al. 2012, 2015c). The large Mg isotope fractionation in carbonates also has the potential to provide constraints on the evolution of seawater chemistry, paleoclimate environments, and the origin of dolostone (Saenger and Wang 2014). Finally, biological processes significantly fractionate Mg isotopes (Bolou-Bi et al. 2012); hence Mg isotopes may be used to trace biological processes in the deep time.

Summary

The wide distribution of Mg in major reservoirs, coupled with large equilibrium and kinetic isotope fractionation at high- and low-temperature processes, makes Mg isotope geochemistry a promising tool for a high-precision thermometry, a powerful method for telling the nature of mineral zoning and a unique tracer for crust-mantle interactions and biological processes.

Magnetism

H. Tsunakawa[1] and Y. Yamamoto[2]
[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan
[2]Center for Advanced Marine Core Research, Kochi University, Kochi, Japan

Definition

All substances can generate the magnetic field more or less, that is, the magnetism. The magnetism is generally categorized as the diamagnetism, paramagnetism, ferromagnetism, antiferromagnetism, and ferrimagnetism. The term "magnetic" is often used as ferromagnetic (including ferrimagnetic), while that of "nonmagnetic" is quoted as non-ferromagnetic.

Introduction

The magnetism basically originates from electrons of a substance. The diamagnetism is caused by the orbital effect of an electron, while the paramagnetism, ferromagnetism, antiferromagnetism, and ferrimagnetism are unique properties due to spin magnetic moments of unpaired electrons in atoms and ions of transition elements (e.g., Fe, Co, Ni). Magnetic properties of a substance and their mechanisms have theoretically and experimentally been studied in physics of the magnetism (e.g., Chikazumi 2009). In the Earth and planetary sciences, mineral magnetic properties and their applications have been investigated to research subjects of the rock magnetism (e.g., Dunlop and Özdemir 1997) and the paleomagnetism (e.g., McElhinny and McFadden 2012).

Diamagnetism

Electrons orbiting an atomic nucleus in an ambient magnetic field generate an opposite field. This magnetism is called the diamagnetism and appears in all substances. The diamagnetism is interpreted as a result of the electromagnetic induction in the classical electromagnetism. The diamagnetism is very weak and is negatively proportional to the strength of the applied magnetic field:

$$M = \chi_d B$$

where M is the diamagnetism intensity, B is the strength of the applied field, and χ_d is the diamagnetic susceptibility. The diamagnetism is antiparallel to the applied field ($\chi_d < 0$). Most values of $|\chi_d|$ are of the order of 10^{-8} [m^3kg^{-1}] with little change with temperature. For example, χ_d is -0.90×10^{-8} m^3kg^{-1} for water (H_2O) and -0.62×10^{-8} m^3kg^{-1} for quartz (SiO_2) at room temperature.

Paramagnetism

Transition elements (e.g., Fe, Co, Ni) and their ions have spin magnetic moments of unpaired electrons. Without an ambient magnetic field, spin magnetic moments have random orientations due to the thermal agitation if there are no effective interactions among the moments. When the magnetic field is applied, orientations of the moments tend to be aligned in parallel to the applied field. This magnetism is the Curie paramagnetism. The Curie paramagnetism of terrestrial rocks is often called the paramagnetism in a simple manner.

A rate of the parallel magnetic moments is proportional to the applied field strength:

$$M = \chi_p B$$

where M is the paramagnetism intensity, B is the strength of the applied field, and χ_p is the paramagnetic susceptibility. The paramagnetic susceptibility is subjected to Curie's law:

$$\chi_p = \frac{C}{T}$$

where C is the Curie constant and T is the absolute temperature in unit of kelvin. If a paramagnetic substance contains n atoms (or cations) with spin magnetic moments per unit volume, then

$$C = \mu_0 \frac{n\mu^2}{3k}$$

where μ is the effective spin magnetic moment per atom, k is the Boltzmann constant ($= 1.3806 \times 10^{-23}$ JK^{-1}), and μ_0 is the permeability of free space ($=4\pi \times 10^{-7}$ Hm^{-1}).

Mafic silicate minerals (e.g., pyroxene, olivine) containing iron elements show the Curie paramagnetism. The paramagnetic susceptibilities of these minerals depend mostly on Fe^{2+} and Fe^{3+} contents. As for olivine, fayalite (Fe_2SiO_4) has $\chi_p = 126 \times 10^{-8}$ m^3kg^{-1} at room temperature while forsterite (Mg_2SiO_4) shows the diamagnetism ($\chi_d = -0.39 \times 10^{-8}$ m^3kg^{-1}).

There is the other type of the paramagnetism, called the Pauli paramagnetism. This mostly appears in some metals due to free electrons (e.g., aluminum). The susceptibility is positive and almost temperature-independent. The Pauli

paramagnetism is comparable to the diamagnetism in strength ($\chi_p \sim 10^{-8}$ m^{3}kg^{-1}).

Ferromagnetism

Strong interaction works among spin magnetic moments in the ferromagnetic substances (e.g., αFe, kamacite of Fe-Ni alloy), that is, the exchange interaction as a quantum mechanical coupling. Adjacent spin magnetic moments are ordered in parallel to each other, resulting in the spontaneous magnetization. The spontaneous magnetization exists even in the absence of the ambient magnetic field, which is quite different from the diamagnetism and the paramagnetism. As the temperature increases, the spontaneous magnetization decreases due to the thermal agitation and then disappears above the Curie temperature (T_C).

According to the Weiss's theory, the exchange interaction is approximated with the magnetic force in the "molecular field" proportional to the spontaneous magnetization intensity. Assuming the Boltzmann distribution, the spontaneous magnetization per unit volume (M_s) is expressed in the following equation.

$$M_s = n\mu L(\alpha)$$

$$\alpha = \mu_0 \frac{\mu w M_s}{kT}$$

where $L(\alpha)$ is the Langevin function and w is a proportional coefficient of the molecular field. Since the above equations give the relationship of M_s with T, T_C is given for $M_s \to 0$. For $T \leq T_c$, $M_s(T)/M_s(0) \approx (1 - T/T_c)^{1/2}$ in a rough approximation, while $M_s(T)/M_s(0) \approx (1 - T/T_c)^{\gamma}$ in the experiment. For iron metal (αFe), $M_s(20\ ^\circ\text{C}) = 1714$ kAm^{-1} (or emu cm^{-3}), $T_c = 770\ ^\circ$C, and $\gamma = 0.34$.

In the quantum mechanical treatment, the Langevin function is replaced by the Brillouin function. For the magnetization of ferromagnetic mineral, size and shape of the mineral should be considered as in subsection of the rock magnetism and the paleomagnetism. Above T_C, ferromagnetic substances show the paramagnetism under the Curie-Weiss law of the following equation.

$$\chi_p = \frac{C}{T - T_C}$$

Antiferromagnetism

In the antiferromagnetic substance, adjacent spin magnetic moments are ordered in antiparallel to each other by the negative exchange interaction. This effect results in null spontaneous magnetization, called the antiferromagnetism. In the case of compounds, strong coupling works through anions of crystal (e.g., oxygens ion in iron oxides) due to another strong interaction, the superexchange interaction. It sometimes orders spin magnetic moments of cations in antiparallel, resulting in null spontaneous magnetization. This magnetism is also categorized as the antiferromagnetism.

An antiferromagneic substance shows smaller positive susceptibility than the paramagnetic susceptibility when the magnetic field is applied, because of the negative (super)exchange interaction. Above the Néel temperature (T_N), the thermal agitation overwhelms the (super)exchange interaction. Thus the antiferromagnetism disappears, and the paramagnetism appears in the similar way to the ferromagnetic substance.

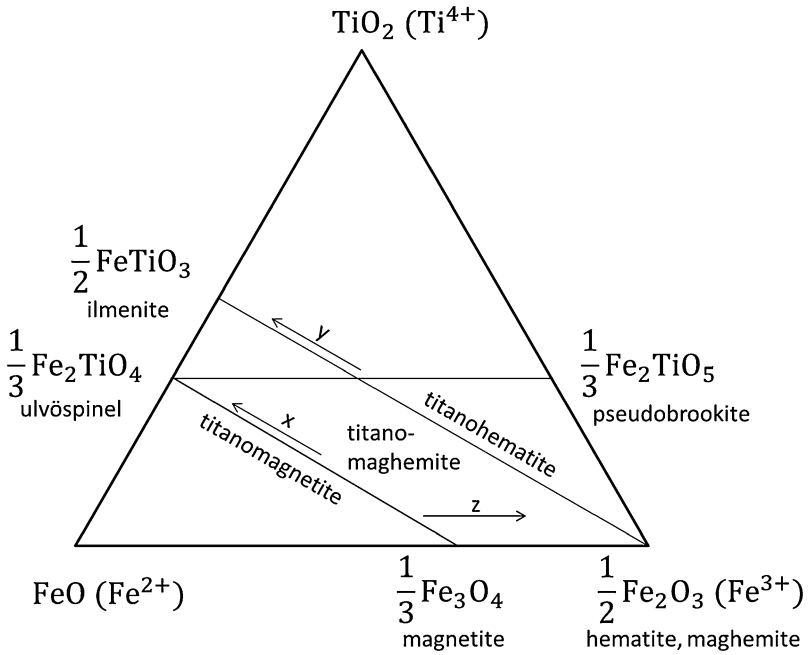
Hematite (αFe_2O_3) is known to be one of the major terrestrial magnetic minerals showing the antiferromagnetism. However it has a weak spontaneous magnetization ($M_s \approx 2.5$ kAm^{-1}) between the Morin transition temperature ($T_M \approx -20\ ^\circ$C) and the Néel temperature ($T_N = 675\ ^\circ$C). This weak magnetization is caused by the spin-canted magnetization: the sublattice magnetizations are mostly in antiparallel direction but are slightly canted in perpendicular to the basal plane of hematite. Such magnetization is called the canted ferromagnetism or the parasitic ferromagnetism, and the Néel temperature is taken as the Curie temperature.

Ferrimagnetism

In some substance with the negative (super)exchange interaction, different magnetic moments of cations in sublattices result in the spontaneous magnetization. This magnetism is called the ferrimagnetism. As the temperature increases, the ferrimagnetism decreases and disappears above the Curie temperature (T_c) in the similar way to the ferromagnetism.

For magnetite (Fe_3O_4: $Fe^{2+}Fe^{3+}{}_2O_4$) of spinel crystal structure, there are two sites in cation sublattices: Fe^{3+} in A sites, and Fe^{2+} and Fe^{3+} in B sites. A magnetic moment of Fe^{2+} is $4\mu_B$ while that of Fe^{3+} is $5\mu_B$, where μ_B is the Bohr magneton (9.27401×10^{-24} J T^{-1}). As the negative superexchange interaction works through O^{2-} between A and B sites, magnetic moments in A and B sites are antiparallel. This results in cancelled magnetic moments of Fe^{3+} in A and B sites, but magnetization due to Fe^{2+} in B sites remains as the spontaneous magnetization with $M_s(20\ ^\circ\text{C}) = 480$ kAm^{-1}.

The ferrimagnetism is inseparably related to the crystal structure as well as the contained cations. M_s of magnetite



Magnetism, Fig. 1 Major magnetic minerals of terrestrial rocks are shown in the $TiO_2-FeO-Fe_2O_3$ ternary diagram. Parameters of x (titanomagnetite soli-solution line), y (titanohematite soli-solution line), and z (low-temperature oxidation line of titanomagnetite) are explained in the text

with Fe^{2+} and Fe^{3+} monotonously decreases as the temperature increases ($\gamma = 0.43$) with $T_c = 580\ ^\circ C$. Some ferrimagnetic substances behave in quite different manner for the temperature dependence of M_s. For example, Li-Cr ferrite shows negative to positive M_s with increasing temperature. A specific titanohematite with a negative M_s causes the self-reversed thermoremanent magnetization as mentioned in subsection of the rock magnetism.

Magnetic Minerals of Terrestrial and Extraterrestrial Rocks

Rock magnetism is a research field on magnetic minerals in terrestrial and extraterestrial rocks to utilize them. Major magnetic minerals of terrestrial rocks are iron and titanium oxides, in particular, titanomagnetite, titanohematite, and titanomaghemite (Fig. 1).

Titanomagnetite is the ulvöspinel (Fe_2TiO_4) – magnetite (Fe_3O_4) solid solution of cubic spinel crystal structure and expressed as $Fe_{3-x}Ti_xO_4$ or $Fe^{2+}{}_{1+x}Fe^{3+}{}_{2-2x}Ti^{4+}{}_xO^{2-}{}_4$ ($0 \le x \le 1$). As x increases, M_s and T_C gradually decrease: $M_s = 480\ kAm^{-1}$ and $T_C = 580\ ^\circ C$ for ferrimagnetic magnetite (x = 0), while $M_s = 0$ and $T_N = -153\ ^\circ C$ for antiferromagnetic ulvöspinel (x = 1). High-temperature oxidation (or deuteric oxidation) frequently occurs during formation of titanomagnetites of subaerial volcanic rocks, resulting in exsolved ilmenite as thin lamellae. The antiferromagnetic lamellae effectively divide the host ferrimagnetic titanomagnetites into many tiny parts of Ti-poor titanomagnetite which can have stable remanent magnetizations.

Titanohematite, sometimes called hemoilmenite, is the ilmenite ($FeTiO_3$) – hematite (αFe_2O_3) solid solution of rhombohedral crystal structure: $Fe^{2+}{}_yFe^{3+}{}_{2-2y}Ti^{4+}{}_yO^{2-}{}_3$ ($0 \le y \le 1$). Ilmenite (y = 1) is antiferromagnetic ($T_N = -233\ ^\circ C$), while hematite (y = 0) shows the canted ferromagnetism ($T_C = 675\ ^\circ C$) as in subsection of the antiferromagnetism. The titanohematite of intermediate composition ($y \approx 0.5 - 0.7$) exhibits ferrimagnetic behavior to result in the self-reversed thermoremanent magnetization.

Titanomaghemite is the low-temperature oxidation product of titanomagnetite, a degree of which is expressed by the oxidation parameter z ($0 \le z \le 1$). The oxidation changes Fe^{2+} cations into Fe^{3+} with lattice defects. Magnetite, the end-member of titanomagnetite, changes to maghemite (γFe_2O_3, z = 1). It is known that magnetic minerals of the mid-ocean-ridge basalt (MORB) are initially Ti-rich titanomagnetites of $x \approx 0.6$ ($M_s \approx 125\ kAm^{-1}$ and $T_C \approx 150\ ^\circ C$) in most cases. Titanomagnetites of MORB often undergo the low-temperature oxidation, transforming to titanomaghemites.

Iron sulfides are often contained in sedimentary, granitic, and metamorphic rocks. Monoclinic pyrrhotite (Fe_7S_8) is ferrimagnetic ($M_s \approx 80\ kAm^{-1}$, $T_C = 320\ ^\circ C$). Greigite

(Fe_3S_4) is ferrimagnetic ($M_s \approx 125$ kAm^{-1}, $T_C \approx 330$ °C). Pyrite (FeS_2) is paramagnetic while troilite (FeS) is antiferromagnetic ($T_N = 305$ °C). Hydrous iron oxides are found in sediments, soils, and weathered rocks. Goehtite (αFeOOH) is antiferromagnetic ($T_N = 120$ °C) but sometimes ferrimagnetic with very weak magnetization.

The lunar rocks contain kamacite, a ferromagnetic iron-rich Fe-Ni alloy (5–10% Ni) and ilmenite. Magnetic minerals of meteorites are mainly composed of Fe-Ni alloys and magnetites, contents of which depend on the meteorite type. Iron meteorites are composed of Fe-Ni alloys: kamacite, taenite (30–70% Ni), and tetrataenite (~50% Ni), often associated with the Widmanstätten pattern of kamacite and taenite due to very slow cooling at the formation. Magnetic minerals of the Martian rocks have not clearly been identified although some minerals were reported for the Martian soils and meteorites.

Recent progress in the rock magnetism has resulted in significant developments of the environmental magnetism. Magnetic minerals found in sediments (e.g., deep sea sediments, loess) are detrital, aeolian, and authigenic origins which are more or less affected by the climate and by the surrounding environment. Thus variation in magnetic characteristics of sediments is usable as a proxy for past climate and environmental changes.

Remanent Magnetization and the Paleomagnetism

Rocks containing ferro- and/or ferrimagnetic minerals acquire "fossil magnetization" in the ambient magnetic field when they are formed. This is the remanent magnetization, sometimes called the remanence. The natural remanent magnetization (NRM) can give a record of the past magnetic field and has widely been used for restoration of the past geomagnetic field in the paleomagnetism.

Spontaneous magnetization of the magnetic mineral tend to be oriented along the ambient magnetic field, minimizing the magnetic energy against the disturbance such as the thermal agitation. The remanence acquisition is considered as a statistical process, since a rock is regarded as an assemblage of many magnetic minerals. When the ambient field is weak like the geomagnetic field, probability of spontaneous magnetizations parallel to the ambient field is linearly changed with strength of the field. Thus the remanence intensity is proportional to the strength of the ambient field. These parallelism and proportionality are the bases of the paleomagnetism.

Igneous rocks acquire the remanent magnetization during cooling, called thermoremanent magnetization (TRM). As the rocks are cooled from T_C, a parallel component of spontaneous magnetizations becomes larger and is fixed as TRM at the blocking temperature (T_B) where the thermal agitation is enough smaller than the magnetic energy. TRM is considered as the most reliable record of the past geomagnetic field direction (paleodirection) and intensity (paleointentisity), although TRM acquisition is nearly sporadic.

Sediments acquire remanent magnetization at the deposition in the ambient field, since magnetic particles in water (or air) are forced to be parallel to the field. After deposition, orientation of the magnetic particle is locked mainly due to the compaction. This type of the remanent magnetization is called the depositional remanent magnetization (DRM) and/or the post-DRM (pDRM). They have an advantage to give a continuous record of the paleodirection and paleointensity.

Stability of the remanence is sometimes critical in the paleomagnetic study since old rocks have experienced various geological events. If the remanence is stable enough against changes in the ambient field and temperature, a record of the past magnetic field is recovered as a primary component with good reliability. If the remanence is exposed to temperature higher than T_B, the remanence is reset. Reset of the remanence also occurs in the magnetic field larger than the magnetic coercive force of the magnetic grain (often called the coercivity, B_C). Long-time exposure in a weaker field than B_C is possible to reset the remanence by gradual progress of thermal equilibrium. These resets are the process of "remagnetization" yielding a secondary component.

In general the stable remanence is carried by relatively smaller magnetic grains with high T_B and B_C. For terrestrial rocks, carriers of stable remanence are mostly submicron grains of titanomagnetite in which the spontaneous magnetization is uniform due to the single-domain (SD) structure. Larger grains are magnetically divided into multiple domains, that is, the multi-domain (MD) structure. Threshold size between SD and MD is 0.05–0.08 μm for magnetite and ~0.2 μm for Ti-rich titanomagnetite (x = 0.6). If magnetic grains are very small (<~0.03 μm for magnetite), their T_B's become lower than the room temperature resulting in no remanence (the superparamagnetism).

It is not easy to identify submicron magnetic carriers by an optical microscope. In the standard experiment of remanence carriers, magnetic minerals of a bulk sample are identified with measurement of the Curie temperature and with demagnetization by heating and/or applying the alternating field. Applying a strong DC field, measurements of hysteresis curve, and remanence acquisition curve are often used as the nondestructive inspection.

According to paleomagnetic studies, the geomagnetic field has varied on archeological and geological time scales. The largest change is the polarity reversal and the present polarity initiated at ~0.8 Ma. The direction and intensity of the geomagnetic field also change, called the (paleo)secular variation. When averaging the secular variation, the geomagnetic field is almost the geocentric axial dipole field, by which the paleolatitude is estimated in the tectonics. Based on satellite observations, Moon and Mars exhibit crustal magnetic anomalies, suggesting existence of an ancient core dynamo.

Summary

Magnetism is categorized as the diamagnetism, paramagnetism, ferromagnetism, antiferromagnetism, and ferrimagnetism. The diamagnetism and paramagnetism emerge when the magnetic field is applied. The ferromagnetism, antiferromagneism, and ferrimagnetism are originated from the spontaneous magnetization of magnetic minerals, which persists in null ambient field. Terrestrial rock contains ferro- and ferrimagnetic minerals, for example, titanomagnetites. The ferro- and ferrimagnetic minerals allow us to estimate the past magnetic field through remanent magnetizations of those rocks. Advanced studies in the rock magnetism, the paleomagnetism, and the planetary magnetism related to the crustal magnetic fields are referred elsewhere (e.g., Kono 2015; Spohn 2015).

Element Data

Atomic Symbol: Mn
Atomic Number: 25
Atomic Weight: 54.9380
Isotopes and Abundances: ^{55}Mn 100%
1 Atm Melting Point: 1246 °C
1 Atm Boiling Point: 2061 °C
Common Valences: $^{+}$2, $^{+}$3, $^{+}$4, $^{+}$6, and $^{+}$7
Ionic Radii: in picometers

Mn(II)	4-coordinate, tetrahedral	80.0
Mn(IV)	4-coordinate, tetrahedral	53.0
Mn(V)	4-coordinate, tetrahedral	47.0
Mn(VI)	4-coordinate, tetrahedral	39.5
Mn(VII)	4-coordinate, tetrahedral	39.0
Mn(II)	6-coordinate, octahedral	81.0
Mn(II)	6-coordinate, octahedral, high spin	97.0
Mn(III)	6-coordinate, octahedral	72.0
Mn(III)	6-coordinate, octahedral, high spin	78.5
Mn(IV)	6-coordinate, octahedral	67.0
Mn(VII)	6-coordinate, octahedral	60.0
Mn(II)	8-coordinate	110.0

Pauling Electronegativity: 1.55
First Ionization Potential: 717.4
Chondritic (CI) Abundance: 1916 ppm (Palme and O'Neill, 2014)
Silicate Earth Abundance: 1050 ppm (Palme and O'Neill, 2014)
Crustal Abundance: 950–1000 ppm
Seawater Abundance:
2×10^{-10}–1.9×10^{-9} kgL^{-1}
Core Abundance: ~300 ppm

Properties

Manganese (Mn) is a transition metal located between chromium and iron in the periodic table of elements. Common oxidation states are $^{+}$2, $^{+}$3, $^{+}$4, $^{+}$6, and $^{+}$7, but possible oxidation states ranging from $^{-}$3 to $^{+}$7 (CCREM 1987) have been

reported. Oxidation states that are unstable in acidic solutions can exist in basic solutions, and conversely (Rayner-Canham and Overton 2003).

History and Use

Use of Mn dates from Stone Age. Mn dioxide was used as a pigment in cave paintings. Ancient Romans and Egyptian added Mn compounds to color glass (Sayre and Smith 1961; Chalmin et al. 2006). Today, Mn is used in steel, battery, and ceramic productions; as a micronutrient in feed for plants and animals; and as an oxidant in organic syntheses (Post 1999). Manganese is also used as an alloying element in US coins (Kuwahara et al. 2001).

The top five producers of Mn with reserves reported in metric tons (MT) are the following: South Africa, 200 MT; Australia, 91 MT; Brazil, 50 MT; China, 44 MT; and Gabon, 22 MT (USGS 2016). Common Mn ore minerals include: braunite ($Mn^{2+}Mn_6^{3+}SiO_{12}$), hausmannite ($Mn^{2+}Mn_2^{3+}O_4$), psilomelane (massive hard manganese oxides), and pyrolusite (Mn^{4+} O_2) (Kirshnaswamy and Sinha 1988). Mn is also present in polymetallic nodules on the sea floor, in fresh water (Rossmann and Callender 1968; Cronan and Thomas 1970) and lacustrine basins (Cornwell and Kipphut 1992).

Geochemical Behavior

Mn in the solar system is used to interpret both early solar chronology and modern observations. ^{53}Mn, with a half-life of 3.7 million years, decays to ^{53}Cr. Variations in Mn and Cr isotope ratios in meteorites provide a mechanism for radiometric dating solar bodies and support theories of nucleosynthetic processes prior to the coalescence of the solar system (Birck and Allegre 1988). Identification of manganese oxides on the surface of Mars suggests the presence of atmospheric oxygen and possible groundwater in the ancient past (Lanza et al. 2016).

Concentration of Mn in carbonaceous Ivuna (CI) chondritic meteorites is 1930 ppm (Lodders 2010). Presently, the total Earth concentration of Mn is approximately 1050 ppm. Wade and Wood (2005) reported a Mn concentration of 1150 ppm for the core during accretion, while the current Mn concentration for the core is estimated to be approximately 300 ppm (McDonough 2014). Earth crustal Mn concentrations range between 950 and 1000 ppm, localized in igneous, metamorphic, and sedimentary rocks (Post 1999). Mn moves through two global crustal cycles that are inter-related by the hydrologic cycle, i.e., the water-terrestrial rock cycle and the lacustrine/marine sediment-water cycle.

Mn geochemistry is complex and controlled primarily by pH-Eh conditions (Kabata-Pendias, 2010). Aqueous Mn^{2+} mainly forms from the weathering of igneous and metamorphic rocks (De Vitre and Davison 1993). Mn^{2+} is mobile under anoxic conditions (Hylander et al. 2000) but becomes insoluble when oxidized to Mn^{3+} and Mn^{4+} and forms insoluble hydrous oxides. The E_h-pH values that determine the solubility and deposition of Mn are illustrated in of Maynard 2014. More oxidized species, e.g., permanganate, are located at positive potentials, while more reduced species (e.g., Mn^0) are found at negative potentials. More basic species are located in the high pH regions and the more acidic species at low pH. A vertical division, e.g., one between Mn^{2+} and Mn $(OH)_2$, indicates an equilibrium that depends on pH and not a redox process. Dissolved Mn^{2+} is stable over the range of pH values found in natural fresh and saline waters (5–8) under mildly reducing conditions. Under oxidizing conditions, Mn^{4+} oxides are highly insoluble. Mn^{2+} carbonates (e.g., rhodocrocite [$MnCO_3$]) are insoluble at high pH in CO_2-rich environments. The predictable E_h-pH relationships for manganese and iron provide a mechanism for separation in slightly reducing sediments (few centimeters below the surface). Because soluble Mn has a larger stability field than soluble iron in that environment, Mn^{2+} is mobilized in pore water while iron is immobilized, either as an oxide or in the presence of sulfur, a sulfide.

Microorganisms are also involved in Mn movement through both global crustal cycles. At circumneutral pH, soluble Mn^{2+} can be oxidized to insoluble Mn^{3+}, Mn^{4+} by Mn-oxidizing microorganisms at rates that are several orders of magnitude faster than abiotic oxidation (Morgan 2005). Microorganisms can also reduce Mn^{4+} to Mn^{2+} (Nealson and Myers 1992).

More than 100 Mn minerals have been identified (Kirshnaswamy and Sinha 1988), formed under a wide range of environmental conditions. The basic structure of most Mn oxides is the MnO_6 octahedron, arranged in either layers or chains/tunnels. Mn oxides have very large surface areas (Dixon and White 2002). In the layered Mn oxide structure (e.g., birnessite [$(Na,Ca,K)_x(Mn^{4+},Mn^{3+})_2O_4 \bullet$ $1.5(H_2O)$]), water and cations can be adsorbed and/or exchanged between the layers. Hollandite [$Ba(Mn^{4+}$, $Mn^{2+})_8O_{16}$], a tunnel-structure, can be partially filled with water molecules, and large uni- or divalent cations (Post 1999). Mn is commonly associated with some transition metals, e.g., Co, Ni, Cu, Zn, Pb, Ba, Tl, W, and Mo, because of the negatively charged $Mn(OH)_4$ and MnO_2 structures (Kabata-Pendias 2010). Highly reactive $Mn^{3+,\ 4+}$ oxides are among the strongest oxidants in natural systems, capable of oxidizing Fe^{2+}, As^{3+}, Ce^{3+}, Pu^{4+}, Co^{2+}, Cr^{3+}, and Au^{1+} (Ta et al. 2015). Because of these properties, Mn oxides control the mobilization and dispersion of metal ions, including heavy metal ions, in soils and sediments (Post 1999).

Pyrolusite (MnO_2) and rhodochrosite are the two most common Mn-containing minerals. Mn oxyhydroxides, e.g., vernadite [$(Mn^{4+},Fe^{3+},Ca,Na)(O,OH)_2 \bullet n(H_2O)$], todorokite [$(Na,Ca,K)_2(Mn^{4+},Mn^{3+})_6O_{12} \bullet 3–4.5(H_2O)$], and birnessite are found in marine Mn nodules (Hein and Petersen 2013). Manganite has been identified as the principal mineral in

shallow water continental-margin nodules (Glasby 1972). Todorokite $[(Na,Ca,K)_2(Mn^{4+},Mn^{3+})_6O_{12}•3–4.5(H_2O)]$, buserite ($Na_4Mn_{14}\ O_{27}•21H_2O$), and birnessite are the most common biogenic Mn oxyhydroxides (Tebo et al. 2005). Biogenetic Mn oxides/oxyhydroxides are cryptocrystalline sheet-like particulates with large surface areas and, like abiotic Mn minerals, are highly reactive (Tebo et al. 2005).

Mn is also present in minerals as an accessory component as it readily substitutes for Fe^{2+} and Mg^{2+} (Ure and Berrow 1982). During magmatic processes, Mn is preferentially incorporated into ferromagnesian silicates, such as olivines, pyroxenes, and clinopyroxenes (Sobolev et al. 2007; Qin and Humayun 2008; Le Roux et al. 2011). In metamorphic rocks, Mn is present in garnets, amphiboles, and calcite (Temmam et al. 2000; Hawthorne et al. 2012).

Biological Utilization and Toxicity

The average human body contains approximately 12 mg Mn (Emsley 2013), stored mainly in the kidneys, liver, thyroid, pituitary, pancreas, and bone (Watts 1990). Manganese is an essential element in humans functioning as an enzyme co-factor and as a constituent of metalloenzymes (Zidenberg-Cherr and Keen 1987; Lucchini et al. 2014). Humans can be exposed to Mn via inhalation, food consumption, and ingestion of water (NAS 1980; US EPA 2004). Exposure to elevated levels of Mn can cause neurological disorders (Gerke et al. 2016), and if humans are exposed to Mn concentrations greater than 500 mg m^{-3} it is considered immediately dangerous to life and health (http://www.cdc.gov/niosh/idlh/7439965.html).

Definition

Mantle Geochemistry: The study of Earth's mantle by investigating its chemical and isotopic composition.

Basic Facts About Earth's Mantle

Earth's mantle extends from the core-mantle boundary at 2900 km depth, the Gutenberg discontinuity, to the base of Earth's crust, the Mohorovičić discontinuity, at <10 km depth beneath the oceans and ~40–70 km beneath the continents. With about two thirds of Earth's mass, the mantle is the largest silicate reservoir of our planet. Oxygen (O), Mg, Si, Fe, Ca, and Al are its main constituents (Palme and O'Neill 2014). The mantle is mostly peridotitic in composition, with varying mineral assemblage that adapts to the large range of pressure-temperature conditions in the mantle. At upper mantle pressures, a typical mantle peridotite with a density of 3300 kg m^{-3} and a temperature of ca. 1600–1700 K is made up of about 55% olivine, 35% ortho- and clinopyroxene, and up to 10% of an Al-bearing phase, i.e., plagioclase, spinel, or garnet. Adapting to increasing pressure, these minerals transform to progressively denser minerals in the deeper mantle. At ca. 410 and 660 km depth, abrupt increases in mantle density – by about 4 and 9%, respectively – cause sharp discontinuities in seismic velocity. These are caused by structural transformations of the most abundant mineral: from olivine to wadsleyite at ca. 410 km and from spinel to bridgmanite (silicate-perovskite) and magnesiowustite at ca. 660 km depth (Kind and Li 2015). Deeper than 660 km, seismic wave speeds increase continuously until about ca. 200–300 km above the core–mantle boundary (CMB), where a sudden decrease in seismic velocity defines the so-called D″ discontinuity (in short: D″). The observed decrease in seismic velocity and the depth range over which it occurs varies. The most likely cause for occurrence of the D″ is the transition of bridgmanite to post-perovskite (e.g., Cobden et al. 2015; Lay 2015; Garnero et al. 2016). The region between the D″ and the CMB exhibits several complex seismic features (Lay and Garnero 2004; Lay 2015), the most prominent being two large low-shear-wave-velocity provinces (LLSVP), one beneath the central Pacific Ocean and one beneath Africa (Lay et al. 2006). In addition, there are intermittent thin structures with very low seismic wave velocities directly above the CMB, termed ultra-low-velocity zones (ULVZ; Williams and Garnero 1996). The observed seismic heterogeneity of the lowermost mantle above the CMB is likely caused by a complex interplay between phase changes (bridgmanite to post-perovskite), large variations in temperature, mantle composition, or even the presence of partial melt (Garnero et al. 2011; Tackley 2012; Cobden et al. 2015; Deschamps et al. 2015; Lay 2015; Garnero et al. 2016). At the CMB, the mantle has finally reached a density of about 5600 kg m^{-3} and a temperature of ca. 2400–2700 K, which is approximately 1200–1800 K cooler than the outer core. This interface between the solid silicate mantle and the liquid Fe alloy outer core (CMB) thus forms a pronounced thermal boundary layer.

Mantle Convection, Plate Tectonics, and Volcanism

The thermal boundary layers at the CMB and Earth's surface drive solid-state mantle convection: the rise of hot buoyant

material from the interior and the sinking of cold, dense (negatively buoyant) material from the surface. In the present Earth, cold, dense oceanic crust is subducted into the mantle, where it penetrates the 660 km discontinuity and sinks into the lower mantle, in some cases after temporarily stagnating at that depth (Fukao et al. 1992; Grand 1994; van der Hilst et al. 1997; Fukao and Obayashi 2015). Hence a current mode of whole-mantle convection is established, where material is cycled throughout the entire mantle. The vigor of convective motion is described by the Rayleigh number, Ra, a dimensionless parameter that relates thermal buoyancy, which drives mantle convection, and viscosity and thermal diffusivity, which impede mantle convection; the latter by erasing temperature differences that cause thermal buoyancy (Ricard 2015). Hence a greater temperature contrast between a hot basal (the CMB) and cold upper boundary layer (Earth's surface) results in more vigorous convection. Higher viscosity, especially of the lower mantle – which is estimated to be 1 or 2 orders of magnitude more viscous than the upper mantle (e.g., Lithgow-Bertelloni and Richards 1998; van Keken et al. 2014) – decreases convective vigor. The pattern and speed of mantle convection is thus largely determined by its temperature, viscosity, and compositional structure.

The subduction of cold dense oceanic crust is not only a key parameter for mantle convection, it is also the main driving force for plate tectonics (Forsyth and Uyeda 1975), resulting in moving continents, mountain building, and volcanism mostly at plate margins. In response to plate spreading at mid ocean ridges, for example, shallow mantle rises passively and melts partially through adiabatic decompression to form the oceanic crust. This process is responsible for most (about 80%) of Earth's volcanism. The oceanic crust is eventually subducted at convergent plate margins, where new basaltic and andesitic crust is generated by fluid-induced melting of the mantle wedge overlying the subducted slab. Volcanism at convergent plate margins is the second most voluminous type of volcanism on Earth. The eventual subduction of oceanic crust and residual mantle lithosphere into the deeper mantle trigger an upward return flow of hot mantle from the deep interior. An additional source for hot, buoyant material originates from internal thermal boundary layers, most prominently the CMB. Hot, buoyant material may rise from thermal boundary layers in form of focused cylindrical plumes and melt in the shallow mantle away from plate boundaries. Such mantle plumes are thought to source most, but not all, of Earth's "hotspot" volcanism (e.g., Morgan 1971; Steinberger 2000; White 2010, 2015a). On a global scale, this so-called intraplate volcanism is much less voluminous than mid ocean ridge and convergent margin volcanism, but it can nevertheless produce massive volcanic eruptions that form large igneous provinces (LIP), either on continents or the ocean floor. Examples are the Deccan Trap flood basalt province in India and the submarine Ontong Java plateau in the SW Pacific, respectively.

This interplay between mantle convection and plate tectonics on modern Earth has established a global cycle of ocean crust generation by partial mantle melting and its subduction into the mantle. In this way, the mantle has evolved continuously since the onset of plate tectonics.

Initially, however, Earth was much hotter than today owing to (1) the release of gravitational energy during accretion, (2) core formation, and (3) larger radioactive heat production. A hotter and therefore less viscous mantle convects more vigorously. It also starts to melt at greater depth (McKenzie and Bickle 1988), resulting in a greater amount of melt production and the formation of a thick oceanic lithosphere comprising the oceanic crust and underlying residual mantle. The Archean mantle was about 100–300 K hotter than at present (Herzberg et al. 2010). Thus the oceanic lithosphere cooled less effectively and stayed thermally buoyant (e.g., Davies 1992; van Thienen et al. 2004). Whether plate tectonics can occur under such conditions remains enigmatic. In addition, the lower convective stress imposed by a hotter, less viscous mantle may keep the oceanic crust from breaking apart. The Earth may therefore have started out in a stagnant-lid phase, where mantle convection occurred beneath an intact, strong, and immobile lithosphere (Moresi and Solomatov 1995, 1998). However, if the stresses imposed by convection exceed the lithospheric strength, the oceanic lithosphere may break apart and sink back into the mantle (Moresi and Solomatov 1998; O'Neill et al. 2007; van Hunen and van den Berg 2008). Other recently proposed subduction-initiating mechanisms are heat pipe volcanism (Moore and Webb 2013), destabilization of the lithosphere (Rey et al. 2014), or the accumulation of grain damage (Foley et al. 2014). Moreover, if the oceanic crust transforms to eclogite (at $>$40 km depth), the oceanic lithosphere becomes dense enough to subduct (van Hunen and van den Berg 2008). The hotter oceanic lithosphere is also rheologically weak, however, and may become too weak to support its own weight, resulting in slab break-off (van Hunen and van den Berg 2008). The latter causes a temporary loss of slab pull of the dense subducting crust, initiating a period of absent or very slow subduction. In other words, an episodic style of subduction and plate tectonics may occur (Moresi and Solomatov, 1998; O'Neill et al. 2007; Silver and Behn 2008; van Hunen and van den Berg 2008; Moyen and van Hunen 2012; Gerya 2014). These short-term episodes of proto-subduction in the early Earth may have evolved into longer periods of subduction, and hence plate tectonics, as mantle temperature decreased (O'Neill et al. 2007; Sizova et al. 2010; van Hunen and Moyen 2012; Moyen and van Hunen 2012; Moore and Webb 2013).

When exactly a plate tectonic regime similar to modern Earth has been established remains uncertain. The occurrence

of up to 4.4 Gyr old granite-derived zircons implies the existence of thick continental crust, which may have been generated in a subduction zone setting in the Hadean (4.56–4.0 Ga; Harrison 2009; Shirey et al. 2008), although this interpretation remains controversial (e.g., Kemp et al. 2010). Geochemical and petrologic evidence suggests that plate tectonics could have started locally in the early Archean (4.0–3.2 Ga) and progressively became more wide-spread in the late Archean (3.2–2.5 Ga; Condie and Kröner 2008; Shirey and Richardson 2011). Modern-style plate tectonics, operating under similar conditions and producing a similar geologic record as today (e.g., ophiolites, ultrahigh pressure terranes, and paired metamorphic belts), has been firmly established since at least the Neoproterozoic (<1 Ga ago; Stern 2005). The key here, however, is that Earth's mantle may not always have operated in the same way as it does today. Mantle convection and, especially, the interaction between Earth's crust and mantle have probably changed, or simply operated under different conditions in the past.

Mantle Geodynamics

For the present Earth, geodynamics describes the interplay between mantle convection and plate tectonics. The subduction (recycling) of oceanic crust, or more generally the interaction between Earth's crust and mantle, introduces compositionally distinct material into Earth's mantle, where it becomes dispersed by convective stirring. The physicochemical nature of the materials and the convective flow field determine the manner and timescale of their dispersal. Hence the geodynamics of Earth's mantle shapes its compositional structure and evolution and is the framework for interpreting the available geochemical information.

The processes that disperse compositionally distinct material in Earth's convecting mantle are often loosely described as "mixing." It is instructive, however, to use exact terminology in this context. Following Tackley (2015), "mixing requires the homogenization of chemical differences by a combination of stirring and chemical diffusion. Stirring involves stretching, the elongation of material into a thin tendril or lamella by strain caused by the convective flow. This greatly increases the surface area of the material and decreases its width, facilitating chemical diffusion." Solid state chemical diffusion of most elements in Earth's silicate mantle is extremely slow, acting over submeter length scales over geologic time (Hofmann and Hart 1978; Hart 1993). However, the length scale over which the mantle is sampled may differ from the diffusive length scale in the mantle. Materials may therefore not have to be stretched to submeter scales to become "invisible" as compositionally distinct entities. The reason is that "sampling" of the mantle may homogenize compositional heterogeneity over a length (volume) that is greater than the diffusive length scale in the mantle (Olson et al. 1984a; Olson et al. 1984b; Tackley 2015). This sampling scale may simply be the scale (volume) of sampling of mantle rocks (peridotites). It can also refer to partial melting and the subsequent extraction and mixing of melts when using basalts to study mantle heterogeneity (see discussion below).

The "mixing time" is a parameter that determines how long compositional heterogeneity can survive in the mantle. According to Tackley (2015) this is "the time required for heterogeneous materials to get stretched to the length scale of diffusion or sampling, whichever is larger." "Mixing" times remain highly uncertain, because the underlying geodynamic models have made different assumptions about the final length scale of the materials and the speed and nature (turbulent versus laminar) of convective flow (e.g., Olson et al. 1984b; Hoffman and McKenzie 1985; Gurnis and Davies 1986; Christensen 1989; Kellogg and Turcotte 1990). When these models are scaled to similar parameters, a "mixing" time of 3–4 Gyr results for stretching crust to the submeter length scale (Tackley 2015).

Hence the general perception is that mantle convection acts to attenuate compositional heterogeneities, but it may also generate or preserve regions in its convective flow field where material gets isolated for geologically significant timescales (10^6–10^9 years). For example, dispersal across convective cells can be far slower than within a single convective cell (van Keken et al. 2014; Tackley 2015). Some dense materials may also sink to internal boundary layers, especially the CMB region. In this way, the Earth may even have preserved some initial compositional heterogeneity or layering, for example, from magma ocean crystallization (Labrosse et al. 2007) or through potential isolation of early formed reservoirs (e.g., Boyet and Carlson 2005; Tolstikhin and Hofmann 2005). Geodynamic models indeed suggest that layers up to several 100 km thick can survive at the CMB over Earth's entire history (4.56 Gyr), given that they are 2–3% denser than the surrounding mantle. The exact residence time and thickness of the layer, however, strongly depend on its density and viscosity contrast to the surrounding mantle. Dense material at the CMB can not only form during Earth's initial differentiation but also throughout a large part of its history by subduction of oceanic crust (see discussion above). Recent experiments suggest that subducted oceanic crust is denser than the surrounding mantle over its entire depth range (Ricolleau et al. 2010). Thus it will sink to and accumulate at the base of the mantle (CMB). The CMB may therefore be a region that facilitates storage of dense, compositionally distinct materials, consistent with the geophysical evidence for so-called thermochemical piles (Tackley 2012; Deschamps et al. 2015; Lay 2015; Garnero et al. 2016). It may also be the primary source region of mantle plumes (Hofmann and White 1982; French and Romanowicz 2015).

Mantle convection and plate tectonics therefore affect a number of parameters that strongly influence the mantle's chemical evolution. Among the most important are the rate of cycling and the degree of dispersion of different materials in the mantle (e.g., Huang and Davies 2007; van Keken et al. 2014; Tackley 2015). Ultimately, however, at the next passage through a melting zone, the (compositionally distinct) materials partially remelt to form new oceanic crust. Thereby part of the original heterogeneity gets transferred to the crust and, eventually, after some storage time, gets reintroduced back into the mantle in reincarnated form. Another key parameter for understanding the geochemical evolution of the mantle is therefore the processing rate, which is the time it takes for a given volume of mantle to pass through an upper mantle melting region, mostly beneath mid ocean ridges. This parameter is highly uncertain. Current estimates range from ~10 to ~3 Gyr (Tackley 2015; and references therein). On the basis of the present oceanic crust production rate ($A = 2.7–2.9\ km^2\ year^{-1}$), the depth interval of mantle melting (d ~80 km), and mantle density ($\rho = 3000–3300\ kg\ m^{-3}$), a processing rate $P = Ad\rho$ of about $6.5–7.5 \times 10^{14}\ kg\ year^{-1}$ can be calculated (Stracke et al. 2003a; Tackley 2015). At such processing rates, it takes about 5.2–6.2 Gyr to process a mass equivalent to that of the entire mantle (4×10^{24} kg) through a melting regime in the upper mantle. This implies that most of Earth's mantle could have melted at least once during its up to 4.56 Gyr history. Interestingly, the preservation of mantle heterogeneities is mostly determined by the mantle processing rate, and less dependent on other parameters of mantle convection, such as the geometry, viscosity structure, and vigor of convection (Rudge et al. 2005; Huang and Davies 2007).

In summary, geophysical (seismic) studies provide valuable information about the present thermal and compositional structure of Earth's mantle. Numerical geodynamic models of mantle convection and plate tectonics provide valuable information about how the Earth's mantle could have evolved over time. However, the actual composition of the Earth's mantle can only be studied by direct chemical and isotopic investigation of mantle-derived rocks. These provide a picture of its current composition, the extent and scale of mantle heterogeneity, but also a time-integrated perspective about its compositional evolution through geologic history.

Probing Earth's Mantle

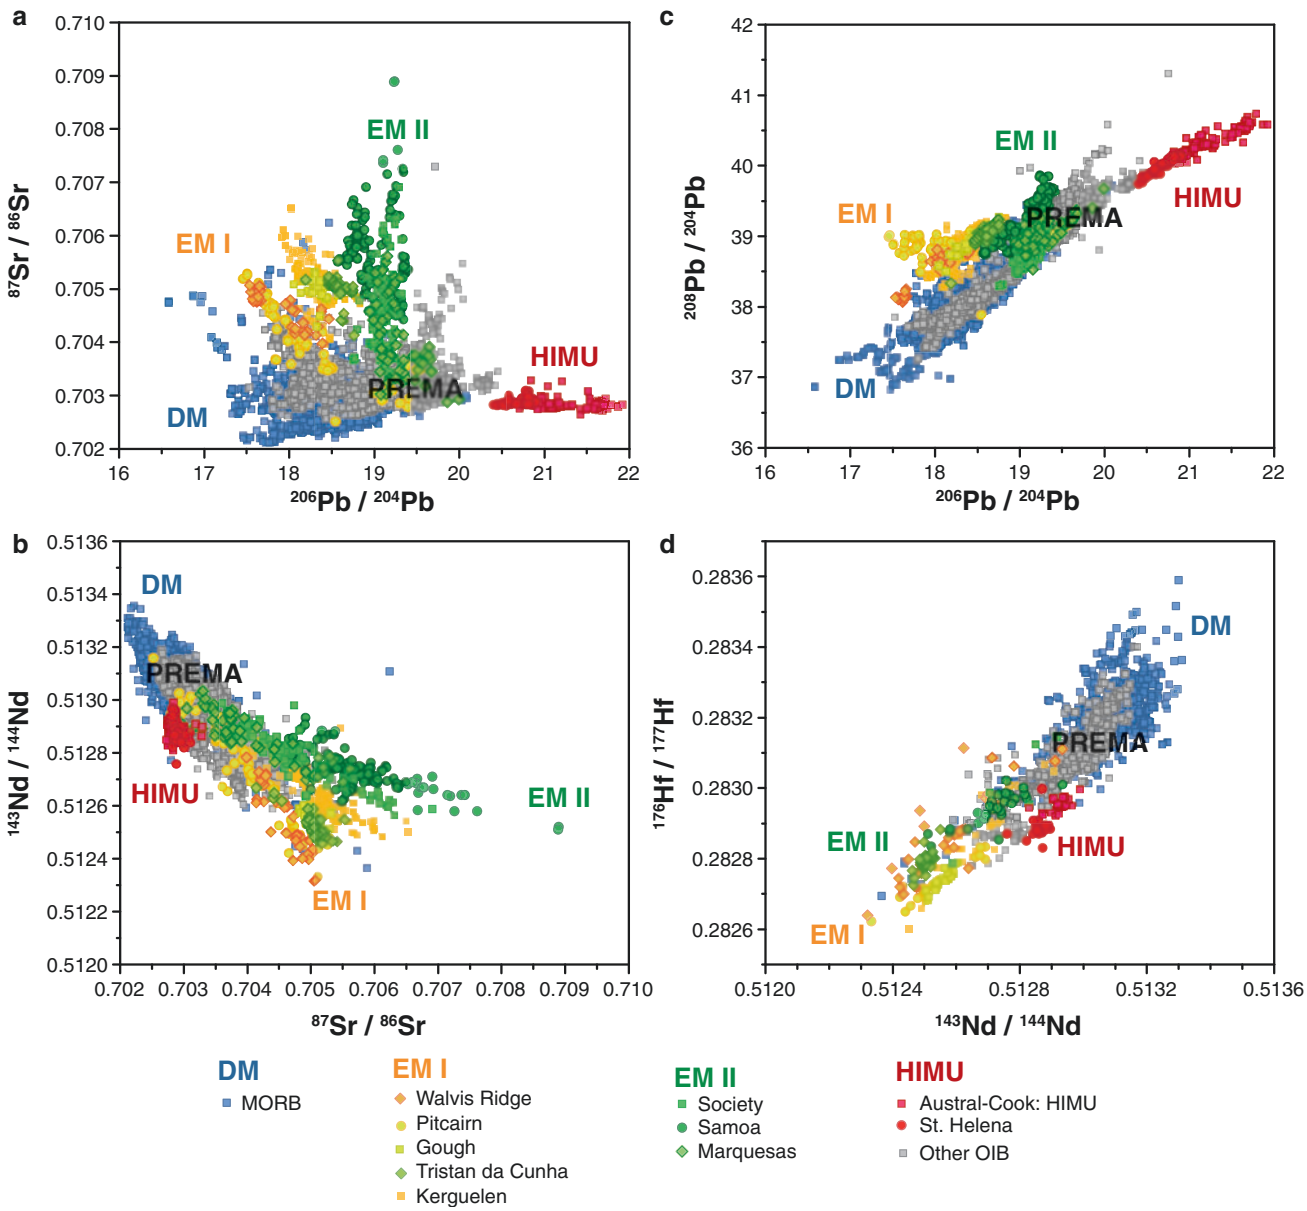
Probing the Earth's mantle poses the fundamental problem that most of it is inaccessible. Direct sampling of mantle rocks (mostly peridotites) is only possible at a few localities worldwide where mantle fragments are exposed. These are ophiolite complexes and peridotite massifs on continents, and abyssal peridotites exposed on the ocean floor at transform faults, oceanic core complexes, or slow spreading ridges. Xenoliths in continental or oceanic basalts are small samples of the continental lithospheric or oceanic mantle. Abyssal peridotites are often highly altered through interaction with extracted melt and seawater. Peridotites from ophiolites, peridotite massifs, and mantle xenoliths are also generally affected by melt-rock interaction (metasomatism) and weathering, and are sometimes metamorphosed (Bodinier and Godard 2014).

Owing to the scarcity, small scale, and prevalent modification by secondary processes (metamorphism, metasomatism, alteration) of most available mantle samples, the composition of the Earth's mantle is mostly studied through basalts erupted on the ocean floor. Oceanic basalts are large-scale partial melts from the Earth's mantle that escape contamination by the continental crust and thus indirectly record mantle composition. It has mostly been the numerous isotope and trace element studies of oceanic basalts, therefore, that have shaped our perception of mantle geochemistry over the last five decades (Hofmann 2014; White 2015b).

Chemical Geodynamics

Before the discovery of plate tectonics and the availability of isotope ratio data on mantle-derived rocks, Earth's mantle was thought to be compositionally homogeneous. Only the first isotope data on oceanic basalts (Gast et al. 1964) showed that Earth's mantle is chemically and isotopically heterogeneous and that chemical differences must be able to persist over geologic timescales (several 10^6–10^9 years). Since then, the picture of mantle geochemistry has changed considerably.

A fundamental observation is that mantle-derived melts from different tectonic settings, specifically basalts generated at mid ocean ridges (MORB) and ocean islands (OIB), display systematic isotopic differences. Ocean island basalts (OIB) generally range to higher Sr- and Pb-, but lower Nd- and Hf radiogenic isotope ratios than MORB (Fig. 1), and are isotopically more diverse. These differences were recognized 40–50 years ago (in Sr and Pb isotope ratios at the time; e.g., Hart et al. 1973; Schilling 1973; Sun et al. 1975) and explained in the context of a layered mantle. These early observations were consistent with a lower mantle that was assumed to be "primitive" and an upper mantle that is "depleted." "Primitive" means that it is identical in composition to the bulk silicate earth (BSE), the portion of the Earth that remained after its metal core was extracted. "Depleted" means deprived in those elements that do not easily fit into the crystal lattices of mantle minerals, the so-called incompatible



Mantle Geochemistry, Fig. 1 Diagrams of (**a**) $^{206}Pb/^{204}Pb$ versus $^{87}Sr/^{86}Sr$, (**b**) $^{87}Sr/^{86}Sr$ versus $^{143}Nd/^{144}Nd$, (**c**) $^{206}Pb/^{204}Pb$ versus $^{208}Pb/^{204}Pb$, and (**d**) $^{143}Nd/^{144}Nd$ versus $^{176}Hf/^{177}Hf$, in global mid ocean ridge (*MORB*) and ocean island basalts (*OIB*). On a local scale, for example, on the scale of one ocean island or ridge segment, the basalts form linear trends or vectors. On a global scale, the variation is systematic: the local-scale linear trends combine to form arrays that point in 4 or 5 general directions. Formerly, the most extreme isotope ratios at the endpoints of these arrays were interpreted as representing 5 different mantle reservoirs: *1*) the uppermost mantle sampled by MORB, termed Depleted Mantle (*DM*), originally also depleted MORB mantle (*DMM*). The other reservoirs are sampled mostly by OIB and were thought to represent deeper mantle reservoirs. The different varieties are *2*) and *3*) Enriched Mantle 1 and 2 (EM I and EM II), *4*) a compositional range internal to the observed arrays tapped by many OIB and MORB termed PREvalent MAntle (PREMA), and *5*) mantle reservoirs characterized by long-term evolution with high $\mu = {}^{238}U/^{204}Pb$ (HIMU). Compositions intermediate between these 5 end-members were thought to arise from mixing between the large-scale mantle reservoirs (Zindler and Hart 1986; Hart 1988). Since the seminal study by Zindler and Hart (1986), however, the general perception of Earth's mantle has evolved. Today, Earth's mantle is thought to be chemically and isotopically heterogeneous on a range of scales, from the global to the mineral grain scale. This compositional and isotopic heterogeneity likely reflects the continuous depletion by partial melting and the replenishment by recycling different crustal and lithospheric materials back into the mantle over geologic history. Hence the observed systematic variation of isotope ratios in mantle-derived rocks in form of arrays rather reflects a limited number of pathways through which mantle heterogeneity evolves (White 1985; Willbold and Stracke 2010; Stracke 2012; White 2015a; White 2015b). Although the perception of the Earth's mantle has changed, the acronyms DM, EM I, EM II, PREMA, and HIMU remain useful for describing the isotopic variation in mantle-derived melts. The underlying isotope data are taken from the compilation by Stracke (2012)

elements (e.g., Cs, Rb, Ba, Th, U, Nb, Ta, K, Sr, Zr, Pb, Hf, Ti, Na, and the rare earth elements). The process by which incompatible elements become depleted is partial melting, usually at shallow (<100 km) depths in the mantle. Hence formation of the crust by partial melting of the mantle leaves a residual "depleted mantle" (DM). Early geochemical mass balance or "box" models (Allègre et al. 1979; Jacobsen and Wasserburg 1979; O'Nions et al. 1979; DePaolo 1980) inferred that about 30–50% of the mantle must become depleted to account for the incompatible element inventory of Earth's continental crust. This fraction roughly corresponds to the mantle above the 660 km discontinuity which was thought, at the time, to form a boundary between a continuously evolving depleted mantle and an isolated lower mantle which remains "primitive" in composition. Hence MORB were explained by partially melting the depleted upper mantle and OIB by melting materials that consist of a variable mix of depleted upper mantle and primitive lower mantle that rises in the form of mantle plumes (e.g., DePaolo and Wasserburg 1976; Allègre et al. 1979; O'Nions et al. 1979).

With an increasing amount of data it became clear, however, that isotope ratios in OIB range to values that are more extreme than the inferred "primitive" values. As a consequence, five compositionally distinct reservoirs in the mantle were invoked (Zindler and Hart 1986; Fig. 1). These were: (1) the uppermost mantle sampled by MORB, termed Depleted Mantle (DM), originally also termed depleted MORB mantle (DMM). The other reservoirs are sampled mostly by OIB and were thought to represent deeper mantle reservoirs. The different varieties are (2) and (3) Enriched Mantle 1 and 2 (EM I and EM II), (4) a compositional range internal to the observed arrays tapped by many OIB and MORB termed PREvalent MAntle (PREMA), and (5) mantle reservoirs characterized by long-term evolution with high $\mu = {}^{238}U/{}^{204}Pb$ (HIMU). The observed systematic isotope variation in Fig. 1 – in form of arrays that point in 4 or 5 general directions – was explained by mixing these large-scale mantle reservoirs (Zindler and Hart 1986; Hart 1988). Although consistent with the observations, there are several problematic aspects with this interpretation. For example, mixing is observed between some, but not all of these proposed reservoirs (Stracke et al. 2005; White 2015b), and the pattern of the arrays require selective mixing of some components before mixing with others (e.g., Hamelin et al. 1986; Hanan et al. 1986; Douglass and Schilling 2000; Stracke 2012). The latter is especially problematic if "mixing" is thought to occur in the solid state during passage through the mantle (Stracke 2012), a rather unlikely scenario (see discussion above). More importantly, however, it is now known that Earth's mantle is a dynamic, continuously evolving system with mass exchange between the lower and upper mantle. The main driving mechanisms are plate subduction and mantle convection, which also continuously disperse compositionally distinct material within the mantle. In such a dynamic system, it is virtually impossible to maintain a mantle with only five large-scale reservoirs with unique isotope composition (Stracke 2012). The latter would imply that no more than five different geologic events have introduced compositionally different materials into the mantle.

Nevertheless, the observation that isotope arrays point to 4–5 general directions suggests that there is limited number of pathways through which isotopic heterogeneity has developed in the mantle (White 1985; Willbold and Stracke 2010; Stracke 2012; White 2015b). Seemingly, there are a range of processes through geologic time that introduce materials with common geologic heritage and similar composition into the mantle, which then evolve towards broadly similar isotopic compositions.

Processes that Generate Mantle Heterogeneity

Mantle composition has evolved continuously. Because it appears likely that subduction has occurred through most of Earth's history, most of the observed chemical and isotopic variability can be explained within a simple conceptual framework: depletion by partial melting and replenishment by large-scale chemical recycling of the generated oceanic and continental crust back into the mantle (e.g., Willbold and Stracke 2010; Stracke 2012; White 2015a; White 2015b).

On basis of the geodynamic premise that most of the mantle melted at least once in its history (see discussion above), the entire mantle should be variably depleted. However, geochemical mass balance models –based on comparing chemical and isotopic composition of continental crust and mantle – are inconclusive, suggesting that anywhere between 30% and 100% of the mantle could be depleted by melt extraction (e.g., Jacobsen and Wasserburg 1979; O'Nions et al. 1979; DePaolo 1980; Allègre et al. 1983; Zindler and Hart 1986; Hofmann 1988; Boyet and Carlson 2006). The exact fraction of depleted mantle and its overall extent of depletion thus remain unknown. It is clear, however, that partial melting not only extracts incompatible elements from the mantle into the newly formed crust, it also changes the mantle's mineralogical composition by preferentially melting some minerals, particularly clinopyroxene and garnet. Partial melting therefore makes the mantle more refractory, that is, it will produce less melt during its next passage through a melting region in the shallow mantle (for a given temperature; e.g., Salters et al. 2011; Zhou and Dick 2013). Eventually, upon repeated or extensive melting, a given parcel of mantle will become too refractory to produce any further melt, thus effectively limiting the extent of mantle depletion. A large fraction of the total mantle should therefore be mineralogically, compositionally, and isotopically heterogeneous depleted mantle.

This continuous depletion of Earth's mantle through partial melting is counteracted by introducing incompatible element-enriched and isotopically diverse materials back into the mantle. Since the onset of plate tectonics, the primary mechanism for this replenishment has been the subduction of oceanic lithosphere and the overlying sediments, which are the weathering products of the continental crust. Accompanying subduction is the tectonic erosion of the overlying arc crust, which introduces a large amount of (lower) continental crust into the deeper mantle, on the order of the volume of today's continental crust (~2×10^{22} kg) over the course of Earth's history (Clift et al. 2009; Stern 2011; Tatsumi et al. 2014). It is also possible that parts of the subcontinental lithospheric mantle and attached lower crust become denser, thus gravitationally unstable, and sink back into the mantle (e.g., Houseman et al. 1981; McKenzie and O'Nions 1983; Arndt and Goldstein 1989; Kay and Kay 1991; Kay and Kay 1993; Rudnick 1995; Jull and Kelemen 2001). All of these processes transport crust and lithosphere back into the deeper mantle. Once there, the recycled materials become stretched, intermingled, and dispersed by mantle convection. The mantle can thus be envisaged as a collection of recycled materials (presumably from different processes) interspersed in a variably depleted peridotitic mantle "matrix."

All of these mechanisms are thought to contribute to mantle heterogeneity. Isotopic variability along the DM-PREMA array (Fig. 1), for example, is likely caused by continuous production and recycling of oceanic crust (e.g., Christensen and Hofmann 1994; Donnelly et al. 2004; Rudge et al. 2005; Stracke et al. 2005; Rudge 2006; Kellogg et al. 2007). Ancient recycled oceanic crust with different compositions thereby accounts for the enriched, PREMA-type signatures (Fig. 1), whereas partial melting is expected to produce a range of variably depleted residual peridotites (DM). Most of the enriched mantle (EM I and EM II) signatures in MORB and OIB (Fig. 1) can be produced by recycling the compositionally distinct upper and lower continental crust (e.g., Chauvel et al. 1992; Willbold and Stracke 2006; Jackson et al. 2007; Chauvel et al. 2008; Willbold and Stracke 2010; Stracke 2012). Other, more elusive processes create exotic signatures (HIMU, Fig. 1), but overall account for only a small part of the observed mantle heterogeneity. Additional processes that contribute to mantle heterogeneity are metasomatism of the oceanic or continental mantle (e.g., Menzies et al. 1987; McKenzie and O'Nions 1995; Niu and O'Hara 2003; Pilet et al. 2008). These often have a restricted extent and scale, however, and are thus probably of second-order importance for generating global mantle heterogeneity.

Nevertheless, all the processes discussed above transport materials of common heritage that have been processed in a similar, but not identical, manner at different times and locations into the mantle. The various proportions, origins, compositions, and ages of these different materials eventually determine the composition and extent of heterogeneity of a given parcel of mantle rock. Each individual material in a given mantle source may itself be compositionally heterogeneous: the composition of the residual peridotitic mantle may vary because of differing degrees of depletion by melt extraction or refertilization by metasomatism at different times (e.g., Johnson et al. 1990; Bodinier and Godard 2014). Crustal components (oceanic crust, continental crust, and marine sediment) are compositionally and isotopically variable as a result of different conditions of formation (e.g., Plank 2014; Rudnick and Gao 2014; White and Klein 2014), age, varying extents of hydrothermal alteration on the ocean floor (e.g., Staudigel 2014), and modification during subduction (e.g., Bebout 2014; Ryan and Chauvel 2014).

If sampled by partial melting, each mantle source will consequently have a unique, and variable, isotopic composition arising from the various proportions of the different materials it encompasses. The challenge of mantle geochemistry therefore is to identify the number, relative abundance, and nature of these materials – from the local to global scale– with the aim of constraining the importance of the underlying processes and mass fluxes. This is undoubtedly a complex task and hence will be a continuing field of scientific research and debate. It is, however, also of fundamental importance for better understanding the major geochemical cycles and inner workings of our planet.

M

The Scale of Mantle Heterogeneity

Owing to the different composition, size, and distribution of its individual components (e.g., residual peridotitic mantle, various recycled materials), the mantle is heterogeneous on a range of scales, from the 1000 km scale of ocean basins (Dupré and Allègre 1983; Hart 1984), the 1–100 km scale along mid ocean ridges (e.g., Agranier et al. 2005; Graham et al. 2006), down to the cm scale of single hand specimens. The isotopic heterogeneity observed in melt inclusions shows that heterogeneity not only persists down to the kilometer scale of the melting region but perhaps even down to the millimeter scale of individual mineral grains. This shows that heterogeneous components introduced into the mantle become stretched and thinned and are widely distributed throughout the mantle (e.g., Morgan 1999; Meibom and Anderson 2003; Stracke et al. 2003b; Ito and Mahoney 2005; Rudge et al. 2005; Stracke et al. 2005; Kellogg et al. 2007). Large-scale statistical differences caused by differences in the relative abundance of the distinct mantle components may occur, for example, between ocean basins. Whether such potential large-scale "domains" in the Earth's mantle (e.g., DUPAL (Dupré and Allègre 1983; Hart 1984) or SOPITA (Staudigel et al. 1991)) actually represent varying abundances of different materials or are simply an artifact

from different sampling of a statistical distribution of similar materials (e.g., Morgan 1999; Meibom and Anderson 2003; Ito and Mahoney 2005) is a matter of debate. At mid ocean ridges, for example, the observed degree of isotopic variability decreases as the rate of processing of mantle material – as measured by spreading rate – increases (e.g., Allègre et al. 1984; Stracke et al. 2003b; Rubin et al. 2009). These observations confirm that the scale of mantle components is small compared to the maximum dimension over which melts are produced and mixed during melting, melt extraction, and melt evolution. They also show that large-scale tectonic or geodynamic differences of the melting regions (e.g., spreading rate) influence the manner in which heterogeneous mantle components are represented in the erupted melts.

Synthesis

Our perception of the chemical and isotopic composition of Earth's mantle has evolved significantly over the last five decades. It has changed from a homogeneous- to a two-layer mantle (e.g., Hart et al. 1973; Schilling 1973; Sun et al. 1975), to a mantle that comprises a finite number (4 or 5) of large-scale reservoirs (Zindler and Hart 1986), to a mantle that is chemically and isotopically heterogeneous on a range of scales, from the global to the mineral grain scale.

The chemical and isotopic investigation of mantle-derived rocks therefore provides information about the mantle's current state of heterogeneity and its time-integrated chemical evolution on a range of scales. Direct sampling of mantle rocks, for example, allows studying mantle composition down to mineral grain or even smaller length scales. The investigation of mantle composition through studying its melts – basalts – integrates over the sampling volume of partial melting. Depending on the nature of the sampling, therefore, different length scales of compositional heterogeneity in the Earth's mantle may or may not be resolved. Moreover, both the scale and lithological composition of the various mantle materials determine how they are sampled by partial melting. In addition, the subsequent processes of melt extraction, mixing, the reaction of the melts with the mantle through which they pass, and melt differentiation in the crust influence how mantle heterogeneity is preserved in the erupted melts (e.g., Stracke 2012; Rudge et al. 2013). Isolating the information mantle melts convey about mantle composition and evolution thus requires disentangling these various effects, and it should be kept in mind that a bias may persist between source and melt (Stracke 2012).

Investigating different mantle-derived samples grants access to different parts of the mantle. Abyssal peridotites and MORB provide a window into the uppermost mantle that is exposed on the ocean floor, or partially melting in the upper ~100 km of the mantle, respectively. Ocean island basalts (OIB) often, but not always, sample hot, upwelling mantle plumes from thermal boundary layers in the deeper mantle, most prominently the CMB (e.g., Morgan 1971; Hofmann and White 1982; White 2010; White 2015a; White 2015b). Ophiolite complexes and peridotite massifs offer a glimpse of ancient oceanic mantle obducted onto the continents or uplifted subcontinental lithospheric mantle, respectively. Intracontinental basalts sample both the oceanic and subcontinental lithospheric mantle. Although we thus have access to a wide variety of different mantle-derived samples, it should not be forgotten that most of the mantle remains inaccessible. Our perception of global mantle geochemistry is therefore inherently limited and provides only a hint of its actual diversity.

Remaining Questions

How the different pieces of the puzzle of information we collect fit together into a consistent picture of mantle geochemistry is one of the remaining challenges. Different compositional and isotopic parameters often result in different perspectives of mantle geochemistry. One example would be the radiogenic isotope ratios of the noble gases and lithophile elements, which continue to be interpreted within a different framework of mantle geodynamics (e.g., White 2010; Moreira 2013; White 2015a). Novel tools such as the stable isotope ratios of an increasing number of major and trace elements provide a new flux of information that is important for complementing and completing the available information from other tracers. Especially the stable isotope fractionations produced at Earth's surface promise to supply complementary constraints on the mass flux and timing of element cycling between Earth's mantle and crust. These may also contribute to improving our quantitative understanding of how the two opposing processes of mantle depletion and replenishment are coupled to the growth and destruction of continental crust through time.

The exact timescales and related mass fluxes associated with silicate Earth differentiation remain difficult to assess. Nd and Os isotope ratios in abyssal peridotites provide a range of so-called mantle depletion ages (e.g., Harvey et al. 2006; Mallick et al. 2014; Liu et al. 2008) that date back to ca. 2.2 Ga. Signatures of ancient depletion processes can therefore be preserved, but these probably reflect the average timing of a prolonged multistage differentiation and the timescale of mantle stirring or "mixing."

Another unresolved question is whether there is a general compositional dichotomy between the upper and lower mantle as a result of viscosity-related differences in stirring efficiency. In this context it is also important to what extent, if at all, some primordial ("primitive") mantle or early formed reservoirs may have survived. Presently available mantle

samples provide no chemical or isotopic evidence for any remaining truly "primitive" mantle. Storage or isolation of early formed reservoirs over billion-year timescales is only feasible if these are significantly more dense and viscous than the ambient mantle. Moreover, immanent in the very nature of these isolated reservoirs is that any chemical or isotopic evidence for their existence will always be circumstantial, or simply remain elusive. If such reservoirs constitute a significant fraction of Earth's mantle, however, they may bias the composition of the accessible Earth relative to that of the bulk silicate Earth. Whether any isolated (early) or "primitive" reservoirs exist may therefore not only be of conceptual importance for mantle geochemistry. It would also be important for defining the correct reference point for deducing accessible Earth's overall isotopic evolution and for estimating the amount and timing of the mass fluxes among Earth's silicate reservoirs.

Definition

Marine sediment is a mixture of material deposited on the seafloor that originated from the erosion of continents, volcanism, biological productivity, hydrothermal vents, and/or cosmic debris. The contributions of these sediment sources to the seafloor are controlled by wind, ocean circulation, and water depth that collectively determine the transport, deposition, and preservation of each sediment type. The alteration of these sediment types ("authigenesis") is also an important process affecting the final composition of marine sediment.

Introduction

The geochemical composition of marine sediment is diverse. Marine sediment is most commonly classified according to the origin of the material(s) composing the bulk sediment, with end-members being referred to as, for example, aluminosilicate, biogenic, or metalliferous (Table 1). Here, we summarize the broad-scale processes and trends in these compositionally defined end-members and further discuss some of the subtleties in their variabilities that lead to the local, regional, and global diversity of deep-sea marine deposits.

The aluminosilicate(s) in marine sediment can be provided by volcanic and terrigenous sources (authigenic aluminosilicates are described separately below). Volcanic ash grains are produced by continental or oceanic eruptions of igneous compositions. Terrigenous sediment results from physical and chemical weathering of upper crustal rocks exposed at the surface of the Earth. Being aluminosilicates, the major element geochemistry of this sediment type exhibits high concentrations of both Al and Ti (along with other commonly associated elements such as K, Na, Rb, etc.) relative to the other sediment types.

Biogenic sediment results from the production, transport, and preservation of minerals initially produced by either plants or animals. The most common biogenic deposits can be divided into calcareous and siliceous, with biogenic apatite contributing a smaller component. Calcareous deposits are enriched in Ca (e.g., calcite, aragonite, dolomite), and siliceous deposits are enriched in Si (e.g., biogenic opal) relative to the other sediment end-members, while biogenic apatite is enriched in P.

Metalliferous sediment most commonly results from hydrothermal processes along mid-ocean ridges. High concentrations of Fe and Mn typically distinguish the bulk geochemistry of metalliferous sediment from the other sediment types, along with concomitant enrichments in Cu, Zn, and other metals near the ridge (Dymond 1981). Farther from the ridge, sinking particulates or sediment on the seafloor may take up additional metals (e.g., Co, Ni, Cu, Zn, rare earth elements) from the water column. Extraterrestrial spherules and micrometeorites are a minor component of sediment and are also metal rich, with elevated concentrations of Fe, Co, and Ni compared to the other sediment types.

Most deep-sea sediment is a mixture of these three main components. Even sediment dominated by one of the above end-members commonly contains significant amounts of the other components. The distributions of each of these sediment types (e.g., Fig. 1) are controlled by wind, ocean

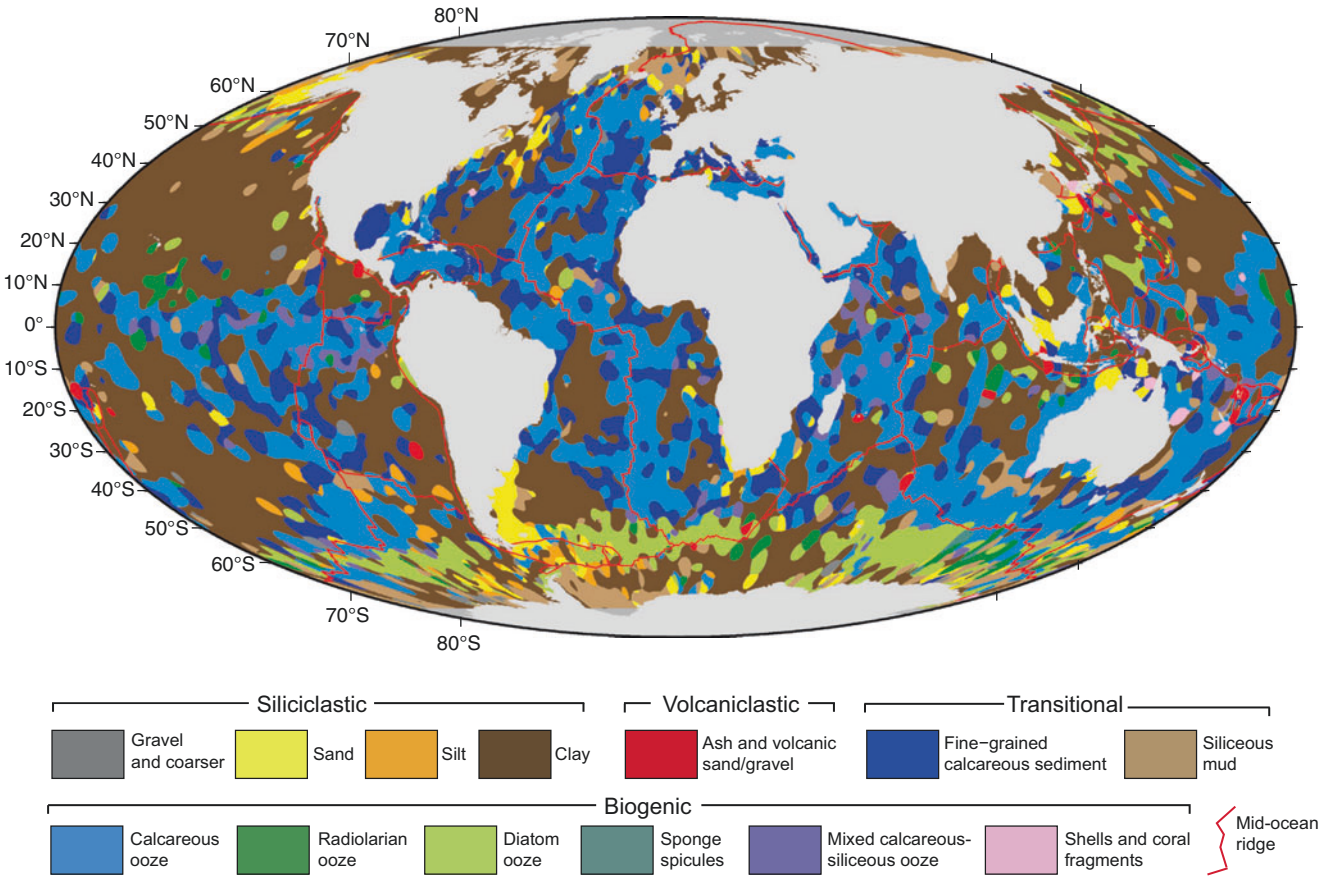
(1973); d = Dymond et al. (1973); f = Fisher and Bostrom (1969); h = Horowitz (1970); hd = Heath and Dymond (1977); v = Vonderhaar et al. (2000); w = Wen et al. (1997); REE = Jarvis (1985) for basal sediments, and Bender et al. (1971) for ridge sediments. Pd and Pt values for shale are an educated guess based on the upper crust values

circulation, and water depth that collectively affect the transport, deposition, and preservation of each sediment type. For example, wind will blow dust into the ocean and cause dust to accumulate more rapidly in regions downwind from an arid source of dust. If the dust is deposited in an area of ocean upwelling that has high biological productivity of calcareous plankton, the dust deposition will be mixed into and diluted by the biogenic input. If this sediment is deposited in water deep enough, the biogenic deposit may be dissolved, and the aluminosilicate dust will become the more dominant sediment type again. The dissolution of the biogenic sediment is likely to occur for carbonates if below the carbonate compensation depth (CCD; Millero 2013) or for biogenic opal due to the undersaturation of seawater with respect to biogenic opal (DeMaster 2014). If either dust or biogenic material is deposited close to a hydrothermal vent system, it will be mixed with a metalliferous component. As such, marine sediment is indeed compositionally diverse.

These transport and preservation processes also cause sediment to be thickest along coastlines close to aluminosilicate sources and near equator, where upwelling of nutrient-rich water stimulates biological productivity in the surface water and biogenic sediment has the potential to accumulate rapidly. The slowest accumulating and thinnest sediment occurs in the center of ocean gyres where there is low productivity, low preservation of what little biogenic component is produced, and extremely low supply of wind-blown material that has traversed the vast distance prior to deposition (Fig. 2).

The Prevalence of Authigenic Components in All Sediment

For all sediment, regardless of initial composition, postdepositional processes may produce additional chemical changes to the sediment. Therefore, the chemical composition of each sediment is not static but is continuously changing based on how it geochemically interacts with the surrounding environment in which it is deposited. The postdepositional reactions are referred to as "diagenetic" or "authigenic" processes. Most commonly, "diagenetic processes" refer to changes taking place in sediment after deposition (Berner



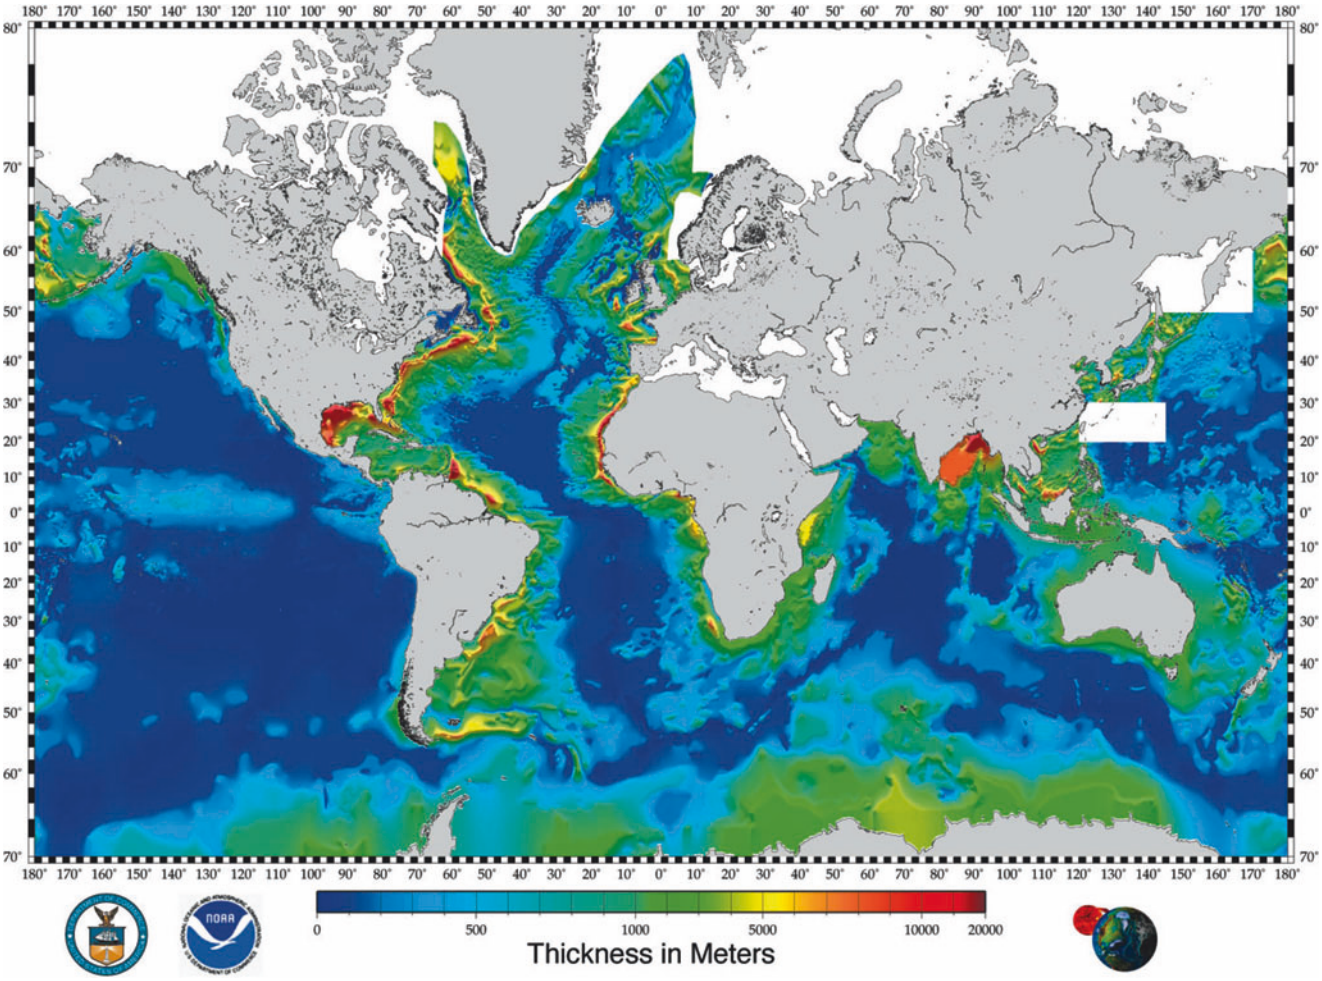
Marine Sediment, Fig. 1 Compilation map of major lithologies of worldwide seafloor sediment (From Dutkiewicz et al. 2015)

1980), while "authigenic processes" refer to the in situ formation of minerals near the seafloor and within the sediment by replacement of a precursor mineral or by direct precipitation from the seawater or surrounding pore fluids (Kastner 1999; Piper and Heath 1989).

The rate at which sediment accumulates (i.e., sedimentation rate), which is inversely related to how long the sediment is in direct contact with ocean bottom water (i.e., the "seawater exposure time"), plays a large role in determining the extent of these reactions (Berner 1980; Ruhlin and Owen 1986). Sediment deposited on the seafloor is initially bathed in ocean bottom water before it is buried and surrounded with porewater. The chemical environment and geochemical reactions that sediment undergoes when exposed to freshly replenished bottom water are very different from the more restricted porewaters. Diagenetic/authigenic reactions in the subseafloor can change individual elemental concentrations, the alkalinity, and/or pH of the porewater. The resulting porewater conditions can subsequently cause additional diagenetic changes. Elements dissolved in porewater can be sensitive indicators of authigenic/diagenetic processes (Schulz 2006) that are dissolving pre-existing minerals or creating new solid phases, commonly referred to as "authigenic minerals."

The use of the term "authigenic minerals" varies between the different research communities studying marine sediment. A number of processes fall under the broad rubric of "authigenesis" including ash alteration, aluminosilicate formation, biogenic deposition, carbonate recrystallization/dolomitization, and biogenic Si diagenesis (including the formation of diagenetic chert), Fe/Mn oxide micronodules or coatings and hydrothermal deposition, geochemical signatures in fish teeth/bones, and/or rare earth and other trace element enrichments. The chemistry of authigenic minerals may be difficult to define as they are usually formed by a combination of a pre-existing minerals and the uptake/release of elements from an aqueous medium (e.g., cation exchange reactions, sorption, or recrystallization). Thus, the composition will include elements from each source. Each of these formation or alteration mechanisms has different implications for the cycling of certain elements involved with each of the sediment types and is discussed in more detail within each section below.

In the context of authigenesis, the concept of "reverse weathering" is a useful construct to consider. Weathering produces ions that are carried by rivers to the ocean where they can reside in a dissolved state over time spans ranging



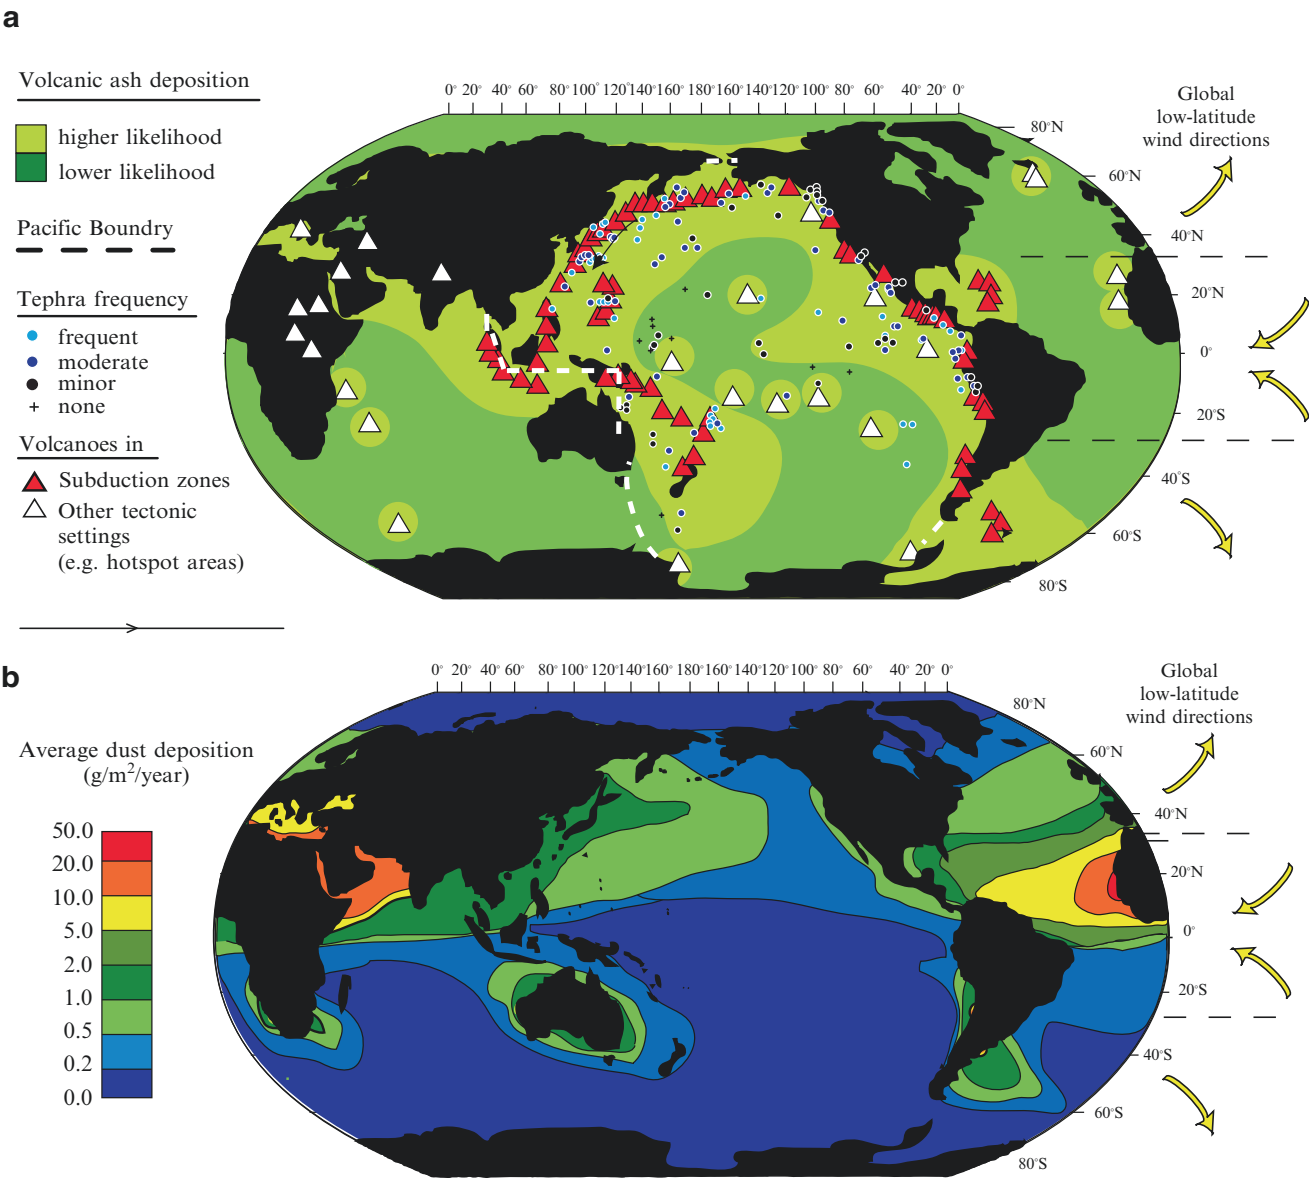
Marine Sediment, Fig. 2 Total sediment thickness of the world's oceans and marginal seas (From Divins 2003)

from several years to hundreds of millions of years (Millero 2013). These ions are eventually removed by biological deposition (e.g., Si or Ca), precipitation with or adsorption onto existing sediment, or incorporation into authigenic aluminosilicates (e.g., Si, Mg, K, Fe). The formation of authigenic aluminosilicates from weathered cations has been referred to as "reverse weathering." The idea of reverse weathering was originally hypothesized by Sillén (1967) and Mackenzie and Garrels (1966) as a removal mechanism to balance the chemical budget of cations (e.g., Mg and K) and HCO_3^- that were transported to the ocean by rivers. Since then, studies have examined the uptake of many of these elements via the existence of authigenic aluminosilicates and basalt alterations associated with hydrothermal fluxes. The presence of authigenic aluminosilicate grains is documented in river delta sediment (e.g., Michalopoulos and Aller 2004), equatorial Pacific biogenic deposits (e.g., Hurd 1973), and pelagic sediment (e.g., Cole 1985). While many of these studies explain their findings with a specific reaction proposed by Mackenzie and Garrels (1966), the specifics and broad suite of reverse weathering reactions that are actively occurring, and their linkages to the carbon cycle, are not yet fully understood.

Aluminosilicates

The Ubiquitous Presence of Volcanic Ash

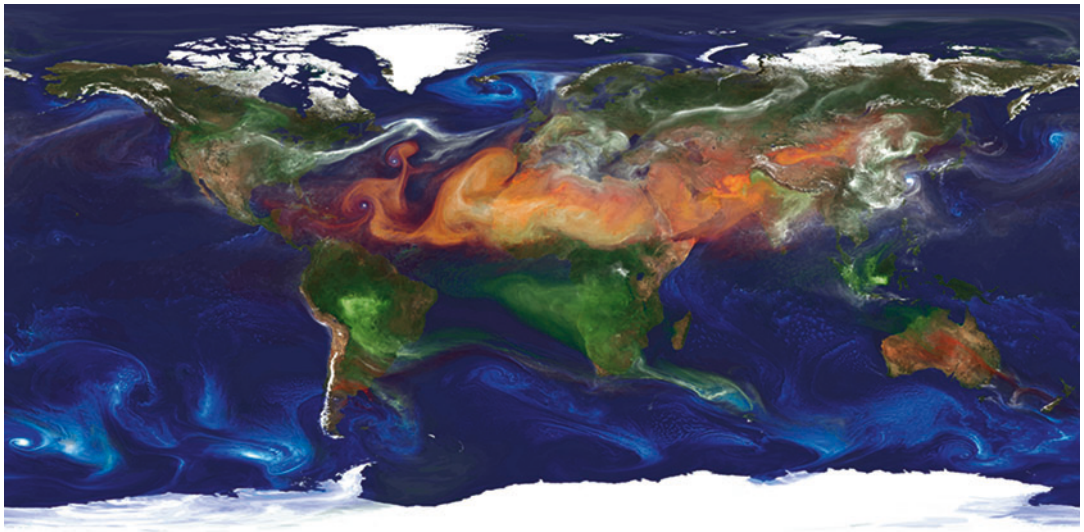
Volcanic ash has long been recognized in marine sediment, and, given the prevalence of oceanic and continental arc volcanism around the globe, its presence is nearly ubiquitous (Fig. 3a). However, the presence/absence of very fine-grained ash material, and identification of its composition in particular, is challenging given its broad classification as an "aluminosilicate." Volcanic ash can range in composition from mafic to felsic depending on the eruptive source. The major element concentrations of average intermediate ashes (e.g., dacite) are very similar to an average continental crust composition, but the trace and rare earth element concentrations are more variable between the two.



Marine Sediment, Fig. 3 (**a**) Likelihood of volcanic ash deposition in marine sediment. *Lighter green* represents higher likelihood, and *darker green* represents lower likelihood. (**b**) Averaged annual mineral dust fluxes into the world ocean. See figure for color scale (Both images from Olgun et al. 2011)

Deposits of volcanic ash can occur as layers or dispersed in the bulk sediment both on continents and in marine sediment (Ninkovich et al. 1978; Carey and Sigurdsson 1980; Straub and Schmincke 1998; Scudder et al. 2016, and references therein). The term "ash" is generally used in the field of volcanology as a grain size definition (32 μm to 2 mm, e.g., Fisher and Schmincke 1984) for explosive volcanic products (i.e., tephra). Here we use "ash" to indicate a product (mostly volcanic glass) from explosive volcanism no matter which grain size a particle may have. Therefore, we define "discrete ash layers" as a volcanic product that is present as clearly visible beds in the marine sediment that are ash layers of millimeter to centimeter or greater thickness. Less widely recognized than the discrete layers of ash is what has been referred to as "dispersed" ash. "Dispersed ash" is defined as volcanic ash material of various grain sizes (including single μm grains) that is mixed throughout the bulk sediment. This ash occurs in addition to the discrete ash layers (Scudder et al. 2009, 2014, 2016). Dispersed ash is the result of bioturbation of pre-existing discrete ash layers, the settling of airborne or subaqueous ash through the water column, transport by rivers and currents from terrestrially exposed ash deposits, and other processes (e.g., Kutterolf et al. 2014).

The presence of dispersed ash in the marine record has previously been largely overlooked because it is difficult to



Marine Sediment, Fig. 4 Map of modeled global aerosols. *Red*, dust from the surface; *blue*, sea salt; *green*, smoke from fires; *white*, and sulfate particles from volcanoes and fossil fuel emissions (From NASA Center for Climate Simulation at Goddard Space Flight Center http://gmao.gsfc.nasa.gov/research/aerosol/modeling/)

identify petrographically as a result of its general extremely fine grain size (Rose et al. 2003 and references therein) and/or alteration to authigenic clay (Sigurdsson et al. 1997; Plank et al. 2000). Such alteration (e.g., Schacht et al. 2008) often results in fine-grained material that is unable to be differentiated from detrital terrigenous clay (non-ash, derived from land) on the basis of visual study alone. Recent geochemical studies have found that dispersed ash makes up on average ~30 wt. % of marine bulk sediment (Ziegler et al. 2007; Scudder et al. 2009, 2014; Dunlea et al. 2015a, b), which is consistent with the more qualitative approaches such as the examination of smear slides (Cambray et al. 1993). Ash is commonly altered on and/or below the seafloor by diagenetic reactions. Amorphous volcanic ash shards deposited in marine environments are commonly dissolved, hydrated, and altered on and/or in the seafloor to become zeolite or clay (e.g., smectite) minerals. During the reactions between the grain and seawater or porewater, some elements (e.g., Si, Mg, K) are lost or gained (Gardner et al. 1986; Desprairies et al. 1991; Kastner 1999; Straub et al. 2015), while other elements are immobile, and their concentrations remain relatively unchanged from the parent ash (e.g., Al, Ti, Cr). Weathering of igneous rocks also produces volcanic sediment with a composition reflective of the composition of the eruptive source, although certain element concentrations may be changed during erosion/alteration processes (Pickering et al. 2013).

Eolian Transport and Deposition of Terrigenous Dust

Wind blowing over the continent can entrain dust and transport it long distances from the original site of weathering (e.g., Mahowald et al. 2005). The availability of dust and the direction of the prevailing wind(s) influences where eolian material is deposited on the seafloor (Fig. 3b). The Northern Hemisphere has more continents and thus more dust available to be blown into the ocean. Overall, the dust fluxes in the Northern Hemisphere are an order of magnitude higher than in the Southern Hemisphere, where there are fewer continents and less dust to be transported (Fig. 4). On a regional scale, higher rates of dust deposition occur in regions of the ocean that are closer to and downwind of dust sources (Fig. 3b). The most significant dust sources are arid deserts located below the dry, descending air from Hadley Cell circulation at latitudes of 30°N and 30°S and/or in rain shadows. There is also more dust available for transport in regions that previously experienced rainfall and then became more arid (e.g., the Bodéle Depression in the Sahara Desert) (Schepanski et al. 2009).

During sediment transport, whether in air or water, minerals begin to separate according to size and density. Sedimentary sorting results in an enrichment of heavy minerals (e.g., zircon, monazite, magnetite, rutile) in a relatively coarse size fraction of the sediment. However, these minerals also are present in the finest fractions of eolian-derived sediment as well and can exert a large influence on the resulting sediment composition (Glaccum and Prospero 1980). Thus, repeated reworking (recycling) of sediment tends to strongly enrich deposits associated with heavy minerals (e.g., Zr, Hf, Th, and/or Ti).

Other Transport Mechanisms of Lithogenic Material

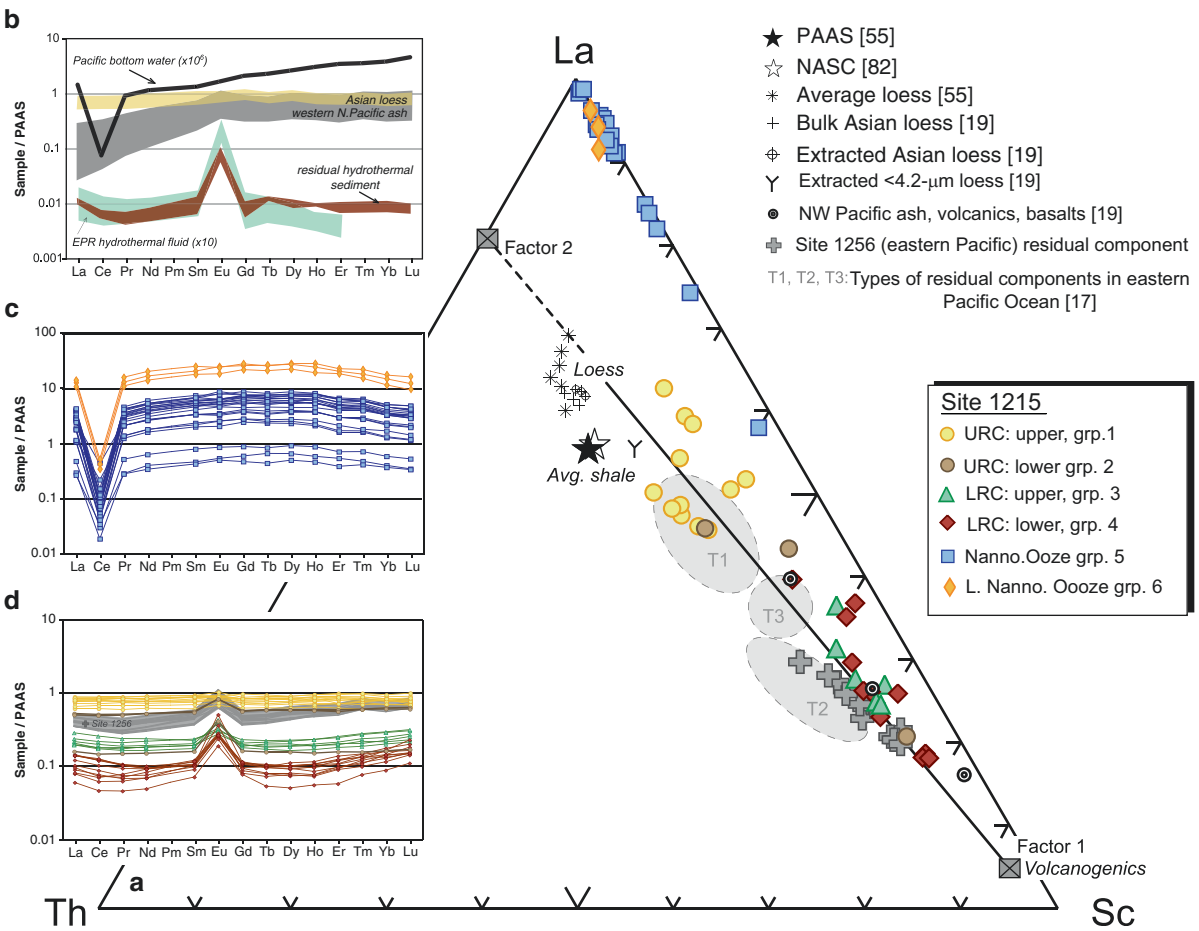
There are a few other mechanisms by which aluminosilicates can be transported to the ocean floor. Rivers transport sediment and deposit it near where a river connects to the ocean. Although confined relatively to the coast, riverine deposits

can be extensive and are responsible for some of the thickest deposits of marine sediment (Fig. 2). Sediment and rocks can be frozen into an iceberg that breaks off from glaciers and floats out to sea. The icebergs can travel thousands of kilometers before they melt and release the sediment and rocks frozen inside into the ice to the bottom of the sea. The material deposited by this mechanism is commonly referred to as ice-rafted debris (IRD).

Turbidity currents can also transport or rework sediment on the seafloor. A turbidity current is a quick moving, downslope flow of sediment-laden water. These flows can be triggered when a sediment deposit on a slope becomes too steep, or when a seismic tremor or storm causes the deposit to become unstable and flow downhill.

Identifying Aluminosilicate Sediment Provenance

As discussed earlier, the common aluminosilicate nature of volcanic ash and dust means that they have similar major element composition, and differentiating between the two is challenging. However, there are distinct differences, particularly in the relative proportions of trace elements, that allow volcanic ash and non-ash terrigenous material to be geochemically distinguished from one another. For example, in the Caribbean Sea, average shale and discrete ash layers have similar Al concentrations; however, the Cr concentrations are ~110 ppm and <3 ppm respectively. Therefore, variations in the ratio Cr/Al measured in the sediment reveal the relative proportions of dust vs. ash mixed within the bulk sediment (Peters et al. 2000). Additionally, sample concentrations plotted on ternary diagrams (e.g., La-Sc-Th) and PAAS-normalized rare earth element (REE) patterns can be compared to reference material (Fig. 5b) and aid in determination of the sedimentary components. However, in complex systems, many aluminosilicate sources may be mixed to compose the bulk sediment. In such cases, multivariate statistical analyses can help differentiate and quantify the contributions



Marine Sediment, Fig. 5 (**a**) La-Sc-Th ternary diagram plotting samples from Site 1215 (central Pacific) and Site 1256 (eastern Pacific) as well as possible end-member compositions for comparison. (**b**) Reference rare earth element (REE) concentrations normalized to an average shale composition (PAAS). (**c**) REE concentrations normalized to PAAS of leached biogenic sediment at Site 1215. from many different aluminosilicate sources (e.g., Leinen and Pisias 1984; Pisias et al. 2013; Dunlea et al. 2015a; Scudder et al. 2016).

Biogenic Sediment

In the broadest sense, biogenic sediment results from the production, preservation, and diagenetic modification of minerals initially produced by either plants or animals. In addition to organic matter (C_{org}), the vast majority of this sediment is predominated by (i) calcareous shells and oozes precipitated as calcite (hexagonal $CaCO_3$) and/or aragonite (orthorhombic $CaCO_3$), and sometimes authigenically modified to aragonite or dolomite ($CaMg(CO_3)_2$; (ii) siliceous tests/frustrules and oozes (amorphous opal) that can be diagenetically changed into minerals in the opal to quartz series; and (iii) biogenic apatite (e.g., $Ca_{10}(PO_4,CO_3)_6F_2$).

Calcareous Deposits

Some microorganisms that live in seawater, including foraminifera, coccolithophores, pteropods, and others, produce calcareous tests and shells made of calcium carbonate mineral(s) ($CaCO_3$). When the skeletal remains are deposited deeper than a certain depth in the ocean (referred to as the carbonate compensation depth or CCD; Millero 2013), the calcareous shells of the microfossils dissolve (see "carbonate compensation depth" entry in this encyclopedia). If the seafloor is shallower than the CCD, the calcareous shells are more likely to be preserved, although respiration-driven dissolution (Emerson and Bender 1981; Emerson 1985) also plays an important role in carbonate preservation (or lack thereof). Thus, calcareous deposits are found in relatively shallower regions of the seafloor (the flanks of mid-ocean ridges) and below regions of high biogenic carbonate production (e.g., equatorial Pacific upwelling) where the rate of export flux to the seafloor is greater than the dissolution (Goldberg and Arrhenius 1958; Fig. 1). The mineralogy and chemistry of carbonate sediment is reviewed in more detail in Arvidson and Morse (2014).

Planktic and benthic foraminifera incorporate trace amounts of Sr and Mg into the lattice structure of their shells (tests). The incorporation of Mg into calcite is endothermic, and thus more Mg is incorporated into the crystal when the foraminifera are growing at higher temperatures (Lear et al. 2000). Therefore, a high Mg/Ca ratio implies a high temperature of formation, but the geochemical response to temperature can also be influenced by species-specific factors. Some calcareous organisms (e.g., coral aragonite) incorporate Sr into the mineral structure in trace amounts. The precise Sr/Ca ratio in the coral skeleton shows an inverse correlation with the temperature of the seawater at the time of its biomineralization (Rosenthal et al. 2004). Analyses of these Mg/Ca and Sr/Ca ratios in certain calcareous microfossils are used to reconstruct seawater temperatures in the past, but post-depositional recrystallization can affect the record.

Dolomite is a minor component observed in the seafloor sediment as nodules and layers created by diagenetic processes. While the creation of dolomite by substitution of Mg for Ca in calcite ($CaCO_3$) is chemically simple, the dynamics of dolomitization are still being understood. Studies have shown that dolomitization does not require the adjacent aqueous solutions to be supersaturated with respect to calcite or dolomite and that the conversion of dolomite to calcite is not a dissolution-precipitation reaction, but instead a detailed, fine-scale replacement of the pre-existing mineral phase (Merino and Canals 2011).

Siliceous Deposits

Siliceous deposits include sedimentary rocks such as bedded and nodular chert, as well as their diagenetic precursors of deep-sea oozes composed of diatoms, radiolaria, spicules, and silicoflagellates. Although chert accounts for much less than 5% of all sedimentary rocks, siliceous deposits are important components of modern deep-sea sediment in all ocean basins (Fig. 1) and are host to a variety of ore deposits on land (Hein 1987). Important mineralogical associations include barite and phosphorite (associated due to their common formation with siliceous oozes in regions of high biological productivity), as well as petroleum (e.g., Monterey Formation of California, USA; Garrison et al. 1981), uranium, and banded iron formations (e.g., Trendall and Morris 1983). The formation and diagenesis of siliceous deposits is reviewed in further detail in DeMaster (2014).

The mineralogy and preservation of biogenic silica deposits are controlled by diagenetic reactions. Amorphous biogenic silica (opal-A) is secreted by the given plant (e.g., diatom) or animal (e.g., radiolarian) organism. Due to the undersaturation of seawater with respect to opal, the vast majority of the opal-A material dissolves on or within the uppermost centimeters of the seafloor. Preservation of opal-A reaches maximum values of 15–20% in regions of elevated productivity (e.g., McManus et al. 1995), with more typical values being $\leq$10% (e.g., Archer et al. 1993). During burial, continued dissolution of opal-A, and eventual precipitation of disordered cristobalite/tridymite (opal-CT), is both thermodynamically and kinetically regulated (e.g., Williams and Crerar 1985; Meister et al. 2014). Through this process, as well as through the final diagenetic transition from opal-CT to biogenic quartz, the composition of the host sediment plays an important role, with various factors such as the amount of clay or organic material influencing diagenetic rates of formation (e.g., Kastner et al. 1977; Isaacs 1982; Hinman 1990; Bohrmann et al. 1994; Tanner et al. 2013). These diagenetic transformations also profoundly affect the final chemical composition of the resultant chert, primarily due to the

addition of silica as a diluent and associated removal of other elements (e.g., Ca Sr, P, plus others) (Brueckner and Snyder 1985; Murray 1994; Dong et al. 2015). Although there are notable stratigraphic contrasts between bedded and nodular cherts (e.g., Jenkyns and Winterer 1982; Wang et al. 2009), the chemical processes acting during their diagenetic formation are very similar (Tada 1991; Murray et al. 1992).

Biogenic Apatite

Calcium phosphate minerals are a minor component in sediment but if they become concentrated can have a significant effect on the Ca and P concentrations on the bulk sediment in which they are mixed (Ruttenberg 2014). Mineral phosphate is incorporated in marine sediment primarily in the form of authigenic carbonate fluorapatite (CFA) (e.g., $Ca_{10}(PO_4, CO_3)_6F_2$). CFA is a major component of the hard parts of marine fish, such as scales, bones, and teeth, which are deposited in the seafloor. Additionally, diagenesis of P-bearing phases in marine sediment and P exchange with porewater can lead to the authigenic formation of CFA (Ruttenberg and Berner 1993; Filippelli 2011).

Organic matter is generally the primary source of P to marine sediment (Froelich et al. 1982). Of the organic matter, and thus P, in marine sediment, most is deposited in continental margins (Berner 1982). However, in slowly accumulating sediment (such as the center of ocean gyres), the long seawater exposure time allows rare earth elements and other trace elements to be incorporated into the phosphate mineral structure, enriching the average sediment composition in these trace and rare earth elements (Takebe 2005). Therefore, extremely slowly accumulating sediment can concentrate apatite because no other sediment types are diluting the deposition of apatite (e.g., Zhou and Kyte 1992). Even if apatite is still a relatively small component of the pelagic clay (~2–10%), it can strongly influence or even control Ca and P concentrations of the bulk sediment where no calcareous deposits occur (Dunlea et al. 2015a).

Organic Material and Redox-Sensitive Elements

Organic material is often deposited with the biogenic material described above and can affect the geochemical composition of sediment. In the center of ocean gyres, organic material is barely detectable in the sediment. Higher concentrations of elements from organic material (e.g., C, N, P) occur in marine sediment near the coasts and beneath regions of high surface productivity. Oxygen in the bottom water or porewaters will degrade the organic material via oxidation. When organic matter is buried deeper and all of the oxygen is consumed, other inorganic chemical species will begin to degrade the organic material. These reactions and changing redox states cause certain elements to become mobile and will diffuse through the porewaters until they reach a redox state where they return to the solid phase. Redox-sensitive elements (e.g., Fe, Mn, Mo, V, U) can become depleted or concentrated in marine sediment depending on the redox state of the surrounding porewaters.

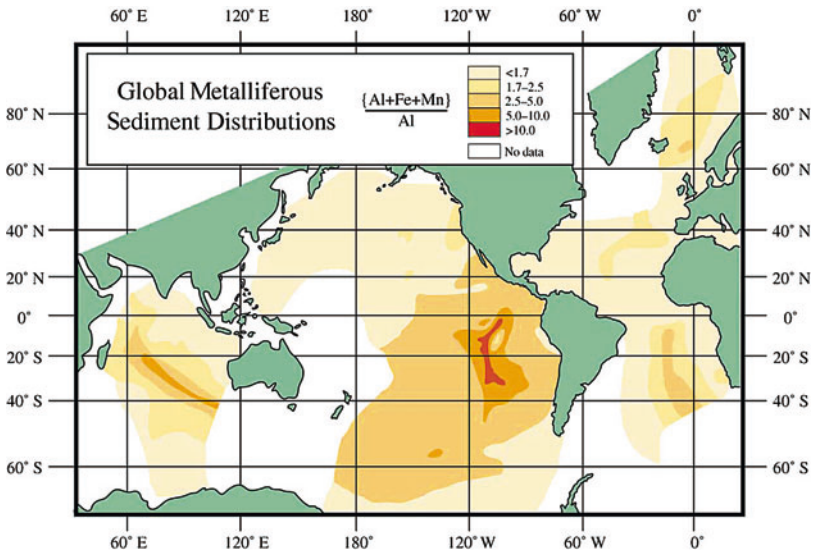
Metalliferous Sediment

Sediment can become enriched in metals near mid-ocean ridges due to precipitates from a hydrothermal plume but also further from the ridge when sedimentation rates are slow enough to scavenge and concentrate metals from the water column (Boström and Peterson 1969; Gurvich 2006). The hydrothermal fluids of the vent system are greatly enriched in Fe, Mn, Cu, Zn, Ni, and other elements (Von Damm et al. 1985; Elderfield and Schultz 1996). Hydrothermal fluids enriched in metals react with ambient seawater and are primarily deposited on the crest and flank of the ridges (Fig. 6). There, they may undergo additional reactions on or within the sediment to form "hydrothermal" metalliferous sediment, enriched in those elements and others as well (e.g., Dymond 1981).

Further from the ridge, metals in the seawater (from dispersed hydrothermal plumes or weathered from continents) can be deposited with, adsorbed onto, or incorporated into sediment as Fe/Mn-oxyhydroxide micronodules or coatings on existing grains. As accumulation rates decrease, the longer seawater exposure time allows metals to be increasingly scavenged from seawater onto sediment or onto sinking particles that continually form metalliferous sediment (Ruhlin and Owen 1986; Dunlea et al. 2015a). This "hydrogenous" (also referred to as "hydrogenetic" or "diagenetic" by some researchers) metalliferous sediment accumulating further from MORs is enriched in different metals (e.g., Co, Ni, REEs) than "hydrothermal" metalliferous sediment, in addition to Fe and Mn (Marchig and Erzinger 1986; Ruhlin and Owen 1986; Li and Schoonmaker 2014).

Since the dissolved constituents of chemical species derived from hydrothermal plumes can travel thousands of kilometers away from the mid-ocean ridge (e.g., Fitzsimmons et al. 2014; Resing et al. 2015), they are the source of some metals enriched in the "hydrogenous" sediment. Thus, there is no exact distinction between these two types of metalliferous sediment, and it is more informative to recognize the spatial gradient between the two. In general, the maximum influence of hydrothermal input occurs in the axial zone of the source ridge, with a gradual decrease at distances away from the axis (Lyle 1986). Ancient non-lithified and lithified analogues of metalliferous sediment that accumulated in paleoceans and paleoseas occur on the continents and islands within ophiolite belts (e.g., Murray et al. 1990 1991).

In addition to concentrating certain trace elements, authigenic aluminosilicate formation has been documented in high-temperature hydrothermal vent fluids (e.g., Cole and

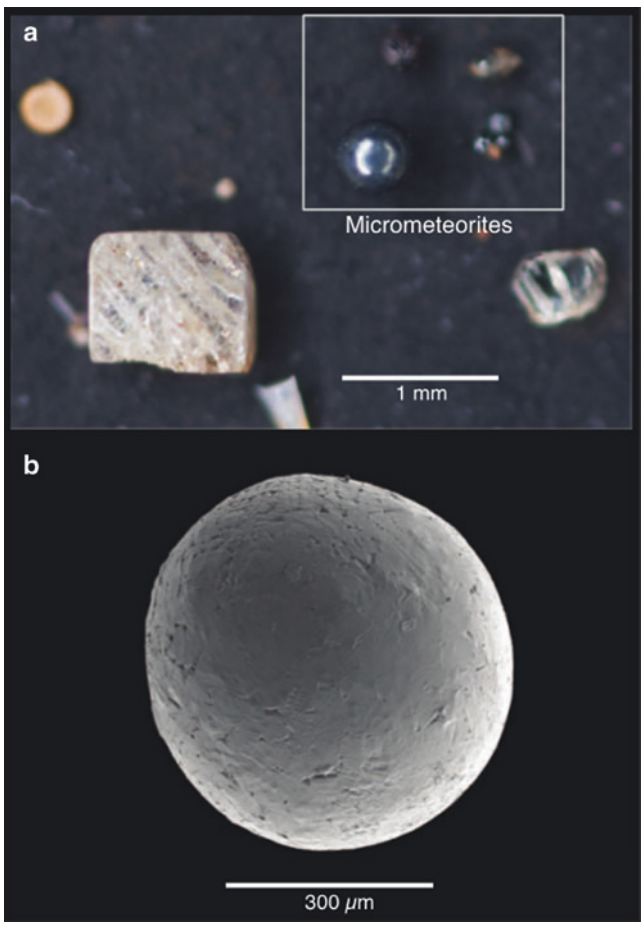


Marine Sediment, Fig. 6 Map of (Al + Fe + Mn)/Al for seafloor marine sediment depicting the global distribution of metalliferous sediment. The highest concentrations of Fe and Mn relative to Al occur near mid-ocean ridge axes (From German and Seyfield 2014)

Shaw 1983), and low-temperature hydrothermal-rich sediment (e.g., Cole 1985; Cuadros et al. 2011). Although Mg is absent in pure hydrothermal fluids (Elderfield and Schultz 1996), reactions with ambient seawater can cause these authigenic aluminosilicates to be enriched in Mg and may be a significant sink for Mg in the ocean (Cuadros et al. 2011). Authigenic aluminosilicates in sediment can also form from the alteration or erosion of basalt (Haymon and Kastner 1986). The sediment formed from basalt alteration will have some refractory element proportions similar to the original basalt, but other elements will be enriched or depleted during the alteration.

Minor Metal Contributions from Cosmic Dust

Between 5 and 270 metric tons of cosmic dust (or micrometeorites) are accreted to Earth everyday (Plane 2012). The main sources of cosmic dust are collisions between asteroids and the sublimation of comets as they approach the sun on their orbits through the solar system. Micrometeorites were first identified in marine sediment during the *HMS Challenger* scientific expedition in 1873–1876 when they isolated extraterrestrial spherules by their magnetic properties (Murray and Renard 1883). The composition of average meteorites and chondrites is enriched in Fe, Ni, Cu, and Co and is discussed in more detail in McDonough and Sun (1995). While the micrometeorites and spherules (e.g., Fig. 7) are more concentrated and easier to identify in slowly accumulating pelagic sediment and crusts (Millard and Finkelman 1970; Murrell et al. 1980; D'Hondt et al. 2011), they still are not significant enough to influence the element concentrations of the bulk sediment relative to other sources (Stuart and Lee 2012; Dunlea et al. 2015b).



Marine Sediment, Fig. 7 (**a**) Photomicrograph of micrometeorites isolated from South Pacific Gyre pelagic clay sediment, IODP Expedition 329, Site U1365. (**b**) Scanning electron microscope image showing surface details of the larger micrometeorite in (a) (From D'Hondt et al. 2011)

Summary

Marine sediment is compositionally diverse. From the geochemical perspective, sediment is most commonly classified according to the origin of the material(s) composing the bulk sediment, with end-members being referred to as aluminosilicate, biogenic, or metalliferous. Most deep-sea sediment is a mixture of these three main components. The aluminosilicate (s) in marine sediment can be provided by volcanism (eruptions of igneous material) and terrigenous sources (erosion of upper crustal rocks). Biogenic sediment (calcareous, siliceous, apatite) is initially produced by either plants or animals. Metalliferous sediment most commonly results from exhalative processes along mid-ocean ridges and/or uptake of dissolved metals from seawater. Extraterrestrial debris contributes a trace amount of metal-rich material as well. The distributions of each of these sediment types are controlled by wind, ocean circulation, and water depth that collectively affect the transport, deposition, and preservation of each sediment type. For all sediment, regardless of initial composition, postdepositional processes (authigenesis or diagenesis) cause geochemical changes based on how the sediment interacts with the surrounding environment in which it is deposited.

Mass Transfer

Peter C. Lichtner
OFM Research—Southwest, Santa Fe, NM, USA

Definition

Mass transfer involves the movement of matter from one location to another or from one phase to another, through the processes of advection, diffusion, dispersion, and chemical reaction (Lichtner 1996). For many applications in geochemistry, a porous medium must be considered which consists of voids filled with liquid and gas and a solid framework made up of aggregates of mineral grains. To describe such systems mathematically, the concept of a continuum is used in which the properties of the system are assumed to vary continuously over space, with the possible exception of material discontinuities at boundaries. The existence of a representative elemental volume, or REV, which characterizes the system locally is assumed. The REV is large compared to grain and pore sizes so that it is possible to define meaningful average quantities but small compared to variations in the fundamental variables describing the system, such as temperature, pressure, and solute concentration. It should be noted that the continuum formulation does not account for the distribution of solids and pore geometry within a REV.

Diffusive Flux

Diffusive mass transfer takes place in response to a gradient in concentration, or more generally chemical potential, according to Fick's law which in a pure phase has the form

$$\vec{J}_i = -D\vec{\nabla}C_i, \tag{1}$$

for the ith chemical constituent with concentration C_i, where D is the diffusion coefficient and where the gradient operator $\vec{\nabla}$ is defined as $\vec{\nabla} = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$. Thus, for example, the x-component of the flux describes diffusion along the x-axis according to

$$(J_i)_x = -D\frac{\partial C_i}{\partial x}. \tag{2}$$

The diffusion coefficient is actually species dependent; however, this leads to a rather complicated description with the introduction of an electric field to enforce charge balance in the case of diffusion of cations and anions (Haase 1969; Lichtner 1985; Lichtner 1996).

In a porous medium, the diffusive flux within a pore volume is related to the bulk flux by

$$A_{\text{pore}}J_{\text{pore}} = AJ, \tag{3}$$

where J denotes the bulk diffusive flux and J_{pore} the diffusive flux through the pore space. It follows that

$$J = \frac{A_{\text{pore}}}{A}J_{\text{pore}}. \tag{4}$$

It is generally assumed that the areal porosity is equal to the volumetric porosity

$$\varphi = \frac{A_{\text{pore}}}{A} = \frac{V_{\text{pore}}}{V}, \tag{5}$$

where A_{pore} and V_{pore} denote the cross-sectional pore area and pore volume, respectively, with bulk area A and volume V. In addition, the diffusive flux in a porous medium is modified by the tortuosity τ representing the length of a fluid pathway between two points compared to a straight line. The diffusive flux in a porous medium then becomes

$$\vec{J}_i = -\varphi\tau D\,\vec{\nabla}C_i. \tag{6}$$

The tortuosity is also considered to be a function of porosity through various empirical constitutive relations.

Another mass transfer process occurring in porous media is dispersion typically described as a Fickian-like process but requiring a dispersion tensor (Bear and Cheng 2010). The tensorial property accounts for dispersive mass transfer along and perpendicular to the direction of flow as opposed to the coordinate axes. However, there is evidence that the process is not Fickian (see Bear and Cheng (2010) for more details).

Advective Flux

Advective transport describes the movement of some quantity via the bulk fluid flow, for example, flow through a pipe, column filled with sand, or a river. For flow in a porous

medium, Darcy's law is used in which the volumetric flow rate q, a vector, is given by in the absence of gravity

$$\vec{q} = -\frac{k}{\mu}\vec{\nabla} p, \tag{7}$$

proportional to the rock permeability k and pressure gradient $\vec{\nabla} p$ and inversely proportional to the fluid viscosity μ. The advective flux of the ith constituent has the form

$$\vec{F}_i = \vec{q}\, C_i. \tag{8}$$

The Darcy velocity is related to the average pore velocity $\vec{v}$ through the porosity φ

$$\vec{v} = \frac{\vec{q}}{\varphi}. \tag{9}$$

Chemical Reactions

Chemical reactions describe mass transfer within a single phase (homogeneous reactions) or between two or more phases (heterogeneous reactions). This form of mass transfer may be formulated in various representations. For homogeneous reactions mass transfer is described through a reaction rate Γ_r of the rth reaction that can be written in the general form

$$\varnothing \rightleftharpoons \sum_i \nu_{ir} A_i, \tag{10}$$

with stoichiometric coefficients ν_{ir}, dimensionless constants giving the number of moles of the ith chemical constituent in the rth reaction and assigned as positive for products, negative for reactants as the reaction proceeds from left to right, and zero if the species does not occur in the reaction. The reaction rate is defined by

$$\frac{1}{\nu_{ir}}\frac{dC_i}{dt} = \Gamma_r, \quad \nu_{ir} \neq 0, \tag{11}$$

and is the same for all species involved in the reaction.

For heterogeneous reactions, however, involving more than one phase the situation is much more complicated (Lichtner 2016). One approach is to treat heterogeneous reactions in the same manner as a homogeneous reaction through the use of the mineral-specific surface area—area per unit volume—and this is the approach taken in what follows. The rate is then averaged over a REV. An alternative, but more complex approach, is to impose boundary conditions at the liquid–solid interface which equates the reaction rate at the surface to the solute flux. Such an approach is used in pore-scale models.

Reaction rates may be calculated either by specifying a kinetic rate law or assuming conditions of local equilibrium and imposing law of mass action constraints to calculate the rate. In the case of mineral reactions, the latter assumption leads to the formation of chemical shock fronts.

The reaction rate for local chemical equilibrium Γ_r^{leq} is obtained in the limit as the kinetic rate constant approaches infinity. A typical rate expression corresponding to Eq. 10 has the form

$$\Gamma_r = k_r\left(1 - \frac{Qr}{K_r}\right), \tag{12}$$

with activity product

$$Q_r = \prod a_i^{\nu_{ir}}. \tag{13}$$

For a finite rate constant k_r, equilibrium is achieved when

$$K_r = Q_r, \tag{14}$$

which implies the reaction rate is zero. However, direct calculation in the limit $k_r \to \infty$ gives the indeterminate result

$$\Gamma_r^{\text{leq}} = \lim_{k_r \to \infty} \Gamma_r \to \infty \times 0 \tag{15}$$

To obtain the actual value for the local equilibrium rate, it is necessary to solve the reactive transport equations constrained by the corresponding algebraic mass action relations given by Eq. 14.

Mass Conservation

From the constituent fluxes for diffusion, advection, and reaction, mass conservation equations can be derived. Given a finite bulk volume V of a porous medium with porosity φ, the change in the number of constituents inside the volume can be related to the constituents entering and leaving the volume and their internal generation and consumption by the conservation equation

$$\frac{d}{dt}\int_V \varphi C_i dV = -\int_S \left(\vec{F}_i + \vec{J}_i\right).\, \vec{n}\, dS + \int_V \Gamma_{id} V, \tag{16}$$

where S denotes the surface of the volume V, $\vec{n}$ denotes the unit normal to the surface, and Γ_i represents the reaction rate or source/sink term, which, for example, could be associated with the presence of a well. The minus sign multiplying the surface integral occurs because the flux of matter flowing out of the volume is taken to be positive.

The finite volume conservation equation can be converted into a local conservation equation (meaning at a point $\vec{r}$ in

space) by making use of Gauss' equation. This equation states that the integral of the divergence of a vector field over a finite volume is equal to the integral over its surface according to the equation

$$\int_S \vec{U} \cdot \vec{n}\, dS = \int_V \vec{\nabla} \cdot \vec{U}\, dV \tag{17}$$

Applying Gauss' equation to the finite volume conservation equation enables the surface integral to be converted to a volume integral

$$\int_S \left(\vec{F}_i + \vec{J}_i\right) \cdot \vec{n}\, dS = \int_V \vec{\nabla} \cdot \left(\vec{F}_i + \vec{J}_i\right) dV \tag{18}$$

Substituting this relation back into Eq. 16 and collecting all terms inside the volume integral then yields

$$\int_V \left\{ \frac{\partial}{\partial t} \varphi C_i + \vec{\nabla} \cdot \left(\vec{F}_i + \vec{J}_i\right) - \Gamma_i \right\} dV = 0. \tag{19}$$

Since the volume is completely arbitrary, in order for the integral to vanish identically, it is necessary that the integrand vanishes leading to the local conservation equation

$$\frac{\partial}{\partial t} \varphi C_i + \vec{\nabla} \cdot \left(\vec{F}_i + \vec{J}_i\right) = \Gamma_i. \tag{20}$$

This is a partial differential equation representation of the finite volume conservation equation for the *i*th constituent. The equation relates the change in concentration at a point in space based on a continuum representation of a porous medium to the divergence of the flux and generation rate at that point. For immobile species such as minerals, the flux terms are zero.

To fully describe the coupling between the various properties caused by changes in material properties such as porosity, tortuosity, permeability, and others due to chemical reactions, additional constitutive relations are required that have not been discussed here. These constitutive equations can result in reaction instabilities, for example, producing such effects as wormhole dissolution patterns. However, they are empirical relations that are not well understood. Mineral surface and its change with reaction is one such relation that is very difficult to quantify.

Applications

There are numerous applications of the reactive transport equations to various problems both at laboratory and field scales. These include nuclear waste disposal, geothermal energy, biogeochemical processes, and issues related to climate change such as permafrost degradation.

Geochemical processes such as contaminant migration including colloid-facilitated transport and colloid filtration, karst formation, interaction between soil and atmosphere in climate modeling, geochemical weathering (Moore et al. 2012), and many others have been described with the aid of reactive transport equations (Appelo and Postma 1993; Steefel et al. 2005).

Recently, reactive transport equations have been applied to a wide spectrum of diverse processes including colloid-facilitated transport of sulfonamides in groundwater arising from dissolved organic matter (Zhou et al. 2016).

Finally, the single continuum formulation can be extended to multiple interacting continua to account for fractured porous media characterized by a bimodal distribution in material properties corresponding to fractures and the rock matrix (Lichtner and Karra 2014).

Because of a large number of equations that are necessary to solve simultaneously for large-scale multicomponent problems, complex computer codes have been developed to solve the reactive transport equations using massively parallel computing machines with hundreds of thousands of processor cores (Hammond and Lichtner 2010).

Summary

Mass transfer consists of contributions from advection, diffusion, and chemical reactions. These processes are coupled through mass conservation equations resulting in a system of generally nonlinear partial differential equations that must be solved numerically. The theory has been applied to a wide set of diverse problems in geochemical systems.

Element Data
Atomic Symbol: **Hg**
Atomic Number: **80**
Atomic Weight: 200.592 g/mol
Isotopes and abundances: ^{196}Hg 0.15%, ^{198}Hg 9.97%, ^{199}Hg 16.87%, ^{200}Hg 23.1%, ^{201}Hg 13.18%, ^{202}Hg 29.86%, ^{204}Hg 6.87%
1 Atm Melting Point: −38.85 °C
1 Atm Boiling Point: 356.66 °C
Common Valences: 0, 1+, 2+
Ionic Radii: 97 pm (3-fold, 1+), 119 pm (4-fold, 1+), 69 pm (2-fold, 2+), 96 pm (4-fold, 2+), 102 pm (6-fold, 2+), 114 pm (8-fold, 2+)
Pauling Electronegativity: 2.0
First Ionization Potential: 1007.1 kJ/mol
Chondritic (CI) Abundance: 13.6 mg/kg
Silicate Earth Abundance: 0.006 mg/kg
Crustal Abundance: 0.05 mg/kg
Seawater Abundance: 0.05×10^{-9} kg/L
Core Abundance: 0.05 mg/kg

Properties

Mercury is a metallic element that is liquid at room temperature, silver in color, and very dense. The metal occurs primarily as a sulfide (cinnabar) in the Earth's crust, a vapor in the Earth's atmosphere, and an aqueous complex with dissolved organic matter (DOM) in natural waters. Mercury forms amalgams with many other metals, including copper, lead, gold, and silver. Monomethylmercury (CH_3Hg^+ or MeHg), produced primarily by conversion of Hg^{2+} by anaerobic microbes, is toxic to human and ecological receptors.

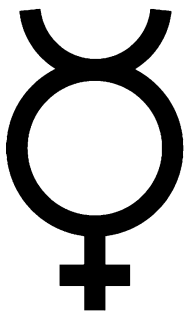
History and Use

Mercury is one of the seven metals known since antiquity, along with copper, gold, iron, lead, silver, and tin. Its name derives from the Roman god Mercurius, known for speed and mobility. The atomic symbol Hg is derived from the Greek *hydrargyrum* meaning water silver, in reference to its liquid nature and color at standard temperature and pressure. A common name for liquid, elemental mercury is quicksilver. The ancient, alchemical symbol for the element mercury (Fig. 1) is the same symbol used for the planet Mercury, the only such pairing.

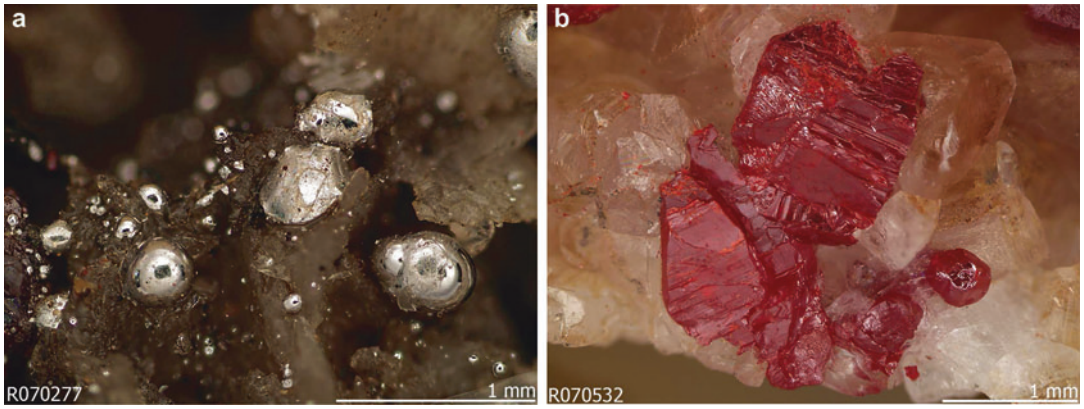
Ancient civilizations used mercury for ceremonial and symbolic purposes; large quantities of the pure liquid have been found in tombs in China, Egypt, and Central America. Alchemists tried for centuries to make precious metals from mercury and various forms of sulfur. The failure of these efforts helped lead to modern chemistry.

Large mercury mines at Almadén, Spain; Idrija, Slovenia; and Huancavelica, Peru accounted for most of global mercury production prior to 1850 CE. Between 1850 and 2000 CE, significant mercury production continued in Spain and Slovenia and also took place in the United States (primarily California), Italy, China, Mexico, and the former USSR (Hylander and Meili 2003).

Historically, mercury was used for recovery of gold and silver by amalgamation, since at least 500 BCE. Large-scale precious-metal mining operations phased out amalgamation in favor of cyanide extraction in the early 1900s; however, artisanal miners in many countries continue to use mercury (Telmer and Veiga 2009). Mining and mineral processing have contributed millions of kg of mercury to the environment, and mercury-contaminated landscapes continue to pose environmental challenges.



Mercury, Fig. 1 Alchemical symbol for mercury



Mercury, Fig. 2 Photographs of mercury minerals. (**a**) native mercury (Hg), RRUFF 070277, in massive and drusy quartz from the Socrates mine, Sonoma County, California, USA; (**b**) cinnabar (HgS), RRUFF 070532, on calcite from Caracas, San Luis Potosi, Mexico; from Hazen et al. (2012); used by permission from the Mineralogical Society of America and from RRUFF (Lafuente et al. 2015)

Other industrial uses of mercury have included pigment (vermillion), explosives (fulminate), medical, dental, agricultural (fungicide), electrical devices, measuring instruments, lighting, batteries, catalysts, paint, and chlor-alkali processing (Hylander and Meili 2005). Most of these industrial uses have been phased out, especially after information regarding mercury toxicity became widely known in the late 1960s.

Isotopes and Cosmochemistry

There are seven stable isotopes of mercury: ^{196}Hg, ^{198}Hg, ^{199}Hg, ^{200}Hg, ^{201}Hg, ^{202}Hg, and ^{204}Hg. Of 33 known radioisotopes, the two longest living are ^{194}Hg, with a half-life ($t_{½}$) of 444 yr, and ^{203}Hg ($t_{½} = 0.128$ yr).

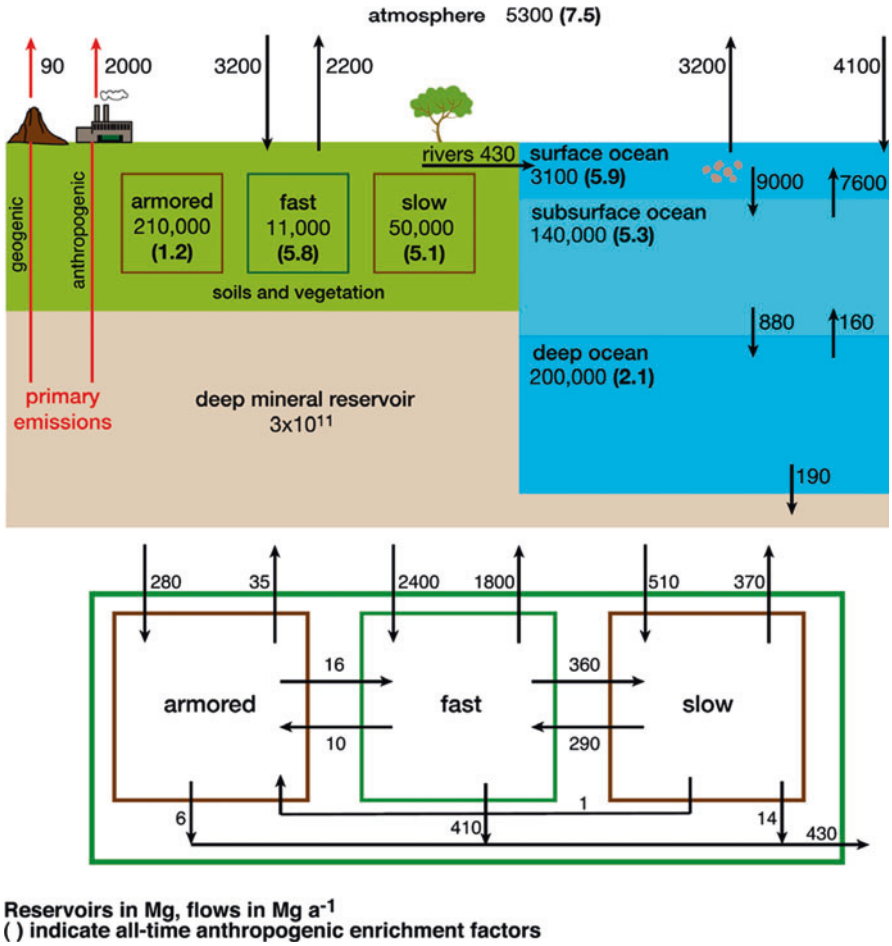
Stable isotopes of mercury are increasingly being used to trace mercury sources and biogeochemical processes in the environment (see *Mercury Isotopes*).

Mineralogy and Geochemistry

Based on Goldschmidt's classification, mercury is a chalcophile element. In minerals, mercury cations bond to oxygen, other chalcogenides (As, S, Sb, Se, and Te), and halides (Br, Cl, and I), as well as with arsenate, carbonate, phosphate, silicate, sulfate, and other anions (Hazen et al. 2012). The most common mercury minerals in the Earth's crust are cinnabar (α-HgS, rhombic) (Fig. 2), metacinnabar (β-HgS, cubic), and livingstonite ($HgSb_4S_8$, monoclinic); mercury also occurs in solid solution in sulfides (e.g., sphalerite, ZnS, cubic) and sulfosalts (e.g., tetrahedrite-tennantite, $(Cu,Fe)_{10}(Fe,Zn)_2(Sb,As)_4S_{13}$, cubic). As of 2012, there were 90 known minerals with mercury as an essential or important constituent (Hazen et al. 2012).

Because of its high volatility, mercury has low abundance in the solar photosphere and is greatly depleted in most meteorites (e.g., Allende CV chondrite) relative to CI chondrites, the most primitive meteorite class. Grains of HgS found in CM chondrites (Devouard et al. 1998) may have formed by aqueous alteration rather than directly from the solar nebula. Mercury may have been incorporated in meteorite parent bodies as a trace element in metal alloys, Fe-Ni sulfides, or as a chemisorbed species (Lauretta et al. 1999).

On Earth, the global mercury cycle features fluxes to the atmosphere and hydrosphere from natural sources including volcanoes, geothermal areas, forest fires, erosion, evasion from saline and fresh waterbodies, and soil degasification and also from anthropogenic sources including fossil-fuel combustion, chlor-alkali plants, mining, and other industrial pollution (Fig. 3). In the atmosphere, Hg^0 has an average residence time of about 6 months and is converted to Hg^{2+}, a more soluble form that is incorporated in precipitation and dry deposition (Fitzgerald and Lamborg 2014). Model results accounting for pre-1850 anthropogenic emissions (Amos et al. 2013) indicate that 57–60% of present-day deposition represents legacy anthropogenic mercury previously deposited and subsequently reemitted, ~26% is from primary anthropogenic emissions, and 13–17% is natural (Fig. 3). The largest anthropogenic Hg emissions in 2010 were from artisanal and small-scale gold mining (37%), coal burning (24%), nonferrous metal production (10%), and cement production (9%) (UNEP 2013). Releases of Hg to water are dominated by point sources from nonferrous metal production and consumer product waste, with smaller contributions from chlor-alkali plants and oil refining; nonpoint sources of Hg from contaminated sites are primarily from Hg and precious-metal mining sites (UNEP 2013).



Mercury, Fig. 3 Simulated present-day global Hg budget and all-time anthropogenic enrichments factors. Terrestrial-atmosphere exchange is given in the *top panel* for the sum of terrestrial reservoirs. The *bottom panel* shows the breakdown and cycling between the different terrestrial reservoirs. All terrestrial reservoirs receive inputs from Hg^{2+} deposition (fast = 800, slow = 510, and armored = 280 Mg yr^{-1}). The fast reservoir also receives inputs from Hg^0 deposition (1600 Mg yr^{-1}). All terrestrial reservoirs lose Hg through respiration (fast = 520, slow = 360, and armored = 30 Mg yr^{-1}) and biomass burning (fast = 320, slow = 9, and armored = 5 Mg yr^{-1}). Photoreduction from the fast terrestrial reservoir is 950 Mg yr^{-1} (From Amos et al. (2013); used by permission from John Wiley and Sons and the American Geophysical Union)

Aqueous Behavior

According to hard and soft acids and bases theory, Hg^{2+} is a soft cation, which has stronger binding affinity with soft anions relative to hard anions ($SeH^- > SH^- > OH^- > Br^- > Cl^- > F^-$, Riccardi et al. 2013). In natural waters, dissolved Hg^{2+} has a strong affinity for DOM. Laboratory experiments (Haitzer et al. 2002, 2003) and spectroscopic studies using extended X-ray absorption fine structure (Xia et al. 1999) have demonstrated that aqueous Hg^{2+} binds strongly to thiol/sulfhydryl (SH^-) groups on DOM. In surface waters carrying suspended sediment, inorganic mercury transport is dominated by particulates, which reach highest concentration during high-flow conditions.

Some microbes convert Hg^{2+} to MeHg, typically at anoxic to sub-oxic conditions in the water column or in shallow sediments of lakes, reservoirs, stream channels, floodplains, estuaries, and the oceans. Sulfate-reducing bacteria and iron-reducing bacteria are considered the primary agents in microbial methylation of Hg^{2+} (Gilmour et al. 1992; Ullrich et al. 2001; Fleming et al. 2006; Kerin et al. 2006).

The genetic basis for microbial methylation of Hg^{2+} was discovered by Parks et al. (2013); a corrinoid acts as a methyl carrier, and Fe-S proteins are electron donors for corrinoid cofactor reduction. Abiotic methylation of Hg^{2+} also occurs by reaction with humic matter (Weber 1993) or acetic acid (Gårdfeldt et al. 2003), and by sunlight-mediated Hg^{2+}-DOM interactions (Siciliano et al. 2005), but is considered to be minor compared with net microbial methylation in most environments (Ullrich et al. 2001). Nanoparticles of HgS may be bioavailable to Hg-methylating bacteria (Zhang et al. 2014) and may be stabilized against aggregation by DOM (Graham et al. 2012).

The net rate of Hg^{2+} methylation is the difference between rates of Hg^{2+} methylation and MeHg degradation (demethylation), which also takes place by both biotic and abiotic pathways. Microbial pathways of demethylation include reductive demethylation (producing CH_4) and oxidative demethylation (producing CO_2). The reductive demethylation pathway typically results in reduction of Hg^{2+} to Hg^0, whereas the oxidative pathway liberates Hg^{2+} that is available for re-methylation. Abiotic degradation of MeHg occurs by exposure to UV radiation.

The chemical speciation of Hg^{2+} influences its availability for methylation. Speciation of Hg^{2+} has been determined by pyrolysis (Biester and Nehrke 1997), selective extraction

(Bloom et al. 2003), and EXAFS (Kim et al. 2003). Experiments with mercury stable isotope tracers (Jonsson et al. 2012) have determined the following order of availability for methylation: aqueous Hg^{2+} > Hg^{2+}-NOM (natural organic matter) > Hg^{2+}-FeS (mackinawite) > α-HgS (cinnabar) > β-HgS (metacinnabar). Methylation of Hg^{2+} and exposure of aquatic organisms to MeHg may be disconnected spatially or temporally because of transport controls (Jonsson et al. 2014; Eagles-Smith et al. 2016).

Biological Utilization and Toxicity

Most research has indicated that mercury has no beneficial function and is toxic to all forms of life to varying degrees, depending on its chemical form. Recent findings suggest a possible physiological role for Hg^{2+} in bacteria, whose phototropic growth rate increased with increasing Hg^{2+} concentration (Grégoire and Poulain 2016).

In humans, MeHg is a neurotoxin that crosses the blood-brain barrier. At highest risk for health problems related to MeHg exposure are children under 18 and developing fetuses. Symptoms from severe exposure to MeHg (Minamata disease) include ataxia (loss of muscle control), numbness in extremities, sensory loss, speech impairment, and tremors; in infants with fetal exposure, symptoms include growth and developmental problems, mental retardation, microcephaly, and seizures (Harada 1995; Harada et al. 2005). Chronic exposure to lower levels of methylmercury (the "lesser Minamata" profile) is associated with dizziness; dysesthesia; fatigue; hair loss; hand and leg tremor; gastrointestinal upset; headache; insomnia; memory loss; metallic taste; nausea; pain in joints, back, or chest; staggering; and trouble thinking or preforming complex tasks (Fukuda et al. 1999; Hightower 2009). The principal pathway to human exposure is consumption of high-trophic-level fish with elevated methylmercury concentrations. Mercury fish consumption advisories in 49 of 50 states in the USA recommend limited or no consumption of Hg-contaminated fish, with more restrictive recommendations for more sensitive groups.

Dimethylmercury ($(CH_3)_2Hg$), which exists in pure form as a liquid with high vapor pressure, is even more neurotoxic to humans than monomethylmercury. The death of a researcher from a single exposure to "one to several drops" of dimethylmercury that permeated through a latex glove (Nierenberg et al. 1998) led to improved guidelines for safe handling (OSHA 1998).

Inhalation of mercury vapor can produce harmful effects on the human kidneys, lungs, and digestive, immune, and nervous systems and can be fatal. In the late 1800s, hatmakers who used mercury to create felt from animal hairs were exposed to mercury vapors leading to "mad hatter's" syndrome, also known as "the Danbury shakes" (Bigham et al. 2005). In addition to being neurotoxic, inorganic Hg^{2+} is nephrotoxic (kidneys), hematotoxic (blood), and genotoxic (DNA).

Ecological effects of MeHg have been documented in birds, fish, and mammals (Scheuhammer et al. 2007). Chronic effects include reproductive impairment. The primary pathway to ecological MeHg exposure is diet. MeHg biomagnifies by three- to fivefold per step in aquatic food webs, concentrating in proteins as cysteine complexes. Bioaccumulation factors (ratio of MeHg in organism to water) range from ~10^3 in phytoplankton to ~10^7 in predatory fish.

Summary

Mercury is a trace element that is concentrated in hydrothermal mineral deposits and active geothermal systems. It has a strong affinity for reduced sulfur, occurring primarily in sulfide minerals and as aqueous complexes with thiol functional groups on natural organic matter. Mercury has no known beneficial function in higher organisms and is differentially toxic depending on its speciation. Monomethylmercury, a potent neurotoxin, is readily bioaccumulated and biomagnifies with increasing trophic level in food webs. Mercury had many industrial uses historically, but most have been phased out because of toxicity concerns. Legacy sources of mercury from historical mining and other anthropogenic activity persist in many areas, and global mercury pollution continues from fossil-fuel combustion, affecting human health and ecosystems.

Mercury Isotopes

Bridget A. Bergquist
Department of Earth Sciences, University of Toronto, Toronto, ON, Canada

Introduction

Mercury is a globally distributed pollutant that bioaccumulates in aquatic food webs, leading to dangerous exposure in humans and wildlife (Driscoll et al. 2013; Fitzgerald and Lamborg 2014). Despite decades of research, there are still knowledge gaps that hinder the understanding of both the modern and past Hg cycle and make it challenging to predict how changes in emissions and climate will affect the Hg cycle (Amos et al. 2013; Fitzgerald and Lamborg 2014; Amos et al. 2015). A rapidly growing tool to study Hg is Hg stable isotope geochemistry, which was largely driven by the discovery of large mass independent fractionation (MIF) of Hg isotopes both experimentally and in nature (Buchachenko et al. 2004; Bergquist and Blum 2007; Buchachenko et al. 2007). Hg is unique in that it exhibits several types of stable isotopic fractionation including conventional mass-dependent fractionation (MDF) and at least three types of MIF. Although Hg isotope geochemistry is a young field, both MDF and MIF signatures are already being used to successfully trace sources, quantify certain transformations of Hg, and understand bioaccumulation of Hg in the environment (see reviews: Bergquist and Blum 2009; Hintelmann 2012; Blum et al. 2014). Hg isotopes are also being developed as proxies of large volcanic inputs and other environmental changes in the geologic record (Grasby et al. 2016; Thibodeau and Bergquist 2016; Thibodeau et al. 2016).

Methods and Nomenclature

There are seven stable isotopes of Hg that undergo isotopic fractionation in nature: ^{196}Hg (0.15%), ^{198}Hg (9.97%), ^{199}Hg (16.87%), ^{200}Hg (23.1%), ^{201}Hg (13.18%), ^{202}Hg (29.86%), and ^{204}Hg (6.87%). All are measured simultaneously with high precision by cold vapor multicollector inductively coupled plasma mass spectrometry (CV-MC-ICPMS). Most methods introduce Hg to the mass spectrometer as Hg^0 vapor after reduction of Hg^{2+} in a solution, with the Hg^0vapor being stripped from the solution on a gas-liquid separator (Lauretta et al. 2001). One of the largest challenges with making accurate and high precision measurements by MC-ICPMS is that the instrument itself induces large instrumental mass fractionation, which is sensitive to sample matrix that needs to be corrected in order to obtain the natural isotopic composition of a sample. Blum and Johnson (2017) recently reviewed the state-of-the-art techniques and difficulties associated with Hg isotope measurements. In brief, the highest quality measurements quantitatively separate and purify Hg from complex matrices and use both strict sample-standard bracketing and a thallium internal monitor to correct for instrumental mass bias.

Hg isotopic values are reported using conventional delta notation (δ) as per mil (‰) deviations from the NIST 3133 reference material (Eq. 1) (Blum and Bergquist 2007).

$$\delta^{xxx}\mathrm{Hg} = \left[\left(^{xxx}\mathrm{Hg}/^{198}\mathrm{Hg}\right)_{\mathrm{sample}} / \left(^{xxx}\mathrm{Hg}/^{198}\mathrm{Hg}\right)_{\mathrm{NIST3133}} - 1\right] \times 1000 \quad (1)$$

where xxx is the mass of the Hg isotope (^{199}Hg, ^{200}Hg, ^{201}Hg, ^{202}Hg, ^{204}Hg). Most groups use the ^{202}Hg/^{198}Hg ratio (i.e., δ^{202}Hg) to report MDF.

MIF values of Hg are reported using capital delta notation (Δ) also in units of per mil (‰), which is the deviation in the measured isotope ratios from the theoretically predicted isotope ratios by MDF (Eqs. 2, 3, 4, and 5). Typically, kinetic MDF laws (Young et al. 2002) are used to estimate MIF unless authors are confident that equilibrium conditions existed in their study.

$$\Delta^{199}\mathrm{Hg} = \delta^{199}\mathrm{Hg} - \left(0.2520 \times \delta^{202}\mathrm{Hg}\right) \quad (2)$$

$$\Delta^{200}\mathrm{Hg} = \delta^{200}\mathrm{Hg} - \left(0.5024 \times \delta^{202}\mathrm{Hg}\right) \quad (3)$$

$$\Delta^{201}\mathrm{Hg} = \delta^{201}\mathrm{Hg} - \left(0.7520 \times \delta^{202}\mathrm{Hg}\right) \quad (4)$$

$$\Delta^{204}\mathrm{Hg} = \delta^{204}\mathrm{Hg} - \left(1.4930 \times \delta^{202}\mathrm{Hg}\right) \quad (5)$$

Mechanisms of Hg Isotope Fractionation

Much like the traditional stable isotope systems (i.e., C, O, S, H, N), Hg MDF is ubiquitous in nature and occurs during abiotic and biological redox, speciation, and phase changes. MDF occurs because atoms with different masses affect the vibrational energies and activation energies of molecules and their bonds as well as molecular and atomic velocities and diffusivity (Bigeleisen and Mayer 1947; Urey 1947; Bigeleisen 1949; Schauble 2004). Kinetic and equilibrium reactions follow MDF laws, and the relationships between the different isotopic ratios can be predicted using atomic masses.

In addition to MDF, Hg isotopes also exhibit a 10‰ range in MIF in natural samples (Blum et al. 2014). Unlike Hg MDF, large Hg MIF is thought only to occur in photochemical reactions, with different photochemical reactions displaying unique patterns of MIF for different isotopes of Hg. Because MIF signatures are only affected by a limited number of reactions, the extent and ratio of MIF from different isotopes is often preserved and can be used as a reliable tracer of different sources when the sources have different MIF signatures. At present, three different types of MIF are observed for Hg isotopes including (1) large odd-mass Hg MIF (odd-MIF) caused by magnetic isotope effect (MIE) during aqueous and heterogeneous surface photochemistry, (2) small odd-MIF caused by nuclear volume effect (NVE), and (3) even-mass Hg MIF (even-MIF) that is thought to occur during atmospheric photochemical gas phase reactions.

The largest Hg MIF is produced by the MIE, which occurs during kinetic reactions containing radical pair intermediates (Turro 1983; Buchachenko 2001). In particular during photochemical reactions, the MIE can change the rate of reactions for the odd Hg isotopes relative to the even isotopes because of their nonzero nuclear spin and nuclear magnetic moments, which interact with the magnetic moments of unpaired electrons. In addition, the radical pair intermediate must be long lived enough for the MIE to be expressed. Thus, the MIE is observed in aqueous or heterogeneous photochemical reactions, and not gas phase photochemical reactions, because the MIE requires a solvent cage (e.g., water) to extend the lifetime of the radical pair so that MIE can compete with dissociation into free radicals.

The other odd-MIF mechanism for Hg is the NVE, which is also referred to as the nuclear field shift effect, and results in smaller MIF for Hg (less than 0.5‰) (Estrade et al. 2009; Zheng and Hintelmann 2010; Ghosh et al. 2013). The NVE is only observed for heavier elements and arises due to nuclear volumes and charge radii not scaling linearly with mass when isotopes get bigger (Bigeleisen 1996; Schauble 2007). Even-odd differences arise because odd isotopes have nuclear charge radii that are smaller than what would be predicted by mass. Differences in nuclear charge radii affect bond strengths, which can result in isotope fractionation that does not correlate with the differences in isotope mass.

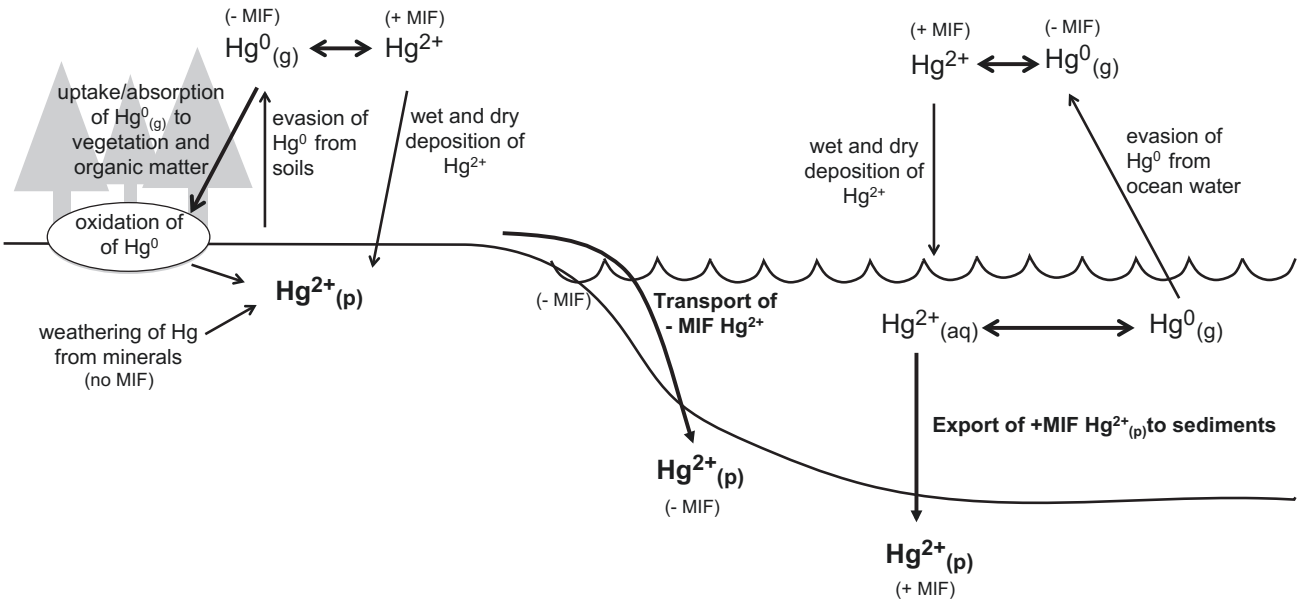
MIF Hg anomalies that are not odd isotope only are also observed in atmospheric samples and samples that have a high proportion of atmospherically derived Hg (Gratz et al. 2010; Chen et al. 2012; Demers et al. 2013; Rolison et al. 2013; Demers et al. 2015; Strok et al. 2015). These MIF anomalies are referred to as even-MIF, and currently the mechanism of even-MIF is not known and the isotope effect may affect both even and odd isotopes. It is proposed to occur during gas phase atmospheric photochemical oxidation of Hg^0 (Chen et al. 2012; Sun et al. 2016).

Hg MIF Cycles

Together both MDF and MIF are used to understand Hg cycling in the environment, but MDF is not as simple to summarize because MDF occurs during many processes including those that impart MIF. Thus, the simpler MIF cycles will be summarized here.

Hg exists in the atmosphere mostly in its reduced form, gaseous elemental Hg^0, which has a long residence time (~0.5 to 1 year) allowing it to be distributed globally (Fitzgerald and Lamborg 2014). Hg in the atmosphere is emitted from both primary and secondary sources with primary sources accounting for less than half of the total Hg emissions to the atmosphere (UNEP 2013; Fitzgerald and Lamborg 2014; Amos et al. 2015). Primary sources are dominantly anthropogenic today (e.g., coal combustion, gold mining). Most emissions are secondary sources with Hg being re-emitted back to the atmosphere after deposition from waters, soils, and biomass burning.

Hg that cycles through atmospheric, marine, and terrestrial reservoirs will likely acquire MIF through some sort of photochemistry (see Fig. 1). Gaseous Hg^0 in the atmosphere has slight negative odd-MIF, resulting from photochemical reduction in surface waters and cloud droplets. In contrast, atmospheric Hg^{2+} species have positive odd-MIF due to photochemical reduction in cloud droplets. When Hg deposits to surfaces, it deposits as either Hg^0 or Hg^{2+}. Soils tend to have negative odd-MIF because most of their Hg comes from Hg^0 that was taken up by plants, which uptake Hg^0 through their stomata and transfer it to soils by litterfall. Sediments far from runoff sources (e.g., open ocean sediments) that transport negative odd-MIF Hg from soils and surfaces tend to have positive odd-MIF Hg since their main source of Hg is through wet and dry deposition of Hg^{2+}. Many sediments



Mercury Isotopes, Fig. 1 A simplified schematic of the odd-MIF cycle of Hg isotopes. The +MIF and –MIF are the signature of the odd-MIF associated with the pool of Hg

receive Hg from both runoff and direct Hg^{2+} deposition and thus have isotopic compositions that are a mixture of Hg^0 and Hg^{2+} isotopic signatures.

Even-MIF is produced in the atmosphere and is thought to occur during photochemical gas phase oxidation of Hg^0. It is observed in atmospheric Hg^{2+} species, which have positive $\Delta^{200}Hg$ and negative $\Delta^{204}Hg$ (Gratz et al. 2010; Chen et al. 2012; Demers et al. 2013; Enrico et al. 2016). Because oxidized Hg^{2+} species are less than 10% of total atmospheric Hg, the oxidization of Hg^0 to Hg^{2+} imparts a bigger isotopic signature on the Hg^{2+} than the large Hg^0 pool. Thus, very little even-MIF is observed in Hg^0. Because of this, even-MIF is a good tracer of atmospheric inputs of Hg^{2+} species.

Select Applications

Tracing Isotopically Distinct Pools of Hg in Sediments and Surface Waters

One of the more practical applications of Hg isotopes, both MDF and MIF signatures, is source identification and tracing of Hg from anthropogenic sources in surface waters and ecosystems (e.g., Foucher et al. 2009; Feng et al. 2010; Perrot et al. 2010; Sonke et al. 2010; Gehrke et al. 2011a; Bartov et al. 2013; Foucher et al. 2013; Wiederhold et al. 2015; Donovan et al. 2016; Jimenez-Moreno et al. 2016). The success of this application is largely due to the particle-reactive behavior of Hg. Many studies show that the majority of Hg (>90%) in a diverse range of aquatic systems is transported in association with particles, dominantly particulate organic carbon and clays minerals (Benoit et al. 1998; Mason and Sullivan 1998; Roulet et al. 1998; Appleton et al. 2001; Lawson et al. 2001; Choe et al. 2003; Conaway et al. 2003). Because Hg released into aquatic systems quickly absorbs to particles and does not significantly participate in transformations that would lead to Hg isotopic fractionation, anthropogenic Hg released from point sources into aquatic systems often maintains its source signature. In addition, Hg from anthropogenic sources such as gold mining and industrial sources is typically isotopically distinct from background runoff from soils and land (see review: Blum et al. 2014).

An example of tracing multiple sources of Hg into a complex aquatic ecosystem was in San Francisco Bay. By analyzing Hg isotopes in the sediments, two distinct sources were observed entering the bay (Gehrke et al. 2011a). A clear pattern was observed with isotopically heavier Hg entering the southern parts of the bay from historic Hg mine waste and isotopically lighter sources impacting the more northern part of the bay, which were from historic gold mining and modern industrial Hg. In addition to sediments, the Hg contamination was traced into the food web (Gehrke et al. 2011b). Even though isotopic fractionation occurs during methylation, incorporation into the food web, and trophic transfer, the isotopic differences in the distinct sources of Hg entering the bay were maintained within fish.

Source Tracing in Atmospheric Samples

Because of the difficulties in collecting enough atmospheric Hg for isotopic analyses, the application of source tracing in the atmosphere is not as developed as aquatic source tracing. However, methods are improving and initial studies show that isotopic differences exist that will be useful for source

apportionment for both gaseous Hg^0 (Gratz et al. 2010; Rolison et al. 2013; Demers et al. 2015; Fu et al. 2016) and oxidized Hg^{2+} species in the atmosphere (Estrade et al. 2010; Gratz et al. 2010; Chen et al. 2012; Rolison et al. 2013; Sherman et al. 2015; Das et al. 2016; Huang et al. 2016; Xu et al. 2017). In particular, the many sources of Hg^0 to the atmosphere have large differences in the isotopic composition. This coupled with the relative stability of Hg^0 should allow for local sources to be distinguished from regional and global background signatures.

Tracing What Pools of Hg Are Bioaccumulated in the Food Web

Once in aquatic systems, Hg can be transformed into methylmercury (MeHg), the form of Hg that bioaccumulates in aquatic food webs and poses a health risk for humans and wildlife via fish consumption (Mason et al. 1995; Driscoll et al. 2013; Fitzgerald and Lamborg 2014). Methylation in the environment can happen in many environments, and the links between Hg sources, methylation, and MeHg in biota are not easy to trace. Because different pools of MeHg can have different isotopic signatures, Hg isotopes can be useful in understanding how Hg is getting into the food web. There are many studies of Hg isotopes in freshwater biota (e.g., Bergquist and Blum 2007; Gantner et al. 2009; Laffont et al. 2009; Perrot et al. 2010; Gehrke et al. 2011b; Kwon et al. 2012; Sherman and Blum 2013; Tsui et al. 2014; Kwon et al. 2015; Lepak et al. 2015; Xu et al. 2016) and marine biota (e.g., Senn et al. 2010; Blum et al. 2013; Zheng et al. 2015). Hg isotopes in fish and biota reflect many factors including where Hg is methylated, species of Hg accumulated, trophic level, what depth MeHg is foraged from, the residence time of MeHg, and the source of Hg for methylation.

Understanding Depositional Patterns of Hg to Soils

An exciting application of Hg isotopes is as a tool to quantify sources of Hg to soils (Demers et al. 2013; Jiskra et al. 2015; Enrico et al. 2016; Zheng et al. 2016; Obrist et al. 2017). Soils are one of the largest reservoirs of Hg, and they are important sinks of anthropogenic Hg as well as potential sources of Hg to downstream ecosystems and the atmosphere. Hg can be deposited to soils via Hg^0 uptake and adsorption by plants and soils or via dry and wet deposition of oxidized Hg^{2+} species, or Hg can weather from parent rock material. These three different sources of Hg have very different Hg isotopic signatures (both MDF and MIF), and isotopic mixing models can estimate the contribution of the different sources. All sites studied thus far are dominated by Hg^0 deposition, with deposition of Hg^{2+} species being mostly less than 30% and contributions from parent rock Hg even less. Furthermore, in a study of 10 sites across North America, Zheng et al. (2016) found that Hg isotopes in forest soils showed strong correlation to precipitation. The correlation is driven by a higher proportion of Hg^0 deposition at wetter sites, which is likely driven by their higher forest productivity (thus higher plant-derived Hg inputs) and more developed organic horizons that may enhance direct Hg^0 uptake.

Past Proxy of Volcanic Hg

In addition to understanding the modern cycle of Hg, Hg chemostratigraphy is being developed as a tool to investigate the connection between changes in volcanism and mass extinctions (see review: Bergquist 2017). Most of the largest extinctions on Earth are associated with large igneous province volcanism (LIPS), but whether these LIPS triggered the mass extinctions is disputed largely due to the difficulty in correlating evidence for LIPS with mass extinction records (Bond and Wignall 2014; Bond and Grasby 2017). Because large amounts of Hg are emitted from volcanism, it is argued that increases in Hg preserved in the sedimentary records with the fossils can be used as a proxy for increased volcanic inputs. However, this interpretation has been challenged (Font et al. 2016; Smit et al. 2016) and this has led to arguments over whether elevated Hg in marine sediments is actually due to increased volcanism versus other sources, increased preservation of Hg, or postdepositional enrichments of Hg.

Since different sources of Hg and mechanisms for enriching Hg in sediments may have different isotopic signatures, Hg isotopes can help resolve the source of elevated Hg during extinction events (Grasby et al. 2016; Thibodeau et al. 2016). Although there is not much data on volcanic Hg, it appears that volcanic Hg and Hg from biomass and organic rich rocks have very different isotopic signatures (Zambardi et al. 2009; Blum et al. 2014). Thibodeau et al. (2016) measured Hg and Hg isotopes across the end-Triassic mass extinction. Elevated Hg was observed throughout the extinction intervals, and biotic recovery did not occur until after Hg levels returned to background levels. The Hg isotopic signatures associated with the elevated Hg were consistent with volcanic Hg. Grasby et al. (2016) also observed elevated Hg through the end-Permian extinction, but the Hg isotopic signatures were more consistent with biomass and organic rich rocks. Thus, the Hg anomalies were interpreted to be from massive wildfires and increased soil erosion. There is a lot of potential for exploring the links between major biotic and environmental changes and volcanism in the past using Hg concentrations and Hg isotopes (Thibodeau and Bergquist 2016).

Summary

The field of Hg stable isotope geochemistry is a rapidly expanding field that has proven extremely useful in understanding and quantifying many aspects of the Hg

biogeochemical cycle. Furthermore, the application of Hg isotopes is now expanding beyond the Hg cycle. As more laboratories become capable of producing high quality data, it will be exciting to see what new discoveries Hg isotopes will help yield.

Metamorphic Reactions and Processes

Eleanor C. R. Green
Institute of Geochemistry and Petrology, ETH Zürich, Zürich, Switzerland

Definition

A metamorphic reaction is a **chemical reaction** that produces, or changes, an assemblage of metamorphic mineral and fluid phases in a rock. The changes affect the compositions of the phases and may also include changes in the phases that are present. Metamorphic processes are those processes that drive metamorphic reactions, by causing a change in the chemical conditions of the rock, such as the pressure or temperature. Metamorphic processes also commonly drive **deformation**.

Introduction

A metamorphic rock is a rock that has undergone mineralogical changes due to changing thermodynamic conditions since its formation. Prior to any metamorphism, the original rock, or protolith, may have been formed by solidification of a melt (an igneous protolith) or the lithification of discrete grains derived from weathering (a sedimentary protolith). Mineralogical changes are driven by metamorphic processes, which give rise to a great diversity of metamorphic minerals and mineral assemblages. Mineralogical change can be viewed as a change in the lattice structures – that is, the minerals – present in the system. The lattice structures differ in their capacity to accommodate a given element. Thus, a change in the available lattice structures is accompanied by redistribution of elements among the lattices. Both the change of available lattice structures and the redistribution of elements can be described as "metamorphic reaction."

The mineral assemblage present in a rock is the source of the rock's physical properties. It is well known that the conversion of basalts and gabbros to eclogite in a subducting slab entails a ~10% increase in density, which contributes significantly to **slab pull** and thus the **subduction** process itself (Aoki and Takahashi 2004; Arrial and Billen 2013; Chen et al. 2013; Hacker et al. 2003; Peacock 1993). Rock rheological properties, and tensorial properties such as seismic wave velocities and thermal conductivity, are functions not only of the mineral assemblage but also of its **microstructure**. Metamorphic processes influence the broader evolution of the Earth.

Metamorphic geology attempts to interpret metamorphic rocks in terms of the processes that generated them. One of its great assets is the mathematical framework of thermodynamic **phase equilibrium**. The **phase equilibrium** framework can be used to model metamorphic processes quantitatively, as long as these processes operated close to equilibrium. This entry assumes that preserved metamorphic mineral assemblages were generally in thermodynamic equilibrium, to a good approximation, when they ceased to evolve. The assumption is broadly justified by the sequences of assemblages observed in the eroded remains of mountain belts, repeated through space and time, which inspired a qualitative thermodynamic interpretation many decades before quantitative modeling was possible (e.g., Eskola 1920; Turner 1948).

In recent years, much effort within metamorphic geology has been expended on the development and application of quantitative thermodynamic modeling. To enable such

modeling, equations of state must be calibrated to represent the thermodynamic properties of the phases involved. The ultimate goal is to predict the stable mineral assemblage, including the distribution of elements among the minerals, under a given set of conditions. An applied metamorphic study commonly starts with fieldwork accompanied by petrographic interpretation and mineral analysis of rock samples. Using quantitative modeling, it aims to reconstruct the pressure–temperature–time path along which the rock traveled during its mineralogical development. The history of the rock in pressure–temperature space is a history of the metamorphic processes that acted on it and a window into the tectonic or magmatic processes that drove metamorphism.

A wide range of metamorphic processes can be described within the framework of equilibrium thermodynamics. Thermodynamic analysis is not, however, sufficient to link metamorphic processes with the tectonic or magmatic processes in which they originate. Most obviously, the thermodynamic approach does not include time as a variable, so thermal models must be developed that can be compared with geochronological data. The last section of this entry addresses the integration of various geophysical, geochemical, and thermodynamic methods into full geodynamic models.

Metamorphic Environments

Metamorphic processes take place in a number of terrestrial environments. Necessarily, these are environments in which the thermodynamic stability fields of new mineral assemblages are accessed and in which kinetic barriers to thermodynamic equilibration are overcome on a significant length scale. High temperatures and the presence of fluid facilitate the **diffusion** of ions down **chemical potential** gradients, forming more thermodynamically favorable chemical structures. For example, metamorphic processes take place where a system of **hydrothermal fluid** transfer or circulation can be maintained, where rock is heated through burial in compressional regimes, and where heat is advected via intruding magmas and conducted into the host rock. Hydrothermal metamorphism plays an important role in the concentration of ores ("mineralization") and is thus a focus of economic geology (Pirajno 1992). It is pervasive at mid-ocean ridges and is also associated with magmatic intrusions into continental crust. When such intrusions cause local mineralogical changes due to conduction of heat into country rock, the process is known as contact metamorphism and the affected area is described as a contact aureole. In contrast, metamorphism affecting a large area is known as regional metamorphism. It is generally tectonic in origin and accompanied by **deformation**. The study of regional metamorphism has been a primary driver for the development of metamorphic geology as a discipline and tool.

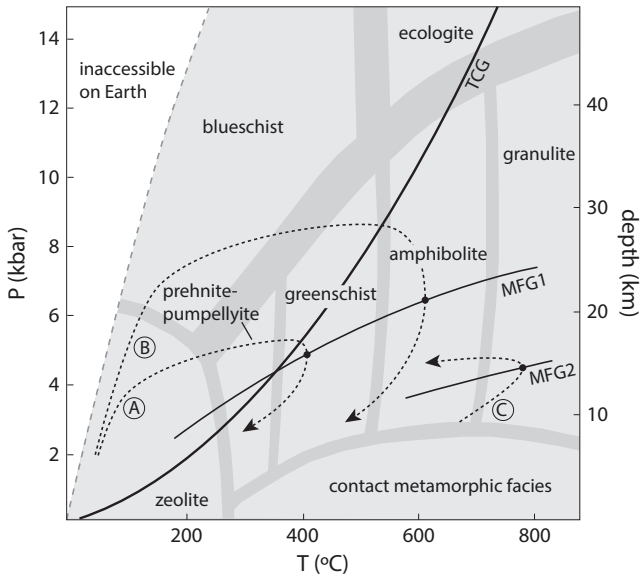
A Conceptual Model for Regional Metamorphism

Long before a detailed thermodynamic interpretation of metamorphism had been established, it was known that particular sequences of metamorphic rocks are repeated around the globe. A well-known example is that of Barrow zones, in which a series of index minerals (chlorite, biotite, garnet, staurolite, kyanite, and sillimanite) are developed in metapelites with increasing degree of metamorphism (increase of metamorphic grade). The consistency of such patterns across both space and time could be explained if rocks of similar bulk composition were to crystallize the same sequence of mineral assemblages while traversing the same region of pressure–temperature (P–T) space. This is the basis of the **metamorphic facies** concept, attributed to Eskola (1920). A **metamorphic facies** comprises rocks from the same compositional group (metabasites, metapelites, or calcareous rocks) that formed within a particular region of P–T space and therefore contain a predictable set of key minerals. Most of the facies proposed by Eskola (1920), and later Fyfe and Turner (1966), were defined in terms of the mineral assemblages seen in metabasic rocks. For example, the amphibolite facies occupies a P–T interval of approximately 2–10 kbar and 550–700 °C (Fig. 1). In this facies, a metabasic rock will contain a mineral assemblage characterized by hornblende + plagioclase. A metapelite, on the other hand, does not have a single set of index minerals that directly corresponds to the amphibolite facies. Instead, index minerals such as garnet, staurolite, kyanite, and sillimanite occupy various P–T intervals that overlap with amphibolite facies conditions. The names of the metabasite facies are often used to refer to regions of P–T space, even if the rock under discussion is metapelitic or calcareous.

Maps locating metamorphic mineral facies quantitatively in P–T space were presented by, for example, Fyfe and Turner (1966) and have been extensively investigated through experiment and thermodynamic modeling (Miyashiro 1961; Moody et al. 1983). The wide boundaries separating facies in Fig. 1 reflect variation in bulk composition within the metabasite compositional group, especially with respect to the fluid components.

Two ideas must now be established so that the facies concept can be understood in detail. The first of these is the idea of local or mosaic equilibrium, summarized in Korzhinskii (1959) and Thompson (1959). This describes what, in practical terms, is meant by a rock being "at equilibrium" at an instant in time. Starting from any given spatial origin, chemical equilibration with neighboring grains takes place out to a radius defined by the **diffusion** length scale of the rock at that time. From a thermodynamic perspective, the rock "system" extends only as far as this kinetically controlled limit.

The second core insight extends beyond the purview of instantaneous thermodynamic equilibrium, introducing the



Metamorphic Reactions and Processes, Fig. 1 A diagram in pressure–temperature (*P–T*) space, with depths also marked, showing the location of metamorphic facies and a selection of thermal gradients and rock *P–T* paths. **Metamorphic facies** are shown in *gray*. Since the occurrence of their characteristic mineral assemblages is also a function of bulk composition, they occupy loosely defined regions of *P–T* space, as suggested by the broad borders shown. A typical continental geotherm (*TCG*) is represented. Rock packages *A* and *B* come from different depths in the same column of rock, undergoing metamorphism during burial and exhumation. They follow the clockwise *P–T* paths shown as dotted curves. These paths indicate a phase of rapid burial, followed by a phase of heating that continues after exhumation has begun. The shallower rock A reaches its maximum temperature, marked by a *black dot*, before the deeper rock *B* does. The mineral assemblages preserved in *A*, *B*, and other rocks in the column record a locus of *P–T* points, the metamorphic field gradient. This is assumed to represent the locus of maximum temperature points, as shown in the figure (*MFG1*). However, MFG1 does not resemble the path taken by any one rock package. Rock *C* is from an unrelated location. It experiences heating of magmatic origin, to well above the TCG, while undergoing shallow burial. After the episode of heating is over, it cools near isobarically. Its mineral assemblage records a point on metamorphic field gradient *MFG2*

dimension of time. Consider first the path taken by a small package of rock through *P–T* space, during a regional metamorphic event comprised of burial followed by exhumation. The rock experiences prograde metamorphism through an up-temperature sequence of facies, until it reaches a maximum temperature, loosely defined as the "metamorphic peak." As it begins to cool, it undergoes further retrograde metamorphic evolution, until the length scale of local equilibrium becomes negligible due to cooling and loss of fluid availability. Petrographic and thermodynamic analysis may constrain multiple points on this rock's pressure–temperature–time (*P–T–t*) path (Vernon and Clarke 2008, Chap. 3). For a typical burial and exhumation process, such as that responsible for Barrow zones, the *P–T–t* path will be clockwise as shown in Fig. 1, with peak pressure reached before peak temperature. This is because the rock heats up only slowly in response to burial, by conduction from the warmer surroundings, with temperatures continuing to rise for some time after exhumation begins.

In such a typical burial and exhumation process, correlated *P–T–t* paths are taken by different small packages of rock at different depths within the same overall column of rock. Packages at shallower depths in the column experience lower maximum temperatures than packages deeper in the column (Fig. 1). Furthermore, shallower packages reach their peak temperature earlier than deeper packages, reflecting the evolution of the metamorphic geotherm by conductive relaxation over the course of exhumation. Thus, sequences of metamorphic assemblages record the thermal evolution of a tectonic unit with respect to the time and depth coordinates, throughout much of the causal event. The various tectonic and magmatic drivers of metamorphism are associated with characteristic styles of *P–T–t* path. In contrast to the clockwise path described above, for example, magmatic heating at low pressure typically generates a rather flat, anticlockwise *P–T–t* path. Heating is accompanied by a small increase in pressure as the crust deforms and thickens and is followed by near-isobaric cooling (Fig. 1).

The concept of **metamorphic facies** was understood from the beginning as a manifestation of thermodynamic control on mineralogical development, led by the work of Eskola (1920) and Goldschmidt (1915) on metabasite facies and the application of the **Gibbs phase rule**. Nevertheless, a period of decades elapsed between these pioneering studies and the development of a broad consensus that thermodynamic equilibrium operates throughout the prograde path of a rock. A decisive contribution was made by Carmichael (1969), who described how metamorphic reaction could take place continuously along the prograde path, even when reacting grains were spatially separated within the equilibrium length scale (see following section). Arguably, the conceptual model for metamorphism that is outlined above was completed by England and Richardson (1977). These authors modeled the thermal evolution of tectonically thickened continental crust, eliciting the asynchronous nature of *P–T–t* paths in a column of rock. An excellent summary of metamorphic processes in orogeny, including a much more detailed scientific history, is given by Johnson and Harley (2012), Chap. 7.

A Model System for Metamorphic Phase Equilibria

The **metamorphic facies** concept invokes a thermodynamic system in which pressure and temperature are externally imposed, with their conjugate variables, volume, and entropy, assuming values in response. Likewise, the system is implied to have a fixed bulk chemical composition, with the conjugate variables of **chemical potential** being dependent. Applying

the local equilibrium paradigm, it is evident that the system comprises a volume contained within the **diffusion**-determined length scale of equilibration. To first order, the bulk composition of the system refers to the bulk composition within this volume, although this definition is qualified below. Control by bulk composition in rocks can be contrasted with the buffering of the **chemical potential** of O_2, μ_{O_2}, in a petrological experiment. The experiment is buffered in order to modulate the gain or loss of the mobile H_2 component through the walls of the capsule, which must then take place such as to maintain μ_{O_2}.

Pressure P, temperature T, and **chemical potential** μ_i of component i are intensive variables, subject to contact equilibrium, meaning that they spontaneously evolve to be constant in all parts of a system. A preliminary condition for defining **phase equilibrium** within the system is then that $\nabla P = 0, \nabla T = 0$, and $\nabla \mu_i = 0$, where ∇ is the gradient operator, such that $\nabla x = 0$ implies spatial uniformity. It is usually assumed that there are no significant barriers to the spatial equilibration of temperature and pressure, since these can be transmitted directly through mineral lattices in the form of vibrational phenomena. The process of attaining $\nabla \mu_i = 0$ is slower, since this involves redistribution of matter within the system by **diffusion**. It is the spatial extent of contact equilibrium of the μ_i that limits the system volume. In recent work, however, Tajčmanová et al. (2014) proposed that gradients might be maintained in pressure over a length scale for which $\nabla \mu_i = 0$, in some scenarios.

In a system with pressure, temperature, and bulk composition held constant, the appropriate formulation of equilibrium is that of **Gibbs–Duhem**:

$$S\,dT - V\,dP + \sum_i n_i\,d\mu_i = 0, \tag{1}$$

where S is the system entropy, V the volume, and n_i the amount of component i in the system. The **Gibbs–Duhem** relation states that the temperature, pressure, and chemical potentials in the system cannot vary independently of each other while at equilibrium. As a rock proceeds along its P–T–t path, maintaining equilibrium and a constant bulk composition, the chemical potentials of components continuously adjust in response to changing pressure and temperature. As this takes place, material is spatially redistributed, countering the tendency for chemical potential gradients to develop in space. Since the driving force of any nonuniform **chemical potential** is felt across the equilibration length scale, any two grains within the equilibrated volume are in chemical contact, whether or not they are in physical contact. Thus, the spatial distribution of phases is irrelevant from the perspective of **phase equilibrium**; rather, the thermodynamic changes to the equilibrium assemblage are quantified as changes to mineral compositions and mineral modal proportions. These principles encapsulate and generalize the arguments made by Carmichael (1969), in explaining why, during Barrovian metamorphism, the replacement of kyanite by sillimanite in Barrovian metamorphism usually involves **nucleation** of sillimanite at a distance from the kyanite. As the system is chemically unified, sillimanite is not obliged to grow directly from kyanite, but instead grows where the energy barriers to **nucleation** are smaller.

It is not necessarily the whole of each grain that participates in the equilibrium among minerals. More precisely, equilibrium is maintained along grain edges, with cation exchange taking place at the grain interfaces, and grain-boundary **diffusion** mediated by metamorphic fluid. Within-grain **diffusion** may be orders of magnitude slower than fluid-mediated **diffusion** along grain boundaries, and thus equilibration within grains may not keep pace with the evolving composition at grain boundaries. This may give rise to compositional zoning in individual grains. In reality, **diffusion** rates vary among chemical components i, and in different minerals, and so therefore do length scales over which equilibration occurs. Aluminum, for example, is rather immobile, as discussed by Carmichael (1969). Both of these factors would, in theory, be taken into account in establishing the true bulk composition of the system.

Quantitative Thermodynamic Modeling: Equations of State

The previous section established a standard thermodynamic system that can be used for modeling **phase equilibrium** in many metamorphic contexts. Subsequent sections will discuss quantitative thermodynamic modeling in practical terms. It is first necessary to outline how the thermodynamic properties of individual mineral phases are captured in mathematical form and how quantitative multiphase equilibria are calculated based on these properties.

The focus of this entry is a category of thermodynamic models of mineral phases that will be described as "comprehensive" models. "Comprehensive" models contain sufficient chemical components to be used in forward calculations approximating natural metamorphic mineral assemblages. They are built on internally consistent datasets of end-member properties and comprise multidimensional **activity–composition** relations, involving mixing-on-sites and sometimes order–disorder. Examples are the models of White et al. (2007, 2014a) and Green et al. (2016). In concentrating exclusively on the use of comprehensive models, this entry passes apologetically over a long history of qualitative and quantitative thermodynamic modeling within metamorphic petrology. This history begins with the first application of Gibbs phase rule to metamorphic mineral assemblages by Goldschmidt (1915). It includes fundamental insight into metapelite phase relations acquired by projection

(Thompson 1957) and encompasses a major literature on single-reaction geothermometry and geobarometry.

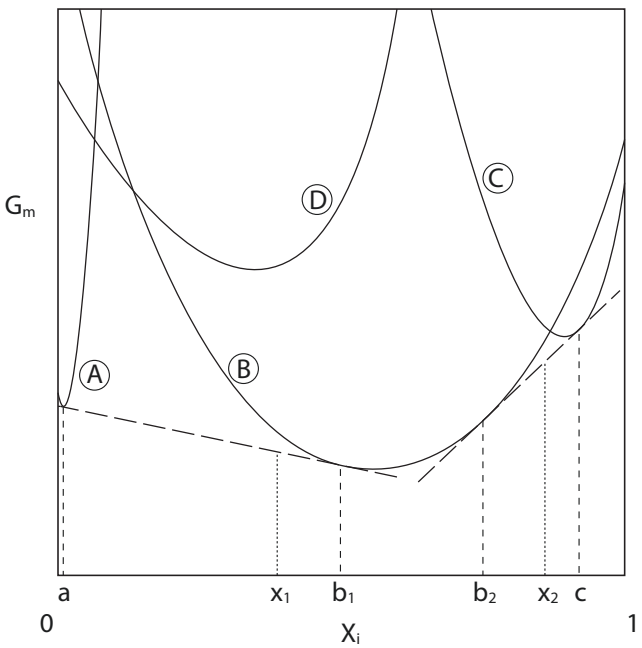
The ultimate goal of a thermodynamic modeler is to take each metamorphic mineral and construct a realistic equation of state for it. The equation of state is a function that represents the response of the mineral's state variables to changing conditions imposed upon it. For a pure end-member of a mineral in metamorphic geology, it is generally sufficient to construct the state variable volume, enthalpy, and entropy as a function of temperature and pressure (though in fact, if a mineral lattice behaves elastically as required at equilibrium, it undergoes tensorial strain and is strictly governed by the stress tensor rather than the pressure). These properties are then assembled in order to derive the **Gibbs energy**. For minerals that undergo **solid solution**, these same properties are also functions of the mineral's composition.

Among the common rock-forming minerals, there is often good experimental data constraining the equation of state for the main end-members of **solid solution**s. Such data comprise detailed measurements of isobaric heat capacity, isothermal compressibility, and thermal expansivity (e.g., Angel et al. 1988; Robie and Hemingway 1995; Winter and Ghose 1979). An internally consistent dataset of end-members, such as that of Holland and Powell (2011), collates all such measurements and subjects them to some form of optimization procedure. The use of an internally consistent dataset helps to fill gaps in experimentally measured end-member data and to overcome inconsistencies in the experiments. The latter might arise if, for example, a crystal grown in an experiment were to undergo a symmetry change during quenching, such that the measured phase was not the same as the equilibrium one, or if its equilibrium properties were significantly affected by chemical impurities or structural defects.

At an arbitrary intermediate composition in a phase showing **solid solution**, there is unlikely to be much direct information. As a result it is commonplace to treat **solid solution**s as a mixture of end-members, taking end-member thermodynamic properties from an internally consistent dataset and describing the properties due to mixing separately, via an **activity–composition** (a–x) model. The a–x model is calibrated semiempirically; the calibration makes use of available data, which usually lie along binary compositional joins, but also relies on heuristic inferences about the likely magnitudes of parameters (Powell et al. 2014). The simplest type of a–x relation to demonstrate a thermodynamic form is the ideal mixing-on-sites model. Here, the enthalpy is that of a mechanical mixture of end-members, while the entropy is purely configurational and summed over each of the sites in the mineral where cation mixing takes place. In recent years the ideal mixing-on-sites model has been largely replaced by more complex forms of a–x relation, in which ideal mixing-on-sites is augmented by, for example, strongly nonideal enthalpies of mixing and representations of cation order–disorder. The ultimate requirement for such models is that the forward calculations should compare well with observations (see, e.g., Diener and Powell 2012; Green et al. 2016).

Quantitative Thermodynamic Modeling: Calculating Multiphase Equilibria

Once a thermodynamic model is available to represent each of the required phases, the stable mineral assemblage can be calculated. A common approach is the **Gibbs energy** minimization method. Each thermodynamic model is written in the form of a **Gibbs energy** surface in P–T–X_i space. At a given bulk composition, the lowest-energy common tangent is sought among the **Gibbs energy** surfaces for all the phases (Fig. 2). The tangent will usually involve a subset of the phases under consideration. The equilibrium composition of each phase in the subset is given by the intersection of its **Gibbs energy** surface in X_i space with the tangent, and the modal proportion of the phase can be found by mass balance.



Metamorphic Reactions and Processes, Fig. 2 The common tangent construction for identifying stable assemblages. The chemical system is binary, i.e., it has two components, i and j, and composition can be expressed by the proportion of i, X_i. Gm is the **Gibbs energy** of phases A–D, which are mixtures (they might be **solid solution**s or fluids). For each phase, the **Gibbs energy** is plotted as a function of composition, at a fixed pressure and temperature. At bulk composition x_1, the stable assemblage is $A + B$, where A has composition a and B has composition b_1. The molar proportion of B in the assemblage is given by the fractional distance of x_1 along the path $X_i = a$ to $X_i = b_1$. For bulk composition x_2, the stable assemblage is $B + C$, where B has composition b_2 and C has composition c. Between compositions b_1 and b_2, the stable assemblage would simply be phase B, with a composition equal to the bulk composition. Phase D is nowhere part of the stable assemblage

Alternatively, the problem can be formulated by breaking down the **Gibbs energy** for phase p into expressions for the chemical potentials of the end-members in the model, writing $G = \sum_m c_m \mu_m$. Here, at (P, T), c_m is the proportion of the end-member m in phase p, and μ_m is its **chemical potential**. The chemical potential is given by

$$\mu_m = \left(\frac{\partial G}{\partial n_m}\right)_{P,T,n_{l\neq m}} = \mu_m^0 + \mathrm{R}T\ln\left(a_m^p\right), \qquad (2)$$

where G is the **Gibbs energy** of the phase, μ_m^0 is the **chemical potential** of the pure end-member at (P, T), R is the gas constant, and a_m^p is the activity of m in phase p. This form highlights the relationship between μ_m and a_m^p, with a_m^p related to the composition of the phase via the a–x model. Next, an independent set of balanced reactions among the end-members of co-existing phases is written. For each reaction in the independent set, a statement of chemical equilibrium can be written in the form

$$\sum_m \nu_{m,r}\,\mu_m = 0, \qquad (3)$$

where $\nu_{m,r}$ is the reaction coefficient of end-member m in reaction r and μ_m is its **chemical potential**. Smith and Missen (1982) show that this set of equilibria equates to fixing constant chemical potentials throughout the system, where the chemical potentials might alternatively be defined in terms of oxides, for example. Equilibrium phase compositions and modal proportions are then found by solving a set of simultaneous nonlinear equations, consisting of the independent set of statements of chemical equilibrium (Eq. 3), combined with mass balance constraints. This latter method is in some ways more mathematically tractable than the **Gibbs energy** minimization method, though it does not directly show which assemblage is the most stable one possible.

Quantitative **phase equilibrium** calculations are easily carried out using specialized software. Programs currently used for metamorphic problems include Perple_X (Connolly 2009), THERIAK-DOMINO (de Capitani and Petrakakis 2010), and THERMOCALC (Powell and Holland 1988). The practicalities of calculation via an independent set of reactions are discussed in Powell et al. (1998) and the **Gibbs energy** minimization method by Connolly (2009). Readers should be aware, however, that automated methods have no built-in metamorphic insight and not necessarily any understanding of thermodynamic requirements that should constrain, for example, the topology of a calculated phase diagram. They do not replace more traditional approaches to interpreting and characterizing stable phase relations. Such methods are discussed by, for example, Vernon and Clarke (2008).

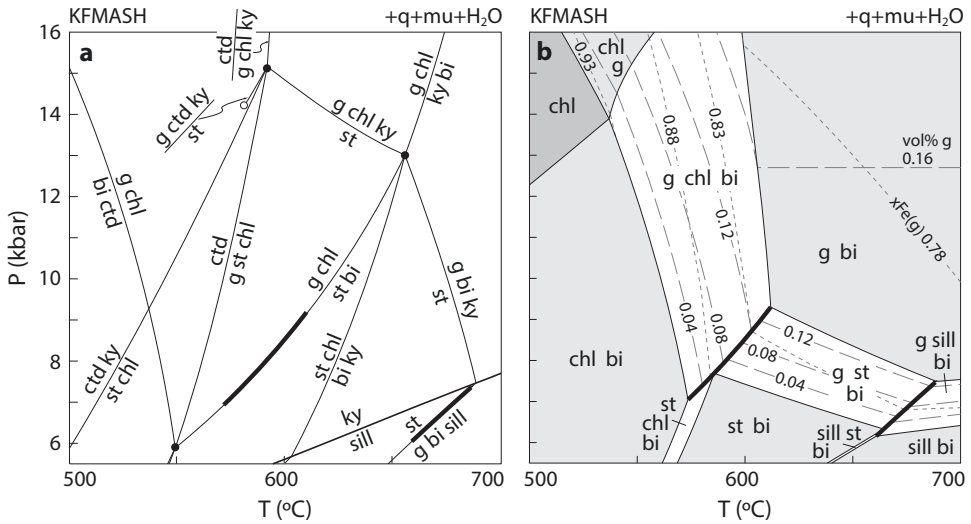
Forward Modeling of Metamorphic Phase Equilibria: Grids and Pseudosections

Forward modeling of phase equilibria consists of calculations made to predict the thermodynamically stable assemblage in an idealized model system, under conditions chosen by the user. The specification of the thermodynamically stable assemblage includes the phase compositions and modal proportions. Calculations are usually used to build up a phase diagram that summarizes the predictions in a form pertinent to the motivating problem.

Figure 3 shows two related phase diagrams, calculated in the relatively simple system K_2O–FeO–MgO–Al_2O_3–SiO_2–H_2O (KFMASH), with muscovite, quartz, and a pure H_2O fluid "in excess," i.e., present in all assemblages. Panel (a) of the figure is a **petrogenetic grid** or P–T projection. A **petrogenetic grid** shows the relationship in P–T space between stable portions of univariant equilibria, summarizing the changes in stable assemblage (a univariant equilibrium has a single degree of freedom with respect to thermodynamic variables and so appears as a curve in P–T space, with T and all mineral compositions being fully specified if a value for P is given). **Petrogenetic grid**s have a long history in metamorphic geology. Semiquantitative grids were constructed based on inferences from field and experimental observations (e.g. Harte and Hudson 1979), combined with Schreinemakers stability analysis derived from the **Gibbs phase rule**. Using such diagrams, the expanding dataset on metamorphic mineral assemblages in rocks could be logically assembled. Quantitative **petrogenetic grid**s began to be calculated once internally consistent thermodynamic datasets became available (e.g. Spear and Cheney 1989). Sets of grids, in various informative chemical systems, are still routinely published with new families of thermodynamic models (e.g. White et al. 2014a).

In applied forward modeling studies, it is rare to need to calculate a new **petrogenetic grid**. The most commonly calculated type of phase diagram is a **pseudosection**, as shown in Fig. 3b. A **pseudosection** is a map of the stable phase assemblages present at a given bulk composition, most often in P–T space. Individual **pseudosection**s must be calculated for multiple samples in a study. **Pseudosection**s were first envisaged by Hensen (1971).

The P–T **pseudosection** in Fig. 3b will now be considered in detail. The backbone of the figure is made up of the segments of univariant reaction that can be "seen" by the bulk rock composition, highlighted as heavy lines that correspond to segments of the reactions in Fig. 3a. In a **pseudosection** calculated for more components, fewer and shorter segments of univariant reaction would likely be "seen" by the bulk composition. Either side of a univariant reaction lie at divariant fields (white), labeled with three non-excess phases. The divariant fields give way to trivariant fields (pale gray, two non-excess phases), which give way likewise to a



Metamorphic Reactions and Processes, Fig. 3 Comparison of calculated phase diagrams in the system K_2O–FeO–MgO–Al_2O_3–SiO_2–H_2O (KFMASH), with quartz, muscovite, and a pure H_2O fluid in excess, that is, everywhere present. The diagrams were calculated with the thermodynamic models of White et al. (2014a), using the software THERMOCALC. Mineral phases are biotite (*bi*), chlorite (*chl*), chloritoid (*ctd*), garnet (*g*), kyanite (*ky*), muscovite (*mu*), quartz (*q*), sillimanite (*sill*), and staurolite (*st*). (**a**) A **petrogenetic grid** showing stable univariant reactions. Invariant points in the KFMASH system, where five non-excess phases are stable, are shown as *black dots*. An *open dot* indicates where the g + ctd + ky = st reaction runs into its KFASH subsystem and terminates. *Heavy lines* indicate segments of reaction that also appear in (**b**). The **petrogenetic grid** for these thermodynamic models was first presented by White et al. (2014a), Fig. 1a. (**b**) A *P–T* **pseudosection** showing the stable phases present in a rock of bulk composition (mole %) K_2O: 3.38; FeO; 8.18; MgO: 4.29; Al_2O_3: 10.56; SiO_2: 73.59. Univariant reactions "seen" by the bulk composition are shown as heavy *black curves* and correspond to the heavy curves in (**a**). *White* fields are divariant, *pale gray* fields trivariant, and *darker gray* fields quadrivariant. Contours of vol% garnet are shown as *gray long–dashed curves*, with discontinuities across univariant reactions. Contours of $x_{Fe} = \frac{Fe^{2+}}{Fe^{2+}+Mg}$ in garnet are shown as *short-dashed curves* and are continuous across univariant reactions. A **pseudosection** for the same rock composition, covering a larger *P–T* window, can be seen in White et al. (2014a), Fig. 4a

quadrivariant field (dark gray, labeled with "chl," top-left quadrant). Along univariant reactions and in divariant fields, the compositions of phases are independent of the bulk composition. This ceases to be true for fields of higher **variance**, as mass balance requirements become necessary to specify the equilibria fully. Geometric constraints are imposed on the **pseudosection** topology by the **Gibbs phase rule**. Counting the univariant reactions as infinitely thin fields containing four phases (plus the three phases in excess), assemblages change by exactly one phase when crossing a boundary. Intersections occur between two boundaries, along each of which one phase enters or leaves the assemblage. Thus, intersections involve a meeting of four fields, in which two fields on opposite sides of the intersection contain n phases, while the two remaining fields contain $n - 1$ and $n + 1$ phases.

Across fields, mineral compositions and modal proportions change continuously. Modal and compositional contours show discontinuities in slope where they cross field boundaries. Across univariant reactions, modal proportions show absolute discontinuities in values, since mass balance must be achieved while exchanging one phase for another in the assemblage. In the metamorphic literature, the term "metamorphic reaction" is often used to describe the compositional changes, growth, and consumption of minerals that take place while traversing fields. Alternatively the term "metamorphic reaction" may be reserved for univariant reactions. In most cases, new phases do not enter or leave the assemblage via a univariant reaction. Instead they simply leave the assemblage when their mass-balanced modal proportions reach zero; or, conversely, they enter the assemblage once mass balance is consistent with positive proportions of the mineral. For example, on a down-temperature trajectory at 10 kbar across Fig. 3b, garnet leaves the assemblage on falling below 575 °C at the boundary of a divariant field.

For a given rock sample of interest, establishing a suitable bulk composition to use in a **pseudosection** calculation is nontrivial. Building on the discussion in a previous section, an appropriate bulk composition would represent a volume with dimensions equal to the length scale of equilibration, including only the rims of **zoned minerals**. This idealized volume is sometimes described as the "(effective) equilibration volume," although this idea is notional, given that the equilibration length scale varies by chemical component. In principle a representative equilibrium length scale may be estimated via careful petrographic analysis in thin section, and point counting may be used to eliminate grain cores. More often, however, the bulk composition used for modeling is simply an XRF analysis of a whole-rock sample. The bulk

composition used for a **pseudosection** may contribute to the uncertainties in the modeling by a magnitude comparable to the uncertainties in the thermodynamic models themselves (Green et al. 2016; Palin et al. 2016a). Certain components of the bulk composition are notoriously difficult to assess: the bulk ferrous to ferric iron ratio is rarely analyzed, while volatile components present at the time of equilibrium will not normally be preserved in the rock. There is no reliable way to compensate for this missing information, so instead it is important to test the sensitivity of the **pseudosection** calculations to the unknown components. This can be done by calculating **pseudosection**s of T at fixed P or P at fixed T, versus the component of interest, keeping other components of the bulk composition constant. The latter figures are known as T–X or P–X **pseudosection**s.

Like all modeling that generates compelling diagrams as output, there is a danger of taking the results of **phase equilibrium** modeling too literally. A first-order requirement is to test the output against natural and experimental observations. **Pseudosection**s can be used to explain Barrow zone metamorphic sequences, as well as the lower pressure Buchan zone series, with key minerals appearing and disappearing at plausible temperatures (Johnson et al. 2015; White et al. 2014b). They reproduce experimental data on partially molten amphibolites and granulites (Green et al. 2016). Considering that the thermodynamic models are calibrated largely on measurements of individual mineral end-member properties, this represents a remarkable success for current thermodynamic model development and indeed for the thermodynamic view of metamorphism as a whole. Nevertheless, the results of individual calculations should be treated with appropriate skepticism.

Forward Modeling of Metamorphic Phase Equilibria: Thermobarometry

Perhaps the most common use of **pseudosection**-based forward modeling is in **thermobarometry** – that is, estimating the P–T conditions of the peak metamorphic mineral assemblage. The **pseudosection** approach to **thermobarometry** is a case of forward modeling to solve the inverse problem. The calculation of a **pseudosection** is clearly a forward approach, since it involves applying a range of driving thermodynamic variables and calculating the resulting mineral assemblages. However, the ultimate aim is to establish the thermodynamic conditions that gave rise to a mineral assemblage. **Pseudosection thermobarometry** should be contrasted with the approach of "classical **thermobarometry**," a straightforwardly inverse method in which a geothermometer/geobarometer reaction pair is used to solve for pressure and temperature given the observed mineral compositions (e.g., Bhattacharya et al. 1992; Johnson and Brown 2004; Kohn and Spear 1989; Powell and Holland 2008). In this comparison, a major strength of the **pseudosection** approach is that it incorporates the observed bulk rock composition as a constraint. This helps in assessing realistic uncertainties on the estimated pressure and temperature. It also acts as a check that there are no serious flaws in the relationship between pressure, temperature, and mineral composition that is encoded in the thermodynamic models.

In applying **pseudosection** modeling to **thermobarometry**, the aim is to associate the peak metamorphic assemblage observed in thin section with a matching field on the **pseudosection**. The position of this field in P–T space indicates a window in which the peak metamorphic conditions may be found. The size of the window suggests the magnitude of the uncertainty in this P–T estimate. It should be interpreted with some care, however. The 2 σ uncertainty in the position of field boundaries might be up to ±100 °C and ±2 kbar, derived from uncertainties in both the thermodynamic model calibration and the bulk composition (Green et al. 2016; Palin et al. 2016a; Powell and Holland 2008). The calculation of T–X or P–X **pseudosection**s will indicate whether the uncertainties are much increased by the estimate of volatile and oxidized components in the thermobarometric study. If the field in which the observed assemblage is found is much smaller than the uncertainty in the field boundaries, then the uncertainty in the field boundaries is more indicative than the size of the field – after all, within the model uncertainties, the field might not exist at all. Conversely, the observed assemblage might not appear on the **pseudosection**, but might differ from a calculated assemblage only by a mineral that appears in a small proportion. This might arise from uncertainties in the modeling, rather than a major failure thereof. Alternatively, a discrepancy between rock and **pseudosection** may indicate that one of the observed phases does not belong to the equilibrium assemblage.

The uncertainties suggested above are much larger than are quoted for many single-reaction barometers and, especially, thermometers. Single-reaction thermobarometers are often carefully calibrated based on a wide range of observations of coexisting minerals. The stated uncertainty reflects how well the calibration can be made to fit this selection of data, given the assumptions made in data processing. However, it is not truly a measure of the uncertainty on the estimated pressure or temperature when the single-reaction barometer or thermometer is applied to a rock. The uncertainty will not allow for the significant bias that might arise from, for example, the assumed ferric to ferrous iron ratio in the calibration of a Fe–Mg exchange thermometer. Nor will it take account of experimental bias, if the dataset is calibrated against experimental data, or bias in prior estimates of rock equilibration pressures or temperatures, if calibrated against a natural dataset. By contrast, the calibration of the comprehensive models described above includes data from a range of

complementary sources that tend to expose bias. The larger values of uncertainties assigned to **pseudosection thermobarometry** may represent the limits of the pressure and temperature constraints that can be obtained from a general rock, given current knowledge of mineral thermodynamics. Powell and Holland (2008) present a detailed discussion of uncertainties in single-reaction and **pseudosection thermobarometry**.

Alternative Thermodynamic Systems

So far this entry has only discussed one conceptual framework, in which thermodynamic equilibrium is controlled by pressure, temperature, and bulk composition. This framework appears to be a powerful model for understanding rocks on a prograde *P–T–t* path, as the coherence of the facies concept testifies. Metamorphic processes are, however, diverse. The categories of process described in this section entail a different view of the thermodynamic system. In most of these categories, it is the bulk composition that can no longer be treated as a constant property of the system. Such processes can still be treated quantitatively with the "comprehensive" thermodynamic models discussed above, although, in some cases, the process of calculation is laborious using existing software.

Many metamorphic processes are open-system processes involving fractionation, with material systematically added to or excluded from the system over time. A well-known example is the progressive sequestration of material into the cores of porphyroblasts such as garnet. As the porphyroblast grows, its center becomes isolated from the equilibrated system due to low **diffusion** rates within grains, and this changes the effective bulk composition of the system. Another example is the progressive loss of melt from a system, although this may occur episodically rather than continuously, as pressure builds in the pore space. Fractionating systems can be approximated in forward modeling by iteratively modifying the bulk composition to remove the newly excluded phase (e.g., Marmo et al. 2002; Palin et al. 2016b).

A different category of open-system process is one involving metasomatism, in which net mass transfer causes a change in local bulk composition that is not related to, but instead controls, changes in local phase equilibria. This category would include a scenario of "external buffering," whereby fluid of a given composition enters a rock over a long time period, preventing the evolution of fluid composition by reaction with solid phases that would occur in the absence of incoming fluid.

While rocks seem to undergo prograde metamorphism at constant bulk composition, a much larger range of processes may operate along the retrograde *P–T–t* path, particularly in rocks of high metamorphic grade. White et al. (2008) discuss the formation of coronae around porphyroblasts on the retrograde path. They successfully model the observed coronae as a case of stranded equilibrium, in which **chemical potential** gradients were unable to flatten over the width of the reaction rim owing to a diminishing length scale of **diffusion**. The controlling variables of the system in this instance are pressure, temperature, and **chemical potential**. Because such reaction-driven **microstructure**s indicate kinetic barriers to complete equilibration, they are sometimes interpreted as disequilibrium features that lie outside the paradigm of thermodynamic equilibrium. However, in the coronae, **chemical potential** gradients are quite well defined and behave systematically and predictably from core to rim. Consequently, at each point along a radial path from the porphyroblast through the corona to the matrix, a local equilibrium can be considered to apply, with a full set of thermodynamic variables operating, though the values of key **chemical potentials** vary along the radial path.

It can easily be imagined that volume may replace pressure as the constant variable in some processes, if only transiently. Melt loss is often modeled as a constant-pressure process, under the assumption that melt is expelled when it reaches a threshold volume fraction of the assemblage. However, the system might sometimes resemble a rigid, constant-volume pore space, in which melt accumulates until it reaches a threshold pressure. Powell et al. (2005) consider this possibility and, more generally, discuss the appropriate choice of independent variables in a range of contexts.

Phase Equilibrium and Deformation

Thermodynamic equilibrium modeling is a well-validated approach for interpreting metamorphic processes. It predicts the stable mineral assemblage present in a rock, including mineral compositions, under given thermodynamic conditions. The simplest metamorphic processes involve local equilibrium at fixed pressure, temperature, and bulk composition, requiring no spatial or time dimensions to be considered in the problem.

The thermodynamic framework is not, of course, enough to explain everything seen in a metamorphic thin section. High-grade metamorphic rocks show distinctive **microstructure**s, which, except in cases such as the reaction coronae described above, are deformation-induced phenomena. As these rocks approach peak metamorphic temperature, ductile **deformation** can be expected to occur continuously and pervasively. **Deformation** transports matter in response to differential stress, dependent on bulk rheological properties, while contact equilibration of **chemical potential** entails movement of cations to achieve a lowest-energy distribution among mineral lattices. Hypothetically these conflicting forces could inhibit equilibrium; certainly there is likely to

be intense interplay between them on the thin section scale. It is through **deformation** that the volume of an assemblage can change with pressure. Meanwhile, metamorphic reactions influence rheological properties, causing the growth of strong grains such as garnet, and weakening other parts of the system when **aqueous fluid** is generated as a reaction product. The success of prograde-path thermodynamic modeling suggests that **deformation** can be neglected at peak metamorphic conditions, implying that **diffusion** down **chemical potential** gradients keeps pace with the stress-driven movement of material. The retrograde path is more complicated (e.g., Hobbs et al. 1984; Vernon and Ransom 1971), and the outcome of interactions between **deformation** and equilibration becomes difficult to predict. For example, **deformation** gives rise to channelized fluid movement, and late-stage metamorphic reactions occur along and adjacent to these channels after reaction has ceased in the dry parts of the rock due to the greatly limited **diffusion** rates. The fluid promotes reaction by enhancing **diffusion** and is also a reactant in the formation of hydrous retrograde mineral assemblages.

Metamorphic Processes in the Wider Geological Context

The thin section to outcrop scales is of ongoing interest to metamorphic petrologists as a means of gaining insight into metamorphic processes. Over such scales, equilibrium thermodynamics predicts the stable mineral assemblage present in a rock, while fabrics and **microstructure**s record the rock's response to differential stress. However, metamorphic histories of individual rocks are key to understanding Earth processes on much greater scales – processes that leave metamorphism as their imprint on the geological record. Geodynamic modeling addresses the evolution of the planet on a regional or whole-Earth scale, being concerned with the distribution of materials and heat. In an early example, the tectonothermal models of England and Richardson (1977) described the evolution of isotherms by conductive relaxation during orogeny and in a subducted sediment wedge. Thanks to increasing computational power, considerable physico-chemical complexity can now be incorporated into geodynamic models. In a detailed model on an appropriate length scale, the crust is represented as a series of layers with different **rheology** corresponding to different rock types (e.g., Beaumont et al. 2009). Future geodynamic modeling will be directly integrated with **phase equilibrium** calculations.

Phase equilibrium studies model the chemistry of **major** and **minor elements** that significantly affect equilibria. However, an array of geochemical methods provide key information linking metamorphism with **geodynamics**. **Radiometric dating** allows ages to be assigned to metamorphic events. Since thermal conduction and tectonic movements are both associated with characteristic timescales, the age data obtained in a given metamorphic terrane can help distinguish between possible scenarios driving the metamorphic event (Agard et al. 2009). **Trace element** analysis is used to infer paleotectonic environments and to track processes such as partial melting. While they are not considered to have a meaningful influence on the equilibrium assemblage, they partition variably into different phases, producing distinctive patterns which are then treated as markers of processes that have otherwise been erased from the metamorphic record. Ideally, all three geochemical approaches would be approached in an integrated way. Konrad-Schmolke et al. (2008) and Palin et al. (2016c) make an attempt at this, discussing the relationship between **phase equilibrium** and trace element modeling. However, to combine these complementary methods fully, a vastly more detailed knowledge of partition coefficients will be needed, characterizing their dependence on the mineral composition.

Summary

Metamorphic processes involve changes of mineral assemblage and hence material properties of rocks, in response to Earth processes that redistribute heat and rocky material. Feedbacks between the two oblige Earth scientists to pay metamorphic geology close attention. The study of metamorphic processes requires an understanding of rocks as chemical systems, containing crystalline lattice phases (minerals) and fluids. Quantitative thermodynamic modeling provides an invaluable framework through which to explore such chemical systems and their response to the controlling variables of pressure and temperature.

Meteorites

Michael K. Weisberg
Department of Physical Sciences, Earth and Planetary Sciences, Kingsborough Community College and Graduate Center, City University of New York, New York, USA

Definition

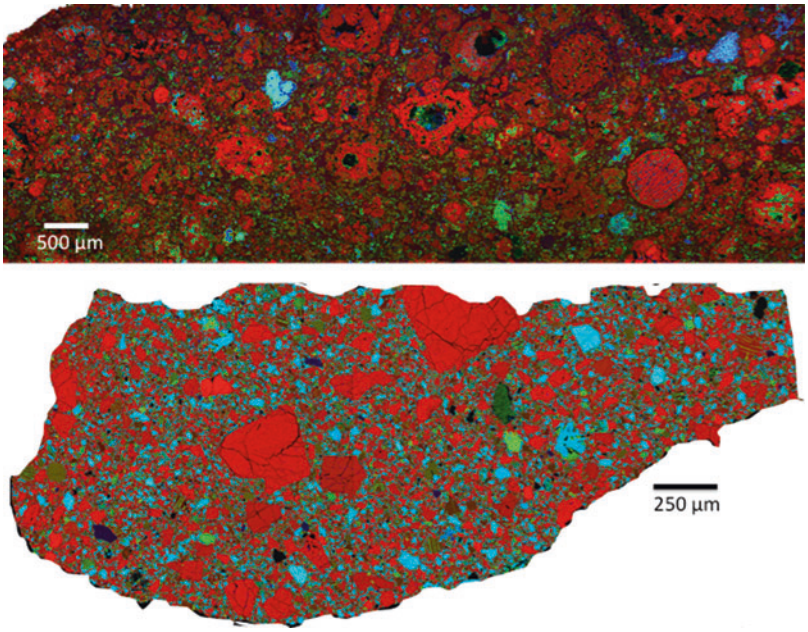
Meteorites are rock fragments dislodged from a celestial body, launched into interplanetary space, which pass through the Earth's atmosphere and land on the surface. However, rocks that similarly fell to the surface of the Moon and Mars (or any other planetary body) are also meteorites. Additionally, a rock launched from a planetary body and falls back to that same body is also considered a meteorite. A comprehensive definition (from Rubin and Grossman 2014) is a meteorite is a natural, solid object larger than 10 μm in size, derived from a celestial body, that was transported by natural means from the body on which it formed to a region outside the dominant gravitational influence of that body and that later collided with a natural or artificial body larger than itself (even if it is the same body from which it was launched). Weathering and other secondary processes do not affect an object's status as a meteorite as long as something recognizable remains of its original minerals or structure. A meteorite that is between 10 μm and 2 mm in size is called a micrometeorite. A meteoroid is a 10-μm- to 1-m-size natural solid object moving in interplanetary space. A micrometeoroid is a meteoroid 10 μm to 2 mm in size.

Meteorites represent a remarkable range of Solar System materials and record an extensive range of conditions and processes from the early history of the Solar System to geological processes on asteroids and planets to the evolution of stars and life. Most meteorites are thought to have originated from the asteroid belt, some, such as CI chondrites, may be from comets, and some are from the Moon and Mars. Spectral reflectance and space missions provide the data for linking meteorites to specific asteroids. For example, ordinary chondrites have spectral features similar to S-type asteroids. This relationship was confirmed when samples from the S-type asteroid called 25143 Itokawa, returned by the Hayabusa mission, were shown to have mineral compositions and oxygen isotope ratios identical to the L group of ordinary chondrites.

Types of Meteorites

Meteorites are considered falls or finds. The former indicates that it was observed to fall and then recovered, whereas finds are collected but no witnessed account of it falling. Based on the ratio of metal to silicate, meteorites are divided into stones, stony irons, and irons with stones dominated by silicate minerals; irons are mostly Fe,Ni metal and stony irons are intermediate mixtures of silicates and Fe,Ni. The major silicate minerals in most meteorites are olivine [$(Fe,Mg)_2SiO_4$] and/or pyroxene [$(Fe,Mg,Ca)SiO_3$] and feldspar group [$KAlSi_3O_8 – NaAlSi_3O_8 – CaAl_2Si_2O_8$] minerals. The major metallic (Fe,Ni) minerals are kamacite and taenite, and a common sulfide is troilite (FeS). Stony meteorites from asteroids are divided into chondrites and achondrites. Chondrites are so named due to the presence of small (~ millimeter-sized) spherical inclusions called chondrules and are essentially sedimentary rocks composed of mixtures that may include chondrules, lithic and mineral fragments, metal and sulfides, calcium-aluminum-rich inclusions, amoeboid olivine aggregates, organic materials, presolar grains, and a fine-grained matrix (Fig. 1). They are meteorites that have unfractionated elemental abundances relative to the sun, except for volatility-related depletions (Figs. 2 and 3). They are over 4.5 billion years old and are generally interpreted to be from primitive (undifferentiated) Solar System bodies (asteroids and/or comets). However, paleomagnetic study of the Allende CV chondrite shows that it records a parent body magnetic field suggesting it resided on a body that may have had a differentiated interior with a metallic core (Weiss et al. 2010).

Materials from asteroids that have been modified (melted) through planetary-scale differentiation are called achondrites. These meteorites are generally igneous rocks (e.g., basalts) or breccias of igneous rock fragments (Fig. 1). The term primitive achondrite is applied to recrystallized rocks that may retain textural or chemical memory of their chondrite

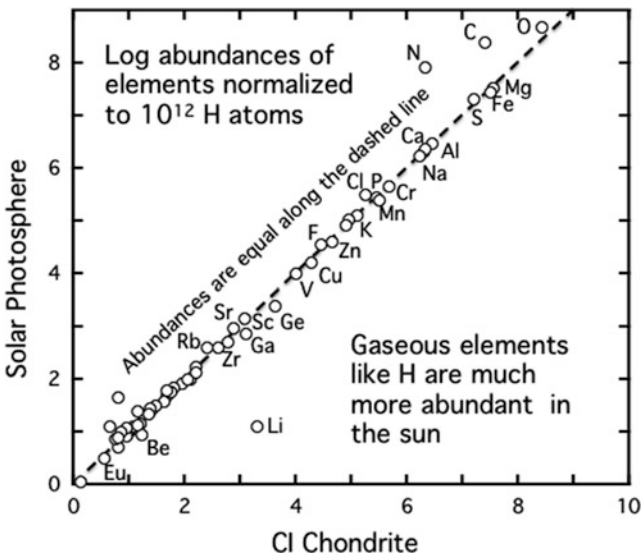


Meteorites, Fig. 1 Mg-Ca-Al (red-green-blue) composite element map of the Vigarano CV3 chondrite (*top*) and the Zmenj howardite (*bottom*). The image of Vigarano shows chondrules of different textures and compositions. Most chondrules are red, due to the magnesian composition of their olivine and pyroxene that dominate the chondrules with minor blue to green (Al,Ca-rich) mesostasis interstitial to the mafic silicates. Calcium-aluminum-rich inclusions are blue due to the high abundance of Al-rich minerals such as anorthite, melilite, and/or fassaite. (Image courtesy of Denton Ebel, American Museum of Natural History.) The Zmenj howardite is an achondrite breccia of olivine (*bright red*), pyroxene (*darker red*), plagioclase (*blue*), and Ca-pyroxene (*green*) (Image courtesy of Joseph S. Boesenberg, Brown University)

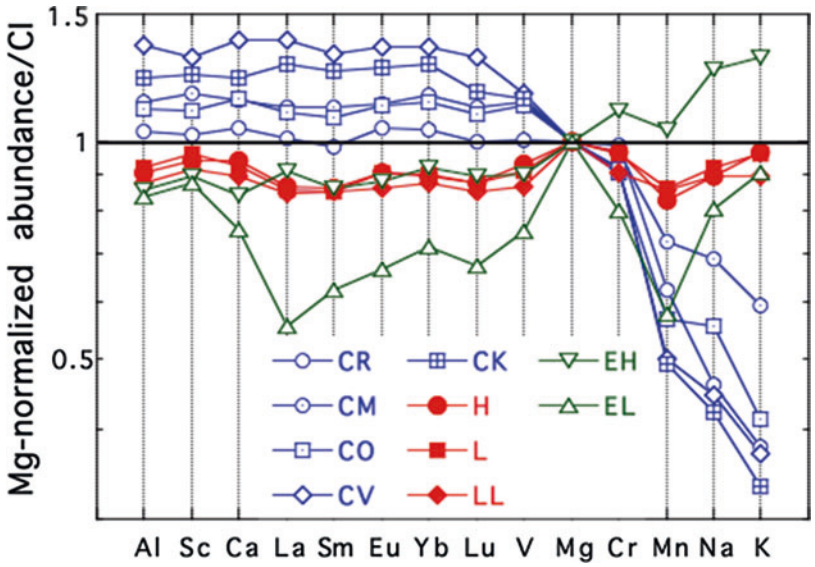
precursors. Some primitive achondrites may represent melts, partial melts, or melt residues from local heating events on planetary bodies during the earliest stages of planetary differentiation or possibly from local impact events (e.g., McCoy et al. 1996).

Chondrites

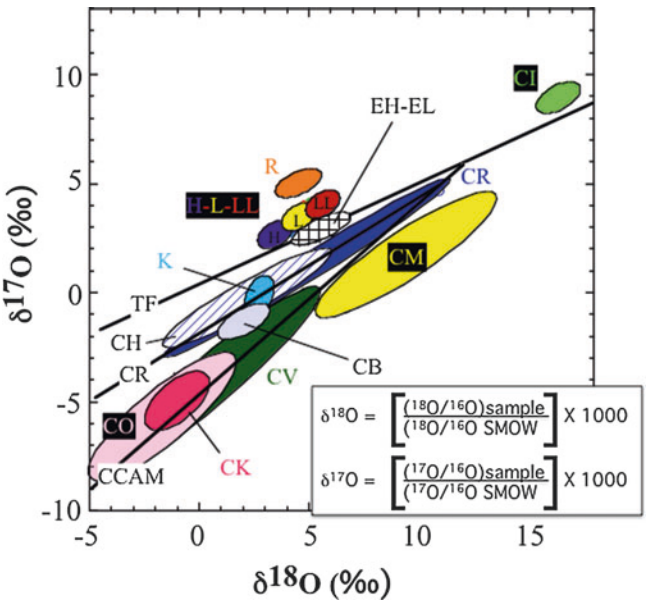
The chondrites are classified into groups based on a combination of their petrologic features (e.g., chondrule abundance, chondrule size, mineral assemblages, and mineral compositions), whole rock chemistry (Fig. 3), and oxygen (and other stable) isotope ratios (Fig. 4). The chondrites are classified as O (ordinary), C (carbonaceous), and E (enstatite) with numerous others that do not easily fit into these three categories. These "classes" are further subdivided into groups. Eight carbonaceous chondrite groups are currently recognized. These include CI, (Ivuna-like), CM (Mighei-like), CO (Ornans-like), CV (Vigarano-like), CK (Karoonda-like), CR (Renazzo-like), CB (Bencubbin-like), and CH (high iron – ALH 85085-like). The ordinary chondrite groups are named H, L, and LL, based on the abundance of iron and the ratio of metallic iron (Fe^0) to oxidized iron



Meteorites, Fig. 2 Abundances of elements (normalized to 10^{12} H atoms) in the solar photosphere plotted against the abundances of elements in CI chondrite showing that CI chondrites have essentially solar composition except for the highly volatile elements. The composition of the Solar photosphere was measured by spectroscopy and the chondrites were analyzed in the laboratory (Data are from Grevesse and Suaval (1998), as reported by Palme and Jones (2003))



Meteorites, Fig. 3 Average Mg- and CI-normalized abundances of elements in the different chondrite groups. Elements are according to volatility. Most chondrites are unfractionated from CI (solar) with respect to the refractory lithophile elements and show increasing depletions related to volatility (Data from Kallemeyn and Wasson (1981, 1982, 1985), Kallemeyn et al. (1978, 1989, 1991, 1994, 1996), Sears et al. (1982), and Wasson and Kallemeyen (1988))



Meteorites, Fig. 4 Oxygen three-isotope diagram showing the fields occupied by the different chondrite groups. TF refers to the terrestrial fractionation line; CCAM is the carbonaceous chondrite anhydrous mixing line. Also shown is a line defined by the CR (and related CB and CH) chondrites (Modified from Weisberg et al. (2006), data from Clayton and Mayeda (1984) and Clayton and Mayeda (1996, 1999))

(FeO): H chondrites have the highest iron content and highest Fe^0/FeO ratios (H, 0.58; L, 0.29; LL, 0.11) among ordinary chondrites and LL chondrites the lowest. In the equilibrated ordinary chondrites (petrologic types 4–6), this is also reflected in their olivine [(in mol% Fa) (H, 16–20; L, 23–26; LL, 27–32) and low-Ca pyroxene endmember compositions. Based on mineralogy and bulk chemistry, the enstatite chondrites are divided into EH (high iron) and EL (low iron) groups (Keil 1969). The R (Rumuruti-like) chondrites have whole chondrite and oxygen isotopic characteristics that preclude their affiliation to either the C, O, or E chondrite classes, as do the K chondrites.

There are a number of chondrites that do not fit into any of the existing groups. These meteorites are referred to as anomalous or ungrouped. They may be anomalous members of chondrite groups or the first representatives of new groups. For example, two metal-rich chondrites (Northwest Africa 5492 and Grosvenor Mountains 95551) were recognized to be similar materials distinct from any other chondrite group and have been interpreted to be the first samples of a new "G" chondrite group (Weisberg et al. 2015).

Chondrites record a range of aqueous and thermal alteration and are assigned values (on a scale of 1–7, referred to as petrologic types) depending on the degrees to which they have been altered. The most primitive, least altered chondrites, considered to be essentially pristine, are labeled type 3.00. Few chondrites are considered to be type 3.00. One example is Acfer 094, an ungrouped C chondrite that shows a minimal amount of secondary alteration. Chondrites that have been altered by pre-terrestrial water-rock interactions have values less than 3.0 with type 1.0 indicating the highest degree of aqueous alteration. Type 1.0 chondrites are dominated by serpentine and clay minerals and lack any anhydrous silicates. Chondrites that have been thermally altered and show some degree of recrystallization and/or chemical equilibration have values greater than 3.00 with type 7 indicating the highest degree of thermal alteration and recrystallization.

Components of Chondrites

Chondrules are the most common components of many chondrite groups, particularly the ones designated type 2 and 3. Chondrules are igneous spheres formed by flash heating at temperatures of ~1720 to 2120 K followed by rapid cooling. In types 4–7, chondrule boundaries become progressively indistinct due to recrystallization. In most type 1 chondrites, such as the CI group, chondrules are not present, and it is unclear whether they were present in the protolith prior to extensive aqueous alteration or if they were never present in these chondrites at all. The heat source for chondrule formation remains a major unresolved question in meteorite studies. Lightening, shock waves, and current sheets in the early Solar Nebula as well as collisions between early-formed planetesimals have been proposed.

Calcium-aluminum-rich inclusions (CAIs), sometimes called refractory inclusions, are materials that are noteworthy for being rich in refractory element-bearing minerals. Some are interpreted to be fluffy, unmelted aggregates of minerals that condensed from the Solar Nebula. They are generally dated (based on ^{26}Al-^{26} Mg, ^{207}Pb-^{206}Pb and I-Xe isotope systems) to be older than chondrules by about 2–3 million years and generally considered the first solids formed from the Solar Nebula gas. Based on the ^{207}Pb-^{206}Pb isotope system, some CAIs are as old as 4568 Ma (Bouvier and Wadhwa 2010). Their mineral assemblages and compositions bear resemblance to predictions of minerals expected to condense from gas of solar composition as it cools under equilibrium conditions.

Interstitial to the chondrules and CAIs is a fine-grained (micrometer-submicrometer-sized) component of chondrites referred to as matrix. Matrix is a mixture of materials that range from being highly primitive in some chondrites to highly altered in others (e.g., CM chondrites). It is a component of chondrites dominated by silicates but also harbors primitive amorphous materials, organic matter, and interstellar (presolar) grains. Interestingly, although all chondrites are mixtures of many components, their whole rock chemistries average out to near solar. This has led to the hypothesis of complementarity and that the components of each chondrite group formed locally within the early Solar System.

Achondrites

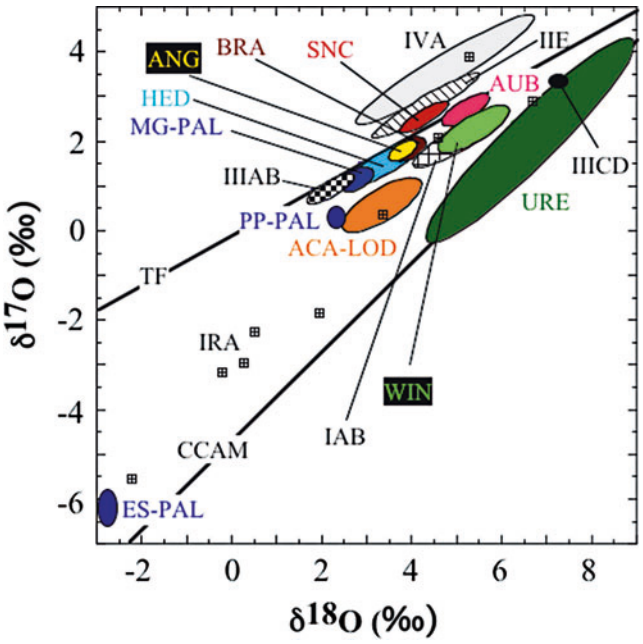
The achondrites are derived from parent bodies that experienced large-scale partial melting, isotopic homogenization, and subsequent differentiation. Achondrite groups include the genetically related eucrites, diogenites, and howardites, the angrites, and the aubrites. Mesosiderites and pallasites are stony irons from differentiated bodies and thus can be considered as related to achondrites. Primitive achondrite groups include ureilites, acapulcoites and lodranites, brachinites, and winonaites.

Eucrites and diogenites are basalts and orthopyroxene cumulates, respectively, thought to have originated in near-surface lava flows or intrusives on a common asteroidal parent body. However, most eucrites and diogenites are brecciated. Howardites are polymict breccias containing eucrite and diogenite components (Delaney et al. 1984). Howardites, eucrites, and diogenites have similar whole-rock oxygen isotopic compositions and similar Fe/Mn ratios in their pyroxenes, suggesting a close genetic relationship, and are sometimes referred to as HED meteorites. Similarities in the mineralogical compositions of the HEDs and the surface mineralogy of asteroid 4 Vesta, as determined by ground-based visible and near-infrared reflectance spectroscopy, suggests that the HEDs are derived from this asteroid (Binzel and Xu 1993; McCord et al. 1970). This link is supported by data from the Dawn space mission, which orbited Vesta between 2011 and 2012.

Angrites are medium- to coarse-grained (up to 2–3 mm) igneous rocks of generally basaltic composition but with mineralogies consisting of Ca-Al-Ti-rich pyroxene, Ca-rich olivine, and anorthitic plagioclase with accessory spinel, troilite, kirschsteinite, whitlockite, titanomagnetite, and Fe,Ni metal (Mittlefehldt et al. 1998; Mittlefehldt and Lindstrom 1990; Yanai 1994). Oxygen isotope compositions of the angrites are similar to those of the HED meteorites, brachinites, and mesosiderites (Fig. 5). However, the mineralogies and compositions of the angrites suggest that they are not related to any of these other meteorite groups.

The aubrites are highly reduced achondrites with mineral assemblages, mineral compositions, and stable isotope ratios similar to the enstatite chondrites and are often referred to as enstatite achondrites (Watters and Prinz 1979). All of the aubrites are breccias with the exception of the Shallowater aubrite, which has an igneous texture. They consist mostly (~75–95 vol%) of nearly FeO-free enstatite, with minor albitic plagioclase and nearly FeO-free diopside and forsterite. Other phases include accessory Si-bearing Fe,Ni metal and a variety of sulfides similar to those in the enstatite chondrites (Wheelock et al. 1994). The highly reduced-state, oxygen isotope composition and the presence of ferroan alabandite [(Fe,Mn)S] in the aubrites link them to the EL chondrites. However, they are probably derived from different asteroidal parent bodies (Keil 1989).

Mesosiderites are breccias composed of roughly equal proportions of silicates and Fe,Ni metal plus troilite (Floran et al. 1978; Hewins 1983). Their silicate fraction consists of mineral and lithic clasts in a fine-grained fragmental or igneous matrix. The lithic clasts are largely basalts, gabbros, and pyroxenites with minor amounts of dunite and rare anorthosite. Mineral clasts consist of coarse-grained orthopyroxene, olivine, plagioclase, and Fe,Ni-metal.



Meteorites, Fig. 5 Oxygen three-isotope diagram showing the fields for the achondrite groups. *ACA-LOD* acapulcoites and lodranites; *ANG* angrites; *AUB* aubrites; *BRA* brachinites, *HED* howardites, eucrites, diogenites; *IRA* ungrouped irons; *SNC* shergottites, nakhlites, chassignites; *WIN* winonaites; *MG-PAL* main group pallasites; *PP-PAL* pyroxene pallasites; *ES-PAL* Eagle Station Pallasites. IVA, IIAB, IICD, and IIE are iron meteorite groups (From Weisberg et al. (2006))

The pallasites are essentially olivine (35–85 vol%)-metal (and troilite) assemblages. There are three different types of pallasites that are distinguished by differences in their silicate mineralogy and composition, metal composition, and oxygen isotope composition. These include the main group pallasites, the Eagle Station pallasites, and the pyroxene-pallasites (Boesenberg et al. 2000; Mittlefehldt et al. 1998). The differences among the pallasite groups suggest that they originated on separate asteroidal bodies.

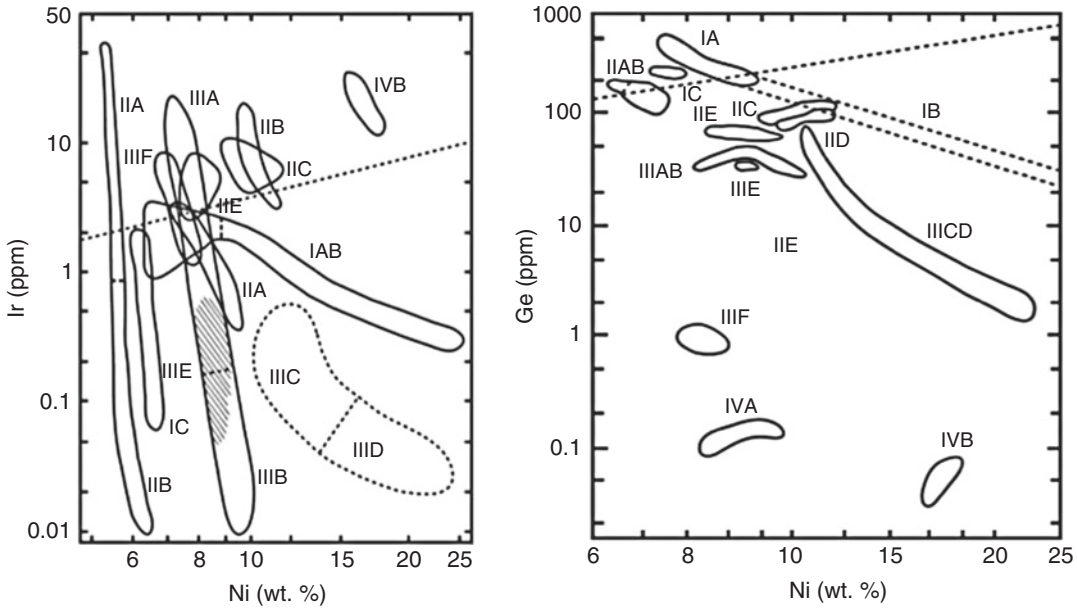
The ureilites are an example of a primitive achondrite. They are a major meteorite group with over 400 known specimens. Most are monomict and more than 25 are polymict breccias. They have textures, mineralogies, and lithophile element chemistries that suggest they are highly fractionated rocks from an achondrite parent body, yet their oxygen isotope compositions do not follow a mass-dependent fractionation trend characteristic of planetary differentiation. Instead, they plot along the CCAM line, overlapping the CV chondrites (Fig. 5) (Clayton and Mayeda 1988). The ureilites are olivine-pyroxene rocks with interstitial carbon (graphite and micro-diamonds) mixed with metal, sulfides, and minor silicates. Most are essentially devoid of feldspar with the exception of the polymict ureilites and some rare exceptions. Ureilites can be subdivided into three major types (olivine-pigeonite, olivine-orthopyroxene, and polymict ureilites).

The acapulcoites and lodranites are closely related primitive achondrites. The acapulcoites are fine-grained (150–230 μm), equigranular rocks composed of olivine, pyroxene, plagioclase, metal, and troilite, while lodranites are coarse-grained (540–700 μm) olivine, pyroxene rocks depleted in troilite and plagioclase (McCoy et al. 1996; Mittlefehldt et al. 1998; Nagahara 1992). The whole-rock oxygen isotope compositions of acapulcoites and lodranites overlap on the three-isotope diagram (Fig. 5). Rare relict chondrules have been reported in several acapulcoites suggesting that they are close to their chondrite precursor. Brachinites are olivine-rich primitive achondrites that are close to chondritic and unfractionated in composition. Winonaites are primitive achondrites that have roughly chondritic mineralogy and chemical composition, but achondritic, recrystallized textures (Benedix et al. 1998; Kimura et al. 1992).

Irons

The iron meteorites consist mostly of Fe,Ni and are known for their characteristic Widmanstätten structure, an intergrowth of the Fe,Ni phases kamacite and taenite. These meteorites are windows in to the interior (cores) of differentiated bodies. Currently, there are 13 recognized groups of iron meteorites based on their Ni and trace siderophile element (Ga, Ge, Ir) abundances (Fig. 6) (Choi et al. 1995). Letters combined with Roman numerals are used to name the groups (e.g., IA, IVB). Ga and Ge are the most volatile siderophile elements and tend to be strongly fractionated between the iron groups. Geochemical differences between the groups are due to pre-accretion processes, but the geochemical trends within some of these groups are consistent with fractional crystallization, with each group forming in the core of a separate asteroid (Scott 1972). A large number (as much as 40%) of iron meteorites do not fit into the well-described groups. These ungrouped irons may represent extreme fractional crystallization products of the known groups, others could be impact melt products, as opposed to forming as cores. Some may represent the only sample of their parent asteroid.

Some irons contain silicate inclusions (e.g., IAB, IIICD, and IIE). They contain variable amounts of low-Ca pyroxene, high-Ca pyroxene, olivine, plagioclase, troilite, graphite, phosphates, and Fe,Ni-metal and minor amounts of daubreelite and chromite. These irons do not show large fractionations in siderophile elements as in the other irons, and their origin has been debated; suggested origins include crystallization of an S-rich core, partial asteroidal differentiation followed by impact mixing, and formation in isolated impact melt pools (Kracher 1982; McCoy et al. 1993). The IAB and IIICD irons have mineralogy and oxygen isotope



Meteorites, Fig. 6 Classification of iron meteorites based on siderophile element (Ni, Ir, Ga) abundances (Modified from Scott and Wason (1975))

compositions (Fig. 5) similar to winonaites, and it has been suggested that the silicate inclusions in IAB and winonaites formed on the same or similar parent body (Benedix et al. 2000).

Martian Meteorites

The Martian meteorites are rocks from the crust of Mars. They are volcanic (e.g., basaltic shergottites and nakhlites) and plutonic (lherzolitic and olivine-phyric shergottites, Chassigny, ALH 84001) rocks (McSween 2002; McSween and Treiman 1998; Mittlefehldt 1994). Their oxygen isotope compositions define a unique slope-0.52 mass fractionation line in three-isotope space (Fig. 5) suggesting their origin from the same, differentiated parent body. The relatively young crystallization age of some of these meteorites (<1.3 Ga) suggests derivation from a planet-sized body. Most importantly, gases trapped in impact-produced glass inclusions and veins in some Martian meteorites are compositionally similar to the Martian atmosphere, as determined by the Viking Landers, indicating that these meteorites are from the planet Mars (Bogard and Johnson 1983; Nyquist et al. 2001).

While all other Martian meteorites have relatively young crystallization ages, the age of ALH 84001 is ~4.5 Ga and, thus, is a fragment of the ancient Martian crust. It consists mainly of coarse, up to 6-mm long, orthopyroxene crystals (96%), with minor chromite, plagioclase (maskelynite), phosphate, and accessory phases such as olivine, augite, pyrite, and carbonates. One of the most historically intriguing aspects of this Martian meteorite is that it had been interpreted to contain fossils of nano-bacteria, as well as other evidence of life, of Martian origin (McKay et al. 1996).

Lunar Meteorites

Lunar meteorites include a wide range of rock types including brecciated and unbrecciated mare basalts, mixed mare/highland breccias, highland regolith breccias, and highland impact-melt breccias (e.g., Papike et al. 1998). The lunar meteorites have mineral chemistries (e.g., Fe/Mn ratios in pyroxenes) and bulk chemical and oxygen isotope compositions similar to samples collected by the Apollo and Luna missions. However, some lunar meteorites come from areas not sampled by these missions and some (e.g., Northwest Africa 773) sample lithologies unknown from and thus complement the mission samples. NWA 773 consists of two lithologies, a fragmental regolith breccia and an olivine gabbro.

Deciphering the Meteorite Record

Stable isotopes, particularly the three isotopes of oxygen (^{16}O, ^{17}O, and ^{18}O), have played a major role in classifying meteorites as well as identifying genetic relationships between meteorite groups and tracing primary and secondary processes (Clayton 2003). Plotted on a three-isotope diagram ($\delta^{17}O$ vs. $\delta^{18}O$, Figs. 4 and 5), various meteorite groups occupy specific regions, supporting their classification by

other techniques. The line labeled TF on Figs. 4 and 5 is the terrestrial fractionation line. The 0.52 slope indicates that all materials plotting along this line may be related by mass-dependent fractionation. Note that all rocks from both the Earth and Moon plot along this line. Primitive meteorites plot on lines defined by mixing of ^{16}O–rich and ^{16}O–poor oxygen reservoirs, as opposed to mass-dependent fractionation. For example, many of the C chondrites plot along a slope ~ 1 line, often referred to as the carbonaceous chondrite anhydrous mixing (CCAM) line. Most C chondrites occupy regions below, whereas O and R chondrites generally plot above, the TF line. Interestingly, E chondrites and their achondrite equivalents (the aubrites) plot on the TF line overlapping the Earth and Moon. This has led to the inference that the E chondrites are genetically related to the Earth-Moon system. This relationship is further supported by stable isotopes of Cr, Ti, Ni, and Zn (Javoy 1995; Paniello et al. 2012; Warren 2011). The only exception is Si isotopes, which are different (Fitoussi and Bourdon 2012; Savage and Moyier 2013).

Summary

As of 2017, there are more than 60,000 known meteorites (as reported in the Meteoritical Bulletin Database of the Meteoritical Society). Most of these are derived from asteroids, some may be from comets, 190 are Martian meteorites and 293 are from the Moon. They are a valuable, wide-ranging resource of Solar System materials available for geochemical analysis, providing objects from the earliest history of our Solar System. They include materials from both primitive (undifferentiated) and differentiated asteroids; they reveal the age of the Solar System and give us the only samples we currently have from the crust of Mars.

Mid-Ocean Ridge Basalts (MORB)

Charles H. Langmuir
Department of Earth and Planetary Sciences, Harvard University, Cambridge, MA, USA

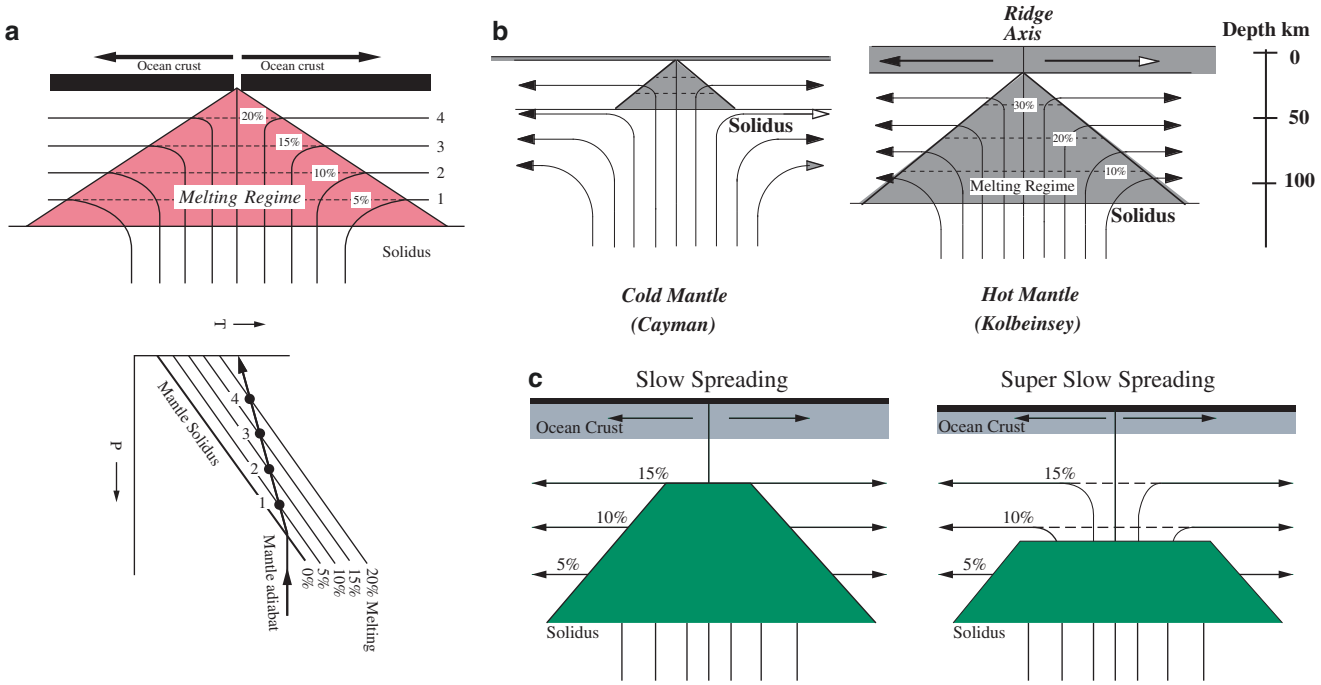
Definition

Mid-ocean ridge basalts are the volcanic rocks erupted at the global system of ocean ridges. They are the most common volcanic rock type on Earth. They provide insights into the mantle from which they are derived by partial melting and the processes in ocean ridge volcanic systems through which they pass on their way to the surface.

Introduction

The global system of ocean ridges is a continuous line of volcanism that wraps around the globe reaching a total length of more than 60,000 km. Ridges are the sites of formation of new oceanic crust, and over time have created the entire ocean floor, with the exception of some additions through intraplate volcanism and sediments that gradually accumulate as the crust ages. The rocks created at ocean ridges are the most common rocks on Earth, covering two-thirds of the Earth's surface, i.e., oceanic crust. Ocean ridge volcanism is about 75% of all volcanic activity on Earth (Crisp 1984), but is largely hidden from view since most of it occurs several thousand meters below sea level. The ocean ridge volcanoes erupt basaltic magmas called "ocean ridge basalt." While not all ocean ridges are in the middle of their hosting oceans, this basalt has become known as "mid-ocean ridge basalt," or MORB. MORB is the most common volcanic rock type in the world.

MORB began to be investigated only in the 1960s, just after the discovery of the mid-ocean ridge and the development of plate tectonics. Steady sampling over the last 50 years has gradually provided data on more than 30,000 samples that can be used to define the average composition and variability on all scales. With the advent of a global public database, PETDB (www.petdb.org) (Lehnert et al. 2000), all published location and geochemical data for these ocean ridge samples



Mid-Ocean Ridge Basalts (MORB), Fig. 1 Illustration of the means by which parental magmas for MORB are generated in the mantle. A: Demonstration of how decompression of the mantle beneath the ridge leads to a melting and a "melting regime" where melt forms and is extracted to form the oceanic crust. B: Illustration of the effect of mantle temperature on the melting regime; colder mantle intersects the solidus at shallower depths, hence melts less and creates thinner crust. C: Illustration of the effect of spreading rate on the melting regime at constant temperature. As spreading rate decreases, cooling from the surface is able to penetrate more deeply into the mantle, stopping melting at greater depth

M

are available. Even unpublished data from US cruises are also available. There are many additional unpublished locations and data from European, Russian, Japanese, and Chinese cruises that are not in the public domain. All samples in PETDB can be readily visualized in a geographical reference frame using GEOMAPAPP (www.geomapapp.org) (Carbotte et al. 2004). The last few decades have thus revealed and defined the most abundant rock on Earth.

MORB as a Product of Pressure Release Melting

Because the ridges are constantly spreading apart, there is little impediment to the magmas reaching the surface, and for that reason, MORB are the most direct products of Earth's interior and the least modified during ascent. The mean composition of MORB then defines the composition of Earth's most extensive crustal reservoir, and is as well the best available constraint from which the composition of the upper mantle can be inferred.

MORB compositions are influenced by the primary melt that is formed by partial melting of the mantle, and the processes of chemical exchange and removal of crystals (called "differentiation") that take place during cooling before eruption. The primary melt is influenced by the temperature, pressure, and composition of the mantle. In general, MORB are generated by "pressure release melting" (Fig. 1a). The temperature at which the mantle begins to melt, called the solidus, increases substantially with pressure. Therefore, at high pressures, the mantle is solid, but as it rises beneath the ridge, the pressure decreases, and melting begins as the solidus is crossed. The amount of melting is then controlled by the depth at which the crossing of the solidus occurs, and the distance over which the mantle rises as it melts. Mantle at higher temperatures will begin melting deeper, and hence rise further, melting more than mantle that is cooler (Fig. 1b). At very slow spreading rates, surface cooling penetrates into the mantle, causing slightly lower extents of melting in these settings (Fig. 1c). The amount of melt may also be influenced by the chemical composition of the mantle.

Once the melts exit the melting regime, they may interact with the cold mantle lid overlying the melting regime, and then cool and crystallize in the crust, forming the lower oceanic crust, before the lavas are erupted on the sea floor. The erupted melts then have been influenced by multiple processes – melting of the mantle, transport of the melts through the uppermost mantle, and cooling and crystallization within the crust. Constraints on the importance and consequences of these various processes come from experiments, theory, and the compositions of MORB themselves, and how these compositions vary in different settings around the ocean ridge system.

Average MORB Compositions

Information about the chemical compositions of MORB comes from three distinct types of measurements, all of which are available through PetDB. The first are the major elements, generally referring to those oxides that are present at levels higher than about 0.05 wt.%. The major elements are conveniently measured on MORB glasses by electron microprobe, leading to a very large data set of tens of thousands of analyses. Major elements provide information about extents of cooling in the crust, as well as the composition and extent of melting of the mantle from which they are derived. Trace elements have been more difficult to determine but now are routinely measured by inductively-coupled plasma mass spectrometry, from which thousands of analyses are available. Trace elements provide more information about the variations in the composition of the mantle source that melted. The most difficult measurements are those of the radiogenic isotopes, but for the commonly measured isotopes of Sr, Nd, and Pb, there is also a substantial data set of many thousands of measurements, with progressively less data for Hf, Os, and the noble gases. The isotopic compositions are the most direct indication of the mantle source, and because their evolution is time dependent, they also provide constraints on the long-term history of the mantle sources of MORB.

The mean composition of MORB has been best determined by Gale et al. (2013), who used all the available data from PETDB and added several thousand additional analyses. MORB volcanism occurs along long cracks in the ocean crust that are periodically offset by transform faults or other smaller offsets. These offsets demark the boundaries between ridge segments. There are about 750 ridge segments along the entire ocean ridge. To avoid the problem of uneven sampling along the ridge system, Gale et al. first constructed averages for each ridge segment, and then ridge segment averages were averaged. Earlier efforts defining mean compositions, based on simple averages of smaller numbers of samples (Sun and McDonough 1989; Hofmann 1988; Arevalo and McDonough 2010), nonetheless came up with rather similar values, suggesting the mean composition is now well determined (Table 1).

A distinctive type of ocean ridge basalt is erupted at spreading centers behind active convergent margins, called back-arc basins. These back-arc spreading centers erupt back-arc basin basalts (BABB) (Sinton and Fryer 1987) that are distinguished from MORB from open ocean spreading centers by their inclusion of an "arc component" in their chemical composition, which varies in composition with distance to the arc (Langmuir et al. 2006; Kelley et al. 2006). When the back-arc spreading center is close to the arc, the BABB have high K_2O and H_2O, reflecting contributions from the downgoing slab.

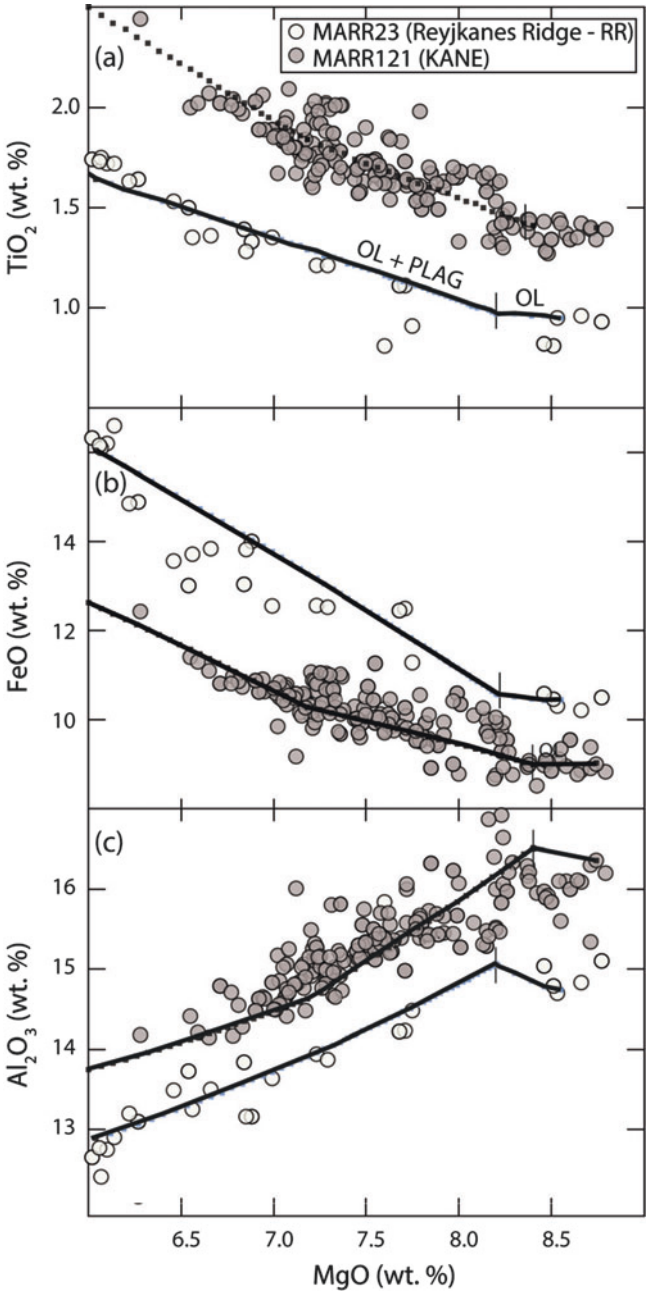
In addition to BABB, other diverse components make up the global average, and the regional diversity of compositions reveals much about the composition and history of the mantle. Major elements, trace elements, and isotopes each provide different sets of information.

Major Elements and Mineralogy

The mineralogy of MORB is straightforward. Olivine is the first phase to crystallize, followed by plagioclase and then clinopyroxene. At much lower temperatures, Fe-Ti oxides and low Ca pyroxene can appear, although these phases virtually never appear as phenocrysts in MORB. In almost all sampled MORB olivine and plagioclase are the most abundant phenocrysts. Clinopyroxene is less common. Fe-Ti oxides occur largely in the groundmass. Removal of these phases during cooling in the crust and uppermost mantle leads to the "liquid line of descent," the path of compositions created by cooling and removal of crystals. Calculations based on experimental data can be used to model the liquid lines of descent very accurately. What is remarkable about many MORB suites is how well samples from a particular region lie along liquid lines of descent calculated from the highest temperature basalts from the same region. Examples of MORB suites and liquid lines of descent from different regions are shown in Fig. 2. The oxide MgO is used as the horizontal axis because it is a very effective proxy for the temperatures of erupted magmas. The mean erupted temperature appears to vary slightly with spreading rate for MORB far from hot spots (Rubin and Sinton 2007), with slightly lower eruptive temperatures at faster spreading ridges, probably because of shallower magma systems that are more efficiently cooled by the surface.

The simplicity of MORB major element variations on a segment scale, illustrated for two segments in Fig. 2, is surprising given the great complexity that has emerged from the study of the plutonic rocks of the lower portions of ocean ridges (see e.g., Lissenberg et al. 2013). Very complex processes are apparent in the plutonic rocks, leading many in that community to argue that the liquid lines of descent of MORB should be very complicated and difficult to unravel (Coogan and O'Hara 2015). Given the plutonic complexity, it is remarkable how well individual MORB suites plot along simple liquid lines of descent. Whatever the origin of this fact, this observation makes it possible to back-project lower temperature MORB to the higher temperature (higher MgO) compositions that are more closely related to melts coming out of the mantle. These corrected compositions can then best

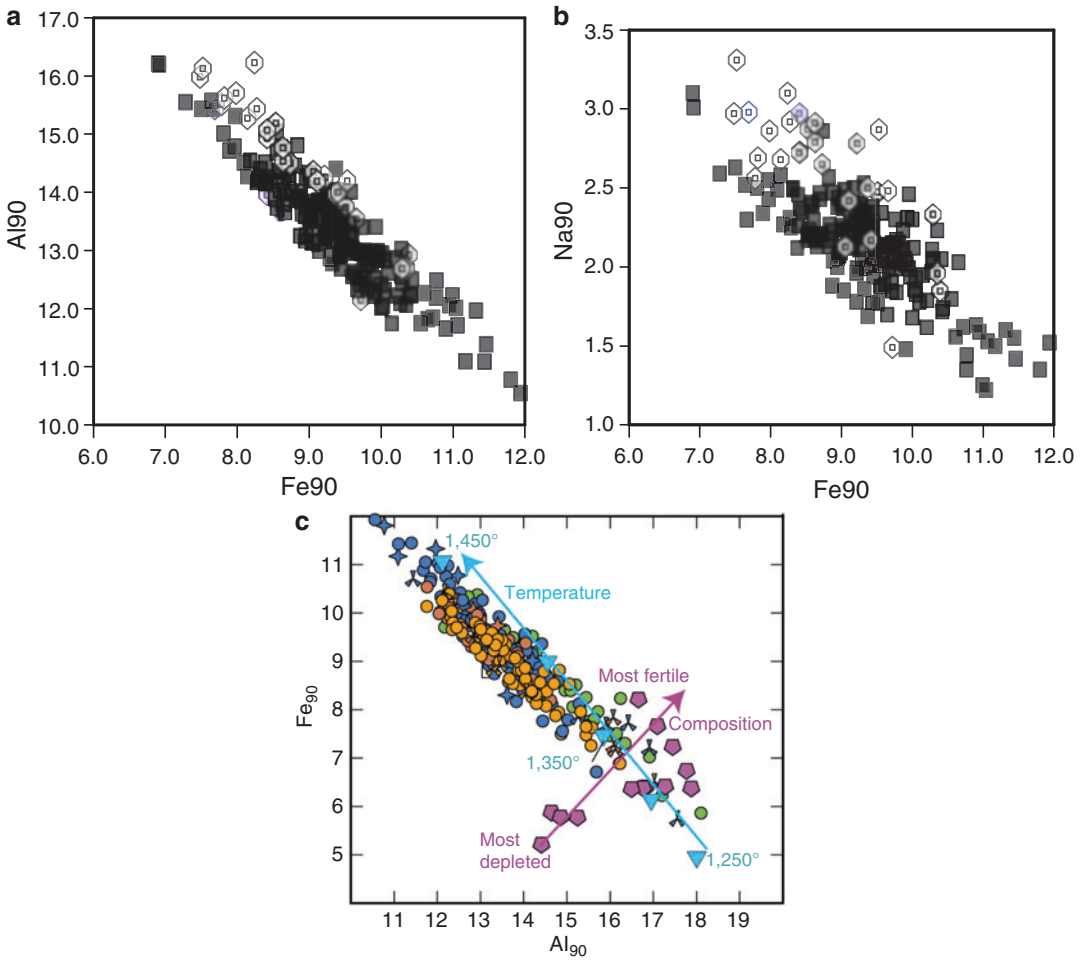


Mid-Ocean Ridge Basalts (MORB), Fig. 2 Data from a shallow (Reykjanes) and a deep (Kane) ridge segment with liquid lines of descent showing the smooth trends exhibited by lavas from individual ridge segments, and the large contrasts between mean compositions from different ridge segments. Note that the deeper ridge segment has lower Fe and Ti, and higher Al (and Na, not shown) than the shallower ridge segment (Modified from Gale et al. 2014)

be used to understand how MORB form, and what controls the variations exhibited by liquid lines of descent from different regions.

One method to correct, or normalize, compositions is to move them back along a liquid line of descent to a constant MgO content, normally 8 wt.%, which has the advantage of providing normalized compositions within the range of MORB observations (Klein and Langmuir 1987). Alternatively, compositions can be back-tracked to a composition in equilibrium with the mantle, which has an olivine composition of Fo_{90} or 90% of the MgO end-member (Stolper and Newman 1994). Gale et al. (2013) showed that the two methods produce similar results. $Na_{8.0}$ or Na_{90} refers to Na_2O contents normalized to a particular value. Normalizing in this way then allows comparisons of parental compositions around the global system of ocean ridges. These comparisons then show the systematics of MORB major element compositions, and allow a demonstration of how these systematics relate to tectonic variables such as spreading rate, proximity to hot spots, and the overall depth of the ridge axis.

Figure 3a, b shows the relationships among MORB major elements for individual ridge segments normalized to Fo_{90}, for ridge segments that have more than three samples available (Gale et al. 2014). The data are systematic and show clear relationships. Fe_{90} is negatively correlated with Si_{90}, Al_{90}, and Na_{90}, while Na_{90} and Al_{90} are positively correlated. The slowest spreading ridges, with spreading rates less than 20 mm/year, indicated by the open symbols in Fig. 3a, b, are slightly offset from the data from faster spreading ridges. There are also correlations between these chemical parameters and the depth of the segment from which the samples were recovered. Samples from shallow ridges have lower



Mid-Ocean Ridge Basalts (MORB), Fig. 3 Variation of segment average major element compositions corrected to a composition in equilibrium with mantle olivine. A,B, Data for all segments except back-arc basins and hot spot centers with Th90 > 0.5. Super-slow spreading ridge segments are indicated by the open symbol. They are offset to higher Na90 and Al90 owing to a thick lithospheric lid at super-slow spreading rates. C,D Comparison of the data to trends for variable mantle temperature and variable mantle composition. *Pentagons* are experiments on mantle of different compositions. *Arrows* are calculated variations for temperature and composition. Note the principal component of the variation is well explained by mantle temperature, and not by mantle composition (Segment averages are from Gale et al. 2014)

$Na_{8.0}$, $Al_{8.0}$, and $Si_{8.0}$, and higher $Fe_{8.0}$ than samples from the deepest ridges. This contrast is also apparent by examining the liquid lines of descent in Fig. 2.

Klein and Langmuir (1987) originally proposed that these systematic variations in ocean ridge compositions were primarily the result of variations in mantle temperature, an inference that had been partially suggested on the basis of abyssal peridotite data by Dick et al. (1984). The reasoning behind this model is straightforward, and illustrated in Fig. 1b. Where the mantle is hotter, it begins melting at greater depth, and melts more as the mantle upwells toward the surface. This creates a large melting region with high extents of melting at ridges that overlie hotter mantle as compared to ridges that overlie colder mantle. The larger extents of melting dilute the Na and Al contents of the melts, while the elements Si and Fe are primarily responsive to the mean pressure of melting. The deeper average melting regime where the mantle is hot leads to higher pressures of melting and hence lower Si and higher Fe contents. The ocean crust is buoyant relative to the mantle. The large and deep melting regimes where the mantle is hotter lead to greater extents of melting and hence greater thicknesses of ocean crust, which rise to higher elevations as they equilibrate gravitationally with the underlying mantle. These early inferences remain consistent with all the new observational and experimental data.

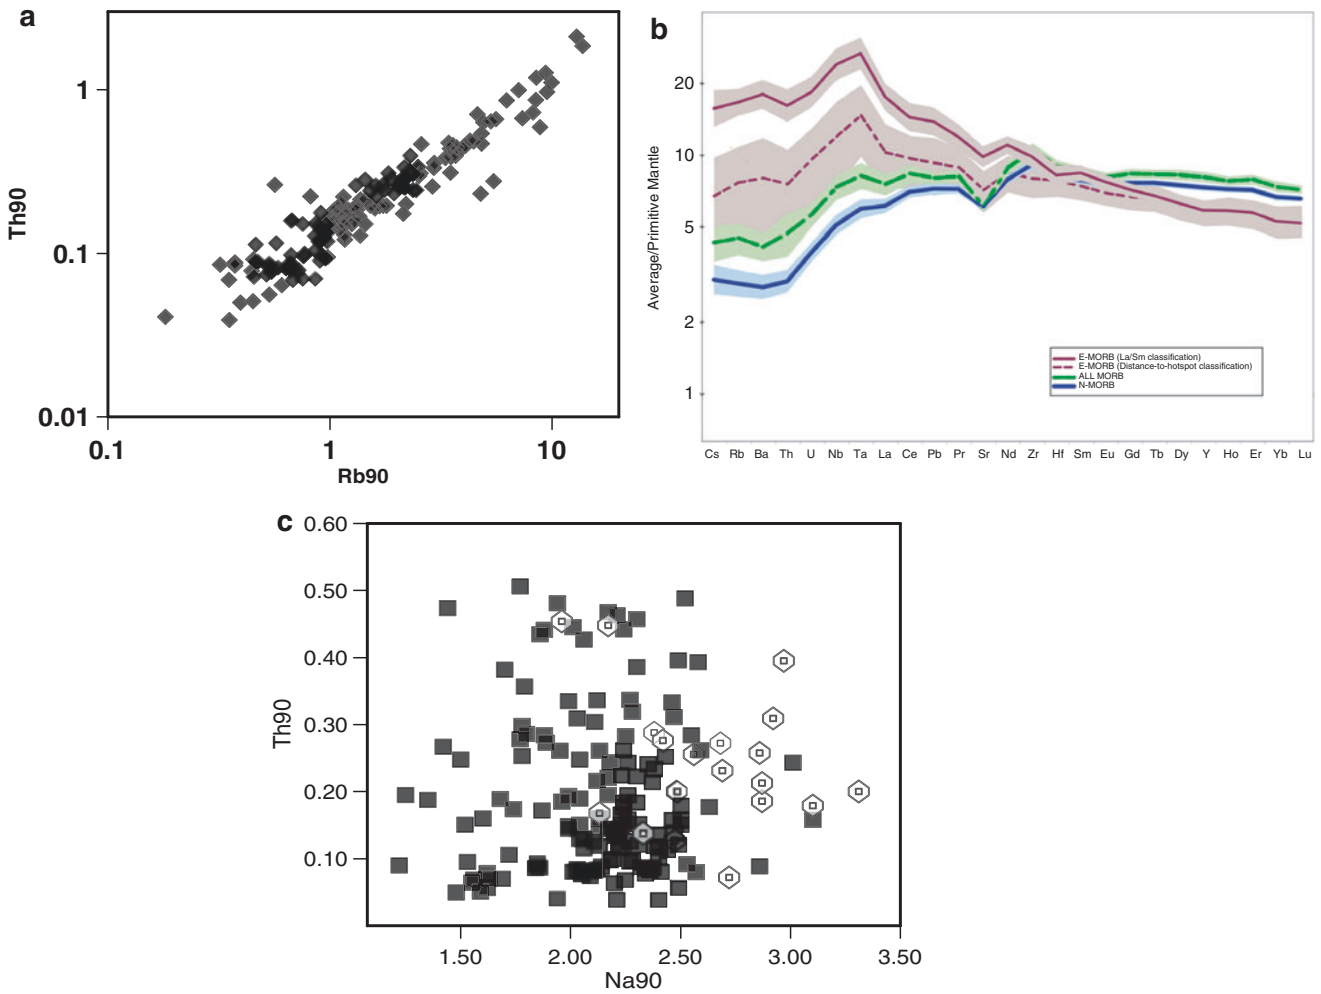
Two alternative hypotheses have been proposed to account for the variations in ridge compositions seen in Fig. 3. Shen and Forsyth (1995) proposed that the dominant control was spreading rate. A thicker lithospheric lid at slower spreading rates (see Fig. 1c) would create smaller extents of melting, and the highest values of $Na_{8.0}$ do indeed occur primarily at the slowest spreading ridges. Niu and O'Hara (2008) proposed that the dominant control was mantle composition. They suggested that deeper ridges were underlain by sources with higher Na and lower Fe contents, which would lead to a mantle of higher density. The high density of the mantle would cause the ridge to be deep, and the high Na contents of the mantle source would lead to the high Na contents observed in basalts at the slowest spreading rates.

Both these arguments have elements of truth. As is apparent in Fig. 3a, b, the slowest spreading ridges do tend to have higher Na contents. This offset occurs across the entire range of mantle temperatures, however, and is a second-order effect. There must also be a range of mantle compositions at ocean ridges. This is very apparent in the trace element and isotope compositions, which are distinctive at and near ocean islands. Model curves for the effects of mantle composition, however, shown in Fig. 3c, d, show that the compositional variations produced by such inevitable variations are orthogonal to the main trend of the data, so this must also be a second-order effect. These conclusions are reinforced by the recent seismic data that show slower seismic velocities, and hence higher mantle temperatures, beneath ocean ridges with thicker crust (Dalton et al. 2014).

Back-arc basins also occupy a large range of mantle temperatures (Klein and Langmuir 1987; Taylor and Martinez 2003; Langmuir et al. 2006; Kelley et al. 2006), encompassing almost the entire range observed at open ocean ridges. The melting mechanisms in this environment, however, must greatly differ from the open ocean ridges, because very low $Ti_{8.0}$ and $Na_{8.0}$ at back-arc basins coincide with very low Fe contents. In general, back-arc basins are derived by higher extents of melting for the same depth as other ridges, owing to the water present in their source regions that causes higher average extents of melting in those environments.

Trace Elements

Trace elements show much larger variations than the major elements – up to a factor of 100 for the most highly incompatible elements such as Ba, Rb, and Th (Fig. 4a). These large trace element variations lead to the terms "enriched" and "depleted" when referring to MORB. The boundary between "enriched" and "depleted" generally refers to rare earth element (REE) patterns that are enriched or depleted in the lighter REE relative to chondritic meteorites, which reflect the bulk Earth composition (Sun et al. 1979) Fig. 4b). The ratio $(La/Sm)_N$, where the "N" refers to normalization to chondritic meteorites, reflects this enrichment or depletion. Since there are many more measurements of major elements than REE, the major element ratio K_2O/TiO_2 is often used as a proxy for $(La/Sm)_N$. Enriched MORB (E-MORB) have $(La/Sm)_N > 1.5$, which corresponds to $K_2O/TiO_2 \sim 0.2–0.25$, depending on the region. E-MORB are in part associated with ridges near ocean islands, as documented extensively by Schilling and coworkers (Schilling 1975; Schilling et al. 1982), but also occur sporadically along sections of ridges far from any known islands or hot spots. D-MORB are strongly depleted in the lighter REE, and have $(La/Sm)_N \sim 0.6$. The most commonly erupted MORB, N-MORB, has $(La/Sm)_N$ of ~0.8. There has also been a term for MORB in between N-MORB and E-MORB, called T-MORB (T for transitional). A boundary between N-MORB and T-MORB would occur at $(La/Sm)_N = 0.8$, or $K_2O/TiO_2 = 0.12$. In fact, there is a continuous range from highly depleted to very strongly enriched, and the boundaries between the different classes are quite arbitrary. But generally speaking, T-MORB have flat REE patterns, E-MORB have enriched patters, and N- and D- MORB have depleted patterns. The overall trace element patters from one ocean basin to another are remarkably similar – there is a progressive continuum from "enriched" to "depleted" that is widespread.



Mid-Ocean Ridge Basalts (MORB), Fig. 4 (**a**) Plot of Ba versus Th for segment averages corrected for fractionation to equilibrium with mantle olivine showing almost two orders of magnitude variations. Variations are greater than two orders of magnitude in individual samples. Note that the factor of variation far exceeds those shown for the major elements in Fig. 3 (Data from Gale et al. 2013). (**b**) Examples of normalized trace element abundances for average MORB, normal MORB far from hot spots, and enriched MORB. Normal MORB are depleted in the lighter rare earth elements (La, Ce), while enriched MORB are enriched in these and other elements. (**c**) Demonstration of the complete lack of correlation between highly incompatible elements and major elements. Segments from hot spot centers with Th90>0.5 have been excluded for clarity. They would simply extend the vertical axis to higher values

The trace element data along with the isotopes discussed below provide convincing evidence for mantle heterogeneity. The major elements suggest extents of melting vary by a factor of three – far less than would be able to account for the trace element variations. Furthermore, there is no correlation between highly incompatible elements and the major elements (Fig. 4c). In addition, enriched MORB often occur in the vicinity of ocean islands, and these regions are high temperature, leading to low abundances of elements such as Na.

Clearly, there are processes that greatly modify the highly incompatible trace element composition of the mantle without having significant effects on its major element composition. A common hypothesis for trace element-enriched MORB is the presence of recycled crust in the mantle, more enriched than the mantle itself, which melts out to produce enriched compositions (Hofmann and White 1982). A difficulty with this model is that recycled crust should also modify the major element composition of the mantle, making it difficult to explain the lack of correlation between major and trace elements. An alternative model is that the heterogeneity is created by the ubiquitous movement of low degree melts (Langmuir et al. 1992; Niu et al. 2002; Donnelly et al. 2004), which are small in mass but extremely high in trace element concentrations. Adding a percent or two of such a melt can change source abundances by orders of magnitude, while having negligible effect on the major elements. The origin of the trace element heterogeneity in MORB is far from settled.

Radiogenic Isotopes

Radiogenic isotopes show substantial variations in MORB, though much smaller in magnitude than the variations that are observed on ocean islands. The hallmark of virtually all isotopic values is that they reflect a long-term depletion of the mantle source relative to bulk Earth compositions. This depletion is consistent in general with the trace element depletion relative to chondritic meteorites. The depleted upper mantle reservoir indicated by the isotopes is widely considered to be the complement of the overall enriched compositions that characterize the continental crust.

In detail, the isotopic variations are complex (see review by White and Klein 2014). There are subtle differences between the Atlantic, Pacific, and Indian Ocean basins which are not yet clearly explained, but seem to require two distinct processes that have given rise to the diverse heterogeneity (Iwamori et al. 2010). The south Atlantic and Indian oceans are marked by variations that have been called the "Dupal anomaly" (Hart 1984), which tends to have higher values of $^{87}Sr/^{86}Sr$ at lower values of the Pb isotope ratios such as $^{206}Pb/^{204}Pb$. Within any one region, there are rough correlations between the parent/daughter ratios and the radiogenic isotopes, but this relationship is not global. This is not surprising, since trace elements can be strongly influenced by very recent processes, while the radiogenic isotopes are integrating a multibillion year history.

Outstanding Problems

The current knowledge of MORB is based almost entirely on abundant sampling along active ocean ridges where the youngest volcanic rocks are exposed. Older rocks become rapidly covered in sediment, and even when recovered they cannot be dated easily because of their alteration and very low potassium contents. It is often thought that ridges go through cycles of more and less abundant volcanism, which should be expressed in MORB compositions, and there is also the possibility of longer term variations with time. This temporal domain is virtually unexplored.

There is another large remaining conundrum, which is the relationship between the plutonic rocks that make up two-thirds of the ocean crust, and the lavas that are easily sampled at the surface. Work on the small numbers of plutonic rocks that have been recovered show a diverse set of complex processes operated on them. How this complexity can be reconciled with the very straightforward liquid lines of descent and global systematics that are evident in the erupted lavas will be an unfolding future story. How this story unfolds may also have consequences for the current interpretations of MORB compositions.

Summary

MORB are the most common rock type on Earth, and have become well characterized by five decades of study leading to tens of thousands of chemical analyses.Variations in the temperatures of eruption are largely controlled by crustal processes, which lead to liquid lines of descent at various pressures.Variations in parental magma compositions are controlled largely by mantle temperature.Hot mantle leads to higher extents of melting, thicker crust, and shallower ocean ridges.Variations in spreading rate and mantle composition are important second-order effects for the major elements and total melt production.Highly incompatible trace elements and isotopes are controlled largely by mantle heterogeneity.The relationship between the erupted volcanics and the thick plutonic sequences that make up most of the ocean crust poses puzzling problems that remain to be fully elucidated.

Mineral Defects

Kurt Schwartz[1] and Maik Lang[2]
[1]GSI Helmholtz Center for Heavy Ion Research, Darmstadt, Germany
[2]Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, USA

Definition

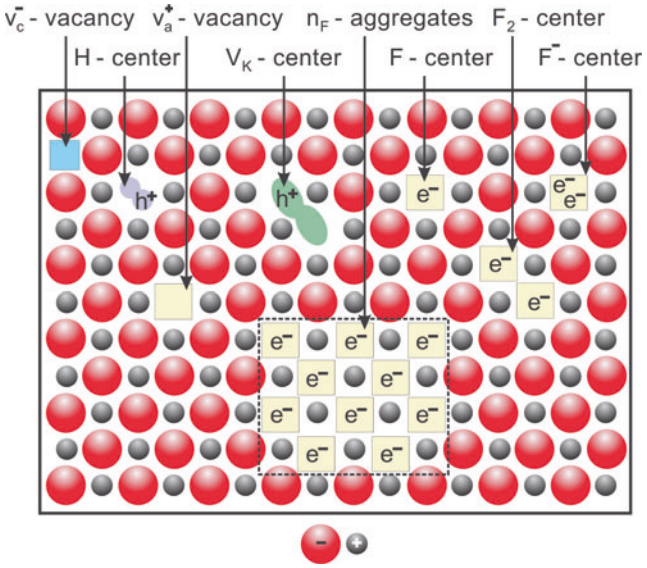
Crystal defects can be most simply defined as distortions of the periodic arrangement of atoms in a "perfect" crystalline lattice. Above absolute zero temperature, defects are present in all crystals at certain concentrations. An increase in temperature increases the number of defects significantly. Depending on their dimensions, defects can be classified into point defects, line defects, planar defects, and bulk defects. Defects can be introduced in minerals through various means, such as self-radiation. Radiation-induced defects in minerals have been observed long before the discovery of radioactivity. Berzelius observed thermo-luminescence in gadolinite ($(Y,Ce)_2Fe^{2+}Be_2O_2(SiO_4)_2$) caused by α-decay of uranium and thorium trace elements (Berzelius 1815). Unaware of the underlying processes, Baumhauer etched fission-fragment tracks in apatite as early as the nineteenth century (Baumhauer 1894).

Classification of Defects

1. *Point (zero-dimensional) defects*

Point defects are distortions at a single lattice position, such as vacant atomic sites, which are called vacancies (Itoh and Stoneham 2001; Kittel 2004). Due to electrical charge neutrality, an equal number of anion and cation vacancies must be present at any time in ionic crystals (*Schotky defects*). *Frenkel defects* are a type of vacancy – interstitial pairs in the lattice, which can form if an atom is moved from its lattice site into an interstitial position. In ionic crystals both anion and cation Frenkel defects exist. Point defects can also be impurity elements substituting regular atoms (anions or cations in ionic crystals). Such defects can be introduced by contamination of minerals with foreign species. If the equilibrium charge of the impurity atom is different from the host crystal, vacancies can compensate the charge difference, e.g., Mg^{2+} impurity in NaCl (rock salt) has the microstructure of $Mg^{2+}v_c^-$ (v_c^- is a cation vacancy having a negative charge). The large variety of point defects that can be present in a mineral are illustrated in Fig. 1 for NaCl. Point defects are also color centers in dielectric materials which give rise to color in some minerals.

The point-defect concentration depends on temperature. The equilibrium concentration of vacancies (n) is equal to $n/N = \exp(-E_v/k_BT)$, where E_v is the energy to create a vacancy, N is the concentration of lattice atoms (ions), and k_B is the Boltzmann constant. For example, vacancies in NaCl have an E_v of about 2 eV, which corresponds to an anion vacancy concentration of $n_{va} \sim 5 \times 10^{11}\text{cm}^{-3}$ at T = 1000 K (close to the melting point).



Mineral Defects, Fig. 1 Color centers in NaC1 crystals: v_c^- – cation vacancy; H – anion molecule X_2^- replacing an regular anion; v_a^+ – anion vacancy; V_K – anion molecule X_2^- replacing two regular anions (self trsapprd hole); nF – F-center aggregate (quasi Li colloid); F – center ($v_a^+e^-$), F_2 – ($2v_a^+2e^-$); F^- – ($v_a^+2e^-$)

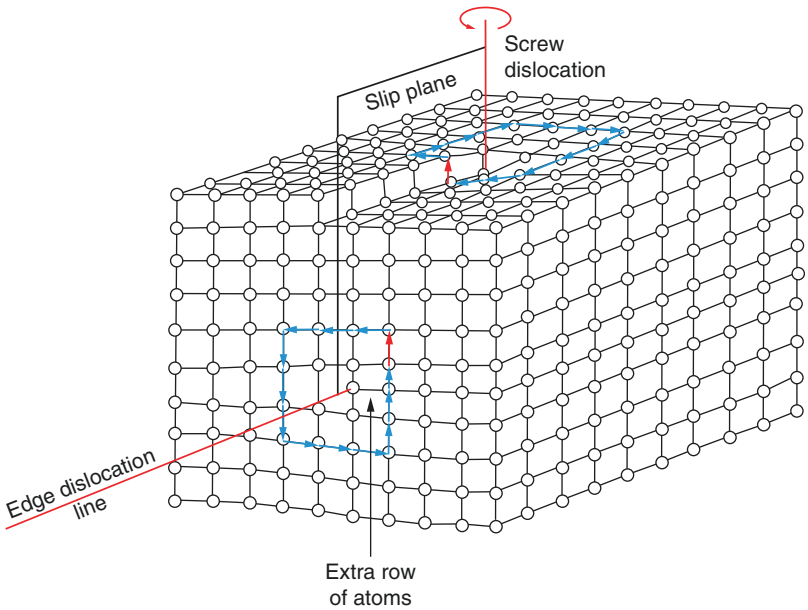
At elevated temperatures, point defects are mobile and can interact with other defects forming complex defects or defect aggregates (see Fig. 1). The defect diffusion coefficient is equal to $D(T) = D_0\exp(-Q/k_BT)$, where D_0 is the pre-exponential coefficient and Q the activation energy. Usually the magnitude of Q is larger for vacancies than for interstitials. In NaCl, Q is for both anion and cation vacancies about 2 eV, whereas for neutral chlorine interstitial atoms Q = 0.1 eV.

2. *Line (one-dimensional) defects*

The main line defects within an atomic structure are dislocations. There are two types of dislocations – edge and screw (Fig. 2). Edge dislocations are an additional half- plane of atoms introduced into the lattice. Screw dislocations are usually produced by an atomic-step spiral during crystal growth. Mixed edge and screw dislocations are present in many minerals. The main characteristic for dislocations is the Burgers vector (***b***), which is determined by the so-called Burgers-circuit – the missing link is the vector ***b*** (Fig. 2). For edge dislocations, ***b*** is normal to the dislocation line, and for screw dislocations, ***b*** is parallel. The Burgers vector determines the dislocation formation energy (E_{disl}) and is approximately $E_{disl} \sim Gb^2$, where G is the shear modulus (the magnitude for G in various solids is in the range of 10–150 GPa).

Edge and screw dislocations are created by deviations during growth processes, internal mechanical stresses, and plastic deformations. Dislocations are also mobile at elevated temperatures and can interact with other defects to annihilate or form more complex defect structures. Line defects can be also created by aggregation of point defects (vacancies or

Mineral Defects, Fig. 2 Edge and screw dislocations



interstitials), which occurs, for example, in ionic crystals as a result of particle irradiation (Hobbs et al. 1973; Hirth and Kubin 2009).

3. *Planar (two-dimensional) defects*

The main planar defects are stacking faults, which are defined as local discontinuities in the stacking sequence of the periodic atomic arrangement in the lattice, e.g., ABC in cubic crystals. Details on the structure of stacking faults depend on the crystal symmetry of the host material. Planar defects can be introduced into a material during crystal growth, by interaction of point defects/dislocations, and by plastic deformation. Stacking faults are more commonly observed in layered minerals.

4. *Bulk (three-dimensional) defects*

Three dimensional or bulk defects are voids, cracks and impurity clusters. Bulk defects occur on a much larger scale than all other aforementioned crystal defects. Voids are lattice regions with a large number of missing atoms from regular lattice sites, i.e., vacancy aggregates. Voids can form during mineral growth, under irradiation, and plastic deformation.

Finally, impurity atoms of large concentrations can form impurity clusters that lead to local material regions with different phases than the host mineral, the so-called precipitates.

Radiation Damage in Minerals From Self-irradiation

Radiation effects in solids were first observed in colored rock salt (NaCl) and fluorite (CaF_2) minerals (Dyar and Guntar 2008). Various minerals can emit a thermo-luminescence signal as a consequence of the presence of radiation-induced defects (Berzelius 1815). Radiation damage in minerals is created through the decay of unstable, natural-occurring radioactive isotopes (^{226}Ra, ^{238}U, ^{232}Th, etc.) that are incorporated in minerals during or after formation. These heavy isotopes were produced by supernova explosions long before the birth of our solar system. The overall level of radiation from these radioisotopes on Earth is currently low. Nevertheless, over geological time intervals, significant amount of radiation damage can accumulate that can lead in extreme cases to the loss of crystallinity of an entire mineral sample (Ewing et al. 2000).

Radiation-damage studies in solids were mainly stimulated by the need of materials for nuclear applications in the 50s of the twentieth century. There are two general mechanisms for damage creation in solids: atomic displacements (Seitz and Koehler 1956) and electronic excitations (Itoh and Stoneham 2001). Atomic displacements lead to the formation of vacancies and interstitials in all materials from metals to insulators, while electronic excitation creates radiation damage only in the latter. Primary atomic displacements induce secondary collisions, and at high absorbed doses, defect aggregates, dislocations and bulk defects are created.

In the 60s of the last century, a new electronic mechanism of Frenkel-defect creation was proposed for ionic crystals. It was observed that different types of radiation (X- or γ-rays, electrons, α-particles, etc.) produce electron–hole pairs and excitons in insulators, which eventually form Frenkel pairs (vacancies and interstitials, see (Itoh and Stoneham 2001) and references within). This electronic or exciton mechanism is active in some dielectric materials if the energy of the electronic excitations, E_{exc}, is higher than the energy required to create a Frenkel pair E_{FD}. The exciton mechanism can explain the formation of structural defects in some materials from initial electronic excitations. Once the Frenkel pairs are created, they can move and produce color centers and, at higher radiation dose, defect aggregates and dislocations. In insulators, the exciton mechanism is much more efficient in producing defects than atomic displacements. Alkali halides and alkaline earth halides have an active exciton mechanism, whereas it is absent in many oxides (MgO, Al_2O_3, Y_2O_3 etc.). Radiation damage can only be created in these oxides through atomic collisions.

Of special interest is damage in minerals that is induced by nuclear fission of uranium ($^{238}U^{92}$) which is as trace element present in many minerals. The spontaneous fission is a radioactive decay event, in which a uranium nucleus splits in two daughter products $^{238}U^{92} \rightarrow {}^{140}Xe^{54} + {}^{96}Sr^{38} + 2^{1}n^{0}$ (one example of many possible daughter-product pairs) that carry a high kinetic energy (about 200 MeV in total). The fast fission products slow-down in the mineral lattice and produce a trail of damage, the so-called ion tracks (Itoh and Stoneham 2001; Itoh et al. 2009). An ion track is in general a small, cylindrical damage region around the ion path with the length between 10 and 100 μm and a diameter of only a few nanometers.

Radiometric Dating

Radiometric dating is a technique used for mineral or rock samples containing radioactive isotopes. The method is based on a chain of radioactive decays which lead to a stable daughter element, e.g., $^{238}U^{92} \rightarrow {}^{206}Pb^{82}$ or $^{235}U^{92} \rightarrow {}^{207}Pb^{82}$. The radioactive decay has a different rate for various elements and the main parameter for the decay is the half-life time $\tau_{1/2}$. During this time, half of the initial radioactive parent atoms decay. The decay process can be described by the following age equation: $t = \lambda^{-1}\ln(1 + N_f/N_0)$, where t is the age of the mineral, N_f is the number of final isotopes (daughters), N_0 is the number of initial radioactive atoms

(parents), and $\lambda = \ln 2/\tau_{1/2}$ is the decay constant of the radioactive isotope. The decay constant λ is known for all radioactive isotopes, while the concentration of initial and final isotopes N_0 and N_f must be determined by modern analytical techniques with a high accuracy (Wagner and Van der Haute 1992). It should be noted that the time t only represents the age of the host mineral if the radionuclides were incorporated during mineral formation. Otherwise, this parameter refers to the elapsed time since radionuclide incorporation. If the mineral is exposed to elevated temperatures during some time of the decay of radionuclides, they become mobile and diffuse through the mineral. Above a critical temperature, which depends on the chemical composition of the mineral, the unstable radioactive elements or the stable daughter products will diffuse out of the host mineral, which puts the limit to this type of dating. It was shown that the presence of defects will affect the diffusion process (Shuster and Farley 2009).

For the decay process $^{238}U^{92} \rightarrow {}^{206}Pb^{82}$ the half-life is $\tau_{1/2} \approx 4.5 \times 10^9$ years and for $^{235}U^{92} \rightarrow {}^{207}Pb^{82}$ $\tau_{1/2} \approx 700 \times 10^6$ years. Thus, these uranium isotopes can be used to determine the age of extremely old minerals and rocks. The oldest mineral dated is zircon, $ZrSiO_4$ (found in Australia), having an age of $(4.404 \pm 0.008) \times 10^9$ years. This has led to the conclusion that the oldest minerals formed shortly after the birth of Earth.

To determine ages of much younger geological samples, other isotopes are needed with a significantly shorter half-life, such as those used in the Rb-Sr method with $\tau_{1/2} \approx 50 \times 10^6$ years or ^{14}C with $\tau_{1/2} \approx 5700$ years (more details in Wagner and Van der Haute 1992).

Fission Tracks in Minerals

The principle of fission-track dating is similar to that of other radioactive dating techniques. Unstable $^{238}U^{92}$ nuclei ($\tau_{1/2} \approx 8.4 \times 10^{15}$ years) undergo spontaneous fission and produce two medium-sized daughter products of high kinetic energy (e.g., 80-MeV ^{132}Xe). These fission fragments induce tracks in the host mineral that exhibit a high sensitivity for chemical etching. Chemical etching is used to enlarge fission tracks to micrometer scale (in the form of hollow features) until they are detectable by optical microscopy. This yields the concentration of fission tracks, which is equal to the concentration of daughter products. The estimation of the present concentration of $^{238}U^{92}$ is more complicated and requires modern analytical methods, such as neutron-activation analysis. For this technique, the mineral is bombarded with thermal neutrons that induce nuclear fission of $^{235}U^{92}$, which is easily measured via the detection of fission products. The ratio of $^{238}U^{92}/^{235}U^{92}$ is known and the age of the geological or archeological sample can be determined using the previously described age equation. Fission-track dating is used to date some of the oldest minerals. Since defects anneal at high temperature, tracks recover and shrink in size. Thus, the track-size distribution also contains information about the thermal history of a mineral. If the temperature is high enough to anneal all fission tracks, the clock is reset to "zero." The critical temperatures for zircon, $ZrSiO_4$, and titanate, $CaTiSiO_5$, are about 240 °C and 300 °C, respectively. Fission track formation and annealing under conditions relevant to Earth's interior has been simulated by combining simultaneously irradiation, high temperature and high pressure and applying state-of-the-art materials characterization techniques (Lang et al. 2009; Kluth et al. 2012; Li et al. 2012).

Summary

There exists a wide range of defects in minerals from individual point defects to large, three-dimensional defect structures. Defects are induced in minerals through different processes, such as during crystal growth and self-irradiation. Defects diffuse at elevated temperatures and oftentimes form more complex defects or anneal with each other. Defects can dramatically change the physio-chemical properties of a material (Itoh and Stoneham 2001; Kittel 2004). One of the most prominent examples is the color of minerals, which can be induced by the underlying defect structure. Finally, defects are of great importance in geochronology, and fission-tracks are, for example, used to obtain the thermal history of archeological and geological samples.

Mineral Genesis

Alain J. Baronnet
Aix-Marseille Université, CNRS, CINAM, Campus Luminy, Marseille, France

Definition

Mineral genesis addresses the questions of where, why, and how minerals form and disappear, on and in the Earth (see also ► Crystal Chemistry).

The Crystalline Earth and Its Dynamics

Minerals, essentially as natural crystals, are the major constituents of the core, the mantle, and the crust of our planet. In the mantle, they form the viscous solid matter involved in slow convective movements which act as the force-transmitting medium for plate tectonics. As such, minerals undergo phase transitions, polymorphic transitions, and more generally nucleation, growth as well as resorption. This occurs in response to local and/or temporal changes in pressure/stress, temperature, and chemical composition. Internal heat production of the Earth is ultimately the cause of mineral dynamics. Most active and diverse kinetic phenomena of these kinds are expected to take place where temperature gradients and chemical gradients are prominent, i.e., in and on the crust.

Mineral growth in the continental crust is mainly located at:

1. Cooling magmas, either intrusive or effusive
2. Metamorphic regions connected to orogens
3. Continental hydrothermal aureoles developed in country rocks in relation to cooling intrusive bodies
4. Weathering and bio-materials located at the relatively sharp interface between the geosphere and atmosphere or ocean floor

Mineral growth is promoted in the oceanic crust mainly at:

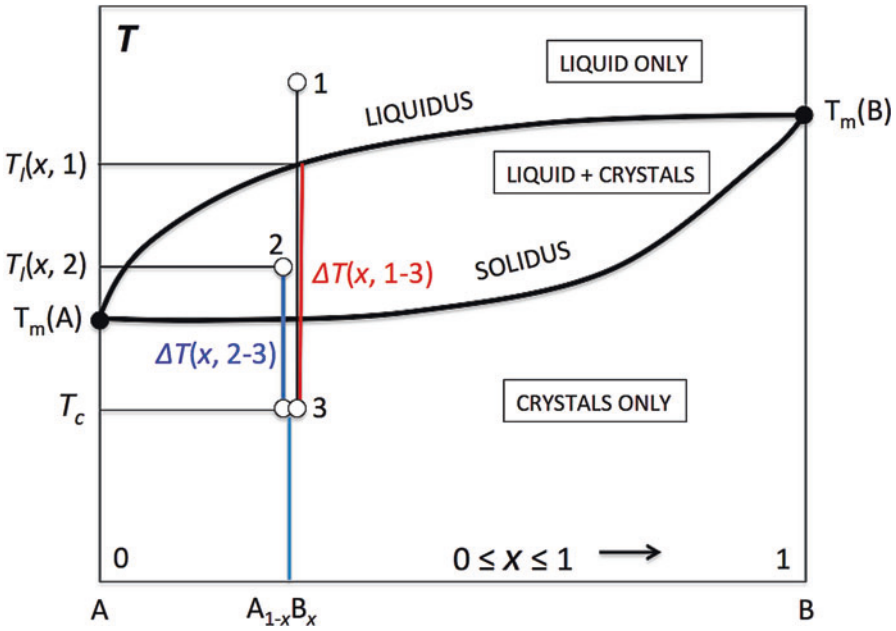
1. Magma reservoirs/newly born tectonic plate interfaces and at hydrothermal vents, close to mid-oceanic ridges
2. The seafloor-seawater interface where freshly deposited sediments start to lithify in depth
3. Sinking tectonic plates, where the moving material cross-cuts isotherms and therefore recrystallize to adapt to more severe pressure-temperature conditions

Mineral resorption, as melting or dissolution, roughly balances mineral production in volume, at the million-years timescale. Mineral sinks are mainly at the solid tips of diving plates and below the mid-ocean ridges where ascending mantle material undergoes partial melting due to depressurization and ocean water income. On the other hand, aqueous solutions of various salts insure dissolution, transport, and crystallization of many mineral species, especially those involved in ore deposits. This takes place when solutions flow through porous and/or fractured rocks. Convective flow is activated by locally contrasted water densities. These density contrasts are sensitive to abrupt geological events like a magma intrusion in the crust that disturbs the normal geothermal gradient. Accordingly, hydrothermal convecting systems develop in country rocks around hot intrusive magmas, as well as inside the cooling oceanic crust mostly cooled down from the top by seawater.

Departure from Equilibrium for Mineral Birth and Growth

Like any crystal, a mineral has to nucleate and grow up to a microscopic or macroscopic size before be considered a solid phase. Crystalline nucleation (birth) and growth (size increase) stages follow each other necessarily, whereas resorption (size decrease) may occur on occasion. They all need some departure from equilibrium in the geologic host system. Nucleation and growth need a positive departure from equilibrium, while resorption needs a negative one. Such departures are expressed in a condensed way by:

$$\Delta\mu = \mu_l - \mu_c$$



Mineral Genesis, Fig. 1 Definition of supercooling ΔT in a binary mineral system. A and B are the two pure mineral end-members of the $A_{1-x}B_x$ solid solution compositions. T_m(A) and T_m(B) are melting points of A and B, respectively. Cooling from above the liquidus temperature (*1*) down to a subsolidus crystallization temperature (*3*) corresponds to the efficient supercooling $\Delta T = T_l(x, 1) - T_c$. Cooling now from the subliquidus region (*2*) down to (*3*) gives $\Delta T = T_l(x, 2) - T_c$

with $\Delta\mu$ as the difference of the chemical potential of the minimum mineral unit in the surrounding medium μ_l and its chemical potential once in the crystal μ_c. The lowest μ represents the preferred (equilibrium) state for the crystal unit. Thus, $\Delta\mu$ is the driving force for crystallization ($\Delta\mu > 0$) or resorption ($\Delta\mu < 0$).

For growth or resorption from the melt, undercooling $\Delta T = T_l - T_c$ refers to the driving force for crystallization (Fig. 1). For small departures from equilibrium, $\Delta\mu$ is linearly related to ΔT by:

$$\Delta\mu = \Delta H_l \cdot \Delta T / N \cdot T_l$$

where ΔH_l is the fusion latent heat of the crystal, N the Avogadro number, and T_l the liquidus temperature.

Note that ΔT is always related to T_c, the actual crystallization temperature. The direct use of ΔT would require natural conditions under which the abrupt cooling step of the melt is followed by a T_c plateau (isothermal drop) instead of the more realistic, almost linear, cooling rate of a magma. However, a positive and continuous correlation exists between the cooling rate (dT/dt) and ΔT regarding nucleation and growth features.

For growth or dissolution from aqueous solutions, where at least a binary mixture (solute and solvent) is present, the departure from equilibrium writes:

$$\Delta\mu = \mathrm{k}T_c \ln\left(a/a_{eq}\right)$$

where k is the Boltzmann's constant, and a and a_{eq} are the actual and the equilibrium activities of the minimal mineral unit, respectively. More precisely, (a/a_{eq}) relies on the product of the actual activities of all chemical species in solution divided by the equilibrium constant at T_c. For the most general case of sparingly soluble minerals (e.g., silicates), activities are well approximated by concentrations, X, expressed in mole fractions. Introducing the relative supersaturation σ of the solution regarding the solute:

$$\sigma = \left(a - a_{eq}\right)/a_{eq} \approx \left(X - X_{eq}\right)/X_{eq}$$

so that:

$$\Delta\mu = \mathrm{k}T_c \ln(1 + \sigma)$$

that is $\Delta\mu \approx \mathrm{k}T_c\sigma$ for small supersaturations. In solution growth, the driving force of crystallization is thus directly proportional to the relative supersaturation. This force can now be varied at constant crystallization temperature.

Solid-state growth as a "crystals-to-crystals" transformation prevails during crystallization of medium-grade to high-grade metamorphic rocks. In this case, departure from equilibrium is accounted for by the concept of "overstepping" which measures the amount of penetration inside the stability field of the mineral phase(s) of interest drawn in the suitable phase diagram. Mineral transformations in low-grade metamorphic rocks and surficial environments take place mostly by a dissolution-crystallization process. In these cases, the higher solubility of the unstable parent mineral maintains a suitable supersaturation with respect to the less soluble, stable, daughter mineral.

Nucleation of Minerals

Primary Nucleation and Secondary Nucleation

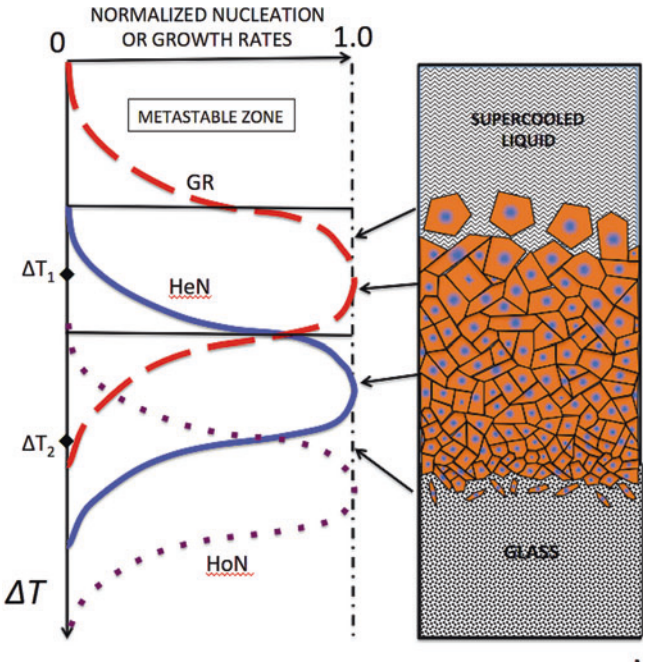
Primary nucleation corresponds to the early first appearance of crystals of a new-born phase. This phenomenon is quantified by the nucleation rate N as the number of crystal nuclei

which appear in a unit volume per unit time (see also ▶ Crystal Chemistry). Homogeneous primary nucleation (HoN) is a concept in which nuclei appear at random in the system. Although HoN rates may be reasonably predicted, Nature proceeds by heterogeneous primary nucleation (HeN) instead, i.e., nuclei appear on singular places of the system (dirt particles; boundaries of the system: walls of a magma chamber, solution–air interface; preexisting crystals acting as substrates, grain boundaries between neighboring minerals in metamorphic rocks, etc.).

Nucleation is the most energy-consuming event in crystals life. Compared with other crystal growth processes, it usually needs a large $\Delta\mu$ to start being significant (Fig. 2). Difficulty of nucleation comes from the high energy cost for creating the new surface of nuclei against their always positive surface energy/tension. The smaller the crystal embryo, the higher its surface/volume ratio and therefore the higher this surface energy relative contribution. This originates a nucleation barrier to be overcome thanks to a minimum applied $\Delta\mu$ for nucleation to start. Below this critical $\Delta\mu$, there is a dead zone or metastable zone in which no spontaneous nucleation would take place. Beyond the metastable zone, N increases steeply to become explosive (crystalline precipitation). However, from the melt, from a devitrifying glass and for highly soluble minerals in aqueous solutions (e.g., halite NaCl, chalcantite $CuSO_4$—$5H_2O$), the metastable zone is narrow so that small N may be maintained. On the other hand, sparingly soluble minerals (layer silicates in general and clays in particular, calcite $CaCO_3$, apatite $Ca_5(PO_4)_3(OH,F,Cl)$, etc.) may have huge metastable zones and explosive nucleation becomes the rule in free aqueous solutions. At near ambient temperatures, it is common that such minerals nucleate in fact from precursor phases that may or may not (e.g., hydrogels) be poorly crystalline themselves and may precipitate first. The benefit of this process is the lowered interface energy between the precursor phase and the final phase. This process is adopted in mostly abiotic contexts like in poor soils as well as in a purely organic context like during carbonate biomineralization of mollusk shells.

Magmatic crystallization along a cooling path may disturb the predicted order of phase nucleation. For instance, in basic silicate melts with diopside composition, CaO—MgO—$2SiO_2$ olivine $(Mg,Fe)_2SiO_4$ may crystallize prior to the stable clinopyroxene $CaMg(SiO_3)_2$, thus violating attempts from the equilibrium phase diagram (Kirkpatrick et al. 1981). Silica monomers are common in the melt and in the olivine structure, whereas they contrast with the silica chain structure of diopside. Accordingly, the interface energy of olivine against the melt will be lower than that of diopside, therefore favoring easy nucleation (Kirkpatrick 1983). It is a general rule that metastable and unstable phases nucleate more easily than stable phases at moderate temperatures!

Nucleation phenomena are dramatically different at high departure from equilibrium, when taking place in aqueous solutions compared to those in magmas. In solutions, the nucleation rate increases monotonously to infinity for large values of σ with the size of critical nuclei, those having been able to overshoot the nucleation barrier, decreasing to the size of the "structural formula volume." It is not so in melts, where ΔT increase means a decrease of T_c and therefore increased viscosity of the liquid. High viscosity involves difficult rearrangement of potential crystal-building units to form nuclei, thereby slowing down nucleation (Fig. 2). Under extreme departure from equilibrium, amorphous or crystalline precipitates form from solutions, and glass from the melt. These extreme conditions are fulfilled at hydrothermal submarine trenches where solutions are quenched (300–400 °C to 4 °C in a few seconds), at the crust of fluid acidic lava flow (obsidian), and during submarine basic lava eruptions on the seafloor (pillow lavas).



Mineral Genesis, Fig. 2 Normalized homogenous (HoN), heterogeneous (HeN) nucleation, and growth (GR) rates as a function of melt supercooling ΔT- Left hand side. Resulting amorphous and crystalline material facing these crystallization regimes in case of a unique ΔT applied- Right-hand side. Under increasing ΔT's we observe successively: (1) a metastable zone as a liquid (no nuclei available for possible crystal growth); (2) assemblage of coarse crystals (sluggish nucleation with high growth rates) with or without a residual liquid; (3) "dry" assemblage of medium-sized crystals (both significant nucleation and crystal growth rates); (4) "dry" assemblage of fine-grained crystals (abundant nucleation but small growth rates); (5) crystallites embedded in glass (explosive nucleation and small crystal growth rates shortly applied); (6) liquid frozen as a glass (zero values for both heterogeneous nucleation and growth rates). Basalt crystallization may be envisaged as following a two-step process: small ΔT_1 applied in the magma chamber giving large phenocrysts in a liquid followed by a high ΔT_2 in the lava during the eruption, giving then tiny microlites in a residual glass issued from the former liquid

Secondary nucleation is a mechanism of production of new crystals of an otherwise already existing phase by mutual shocks and/or scratches. It is not uncommon during tectonic shear of brittle metamorphic rocks and water/ice transport of detrital rocks, but virtually absent in hydrothermal and igneous rocks. In hydrothermal systems, minerals are not allowed to "fly around" to collide since they nucleate heterogeneously on opening walls of veins, caves, druses, or other substrates. In viscous melts, they can hardly impinge each other while they move as following viscous flow lines (Jambon 1980).

Crystal Growth of Unique Mineral Grains

The growth stage follows nucleation and leads to a crystal of microscopic or macroscopic size. The critical nucleus size is the size of the crystal above which it enters crystal growth strictly speaking. At fixed temperature, this size is an inverse function of the departure from equilibrium. It may theoretically vary from infinite size at equilibrium (no growth) to the size of a single formula unit at very large departures (no nucleation).

A freely growing crystal usually looks like a polyhedron limited by flat faces. It is the feeding of the outer surface of this polyhedron by "growth units (= chemical formula units)" that make faces advance outward parallel to themselves, and therefore the crystal to grow as a whole. The mineral habit (Kostov 1965; Kostov and Kostov 1999; Sunagawa 1987), as the observed crystal shape, is determined by the ratio of the mean growth rates of adjacent faces. This shape is bounded by the slowest growing faces among all those dense in their surface atomic structure and may be modeled by the Bravais-Donnay-Harker law (Bravais 1866; Donnay and Harker 1937). "Well-developed" faces are in fact those with the slowest growth rate!

Both the growth rates and the growth mechanisms of a single face depend on:

1. Its surface crystal structure
2. The presence of adsorbed impurities (including the solvent) on it
3. The presence of outcropping dislocations with dominant screw type (see ▶ Mineral Defects)
4. The amount of positive disequilibrium in the system
5. The relative flux (amplitude and direction) of the growth medium with respect to it
6. Temperature T_c, although moderately

Pressure has little effect.

Growth Mechanisms of Individual Faces

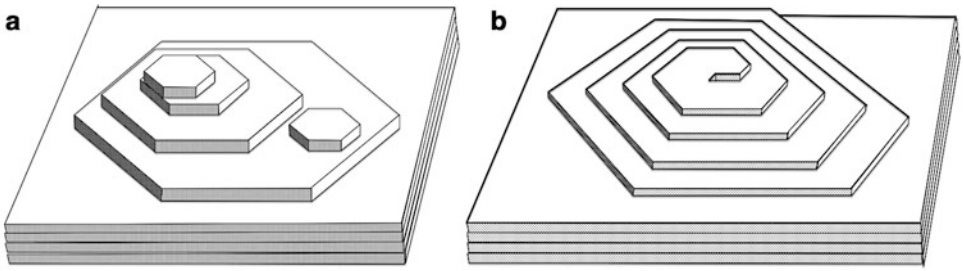
The crystal structure of a face is primarily a planar cut of the 3-D crystal structure parallel to it. In complex mineral structures, this cut exposes the surface which offers the lowest density of broken bonds with the weakest bond strengths, or an appropriate combination thereof. For example, the (001) face of potash mica growing from solution will expose the alkali-bearing interlayer where K─O bonds are the weakest. The actual surface rearranges itself to compensate for the rupture of symmetry of bonding and for the disturbed electric charges. All faces belonging to the same crystallographic form, that is, they are crystallographically equivalent, have the same surface structure, e.g., (100), (010), (001), $(\bar{1}00)$, $(0\bar{1}0)$, and $(00\bar{1})$ of the {100} cubic form of galena. Potential faces of a mineral can be classified into three structural types based on the arrangement of atomic, ionic, or molecular bonding running parallel to the face (Hartman and Perdok 1955): (1) F faces (F for flat) as smooth faces for which at least two interconnected and uninterrupted chains of strong bonds are present, i.e., inside the (001) face of mica in which three distinct . . .O─Si─O─Si─O─Si. . . of such periodic bond chains (PBC's) are present; (2) S faces (S for stepped) as striated faces with a single set of PBC's; (3) K faces (K for kinked) looking like rough faces and containing no PBC.

In minerals with a complex composition and structure, the classification of a face may be ambiguous because bond chains are commonly of different strengths so that there is a gradual continuity between those three types.

Almost only F faces are present on the habit of minerals. Relative growth rates of S and K faces are too fast for those faces to be able to truncate the polyhedron made by F faces.

Under moderate $\Delta\mu$, F faces grow layer-by-layer. There are two possible layer-by-layer growth mechanisms (Fig. 3a, b): the two-dimensional nucleation mechanism (TDNM; Stranski 1928) and the spiral growth mechanism (SGM; Burton et al. 1951; Dekeyser and Amelinckx 1955). The TDNM is the most energy-consuming process since it implies the repeated birth (nucleation) of new growth islands in which most of the growth units are poorly linked to the substrate. On the other hand, the layer spreading is rather easy. Therefore, TDNM requires a large $\Delta\mu$ and is identified by the presence of single or piled-up growth islands on the face (Fig. 3a).

The SGM is constrained by the outcrop of one screw dislocation (see ▶ Mineral Defects) or more, on the face. A spiral step (Fig. 3b) starts from each dislocation outcrop and winds up permanently around it. Growth units stack here tightly at the border of the step. The latter is permanently present during growth while insuring extension of the helical lattice plane. Here the growth normal to the face is achieved by lateral spread of spiral steps. SGM requires small $\Delta\mu$'s only since the birth of a new layer becomes unnecessary. This is the usual growth mechanism of an F face on macroscopic minerals (Sunagawa 1977, 1984). Well-localized and sharp-tipped growth pyramids (growth hillocks) on a face reveal



Mineral Genesis, Fig. 3 Layer-by-layer growth mechanisms of a flat face: (**a**) two-dimensional nucleation mechanism evidenced by scattered and piled-up growth islands, (**b**) spiral growth mechanism: the growth pyramid is centered by the step source, i.e., where the screw dislocation line outcrops. The successive turns of the unique polygonal growth step form pyramid facets made by regular "trains of steps."

outcropping screw dislocations. For both TDNM and SGM, the feeding of the face by growth units is mainly controlled by surface diffusion of growth units. At intermediate $\Delta\mu$'s, volume diffusion of growth units becomes rate-limiting so that growth on crystal corners and edges prevail, thus giving an hollow-faced habit (hollow crystals to skeletal crystals, ultimately dendrites).

Under high to very high $\Delta\mu$'s, F faces may lose their planar form and become rough (kinetic roughening).

Growth Events and Mineral Habit Changes

Following the supersaturation/undercooling decay, which follows nucleation of a mineral phase, the sequence of growth events for a single crystal may be (Sunagawa 1977; Baronnet 1984):

1. Heterogeneous 3-D nucleation
2. Face development by 2-D nucleation
3. Generation of screw defects
4. Final spiral growth stage. The crystal may stop growing at stage (2) if screw dislocation(s) did not form

When considering the set of faces as a whole, the crystal habit changes with time as follows. Soon after nucleation, it may possibly adopt a dendritic/hollow/skeletal habit (e.g., Welsch et al. 2013) for which surface energy is far from minimized in case of very high $\Delta\mu$'s: spinifex texture of olivine and/or pyroxenes in pillow lava, snow crystals are examples. This habit then re-organizes into a rather anisotropic shape, where re-entrant pits disappear and elongation occurs along the strongest PBC directions, e.g., [001] for acicular to prismatic pyroxenes and amphiboles, and [100], [110], $[1\bar{1}0]$ together for micas and clay minerals giving a {001} flattened habit. This emphasizes the relatively high growth rates of faces on which strong dangling bonds occur. With further decay of $\Delta\mu$, such habit anisotropy decreases to give a more compact (isometric) shape. If true equilibrium of the crystal with its medium could be reached, then the crystal would adopt its equilibrium shape on which any (*hkl*) face is at a distance from the crystal center proportional to its crystal–medium interface free energy. This ideal situation is rarely met in Nature, except for some daughter minerals in fluid inclusions (e.g., NaCl and KCl as perfect cubes) and with the negative shape of cavities in alpha-quartz containing primary fluid inclusions.

Specific impurity or inhibitor atoms, ions, or molecules may slow down or even stop the growth of specific faces and/or make new faces appear. Trace amount of Mg, Mn, and Sr, or Ca/CO_3 imbalance, deeply modifies the synthetic habit of calcite (Paquette and Reeder 1995). They act even in trace amounts as they may poison the few growth unit incorporation sites (kinks) present on an F face. Subsequent incorporation in the crystal bulk structure may or may not happen. Accordingly, chemical characterization of the past growth medium from habit observations is hazardous.

Unequal partition of screw dislocations among symmetrically equivalent faces may "distort" the growth habit, altering its apparent symmetry, this being due to central distances of symmetry-equivalent faces no longer equal. Certain "whisker" or needle-like habits are striking examples where the tip face grows fast by a unique/axial spiral while other lateral faces are stopped as defect-free faces, i.e., not able to grow anymore by the TDNM mechanism under insufficient $\Delta\mu$ (halite NaCl, sphalerite ZnS).

The flux of the growth medium with respect to the faces may also lead to face development dissymmetry, provided growth is at least partly volume-diffusion controlled. Faces upstream grow quicker than faces downstream, and laminar flow results in a better face quality in the former case. Fluid inclusions form preferentially behind downstream faces because of a turbulent flowtail: anisotropy and polarity of the quality of alpha-quartz crystals have been used to identify solution flow directions in hydrothermal veins.

Resorption of Unique Mineral Grains

Dissolution or melting of minerals also starts from their surfaces. Preferential sites for resorption are corners and edges where detachment of dissolution units is the easiest.

Etch pits with the shape of inverted pyramids, often centered on defects, also form on flat faces. Rounded shapes result, but they are transient. Starting from a sufficiently large crystal or from a crystal polished as a sphere would lead to a polyhedral, now stationary, habit. The latter would be limited by the fastest resorbing faces, i.e., those which were growing formerly the fastest, and therefore which were not present on the growth habit. Consequently, neither euhedral nor rounded habits are fully confident indicators of growth or resorption, respectively.

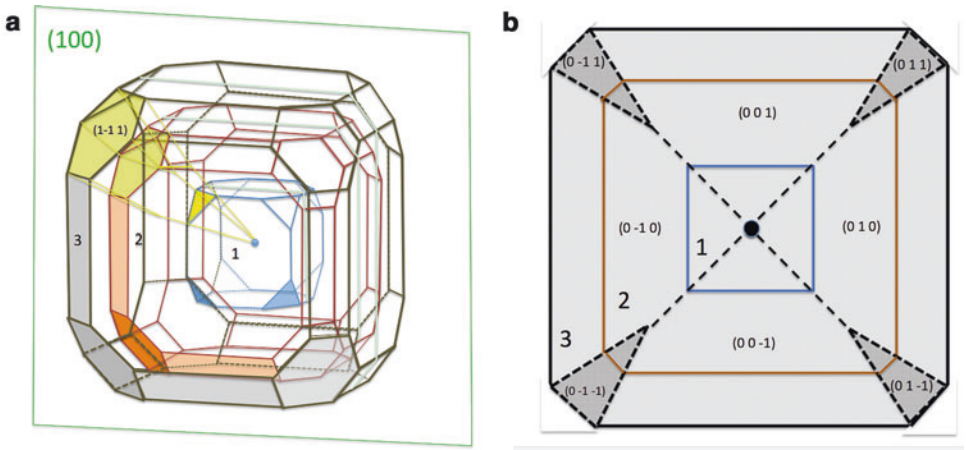
Growth and Sector Zonings

Irregularities in growth rates of individual faces, volume diffusion-growth rate feedback, temperature, and/or changes in the mother medium chemistry are major sources of growth zoning. Such growth zoning consists of "ghost-in-ghost" marks that trace successive growth habits of single crystals during their life time (Fig. 4a, b). Unconformities similar to those known in structural geology may develop if one or more resorption stages occurred during the growth history.

Sector zoning refers to isochronous and different chemical compositions left in the crystal volume behind distinct faces which are not crystallographically equivalent: sand-glass marks in Ti-rich augite, Ag-rich {111} versus Ag-poor {100} forms of argentiferous galena (Fig. 4a), etc. Individual crystal sectors are often inward-pointing pyramids that are the part of the crystal bulk swept across by a growing face. Both growth and sector zonings are indications of global disequilibrium of the crystal with respect to its surrounding. This is far from detrimental since the growth history of a mineral can be read in this case (Baronnet 1984; Sunagawa 1984).

Collective Behavior of Growing Minerals

Explosive nucleation on foreign dots or spherical substrate followed by anisotropic growth results in fibroradiating textures where individual crystals radiate out because of geometrical selection (fibrous zeolites, malachite $Cu_2(OH)_2CO_3$, etc.). Another example is crystal branching, a common process by which spherulites form, for which crystals nucleate continuously on already formed crystals while keeping a repeatable, usually small, disorientation. This disorientation may, or more commonly may not, be a twin operation. For example, branching originates the macroscopically "curved faces" of dolomite $CaMg(CO_3)_2$ or azurite $Cu_3(OH)_2(CO_3)_2$, sheaves of stilbite $NaCa_2Al_5Si_{13}O_{36}$—14 H_2O, twisted fibers of chalcedony SiO_2, and more generally split crystals and spherulites (Grigor'ev 1965). These crystals of less crystallographic quality are now called mesocrystals (Cölfen and Antonietti 2008). The latter are also quite common among biominerals which are no more pure minerals but organo-mineral composites at different scales. They are envisaged to form mostly by particle attachment or



Mineral Genesis, Fig. 4 Galena morphology as a euhedral crystal with cubic symmetry that may combine the {1 0 0}, {1 1 0}, and {1 1 1} forms. (**a**) Three stages of growth (1–3) of the same single crystal illustrating varying mean growth rate ratios between the different forms. The early morphology {1 0 0} + {1 1 1} (a cube truncated at each corner; stage 1, blue) evolves to {1 0 0} + {1 1 1} + {1 1 0} (the same but in addition truncation of all edges of the cube; stages 2, brown and 3, grey). The trajectory of the (1 −1 1) face is highlighted as yellow lines as the edges of the (1 −1 1) growth sector pyramid. Note that any morphology feature wins one dimension once buried inside the growing crystal: corners become lines, edges become surfaces, and surfaces become volumes. All faces of the same form assumed to grow at the same rate. (**b**) (1 0 0) cross-section of the same crystal passing through its center (pale green traces in (**a**)); here the ratio of overgrowth widths along <1 1 0> and <1 0 0> is equal to the ratio of the mean growth rates of {1 1 0} and {1 0 0} in the same time interval

self-organization (discontinuous growth) in the growth medium (De Yoreo et al. 2015). Even purely mineral-mineral crystalline composites are able to mimic life-evocating shapes of "fossils" of primitive organisms, thus rendering extra-planetary recognition of life from recovered "fossil" morphologies somewhat hazardous (Garcia-Ruiz et al. 2009, 2017).

When growth conditions tend to equilibrium from positive departures, a set of crystals of the same mineral will evolve toward reducing its excess surface free energy by changing its grain size. Smallest crystals will resorb, while the biggest will grow at their expense so that their number will decrease and their mean grain size as a whole will increase. This is the so-called Ostwald ripening process (Ostwald 1897), which originates from increased solubility or decreased melting point for crystal sizes mainly in the micrometer range and below. Mineral ripening (Baronnet 1982) operates frequently in monomineralic rocks exposed a long time to metamorphic and hydrothermal conditions (calcite in marbles, alpha-quartz in quartzites, illite in diagenetic rocks, and hydrothermal veins, etc.), and in case of highly soluble minerals near ambient conditions. A unique crystal with its equilibrium shape per mineral phase would be the very end of ripening in a closed system.

Conclusions

Appearance and development of minerals on and in Earth are strongly linked to positive departures from thermodynamic equilibrium caused by the moving matter of our planet. Destabilized mineral systems try their best to walk a while along the pathway toward a new equilibrium. Mineral crystallization participates to this trip. Despite the huge timescales of the Earth history, true equilibrium is rarely reached in rocks. This is the reason why we are able to learn a lot on mineral genesis from reading the mineral structures, microstructures, habits, textures, and chemistry (e.g., Cordier and Leroux 2008), because most of such kinetic fingerprints were not rubbed out by equilibrium attainment.

Geosciences Group, Pacific Northwest National Laboratory, Richland, WA, USA

Definition

Mineralogy is the scientific study of minerals. The issue at hand is the definition of the term "mineral," which was first used in Medieval Latin in the late fourteenth century as *minerale*, or "something mined." The term survives today in common use forms, for example, "mineral water" and "vitamins and minerals" that have nothing to do with the science of mineralogy. The minerals of mineralogy are most traditionally defined in the past decade or two as naturally occurring inorganic substances, produced by geochemical processes, with an ordered, repeating atomic arrangement (a crystalline substance) whose composition can be described by a chemical formula resulting in a definite, but not necessarily fixed, composition. Samples of the same mineral vary in terms of minor and/or trace element composition, and in the case of solid solution, major element composition as long as these substitutions do not change the average crystalline atomic structure. If a change does occur, a new mineral name, not just a varietal name, would be warranted. However, the formal definition of mineral, and therefore mineralogy, is changing (see last section of this article below).

Introduction

The scientific definition of "mineral" has changed with time precisely because the term goes back centuries. As our understanding of these substances advance (Skinner 2005; Dyar et al. 2008; Klein and Dutrow 2008; Klein and Philpotts 2012; Nesse 2012; Haldar 2013; Vaughan 2014), and as we better understand Earth systems science (the extraordinary connectedness of all scientific fields), so does our organization of how we perceive and organize concepts. The general trends have been to modernize the definition to remove what may be historically arbitrary, or even unnecessary, and to also change the definition from more exclusive to one that is more inclusive. For example, natural philosophers centuries ago separated the planet into categories of air, water, and earth and earth into animal, vegetable, and mineral. From this, most definitions well into the twentieth century (and even a few today) exclude inorganic, crystalline compounds produced directly by living organisms (e.g., carbonate minerals that later form a limestone) or indirectly (sulfides that form extracellularly, but as a result of biochemical processes that later become an ore deposit) as not being minerals due to their biologically related origins. This exclusion serves no purpose, and several more recent definitions of minerals have not carried on this exclusionary practice. Equivalently, the part of most mineral definitions that necessitate traditional views of highly ordered crystallinity is also beginning to fall away. The great majority of mineral definitions still state that minerals must be crystalline, which have precisely ordered arrangements of atoms, and are periodic, that is, repeating the same structural units (unit cells), over and over again as described by conventional translational symmetry. However, common and exceptionally important environmental minerals, for example, ferrihydrite and schwertmannite, are accepted by the International Mineralogical Association (IMA) as minerals, but the structure of ferrihydrite is highly disordered, and schwertmannite is poorly ordered within nanoregions that are separated by amorphous material. The IMA also accepts the naturally occurring quasicrystal, icosahedrite, as a mineral. Icosahedrite possesses highly ordered atomic arrangements, but, as a quasicrystal, it is not periodic, lacking conventional translational symmetry. Some now consider naturally occurring organic crystals, and even liquid crystals, as minerals, but, in all of these cases, there is much debate.

In 2009, the IMA set up various commissions and working groups to try to drive forward new mineral classification schemes, and how each will be defined based on all the new findings and evolving thought in the mineralogical sciences.

History

Mineralogy is thought to be one of the earliest fields of science. Like plants, animals, and water, minerals (and rocks which are most typically solid aggregates of one or more minerals) have always been resources readily available to hominids (any of the ancient family of erect bipedal primate mammals, of which only *Homo sapiens* exist today). As cognitive ability led to recognition of mineral properties and eventually experimentation, minerals clearly became one of the core ingredients of the development of the first technologies. Witness the Stone Age, which would last for over 3 million years, defined by fashioning minerals and rocks ideal for cutting, grinding, and pounding, as well as for producing very sharp edged and highly pointed objects. The Stone Age was followed by the Bronze Age which began in approximately the sixth millennium BCE. This time was near the beginning of the extraction of specific metals (copper and tin to make bronze, but also gold – traceable to at least the fifteenth millennium BCE – and many other metals) from rocks and minerals. This was followed by the Iron Age near

the beginning of the first millennium BCE using iron-based minerals that provided even a much wider range of technological advantage. These rock/mineral extraction and production technologies, along with the earlier stone tools developed during the Stone Age, radically changed the world under which the first civilizations began due to the beginnings of agriculture and domestication of animals as far back as the ninth millennium BCE.

Using a different line of reasoning which is just as transformative to human development, imagine the technological advantage of being able to make fire "on demand." This was done, in part, by the discovery that forcefully impacting or striking certain minerals or rocks, such as pyrite, marcasite, or pentlandite, against a hard surface like flint or quartzite can produce sparks suitable for starting fires. Anthropologists are not certain of the first users of mineral-based strikers, but it is clear that *Homo erectus*, some 400,000 years ago, were using fire. Much more recently in the Paleolithic period, some 40,000–50,000 years ago, *Homo sapiens* made fire routinely, and fire strikers in some (or perhaps many) cases may have been used. Very effective iron strikers are well known from near the beginning of the Iron Age forward, probably starting nearly 3 millennia ago.

Fast-forward to today, to the present beginnings of the third millennia AD, we find that mobile phones (i.e., pocket computers, very powerful ones) would not work without elements extracted from minerals containing rare earth elements. The latest jet engine technology would not stand a chance without exotic metal technologies that depend on many other common and rare elements across the periodic table which are only made available by finding economically viable concentrations of certain minerals (not easy to do, to say the least) and discovering economically viable and hopefully environmentally safe ways to extract target elements from those minerals (also a great scientific and technical challenge). Just as importantly, and ultimately much more central to our very existence, key proteins (e.g., enzymes) in our bodies cannot function without metallic cofactors (reactive components in proteins) held within amino acid chains, elements that even in us were sourced via the (bio) geochemical weathering of minerals. Simply put, biology does not work without minerals. And as far as the origin of life itself, scientists that study this typically include minerals, or mineral components, as substrates and/or catalysts in reactions critical to processes that are central to the core of their constructs, experiments, and hypotheses.

Because of the central role that minerals have always played in human history, mineralogy was one of the first sciences to be developed, even, perhaps surprisingly, before the science of geology (Laudan 1987). James Hutton, the eighteenth century Scottish naturalist and founder of modern geology, considered Georgius Agricola, the sixteenth century German physician – natural historian who classified about 600 minerals – as the founder of what we know today as the science of mineralogy. Agricola's most famous work, *De re metallica* (Latin, for *On the Nature of Minerals*) was written entirely in Latin and published in 1556, the year after his death. It was a brilliant and complete treatise (for its time) on minerals, mining, and processing/smelting for metal recovery. This work was also key in the history in the development in the science of chemistry and curiously was first translated to English by Herbert Hoover, who would later become President of the United States in 1929, and his wife, a geologist. This late sixteenth-century work completely replaced the work of Pliny the Elder in this general field of knowledge. Pliny was the first century Roman naturalist who was also the author of the very first encyclopedia. In the centuries after Agricola, and now every single decade, mineralogy continues to advance as an ultramodern and vibrant science.

Mineral Types, Numbers, and Classification

Minerals exist in every part of the Earth system, from high in the atmosphere to deep in the oceans and everywhere in between, and are by far the major constituent of our rocky planet. They also make up meteors and are in fact found throughout the universe, surely making up or contributing to countless other planets (perhaps 100 billion in this galaxy alone, and there are more than 100 billion galaxies altogether). Within galaxies, nebulae are solar system incubators which are made up of high concentrations of gas and dust; the dust consisting of a wide assortment of mineral nanoparticles which represent groups of minerals that we would readily recognize such as oxides, silicates, sulfides, and carbonates. These are the mineral components of future planets. As on this planet, elements from the entire periodic table are available. Temperature and pressure conditions vary dramatically during planetary formation and aging, and in the presence of reactants and catalysts in solid, liquid, and gaseous forms, mineral formation of every conceivable species will be created.

To date, from everywhere on and in Earth that is accessible to us, as well as from our moon, meteorites, and interplanetary dust particles, just over 5,000 minerals have been identified, characterized, and accepted, with a few hundred more awaiting IMA approval, and a few to several tens of new minerals still newly discovered every year.

On this planet, with the makeup of Earth's crust being mostly the elements silicon and oxygen (about 75% by mass), a little over 90% of the crust is made up of silicate minerals (any mineral that has at least silicon and oxygen as major components), of which there are well over 1,000 known varieties. Other elements most commonly found in silicates are the rest of the most common elements represented in the crust, namely (in decreasing order of abundance), aluminum,

iron, calcium, sodium, potassium, and magnesium. Quartz (SiO_2) is the "simplest" and most common single mineral in the crust, but the feldspar group primary minerals (nominally albite $NaAlSi_3O_8$, orthoclase $KAlSi_3O_8$, and anorthite $CaAl_2Si_2O_8$) are by far the most common collectively. Silicates stable at high pressures make up even a higher percentage of the Earth's mantle, which is 84% of the entire Earth by volume.

The basic building block of silicate minerals is the silica tetrahedron $[SiO_4]^{4-}$. Note that aluminum, the next most abundant element in the crust after oxygen and silicon, also forms tetrahedra $[AlO_4]^{5-}$, and silica, or silica and alumina tetrahedra, polymerize (link together) to various extents to form the different types of silicate minerals. The other most common elements chemically bond the various polymerized units together, giving us the vast variety of known silicates. Complete, three-dimensional polymerization generates the tectosilicates (also known as framework silicates); two-dimensional polymerization generates the phyllosilicates (also known as sheet or layer silicates – micas and clays are members of this type); one-dimensional polymerization generates the inosilicates (also known as chain silicates, with amphiboles representing double chains species and pyroxenes representing single chains); ring polymerization generates cyclosilicates; individual silica tetrahedron generate the orthosilicates (also known as island silicates, with olivine as the prime example).

With the dominance of oxygen and silicon in our crust and mantle, one might think that the rest of the mineral kingdom on Earth (nearly 4,000 more minerals) would be relegated to corners of the planet, and with little importance. Nothing could be further from the truth. These minerals provide most of the absolutely necessary elements needed by living organisms (from phosphorus that is key to building the backbone of DNA and RNA to the cellular energy molecule, ATP, to all necessary micronutrients), and most synthetic material components besides carbon for plastics, that is, all that goes into metallic materials (from steel to wiring to airplane wings), semiconducting metals (all electronics and computers), and ceramics and glass (from dinner plates and bricks to windows). Modern civilization would not be possible without all these minerals. Nonsilicate minerals also include the minerals made from single elements (e.g., gold, copper, sulfur, carbon – graphite and diamond). The thousands of other nonsilicate minerals are classified according to the mineral formula's anionic element or groups, with the rest of the periodic table involved. These mineral classes (with the anionic element or group in parentheses along with a type example – name and mineral formula – for each) include the sulfides ($S^{1-,2-}$, pyrite FeS_2); oxides (O^{2-}, hematite Fe_2O_3); hydroxides (OH^-, goethite FeOOH); carbonates (CO_3^{2-}, calcite $CaCO_3$); sulfates (SO_4^{2-}, gypsum $CaSO_4 . H_2O$); phosphates (PO_4^{2-}, apatite $Ca_5(PO_4)_3(OH)$); and halides (Cl^- and F^-, halite NaCl and fluorite CaF_2).

Present and Future Challenges in the Mineralogical Sciences

Harrison et al. (2013) oversaw a 2-year project in which mineralogists (and Earth, planetary, and environmental scientists in related fields) from around the world were asked to consider the greatest present and future questions facing the mineralogical sciences, such that if they would be answered, they would make the biggest difference from the most fundamental to the most applied applications. All of the results from the open survey were condensed down to 100 questions (this list can be downloaded at www.elementsmagazine.org/under the Supplements tab). The very nature of the survey itself speaks clearly to the relevance and staying power of this ancient, now modern science, which is the simple fact that minerals are related, either directly or indirectly, to every subfield of all the Earth, planetary, and environmental sciences. Whether one is a paleontologist or an atmospheric scientist, a geomorphologist, or an aqueous biogeochemist, studying the early solar system or the evolution of Earth's crust, minerals are important, or perhaps entirely central, to your field of study.

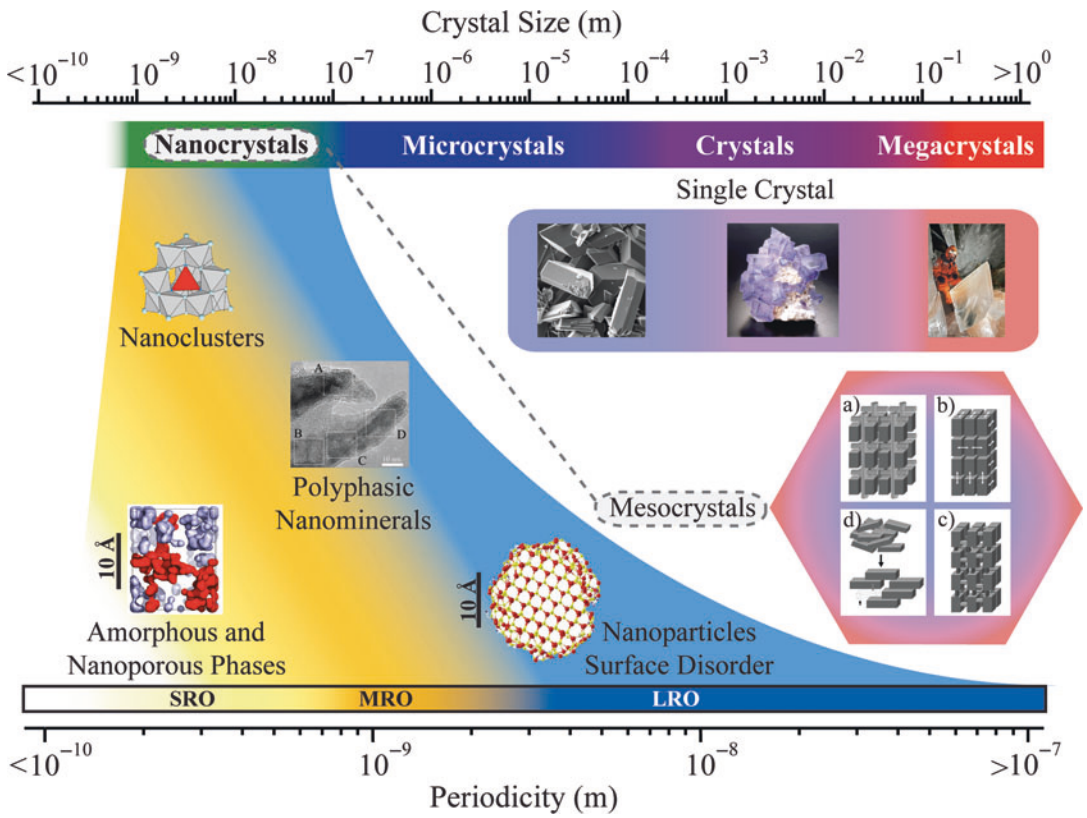
Of all mineral sciences-related subjects, the science of Earth sustainability deserves a special mention. In the face of continuing human population pressures and the fact that atmospheric, soil, groundwater, and biosystem resources are approaching or have already begun to cross decline thresholds, mineralogy holds a central position in understanding how to achieve a sustainable state for Earth. It is well known that most physical, chemical, and biological processes on Earth are either influenced to some degree or fully driven by the properties of minerals. But with only approximately 5,000 mineral species presently described – not many relative to millions of prokaryotic and eukaryotic species combined – their diversity and range of influence may seem, by comparison, relatively modest. Yet minerals exert their influence by constituting (as they always will) the bulk of this Earth system and having a wide range of compositions and structures that are expressed in a remarkable (even dramatic) diversity of physical and chemical properties. Further, minerals are more complex than previously thought because of the discovery that their chemical and physical properties vary as a function of particle size when smaller than a few to perhaps as much as several tens of nanometers in at least one dimension. These variations are most likely due, at least in part, to differences in surface and near-surface atomic structure, as well as crystal shape and surface topography as a function of size in this smallest of size regimes. It has now been established that these variations make a difference in important geochemical and biogeochemical reactions and kinetics, forming the "new" science of nanomineralogy. This recognition is broadening and enriching our view of how minerals influence the hydrosphere, pedosphere, biosphere, and atmosphere (Hochella et al. 2008).

Mineralogy is as important to Earth sustainability issues as most other branches of science. But as has become apparent, it

is the combination of mineralogy with other sciences, such as hydrology and aqueous geochemistry, biogeochemistry, microbiology, atmospheric science, nanoscience, and the medical sciences that makes it so powerful. Starting with the advent of Stone Age tools to fire strikers, minerals have made vital contributions to the human endeavor for literally hundreds of thousands of years. Direct contributions, in terms of the extraction of mineral resources, will continue indefinitely. However for the future, it is the interaction of minerals with the human-impacted hydrosphere, atmosphere, and biosphere that will play a big role in dictating the sustainability, or, if not, the failed sustainability, of planet Earth.

Conclusion

As we have seen above, humans have recognized and utilized minerals with extraordinary creativity for many millennia. Clearly, this utilization has literally changed the world. A modern view of the science of minerals, through which we can easily recognize today as a very careful observational and systematic study, was brought to us over 450 years ago by Georgius Agricola. The centuries in between did not disappoint, with thousands of major developments in our understanding of this planetary construction material. Whether using minerals to understand plate tectonics, the origin of life, global climate change, or catalytic chemistry on a grand scale, they have unlocked more secrets than most observers can imagine. Now, by using powerful computers backed by ingenious software and models, transmission electron microscopes that have subatomic-resolution analytic capabilities, and synchrotrons that cost hundreds of millions of dollars producing light with unimaginable peak brilliances for science, and the very serious connection with other sciences, in particular physics and biology, it is not surprising that our view of minerals has changed, certainly including in ways that we could not have anticipated. This should indicate that a new look at the mineral kingdom is in order. One way to do that is shown in Fig. 1. The figure (from Caraballo et al. 2015) uses the concept of short-, medium-, and long-range atomic order, or just order for short (SRO less than a nanometer, MRO 2–3 nm, and LRO more than 3 nm, respectively, with "order" referring to the perfection/reproducibility/periodicity of the atomic arrangement of the material; the more perfectness over many atomic



Mineralogy, Fig. 1 Schematic organization of naturally occurring materials using periodicity (short, medium, and long-range order) as the key parameter, and secondarily crystal size. Glasses only exhibit SRO, with the mineral kingdom exhibiting MRO and LRO, and a remarkable range of crystal sizes (see text for further discussion). Four types of mesocrystals are shown within the inset based on the materials/forces that hold/align the crystalline units together: (**a**) organic matrices, (**b**) physical fields and interparticle forces, (**c**) mineral bridges, and (**d**) space constrains (From Caraballo et al. (2015). See this reference for details)

dimensions, the higher the order). A glassy/amorphous material has only SRO, moving only weakly into MRO. Crystalline materials possess MRO (the smallest nanominerals) to LRO.

In Fig. 1, the lower Y-axis shows periodicity on an absolute distance scale (showing the ranges of SRO, MRO, and LRO using shades of white, yellow, and blue), as well as crystal size that becomes particularly important in the nanoscale, a new definition of the term "mineral" (entirely what the term "mineralogy" is based upon) emerges. Because amorphous materials, those showing only SRO, have unique chemical and mechanical characteristics, they deserve a major – and separate – materials category (naturally occurring glass is not a mineral). This is nothing new and has been supported by vast amounts of science for more than a century. However, as soon as a naturally occurring material shows atomic order even in the MRO range (e.g., the smaller nanocrystals, and polyphasic nanominerals like schwertmannite), it can now be defined as a mineral. Further, due to the inextricable link between the biotic and abiotic worlds around Earth's near surface, biominerals are minerals, as much so as a mineral in a rock or a meteorite, or a naturally occurring organic crystal. There are no other requirements that are needed to define a mineral. The definition becomes simple and inclusive, stripping away unnecessary requirements:

Definition: Mineralogy is the science of minerals. Minerals are naturally occurring materials that show at least medium-range atomic order.

Compare that with the unimaginably complex world of proteins, whose types number in the millions. Definition: Proteins are large macromolecules consisting of one or more long chains of amino acid residues.

Element Data

Atomic Symbol: **Mo**
Atomic Number: **42**
Atomic Weight: 95.94 g/mol
Isotopes and Abundances: Seven stable isotopes ^{92}Mo (14.84%), ^{94}Mo (9.25%), ^{95}Mo (15.92%), ^{96}Mo (16.68%), ^{97}Mo (9.55%), ^{98}Mo (24.13%), and ^{100}Mo (9.63%)
1 Atm Melting Point: 2,623 °C
1 atm Boiling Point: 4,639 °C
Common valences: +VI, +V, +IV, +III, +II, +I, 0, and-II
Ionic Radii: 210 pm
Pauling Electronegativity: 2.16
First Ionization Energy: 684.32 kJ mol^{-1}
Chondritic (CI) Abundance: 1–2 ppm
Silicate Earth Abundance: 25–66 ppb
Crustal Abundance: 1–2 ppm
Seawater Abundance: 9.8 ppb
Core Abundance: 5 ppm

Properties

From a geochemical perspective, molybdenum (Mo) is fascinating because it has seven stable isotopes and seven oxidation states that can be accessed at low reduction potentials. Molybdenum's wide range of geochemical variability makes it particularly relevant in studies of Earth processes. Its versatility in redox behavior also makes Mo a vital metal center in the active site of numerous enzymes (Leimkühler and Iobbi-Nivol 2015).

History and Use

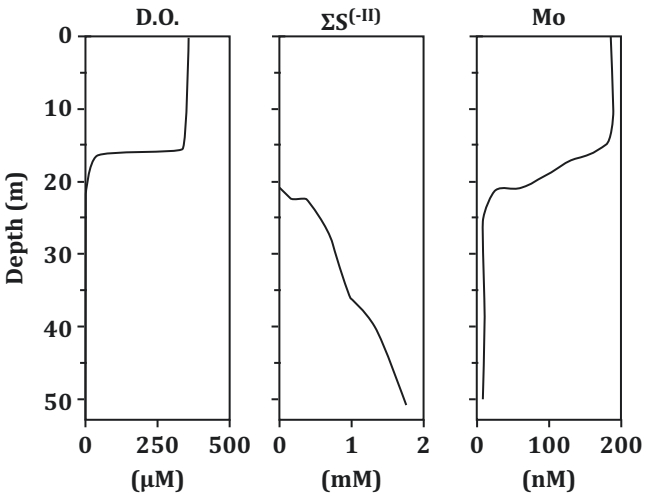
Molybdenum is a transition metal discovered in 1778 by Carl Scheele. The name derives from *molybdos*, ancient Greek for lead, because molybdenite (a Mo-rich ore) was often confused with lead. Molybdenum has important applications in metallurgy, while also serving as an essential micronutrient for life. In recent years, its elemental and isotopic distributions through history have emerged as effective geochemical proxies for tracking the oxygenation history of Earth's early oceans and atmosphere.

Molybdenum's average concentration in Earth's crust is 1–2 ppm (McLennan 2001). The main economic source of Mo is molybdenite ($Mo^{IV}S_2$), although molybdate minerals such as wulfenite ($PbMo^{VI}O_4$) and powellite ($CaMo^{VI}O_4$) are also extracted. Most of the Mo produced worldwide is for metallurgical applications, mainly in alloys (Braithwaite and Haber 2013). Minor Mo applications include use as a fertilizer, a lubricant (MoS_2), and for medical imagery (radioisotope ^{99}Mo).

Molybdenum Geochemistry

Chemical weathering of molybdenite ores and other Mo-containing sulfide phases, such as pyrite, releases Mo in the environment where it is transported via association with organic matter and iron (Fe)/manganese (Mn) oxyhydroxides into aquatic systems (Wichard et al. 2009; Glass et al. 2013). In the modern oxic ocean, Mo exhibits a conservative behavior, a very long residence time (~440 kyr), and has the highest concentration among the transition metals (~105 nM; Miller et al. 2011). In most freshwaters, dissolved Mo concentrations are in the low nanomolar (nM) range (Chappaz et al. 2008; Glass et al. 2013).

Thermodynamic models predict Mo speciation in oxygenated waters is dominated by the oxyanion molybdate ($Mo^{VI}O_4^{2-}$), although recent studies are investigating the possible importance of Mo(V) and (VI) species in seawater (Wang et al. 2009, 2011). Molybdenum burial in sediment under oxic conditions is controlled by adsorption reactions involving molybdate and Fe/Mn oxyhydroxides (Chappaz et al. 2008; Scholz et al. 2013).



Molybdenum, Fig. 1 Dissolved oxygen (*DO*), sulfide (ΣS-II), and Mo concentrations in water column from a meromictic lake (Modified from Geochimica et Cosmochimica Acta, Vol. 165, Havig, J. R., McCormick, M. L., Hamilton, T. L., and Kump, L. R. (2015), The behavior of biologically important trace elements across the oxic/euxinic transition of meromictic Fayetteville Green Lake, New York, USA, 389–406, Copyright (2016), with permission from Elsevier). Note the high solubility under oxic water-column conditions and the rapid decline in Mo levels in the presence of dissolved sulfide

In sulfidic waters, oxygen atoms in molybdate (MoO_4^{2-}) are progressively replaced by sulfur atoms to form thiomolybdate species ($MoO_{4-x}S_x^{2-}$;Helz et al. 1996; Erickson and Helz 2000; Vorlicek et al. 2015). This substitution reaction is usually coupled with a steep decline in total Mo concentrations at the interface between oxygenated and sulfidic waters (Fig. 1) (Emerson and Huested 1991; Havig et al. 2015).

Two main pathways can lead to Mo burial in sediments under sulfidic conditions: (1) reaction with Fe–S mineral phases and (2) interaction with organic matter (Helz et al. 2011; Dahl et al. 2013; Chappaz et al. 2014; Ardakani et al. 2016; Dahl et al. 2016). The net result is non-conservative behavior under sulfidic conditions and sediment enrichments that can exceed crustal levels by two orders of magnitude when appreciable levels of dissolved sulfide extend into the water column.

Biological Utilization and Toxicity

Almost all life forms utilize Mo-containing enzymes, although many more types of Mo enzymes are present in prokaryotes than eukaryotes (Zhang and Gladyshev 2008). Molecular phylogenies suggest the great antiquity of Mo-containing enzymes and their likely existence in the

last universal common ancestor (Schoepp-Cothenet et al. 2012). The oxyanion molybdate ($Mo^{VI}O_4^{2-}$) may have been involved in prebiotic synthesis of RNA (Benner and Kim 2015).

Over 50 enzymes involved in the global cycles of carbon, nitrogen, and sulfur, as well as four that are essential to human health, require Mo as a metal cofactor (Schwarz et al. 2009). Molybdenum is most commonly incorporated into enzymes bound to heterocyclic pterin molecules ("molybdopterins"), with the important exception of the molybdenum-iron cofactor in nitrogenase, the microbial enzyme that catalyzes the reduction of dinitrogen (N_2) gas to ammonia (Fig. 1). Recent isotopic evidence suggests that biological fixation by Mo nitrogenase dates back to at least 3.2 billion years ago (Stüeken et al. 2015), although molecular clock dating suggests a later origin (Boyd and Peters 2013).

Due to the importance of Mo in the nitrogen cycle, low levels of this metal may limit key steps in microbial nitrogen fixation and nitrate assimilation by plants and phytoplankton (Glass et al. 2012). Microbial nitrate respiration may also be limited by low nM Mo concentrations in anoxic groundwaters (Thorgersen et al. 2015). It is also possible that scarce Mo in the ancient oceans stalled aspects of the early evolution of life (Anbar and Knoll 2002; Glass et al. 2009; Lyons et al. 2014 2015).

A Powerful Paleo-Redox Proxy

Molybdenum's unique redox properties and its high number of natural isotopes have attracted the attention of geoscientists studying Earth's early oxygenation history, including relationships to the early prokaryotic and eukaryotic life. For example, patterns of Mo enrichment in organic-rich marine rocks deposited beneath euxinic (anoxic and sulfidic) waters can track the earliest onset of oxidative weathering (Anbar et al. 2007), the presence of local euxinia (Scott and Lyons 2012), the strength of the connection between a given basin and the open ocean (Algeo and Lyons 2006), and the areal extent of euxinia in the ancient ocean on a global scale (Scott et al. 2008; Reinhard et al. 2013; reviewed in Lyons et al. 2014). The isotopic composition of Mo in euxinic deposits can similarly fingerprint the global extent of euxinic marine deposition (Arnold et al. 2004; Poulson et al. 2006; Dickson et al. 2012; Kendall et al. 2015).

Summary

Molybdenum's economic importance remains intact despite the many uncertainties about Mo geochemistry (Braithwaite and Haber 2013). Among those gaps, two stand as major opportunities for future research: (1) the specific mechanisms controlling Mo burial in anoxic sedimentary records and (2) a refined understanding of how varying levels of Mo bioavailability in ancient oceans may have contributed to (or limited) the evolution of life on Earth. Nevertheless, enough is known already about the relationships to marine redox conditions and the presence of sulfide in particular to place molybdenum among the most useful trace metals in studies of coevolution of the environment and life on ancient Earth.

Introduction

Molybdenum isotopes are produced by three nucleosynthetic processes: the p- (proton process), r- (rapid neutron capture), and s- (slow neutron capture) processes. The seven naturally occurring isotopes (^{92}Mo, ^{94}Mo, ^{95}Mo, ^{96}Mo, ^{97}Mo, ^{98}Mo, and ^{100}Mo) are all stable or extremely long-lived: ^{100}Mo decays to ^{100}Ru with a half-life of ~10^{19} years (NNDC Chart of Nuclides). These isotopes extend over a mass range of ~8% and their natural abundances are rather uniform (~9%

to 25%). These characteristics, in conjunction with improvements in mass spectrometry since the mid-1990s, have resulted in the detection of small fractionations of Mo isotope ratios in meteoritic and terrestrial samples. It is now known that Mo isotopes are heterogeneously distributed in the solar system, resulting in mass-independent variations of Mo isotope ratios in meteoritic samples (Burkhardt et al. 2011). Compared to meteorites, Earth is enriched in s-process Mo isotopes implying, in conjunction with oxygen isotope data, that meteorites might not be representative of the Mo isotopic composition of the bulk Earth (Burkhardt et al. 2011). The improvements in mass spectrometry have also resulted in the recent revision of the absolute isotopic composition and atomic weight of terrestrial Mo (Berglund and Wieser 2011).

Isotope fractionations may vary with the masses of the isotopes: mass-dependent fractionation or be mass-independent (MIF), e.g., as a result of nucleosynethic processes. The only known natural terrestrial MIF of Mo is in samples from the Oklo natural reactor in Gabon (Bros et al. 2003; Wieser et al. 2012). In contrast, investigations since the late 1990s have shown that mass-dependent fractionation of Mo isotopes in natural samples ranges over 2.4‰/amu and may result from a wide range of physical, chemical, and biological processes (Fig. 1 and references therein).

Analytical Methods

Molybdenum isotope ratios are measured by thermal ionization mass spectrometers (TIMS) and multicollector inductively coupled-plasma mass spectrometers (MC-ICP-MS). Analysis of Mo isotopes by TIMS has a long history dating back to the 1960s (see: Wieser and De Laeter 2007) and continues to be used and improved. However, it was the advent of MC-ICP-MS in the 1990s with its improved analytical precision and smaller sample size requirements, compared to TIMS (Lee and Halliday 1995; Anbar et al. 2001; Siebert et al. 2001), that provided the impetus for the development of Mo isotope geochemistry. Most Mo isotope ratios today are measured by MC-ICP-MS.

Molybdenum isotopic compositions are typically reported in delta-notation, as per mil (‰) deviations in the $^{98}Mo/^{95}Mo$ ratio relative to a reference standard:

$$\delta^{98}Mo/^{95}Mo_{sample}(‰) = \left(\left({}^{98}Mo/^{95}Mo_{sample}/{}^{98}Mo/^{95}Mo_{standard}\right) - 1\right) \times 1000$$

In the absence of a certified standard reference material (SRM) for Mo isotope ratios, initial choices of reference standard were arbitrary. Recently, however, the NIST SRM 3134 has been proposed as the international reference standard for Mo isotopes and a number of interlaboratory calibrations have been made (e.g., Goldberg et al. 2013).

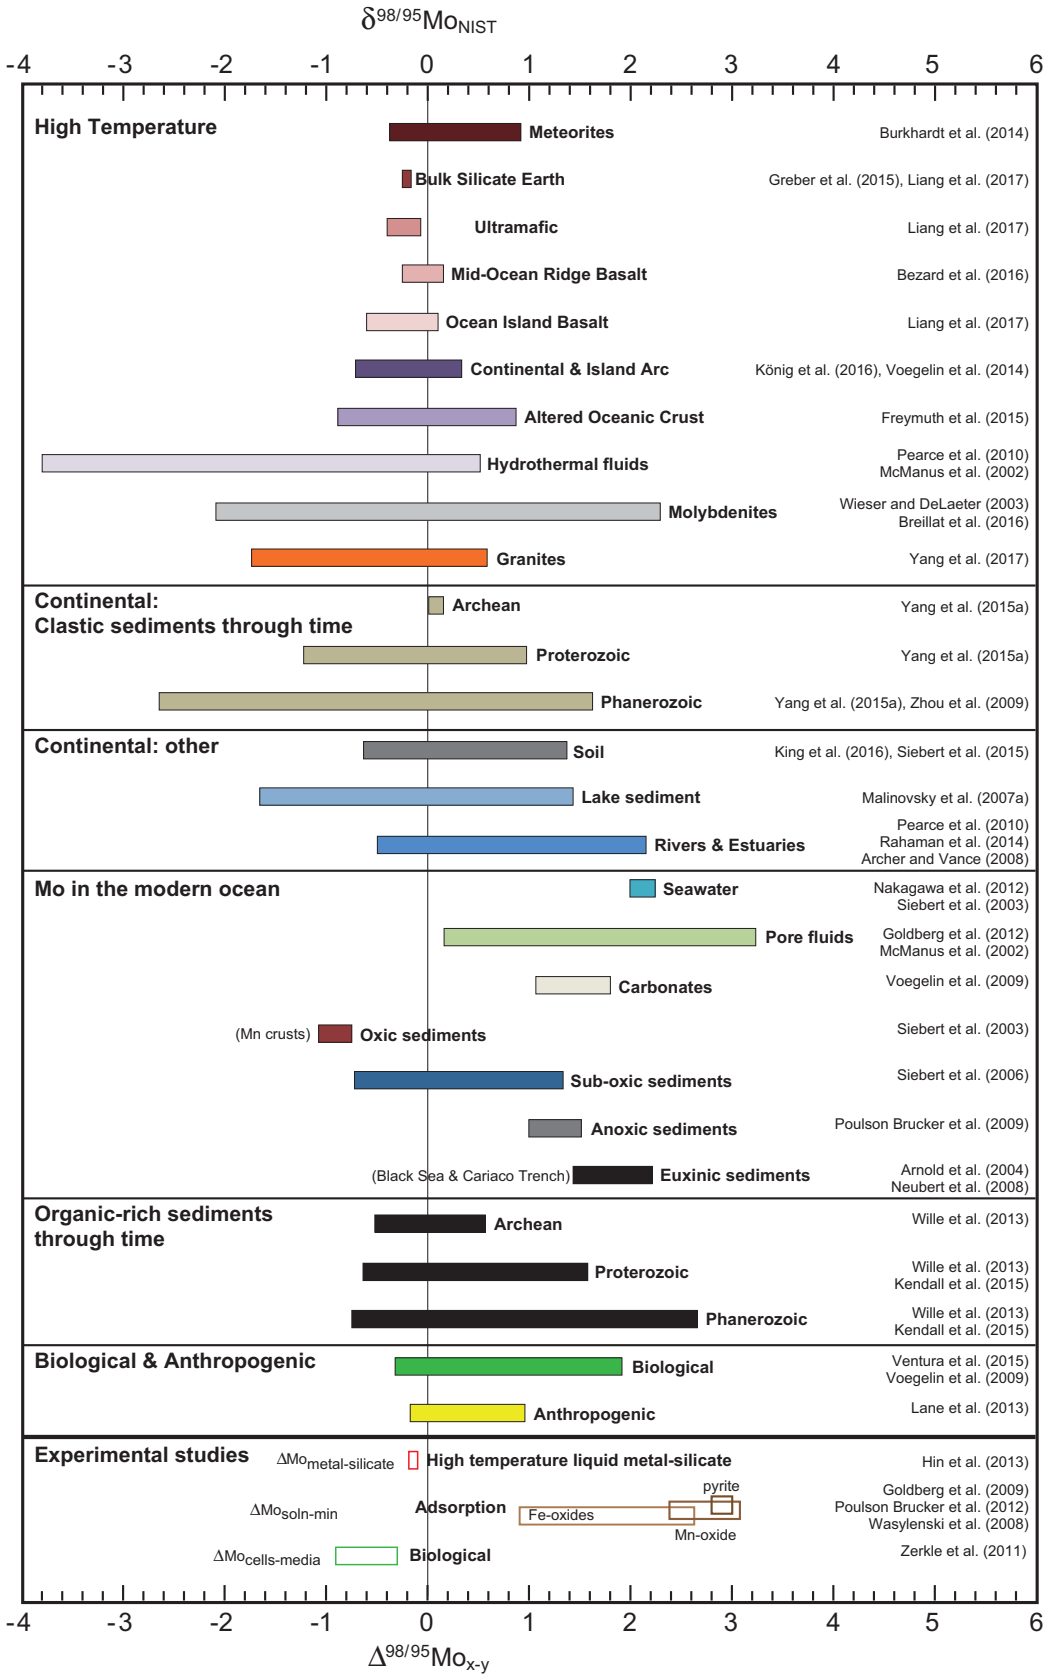
Natural Mass Dependent Fractionation

The important biogeochemistry of Mo, which involves varied redox chemistry and covalent bonding, both known drivers of isotope fractionation, made this element an early target for investigation of stable mass-dependent isotope fractionation in a heavy metal (Anbar 2004). Initial studies focused on samples from low temperature environments and were quick to notice the similarity in the isotopic composition of Mo in seawater and in sediments deposited under euxinic conditions (i.e., anoxic and sulfidic) and the large isotope fractionation between Mo in seawater and in manganese crusts, which form in oxic seawater conditions (Fig. 1). This led to the proposal that the $\delta^{98}Mo/^{95}Mo$ of seawater might covary with the relative proportions of anoxic (sic) and oxic sedimentation and thus be utilized as a paleoredox proxy (Barling et al. 2001; Siebert et al. 2003).

The hypothesis that Mo isotope fractionation between seawater and Mn crusts resulted from inefficient scavenging of Mo by Mn oxides under oxic conditions was confirmed experimentally (Barling and Anbar 2004), while the lack of isotope fractionation between seawater and euxinic sediments was attributed to the quantitative removal of Mo from the water column under euxinic conditions (Helz et al. 1996). Theoretical and sample based studies determined that Mo isotopes are fractionated during the step-wise conversion of molybdate (MoO_4^{2-}) to tetrathiomolybdate (MoS_4^{2-}), but that this is only expressed under conditions where removal of Mo from the water column is nonquantitative (Tossell 2005; Nägler et al. 2011).

Application of Mo isotopes as a paleoproxy requires a sound understanding of the modern marine Mo cycle and characterization of the sources and sinks of Mo (Anbar and Rouxel 2007). Recent data (Fig. 1) have confirmed the isotopic homogeneity of seawater and characterized sources (rivers and hydrothermal fluids) and sinks (oxic, suboxic, anoxic and euxinic, marine sediments, and carbonates) for Mo in the modern ocean. These have been used to revise the original simple box model on which the paleoproxy was based (e.g., Cheng et al. 2015). Since the first application of Mo isotopes as a paleoredox proxy by Arnold et al. (2004) it has become clear that Mo isotopes are not a stand-alone paleoredox proxy, but rather a useful tool in a multiproxy approach to understanding paleoredox (Lyons et al. 2009).

Application of Mo isotopes as a paleoproxy has largely been focused in the Archean and Proterozoic where they have contributed, in conjunction with other paleoredox proxies, to understanding the rise of oxygen in Earth's early ocean (Lyons et al. 2014). The evolution of oxygenic photosynthesis is generally accepted to be the cause of the rise of oxygen in the atmosphere and oceans, but when this happened is still intensely debated (Farquhar et al. 2011). Planavsky et al. (2014) have used $\delta^{98}Mo/^{95}Mo$ values consistent with Mn oxide interaction to infer oxygenic photosynthesis in



Molybdenum Isotopes, Fig. 1 (continued)

Archean (2.95 Ga) shallow marine settings. However, it is the Mo isotope record in organic-rich sediments that has received the most attention, providing evidence for a reducing atmosphere in the Archean prior to 2.7 Ga and early "whiffs" of oxygen prior to the Great Oxidation Event (Wille et al. 2013 and references therein). This record exhibits a ~2‰ range in $\delta^{98}Mo/^{95}Mo$ through most of the Proterozoic, intermediate between the narrow range of Archean $\delta^{98}Mo/^{95}Mo$ (<1‰) and the Phanerozoic/present day range (>3‰), reflecting the increasing proportion of oxic ocean floor (Fig. 1). The Phanerozoic is however punctuated by Ocean Anoxic Events and more local fluctuations in ocean redox that have been investigated using Mo isotopes (e.g., Dickson et al. 2016). Molybdenum isotopes have also been used to investigate the connection between ocean redox and radiations and extinctions of the fossil record since the Ediacaran (ca. 635–542 Ma; e.g., Chen et al. 2015).

Most paleoredox studies have been on the marine record but more recently attention has turned to continentally derived clastic sediments. These provide a record of contemporaneous atmospheric oxygen levels and like the marine record of organic-rich sediments, testify to the rise of oxygen through Earth's history (Fig. 1). The average Mo isotopes of clastic sediments show that the continental crust has become lighter over time suggesting that supracrustal processes have resulted in the preferential loss of heavy Mo to the hydrosphere (Yang et al. 2015a). Samples from other continental settings such as estuaries, lakes, and in soils have received less attention, as has Mo isotope fractionation related to biological and human activity (Fig. 1).

Even though it has been clear from Mo isotope measurements of molybdenites (Breillat et al. 2016 and references therein) that hydrothermal processes (200–1200 °C) are associated with significant Mo isotope fractionation (Fig. 1), the potential for Mo isotope fractionation in other high temperature environments has been largely overlooked until recently. It is now known that magmatic systems, particularly those involving a fluid phase (subduction zone volcanics and granites), exhibit Mo isotope fractionations spanning nearly 2.5‰. In contrast, Mo isotope fractionation is absent during crystal fractionation in anhydrous magmatic systems (Yang et al. 2015b). Mo isotope variations in the mantle, MORB, and OIB are small and may reflect the presence of residual sulfide melts during small degrees of partial melting of the mantle (Liang et al. 2017). The Mo concentrations and isotopic compositions of basalts, komatiites, and peridotites have also been used to constrain the Mo concentration and isotopic composition of the BSE (Fig. 1). Average Mo isotope ratios for magmatic iron meteorites and enstatite-, ordinary- and carbonaceous chondrites typically overlap the BSE estimate, while Mo isotopes derived from the silicate portion of differentiated planetary bodies trend to values heavier than terrestrial magmatic samples (Burkhardt et al. 2014). Lunar basalts have Mo isotopes similar to MORB (Burkhardt et al. 2014).

Interpretation of Mo isotope fractionation in natural samples is aided by theoretical and experimental investigations of processes with the potential to fractionate isotopes. The relatively few such studies have investigated biological activity, adsorption, aqueous speciation (Malinovsky et al. 2007b), leaching of mine waste (Skierszkan et al. 2016), and partitioning between metal and silicate liquids (Fig. 1).

Summary and Conclusions

The seven naturally occurring isotopes of Mo have rather uniform abundances and extend over a mass range of ~8%. These characteristics, in conjunction with the interesting biogeochemistry of Mo, made Mo an early target for investigation of stable mass-dependent isotope fractionation in a heavy metal. To date, fractionation of Mo isotope ratios in natural samples range over 2.4‰/amu. Investigations have focused predominantly on marine samples leading to a better understanding of the modern marine Mo cycle. Initial observations of the contrasting Mo isotopic compositions of modern oxic and euxinic sediments led to the proposal that the $\delta^{98}Mo/^{95}Mo$ could be developed as a paleoredox proxy. Since then Mo isotopes have become a useful tool in multiproxy investigations of paleoredox, contributing in particular, to understanding of the rise of oxygen through Earth's history.

Mo isotope fractionation is less well documented in samples from continental environments, for biological and human activity and for samples from high temperature settings. There have also been comparatively few theoretical and experimental investigations of Mo isotope fractionation. Given the wide range in $\delta^{98}Mo/^{95}Mo$ in samples associated with high and low temperature fluids, analysis and theoretical and experimental investigations of samples and processes involving a fluid phase seem likely to be promising areas of future research.

Synonyms

Native elements

Definition

Native minerals are basically the natural substances that occur in the state of chemical elements or their alloys.

Classification

The term "native minerals" is not used but "native elements" or simply "elements" in the field of mineralogy, and some minerals that occur as carbides, nitrides, silicides, and phosphides as well as chemical elements or their alloys are traditionally classified into the class of "native elements and alloys" (Gaines et al. 1997) or simply "elements" (Strunz and Nickel 2001). As of 2014, the mineral names including native minerals are summarized in Fleischer's glossary of mineral species (Back 2014).

Native minerals are divided to the following three groups.

1. Metals and intermetallic alloys

A few native metals have nearly pure composition, but almost all of them are under the state of solid solution, e.g., between Au and Ag (Fig. 1) (referred as electrum), which are isostructural, and among Os, Ir, and Ru (referred as iridosmine) in case of different structure in pure metals, respectively, or intermetallic alloys, e.g., between Hg and other metals (referred as amalgam). In this group, 33 minerals are recognized as native elements composed of 25 elements such as Al, Ti, V, Cr, Fe, Ni, Cu, Zn, Mo, Ru, Rh, Pd, Ag, Cd, In, Sn, Sb, W, Os, Ir, Pt, Au, Hg, Pb, and Bi. Intermetallic alloys are recognized as 50 species. Among them, $Al_{63}Cu_{24}Fe_{13}$ and $Al_{71}Ni_{24}Fe_5$ discovered from meteorites have unusual quasicrystalline structure with quasiperiodic fivefold or tenfold rotation symmetry and were approved as new minerals under the name of icosahedrite in 2012 and of decagonite in 2015, respectively, by the Commission on New Minerals, Nomenclature and Classification, IMA.

2. Nonmetals

In this group, five native elements are recognized such as C, Si, S, As, and Te. Carbon and sulphur minerals have nearly pure composition, and four polymorphs (diamond, graphite, chaoite, and lonsdaleite) and three polymorphs (sulphur, sulphur-β, and rosickýite) exist, respectively. Arsenic minerals generally have solid solution between Sb, e.g., stibarsen ($Sb_{0.5}As_{0.5}$); in addition, three polymorphs (arsenic, arsenolamprite, and pararsenolamprite) exist.

3. Metallic and nonmetallic carbides, nitrides, silicides, and phosphides

In the field of mineralogy, these compounds traditionally are classified as native elements. Many minerals of this group have been discovered from extraterrestrial materials and two species are known as carbides (e.g., cohenite, $(Fe,Ni,Co)_3C$), four species as nitrides (e.g., osbornite, TiN), six species as silicides (e.g., hapkeite, Fe_2Si), and eight species as phosphides (e.g., barringerite, $(Fe,Ni)_2P$).

The occurrences of the native elements are divided into nine types: (1) in terrestrial rocks, (2) in ultramafic rocks (including kimberlite and lamproite) (account for about 38%), (3) in mafic rocks, (4) in felsic rocks, (5) in

Native Minerals, Fig. 1 Photomicrograph of native gold crystals in hydrothermal quartz vein from the Nakase mine, Hyogo Prefecture, Japan. Field view: approximately 3.5 × 4.0 mm

metamorphic or metasomatic rocks, (6) in hydrothermal veins (account for about 18%), (7) in others (oxidation products, volcanic sublimate, etc.) and (8) in placer deposits (unknown original rocks), and (9) in extraterrestrial materials (meteorites, cosmic dusts, lunar rocks, etc.) (account for about 21%).

The mineral names of the native elements, chemical compositions, crystal system, and main occurrences are demonstrated in Table 1.

Summary

136 mineral species are classified into groups of native minerals (native elements) such as chemical elements or their alloys, carbides, nitrides, silicides, and phosphides (CNMNC 2016).

Native Minerals, Table 1 Mineral names of native elements. Mineral names are arranged alphabetically in every group. Abbreviations are as follows: (1) UL, (2) MF, (3) FL, (4) MT, (5) HY, (6) OT, (7) PL, and (8) ET. Also crystal systems are as follows: cubic, cub; tetragonal, tet; hexagonal, hex; trigonal (rhombohedral), trig; orthorhombic, orth; monoclinic, mon; triclinic, tric

Mineral name	Composition	Crystal system	Main occurrence
(Native metals)			
Aluminum	Al	Cub	MF, HY, OT
Antimony	Sb	Trig	HY
Awaruite	$Ni_2Fe \sim Ni_3Fe$	Cub	UL
Bismuth	Bi	Trig	HY
Cadmium	Cd	Hex	MF
Chromium	Cr	Cub	PL (inclusions in diamond)
Copper	Cu	Cub	OT, MT
Gold	Au	Cub	HY, PL
Garutite	(Ni,Fe,Ir)	Hex	UL
Hexaferrum	(Fe,Os,Ru,Ir)	Hex	UL
Hexamolybdenum	(Mo,Ru,Fe)	Hex	ET
Indium	In	Tet	FL
Iridium	Ir	Cub	UL, PL
Iron (kamacite = Ni-bearing iron)	Fe	Cub	MF, ET
Lead	Pb	Cub	MT, HY
Mercury	Hg	Trig (<−38.9 °C)	HY
Nickel	Ni	Cub	UL, MT
Osmium	Os	Hex	UL, PL
Palladium	Pd	Cub	UL, OT
Platinum	Pt	Cub	UL, MF, HY, PL
Rhodium	Rh	Cub	UL

Natural Gas

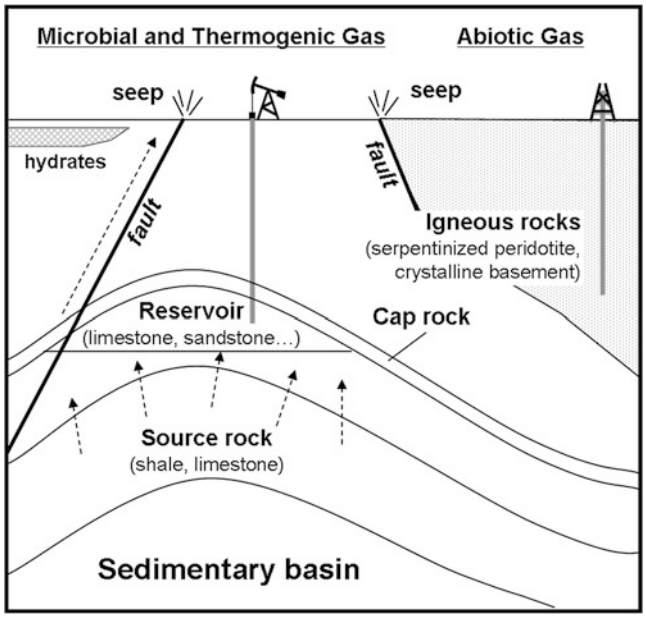
Giuseppe Etiope
Sezione Roma 2, Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy

Definitions

Natural gas is a mixture of gaseous hydrocarbons and nonhydrocarbon gases typically produced in subsurface sedimentary rocks, frequently associated with crude oil or coal beds. Hydrocarbon gases are almost exclusively alkanes, dominantly methane (CH_4, generally from 70 to 90 vol.%), and, subordinately, ethane (C_2H_6, 1 to 10 vol.%), propane (C_3H_8, generally <5 vol.%), and butane (C_4H_{10} < 1–2 vol.%). Nonhydrocarbon gases, such as CO_2, N_2, He, H_2, and H_2S, are generally present as minor constituents. Natural gas is formed through microbial or thermal degradation of organic matter in sedimentary rocks, typically shale or limestone (source rocks), in coal-beds, and through oil cracking and biodegradation. The gas can move inside the porous source rocks (primary migration), migrate to external rocks and accumulate in trapped permeable "reservoir" rocks (secondary migration), and move from a reservoir to another, or seep to the Earth's surface (tertiary migration and seepage; Fig. 1) (Hunt 1996; Etiope 2015).

In the petroleum geology literature, the term "natural gas" does not refer to geothermal or volcanic H_2O- or CO_2-rich gas where hydrocarbons are a minor component. The term can however include hydrocarbon-rich gas originated abiotically, in considerable concentrations (up 90 vol.%), in some igneous rocks (see "Origin").

The methane produced in subsurface source rocks is typically "fossil," i.e., radiocarbon (^{14}C) free (carbon older than 50,000 years BP) and can be termed "geological methane." Modern microbial methane is instead produced and dispersed



Natural Gas, Fig. 1 Scheme of the main natural gas occurrences

within shallow sediments and bottom waters in estuaries, deltas, bays, lakes, marshes, wetlands, and shallow permafrost. Although this modern gas could also be broadly called "natural gas," it does not represent a fossil-fuel source for petroleum industry and literature.

Origin

The natural gas currently exploited as energy source originates through the microbial or thermal degradation of organic matter, coal, or oil in sedimentary rocks, typically shale and limestone. Microbial and thermogenic gases are cumulatively termed *biotic* because of the derivation from biologic compounds, mainly lipids and carbohydrates, in marine (sapropelic) and terrestrial (humic) organic matter.

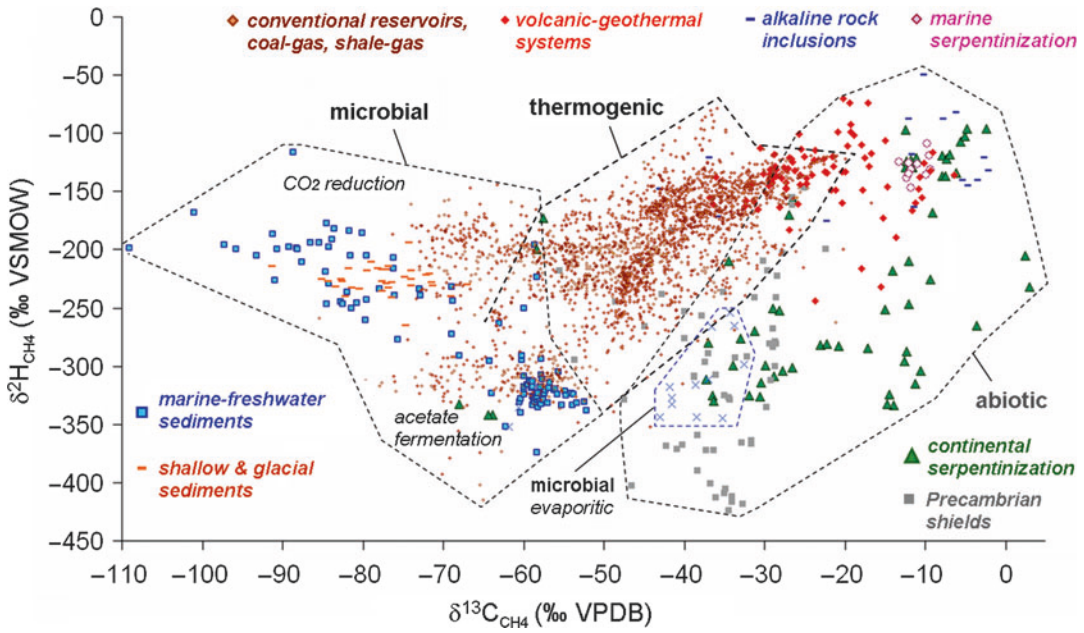
Microbial (or biogenic) gas is mainly produced during diagenesis of sediments (Hunt 1996) by specialized microorganisms that decompose organic matter and form CH_4 at relatively low temperatures (typically up to 60–80 °C; or above 100 °C by extremophiles in special hydrothermal systems). Although the term "bacterial methane" is also used in the literature, it should be remembered that Bacteria do not produce methane, only Archaea do it. After organic matter is decomposed, methane is formed through two main biochemical pathways: CO_2 or carbonate reduction ($CO_2 + 8H^+ + 8e^- \rightarrow CH_4 + 2H_2O$), and acetate fermentation ($CH_3COOH \rightarrow CH_4 + CO_2$), depending on burial depth and organic matter (e.g., Whiticar et al. 1986). In special conditions, trace amounts of ethane and propane can be formed (Formolo 2010). Microbial methane is also produced in coal-beds, in early and late stages of coalification (Rice 1993) and by oil biodegradation (secondary microbial methanogenesis), via carbonate reduction. This secondary microbial gas may constitute large gas resources (Milkov 2011). Microbial gas is very dry, i.e., it consists almost entirely of methane. Generally (but not always), it indicates relatively shallow gas source rocks and reservoirs.

Thermogenic gas is produced in deeper sedimentary rocks by the thermal degradation (catagenesis) of organic matter, kerogen, coal (primary cracking), or oil (secondary cracking) at higher temperatures, typically up to 250 °C. Organic matter maturation includes a series of intermediate products, such as geopolymers (kerogen), bitumen, then converted into hydrocarbons, as described in classic petroleum geochemistry literature (e.g., Tissot and Welte 1984; Hunt 1996). Vitrinite reflectance is the main parameter to define thermal maturity (Hunt 1996). Thermogenic gas can be independent from or associated with oil reservoirs and can have variable amounts of ethane, propane, butane, and heavier (C_{5+}) hydrocarbons. It also frequently contains measurable quantities of non-hydrocarbon gases.

Abiotic hydrocarbon-rich gas can be produced in special geological conditions by chemical reactions that do not require the presence of organic matter. These reactions include gas-water-rock reactions (for example, Fischer-Tropsch type reactions, like the Sabatier reaction between carbon dioxide and hydrogen) occurring at relatively low temperatures, often below 150 °C, in mafic and ultramafic rocks (Etiope and Sherwood Lollar 2013). Abiotic methane is also produced, in low concentrations (typically parts per billion to parts per million), by magmatic and high temperature (>250 °C) reactions in geothermal systems (Etiope and Sherwood Lollar 2013) but, as anticipated above, it is not typically termed "natural gas."

Nonhydrocarbon gases (mainly CO_2, N_2, H_2S, H_2, and He) are often associated with hydrocarbons as they can originate through organic or inorganic processes that can occur within, beneath, or in proximity to the petroliferous sedimentary rocks (Hunt 1996). The organic processes are mainly thermogenic, e.g., kerogen decarboxylation (producing CO_2 during catagenesis), thermochemical sulfate reduction (producing mainly H_2S), thermal degradation of organic N-containing compounds (producing N_2), and oil biodegradation (producing mainly CO_2 after hydrocarbon production). Bacterial sulfate reduction can also produce H_2S and CO_2. Inorganic reactions include kaolinite-carbonate reactions (producing CO_2), metamorphism of ammonium-rich clays (producing N_2), thermo-methamorphism of limestone (CO_2), radioactive decay of U and Th (producing He), and magma degassing (mainly CO_2 and He).

The identification of natural gas origin may start observing the relative abundance of methane (C_1), ethane (C_2), and propane (C_3) (i.e., the Bernard ratio $C_1/(C_2 + C_3)$, or the gas



Natural Gas, Fig. 2 Stable C and H isotope values of methane (CH_4) in different geological systems and related genetic mechanisms (biotic and abiotic). Biotic (microbial and thermogenic) gas data are from a global inventory of natural gas in conventional (reservoir) and unconventional (shale-gas, coal-gas) petroleum systems (Sherwood et al. 2017), and from Coleman et al. (1988), Whiticar et al. (1986) and Tazaz et al. (2013). Abiotic gas data are from Etiope and Sherwood Lollar (2013), Etiope et al. (2016), and Etiope (2017a, b). Abiotic gas must be considered as "dominantly abiotic," as it may be mixed with variable amounts of biotic gas

wetness, expressed as $\Sigma C_{2-5}/\Sigma C_{1-5}$). Microbial gas generally has a Bernard ratio > 1000. But this diagnostic tool may be misleading as it fails to detect post-genetic alterations of the molecular composition of the gas (molecular fractionation of thermogenic gas leading to high Bernard ratios) and secondary genetic processes (secondary microbial methane). The critical step for identifying the origin of natural gas is the analysis of the stable isotope composition of carbon ($^{13}C/^{12}C$) and hydrogen ($^{2}H/^{1}H$) in methane (expressed as $\delta^{13}C$ and $\delta^{2}H$ in ‰ (per mil) relative to Vienna Pee Dee Belemnite, VPDB, and Vienna Standard Mean Ocean Water, VSMOW, standards; e.g., Schoell (1980)). The isotopic data are typically plotted in a $\delta^{13}C$ vs. $\delta^{2}H$ diagram, an empirical diagram that differentiates the genetic fields of microbial, thermogenic, and abiotic methane (Fig. 2). Worldwide occurrences of thermogenic and microbial gases have a well-defined distribution in regards to carbon and hydrogen isotopes. Microbial methane is generally characterized by $\delta^{13}C$ values lower than −50‰. Thermogenic methane is typically in the range between −50 and −30‰; but highly mature source rocks can provide methane with $\delta^{13}C$ values up to −20‰, and low maturity rocks (early thermogenesis) can lead to values as low as −70‰. Abiotic CH_4 has a wide range of $\delta^{13}C$ and $\delta^{2}H$ values and, although overlapping with part of the thermogenic field, is characterized by an overall shift towards more ^{13}C–enriched and more ^{2}H–depleted values (Fig. 2).

Use of $\delta^{13}C$ in relation to the Bernard ratio is beneficial for determining the mixing between microbial and thermogenic gas and the source rock maturity. The changes in the molecular and stable isotopic composition of natural gas with increasing thermal maturity are a direct result of the kinetics of the formation mechanisms. During the first stages of catagenesis, at relatively low temperatures (low maturity), gas is "wet" (i.e., rich in alkanes heavier than methane). Wetness (defined above) can range between 10 and 100. With increasing maturity (time and temperature) gas becomes "dry," less rich in C_2–C_5 due to the thermal cracking of heavy alkanes. Wetness can drop to values below one. If the carbon isotopic composition is not evaluated, this type of dry thermogenic gas can be confused with microbial gas, which generally has wetness <0.1. Additional interpretative tools use the isotopic composition of nonhydrocarbon gases (especially CO_2 and N_2).

Occurrences

Natural gas occurs in porous, sedimentary, organic-rich source rocks (shales, marls, and limestones), and coal-beds, where it is initially generated, and in more permeable sedimentary rocks (sandstones, fractured limestones) and, not rarely, even in igneous and metamorphic rocks (fractured volcanic or crystalline basement rocks; e.g., Farooqui 2009),

where it accumulated. Permeable reservoir rocks represent "conventional" gas resources. Scarcely permeable reservoirs (e.g., tight-gas sandstones) and source rocks (shale-gas) represent "unconventional" resources, as they require stimulation methods to improve economic recovery rates. Gas hydrates and coal-beds (coal-bed methane, CBM; or coal seam gas, CSG) are also unconventional gas resources.

More than 50% of conventional reservoired oil and gas was generated by source rocks formed within two relatively short geological time periods, between 144 and 169 Myrs ago (Upper Jurassic) and between 88 and 119 Myrs ago (Aptian-Turonian) (Klemme and Ulmishek 1991). From the reservoir rocks, natural gas can migrate through faults to the Earth's surface (seepage), entering shallow aquifers, soil, and the atmosphere via diffuse exhalation (microseepage), springs and seeps (macroseeps), such as mud volcanoes, and oil or gas seeps, including natural "eternal" fires (Etiope 2015). Natural gas source rocks, reservoirs, and seeps are distributed throughout the petroliferous sedimentary basins of all continents. The largest gas reservoirs are located in Russia, Iran, Qatar, and Algeria.

In ocean bottom sediments, microbial or thermogenic natural gas can occur as gas hydrates or clathrates, ice-like crystalline solids stable under specific pressure and temperature conditions, composed of rigid cages of water molecules that enclose guest gas molecules. Methane hydrates generally occur in deep-sea sediments or shallow seabed in Arctic regions, and likely contain one order of magnitude more methane than the 220 Gt of carbon estimated to occur in all conventional gas reservoirs (Milkov 2004). Permafrost on land, in subpolar regions, may also host significant amounts of methane clathrates, either microbial or thermogenic.

Abiotic natural gas has been widely reported, in concentrations reaching orders of 80–90 vol.%, in deep boreholes in crystalline shields in Canada, South Africa, and Finland (Sherwood Lollar et al. 1993), and in surface seeps and springs in serpentinized ultramafic rocks (peridotites) of continental ophiolites, peridotite massifs, and igneous intrusions, in at least 17 countries in North America, Europe, Asia, and Oceania (Etiope and Sherwood Lollar 2013; Etiope and Schoell 2014; Etiope 2017b). Volumes of this gas in the rocks are not known but the high gas flux, observed at the surface in some cases, suggests the presence of pressurized pools.

Energy Resource

Natural gas in conventional and unconventional petroleum systems is a nonrenewable resource. Thermogenic gas accumulations account for approximately 80% of the world's natural gas resources (Rice 1993). Shale-gas represents an increasingly important source of gas in the United States, Canada, and China. Commercial accumulations of abiotic methane have not been identified by the petroleum industry, so far; less than 1% of the CH_4 in most oil and gas fields was estimated to be abiotic (Jenden et al. 1993). The recent discoveries of abiotic gas in continental ultramafic rocks and Precambrian crystalline shields could, however, represent new resource prospects for the future.

In total, natural gas accounts for about 24% of the world's energy consumption. Global natural gas production, consumption, and reserves have been estimated (end of 2015) at approximately 3539, 3469, and 186,900 billion cubic meters, respectively (BP 2016).

Summary

Natural gas is a mixture of hydrocarbons (methane, ethane, propane, butane) and nonhydrocarbon gases (CO_2, N_2, H_2S, H_2, and trace amounts of noble gases) originated in sedimentary source rocks (shales, marls, and limestones) and stored in reservoir rocks (sandstones, limestones, and subordinately igneous/metamorphic rocks). The gas is produced biotically by microbial or thermal degradation of marine (sapropelic) or terrestrial (humic) organic matter in marine sediments and coal formations (coal-bed gas), and by oil cracking and biodegradation. Abiotic natural gas, generated by gas-water-rock chemical interactions (e.g., Fischer-Tropsch type reactions), has been increasingly discovered in recent years in Precambrian shields and serpentinized ultramafic rocks in ophiolites and peridotite massifs. Microbial and thermogenic gas can also be stored as hydrates in marine sediments and onshore permafrost. From source rocks and reservoirs, the gas can migrate along faults to the Earth's surface, where it exhales to the atmosphere through gas seeps and mud volcanoes. Reservoired natural gas presently accounts for one fourth of the world's energy consumption.

Pauling Electronegativity: 1.14
First Ionization Potential: 5.5250 eV
Chondritic (CI) Abundance: 0.475 ppm
Silicate Earth Abundance: 1.25 ppm
Crustal Abundance: 20 ppm
Seawater Abundance: 2–60 pmol/kg
Core Abundance: ~0

Properties

Neodymium (Nd) is a silvery-white-yellow metal with an atomic number (Z) of 60, electronic configuration of [Xe] $4f^4 6s^2$, and atomic weight of 144.242(3) (Meija et al. 2016a, b). It is a group IIIB inner transition element and one of the lanthanide and rare-earth elements. Neodymium is a refractory element, with a melting point of 1294 K, boiling point of 3347 K, and density of 7.01 g/cm^3. It is a lithophile element under the Goldschmidt classification, and it is dominantly found in the trivalent state, with Nd^{3+} ionic radius of ~1.12×10^{-10} m at eightfold coordination.

History and Use

Nd was discovered in 1885 by Austrian chemist Carl F. Auer von Welsbach and is named from the Greek word *neos*

didymos (new twin) (Holden 2001). The usage of neodymium has increased significantly in the last three decades after the discovery of neodymium-boron-iron alloys that make very strong permanent magnets. These magnets have found its use in a wide variety of electronics and electric motors. Nd is also used in the manufacturing of crystals for lasers and didymium glass used for glass blowing and welder's goggles. As Nd is incompatible in all major rock-forming minerals, it concentrates in late-stage highly differentiated melts and accessory minerals, like phosphates. The main commercial sources of Nd are currently rare-earth element-rich carbonatite deposits, where the key mineral is bastnaesite $(REE)CO_3F$, monazite $(REE)PO_4$, and some carbonate-bearing iron oxide deposits (Kiruna type, Sweden, Bayan Obo, Mongolia). In all cases, Nd is found together with other light rare earths (La, Ce, Pr, Sm).

Geochemical Behavior

The major importance of Nd is that it is one of the larger trivalent rare-earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group. ^{143}Nd is also the decay product of ^{147}Sm, and ^{142}Nd is the decay product of ^{146}Sm. Nd has two radioactive isotopes, ^{144}Nd with a half-life ($T_{1/2}$) of 2.4×10^{15} years (McSween and Huss 2010) and ^{150}Nd with a half-life of 9.11×10^{18} years (Argyriades et al. 2009), both too long to have any practical applications in geochronology and are thus considered effectively stable.

As a lithophile element, Nd is thought to wholly partition in the silicate portion of the Earth with effectively no Nd in the Earth's core. Primitive CI-chondrite meteorites, thought to represent the initial composition of the solar nebular for refractory elements, have an estimated 0.457–0.474 ppm Nd concentration (McDonough and Sun 1995; Palme and O'Neill 2003). The Nd concentration of the primitive mantle (or bulk silicate earth) is estimated at 1.25–1.37 ppm (McDonough and Sun 1995; Palme and O'Neill 2003). Due to its relatively large ionic radius and 3+ charge, Nd is moderately to highly incompatible in upper mantle mineralogy (olivine, pyroxene, spinel, and garnet). Of these minerals, clinopyroxene has the highest Nd concentrations (typically in the order of several ppm or less), where Nd substitutes for Ca in the M2 crystallographic site that is of similar size ($\sim 1 \times 10^{-10}$m) as the Nd ionic radius in eightfold coordination, likely through a coupled substitution of Al^{3+} for Si^{4+} or Na^{1+} for Ca^{2+} (Wood and Blundy 2001). As an incompatible element, Nd is preferentially concentrated in melts from the mantle, and its concentration in the continental crust is near 20 times than of the primitive mantle, between 16 and 27 ppm, with an average of 20 ppm (Rudnick and Gao 2003), the range being largely due to the uncertainty of the proportions of upper, middle, and lower crust in reconstructing the bulk continental crust composition. In turn, the upper mantle source of mid-oceanic ridge volcanism and the presumed residue of continental crust extraction is depleted in Nd relative to the primitive mantle with Nd concentration estimated between 0.71 and 0.58 ppm (Salters and Stracke 2004; Workman and Hart 2005). The mean Nd concentration of mid-oceanic ridge basalts, the most voluminous volcanism on Earth sourced from this depleted mantle, is 12 ± 0.78 ppm (Gale et al. 2013).

Due to the different compatibility of Sm and Nd in most petrogenetically important minerals, melting and crystallization processes create variable Sm/Nd ratios in minerals and melts that over time generate variable amounts of radiogenic ^{143}Nd over the stable ^{144}Nd, denoted by the $^{143}Nd/^{144}Nd$ ratio, making the $^{147}Sm/^{143}Nd$ decay system, one of the most important geochronological and isotope tracer systems. ^{142}Nd, the decay product of now extinct ^{146}Sm with a somewhat uncertain half-life of 68 Ma (Kinoshita et al. 2012) to 103 Ma (Marks et al. 2014), is an increasingly important tracer in evaluating the evolution of the terrestrial mantle during the first 300 hundred million years of Earth's history (Rizo et al. 2012), and the terrestrial $^{142}Nd/^{144}Nd$ isotope systematics are central in the discussion of whether Earth evolved with a chondritic composition or not (Carlson and Boyet 2009).

In typical seawater composition and pH = 8.2, Nd exists primarily as a carbonate ion species $Nd(CO_3)_2^-$ and $NdCO_3^+$. In the absence of strong organic complexing ligands, like humic acids (Sonke and Salters 2006), Nd is highly particle reactive and readily adsorbed in hydrated Fe and Mn oxide phases and particulate surfaces (Schijf et al. 2015), resulting in very low concentrations in seawater on the order of 2–60 pmol/kg (Goldstein and Hemming 2003). In the pelagic ocean setting, Nd concentration increases with depth, which appears to be controlled by processes involving sinking particles. Despite the nutrient-like behavior of Nd concentrations, Nd isotopes vary with salinity (e.g., von Blanckenberg 1999) suggesting a residence time shorter than ocean mixing (~1500 years, Broecker and Peng 1982). The residence time of Nd in seawater ranges from 200 to 1000 years (Tachikawa et al. 1999; Arsouze et al. 2009; Rempfer et al. 2011).

Biological Utilization and Toxicity

Nd does not appear to have a specific biological function, likely due to its extremely low concentration in natural waters that prevented organisms for developing a use for it. Yet, some evidence suggests that under acidic conditions where Nd becomes increasingly soluble, methanotrophic microbes can utilize Nd and other light rare earths to stimulate growth

(Pol et al. 2014). Neodymium is thought as moderately toxic in humans, although specific data is scarce. Neodymium dusts and salts are considered as irritating to the eyes and mucus membranes and moderately irritating to the skin (Rim et al. 2013). However, as Nd concentrations are low in the environment, any health effects are mostly anecdotal and appear isolated to those with occupational exposure either closely related to mining or processing of the ore (Pagano et al. 2015).

Neodymium Isotopes

Michael Bizimis and Howie D. Scher
Earth and Ocean Sciences, University of South Carolina, Columbia, SC, USA

Introduction

Isotope ratios of Nd are key geochemical tracers for unraveling the compositional evolution of terrestrial planets, as well as an important geochronometer. Neodymium has seven natural isotopes: ^{142}Nd (27.153%), ^{143}Nd (12.173%),

^{144}Nd (23.798%), ^{145}Nd (8.293%), ^{146}Nd (17.189%), ^{148}Nd (5.756%), and ^{150}Nd (5.638%) (Meija et al. 2016). ^{147}Sm decays to ^{143}Nd through α-decay with a half-life of 1.06×10^{11} year that corresponds to a decay constant ($\lambda_{Sm}{}^{147}$) of 6.54×10^{-12} year^{-1}. ^{146}Sm decays to ^{142}Nd through α-decay and a half-life estimated between 68×10^6 year (Kinoshita et al. 2012) and 103×10^6 year (Meissner et al. 1987; Marks et al. 2014). Due to its slightly lower ionic radius, Sm is generally more compatible than Nd in the Earth's mantle. The fractionation of Sm from Nd during melting and crystallization processes changes the Sm/Nd ratios in minerals, which, over time, will change the relative abundance of ^{143}Nd and ^{142}Nd. These changes in Nd isotopes are important for understanding the evolution of different terrestrial reservoirs and the processes that influence their chemical evolution.

Nd Isotope Ratio Determinations

Neodymium is chemically isolated from other elements by cation-exchange chromatography (Richard et al. 1976; Pin and Zalduegui 1997). Neodymium isotope ratios are determined by thermal ionization mass spectrometry (TIMS) or by multicollector inductively coupled mass spectrometry (MC-ICPMS). During ionization and/or transmission through the mass spectrometer, the Nd isotope ratios fractionate relative to their true value as a function of their mass. This instrument-induced mass fractionation is typically described by an exponential mass law and can thus be corrected for if one (stable) ratio is known a priori. The ratio ^{146}Nd/^{144}Nd = 0.7219 is conventionally used for this fractionation correction (Hamilton et al. 1983). Additional instrument bias can be corrected by measuring a widely available pure Nd standard, typically the "La Jolla" standard with accepted ^{143}Nd/^{144}Nd = 0.511858 (Lugmair and Carlson 1978) or the JNdi-1 with accepted ^{143}Nd/^{144}Nd = 0.512115 (Tanaka et al. 2000). When data from different laboratories is compared, care should be taken that measurements are normalized to the same standard value to avoid interlaboratory bias. Table 1 shows typical high-precision Nd isotope ratio determinations by TIMS for the La Jolla and JNdi-1 standards (Carlson et al. 2007).

The ^{147}Sm-^{143}Nd Decay System

For a closed system where the parent and daughter isotopes remain undisturbed from any process other than radioactive decay, ^{143}Nd/^{144}Nd will increase over time due to the decay of ^{147}Sm to ^{143}Nd according to the decay equation:

$$\frac{^{143}\mathrm{Nd}}{^{144}\mathrm{Nd}} = \left(\frac{^{143}\mathrm{Nd}}{^{144}\mathrm{Nd}}\right)_i + \frac{^{147}\mathrm{Sm}}{^{144}\mathrm{Nd}}\left(e^{\lambda_{\mathrm{Sm}}t} - 1\right), \quad (1)$$

where ^{143}Nd/^{144}Nd is the measured (i.e., present day) isotope ratio of the sample, ^{147}Sm/^{144}Nd is the measured parent-daughter ratio, ^{143}Nd/^{144}Nd$_i$ is the initial ratio of the sample at the time that the Sm-Nd system became closed to mass exchange, and t is the time since system closure.

The ^{147}Sm/^{144}Nd parent-daughter atom ratio is calculated from the Sm and Nd concentrations as

$$\frac{^{147}\mathrm{Sm}}{^{144}\mathrm{Nd}} = \left(\frac{[\mathrm{Sm}]/\mathrm{Sm}_{\mathrm{AtW}} * \mathrm{N_A} * {}^{147}\mathrm{Sm}_{\mathrm{AtAb}}}{[\mathrm{Nd}]/\mathrm{Nd}_{\mathrm{AtW}} * \mathrm{N_A} * {}^{144}\mathrm{Nd}_{\mathrm{AtAb}}}\right), \quad (2)$$

where [Sm] and [Nd] are concentrations, $\mathrm{Sm_{AtW}}$ and $\mathrm{Nd_{AtW}}$ are element atomic weights, $^{147}\mathrm{Sm_{AtAb}}$ and $^{144}\mathrm{Nd_{AtAb}}$ are the abundance of the two isotopes, and $\mathrm{N_A}$ is Avogadro's number.

For a set of cogenetic samples with identical ^{143}Nd/^{144}Nd$_i$ and variable ^{147}Sm/^{144}Nd, for example, rocks from a common source or minerals from within a single rock, their ^{143}Nd/^{144}Nd ratios will increase over time proportionally to their ^{147}Sm/^{144}Nd and will fall along a straight line on a ^{143}Nd/^{144}Nd vs. ^{147}Sm/^{144}Nd plot, called the isochron. The slope of this line ($e^{\lambda t} - 1$) allows calculation of the age of the samples, i.e., the time since the Sm-Nd system closed. As Sm and Nd are generally immobile in fluids and low-temperature alteration, the Sm-Nd isotope system is well suited to date ancient rocks. This is especially useful for mafic rocks that generally have a greater range in Sm/Nd ratios than felsic rocks. An example of dating of Archean mafic rocks is shown in Fig. 1 for a series of ancient lavas with island arc affinities (rhyolites, basalts, boninites) from the Gadwal greenstone terrane, Dharwar craton, India, where ^{143}Nd/^{144}Nd versus ^{147}Sm/^{144}Nd values form a well-defined isochron of 2.7 Ga (Khanna et al. 2014).

Of the common petrogenetic minerals, garnet most strongly fractionates the Sm/Nd ratio. Sm is significantly

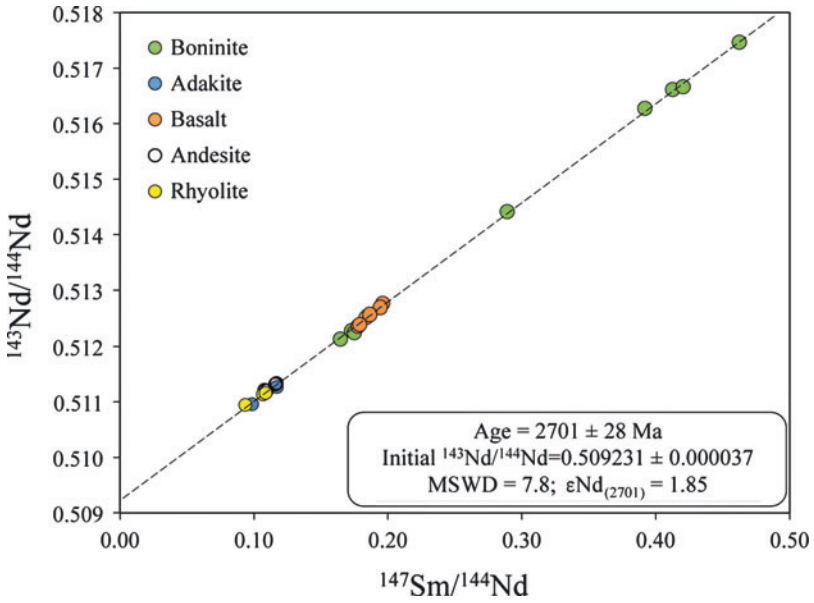
The ^{146}Nd/^{144}Nd ratio is the measured ratio. The other ratios are corrected for fractionation relative to ^{146}Nd/^{144}Nd = 0.7219. After Carlson et al. (2007)



Neodymium Isotopes, Fig. 1 An example of a Sm-Nd isochron constructed by island arc-related metavolcanics from Gadwal greenstone terrane, Dharwar, India. After (Khanna et al. 2014). The best-fit line defined by these rocks has an age of 2.701 ± 0.028 Ga. The intercept defines the initial $^{143}Nd/^{144}Nd_i$ of the source of the volcanics with a calculated $\varepsilon_{Nd(2,701)} = 1.85$. This positive value suggests that the source of these volcanics is a depleted mantle that evolved over time with a time-integrated Sm/Nd ratio greater than CHUR. Isochron age was calculated with the program ISOPLOT (Ludwig 2003)

more compatible than Nd in garnet, leading to high Sm/Nd ratios and significant ingrowth of ^{143}Nd over time, making garnet geochronology an important tool for dating metamorphic processes (Baxter and Scherer 2013). Recent advances in sample manipulation and mass spectrometry allow age determinations of separate domains within single garnet crystals by the Sm/Nd isochron method, providing high spatial and temporal resolution of growth rates and metamorphic reaction rates (Ducea et al. 2003; Pollington and Baxter 2011).

The Nd Isotopic Evolution of the Earth and the CHUR Reservoir

The Nd isotopic evolution of the Earth is thought to be described by the "chondritic uniform reservoir" or CHUR (DePaolo and Wasserburg 1976). This assumes that the material from which Earth was accreted had Sm/Nd and $^{143}Nd/^{144}Nd_i$ similar to chondritic meteorites. This assumption is justified, as both Sm and Nd are refractory elements with similar condensation temperatures. Sm and Nd are also lithophile, hence exclusively incorporated in silicate minerals and Earth's silicate reservoirs (crust and mantle). The CHUR composition is $^{143}Nd/^{144}Nd_{CHUR} = 0.512630$ and $^{147}Sm/^{144}Nd_{CHUR} = 0.1960$ leading to a solar system initial composition of $^{143}Nd/^{144}Nd_{SSI} = 0.506686 \pm 0.000070$ at 4.5685×10^9 year (Bouvier et al. 2008). The bulk silicate Earth is generally thought to have the same $^{143}Nd/^{144}Nd$ evolution as CHUR (but see below for the ^{142}Nd), thereby making the CHUR values a useful reference point for evaluating the time-integrated Sm/Nd evolution of different terrestrial reservoirs.

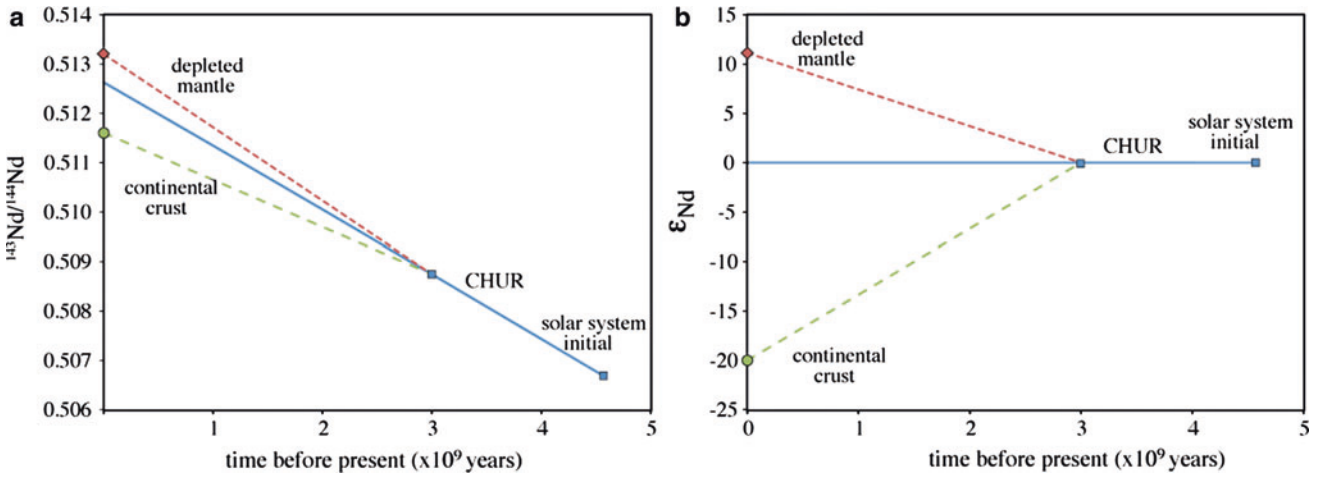
ε_{Nd} Notation

The comparison between different reservoirs and CHUR is facilitated best with the ε_{Nd} notation, which is the normalized difference of the sample's $^{143}Nd/^{144}Nd$ ratio relative to $^{143}Nd/^{144}Nd_{CHUR}$ in parts per 10,000:

$$\varepsilon_{\mathrm{Nd}} = \left(\frac{\frac{^{143}\mathrm{Nd}}{^{144}\mathrm{Nd}}rock}{\frac{^{143}\mathrm{Nd}}{^{144}\mathrm{Nd}}CHUR} - 1 \right) \times 10000 \qquad (3)$$

Rocks with $^{143}Nd/^{144}Nd$ higher than $^{143}Nd/^{144}Nd_{CHUR}$ have positive ε_{Nd} and those with lower $^{143}Nd/^{144}Nd$ than $^{143}Nd/^{144}Nd_{CHUR}$, negative ε_{Nd}. For example, mid-oceanic ridge basalts have a mean $^{143}Nd/^{144}Nd = 0.513074$ (Gale et al. 2013) and $\varepsilon_{Nd} = 8.5$ (typical range of ε_{Nd} 5 to 12), consistent with a derivation from the depleted mantle with greater time-integrated Sm/Nd ratio than CHUR. Crustal rocks have negative (and also highly variable) ε_{Nd} consistent with an origin from a reservoir with low time-integrated Sm/Nd ratio compared to CHUR (Fig. 2). Rocks with ε_{Nd} between that of the depleted mantle and the crust, for example, some ocean island basalts or arc lavas, are often thought to originate from a source that contains crustal material that was recycled back into the mantle (Hofmann 1997). The positive ε_{Nd} of mid-oceanic ridge magmas and negative ε_{Nd} of crustal rocks have led to the generally accepted paradigm that extraction of continental crust left behind a melt-depleted mantle that is now the source of mid-oceanic ridge volcanism.

From the decay Eq. 1, the initial $^{143}Nd/^{144}Nd_i$ ratio of a rock at the time of its formation can be calculated from its measured $^{143}Nd/^{144}Nd$ and $^{147}Sm/^{144}Nd$, provided that its age



Neodymium Isotopes, Fig. 2 (**a**) Schematic evolution of the $^{143}Nd/^{144}Nd$ ratio of the depleted mantle and continental crust relative to the chondritic uniform reservoir (*CHUR*), here taken as equivalent to the primitive mantle. This example assumes a depleted mantle and continental crust reservoirs with present-day $^{143}Nd/^{144}Nd$ of 0.5132 and 0.5116, respectively, and single-stage evolution from CHUR 3×10^9 ago. The depicted depleted mantle has higher $^{147}Sm/^{144}Nd = 0.225$ and the crust lower $^{147}Sm/^{144}Nd = 0.144$ ratios than CHUR and evolve to more radiogenic and unradiogenic $^{143}Nd/^{144}Nd$ ratios, respectively, than CHUR over time. (**b**) Same data as in (**a**) but the $^{143}Nd/^{144}Nd$ isotope compositions of these reservoirs are compared using the ε_{Nd} notation. CHUR, by definition, has $\varepsilon_{Nd} = 0$. The depleted mantle with higher $^{147}Sm/^{144}Nd$ ratio than CHUR has increasingly positive ε_{Nd} over time, and the continental crust with lower $^{147}Sm/^{144}Nd$ ratio than CHUR has increasingly negative ε_{Nd}

is known. The ε_{Nd} notation can be used to compare the initial $^{143}Nd/^{144}Nd_i$ of a rock at some time t in the past, to that of CHUR at the same time t, ($CHUR_t$), by calculating $^{143}Nd/^{144}Nd_{CHUR(t)}$ at time t using the present-day CHUR values above and substituting in Eq. 3.

Time-Integrated Sm/Nd Ratios of Terrestrial Reservoirs and Model Ages

The $^{143}Nd/^{144}Nd$ of a rock, or any reservoir, effectively records the time-integrated fractionation of the Sm/Nd ratio in that rock. As Sm is more compatible than Nd in the Earth's mantle, melting creates residual rocks with relatively high Sm/Nd that generate over time higher, i.e., more radiogenic, $^{143}Nd/^{144}Nd$ than the bulk silicate Earth (primitive mantle) with CHUR composition. In turn, melts generated from the mantle, for example, melts giving rise to the continental crust, have lower Sm/Nd and evolve over time toward relatively lower, or less radiogenic, $^{143}Nd/^{144}Nd$ than CHUR. This concept is shown schematically in Fig. 2, where the $^{143}Nd/^{144}Nd$ evolution of three reservoirs, namely, CHUR, depleted mantle, and continental crust, is plotted as a function of time. $^{147}Sm/^{144}Nd$ (and therefore Sm/Nd) of the depleted mantle reservoir is calculated assuming it was extracted from CHUR at a single event some time t in the past. If a younger age of extraction from CHUR is chosen, the $^{147}Sm/^{144}Nd$ of that reservoir will be higher, and the $^{143}Nd/^{144}Nd$ versus time evolution curve will be steeper to reach the present-day $^{143}Nd/^{144}Nd$ of the reservoir, demonstrating the concept of time-integrated fractionation.

Conversely, if the parent-daughter ratio of the rock or reservoir is known, and it has not changed over time due to secondary processes like alteration, then the time of extraction of that rock from bulk silicate Earth (or any other reservoir) can be calculated. In other words, this "model age" is effectively the time when the rock had the same isotopic composition as its parental reservoir. The concept of model age has been proven useful for estimating the age and rate of extraction of continental crust from bulk silicate Earth or the depleted mantle (Allègre and Rousseau 1984; Arndt and Goldstein 1987; Hawkesworth and Kemp 2006).

This initial Nd isotope composition, or $\varepsilon_{Nd(i)}$, allows tracking the Nd isotopic evolution of mantle reservoirs and the crust-mantle system over time. The generally robust behavior of the Sm/Nd system during alteration allows precise dating of Archean rocks and has been central in the investigation of the Earth's early silicate differentiation history. Mafic Archean rocks as old as about 3.7–3.8 Ga have positive $\varepsilon_{Nd(i)}$ (Bennett et al. 1993; Frei et al. 2004; Blichert-Toft and Puchtel 2010; Hoffmann et al. 2011). This requires that by 3.7 Ga, there already existed a mantle reservoir with higher Sm/Nd ratio than CHUR, suggesting an early differentiation of the Earth. This further requires the formation of a complementary enriched reservoir with lower Sm/Nd than CHUR.

The ^{146}Sm-^{142}Nd System

Excess ^{142}Nd (i.e., high $^{142}Nd/^{144}Nd$) in some ~3.8 Ga old rocks from Isua, Greenland, compared to modern terrestrial samples, requires that a depleted reservoir with high Sm/Nd

ratio had already formed while ^{146}Sm was still extant, between 4.53 and 4.42 Ga (Caro et al. 2006; Bennett et al. 2007; O'Neil et al. 2008; Rizo et al. 2011). This early, depleted reservoir must have survived convective mixing in the early Archean-Hadean time for about 700 Ma after formation of the Earth, in order to become the source of these Isua rocks at 3.8 Ga. The lack of ^{142}Nd excesses in terrestrial samples after 2.7 Ga (Debaille et al. 2013) requires subsequent destruction of that early depleted reservoir, possibly due to convective stirring and mixing in the mantle (Caro 2011).

A puzzling aspect of the ^{142}Nd isotope systematics is that chondrite meteorites have a variable ^{142}Nd deficit (average 20 ppm) compared to terrestrial samples (Boyet and Carlson 2005; Carlson and Boyet 2009; Gannoun et al. 2011). To explain this discrepancy, it was originally proposed that the Earth begun with a chondritic composition, followed by early differentiation and isolation of an incompatible element-enriched, low Sm/Nd reservoir from the rest of the convecting planet (a so-called "hidden" reservoir) within the first 30 My of the Earth's history (Bourdon et al. 2008; Carlson and Boyet 2009). An alternative is that the Earth formed from material with higher Sm/Nd ratio than CHUR, i.e., the Earth is non-chondritic (Caro and Bourdon 2010). Yet, the observation that meteorite ^{142}Nd anomalies also correlate with ^{145,148,150}Nd anomalies points to nucleosynthetic Nd heterogeneity in the early solar nebula (Gannoun et al. 2011; Burkhardt et al. 2016; Fukai and Yokoyama 2016), which would eliminate the need for a hidden reservoir or a significantly non-chondritic Earth.

Seawater

The distribution of Nd in seawater is closely correlated with salinity (von Blanckenburg 1999) leading to its use as a conservative tracer of ocean circulation (Goldstein and Hemming 2003). As the Sm-Nd isotope system is not appreciably disturbed during weathering and transport, the Nd isotope signature of the weathering flux into the oceans reflects the age and lithology of crustal sources (Roy et al. 2007). Due to the short residence time of Nd in seawater and the fortuitous distribution of ancient and juvenile crustal material over the Earth's surface, major water masses can be traced using Nd isotopes as they mix in the thermohaline circulation with deep waters. Pioneering work in this field first illustrated ocean basin scale Nd isotope variations (Piepgras and Wasserburg 1980; Piepgras and Wasserburg 1982; Shaw and Wasserburg 1985; Piepgras and Wasserburg 1987) and highlighted the use of seawater Nd as a water mass tracer in the modern and ancient oceans. In general, the North Atlantic waters have low ^{143}Nd/^{144}Nd and highly negative ε_{Nd} (<-13), while Pacific waters have more radiogenic ^{143}Nd/^{144}Nd and less negative ε_{Nd} (<-3), and Indian and Southern Ocean waters fall in between. The low ε_{Nd} of North Atlantic waters is explained by the North Atlantic basin being surrounded by old, highly unradiogenic crustal rocks (e.g., the Canadian shield), while the Pacific basin is surrounded by younger volcanic systems with contributions from the depleted mantle. Critically, the conservative behavior of Nd isotopes is not compatible with observations of nutrient-like behavior of Nd concentrations, which has been termed as the "Nd paradox" (Goldstein and Hemming 2003) and points to a missing flux of Nd into the oceans. Detailed depth profiles of seawater Nd isotopes also revealed significant deviations from conservative behavior along continental margins (Jeandel et al. 2007), pointing to some possible sources of Nd to the oceans. Recent work to resolve this paradox has focused on submarine groundwater discharge (Johannesson and Burdige 2007) pore fluid flux at the margins (Abbott et al. 2015) and eolian inputs (Greaves et al. 1999). During planning for the international GEOTRACES (www.geotraces.org) program, Nd isotopes were identified as a key parameter that will be measured at every GEOTRACES station. Nd isotope results from international GEOTRACES cruises in the Atlantic Ocean, Ross Sea, Pacific Southern Ocean, and Bay of Bengal highlight the importance of advection of water masses in the Nd isotope systematics of seawater (Stichel et al. 2012; Amakawa et al. 2013; Basak et al. 2015; Stichel et al. 2015; Lambelet et al. 2016).

Summary

The radioactive decay of ^{147}Sm into ^{143}Nd and ^{146}Sm into ^{142}Nd through time has produced variations in Nd isotope ratios in terrestrial and extraterrestrial materials. As Sm is more compatible than Nd during melt extraction from the mantle and during crystallization of mafic minerals, there are significant differences in the Sm/Nd ratio and Nd isotopic composition of rocks and minerals on and within the Earth. As a result, variations in Nd isotopes have proved to be extraordinarily useful in geochronology, igneous and metamorphic petrology, and terrestrial and marine provenance studies.

Sun Abundance (Solar photosphere) [Calculated]: Ne/H = 6.9 10^{-5} (Alecian et al. 2005)
Bulk Solar Wind Abundance [Measured]: Ne/H = 6.6 10^{-5} (Heber et al. 2012)
Chondrites CI Abundance: 360 ± 160 ppt (Mazor et al. 1970)
Phase Q Abundance: 30–1400 ppt (Busemann et al. 2000)
Atmosphere Abundance: 18.18 ppm (volume)
Depleted Mantle Abundance: 0.1–0.5 ppt (weight) (Moreira and Kurz 2013)
Core Abundance: Unknown
Seawater (Pacific) Abundance: ~18 10^{-8} cm^3 g^{-1} at STP (e.g., (Bieri et al. 1966).

Properties

Neon is the second noble gas, the family of elements of the last column of the periodic table. It is chemically inert.

History and Use

Neon was discovered a few years after argon, in 1898, by Ramsay and Travers (1898). Its atomic number is 10 and it has three stable isotopes 20Ne, 21Ne, and 22Ne. Its atomic mass is 20.179, which reflects the relative proportion of the three isotopes (90.48, 0.27, and 9.25%, respectively (Eberhardt et al. 1965)). The neon isotopes ^{20}Ne and ^{22}Ne were discovered by Thomson (1913), whereas the existence of the less abundant neon isotope 21Ne was suggested by Aston (1920) and later proved by Hogness and Kvalnes (1928). Neon is a gas at normal pressure and temperature conditions. It has a low solubility in silicates ($k \sim 2.5 \times 10^{-4}$ cm^3 STP/g/bar at 1400 °C) and in water ($k \sim 10^{-2}$ cm^3 STP/g/bar at 7.5 °C) (Jambon et al. 1986; Lux 1987; Potter and Clynne 1978; Sano and Takahata 2005). Neon is atmophile and one of the most volatile elements in the solar nebula (half-temperature of condensation of 9.1 K (Lodders 2003)). The main budget of terrestrial neon is the atmosphere where it represents ~18.18 ppm in volume, the second most abundant noble gas on Earth, after argon.

Industrial neon can be extracted from air by distillation. Air is compressed and cooled to remove water, CO_2, and other impurities. The purified air is then cooled again until the gases turn into liquids. Then, in distillation towers, neon is separated from other gases. There are not many industrial uses of neon. Neon is mainly employed as filler in lamps and signs (with argon) and in lasers. Neon is a noble gas, rare, so no

mineral is formed by neon. It is not toxic and not used in biological utilization.

Neon is extracted from geological samples in different ways depending of the sample type. For mantle-derived samples, crushing under vacuum is common to release neon contained in fluid or melt inclusions such as minerals or silicate glasses. Heating and melting under vacuum is also used for all solids in order to fully degas the samples. UV laser allows in situ analyzes with ablation spots with a diameter of ~50 μm. Small samples (~0.1 mg) can be degassed using lasers of appropriate power (e.g., Yb-doped laser). All these extraction techniques have in common that they are performed under vacuum to avoid air contamination in the samples.

The neon dissolved in water can be extracted by vaporizing water under vacuum, which allows the noble gases to leave the liquid phase because of their low solubility. After the extraction phase from the samples, the gas purification consists generally in the exposure to hot titanium sponge and/or to nonevaporable getters (made of Zr, Al, V, Fe) at high temperatures (>600 °C) in order to crack all the reactive molecules and to trap all the atoms except those of noble gases. Hydrogen is trapped at room temperature on these getters. Once the gas has been purified, noble gases are generally separated on activated charcoal at different temperatures. He is separated from other noble gases at ~20 K whereas neon will be introduced from heavy noble gases at ~70 K. Neon is then expended into the mass spectrometer for analysis. Due to its low abundance in mantle-derived samples (e.g., less than a ppt in mid-ocean ridge basalts), neon is difficult to analyze and the analytical blanks are often a major issue. This is less critical for more gas rich samples such as meteorites or water samples. The very low abundances also require the measurement of neon by mass spectrometry in static mode (no pumping) and most often, detection on electron multipliers instead of faraday cups.

Although one of the most abundant elements in the Solar System (the 5th) (Alecian et al. 2005), neon is very rare in chondrites and in terrestrial planets (less than 1 ppb in CI (Mazor et al. 1970), and 11 ppt in Earth in g/g of planet). This reflects its highly volatile behavior during condensation in the solar nebula. Its origin on Earth is debated as it is for other volatiles, and it can be threefold: chondritic (late veneer or during late accretion) (Marty 2012; O'Brien et al. 2014), solar (dissolution of solar gases of a primary solar atmosphere into a molten primitive Earth followed by its degassing after the loss of this primary atmosphere (Sasaki 1999)), and cometary (Bar-Nun and Owen 1998). The neon isotopic composition in the Earth's mantle suggests a contribution of solar neon during accretion (solar wind implantation or dissolved solar gases) (Honda et al. 1991; Sarda et al. 1988), but the neon isotopic composition of the atmosphere requires either a neon loss from the atmosphere with isotopic fractionation (Hunten et al. 1987) or a chondritic addition (Marty 2012).

Summary

Neon, the second noble gas, was discovered in 1898 by Ramsay and Travers. On Earth, it is the second noble gas in abundance due to its very high volatility. Its origin on Earth is still debated, but it is generally proposed that it involves a mixture of chondrites, comets, and solar gases either by a dissolution of a primordial atmosphere into a magma ocean or by solar wind implantation in planetary precursors formed closed to the Sun.

Neon Isotopes

Moreira Manuel
Institut de Physique du Globe de Paris, Sorbonne Paris Cité, UMR CNRS 7154, Université Paris Diderot, Paris, France

Definition

Neon, the second element of the noble gas family, has three stable isotopes: ^{20}Ne, ^{21}Ne, and ^{22}Ne.

Introduction

The two most abundant isotopes (^{20}Ne and ^{22}Ne) were discovered in 1913 by Thomson using the first "mass spectrometer" ever built (Thomson 1913). They are the first stable isotopes of the same element that have been discovered. In 1920, Aston suggested the existence of the ^{21}Ne (Aston 1920), which was later confirmed in 1928 by Hogness and Kvalnes (1928). The relative abundance in the atmosphere of the three neon isotopes has been estimated by several authors (Dibeler et al. 1947; Nier 1950; Vaughan et al. 1934), and the commonly adopted values are those of Eberhardt et al. (1965), who determined the following abundances: 90.50 ± 0.07% ^{20}Ne, 0.268 ± 0.002% ^{21}Ne, and 9.23 ± 0.07% ^{22}Ne. This corresponds to isotopic ratios of 9.80 ± 0.08 and 0.0290 ± 0.0003 for ^{20}Ne/^{22}Ne and ^{21}Ne/^{22}Ne, respectively, for the Earth's atmosphere.

The Primordial Composition: The Solar Neon

The determination of the neon isotopic ratio of the Sun has been the subject of many works on meteorites and lunar samples returned by the Apollo and the Luna missions. Early in the 1960s, noble gas measurements on primitive meteorites have suggested that the solar ^{20}Ne/^{22}Ne ratio is 30% higher than the atmospheric one (Zähringer 1962). A ^{20}Ne/^{22}Ne ratio above 13 for the solar wind, higher than the Earth's atmosphere ratio of 9.80, was confirmed by the analyzes of lunar soil grains (Eberhardt et al. 1970) and of metal foils exposed to the solar wind for a few hours during the Apollo 11 and 12 landings (Geiss et al. 1970). The solar wind isotopic ratios have been precisely estimated on the Genesis targets exposed to the solar wind for 850 days after their return (e.g., Grimberg et al. 2006; Heber et al. 2009; Pepin et al. 2012). The solar wind is isotopically fractionated compared to the photosphere and therefore does not provide the composition of the Sun. Heber et al. (2009) have corrected for this isotopic fractionation and proposed that the ^{20}Ne/^{22}Ne ratio of the Sun is 13.36 ± 0.09 (Heber et al. 2012), whereas the solar wind ratio is above 13.7 (Grimberg et al. 2006; Heber et al. 2009; Pepin et al. 2012).

Reactions Producing Neon Isotopes in Solids

Although the three neon isotopes mostly have a primordial origin, two processes can alter the neon isotopic compositions in crustal and mantle rocks, as well as in extraterrestrial materials. Neon isotopes are produced by cosmogenic and nucleogenic reactions. Cosmogenic isotopes are produced during spallation reactions on major elements induced by either high-energy protons in space or by secondary neutrons and muons produced in the atmosphere reaching the surface (the first meters) on Earth. The production ratios in meteorites are ~0.8 and ~0.9 for ^{20}Ne/^{22}Ne and ^{21}Ne/^{22}Ne, respectively (from the stony meteorites compilation of Schultz and Franke 2000) and ~1 and ~0.8 in terrestrial quartz (Niedermann et al. 1993). The cosmogenic isotopes are used in geomorphology and in cosmochemistry to determine exposure ages. In addition to spallation processes, nucleogenic reactions can also alter the trapped neon isotopic compositions. The major nucleogenic reactions producing neon isotopes are ^{17}O(α, n)^{20}Ne, ^{18}O(α,n)^{21}Ne, and ^{25}Mg(n,α)^{22}Ne with production ratios of ~0.3 and ~3.5 for ^{20}Ne/^{22}Ne and ^{21}Ne/^{22}Ne, respectively (Leya and Wieler 1999; Yatsevich and Honda 1997). This process is significant in U and Th rich materials, which is the case of crustal minerals and rocks. Nucleogenic neon is also observed in the mantle-derived rocks and allows explanation of the variation of the ^{21}Ne/^{22}Ne ratio in oceanic basalts sources (Honda et al. 1991; Sarda et al. 1988). These

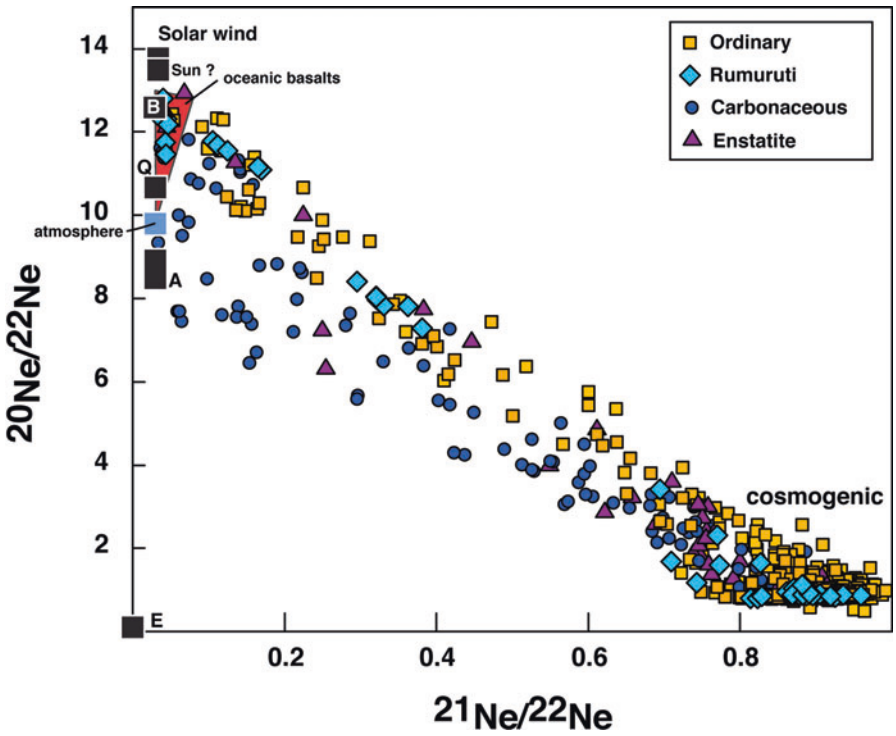
secondary reactions producing neon isotopes tend to decrease the $^{20}Ne/^{22}Ne$ and increase the $^{21}Ne/^{22}Ne$.

Neon in Chondrites: The Neon Alphabet

Neon isotopes show the existence of mainly four components in variable proportions in chondrites. These components are the implanted solar wind, presolar grains (diamonds, SiC, graphites), the cosmogenic end-member discussed above and the phase Q, and a carbonaceous phase mainly carrying the heavy noble gases (Fig. 1). These components can be found in the literature with various names, leading to the concept of the "neon alphabet" (Q, P1, Ne-A1; e.g., Ott 2014). Neon-B refers to implanted solar wind. This component has a $^{20}Ne/^{22}Ne$ of ~12.5–13.0 and is observed in gas-rich meteorites and lunar soil grains (Black 1972; Black and Pepin 1969). Before 2007, Neon-B was proposed to represent a mixture between the "normal" implanted solar wind and implanted neon from solar flares (Solar Energetic Particles, SEP). However, this has been challenged after the analyzes of Genesis probe targets (Wieler et al. 2007). Neon-B rather characterizes the implanted solar wind at steady state coupled with sputtering since it has been shown that neon isotopes are fractionated during solar wind implantation (Grimberg et al. 2006). A scenario able to explain the neon isotopic composition of neon B proposes that the heavy isotopes are implanted deeper than the light ones, leading to a surface of the grains enriched in light isotopes. When sputtering occurs, it produces an isotopic composition heavier than that of the solar wind itself (Raquin and Moreira 2009). Presolar grains have neon isotopic compositions different from those of the Sun. They show $^{20}Ne/^{22}Ne$ ratios of 8.5–8.9 for presolar diamonds, with values down to 0.01 for presolar SiC and graphite, the later suggesting a pure ^{22}Ne component either deriving from the radioactive decay of ^{22}Na or from the direct nucleosynthetic production of pure 22Ne. This later component has however little influence of the global budget of neon in chondrites, which is mainly dominated by Neon-B, presolar diamonds, and cosmogenic neon.

Solar-Like Neon in the Earth's Mantle

Since the pioneering works of Craig and Lupton (1976), Kyser and Rison (1982), Poreda and Radicati di Brozolo (1984), and Sarda et al. (1988), it is clearly established that the mantle shows a solar-like composition, different from the atmospheric composition and from carbonaceous chondrites. Neon in Midocean-Ridge Basalts (MORB) and Oceanic Island basalts (OIB) show a mixture between the atmospheric component and a component having a $^{20}Ne/^{22}Ne$ ratio higher than 12.5, which can only reflect a solar origin (Honda et al. 1991 1993; Moreira et al. 1995 2001; Sarda et al. 2000; (Porcelli et al. 2001; Sasaki 1999; Yokochi and Marty 2004; Mukhopadhyay 2012). The exact origin of the solar component in the mantle is still matter of debates because three origins are possible. The subduction of cosmic dust



Neon Isotopes, Fig. 1 Neon isotopes in chondrites, in the solar wind and of the probable Sun neon isotopic ratios. The red triangle shows the isotopic compositions of oceanic basalts (MORB and OIB). Neon end-member (A, Q, E, and cosmogenic) are also represented. The figure is modified from Moreira (2013)

(interplanetary dust, or IDP) having implanted solar wind into the OIB and MORB sources has been proposed as a possible origin for the solar-like neon in the mantle (Allègre et al. 1993; Anderson 1993). However, only the smallest IDPs (<10 μm) contribute to the He and Ne budget in sediments because they do not suffer significant heating during the entry into the atmosphere (Farley et al. 1997). The largest ones reach temperatures high enough to degas them. Therefore only a very small fraction (~0.5%) of the extraterrestrial material falling onto Earth contributes to solar helium and neon in sediments that could be subducted, which is not enough to explain the neon budget of the Earth's mantle. Moreover, it appears difficult for the implanted solar neon to survive subduction due to its relatively high diffusivity (Hiyagon 1994; Schwarz et al. 2005). Therefore, it seems unlikely that the solar-like neon observed in the mantle is derived from the subduction of cosmic dust. A primordial origin deriving either from the dissolution of solar gases captured by the planet (Porcelli et al. 2001; Sasaki 1999; Yokochi and Marty 2004; Mukhopadhyay 2012) or from the solar wind irradiation of planetary precursors is therefore proposed and still matter of discussion (Raquin and Moreira 2009; Tolstikhin and Hofmann 2005; Trieloff et al. 2000).

Atmospheric Neon: Late Veneer or Atmospheric Loss?

The difference between the atmospheric and solar $^{20}Ne/^{22}Ne$ observed in the mantle has been explained in two ways. The neon in the mantle has a solar-like isotopic composition (Honda et al. 1991; Sarda et al. 1988). Therefore, if the atmosphere was degassed from the mantle, its Ne composition should have been solar, different from the present-day composition of the atmosphere. Neon loss from the atmosphere with a preferential loss of ^{20}Ne compared to ^{22}Ne can explain the atmospheric $^{20}Ne/^{22}Ne$ (Hunten et al. 1987). On the other hand, late addition of chondrites with a Neon-A signature can also explain the atmospheric composition by mixing between solar neon degassed from the mantle and chondritic neon, corresponding to ~1% of late veneer material (Marty 2012).

Summary

Neon has three stable isotopes. In geochemistry and cosmochemistry, neon isotopes are mainly used either to date exposure ages using the cosmogenic production or as a tracer of the origin of volatiles on Earth. They provide significant constraints on the origin and evolution of the Earth's atmosphere.

Neutron Activation Analysis

James R. Budahn
U.S.Geological Survey, Denver, CO, USA

Definition

Neutron activation analysis (NAA), discovered in 1936, is an analytical technique that relies on the measurement of gamma rays emitted from a sample that was irradiated by neutrons. The rate at which gamma rays are emitted from an element in a sample is directly proportional to the concentration of that element. The major advantages of NAA are that (1) it is a multielement technique capable of simultaneously determining up to about 50 elements in many materials; (2) it is nondestructive and therefore does not suffer from the errors associated with sample preparation, the most important source of error in most analytical techniques; (3) it has very high sensitivities for most of the elements that can be determined by NAA, most detection limits range from 0.05 to 50 ppm; (4) it is highly precise and accurate, overall errors of less than 2% relative standard deviation can be achieved for many elements; and (5) samples as small as a few micrograms can be analyzed by NAA.

Principle

The process for analyzing samples by NAA involves irradiating them at or near a neutron source. Neutrons are captured by naturally occurring elements in the sample to produce unstable radioactive isotopes (radionuclides). Beta particles, and in some cases gamma rays, are emitted from the radionuclides to produce stable nuclei. The energies of these gamma rays are, in general, distinct for a specific nuclide, and the rate at which these photons are emitted with a particular energy can be measured using high-resolution semiconductor detectors. Because the production and decay rate of gamma-ray radiation are dependent on the half-life of the nuclide, elemental measurements can be optimized by varying the irradiation and the decay times (i.e., how long the sample is near a neutron source and when the sample is counted).

Procedure

The most common procedure for NAA involves encapsulating the samples and suitable standards in heat-sealed polyethylene or quartz vials and simultaneously irradiating them in a research nuclear reactor. Typical research nuclear reactors have neutron fluxes ranging between 10^{10} and 10^{15} n/cm^2/s. Ideally, the samples are irradiated in a "lazy susan" facility that revolves around the core of the reactor, thereby ensuring that the samples and standards experience the same neutron fluence (i.e., flux multiplied by time). Alternatively, samples can be irradiated by neutron point sources, such as californium-252, that have neutron fluxes ranging between 10^5 and 10^{10} n/cm^2/s. Following sequential decay periods, each standard and sample is counted utilizing high-resolution germanium detectors coupled to a multichannel analyzer system. Counting of samples over sequential decay periods optimizes the determination of 35–50 elements in various types of samples. The analyzer system converts the signals that result from gamma-ray photons impinging the detector into digital electronic pulses and stores this information into a few energy-related channels (i.e., an energy region). Gamma-ray counts accumulated in an energy region above the background counts produce photopeaks. After the counting is complete, these data are processed using sophisticated computer programs that smooth the spectral data and determine the net areas of the gamma-ray photopeaks and translate the area data into count rates (e.g., cpm). These programs are capable of resolving overlapping and complex photopeak energy regions. Final data reduction procedures involve correcting the count rate data for decay time differences, electronic deadtime losses, and unresolved interferences and comparing the sample data (e.g., cpm/weight) to the standard data (e.g., cpm/μg) to calculate elemental abundances in the sample. In some cases, especially when it is not practical to irradiate multiple standards, elemental abundances can be determined using the k_0 method which is based on activities (i.e., cpm/ug) calculated from activation equations.

Errors In Analysis

The principal error in the analysis of materials by NAA is the counting statistic error, which is based on the signal-to-background ratio at the gamma-ray energy region of interest. A one-sigma error for a photopeak area determination is approximately equal to the square root of the total counts (i.e., background plus net counts) divided by the net counts. For example, a peak area determination with 2000 total counts and a net area of 1000 counts produces a counting error of about 4.5%. An additional error for some elemental determinations is due to unresolved interferences. The most serious interferences are those that result when identical radionuclides are produced from different nuclear reactions: for example, high concentrations of U fission products can significantly interfere with the accurate determination of La, Ce, Nd, Mo, and Zr abundances. In addition, the determinations of some elements can suffer because the photopeaks produced by gamma rays emitted by two or more radionuclides are not readily resolved. In these cases, empirical corrections are integrated into the data reduction procedure.

Self-shielding is a phenomenon that occurs when the neutron flux experienced by a sample is attenuated, thereby reducing the neutron activation of the nuclides in self-shielded samples. This effect occurs when a sample contains extremely high concentrations of elements with very high probabilities that a neutron will be captured, which is measured in terms of a neutron capture cross section.

Other errors can result from inhomogeneous neutron fluxes and not maintaining the identical distance between the samples and the detector.

Detection Limits

Elemental detection limits for NAA are variable because of variations in nuclear parameters. Specifically, the production of a radionuclide depends on the neutron capture cross section of the target isotope of the specific element. In general, elements that have cross sections less than 2 barns (a barn being equal to 10^{-24} cm^2) have detection limits greater than 2 ppm, whereas elements with cross sections greater than 5 barns have detection limits less than 1 ppm. Also important is the number of gamma rays emitted by a radionuclide (i.e., the branching intensity). In some cases, only a small fraction of the total emissions from a specific nuclide is in the form of gamma rays. Another important nuclear parameter affecting detection limits is the isotopic abundance of the target nuclide. Detection limits are also matrix dependent. Samples with high concentrations of readily activated elements and that emit a considerable number of high-energy gamma rays, such as Na and Sc, can generate high background count rates, which raise the detection limits. Some of these emissions can blocked from detection by electronic anticoincidence techniques, thereby reducing the background rates.

Summary

Neutron activation analyses remain at the forefront of techniques for the quantitative multielement analyses of major, minor, and trace elements in hundreds of different types of materials. NAA is especially important in the analyses of geochemical reference materials because of the nondestructive nature of the technique. The following list includes some materials that have been readily analyzed by NAA: fish, teeth, bones, chemicals, bird feathers, wheat, metal, alloys, rocks,

animal shells, wood, tree needles, soil, rocks, lunar samples, meteorites, minerals, water, hair, fingernails, fossils, bullets, paint, silica glass, and biomass fuel oils.

Properties

Nickel has an atomic number of 28, an atomic weight of 58.69, and a density of 8.9 g/cm^3. It is a silvery metal that melts at 1455 °C and boils at 2913 °C; it is magnetic, malleable, and ductile and conducts electricity (www.rsc.org/periodic-table).

Ni has five naturally occurring stable isotopes and up to 18 radioactive isotopes, all long extinct. Up to 0.4 permil difference in Ni-isotope composition is observed between coexisting kamacite and taenite in iron meteorites and is ascribed to diffusion during exsolution and cooling (Lazar et al. 2012). However, the isotopic composition of Ni in chondritic meteorites and Earth is probably identical within current analytical capabilities (Lazar et al. 2012). Significant fractionation of Ni isotopes can occur in low-temperature processes such as lateritic weathering of ultramafic rocks; progressive weathering leads to isotopically lighter soils ($\Delta^{60}Ni_{Soil\text{-}Bedrock} = -0.47$ ‰) (Ratié et al. 2015).

Ni is a transition element, with the electronic configuration [Ar]3d^{8}4s^2; consequently it shows both siderophile (iron-loving) and lithophile (silicate-loving) behavior. In the crust and upper mantle, it normally occurs as Ni^{2+}, whereas in the Earth's core, it is alloyed with iron.

History and Use

Nickel (Ni) was first isolated from NiAs (niccolite) and named by A. F. Cronstedt in 1751. The name derives from the Saxon "nickel," a malicious sprite ("Kupfernickel") who prevented them from extracting copper from niccolite, which they had mistaken for chalcopyrite ($CuFeS_2$). Its properties were determined by J.B. Richter in 1804.

The main use of Ni (*ca* 65%) is for the production of stainless steel, with demand increasing by ca 5%/annum (International Nickel Study Group; www.insg.org). It is also used in the production of nonferrous alloys or so-called "superalloys" which show better resistance to corrosion and are widely used in jet engines and turbines. Smaller proportions are used in various surface treatments such as electroplating and as hydrogenation catalysts.

Ores and Production

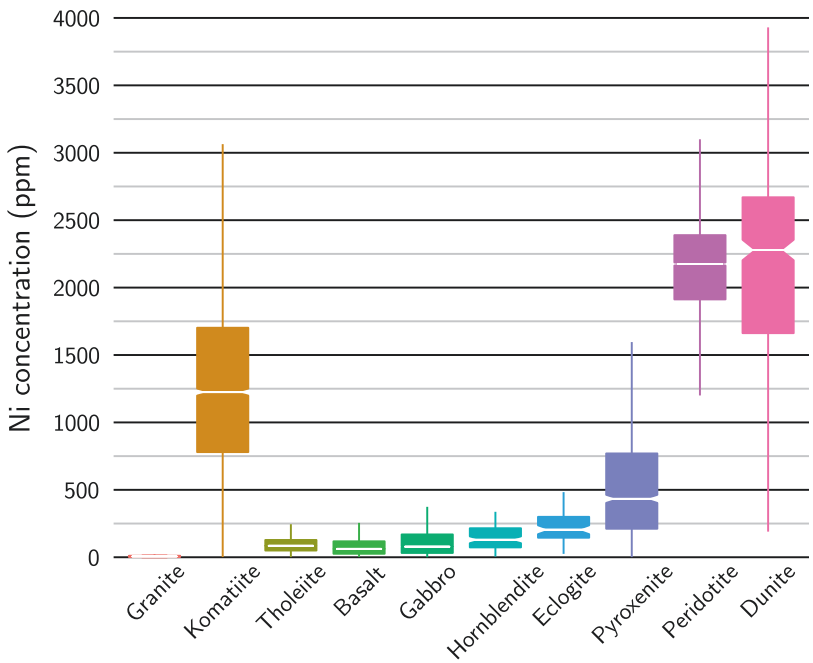
World usage of Ni amounts to between 1.8 and 2 million tonnes/year (2014–2015).

Nickel is mined almost entirely from two types of deposit, magmatic sulfides and lateritic horizons, developed through the weathering of ultramafic rocks, usually in tropical areas (e.g., New Caledonia, Venezuela, the Dominican Republic, Brazil, Madagascar, and eastern Australia). Magmatic sulfides occur in ultramafic lava flows (komatiites; Fig. 1) in Archean cratons, in large intrusions of layered gabbros, and in the Sudbury giant impact crater. In all of these, the major ore mineral is pentlandite $(Ni,Fe)_9S_8$, but Ni also forms a range of other sulfides, arsenides, and antimonides. While magmatic sulfide ores are important resources, >70% of the world's supply of Ni is mined from lateritic deposits. During weathering, Ni concentrates in Ni-bearing limonite (Fe oxyhydroxide) and garnierite (referring to a group of green Ni-bearing magnesium phyllosilicates including serpentine, talc, sepiolite, smectite, and chlorite) in the middle-upper parts of the weathering profile, providing a resource that is easily mined and processed.

Geochemistry

The cosmic abundance of Ni estimated from carbonaceous chondrites is 10,910 ppm (Palme et al. 2014); estimates for its abundance in Earth lie between 17,000 and 19,000 ppm. Most of this is concentrated in the Earth's core; analyses of iron meteorites suggest the core contains *ca* 5 wt% Ni (McDonough 2014), leaving *ca* 1860 ppm in the mantle (Palme and O'Neill 2014) and 47 ppm in the continental crust (Rudnick and Gao 2014). Ni substitutes readily into the Mg-rich minerals of the mantle and is largely retained in the residue during partial melting. Ni concentrations in the crust are correspondingly quite low. The worldwide distribution of Ni in different rock types is shown in Fig. 1; Fig. 2 provides more detail on its distribution in mantle rocks. The variability shown in Fig. 2 is easily understood in terms of the relative abundance of Ni in the important minerals of mantle rocks (Fig. 3). This behavior is related to the charge and ionic radii of Ni. Under crustal and upper mantle conditions, the most common oxidation state of nickel is Ni(II). The effective ionic radius of Ni(II) depends on its coordination number ($^{[4]}$Ni, 0.55 Å; $^{[4]}$Ni square, 0.49 Å; $^{[5]}$Ni, 0.63 Å; and $^{[6]}$Ni, 0.69 Å). The identical charge and similarity in ionic radii between $^{[6]}$Ni and $^{[6]}$Mg allow significant substitution of Mg by Ni in olivine, the main Ni bearer among mantle-related minerals (Fig. 3). In addition, these distributions reflect mineral-mineral partitioning. Ni can substitute for Mg but not for Ca, which explains the higher Ni concentration in orthopyroxene compared to clinopyroxene (Fig. 3). Ni substitution may also be favored in the Mg site of spinel, which is smaller than the Mg site of garnet.

The solubility of Ni in pure water is low (<2 μg/L), but in the presence of dissolved organic compounds, it can form complexes that are soluble. In anoxic conditions, it precipitates in sulfide phases (NiS, pyrite). Atmospheric concentrations of Ni are dominated by anthropogenic pollution, principally from the burning of oil, and have increased by



Nickel, Fig. 1 Distribution of Ni concentration in various lithotypes (Data from GEOROC, Sarbas and Nohl (2008); 18,359 analyses). The boxes represent the first and third quartiles of the data distribution. The horizontal line represents the median, and the width of the adjacent notches shows the 95% confidence interval about the median. The "whiskers" represent 1.5 x midrange (arithmetic mean of maximum and minimum values) beyond the first or third quartile

a factor of >500 since the beginning of the Industrial Revolution (Pacyna and Pacyna 2001). Contributions to atmospheric Ni from smelting operations account for *ca* 10% of the total; they have declined in recent years due to better emission controls, but previously devastated large areas in the vicinity of smelters at, e.g., Sudbury in Canada and the Kola Peninsula in arctic Russia.

Biological Utilization and Toxicity

Ni is known to be toxic in high doses, but they are reached only in special situations. However, Ni contamination of groundwater can represent a hazard, especially in acidic conditions where it can be leached from soils (Nieminen et al. 2007).

Nickel is an important micronutrient in the oceans, and dissolved Ni is variably enriched (ca 10 nM/kg) in deeper waters and depleted (ca 2 nM/kg) in surface waters, following the pattern of other micronutrients such as Fe and Zn, as well as P and Si. This distribution suggests that diatoms actively control the distribution of Ni in ocean waters (Twining et al. 2012). The methanogenic bacteria that dominated Archean life appear to have been addicted to Ni. It has been proposed that a decline in the Ni contents of banded iron formations late in the Archean reflects a decrease in the availability of Ni in ocean water. This "nickel famine" may have led to the rise of the cyanobacteria, and their production of oxygen led in turn to the Great Oxidation Event at the end of the Archean (Saito 2009; Konhauser et al. 2009), allowing the evolution of multicellular life.

Summary

Nickel shows a very diverse range of geochemical behavior, being both a siderophile and a lithophile element. It has been important to mankind since the Bronze Age and is a mainstay of modern industrial society. It also is an essential element in the biogeochemistry of the oceans.

Niobium

Carsten Münker
Institut für Geologie und Mineralogie, Universität zu Köln, Köln, Germany

Element Data
Atomic Symbol: **Nb**
Atomic Number: **41**
Atomic Weight: 92.90637
Isotopes and Abundances: ^{93}Nb, 100%
1 Atm Melting Point: 2477 °C
1 Atm Boiling Point: 4744 °C
Common Valences: 5+
Ionic Radii: 6-fold: 64 pm
Pauling Electronegativity: 1.6
First Ionization Potential: 652 kJ/mol
Chondritic (CI) Abundance: 283 ppb
Silicate Earth Abundance: 595 ppb
Crustal Abundance: 8 ppm
Seawater Abundance: 1–4 pmol/kg
Core Abundance: 450–500 ppb

Properties

Niobium is a transition metal of low toxicity with the atomic number of 41. Niobium has one stable isotope (93) with an atomic mass of 92.90637(2) (CIAAW 2015) The now extinct isotope ^{92}Nb with a half-life of 34.7 Ma is currently being investigated as a potential chronometer in cosmochemistry

(e.g., Münker et al. 2000, Schönbächler et al. 2000), decaying to ^{92}Zr by electron capture. In nature, Nb occurs in +5 valence state, although lower valence states are known from synthetic systems. Its atomic radius is 146 pm and its ionic radius in +5 valence state and sixfold coordination is 64 pm (Shannon 1976). Due to its high ratio of charge to ionic radius, Nb is classified in geochemistry as *high field strength element*.

History and Use

Niobium was first discovered in 1801 by the English chemist C. Hatchett (1802), which he named *columbium.* In 1845, the German chemist Heinrich Rose (1845) discovered that Ta-rich minerals contained a second element he named *niobium*, after Niobe, the daughter of Greek mythological figure Tantalus, reflecting the extreme geochemical similarity between Nb and Ta. It was subsequently discovered that *columbium* and *niobium* are identical. Not until 1949 was the name *niobium* adopted as official name for the element, but since then *columbium* had been used frequently in the North American literature, in particular in metallurgy.

Economically important Nb deposits are hosted by carbonatites or pegmatitic granites that in most cases exhibit a paired enrichment of both Nb and Ta to ore grade level. Important economical grade minerals include pyrochlore and columbite/tantalite, the latter mineralization is often referred to as COLTAN. Countries with the world's largest Nb deposits include Brazil, Canada, Australia, and some African countries, with Brazil presently supplying most of the industrially used Nb (USGS 2015). Technically, Nb is mainly used as steel alloy, for instance, in gas pipelines, jet and rocket engines, heat-resisting equipment, and superconducting alloys.

Geochemical Behavior

Niobium is a highly refractory element with a 50% condensation temperature of 1559K (Lodders 2003) and has traditionally been regarded as behaving lithophile during Earth's differentiation. Ratios of Nb and similarly refractory elements like Ta or Zr are nearly constant in most groups of chondrites, and only CV chondrites rich in refractory components deviate from this general pattern (Münker et al. 2003). The solar system abundance of Nb as estimated from CI chondrites is 283 ppb; the estimated abundance in the bulk silicate Earth is 595 ppb (Münker et al. 2003 in Palme and O'Neill 2014). The estimate for the bulk silicate Earth takes into account recent findings that, in contrast to its entirely lithophile geochemical twin Ta, Nb behaved moderately siderophile at the low oxygen fugacities prevailing during early core formation on Earth (Wade and Wood 2001). This provides a viable explanation why silicate Earth's Nb/Ta is significantly lower (14.0 ± 0.3) than the chondritic Nb/Ta of 19.9 ± 0.6 (Münker et al. 2003). The corresponding concentration of Nb in the core is between 450 and 500 ppb, assuming that all of the missing Nb in the silicate Earth has indeed been sequestered into the core (Wade and Wood 2001). There are suggestions that some of the missing Nb is stored via subduction zone processes in silicate reservoirs in the deep Earth and not in the core (e.g., Rudnick et al. 2000; Kamber and Collerson 2000). However, the observation that Nb/Ta in early Archean mafic rocks is indistinguishable from values in Phanerozoic rocks (Münker et al. 2003) argues against this view.

During silicate melting on Earth, Nb behaves highly incompatible in mantle minerals and is therefore depleted in the mantle and enriched in the crust. In the continental crust, the Nb content is estimated to 8 ppm with a content of 12 ppm and an Nb/Ta between 12 and 13 in the upper crust (Barth et al. 2000; Rudnick and Gao 2014). Relative to similarly incompatible elements like La or U-Th, however, Nb is markedly depleted in the continental crust, mirroring its selective depletion in subduction zone magmas that contributed to the bulk of the continental crust. The selective depletion of Nb in subduction-related lavas and the continental crust is caused by its lower solubility in subduction zone fluids and by its retention in Ti-rich phases like rutile in subducting oceanic crust and possibly in subducting sediments (e.g., Zack et al. 2002; Hermann and Rubatto 2009). Together with its geochemical twin Ta, Nb is therefore a viable tracer for elemental mass balances in subduction zone systems, and it is now known that Nb can be soluble in subduction zones to some extent at high pressures and in Cl^-- and F^--rich environments, leading to distinct Nb/Ta fractionation patterns (e.g., Münker et al. 2004; König et al. 2010; Kirchenbaur and Münker 2015). Hence, employing Nb/Ta ratios in igneous and metamorphic rocks has now become an important tool to better understand the role of residual phases such as rutile, titanite, or amphibole during silicate melting.

Due to its high valence state, Nb tends to hydrolize easily and is not very soluble in seawater, with an estimated concentration between 1 and 4 pmol/kg (Firdaus et al. 2011; Bruland et al. 2014). Notably, elevated Nb/Ta in seawater as high as 85 (Firdaus et al 2011) indicate that Nb can be highly fractionated from its geochemical twin Ta in aqueous systems, likely due to their different complexing behaviors. Once more data will become available for aqueous systems, combined Nb and Ta studies may have great potential to better understand weathering processes and ocean circulation.

Biological Utilization and Toxicity

Niobium has no known biological role. Niobium salts have been shown to be toxic, but only at very high doses (Haley et al 1962).

Summary

Niobium is a highly refractory incompatible element and one of the high field strength elements. Although generally considered lithophile, it has some siderophile tendency, and up to 500 ppb, Nb may be in the core. It has low solubility and is generally considered immobile. Compared to elements of similar incompatibility, it is depleted in the Earth's crust and in subduction zone magmas.

Nitrogen

Pierre Cartigny
Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Université Paris Diderot, Paris, France

N

Element Data

Atomic Symbol: **N**
Atomic Number: **13**
Atomic Weight: 14.0067 g/mol
Isotopes and Abundances: ^{15}N (0.36%), ^{14}N (both stable)
Dinitrogen (78 molar percent of atmosphere) is gaseous at standard Pressure and Conditions.
Common Valences: primarily −3 (nitride, ammoniac), 0 (dinitrogen) and +5 (nitric acid)
Chondritic (CI) Abundance: ~2500 ppm
Silicate Earth Abundance: 2–20 ppm
Crustal Abundance: 83 ppm
Core Abundance: –

Properties

Nitrogen is the 5th element of the periodic table. With an electronic structure [He] $2s^2$ $2p^3$, nitrogen can either lose or gain up to five and three electrons, respectively, and can

therefore occur under a wide range of redox states from −3 to +5. The main reduced to oxidized species include nitride (N^{3-} in diamond, ammonium, and ammoniac), atmospheric dinitrogen gas (N^0 in N_2) to oceanic dissolved nitrate (N^{5+} in NO_3^-).

Nitrogen has 16 isotopes, two are stable (^{14}N ~ 99.64%, ^{15}N ~ 0.36%), the 14 others being radioactive with too short half-lives (<10 min) to have any potential geochemical application. Resulting atomic mass of nitrogen of 14.0067 (Coplen 2001) and variations in its stable isotope ratio is a central tool in stable isotope geochemistry.

Nitrogen is the fifth most abundant element in the solar system (~1105 ppm N, Lodders 2003) and is comparatively depleted on Earth with estimated Bulk Earth of ~3 to ~28 ppm N (Cartigny and Marty 2013). On Earth, nitrogen is unevenly distributed. The atmosphere is a nitrogen-rich reservoir where N_2 gas represents 78.084% mole fraction (~3.9×10^{21} g N) together with minor but significant greenhouse gases such as nitrous oxide (N_2O), other nitrogen oxides (NO_x, 100 ppt–1 ppm), ammonia (NH_3, 10 ppt–1 ppb), and particulate nitrate and ammonium (1 ppt–10 ppb) occurring in aerosols (Brasseur et al. 1999). The crust and sediments typically contain 100–1000 ppm levels (Busigny and Bebout 2013), the Earth's mantle is N-poor with estimated N-contents of 0.26–36 ppm. The nitrogen content of the Earth's core remains unknown with contradicting experimental evidence.

The main source of nitrogen to the hydrosphere is atmospheric in origin being massively cycled by biological activity (at a rate of ~2×10^{14} g N/y; Galloway 2003), particularly by primary producers (e.g., phytoplankton and cyanobacteria). Without a strong return flux (denitrification and anaerobic ammonium oxidation), present-day atmospheric nitrogen (~4×10^{21} gN) would be entirely sequestered within less than 100 million years (My).

Unlike other elements, crustal nitrogen is originally sourced from the atmosphere by biological activity (i.e., mantle nitrogen contribution and abiotic atmospheric reduction are negligible). Nitrogen enters the rock cycle as organic matter matures releasing nitrogen as ammonium ion (NH_4^+). Having similar charge and ionic radius to potassium, ammonium then substitutes for – and follows the fate of – potassium in potassic minerals (e.g., clays, feldspars, and micas; Busigny and Bebout 2013). The occurrence of ammonium in crustal rocks is therefore primarily of atmospheric origin.

Very few N-forming minerals exist in nature; they occur in very specific environments such as volcanic fumerolles, evaporitic systems, atmospheric deposits (Atacama desert), or meteorites (see Table 1 in Holloway and Dahlgren 2002). Ammonium is generally only a substitutional impurity, buddingtonite the ammonium feldspar ($NH_4AlSi_3O_8$) being a noticeable case. Nitrate-forming minerals are rare as well (nitrate is a very soluble species), but it is worth mentioning that nitre (KNO_3, the word *nitrogen* coming actually from *nitre-forming*) and saltpetre were important sources of nitrogen entering the composition of gun-powder and fertilizers.

Nowadays, since the advent (1909–1913) of industrial abiotic dinitrogen reduction into ammoniac through the so-called Haber-Bosch process where $N_2 + 3H_2 \rightarrow NH_3$ (Bosch 1966), the main source of nitrogen entering fertilizers is actually atmospheric with over 1.4×10^{14} gNH_3 produced every year, i.e., close to the flux of biological nitrogen fixation. Present-day nitrogen cycle is thus a good example of a heavily anthropized cycle. Nearly 100% of world production of synthetic ammonia relies on the Haber-Bosch process and the resulting massive production (and use) of fertilizers is generally described as the *detonator of the population explosion* (Smil 1999). With only half of fertilizers being fixed by plants, nitrate pollution of groundwaters, rivers, and estuaries leads to biological blooming which results in anoxic waters during their subsequent degradation.

Definition

The nitrogen cycle describes the biogeochemical transformation of the element nitrogen into a variety of chemical species within ecosystems the transfer of those nitrogen-containing species among atmospheric, terrestrial, and aquatic ecosystems.

Pools in the Nitrogen Cycle

The vast majority of global nitrogen (N) is in a form or setting that makes it unavailable to organisms for their uptake and metabolism. Atmospheric nitrogen (in the form of N_2) makes up roughly 50% of the total nitrogen on Earth; the remaining nitrogen is primarily in rocks of Earth's mantle and crust and is highly unavailable biologically (Canfield et al. 2010). Nitrogen in rocks is generally in the form of NH_4 in silicates (clays), although a few NO_3- bearing minerals are known. In igneous rocks, N content is usually <0.1 wt%. Nitrogen in sedimentary rocks can be much higher (up to ~2 wt%). Due to the low reactivity of rock-derived nitrogen, nitrogen in the mantle and crust of the Earth is typically excluded from consideration in the nitrogen cycle. Atmospheric nitrogen thus holds roughly 90% of the nitrogen relevant to the global nitrogen cycle, with nearly all of that nitrogen in the form of N_2 (Chapin et al. 2011). The ocean holds the second largest pool of nitrogen (roughly 9%), but a sizeable portion of this nitrogen (99.98%) is located in ocean sediments and deep water (Chapin et al. 2011) and thus has a very low turnover time relative to other terrestrial and aquatic pools. In the terrestrial pool of the nitrogen cycle, soils hold roughly 23 times the total nitrogen found in terrestrial biomass (Chapin et al. 2011). Most soil nitrogen is in organic form, due to the rapid uptake of nitrogen by organisms; the pool of inorganic nitrogen in soil at any given time is very small (Schlesinger and Bernhardt 2013).

Overview of Nitrogen Cycle

The nitrogen cycle involves incorporation of nitrogen into biological molecules and the breakdown of those molecules into inorganic forms of nitrogen that have varying biological availability and reactivity. The largest pool of nitrogen on Earth is the atmosphere, where the dominant form of nitrogen is N_2 gas. The formidable energy required to break the triple bond in N_2 gas means this large pool of nitrogen is predominantly unavailable biologically. However, two to three billion years ago, both photosynthesis and the microbial process of N_2 fixation, which converts one mole of N_2 to two moles of ammonia (NH_3) using nitrogenase, evolved. Photosynthesis and N_2 fixation created larger pools of organic carbon and bioavailable nitrogen in terrestrial and aquatic systems; these molecules were now available for processing and recycling by other organisms. Of the 203 Tg of reactive (biologically available) nitrogen generated annually from natural sources, one-third is terrestrially derived and two-thirds are marine-derived (Table 1; e.g., Fowler et al. 2013). Most organisms cannot fix nitrogen, but rather obtain nitrogen as NH_4^+, NO_3^- (which is then converted to NH_4^+ through assimilatory NO_3^- reduction), or as organic nitrogen (Fig. 1). The latter is the form in which many heterotrophs (including animals and fungi) obtain nitrogen, while plants and some heterotrophs (including bacteria) are able to use inorganic forms of nitrogen. Bioavailable forms of inorganic nitrogen range from fully reduced to fully oxidized forms and include NH_3, NH_4^+, NO, NH_2OH, N_2O, NO_2^-, and NO_3^- (Fig. 1, Table 2).

A number of different reactions govern fluxes of nitrogen between different types of bioavailable forms and between terrestrial, aquatic, and atmospheric pools of

Nitrogen Cycle, Table 1 Global nitrogen fluxes (Table modified from Fowler et al. 2013)

Nitrogen fluxes	Tg N $year^{-1}$
Sources of fixed nitrogen	
Anthropogenic	
Fertilizer production	100
Chemical production	20
N_2 fixation, agricultural	60
Combustion to NO_x	40
Natural	
Lightning	5
N_2 fixation, marine	140
N_2 fixation, terrestrial	58
Sinks for fixed nitrogen	
Denitrification, marine	100–280
N burial, marine	20
Nitrogen fluxes between pools	
Wet and dry atmospheric deposition	100
NH_3 emissions, terrestrial	60
NH_3 emissions, marine	9
N_2O emissions, marine	5.5
NO emissions from soil	5
N_2O emissions from soil	13

NO_2^-	+III
NO_3^-	+V

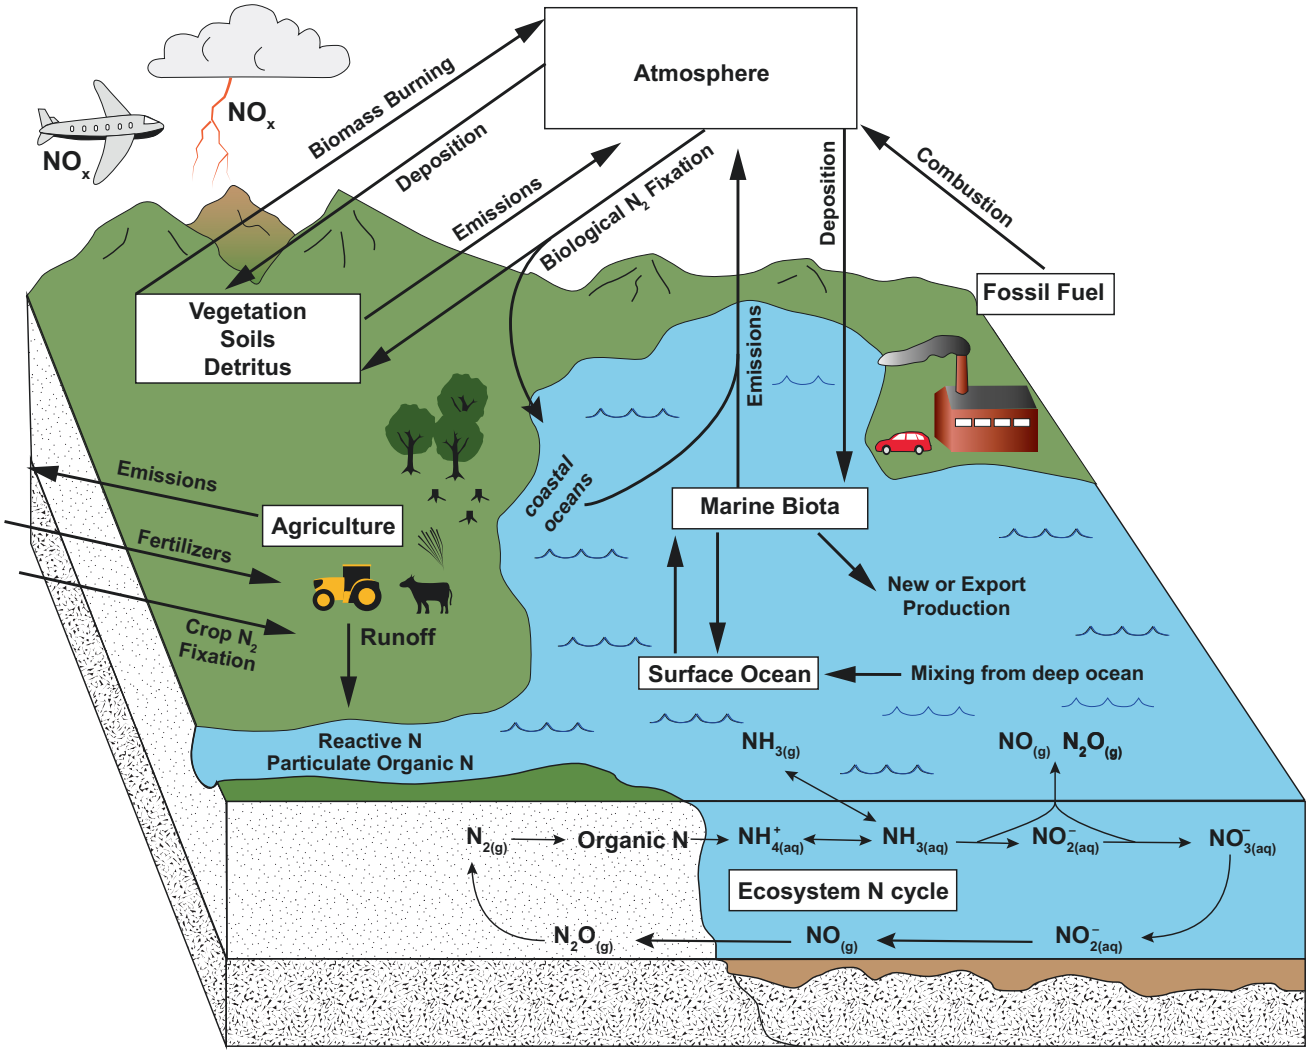
nitrogen (Figs. 1 and 2). Nitrogen is cycled internally in terrestrial and aquatic systems primarily via the metabolic processes of microbes and plants (assimilation, mineralization, nitrification, and dissimilatory nitrate reduction to ammonium (DNRA)). These processes are especially sensitive to oxygen and pH and are typically highly coupled with one another. A subset of microbial processes in terrestrial and aquatic systems (i.e., denitrification, anammox, and, to a lesser extent, nitrification) returns nitrogen to the atmosphere in the form of nitrogen gas (NO, N_2O, N_2).

Humans have radically altered the global nitrogen cycle. The invention of the Haber-Bosch process (a synthetic nitrogen fixation reaction) in the early 1900s allowed the industrial production of NH_4^+ for fertilizer. This process has radically altered the nitrogen cycle by more than doubling the amount of bioavailable nitrogen in terrestrial systems (Table 1). The dramatic increase of bioavailable nitrogen in both aquatic and terrestrial systems has had large impacts on ecosystems, altering both internal fluxes of nitrogen and feedbacks between the atmosphere and biosphere. Human activities, including combustion of fossil fuels, changes in land use, and inputs of inorganic nitrogen to terrestrial and aquatic systems in the form of fertilizer, have greatly increased fluxes of nitrogen (NO_2, NO, N_2O) to the atmosphere.

Fluxes in the Nitrogen Cycle

Major fluxes in the nitrogen cycle are either internal to terrestrial, aquatic, or atmospheric pools or move nitrogen between these pools (Fig. 2). Fluxes are mediated primarily by biological transformations (i.e., microbial respiration and plant production); less common are a few abiotic phenomena that convert nitrogen from one molecular form to another. The key flux in the nitrogen cycle, nitrogen fixation, is a microbial process that moves atmospheric nitrogen (N_2) into a form useable by plants and other microbes (NH_4^+). Although not typically considered a major component of the nitrogen cycle, abiotic chemical reactions can convert some forms of nitrogen gas into forms that enter terrestrial and aquatic pools. For example, lightning strikes are responsible for a small amount of nitrogen fixation (~2% of annual nitrogen fixation; Galloway et al. 2008), and various forms of nitrogen gas are miscible (NH_3) or reactive (NO_x) with water, which moves nitrogen from the atmosphere to aquatic and/or terrestrial systems. Current models suggest that in the early Earth's atmosphere, long prior to the evolution of nitrogen fixation, lightning and high-energy meteorite impacts were primarily responsible for producing NO that would be converted to NO_3^- and NO_2^- through photochemical and aqueous phase reactions (Canfield et al. 2010).

Internal cycling of nitrogen within terrestrial and aquatic systems largely involves conversion of nitrogen between various inorganic, biologically reactive forms and between inorganic and organic forms of nitrogen. Figure 2 shows an example of internal cycling within a coastal marine ecosystem (labeled "Ecosystem N cycle"), where nitrogen moves between different inorganic and organic forms, as well as gaseous (g) and aqueous (aq) forms. Ecosystem cycling includes the following major fluxes: **nitrification** (microbial oxidation, over several intermediary steps, of NH_4^+ to NO_3^-),



Nitrogen Cycle, Fig. 2 The nitrogen cycle. Fluxes occur between major global pools (atmospheric, terrestrial, and aquatic ecosystems) and between pools within these ecosystems. An example of internal ecosystem cycling is shown for a coastal marine ecosystem (labeled "Ecosystem N cycle"), where nitrogen moves between different types of molecules, including inorganic and organic, and gaseous (g) and aqueous (aq) forms. Human activities, including agricultural practices, fossil fuel combustion, and biomass burning, have heavily influenced the nitrogen cycle. Anthropogenic influence includes increased inorganic (reactive) flux from the terrestrial to aquatic pool through runoff, and increased nitrogen flux (of nitrogen gases) from the terrestrial to atmospheric pool. Atmospheric deposition of reactive nitrogen onto terrestrial ecosystems has also increased due to human activities

NO_3^- reduction (to NO_2^-), **dissimilatory nitrate reduction to ammonium (DNRA)** (microbial reduction of NO_2^- to NH_4^+), **assimilation** (NH_4^+ to organic nitrogen), and **mineralization** or **ammonification** (organic nitrogen to NH_4^+) (Fig. 1). **Denitrification** and **ammonia oxidation (anammox)** by microbes convert NO_3^- and NH_4^+, over a few intermediary steps, to nitrogen gas, returning nitrogen to the atmosphere (Fig. 1). The terminal form of nitrogen in both these processes is N_2. Microbial nitrification and abiotic NH_4^+ volatilization can also result in the production of N_2O and NH_3^+ gas, respectively (Fig. 1).

The concentration of oxygen (redox status) in water, soil, and sediments strongly influences which processes related to nitrogen cycling can occur in a given system at a given point in time (Fig. 1, Table 2). Nitrogen loses and gains electrons during abiotic and biotic chemical transformation, with the oxidation state of nitrogen ranging from −3 to +5 (an eight electron difference). Nitrification is an oxidizing reaction that requires the largest transfer of electrons (oxidation state change of −3 to +5) in the nitrogen cycle and thus requires high oxygen availability. This process is carried out in several steps that transfer oxygen to the nitrogen molecule: first, bacteria (primarily *Nitrosomonas* species) convert NH_4^+ to NH_2OH using the enzyme ammonium monooxygenase and NH_2OH to NO_2^- using hydroxylamine oxidoreductase. *Nitrobacter* species are then primarily responsible for

converting NO_2^- to NO_3^- using the enzyme nitrite oxidoreductase. Most other fluxes in the nitrogen cycle (denitrification, nitrogen fixation, DNRA, and anammox) are reduction reactions that occur under anaerobic conditions. Anammox does involve an increase in oxidation state for its final step (i.e., N_2H_4 to N_2, catalyzed by hydroxylamine oxidoreductase), but this reaction is anaerobic nonetheless.

Coupling of Fluxes and Flux Balances

Because the products of one process involving nitrogen are often the inputs for another, fluxes in the nitrogen cycle are coupled with and balance one another. For example, denitrification relies on nitrification in the absence of external NO_3^- inputs, which leads to a predominance of coupled nitrification-denitrification in many ecosystems. Nitrogen assimilation is tightly coupled to mineralization and is controlled by nutrient limitations. If organisms in an ecosystem are limited in their metabolic processes by nitrogen relative to other needed nutrients (e.g., carbon and phosphorus), nitrogen assimilation will constitute a larger flux than nitrogen mineralization, and organic nitrogen will constitute a larger pool within that system than those of biologically available (inorganic) nitrogen species. The nitrogen cycle is thus tightly coupled with that of phosphorus and carbon, globally and within ecosystems. Finally, the balance between N_2 fixation and denitrification in terrestrial and aquatic ecosystems determines total global terrestrial and marine pool sizes (see Table 1).

Fluxes of nitrogen between different pools is also tightly linked with fluxes of water, both because the presence of water in a terrestrial system can influence redox status of soils, and therefore internal cycling, and because water can transport nitrogen in the form of dissolved gas and ions. Because NO_3^- is highly soluble in water compared to NH_4^+, for example, and less readily adsorbed to charged surfaces in soil, NO_3^- tends to be the dominant form of inorganic nitrogen that is transported between terrestrial and aquatic systems.

Anthropogenic Alterations to the Nitrogen Cycle

Human activities have had both direct and indirect effects on pools and fluxes in the nitrogen cycle, but never so much as in the last century. One of the most seminal changes by humans in the nitrogen cycle has been perpetuated by the invention of the Haber-Bosch process, or industrial-scale N fixation. The invention of this process was a tremendous boon for global food supply and resulted in increased population growth worldwide. However, it has also doubled the production of reactive N in terrestrial ecosystems (Fowler et al. 2013). Inadvertent N fixation also occurs through other anthropogenic activities, i.e., fossil fuel combustion and industrial processes (e.g., electricity production). Nitrogen-fixing agricultural crops cultivated by humans also contribute significant amounts of reactive N to terrestrial ecosystems (Fowler et al. 2013) (Table 1). The result of these large anthropogenic sources of reactive N has been doubling in global N cycling over the last century (Fowler et al. 2013). Further, reactive N is accumulating in the environment, because although roughly 20%, by some estimates, of N fertilizer is lost to the atmosphere as N_2 in croplands, gaseous nitrogen emissions cannot keep pace with N fertilizer applications (Wang et al. 2017).

Hydrologic and atmospheric transport processes disperse reactive N widely outside of where it is formed, and this dispersal can have large-scale, cascading environmental consequences (Galloway et al. 2003). For example, urban and agricultural runoff transports inorganic nitrogen (especially NO_3^-) deposited as fertilizer in terrestrial systems to freshwater aquatic systems; this reactive nitrogen eventually makes its way to estuaries. Although a great deal of reactive N is denitrified when it reaches marine systems (Table 1), excess reactive nitrogen in surface water causes eutrophication, hypoxia, loss of biodiversity, and habitat degradation in aquatic systems in general and coastal ecosystems in particular on a global scale (Galloway et al. 2003; McCrackin et al. 2017). NO_3^- is also a ubiquitous contaminant in aquifers worldwide due to fertilizer use; NO_3^- in drinking water can cause a number of human health problems (Spalding and Exner 1993). The emissions of nitrogenous trace gases (NH_3, NO_x, N_2O) have increased exponentially from preindustrial emissions, with the source being primarily terrestrial soils (Table 1); this is largely due to conversion of nitrogen fertilizer by microbes into gaseous forms of nitrogen (Galloway et al. 2003). Fossil fuel combustion is the primary source of NO_x gases to the atmosphere, however (Table 1). Reactive nitrogen in the atmosphere in the form of NO_x is linked to the oxidizing capacity of the atmosphere, and plays a key role in the photochemical production of ozone, which in turn increases pollution (smog) in and the greenhouse potential of the troposphere (Galloway et al. 2003; Fowler et al. 2013). N_2O is a potent greenhouse gas with 298 times the atmospheric heat-trapping ability of carbon dioxide (CO_2) over a 100-year period, on a per-molecule basis. It is relatively inert in the troposphere, but plays a role in stratospheric ozone destruction (Portmann et al. 2012). Finally, NH_x, NO_y (all oxidized forms of nitrogen other than N_2O), and organic nitrogen can fall from the atmosphere onto terrestrial and aquatic systems as dry or wet deposition, resulting in ecosystem acidification, fertilization, and eutrophication (Galloway et al. 2003). Atmospheric transport and subsequent deposition of reactive nitrogen was estimated to be 34 Tg N $year^{-1}$

during the preindustrial area, but had increased to 100 Tg N $year^{-1}$ in 1995; in 2050, this process is estimated to increase to 200 N $year^{-1}$ (Galloway et al. 2008).

Summary

Nitrogen is an essential element for all life, yet the vast majority of nitrogen on the Earth exists as N_2 gas – a form that is unavailable to most organisms. Nitrogen has a wide range of redox states, and life has evolved many complex nitrogen cycling metabolisms to obtain and retain this most valuable element. Reactions that convert nitrogen among different species, including (but not limited to) N_2, NH_4^+, NO_3^-, and organic nitrogen, are present in all domains of life. These reactions are generally coupled to energy-yielding metabolisms; however, nitrogen fixation ($N_2 + 6H^+ \rightarrow 2NH_3$) requires significant energy input, and 16 ATP are needed for this reaction. Because nitrogen is often the limiting nutrient in both aquatic and terrestrial ecosystems, the nitrogen cycle is necessarily tightly coupled to the global cycles of phosphorus and carbon. The pre-anthropogenic global nitrogen budget was essentially in balance between N_2 fixation (predominantly by microbes) and microbial denitrification. In the twentieth century, however, human activity has had a profound impact on the nitrogen cycle, second only to the human impact on the carbon cycle. Anthropogenic nitrogen fixation, primarily through the Haber-Bosch process, which produces NH_3 from atmospheric N_2, has disrupted the balance between nitrogen sources and nitrogen sinks. Nitrogen sources now exceed nitrogen sinks by more than 40% and perhaps as much as a factor of three (see Table 1). This excess reactive nitrogen from anthropogenic inputs has caused eutrophication, hypoxia, increases in greenhouse gases (e.g., N_2O), loss of biodiversity, and habitat degradation in aquatic coastal ecosystems.

N

Nitrogen Isotopes

Pierre Cartigny and Vincent Busigny
Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Université Paris Diderot, Paris, France

Introduction

Together with those of carbon, nitrogen stable isotopes (^{14}N and ^{15}N) represent one of the most widely applied tracers in isotope geochemistry, with over 120 articles published every year having "nitrogen isotopes" in their title. Nitrogen is cycled between the different envelopes of the Earth – hydrosphere, atmosphere, crust, and mantle – and can occur as various species depending on pressure, temperature, and redox conditions. The origin and fate of nitrogen between these pools can be constrained using its isotope composition.

Nitrogen isotopes are primarily used in the fields of environment and paleoenvironment studies, sediment diagenesis, soil formation and evolution, and archeological and paleodiet studies. There are comparatively less applications in the

field of cosmochemistry and high-temperature geochemistry (i.e., mantle and crustal environments), and this reflects the need to use more complex analytical techniques compared with the former.

This entry provides a brief overview of questions that have been addressed using natural variations of N stable isotopes. It will omit studies that used either artificially ^{15}N–enriched compounds; these are commonly used in plant physiology and agriculture to establish detailed biogeochemical mechanisms (e.g., identify and quantify the biological and chemical pathways between these N pools). It is however worth mentioning that the semiconservative DNA replication – rejecting the conservative and dispersive hypotheses – was demonstrated using ^{15}N–enriched (Meselson and Stahl 1958).

Nitrogen Stable and Unstable Isotopes

Nitrogen has two stable isotopes, ^{14}N (~99.632%) and ^{15}N (~0.368%), leading to an atomic mass of 14.0067. Fourteen radioactive isotopes have been identified but have too short half-lives to be useful in geochemistry. Note however that ^{13}N (half-life ~9.92 min) is used in medical studies for positron emission tomography (PET). It requires ^{13}N to be made on-site in a cyclotron, $^{13}NH_3$ being synthesized and injected to the patient for PET imaging to deduce a large number of cardiac parameters (blood flux, volume of the ventricles) and, if any, cardiac abnormalities. In the following, the term "N isotopes" will refer only to N stable isotopes (^{14}N and ^{15}N).

The two stable isotopes of nitrogen are neither radioactive nor radiogenic. Therefore, on a bulk Earth scale, their abundance did not change through time. The relative abundance of N isotopes on Earth is grossly speaking that of our solar system, and they were produced in stars as part of the so-called C-N-O cycle (see Furi and Marty 2015 for a more subtle assessment). Atmospheric ^{14}N is the main source of ^{14}C($^{14}N + n \rightarrow {}^{14}C + {}^{1}p$), which decays back to ^{14}N with a half-life of 5730 ± 40 years. This reaction in particular ($^{14}N \rightarrow {}^{14}N$) and other reactions (e.g., ^{14}C production from ^{17}O) are not significant enough to change the abundance of terrestrial ^{14}N through time. The same applies to ^{15}N; its abundance did not change through time.

Stable isotope variations of terrestrial nitrogen originate from vibrational effects and are therefore quite limited. Terrestrial $^{15}N/^{14}N$ ratios range mostly between 3.356 and 3.750×10^{-3}, and these variations are expressed using the conventional delta notation where $\delta^{15}N_{sample} = [(^{15}N/^{14}N_{sample})/(^{15}N/^{14}N_{atmospheric\ nitrogen}) - 1] \times 1000$ with $^{15}N/^{14}N_{atmospheric\ nitrogen} = 0.0036764 \pm 0.0000041$ (Junk and Svec 1958; Mariotti 1983). In cosmochemical studies, the variations are much larger ($^{15}N/^{14}N$ from 1.838 to 22.059×10^{-3}), and these result from stable isotope fractionation processes, nuclear reactions, and nucleosynthetic anomalies. In the literature, these large variations are expressed using either $^{15}N/^{14}N$ or $^{14}N/^{15}N$ ratios and/or $\delta^{15}N$ notation.

Analytical Techniques

Nitrogen isotopes are almost exclusively measured using N_2 as an analyte and electron-impact gas-source ion-ratio mass spectrometers (IRMS) operating in dynamic pumping mode (i.e., the sample is either ionized, accelerated, and detected or immediately pumped away). Historically, nitrogen was extracted from its matrix, quantitatively converted to N_2 gas, purified using *offline* vacuum extraction techniques before being analyzed by dual-inlet mass spectrometry. Sample size is typically >5 micromoles and precision on $\delta^{15}N$ better than 0.1‰ (1σ). The historical method for solid sample analysis (e.g., rocks, minerals, soils) – generally referred to as Dumas combustion – consists in oxidizing the sample in a sealed tube at ~900 °C, nitrogen oxides (if any) being reduced by copper at ~600 °C and CO_2, SO_2, and H_2O being separated from N_2 using either liquid nitrogen or calcium oxide (e.g., Kendall and Grim 1990). Presently, nitrogen can be extracted using various methods, including crushing, laser ablation, and laser or furnace heating (either in oxidized, inert, or reducing conditions), and purified using gas chromatography and/or chemical and cryogenic techniques. It is also worth mentioning that N and O isotopes of nitrate are commonly analyzed using cultured denitrifying bacteria releasing N_2O.

The coupling of elemental analyzers to IRMS (EA-IRMS) in the early 1980s opened the path to online, nearly fully automated, analyses of N content and isotope composition (Preston and Owens 1983). The sample loaded in tin capsule is combusted (flash combustion) in a stream of helium. This releases C, N, S, and H, which are converted to CO_2, N_2, SO_2, and H_2O using various chemical compounds (including Cu at ~600 °C) and are subsequently separated using gas chromatography. This method does not require prior vacuum N extraction and purification, is slightly more sensitive than the abovementioned method, and can produce several dozen of analyses per day, still with very good precisions on $\delta^{15}N$ better than 0.15‰ (1σ).

These two techniques account for the majority of applications of $\delta^{15}N$ in geochemistry. Both of them require submicromole N amount, and, in most cases, data are obtained together with C isotope composition. Yet for smaller samples size (sub-nano to even picomole of N), these techniques are not sensitive enough and require other types of instrumentation such as static vacuum mass spectrometers (as used in noble gas geochemistry). In this case, the sample gas is entirely introduced, expanded, and analyzed in the mass spectrometer, leading to an increase of sensitivity by several orders of magnitude but a decrease of precision to

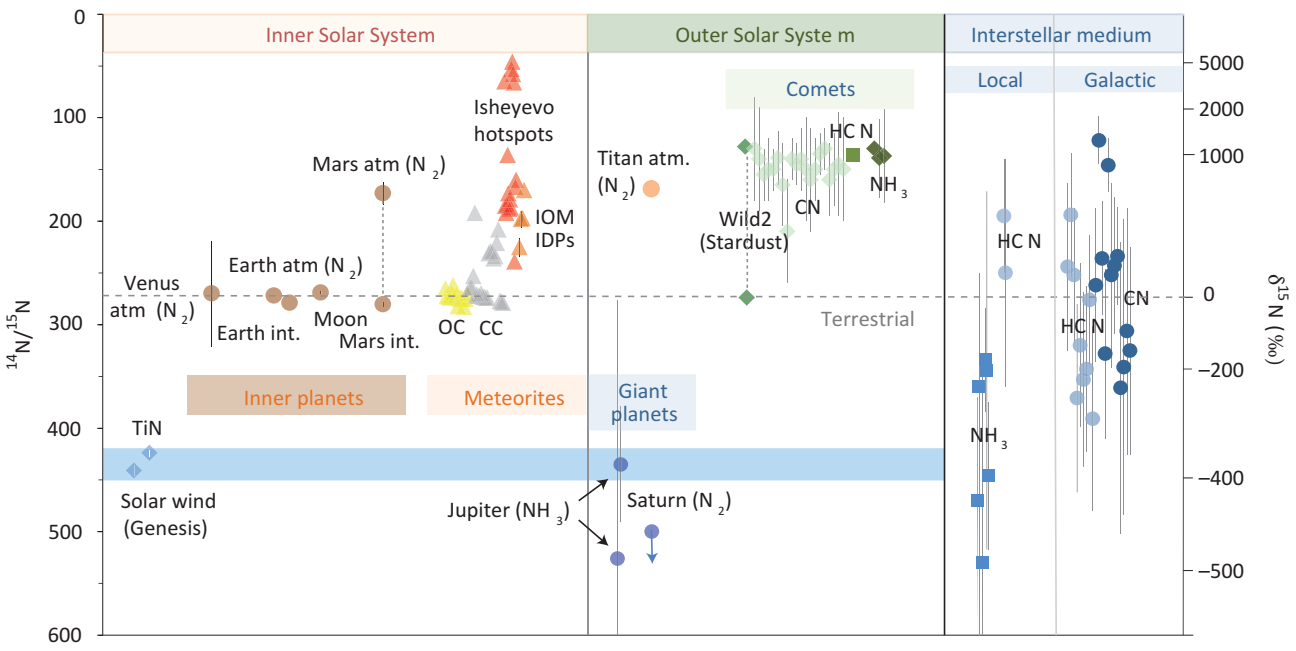
typically ±1‰ (Wright et al. 1988; see *analytical boxes* in Cartigny and Marty 2013; Furi and Marty 2015). Offline extraction and purification methods are the same as above, nitrogen being also analyzed as N_2, but special care is required to monitor atmospheric contamination. To date, this type of technique has been limited to less than ten laboratories in the world.

Secondary ion mass spectrometry (SIMS) provides alternative to determine N isotope composition on small samples. This method is almost nondestructive and can operate at high spatial resolution (typically ~ 20 μm), the isotope analysis being determined from secondary CN^- ions. This method is precise but requires standards having the same composition than the investigated samples, so that precision and accuracy vary as a function of both matrix and N concentration (~1‰ for $\delta^{15}N$ in diamonds, to 20‰ for the analysis of solar wind nitrogen, Marty et al. 2011). High-resolution SIMS are quite expensive instruments and therefore restricted to few laboratories (and even less are involved in the analysis of $\delta^{15}N$). Remote analysis of comets or molecular clouds can be determined using high-resolution spectroscopy for molecules/ions such as HCN, NH_2, and NH_3 but not N_2. The precision is typically of several tens of per mil. Similar methods (high-resolution IR spectroscopy) are presently being developed for the analysis of non-symmetric terrestrial gaseous N-bearing molecules such as N_2O. Finally, the development of site-specific N isotope composition is emerging with applications in forensic (Aranda et al. 2011, a field outside the scope of this overview) and atmospheric (Toyoda and Yoshida 1999; Heil et al. 2014) sciences.

Cosmochemistry

Nitrogen isotope composition varies greatly among extraterrestrial materials (sometimes even within a single object), and, for many years, no clear understanding of the mechanisms driving N isotope variability was achieved. A long-standing hypothesis was that N isotope variability of meteorites reflects isotopic heterogeneity of the solar nebula. Indeed, N isotopes are synthesized by two distinct astrophysical processes (^{14}N during hydrostatic hydrogen burning and ^{15}N during explosive hydrogen and helium burning), and the isotope variability could thus reflect variable influx from different stars to the solar system. At present, the role of chemical, likely photochemically induced, reactions is emerging (Furi and Marty 2015), i.e., with a view rather similar to that deduced from O isotope cosmochemistry.

The key observation is that the Sun (and therefore the primitive solar nebula) is enriched in light N isotope ($\delta^{15}N \sim -400$‰, Marty et al. 2011, Fig. 1) with respect to meteorites and planets, a result strikingly similar to what is observed for O isotopes. Such ^{15}N–depleted compositions are also found only in rare refractory nitride minerals (TiN) and the atmosphere of giant planets, including Jupiter and Saturn (Fig. 1). The former are described as representing



Nitrogen Isotopes, Fig. 1 Nitrogen isotope variations in solar system objects and reservoirs. The value of the protosolar nebula (blue shading) is defined by the measurement of solar wind nitrogen, TiN, and the atmospheres of the giant planets: all other solar system objects are comparatively significantly enriched in ^{15}N (From Furi and Marty 2015, reproduced with permission)

high-temperature solar nebula condensate, whereas the latter acquired their N isotope composition by accretion of the gas left from the Sun accretion and/or trapped nitrogen flushed from the inner disk by the protosun.

All other objects including primitive and differentiated meteorites are comparatively enriched in ^{15}N (Fig. 1), typically by 400 ± 50‰ ($\delta^{15}N \sim 0 \pm 50$‰). Significant differences exist among primitive meteorites classes and within a group of meteorites. The most reduced (enstatite chondrites) are more depleted in ^{15}N ($\delta^{15}N$ from −50 to 0‰, average ~ −25‰; Grady et al. 1986) than the more oxidized carbonaceous CI and CM chondrites ($\delta^{15}N \sim +40$‰; Kerridge 1985). Other carbonaceous chondrites display a large range, with CV and CO being characterized by the more negative $\delta^{15}N$ values of this group ($\delta^{15}N \sim -20$ and −10‰, respectively). Ordinary chondrites show average $\delta^{15}N$ values close to that of the Earth's atmosphere (~0‰; Hashizume and Sugiura 1995).

Various reservoirs of telluric planets including Earth, Mars interior, Venus atmosphere, and the Moon have mostly similar N isotope compositions, consistent with their formation within the inner part of the accretion disk. Interestingly, both Mars and Earth show atmospheric ^{15}N enrichment compared to their mantle of ~600 and ~5‰, respectively, and this originates from two different processes. For Mars, atmospheric ^{15}N enrichment reflects hydrodynamic escape or pickup charge exchange with solar wind ions and subsequent nonthermal escape with preferential loss of ^{14}N to space. Given that there is neither evidence for recent tectonic activity nor biological fixation, N exchange and re-equilibration between Mars inner and outer reservoirs appear unlikely. In contrast, owing to its larger size, the occurrence of life, and plate tectonics, the case for Earth is fundamentally distinct from Mars and discussed hereafter. Finally, it is worth noting that Earth is comparatively depleted in ^{15}N compared with most primitive meteorites, including carbonaceous chondrites. The only class of meteorites with $\delta^{15}N$ values matching those of bulk silicate Earth is enstatite chondrites. Together with O isotopes, nitrogen was one of the first recognized elements to share similarities with this class of meteorites. Since then, such similarity has been extended to many elements such as Zn, Mo, Ru, Cr, Sr, Ti, and Ca (Javoy et al. 2010).

In detail, a single meteorite can display strong N isotope heterogeneity, reflecting a multitude of processes and origins. For example, the Isheyevo carbonaceous chondrite shows a range > 5000‰ (Fig. 1). Presolar grains carry tremendous isotope anomalies ($^{15}N/^{14}N$ from ~$0.2 - 100 \times 10^{-3}$, Zinner et al. 2007), but the low concentration of this component in meteorites induces limited isotope variability on bulk samples. Spallation reactions can produce significant amount of light elements, including nitrogen. They are most recognizable on the rare isotopes (i.e., ^{15}N enrichment) and can be easily targeted using exposure proxies (e.g., $^{38}Ar/^{36}Ar$). More importantly for this overview, $\delta^{15}N$ variability also reflects photochemically induced isotope fractionation effects, and the large isotope fractionation between N-bearing molecules (HCN and NH_3, Fig. 1) is a likely illustration (next section also reports a case for photochemical effects on Earth). By analogy with the so-called mass-independent fractionation of O isotopes, N isotope variations could result from photochemistry during interactions with UV light originating from the forming Sun and/or other stars. For instance, N_2 could react and form molecules such as ammonia or cyanide that would then be transferred/condensed to ice and dust and subsequently to meteorites and planets. As for O isotopes, the exact mechanism remains unclear and UV photochemical effects could result from isotope selective reactions or reflect self-shielding effects. Accordingly, compared with heavy elements that are commonly used to trace solar nebula heterogeneity, light elements such as N bear the potential to highlight chemical processes that occurred in the solar nebula.

Atmospheric Nitrogen Species and Deposits

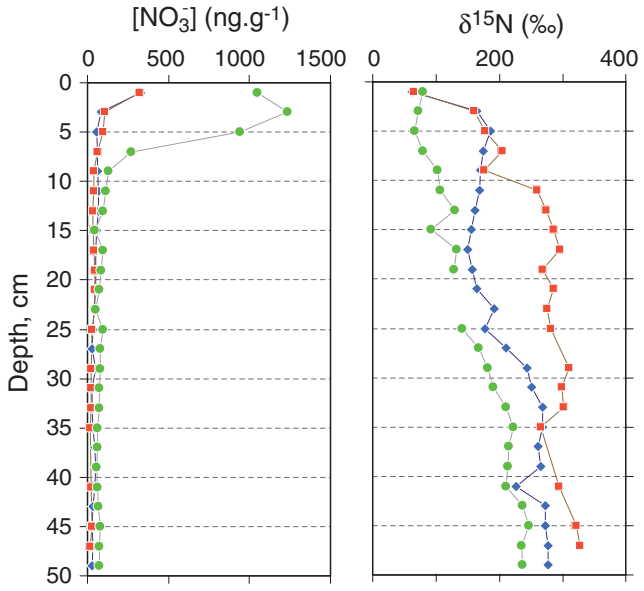
The main (i.e., 78% molar fraction) gaseous species of Earth atmosphere is diatomic nitrogen (N_2). The isotope composition of atmospheric N_2 is homogeneous and used as the international reference for $\delta^{15}N$ notation, i.e., $\delta^{15}N_{atmosphere} \equiv 0$‰ (Mariotti 1983). Several other N-bearing gas and/or aerosols occur in the atmosphere such as NH_4, N_2O, NO_X, or HNO_3, and their origin and fate can be studied from their N isotope composition.

A good example of photochemically induced isotope fractionation is illustrated by nitrate recorded in Antarctic snow/ice, which shows large range of $\delta^{15}N$ values from 0 to +300‰ (Savarino and Morin 2011, Fig. 2). This range results from the photolysis of nitrate in snow, leading to the release of ^{15}N–depleted NO_x and the accumulation of residual ^{15}N–enriched nitrate. This process can be modeled using a Rayleigh distillation (with a fractionation factor $\alpha \sim 0.94$, i.e., −60‰) and seems to be only expressed where snow accumulation rates are low. For other locations such as Greenland, where accumulation rates are higher and for which photochemical processing of nitrate is accordingly less important, the N isotope composition of nitrate is consistently less variable, although very negative $\delta^{15}N$ values can be reached (down to −60‰). In contexts where accumulation rates are the largest (e.g., Greenland Summit), the secular evolution of $\delta^{15}N$ values from ~ +10 down to ~ 0‰ in preindustrial times to present (Fig. 3) was suggested to reflect the anthropogenic influence on the N cycle (Hastings et al. 2009). Along with the development of industrial N fixation at the beginning of the twentieth century, the N cycle became massively anthropogenized, with present-day industrial nitrogen fixation close to biological flux (~2×10^{14} gN.yr.$^{-1}$, Galloway

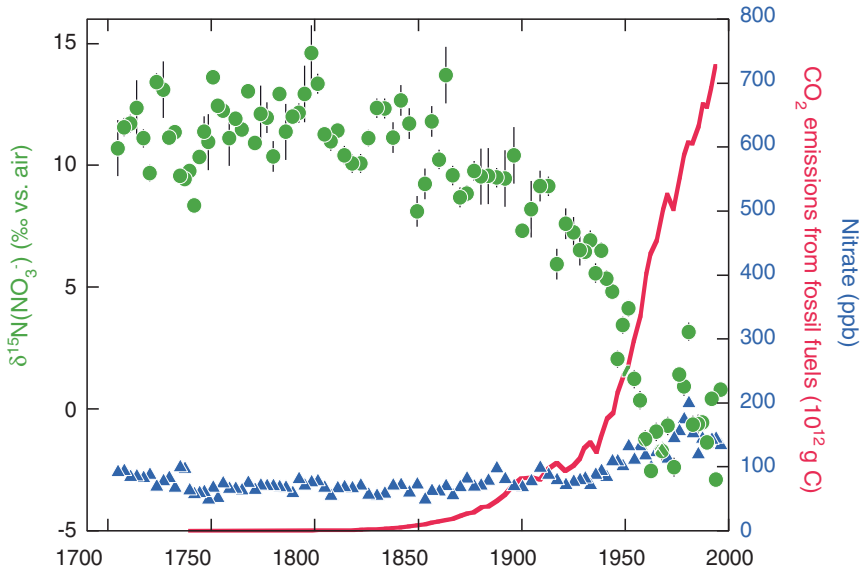
2003, with $\delta^{15}N$ ~0‰, Michalski et al. 2015), consistent with the trend of decreasing $\delta^{15}N$ through time (Fig. 3). However, the observed trend is challenged by the lack of known values at ~ + 10‰ for preindustrial sources and could instead relate to an increase in anthropogenic atmospheric acidity, the isotope variation reflecting the resulting change in nitrate partitioning between gas and particles (Geng et al. 2014).

Another application of N isotopes consists in quantifying abrupt temperature changes from gas bubbles trapped in ice. The variability does not reflect changes in atmosphere composition because N_2 and Ar have long residence times. Two combined effects contribute to $\delta^{15}N$ variability. The first effect corresponds to gravitational fractionation in the first ~100 m of the ice sheet, which behaves as a porous media, and the second effect is thermal fractionation resulting from abrupt temperature warming (Severinghaus et al. 1998). After an abrupt increase in air temperature – as illustrated by the so-called Dansgaard-Oeschger events in Greenland ice cores – the resulting temperature gradient leads to heavier gas species ($^{15}N^{14}N$, ^{40}Ar, $^{18}O^{16}O$) in the colder, i.e., deeper part of the firn. When used together with Ar isotopes, it allows deducing both the magnitude of temperature increase (typically >10 °C with precision of ~2.5 °C) and duration (typically <100 years) for most of the Dansgaard-Oeschger events (Landais 2011).

Among atmospheric compounds, nitrous oxide (N_2O, half-life of 120 years) receives peculiar attention because it is a powerful atmospheric greenhouse gas (~ 300 times more efficient than CO_2) and is a cause of ozone layer depletion. The concentrations of N_2O in the atmosphere have increased from 270 to 330 ppm since preindustrial times. The average $\delta^{15}N_{bulk}$ of tropospheric N_2O is 6.5‰, yet varying with location and time and decreasing by 0.040‰/yr (Rockmann and Levin 2005). Emissions are biotic, with the majority (~2/3) being produced in soils from bacterial and fungal anaerobic denitrification and aerobic nitrification processes (see next section). The other part is produced in the ocean, but N_2O origins, fluxes, and fate are still poorly constrained in this environment. In soils, N_2O emissions depend upon a large number of parameters including agricultural practices (N application rate, crop type, fertilizer type) and soil conditions (soil moisture, soil organic C content, soil pH, and texture) resulting in a large variability on both spatial and temporal scales (Thomson et al. 2012). To better address



Nitrogen Isotopes, Fig. 2 Typical snow pit profiles in central Antarctica (Dome C) showing the strong denitrification of the snow in a very short depth accompanied by a strong ^{15}N enrichment of nitrate (Modified from Savarino and Morin 2011)



Nitrogen Isotopes, Fig. 3 Secular evolution of $\delta^{15}N$ of nitrate (solid circles) and nitrate concentration (open triangles) in a 100 m ice core from Summit, Greenland, spanning ~1718 to 2006 together with global CO_2 emissions from fossil fuels. The trend was originally suggested to reflect a change in $\delta^{15}N$ emissions (Hastings et al. 2009) but was recently suggested to reflect a change in atmospheric acidity (Geng et al. 2014) (Modified from Hastings et al. 2009)

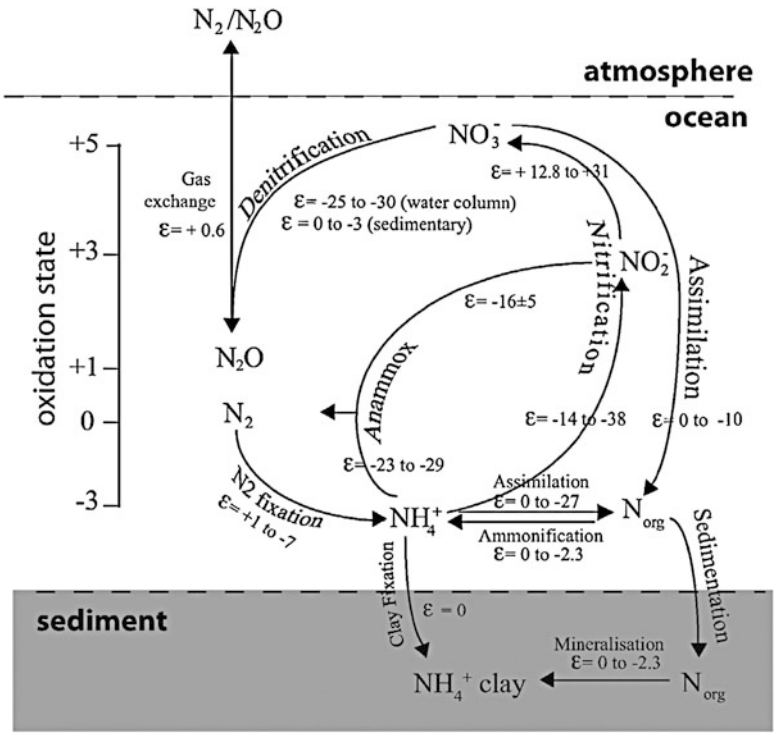
this issue, studies now commonly include site-specific analysis of nitrogen (the isotope composition of internal and external nitrogen atoms within N_2O). Notably, there is a strong site preference of ~18.7‰ for the central N atom (Yoshida and Toyoda 2000) with temporal trends being ~−0.064 and −0.014‰/yr. for terminal and central N atom, respectively (Rockman and Levin 2005). Clearly, N isotope geochemistry is central for understanding the global N_2O cycle.

Finally, the analysis of N isotope composition of urban and rural aerosols is developing, but its interpretation is generally simplified to isotope fingerprinting, i.e., N isotope composition reflecting the characteristics of their source, neglecting therefore secondary processes that can be significant (Widory 2007 and see above). Much remained to be done in this field.

Paleoenvironment and Paleo-Ecosystem Reconstruction

Nitrogen in sedimentary rocks initially derives from the atmosphere, and in the absence of life, there would be no nitrogen in sediments. Moreover, without a strong return flux, atmospheric nitrogen would be fixed by biological activity within 100 My (1.4 10^{14}gN/yr., Galloway 2003). In sediments, nitrogen is mostly carried by organic matter and detrital K-bearing minerals such as clays or feldspars, in which ammonium (NH_4^+) enters by substitution with potassium (K^+) due to similar charge and ionic radius. The nitrogen isotope signature of bulk sedimentary rocks reflects mostly primary organic matter composition and is often used as a proxy of marine paleoenvironments and paleo-ecosystems. There are two main reasons for studying N in sedimentary rocks. First, N is a major nutrient, essential to all kinds of biological activity/organisms on Earth. It constitutes the basis of molecules such as amino acids, DNA, RNA, and proteins, and therefore the N isotope signature can provide constrains on specific metabolic activity, probing traces of life in the sedimentary record (Honma 1996). Second, N is a redox-sensitive element, with diverse chemical species (e.g., N_2, NO_3^-, NH_4^+) controlled by local redox conditions. The nitrogen isotope composition will depend on the fate and recycling of nitrogen compounds in the ocean and can shed light on the redox structure of the ocean, which is of particular interest for Precambrian environment reconstruction but also for understanding changes in the Phanerozoic such as those related to Cretaceous oceanic anoxic events (OAE). The modifications of sedimentary N isotope composition through time can thus be used as a proxy of biological evolution and varying environmental conditions (see reviews by Ader et al. 2016; Stueken et al. 2016).

Nitrogen enters the oceanic biogeochemical cycle through N_2 fixation by aerobic or anaerobic autotrophs (such as phytoplankton and cyanobacteria) in which N_2 is reduced to NH_4^+ and assimilated with minimal isotope fractionation (−2 to +1‰; e.g., Wada et al. 1975, Fig. 4). This reaction is based on nitrogenase enzyme, which requires molybdenum as a cofactor. Recent experimental study demonstrated that

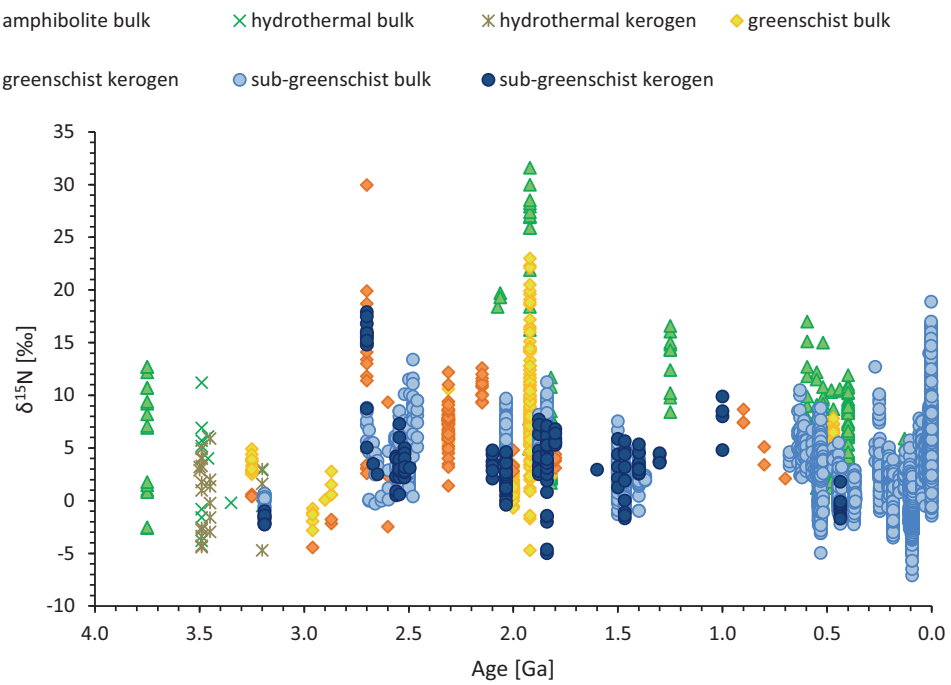


Nitrogen Isotopes, Fig. 4 Schematic diagram of the principal biogeochemical processes driving the modern N cycle. Nitrogen isotope fractionations are expressed using the ε-notation where $\varepsilon_{reactant\text{-}product} \sim {}^{TM}_{reactant} - \delta_{product}$ (Reproduced from Ader et al. (2016) with permission)

alternative cofactors such as Fe and V can also be used and produce larger isotope fractionation with organic matter depleted in ^{15}N down to −8‰ relative to N_2 (Zhang et al. 2014). After their death, organic matter mineralization releases N as ammonium (NH_4^+), with very little isotopic fractionation. In the presence of free O_2, NH_4^+ is oxidized to nitrate (NO_3^-) during a two-step process called nitrification, which is associated with significant N isotope fractionation >20‰ (Sigman et al. 2009, Fig. 4). This fractionation is rarely expressed in modern marine environments since the transformation of NH_4^+ to NO_3^- is generally complete. In O_2-depleted environments such as oxygen minimum zones or anoxic sediments, nitrates are partially reduced by denitrification or anammox (i.e., anaerobic ammonium oxidation) into gaseous N_2 or N_2O (for N_2O see atmospheric section). During denitrification, ^{14}N is preferentially released relative to ^{15}N, leaving residual marine NO_3^- enriched in heavy isotope (average marine $\delta^{15}N_{NO3-}$ ~ +5‰, Fig. 4). The heavy isotope signature of NO_3^- is transferred by assimilation to organisms living in the water column and then recorded in sedimentary organic matter. Accordingly, assuming a steady-state system, the N isotope composition of organic matter in modern marine environment reflects mainly the relative proportion of N denitrification and fixation. In O_2-free environments such as the Archean oceans, nitrification and thus subsequent denitrification are unlikely, and dissolved N species are probably dominated by NH_4^+ (Beaumont and Robert 1999). Ammonium can be assimilated by living organisms with an isotope fractionation up to −27‰, favoring ^{14}N in organic matter (Pennock et al. 1996). In the case of quantitative NH_4^+ consumption, this fractionation is, again, not expressed, and the $\delta^{15}N$ of dissolved NH_4^+ is readily recorded in sedimentary organic matter. For instance, ammonium assimilation has been invoked from negative $\delta^{15}N$ down to −5‰ recorded in sediments from the ~2.2Ga Aravalli Supergroup, India (Papineau et al. 2009, Fig. 5).

Postdepositional Modifications of Sedimentary N Isotope Composition

An important aspect of ancient sedimentary rock studies is the evaluation of possible $\delta^{15}N$ modifications related to diagenesis and metamorphism (Ader et al. 2016, Fig. 4). Organic matter degradation occurs in water column and near sediment-water interface during early diagenesis and during thermal maturation associated with burial diagenesis and metamorphism. In oxic environments, early diagenesis can impart a shift in $\delta^{15}N$ values toward more positive values, up to ~3‰ (Lehmann et al. 2002). In contrast, organic matter degradation under anoxic and suboxic conditions either preserves original nitrogen isotope values or slightly lowers $\delta^{15}N$ values down to −1‰ (Lehmann et al. 2002). Metamorphism



Nitrogen Isotopes, Fig. 5 Secular trends in nitrogen isotope of marine samples, separated by metamorphic grade. Note that sub-greenschist and green schist facies kerogens (evolved organic matter) and bulk rock samples typically overlap, suggesting limited metamorphic alteration. However, amphibolite facies rocks tend to be characterized by ^{15}N–enriched compositions compared with samples of lower metamorphic grade. The large variations of $\delta^{15}N$-values through time emphasized from low metamorphic grade samples therefore highlight profound changes in the nitrogen cycle (Modified from Stueken et al. (2016) with the very kind help of the first author)

associated with sediment burial induces only minor modifications (< 1‰) for metamorphic grade lower than greenschist facies (see review in Ader et al. 2016; higher metamorphic grade is discussed below).

Selected Applications of N Isotopes to the Sedimentary Record

One of the most important changes in the Earth history is the oxygenation of the ocean and atmosphere. The oxygenation of the atmosphere occurred about 2.4 Gy as recorded by mass-independent fractionations of S isotopes; for the ocean the situation is not so clear, and, over the last 20 years, N isotopes have been used to discuss this issue (Beaumont and Robert 1999; Zerkle et al. 2017 and ref. therein). The rationale is that N forms NO_3^- in the presence of dissolved O_2, and due to subsequent partial denitrification, the residual NO_3^- becomes increasingly enriched in heavy isotopes, thus imparting positive $\delta^{15}N$ values in organic matter deposited in sediments. The compilation of all data available places the onset of marine dissolved NO_3^- in the Neoarchean and Paleoproterozoic (Stueken et al. 2016). Extremely positive $\delta^{15}N$ values, up to +50‰ (Thomazo et al. 2011; Stueken et al. 2015a, Fig. 5), were observed in sedimentary rocks from the 2.7 Ga Tumbiana Formation and could correspond to the first oxidative distillation of the NH_4^+ reservoir (Thomazo et al. 2011). An alternative interpretation suggested that volatilization of NH_3 in an alkaline lake could leave residual NH_4^+ enriched in heavy isotope (Stueken et al. 2015a) but such high values have not yet been found even in the most alkaline modern lakes.

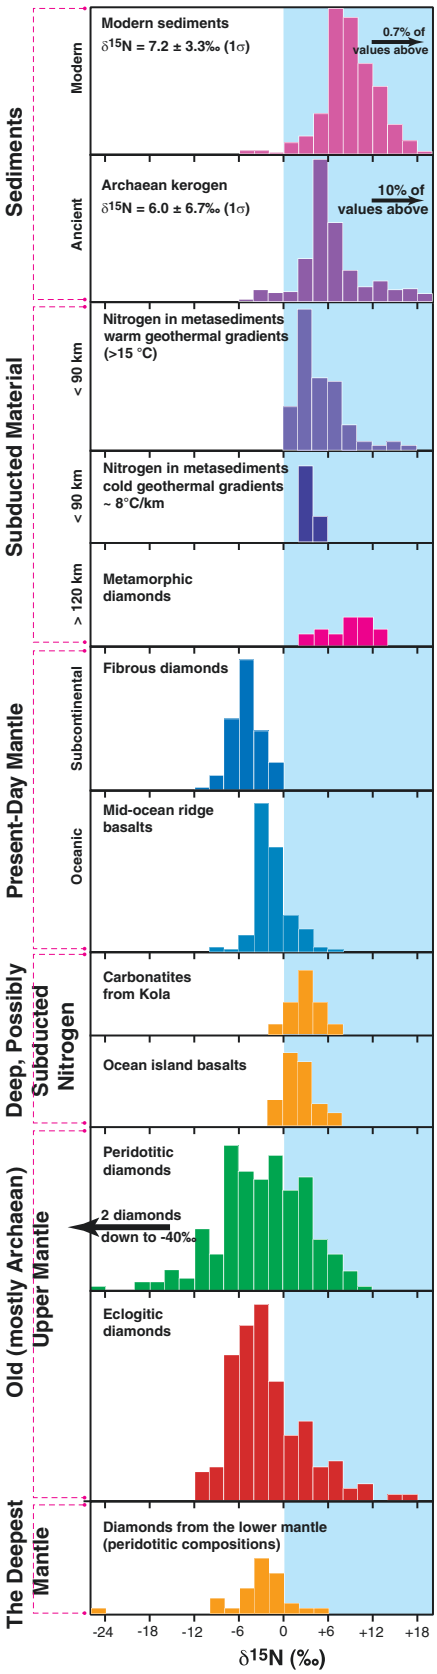
In parallel to the reconstruction of ocean redox structure, N isotopes of the sedimentary record have been used as tracers of metabolic activity. For instance, $\delta^{15}N$ values near 0‰ measured in 3.2–2.75 Ga sedimentary rocks of low metamorphic grade (Fig. 5) indicate that the biomass was dominated by N_2-fixing autotrophic organisms (Stueken et al. 2015b). This finding places a minimum age constraint of 3.2 Ga on the origin of biological N_2 fixation. If we consider that the occurrence of nitrogen in sedimentary rocks attests for the occurrence of life, then the minimum age constraint becomes 3.8 Gy (Honma 1996).

In the Phanerozoic, low $\delta^{15}N$ values (−7 to 0‰, Fig. 5) are systematically observed in sediments deposited during Cretaceous OAE and are associated with high concentration of total organic carbon (up to 20%). These low $\delta^{15}N$ values are interpreted as evidence for N_2-fixing organisms thriving in a water column highly depleted in oxygen, which would be related to warm and wet greenhouse climate periods and associated thermohaline stratification of the ocean (e.g., Rau et al. 1987; Zhang et al. 2014). Intense denitrification would in this case limit any contribution of residual nitrate to the bulk $\delta^{15}N$ signature of the biomass. A compilation through the entire Phanerozoic shows that low and high $\delta^{15}N$ values correspond to greenhouse and icehouse climate periods, respectively, thus suggesting that long-term $\delta^{15}N$ variations are controlled by climate rather than redox variations (Algeo et al. 2014). Sedimentary denitrification would dominate during greenhouse periods owing to higher eustatic (global sea-level) elevations and greater on-shelf burial of organic matter, whereas water-column denitrification would dominate during icehouse modes owing to lower eustatic elevations.

Nitrogen Chemical Geodynamics

Biological activity does not only mediate transfers from the atmosphere to sediments (see above) but also to the crust and the mantle. Nitrogen is a unique element because it originally requires living organisms to enter the rock record (abiotic reactions exist but are negligible, see below). It thus represents a unique tracer of chemical geodynamics. In this context too, N isotopes have been successfully applied. For instance, they have been used to constrain and quantify the loss of nitrogen and other fluid-mobile elements during subduction. Nitrogen isotopes were also used to trace the presence of subducted surface material in the Earth's mantle because a significant difference exists between mantle and surface N isotope signatures, being, respectively, ^{15}N–depleted and ^{15}N–enriched relative to the atmosphere (see Cartigny and Marty 2013).

As mentioned above, the introduction of N into the rock record arises from maturation of organic matter, which releases ammonium ions. Ammonium is then substituted for potassium, thus following the fate of potassic minerals: mainly clays at low P-T conditions and micas under higher metamorphic grade (Busigny and Bebout 2013 for review). As temperature increases, metamorphic reactions can induce fluid devolatilization. The release of ^{15}N–depleted fluids (N_2 and/or NH_3) produces an increase of $\delta^{15}N$ value in the residual rock, typically from $\delta^{15}N \sim +5$ up to +15‰ (Bebout and Fogel 1992). The nitrogen budget can be derived from Rayleigh model, based on theoretical fractionation factors, ammonium content, and correlations with large ion lithophile elements (K, Rb, and Cs). An important result is that N in subduction zones can either be preserved or released during metamorphism, depending on geothermal gradient. In *cold* (e.g., 8 °C/km) subduction zones, N is stable and preserved in potassic minerals (e.g., phengitic micas), and $\delta^{15}N$ remains constant. Nitrogen is thus massively subducted to depths in excess of 90 kilometers. In contrast, significant amounts of N are devolatilized in *warm* subduction zones (> 15 °C/km). At present, the average fluxes of N input in subducted slab and output from volcanic arcs by degassing are 9.6×10^{11} and 0.7×10^{11} gN/yr., respectively (Busigny et al. 2011). Therefore about 80% of N buried in subduction zones is recycled to the deep mantle and is characterized by a majority of positive $\delta^{15}N$ values (Fig. 6).



Nitrogen Isotopes, Fig. 6 Comparative histograms of $\delta^{15}N$ values for modern and ancient sediments, subducted nitrogen (warm and cold environments), present-day convective mantle, ancient mantle and lower mantle, and magmas possibly sampling nitrogen recycled to mantle depths. Note that modern and ancient sediments do not reveal any obvious secular isotopic trends (but see Fig. 5) (From Cartigny and Marty 2013)

The Earth mantle contains little nitrogen (likely between 0.26 and 36 ppmN), and its study remains limited to few samples such as diamonds, basaltic glasses (and their gas vesicles), and volcanic fumaroles. Nitrogen isotopes remain difficult to investigate primarily owing to atmospheric contamination (although this can be quantified using Ar isotopes) and assimilation. The exception is diamond since N is the main diamond impurity (with an average concentration of 150 ppmN) but for which genesis ages and depth of formation remain often under-constrained. The $\delta^{15}N$ values of samples from the Earth mantle are scattered but are primarily negative. Importantly, both the so-called diamond coats and fibrous diamonds and mid-ocean ridge basalts (all <500 My) distinctively point to a present-day mantle $\delta^{15}N \sim -5‰$ (Fig. 6). Older diamonds (possibly Archean) with silicate inclusions pointing to peridotitic composition display more scattered $\delta^{15}N$ values with two third being negative. This makes N isotope a powerful tracer of recycled material and was used to discuss the origin of eclogitic (i.e., basaltic) composition, their ^{13}C–depleted isotope composition being often attributed to recycling of organic matter in the mantle. Yet their $\delta^{15}N$ are strikingly similar to peridotitic diamonds and do not emphasize a recycled origin for most of them (Cartigny and Marty 2013 for review). However consistent evidence for deep recycling of nitrogen was found from the study of metamorphic diamonds formed in crustal rocks subducted to ultrahigh pressures (> 3.5 GPa), some lamproïtes, ocean island basalts, and some deep diamonds (Cartigny and Marty 2013 for review).

The average flux of N in modern subduction zones, subtracted from N loss in volcanic arcs, is seven times larger than mantle degassing flux (Busigny et al. 2011). This implies that crustal N is preferentially recycled to the mantle, likely inducing secular evolutions of atmospheric, crustal, and mantle N contents. Given their isotope characteristics, the exchanges between ^{15}N–enriched surface materials and ^{15}N–depleted mantle also predict secular evolutions of their N isotope compositions which have been searched in crustal and mantle records. Although there is no consensus yet, addressing this question is fundamental. If the Archean atmosphere had ~2 to 3 present nitrogen atmospheric levels (NAL), it would result in N_2 radiative forcing (i.e., N_2 as a greenhouse gas), resulting from pressure broadening and Rayleigh scattering. It could explain why the Earth remained warm despite the faint young sun, i.e., without requiring high amounts of greenhouse gases such as CO_2 or methane (Goldblatt et al. 2009; Wordsworth and Pierrehumbert 2013). Considering an average N content of the continental crust of 83 ppmN (Rudnick and Gao 2003)

with a $\delta^{15}N$ value of +6‰ and that crustal N is of atmospheric origin, without biological activity, present nitrogen atmospheric level (NAL) would be 20% higher with a $\delta^{15}N > 1.2‰$. These are minimum values as some nitrogen was recycled in the Earth's mantle. Yet, the study of fluid inclusions and crustal/sedimentary (Archean and Proterozoic) rocks led, so far, to contradicting conclusions. Studies of several Archean crustal rocks (giant quartz veins) and 2.7 Gy kerogens suggest significant $\delta^{15}N$ evolution of atmospheric nitrogen from $>$ + 40‰ to present value of 0‰ (Jia and Kerrich 2004) when others evidenced rather constant $\delta^{15}N$ values (Marty et al. 2013). Similarly, NAL may have decreased (from 3 NAL, Goldblatt et al. 2009) or increased (from 0.5 NAL, Marty et al. 2013) through time. Mantle $\delta^{15}N$ values could have evolved from more negative values (e.g., from $< -40‰$), but the evidence presently relies on a few samples, and if any, this evolution happened early in the Earth history, Archean samples pointing to $\delta^{15}N$ values $\sim -5‰$ (Cartigny and Marty 2013). Here, further studies are needed for reaching a consensus.

The Neglected Role of Abiotic Reactions

In the modern oxic world, atmospheric nitrogen fixation is primarily driven by biological activity, but in the ancient anoxic world, the role of abiotic atmospheric nitrogen reduction might have been significant. This is a fundamental issue as it raises the question of abiotic amino acids genesis (see discussion in Stueken et al. 2016). By analogy with the Miller's experiments (Miller 1953), we need to understand whether present and ancient deep hydrothermal systems could represent favorable environments where significant abiotic nitrogen reduction might occur. In this case, high concentration of ammonium in clays or micas would not necessarily represent an indirect evidence for life. At present, abiotic nitrogen reduction remains little investigated (see the experimental work by Brandes et al. 1998). Such reactions have been suggested in hydrothermal systems and were characterized by very negative $\delta^{15}N$ values down to $\sim -16‰$ (Li et al. 2014). Much work remains to be done in this field, and N isotopes of future studies may provide fingerprints of biotic vs. abiotic processes.

"You Are What You Eat": Paleo-Diet and Archeological Investigations

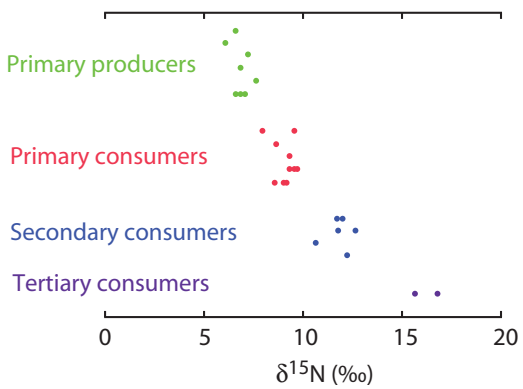
The application of N isotopes to paleo-diet and archeological investigations (this section) and in forensics science (next section) is primarily a *fingerprinting* approach. This kind of approach involved generally multi-isotope systems (C, H, O, B, Sr, Pb, etc.) but is restricted here to N isotopes.

Application of N isotopes to determine paleo-diets relies on two observations. First, as N is cycled through the body of animals/humans, ^{14}N is preferentially lost, leading to ^{15}N enrichment of tissues (DeNiro and Epstein 1981). This is also illustrated by ^{15}N depletion of urine relative to the diet. Throughout the trophic chain, the predators gain the N isotope composition of their preys, which is then further ^{15}N–enriched, typically by 3‰ (Minagawa and Wada 1984; Fig. 7). Therefore N isotope composition indicates the trophic level position of both marine and continental organisms (Fig. 7). Second there is a difference between continental (grass, wheat, fruits) and marine (seashells, fish, algae) diets, the former being ^{15}N–depleted relative to the latter. This difference also exists for carbon and can be jointly used with N isotopes. Therefore, although there are some overlaps, a vegetarian will be more ^{15}N–depleted than someone being omnivore or eating only meat.

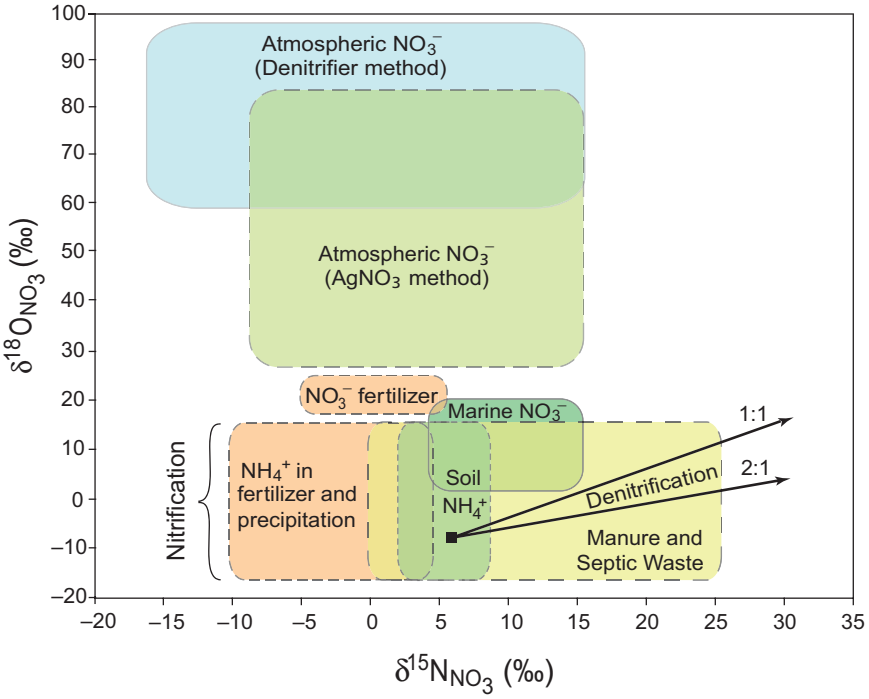
These applications extend beyond the field of geochemistry but provide a good example of interdisciplinary interactions with the field of human sciences. Typically undertaken with the analysis of C isotopes (e.g., to constrain the proportion of C3 and C4 plant species in the diet of herbivores), N isotopes revealed when agriculture was introduced in the diet and more generally when a group changed their subsistence strategy. Nitrogen isotopes demonstrated that Neanderthals had large herbivores on their diet, therefore implying that they were top-level predators and accomplished hunters (Richards and Trinkausc 2009). Similarly, the zonation of tooth can help archeologists determine when animals or humans weaned their babies and, again, what kind of food they had.

Forensics Science with a Focus on Nitrate Pollution

Nitrogen isotopes remain less used than carbon and hydrogen isotopes in forensics science, which are collectively used as a

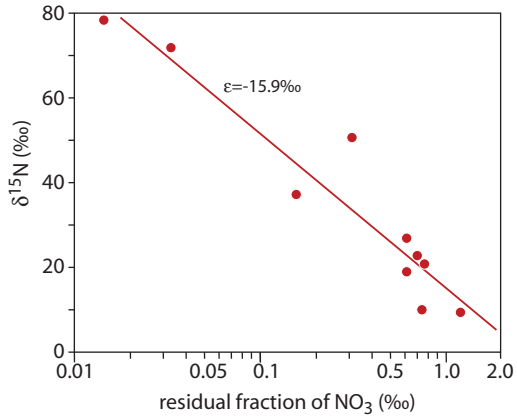


Nitrogen Isotopes, Fig. 7 Illustration of the stepwise enrichment of $\delta^{15}N$ along food chains (Modified from Minagawa and Wada 1984)



Nitrogen Isotopes, Fig. 8 Typical values of $\delta^{15}N$ and $\delta^{18}O$ of nitrate derived or nitrified from various N sources. Atmospheric. The two arrows indicate typical expected slopes for data resulting from denitrification of nitrate with initial $\delta^{15}N = +6‰$ and $\delta^{18}O = -9‰$. The typical ranges of $^{TM18}O_{NO3}$ values produced by nitrification of ammonium and organic matter are denoted by "nitrification" (Modified from Kendall et al. 2007)

fingerprint to distinguish genuine products from counterfeits. In this section, we will specifically focus on a very important application that arises from the anthropization of the N cycle. With only half of fertilizers being fixed by crop plants and owing to nitrate (NO_3^-) release from intensive agriculture, *nitrate concentrations in drinking water supplies have risen above acceptable levels in many areas of the world* (Kendall et al. 2007). Increase in nitrate levels of groundwaters, rivers, and estuaries induces biological blooming which leads, due to the subsequent degradation of organic matter, to eutrophic waters in many locations. Monitoring nitrate levels and determining their sources and fate and the role and rate of (bio-) remediation are key data to understand and subsequently change common practices (although sometimes the *good* practice could consist in stopping pumping water of a contaminated aquifer !). Understanding the origin and fate of nitrate can be complex because various sources exist (Fig. 8): fertilizers which contain both ammonium ($\delta^{15}N$ from −10 to +5‰ that will get oxidized to nitrate) and nitrate ($\delta^{15}N$ from −10 to +5‰), animal and septic manure ($\delta^{15}N$ from 0 to +25‰), and atmosphere deposits (but also organic nitrogen) and owing to isotope effects that occur through biotic denitrification mechanisms (see paleoenvironments and paleo-ecosystems section). However, in most cases, the sources are known (Fig. 8) and studied, and mixing processes can be modeled and distinguished from isotope variations related to other physico-chemical reactions. Denitrification isotope effects can be recognized from the slope ~1 to ~2 between $\delta^{15}N$ and $\delta^{18}O$ evolving toward ^{15}N- and ^{18}O–enriched isotope



Nitrogen Isotopes, Fig. 9 Dependence between nitrogen isotope ratio and the fraction of residual nitrate in a sandy aquifer. Note the linear trend between the two parameters when the nitrate concentration is displayed in logarithmic scale: this is typical of open-system process (Rayleigh distillation) here typified for nitrate reduction (Modified from Böttcher et al. 1990)

compositions (see Fig. 8). This relationship allows both a quantitative modeling and forecasting the evolution of nitrate concentration (Böttcher et al. 1990; Fig. 9). Extrapolation of $\delta^{15}N$ and $\delta^{18}O$ values to their likely origin allows to recognize the source of nitrate pollution. It is worth noting that N isotopes can only develop their full potential in conjunction with other geochemical parameters, including boron, strontium, and oxygen (both $\delta^{18}O$ and $\delta^{17}O$) isotopes (Kendall et al. 2007; Widory et al. 2004). Finally, because

residual nitrate evolves toward ^{15}N–enriched compositions (modulo the isotope fractionation during assimilation and processes through the animal body), inputs of nitrate into estuaries or coastal ecosystems can easily be recognized by increasing $\delta^{15}N$ through time.

Conclusion

Despite being unevenly distributed on Earth and in extraterrestrial samples, several methods have been developed to analyze accurately N content and isotope composition. In modern and primitive Earth, the cycling of atmospheric nitrogen to the silicate Earth requires biological activity, and this makes nitrogen a unique tracer of life in the rock record. In every overviewed contexts, N isotopes have brought unique constraints that could hardly be deduced from other geochemical systems. It is however worth mentioning that N isotopes can only reach their full potential when considered together with other systematics.

Noble Gases

Chris J. Ballentine and Peter H. Barry
Department of Earth Sciences, University of Oxford, Oxford, UK

Definition

The noble gases occupy Group 0 (column 18) of the periodic table, comprised of the following elements: helium, neon, argon, krypton, xenon, and radon (not discussed here). They are colorless, odorless, monatomic, and unreactive gases at standard temperature and pressure.

Introduction: History and Uses

***Helium*:** The spectral signature of helium was first observed from the Sun by Janssen and Lockyer in 1868, with Lockyer

credited for proposing this as a new element. Helium was first isolated and identified in clevite, a uranium-rich mineral, by both Cleve and Langlet and independently by Ramsay in 1895.^{4}He is formed by alpha particles during the decay of natural uranium and thorium in the crust, with commercial sources provided in rare natural gas fields containing helium at concentrations between ~0.1 and 0.3%.

Helium is used in many cryogenic applications, most notably as a liquid in the cooling of superconducting magnets used in medical MRI scanners, but is also used for pressurizing and gas purging in many industrial applications, controlled atmospheres, specialist welding, leak detection, and breathing mixtures. In 2006, total global proven reserves and probable resources were estimated to be 51.9 billion standard cubic meters. In 2014, global helium production/use was estimated to be 180 million standard cubic meters (USGS 2015).

***Neon*:** Discovered in air by Ramsay and Travers in 1898, the main source of commercial neon today is through cryogenic fractional distillation of liquid air. Best known for its use as a lighting source in neon discharge tubes, it is also a vital component in excimer laser gas mixes used by semiconductor manufacturers. Semiconductor lithography applications using excimer lasers account for 70% of neon demand with global production in 2014 at ~400 million liters liquid neon (Corbett et al. 2015).

***Argon*:** Cavendish first observed argon in 1785 as a residual gas after removing all chemically active species from air. It was later confirmed as a component of air and subsequently named by Ramsey and Rayleigh in 1894. Like neon, the main source of commercial argon today is obtained through cryogenic fractional distillation of liquid air. This process produces ~700,000 tonnes of argon globally each year (2001). Argon is used as an inert blanket gas in the microchip and food industries and in cryogenics when the less expensive but more reactive nitrogen is not an appropriate coolant. Additional uses of argon include laser applications, to generate high energy plasma and – in liquid phase – as a scintillation target for neutrino and dark matter detectors (Acosta-Kane et al. 2008).

***Krypton*:** Discovered in 1898 by Ramsay and Travers in air, commercial krypton is also produced by cryogenic fractional distillation of air. Krypton gas finds use in lasers, as a filling for double glazing, incandescent lights, and specialist cryogenic uses as a liquid.

***Xenon*:** Also discovered in 1898 by Ramsay and Travers. Commercial xenon is produced by cryogenic fractional distillation of air. Global production is about 10,000 m^3 at standard pressure and temperature (6 tonnes) of which 15% is used in medical applications as an anesthetic. In addition, xenon gas is used in modern flash bulbs; in the liquid form, it is used as a supercritical solvent, as a scintillation target for dark matter detectors, and as fuel for ion propulsion engines used in satellite positioning (Royal Society of Chemistry 2016).

Cosmochemistry

The isotopic compositions and abundances of the noble gases in the Sun are referred to as the solar composition. This provides the reference point for chemically differentiating between meteoritic, cometary, and planetary materials. The best analog for the solar composition is solar wind, and its noble gas composition has been successfully determined by the recent NASA Genesis return mission, which trapped solar wind implanted into a variety of target materials (Wiens et al. 2007; Meshik et al. 2014; Crowther and Gilmour 2013) and returned them to Earth for analysis.

The observed differences between solar and terrestrial compositions are used to identify the various origins and processes that trap volatile elements during meteorite and planetary formation (Marty 2012; Halliday 2013). Some noble gases are produced by radioactive decay and cosmogenic reactions; excess abundances in these isotopes are used to provide temporal constraints on these trapping and formation processes.

Similar to other highly volatile elements such as nitrogen and carbon, the noble gas composition of the most primitive meteorites and carbonaceous chondrites are depleted by several orders of magnitude relative to the solar abundance of silicon; solar volatiles are not efficiently captured in rock-forming bodies. Superimposed upon this general depletion, light noble gases are more depleted than heavy gases (He < Ne < Ar < Kr < Xe). Furthermore, lighter isotopes of the same element are more depleted than heavier isotopes relative to the solar reference (Huss et al. 1996; Busemann et al. 2000; Ott 2014).

Noble gases in meteorites are trapped in different solid phases. For example, most of the Ar, Kr, and Xe found in meteorites are found in a carbonaceous residue that remains after Hf/HCl acid treatment (i.e., "Q-phase"). In addition to Q-phase gases, noble gases are found in silicon, carbon, graphite, and nano-diamonds formed before the collapse of the solar nebula. The latter "pre-solar grains" provide isotopic compositions of Kr and Xe that are formed by s-, r-, and p-nucleosynthetic processes occurring in stars and supernovae (Ott 2014).

In addition to Q-phase and pre-solar noble gases, significant sources of noble gas, particularly He and Ne, include ion implantation of solar wind and noble gases produced by the high energy impact of cosmogenic rays. The latter provide a crucial temporal history of meteorite breakup exposing fresh surfaces (Wieler et al. 2016) and the travel time of Martian meteorites between ejection from Mars and impact on Earth (Nyquist et al. 2001).

Cometary activity and meteorite breakup deliver ^{3}He-rich material to Earth in the form of interplanetary dust particles (IDPs). These provide a significant cosmogenic flux to Earth, as IDPs retain solar wind implanted ^{3}He, which can be resolved in ocean floor sediments. Over periods of known IDP deposition, ^{3}He concentrations provide a measure of sedimentation rate. In areas of known sediment accumulation, variance in IDP flux can be attributed to, for example, high levels of cometary activity (McGee and Mukhopadhyay 2013).

Mantle Geochemistry

Three dominant sources of noble gases exist in the Earth's mantle: (i) those trapped during the accretionary process, (ii) noble gases recycled from the planetary surface into the mantle, and (iii) those produced by the decay of extinct (^{244}Pu and ^{129}I) and extant radionuclides (U, Th, and K) within the mantle. The first work on mantle materials soon identified a dichotomy; all samples from mid-ocean ridges exhibit a very narrow range in ^{3}He/^{4}He (7–9 R_A) (where R_A = the ^{3}He/^{4}He of air = 1.4×10^{-6}), whereas most plume-influenced samples from intraplate volcanics have ^{3}He/^{4}He values significantly higher (>9 R_A) and some lower than those from the mid-ocean ridges. Due to the fact that ^{3}He is dominantly sourced during accretion and ^{4}He through the radioactive decay of U and Th, this ratio provides a proxy for ^{3}He/U ratios in different mantle domains. The resulting layered mantle model dominated the community understanding of mantle structure and evolution for a quarter of a century, a mantle in which a well-mixed upper mantle, above the 660 km seismic discontinuity, was lithophile depleted (see lithophiles) and degassed compared to a less depleted, heterogeneous, and more volatile rich lower mantle (Kurz et al. 1982; Allègre et al. 1983; O'Nions and Oxburgh 1983; Moreira 2013). Later improvements in seismic observation of the mantle and numerical simulation of mantle convection found significant mass transfer between upper and lower mantle and a far more complex picture than the two layered mantle model (Van Der Hilst et al. 1997; Van Keken et al. 2002).

The Ne isotopic composition of mid-ocean ridge source mantle is indistinguishable from the solar-wind-irradiated trapped component found in meteorites (Trieloff et al. 2002; Ballentine et al. 2005; Ballentine and Holland 2008). In contrast, there is some evidence in plume-derived Ne isotopes of a solar nebular signature (Yokochi and Marty 2004; Mukhopadhyay 2012), although this interpretation remains contested (Moreira 2013). Similarly, the primordial MORB-source mantles Kr and Xe are also consistent with delivery of a trapped component within accreting material (Holland et al. 2009; Caracausi et al. 2016). This result precludes models in which the dominant sources of volatiles in Earth's mantle are derived from equilibration of an early magma ocean with a massive early (solar) atmosphere.

Xe isotopic values approaching solar values have nevertheless been found in some plume-derived samples, and this may suggest an early accretionary role for solar nebula gases (Yokochi and Marty 2004; Mukhopadhyay 2012). Because ^{129}I decays to ^{129}Xe ($t_{1/2}$ = 15.7 Ma), ^{129}Xe/^{130}Xe isotopic compositions can be used to infer source I/Xe compositions in the earliest Earth history. Results from the Iceland plume show that volatiles from this source have lower I/Xe than mid-ocean ridge samples, and that this signature has been preserved since ^{129}I became extinct in the first ~100 Ma of Earth history. This data is also used to argue that mixing of noble gases from the Iceland plume mantle source with mid-ocean ridge sourced volatiles does not occur at any significant level (Mukhopadhyay 2012).

The primordial heavy noble gases in the mid-ocean ridge basalt source mantle are accompanied by atmosphere noble gases with an elemental composition consistent with subduction of an ocean/pore-fluid signature into the mantle (Holland and Ballentine 2006). This oceanic pore-fluid signature is observed in both halogens and noble gases in fluids subducted to ~100 km depth (Sumino et al. 2010), demonstrating preservation of the pore-fluid signal to depths at which transfer into the deeper mantle can be envisaged. Linking subduction flux of the noble gases to volatile species such as carbon and nitrogen (Marty and Jambon 1987; Barry and Hilton 2016) has provided a powerful tool to trace major volatile subduction into the mantle (Hilton et al. 2002).

The location and processes, recorded by the noble gases, that enable preservation of different accretionary volatile components in the mantle since the formation of Earth and the superposition of radiogenic and recycled noble gases remain at the frontier of the current research effort.

Earth's Atmosphere

The noble gas composition of Earth's atmosphere is well mixed and provides the reference abundance and isotopic composition for most noble gas terrestrial studies (e.g., Sano et al. 2013). With the exception of ^{40}Ar and He, the atmosphere contains >98–99% of all terrestrial noble gases. The pattern of the non-radiogenic noble gas isotopes is, similar to chondrites, strongly depleted in both light elements and light isotopes relative to solar. Xe abundances are, however, depleted by an order of magnitude more than would be expected using the chondritic pattern as a reference, and very strongly isotopically fractionated. This is often referred to as the "missing xenon" paradox (Marty 2012).

Xe isotopes derived from the extinct radioisotopes ^{129}I and ^{244}Pu can be resolved in the atmosphere. These are highly depleted relative to predicted amounts and are used to argue

that the earliest atmosphere was not retained until "closure" at ~40–100 Ma after the Earth formed (Pepin and Porcelli 2006; Avice and Marty 2014). The proportion of radiogenic noble gas isotopes from extant radionuclides has increased in the atmosphere over geological time due to Earth degassing. This is most notably seen in ^{40}Ar relative to ^{36}Ar and is a key measure of mantle outgassing efficiency and continental crustal growth (Allègre et al. 1996; Pujol et al. 2013). Analysis of fluids trapped in ancient minerals and free fracture fluids shows a light isotope enrichment in shielded Xe isotopes (^{124,126,128}Xe) (Pujol et al. 2011; Holland et al. 2013). It is argued that this is evidence of xenon loss from Earth's atmosphere that provides one explanation for the missing xenon (Pujol et al. 2011; Marty 2012).

Over the last 1Ga, changes in the isotopic composition and partial pressure of the noble gases in the terrestrial atmosphere have been small and implicitly assumed negligible in work using the modern atmosphere as a reference.

Ice, Oceans, and Crustal Fluids

The physical processes of diffusion and solubility which fix atmosphere-derived noble gases into ice and water are well understood. Small differences in environmental conditions such as temperature and salinity provide measurable changes in the noble gas content of ice and water, preserving temporal records of environmental change.

Transient temperature gradients fractionate air trapped within firn through thermal diffusion which is then preserved in air bubbles in ice. Ice cores therefore provide a temporal record of both temperature change and rate of change (Severinghaus and Brook 1999; Winckler and Severinghaus 2013).

Similarly, when water equilibrates with the atmosphere, the concentration of noble gases in the water phase is determined by the temperature and salinity of the water as well as the partial pressure of the noble gases. Dynamical features of air dissolving into water can introduce nonequilibrium air concentrations into the water, but these are reasonably well understood.

In ocean environments, noble gas concentrations that deviate from equilibrium are used to diagnose and quantify ice formation, melting, and/or bubble injection through increased wave activity. Argon can be used to provide a baseline for N_2 and O_2 activity, allowing differentiation between physical and biogeochemical activity and thus identification of the processes controlling biologic production and denitrification.

Non-atmosphere input occurs in the form of ^{3}He from mid-ocean ridges and atmosphere tritium decay ($t½ = 12.3$ years). The former provides a tool for deriving basin-scale mixing, global model verification, and trace element addition to different ocean bodies through hydrothermal activity. The latter provides information about the age and extent of recent surface water incursion (Schlosser and Winckler 2002; Stanley and Jenkins 2013).

On the continents for a known location (altitude) and freshwater recharging an aquifer (near zero salinity), local temperatures at recharge can typically be determined from the noble gas concentrations in water to better than ±0.3–0.5 °C (Ballentine and Hall 1999). With knowledge of the mean residence time of the water in a given aquifer, changes in the local paleoclimate can be reconstructed (Kipfer et al. 2002; Aeschbach-Hertig and Solomon 2013).

Like ocean water, tritium-^{3}He can be used to provide a mean residence time (MRT) for young (<50 years) groundwaters. ^{85}Kr ($t½ = 10.76$ years) released into the atmosphere by anthropogenic nuclear activity has similar potential but requires large sample volumes and specialized atom trap trace analysis (ATTA) techniques. Cosmogenically produced ^{39}Ar ($t½ = 269$ years) is formed in the atmosphere and has the potential to significantly extend the capability to trace young groundwater. It also requires ATTA technology for analytical determination; however, recent advances in the technique has allowed for smaller sample quantities to be accurately measured (Yang et al. 2013; Ritterbusch et al. 2014).

With the development of ATTA, cosmogenic ^{81}Kr can now also be determined in groundwater and ice. With a half-life of 229,000 years., ^{81}Kr extends the ability to date water MRTs and ice core ages beyond the limit of ^{14}C dating to over ~1 Ma (Aggarwal et al. 2015). For fluids with MRTs >1 Ma, the radiogenic noble gases (^{4}He, ^{21,22}Ne, ^{40}Ar, ^{131,132,134,136}Xe) can be used if the accumulation rate is known (Ballentine and Burnard 2002). For a closed system which releases all noble gases into the fluid phase, this is given by the concentration of radioelements and has been used to identify fluids in the crust >1 Ga (Holland et al. 2013). When an aquifer is open to flux into the system, the external flux rate needs to be determined; this may be from local proximal formations with high radioelement concentrations (Tolstikhin et al. 2011) or by using flux estimates based on the steady-state release of radiogenic noble gases from the whole crust (Torgersen 2010).

When a second fluid phase such as natural gas, oil, or carbon dioxide passes through the groundwater system, the noble gases equilibrate between phases as a function of local conditions (temperature, pressure, and salinity) and fluid volume ratio, and/or whether the process is open or closed system (Zhou et al. 2005; Barry et al. 2016). In well-behaved systems, the resulting noble gas content of either phase preserves a quantitative record of this phase interaction. This has been used to identify the role of groundwater in oil and gas migration to trap and identify sources and sinks of non-hydrocarbon gases such as CO_2, N_2, and commercial helium accumulation (Ballentine et al. 2002; Gilfillan et al. 2009; Prinzhofer 2013, Byrne et al. 2016). Similar principles apply in hydrothermal systems where boiling or other phase

separation processes can be traced (Sano and Fischer 2013) and their role in mineral deposition investigated (Kendrick et al. 2001).

Geochronology

Noble gas accumulation rates within minerals provide a wealth of information for geochronological applications throughout cosmochemistry and the Earth sciences. Arguably the largest impact has been the exploitation of K decay to ^{40}Ar ($t½ = 1250$ Ma). Early development of K-Ar was very rapidly superseded by reactor neutron conversion of K to ^{39}Ar, with simultaneous measurement of ^{40}Ar-^{39}Ar providing accuracy and a temporal range applicable "from archaeology to planetary sciences" (Kelley 2002; Jourdan et al. 2016).

A related offshoot to ^{40}Ar-^{39}Ar chronology is the conversion of halogens (F, Cl, Br, I) by neutron reaction to noble gas isotopes, providing a powerful analytical tool for halogen determination in samples where other techniques (particularly for Br and I) do not provide the necessary sensitivity (e.g., Ruzié-Hamilton 2016).

Cosmogenic nuclides provide surface exposure ages on meteorites and terrestrial surfaces alike (Niedermann 2002; Dunai et al. 2007; Wieler et al. 2016), while (U-Th)/He takes advantage of the low closure temperature in minerals (e.g., apatite) and provides a thermochronological history that can delineate the cooling history of rocks in a temperature range unobtainable by other techniques (Farley 2002, Reiners et al. 2004).

Summary and Conclusions

Noble gases have a wide array of terrestrial geochemical applications in addition to great utility in cosmochemistry. Due to the unique sources of different isotope species, the noble gases can be readily exploited to differentiate between atmospheric, mantle, crustal, and extraterrestrial volatile sources. Furthermore, radiogenic noble gas species can be used to provide temporal constraints on the timing of geologic closure events. Together, noble gases form a unique and extremely diverse set of geochemical tracers that have far-reaching applications in Earth and planetary sciences.

Synonyms

Continuous wave NMR (CW-NMR); Fourier transform NMR (FT-NMR); Magnetic resonance; NMR; Solid-state NMR (SSNMR)

Definition

Nuclear magnetic resonance (NMR) is a powerful analytical tool to both elucidate structure and measure dynamics of chemical systems. Using a powerful magnet and radio-frequency (RF) pulses, the spins of nuclei are perturbed and allowed to relax, generating signals specific to the chemical environment the nuclei are contained within. A broad range of nuclei are NMR active (most notably ^{1}H, ^{13}C, and ^{29}Si). Chemical analysis can be performed on both liquid and solid samples, with sample volumes ranging from microliters to milliliters. Analysis can also be performed at variable temperatures and pressures using specialized probe designs.

Governing Physics

NMR relies principally on the idea that every nucleus has an inherent spin, which is a type of angular momentum that is not defined in the classical sense. Classical spin deals with the rotation of a particle around a central axis – with this rotation comes an angular momentum vector that points orthogonally to the direction of the rotation. Nuclear spin has no basis in rotational motion, yet it still acts as an angular momentum vector – it is an intrinsic property of the nucleus. Wolfgang Pauli theorized that electrons have spin of one-half, and it has since been shown that neutrons and protons also have spin of one-half (Levitt 2008). Here it can be noted that particles with half-integer spin (like the electron, proton, and neutron) are known as "fermions" and particles with integer spin (such as the photon) are known as "bosons."

Nuclear spin (also referred to as I) manifests itself in different isotopes depending on the amount of neutrons and protons in the nucleus. The two main isotopes of hydrogen, ^{1}H and ^{2}H, are chemically identical because they share the same number of protons and electrons (one each), but they differ by one neutron – this causes the nuclear spin to be different ($I = ½$ and 1, respectively). As NMR is the measurement of species with nuclear spin, I must be greater than 0 for the nuclei to be considered "NMR active." I is equal to 0 when the number of protons and the number of neutrons in the nucleus are even numbered, such as the case with ^{32}S (16 protons and 16 neutrons). In all other instances (odd/odd, odd/even, and even/odd pairings of protons and neutrons), the nuclei are NMR active (Hore 1995). Nuclei with spin one-half (^{1}H, ^{13}C, ^{31}P, ^{29}Si, etc.) are the simplest to understand, but quadrupolar nuclei ($I > ½$, such as ^{2}H, ^{17}O, ^{27}Al, etc.) exist and are of great importance in the field of NMR spectroscopy. There are $2I + 1$ degenerate spin states associated with I, as in the case of classical angular momentum. Thus, for a spin $I = ½$ nuclei, there are $2(½) + 1 = 2$ degenerate spin states.

NMR spectroscopy probes what is known as the Zeeman effect. The Zeeman effect occurs when identical spin states are placed in a magnetic field and split into distinct energy levels. Particles with angular momentum have a magnetic moment such that $M = \gamma\hbar I$, and these magnetic moments will align with the strong static field. Here, γ is the gyromagnetic ratio. For a spin one-half system, this causes the spins to align either parallel or antiparallel to the external magnetic field, with enough thermal energy in the system (via a Boltzmann distribution of spins) to cause an almost even population in each energy level, though there are slightly more spins in the parallel state – this is why NMR is known as an insensitive measurement. The slight excess of spin in the parallel state leads to a magnetic moment, which does not align perfectly with the external magnetic field (due to the quantization of the energy levels from the Zeeman effect). There is thus some magnetization in the xy-plane, but this averages to zero due to the precession of the magnetic moment. The skewed nuclear magnetic moment in the static field experiences a torque, which will change the direction of the angular momentum of the nucleus. This torque causes the spin to move and is known as Larmor precession. This precession occurs at what is known as the Larmor frequency (with γ the gyromagnetic ratio and B_0 the strength of the external magnetic field):

$$\omega_L = \gamma B_0 \tag{1}$$

The magnetic moment can be interpreted as a stationary vector by using the rotating frame approximation, where the frame of reference for the moment is rotating with the same frequency and direction as the Larmor frequency in the xy-plane. This approximation allows the z-magnetization to be seen as a stationary, vertical vector.

The Larmor frequency equates the strength of the static magnetic field to the frequency of precession. This frequency is also the frequency of light that is needed to excite the spins in the lower energy state to the higher energy spin state, following Planck's equation. This excitation is the central phenomenon in NMR, probing the different energy levels of

the spin states. In large external magnetic fields, the Larmor frequency of the proton (^{1}H) lies in the range of radio-frequency (RF) along the electromagnetic spectrum. Thus, RF waves are used to excite the nuclear spins to probe the chemical environments of the analytes at hand.

The NMR Experiment

A typical NMR experiment follows this formula:

1. An ensemble of spins is placed inside a static magnetic field.
2. The sample is irradiated with an RF pulse to focus the spins.
3. The spins are allowed to relax back to the original orientation, and the induced current is measured.
4. The irradiation is repeated many times to enhance the net signal.
5. The data is analyzed after the "free induction decay" is transformed from the time domain to a frequency domain via a Fourier transform.

Starting off with the first step in the sequence, it is necessary to place the sample into a strong static field such that the spins split by the Zeeman effect, leading to a net magnetization parallel the external field, and the magnetic moments of the spins precess as previously described.

An RF pulse is sent through a resonant circuit (with the coil centered on the sample) to start the second step. This pulse effectively applies a magnetic field (generally called B_1) to the z-directional magnetization vector, M_z, to focus it into the xy-plane. The pulse is tuned in both duration and power such that M_z is shifted 90° onto either the x- or y-axis, which yields the following equation for the magnetization under the rotating frame approximation:

$$M_x(t) = M_{z,0} \tag{2}$$

With the magnetization tipped into the x-direction (in the case above), the pulse is turned off, and the spectrometer is turned to the receive mode and thus begins the third step. The magnetic moments start to relax back to their original directions in the static magnetic field, B_0. The magnetization in the x-direction is given by

$$M_x(t) = M_{z,0}\cos(\omega_L t)e^{-t/T_2} \tag{3}$$

Without the magnetic field B1, the magnetic moments oscillate around the z-axis with the Larmor frequency. The cosine wave is at a maximum at t = 0, and the exponential is added as a damping factor to account for the relaxation (in this case, the damping factor is spin-spin relaxation which accounts for the T_2 constant) back to where the magnetization is in the z-direction. As the magnetic moments oscillate, they induce a current in the coil (as a moving magnetic field will always induce an electric current). This current is then measured by the coil that surrounds the sample and leads to the "free induction decay" or FID, mentioned above.

Steps 1–3 are repeated multiple times to increase the signal, as each successive FID builds upon the last to create one superimposed FID. The signal-to-noise ratio scales with the square root of the number of scans. Once the desired signal-to-noise ratio (and signal amplitude) has been achieved, data collection is finished, and a Fourier transform of the FID from the time domain (t) into the frequency domain (Ω) is implemented:

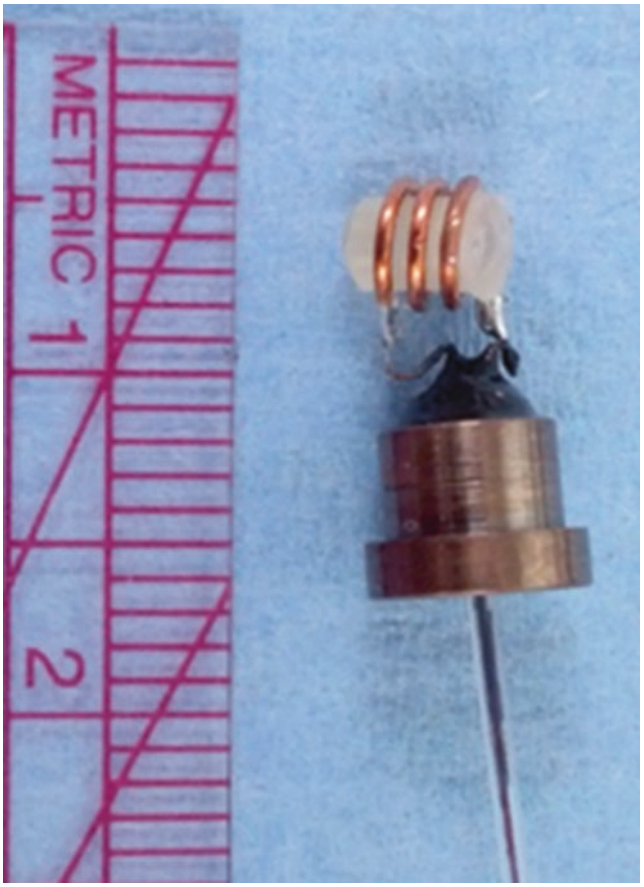
$$S(\Omega) = \int_0^\infty s(t)e^{-i\Omega t}dt \tag{4}$$

The Fourier transform is a complex function, as it consists of real and imaginary parts. The real portion of the spectrum is known as the absorption spectrum, while the imaginary portion is known as the dispersive spectrum. The absorption spectrum is the spectrum associated with FT-NMR analysis, and it is a plot of the different Larmor frequencies of the nuclei in the ensemble (and the molecule overall), measured along the x-axis as a difference from the carrier frequency that was pulsed through the sample. The Larmor frequency of each nucleus depends on the chemical environment it experiences – thus, separate signals that show up on the spectrum indicate separate magnetic environments. This fact helps to elucidate the structure of the chemicals under consideration since the structural settings give rise to differences in the magnetic environments. Functional groups can be identified; bond distances, bonding, conformations, and rates of interconversion can all be measured.

Instrument Design

The NMR instrument can be separated into two main components, the magnet and the spectrometer.

The magnet is generally a high-field superconducting coil that takes liquid helium and liquid nitrogen to maintain the currents necessary to produce the large magnetic field. Permanent magnets do exist, but are lower field and do not provide as high a resolution as superconducting magnets. The field strengths of superconducting magnets range from 7 to 23.5 T. The large cylindrical magnet also houses the sample probe. The probe is usually a tunable LC-type circuit



Nuclear Magnetic Resonance, Fig. 1 A simple solenoid sample coil

that provides the irradiation to the sample nuclei. This coil is also sensitive enough to measure the induced current of the nuclei once they start to relax after being perturbed (Fig. 1). To achieve the best resolution, the magnetic field must be homogeneous around the sample. Electromagnets, called "shimming coils," are used to homogenize the magnetic field around the actual sample. Magnetic fields are generated by the application of current to these electromagnets, which constructively or destructively alter the local magnetic field around the sample. The homogenization of the local field leads to sharper linewidths and more symmetric peaks.

The second half of the instrument, the spectrometer, is where the RF synthesizers, duplexers, receivers, and controllers reside. A high-power electrical pulse is sent from the spectrometer to the coil to perturb the nuclei and then is turned off quickly. One of the most important parts to an NMR spectrometer is the high-speed duplexer, which is a very fast switch that protects the sensitive receiving electronics from high-power pulses. The electronics must be able to function in rapid succession, as experiments can occur within microseconds of one another. The modern receiver relies on digital quadrature detection to process the data. The receiver splits the signal from the probe into real and imaginary phases, converts the analog signal to a digital signal, and compares the signal to a reference frequency. This data is then manipulated, and the spectrum is analyzed.

The Bloch Equations

The Bloch equations are a description of how the magnetic moment of the nuclear spins (M) interacts with a static magnetic field (B) after the influence of a strong RF pulse, following the torque equation (Bloch 1946) and using the vector cross product:

$$\boldsymbol{\tau} = \boldsymbol{M}\, x\, \boldsymbol{B} \tag{5}$$

The equation is modified to show how the magnetic moments are changed in the magnetic field, knowing that $\boldsymbol{M} = \gamma\hbar\boldsymbol{I}$ (γ is once again the gyromagnetic ratio of the nuclei):

$$\boldsymbol{\tau} = \hbar\frac{d\boldsymbol{I}}{dt} = \frac{\hbar}{\hbar\gamma}\frac{d\boldsymbol{M}}{dt} = \frac{1}{\gamma}\frac{d\boldsymbol{M}}{dt} \rightarrow \frac{d\boldsymbol{M}}{dt} = \gamma\boldsymbol{\mu}\, x\, \boldsymbol{B} \tag{6}$$

Describing the torque in the laboratory frame of reference, the vectors are defined in three dimensions such that

$$\frac{d}{dt}\begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} = \gamma \begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} x \begin{pmatrix} B_x \\ B_y \\ B_z \end{pmatrix} \tag{7}$$

The overall magnetic field **B** is given by a combination of magnetic fields during the NMR experiment. At the initial point in the experiment, there is a strong static magnetic field $\mathbf{B_0}$ in the z-direction and a smaller R-induced magnetic field $\mathbf{B_1}$ in the xy-plane. If the $\mathbf{B_1}$ pulse is directed in the x-direction, the **B** vector becomes

$$\begin{pmatrix} B_x \\ B_y \\ B_z \end{pmatrix} = \begin{pmatrix} B_1 \cos\omega_{rf}t \\ B_1 \sin\omega_{rf}t \\ B_0 \end{pmatrix} \tag{8}$$

Substituting Eq. (8) into the torque equation, Eq. (7), yields

$$\frac{d}{dt}\begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} = \gamma \begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} x \begin{pmatrix} B_1 \cos\omega_{rf}t \\ -B_1 \sin\omega_{rf}t \\ B_0 \end{pmatrix} \tag{9}$$

The γ is a scalar, and the Larmor and Rabi frequencies are defined as $\omega_{L=}\gamma B_0$ and $\omega_{R=}\gamma B_1$. Substituting these definitions into Eq. (9) yields

$$\begin{pmatrix} \frac{dM_x}{dt} \\ \frac{dM_y}{dt} \\ \frac{dM_z}{dt} \end{pmatrix} = \begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} x \begin{pmatrix} \gamma B_1 \cos \omega_{rf} t \\ -\gamma B_1 \sin \omega_{rf} t \\ \gamma B_0 \end{pmatrix}$$

$$= \begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} x \begin{pmatrix} \omega_R \cos \omega_{rf} t \\ -\omega_R \sin \omega_{rf} t \\ \omega_L \end{pmatrix} \quad (10)$$

which simplifies to

$$\begin{pmatrix} \frac{dM_x}{dt} \\ \frac{dM_y}{dt} \\ \frac{dM_z}{dt} \end{pmatrix} = \begin{pmatrix} \omega_L M_y + M_z \omega_R \sin \omega_{rf} t \\ M_z \omega_R \cos \omega_{rf} t - \omega_L M_x \\ -M_x \omega_R \sin \omega_{rf} t - M_y \omega_R \cos \omega_{rf} t \end{pmatrix} \quad (11)$$

Equation (11) is the set of coupled differential equations known as the Bloch equations in the lab frame. This set is conveniently transformed into the rotating frame of reference, where the z-magnetization is stationary, and the frame of reference rotates with the Larmor frequency, by applying a rotation matrix:

$$\boldsymbol{T}^{rot} = \begin{pmatrix} \cos \omega_{rf} t & \sin \omega_{rf} t & 0 \\ -\sin \omega_{rf} t & \cos \omega_{rf} t & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (12)$$

Redefining new magnetization vectors (u, v, and M_z), Bloch derived

$$\begin{pmatrix} u \\ v \\ M_z \end{pmatrix} = \boldsymbol{T}^{rot} \begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix}$$

$$= \begin{pmatrix} M_x \cos \omega_{rf} t + M_y \sin \omega_{rf} t \\ -M_x \sin \omega_{rf} t + M_y \cos \omega_{rf} t \\ M_z \end{pmatrix} \quad (13)$$

After substituting in u, v, and M_z to the torque equation and solving for the derivatives of these new functions, the end result is

$$\begin{pmatrix} \frac{du}{dt} \\ \frac{dv}{dt} \\ \frac{dM_z}{dt} \end{pmatrix} = \begin{pmatrix} v(\omega_{rf} - \omega_L) \\ -u(\omega_{rf} - \omega_L) - M_z \omega_R \\ v\omega_R \end{pmatrix} \quad (14)$$

This set of coupled differential equations is known as the Bloch equations for a rotating frame of reference and accounts for the perceived oscillation of three directions of magnetization if one were sitting on a packet rotating at the Larmor frequency in the xy-plane.

Bloch noticed the phenomenon of relaxation when deriving these equations (signals decaying along a first-order path versus time) and coined the terms longitudinal (T_1 or spin-lattice) and transverse (T_2 or spin-spin) relaxation times. The longitudinal relaxation time T_1 is the time that it takes for the M_z signal to relax back to its original state after being perturbed by the RF pulse. The mechanism for this relaxation, for the I = 1/2 case, is due to the interaction of the nuclei with its surrounding rotational and vibrational environments. The energy contained in the excited state is dissipated to neighboring electric and magnetic fields. Quadrupolar nuclei as well as paramagnetic ions also allow for fast dissipation of this energy. The transverse relaxation time, T_2, is the time that it takes for the spins to dephase and lose coherence in the xy-plane. This dephasing is an adiabatic process where the energy is dissipated between spins, and information is lost. As the net magnetization is regained in the z-direction but lost in the xy-plane, T_1 is always greater than, or equal to, T_2.

The relaxation pathway that yields T_1 is a first-order process that affects only M_z:

$$M_z(t) = M_{z,eq} - \left(M_{z,eq} - M_z(0)\right) e^{-\frac{t}{T_1}} \quad (15)$$

T_2 is also a first-order process for M_x and M_y, so the two magnetizations are defined as

$$M_x(t) = M_x(0) e^{-\frac{t}{T_2}} \text{ and } M_y(t) = M_y(0) e^{-\frac{t}{T_2}} \quad (16)$$

Substituting these into Eq. (14), the rotating Bloch equations, with relaxation effects:

$$\begin{pmatrix} \frac{du}{dt} \\ \frac{dv}{dt} \\ \frac{dM_z}{dt} \end{pmatrix} = \begin{pmatrix} v(\omega_{rf} - \omega_L) - \frac{u}{T_2} \\ -u(\omega_{rf} - \omega_L) - M_z \omega_R - \frac{v}{T_2} \\ v\omega_R - \frac{M_z - M_0}{T_1} \end{pmatrix} \quad (17)$$

These equations have since been modified to deal with the kinetics of chemical reactions (McConnell 1958). This McConnell formalism has been widely used to determine the rates of exchange reactions in solution, typically in the case where a complexed ligand around a solvated metal ion replaces itself with a free ligand in solution. The rate of exchange for bound water molecules in solution has also been studied for a myriad of metal centers (Helm and Merbach 1999). McConnell postulated that on the NMR timescale, magnetization would not only transfer due to relaxation mechanisms but that nuclei would exchange between sites and affect magnetization transfer as well. For this to

occur, he made a series of assumptions. The first was that the rate of exchange of magnetization was directly proportional to the rate of chemical exchange. The second was that the process could either be described as a set of elementary (one-step) reactions. Thus, for a two-site exchange reaction between sites A and B (depicting first-order or pseudo-first-order reaction conditions), it was formulated that the following equations can be used to depict chemical exchange, with the rates of the forward and reverse reaction given by k_A and k_B, respectively, and from the law of detailed balance, $\frac{k_A}{k_B} = \frac{X_B}{X_A} = P_B$ where "X_i" is the mole fraction of site "i" and P_B is the ratio of mole fractions.

Now the system of equations is split into two, one set for each of the exchanging sites:

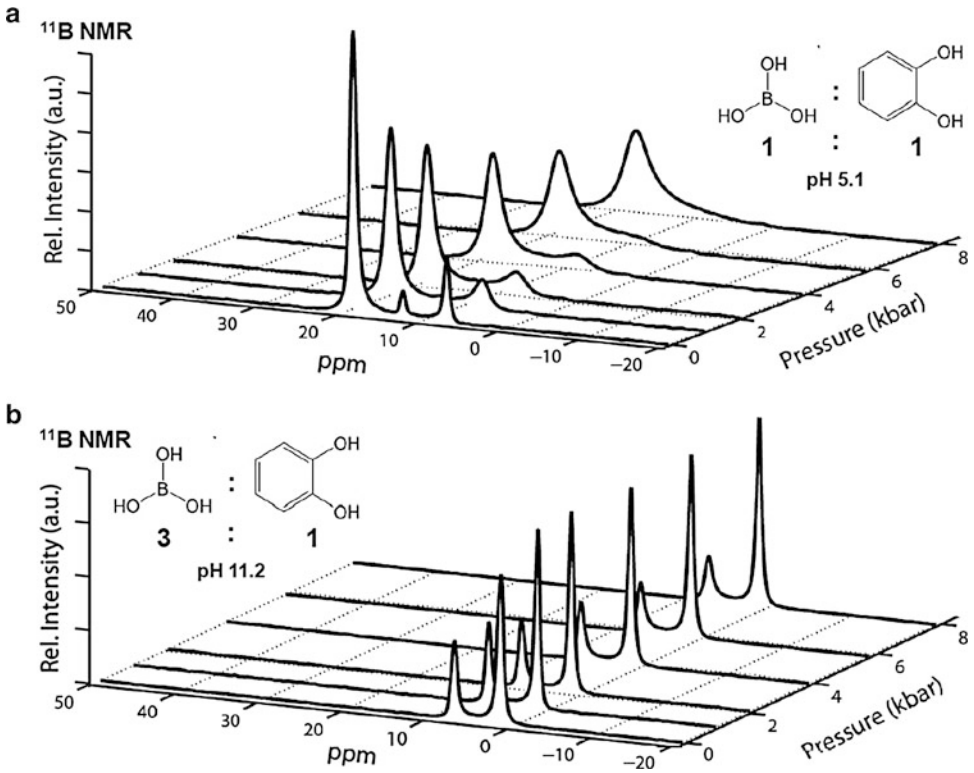
$$\begin{pmatrix} \frac{du_A}{dt} \\ \frac{dv_A}{dt} \\ \frac{dM_{z,A}}{dt} \end{pmatrix} = \begin{pmatrix} v_A(\omega_{rf} - \omega_L) - \frac{u_A}{T_{2,A}} - k_A u_A + k_A P_A u_B \\ -u_A(\omega_{rf} - \omega_L) - M_{z,A}\omega_R - \frac{v_A}{T_{2,A}} - k_A v_A + k_A P_A v_B \\ v_A \omega_R - \frac{M_{z,A} - M_{0,A}}{T_{1,A}} - k_A M_{z,A} + k_A P_A M_{z,B} \end{pmatrix} \quad (18)$$

$$\begin{pmatrix} \frac{du_B}{dt} \\ \frac{dv_B}{dt} \\ \frac{dM_{z,B}}{dt} \end{pmatrix} = \begin{pmatrix} v_B(\omega_{rf} - \omega_L) - \frac{u_B}{T_{2,B}} - k_B u_B + k_B P_B u_A \\ -u_B(\omega_{rf} - \omega_L) - M_{z,B}\omega_R - \frac{v_B}{T_{2,B}} - k_B v_B + k_B P_B v_A \\ v_B \omega_R - \frac{M_{z,B} - M_{0,B}}{T_{1,B}} - k_B M_{z,B} + k_B P_B M_{z,A} \end{pmatrix} \quad (19)$$

These equations look daunting but can be easily solved using desktop mathematical software to yield spectra, or even to fit experimental spectra and extract rate parameters.

Application to Geochemistry

NMR has been used to determine chemical speciation and elucidate the phase and characteristics of minerals (specifically using solid-state NMR as a complementary technique to X-ray crystallography) and has been used to measure reactions that occur in the geosphere. The probes have also been engineered to measure systems under extreme environments. Specifically, high-pressure NMR measurements are now used to understand the chemistry of the deep Earth. Diamond-anvil cells are most widely used with solid-state NMR measurements and can reach



Nuclear Magnetic Resonance, Fig. 2 The complexation of boric acid by catechol as a function of pressure, leading to coalescence at pressures of 0.8 GPa

up to 20 GPa in pressure (Meier et al. 2014). Piston cylinder cells are typically used for solution-state NMR and can reach up to 2.0 GPa in pressure. Solution chemistry at higher pressure is dominated by solvent effects, although the kinetics of reaction can sometimes be measured due to coalescence of signals (Pautler et al. 2014) (Fig. 2).

Conclusion

Nuclear magnetic resonance is an analytical method with profound potential for geochemistry, both in solid and solution state. It is sensitive to molecular structure and chemical dynamics and samples those dynamics at the most important timescales (microseconds to seconds). It is a relatively insensitive, yet nondestructive, technique that is widely pervasive in academia and industry. Although solid-state NMR is relatively common in the geochemical and mineralogical literature, less common is the solution state at geochemical conditions of high temperatures and pressures, though constant advances are being made in this field.

Nucleosynthesis

Jitendra Nath Goswami
Physical Research Laboratory, Ahmedabad, India

Definition

Nucleosynthesis is the creation of all the atomic nuclides known to us through a variety of processes that started with an explosive event, the so-called "Big-Bang" and followed by nuclear processes that include fusion, neutron capture, proton capture, energetic particle interactions, and spallation. Fusion of protons and neutrons led to formation of deuterium, helium, and very little of lithium. It continues today with fusion, neutron, and proton capture in large stars, supernova explosions as well as spallation resulting from collisions between preexisting nuclei and cosmic rays.

Origin and Abundances of the Elements

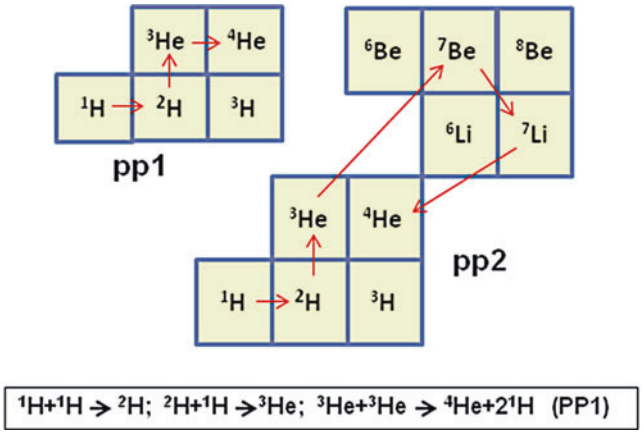
The elements and their isotopes, present in our solar system, and in other stellar systems, are products of nuclear and energetic processes taking place in various astrophysical environments, starting with the "Big-Bang," that marks the beginning of our universe. The term "Nucleosynthesis" broadly refers to the various energetic astrophysical processes involved in the formation of the nuclides known to us.

There are 81 naturally occurring stable elements, starting with Hydrogen ($Z = 1$) to Bismuth ($Z = 83$), along with two unstable elements, Technetium ($Z = 43$) and Promethium ($Z = 61$). In addition, there are nine other unstable elements that include Thorium ($Z = 90$) and Uranium ($Z = 92$). The total number of nuclides, both stable and long-lived, is more than 300.

Studies of early solar system solids, present in meteorites, revealed fossil records of nearly a dozen short-lived, now-extinct nuclides (e.g., ^{41}Ca, ^{26}Al, ^{60}Fe, ^{129}I, ^{244}Pu) that are now identified as products of stellar nucleosynthesis. Injection of these nuclides from an exploding stellar source into the proto-solar cloud is generally considered as the trigger for the collapse of the cloud leading to formation of the proto-Sun and some of the first solar system solids (Goswami and Vanhala 2000). Fossil records (decay products) of these now-extinct radionuclides are preserved in early solar system solids.

Formation of the First Nuclides

Synthesis of the nuclides, in particular, H and He, dates back to the beginning of our universe, following the so-called "Big-Bang" event. The extremely high energy density during the very early stages of our universe provided a high temperature ($>10^{10}$ K) radiation environment dominated by energetic gamma ray photons. The equivalence of energy and matter ($E = mc^2$) led to formation of a rapidly changing populations of subatomic particles, in particular, protons and neutrons, as well as mu-meson, electron, and their antiparticles in such an environment. Although formation and destruction reactions are in equilibrium at this stage, protons will be more abundant because of their lower mass. The formation of deuterons (^{2}H) took place after temperature dropped significantly and followed by formation of ^{3}H, ^{3}He, and ^{4}He. This led to a



Nucleosynthesis, Fig. 1 Hydrogen Burning (PP1 & PP2 Chains)

decrease in abundance of neutrons resulting in lower abundances of ^{7}Li and ^{7}Be. Formation of the first nuclides in the early universe followed two dominant pathways, designated PP1 and PP2 chains and, a minor one, the PP3 chain.

A proposal made by George Gamow and his colleagues in late 1940s (Alpher et al. 1948) suggested that neutrons will constitute a significant fraction of matter following the big-bang event and facilitate production of elements, starting with deuteron, through successive neutron capture. The absence of stable nuclides with mass 5 and 8 made the suggestion untenable.

It was also realized at that time that the energy radiated by the Sun, attributed to its gravitational collapse, cannot sustain solar luminosity for more than tens of millions years, an extremely small duration compared to the age of the Sun, inferred to be in excess of 4 billion years, based on geological evidences. The suggestion that nuclear reactions in stellar interior can replenish energy radiated by the star was based on studies on nuclear transmutation by Hans Bethe (1939), who also proposed the reactions responsible for energy generation in stars and for the Sun in particular (Fig. 1).

Synthesis of Nuclides in Stellar Interior

Two seminal papers in the field of nucleosynthesis, published in 1957 by Burbidge, E. M. et al. and A. G. W. Cameron, provided a broad outline of the nuclear processes taking place in stellar interior and also during explosive stellar events (e.g., supernova) leading to formation of the nuclides. This was preceded by the suggestion that nuclear reactions in stars can lead to formation of chemical elements heavier than helium (Hoyle 1946 1954). It was also established that a few of the low mass nuclides (lithium, beryllium, and boron) are products of energetic particle interactions in space environment (Reeves 1994). These early studies of nucleosynthesis were followed by a large volume of work taking into account the finer details of various stellar sites and nucleosynthesis processes. Explaining the abundances of the elements as well as their isotopes in our Solar System was the main focus and these are now known with very high accuracy (see e.g., Anders and Grevesse 1989; Lodders 2010). The Nobel lectures by Penzias (1979) and Fowler (1984) provide a very engrossing description of the development in the field of nucleosynthesis.

Even though a variety of stellar sources have contributed towards the formation of the Solar System, the very uniform elemental and isotopic composition of solar system matter suggest an *extremely well-mixed proto-solar cloud* whose collapse led to formation of our Solar System. An explosive stellar event, a supernova, is the most probable trigger for this collapse (Goswami and Vanhala 2000).

A new dimension was added to the field of stellar nucleosynthesis following the identification of "stardust" (microscopic interstellar grains), refractory in nature, in primitive meteorites (Anders and Zinner 1993). These grains, nano- to micrometer in size, reveal large isotopic anomalies, relative to average solar system composition and host records of stellar environments in their formation sites (Asymptotic Giant Branch (AGB) star, Novae, Supernovae). This provides a gateway for studies of nucleosynthesis processes in specific stellar environment, beyond the realm of the Solar System (see also, Meyer and Zinner 2006).

Synthesis of the naturally occurring elements and their isotopes present in the Solar System solids may be divided into three broad segments: primordial nucleosynthesis (H, He), energetic particle (cosmic ray) interactions (Li, Be, B), and stellar nucleosynthesis (C and heavier elements). A concise description of these processes is presented in the following.

Primordial Nucleosynthesis

Our ideas of primordial nucleosynthesis are based on the standard Big-Bang model of our universe that suggests formation of hydrogen and nearly all of helium within the first few minutes following this explosive event. The agreement between the predicted relative abundances of the first nuclides (^{1}H, ^{2}H, ^{3}He, ^{4}He) that formed in the early universe, with their observed abundances at present, in regions of our universe, which have not experienced much of chemical evolution, supports this view (Peebles 1971). A very refreshing discussion is also provided by S. Weinberg (1977).

Cosmic Ray Spallation

The next group of elements, Li, Be, and B, are not primary product of stellar nucleosynthesis. These elements are destroyed easily in energetic nuclear processes taking place in stellar interiors. They are produced by interaction of

energetic particles present in interstellar space (Galactic Cosmic Rays) with ambient interstellar matter. Collisions of energetic carbon and oxygen ions in cosmic rays with hydrogen atoms in interstellar medium lead to production of these three elements (see, e.g., Reeves 1994). The source of energetic cosmic rays could be an exploding star (a supernova) or interstellar matter accelerated by supernova shocks. A small fraction of Li is also contributed from primordial nucleosynthesis, while stellar nucleosynthesis adds to the inventory of both ^{7}Li and ^{11}Be.

Stellar Nucleosynthesis

Energy generation in the interior of a star is driven by "nuclear fusion," starting with fusion of hydrogen to form helium (^{4}He), the dominant mode of energy production in stars (Bethe 1939). The fusion chain of exothermic reactions continues with successive burning of He, C, O, and Si in stellar interior, leading to formation of iron (^{56}Fe), beyond which fusion become an endothermic reaction.

Formation of elements beyond the iron group takes place through capture of neutrons by preexisting nuclides and follows two distinct paths, the "s" (slow) or "r" (rapid) process. The proton-rich nuclides that are away from the line of beta-stability are produced by photo-nuclear reactions, the "p" process. An outline of the various nucleosynthesis processes, involving burning of seed nuclides, starting with Hydrogen, is presented in the following.

Hydrogen Burning

There are several pathways for fusion of hydrogen to form helium when the internal temperature of the star exceeds 10^{7} K, sufficient to overcome the coulomb barrier. In solar mass stars, it proceeds via the proton-proton (PP-I) chain:

$$^{1}\mathrm{H}+{}^{1}\mathrm{H}\rightarrow {}^{2}\mathrm{H}+\gamma;{}^{2}\mathrm{H}+{}^{1}\mathrm{H}\rightarrow {}^{3}\mathrm{He}+\gamma;{}^{3}\mathrm{He}+{}^{3}\mathrm{He}\rightarrow {}^{4}\mathrm{He}+2{}^{1}\mathrm{H}$$

Even though produced in small amount, ^{3}He can react through different channels (PP-II and PP-III), yielding ^{7}Be, ^{7}Li, and ^{8}B as intermediate products that finally end up as ^{4}He. In massive star with higher core temperature, conversion of H to He can proceed via C─N─O cycle with ^{12}C, present initially in the star acting as a catalyst. ^{14}N is a major product of the CNO cycle along with minor amounts of ^{13}C,^{15}N and ^{17}O.

Helium Burning

Gradual exhaustion of hydrogen in the core of the star will make hydrogen burning weaker, leading to contraction of the core, and make it dense enough to raise the temperature of the Helium-rich core to ~10^{8} K that can initiate Helium burning. The most important reaction at this stage is the "triple-alpha" reaction that converts ^{4}He to ^{12}C. Several other important nuclides, ^{16}O, ^{18}O, ^{22}Ne, ^{25}Mg, are also produced during this stage via successive exothermic alpha capture by ^{14}N, an end product of hydrogen burning through C─N─O cycle:

$$\begin{aligned}
{}^{4}\mathrm{He}+4\,\mathrm{He}+4\mathrm{He} &\rightarrow {}^{12}\mathrm{C}+\gamma;\\
{}^{12}\mathrm{C}+{}^{4}\mathrm{He} &\rightarrow {}^{16}\mathrm{O}+{}^{4}\mathrm{He};\\
{}^{14}\mathrm{N}+{}^{4}\mathrm{He} &\rightarrow {}^{18}\mathrm{F}+\gamma;\\
{}^{18}\mathrm{F} &\rightarrow {}^{18}\mathrm{O}+\mathrm{e}^{+}+\nu;\\
{}^{18}\mathrm{O}+{}^{4}\mathrm{He} &\rightarrow {}^{22}\mathrm{Ne}+\gamma;\\
{}^{22}\mathrm{Ne}+{}^{4}\mathrm{He} &\rightarrow {}^{25}\mathrm{Mg}+\mathrm{n}
\end{aligned}$$

Successive capture of alpha particles by ^{14}N, end product of hydrogen burning through the CNO cycle, also leads to production of ^{18}O and ^{22}Ne. For stars with mass less than 8 solar mass, He burning marks the last stage of energy generation process that leads to a stellar core enriched in carbon and oxygen.

Carbon and Oxygen Burning

Nuclear burning in stars with mass less than 8 solar mass cannot raise the core temperature needed for nuclear burning beyond helium. They end their life as a cool and dense white dwarf. However, in more massive stars, the core temperature is high enough (10^{9} K) to initiate He burning, followed by successive burning of carbon and oxygen. This leads to production of ^{20}Ne, ^{23}Na, and ^{24}Mg via carbon burning, while ^{28}Si, ^{31}P, and ^{32}Si are products of oxygen burning. Synthesis of elements at this stage can also follow production via capture of alpha (^{4}He) particle and proton by carbon and oxygen that can lead to synthesis of nearly all the elements between Ne and Ar.

Silicon Burning and the "e" (Equilibrium) Process

Silicon burning, the last stage of nuclear fusion in stellar interior, takes place when the core temperature reaches ~3×10^{9} K. The high temperature environment leads to endothermic photo-disintegration of preexisting nuclei around silicon via (γ, α) reaction, prior to initiation of the fusion process. This provides a copious source of alpha particles that are captured by nuclides having intermediate masses leading to formation of precursors of the iron group nuclides. Interactions among the nuclides – alpha particles,

proton, and neutrons – lead to formation of the iron group nuclides with equilibrium abundances; the nuclides having higher binding energy being more abundant. The relative abundances of the iron group nuclides during the "e" (equilibrium) process depend on the nature of both strong and weak nuclear interactions, in particular, electron capture and neutrino emission.

Explosive Nucleosynthesis

The end of silicon burning will leave a massive star with a core composed primarily of Fe-group elements that will be surrounded by layers enriched with elements (H, He, C, O, Ne, Si) that are products of earlier evolutionary stages of the star. Exhaustion of nuclear energy source in the interior of the star will lead to collapse of the stellar core that will trigger an explosion (a supernova event) resulting in expulsion of the outer layers of the star as well as further processing of material in the inner layers of the star. This transient phase of nuclide processing is termed as "explosive nucleosynthesis." The nonequilibrium nature of this phase leads to synthesis of nuclides with very different abundance pattern than those produced in the slow hydrostatic burning inside a stellar object, even though the seed nuclides are the same. The abundance of a sizable number of intermediate mass nuclides in the solar system can be explained as products of "explosive nucleosynthesis."

A low mass star, which generally ends its life as a white dwarf, may also suffer a catastrophic end. This happens if the white dwarf has a companion from which it accretes matter and its mass exceeds a critical mass and become unstable and explodes. Such an explosion is termed as a Type-I supernova to distinguish it from the explosion of high mass massive stars, termed as Type-II supernova. White dwarfs are primarily left over carbon- and oxygen-rich cores of low mass stars, and their explosive end primarily leads to synthesis of iron group of nuclides (Fe, Co, Ni).

Elements Beyond the Iron Group

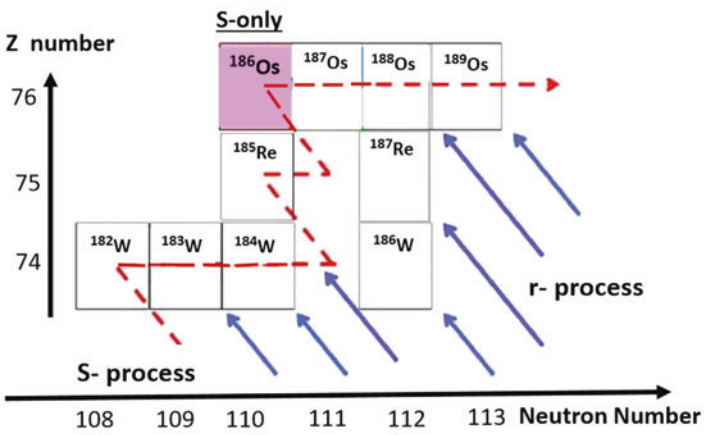
Synthesis beyond the iron group of elements follows two processes that are termed as *r-process,* involving rapid neutron capture, and the *s-process,* characterized by slow neutron capture.

r-Process

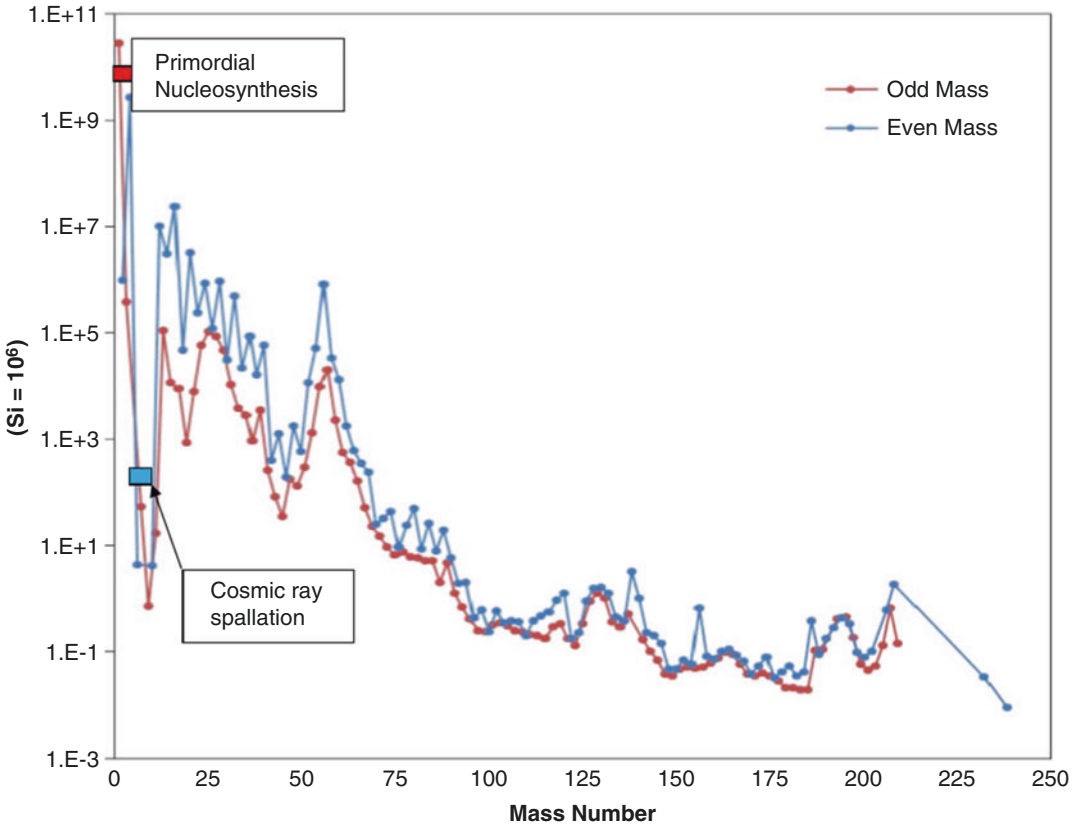
The r-process is effective when the neutron densities are high enough to facilitate build-up of heavier elements beyond iron via successive neutron capture by the Fe group as well as other heavy elements. Even though these elements will be far removed from the line of β-stability, as long as neutron capture rate exceed the beta decay rates, they will eventually suffer successive beta decay and end up as stable high mass nuclide (Fig. 2).

s-Process

Unlike the relatively fast r-process, the slow neutron capture takes place in stellar environments that provide relatively low flux of neutrons over a significant period of time. In such a setting, the neutron capture timescales could be longer than or comparable to beta decay timescales and bypassing unstable neutron-rich nuclide is not possible as in the r-process. The main sources of neutrons for the s-process are the two reactions: $^{13}C\ (\alpha, n)\ ^{16}O$ and $^{22}Ne\ (\alpha, n)\ ^{25}Mg$; ^{22}Ne is a product of successive alpha capture by ^{14}N. Thus, both the seed nuclides (^{13}C and ^{14}N) are products of hydrogen burning via C─N─O cycle. These reactions take place in low mass stars during the red-giant phase of their evolution, following H and He burning, when nuclear burning takes place in a thin He shell between the carbon- and oxygen-rich core and the H-rich outer envelope. He-burning in massive stars is another plausible site for s-process synthesis. Spectroscopic evidence for the presence of the unstable element Technetium in low mass stars (red giant; Merrill 1952) also makes them a plausible site for s-process synthesis providing an important link in the s-process path around mass 100.



Nucleosynthesis, Fig. 2 Pathways for S (slow: red) and R (rapid: blue) processes for synthesis of elements (isotopes) beyond the iron group



Nucleosynthesis, Fig. 3 Abundances of nuclides

p-Process

A group of *proton-rich* stable nuclides having very low abundances cannot be produced by the nucleosynthesis processes outlined above. These are stable neutron-deficient nuclides, heavier than iron, which are observed only in solar system matter and grouped as product of p-process, as they were initially thought to be product of proton capture. However, there is no suitable astrophysical site where proton capture (p, γ) may dominate over photonuclear reaction like (γ, n) or (γ, p). These nuclides are generally considered to be products of photonuclear reaction involving s- and r-process nuclides that lead to formation of proton-rich isotopes which finally end up as proton-rich stable nuclides via (γ, p) and (γ, α) reactions (Arnould and Goriely 2003) (Fig. 3).

Summary

Our understanding of stellar nucleosynthesis processes, since the time of the early work by Burbidge et al. (1957) and Cameron (1957), that attempted to explain the solar system abundances of nuclides compiled by Suess and Urey (1956), based on studies of meteorites as well as spectroscopic observation of the Sun, has improved significantly. It is now possible to identify specific nucleosynthesis processes responsible for synthesis of nuclides present in the solar system and also understand the lower abundances of the odd mass nuclides.

Advances in studies of nucleosynthesis allow one to predict abundance pattern of the Fe-group nuclei and beyond, with a fair degree of accuracy, by considering contributions from both Type-I and type II supernova (Timmes et al. 1995). The s-process systematics can lead to the abundance peaks beyond the iron group, at mass numbers around 84, 138, and 208, with magic neutron numbers 50, 82, and 126, respectively. Another group of heavy nuclides, at mass numbers, 80, 130, and 195, preceding the s-process peaks, can be explained by considering r-process systematics (Fowler 1984). A general discussion of various nucleosynthesis processes and their connection to solar system abundances of nuclides is provided by Cox (1989). Several other areas related to field of nucleosynthesis include chemical evolution of our galaxy that deals with star formation rates, stellar evolution models and stellar nucleosynthesis (see, e.g., Clayton 1988) and cosmo-chronology (Symbalisty and Schramm 1981), timescales of nucleosynthesis of the radioactive nuclides present in the early solar system and, also present day solar system.

A major impetus for studies in Stellar nucleosynthesis came following the discovery of microscopic grains of silicon carbide, graphite, and diamonds in primitive meteorites with

large isotopic anomalies, relative to solar system solids (see e.g., Meyer and Zinner 2006). The stellar origin of these grains can be inferred from the very different abundance pattern of H and C isotopes, relative to solar system matter, thus hosting nucleosynthesis records that are not homogenized as in the case of our solar system.

Synonyms

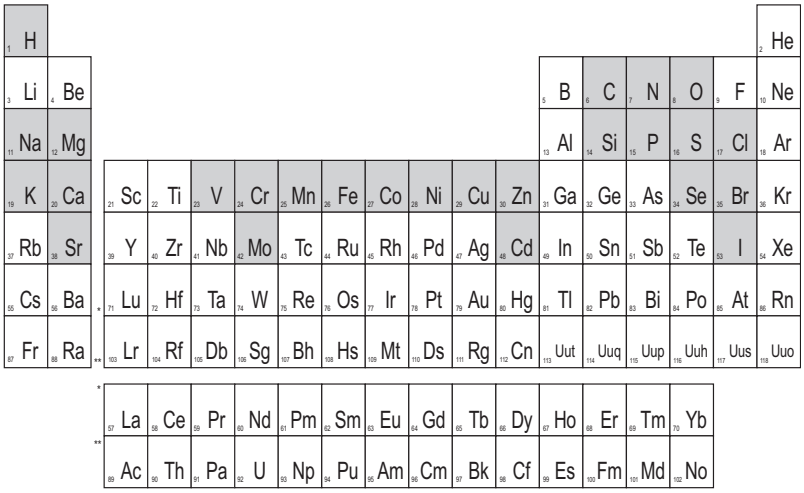
Bioessential compounds; Essential elements

Definition

Nutrients are elements or compounds used by organisms in the production of biomass, cellular function, or related structural material.

Introduction

Nutrients are elements or compounds used by organisms in the production of biomass, cellular function, or related structural material (Odum 1959). Nutrients that are required for proper cellular functioning are described as *essential nutrients*. Traditionally, major essential nutrients (utilized by organisms in approximate percentage or greater abundances in biomass) have been considered to be N, P, and S. However, essential trace nutrients are also required for growth and proper cellular function; these include Fe, Co, Zn, Ni, V, and many others (see Fig. 1). Part of what defines an element as a nutrient is its potential for limitation, which is the reason that O and H are not typically defined as nutrients, even though they are required for the production of biomass, and water is a requirement for all known life. In addition to elements used in biomass, inorganic ions such as Cl^-, Mg^{2+}, Na^+, and K^+ are also required for cellular function and may be considered essential nutrients. Finally, some



Nutrients, Fig. 1 Shaded elements are those identified as nutrients or involved in cellular function

organisms require Si to form inorganic shells and will be growth limited in silicate-depleted environments.

Another important aspect of a nutrient is its chemical form and consequent bioavailability. Different species may have very different abilities to access the nutrients in their environment and may require that a nutrient be in a specific form. For example, ocean waters contain over half a millimole per liter of nitrogen, far in excess of need if all were available for marine organisms. However, most of this N is in the form of dissolved N_2 gas, which, with a very strong triple bond, is not accessible by most organisms for their growth needs. Only organisms with specialized enzymatic systems that can reduce N_2 and form organic nitrogen forms can access this pool (Sohm et al. 2011). Furthermore, not all primary producers can access N in its oxidized forms (e.g., NO_3^- or NO_2^-). Similarly, much of the supply of Fe to the ocean away from continental margins is in the form of insoluble iron oxides that are considered unavailable to primary producers without chemical reduction to more soluble compounds (Norman et al. 2014). Several significant taxa of marine primary producers require Co in the organically bound form of cobalamin (vitamin B-12) in order to use it (Moore et al. 2013).

Nutrient Limitation

The concept of nutrient limitation dates back to the "law of the minimum" developed by Justus von Liebig and expanded upon by FF Blackman (von Liebig 1840; Blackman 1905; Odum 1959). Von Liebig postulated that growth of plants was limited by the scarcest resource and not by total resources. This has been refined to indicate that scarcity is in relation to the relative availability of other nutrients. The most famous of such relationships is the "Redfield ratio" developed by Alfred Redfield (1934). Redfield found that the proportions of carbon to nitrogen to phosphorus used by marine primary producers were 106C:16N:1P. As there is typically less than a 16:1 stoichiometry in bioavailable N vs bioavailable P, N is thought to be the primary limiting major nutrient over long time scales in the ocean. However, there are major regions of the surface ocean (where primary productivity takes place) that contain significant amounts of both bioavailable N and P. These are described as "high-nutrient low-chlorophyll" (HNLC) waters and are limited by the trace nutrient Fe (Moore et al. 2013). In freshwater environments, P is generally thought of as the primary limiting nutrient, especially since the implementation of P-limiting policies to combat eutrophication (Schindler et al. 2016).

There is also considerable evidence for nutrient co-limitation in the environment, where two or more nutrients are found in limiting concentrations. Several regions of the global surface ocean are nearly as depleted in P as N. Addition of only N to these environments results in only a small increase in biomass as compare to addition of both N and P. Other co-limiting nutrient pairs found in the environment have been N, P and Fe, N and Co, Fe and Si, and Fe and Zn (Moore et al. 2013).

Nutrient availability can differ greatly between environments. While Ca and S are plentiful in marine ecosystems, they can be limiting in terrestrial forests and croplands. Such limitation can be exacerbated by enhanced leaching caused by acid rain (St. Clair et al. 2008) and also by the release of toxic elements such as Al during leaching events that may prevent the uptake of Ca (Schaberg et al. 2001).

Organisms can in some cases ameliorate nutrient limitation in their environment. Although the Redfield ratio appears remarkably robust over most of the ocean (Anderson and Sarmiento 1994), individual organisms have shown a wide range of nutrient uptake ratios under simulated limiting conditions (Bertilsson et al. 2003), either by proportional reduction in the cellular production of high N content proteins or P-rich phospholipids or by the substitution of metals in

enzymatic systems (e.g., Co for Zn) (Moore et al. 2013). Over longer time scales, some organisms can evolve to reduce their relative requirements for certain elements (e.g., substituting S for P in membrane lipids) (van Mooy et al. 2009). In addition, organisms employ a wide range of strategies for collecting, storing, and concentrating scarce nutrient resources. These include storage as insoluble intracellular pools (polyphosphates) (Diaz et al. 2016), production of extracellular organic compounds to chelate and solubilize metals (Hopkinson and Morel 2009), and physical movement to gather nutrients from subsurface regions.

Nutrient Proxies

Patterns of nutrient availability in the surface ocean have been investigated using proxies as indicators of past biological productivity and CO_2 uptake (Deutch and Weber 2012). Commonly used proxies include Cd:Ca ratios in foraminifera shells (for P) (Boyle 1988) and the ^{15}N of organic N in sediments, biomarkers, and encased in diatom frustules (for bioavailable N and N-cycling processes) (Ren et al. 2012). Such studies have indicated significant shifts in global nutrient patterns during glacial maxima (Straub et al. 2013). The present-day environment is experiencing a large (2–3× pre-industrial levels) anthropogenic input of N and P from agricultural and industrial sources (Codispoti 2007). This is subsequently exported through runoff and riverine transport to coastal oceanic environments, resulting in the shift of several from oligotrophic (primary producer growth rates and biomass limited by nutrient availability) to eutrophic (containing high primary producer growth rates and biomass limited by light availability or other factors) states (Fulweiler et al. 2012).

Summary

Nutrients comprise a subset of elements and compounds required for life. Environments typically have one or more nutrients that may be considered as limiting or potentially limiting to organism growth. However many organisms can mitigate such limitations by adjustment of required nutrient ratios or substitution of a more abundant nutrient for a more limiting one.

Ocean Biochemical Cycling and Trace Elements

Hein J. W. de Baar, Steven M. A. C. van Heuven and Rob Middag
NIOZ Royal Netherlands Institute for Sea Research, Department of Ocean Systems (OCS), and Utrecht University, Den Burg, The Netherlands

Definition

Ocean biochemical cycling refers to the distribution of nutrients and bio-essential elements at low concentration that is controlled by their uptake by phytoplankton in surface waters, sinking and remineralization of organic remains in deeper waters, and subsequent redistribution by thermohaline circulation.

Introduction

Dissolved inorganic carbon (C as DIC) varies around ~2 millimoles [mM = 10^{-3} M] in seawater and is pivotal for life in the sea. Much less abundant are the nutrients nitrate and phosphate that occur in the micromole [μM = 10^{-6} M] range and are essential for each living organism. Also essential for life are several trace nutrient elements, notably Fe and Zn, that occur in the nanomolar [nM = 10^{-9} M] range or even lower such as Co in the picomolar [pM = 10^{-12} M] range. Several other trace elements also occur in the nanomolar [nM] to picomolar [pM] range. Finally a few ultratrace elements occur in the femtomolar [fM = 10^{-15} M] range in seawater.

The distribution of many of the chemical elements in seawater is strongly controlled by biological processes, not only in the modern ocean but also due to the major role of biological evolution in the chemical evolution of the oceans (Vernadsky 1926; Redfield 1958; Lovelock 1979; Holland 1984).

Ocean Biological Cycle Requires Bio-essential Elements

The primordial atmosphere and ocean did not comprise free O_2 (see ▶ Precambrian Geochemistry). In the mildly reducing Archean ocean (~3.8–2.5 Gy before present), the transition metals manganese (Mn), iron (Fe), cobalt (Co), nickel (Ni), copper (Cu), and zinc (Zn) would have been readily soluble as Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, $CuCl^{2-}$, and Zn^{2+}, respectively (De Baar and La Roche 2003; Saager et al. 1989; Lewis and Landing 1991), and would no doubt have been present at relatively high concentrations in this primordial ocean where reduced sulfide was also present (Turner et al. 2001). As the first life evolved, these transition metals were incorporated in many biochemical functions. As a result, *all* modern cellular organisms living today, prokaryotes and eukaryotes, comprise and hence require the following chemical elements in order of their typical abundance in the living cell:

$$C > N > P >>> Fe > Zn > Mn > Cu > Ni >> Co \quad (1)$$

The major biochemical functions are listed in Table 1.

The initially reducing ocean environment eventually became oxidizing as more and more free O_2 was generated by photosynthesis (Crowe et al. 2013) and the bio-essential trace elements, notably Fe and Mn, precipitated by oxidation. Notably Fe, which once was present abundantly in seawater and therefore incorporated in many biochemical functions during evolution, nowadays is in very low concentrations in seawater and often the limiting bio-essential element for growth of phytoplankton. Thus by producing O_2, the algae eventually themselves caused their own Fe limitation.

Within the marine ecosystem of today, the unicellular phytoplankton or algae and the zooplankton and bacterioplankton are the most abundant in terms of biomass. The net growth or net decomposition of the overall plankton pool corresponds to net loss or gain, respectively, of significant amounts of these nine bio-essential elements in the ambient

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

Ocean Biochemical Cycling and Trace Elements, Table 1 The nine chemical elements that are essential for life and their major biochemical functions, their symbols, and their names in bold print. Essential also relates to the concept that each one of these can occasionally be a limiting element for growth in conditions that may occur of very low availability, i.e., low abundance as per the concepts of limitation after Von Liebig (De Baar 1994). Please be informed that there exist several different types of superoxide dismutases, all with the same function but with quite different metal elements as cofactor. Not listed are hydrogen (H) that occurs in every biological molecule and oxygen (O) that also is very common notably in various organic functional groups; both are so very abundant in the water molecule (H_2O), i.e., never potentially limiting, that they are not being treated as essential elements. Sulfur is listed here, but is abundant as major sulfate ion in seawater and never bio-limiting. The uptake of Mg for chlorophyll is trivial compared to the very high background concentration at ~0.48 mol.L^{-1} of Mg in ambient seawater (Reynolds 2006). Next to the nine elements essential for all life (bold print) and S and Mg, also listed are six more elements that play a role in specific taxonomic groups, among which Si and Ca are most important for formation of hard parts (e.g., shells, frustules, corals) and Mo for N_2 fixation by diazotrophs. Compilation after Twining and Baines (2013) also based on Sunda (1989), Michibata and Sakurai (1990), Frausto da Silva and Williams (1994, 2001), De Baar and La Roche (2003), Wolfe-Simon et al. (2005, 2006), Bruland and Lohan (2003), Bruland et al. (2014)

Atomic number	Mass	Symbol	Name	Major biochemical function

seawater. The more the biology has an impact on the oceanic presence of an element, the more the distribution of such element deviates from salinity. Therefore the ocean distributions of these nine bio-essential elements are non-conservative, i.e., deviating from the constant proportions of the major elements that constitute the overall salinity (see entry ▶ Ocean Salinity, Major Elements, and Thermohaline Circulation).

Other Chemical Elements with a Biological Role

In addition several taxa of marine organisms also incorporate other chemical elements for biological functions (Table 1), and this may, more or less, affect the ocean distribution of such element.

Sulfur (S) is utilized by most organisms, but the background concentration of sulfate in seawater is very high and not really affected. Similarly the uptake of Mg for plant chlorophyll hardly affects the very high background concentration of Mg in seawater.

Bio-calcification is by organisms that secrete hard shells and skeletons of $CaCO_3$ in either crystalline forms of either calcite or aragonite. By removal of both Ca^{2+} and HCO_3^- from seawater, both are also somewhat nonconservative, somewhat because this biological role is small relative to the high abundance of Ca^{2+} and to a lesser extent HCO_3^- in seawater. The major calcite producers in the open ocean are the group of coccolithophorid phytoplankton and the foraminifera zooplankton. The most abundant pelagic aragonite producers are the pteropods, and aragonite also forms naturally in corals and in almost all mollusk shells.

The other major type of hard parts is the opaline silicon oxide (SiO_2) that is produced by the important group of the diatoms among the phytoplankton, which are deemed to represent in the order of ~40% of all primary production in the oceans, and the radiolaria among the zooplankton. The concentration of dissolved silicate in seawater is relatively

modest in the micromole [$\mu M = 10^{-6}$ M] range and non-conservative due to this role in biology. Therefore silicate is commonly classified with the other major nutrients nitrate and phosphate.

There are three more trace elements that have a known biological function in some organisms. Vanadium (V) has very rare biological functions in ascidians (sea squirts) and a few other organisms (Michibata and Sakurai 1990). Molybdenum (Mo) is essential for nitrogen fixation that is one of the important biochemical pathways that play a role in controlling the oceanic nitrogen inventory (La Roche and Breitbarth 2005). Cadmium (Cd) has been found to serve as the pivotal atom in the enzyme carbonic anhydrase of a few diatom species investigated thus far (Xu et al. 2008).

Brief Outline of Marine Ecosystem Cycling of Elements

The basis of the marine ecosystem is photosynthesis, i.e., the primary production in the oceans. This is by either (i) single-cell phytoplankton or (ii) multicellular macroalgae or (iii) the symbiontic zooxanthellae within coral structures. The single-cell phytoplankton can be either prokaryotes, that is, cells without a nucleus, or eukaryote cells that do have a nucleus. Multicellular macroalgae and single-cell zooxanthellae both are eukaryotes. Marine photosynthesis in the oceans tends to follow the overall reaction

$$\begin{aligned} &106\mathrm{DIC} + 122\mathrm{H_2O} + 16\mathrm{NO_3}^- + 1\mathrm{HPO_4}^{2-} \\ &\quad + (\mathrm{Mn, Fe, Co, Ni, Cu, Zn}) + \text{energy} \rightleftarrows \\ &\quad \left[(\mathrm{CH_2O})_{106}(\mathrm{NH_3})_{16}(\mathrm{HPO_4})_1(\mathrm{Mn, Fe, Co, Ni, Cu, Zn})\right]_{\text{organic biomass}} \\ &\quad + 138\mathrm{O_2} \end{aligned} \tag{2}$$

adapted after Redfield, Ketchum, and Richards (1963) but here also including the six bio-essential trace elements (Mn, Fe, Co, Ni, Cu, Zn) for which their very low relative amount is subject of research nowadays (see below section Trace Nutrient Elements). The resulting organic biomass is energetically rich and hence serves as a food and energy source for bacteria and animals in the reverse reaction (2), i.e., remineralization or respiration.

In a real phytoplankton bloom in surface waters or in the ensuing export of biogenic debris into the deeper waters, the element ratio values may deviate considerably from the values given in above Eq. 2. However due to deep ocean mixing, such deviations tend to "average" such that at any given station, the proportions are more close to those in Eq. 2, but still significant variations exist.

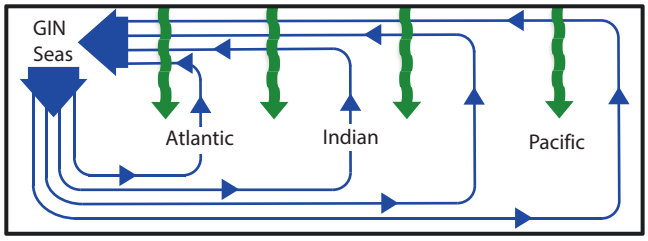
The above stoichiometric constants (i.e.,106, 16, 1, −138), known as the Redfield ratios, were at the time largely based on concentrations measured mostly in the North Atlantic region. Since then variations in ocean distributions of, for example, nitrate and phosphate, and the causes thereof have been discussed on the basis of then available larger more worldwide datasets (Fanning 1992; De Baar et al. 1997), and significant adjusted values of the stoichiometric constants have been derived and advocated (e.g., Anderson and Sarmiento 1994), as reviewed by Sarmiento and Gruber (2006) and others.

Photosynthesis occurs only within the upper euphotic zone of the oceans where it produces major amounts of dissolved oxygen O_2, which can become a few percent oversaturated in daytime during an intense phytoplankton bloom. The euphotic zone is defined as the depth the zone where sunlight is available to the 1% light depth as its lower boundary. In very clear waters, the depth of the euphotic zone can be as deep as 70–80 m. However due to the abundance of algae and other plankton, this is often much less due to "self-shading," while in nearshore waters, the presence of mineral particles (sand, silt) restricts light penetration to just a few meters or less.

The reverse reaction is respiration by either bacteria (here including the Archaea) or zooplankton and higher animals up the food chain to fish, octopus, sharks, and whales. This takes place throughout the water column. Most respiration takes place within the upper water column (<100 m depth) and remineralizes in the order of ~90% of all photosynthetic produced biomass. This respiration consumes dissolved O_2, but this is rapidly replenished from the overlying atmosphere. Also C, N, and P and Fe, Zn, Cu, Mn, Ni, and Co are returned to the seawater and can be used once again for photosynthesis. Overall this is a quite efficient ~90% recycling of resources.

However some ~10% of biomass settles, as mostly dead debris, into the intermediate waters (100–1000 m depth range) and here is remineralized almost completely. Of this remaining 10%, around ~9% of total primary production is remineralized, dissolved O_2 is consumed, and the concentration of O_2 decreases significantly. On the other hand, DIC, nitrate, phosphate, Fe, Zn, Cu, Mn, Ni, and Co are replenished again. Finally the ~1% of primary production that escapes remineralization within the upper 1000 m settles into the deep ocean and is the food supply for all life in the deep waters and in the sediments. Life in deep waters consumes some 0.9% and leaves merely ~0.1% for the benthic biota at the seafloor that consumes ~0.09% such that merely the leftover ~0.01% is buried more or less forever within the sediments.

When now combining (Fig. 1) this biological cycling of elements with the thermohaline circulation of the deep ocean, it is realized that throughout the long journey (lasting 1000–2000 years) of the deep water from the northern North Atlantic, around Antarctica, and eventually ending up in the North Pacific, there is a steady raindown of biogenic debris settling from the surface ocean into the intermediate and deep waters.



Ocean Biochemical Cycling and Trace Elements, Fig. 1 Combination of ocean circulation (*blue arrows*) with vertical settling of biogenic debris (*green arrows*) to explain the concept of accumulation of remineralized DIC and nutrients when deep water becomes older. This figure is redrafted in color after original of Broecker and Peng (1982). Formation of deep water in the Greenland-Iceland-Norwegian (GIN) Seas, see entry on ▶ Ocean Salinity, Major Elements, and Thermohaline Circulation. Notice that for simplicity of the graph, the deep water formation in the Antarctic Ocean is not shown

Within the intermediate and deep waters, the debris is remineralized to dissolved DIC and nutrients, and O_2 is consumed (Eq. 2 in reverse direction). The net result is a steady accumulation of DIC and nutrients, and steady decrease of dissolved O_2, from the relatively "young" northern North Atlantic Deep Water to eventually the quite "old" North Pacific Deep Water (Fig. 2).

Major Nutrient Elements: Nitrate, Phosphate, and Silicate

Due to net photosynthesis (Eq. 2) in surface waters, the dissolved **nitrate** (NO_3^-) and **phosphate** (HPO_4^{2-}) are removed, and very low, often bio-limiting, concentrations remain in surface waters of the temperate and tropical oceans (Fig. 2). In contrast these major nutrients are not fully depleted in surface waters of firstly the Antarctic Ocean and also the equatorial Pacific and the Subarctic North Pacific. These ocean regions represent some 30–40% of the world oceans and are known as the high-nutrient low-chlorophyll (HNLC) waters. For these HNLC waters, we now know that the combination of iron limitation and light limitation prevents the regional phytoplankton to develop blooms to full depletion of the major nutrients. For this HNLC condition, see the below section on "Trace Nutrient Iron (Fe)."

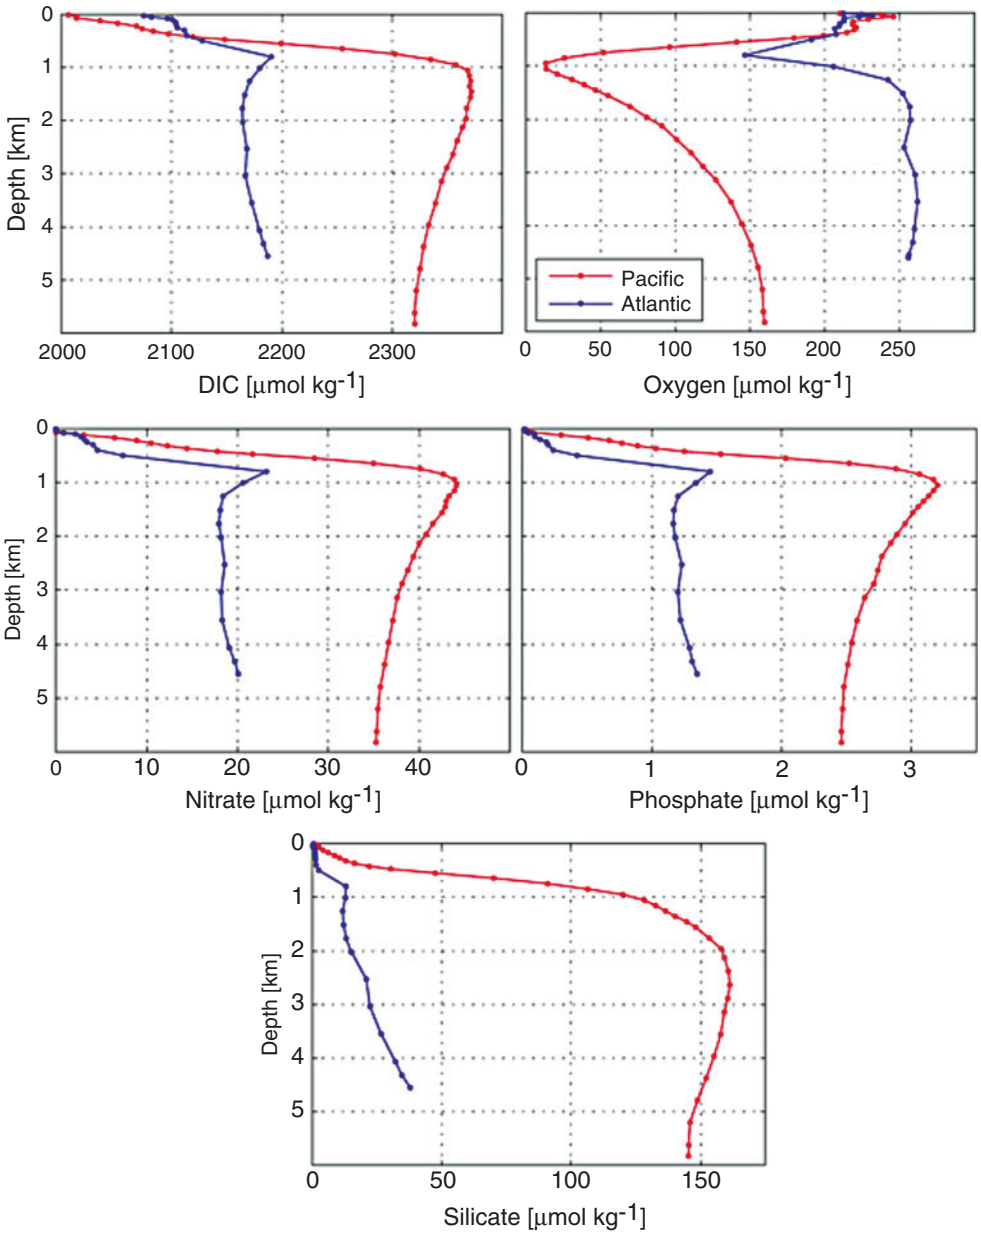
As noted earlier, silicate is an important nutrient for diatoms, which undergo seasonal blooms. At the end of winter, there are ample N, P, and Si in surface waters, and once more sunlight appears in early spring, massive diatom blooms take place. Rapidly within 3–4 weeks, all dissolved Si is removed from surface waters, and the spring diatom blooms collapse due to Si limitation.

Another aspect is that the opaline frustule remains intact in seawater with a low dissolved silicate concentration that actually is strongly undersaturated versus opal. This is because the living diatoms have an organic coating on the frustules, preventing direct contact with the undersaturated seawater and hence preventing dissolution. Yet upon senescence the diatom debris will settle downward and hence export into deeper waters. Meanwhile the organic coating also disappears, e.g., due to bacterial consumption, and the frustules tend to dissolve. The rate of dissolution depends strongly on the surface/volume ratio such that the smaller frustules of small diatoms rapidly disappear due to dissolution, but very large diatom frustules may rapidly (~100 m/day or more) sink all the way down the ~4 km deep water column to the seafloor. Thus overall the dissolution of settling diatom frustules is a balancing act between dissolution and settling, where size plays a key role. As a result the apparent typical depth of opal dissolution is deeper than for respiration input of nitrate and phosphate, and overall the concentration of dissolved silicate increases more steadily with depth (Fig. 2). Again in combination (Fig. 1) with deep circulation, the dissolved silicate in the deep North Pacific is about threefold higher than in the deep North Atlantic (Fig. 2).

At locations where intense blooms of large-size diatoms occur in surface waters, the rain rate of settling opal dominates the sedimentation at the seafloor. Here thick layers of opaline sediments accumulate. Even bottom waters with the highest dissolved silicate at ~150 μM still are undersaturated versus opal, such that the deposit tends to dissolve. This leads to even higher concentrations in the pore waters within the sediments, and the pore water reaches equilibrium such that from there on, the opal remains preserved.

Within the Antarctic Ocean, there is major upwelling of deep waters, bringing ample supply of major nutrients N, P, and Si to the euphotic zone in the surface waters. The circumpolar Antarctic polar Front is the major region where large diatoms utilize this ample supply and grow intensely (Smetacek et al. 1997), and as a result, the underlying sediments comprise thick layers of opal, representing the major (~70%) ocean sink of dissolved Si. When comparing the river input of dissolved Si with the overall dissolved Si budget of seawater, one derives an oceanic residence time of ~10,000 years for Si (Tréguer and Rocha 2013), as compared to the ~1000 years' time of ocean mixing. This implies that, on average, once a Si atom has entered the oceans via rivers, it will be at the surface once every ~1000 years and from there on take part in the cycle of diatom growth and dissolution. This cycle will occur some nine to ten times before the SiO_2 is buried "forever" in the thick layers of opaline diatom ooze.

It has been estimated that worldwide, the cycles of N and Si are of comparable magnitude, i.e., their average ocean cycling is in a Si:N = 1:1 ratio or thereabout (Sarmiento and Gruber 2006). However it is less well realized that large variations exist; most notably the Antarctic diatoms tend to be very heavily silicified such that a ratio Si:N in the 2–3 range is more valid here. Given the key role of large Antarctic diatoms in the global Si cycle (Tréguer and Rocha 2013), and



Ocean Biochemical Cycling and Trace Elements,

Fig. 2 Vertical distributions of the DIC, dissolved oxygen, and the major nutrients nitrate, phosphate, and silicate in the Northwest Atlantic Ocean (*blue*) versus the Northeast Pacific Ocean (*red*). Higher DIC in deep Pacific versus deep Atlantic is due to (i) respiration of organic matter plus (ii) dissolution of $CaCO_3$. Higher nitrate and phosphate in deep Pacific versus Atlantic due to respiration, also explaining the opposite lower dissolved oxygen. Data for Bermuda Atlantic Time-Series Station (BATS) of GEOTRACES cruise GA02-64PE321 aboard RV Pelagia, station 21 (31°45.92′N, 64°04.95′W at 13 June 2010), after Rijkenberg et al. (2015), is available at (www.geotraces.org). Data for North Pacific is from RV Melville cruise 318M2004 along WOCE line PO2, station 119 (30.00°N,159.70°W at 4 August 2004), is available in GLODAP-2 via CCHDO. (https://cchdo.ucsd.edu/cruise/318M200406). Circulation age (Matsumoto 2007) of the deep waters (>1500 m) at the North Atlantic station is ~200 years; the ^{14}C age is ~800 years. Circulation age of the deep waters (>1500 m) at the North Pacific station is ~1100 years; the ^{14}C age is ~2100 years

the key role of the Antarctic Ocean in world circulation, this should not be, but often is, overlooked in simulation modeling of the world ocean biogeochemical cycles.

Trace Nutrient Elements

Each of the trace elements in the oceans does have one or more sources and one or more sinks, respectively, briefly summarized in Panel A (also see entry ▶ Ocean Salinity, Major Elements, and Thermohaline Circulation, its Fig. 1).

The importance in biology of the six bio-essential trace metal elements (Table 1) is in the order Fe > Zn > Mn > Cu > Ni >> Co (as per Eq. 1). However here Fe and Mn are together discussed first, given the great significance of redox chemistry and hydrothermal supply for both elements. Next Zn, Cu, Ni, and Co are discussed and finally the three minor "biological" trace metal elements V, Mo, and Cd that play a special role for some, but by no means all, organisms.

Iron (Fe) is by far the most important trace metal transition element in biology, with many biochemical functions. Here the relative ease of redox between Fe(II) and Fe(III) is pivotal in, for example, electron transfer within the living cell (Table 1).

In the modern O_2-rich ocean waters, the dissolved Fe in 0.2 µm filtered seawater is in the Fe(III) oxidation state and is predominantly (~99%) bound to organic ligands forming Fe (III)-organic complexes. The remaining ~1% is dominated by

the 0.92% inorganic species $Fe(OH)_{3(dissolved)}$ and further 0.045% $Fe(OH)_4^-$, 0.037% $Fe(OH)_2^+$, and merely 3×10^{-11}% free Fe^{3+} ion. In the same O_2-rich seawater conditions, the thermodynamics of the redox half reaction

$$Fe^{2+} \rightleftarrows Fe^{3+} + e \quad (3)$$

predicts the ratio Fe^{2+}/Fe^{3+} of these free ions is $10^{0.42}$ or 2.63 (De Baar and De Jong 2001). Taking this ratio and given the above speciation of Fe(III) states and the speciation of Fe (II) states (Panel B), the overall ratio Fe(II)/Fe(III) is in the order of 10^{-12} in O_2-rich seawater. When now taking a mildly anoxic environment without O_2 and with a sulfide concentration of 10 μM such as in pore waters of reduced marine sediments, Eq. 3 now yields the free ion ratio Fe^{2+}/Fe^{3+} of $10^{17.4}$. Taking into account the speciation, the overall ratio Fe(II)/Fe(III) is in the order of 10^7 in mildly reducing anoxic pore waters. Thus from open ocean waters to mildly anoxic pore waters, the ratio is shifted by a dramatic factor of 10^{19}. This major shift is the key to understanding the driving redox forces for the cycling of Fe in the oceans. Finally, deeper in the sediments at higher S^{2-} concentrations, there occurs precipitation of various iron sulfide deposits, thus removing Fe from solution in pore waters. Thus there is an optimal depth within the sediment where O_2 is absent and S^{2-} is still quite low where mobilization of Fe is optimal for Fe diffusing upward into overlying waters.

Panel A. External sources and sinks of dissolved trace metals in ocean waters

The external sources and sinks, and the several processes within the ocean waters (Panel B), all may affect the distribution of any given trace element in ocean waters.

River inflow is modified by estuarine mixing of the fresh river water with saline seawater. As a result there is massive flocculation of colloids (defined in Panel B) from the original river water. Most of the river inflow of many trace metals, notably Fe, is removed and deposited in estuarine sediments, such that only a small percentage truly enters the oceans but still can be traced over long distances (Klunder et al. 2012b).

Aeolian deposition into surface waters of dust coming from the continents may be either as wet deposition with rainwater or as dry deposition. Rainwater has a wide range of pH values with final deposition in the pH range 4–7, i.e., acidic and more favorable for partial dissolution of metals from dust than surface seawater at pH ~8 (Jickells and Spokes 2001).

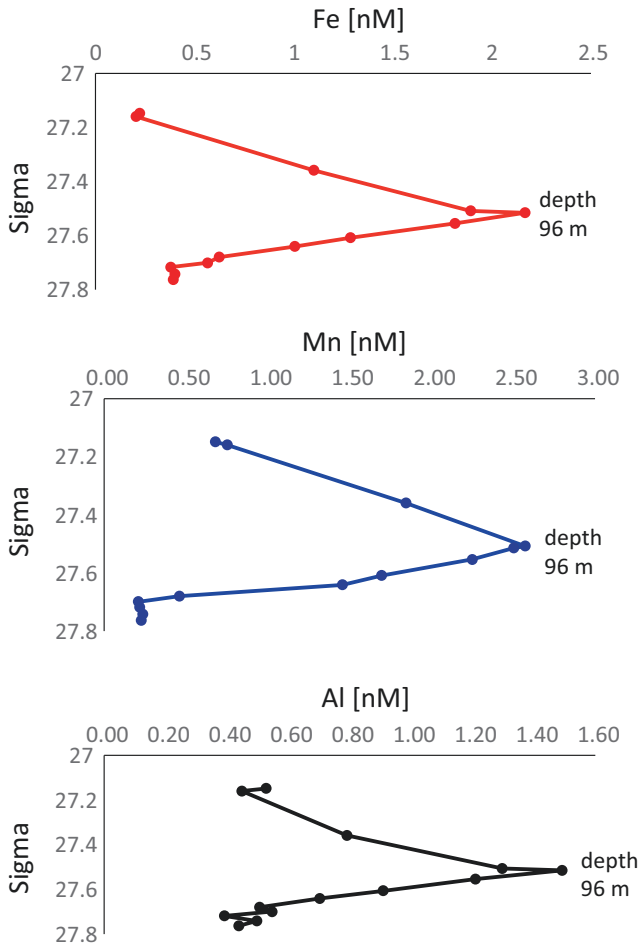
Oxidation and reduction (redox) affects those metals that have two or more oxidation states within the overall redox range of the oceans, sediments, and hydrothermal vents. In the modern O_2-rich ocean, the major dissolved states Mn^{2+} and Fe^{3+} are thermodynamically unstable and tend to deposit solid oxyhydroxides such as MnO_2 and $Fe(OH)_3$ but more often some poorly defined amorphous Fe-Mn oxyhydroxide phases. Within marine sediments the respiration of organic matter (reverse Eq. 2) by bacteria consumes the available O_2 in pore waters, and supply from overlying waters is slow due to restricted vertical diffusion. Once the dissolved O_2 is almost all removed, other specialized bacteria take over and use other oxidants (electron acceptors) that are more favorable under the conditions. These are in sequence first the dissolved nitrate NO_3^- being reduced to ammonia (NH_4OH) with nitrite (NO_2^-), nitrous oxide (N_2O), and N_2 as intermediates or also end products. Once nitrate is depleted, there secondly follows the reduction of solid MnO_2 to high concentrations of dissolved Mn^{2+} and thirdly reduction of solid $Fe(OH)_3$ to high Fe^{2+} concentrations. These very high concentrations of Mn^{2+} and Fe^{2+} in the pore waters diffuse upward in bottom waters from where they are by ocean lateral mixing transported to the open ocean, with steady loss due to the very slow or slow oxidation of Mn^{2+} and Fe^{2+}, respectively. Similar redox chemistry is known to take place for dissolved cerium Ce^{3+} versus solid oxidized CeO_2. Deeper in the sediment, there is reduction of the abundant sulfate SO_4^{2-} to the reduced sulfite S^{2-} state. Latter sulfide leads to precipitation of generally very insoluble FeS, CuS, ZnS, and CdS.

Hydrothermal vent effluents at mid-ocean ridges have a high temperature in the 300–400 °C range and are very strongly reducing. This is accompanied by very high concentrations of reduced Mn^{2+} and Fe^{2+} as well as elevated concentrations of dissolved Co, Cu, Zn, Ag, Cd, and Pb (Von Damm et al. 1985). Once in contact with ambient, cold (2 °C), O_2-rich seawater, most of the Fe and Mn precipitate again as oxyhydroxides, also including the other metals, this leading to metalliferous sediments on the crest of mid-ocean ridges.

(*continued*)

For example, near Elephant Island, Antarctica, there is a distinct plume of dissolved Fe coming off the extensive shelf sediments, clearly discernible and accompanied by higher levels of Mn and Al versus the low background concentrations (Fig. 3).

When the bottom waters overlying anoxic sediments also have a low O_2 content, such as in the 100–1000 m depth range of the Northwest Indian Ocean or in the subsurface waters at the East Equatorial Pacific, this dissolved Fe can be



Ocean Biochemical Cycling and Trace Elements, Fig. 3 Distinct plumes of coinciding elevated dissolved Fe, Mn, and Al coming off the shelf near Elephant Island, Antarctica. Concentrations in nanomolar per liter [nM = 10^{-9} Mol.L^{-1}]. Vertical axis is sigma for density (e.g., sigma = 27.6 for density = 1027.6 kg.m^{-3}) increasing steadily with increasing depth. The maximum concentrations are at ~96 m depth (After Klunder et al. (2014). Data in Geotraces IDP 2014 (www.geotraces.org))

maintained at elevated concentrations in the order of 1–6 nM (Landing and Bruland 1987; Saager et al. 1989; Vu and Sohrin 2013).

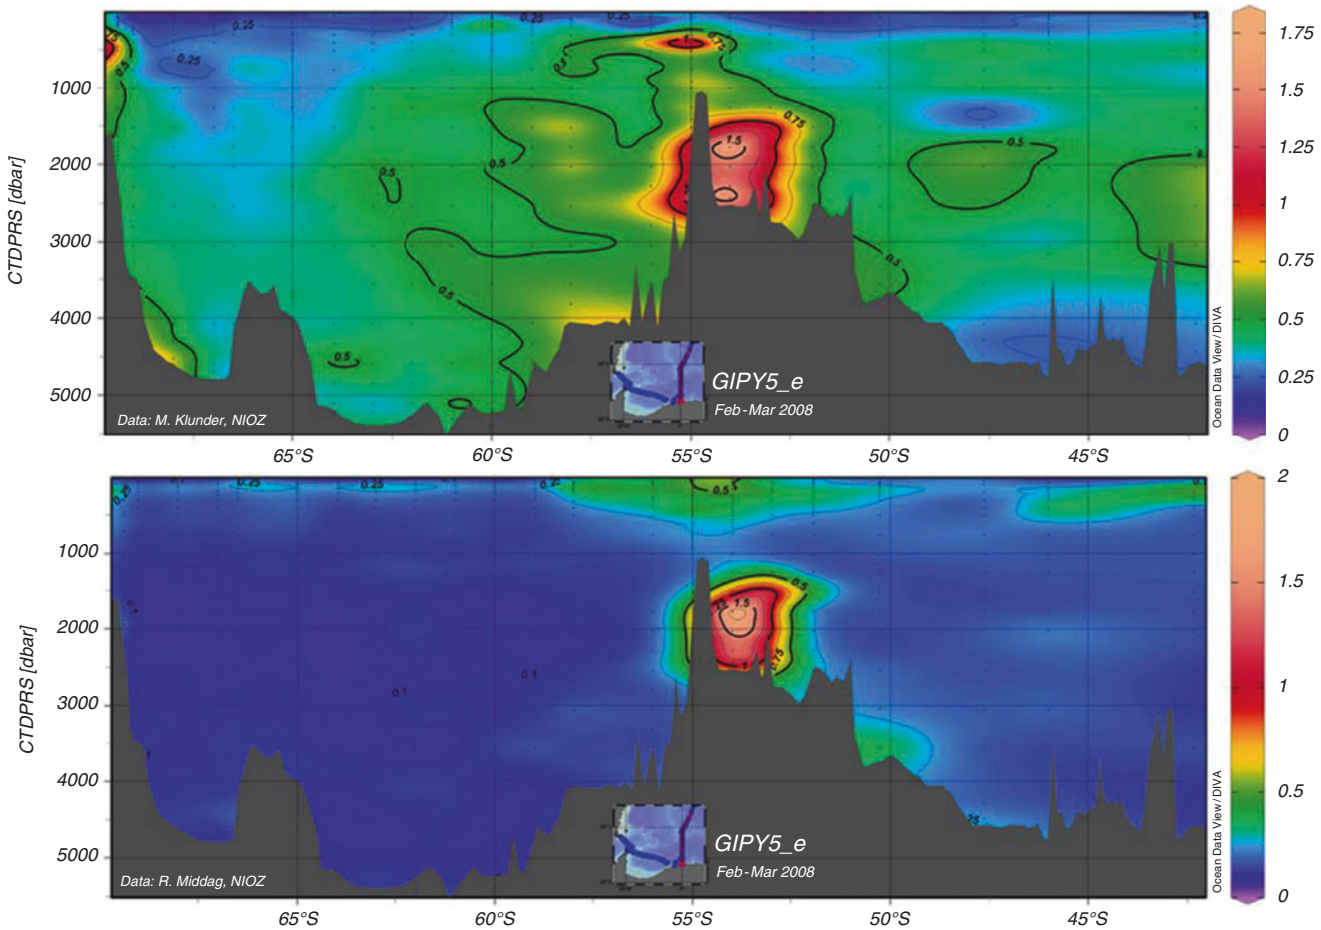
In the high temperatures (300–400 °C) of extremely reducing hydrothermal effluents, the concentration of dissolved Fe may be as high as 1–2.5 millimolar (e.g., Von Damm et al. 1985, 1998), i.e., some three to eight million times higher than ambient deep ocean water. However due to mixing with ambient cold and oxidizing seawater, this is rapidly removed by oxidation and sedimentation on the ridge crest forming metalliferous sediments. Nevertheless the hydrothermal Fe source is so highly enriched that, despite the major loss at the ridge crest sediments, the plume can be traced at million-fold lower 1–3 nM Fe concentrations over hundreds of kilometers versus the low background concentration of Fe at ~0.3–0.4 nM in deep waters. For example, at the Antarctic Zero Meridian, there is an extensive ~1200 km wide plume of hydrothermal Fe near the Bouvet triple junction where three mid-ocean ridges meet (Fig. 4) and where undoubtedly intense hydrothermal effluents must exist. This plume is accompanied with high Mn also from hydrothermal input. Similarly at the Arctic Gakkel Ridge, an extensive hydrothermal plume of both Fe and Mn was found (not shown; Klunder et al. 2012a, Middag et al. 2011a), extending more than 500 km. Similarly extended plumes have been recently reported for the Pacific Ocean (Resing et al. 2015). Over that extent the concentrations of dissolved Fe and Mn steadily diminish due to combination of continued oxidation as well as dilution by mixing with ambient waters low in Fe and Mn. The decrease of dissolved Fe continues until a threshold concentration is reached that equals the concentration of Fe-binding organic ligands that from there on maintain the remaining dissolved Fe in solution. For assessing the net hydrothermal supply of Fe to the world oceans at large, this far-field extent of the relatively low-level (1–3 nM) plumes (Klunder et al. 2011, 2012a, 2014) with their slow chemical changes is most relevant.

The longest ocean trace element section thus far is in the West Atlantic Ocean and nicely shows all the processes contributing to the distribution of dissolved Fe (Fig. 5). There is a hydrothermal plume at ~2500 m depth just south of the equator that despite the long westward distance away from the Mid-Atlantic Ridge still is discernible versus the low 0.4–0.6 nM background deep dissolved Fe. Just north of the equator (~10 °N), the subsurface Fe maximum at 200–1000 m depth coincides with a strong O_2 minimum suggesting a reductive source of the elevated Fe. These O_2 minimum waters flow westward ("into the paper"), then turn around clockwise, and more northerly (~40 °N) become an eastward return flow that still carries the elevated Fe signal.

Sahara dust input causes elevated dissolved Fe in surface waters in the 20–30 °N region, accompanied by higher Mn and Al as well, where Al is the classical tracer of dust supply (Fig. 6). This high Fe in otherwise oligotrophic (nutrient-depleted) surface waters does support N_2 fixation by *Trichodesmium* phytoplankton in the Sargasso Sea near Bermuda.

Iron Limitation of High-Nutrient Low-Chlorophyll (HNLC) Regions

There are three regions where major nutrients N, P, and Si are in ample supply in surface waters, but still phytoplankton blooms are not able to utilize this resource. These are the Southern Ocean and the equatorial Pacific and Subarctic North Pacific, together representing ~30% of ocean surface waters. The hypothesis of Fe limitation of these HNLC regions was first tested in Fe addition experiments in bottle



Ocean Biochemical Cycling and Trace Elements, Fig. 4 *Upper* graph: dissolved Fe at a 3000 km long section at the Antarctic Zero Meridian after Klunder et al. (2011). Vertical axis is pressure [decibar] that is virtually identical to depth [meter]. Notice very low Fe in surface waters notably near the Antarctic continent, vertically separated from the enriched hydrothermal plume at great depth >1000 m. *Lower* graph: dissolved Mn along the same section after Middag et al. (2011b). Notice very low Mn in surface waters notably near the Antarctic continent, vertically separated from the enriched hydrothermal plume at great depth >1000 m. The elevated Mn at the surface at 54 °S is due to a recent aeolian dust event, also found for Fe at the surface (less distinct in the above contour plot) and dissolved Al at the surface (not shown) (Data in Geotraces IDP 2014 (www.geotraces.org). Graphics www.eGeotraces.org using Ocean Data View (R. Schlitzer))

incubations in the Subarctic North Pacific (Martin and Fitzwater 1988) and in the Southern Ocean (De Baar et al. 1990; Buma et al. 1991). Next at the Polar Front, it was found that local naturally elevated Fe concentrations made the difference in stimulating three distinct blooms of phytoplankton accompanied by uptake of CO_2 (de Baar et al. 1995; Smetacek et al. 1997).

These and other findings led to a suite of large-scale *in situ* Fe fertilization experiments where an area of 50 km^2 or even 200 km^2 ocean surface water was fertilized with dissolved Fe. The major finding was that indeed, Fe addition did always stimulate phytoplankton blooms, but light limitation due to deep mixing in storms did also play a key role (de Baar et al. 2005). Therefore we now know that the phytoplankton in the HNLC regions is limited by a combination of light and iron limitation. The surface water values of Fe in the Antarctic (Fig. 4) are very low, notably ~0.1 nM near the Antarctic continent. There may be several reasons for this. Here the very deep (~1500 m) shelf under the continental ice sheet extending far over the sea is exceptional as it is not a source of Fe to overlying waters. The ice sheet acts as a cap largely preventing any biochemistry in the water column, and hence the underlying sediment is not a source of reduced Fe. In addition, the low dissolved Fe around Antarctica is due to very low dust input.

Panel B. Processes within ocean waters affecting the distribution of dissolved trace metals

Colloids. Throughout natural waters, both freshwater and seawater, there exists a continuum of physical/chemical state from truly dissolved to a wide range of colloidal sizes to truly particles. In the open

ocean, colloids can be defined by ultrafiltration methods to be in the ~0.02–0.2 μm (micron) size classes (Nishioka et al. 2001, 2005), the pool <0.02 μm then is defined as the soluble fraction, and all sizes above 0.2 μm are defined as particles. Colloids can play a significant role, for example, formation of Fe colloids in hydrothermal plumes. However due to space restrictions, here we must largely ignore the colloids and operationally define the dissolved trace metals by the size cutoff of 0.2 μm pore size filtration devices.

(*continued*)

Chemical speciation of dissolved trace metals results from the interaction of the free metal ion, for example, Fe^{3+} interacts with those ions of seawater to which it has great chemical affinity. For example, taking into account only the inorganic ions in seawater, the total dissolved Fe comprises 92% $Fe(OH)_{3(dissolved)}$, 4.5% $Fe(OH)_4^-$, 3.7% $Fe(OH)_2^+$, and merely 3×10^{-9}% free Fe^{3+} ion (Millero et al. 1995). Thus the concentration of free Fe^{3+} ion is a factor 3×10^{-11} less abundant than the total dissolved Fe(III). For the reduced Fe(II) state that can occur due to

(*continued*)

photoreduction (see below), there are 76% free Fe^{2+} ion, 23% $FeCO_{3(dissolved)}$, and minor concentrations of $FeHCO_3^+$, $Fe(CO_3)_2^{2-}$, and $Fe(OH)^+$ ions. Similar inorganic speciations have been calculated for all trace metal elements in seawater (Turner et al. 1981; Byrne et al. 1988). These calculations also include other divalent metals like Co(II), Ni(II), Cu(II), and Zn(II), trivalent metals like Al(III), and the REE(III), as well as for those metals existing as oxyanions such as V existing predominantly as vanadate HVO_4^{2-} ion, Cr existing mostly as chromate CrO_4^{2-} ion, and Mo existing mostly as molybdate MoO_4^{2-} ion.

Organic complexation of the free ion by dissolved organic ligands (largely unknown functional groups) has been found to be very significant for several trace metals, most notably Fe, Zn, Cu, and Co, that also happen to be bio-essential trace elements, as well as Cd that shows a strong relationship with the biological cycle. Using voltametric techniques it has been found that ~99% of dissolved Fe is organically bound (Gledhill and Van den Berg 1994; Gledhill and Buck 2012). The above inorganic speciation thus represents merely ~1% of the total dissolved Fe. Similarly 98% of dissolved Zn is bound by organic complexes. Notably for Fe this organic complexation is favorable for maintaining dissolved Fe in solution; without the stabilization by organic complexation, most of the dissolved Fe would tend to be removed by oxidative precipitation.

Photoreduction within the upper euphotic zone of the oceans is known to cause a (diurnal) shift from the Fe(III) to the Fe(II) oxidation state, with implications for overall distribution of Fe in different pools, and hence the availability of Fe for uptake by biota (Rijkenberg et al. 2004, 2005, 2006). Similarly photoreduction of particulate MnO_2 may lead to Mn dissolution such that the dissolved Mn^{2+} in surface seawater increases (Sunda et al. 1983; Sunda and Huntsman 1988, 1990, 1994) in favor of uptake by biota.

Uptake by phytoplankton (and also by bacteria and viruses) of bio-essential elements Mn, Fe, Co, Ni, Cu, and Zn is a major pathway in the ocean cycling of these trace metals, as per Eq. 2. Net result is the removal of dissolved metals from the euphotic zone (the upper water down to 1% penetration of incoming sunlight, typically 40–80 m depth in open oceans) in surface waters (all waters shallower than 100 m depth). The true internal metal content of phytoplankton has been difficult to distinguish from metals adsorbed at the outside of the cell; see below adsorptive scavenging. However novel irradiance techniques using a

(*continued*)

synchrotron have been a breakthrough in being able to clearly discern internal "true biological" metal atoms from those adsorbed external on the outside of the cell wall (Twining 2003; Twining and Baines 2013). Upon senescence by nutrient limitation and/or grazing or viral lysis, some "dead" biogenic debris settles down into intermediate waters (100–1000 m depth) where most is remineralized and the metals return to the dissolved state. Particles settling below 1000 m further mineralize and further return the metals to the dissolved state.

Adsorptive scavenging is the removal of dissolved trace metals from seawater by adsorption onto the outer surfaces of settling biogenic particles. This is very effective for adsorption of positive ions; the negatively charged oxyanions are not affected. Some redox metals, notably Mn and Fe, will next oxidize further at this surface, and such freshly formed Fe-Mn oxyhydroxides are known to be very effective adsorbing agents for a suite of other trace metals. Otherwise organic functional groups of the particles also are deemed to be effective scavengers (Balistrieri et al. 1981). Upon settling into intermediate (100–1000 m depth) and deep (>1000 m depth) waters, the biogenic debris is respired, and the trace metals are remineralized back again as dissolved metals into the seawater. Some trace metals immediately adsorb again onto other deep particles and are once again removed from solution. From concentrations of dissolved trace metals that remain in surface waters, it is impossible to derive how much has been removed by true internal biological uptake and how much removed by external adsorptive scavenging. However in the deep waters, one may discern deep water scavenging simply when the concentration of a bio-essential trace metal is less than expected from the concentration of a major nutrient phosphate or silicate. From such approach we know that there is significant deep water scavenging of Fe, Mn, Cu, and Ni, but apparently not of Zn and Cd.

Manganese (Mn) is essential in several metalloproteins within marine phytoplankton (Table 1). In seawater it exists in the reduced [Mn^{2+}] state that in the well-oxygenated open ocean is prone to slow oxidation to the insoluble MnO_2. However in reducing sediments of the continental shelf, the MnO_2 dissolves again to high levels of [Mn^{2+}] in pore waters, and the [Mn^{2+}] diffuses into overlying waters, where it can be traced over long distances (Wu et al. 2014). In an oxygen minimum zone, this higher [Mn^{2+}] can be mixed over even longer lateral distances, e.g., in the East Equatorial Pacific (Martin and Knauer 1985) and the Northwest Indian Ocean (Saager et al. 1989).

In the open ocean, the surface water concentrations of dissolved Mn can range up to ~2–4 nM due to partial dissolution of aeolian dust supply from land. Photoreduction of Mn in the euphotic zone is known to enhance such dissolution (Sunda et al. 1983; Sunda and Huntsman 1988, 1990, 1994). The ~2–4 nM concentrations are deemed to be in ample supply for the needs of phytoplankton. In surface waters of the remote Southern Ocean with low dust input, the dissolved Mn is considerably lower in the 0.1–0.9 nM range (Fig. 4; Middag et al. 2011b, 2012, 2013). The lowest values in the 0.04–0.12 nM range are near the Antarctic continent, where the very deep (~1500 m) shelf under the extended continental ice sheet is exceptional as it is not a source of Mn (Middag et al. 2011b), as opposed to the extensive shelves around the Antarctic Peninsula acting as a source of Mn (Fig. 3) due to reductive dissolution in the anoxic pore waters (Middag et al. 2012, 2013).

In Antarctic surface waters, the net removal of dissolved Mn covaries with net removal of part of the dissolved phosphate, with an apparent Mn:P uptake ratio by plankton in the 0.36–0.39 $\times$ 10^{-3} mol.mol^{-1} range (Middag et al. 2011b, 2013). In the deep waters of Atlantic and Antarctic Oceans, the dissolved Mn is remarkably uniform at very low 0.1–0.15 nM concentrations (Van Hulten et al. 2017). However, Mn plumes with much higher concentrations up to 3 nM or even 10 nM (Arctic Gakkel Ridge) exist over mid-ocean ridges due to hydrothermal input, the plumes extending several hundred kilometers horizontally and almost 1000 m above the ridge crest (Middag et al. 2011a, b; Resing et al. 2015, Wu et al. 2014). Sampling with submersibles of the emitting high temperature strongly reducing vent fluid gives very high Mn concentrations up to ~1 millimolar concentration, i.e., up to ten million times the low background dissolved concentration of ~0.1 nM (Von Damm et al. 1985, 1998 versus Middag et al. 2011b, 2013; Van Hulten et al. 2017). Just like for Fe (see above), most of the hydrothermal Mn deposits rapidly in metalliferous sediments at the ridge crest, yet the million times lower 1–10 nM concentration remaining in the plume can be seen over more than 1000 km away from the ridge crest, versus the low 0.1 nM background concentration in deep waters (Fig. 4).

Zinc (Zn) is the second most important trace metal element in biology. Its most important function is in the enzyme carbonic anhydrase that enhances the reaction rate some ten million times for the conversion of bicarbonate HCO_3^- ion to CO_2. For phytoplankton this is most helpful as it allows to take up not only CO_2 but also HCO_3^-, which is far more abundant, and convert the latter to CO_2, which is necessary as only CO_2 is utilized in photosynthesis. Thus at conditions of relatively low ambient $[CO_2]_{aqueous}$, the algae can also assimilate HCO_3^-.

The divalent Zn(II) state in seawater is ~98% bound by organic complexation with dissolved organic molecules; the remaining is ~1.5% free [Zn^{2+}] ion and ~0.5% inorganic species [$ZnCO_{3(aqueous)}$] and [$ZnSO_{4(aqueous)}$]. Presumably the 98% organic complexation helps to maintain the Zn in solution because the free [Zn^{2+}] ion is prone to loss due to adsorptive scavenging on marine particles.

The ocean distribution of dissolved Zn very closely follows that of major nutrient silicate (Fig. 5). This is consistent with its biochemical functions (Table 1), and perhaps the close relation with silicate hints at a key biological relationship with diatoms. Surface water concentrations are low in the order of 0.1 nM but higher at 2–3 nM in the Antarctic Ocean, such that this is not only a HNLC region for major nutrients but also for trace nutrient Zn. Deep water concentrations increase from 2 nM in the deep North Atlantic to 6–8 nM in the deep Antarctic to 10 nM in the deep North Pacific.

Copper (Cu) has several functions in biology (Table 1). In seawater the divalent Cu(II) state is virtually 100% bound by strong organic complexation. There is ample total dissolved Cu at ~0.5–1.5 nM in surface waters of the North Atlantic, and therefore Cu is deemed not to be limiting for phytoplankton growth, unless the very strong organic complexation would hinder plankton uptake. The concentration increases steadily with depth to 2.0–2.5 nM at around 4000 m depth. This steady increase resembles that of major nutrient silicate. Nevertheless when comparing the deep North Atlantic with the deep North Pacific, the steady increase of dissolved silicate with increasing age of deep water is hardly followed by an increase of dissolved Cu in older deep waters of the Pacific. Therefore it is generally assumed that there is net scavenging removal of Cu from deep waters that prevents Cu from accumulating a high dissolved concentration in old deep waters.

Nickel (Ni) has perhaps the least biochemical functions of the bio-essential trace elements (Table 1). In seawater Ni dominantly exists as the free hydrated Ni(II) state. The vertical distribution of Ni is perhaps best described by a correlation with both phosphate and silicate. There is ample Ni at ~2 nM in surface waters; therefore Ni is deemed not to be a limiting element for phytoplankton growth.

Cobalt (Co) has a key functionality as the metallocenter of vitamin B12 and can also substitute for Zn in carbonic anhydrase. Cobalt exists in the Co(II) state in seawater and is for ~90% bound as Co-organic complexes. Cobalt also has similar redox chemistry to that of iron and manganese. The oxidized Co(III) state is highly insoluble due to precipitation of Co(III) oxyhydroxides. Conversely, at low ambient O_2, this may be reduced again, and Co(II) is remobilized into the dissolved state. Indeed concentrations of Co, Fe, and Mn are considerably higher in O_2 minimum zones, such as off West Africa (Noble et al. 2012).

Vanadium (V) exists in seawater primarily as the vanadate oxyanion [HVO_4^{2-}] (Butler 1990) at a concentration between 30 and 36 nmol.kg^{-1} (Collier 1984). The role of

V in proteins found in blood cells of ascidians (sea squirts) is very special (Michibata and Sakurai 1990) and most intriguing but so unique that it does not affect the concentration of V in ocean waters.

Molybdenum (Mo) is together with Fe required for the process of N_2 fixation by the so-called diazotrophs (N_2 fixers) among which *Trichodesmium* is the "model" organism (La Roche and Breitbarth 2005). Molybdenum exists in seawater as Mo(IV) in the molybdate oxyanion state [MoO_4^{2-}] and as such not prone to adsorptive scavenging loss. The high concentration in seawater at ~104 nM renders Mo the most abundant trace metal element in the oceans, where it is deemed a conservative element varying only slightly as function of salinity (Collier 1985). Given this high abundance, Mo is by no means limiting for growth and functioning of the diazotrophs; however, the other trace element Fe as required for N_2 fixation is often very low and limiting in surface waters. The process of N_2 fixation also requires high seawater temperatures above ~20 °C. In the warm waters of the Sargasso Sea, directly under the influence of major deposition of Fe-rich aeolian dust derived from the Sahara, there exists an important niche for *Trichodesmium* to form major blooms. Recently the requirement of temperatures above ~20 °C has been challenged (Rivero-Calle et al. 2016).

Cadmium (Cd) was long considered to have no biological function, at most toxic, as it may as a look-alike of Zn occupy, and hence disable, places in the cell where Zn ought to be and function. However the discovery of the very close relationship of dissolved Cd with major nutrient phosphate in the oceans (Boyle et al. 1976; Bruland 1980) led to more investigations of interactions between Cd and phytoplankton. Now we know that in fact Cd can substitute for Zn in phytoplankton, in conditions where there is not enough Zn available. Moreover there exist intrinsic Cd-cofactored carbonic anhydrases, for certain diatoms thus far studied, i.e., sometime during biological evolution, this true Cd-based enzyme has developed (Lane and Morel 2000; Lane et al. 2005; Xu et al. 2008). In seawater the Cd(II) exists for some 64% as an organic complex, the remaining Cd(II) exists for some 30% as chlorine inorganic species, and merely 3% free [Cd^{2+}] ion.

In general surface water concentrations of Cd are very low indicating uptake and/or scavenging removal by plankton. However surface waters of the Southern Ocean have high dissolved Cd, thus here also mimicking the HNLC condition of phosphate. The North Atlantic Deep Water (NADW) originates from Atlantic surface waters and has relatively low concentrations of both Cd and phosphate, as opposed to the high concentrations in the Antarctic Intermediate Water (AAIW) and Antarctic Bottom Water (AABW) coming from the south and flowing northward.

An Update on the Extended Redfield Stoichiometry

The stoichiometry of the nine bio-essential major and trace elements most likely varies considerably between phytoplankton species, as well as due to some degree of adjustment that the algae can make vis-à-vis availability of each of these nine essential elements in the ambient seawater. Conversely depending on the essential elements being more or less available, the composition of the plankton will vary, albeit within certain limits below which the cell cannot function anymore.

During more than 25 years, it has been, and still very much is, a challenge to resolve the stoichiometric "constants" of the six bio-essential trace metals (e.g., Bruland et al. 1991; De Baar et al. 2008). In an excellent recent review by Twining and Baines (2013), the various approaches have been synthesized. From this the order of magnitude values are listed in Table 3, by no means as the final truth but merely as an indication of the current state-of-the-art.

In general the mixing of ocean waters tends to some extent to "average" the wide variability in living plankton and settling biogenic debris. Nevertheless the distributions of each of the nine bio-essential elements in the oceans have more variability than most people realize, this also for the "classical" major elements. Therefore upon further investigations, it remains to be seen whether or not the ranges as listed in Table 3 (e.g., 117 ± 14 for carbon or $(10 \pm 9) \times 10^{-3}$ for iron) will in due course become either narrower or wider.

Recently completed and ongoing world ocean research programs such as WOCE, CLIVAR, and GEOTRACES (www.geotraces.org) are providing newer, larger, and more accurate datasets of the dissolved major and trace elements, which undoubtedly will lead to future adjustments and refinements in the numbers presented in Table 3. For example, the apparent biological uptake ratio Mn/P derived from water column profiles of GEOTRACES in 2008 in the Southern Ocean is in the $0.3–0.4 \times 10^{-3}$ range (Middag et al. 2013), that is, in the lower part of the range in Table 3.

Other Trace Elements

Recently Bruland et al. (2014) produced an excellent overview of the trace metals in seawater that comprises all trace elements, those with key biological functions as above discussed and virtually all of those, more than 40 elements, that are not bio-limiting, their abundance not controlled by biology, or without a biological function at all. They also provide an extensive table comprising almost all trace elements and their abundance in seawater. Below only 3 of the 55 nonbiological trace elements are discussed, but Table 4 comprises all 55 largely abiotic trace elements, complementary to Tables 1 and 2 for "biological" elements.

Ocean Biochemical Cycling and Trace Elements, Table 2 Concentrations in seawater of the nine chemical elements that are **essential for all life in bold print** as well as four chemical elements that play a role in specific taxonomic groups. Each element symbol is preceded by its atomic number #. Major dissolved inorganic species, i.e., not taking into account here the strong organic complexation for several trace elements as discussed in main text for such element. Given concentrations are typical values; real concentrations vary around these as function of depth and geographic location. Not listed are Mg and Ca that also play a role in specific taxonomic groups but are listed among the major ions of sea salt (see entry ▶ Ocean Salinity, Major Elements, and Thermohaline Circulation), as is S in abundant dissolved sulfate, and hence Mg, Ca, and S never are bio-limiting

#		Major inorganic species	Concentration	North Atlantic Ocean		Antarctic Ocean		North Pacific Ocean	
			Unit	Surface	Deep	Surface	Deep	Surface	Deep
6	**C**	HCO_3^-	[μmol.kg^{-1}]	2050	2200	2210–2220	2240–2260	2000	~2350
7	**N**	NO_3^-	[μmol.kg^{-1}]	<1	25	25–30	30–38	<1	45
14	Si	H_4SiO_4	[μmol.kg^{-1}]	<1	40	35–63	83–129	<1	170
15	**P**	HPO_4^-	[μmol.kg^{-1}]	<0.1	1.2–1.5	1.6–1.9	2.26–2.35	<0.1	2.5–3.3
23	V	HVO_4^{2-}	[nmol.kg^{-1}]	Quite uniform at ~30–37 [μmol.kg^{-1} in all ocean waters, mostly conservative					
25	**Mn**	Mn^{2+}	[nmol.kg^{-1}]	0.2–3.0	0.1–0.15	0.04–0.5	~0.1	~1–2	~0.2
26	**Fe**	$Fe(OH)^{2+}$	[nmol.kg^{-1}]	0.2–2.0	0.6	0.02–0.1	0.4	0.05	0.6
27	**Co**	Co^{2+}	[pmol.kg^{-1}]	30	60	20–85	~60	10–50	50–250
28	**Ni**	Ni^{2+}	[nmol.kg^{-1}]	2	4	5.5–6.5	5.5–7.0	2.1	11
29	**Cu**	$CuCO_3^0$	[nmol.kg^{-1}]	1 ± 0.5	1.3–2.2	1–2	2–4	<0.5	5
30	**Zn**	Zn^{2+}	[nmol.kg^{-1}]	0.1	2	2.5–3.1	6.2–7.8	0.07	9
42	Mo	MoO_4^{2-}	[nmol.kg^{-1}]	Quite uniform at ~104 μmol.kg^{-1} in oceans, conservative varying slightly with salinity					
48	Cd	$CdCl_2^0$	[pmol.kg^{-1}]	10	300	400–600	770–860	1.4	1100

Ocean Biochemical Cycling and Trace Elements, Table 3 An illustration of the current (2017) state-of-the-art for the order of magnitude of stoichiometric "constants" for the extended Redfield Eq. 2. As per the latter Eq. 2, the data are normalized to value 1 for P (phosphorus). Values for major elements C, N, P, and O_2 after Anderson and Sarmiento (1994). Instead for the trace elements Fe, Zn, Mn, Cu, Ni, and Co, typical ranges are given after Twining and Baines (2013; their Fig. 4)

Major elements	C	(117 ± 14)
	N	(16 ± 1)
	P	1
	O_2	(−170 ± 10)
Trace elements	Fe	(0.2–20) × 10^{-3}
	Zn	(0.1–0.6) × 10^{-3}
	Mn	(0.2–4.0) × 10^{-3}
	Cu	(0.2–2.0) × 10^{-3}
	Ni	(0.1–1.8) × 10^{-3}
	Co	(0.005–2.0) × 10^{-3}

Aluminum (Al) has a high abundance in rocks and soils of the planet but has very low concentrations in the oceans. Dissolved trivalent Al is highly prone to adsorption on particles and perhaps the ultimate scavenging-type trace element in the oceans. The major external source for Al is deposition of aeolian dust coming from the continents. Consequently, an elevated concentration of dissolved Al in surface seawater is strong evidence for dust input, notably Sahara dust that is blown by prevailing winds all across the North Atlantic in the 10–20 °N region (Fig. 6). However due to the intensive scavenging loss, Al rapidly disappears from seawater. This is nicely shown in Fig. 7 where at first glance the distribution of Al looks like that of major nutrient silicate, yet in fact it is the opposite. Where silicate is low, Al is high; where Si is high, Al is low. This amazing mirror image of Al versus Si is partly due to North Atlantic surface water being depleted in nutrient Si but receiving massive supply of Al in aeolian dust from the Sahara.

Ocean Biochemical Cycling and Trace Elements, Table 4 Concentrations in seawater of the 55 trace elements that are not bio-limiting, and/or their abundance not controlled by biology, or without a biological function at all. For elements with key biological functions, see Tables 1 and 2. Not listed are noble gases and elements of which no stable isotopes exist in seawater, although radioisotopes ^{232}Th and ^{238}U with very long half-life are listed; the long half-life is such that these are treated as virtually stable isotopes in the oceans. This Table 4 is based on the informative Table in Bruland et al. (2014), plus a few extra chemical elements not listed by Bruland et al. (2014)

Atomic number	Symbol	Name	Major species	Concentration range	Concentration typical
3	Li	Lithium	Li^+	(Conservative)	25.9 μmol.kg^1
4	Be	Beryllium	$Be(OH)^+$, $Be(OH)_2{}^0$	4–30 pmol.kg^{-1}	~23 pmol.kg^{-1}
5	B	Boron	H_3BO_3	(Conservative)	416 μmol.kg^{-1}
13	Al	Aluminum	$Al(OH)_4{}^-$, $Al(OH)_3{}^0$	0.3–40 nmol.kg^{-1}	~2 nmol.kg^{-1}
21	Sc	Scandium	$Sc(OH)_3{}^0$	8–20 pmol.kg^{-1}	~16 pmol.kg^{-1}
22	Ti	Titanium	$Ti(OH)_4{}^0$, $TiO(OH)_2{}^0$	6–250 pmol.kg^{-1}	~150 pmol.kg^1
24	Cr	Chromium	$CrO_4{}^-$	3–5 nmol.kg^{-1}	~4 nmol.kg^{-1}
31	Ga	Gallium	$Ga(OH)_4{}^-$	5–60 pmol.kg^{-1}	~20 pmol.kg^{-1}
32	Ge	Germanium	H_4GeO_4	1–100 pmol.kg^{-1}	~70 pmol.kg^{-1}
32	Ge	MethylGe	$CH_3Ge(OH)_3{}^0$, $(CH_3)_2$, $Ge(OH)^0$	(Two conservative species)	400 pmol.kg^{-1}
33	As	Arsenic	$HAsO_4{}^{2-}$	17–25 nmol.kg^{-1}	23 nmol.kg^{-1}
34	Se	Selenium	$SeO_4{}^{2-}$	0.5–2.3 nmol.kg^{-1}	1.8 nmol.kg^{-1}
37	Rb	Rubidium	Rb^+	(Conservative)	~1.4 μmol.kg^{-1}
39	Y	Yttrium	$Y(CO_3)^+$, $Y(oh)_2{}^+$	60–300 pmol.kg^{-1}	200 pmol.kg^{-1}
40	Zr	Zirconium	$Zr(OH)_5{}^-$, $Zr(OH)_4{}^0$	9–300 pmol.kg^{-1}	~160 pmol.kg^{-1}
41	Nb	Niobium	$Nb(OH)_6{}^-$, $Nb(OH)_5{}^0$	1–4 pmol.kg^{-1}	~ 3 pmol.kg^{-1}
43	(Tc)	(Technetium)	(Does not occur in nature, except extinct Oklo natural nuclear fission reactor in Gabon)		
44	Ru	Ruthenium	$Ru(OH)_n{}^{4-n}$		<50 fmol.kg^{-1}?
45	Rh	Rhenium	$Rh(OH)_n{}^{3-n}$, $Rh(cl)_n{}^{3-n}$	0.4–1 pmol.kg^{-1}	0.8 pmol.kg^{-1}
46	Pd	Palladium	$PdCl_4{}^-$	0.2–1 pmol.kg^{-1}	~0.7 pmol.kg^{-1}
47	Ag	Silver	$AgCl_2{}^-$, $AgCl_3{}^{2-}$	1–35 pmol.kg^{-1}	20 pmol.kg^{-1}
49	In	Indium	$In(OH)_3{}^0$	0.04–2 pmol.kg^{-1}	~0.1 pmol.kg^{-1}
50	Sn	Tin	$SnO(OH)_3{}^-$, $Sn(OH)_4{}^0$	1–20 pmol.kg^{-1}	4 pmol.kg^{-1}?
51	Sb	Antimony	$Sb(OH)_6{}^-$	(~Conservative)	1.6 nmol.kg^{-1}
52	Te	Tellurium	$Te(OH)_6{}^0$	0.5–1.5 pmol.kg^{-1}	~0.6 pmol.kg^{-1}
53	I	Iodine	$IO_3{}^-$	350–460 nmol.kg^{-1}	450 nmol.kg^{-1}
55	Cs	Cesium	Cs^+	(Conservative)	2.2 nmol.kg^{-1}
56	Ba	Barium	Ba^{2+}	30–150 nmol.kg^{-1}	110 nmol.kg^{-1}
57	La	Lanthanum	$LaCO_3{}^+$	8–40 pmol.kg^{-1}	~35 pmol.kg^{-1}
58	Ce	Cerium	$CeCO_3{}^+$	1.5–10 pmol.kg^{-1}	5 pmol.kg^{-1}
59	Pr	Praseodymium	$PrCO_3{}^+$	1–8 pmol.kg^{-1}	4 pmol.kg^{-1}
60	Nd	Neodymium	$NdCO_3{}^+$	4–50 pmol.kg^{-1}	30 pmol.kg^{-1}
61	(Pm)	(Promethium)	Does not occur in nature (unstable radioisotopes can form in nuclear reactor)		
62	Sm	Samarium	$SmCO_3{}^+$	1–10 pmol.kg^{-1}	5 pmol.kg^{-1}
63	Eu	Europium	$EuCO_3{}^+$	0.2–2.5 pmol.kg^{-1}	0.8 pmol.kg^{-1}
64	Gd	Gadolinium	$Gd(CO_3)^{2-}$	1.5–12 pmol.kg^{-1}	9 pmol.kg^{-1}
65	Tb	Terbium	$Tb(CO_3)^{2-}$	0.5–2 pmol.kg^{-1}	~1 pmol.kg^{-1}
66	Dy	Dysprosium	$Dy(CO_3)^{2-}$	2–14 pmol.kg^{-1}	9 pmol.kg^{-1}
67	Ho	Holmium	$Ho(CO_3)^{2-}$	0.8–2.2 pmol.kg^{-1}	1.6 pmol.kg^{-1}
68	Er	Erbium	$Er(CO_3)^{2-}$	1.5–12 pmol.kg^{-1}	10 pmol.kg^{-1}
69	Tm	Thulium	$Tm(CO_3)^{2-}$	0.3–2 pmol.kg^{-1}	1 pmol.kg^{-1}
70	Yb	Ytterbium	$Yb(CO_3)^{2-}$	1–12 pmol.kg^{-1}	6 pmol.kg^{-1}
71	Lu	Lutetium	$Lu(CO_3)^{2-}$	0.2–2 pmol.kg^{-1}	~1 pmol.kg^{-1}
72	Hf	Hafnium	$Hf(OH)_4{}^0$, $Hf(OH)_5{}^-$	0.06–1 pmol.kg^{-1}	~0.3 pmol.kg^{-1}
73	Ta	Tantalum	$Ta(OH)_5{}^0$	0.01–0.3 pmol.kg^{-1}	~0.1 pmol.kg^{-1}
74	W	Tungsten	$WO_4{}^{2-}$	(Conservative)	55 pmol.kg^{-1}
75	Re	Rhenium	$ReO_4{}^-$	(Conservative)	40 pmol.kg^{-1}
76	Os	Osmium	$H_3OsO_6{}^-$	3–8 fmol.kg^{-1}	~ 6 fmol.kg^{-1}

(*continued*)

Ocean Biochemical Cycling and Trace Elements, Table 4 (continued)

Atomic number	Symbol	Name	Major species	Concentration range	Concentration typical
77	Ir	Iridium	$Ir(OH)_3^0$ (?)	0.5–1 fmol.kg^{-1}	
78	Pt	Platinum	$PtCl_4^{2-}$?	0.2–1.5 pmol.kg^{-1}	~0.8 pmol.kg^{-1}?
79	Au	Gold	$AuCl_2^-$?, $Au(OH)_3^0$?	10–100 fmol.kg^{-1}	~50 fmol.kg^{-1}
80	Hg	Mercury	$HgCl_4^{2-}$	0.2–10 pmol.kg^{-1}	~1 pmol.kg^{-1}?
81	Tl	Thallium	Tl^+, $TlCl^0$	60–75 pmol.kg^{-1}	70 pmol.kg^{-1}
82	Pb	Lead	$PbCO_3^0$	4–150 pmol.kg^{-1}	~10 pmol.kg^{-1}
83	Bi	Bismuth	$Bi(OH)^{2+}$, BiO^+	0.04–0.5 pmol.kg^{-1}	~0.1 pmol.kg^{-1}
90	^{232}Th	Thorium	$Th(OH)_3(CO_3)^-$?	0.3–0.6 pmol.kg^{-1}	~0.3 pmol.kg^{-1}
92	^{238}U	Uranium	$UO_2(CO_3)_3^{4-}$	(Conservative)	~13.5 nmol.kg^{-1}

In contrast, in the Antarctic Ocean, the surface silicate is high (HNCL region), but with the Antarctic being so remote from land, there is no significant dust input of Al. As a result the Antarctic waters are high in Si and very low in Al (Middag et al. 2011c, 2012, 2013). When these Antarctic waters flow northward as AAIW and AABW into the Atlantic basin, they bring along the high Si but low Al signal. This in combination with intensive scavenging may explain the opposite distributions. Indeed by ocean biogeochemical simulation modeling of these processes, it is possible to reproduce the distributions of both Si and Al along this section (Van Hulten et al. 2014).

Iridium (Ir) has the record of lowest concentration of trace elements in the oceans. Iridium is extremely rare in the Earth's crust. This in fact is the reason why an anomalous Ir-enriched layer in sedimentary rocks was identified as clear evidence of asteroid impact, asteroids having a higher Ir concentration than crustal rocks of planet Earth (Smit and Hertogen 1980; Alvarez et al. 1980). This asteroid impact is deemed to have caused the demise of the dinosaurs. Iridium is trivalent in seawater and akin to above trivalent Al likely to be also rapidly scavenged. Thus any input from land that in the first place already comprises very little Ir would next also be removed quickly from the ocean water column. Indeed dissolved Ir is extremely low in the 0.5–1.0 femtomolar range (1 femtomol. L^{-1} = fM = 10^{-15} mol.L^{-1}) (Anbar et al. 1996).

Lead has a very low natural background dissolved concentration (Pb<10 pmol), and this is consistent with the fact that it is very susceptible to adsorptive scavenging. However due to the use from ~1930 onward of gasoline with tetraethyl-Pb additive (as an antiknock agent), massive amounts of Pb have been emitted in the atmosphere over North America and Europe. This large-scale pollution was noticed by Claire Patterson through his efforts to date the age of our planet using Pb isotopic abundances in rocks, which occasionally led to spurious results. Patterson realized this was due to inadvertent contamination in his laboratory and was one of the first geochemists to construct a clean room laboratory and to develop and apply rigorously ultraclean methods. This was successful, and eventually in 1956, the date of the Earth was estimated at 4.55 billion years, a value repeatedly confirmed.

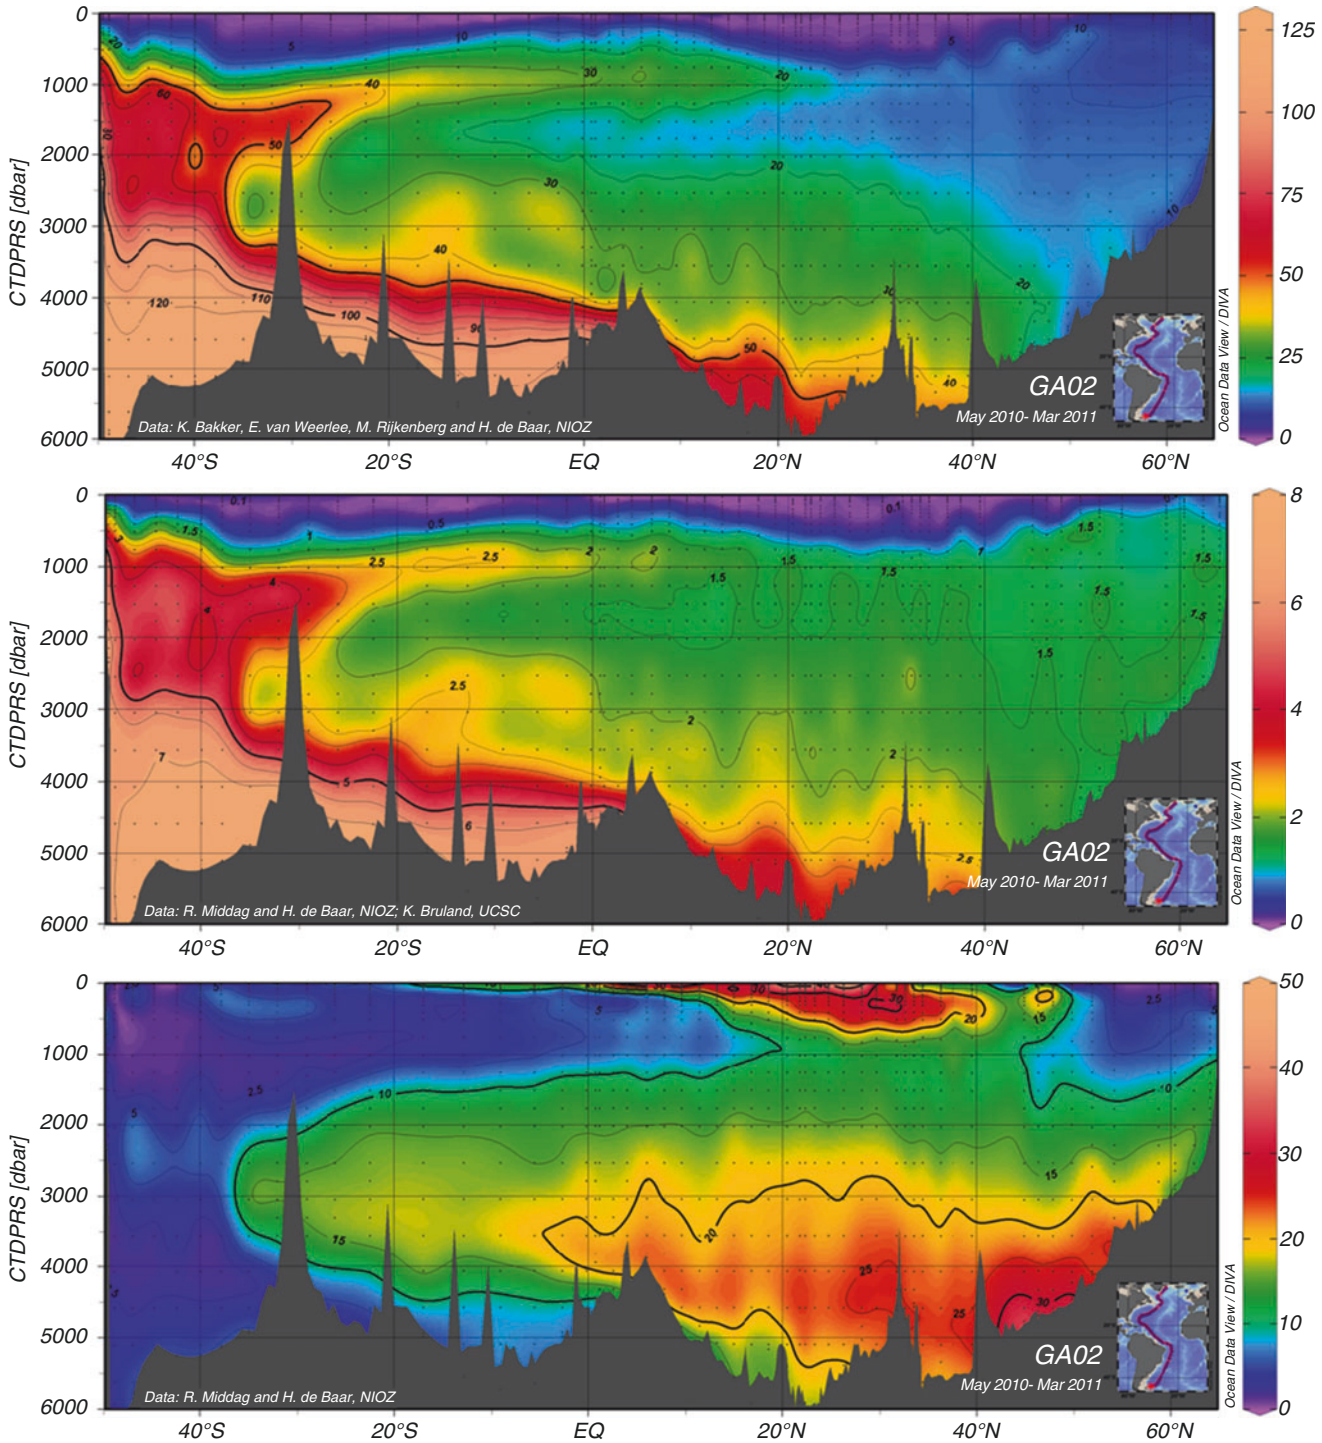
Meanwhile Patterson initiated pioneering work to detect traces of Pb in the environment. Using the best ultraclean sampling methods of the time, samples were collected and analyzed for dissolved Pb in the Pacific Ocean and in year 1979 in the Sargasso Sea near Bermuda in the North Atlantic Ocean (Flegal and Patterson 1983; Schaule and Patterson 1981, 1983). Due to prevailing wind directions, the North Atlantic is downwind of North America and major recipient of the anthropogenic Pb signal.

Moreover, Patterson almost singlehandedly crusaded to abandon Pb in gasoline and eventually succeeded, such that the emissions of Pb into the atmosphere have greatly diminished from the late 1970s onward (Bryson 2003). The Bermuda Atlantic Time-Series Station (BATS) showed that concentrations of dissolved Pb steadily decreased from maximum ~160–170 pM in the upper 500 m in 1979 (Schaule and Patterson 1983) to ~20 pM in the same 500 m depth range in year 2011(Boyle et al. 2014).

Using the most advanced state-of-the-art clean PRISTINE sampling equipment (Rijkenberg et al. 2015) along the complete West Atlantic section (including the BATS site), the dissolved Pb was measured (Fig. 8).

The upper waters of the North Atlantic nowadays have lower dissolved Pb than in the 1979–2008 era, but the subsurface waters in the ~500 to ~2500 m depth range still carry part of the pollutant signal of past high Pb emissions. Given the scavenging-type nature of dissolved Pb, luckily this pollutant signal will eventually disappear from the ocean water column. In the southernmost part of the section, it is noticed that the subsurface waters of Antarctic origin (AAIW at ~1000 m and AABW over the seafloor) are virtually free of Pb, apparently truly "pristine," due to the fact that the dust supply to the Antarctic Ocean is very low.

Combination of this long section (Fig. 8) with two meridional sections in the North and South Atlantic, by the USA and the UK, respectively, has been shown and discussed by Malakoff (2014).



Ocean Biochemical Cycling and Trace Elements, Fig. 7 Section West Atlantic, Geotraces GA02. *Upper* graph: silicate [µmol/kg], after Middag et al. (2015a). *Middle* graph: Zn [nM], after Middag et al. (2015b). *Lower* graph: Al [nM] after Middag et al. (2015a). Vertical axis is pressure [decibar] that is virtually identical to depth [meter] (All data as shown here by Middag and coworkers is in Geotraces IDP 2014 (www.geotraces.org). Summary

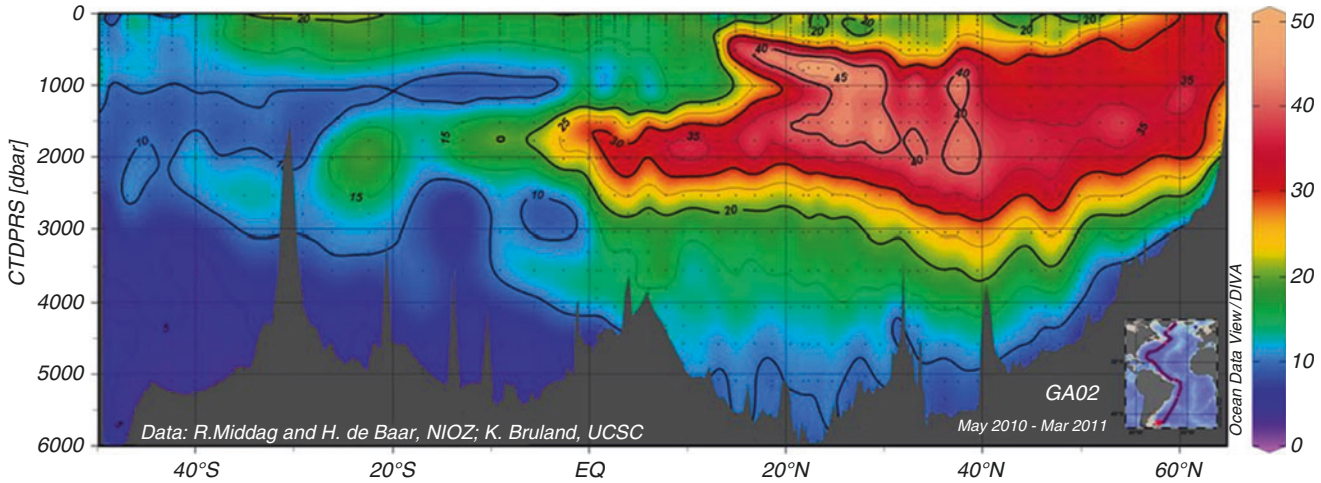
The natural chemical elements exist in seawater in concentrations ranging over 15 orders of magnitude from Cl at ~0.56 mol.kg^{-1} seawater down to Ir at ~0.5 × 10^{-15} mol.kg^{-1} seawater. The most abundant ions exist in constant proportions. Together these major ions constitute the dissolved salt content or salinity of seawater.



Ocean Biochemical Cycling and Trace Elements, Fig. 8 Section of dissolved Pb in the West Atlantic Ocean, Geotraces. Vertical axis is pressure [decibar] that is virtually identical to depth [meter]. The still contaminated North Atlantic waters and overall surface waters are in contrast with the subsurface waters of Antarctic origin (AAIW at ~1000 m and AABW over the seafloor) that are virtually free of Pb. The vertical profile of this dataset at the BATS near Bermuda is reported by Middag et al. (2015) (See also Malakoff 2014). All data as shown here by Middag and coworkers is in Geotraces IDP 2014 (www.geotraces.org). Graphics www.eGeotraces.org using Ocean Data View (R. Schlitzer)

Life in the oceans requires not only C, N, and P but also six trace nutrient elements Mn, Fe, Co, Ni, Cu, and Zn. Photosynthesis by marine algae utilizes these overall nine nutrient elements from seawater in fairly uniform proportions or stoichiometry. The reverse remineralization or respiration by marine bacteria and animals recycles these nutrient elements back into the seawater. Moreover important taxonomic groups also use other chemical elements, most notably Ca for producing $CaCO_3$ shells and coral reefs and Si for producing opaline SiO_2 external frustules of diatom algae. In the temperate and tropical oceans, the major nutrients N, P, and Si are depleted from surface waters. In contrast in the Antarctic Ocean and some other high-nutrient low-chlorophyll (HNLC) regions, there are plenty of major nutrients N, P, and Si, but the ecosystem is limited due to a lack of Fe in combination with light limitation. Due to deep remineralization, there are higher concentrations of nutrients N, P, Si, Co, Ni, Cu, and Zn in deep waters. The trace nutrients Mn and Fe have multiple oxidation states. Both Mn and Fe are involved in the biological cycle but also are affected by aeolian dust supply, oxidative scavenging removal from seawater, and opposed reductive dissolution within anoxic marine sediments and supply from hydrothermal vents.

The remaining 55 chemical elements and their low concentrations in seawater are listed. Yet only three are discussed: Al is the key tracer for aeolian dust input into the oceans, Ir has the record of lowest concentration in seawater, and Pb has elevated abundance due to past use of leaded gasoline.

Ocean Salinity, Major Elements, and Thermohaline Circulation

Hein J. W. de Baar, Steven M. A. C. van Heuven and Rob Middag
NIOZ Royal Netherlands Institute for Sea Research, Department of Ocean Systems (OCS), and Utrecht University, Den Burg, The Netherlands

Definition

Salinity is the total amount of dissolved salts in seawater, generally reported in grams/kg (parts per thousand). Salinity is in turn dominated by only a few major elements in ionic form: Na^+, Mg^{2+}, Ca^{2+}, K^+, Sr^{2+}, Cl^-, SO_4^{2-}, Br^-, F^-, and HCO_3^-. Temperature together with salinity determines the density of seawater, which governs the vertical circulation of the oceans, known as the thermohaline circulation.

Introduction

Ocean geochemistry is the discipline focusing mostly on the inorganic constituents of seawater in the world oceans. Interactions with biology and organic chemistry, and external sources and sinks, such as rivers, atmosphere, hydrothermal vents, and sediments, do play a role. Marine geochemistry comprises a far wider range including other aspects of inorganic geochemistry and organic geochemistry, and secondly not only the seawater but also investigations focusing on the underlying marine sediments and their inorganic and organic contents.

Seawater comprises above all the water molecule (H_2O) and in addition all of the existing 91 chemical elements in their dissolved state in water, in concentrations ranging many orders of magnitude. Most abundant at ~0.5–0.6 moles per liter (M for molar) are the major constituents of dissolved

Ocean Salinity, Major Elements, and Thermohaline Circulation, Table 1 The major ion composition of seawater at salinity S = 35.

Ion	Atomic weight (or molecular for SO_4^{2-})	Ocean concentration [gram.kg^{-1}] at S = 35	Ocean concentration Molar [mol. L^{-1} = mol.dm^{-3}]	Rivers average concentration (Molar [mol.dm^{-3}])	Ocean residence time versus rivers input [Year]
Cl^-	35.453	19.354	0.55952	0.00023	83,900,000 (83.9 million)
SO_4^{2-}	64.063	2.712	0.0282		
Br^-	79.904	0.0673	0.00086		
F^-	18.998	0.0013	0.0000068		
B	10.811	0.0045	0.000416	0.0000017	8,500,000 (8.5 million)
HCO_3^-			~0.0018 (variable)		
Na^+	22.990	10.76	0.48067	0.000315	52,600,000 (52.6 million)
Mg^{2+}	24.305	1.29	0.054	0.000000016	11,600,000 (11.6 million)
Ca^{2+}	40.078	0.4121	0.00106	0.00364	1,000,000 (1 million)
K^+	39.098	0.399	0.0105	0.0000345	10,500,000 (10.5 million)
Sr^{2+}	87.62	0.0079	0.000081	0.0000007	4,000,000 (4 million)

Latter value is close to the world average salinity 34.7 of the modern ocean. Compilation after Dittmar (1884), Wilson (1975), Quinby-Hunt and Turekian (1983), Murray (1992), and Sarmiento and Gruber (2006). Riley (1965) described the historical development of salinity and its measurement. The molar concentrations in seawater at S = 35 have been calculated from the original [gram.kg^{-1}] divided by the atomic weight and adjusted for a "typical" density of seawater of 1027 [gram.dm^{-3} = kg.m^{-3}] or 1.027 kg/Liter. This chosen density is merely an example value, in this choice for water with temperature of ~10 °C at the sea surface (density) or collected from the deep and brought up to the surface (potential density). Calcium (Ca) varies somewhat (~1%) between surface waters and deep waters. Mg and Sr are in the same group in the periodic table as Ca and also show some variations, that however are too small deviations from being "conservative" to affect salinity at its current accuracy. Boron (B) exists as both neutral $B(OH)_3$ and negatively charged $B(OH)_4^-$ ion in seawater, their relative proportion being a function of pH (Dickson 1990). At "typical" pH = ~8 for modern surface waters the concentration of $B(OH)_4^-$ is insignificant for the current accuracy of measured conductivity from which salinity is calculated. Similarly, the HCO_3^- ion is barely significant for overall conductivity, i.e., derived salinity. For the overall world ocean, a "typical" salinity of 35 is commonly used. Similarly in laboratory experiments, and in all sorts of calculations, one commonly uses a salinity of 35

seasalt, the ions Na^+ and Cl^- (Table 1). These and other major elements are the topic of this chapter.

Three orders of magnitude less abundant is Dissolved Inorganic Carbon (C as DIC) varying around ~2 millimoles [mM = 10^{-3} M], and pivotal for life in the sea; this is treated in the chapter on "▶ Carbonate Minerals and the CO_2-Carbonic Acid System" (Lerman and Mackenzie, this volume).

Much less abundant are the nutrients nitrate and phosphate that occur in the micromole [μM = 10^{-6} M] range and are essential for each living organism. Also essential for life are several trace nutrient elements. The nutrients, trace nutrients, and other trace elements are treated in the chapter on "▶ Ocean Biochemical Cycling and Trace Elements" (De Baar et al. this volume).

Most of the chemical elements have several isotopes, which can be either radioactive isotopes or stable isotopes, that provide useful insights into ocean processes and are described in other chapters.

Major Ions in Seawater and Salinity

Upon accurate analyses of 77 seawater samples, Dittmar (1884) confirmed previous findings of Marcet and of Forchhammer that, regardless of the absolute concentration of the total solids, the ratios between the more abundant major chemical elements are virtually constant (Table 1). Since then, these major constituents of seawater are classified as being "conservative." Variation is ascribed exclusively to there being more or less pure water in anyone given sample of seawater due to net precipitation or net evaporation at the sea surface, respectively, or due to mixing of two water masses with different total salt content. These findings lead to the concept of salinity (after Forchhammer), that is the total amount of dissolved salts in seawater. Salinity is expressed as gram per kg seawater [absolute salinity; gram.kg^{-1}] that is dimensionless and hence can also be expressed as per mille unit $^0/_{00}$ or nowadays as practical salinity without any unit at all (IOC 2010).

The salinity in the world oceans varies in a narrow range between ~33 and ~38, such that 35 is taken as the "typical" value (Table 1). The nice thing of the uniform proportions is that when you measure just one, you know them all, and also their summation, the salinity. This was done for 65 years until the ~1960s by measuring the chlorine concentration and from this calculate salinity. Nowadays, the salinity is measured by the electrical conductivity of seawater that depends on the total amount of ionic charges, the more charged ions, the better the conductivity, and the higher the derived salinity. The combined and very accurate measurements by electronic sensors throughout the ~4000 m deep water column of the oceans of conductivity (for salinity); in situ temperature; and pressure (for depth) yield the three key variables Salinity,

O

Temperature, and Pressure (S, T, p) that together determine the density [kg.dm^{-3}] of seawater at the given location and depth. The density is calculated very accurately with the thermodynamic equation of state of seawater (IOC 2010). For the two other parameters, the temperature in the oceans varies from around −1.85 °C (the freezing point of seawater) to ~25 °C or in some tropical seas even 30 °C or higher; nevertheless, the temperature of deep ocean waters is quite uniform around ~2 °C. The pressure increases with depth to 380 atmosphere at the average ~ 3800 m depth of the oceans, or at most ~1000 atm in the deepest ~10 km deep oceanic trenches.

The variations of density are small, but extremely important as these small differences in density of different water masses are the drivers of the "thermohaline" circulation of the oceans. The density of ocean waters ranges from ~1020 to ~1030 gram.dm^{-3} (or kg.m^{-3}), i.e., seawater is 2–3% more dense (heavier) than pure water. The very small range of about 1% (i.e., from 102% to 103%) of the overall density represents the complete window that drives the circulation. Therefore physical oceanographers are keen to obtain very accurate estimates of salinity, currently at around the third decimal point, e.g., 35.456 with an accuracy of ±0.001.

One must be aware of minor deviations of some chemical elements from the constant proportions, i.e., from being conservative. For example, Dittmar (1884) already noticed that the Ca^{2+} in deep water samples was slightly higher than in the upper waters. This is due to the net uptake from upper water by biocalcification, that is the production by organisms of solid $CaCO_3$ for biogenic shells and corals.

$$Ca^{2+} + 2\,HCO_3^- \rightleftarrows CaCO_{3(crystalline)} + CO_2 + H_2O \quad (1)$$

Upon senescence of the shell-forming organism, the heavy (density ~ 2700 kg.m^{-3}) $CaCO_3$ shells settle into deep waters and beyond a given depth horizon enter waters that are undersaturated versus solid $CaCO_3$, such that the shells slowly dissolve. The overall result is that the deep waters comprise, on average, about 1% more dissolved Ca^{2+} ions than the surface waters.

The relative composition of the dissolved salts in seawater appears to have been fairly very uniform over the past 541 million years to present, the Phanaerozoic Eon. Evidence for this comes from marine evaporite deposits (e.g., Ryan 2008). Occasionally a semi-enclosed sea has become completely enclosed, and during evaporation of the water, the seasalt has deposited in a well-known sequence in the reverse order of the solubilities of the minerals. Therefore the order of precipitation from sea water is:

1. Calcite ($CaCO_3$) and dolomite ($CaMg(CO_3)_2$)
2. Gypsum ($CaSO_4$-$2H_2O$) and anhydrite ($CaSO_4$).
3. Halite (i.e., common salt, NaCl)
4. Potassium and magnesium salts

Given the dominance of Na^+ and Cl^- in seawater, the thickness of the halite layer (NaCl) amounts to some 90% of the overall deposit. When adding up the contents of all the layers, one finds the ratio of elements to be the same as in modern seawater. Given the age of the studied evaporite deposit one knows that, at that time in the past, the dissolved seasalt was the same composition as today.

For example, the Messinian Salinity Crisis (MSC) that occurred from 5.96 to 5.33 million years in the past is deemed to be caused by the closing and opening again, perhaps several times, of the Strait of Gibraltar, thus cutting off the Mediterranean Sea from the Atlantic Ocean (Hsu 1983; Roveri et al. 2014). This caused complete dessication of the Mediterranean Sea, perhaps several times, and as a result thick packages of evaporites were laid down and nowadays can be found and sampled in the sediments throughout the Mediterranean Sea. The water from the Mediterranean would have been redistributed in the world ocean, but not the salt that remained in the deposits. As a result there must have been a global decrease in salinity. The total element composition of the MSC evaporites closely confirms that of modern seawater. From worldwide estimates of all such evaporite deposits and their ages, it is concluded the seawater composition has been fairly stable during at least the past 541 million years, although some deviations are known (e.g. Blättler and Higgins 2014).

Residence Times and Mass Balance

In the hydrological cycle, the oceans lose water by evaporation and rivers return the water to the ocean. The river water contains very little dissolved salts (Table 1), and also in very different proportions than seawater. Notably in Table 1 for the positive ions in river water the predominance is

$$Ca^{2+} > Mg^{2+} > K^+ > Na^+ > Sr^{2+} \quad (2)$$

whereas in seawater the predominance is

$$Na^+ > Mg^{2+} > Ca^{2+} > K^+ > Sr^{2+} \quad (3)$$

For the ocean one may assume that the inflow of water does on average equal the net loss by evaporation, a stable situation and that is called a steady state. When now dividing the large ocean volume of 1330×10^6 km^3 by the annual ~36×10^3 km^3.year^{-1} freshwater inflow one obtains the ~37,000 years residence time of water in the oceans, this relative to river inflow (plus groundwater discharge).

Next one can for the major chemical elements (Table 1) multiply this water residence time with the ratio of concentrations [mol.dm^{-3}] in seawater and in river water

$$Residence\ time = (volume_{ocean}/inflow_{rivers}) \times (concentration_{ocean}/concentration_{rivers}) \quad (4)$$

and obtain the residence time [year] of major elements in the oceans (Table 1). These residence times are very long, from 52.6 million to 83.9 million years for major elements Na and Cl, respectively, to ~10 million years for Mg and K, but "only" 1 million year for Ca. For the latter, this results from biocalcification. While, as already mentioned, some of these shells dissolve again in the deep sea, a portion remains intact and becomes buried within marine sediments as lime deposits.

If their concentrations do not change through time, then a steady state must exist, by and large, for each of the dissolved major elements of the seasalt. Somehow the loss term from seawater must be found in marine deposits. An obvious removal term of dissolved major ions is the occasional formation of marine evaporites at various locations of the globe, such as those underlying the Mediterranean Sea. Another sink are the vast and often also quite thick calcareous minerals, the buried fossil shells of $CaCO_3$, that also comprise some trace amounts of akin elements Mg and Sr. Also, because the crystal $CaMg(CO_3)_2$ or dolomite is thermodynamically more stable than $CaCO_3$ (limestone), very slow post-depositional transformation, i.e., dolomitization, occurs within the sediments.

$$2\ CaCO_{3\ (limestone)} + Mg^{2+} \rightleftarrows CaMg(CO_3)_{2\ (dolomite)} + Ca^{2+} \quad (5)$$

As a result, the concentration of Mg^{2+} in pore waters of such sediments is lower than in the overlying seawater, and extra Mg^{2+} diffuses from the sea into the sediment pore waters. This is an extra loss term for Mg^{2+} from seawater.

Another sink term for Mg, and K, is their reaction with degraded clays coming from land and suspended in the river outflow, to various marine type clay minerals that in the process have taken up extra Mg and K. This "reverse weathering" hypothesis (Mackenzie and Garrels 1966) was at first difficult to test in the laboratory due to the very slow reactions. However, this was eventually demonstrated in long-term experiments on the formation of authigenic aluminosilicates in the sediments of the Amazon delta (Michalopoulos and Aller 1995). Meanwhile the discovery in 1977 and beyond of hydrothermal circulation of seawater at Mid Ocean Ridges did provide an answer at least for Mg (Corliss et al. 1979). The cold (~2 °C) deep seawater entering the rocks through cracks heats up enormously and reacts with the rocks, and the hot seawater plumes coming out at ~380 °C have lost all dissolved Mg. Hence, hydrothermalism is a major sink for removal of Mg from ocean waters.

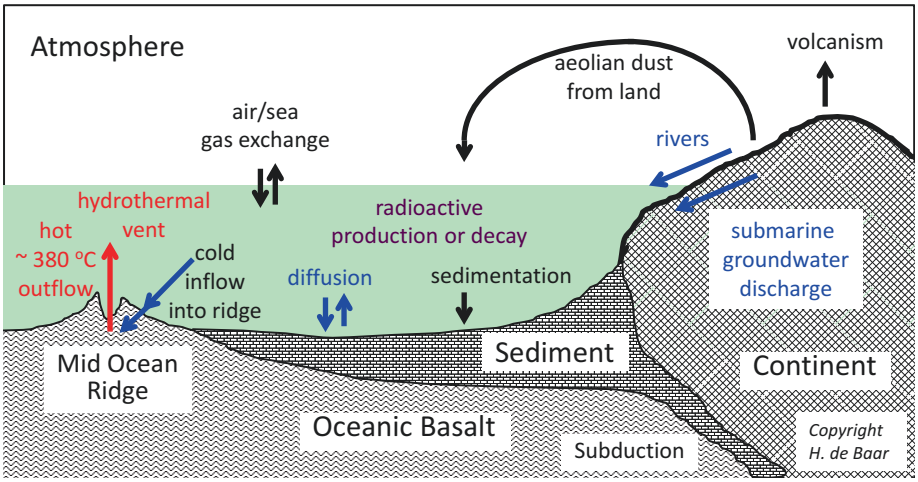
The top 10 rivers in terms of water discharge supply the majority of all fresh water and its dissolved ions into the oceans (Martin and Meybeck 1979). For example, the Amazon, Zaire, and Mississippi rivers draining into the Atlantic Ocean, together represent almost 50% of all river inflow into the world oceans. Almost all large rivers are regularly monitored for volume flow and dissolved major ions, such that, despite interannual variability, a quite reliable worldwide estimate can be obtained, at least for our era.

Overall, the above simple approach merely comparing river supply with ocean content and loss to evaporites, limestone deposits, reverse weathering, and hydrothermalism is quite satisfactory as a steady state model for the, mostly conservative, major elements of seawater (Table 1). However, many minor and trace elements (see chapter "▶ Ocean Biochemical Cycling and Trace Elements") require a more complete concept of ocean mass balance (Fig. 1) including consideration of several other sources and sinks:

- River input source
- Aeolian supply source of terrestrial dust as either dry deposition or wet deposition
- Gas exchange with the atmosphere notably for CO_2 and O_2, as source or as sink
- Hydrothermal supply or loss, for example, an iron source (Fe), or sink of magnesium (Mg)
- Radioactive production source or radioactive decay loss within the oceans
- Sedimentation loss
- Diffusive fluxes into or out of sediment pore waters

This also implies that for deriving a steady state mass balance for any one chemical element of interest, one has to add up all the sources, as well as add up all the sinks. Next one somehow hopes these are equal, or adjusts these, such that the sum of sources more or less equals the sum of sinks. Finally one can compare these sums [moles.year^{-1}] with the total ocean inventory [moles] to derive a residence time [year] for the given chemical element.

During the Last Glacial Maximum (LGM), large ice caps covered large parts of North America and Europe. The volume of these ice caps corresponded with an ~120 m lower sea level than today. As a result of the corresponding lower overall volume of the seawater in the oceans, the salinity was higher in the LGM (Adkins et al. 2002), with a different salinity distribution in the major oceans than today, but the relative proportions of dissolved salts remained the same. Modern day salinities are all within 0.5 of the global average salinity of 34.7, whereas salinities during the last glacial



Ocean Salinity, Major Elements, and Thermohaline Circulation, Fig. 1 Box cartoon of ocean inventory box (azure color) with all sources and sinks, and in steady state ideally: $\Sigma_{sources} = \Sigma_{sinks}$, where $\Sigma_{sources}$ = Rivers + dust + air to sea gas inflow + hydrothermal input + radioactive production + diffusion from sediment and Σ_{sinks} = Air to sea gas outflow + hydrothermal output + radioactive decay + sedimentation + diffusion into sediment

maximum (LGM) ranged from 35.8 in the North Atlantic to as high as 37.1 in the Southern Ocean.

Circulation of Deep Ocean Waters

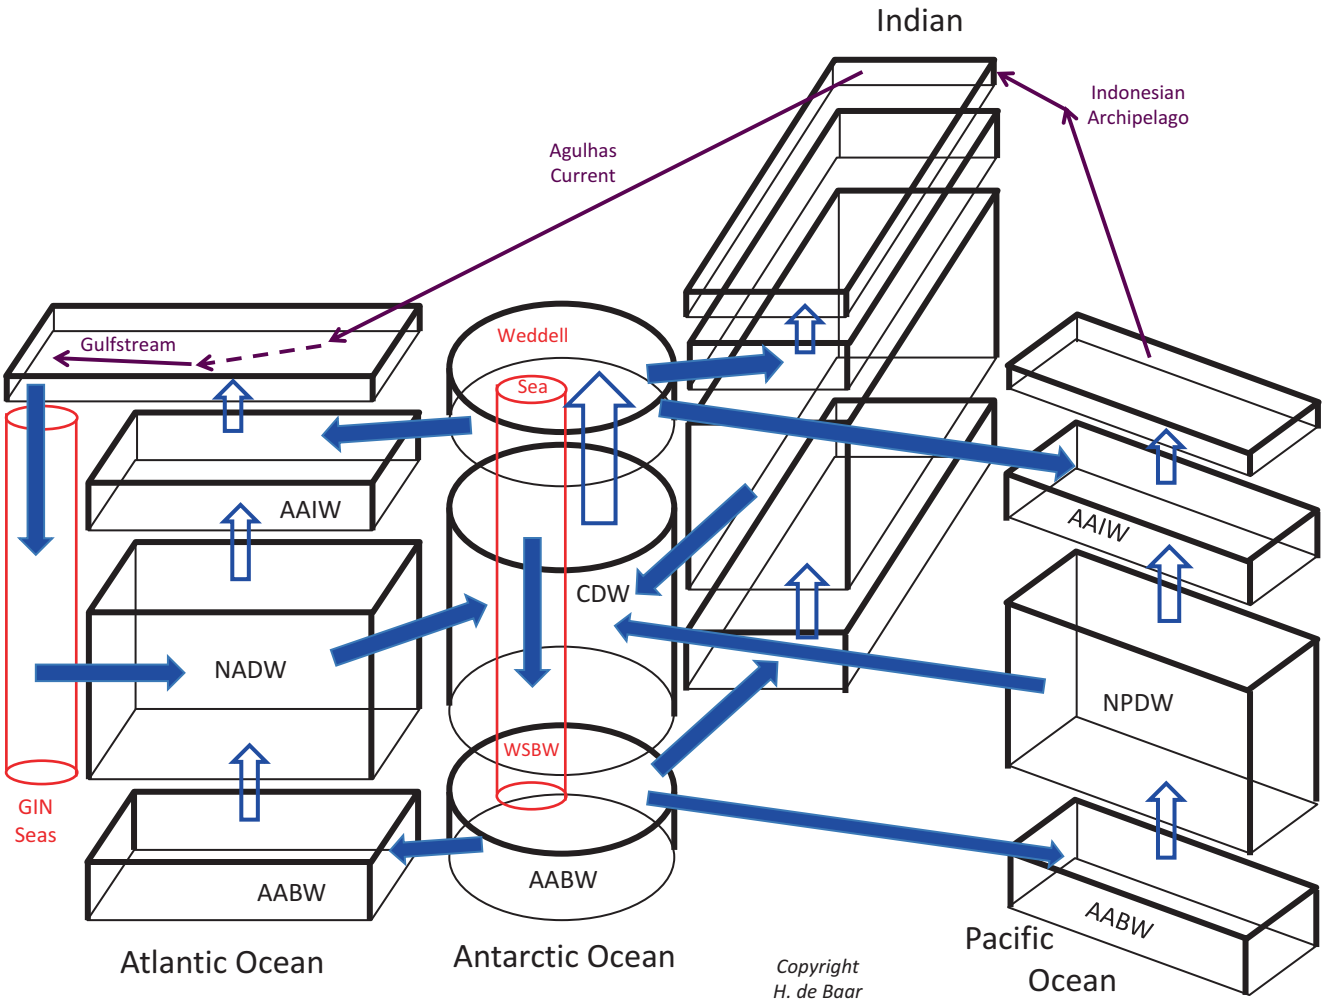
The world ocean distributions of chemical elements are more strongly controlled by the circulation of deep ocean waters, that is all waters below ~500 m depth, than by the circulation of the upper ocean (all waters shallower than ~500 m). Thus in order to understand the cycling and distribution of the chemical elements, one at least also needs to have some understanding of the deep Thermohaline Circulation (Van Aken 2007).

The ultimate driver of this deep circulation is the formation of deep waters. This sinking is primarily caused by a seasonal increase of density in the winter in polar regions. Firstly by winter cooling; secondly by seasonal formation of sea-ice resulting in the remaining seawater having a higher salinity, the water overall gets a higher density.

In the Arctic region, this winter process is most intense in February in the Greenland-Iceland-Norwegian Seas (GIN-Seas; Hopkins 1991; Van Aken 2007; Seidov et al. 2013, 2014) north of Iceland. This deep basin fills up with this denser water and overflows at the relatively shallow Denmark Strait between Iceland and Greenland, and the straits between Iceland, the Faeroes, and Scotland. These overflows sink again to near the bottom of the northern North Atlantic Ocean and flow southwards, along the Western Atlantic Ocean basin due to Coriolis acceleration. This North Atlantic Deep Water (NADW) also picks up some waters that were formed in winter in the Labrador Sea (between Canada and Greenland) that are less dense and therefore sink only to ~1200 m depth. Moreover within the Mediterranean Sea there is heating and net evaporation of seawater. This warmer but more saline (S ~ 38) water sinks and eventually overflows at Gibraltar Strait into the Atlantic Ocean, where this Mediterranean Overflow Water (MOW) spreads out at ~1200 m depth as far as the West Atlantic. By vertical mixing, the MOW causes the underlying NADW to become more saline.

After some 400–500 years, the NADW enters the Antarctic Circumpolar Current. In the Antarctic Weddell Sea, there is similar formation of cold Weddell Sea Deep Water (WSDW) during the Antarctic winter (July–August). This eventually outflows into all three major ocean basins as Antarctic Bottom Water (AABW). At the Antarctic Polar Front, there is also sinking of waters but only to ~1000 m depth, this Antarctic Intermediate Water (AAIW) also outflows into all three major ocean basins. As a result of these outflows of Antarctic origin waters, the deep Indian Ocean is filled up until its boundary with Asia at 20–30 °N. The oldest deep waters of the northern Indian Ocean have an "age" of ~1000 years; in other words, it has been ~1000 years ago that this water last was at the surface. Similarly, the deep Pacific Ocean fills from south to north and in the deep North Pacific Ocean exists the oldest deep waters with ages in the 1500–1800 or even 2200 years range.

The abovementioned ages are based on the distribution of ^{14}C in the deep oceans. More recently, Matsumoto (2007) has revised these conventional ages (his Fig. 1) by accounting for two key mechanisms and has arrived at somewhat younger ages (his Fig. 4), notably ~200 years for the Northwest Atlantic location, and ~1200 years respectively for the Northeast Pacific region. The age difference of ~1000 years between these two positions would then be a bit less, but still very long. Other age estimations have been made (Khatiwala et al. 2012;



Ocean Salinity, Major Elements, and Thermohaline Circulation, Fig. 2 Simplified scheme of circulation in the deep ocean basins. Filled blue arrows are (vertical) deep water formation and (horizontal) flow. Formation of deep waters shown in red. Not shown are several other (smaller) sources, in the Labrador Sea, the Mediterranean Overflow Water (MOW), in the Ross Sea and along some other sectors around Antarctica. The open blue arrows are for general upwelling that closes the water budget by returning water to the uppermost boxes in all oceans. From the Pacific Ocean, there is a return flow (shown in purple) via the Indonesian Archipelago, Agulhas Current, Gulf Stream resuppplying the GIN-Seas. Antarctic Ocean is all waters south of the Antarctic Polar Front (APF) at ~50 °S, the APF is defined by the surface expression of the 2 °C isotherm (Deacon 1984). Drafted after similar schemes that exist in the literature (e.g. Schmitz 1996; his Fig. I-91 at page 106) and at the internet (e.g. http://ccsr.aori.u-tokyo.ac.jp/old/ehtml/eocean.html)

Gebbie and Huybers 2012) yet all agree that the age difference between deep North Atlantic and deep North Pacific Oceans is in the order of ~1000 years or more (Fig. 2).

Summary

Salinity of seawater in the oceans comprises the small number of chemical elements that occur in very high concentration in seawater. These major elements in seawater have very long residence times in the oceans, for example, 52.6 million and 83.9 million years for major elements Na and Cl, respectively, and ~10 million years for Mg and K, but "only" 1 million year for Ca. This in comparison to the relatively very brief mixing time of seawater between the ocean basins in the order of "merely" ~1000 years yields a very constant ratio of these major elements in seawater. One exception is again Ca that due to its involvement in the biogeochemical cycle of $CaCO_3$ shells and corals has a slightly lower concentration in surface waters relatively to deep waters. From quantitative studies of worldwide evaporite deposits, it has been estimated that the seawater composition has been fairly stable during at least the past 541 million years. In the modern ocean, the "thermohaline" circulation of deep waters is driven by small differences of seawater density due to differences in temperature and salinity.

Winter cooling and sea-ice formation in polar winters cause surface waters to become more dense and sink into

the deep polar seas, from where these waters outflow into all other oceans.

Oceanic Island Basalts

Matthew Gerard Jackson
Department of Earth Science, University of California Santa Barbara, Santa Barbara, CA, USA

Definitions

Ocean island basalts (generally referred to as OIBs) are a type of basalt erupted within the oceans, mainly in intraplate settings. Thus, OIB volcanism contrasts with the other principal types of volcanism in the ocean basins that occur along plate boundaries: mid-ocean ridge basalt (MORB) volcanism, where basalt is erupted at divergent plate boundaries, and subduction zone (or arc) volcanism, where lavas are formed in association with subduction at convergent plate boundaries. OIBs are erupted at volcanic hotspots, which correspond to the surface location of upwelling mantle plumes. Mantle plumes are buoyantly upwelling regions of the mantle that are thought to have unusually high mantle temperatures.

OIB, Hotspots, and Mantle Plumes

Many hotspots are located in intraplate settings in the oceans. However, some hotspots are colocated with mid-ocean ridges (e.g., Iceland hotspot), and at least one hotspot is located near a subduction zone, and complicated plume-trench interactions are suggested (e.g., Samoa hotspot). In the latter case, the subducting Pacific plate may interact with the upwelling Samoan plume, drawing the plume toward the downgoing slab (Druken et al. 2014).

While the term "ocean island basalt" corresponds to rock formed by intraplate volcanism that occurs in the ocean basins, OIBs are not always basaltic. OIBs encompass a broad range of compositions and span both tholeiite and alkali basalt compositions. While primitive OIBs are basaltic, highly evolved equivalents also exist, and intraplate hotspot lavas with phonolitic, trachytic, or dacitic compositions also occur. In fact, rhyolitic eruptions are common at the large central volcanoes of Iceland, and these provide an important example of the extreme variation in lava compositions identified at oceanic hotspot localities. Carbonatites, which are mantle melts composed of primary mantle carbonates, offer an additional example of the extreme compositional variability present in oceanic hotspot lavas.

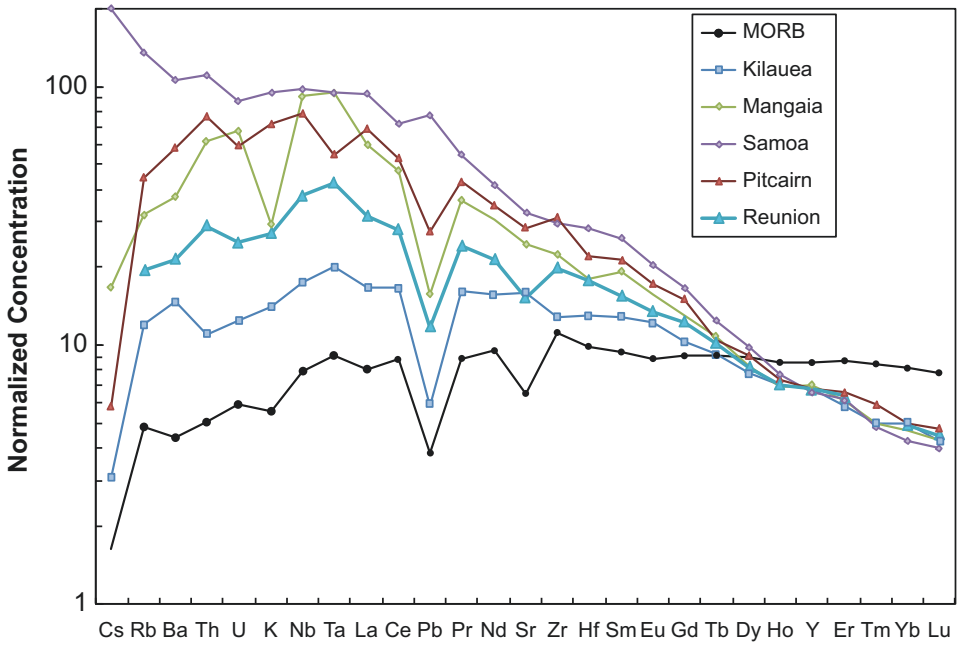
Ocean island basalts do not erupt strictly on islands. In fact, most of the volume of intraplate hotspot volcanism is erupted underwater. Many intraplate hotspot volcanoes never breach the water surface to erupt lavas subaerially, and these hotspot volcanoes exist as submarine seamounts for their entire lifespan. Oceanic hotspot volcanoes that do breach the water surface to become islands ultimately subside thermally after volcanism ceases. Thus, the processes of thermal subsidence and subaerial erosion, which effectively reduce the mass of the volcano above water, act to turn ocean islands into seamounts. Indeed, most OIBs are actually found as seamounts (Staudigel and Koppers 2015).

OIBs erupted at the Hawaiian (Weis et al. 2011) and Louisville (Koppers et al. 2012) hotspots can be explained by upwelling of a deep-seated, thermally buoyant mantle plume that partially melts beneath the oceanic plate, and the resulting melts upwell to feed an active hotspot volcano that resides above the hotspot. Because mantle plumes generally drift slowly with respect to plate velocities at the surface, a chain of age-progressive hotspot volcanoes forms over the upwelling mantle plume as the plate moves laterally over the hotspot: younger, active volcanoes are found near the hotspot, and volcanoes further downstream (in the direction of plate motion) are older and volcanically inactive. Most major hotspot-related island chains appear to be plume related (French and Romanowicz 2015), and some hotspot chains are long lived: the Hawaii and Louisville chains have produced volcanism for just over 80 million years, and it is proposed that hotspots currently active in the Cook Islands have been active for over 100 million years (Koppers et al. 2003). In the Indian Ocean, the volcanism associated with the Kerguelen mantle plume spans an age range of ~120 million years (Frey et al. 2000).

However, there does not appear to be a single mechanism responsible for generating hotspot volcanism in the ocean basins. Not all OIB localities are associated with age-progressive chains of volcanoes. Instead, some OIBs are erupted as isolated seamounts that are not part of a chain (e.g., Bermuda), and these isolated seamounts do not clearly relate to a deep-seated or long-lived plume. OIBs are also erupted along chains that do not exhibit age progressions (e.g., the Pukapuka ridge; Janney et al. 2000) and are thus not easily explained by volcanism that results from an upwelling mantle plume. The mechanisms responsible for hotspot volcanism and OIB generation at these localities are not well understood, but could relate to melting of fertile blobs in the upper mantle or shallow melting that results from tectonic stresses in the lithosphere (e.g., Sandwell et al. 1995). These alternative mechanisms for generating hotspot volcanism are not unimportant: there are >45,000 seamounts that extend >1 km above the ocean floor (Staudigel and Koppers 2015), and most of these seamounts are not clearly related to plume-fed hotspot chains.

Geochemistry and Crustal Recycling

The trace element characteristics of OIB vary considerably. Tholeiitic OIB erupted at localities like Hawaii is less enriched in incompatible elements (e.g., Rb, Ba, Th, U) – which prefer to be in the melt relative to the solid mantle that partially melted to generate the melt – than alkalic OIB (Fig. 1). While this may reflect enrichment of incompatible elements in the mantle source of alkalic OIB compared to the mantle source of tholeiitic lavas, a more likely explanation is that alkalic OIBs are the result of lower degree melting of the mantle than tholeiitic OIBs. Indeed, low degrees of mantle melting concentrate the incompatible elements in the melt relative to high degree melting (Schilling and Winchester 1967; Hofmann 2003). The degree of melting depends on both the mantle temperature and the depth to which upwelling mantle can rise. Evidence suggests that mantle plumes are hotter than the ambient depleted upper mantle that sources MORB melts (Putirka et al. 2007; Herzberg et al. 2007), yet hotspot lavas at many localities appear to be the result of low degrees of melting. The paradox of low degree melting at many hotspot localities might be explained by the role of oceanic lithosphere, which is thick in regions where the oceanic plate is old. A thick oceanic lithosphere serves to stop plume upwelling and effectively halts further adiabatic melting, thereby reducing the degree of melting (Dasgupta et al. 2010).

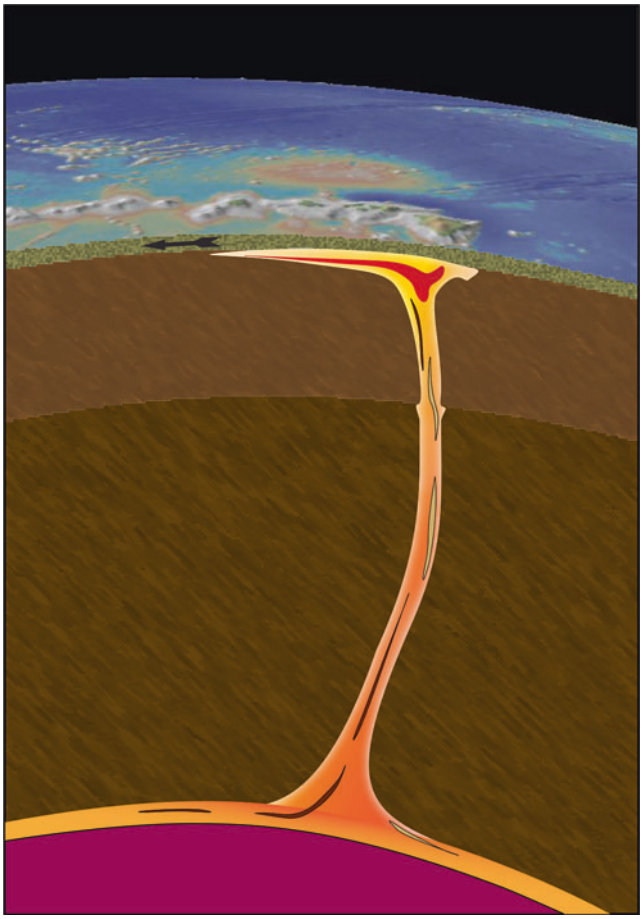


Oceanic Island Basalts, Fig. 1 Primitive mantle normalized trace element patterns for OIB from different localities. Alkalic OIB from Pitcairn, Samoa, and Mangaia is more enriched in incompatible elements than tholeiitic lavas from Hawaii and MORB tholeiites. (Figure modified after White (2013), except for Mangaia (Woodhead 1996) and MORB (Gale et al. 2013).)

The composition of the mantle that melts to generate OIBs provides important insights into the evolution and dynamics of the mantle over geologic time. Unlike major and trace elements, radiogenic isotopic ratios, like $^{87}Sr/^{86}Sr$, $^{143}Nd/^{144}Nd$, and $^{206}Pb/^{204}Pb$, are not fractionated between the mantle and melts that are extracted from the mantle and as such are "fingerprints" of the mantle source of the melts. These isotopic systems provide a window into the composition of the inaccessibly deep Earth that is sampled by OIB. For over five decades, it has been known that basalts from different oceanic islands exhibit heterogeneous radiogenic isotopic compositions (Gast et al. 1964), and the global radiogenic isotopic variability observed in OIBs is described by at least four different isotopic end-members that are often referred to as HIMU (high μ, = $^{238}U/^{204}Pb$), EM1 (enriched mantle I), EM2 (enriched mantle II), and DM (depleted mantle). However, the origin of this isotopic variability is still the source of debate. A long-standing hypothesis is that subducted oceanic crust (Hofmann and White 1982) and continental crust (White and Hofmann 1982) that are isotopically heterogeneous can explain much of the radiogenic isotopic diversity observed in OIB globally. Large amounts of oceanic crust (20 km^3/year) and sediment derived primarily from the continents (0.5–0.7 km^3/year) are subducted into the mantle. If subduction has been operating for three billion years, and if subduction of oceanic crust has been constant over that time period, then ~4% of the mantle's mass is comprised of subduction oceanic crust. Similarly, ~0.1% of the mass of the mantle is subducted sediment. This subducted material enters the convecting mantle where it can reside for billion-year time scales, before being recycled into the mantle source of OIB. OIB from different localities has distinct radiogenic isotopic compositions that have been linked to a diversity of crustal protoliths of different ages that were subducted into the mantle. Stable isotopic measurements of OIB, including oxygen isotopes and mass independently fractionated sulfur isotopes (Eiler et al. 1997; Cabral et al. 2013), support the hypothesis that OIB sample melts of crustal protoliths that were once at the Earth's surface. Additionally, OIB exhibits incompatible element-enriched radiogenic isotopic signatures (higher $^{87}Sr/^{86}Sr$ and $^{206}Pb/^{204}Pb$ and lower $^{143}Nd/^{144}Nd$) that provide powerful evidence that the mantle sources of these hotspots have been enriched by recycling of ancient subducted crustal material into the shallow upper mantle. In comparison, MORB derived from the upper mantle by higher degrees of partial melting tend to exhibit more incompatible element-depleted (lower $^{87}Sr/^{86}Sr$ and $^{206}Pb/^{204}Pb$ and higher $^{143}Nd/^{144}Nd$) radiogenic isotopic compositions. Thus, plate-tectonic processes operating at the surface, including subduction, ultimately control the composition of the mantle sources that melt to generate OIB (Fig. 2).

Primordial Signature from the Deep Mantle

While OIB samples material that was subducted into the mantle, some OIB thought to be sourced by deep-seated mantle plumes exhibits primitive noble gas characteristics (Courtillot et al. 2003). For example, compared to MORB sampling the upper mantle, OIB can have elevated $^3He/^4He$ ratios that are associated with the primitive materials that constitute the building blocks of the terrestrial planets. The preservation of high $^3He/^4He$ in the mantle sources of these lavas suggests that



Oceanic Island Basalts, Fig. 2 The Hawaiian hotspots are thought to be fed by a buoyantly upwelling mantle plume that rises from the core-mantle boundary. (From White, 2014.)

ancient, primitive domains have survived in the mantle in spite of convective mixing processes that have operated in the mantle since Earth's accretion at >4.5 Ga. Supporting the hypothesis that high $^{3}He/^{4}He$ domains sample ancient domains preserved in the mantle, Mukhopadhyay (2012) found that high $^{3}He/^{4}He$ OIB exhibits different $^{129}Xe/^{130}Xe$ than MORB and the Earth's atmosphere. Because all $^{129}Xe/^{130}Xe$ isotopic heterogeneity in the Earth was generated during the lifetime of ^{129}I (half-life of 15.7 million years), the discovery of low $^{129}Xe/^{130}Xe$ in hotspot lavas indicates that the high $^{3}He/^{4}He$ reservoir formed within ~100 million years of Earth's accretion.

Some OIBs are melts of mantle domains that host ancient, primordial signatures and other OIB sample mantle domains that have a component of subducted crust that has been incorporated (recycled) into the mantle that melts to form OIB. In fact, many OIBs exhibit a mixture of primitive and recycled signatures. Regions of anomalously slow seismic velocity in the deepest mantle, referred to as large low shear wave velocity provinces (LLSVPs), are suggested to host both primitive and subducted crustal material that may be intimately associated within the LLSVPs (Li et al. 2014). The bases of deep-seated mantle plumes may extend to the LLSVPs. If mantle plumes are sourced by the LLSVPs, these plumes may convey primitive and subducted material to the shallow mantle where they are melted to generate OIB melts.

Summary

Ocean island basalts result from melting hot, buoyantly upwelling mantle beneath the world's ocean basins. Ocean island basalts sample ancient subducted crust that has been recycled through the mantle. These basalts also provide evidence that ancient, primordial reservoirs have survived in the deep Earth since accretion.

Definitions

An **oil seep** is a place where liquid or semi-solid petroleum, commonly in association with gaseous hydrocarbons, escapes at a low rate to the Earth's surface. Those located on the sea floor produce tar or asphalt that may eventually be transported to the shore where it strands as **coastal bitumen**.

Introduction

Each year an estimated 600,000 metric tons of oil enters the global marine environment from natural seepage (NRC 2003), accounting for 47% of the total annual input and making it the single most important contributor of oil to the world's oceans (Kvenvolden and Cooper 2003). In the wake of major accidental releases of crude oil, such as the *Exxon Valdez* tanker spill in Prince William Sound, Alaska (Kvenvolden et al. 1995), and the *Deepwater Horizon* blowout in the Gulf of Mexico (Boufadel et al. 2014), it becomes necessary to distinguish the resulting marine tar residues from coastal bitumen (natural or anthropogenic) already present on the adjacent shorelines. This is achieved using various isotopic and molecular fingerprinting techniques (Peters et al. 2005).

Seep Locations

One of the first studies of global marine oil seepage, dating from a time when reports of marine seeps were scarce, concluded that there is a strong correlation between areas of high seepage potential and tectonic activity, best exemplified by the tectonically unstable circum-Pacific region (Wilson et al. 1974). Hydrocarbon seeps are now known to be widespread along both active and passive continental margins, and the mechanisms of their formation are varied. Numerous examples are described by Abrams (1996) and Judd and Hovland (2007). Typically, petroleum fluids are released to the seabed from over-pressured subsurface reservoirs where the cap rock has been breached by diapir intrusion, faulting, or other fractures. The resulting seeps are manifest on the seabed as

mud volcanoes, pock marks, and authigenic carbonate deposits (Talukder 2012).

Among the most extensive and best documented oil and asphalt seeps are those in the Gulf of Mexico (Brüning et al. 2010; Sahling et al. 2016), Angola (Jones et al. 2014) and off the coast of southern California (Lorenson et al. 2009). The seeps at Coal Oil Point, Santa Barbara, California (Del Sontro et al. 2007; Farwell et al. 2009; Hostettler et al. 2004) are especially prolific, releasing up to 27,000 liters of oil per day (Hornafius et al. 1999).

Methods of Detection and Sampling

Such seepage may be accompanied by flares of methane and other hydrocarbons rising through the water column that are detectable by sonar techniques (Talukder et al. 2013). Seafloor sampling of seeps typically employs the use of piston and gravity cores, grabs, or remotely operated vehicles which permit more precise sampling of discrete areas of seepage. Where oil films reach the surface, the presence of submarine seeps has been inferred by direct observation from vessels or by using various remote sensing techniques. These include airborne laser fluorescence (Thompson et al. 1991); satellite synthetic aperture radar (De Beukelaer et al. 2003); ship based x-band radar (Crooke et al. 2015); and visual (Hu et al. 2009) and spectral methods (Wettle et al. 2009).

While dispersed in near-surface sediments, exposed on the seafloor, rising through the water column and at the sea surface, the oil undergoes various alteration processes that include evaporative fractionation, water washing, biodegradation, and photo-oxidation. The net result of these processes is to increase the overall viscosity and density of the seeped oil. The progress of this alteration can be monitored by appropriate sampling techniques and organic geochemical analyses (Abrams and Dahdah 2011; Peters et al. 2005).

Upon evaporation and further weathering, surficial oil slicks may produce tar balls or mats (Warnock et al. 2015), some of which are then carried by currents and waves to the shore where they strand as coastal bitumen on ocean beaches.

Origin of Australian Coastal Bitumens

Natural seeps discharging oil into the ocean are common within the Indonesian Archipelago (Noble et al. 2009) where they are the likely sources of the waxy bitumens that strand along the northern, western, and southern coastlines of Australia (Edwards et al. 2016). The evidence for such long-distance transport of tar balls from their as yet unspecified points of origin into Australian waters by a combination of the Indonesian Throughflow (Gordon 2005) and the Leeuwin Current (McGowran et al. 1997) is based on their content of a distinctive suite of biomarker hydrocarbons that are also found in oils from Indonesia (Currie et al. 1992; McKirdy et al. 1986, 1994). These include botryococcane, bicadinanes, oleanane, and 4-methylsteranes. Reports of such bitumen stranding date back to the mid-1800s, although tanker cleaning operations in the Java and Banda seas may augment the current influx of tar balls to the beaches of southern Australia. A study of six beaches in 1991–1992 revealed a maximum waxy bitumen loading of 2 kg per 100 m. Asphaltite, a heavier variety of local coastal bitumen, is less common, arguably less traveled and considered by Hall et al. (2014) to be a manifestation of low-intensity seepage from tar mats exposed by submarine canyons on Australia's southern continental slope. It is carried ashore by a combination of seasonal upwelling currents and winter storms.

Impact on Local Ecosystems

Submarine oil seepage is typically episodic. Its rate is variable in space and time, and yet in places sufficient to impact adversely on local wildlife (Henkel et al. 2014) and the amenity of adjacent beaches. On the other hand, deposits of asphalt emanating from seafloor seeps provide a substrate for extensive and diverse chemosynthetic communities (Cordes et al. 2010; MacDonald et al. 2003; Sahling et al. 2016; Schubotz et al. 2011). In the same manner, both pelagic tar balls and benthic asphaltite may be colonized by a variety of marine biota including goose barnacles, bryozoa, and serpulid worms (Edwards et al. 2016). Thus, it is now recognized that oil seeps are important natural laboratories for understanding not only the fate of crude oil in the marine environment, but also how marine ecosystems adapt to the influx of petroleum.

Conclusions

Oil seeps are the major source of crude oil entering the marine environment. The escape of petroleum hydrocarbons to the seafloor is a natural worldwide phenomenon that has both resource and environmental implications. The presence of a seep is evidence of an active petroleum system in the underlying offshore sedimentary basin and therefore may lead to the discovery of new fossil fuel resources. The composition of the resulting tar or asphalt deposit, at the site of the seep or subsequently washed ashore as coastal bitumen, provides important clues to the age and depositional environment of the parent oil's source rock. Finally, the geographic distribution of tar balls stranded along the adjacent shoreline provides a predictive template for the ultimate destination of any crude oil accidentally released during offshore drilling or production.

Oil Shale

Justin E. Birdwell
Central Energy Resources Science Center, U.S. Geological Survey, Denver, CO, USA

Synonyms

Cannel coal; Immature source rock; Kukersite; Lamosite; Marinite; Tasmanite; Torbanite

Definition

Oil shales are fine-grained sedimentary rocks formed in many different depositional environments (terrestrial, lacustrine, marine) containing large quantities of thermally immature organic matter in the forms of kerogen and bitumen. If defined from an economic standpoint, a rock containing a sufficient concentration of oil-prone kerogen to generate economic quantities of synthetic crude oil upon heating to high temperatures (350–600 °C) in the absence of oxygen (pyrolysis) can be considered an oil shale.

Introduction

The term oil shale is often described as a misnomer, in that the organic component is primarily kerogen, not oil and the mineral matrix is not necessarily clay mineral-rich, but can include a variety of different phases (Miknis and McKay 1983). Oil shales are essentially a type of petroleum source rock, the key differences being that: (1) oil shales have not been buried to sufficient depths or exposed to high enough temperatures for long enough to have generated petroleum; and (2) have organic matter contents that are higher than what is typically considered necessary for a "good" source rock (total organic carbon, TOC > 10 wt%; Cook and Sherwood 1991). Deposits of oil shale are found around the world and range in geologic age from Precambrian to Tertiary. The term has a long history of use, predating the "shale oil" and "shale gas" revolution of the early twenty-first century in the United States. Oil shale is sometimes applied to "shale-hosted oil" or "tight oil" formations, like the Eagle Ford Shale and Bakken Formation, respectively, causing much confusion. Unlike humic coals, oil shales are more prone to generate liquid petroleum products upon heating and contain a higher concentration of mineral matter (>33 wt%; Yen and Chilingar 1976). It should be noted that in addition to being used as a source of synthetic oil, in some cases, oil shales are also burned to generate electricity similar to coal, as is done in Estonia.

Properties

The critical property for determining oil shale resource potential is its grade, defined as the yield of synthetic crude oil generated under pyrolysis conditions normalized to the mass of rock processed. Oil shale grade can be determined by well-established, laboratory pyrolysis methods. Two of the most commonly used pyrolysis tools for characterizing oil shale and other source rocks are the Fischer assay method (ASTM 1990; Johnson et al. 2010) and programmed pyrolysis, more commonly known as Rock-Eval analysis (Peters 1986). Both methods involve rapidly heating a sample (~100 g for Fischer assay; ~100 mg for Rock-Eval) to high temperatures (500–550 °C) and either collecting the synthetic oil product for quantification and possibly subsequent characterization (Fischer assay) or measuring the evolved hydrocarbons and other products with a variety of detectors (Rock-Eval). Results are commonly reported as wt% oil, gallons of oil per short-ton of rock (GPT), or milligrams of hydrocarbons per gram of rock (mg-HC/g). The grade cutoff for determining oil shale commercial viability will depend on a number of factors, but rocks that can generate at least 25 GPT (~10 wt% oil or ~100 mg-HC/g) are generally considered to be commercial grade in the United States (Birdwell et al. 2013). It should be noted that the economic viability of oil shale in most countries is also dependent on high oil prices. For example, development of oil shale resources has not been commercially viable in the United States without subsidies since the 1920s despite the enormous resource potential determined for the principal basins of the Green River Formation (Eocene) in Colorado, Utah, and Wyoming (Johnson et al. 2010; Birdwell et al. 2013).

Categorization schemes for typing oil shales have been developed based on depositional environment and dominant maceral types (Hutton 1987, 1995; Cook and Sherwood 1991). The six types described by Hutton (1987) include terrestrial cannel coal, lacustrine lamosite and torbanite, and marine kukersite, tasmanite, and marinite. Some of these oil shale types contain organic matter derived from petrographically identifiable organisms, such as the planktonic green microalgae *Botryococcus braunii* in some torbanites and green algae *Tasmanites* in tasmanites-type oil shales. Cannel coals are found in New Zealand, Australia, and the United States and contain abundant spores, resins, and organic matter from vascular plants, like vitrinite. The Green River Formation (United States) and Rundle (Australia) Tertiary oil shales are typical examples of lamosites and contain amorphous organic matter derived primarily from lacustrine algae. Devonian-Mississippian oil shales like the New Albany Shale in the eastern United States are often described as marinites and contain organic matter derived primarily from marine phytoplankton.

Oil shales have a wide range of organic matter content (from around 10 up to over 60 wt% TOC) and variable mineralogy across the spectrum of mudrocks. Bitumen (fraction soluble in organic solvents) typically represents around 20wt% of the organic matter present in oil shale (Yen and Chilingar 1976), with the remainder consisting of kerogen (insoluble fraction). The kerogen is generally hydrogen-rich (oil-prone type I or type II kerogens; atomic hydrogen-to-carbon ratios from ~1.0 up to 1.6) with a range of heteroatom (nitrogen, oxygen, sulfur; NSO) contents. For example, the kukersite (Ordovician) found in Estonia is known to be particularly high in oxygen, Ghareb oil shale (Cretaceous) from Israel and Jordan has a very high organic sulfur content, and the kerogen present in Glen Davis torbanite (Permian) from Australia has an unusually low concentration of NSO heteroatoms. Oil shale can contain a range of different mineral phases, including quartz, feldspars, carbonates, various clays, and pyrite. Phosphate minerals are common in some formations, like the Phosphoria Formation (Permian) in the western United States, and calcareous (calcite content >50 wt% on an organic-free basis) marine oil shales are found in several important oil shale deposits. Lacustrine oil shales are often mineralogically very diverse, as demonstrated by the different mineralogical units within the Green River Formation in the Piceance Basin of Colorado (Boak and Poole 2015).

History and Use

The most common use of oil shale historically has been as a source of synthetic liquid crude oil generated by "retorting" or "destructive distillation" (e.g., pyrolysis). Industrial applications of oil shales date back to the nineteenth century in Scotland and other places in Europe, where it was often used as a source of kerosene. This fuel production from oil shale led to the term "kerogen" being defined as the organic precursor of the kerosene product (Jenson 1922). While many oil shale industries ceased operating in the twentieth century, others continue to exist in a number of countries (Dyni 2006), including Estonia, Brazil, China, and Russia using a variety of retorting technologies (Baughman 1978; Speight 2012). Development of oil shale resources are under consideration or in various preliminary stages in the United States, Jordan, Australia, Mongolia, and several other places around the world.

Prospects for utilization of oil shale resources have been inevitably tied to the fortunes of the petroleum industry. During periods of high crude oil prices or concerns over reliable supplies, the development of oil shale has been pursued, particularly in countries with significant resources like the United States (Ogunsola et al. 2013). However, the higher costs associated with the production of synthetic crude oil from oil shale relative to other liquid fuel resources has prevented the widespread development of oil shale in the absence of government subsidies except in a few countries.

Summary

Oil shale deposits around the world represent a substantial but largely untapped petroleum resource. The viability of oil shale as a feedstock for the large-scale production of liquid hydrocarbon fuels continues to be dependent on the cost of producing from conventional crude oil resources and, increasingly, unconventional petroleum sources. The geochemical characteristics of oil shales are similar to those of traditional petroleum source rocks making them useful materials in the study of geochemical processes like petroleum generation through catagenesis and properties of organic-rich sedimentary rocks.

Oil-Oil and Oil-Source Rock Correlations

Norelis D. Rodriguez
Chevron Energy Technology Company, Houston, TX, USA

Definition

Oil-oil and oil-source rock correlations are studies whose primarily objective is to unravel the relationships among oils and source rocks, independent of maturity and/or alteration effects. Oil-oil correlations aim to establish a genetic relationship among multiple oil samples or classifying them into oil families, while oil-source rock correlations aim to establish a genetic relationship between oils and potential source rock intervals (Peters et al. 2005).

Oil-Source Rock Correlation

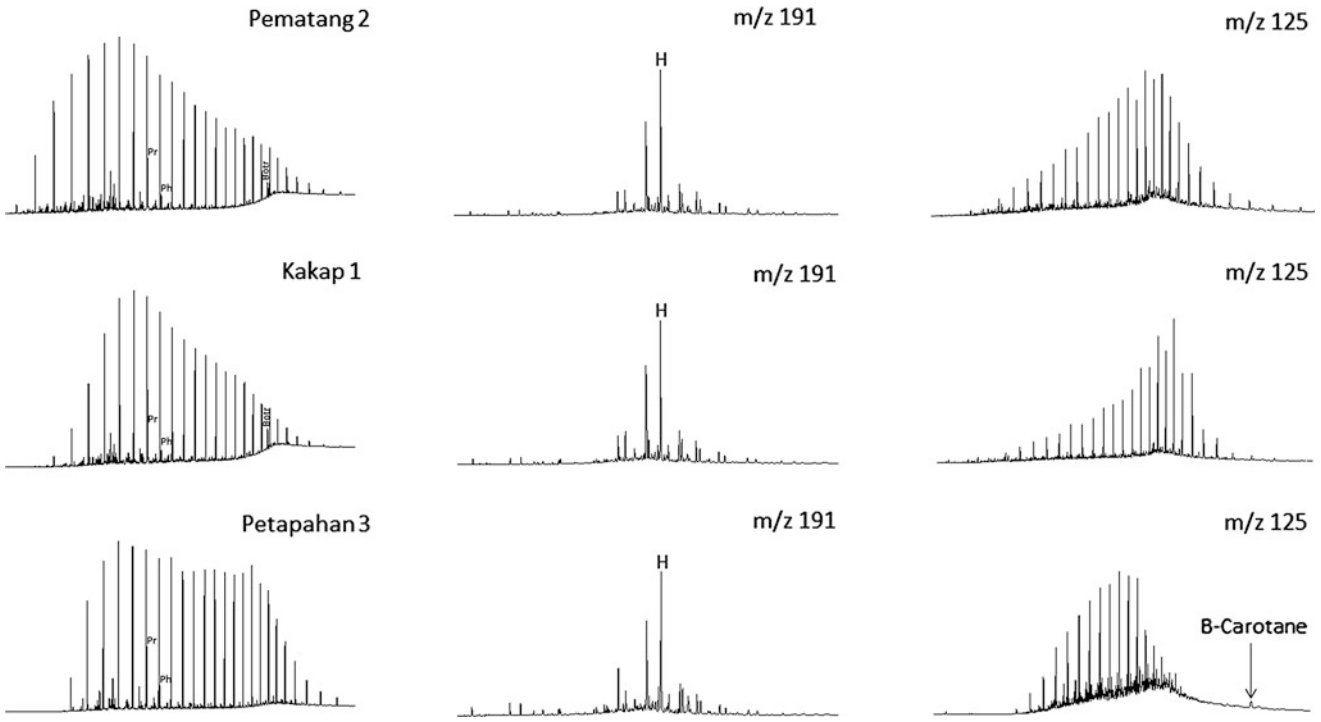
Oil-source rock correlation studies are primarily carried out during oil and gas exploration in order to identify the main source rock intervals within a basin. Defining source rock presence, quality, distribution, and maturity is at the foundation of establishing a working petroleum system (Magoon and Dow 1994). Exploration applications of correlation studies include (1) assessing the number and character of effective source rocks, (2) identifying migration pathways, (3) providing input data for volumetric assessments, and (4) supporting data for oil field development (Waples and Curiale 1999). At a higher resolution, correlation studies can also be used to address reservoir continuity problems in producing reservoirs (Curiale 2008) and to map source rock facies variations within a basin (Peters et al. 1986; Rodriguez and Philp 2015).

Preserved lipid components that can be unmistakably linked to biological precursors in the original organic matter are known as biomarkers (Seifert and Moldowan 1981) and are one of the main data types used in petroleum geochemistry and correlation studies, specifically. Distributions of alkanes, isoprenoids, terpanes, hopanes, and steranes are routinely used in correlation studies. Biomarkers, in combination with bulk compositional data, and isotopic compositions (C, H, S, N) represent the main toolbox used in oil-oil and oil-source rock correlations. Although these organic components are typically used, successful results have also been obtained using trace metals (e.g., Lopez and Lo Monaco 2017) and aromatic hydrocarbons, porphyrins, and NSOs (e.g., Curiale 1994).

Oil-Oil Correlation

Oil-oil correlations are used in lieu of oil-source rock correlations particularly when there is limited access to potential and/or effective source rock samples for analyses. In these instances, correlations among oils from multiple locations allow extrapolations regarding type and potential extension of effective source rocks (Trinidade et al. 1995). Figure 1 provides an example in which oil-oil correlations were used to establish oil families and source rock facies variations in the rift grabens of the Central Sumatra Basin. Close to identical m/z 191 terpane distributions in all three samples indicate they were generated by similar source rock intervals. However, differences in *n*-alkane distributions, as well as in the presence/absence of the biomarkers botryococcane and β-carotane, indicate variations in the depositional environment for these source rock intervals.

Oil-oil and oil-source rock correlations can be difficult in cases where there are (1) multiple source rock units at multiple maturity levels contributing to charge, (2) facies variations within source rock units, and (3) organic variability caused by carrier beds and reservoir rocks (Curiale 2008). Moreover,



Oil-Oil and Oil-Source Rock Correlations, Fig. 1 Example of oil-oil correlation of oils from three grabens in the Central Sumatra Basin. All three samples show almost identical m/z 191 terpane distributions. The Biomarker Botryococcane is present in the Pematang 2 and Kakap 1 sample and absent in the Petapahan 3 sample. Conversely, β-carotane is present in the Petapahan 3 sample and absent in the other two. The Pematang 2 and Kakap 1 samples represent deep lacustrine facies of the Brown Shale Fm., while the Petapahan 3 sample was generated by saline lacustrine facies of the same source rock formation (Rodriguez and Philp 2015)

in-reservoir processes such as biodegradation, thermochemical sulfate reduction, and phase segregation can alter the original oil chemistry. Molecular signatures can be further complicated by processes like migration fractionation and migration contamination (Curiale 2002). Meaningful correlations studies must consider the potential effect of secondary processes, rely on a representative sampling base (Katz, personal communication), and fully integrate the geochemical interpretation with the stratigraphic and structural evolution of the basin.

Oklo Natural Nuclear Reactors

Mark J. Rigali
Sandia National Laboratories, Albuquerque, NM, USA

Fissiogenic isotopes; Fission products

Definition

Natural nuclear reactors have been discovered in the Oklo and the associated Okelobondo and Bangombe uranium ore deposits in the Republic of Gabon on the coast of Equatorial West Africa. The reactors occur as small lenticular bodies of high-grade uranium ore (20–60% by weight) in the uranium ore deposits. The natural reactors reached criticality and began fission reactions 1.95 billion years ago. They operated for as long as 140,000 years. The primary fuel for the natural reactors was a fissionable isotope of uranium, ^{235}U. The reactors were discovered in 1972 when it was realized that ^{235}U was consumed and fission products were produced within seventeen high-grade uranium ore bodies, the Oklo and the associated Okelobondo and Bangombe uranium ore deposits. Today, these natural nuclear reactors serve as useful analogs for on-going research in the development of nuclear waste containment strategies.

Discovery of the Natural Nuclear Reactors

Although the possibility of natural nuclear reactors was considered in the 1950s (Koroda 1956), this prediction was not confirmed until 1972 when a routine analysis of a uranium ore standard at the nuclear-fuel processing plant in Pierrelatte, France, revealed a slight depletion in ^{235}U (Cowan 1976). Uranium has three naturally occurring isotopes in following proportions: 99.27% for ^{238}U, 0.72% for ^{235}U, and 0.0056% for ^{234}U. The measurement indicated that ^{235}U made up 0.7171% of the standard, only slightly lower than 0.72%. However, this value was considered unusually low, and an investigation was started to determine its origin. As scientists considered the cause of the depletion, they initially assumed that the uranium standard had been contaminated with ^{235}U-depleted uranium tailings, a waste product left over from the process used to produce enriched ^{235}U uranium for use as fuel in man-made nuclear reactors (Cowan 1976). When this turned out not to be the case, the investigation led to the Oklo uranium mine in the Republic of Gabon, on the coast of Equatorial West Africa. Analyses on samples obtained directly from the Oklo ore body revealed even greater depletions in ^{235}U. These strongly depleted samples were associated with specific regions of the ore deposit where the ore occurred in concentrations as high as 20–60% uranium by weight. Because there was no known natural process that could fractionate ^{235}U from uranium's more abundant isotope ^{238}U, scientists were initially baffled by the ^{235}U depletions observed in some of the Oklo ore samples. As the investigation continued, an amazing discovery was made. The relative abundances of a number of isotopes unique to nuclear fission reactions were observed in the ^{235}U-depleted ores. The missing ^{235}U had been consumed by fission in the high-grade uranium ore bodies. The conclusion was that nature created the first nuclear reactors to operate on Earth nearly two billion years before Enrico Fermi's nuclear reactor was constructed at Staggs Field in Chicago (Cowan 1976).

Conditions for the Formation of Natural Reactors

What fortuitous circumstances led to the formation of natural fission reactors? Natural nuclear reactors, like their man-made counterparts, require a number of special conditions in order to operate. First, spontaneous fission of ^{238}U takes place, causing its nucleus to split. This produces two or more fragment atoms usually of unequal mass (fission products) γ-rays, and several neutrons. If fissile ^{235}U nuclei are nearby, they can absorb these neutrons and split, releasing more neutrons. The reactions can be sustained if enough ^{235}U nuclei are present to absorb the neutrons produced by previous fissions. Nuclear reactors require significant amounts of fissionable material in order to start and maintain fission reactions. At Oklo, the natural reactor fuel was primarily ^{235}U. Two billion years ago, the rise in atmospheric oxygen mobilized uranium and enabled the dissolution and subsequent reprecipitation of uranium to form the high-grade uranium ore zones where nuclear fission reactions were initiated and sustained (Gauthier-Lafaye 2002). These zones contain 20–60% uranium, mainly in the form of uraninite, UO_2 (Gauthier-Lafaye et al. 1989). In addition to the high concentration of uranium, two billion years ago the relative abundance of ^{235}U was 3.68% of total U and is five times greater than today (0.72%) because ^{235}U decays faster than ^{238}U. A relative abundance of 3.68% is similar to the relative abundance of ^{235}U in the fuel of modern man-made pressure water nuclear reactors (Gauthier-Lafaye 2002). This high relative abundance of ^{235}U together with the high concentrations of uranium ore minerals enabled sustainable fission reactions in the high-grade zones that became the natural nuclear reactors. Yet another requirement for natural nuclear reactor operation is the presence of a neutron moderator. Moderators slow down the neutrons emitted from the fission of ^{235}U so that they are more readily absorbed by other ^{235}U nuclei, sustaining

fission reactions. At Oklo, the neutron moderator was primarily water present in the porous and fractured rocks which host the reactors. However, it has been suggested that carbon associated with organic matter (described below) may have also played a role as a neutron moderator/reflector in some reactors (Naudet 1991; Bentridi et al. 2013). A final requirement is that there is a minimum of neutron poisons in the reactor zones. Elements such as boron, vanadium, and rare earth elements (REEs) can readily absorb neutrons inhibiting or preventing the fission of ^{235}U (Gauthier-Lafaye 2002). These elements were not present in sufficient quantities in the natural reactors to inhibit reactor operation.

Chemical, Physical, and Geologic Properties of the Natural Reactors

To date, 17 natural nuclear reactors have been discovered in the Oklo and the associated Okelobondo and Bangombe uranium ore deposits in the Republic of Gabon (Bentridi et al. 2013). The reactors occur as small bodies in the uranium ores. They vary in size considerably. The largest (reactor 2) is a 12-m by 20-m lens-shaped body that is 50-cm thick, while the smallest, known as the Bangombe reactor, is a 5-m by 1-m lens-shaped body that is a few cm thick (Gauthier-Lafaye 2002). The natural reactors are located in hydrothermally altered and fractured clastic sedimentary rocks. They are found in the 7–10-m thick Cl layer of the basal FA Formation of the 2.1-Ga-old Paleoproterozoic Francevillian Series. The Cl layer consists of beach sands and tidal deposits of fine-grained sandstones, mudstones, and shales. In addition to the high uranium content, occurring mainly as uraninite, authigenic clay minerals, metallic inclusions, small quantities of galena, other sulfides, and hematite are also present in the natural reactors. Many of them also contain variable amounts of solid, graphitic organic matter. This carbon-rich material, also called solid graphitic bitumen, consists mainly of a highly condensed polycyclic aromatic hydrocarbon matrix thoroughly intermixed with poorly crystalline, fine-grained graphite (Nagy et al. 1993; Nagy and Rigali 1993). The solid graphitic bitumen apparently originated as liquid petroleum (Gauthier-Lafaye and Weber 1989) through the reaction of hydrothermal solutions with older organic solids, a process known as hydrous pyrolysis. The petroleum migrated into the reactors enclosing uraninite grains which had participated in the fission reactions and their incorporated fission products. Heat and radiation rapidly turned the viscous petroleum into the graphitic solid. Natural reactors 1–6 at Oklo contain only trace amounts of this carbonaceous substance. Here, the uraninite is associated mainly with clay minerals. The other reactors are organic matter rich with parts of these reactors containing as much as 66% organic carbon by weight. The uraninite occurs with both carbonaceous matter and clay minerals in heterogeneous distributions within these reactors. Some parts of the organic-rich reactors are uraninite in virtually pure clays, and other parts are mainly uraninite enclosed in the solid, graphitic organic substance.

Conditions During Natural Reactor Operation

The natural reactors reached criticality 1.95 billion years ago and operated for ~10^6 years (Gauthier-Lafaye 2002). During this time, ^{239}Pu was produced from the abundant isotope of uranium, ^{238}U, by neutron capture and two subsequent β decay reactions:

$$^{238}\mathrm{U} + \mathrm{n} \rightarrow {}^{239}\mathrm{Np} + \beta-$$

$$^{239}\mathrm{Np} \rightarrow {}^{239}\mathrm{Pu} + \beta-$$

^{239}Pu is also a fissionable material, and small amounts of the ^{239}Pu produced participated in fission reactions at Oklo. However, the majority of the ^{239}Pu created by neutron capture did not fission. It decayed, becoming ^{235}U through the following reaction:

$$^{239}\mathrm{Pu} \rightarrow {}^{235}\mathrm{U} + {}^{4}\mathrm{He}$$

In this manner, the Oklo natural nuclear reactors produced additional ^{235}U to sustain fission reactions. In fact, as much as 45% of the total amount of ^{235}U consumed in fission reactions was produced by the decay of ^{239}Pu (Holliger and Devillers 1981). Taking into account the additional ^{235}U produced by the decay of ^{239}Pu, it is estimated that a total of 6 tons of ^{235}U were consumed by fission reactions in the natural reactors (Naudet 1991). During natural reactor operation at Oklo, temperatures in the reactors reached as high as 400 °C (Gauthier-Lafaye 2002). As a result of heat and circulating fluids, the reactors experienced the progressive dissolution of the quartz sandstone host rock and the concomitant formation of a clay envelope around the reactor cores that was impervious to fluid flow (Bentridi et al. 2013). The cores finally collapsed with the progressive loss of quartz in and around the reactors leading to a significant reduction of porosity and water in the core. Their eventual collapse together with the consumption of significant quantities of the ^{235}U fuel led to the reactor cores becoming subcritical and finally shutting down. In the organic matter-rich reactors where this material appears to have also contributed to neutron moderation, the reactor shutdown may have been due in part to the redistribution and migration of the organic matter as viscous bitumen away from the reactor cores (Bentridi et al. 2013).

Scientific Relevance of the Oklo Natural Fission Reactors

The Oklo natural reactors are complex geologic and geochemical occurrences and are a natural laboratory in which to study the conditions of reactor formation and operation. They present a unique opportunity for scientists to study the long-term geochemical behavior of uranium together with fissiogenic isotopes in geologic environments. Fission products have been retained in the natural reactors and adjacent rocks to varying degrees. U, Th, Pu, and several fission products, including isotopes of Ag, Mo, Sn, Nb, Zr, Bi, Pd, Ru, Rh, Te, La, Nd, Pr, Sm, Ce, and Gd, have been found within the reactors and in the rocks in their vicinity (Curtis et al. 1989; Holliger 1992; Gauthier-Lafaye 2002). While Pu was retained primarily with uranium in the uraninite of the reactors, there is evidence for its migration together with rare earth elements has been found because of their presence in clays and apatites within and near the reactor cores (Bros et al. 1993; Bros et al. 1996). Other fission products such as Tc, Ru, Rh, Pd, and Bi are retained in metallic inclusions found in close proximity to the uraninite. Still others, such as the noble gases, I, Rb Ba, Sr, and Cs, have been lost in large quantities from the uraninite of the reactors and are largely absent in the adjacent host rocks of the reactors (Gauthier-Lafaye 2002). However, evidence for the retention of small amounts of fissiogenic Sr, Ba, and Cs isotopes in one of the reactors, carbonaceous matter-rich natural reactor 10, has been reported (Hidaka et al. 1994; Hidaka and Gauthier-Lafaye 2008). Isotopes of these three elements are of particular interest because they are produced in high yields during nuclear fission, and they are also soluble and readily transported by aqueous solutions in geologic environments.

Because a number of fission and decay products were retained in the natural reactors while still others were lost, the reactors have modern anthropogenic relevance. This relevance can be stated as follows. Since the components and the geochemical and hydrologic environments in and around the natural reactors were able to contain a number of radionuclides, the Oklo natural reactors may be useful analogs for modern nuclear waste containment considerations and strategies (Nagy and Rigali 1993; Gauthier-Lafaye 2002). To date, several decades of studies have revealed that a number of physical and chemical factors have influenced the degree of retention of fission products in the natural fission reactors. Retention of fission products is controlled in part by the mineral assemblages in the natural reactors and their response to microscale variations in pressure and temperature together with the composition of the uraninite fuel (Curtis et al. 1989). Other factors, such as chemical alteration, exsolution, and diffusion, were important mechanisms affecting the loss of Pb and the fission products Mo, Ru, Rh, and Pd from uraninites in the Oklo natural reactors (Janeczek and Ewing 1995). However, many of these fission products were precipitated in galena (PbS) and metallic inclusions or in the immediate vicinity of the reactor zones. In addition, where it is present in the natural nuclear reactors, solid graphitic carbonaceous matter appears to inhibit the migration of U, Pb, and a number of fission products from these reactors (Nagy et al. 1993; Nagy and Rigali 1993). These studies all indicate that Oklo natural reactors have value as analogs for the storage of man-made radioactive waste.

Summary

The Oklo, Okelobondo, and Bangombe uranium ore deposits in the Republic of Gabon are unique as they host the world's only known natural fission reactors. A number of fortuitous circumstances including high concentrations of fissionable ^{235}U, the presence of significant quantities of water, and the absence of neutron poisons contributed to their formation and operation nearly 2 Ga ago. The natural reactors represent complex geochemical and hydrologic milieus. It is important to consider the heterogeneous textural patterns of their components as well as their interaction with the surrounding geochemical environments during 2 Ga of geologic time to properly evaluate their origin as well as their potential utility to modern nuclear waste containment strategies.

Onuma Diagrams

Chenguang Sun
Department of Earth, Environmental and Planetary Sciences, Rice University, Houston, TX, USA

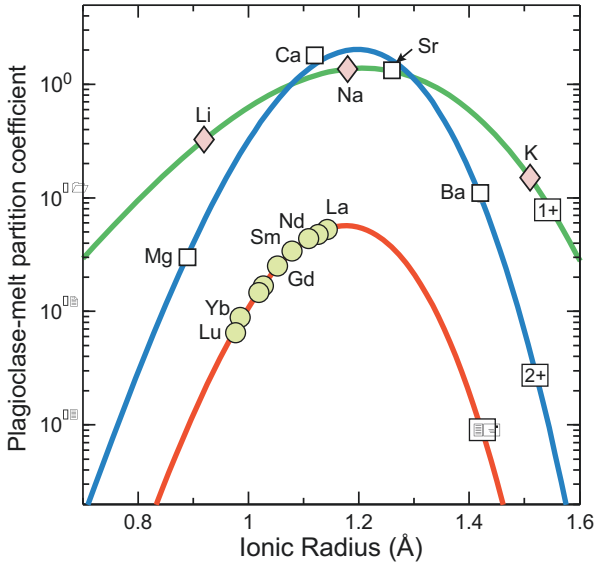
Definition

Onuma diagrams are a type of graphs used in geochemistry to illustrate the systematic variations between **partition coefficients** (see ▶ Partitioning and Partition Coefficients) and ionic radii of major or trace element ions with various valence states. This type of graphs was named after a Japanese geochemist, Naoki Onuma. Together with Hideo Higuchi, Hiroshi Wakita, and Hiroshi Nagasawa, Onuma published the first study using these diagrams (Onuma et al. 1968). In Onuma diagrams, the partition coefficients are plotted on a logarithmic scale, while the ionic radii are shown on a linear scale. Figure 1 is an example showing the partition coefficients of trace elements between plagioclase and clinopyroxene from Sun et al. (2017). As shown in Fig. 1, the partition coefficients of isovalent cations in the large cation site of plagioclase display a parabolic relationship with the ionic radii, whereas the parabolic patterns change tightness with the cation charges. According to the parabola defined by isovalent cations in a specific lattice site, these diagrams can be used to predict partition coefficients of trace element cations with the same charges and to further constrain their site occupancies in a mineral of interest.

History

Previously, Goldschmidt (1937) outlined the effects of cation size and charge on element partitioning through three general rules: (1) ions with the same charge and similar ionic radii have the same partition coefficients; (2) smaller cations have larger partition coefficients than larger cations with identical charges; (3) for cations with similar sizes, those with higher valence states have larger partition coefficients. These general rules remain true under many conditions; however, as demonstrated in Nagasawa (1966), the influences of cation size have to be considered with reference to the major cations in the lattice site. Based on the strain energy change in the crystal lattice, Nagasawa (1966) developed the first quantitative model for partitioning of isovalent cations in ionic crystals. Following Nagasawa (1966), Onuma et al. (1968) measured phenocryst-melt trace element partition coefficients and confirmed that the relative size differences between the trace element cations and the major cations in the lattice site determine the partition coefficients of isovalent cations, which gives rise to the parabolic patterns in Onuma diagrams.

A later study of Brice (1975) developed a similar but simpler model taking account of this effect of size differences, which has been widely since the experimental study of Blundy and Wood (1994). According to the Brice equation, the parabolic pattern in Onuma diagrams is determined by three parameters, the strain-free partition coefficients corresponding to the peak of the parabola, the Young's modulus governing the width of the parabola, and the strain-free cation size controlling the peak position. These lattice strain parameters also vary with the cation charges, which gives rise to the change of parabolic patterns with the cation valence state (see Fig. 1). For a specific lattice site, cations with higher charges have tighter parabolas in Onuma diagrams; however,



Onuma Diagrams, Fig. 1 Onuma diagram showing the partition coefficients of trace elements between plagioclase and a lunar basaltic melt from Run An-Red-2 in Sun et al. (2017). The thick curves indicate the parabola fits to the equation of Brice (1975) for individual groups of isovalent cations

the peak of the parabolas for isovalent cations also vary parabolically with the cation charges and reaches the maximum values when trace element cations have charges similar to the major cations in the lattice site (Wood and Blundy 2003).

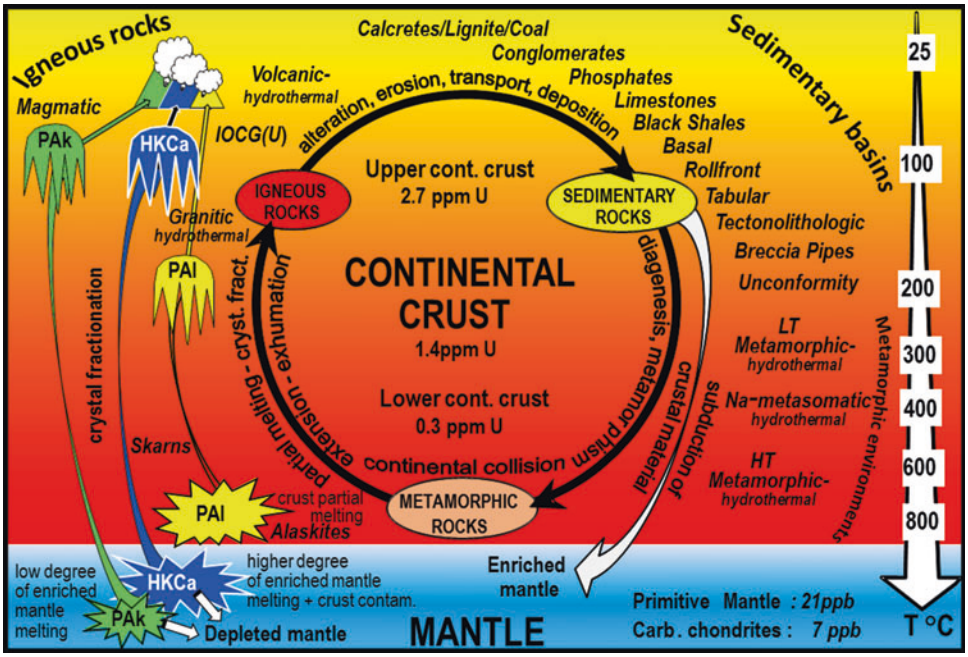
Mineral deposits; Mineral resources

Definition

Strictly speaking, an ore ("mine" in Latin) is a natural rock containing one or more useful substances that can possibly be extracted (mined) and processed to meet the demand of the society. Even if an economic connotation is generally associated with this term, there are many examples of ore mining driven by the imperative need of the substance without economic considerations. A typical example is uranium production during the 1950s which was dictated by the military programs. Moreover, the profitability of a given ore deposit may vary largely through time according to economic conditions and improvements in extractive metallurgy. Concentrations that are of too small volume or too low grade to be mined are called mineral occurrences or showings. The term ore deposit is most commonly applied to rocks containing metallic ore minerals in the native state (e.g., Au, Ag, Cu) or combined with other elements to form more complex minerals oxides (e.g., Fe, Al, Mn), sulfides (e.g., Pb, Zn), silicates (e.g., Ni, V), carbonates (e.g., Ca), phosphates (e.g., rare earth elements: REE), and others. The chemical elements in the Earth's crust are in concentrations (known as the Clarke) from percent level (Si, Al, Na, K, Fe, Mg, Ca) to ppb (milligram/ton of rock), but most of them, in the order of ppm (gram/ton). Metals occur in all types of rocks but usually in concentrations that are too low to be mined. In an ore deposit, the chemical elements are concentrated by factors ranging from 8 for iron deposits to several thousand for gold, uranium, and mercury when compared to the average concentrations in the Earth's crust.

Ore deposits are formed by the same processes that produce ordinary rocks but with a combination of conditions permitting to reach stronger enrichments of the elements or compounds in very small volumes of the Earth's crust, making up what is called a metallogenic system. The processes leading to the concentration of elements and minerals are extremely various. They are driven at depth by dynamic interactions between the Earth's core, mantle, and crust and at the surface by interactions between the hydrosphere, biosphere, and atmosphere. Even meteoritic impacts may play a

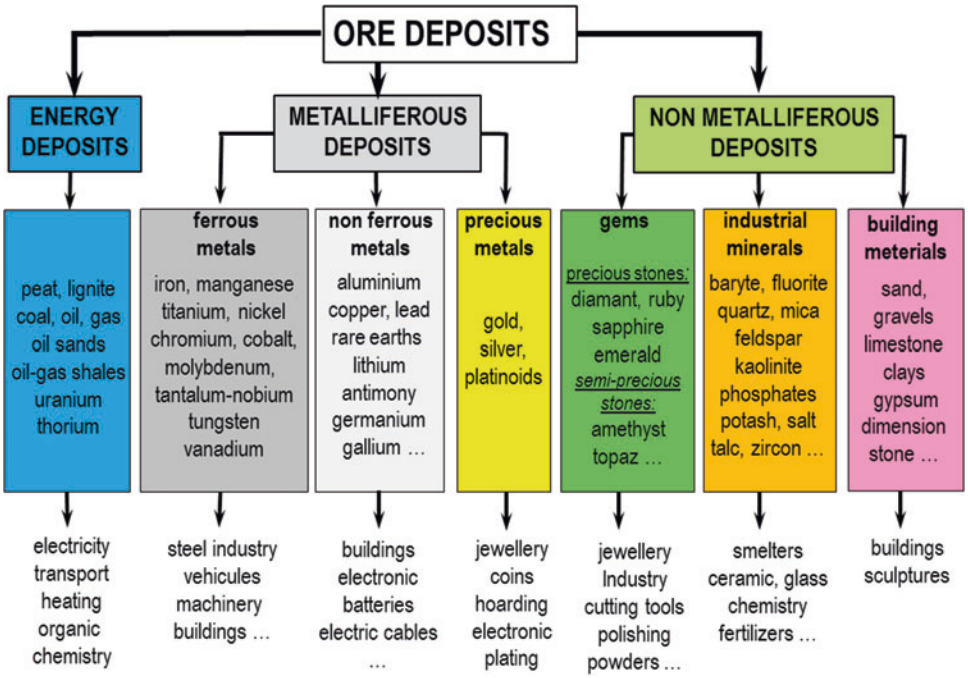


Ore Deposits, Fig. 1 Position of the major types of uranium deposit types (in *italic*) through the geological cycle with the major fractionation mechanisms (Modified from Cuney (2011))

role in the genesis of some deposits. For example, uranium deposits formed at nearly all steps of the geological cycle, from high-grade metamorphic conditions to plutonic, metasomatic, hydrothermal, basinal diagenetic, metamorphic, volcanic, sedimentary, and superficial environments (Cuney 2011) (Fig. 1). Even if the volume of an ore deposit is generally small compared to other common geological units, its genesis commonly involves mass transfer through large sections of the mantle and/or of the Earth's crust. An ore body contains ore minerals intermixed with other minerals, called gangue minerals, from which they must be separated. Mineral processing begins with the crushing of the ore to optimum grind size. The ore minerals are then physically separated from the gangue minerals, taking advantage of differences in their physical properties, such as density, particle size and shape, and electrical, magnetic, and surface properties. The resulting concentrate is then used for metal extraction through a more or less complex extractive metallurgy flow sheet which has to be designed for each type of ore deposits.

By extension, the term ore deposit or mineral deposit is applied to any substance extracted from the continental crust by humans and includes elements that are not metals such as building materials; biogenic substances accumulated and transformed by geological processes, such as sedimentary phosphates, fossil organic materials (coal, oil, and gas), and even fresh water resources; or those extracted from the evaporation of seawater either by natural processes (rock salt, potash, salars) or by human intervention (salt marshes). Mineral resources can be classified into three main groups (Fig. 2):

- The energy deposits or resources (peat, lignite, coal, oil, natural gas, oil and gas shale, oil sands, uranium, thorium), whose major use is to produce much of the primary energy, but fossil fuels are also used for organic synthesis products; they represent more than 90% of the mineral resources produced in the world.
- The metallic deposits or resources that fall into three categories:
- Ferrous metals: with iron and the metals used in alloys with him (Co, Cr, Mn, Mo, Nb, Ni, Ta, Ti, V, W. . .)
- Nonferrous metals: Al, As, Bi, Cd, Cu, Ga, Ge, Hg, Li, Pb, Sb, REE's, Te, Zn. . .
- Precious metals: (Au, Ag, and platinoids) produced in very low volume but, with a very high market value, predominantly used for jewelry or for hoarding and more subordinately for specific industrial applications
- The nonmetallic resources are available in three categories:
- Construction materials representing the most important volume; they are used either in their raw form (sand and other natural stones: granite, limestone, marble...), or grounded (aggregates), or after more or less extensive transformations (clays to produce bricks, limestone and clay to make cement. . .).
- Industrial minerals: e.g., asbestos, barite, clays, industrial diamonds, diatomite, feldspars, fluorite, graphite, gypsum, anhydrite, magnesite, phosphates, potash, salt (rock, brine, and sea salts), sulfur, talc, pyrophyllite, vermiculite, zircon, phosphates, and potash are used for fertilizers, feldspar, and kaolin for ceramics.



Ore Deposits, Fig. 2 The different categories of ore deposits or mineral resources and their main use by the different segments of the society

- Gems including precious stones (diamond, ruby, sapphire, and emerald) and semiprecious stones (tourmaline, amethyst, peridot. . .).

In addition, not all mined ores are strictly natural; more and more frequently tailings from former mines become a profitable ore. For example, in 2013, de Beers recovered 815,036 carats of diamonds from 6,133,799 tons of old tailings surrounding the Kimberley mines in South Africa. Such developments could enable minimizing the footprint of the mineral industry on the environment and also contribute to the sustainable use of the mineral resources.

Classifications

Many geological parameters have been used for ore deposit classification, such as the presence of certain metals or minerals (e.g., gold, magnetite), shape of the ore body (dissemination, vein, layer, etc.), geological environment (continental or marine basins), local tectonic regime (shear zone, breccia), geotectonic setting (collisional, island arc, continental margin), formation temperatures, and chemical composition of the fluids. Individual deposits present an extreme variability due to their formation involving frequently a combination of different processes and factors. Therefore, a classification of ore deposits does not appear straightforward. It is why some authors prefer to classify deposits into associations and types, which are related by common geological setting and paragenesis, but not necessarily by similar genetic processes (Laznicka 1993). Exploration and mining geologists tend to prefer pragmatic and empirical classifications rather than genetically based models. Also, many scientists use the type of rock to which the deposits are spatially associated, such as volcanic- or granite-related, turbidite-hosted gold deposits (Laznicka 1985, 1993; Jebrak and Marcoux 2015). Others use more taxonomic terminologies such as "deposit types" (Cox and Singer 1986; e.g., porphyry copper, orogenic gold, lateritic nickel) or deposit styles (Carlin style Au, Bushveld style PGE (platinum group elements), Witwatersrand style Au, Olympic Dam style IOCG: iron oxide copper gold). Nongenetic classifications are considered to minimize errors and controversy. However, although a stringent genetic classification of ore deposits is very difficult, it should represent an ultimate objective using the progress of scientific research which continuously modifies and improves ore-forming models and mineral system models.

Guilbert and Park (1986) have shown that the evolution of the classifications reflect the development of the knowledge of ore deposit formation increasing with the development of new techniques, experimental work, and modeling. The classification of Guilbert and Park (1986), which derives from the one of Lindgren (1933), is one of the most detailed and comprehensive. In contrast, Robb (2005) selected a classification simply based on the association between ore deposits and the three main categories of host rock, namely, igneous, sedimentary, and metamorphic, which are considered to reflect the fundamental processes active in the Earth's crust. He considers that ores are rocks and can generally be attributed to an igneous or sedimentary/surficial origin. However, such a relation works perfectly for syngenetic deposits

because they are formed at the same time as the host rock itself, but for epigenetic mineralization, such as those deposited by hydrothermal fluids in veins, the ore may occur in virtually any rock type without having any genetic link with the enclosing rock. Moreover, the same ore-forming process can be developed on more than one rock categories within the same deposit, and the formation of many deposits lies in intermediate position between genetic end members. For example, the Kuroko massive sulfide deposits result from combined interplay of volcanic, intrusive, sedimentary, and diagenetic processes. In addition, supergene processes may represent the crucial step to reach economic grade for a mineralization with a primary igneous or sedimentary origin. For example, the genesis of high-grade hematite-banded iron formation includes iron concentration during sedimentation, then during percolation of basinal brines, and finally by tropical weathering.

Compared to ore deposit models, which intend to understand how deposits form, the mineral system approach (Wyborn et al. 1994) focuses on answering the question of "where?" ore deposits form and integrates all geological scales from deposit to continental scales. Four critical elements are considered in the mineral system: (i) the fluid source region; (ii) the metal/other critical solute source regions, both considered at the regional scale; (iii) the fluid fractionation site at the ore district scale; and (iv) the metal depositional site. All these elements are reported on a series of maps in Global Information Systems (GIS; Bonham-Carter, 1994). Then, using the relevant mineral system model for a particular type of deposit, statistical approaches such as "Weights of Evidence" modeling allow the development of predictive maps for targeting the exploration of new deposits (Partington and Sale 2004). Such approaches become essential in finding more and more deeply buried deposits and evaluating economic risks in their exploration.

In the present contribution, we have used and slightly modified the classification of Pohln (2011) which is based primarily on the five main petrogenetic process systems occurring on Earth, which are magmatism, sedimentation, diagenesis, metamorphism, and surficial weathering. We have excluded metamorphosed deposits which just present a modification from pre-existing deposits formed by other processes. The five main types are: (i) magmatogenic, (ii) supergene, (iii) sedimentary, (iv) diagenetic-hydrothermal, and (v) metamorphogenic-hydrothermal ore deposits. Only some of the major deposit types have been selected for more detailed descriptions.

Magmatogenic Ore Deposits

Magmatogenic ore deposits are further subdivided into four subtypes: (i) orthomagmatic base metal deposits, (ii) orthomagmatic deposits related to peralkaline magmas, (iii) pegmatites, and (iv) hydrothermal deposits.

Orthomagmatic base metal deposits mainly include metal oxide (magnetite, ilmenite, chromite), Ni-Cu-sulfide sulfides, and precious metal (Pt, Pd, Au) mineralization. They result from magmatic fractionation with segregation of minerals or sulfide-rich immiscible melt droplets within large silicate basic to ultrabasic magma intrusions. Gravitational settling due to the large density contrast between the residual melt and the minerals and the melt droplets is the fundamental concentrating mechanism. However, the implication of hydrous or carbonic fluids is more and more evidenced in the recent studies. For example, in magmatic Ni-Cu deposits, most sulfide zones carrying appreciable PGE contents are characterized by pegmatitic textures and the presence of hydrous minerals, pointing to a high fluid activity during the magmatic segregation. Orthomagmatic ore bodies generally form layers in stratified magmatic rocks but also lenses or crosscutting dykes and veins. Such deposits occur in a large variety of intrusion styles: Fe-Ni-Cu-sulfide and PGE ores hosted by Archaean komatiite lavas such as those of the Yilgarn Craton in Western Australia; Alpine-type chromium-PGE mineralization settled within ophiolites, and as seams in layered mafic intrusions; Cu-Ni-PGE "reefs" found within layered mafic intrusions; conduit-hosted Cu-Ni-PGE in complex mafic-ultramafic intrusions; Ni-Cu-PGE in magma bodies resulting from meteoritic impact; Cr-PGE in Ural-Alaska-type ultramafic ring intrusions; Ti-Fe in Mesoproterozoic anorthosite-ferrodiorite complexes; Kiruna-type orthomagmatic iron oxide and apatite deposits in intermediate to felsic igneous rocks; apatite-Fe-Nb-Zr, or REE-U-F in carbonatite plugs and nephelinite intrusions. Only three major types of these deposits will be described: chromite deposits, Ni-Cu deposits, and PGE deposits.

Chromite deposits result from fractional crystallization of ultramafic and mafic magmas and gravity settling of Cr-rich spinels which form a cumulate layer at the base of the intrusive. There are two main types of chromite deposits: stratiform and podiform. Stratiform deposits consist of extensive chromite-rich layers (a few millimeters to several meters thick) alternating with silicate layers including dunite, peridotite, pyroxenite, and less commonly gabbroic rocks. They occur within basal portions of Archaean mafic-ultramafic layered intrusions such as the Bushveld Complex in South Africa. These deposits contain large resources of low-grade chromite (average 10.7% Cr_2O_3). Podiform chromite deposits consist of irregularly shaped massive chromite pods. They generally occur in the olivine-rich portions (dunites) of ophiolitic complexes, referred as "Alpine-type," and are located along major faults.

Ni-Cu deposits result from the separation from a parental magma of a sulfur-rich immiscible liquid concentrating Fe-Ni-Cu, from which pyrrhotite (FeS), pentlandite $(Fe, Ni)_9S_8$, and chalcopyrite ($CuFeS_2$) crystallize during cooling. The Ni-Cu ore bodies tend to occur in embayments at or near

the base of intrusions because sulfide liquids are heavier than silicate liquids and therefore sink to the bottom of the magma chamber. The host magmatic bodies consist of layered intrusions, stocks, ultramafic sills, and flows. The largest deposits are of Archaean and Proterozoic age. Typical Ni-Cu deposits include those hosted by the Sudbury layered intrusion (Ontario, Canada), the Kambalda ultramafic flow in Australia, and the Thompson District ultramafic sill in Manitoba (Canada).

Platinum group elements (platinum, Pt; palladium, Pd; iridium, Ir; rhodium, Rh; osmium, Os; and ruthenium, Ru) may occur both with Ni-Cu-sulfide and chromite mineralization. However, the fundamental mechanisms involved in PGE concentration and deposition result from a not so well-understood multistage process. PGE can concentrate during high-temperature deposition of chromites, but they can also be incorporated into immiscible liquids and remobilized and reconcentrated during metasomatic and hydrothermal activity. The PGE production comes dominantly from the Merensky Reef in the Bushveld Complex in South Africa and the Ni-Cu deposits of the Noril'sk-Talnakh District in Russia. The mineralized Merensky Reef forms less than 1 m thick but laterally persistent, disseminated, sulfide-poor horizons within polycyclic mafic-ultramafic cumulate sequences. The principal ore minerals are pyrrhotite, chalcopyrite, pentlandite, PGE, sulfides, arsenides, and tellurides. The Noril'sk-Talnakh deposit is essentially a magmatic Ni-Cu deposit containing high PGE concentrations (6 g/t). The ore bodies occur at or near the base of 50–350 m thick complexly differentiated gabbro-dolerite intrusions emplaced during the late Permian to Triassic time along rifts of the Siberian platform.

Orthomagmatic deposits related to peralkaline magmas are a source of a different set of metals. Peralkaline fractionated magmas are commonly considered to derive from very low degrees of partial melting of the mantle that generates alkali basalts, followed by several stages of magmatic fractionation. Their geodynamic setting is typically anorogenic. They form small to large, commonly concentrically zoned, circular to ovoid plutonic to volcano-plutonic complexes associated with ring dikes. These complexes may comprise a wide range of intrusions, from gabbros to highly fractionated granites or syenites, always emplaced at a very high structural level. Associated ore deposits essentially result from extreme crystal fractionation. The high temperature and peralkalinity of these melts permit a high solubility of incompatible elements such as Zr, REE, U, Th, and Nb and cause their continuous enrichment until the most extreme stages of magmatic fractionation. These ore deposits are always hosted by the last and most fractionated magma batches at the roof or at the margin of the peralkaline plutonic complex. When these melts crystallize, complex Zr-REE-Nb-Th-U silicates, phosphates, and/or oxides are formed. One of the best examples of the REE-U-Zn-Th mineralization is the Kvanefjeld deposit in the Ilimaussaq plutonic complex in southern Greenland which is hosted by layered lujavrites, a highly fractionated peralkaline syenite.

Pegmatites can host a variety of ore minerals containing Be, Li, Rb, Cs, Ta-Nb, U, Th, REE, Mo, Bi, Sn, and W, generally belonging to the group of the so-called rare metals, industrial minerals (feldspars, kaolin, quartz), as well as numerous types of gemstones. Pegmatites are also orthomagmatic deposits but originate either from the extreme fractionation of a parental pluton, generally of granitic composition, which becomes highly enriched in volatiles (water, B, F, Cl) and rare metals or directly from the partial melting of the continental crust (Černý et al. 2005). Equivalents of these types of mineralization also occur in granitic and volcanic rocks. Three main types of mineralized pegmatites/granites are recognized: (i) LCT pegmatites (LCT for Li and columbo-tantalite), equivalent of the peraluminous high phosphorus rare metal granites (PHP-RMG) (e.g., Beauvoir granite in France), spatially associated with large peraluminous leucogranite complexes, with Li-Ta>Nb-Be-Sn mineralization; (ii) NYF pegmatites (NYF for Nb, Y, and F) equivalent of the peralkaline rare metal granites (PAK-RMG), associated with peralkaline granite complexes (A1 type) with Nb>Ta-Zr-REE-U-Th mineralization; and (iii) mixed pegmatites intermediate between the two proceedings probably corresponding to the peraluminous low phosphorous rare metal granites (PLP-RMG) and deriving from extreme fractionation of high-K calc-alkaline granites (A2 type) with Nb≈Ta-Sn mineralization.

Pegmatites typically derived from partial melting in the continental crust are represented by the low-grade disseminated uraninite mineralization concentrated in granitic pegmatoids occurring in migmatitic domains. The type example is the Rössing deposit in Namibia (246,500 t U at 300 ppm U) whose mineralization is hosted by granitic pegmatite sheets called alaskites. They are intrusive into epicontinental sediments metamorphosed to a high grade with partial melting. The large accumulation of mineralized alaskite dikes at Rössing results from the combination of six parameters:

(i) A U-rich source represented by intracontinental platform sediments, probably with synchronous felsic volcanism
(ii) Low degree of partial melting
(iii) Structural control of alaskite emplacement
(iv) A chemical barrier represented by the Rössing Formation marbles, stopping the rise of the alaskitic melts, because of skarn formation reactions with production of carbon dioxide, shifting melt solidus to higher temperatures
(v) A redox barrier represented by graphite and sulfides in the Rössing Formation, creating low fO_2 conditions that prevented U fractionation in magmatic fluids

(vi) Favorable climatic conditions that oxidized uraninite in the weathering zone and precipitate uranophane in fractures that have enriched the upper part of the deposit

Hydrothermal deposits occur within an extreme variety of geological settings. The relative importance of magmatic and external fluids involved in their genesis cannot be always clearly estimated. They are classically considered as formed from metal-enriched magmatic fluids exsolved from crystallizing magma bodies, frequently highly fractionated. However, as an example, the fluids observed in most tungsten deposits from China and Europe correspond dominantly to metamorphic fluids. Also, vein-type uranium deposits occurring within the granites or in enclosing rocks were formed $40–50 \times 10^6$ year after granite emplacement with the involvement of diagenetic and meteoric fluids. In fact, in hydrothermal ore deposits, the origin of the fluids ranges from magmatic to metamorphic, diagenetic, meteoric, and seawater. Indications on the origin of the fluids are provided by isotopic characterization of hydrothermally altered minerals associated with the deposits. Hydrothermal deposits comprise magnetite-Cu-Co-Au, W, Zn-Pb-Ag, Mo-Bi-Au, and Sn-As-Pb-Zn-W-Mo skarns; contact-metasomatic Pb-Ag-Zn ore; iron-oxide-copper-gold (U-REE) deposits (IOCG); Cu-Mo-Au and Sn-W porphyries; Kuroko-type submarine volcanogenic deposits; volcanic-hosted massive sulfides (VMS); Sn-W-Cu veins; epithermal Ag-base metal; and Au-Ag deposits. Many of these deposits are related to plutonic and subvolcanic magma bodies generally of granitoidic composition and occur in the roof of the intrusions or in enclosing metamorphic rocks; VMS and epithermal Au-Ag deposits are developed near the surface in association with volcanic centers on land or submarine.

Porphyry deposits produce mainly Cu-Mo or Cu-Au-Ag, sometimes W. The term porphyry copper refers to very large, low-grade, epigenetic mineralization disseminated within granitic intrusions. There are several episodes of intrusive activity, with several stocks, dike swarms, and intrusive breccias. Porphyritic textures result from their high-level emplacement in the crust. Ore extraction typically requires mass mining techniques with open pit mines that extend over several square kilometers. Porphyry copper provinces coincide, worldwide, with orogenic belts predominantly of Cenozoic and, to a lesser extent, Mesozoic age. The most remarkable one is the series of Circum-Pacific deposits related to oceanic crust subduction settings where they occur in island arcs and at continental margins. Porphyry-type deposits are uncommon during the Paleozoic and are rare during the Proterozoic. Porphyries in island arc settings have primitive initial Sr isotopic ratios ($0.702 < {}^{87}Sr/{}^{86}Sr < 0.705$) reflecting a derivation either from upper mantle material or recycled oceanic crust, whereas the intrusions occurring in continental settings have higher initial Sr isotopic ratios due to interaction with the crust. Mineralization may occur entirely within the stock, or within the country rock, or in both, or in associated volcanics. Sulfide minerals (pyrite, chalcopyrite, bornite, and molybdenite) mostly occur on fractures or disseminated in the potassic alteration zone. Strong alteration zones develop in and around mineralized granitic rocks and may reach 10–20 times the size of the deposit. Ideally, mineralized porphyries will have a central area associated with secondary biotite or K-feldspar and surrounding shells of quartz and sericite (cream to slightly greenish phyllic zone) and then a greenish chlorite, epidote, sodic plagioclase, and carbonate (propylitic zone) alteration. In some cases, a white argillic zone occurs. The deposits have commonly a central very low-grade zone enclosed by shells dominated by bornite, then chalcopyrite, and finally pyrite. Molybdenite distribution is variable. Radial fracture zones outside the pyrite halo may contain Pb-Zn veins with Au-Ag values. Where sulfide mineralization occurs, surface weathering often produces rusty-stained bleached zones from which the metals are leached and redeposited near the water table to form an enriched zone of secondary mineralization. In the potassic alteration zone, mineralization is associated with vapor-rich fluid inclusions (with SO_2, H_2S, CO_2, HCl, HF, and most Cu and Au) and highly saline fluid inclusions (35 to >70 wt.% of K, Na, Ca, Fe, Mo, and Cu chlorides) which result from the boiling of a magmatic fluid. Numerous features, such as magma compositions; their metal and volatile contents; their state of oxidation; the number, size, relative timing, and depth of emplacement; and variations in the type of country rock, lead to a wide variety of porphyry copper styles. Porphyry systems are dominated by magmatic fluids mixed with variable quantities of meteoric fluids. The average porphyry copper deposit represent about 10^9 t ore at 0.5–1.5% Cu, 0.01–0.04% Mo, and <1.5 g/t Au. Giant deposits contain more than 2×10^6 t Cu, the Chuquicamata supergiant deposit reaches 24×10^6 t Cu, and the largest one, El Teniente in central Chile, contains more than 94×10^6 t Cu. Apart from copper, by-product metals include significant tonnages of Ag, Au, Mo, Re, Pb, Zn, and Mn and minor amounts of As, Bi, Sn, W, U, and Pt.

Epithermal gold deposits occur within 1–2 km of the surface and are deposited in veins or stockworks from hydrothermal fluids at temperatures ranging from less than 100 to about 300 °C. The deposits are often formed at active continental margins in areas of active volcanism. Two types of fluids are distinguished: the so-called low-sulfidation (LS) fluids, which are reduced with a near-neutral pH, and high-sulfidation (HS) fluids, which are more oxidized and acidic. LS fluids are considered to be a mixture of meteoric and magmatic water and gold deposition occurs when boiling occurs, whereas HS fluids are mainly of magmatic origin and gold is deposited when the solution cools and/or mixes with meteoric water. LS deposits may also produce economic

quantities of Ag and minor amounts of Pb, Zn, and Cu, whereas HS systems more often produce Cu and Ag. Similarly to porphyry copper deposits, one of the largest epithermal gold deposit provinces is distributed around the Pacific volcanic "Rim of Fire." Epithermal gold deposits contribute significantly to the world's gold supply. Gold grades are highly variable in epithermal deposits ranging from 1 to more than 150 g/t.

Supergene Ore Deposits

Supergene ore deposits result from weathering. Earth materials interact with water, air, the biosphere, and the energy provided by the sun. During fragmentation and alteration of rocks, metals are concentrated either in situ as an insoluble residuum (e.g., bauxite) or by precipitation after limited movement in soil and ground water (e.g., lateritic nickel deposits). For infiltration deposits, such as those of Cu and U, lateral transport distances may reach 1 to several hundred kilometers. Three subcategories are identified:

(i) Residual deposits which include bauxite and lateritic Au, Fe, and Mn ore deposits
(ii) Supergene enrichment deposits generally developed on primary sulfide ore (Cu, Au, Ag), as lateritic Ni as in New Caledonia and Nb in the Araxa carbonatite in Brazil
(iii) Infiltration deposits that are typically represented by roll-front-type uranium deposits (e.g., Wyoming Province in the USA and the huge province of the Chu-Saryssu and Syr Darya Basins in southern Kazakhstan) occurring in continental to marginal marine sandstone

Roll-front deposits represent the best example of epigenetic U deposition resulting from meteoric water infiltration in sandstone. Host rocks were deposited in fluvial and lacustrine environments, in marine marginal plains, or in channel, lagoonal, and beach-bar settings. The source of U may be U-rich granites or volcanics external to the sediments and/or synsedimentary U trapped in reducing conditions or interlayered U-rich volcanic ashes. The reduced sandstone contains disseminated organic matter and pyrite and occurs down the hydrologic gradient relatively to the oxidized sandstone. The reductants are either of synsedimentary origin, resulting from the maturation of detrital organic matter (plant debris) during diagenesis, or epigenetic, deriving from the infiltration of reduced fluids migrated from deep oil reservoirs along faults (e.g., South Texas). In most models, U is transported by oxidized low temperature meteoric waters infiltrated through permeable sandstones confined between two aquitards corresponding to mudstone or shale. The reduced sandstone is oxidized and takes a pink red color due to hematite, or a yellow-orange color due to limonite, or even may become white gray when iron has been totally leached out. Uranium distribution is controlled by the interplay of the permeability of the sediments and the distribution of reducing components. Bacterial sulfate reduction is increasingly evidenced in the genesis of roll-front deposits and indicated by the presence of framboidal pyrite and strongly negative $\delta^{34}S$ values of secondary pyrite intimately intergrown with coffinite or nyngyoite. The resulting ore bodies exhibit C shapes in cross section and are sinuous along the roll-front interface. In south Kazakhstan, the rolls may extend laterally over more than 100 km. Resources range from a few 10^2t to several 10^4t U, at grades averaging 0.05–0.25% U.

Synsedimentary Ore Deposits

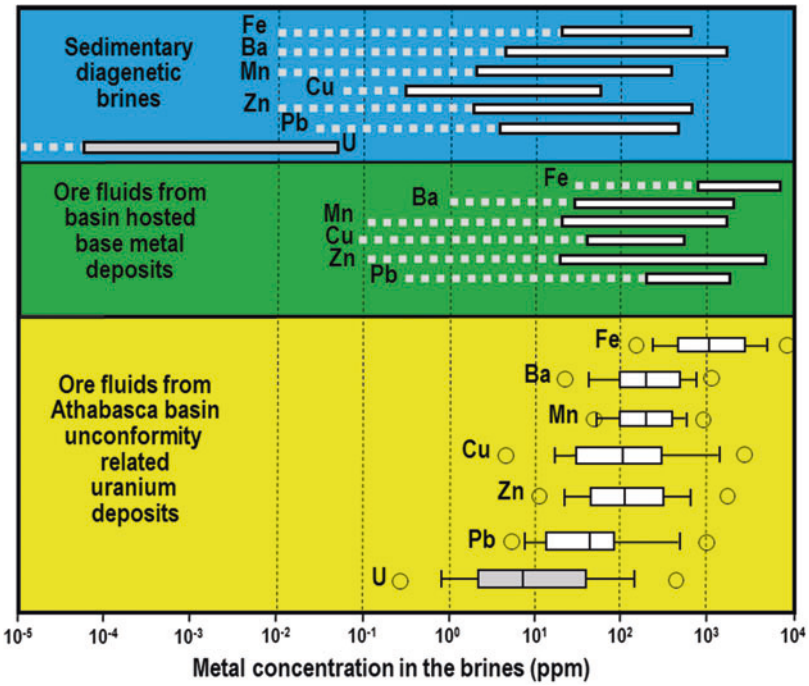
Ore deposits of this type result from exogenous process systems involving physical or chemical transport in water and deposition simultaneously with the sediments. Two subtypes are distinguish according to distance of transport of the metals from their source: (i) allochthonous: colluvial, alluvial, or coastal placers and (ii) autochtonous mainly occurring in marine sediments such as sulfide-rich black shales; sedex-type Cu-Sb-Zn-Pb-Ag (Au); Palaeoproterozoic banded iron formation (BIF) of Algoma- and superior-type and banded Mn ore; oolitic Fe and Mn ore; and deep-sea manganese nodules and crusts (Mn-Cu-Ni-Co-PGE).

Allochthonous synsedimentary ore deposits result from mechanical sorting by density of heavy minerals and their concentration in colluvial to alluvial (Au, U, W, Pt, columbite, cassiterite, diamonds) to coastal (rutile, ilmenite, zircon, monazite) placers.

Autochthonous synsedimentary ore deposits result from metal transport in aqueous solution from land or from seafloor hydrothermal sources for black shales and sedex deposits. The world's largest metal concentrations formed in the Paleoproterozoic when photosynthetic cyanobacteria expanded rapidly, oxidizing the atmosphere and seawater and precipitating iron dissolved in the oceans with the huge banded iron formations. Many giant base metal deposits (sedimentary-exhalative, "sedex" Cu, Pb, Zn) are the product of hot metalliferous fluids venting on the seafloor. In contrast to mid-ocean black-smoker activity, sedex deposits occur along rifts in shallow epicontinental seas.

Diagenetic-hydrothermal Ore Deposits

Three subtypes are recognized: (i) stratabound and/or stratiform sediment-hosted Cu deposits, (ii) Mississippi Valley type (MVT), and (iii) unconformity-related uranium deposits. These deposits result from physical and chemical changes affecting thick sedimentary basins. During basinal subsidence, the salinity of pore fluids increases with temperature and pressure rise to become diagenetic fluids. Such hot chloride-rich fluids are strongly enriched in a large variety of metals (Pb, Zn, Cu, U…) (Fig. 3). They can migrate according to pressure variations, either toward basin margins,



Ore Deposits, Fig. 3 Ranges of metal concentrations in diagenetic brines from sedimentary basins, in ore fluids from basin-hosted base metal (Pb, Zn, Ba) deposits and fluid inclusions associated with the Athabasca unconformity-related deposits (Modified from Richard et al. (2015)). Boxplots show 5th and 95th percentiles (*symbols*), 10th and 90th percentiles (*whiskers*), 25th and 75th percentiles (*box edges*), and the median (*inner bar*). The *boxes* represent the ranges of metal concentrations in each of the selected studies. *Gray* dotted lines represent the lower ranges of metal concentrations

or may infiltrate into the crystalline basement. The deposition of the metals often occurs at low-permeability barriers in copper shales or when redox conditions are reached for unconformity-related deposits.

Stratabound and/or stratiform sediment-hosted Cu deposits are best exemplified by the European copper shale (also known as the Kupferschiefer). It forms a thin strata extending over more than 600,000 km^2 in the Central European Permian rift basin. Economic metal grades are only known to southern basin margins (Silesia in Poland and the Harz District with Mansfeld and Sangerhausen in Germany). The mineralized shale is a euxinic sediment deposited in a shallow sea with a well aerated upper water column. Detrital import was very small with quiet deposition conditions as shown by the preservation of the fine lamination of the sediments. A controversy exists between syn- and epigenetic models. Recent data tend to support an epigenetic diagenetic origin. The ore bodies are perfectly stratiform, but they present crosscutting relations with the copper shale stratum. The metals are considered to be transported by oxidized, sulfate-bearing, Ca-Mg-K-Cl diagenetic fluids flowing up toward basin margins from deeper parts of the basin, leaching the metals from Permian molasse red bed sediments and volcanics. Deposition mechanisms include decreasing T and P; mixing with cool, alkaline, meteoric water; and reduction by reaction with organic matter and sulfides of the shale. Most ore minerals replace rock-forming minerals with microscopic veinlets of different spatial orientation. Copper shale deposits in Poland have grades of 1.2–2.8% Cu and 30–80 g/t Ag. The thickness of the ore bodies varies from 1.2 to more than 20 m. Mining occurs at depths between 600 and 1,200 m. Besides copper, Pb, Ag, Ni, Au, Pd, Pt, Re, Se, and sulfuric acid are produced. Reserves of 2.4×10^9 t of ore are reported. In Germany, the Mansfeld District has produced about 1.5×10^6 t Cu until 1970.

Mississippi Valley type (MVT) Pb-Zn-(F-Ba) deposits correspond to epigenetic ore deposits typically hosted in marine dolostone. Most occur in Cambrian to Triassic rocks. The largest MVT deposits are in North America with the Viburnum Trend and the Old Lead Belt (Southeast Missouri Lead district), Tri-State, Upper Mississippi Valley, Central and East Tennessee, and Pine Point. MVT deposits typically are in districts covering hundreds or even thousands square kilometer. Ore controls are district specific, such as depositional margins of shale units, limestone-dolostone transitions, reef complexes, solution collapse breccias, faults, and basement topography. Most MVT ore districts are the product of regional to subcontinental scale migration of diagenetic brines (10–30 wt% salts) at temperatures comprised between 50 and 200 °C. Typically, the mineralization is epigenetic and stratabound in platform carbonate sequences or in foreland thrust belts, and they occur at shallow depths at the margins of basins, unrelated to any igneous activity. The ore mineralogy is simple: sphalerite, galena, pyrite, marcasite with dolomite, calcite, and quartz as gangue minerals. Carbonate host-rock dissolution leads to slumping, collapse, and brecciation. Individual MVT deposits are generally small, generally less than 10×10^6 t ore. In the Upper Mississippi Valley district, the average deposit size is between 0.1 and 0.5×10^6 t, and a few contained up to 3×10^6 t ore. Deposit grades rarely exceed 10% Pb+Zn. An exception is the Polaris deposit, in the Canadian Arctic Archipelago with 22×10^6 t ore at 18% Pb+Zn. Most deposits have Zn/(Zn+Pb) values between 0.5 and 1.0.

Unconformity-related uranium deposits mainly occur in the Athabasca Basin (Saskatchewan, Canada) and in the vicinity of the Kombolgie Basin in the Northern Territory, Australia. The deposits associated with the Athabasca Basin represent the world largest high-grade U ore bodies (up to 19.5% U for about 260,000 t U for the McArthur deposit). They are located in the vicinity of an unconformity between an Archaean to Paleoproterozoic basement and a Paleo- to Mesoproterozoic intracontinental siliciclastic basin. Their exceptional grade and size results from the combined efficiency of a series of U-fractionation mechanisms. U enrichment of the basement is exceptional with considerable amounts of uranium trapped in the Paleoproterozoic epicontinental platform sediments, comprising U-rich graphitic schist, meta-arkose, and calc-silicate, in uraninite-bearing leucogranites and pegmatoids derived by partial melting of these metasediments during the Hudsonian orogenesis, followed by the emplacement of Paleoproterozoic Th-U-rich high-K calc-alkaline granitoids, and finally the formation of late Hudsonian vein-type U deposits (e.g., Beaverlodge, Gunnar). High efficiency of U extraction from source rocks is shown by the alteration of highly refractory minerals such as monazite and zircon in the sandstone, the regolith, and the basement by acidic, hot (160–220 °C, about 1 kbar), oxidized, and Na-Ca-Mg-rich (up to 6 molar Cl) basinal diagenetic brines generated within continental, oxidized, organic-free, siliciclastic formations. The brines are very similar to MVT brines with high contents of Fe, Cu, Zn, and Pb but differ by their high U content (Fig. 3). Exceptional trapping conditions resulted from (i) the strong redox gradient developed between the oxidized basal Athabasca sandstone and the epicontinental Paleoproterozoic carbon-rich metasediments of the basement and (ii) the creation of large openings by reverse faulting and intensive quartz dissolution.

Metamorphogenic-hydrothermal Ore Deposits

Prograde and retrograde metamorphogenic-hydrothermal ore deposits comprise orogenic Au deposits in accretion-subduction collision complexes, a large part of the Cu-Co ore deposits of the Copperbelt in Zambia and the Democratic Republic of Congo, and the Mt Isa copper deposit in Australia. During prograde metamorphic, dehydration reaction occurring within large volumes of rocks liberates a huge mass of fluids with variable salt, CO_2, CH_4, and N_2 contents. These fluids can transport metals which will precipitate where chemical and physical traps are present. Orogenic gold deposits are commonly related to such processes.

Mine Life Cycle

Mining activities start with the exploration and evaluation of an area of interest. If the evaluation is positive, a mine can be developed, and commercial mining production can start. However, the phases before production take a long time and require large capital investments. There are five main phases in the development of a mine.

Phase 1 – Exploration means the search for mineral resources suitable for a profitable exploitation. It includes researching and analyzing all the geological information and historic exploration data already available on the area in libraries; geological surveys; Ministry of Mines; reports from former exploration companies, conducting topographical, geological, geochemical, and geophysical studies to delineate the most prospective areas; and exploratory drilling, trenching, and sampling for ranking the prospectivity of the discovered anomalies and showings. GIS softwares are now commonly used to compile all available information and to build prospective maps allowing to choose the best targets for their detailed evaluation. Contacts and diffusion of the information about the work which is being done with the country and local authorities and with the local population has to start since the beginning of the operations and has to be repeated regularly. Also, a baseline assesses the state of the land before mining, including measurement of geochemical background concentration of metals in waters, soil, plants, and fauna. The biologic diversity and the existence of potentially endangered species have to be surveyed.

Phase 2 – Evaluation means determining the technical feasibility and commercial viability of a discovered mineral resource. It includes determining volume and grade of deposits by systematic grid drilling, evaluating and testing ore extraction methods and metallurgical ore treatment processes, surveying transportation and infrastructure requirements, and conducting prospective market and finance studies. This stage leads to the production of a feasibility study that provides estimations of the proved and probable mineral reserves which is used for taking the decision to develop a mine.

Phase 3 – Development involves establishing access to and commissioning facilities to extract, treat, and transport the ore from the deposit and associated preparations for commercial production. Depending on the selected type of mining, it may include constructing roads and tunnels and removal of overburden and waste rock for the development of open pits, excavations, sinking shafts, and underground drifts.

Phase 4 – Production corresponds to the activities of obtaining a saleable product from the ore deposit on a commercial scale. It includes the geometallurgic extraction of the product and any processing before sale.

Phase 5 – Closure occurs after mining operations have ceased and includes restoration and rehabilitation of the site using the budgets which have been provisioned since the phase 2.

The budget of exploration and mine development increases dramatically at each phase, because of increasing costs of the technologies which are used. After each phase, the

manager has to decide whether it is worth to continue the development of the exploration/mining project or to stop it.

The Environment and Public Acceptance

In the middle of the sixteenth century, Agricola, in his book "*De Re Metallica*," already reports that mining was criticized for its harmful effects on the environment and more surprisingly also on moral aspects, accusing mining to have only an objective of personal enrichment. Five centuries later, such critics remain the main grounds of the opposition to the mining industry. One of the most visible effects of mining is the creation of large to extremely large excavations and the storage of mine tailings which may represent a long-term source of pollution of the surrounding biosphere and waters, when not adequately managed. However, during most mining, only a very limited amount of land is disturbed compared to total landmass, and the disturbance is generally only locally visible. For example, Natural Resources Canada has estimated that less than 0.01% of Canada's total landmass was used in metal and mineral mining in over 100 years. But the image of mining activity is strongly tarnished by a series of catastrophic events such as the failure of the Bento Rodrigues dam in Brazil in November 2015, liberating huge amounts of iron ore tailings and causing the death of at least 17 persons. Even technologies, such as geothermal power plants considered as having low footprint, generate environmental problems with the production of salty waters enriched in heavy metals. Therefore, steady improvements of the environmental impacts of mining and continuous information of the populations since the first stages of exploration to gain a better societal acceptance of the mining projects are a necessity. Compromises have to be found, because the location of mineral deposits is dictated by nature and every citizen consumes minerals and mineral-derived products for building and heating homes, transport, electronic equipments, medicinal use, and numerous articles of daily life. It should be also taken into consideration that mining activity is creating some the highest amounts of value per unit area of land used. Also, mining should not be only developed in remote countries, where the mining law may be less constraining for preserving the quality of the local environment and the welfare of the local population. In many countries, especially in Canada and Australia, the mining laws are extremely strict. The law dictates that miners should pay to remediate the damage they cause and requires applicants of prospecting or mining rights to make financial provisions for the rehabilitation or management of negative impacts on the environment before the opening of the mine. The provisions are meant to ensure that the state will not be burdened with rehabilitation costs.

Taking a different view angle, mines can also be considered as potential disposal sites for the safe storage of society's unavoidable production of toxic or nontoxic waste. But for the most hazardous substances such as high-level nuclear wastes, underground waste disposal are specifically built. The technologies developed for the selection of such waste disposal sites and the ways of storing the waste benefit greatly from the lessons learned from the scientific study of ore deposits and underground mining. These operations have revealed how Mother Nature has preserved hazardous solid and gaseous substances in the form of mineral deposits such as huge reservoirs of natural gas during hundreds of 10^6 year, very high-grade uranium deposits as in the Athabasca Basin in Canada since 1.5×10^9 year, and even natural nuclear reactors at Oklo in Gabon, since 2×10^9 year.

Sustainable Mining

Mineral resources are considered as nonrenewable resources, except for the sodium, potassium, and magnesium salts harvested from seawater evaporation and some sands and gravel deposits which can be renewed by the continuous erosion of the reliefs. A sustainable management of the ore resources should ideally respect the following rules: (i) comprehensive extraction of valuable substances from the ore, (ii) the lowest possible consumption in their use, (iii) improvement of their recycling rate, and (iv) increase in the efficiency of using natural resources, especially energy. In fact, comprehensive extraction of the valuable substances from a given ore is limited by rapidly increasing costs and energy consumption when mining lower-grade ores, increasing the rate of recovery, and/or extracting additional substances occurring in the same ore body. For example, in the huge Olympic Dam IOCG deposit in Australia, Cu-Au-Ag-U are simultaneously recovered. However, the deposit also contains large resources of other elements such as iron (10–90% hematite), rare earths (45×10^6 at ~0.5% REE), and other elements which are not recovered because the processing costs would be too high in the present economic conditions. Despite the improvements made in the recent years in the use of natural resources in developed countries, a moderation in the growth of ore mineral extraction is not foreseeable in the near future because of the increasing demand of developing countries and the rapid growth of the world population.

Metals are high-value resources and can in principle be easily reused and recycled to turn waste into resources. The expected benefits of recycling are reduced environmental impacts by minimizing primary metal production and increased security of metal availability, but metal recycling still replaces only a small part of the primary production for most of them. Recycling is limited by the barrier of the cost of recovery. Today up to 90% of the steel reaching its end of life is recycled, but some of the elements from the alloys cannot be recycled. While in some cases they may contribute to the

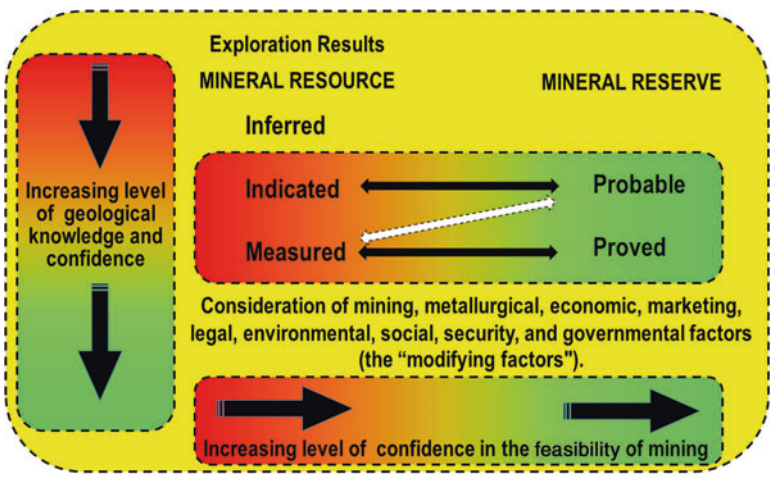
quality of the recycled steel (e.g., silicon, Mo, Nb, Mn, and W), other elements such as copper or platinum group elements are lost and may decrease the performance of the recycled products. A UNNEP (2013) report provides a comprehensive review of the possibilities and limits of metal recycling.

An ever-going debate is the question about the existence of a sufficient mass of ore minerals for an ever-increasing consumption of our society and the preservation of the resources for the future generations. Theoretically, as our planet has a limited size, the mineral resources are in principle finite. One of the first alarms was given by the Club of Rome in 1972 which predicted a shortage of mineral resources for the years 1990–2000. The imminent scarcity of many minerals is regularly announced in the media but has not yet arrived. Peak production has been predicted for many metals but has been always shifted through time. The "life index" calculated from the ratio between the total known reserves of a given substance and its yearly world consumption (R/C) is totally misleading, because reserves given by the mineral industry correspond to the amount of ore minerals which has been carefully estimated by regular drilling. The capital investment for reserve estimations being very large, mining companies limit their evaluations typically for the next 5–30 years. Consequently, a division of total known reserves by the yearly consumption (R/C) will systematically predict that in 5–30 years' time, our economy will run out of the respective minerals. The confusion mainly results from the misunderstanding of the terms reserve and resource. As stated above, a reserve is an estimation made by mining companies of a natural material of intrinsic economic interest in such form, quality, and quantity that it can be mined in the present of foreseeable future legal, economic, and technological conditions. The reserves are defined according to rigorous reporting procedure such as the JORC code in Australia, CIM (Canada), SME (USA), SAMEREC (South Africa), PERC (Europe), and now CRIRSCO which intend to provide a generic international standard stripped of legal or regulatory components that apply only within individual countries, for international reporting of exploration results, mineral resources, and mineral reserve evaluations.

Comparatively to the mineral resources, the reserves are less well defined because of a lower level of geological knowledge. With increasing capital investments, additional geological investigations are performed to increase the confidence in the evaluation of the resources from inferred to indicated and measured (Fig. 4). Then, after taking into consideration the mining techniques and the feasibility of metallurgical processing of the ore, economic, marketing, legal, environmental, social, security, and governmental factors, the resources can be upgraded as reserves. The reserve is probable or proven according to the degree of the knowledge of the geology of the deposits, mainly constrained by the density of drilling.

Besides, it should be taken into consideration that the search for most mineral commodities has generally not gone much deeper than a few hundred meters below the surface and mostly land has been explored for mineral deposits. The deepest mines are known for gold deposits which may reach a depth of 4,000 m. Metal mining on the continental platforms and seafloor has a large future potential. Science and technology will continue to improve to enable the exploration of deeper and less accessible part of the Earth, to mine lower-grade deposits, and to process more refractory ore, to provide the mineral resources needed for the development of the world community.

Additionally, many mineral substances are increasingly replaced by synthetic products. For example, steel in cars is replaced by plastic, carbon fibers, and ceramics. The availability of some critical raw materials may become temporally limited, especially when their production is dominantly controlled by one country, which makes possible political decisions distorting the markets. But recent events have shown that mining companies are able to react rapidly to temporary mineral commodity shortage through the discovery of new



Ore Deposits, Fig. 4 CRIRSCO-type general classification scheme for ore deposit resources and reserves

deposits and the industrial research is also capable to rapidly find substitutes. But, finally the most important constraint in the future, for increasing ore mineral production, will be the cost of energy. The mining and mineral industries worldwide use large amounts of energy, in the order of 4–7% of the present global energy use. The cost of mineral resource extraction and processing and the amount of energy required to produce are mainly driven by three physical parameters:

(i) The average grade of the metal being mined, which is proportional to the amount of rock to be moved and processed, to which the importance of the overburden to be removed has to be added
(ii) The average grain size of the ore mineral which constrains the amount of energy required for comminution and beneficiation
(iii) The Gibbs free energy of the metal in its typical host mineral which is proportional to the energy requirement of smelting

Therefore, decreasing the grade of the mined substance, increasing the degree of recovery by finer grinding, and processing more refractory minerals increase the cost of production and the quantity of necessary energy. Nevertheless, new ore processing technologies, such as in situ recovery of metals by injecting fluids able to dissolve the ore minerals directly in the ore bodies, already used extensively since the 1960s for uranium in roll-front deposits, application of pulsed fields of high intensity (electromagnetic, microwaves, or mechanical) that induce the formation of micro-fractures that weaken the rock and facilitate the access of the chemical reaction for the dissolution of the ore minerals, and bio-heap leaching, represent much less energy-demanding technologies. Bio-heap leaching requires lower capital and operating costs; no milling step can be used to process low-grade ores, wastes, and small deposits; and the metal tenor may be built up by recycling solution over heaps.

Summary and Conclusions

Ore deposit study and the development of guides for their exploration is the objective of metallogeny. Besides the series of synthetic books on the geology of ore deposits referred in the present paper, Hedenquist et al. (2005) offer a recent synthesis of the metallogenic concepts for most deposit types. In the future, the consumption of mineral resources is expected to continue to increase worldwide, both because of the strong demographic growth and the improvement of living conditions in emerging countries. Despite the progress of recycling, new supply of raw materials based on the discovery of new deposits will remain a necessity. Exploration is therefore the first step in a quest for mineral and energy resources which will continue to increase strongly in the twenty-first century. Such a development will be fundamentally based on innovation, conceptual innovation in ore deposit scientific research, and technological innovation for the development of new mining and ore processing techniques. Metallogeny in the twenty-first century will tend to go toward the understanding of increasingly larger systems with the development of techniques such as multispectral satellite imagery, of GIS systems 3D modeling, and of investigations at an ever more detailed scale of the deposits, their minerals, and the ore-forming fluids with increasingly powerful analytical tools. The metallogenic scientific research will increasingly be shifted from a dominantly descriptive understanding of the system to a process-based approach of the mineral systems at all scales. Deposits will be searched in less accessible parts of the globe, at greater depths, and under the oceans, and sustainability of mining will be improved by using more efficient metallurgical processing and extracting useful commodities from rocks that traditionally have not been thought to be viable ores. Societal acceptance will be the major challenge.

Organic Facies

R. Paul Philp
ConocoPhillips School of Geology and Geophysics, University of Oklahoma, Norman, OK, USA

Definition

An organic facies is a mappable subdivision of a designated stratigraphic unit, distinguished from the adjacent subdivisions on the basis of both the chemical and petrographic characteristics of its insoluble organic constituents (palynofacies or macerals), without regard to the inorganic aspects of the sediments, which in turn permits the prediction of the likely occurrence, and lateral variability, of hydrocarbon source potential as a function of depositional environment.

Introduction

The concept of organic facies has evolved over the past 40 years following early publications by Rogers (1980), Jones and Demaison (1982), and Jones (1987). In the past two decades, knowledge and understanding of organic facies has become even more important with the enormous changes in exploration strategies resulting from, first, the shale gas boom and, second, the shale oil boom which followed a few years later. In both of these cases, the initial successes evolved as a result of breakthroughs in horizontal drilling technology in the mid-1990s which were subsequently combined with hydraulic fracturing leading to production of gas and oil from shales previously thought of only as source rocks but which were subsequently realized to be both source and reservoir rocks. Properties of the shales, particularly permeability, prevented the efficient expulsion of the oil, and if the maturity levels were high enough, the trapped oil was converted to gas and if not it remained there as oil. In both cases, the hydraulic fracturing releases the tightly trapped oil or gas such that it can be produced. Evaluation of the shales to find the most potentially productive organic facies is now a key part of any successful exploration strategy. A similar approach has been developed characterizing and mapping the most productive lithofacies, and clearly future work should focus on integrating data used to characterize lithofacies and organic facies.

Prior to discussing the evolution of organic facies, a broad definition of the concept will be provided. The characterization of organic facies integrates petrographic and geochemical techniques to study the insoluble organic matter, or kerogen, in source rocks. The microscopy or petrography provides information on the palynofacies, or macerals, and characterizes all aspects of the kerogen assemblage: in other words identification of individual insoluble particulate components (macerals) and assessment of their absolute and relative proportions and preservation states. (It can be argued that there are differences between palynofacies and macerals. In my opinion, there are more similarities than differences, and to a large extent, it depends upon the method of identifying the insoluble organic constituents which are ultimately collectively referred to as kerogen. It should also be noted that the concept of palynofacies was first introduced by Combaz (1964). He defined palynofacies to mean the relative proportions of microscopic organic constituents remaining after treatment of the rock with HCl and HF plus a concentration step, which is basically the same process used to isolate kerogen.) A useful and comprehensive review article on the evolution of the concept of palynofacies and organic facies was published in 2012 by Filho et al. (2012). When combined with the geochemical data, such as total organic carbon (TOC) or richness of the source rock HI-hydrogen index from Rock Eval data), the organic facies model describes the conditions of the depositional environment and the hydrocarbon source rock potential. In recent years, there has been a concerted effort to integrate bulk geochemical parameters as well as the more specific molecular geochemical parameters based on molecular biomarkers when defining organic facies. These compounds (biomarkers) in many cases are associated with a specific type of organic matter and therefore provide another parameter to identify the organic matter or facies and add another layer of confidence when attempting to delineate the distribution of a specific organic facies within a petroleum

system. In other words, it brings together the petrographic characterization and geochemical characteristics based on the organic (preliminary insoluble) matter in the source rock. Taken together data from these two disciplines can be used to define mappable source rock units within a basin and provide a far better assessment of the petroleum potential of various facies within a particular petroleum system. In addition the development of the organic facies concept allows the prediction of the likely occurrence (and lateral variability) of hydrocarbon source potential as a function of the depositional environment. Variability may be observed at the slide scale (cms) or basin scale (kms) depending on the objectives of the study being undertaken at any time. Characterization of organic facies can be used to identify both small and large cycles related to transgressive-regressive events based on paleoecological and paleoclimate conditions.

Kerogen

A more detailed discussion on kerogen can be found elsewhere in the volume, but it is important when trying to understand how the organic facies concept evolved to include a brief review on our understanding of kerogen and how these views have changed over time. It is important since as our understanding of kerogen changed that in turn led to the development of the organic facies concept. Today it is commonly accepted that kerogen, the insoluble organic fraction in sedimentary rocks, is the key intermediate in oil and gas production. The understanding of kerogen has changed over time but really started to receive attention following the publication of a paper by Forsman and Hunt (1958) and then the paper by McIver (1967) at the World Petroleum Congress that formalized the role of kerogen in oil and gas production. (The word kerogen itself is from two Greek words, *keros* and *gen*, meaning oil or gas forming.) Kerogen by definition is the fraction of organic matter that is totally insoluble in all organic solvents and remains after all the minerals, including carbonates, silicates, and pyrites, have been removed. Kerogen generally represents the bulk of organic carbon present in a source rock, and it comprises the various macerals that can be related to the organic facies. So while the general concept of kerogen has been with us for many years and has not really changed, our understanding of the structure of kerogen has changed dramatically over time.

Following the recognition of kerogen and its role in the generation of oil and gas, there were many publications in the 1960s and 1970s that were related to developing a molecular structure for kerogen and suggesting that it was polymer, although no monomers were ever identified (Durand 1980), and it was finally realized there are no unique molecular structures for kerogen. It soon became apparent that a far more useful characteristic related to kerogen structure was based on the elemental composition of kerogen, in the same manner coal chemists had been characterizing coals based on the elemental composition (van Krevelen 1961). It should also be noted that coal petrographers had also been characterizing coals based on their petrographic composition for many years as documented in the classic book by Stach and the Teichmullers (1982), originally published in the 1960s. Tissot and Welte (1984) saw the similarities between coal characterization and kerogen characterization and introduced a kerogen classification scheme based on the H/C and O/C ratios in the same manner as the coal classification scheme developed years earlier by van Krevelen. Tissot and Welte (1984) proposed that kerogens could be divided in four basic types, namely, types I, II, III, and IV. Kerogens of type I, II, and III, respectively, were proposed to be derived from lacustrine, marine, and higher plant source materials and with the type IV kerogens being an inert form of kerogen, often dominated by inertinite. This was a rather simplistic way of characterizing the kerogens since rarely would you find a pure lacustrine or pure marine, for example. Following the development and commercial availability of the Rock Eval pyrolysis system, kerogens were characterized using the hydrogen index (HI) and oxygen index (OI) rather than the H/C and O/C ratios (Espitalie et al. 1977) as described in the "▶ Kerogen" entry in this volume.

Another significant and landmark breakthrough came when organic petrographers started to look at kerogens under the microscope and recognize that kerogens, just like coals, were made up of many different macerals or palynofacies and not one homogeneous type of organic material with a polymeric structure. Kerogen was actually a conglomerate of remnants of organic materials derived from a variety of sources including marine, lacustrine, and terrestrial sources, and again this combination of macerals gives rise to the different organic facies. The relative proportions of these macerals in the kerogen and their associated H/C and O/C ratios, or HI and OI values, would ultimately determine whether the kerogen was oil prone or gas prone.

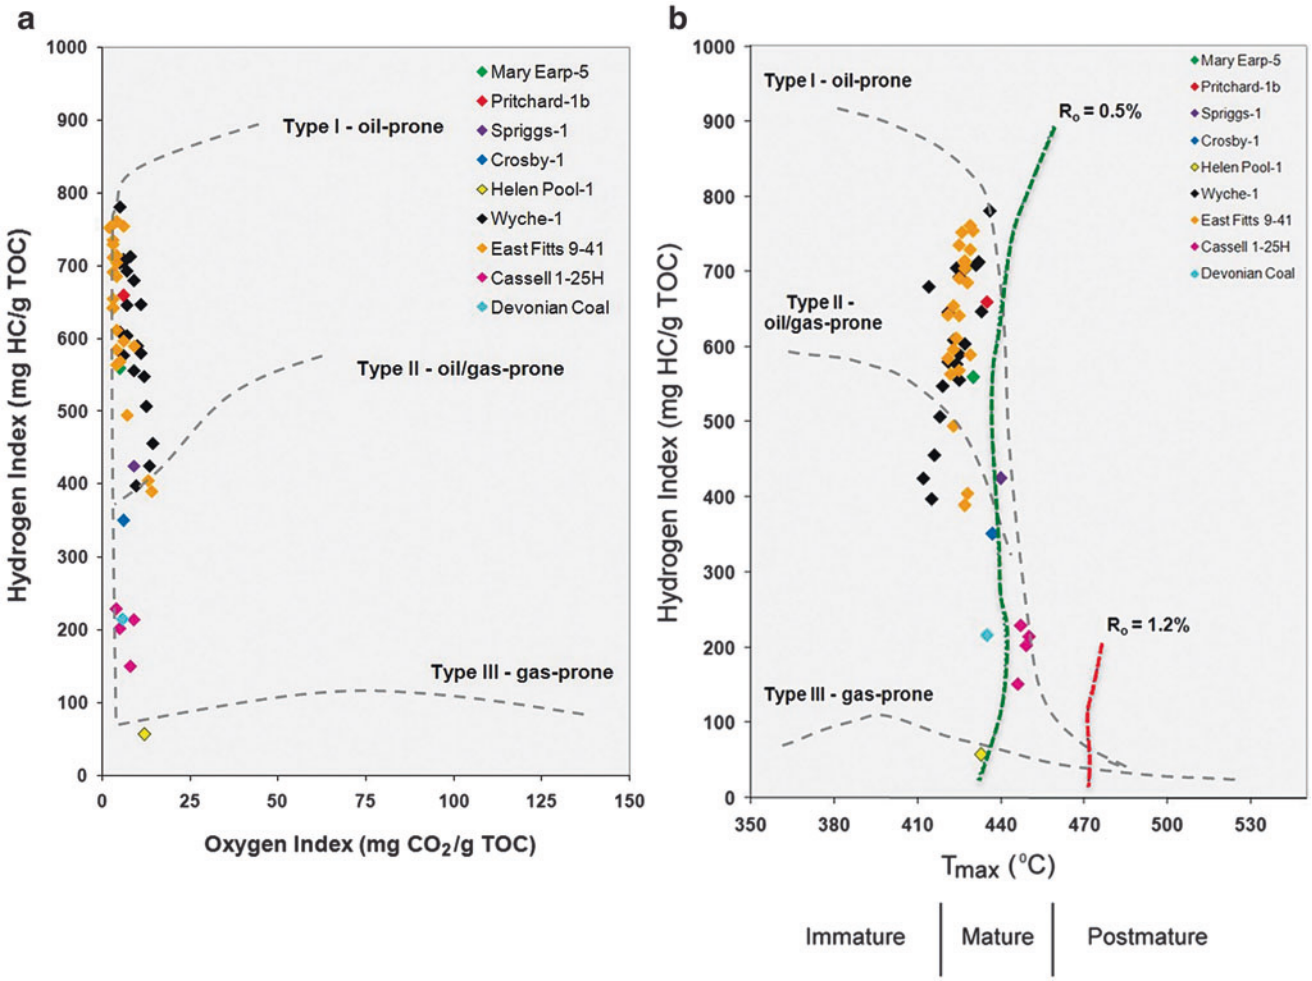
At this point in the early 1980s, it was starting to be recognized that kerogens did not simply exist as the four well-defined types but in reality had a continuum of compositions ranging all the way from lacustrine to the inert form of kerogen, determined largely by source material and the depositional environment. For example, a lacustrine source rock may initially be thought of as a source rock dominated by algal source material. However, within a lacustrine environment, samples collected far offshore in the deeper part of the lake would indeed be predominantly algal, but closer inshore, the facies may also contain a significant input of higher plant material that may have been washed in from the shore or brought in by river transport. Although the near shore sample would be classified as lacustrine, it would have a significant

higher plant component and produce a different product than the sample collected from deeper in the center of the lake.

Organic Facies

The reason for this preceding introduction is to point out that with the significant effort that has been applied to developing these shale gas and shale oil deposits, it has become very clear that shales that were once thought of as homogeneous black shales are in most cases extremely heterogeneous with significant variations in organic matter type and content. This has led to an increased awareness of the concept of organic facies, a term formally introduced by Jones and Demaison in 1982, which did not see extensive use in the early years but has now evolved into a far more widely used concept. The classic definition of organic facies provided by them was: "An organic facies is a mappable subdivision of a designated stratigraphic unit, distinguished from the adjacent subdivisions on the basis of the character of its organic constituents, without regard to the inorganic aspects of the sediments." In the early reports, the geochemical data being utilized was limited to the bulk parameters, such as the Rock Eval data, but more recently, the biomarker data has become an important tool in characterizing the organic facies. Within a shale gas or shale oil prospect, there will be many distinguishable organic facies that will not be equally productive. Hence distinguishing and characterizing the various organic facies will be one very important piece of information that will be used to determine the target depth for any horizontal well that will be drilled to try and optimize production.

Variations in kerogen type within a shale reflect variation in the organic facies, and this is clearly illustrated in Fig. 1a, b which shows a set of samples of similar maturity, close to the onset of oil generation, from the Woodford shale from the Anadarko Basin, Oklahoma. The variations observed in this



Organic Facies, Fig. 1 (**a**, **b**) Rock Eval data showing the variability in samples of the Woodford shale from a number of wells in the Anadarko Basin, Oklahoma. All the samples are just below the onset of oil generation, and hence the differences shown in these diagrams are a result of variations in the organic facies

diagram are not maturity related but reflect variations in the organic facies. This of course leads to the next question: why do we see such variations in the organic matter content and resulting organic facies?

The answer is relatively simple in general terms and can be related to the way in which organic-rich source rocks are formed. Source rocks contain a variety of organic matter derived from many different sources (i.e., plants, algae, fungi, bacteria, etc.) being deposited in a variety of depositional environments. Some of the organic matter gets preserved, some degraded. However as a result of a complex series of reactions related to changes in the depositional environment, changes in salinity of water, temperature, oxicity, and other factors, one particular depositional environment may see a significant variation in the nature of the mixture of organic matter that ultimately gets buried and preserved and generates oil or gas. Furthermore depending on the location of the sample within a specific depositional environment, there may be significant variations in the organic matter content of the source rock. Hence it became clear that kerogens should not be simply divided into these four major types since rarely would you find a "pure" lacustrine or "marine" kerogen. This leads Jones and Demaison to develop the organic facies concept so that rather than having four distinct types of kerogen, there is a continuum of kerogen types with the "pure" lacustrine and "pure" higher plant kerogens being the extremes with all the possible intermediate values in between.

The reason that such a concept is valid and important is that it is widely accepted that different types of source material will generate different types of hydrocarbon products. Thus in very simplistic terms, it can be expected that marine phytoplankton will generate primarily oil, whereas higher plant material will generate gas. Therefore if one automatically assumes your source rock kerogen is a marine kerogen based on the region where it plots on the pseudo-van Krevelen diagram, you would assume it will always primarily produce oil. However a source that is comprised of a mixture of lacustrine and higher plant material can still plot in that same region and would produce a mixture of oil and gas. An understanding of the concept of organic facies would have prevented such an error in the interpretation.

In addition modeling studies designed to predict the quantities of oil and gas that may be generated from a particular source rock type require activation energies and frequency factors as two of the important input factors to the model. These parameters will vary depending on the type of organic matter in the source rock. So again as with the example above, simply assuming that your kerogen is a marine kerogen based on where it plots on the modified van Krevelen plot and ignoring the fact that it could be a mixture of higher plant and lacustrine material will lead to erroneous parameters being used in the model and hence incorrect output from the model. This is discussed in more detail below. Ideally for any model, the most reliable set of parameters will be custom derived for the specific facies under investigation rather than a set of generic parameters available in the literature.

In 1987, Jones published his paper entitled "Organic Facies," and this was probably the first detailed description of the concept in which he defined seven organic facies ranging from type A dominated by algal material with very high HI values (>850 mgs HC/g TOC) to type D reflecting a highly oxidized, reworked kerogen with little hydrocarbon potential. A summary of these types of organic facies is given in Table 1. Tyson (1995) subsequently suggested that these facies could be associated into three groups based on the paleo-oxygenation and redox conditions in the basin in the following manner: types A, AB, B, and BC were deposited under anoxic-dysoxic conditions; types C and CD were deposited under proximal fluvio-deltaic to prodeltaic-oxic shelf conditions, and then type D was deposited under oxic distal conditions. Tyson (1995) also proposed that in addition to the paleo-oxygenation and redox conditions in the basin, other major paleoenvironmental controls included the relative proximity of the depositional site to active siliciclastic sediment and terrestrial OM sources and climatic controls on the preservation, production, and export of terrestrial OM. Table 2 shows a more comprehensive version of the description of organic facies incorporating both the descriptions of Jones (1987) and then the additional information from Tyson (1995).

Organic Facies, Table 1 A summary of the organic facies as defined by Jones (1987)

Organic facies	H/C at 0.5% R_0	Pyrolysis yield		Dominant organic matter
		HI	OI	
A	>1.45	>850	10–30	Algal; amorphous
AB	1.35–1.45	650–850	20–50	Amorphous; minor terrestrial
B	1.15–1.35	400–600	30–80	Amorphous; common terrestrial
BC	0.95–1.15	250–400	40–80	Mixed; some oxidation
C	0.75–0.95	125–250	50–150	Terrestrial; some oxidation
CD	0.60–0.75	50–125	40–150+	Oxidized; reworked
D	<0.6	<50	20–200+	Highly oxidized; reworked

Organic Facies, Table 2 A combination of geochemical data and palynofacies characteristics that can be used to characteristic organic facies. While this table does not indicate nature of products that could be expected from different facies under appropriate maturity conditions, the general trend would be from oil prone to gas prone moving from type A to types CD and D, although type D would probably be nonproductive (Data from Jones (1987), Tyson (1995, 1996). Table reproduced from Filho et al. 2012)

Organic facies	A	AB	B	BC	C	CD	D
Palynofacies characteristics							
% "AOM" of kerogen	Dominant			Mod	Usually low/absent		
"AOM" matrix fluorescence	Highest		Mod-weak		Weak	Usually absent	
% prasinophytes of plankton	Highest	Mod	Rare	Usually very rare			
% phytoclasts of kerogen	Low (dilution)			Mod	Usually dominant		
Opaque: translucent phytoclasts	Often high			Usually low		Increases	
Geochemical characteristics (for immature sediments)							
Hydrogen index	≥850	≥650	≥400	≥250	≥125	50–125	≤50
Kerogen type	I	I/II	II	II/III	III	III/IV	IV
TOC%	5–20+	3–10+		3–3+	≤3	<0.5	
Environmental factors							
Proximal-distal trend	Distal			Proximal		Distal	
Oxygen regime	Anoxic	Anoxic-dysoxic			Oxic		V. Oxic
Sediment accumulation rate	Low	Varies		High		Mod	Low
Organic facies	**A**	**AB**	**B**	**BC**	**C**	**CD**	**D**

Following the work of Jones (1987) and Tyson (1995), Pepper and Corvi (1995) discussed problems associated with accurately defining the kinetic parameters necessary to model the thermal degradation of kerogen resulting from the widespread variability in the composition of the kerogen. In order to simplify their approach, they adopted a relatively simple kerogen kinetic classification scheme based on the organic facies concept and a classification scheme developed by Barwise in the early 1980s but gave no reference for his scheme citing proprietary reasons. Unlike the Jones scheme, they only defined six types of organic facies A–F with some slight differences in their definitions compared to those defined by Jones. Organic facies A–C are dominated by aquatic algal and bacterial derived lipids, with early diagenetic processes determining the ultimate chemistry of marine algal/bacterial soluble organic matter (SOM) in siliciclastic-poor (A) and siliciclastic-rich (B) sediments. Organic facies C lipids are derived from freshwater algae that experienced sulfate – free diagenesis in nonmarine lacustrine basins. Organic facies D–F are all from nonmarine environments with an input of terrigenous organic matter and bacteria. Relative to organic facies F, organic facies D/E has a higher proportion of higher plant/bacterially derived material relative to lignin. However it is still important to recognize that although there are differences in the different schemes for defining the different facies, there are many similarities between them, with the most oil prone being algal rich, and then with increasing terrigenous input and possible oxidation, the facies become oil and gas prone and then gas prone and then inert.

Organic Facies and Sequence Stratigraphy

The concept of sequence stratigraphy is well suited for identifying the environments of deposition and temporal/spatial stratigraphic occurrence of organic facies. The papers by Jones (1987) and Pepper and Cervi (1995) did not make any significant attempts to integrate the organic facies concept with sequence stratigraphic models that have been developed for many years and are now an integral part of interpreting the sedimentary record and predicting organic-rich potential source rocks. It is well established over geologic time that the oceans have risen and fallen in a cyclical manner. A relative sea level cycle consists of (i) a falling and turnaround stage in which lowstand systems tract (LST) strata are deposited, (ii) a relatively rapid rise in sea level in which transgressive tract systems strata are deposited, and (iii) highstand or regressive systems tract strata deposited when sea level rise slows down relative to that responsible for the transgressive systems tract strata. So during LST with falling sea level, the shelf is exposed and eroded leading to a sequence boundary. However at the same time this is transporting land plant material from onshore during the erosion process leading to a facies that will contain both marine and terrestrial higher plant material. But as the sea level turns around and starts to rise, the input of both terrestrial source organic material and also eroded sedimentary material will decrease relative to the LST. The condensed section forms during the TST formation, and this is generally the most organic-rich section and has the greatest potential for source rock formation. During the HST formation, sea level is still

rising, but there is enough sediment being transported to fill any accommodation space on the shelf resulting in the shoreline moving seaward. So when considering that organic facies are differentiated on the basis of their organic matter content and nature of depositional environment, both of which are driven by sea level change, the importance of integrating organic facies with changes in the sequence stratigraphic strata, also driven by sea level changes, should be obvious. Taken together organic facies and sequence stratigraphy can greatly improve the ability to recognize productive source rock units and map these on a basin-wide scale. It has been well documented that there are repetitive lithofacies variations that can be recognized within a sequence stratigraphic framework resulting from the sea level changes and accompanying erosion of sediments and associated deposition in the marine environment. Further integration of organic facies with lithofacies variations into a sequence stratigraphic framework should provide an even better understanding of the temporal and lateral variations of organic-rich shales and ultimately their source potential.

Pepper and Cervi (1995) did provide a limited integration of their organic facies into a sequence stratigraphic framework by indicating that one of the major advantages of using organic facies lies in its potential to link global kinetic parameters to broad sedimentary facies. From a regional seismic survey, a simple paleographical map can be constructed and a rudimentary understanding of the gross depositional environment established with the systems tract strata from which the potential source rock facies could be forecast in the following manner:

Organic facies A – deposited in a transgressive to maximum flooding system on a carbonate platform, lagoon, and intra-shelf topographic depression

Organic facies B – transgressive to maximum flooding system on clastic depositional margin

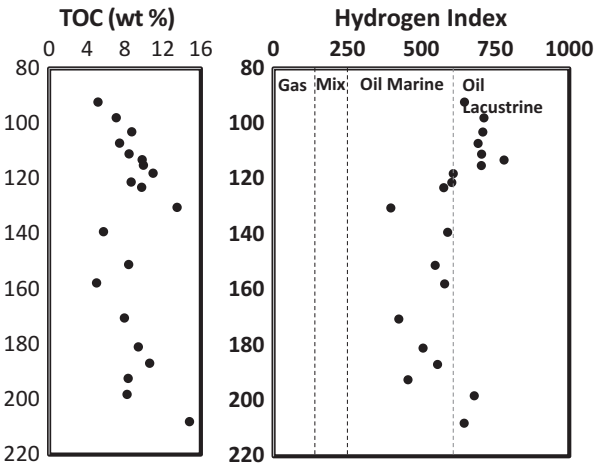
Organic facies C – relative lake high stands with major lacustrine depositional system

Organic facies D/E – developed either behind shoreline of transgressive systems tractor during aggradation of the top sets in response to the highstand system

Organic facies F – essentially belonging to same systems tract as organic facies D/E but generally distinguished on basis of interpreted age, climate/paleoaltitude, or position relative to seismically defined shoreline

Organic Facies Variations in the Woodford Shale, Anadarko Basin, Oklahoma

In Fig. 1 the heterogeneity of the Woodford shale resulting from variations in the organic facies in different wells was illustrated. In order to further illustrate that variability, Fig. 2 shows data from a single core taken through the Woodford



Organic Facies, Fig. 2 Variability in the Woodford shale from a single well as illustrated by variations in the TOC and HI values reflecting variations in the organic facies

shale and illustrates variations observed in two bulk parameters (TOC and HI values). For many years ago, the Woodford shale was thought of as a marine shale of Devonian age. Subsequently it was divided into three distinct facies, the Upper, Middle, and Lower Woodford on the basis of fossil evidence, but under the classic kerogen definition, all of these samples would have been classified as type II kerogens. More recent work has shown organic facies variations within each of the Upper, Middle, and Lower formations due to variations in conditions of the depositional environment, which in turn influenced the type of organisms growing in the water column and input of higher plant material with the changing conditions. It has been shown that over time changing sea level had a significant impact on circulation patterns within the Anadarko Basin leading to restricted circulation during the deposition of the Middle Woodford and development of euxinic conditions. Moving from the Middle Woodford into the Upper Woodford, the basin became less restricted, euxinic conditions were less apparent, and different organisms thrived. This leads to variations in the TOC values within the overall formation and influenced the petroleum potential of different facies within the shale. The important issue here is to illustrate how misleading it is to simply characterize the Woodford as a marine shale and not take into consideration changes in sea level and environmental conditions leading to variability in organic matter content and therefore variations in the potential to produce hydrocarbons for the different facies.

Summary

With the evolution of shale oil and shale gas prospects along with the associated horizontal drilling and hydraulic

fracturing, characterization of organic facies and their association with lithofacies have become an extremely important exploration and production tool. Identification and characterization of organic facies provides valuable information on richness and potential of the source rock. Furthermore when integrated into a sequence stratigraphic framework, along with information on the lithofacies, a comprehensive evaluation on the distribution and production potential of a specific organic facies within a petroleum system can be determined. This is turn provides a more realistic evaluation of potential production from a petroleum system compared to that obtained by simply evaluating a source rock as a kerogen type.

Definition

Organic geochemistry is the study of the origins and fates of organic matter and its constituents in the geosphere (including sediments, soils, rocks, coal, and petroleum), aquatic environments, and atmosphere. It is particularly focused on the interactions of the C cycle with those of other major elements such as major nutrients (N and P), other elements, and trace metals and how these have changed over geological time.

Introduction

Organic geochemistry encompasses studies of the origins and fates of organic matter in sediments, soils, coals, oils, gases, atmosphere, and marine and lacustrine water bodies (Johns 1986; Fleet et al. 1988; Engel and Macko 1993; Killops and Killops 1993; Rullkötter 2003; Volkman 2006). It is a relatively new field of endeavor which traces its origins to the identification by Treibs in 1934 of alkyl metalloporphyrins in crude oils that could be related to the structure of chlorophyll. This landmark research provided the first convincing evidence for the biological origin of some of the constituents of petroleum. Since then the field has expanded greatly and has become considerably more interdisciplinary as it seeks answers to how organic matter is produced, transported, recycled, transformed, and preserved in modern and ancient environments.

Organic geochemistry can be classified into a number of general themes such as: production and fate of organic matter in aquatic ecosystems; chemical and isotopic composition of biologically produced organic matter; transfer of lipids and other biochemicals in aquatic food webs; the effect of environmental conditions on the preservation and degradation of organic matter in modern sediments; processes and reactions leading to the formation of humic and fulvic material, coals, and kerogen; environmental chemistry tracing the source, transport, and fate of organic pollutants; isotope geochemistry; chemical oceanography; organic matter in meteorites and moon rocks; molecular archaeology; assessment of changes to paleoenvironments and climate over geological periods; generation and composition of petroleum and natural gas; catagenesis and destruction of organic matter at high maturities. The field is not limited to studies of lipids and hydrocarbons, but it encompasses studies of amino acids, porphyrins, chlorophylls, carotenoids, sugars, proteins, carbohydrates, and anthropogenic compounds. Scientists in the field also freely borrow knowledge and techniques from the disciplines of chemistry, geology, microbiology, biology, paleontology, ecology, physics, statistics, limnology, and oceanography. This wide knowledge base contributes greatly to the fascination of the subject and its many applications.

Analytical Techniques

Modern organic geochemistry often requires access to highly sophisticated analytical equipment to study the low abundances and complex mixtures of compounds present in geological materials. Capillary gas chromatography (GC) linked to a flame ionization detector (FID) or other detectors is widely used for the analysis of C_1–C_{60} compounds. The most common combination is capillary GC linked to a mass spectrometer (GC–MS) which enables compounds to be identified from their characteristic mass spectra (Philp 1985; Peters et al. 2005). Mass spectrometers include quadrupole, ion trap, magnetic sector, and time of flight. High sensitivity is combined with the requirement to separate small amounts of a compound present in complex mixtures. Recent advances in instrumentation such as the development of a capillary gas chromatograph linked via a combustion tube to an isotope ratio mass spectrometer (GC–irm–MS or CSIA which stands for compound-specific isotope analysis) now permits the $^{13}C/^{12}C$ ratio ($\delta^{13}C$ value) and $^{2}H/^{1}H$ ($\delta^{2}H$ or δD) ratio of individual compounds to be determined. For δD measurements, compounds separated by GC are converted to H_2 through a pyrolysis furnace (typically 0.5 mm i.d. × 34 cm long and operated at ca. 1450 °C). δD values are compared with a reference gas with a known δD value injected via the interface to the MS. CSIA of nitrogenous compounds using GC–irm-MS traditionally includes two separate conversion processes: the oxidation of nitrogenous compounds to N_2 and NOX and the reduction of the NOX to N_2. Recently, Kamata and Chikaraishi (2014) reported an improved system that combines these two processes into one unit by introducing a high-temperature combustion reactor and demonstrated its utility for measuring $\delta^{15}N$ in amino acids.

High performance liquid chromatography (HPLC) is the method of choice for separating and identifying more polar compounds such as carotenoids and chlorophylls, polar lipids including phospholipids, glycolipids and triacylglycerols, glycerol dialkyl glycerol tetraethers (GDGTs) and branched GDGTs (Schouten et al. 2013), bacteriohopanepolyols (BHPs; Talbot et al. 2003), or for high molecular weight compounds.

Pyrolysis, either on-line or off-line, open or closed, is often used to break down the organic matter into smaller components which can then be analyzed by GC–MS and HPLC. Pyrolysis can provide information about the amount, type, and thermal maturity of the organic matter. Off-line (batch) pyrolysis in sealed vessels (e.g., MSSVpy) at specific temperatures, often carried out in gold tubes, has the advantage that products can be isolated for further separation and identification of components. Curie-point or flash pyrolysis at high temperatures (typically 610 °C or 650 °C) produces complex distributions of alkenes and alkanes as well as more polar lipids. In the case of ancient organic-rich sediments, these are often dominated by *n*-alkene/*n*-alkane pairs from breakdown of algal biopolymers (algaenans – see later).

Hydropyrolysis (Hy-Py or Hypy; Berwick et al. 2010) involves the pyrolysis of kerogen, shales, sediments, or biological material at high hydrogen pressures (10 MP) in the presence of a dispersed sulfided molybdenum catalyst. This can convert a high percentage of the kerogen (ca. 30%) into GC-amenable components that were previously covalently bound to the kerogen. Stepwise pyrolysis involves pyrolysis of a kerogen sample initially at a low temperature (typically ca. 300 °C) and the residue is then pyrolyzed again at an increased temperature and the process repeated until further products are no longer obtained. The products are typically swept directly into the GC injector and analyzed by GC–MS. This has the advantage that compounds are released according to their bond strength and so each pyrogram is different and may be enriched in diagnostic biomarkers that might be minor components of a single total flash pyrolysis (e.g., Zhang et al. 2016; Zhang and Volkman 2017).

^{1}H and ^{13}C nuclear magnetic resonance (NMR) and Fourier transform infrared (FT-IR) spectrometers are also used to provide structural information on the organic matter in kerogen, coals, or sediments. NMR is particularly useful for the identification of novel organic compounds, although this usually requires isolation of the compound from complex mixtures. FT-IR has been used in a diversity of applications ranging from identifying the geometry of double bonds in

alkenones to studying the structure of coal and investigating clay-mineral interactions. Electron paramagnetic resonance (EPR) of semiquinone radicals has been used to characterize the humification stages of organic matter and to define different soil fingerprints in speleothems.

Compound-specific radiocarbon (^{14}C) analysis (CSRA) provides information on the $\Delta^{14}C$ values of individual compounds that can be used to identify multiple sources of carbon within an individual sample. Initially, preparative capillary GC or HPLC was used to isolate individual compounds by fraction collection prior to graphitization and CSRA. This procedure is time consuming and careful attention is needed to minimize the introduction of extraneous carbon. Precise ^{14}C measurements are possible on samples of individual compounds provided that they contain at least 20 μg of carbon. More recently, gas ion sources developed for ^{14}C accelerator mass spectrometry (AMS) have been modified and improved to accept CO_2 directly from a GC with pyrolysis interface allowing analytical instrumentation to be directly interfaced to an AMS (Roberts et al. 2013).

The Biomarker Concept

A central concept common to many studies in organic geochemistry is the use of biomarkers (also termed biological markers, chemical fossils (Eglinton and Calvin 1967), and signature lipids) to infer likely sources of organic matter (e.g., Johns 1986; Bianchi and Canuel 2011; Volkman and Smittenberg 2016; Derrien et al. 2017). These organic compounds have a distinct chemical structure which can either exist as such in a particular organism or be related by known microbial or chemical transformation pathways to compounds synthesized by specific groups of organisms. Biomarkers are available for most of the groups of organisms that contribute organic matter to sediments. Many new lipids have been discovered in plants, algae, and bacteria by organic geochemists during the course of organic geochemistry studies. In some cases, the compounds were first identified in sediments and only later was it possible to identify a source organism and even today the sources of some compounds are still unknown (so-called orphan lipids).

The role of genetic changes is crucial to our understanding of how different life forms have evolved over time. DNA sequencing studies can show which organisms possess specific biochemical pathways and are providing a better conceptual basis for understanding why particular biomarkers occur in different organisms. This new information will help establish timelines for the first appearance of a variety of age-diagnostic biomarkers (e.g., Sinninghe Damsté et al. 2004; Briggs and Summons 2014; Volkman 2014 and references therein). In the same way that physical fossils have underpinned our understanding of the evolution of life, organic geochemists use biomarkers to understand the evolution of life's biosynthetic pathways over geological time and thus fulfill the promise inherent in the use of the term "chemical fossil." For example, sterol biosynthesis is an oxygen-intensive process so the presence of complex steranes derived from sterols deposited in ancient rocks not only signals the presence of eukaryotes but also aerobic metabolic processes (Gold et al. 2017). Advances in molecular biology are increasingly being applied to organic geochemical studies of recent sediments to allow identification of organisms present in the depositional environment and to study the processes involved in cycling of major elements such as C and N in different environmental settings (e.g., Coolen et al. 2004, 2008).

Biomarkers for Vascular Plants

Many biomarkers have been described for higher plants, and thus the identification of terrestrial organic matter in sediments is relatively straightforward even when the organic material is transported far from land. Plant wax lipids and lignin phenols are the two most common classes of molecular markers used in these studies, often supplemented with compound-specific isotope data. General markers include long-chain (C_{20}–C_{30}) *n*-alkanes showing strong odd/even predominance and long-chain alcohols and fatty acids showing strong even/odd predominance. Such compounds in atmospheric particles and sediments have been used to estimate the relative contributions of C3 vs. C4 type plants in the source area (e.g., Diefendorf et al. 2011). The major sterol in most plants is 24-ethylcholesterol (sitosterol), with lesser amounts of another C_{29} sterol 24-ethylcholesta-5,22E-dien-3β-ol (stigmasterol) and the C_{28} sterol 24-methylcholest-5-en-3β-ol (campesterol). C_{29} sterols often dominate the sterol distributions in lacustrine sediments, and the predominance of C_{29} steranes in a crude oil is often taken to indicate a high level of plant lipid contribution to the original source rocks (e.g., Peters et al. 2005). Vascular plants contain a variety of diterpenoid and triterpenoid lipids, the latter dominated by oleanane, ursane, and lupane skeletons (e.g., Koch et al. 2011). Other more-specific biomarkers include betulin for birch plants and resin acids for conifers. The latter give rise to a variety of degradation products including the aromatic hydrocarbon retene, which has been used to map changes in plant communities in the ancient past (e.g., Saito et al. 2013).

Biomarkers for Microalgae

Microalgae are major contributors of organic matter to sediments and fortunately they have a variety of distinctive biochemical pathways that give rise to distinctive biomarkers. For example, the polycyclic hydrocarbon dinosterane which occurs in some crude oils is derived from the C_{30} sterol dinosterol, which is common in a class of marine phytoplankton called dinoflagellates. The presence of dinosterane in oils

provides good evidence that some of the organic matter in the oil's source rock was derived from dinoflagellates. Other distinctive algal lipids include very long-chain (C_{37}–C_{40}) alkenones and alkenoates synthesized by certain haptophytes such as *Emiliania huxleyi*, *Gephyrocapsa* spp., *Isochrysis* spp., and *Chrysotila* spp. These compounds are now used routinely to reconstruct past surface ocean temperatures from the ratio of di- and tri-unsaturated alkenones in sediment cores (see later).

Chlorophyll *a* concentrations provide an indirect measure of total phytoplankton biomass in seawater, while the abundance of specific carotenoids can be used to characterize the community composition of marine phytoplankton in oceanic waters. For example, prasinoxanthin is found in certain green microalgae, 19′-hexanoyloxyfucoxanthin in haptophytes, and peridinin in dinoflagellates. Such studies have revealed the important role played by eukaryotic nanoplankton and picoplankton and the prokaryotic cyanobacteria and prochlorophytes in oligotrophic oceanic waters (Wright and Jeffrey 2005).

Microalgae contain abundant fatty acids, and these can show features specific to different algal groups. For example, green algae typically show a dominance of C_{18} polyunsaturated fatty acids (PUFA) whereas dinoflagellates can have high quantities of 22:6n-3, and diatoms contain abundant 20:4n-6 and 20:5n-3. Some dinoflagellates contain unique C_{28} PUFA (Volkman et al. 1998). The nomenclature used here is number of carbon atoms:number of double bonds where (n-x) specifies the position of the double bond closest to the end methyl group. Since PUFA are rapidly degraded in seawater and sediments, their presence can often be used as an indication of organic matter associated with living cells.

Certain sterols can also provide evidence for contributions to the organic matter in recent sediments or seawater from microalgae. C_{28} sterols such as 24-methylcholesta-5,22E-dien-3β-ol and 24-methylenecholesterol are common in diatoms but are not unique to these microalgae. Other interesting sterols in diatoms include those with C-23 side-chain methylation, 4-methyl sterols more usually associated with dinoflagellates, the C_{30} sterol gorgosterol more commonly associated with corals, but now known to be produced by some diatoms, and sterols with Δ^7-unsaturation found in some green algae (e.g., Giner and Wikfors 2011 and references therein). Indeed, as more data have been acquired, it is clear that a great variety of sterol distributions can be found in microalgae including sterols more often associated with other organisms (Volkman et al. 1998). For example, marine eustigmatophytes contain abundant cholesterol more usually associated with animals, while freshwater eustigmatophytes contain 24-ethylcholesterol usually associated with plants.

Another class of unusual biomarkers are C_{25} and C_{30} highly branched isoprenoid (HBI) alkenes which occur in many recent and ancient sediments. A diatom origin was established by the identification of C_{25} HBIs in cultures of *Haslea osteraria* and C_{30} HBIs in *Rhizosolenia setigera* by Volkman et al. (1994). Since then other diatom sources have been identified and a number of applications have emerged including the use of HBI alkenes as indicators of sea-ice extent (Massé et al. 2011; Pieńkowski et al. 2017) and as food-web tracers (Goutte et al. 2013). HBI alkene distributions have also been instrumental in establishing the concept of age diagnostic biomarkers which recognizes that some compounds appear in the sediment record at a defined point in time (e.g., Moldowan 2000). HBI alkanes have not been found in oils or sediments older than 92 Ma (Sinninghe Damsté et al. 2004) which implies that this biosynthetic pathway for HBI alkenes evolved around that time. This concept has proven to be a powerful tool in assessing the age of petroleum samples and for examining the correspondence between the fossil and biomarker record (e.g., Taylor et al. 2006; Briggs and Summons 2014).

Another interesting class of algal lipid is the C_{30} and C_{32} *n*-alkyl diols synthesized by eustigmatophytes (Volkman et al. 1992) and some diatoms (Rampen et al. 2014 and references therein). These compounds have the interesting feature that the dominant isomers in eustigmatophytes are the alkyl-1,15-diols, but in diatoms the alkyl-1,14-diols predominate. These compounds are now used to infer paleotemperatures and upwelling conditions (see later).

Biomarkers for Bacteria

Specific branched and/or unsaturated fatty acids can be used to determine the biomass of different bacterial groups in sediments and seawater. *Iso*- and *anteiso*-branched C_{15} and C_{17} fatty acids and *cis*-vaccenic acid (18:1n-7) are found in many bacteria, whereas 10-methylhexadecanoic acid and *iso*-17:1 are more commonly associated with sulfate-reducing bacteria. The abundance of these acids in the phospholipid fraction isolated from sediments can be used as a measure of the microbial biomass present.

The most common triterpenoid class in sediments are the hopanoids, where they can be found with a variety of functional groups including alkenes, ketones, acids, and alcohols. In most cases these are diagenetic products of C_{35} bacteriohopanepolyols (BHPs; Talbot et al. 2003), although direct inputs of C_{30} hopanoids such as diplopterol and diploptene from bacteria and cyanobacteria are also possible. Intact BHPs can also be found in recent sediments and have shown to be useful tracers for terrestrial soil-derived organic matter in estuaries and coastal environments.

Derivatives of 2-methylhopanoids are prominent biomarkers in modern and ancient sediments and have been used as proxies for cyanobacteria and, by extension, for dating the first appearance of oxygenic photosynthesis. However, substantial evidence from cultures and genomic studies now indicates that some organisms other than cyanobacteria

can make 2-methylhopanoids. Studies have shown that hpnP, the gene encoding the C-2 hopanoid methylase, is found in diverse modern environments but cyanobacterial hpnP genes are rarer and tend to be localized to specific habitats. Ricci et al. (2014) found that hpnP occurrence is significantly correlated with environments known to support plant–microbe interactions and in microbial communities including stromatolites, hot springs, and hypersaline microbial mats. 2-Methylhopanoids are enriched in sessile microbial communities inhabiting environments low in oxygen and fixed nitrogen with high osmolarity.

Biomarkers for Archaea

The domain Archaea includes a variety of fascinating microorganisms including the so-called extremophiles such as methanogens, thermophiles, and halophiles. The discovery of mesophilic archaea showed that not all species within the Archaea are extremophiles and we now know that archaea are widely distributed in nature including the open ocean. Two major clades (named initially simply Group I and Group II) are known and these were classified as members of the Crenarchaeota and Euryarchaeota, respectively. Group I archaea have been reclassified as a separate phylum called Thaumarchaeota and are geochemically interesting since they may be the most ancient archaea and are among the most abundant organisms in the ocean (see Pearson and Ingalls 2013).

Archaea predominantly contain lipids based on isoprenoid biochemistry (Volkman and Maxwell 1986). Methanogens contain a number of distinctive biomarker hydrocarbons including the C_{25} isoprenoid alkane 2,6,10,15,19-pentamethylicosane which is found in modern to Cretaceous marine sediments (Brassell et al. 1981). Other archaeal lipids include 3,7,11,15,18,22,26,30-octamethyldotriacontane found in petroleum and as a degradation product from Messel oil shale kerogen, squalane which is found in some crude oils and 2,6,10,14,18-pentamethylicosane which occurs in halophilic bacteria.

Biphytanyl (C_{40}) isoprenoid hydrocarbon chains from archaeal lipids were first discovered in sedimentary systems more than 30 years ago and since then it has become clear that their source must be environmentally widespread. These chains occur in compounds known as glycerol dialkyl glycerol tetraethers (GDGTs), which is short for *sn*-2,3-di-*O*-biphytanyldiglycerol tetraethers. The core structures are most often abbreviated as GDGT-0, GDGT-1, GDGT-2, GDGT-3, and GDGT-4, with the numerals 0–4 denoting the number of internal cyclopentane rings. The GDGT containing a cyclohexane group is called crenarchaeol and is abbreviated as "cren" or GDGT-5. A related compound that has a longer chromatographic retention time is referred to as the crenarchaeol regioisomer. GDGTs occur as part of intact polar lipids (IPLs) such as phospholipids and glycolipids. These compounds are quite stable in sediments and have been developed into a number of paleoproxies (see later).

Organic Geochemistry of Modern Environments

Biomarker and isotope studies can be used to classify the sources of the organic matter in seawater or sediments into general classes such as vascular plants, microalgae, bacteria, archaea, and secondary consumers (Meyers and Ishiwatari 1993; Volkman 2006; Bianchi and Canuel 2011) as described above. In a few cases, specific biomarkers can even be related to particular species. Since some organisms are restricted to particular environments, the presence of diagnostic biomarkers can be used to infer the environmental conditions which prevailed when the sediment was deposited.

Just as paleontologists use morphological fossils as stratigraphic tools, organic geochemists use "chemical fossils" to define an analogous "molecular stratigraphy." The concept that "the present is the key to the past" has been a driving force for numerous studies of organic compounds in modern aquatic environments. These have provided insights into the sources of organic matter and how it is degraded and transported within each type of ecosystem. For example, the presence of an oxic–anoxic boundary in the water column of bodies such as the Black Sea is recorded in the sediments by the preservation of biomarkers derived from the bacteriochlorophylls and carotenoids of obligate phototrophic green sulfur bacteria present in the water column. Regions of high productivity such as the Black Sea as well as the upwelling areas off Peru and Namibia have been a major focus of organic geochemical studies since these provide recent models for the formation of ancient organic-rich black shales (oil shales and sapropels) which can be excellent petroleum source rocks.

Bulk radiocarbon (^{14}C) measurements have been widely used to constrain the sources, sinks, and processing of sedimentary organic carbon (e.g., Smittenberg et al. 2004). Griffith et al. (2010) constructed a box model that predicts $^{14}C_{TOC}$ in the sediment mixed layer. Their model allows three distinct organic carbon pools to be defined ("degradable," "semi-labile," and "refractory"). This approach has demonstrated the presence of pre-aged organic carbon in surface sediments including soil-derived terrestrial organic carbon, reworked marine organic carbon, and/or anthropogenic carbon. Through the use of compound-specific $\Delta^{14}C$ measurements, Eglinton et al. (1997) were able to show that in the Black Sea there was considerable isotopic heterogeneity in the *n*-alkanes indicating both fossil and contemporary sources. Compounds reflecting different source inputs to the Arabian Sea exhibit a range of 10,000 years in conventional ^{14}C ages. The great advantage of radiocarbon measurements of biomarkers is that sediment chronologies can be constructed independent of detrital organic carbon influences.

Early Stage Diagenesis

Although only a small quantity of the organic matter produced in the water column reaches the sediment due to a range of degradation reactions, the amount of organic carbon in the lithosphere (estimated at 2×10^{16} tonnes) is vastly greatly than that found in the oceans (1×10^{12} tonnes). Once the organic matter is deposited, it is further transformed by bacterial and chemical processes leading to breakdown and transformation of the organic compounds present. Despite decades of research, our understanding of the mechanisms by which organic matter is stabilized and sequestered in aquatic sediments remains far from complete. It is now thought that the intrinsic reactivity of the organic matter supplied to soils and sediments is less important than its distribution in the sedimentary matrix and association with mineral matter such as iron (Eglinton 2012). This controls its accessibility to the organisms that degrade it into simple organic compounds, and ultimately to CO_2.

A difficulty in the use of biomarkers for paleoenvironmental reconstructions is the effect of degradation, both in the water column and sediment, on the distribution of compounds. Nierop et al. (2017) have shown that early diagenetic alteration of organic matter depends largely on the degree of bottom water oxygenation rather than subsequent anaerobic degradation within the sediments, even at longer timescales. Lipids show a wide range of susceptibilities to degradation, but some compounds such as sterols and alkenones are sufficiently resistant that they can be used for reconstructions of depositional conditions that prevailed millions of years ago. Chlorophylls are degraded in marine and lacustrine sediments, mostly to colorless products although some macrocycles survive as porphyrin derivatives. Photodegradative processes can play a significant role in the degradation of lipids and chlorophylls in the water column and even in surface sediments in the case of shallow waters (e.g., Rontani et al. 2012). Cuny et al. (2002) have proposed a "Chlorophyll Phytyl side chain Photodegradation Index," which is the molar ratio of phytyldiol (3-methylidene-3,7,11-trimethylhexadecan-1,2-diol) to phytol, as a measure of the mean amount of chlorophyll photodegraded within the marine euphotic zone.

Carotenoids degrade very rapidly and thus are rarely useful as source indicators in older sediments unless deposited under anoxic conditions. Their degradation rates vary widely and are not simply a function of their high degree of unsaturation. Fucoxanthin and related pigments break down to loliolide, isololiolide, and dihydroactinioliolide (via unstable bicyclic furanoxides) which, however, can be detected in sediments (Repeta 1989).

Polyunsaturated acids (PUFA) are rapidly removed so that their presence in a sediment is usually indicative of living biomass. Similarly, fatty acids present in phospholipids can be used as a measure of microbial biomass. Sterols are more resistant to biodegradation, but they too can be transformed to saturated sterols (stanols), steroidal ketones (including ster-4-en-3-ones), and stanones and unsaturated hydrocarbons (sterenes). Although early research suggested that alkenones might be very resistant to biodegradation, it is now clear that they can be degraded to some extent by bacterial and chemical processes (Rontani et al. 2013). Long-chain *n*-alkanols appear to be relatively stable in soils whereas fatty acids are rapidly turned over.

Lignin from terrestrial plants is considered to be less reactive in soils and oxic sediments than other plant biochemicals such as cellulose, cutin, and free lipids, although substantial degradation can still occur (e.g., Opsahl and Benner 1995). In aerobic soils, white- and brown-rot fungi play a major role in lignin degradation. Once lignin reaches the marine environment, degradation by bacteria or photooxidation becomes important. Lignin is thought to be generally refractory under anaerobic conditions.

Under anoxic conditions, especially when Fe contents are low, sulfur can be naturally incorporated into organic matter leading to the formation of organic sulfur compounds (OSC). This usually proceeds with sulfur attachment to the carbon atom originally substituted with a functional group such as double bond or carbonyl group. The inorganic sulfur species may be either hydrogen sulfide, polysulfides, or elemental sulfur as shown by compound-specific S-isotope studies (Werne et al. 2008). This reaction is geochemically important since it leads to selective preservation of lipid skeletons which otherwise would be quite labile and readily degraded in sediments. It also provides a link between the carbon and sulfur cycles in sedimentary environments.

A recurring theme has been the importance of photic zone euxinia (PZE) in the preservation of organic carbon leading to organic-rich oil shales and exceptional fossil preservation (e.g., Melendez et al. 2013). PZE has been associated with oceanic anoxic events and mass extinction. Under these conditions, the bottom water anoxic layer extends into the photic zone giving rise to layers of anoxygenic phototrophic sulfur bacteria having distinctive biomarkers based on chlorobactane, isorenieratane, and their likely degradation products (C_{15} to C_{31} 2,3,6-aryl isoprenoids) (e.g., Slowakiewicz et al. 2015).

Geosynthesis of organic material can also occur during early diagenesis. For example, macromolecules (also referred to as geopolymers or protokerogen) can be formed by condensation and polymerization reactions involving humic acids, fulvic acids, and humins. With continuing burial, the organic matter is further transformed to become the insoluble organic matter called kerogen. This occurs at relatively low temperatures less than 50 °C and was initially thought to be the main process explaining high contents of organic matter in ancient sediments (e.g., Tissot and Welte 1984). However, it

is now well established that preservation of resistant biopolymers produced by some plants and algae is also a major factor in explaining high contents of organic matter in ancient sediments such as oil shales (Tegelaar et al. 1989; Zhang et al. 2016). These biopolymers are called cutan and suberan in plants and algaenans in microalgae. Note that not all algae produce these polymers (they occur in green algae, eustigmatophytes, and dinoflagellates; Gelin et al. 1999) and a variety of structures, mostly ether-linked, have been described. When subjected to high temperature, these preserved biopolymers can produce abundant aliphatic hydrocarbons having a wide carbon number range typical of that found in petroleum. Isolation of algaenans from microalgae for structural elucidation involves a complex and tedious chemical purification, but a quick indication for the presence of algaenan can be provided by pyrolysis which yields a series of *n*-alkene/*n*-alkane pairs (e.g., Zhang et al. 2016; Zhang and Volkman 2017).

Stable Isotope Geochemistry

Stable isotope ratios are used to deduce origins of organic matter. Much of this work has focused on $^{13}C/^{12}C$ ratios, although this approach is now being extended to nitrogen, sulfur, oxygen, and hydrogen isotopes. The $^{13}C/^{12}C$ ratio in organic compounds reflects the isotopic composition of the original CO_2 or bicarbonate ions plus the combination of thermodynamic and kinetic isotope fractionations occurring during assimilation and metabolism. The range of isotope ratios found varies from one group of organisms to another. Thus, plants which use the C3 pathway have $\delta^{13}C$ values of −23‰ to −34‰, whereas those using the C4 pathway are isotopically enriched and typically range from −6‰ to −23‰.

The isotope ratio of the bulk organic matter in sediments is an average of all the sources present and can be used as a signature of autotrophic carbon fixation. An example of this style of work is that of Vonk et al. (2010) who combined elemental, molecular, and isotopic ($\delta^{13}C$ and $\Delta^{14}C$) analyses to study the sources, degradation, and transport of permafrost-derived soil organic matter from the Kolyma River to the East Siberian Sea. Using a three end-member dual-carbon isotopic mixing model, these authors were able to demonstrate a strong contribution of organic matter from coastal erosion (51 ± 11% to 60 ± 12%) to waters up to 500 km seawards from the coast.

The development of CSIA has revealed remarkable differences in isotope values and confirmed the diversity of sources giving rise to the distributions of hydrocarbons in ancient sediments and crude oils. Measurements of the $^{13}C/^{12}C$ ratio in alkenones in ancient sediments have also enabled calculations to be made of $pCO_2(aq)$ of the oceanic waters present when the sediments were deposited (e.g., Jasper et al. 1994; Benthien et al. 2005).

Another area where $\delta^{13}C$ measurements of individual compounds is providing insights into carbon cycles is the identification of isotopically depleted bacterial lipids typical of methane-oxidizing bacteria (methanotrophs). Such values are often associated with organic-rich oil shales and sediments in which there are oxygen-deficient bottom waters and an active methane cycle. For example, Volkman et al. (2015) found depleted carbon isotope values (−43.7‰ to −50.8‰) in bacterially derived C_{29} and C_{30} neohop-13(18)-enes and hop-17(21)-enes in the Eocene Huadian oil shale in China.

Larsen et al. (2015) have shown that the $\delta^{13}C$ patterns of amino acids accurately record biological sources across widely varying oceanographic conditions. Based on the four most informative amino acids for distinguishing between diatom and bacterial sources (i.e., isoleucine, lysine, leucine, and tyrosine), these authors determined that in sediments from the Peru upwelling, bacterially derived amino acids ranged from 10% to 15% in the sediment layers from the last 5000 years, and up to 35% during the last glacial period. The $\delta^{15}N$ values of amino acids have also proven to be good tracers of food-web relationships and trophic level (Steffan et al. 2013).

Measurements of δD in individual compounds is now becoming more routine although suitable instrumentation is only found in specialist geochemical laboratories. Most attention has focused on *n*-alkanes as recorders of the aqueous environment in which the plant grew. δD ratios of sedimentary biomarkers are now used as paleohydrological proxies over a range of geological timescales although a number of caveats that affect the isotopic fractionation observed between hydrogen in environmental water and hydrogen in lipids need to be considered (e.g., Guenther et al. 2013). The δD of alkenones has also been used as a paleosalinity indicator (see later).

Atmospheric Chemistry

The techniques of organic geochemistry have been widely applied to study the source and fate of atmospheric aerosols and particulate matter (Simoneit 1999). Much of this work has focused on specific volatile pollutants such as polycyclic aromatic hydrocarbons (PAHs), petroleum-derived hydrocarbons, and halogenated compounds such as polychlorinated biphenyls (PCBs). For example, retene and dehydroabietic acid have been utilized as tracers for conifer smoke in urban aerosols. Degradation products from biopolymers (e.g., levoglucosan from cellulose) are also excellent tracers. Geochemists have also studied the transport of plant wax components such as *n*-alkanes, *n*-alkanols, and alkyl esters thousands of kilometers out to sea (e.g., Saliot 2009).

Molecular Archaeology

Another growing application of organic geochemistry is to the field of archaeology, particularly in the characterization of preserved organic materials in pottery. Some applications have included the confirmation that asphalt from the Dead Sea was used in the mummification process from at least 2600 BCE. This finding relied on showing that sterane distributions in modern asphalts and the black material in mummies were identical, and distinct from local oil seeps. Food remains in pottery vessels have been identified from characteristic distributions of fatty acids, sterols, and wax esters thus provide important data on food preferences in ancient civilizations. Wood tar pitches are also amenable to detailed chemical examination and it has been shown that they were in widespread use from the Mesolithic period up to the Middle Ages. Quantities of archaeological material as small as 10–100 mg can be characterized using these GC–MS techniques when combined with new extraction techniques (Correa-Ascencio and Evershed 2014). Genetic fingerprinting techniques are also widely being used although contamination with modern materials still presents considerable analytical problems.

Paleoenvironmental Assessment

Organic geochemistry continues to provide important information about how environments have changed on Earth over time from the biomarker and isotope signatures preserved in ancient sediments. A major focus has been on identifying the biotic and environmental changes associated with major extinction events (e.g., Saito et al. 2014) and for reconstructing paleorecords of past temperature and CO_2 levels.

Proxies for Paleotemperature Changes

Organic geochemists have played a major role in devising a number of lipid proxies to study changes in Earth's climate over geological time (see Wakeham 1993; Eglinton and Eglinton 2008 for reviews). Alkenones provided the first biomarker proxy for climate change and these are now widely used to estimate paleotemperatures (e.g., Volkman 2000; Eglinton and Eglinton 2008) for sea surface temperature (SST) following the discovery that the ratio of di- to tri-unsaturated compounds in haptophytes changes systematically with temperature. The proposal for a new paleotemperature index, $\boldsymbol{U^K_{37}}$, by Brassell et al. (1986), opened up a new field of research in which the concentrations of biomarker compounds could be used for quantitative estimation of the SST prevailing when the sediments were deposited. The $\boldsymbol{U^K_{37}}$ index was later simplified to $U^{K'}_{37}$ by Prahl and Wakeham (1987), since the 37:4 methyl alkenone is only abundant in sediments from colder regions and in some lakes.

$$\boldsymbol{U^K_{37}} = ([37:2] - [37:4])/([37:2] + [37:3] + [37:4])$$
$$U^{K'}_{37} = [37:2]/([37:2] + [37:3]).$$

where the alkenones are designated by (number of carbon atoms):(number of double bonds).

Organic-based proxies have inherent uncertainties due to ecological biases, and indeed studies have shown that $U^{K'}_{37}$ values can be affected to a small extent by biological and abiological processes (e.g., Volkman 2000; Rontani et al. 2013). Nonetheless, $U^{K'}_{37}$ has now been used in numerous paleotemperature studies resulting in hundreds of publications. Various calibrations with temperature have been proposed and there is some evidence for a regional bias (Sikes and Volkman 1993), but the calibration of Müller et al. (1998) is widely applicable.

$$U^{K'}_{37} = 0.033\ \mathrm{T} + 0.069.$$

Note that the alkenone distributions in lacustrine and coastal haptophytes are very different from those found in open marine species and so very different temperature calibrations apply in such cases and these appear to be less robust.

Another paleotemperature proxy is the TEX_{86} proxy which is based on the polar, relatively high molecular weight GDGT tetraether lipids from pelagic archaea (Schouten et al. 2003; Kim et al. 2008).

$TEX_{86} = [III + IV + V'] / [II + III + IV + V']$ where the roman numerals refer to specific GDGT isomers.

There are now many studies using TEX_{86}. For example, Jenkyns et al. (2004) used TEX_{86} to infer an average sea surface temperature of ca 15 °C for the Arctic Ocean about 70 million years ago. This implied an equator-to-pole gradient in SST of ca. 15 °C during this interval and, by extrapolation, suggested that polar waters were generally warmer than 20 °C during the middle Cretaceous (ca. 90 Ma).

The MBT-CBT proxy for the reconstruction of paleotemperatures and past soil pH is based on the distribution of branched glycerol dialkyl glycerol tetraether (brGDGT) membrane lipids. MBT stands for "Methylation of Branched Tetraethers" and CBT stands for "Cyclization of Branched Tetraethers."

$$\mathrm{CBT} = -\log((\mathrm{Ia} + \mathrm{IIb}) / (\mathrm{Ia} + \mathrm{IIa}))$$

$$\mathrm{MBT} = (\mathrm{Ia} + \mathrm{Ib} + \mathrm{Ic}) / (\mathrm{Ia} + \mathrm{Ib} + \mathrm{Ic} + \mathrm{IIa} + \mathrm{IIb} + \mathrm{IIc} + \mathrm{IIIa} + \mathrm{IIIb} + \mathrm{IIIc})$$

Where the compounds listed are specific branched GDGTs.

Peterse et al. (2012) extended the soil dataset on which these proxies were based to 278 globally distributed surface soils of which 26% contained all nine brGDGTs. They presented new transfer functions for the reconstruction of pH based on the CBT index:

$\mathrm{pH} = 7.90 - 1.97 \times \mathrm{CBT}$ ($r^2 = 0.70$; RMSE = 0.8; n = 176), as well as for mean annual temperature (MAT) based on the CBT index and methylation index using the seven most abundant GDGTs (defined as MBT′):

MAT = 0.81 − 5.67 × CBT + 31.0 × MBT′ (r^2 = 0.59; RMSE = 5.0 °C; n = 176). An example is the work of Schoon et al. (2015) who used TEX_{86} to infer SSTs across the Palaeocene-Eocene Thermal Maximum (PETM; ca. 56 Ma) were relatively low before the event, but increased by ca. 7 °C afterwards. At another section (Fur), a remarkably similar temperature record was obtained for MAT using the MBT′-CBT proxy.

LDI (long chain diol index) is a new index based on C_{28} and C_{30} long chain 1,13- and 1,15-alkyl diols synthesized by marine phytoplankton presumed to be eustigmatophytes (Rampen et al. 2012). It is defined as:

$LDI = FC_{30–1,15} / (FC_{28–1,13} + FC_{30–1,13} + FC_{30–1,15})$ where F is the fractional abundance. From a large dataset, Rampen et al. (2012) established a relationship between LDI and sea surface temperature (SST):

LDI = 0.033 × SST + 0.095; R^2 = 0.969, n = 162) over a temperature range of −3 to 27 °C. It is now apparent that extensive oxic degradation can affect the LDI values and thus affect the inferred temperature (Rodrigo-Gamiz et al. 2016). Another complication is the possibility that in nearshore areas there may be large inputs of riverine-derived C_{32} diols (Lattaud et al. 2017).

Studies of cultures of the diatoms of the genus *Proboscia* have shown a strong effect of temperature on the degree of saturation and the chain length distribution of long chain 1,14-alkyl diols quantified as the diol saturation index (DSI) and diol chain length index (DCI), respectively (Rampen et al. 2014). Based on the global spread of alkyl diol abundances, Rampen et al. (2014) have proposed the use of 1,14-diols versus 1,13-diols [C_{28} + C_{30} 1,14-diols]/[(C_{28} + C_{30} 1,13-diols) + (C_{28} + C_{30} 1,14-diols)] as an indicator for high nutrient or upwelling conditions, although this may not be true in all regions.

Some studies have used all three paleotemperature proxies to assess changes in environmental conditions. For example, Plancq et al. (2015) compared three proxies ($U^{K'}_{37}$, TEX_{86}, and LDI) and were able to show that sapropels deposited between 3.1 and 2.8 Ma in the Mediterranean likely reflected better preservation of organic matter, induced by the development of a strong thermohaline stratification of the water column and to oxygen-depleted bottom waters. The second series of sapropels, deposited between 2.7 and 2.6 Ma, was more likely the result of enhanced primary productivity in a weakly stratified water column. Becker et al. (2015) not only compared results from these same three proxies but developed a method for determining all three in a single normal phase high performance LC–atmospheric pressure chemical ionization mass spectrometry (NP-HPLC–APCI-MS) analysis. Reconstructed SST values differed considerably between the proxies for the Last Glacial Maximum (LGM) and the period of sapropel S1 formation at ca. 10 kyr BP, but trends during the late Holocene were similar. Part of the discrepancy was attributed to changes in the composition of alkenone-producing microalgae and partly to habitat change due to changes in nutrient availability.

An important goal in paleoceanography is to reconstruct past ocean salinity. This is usually done using oxygen isotope values of planktonic foraminifera combined with SST reconstructions. However, this approach relies on multiple proxies resulting in potentially large uncertainty. Schouten et al. (2006) showed that salinity and growth rate, but not temperature, affected the δD values of alkenones in *E. huxleyi* and *G. oceanica* in culture. Kasper et al. (2015) therefore tested whether the hydrogen isotope composition of C_{37} alkenones might be used to assess salinity changes in the eastern South African continental shelf in the Mozambique Channel. No clear changes were observed in the δD-alkenone record throughout the 39,000 years of the core record despite known changes in global seawater δD related to glacial–interglacial ice volume effects. This was attributed to a high soil OM input during the glacial period and low input during the Holocene as deduced from BIT index values. The authors suggested that a more pronounced influence of freshwater at the core location during the glacial period resulted in alkenones depleted in D during that time. The correlation between the BIT index and δD of alkenones during the glacial period suggests that increased continental runoff potentially changed the growth conditions of the alkenone-producing haptophytes, promoting coastal haptophyte species with generally more enriched δD-alkenone values.

Petroleum Geochemistry

One of the main commercial applications of organic geochemistry has been to the field of petroleum exploration (Hunt 1979; Tissot and Welte 1984; Brooks and Fleet 1987; Orr and White 1990; Moldowan et al. 1992). These techniques have also proven valuable for studying the origins of gases, coals, oil shales, peats, and lignites. Crude oils are produced when organic-rich rocks are heated to temperatures sufficiently high to crack C–C bonds (so-called oil window). The hydrocarbons produced then migrate to a suitable reservoir rock and will accumulate there provided that a good seal is present. Shale oil occurs when the hydrocarbons are still locked into the rock and can only be produced commercially by fracturing the rock (so-called fracking).

Characteristic distributions of biomarkers (Peters and Moldowan 1993; Peters et al. 2005) have been used to correlate crude oils in reservoirs with their source rocks (e.g., Volkman 1988; see ▶ Hydrocarbons entry). Such information enables the petroleum scientist to identify petroleum migration paths, estimate the oil prospectivity of a field, and suggest

further sites for drilling. Changes in biomarker isomer ratios can be used to infer the extent of thermal maturation and hence whether a potential source rock lies within the "oil window." The presence of specific biomarkers can often be used to deduce the type of environmental setting when the source rock sediments were deposited. Many oils are the result of multiple accumulations, some of which may be biodegraded and water washed.

The formation of petroleum depends on a number of factors including the type and amount of organic matter in the source rocks, the thermal maturity of the organic matter, and the presence of suitable migration pathways, traps, and seals. The type of organic matter, which is usually expressed in terms of maceral composition, can be determined by optical or physicochemical means. Hydrogen-rich macerals such as alginite are considered to be a much better source of petroleum (i.e., they are oil-prone), than inertinite or vitrinite. The reflectance of vitrinite macerals (measured as vitrinite reflectance in units of %Ro) is often used as a measure of thermal maturity; the main phase of oil generation usually occurs in the range 0.65–1.3%Ro.

A commercial instrument called the Rock-Eval is now widely used to characterize source rock samples. In this system, the finely ground source rock is heated in an inert atmosphere under various temperature conditions to yield free hydrocarbons (the S_1 peak) plus hydrocarbons liberated by pyrolysis of the kerogen (the S_2 peak). The amounts of hydrocarbons that can be liberated from the rock (the genetic potential) is simply S_1 plus S_2 expressed as a proportion of the mass of rock. Thermal maturity can be estimated from the temperature at which the maximum in the S_2 response occurs (T_{max}), although this does show some variations between kerogen types.

Basin modeling is now widely used to reconstruct the history of oil and gas generation in a particular region (Welte et al. 1997). In this process, geochemical information about the factors that affect petroleum formation such as source rock quality and migration is integrated with geological information on depositional history, subsidence rates, erosion and tectonic events, and geothermal gradients to provide a conceptual framework showing how the basin evolved. Numerical simulations are then carried out to investigate whether all the factors necessary for oil generation and accumulation can be found in the basin, and at what geological time, thus substantially minimizing the exploration risk.

Many oils are biodegraded in the reservoir, causing characteristic changes in hydrocarbon composition. The first hydrocarbons to be removed are those with simple structures such as the *n*-alkanes and methyl-branched compounds. Isoprenoids and bicyclic alkanes are more resistant and so they are degraded at lower rates. Steranes and diasteranes are remarkably resistant to biodegradation and so they are often used to correlate oils even those with compositions that have been greatly modified by microbial action. Eventually, even steranes can be biodegraded and the first isomers to be removed are those still possessing the original "biological" 20R stereochemistry. Similar techniques are often applied in environmental studies to identify sources of spilled crude oil or to study the pathways by which the oil is degraded in the environment. A notable example was the use of the abundance of the C_{30} hopane as an internal marker for assessing the rate at which oil derived from the *Exxon Valdez* oil spill in Alaska was degraded in sediments (Bence et al. 1996).

The zone of maximum hydrocarbon production is usually referred to as the catagenic zone. At later stages, gaseous hydrocarbons such as methane tend to dominate the hydrocarbons produced and at even higher burial temperatures exceeding 150 °C, the metagenesis stage is reached where the kerogen is converted to a carbon residue.

Organic Matter in Space

Organic geochemical techniques have not been restricted to samples from Earth but have also been used to characterize organic matter in meteorites (Clemett et al. 1993; McKay et al. 1996) and to look for chemical evidence of past life on the moon and Mars. A plethora of papers have appeared since the 1970s on the amino acids found in meteorites (e.g., Shock and Schulte 1990), and a number of hypotheses have been advanced to explain their extraterrestrial formation. These have included Miller-Urey synthesis, Fischer-Tropsch synthesis, photochemical ion-molecule reactions, and aqueous alteration of preexisting condensed phases. More recent work has identified other compound classes such as hydroxy fatty acids, dicarboxylic acids, and polycyclic aromatic hydrocarbons. Complex aromatic molecules have also been identified in interplanetary dust particles. In 1996, NASA scientists put forward evidence that life may have been detected on Mars based on analysis of a Martian meteorite found in Antarctica (McKay et al. 1996), although this was later disputed. This evidence included the presence of polycyclic aromatic hydrocarbons and the occurrence of putative bacteria-like fossils in carbonate globules containing magnetite and Fe-sulfide mineral phases which the scientists conjectured could be explained by biogenic processes.

Summary and Future Prospects

Modern organic geochemistry is a multifaceted, multidisciplinary science which has found applications in a diversity of topics in Earth science and environmental science. In petroleum research, biomarkers have become standard tools for the petroleum industry and new parameters continue to be developed particularly to characterize high maturity or mixed

and biodegraded oils. The area of paleoenvironment assessment has driven many new developments including new biomarker proxies thus greatly increasing our understanding about how Earth's environment has changed over geological time. Organic geochemists have been at the forefront of technological analytical developments and this will undoubtedly continue with an increasing emphasis on measurement technologies that are more sensitive and have better resolution (e.g., 2D gas chromatography: GC × GC) and by extension to a variety of isotopes not just those of carbon and hydrogen.

Organic Matter Degradation and Preservation

Sandra Arndt[1] and Douglas Edward LaRowe[2]
[1]BGeosys, Department Geoscience, Environment and Society (DGES), Université Libre de Bruxelles, Bruxelles, Belgium
[2]Department of Earth Sciences, University of Southern California, Los Angeles, CA, USA

Definition

Organic matter degradation is the disintegration of mainly photosynthetically produced organic matter by microorganisms. It proceeds via multiple enzymatic reactions involving different microorganisms and oxidants as well as a number of intermediate compounds. Depending on the degradation pathway, organic matter is directly oxidized to carbon dioxide, partly oxidized to intermediate compounds or reduced to methane. In the simplest of terms, preservation can be simply defined as the incompleteness of degradation.

Global Importance

Life depends on the continuous recycling of bioactive elements. The resulting global biogeochemical cycles are intimately connected through the biological process of photosynthesis, which fixes energy in carbon bonds and respiration, which breaks the organic bonds and thereby releases energy. On long time scales, organic matter, OM, production generally exceeds respiration and a small fraction of the photosynthetically produced organic carbon escapes degradation to be preserved and buried in sediments (Berner 2003). This small imbalance between photosynthesis and respiration connects the short- and long-term carbon cycles, controls the long-term evolution of atmospheric CO_2, and has enabled the accumulation of oxygen in the atmosphere (Berner 2003). However, compilations of field data reveal that OM production, degradation, and preservation rates vary significantly in space (Burdige 2007; Arndt et al. 2013) and time (Berner 2003). Understanding the processes that control the degradation and preservation of OM during transport and burial is important for predicting the impact and feedbacks of past, present, and future global change on global biogeochemical cycles and climate.

OM Degradation and Preservation in the Earth System

Organic matter represents the largest reactive reservoir of reduced carbon in the Earth system, divided between an estimated 1760 Pg C of soil OM, 1000 Pg C in recent surface sediments (excluding deep sediments), and 688 Pg C dissolved in the ocean (Eglinton and Repeta 2004). Almost all of the organic matter that is degraded or preserved in the Earth System originates from photosynthetic activity in the terrestrial (global net primary productivity, NPP = ~59 Pg C $year^{-1}$) or marine biosphere (global NPP = ~49 Pg C $year^{-1}$). In addition, weathering of old OM in rocks, remobilization of organic matter from thawing permafrost, chemoautotrophy, as well as secondary production by microbes and animals contribute to the global organic matter pool (Eglinton and Repeta 2004; Middelburg 2011). Approximately two-thirds of the terrestrially produced OM is rapidly degraded within soils or glacial environments. The remainder escapes immediate degradation and is either degraded slowly or temporarily stored before being transported downstream with old, weathered OM into lakes, streams, rivers, coastal transition zones and, ultimately, the ocean (Regnier et al. 2013). An estimated 1.9 Pg C $year^{-1} \pm 1.0$ Pg C $year^{-1}$ of total soil C (mostly particulate OM and dissolved OM, but also dissolved inorganic carbon) is exported to inland waters. Only 0.45 Pg C $year^{-1}$ of the terrestrial derived OM reaches the coastal ocean and 0.1–0.35 Pg C $year^{-1}$ makes it to the open ocean (Regnier et al. 2013; Bauer et al. 2013). Thus, the intermittent storage and transport of OM along the land-ocean continuum modulates the degradation of terrestrial OM on short and long timescales. However, the exact amounts of OM that are degraded and temporarily or permanently preserved during its transit from land to ocean remain unknown (Regnier et al. 2013). Like terrestrially derived OM, a large fraction of the OM produced in the surface ocean is rapidly degraded with only approximately 10–20% of the primarily produced OM (of which ca. 27% is dissolved OM) escaping degradation in the surface ocean (Dunne et al. 2007; Hansell and Carlson 2015). Dissolved organic matter, DOM, is transported to the deep ocean by convection and mixing. While a large fraction of the exported DOM is degraded at mid-depths, an estimated 0.1 Pg C $year^{-1}$ is transfered to the large, apparently refractory, deep ocean DOM reservoir (~680 Pg) that persists through multiple ocean mixing cycles (Hansell and Carlson 2015). Particulate OM, POM, sinks to the ocean floor and can also be laterally transported by ocean currents (Eglinton and Repeta 2004). It is further degraded during its transport, resulting in an attenuation of the export flux. Between 0.28% and 30% (5.7% average) of the export flux reaches depths greater than 1.5 km and <1–5% of the export flux is deposited on the seafloor. Degradation during burial further reduces this flux such that <0.3% of the original exported flux is ultimately sequestered in deep sediment layers (Honjo et al. 2008; Dunne et al. 2007; Eglinton and Repeta 2004).

The Process of OM Degradation and Preservation

OM degradation and preservation are often thought of as two sides of the same coin. However, this view is somewhat simplistic. It is important to realize that OM preservation is not solely defined by the absence of degradation but can also be directly controlled by other factors, such as the addition of so-called necromass derived from remnants of bacterial cell walls, cell exudates, or cell lysis products to the sinking or buried OM pool. Nevertheless, OM degradation still exerts the dominant control on OM preservation, and many of the additional controls on preservation are indirectly linked to the process of OM degradation.

The degradation of OM generally proceeds via multiple enzymatic reactions involving millions of different organisms and organic compounds, as well as a number of different oxidants and intermediate compounds (Arndt et al. 2013). Note that although microbes dominate organic matter consumption, fungi, as well as animals, such as corals, sea sponges, and suspension feeders also consume detrital organic matter (Bianchi 2011; Middelburg 2017). A fraction of the consumed carbon is excreted as faeces or pseudofaeces, further contributing to the sedimentary pool.

OM Composition

The composition of OM, from freshly produced to heavily degraded, ranges in size and composition from simple, small monomers to large polymers and humic substances (de Leeuw and Largeau 1993). In the terrestrial biosphere, primary production is mainly carried out by multicellular plants, with litter, roots, and root-zone exudates that often contain rigid polymers such as cellulose and lignin, complex carbohydrates, or phenolic polymers for structural support (de Leeuw and Largeau 1993). In contrast, marine primary production is dominated by single celled organisms and, therefore, rich in lipids and nitrogenous compounds (Burdige 2007; Arndt et al. 2013). All these compounds are present in the environment at various stages of degradation from unprocessed and reactive to highly processed and less reactive OM. In addition, it has also been suggested that, despite its low contribution compared to primary production, secondary production by microbes and animals might exert an important control on the composition of sedimentary organic matter that is eventually buried (Lomstein et al. 2012; Middelburg 2017).

Microbes and Terminal Electron Acceptors

This heterogeneous mix of organic compounds is mainly degraded by millions of individual microorganisms with highly diverse metabolic potentials and requirements in synergetic or competitive interactions (Jørgensen and Marshall 2016; Jørgensen and Boetius 2007; Jørgensen 2006). They can use different oxidants (i.e., terminal electron acceptors, TEAs, O_2, NO_3^-, Mn(VI), Fe(III), and SO_4^{2-}) to degrade OM and produce a number of intermediate organic compounds. Although some microorganisms can take up OM directly, most rely on the production of extracellular hydrolytic enzymes in order to make large organic compounds accessible to the entire community. Fermenters, in turn, are then often required to convert these smaller organic compounds into substrates that can be used by other heterotrophs. Consequently, an interconnected group of microorganisms is often required to break down organic matter into terminal products such as CO_2, H_2, and CH_4. Depending on the degradation pathway, OM is thus directly oxidized to CO_2, partly oxidized to intermediate compounds or reduced to CH_4. The main sequence of these different degradation pathways roughly follows the decreasing amount of energy available from them.

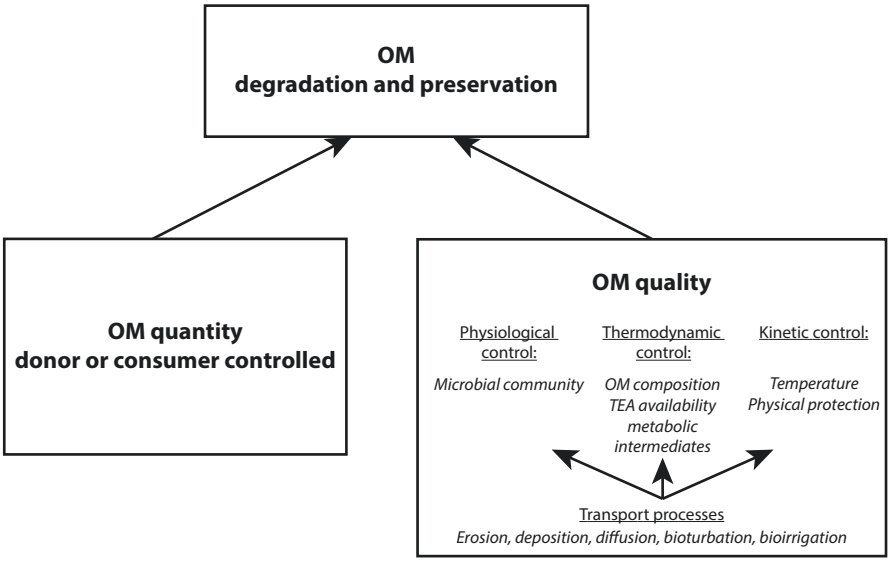
Controls on OM Degradation and Preservation

Although OM degradation and preservation are intimately linked, the relative significance of different mechanisms in controlling OM degradation versus preservation may vary (Burdige 2007). The reason for this difference is the low preservation efficiency of OM in the Earth system. Ultimately, only a tiny fraction of the photosynthetically produced OM is preserved in the sediment and small changes in degradation rates translate into pronounced changes in preservation rates. It is therefore important to keep in mind that a mechanism that exerts only a subtle control on OM degradation may play an import role for OM preservation.

In general, OM degradation and preservation rates are controlled by a dynamic and complex interplay of different environmental factors that can be broadly divided into quantity and quality controls (Fig. 1).

Quantity Control

OM degradation and preservation are first and foremost determined by the quantity of available carbon. In this respect, one can distinguish consumer- and donor-controlled systems (Arndt et al. 2013; Middelburg 2017). Consumer-controlled systems, such as the surface soil layer and the photic layers of aquatic systems and sediments have a control over carbon delivery by enhancing OM production or transport, while donor-controlled systems, such as deep soil layers, the deep ocean, and marine sediments outside of the photic zone, have little or no control over C input. In those systems, organic matter degradation is closely linked to organic matter export efficiencies. For instance, a higher vertical transport rate increases the deposition flux of OM to marine sediments and reduces the degree of alteration and thus the aging of organic matter in the water column.



Organic Matter Degradation and Preservation, Fig. 1 The degradation and preservation of organic matter (*OM*) is controlled by the quantity and quality of organic matter (Adapted from Arndt et al. 2013). The organic matter supply to an environment can be donor or consumer controlled and its degradation and preservation in this environment is thermodynamically and/or kinetically controlled through the different physiological abilities of the resident microbial community that compete for common substrates. In addition, transport processes exert an indirect control through their influence on organic matter alteration (and thus composition), terminal electron acceptor (TEA), metabolic intermediate concentrations, and microbial community structure

Quality Control

Organic matter quality (i.e., its susceptibility to microbial transformation or reactivity) exerts an important influence on rates of OM degradation and preservation. The historic view is that OM quality is primarily determined by its chemical structure. However, it has become increasingly clear that OM quality is "not an inherent, or absolute, property of the organic matter itself, but results from the interaction between the organic matter and its environment" (Mayer 1995). Recent observations and laboratory experiments indicate that OM quality is controlled by a complex and dynamic interplay between OM structure and numerous environmental factors (e.g., Schmidt et al. 2011; Burd et al. 2016). The source and transit path of OM, its composition, the nature of the resident microbial community, temperature, physical protection, macrofaunal activity, deposition rate, and thermodynamic constraints all are thought to influence rates of OM degradation (Arndt et al. 2013; Burd et al. 2016), which vary by at least 10 orders of magnitude (Middelburg 1989).

OM Composition

One of the most important guideposts to understanding the link between OM composition and OM quality is the recognition that terrestrial OM is generally less reactive than marine OM (Burdige 2007). This quality difference has been explained with differences in the chemical structures between terrestrial OM, which is made up of moderately or highly resistant biopolymers, and marine OM, dominated by comparably labile biopolymers (de Leeuw and Largeau 1993). In addition to its original chemical composition, the continuous alteration of OM during transport and burial influences the quality of the residual OM. Observations show a pronounced decrease of OM quality with time (Middelburg 1989). This observation has been explained with preferential degradation of more reactive OM compounds during OM degradation. A continuous degradation of OM during transport and burial will thus result in the selective preservation of unreactive compounds and an overall decrease in OM quality (Tegelaar et al. 1989). In addition, the formation of geopolymers through humification or condensation–polymerization during transport and, especially, burial also contributes to the overall decrease of OM quality with time (Tissot and Welte 1984; Burdige 2007).

Microbial Community Structure

Because a vast array of microorganisms consumes, produces, and transforms organic compounds, the microbial community structure exerts an important control on apparent OM quality. Unlike macrofauna, microorganisms can be dispersed over vast distances in short time spans, have the ability to use different electron donors and acceptors (within one organism), can achieve dormancy, can respond rapidly to shifting environmental variables, and can evolve and exchange genetic material with distantly related organisms much faster than their macroscopic counterparts (Nemergut et al. 2013). The rate at which these organisms are active depends on their access to energy and nutrients, their inherent metabolic capabilities, and the presence and/or absence of other microorganisms and viruses that carry out ecological functions such as

predation and vitamin, antibiotic and extracellular enzyme production (Lever et al. 2015; Jørgensen and Marshall 2016). For instance, it has long been thought that most bacteria cannot ingest organic compounds larger than ~600 g/mol (Decad and Nikaido 1976), but many of the organic compounds that reach sediments are larger than this (e.g., proteins, nucleic acids, lipids). Aerobic organisms have the ability to oxidize organic matter compounds directly to CO_2 but are confined to the usually thin oxic zone (few mm to a cm deep, although it can extend to 100s of meters in the organic lean ocean gyres). In contrast, the anaerobic food chain usually requires an initial hydrolytic step to break down high molecular weight compounds through extracellular and membrane-bound enzymes into smaller organic molecules such as monomeric sugars and amino acids. These hydrolytic products can then be oxidized by microorganisms to CO_2 or transformed by fermenting and acetogenic bacteria to hydrogen and organics such as volatile organic acids. The terminal step in this anaerobic food chain involves the utilization of these latter compounds by microorganisms that reduce manganese/iron oxides, sulfate, or produce methane. In addition, newly discovered physiologies, such as extracellular electron transfer for remote oxidation of OM by cable bacteria (Nielsen et al. 2010), may require revision of the traditional view of OM degradation pathways.

Thermodynamics

Most of the organic matter that is consumed by microorganisms is used to gain energy. Although there are many factors that govern the rates at which organisms will consume energy, there is a growing consensus that the rates at which catabolic reactions proceed in relatively low-energy settings are related to the amount of energy that is available from them (Jin and Bethke 2003; LaRowe et al. 2012). In other words, the rate of OM degradation slows down as the amount of Gibbs energy available from it decreases. The Gibbs energy yield of organic matter degradation is determined by the nature of the available terminal electron acceptor, the organic compounds being processed, and the end products of the decomposition reaction, as well as temperature, pressure, and the chemical composition of the environment (LaRowe and Van Cappellen 2011). For instance, OM degradation rates in anaerobic sediments in which the dominant electron acceptor is sulfate tend to be slower than in oxic settings. When only organic carbon compounds with a low energetic potential remain, reaction rates can slow even further.

Physical Protection

The observed correlation between the content of organic matter in soils and sediments and mineral surface area indicates that physical protection of organic matter by interactions with the mineral matrix exerts an important control on OM degradation and, in particular, preservation (Mayer 1994; Hedges and Keil 1995; Blair and Aller 2012). Sorption of organic matter to mineral surfaces or its inclusion in aggregates provides means of protecting reactive organic matter from degradation during transport and burial and, thus, favors preservation. Multiple mechanisms, such as the protection from or steric limitations of hydrolytic enzyme attack and condensation reactions (Mayer 1994; Hedges and Keil 1995; Eglinton and Repeat 2004) have been proposed to explain the observed physical protection of organic matter by minerals, although this remains the subject of much debate.

Temperature

Like all other biogeochemical processes, temperature is a master variable that generally speeds up reaction rate as it rises. However, organic matter degradation is not a simple chemical reaction, but a complex, multi-step process involving a number of different OM compounds, enzymes, oxidants, and intermediate products. As a consequence, the control of temperature on organic matter degradation rates also depends on physiological adaption, selection pressure, and the reaction path (Arnosti et al. 1998; Finke and Jørgensen 2008; Robador et al. 2010). For instance, organic matter degradation rates in temperate environments strongly increase during the warm season and fall during cooler months. In contrast, organic matter degradation rates in permanently cold Arctic sediments are not necessarily slower than those in temperate or tropical environments (Jørgensen 2006). This seemingly contradictory observation is the direct result of the physiological adaption of the in-situ bacterial community to the prevailing environmental conditions.

Transport Processes

Transport processes, such as bioturbation, bioirrigation, and deposition rates may exert an important direct and/or indirect control on organic matter degradation and preservation (Middelburg 2017). In soils and oxic sediments, invertebrates such as polychaetes rework the upper centimeters and influence degradation rates through feeding and burrowing activities, the ventilation of these burrows, or mixing of fresher organic material to deeper layers. This activity may enhance or inhibit organic matter degradation. For instance, within the bioturbated zone of oxic sediments, short-term redox oscillations, the mixing of fresh and labile with old and degraded OM (so-called priming), bioturbation-mediated particle manipulation, grazing, and excretion/secretion may enhance degradation rates, while the production of tube linings, halophenols, or body structural products and the direct feeding on depositing organic matter could inhibit organic matter degradation (Arndt et al. 2013; Middelburg 2017). In addition, the interaction between different macrobenthic animals may enhance the supply of organic matter to the sediment.

Finally, in marine sediments, organic matter degradation and preservation often correlate with sediment deposition rates. However, deposition rate only exerts a control on organic matter degradation/preservation if deposition rates are high enough and/or the organic matter is unreactive enough to escape degradation in the upper, mixed layer (Emerson et al. 1985). One can broadly distinguish different high deposition settings (Blair and Aller 2012). High-energy, mobile muds generally reveal high organic matter degradation and low preservation due to enhanced oxygen exposure and efficient metabolite exchange. Low-energy facies show low organic matter degradation rates and enhanced organic matter preservation as a result of extreme accumulation rates and, often, high loads of fossil organic carbon. Small, mountainous river systems exhibit the highest organic matter preservation favored by the delivery of large amounts of fossil organic matter and average, but periodically high, accumulation rates.

Summary

Organic matter degradation and preservation play a key role in global biogeochemical cycles and climate. The degradation of OM generally proceeds via multiple enzymatic reactions involving millions of different organisms, billions of organic compounds, and a number of different oxidants, as well as intermediate compounds. As a result, OM degradation and preservation is controlled by a dynamic and complex interplay of different environmental factors. Attempts to isolate the impact of a single variable on the rate of OM degradation have often led to contradictory results. It is therefore becoming increasingly clear that OM degradability is not an intrinsic property of the organic matter itself but an ecosystem property. Correspondingly, the likelihood that a given organic compound will be degraded by a microbial community or be preserved will depend on the chemical formula and structure of that compound, in addition to the metabolic capabilities of the resident microorganisms in response to environmental factors such as electron acceptor and intermediate metabolite concentrations, temperature, and physical associations with minerals or other organic compounds.

Definition

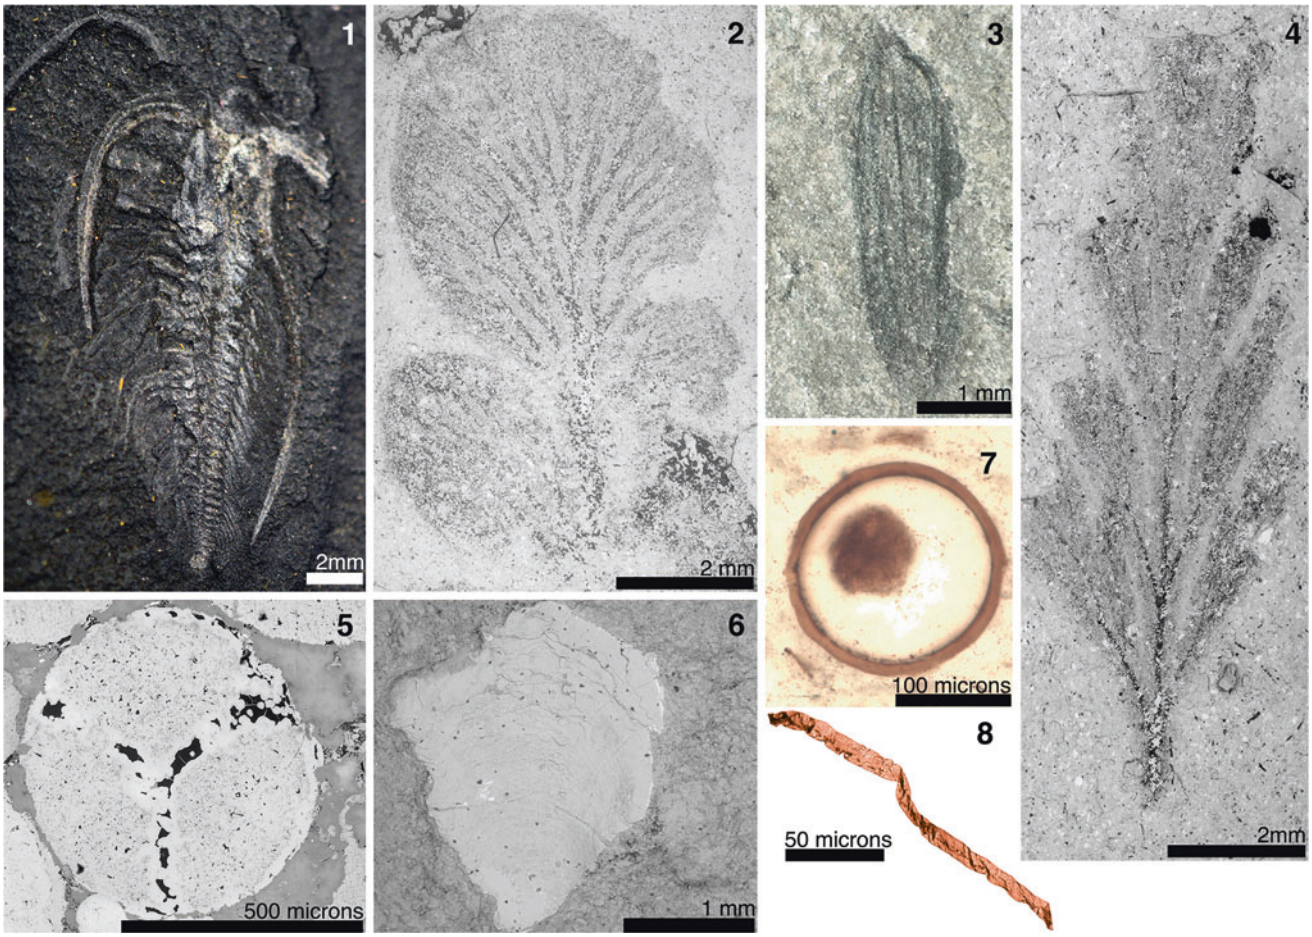
Because all organisms on Earth consist of complex organic biomolecules, any fossil may contain organic matter. Indeed, organic matter represents one of the most common fossil materials, occurring within skeletal elements (shells and bones) and making up organically preserved microorganisms, plants, and exceptionally preserved eukaryotes (i.e., animals and algae with remains of non-biomineralized tissues).

Introduction

Remains of organisms in the geologic record occur in a variety of preservational styles, which vary with regard to fossil composition, scale, and dimensionality, in addition to anatomy and morphology. All fossils have the potential for preservation of organic matter, making such material an active area of paleontological and geobiological research. Overall, fossils vary widely in terms of organic matter quantity, composition, and form. The major types of fossils containing organic matter (Fig. 1) include organically preserved microfossils, skeletal fossils, carbonaceous compressions, fossils of secondarily mineralized soft tissues, and small carbonaceous fossils (thin carbon films freed from rock matrixes via hydrofluoric acid maceration). Skeletons (bones, shells, sclerites, spicules, tests, and teeth) produced by biomineralizing organisms make up the bulk of the fossil record, and observations of organic material within small shelly fossils (Martí Mus 2014), brachiopods (Forchielli et al. 2012), and vertebrate bones (Asara et al. 2007; Surmik et al. 2016) affirm that they sometimes retain organic matter. That said, the preservation of organics within skeletal fossils has historically received little attention. Instead, most research on fossils containing organic matter has focused on organically preserved microfossils, plants, animals, and macroalgae. These fossils occur less commonly than skeletal remains because microbial processes rapidly destroy non-biomineralized tissues in typical sedimentary environments (Muscente et al. 2017). Preservation of such fossils requires circumstances conducive to preservation of organics, specifically, conditions that limit scavenging and microbial decomposition of tissues and ensure organic matter survival over geologic time (Muscente et al. 2017). Regardless of the circumstances responsible for its preservation, the presence of organic matter ultimately allows for integrated studies of fossil morphology, ultrastructure, biochemistry, and physiology.

Sources and Post Burial Processes

Organisms contain various types of organic biomolecules. Proteins, carbohydrates, lipids, and nucleic acids represent the major groups, which in turn, make up an assortment of biopolymers (macromolecules with repeated subunits). Microbial and diagenetic (e.g., thermal maturation) processes result in the degradation and alteration of these biomolecules over time. Prior to burial and throughout diagenesis, microbes drive the chemical decay and decomposition of tissues, a process involving hydrolysis of large molecules into smaller



Organic Matter in Fossils, Fig. 1 Fossils containing organic matter. (*1*) Carbonaceous compression of *Marrella* from Burgess Shale, Canada (Muscente et al. 2017). ones. Although microbial decay always begins prior to thermal maturation, the two processes proceed concurrently late in diagenesis. Thermal alteration causes further degradation, leading to polymerization of biomolecules into long-chain aliphatic compounds (Stankiewicz et al. 2000). This process is sometimes called "kerogenization" (Cai et al. 2012) because it leads to formation of insoluble ("kerogen") components, which are characteristic of organic matter mixtures in the geologic record. Nonetheless, this term is misleading, as polymerization generates an array of compounds, and the mixtures themselves often retain soluble components, like remnants of proteins (Stankiewicz et al. 2000; Schweitzer et al. 2008). Other aspects of diagenesis also alter organic matter from its starting state. Microbial production of sulfide, for example, drives sulfurization and the formation of organosulfur compounds within fossil organic matter (Muscente et al. 2015; McNamara et al. 2016). In any case, the major groups of biomolecules vary considerably in their recalcitrance to microbial processes and thermal maturation, and therefore, in their potential for survival over geologic time. In terms of preservation potential and resistance to decay, biomolecules typically take the following order: nucleic acids < proteins < carbohydrates < lipids < biopolymers (Tegelaar et al. 1989; Briggs 2003).

Organic matter within a fossil may represent indigenous biomolecules of the organism, exogenous organics derived from hydrocarbon migration within a rock, or a mixture of sources. These possibilities can be explored through the application of advanced analytical methods (see below) along with taphonomic analysis. In carbonaceous compressions and small carbonaceous fossils, organic matter occurs as thin films on bedding surfaces. Such layers form through the collapse and coalescence of multiple tissues (Rex and Chaloner 1983) by way of diagenetic polymerization (Stankiewicz et al. 2000). The preservation of fine anatomical details suggests that each thin film derives from a single

organism (Martí Mus 2014), and geochemical analyses of macroalgae compressions generally corroborate this interpretation, showing that within specific geologic deposits, different taxa contain organics with distinct isotopic signatures (Loduca and Pratt 2002). Similarly, geochemical analyses of carbonaceous microfossils, which are typically preserved as hollow, three-dimensional structures with walls and sheaths composed of organic matter, demonstrate that their organics derive from various pathways of carbon fixation (House et al. 2000) and do not record significant averaging of carbon isotope values due to hydrocarbon migration. Even so, diagenetic emplacement of carbonaceous material remains a concern for all types of organically preserved fossils, particularly secondarily mineralized fossils (Muscente et al. 2015).

In skeletal fossils, organics generally represent indigenous materials. These materials derive from the organic matrixes on which the biominerals originally formed and grew (Glover and Kidwell 1993). Fossils of organophosphatic brachiopods sometimes consist of alternating layers of organic-rich and organic-poor phosphatic material, and therefore, closely resemble recent specimens in terms of shell ultrastructure (Zabini et al. 2012). Taphonomically demineralized skeletal fossils also provide evidence of indigenous organic matter. Biomineral dissolution leaves behind carbonaceous residue. If weathering or lab preparation leads to demineralization, the carbonaceous fossil may retain its three-dimensionality, as exemplified in weathered organophosphatic brachiopods (Zabini et al. 2012) and tubular shelly fossils (Muscente and Xiao 2015a). Alternatively, if demineralization occurs early in diagenesis, concomitant with burial compaction, this residue coalesces into a compressed but cohesive fossil (Muscente and Xiao 2015a). This process provides a reasonable explanation for the preservation of skeletal elements as carbonaceous compressions (Martí Mus 2014) and small carbonaceous fossils (Butterfield and Harvey 2012).

Analytical Methods

Geochemical study of organic-walled microfossils has accelerated in recent years with the advent of a number of microanalytical techniques that allow for the analysis of individual fossils. A technique is chosen based on both the questions to be answered and the preservational conditions of the fossils. Some fossils can be extracted from their host matrixes via hydrofluoric or hydrochloric acid maceration, whereas others must be studied in situ in thin (~30 μm) and thick (~150 μm) sections. Applicable analytical techniques include energy dispersive spectroscopy (EDS), confocal laser scanning microscopy (CLSM), secondary ion mass spectrometry (SIMS, Nano-SIMS and time-of-flight SIMS), X-ray near edge absorption spectroscopy (XANES), Raman spectroscopy, and Fourier transform infrared spectroscopy (FTIR).

Scanning electron microscopy (SEM) is typically used to study fossil morphology and ultrastructure and, when combined with energy dispersive spectroscopy (EDS), allows for characterization of organic components and associated minerals (Muscente and Xiao 2015b). Confocal laser scanning microscopy (CLSM) is used to make two- and three-dimensional images of organic fossils based on their fluorescence (Schopf et al. 2006). Kerogen fluoresces weakly with laser excitation, and the strength of the emission is inversely related to the degree of thermal alteration so that more thermally mature fossils are more difficult to image (Czaja et al. 2016).

Mass spectrometry is a common technique to study the carbon isotope compositions of fossil organic matter, which can help constrain the physiology of ancient organisms. Secondary ion mass spectrometry (SIMS) provides the capability of collecting in situ measurements of carbon isotopic values from individual microfossils (House et al. 2000, 2013; Williford et al. 2013). This method and its relatives (Nano-SIMS and time-of-flight SIMS) can be used to produce 2-D elemental or molecular maps of small areas (up to 100 × 100 μm). These can be used to show the relationship of various elements within fossil structures. Such work can illuminate elemental relationships within fossil material and provide data for assessing the biogenicity of objects of uncertain origin (Oehler et al. 2009).

Several techniques are used to determine the composition of organic matter in fossils and to provide evidence of biological origin. XANES is used to characterize molecular components of organic matter (Boyce et al. 2001; De Gregorio and Sharp 2006). This technique typically has a high spatial resolution and can be used to study individual fossil microorganisms and produce 2-D maps (Muscente et al. 2015). Raman spectroscopy and FTIR spectroscopy are in situ techniques that measure the molecular structure of organic and inorganic materials based on vibrations of molecular bonds and larger molecular structures using lasers for excitation. These techniques are typically used to determine the carbonaceous nature and molecular structure of possible fossil organic material (Arouri et al. 2000; Kudryavtsev et al. 2001; Olcott Marshall and Marshall 2014; Schopf and Kudryavtsev 2005). Raman spectroscopy is also used to measure the degree of thermal alteration of fossil organic matter and reconstruct the metamorphic histories of geologic units containing organically preserved fossils (Beyssac et al. 2002; Schopf et al. 2005; Kouketsu et al. 2014).

Complex Organic Biomolecules

As mentioned above, complex biomolecules vary in their rates of degradation. Nucleic acids, for example, contain the most biological information but are also the quickest to degrade. The oldest sequenced genome is from a ~700,000 year old horse preserved in permafrost (Orlando et al. 2013) and extremely degraded DNA has been reported

on the scale of millions of years. It is possible that with advancements in analytical techniques, this ancient DNA can become a rich source of information.

Proteins can provide details of an organism's physiology and evolutionary relationships and can preserve on significantly longer time scales than DNA. In vertebrates, proteins like collagen, which break down into bonded amino acids called peptides, have been reported from a ~68 million-year-old *Tyrannosaurus rex* bone (Asara et al. 2007) and amino acids fragments have been reported from ~235 Ma reptiles (Surmik et al. 2016). Such bold claims, however, require strong support and just as mentioned above, exogenous organic matter and contaminants from the field and lab are a major concern. Indeed, follow-up studies have called into question the provenance of the *T. rex* biomolecules (Buckley et al. 2008) and this story continues to develop. The oldest complete protein so far detected comes from an ostrich eggshell (~3 Ma; Demarchi et al. 2016); the structure of the shell and the protein's affinity for calcite are hypothesized to have enabled this long-term preservation.

Chitin is a long-chain polymer and major constituent in the exoskeletons of arthropods. A modified chitin-protein complex containing up to 59% of the chitin concentrations seen in modern animals has been found in fossil arthropods (310 and 417 million years old; Cody et al. 2010). The decay of this complex is prevented by condensation of fatty acids onto a structurally modified chitin-protein molecular scaffold.

Melanin is a common pigment, which occurs within organelles (melanosomes) in numerous clades of animals. Different types of melanin produce different colors, and the melanosomes that contain them vary in shape and size. Notably, the discovery of fossilized melanosomes ushered in a novel field of paleobiology: the study of color patterns in ancient animals. By studying melanosomes in feathers, for example, paleontologists determined that the well-known feathered dinosaur *Sinosauropteryx* possessed a red and white striped tail (Zhang et al. 2015). Even so, fossilized melanosomes have been a subject of debate (Vinther 2016), as some authors have proposed that the structures are actually fossils of microbes. Recently, various studies have presented evidence that fossilized melanosomes of various ages contain chemical traces of melanin (Lindgren et al. 2012; Colleary et al. 2015; Clements et al. 2016). Such traces represent maturation products of melanin rather than the original biomolecules (Colleary et al. 2015). Nonetheless, such data support the use of fossilized melanosomes for analyses of coloration in ancient life and affirm that work on biomolecule preservation in fossils should remain a top priority.

Summary

Regardless of preservational style, any fossil may contain organic matter, as evidenced by observations of carbonaceous material within skeletal elements, small carbonaceous fossils, carbonaceous compressions, and secondarily mineralized tissues. The organic matter within a specific fossil may represent biomolecules indigenous to the organism, organics introduced via hydrocarbon migration, or compounds derived from both sources. In all cases, organically preserved fossils constitute important windows to the evolutionary history of life on Earth, particularly the rise of microbial life and the radiation of animals. Fossils with indigenous organic matter merit particular attention. Such fossils may contain biomolecules (e.g., chitin and melanin) of paleobiologic and geobiologic significance in diagenetically altered but recognizable forms. Thus, analyses of the organic matter in such fossils may illuminate the original biochemical makeups and affinities of those ancient organisms.

Detrital organic matter; Nonliving organic matter; Organic carbon; Organic matter

Definition

"Organics" is the short form used for detrital organic matter. It is the nonliving remains of organisms found in sediments, soils, and water. It is comprised of organic molecules often in macromolecular form.

Introduction

The sequestration of organic matter (OM) in depositional environments controls the levels of CO_2 in the atmosphere, the global carbon cycle, and hence, climate. The fate of organic matter that is transported from the land to the sea remains one of the fundamental questions in global carbon cycling (Hedges et al. 1997) even after decades of research (Bianchi et al. 2017). There is general agreement that continental shelves represent the largest sink of both terrestrial and marine organic carbon globally, with estimates suggesting that as much as much as a quarter of the total carbon buried in marine sediments is of terrestrial origin (Berner 1982; Hedges and Keil 1995; Raymo 1997). Two important controls on the preservation of organic matter are the composition of the organic matter and the depositional environment.

Detrital organic matter is the nonliving remains of organisms found in sediments, soils, and water. It is comprised of organic molecules often in complex, macromolecular form. The initial source of all complex organic matter is photosynthesis whereby inorganic carbon is fixed by autotrophs. Higher plants, marine or lacustrine algae, or microbes are the dominant primary producers. Once carbon is fixed, that is, reduced to organic molecules by autotrophs, it is a valuable energy source. Heterotrophs consume this organic matter whether living or dead and derive energy from oxidizing it while converting a portion of it to their own biomass. In this process, the composition of the portion of that carbon that is utilized for biosynthesis is modified. Consequently, the composition of the organic matter changes between its initial fixation by autotrophs, through secondary biosynthesis by heterotrophs. Multiple transformations often occur before and during deposition in sediment and soil. Multicellular organisms consume living or nonliving particulate organic matter (POM) and excrete waste, but in aquatic and marine settings, microbes such as bacteria (and others such as Achaea) also utilize dissolved organic matter (DOM) excreted by phytoplankton or released by cell rupture and feeding of heterotrophs. Dissolved organic matter also enters these systems through leaching of soil organic matter. Dissolved organic matter in particular is also subject to nonbiologically mediated reactions such as photodegradation (Blough and Del Vecchio 2002; Del Vecchio and Blough 2002). Despite all the alterations of organic matter along the pathway from production to preservation, many organic compounds still reflect their origins.

Composition of Detrital Organic Matter

Understanding the chemical composition of the sources of organic matter is useful because these can be related to the organic matter preserved in depositional environments and ultimately the sediment record. Collectively, nonliving organic matter in the environment, also referred to as detrital organic matter, is made up of the major biochemicals, protein, carbohydrates, and lipids. Proteins, composed of amino acids, contain most of the organic nitrogen in detrital matter. Carbohydrates are aliphatic compounds composed from simple sugar units and are used as storage molecules and structural materials. Cellulose is the main structural polysaccharide in higher plants. Lipids are composed of a wide range of compounds ranging from fats and waxes to alcohols and oils, and they also include steroids and hydrocarbons. Lignins are structural lipid molecules found in vascular plants that are used in cellular walls and these make up a significant proportion of the biomass particularly in woody plants. Cellulose and lignin are broken down by fungi and other microbes into their constituent units that are found in detrital matter. What distinguishes lipids in detrital organic matter from amino acids and carbohydrates is that amino acids and carbohydrates have structures that are largely ubiquitous among organisms. In contrast lipids, because of their range of distinct structures and the fact that they are preserved, means that even the modified and monomeric units serve as biomarkers for organic matter. This makes them useful for determining sources.

Determining Sources of Organic Matter

Lipids have widely varying reactivities as well as sources and structures. Lipid biomarkers, although a small portion of the total organic pool, have been successfully used to estimate the sources and reactivity of organic carbon in riverine and coastal systems (e.g., Alin et al. 2008; Drenzek et al. 2009; Goñi et al. 2008; Jaffé et al. 2006; Pearson et al. 2001; Sikes et al. 2009). Recalcitrant compounds, such as *n*-alkanes and *n*-alcohols, are widely distributed and well preserved in sediments, and their distribution of chain lengths have proven useful for source determination (Hermes and Sikes 2016; Meyers 1997; Oros and Simoneit 2001; Prahl and Muehlhausen 1989). For example, the longer chain (C_{25}–C_{33}) *n*-alkanes are indicative of epicuticularleaf waxes (Eglinton and Hamilton 1967; Kolattukudy 1976) and shorter chain lengths (C_{15}–C_{25}) come from aquatic and marine plants (e.g., Ficken et al. 2000; Jaffé et al. 2001).

The carbon isotopic composition of organic matter ($\delta^{13}C$) is a useful tool for distinguishing algal- from land-derived sources of organic matter in coastal environments because algal and vascular plants have distinct isotopic signatures

(Jaffé et al. 2001; Kennicutt et al. 1987). Geochemical signatures of $\delta^{13}C$ in organic matter have been used to indicate that there is dilution of land-derived POM by algal sources along estuaries (e.g., Benner 2004). Whereas combining biomarker with bulk $\delta^{13}C$ analyses on particulate organic matter has improved the ability to differentiate sources in these complex environments (e.g., Canuel and Hardison 2016; Sikes et al. 2009). Combining biomarkers with compound specific isotopes and/or multiple isotopes analyses exploits the chemical and isotopic differences among terrestrial vegetation, marine algae, and bacteria. The $\delta^{13}C$ of a biomarker can help constrain its origin. This has proven extremely effective for determining organic carbon sources and uptake in complex coastal systems (e.g., Canuel and Hardison 2016; Canuel and Martens 1996; Goñi et al. 2008; Sikes et al. 2009).

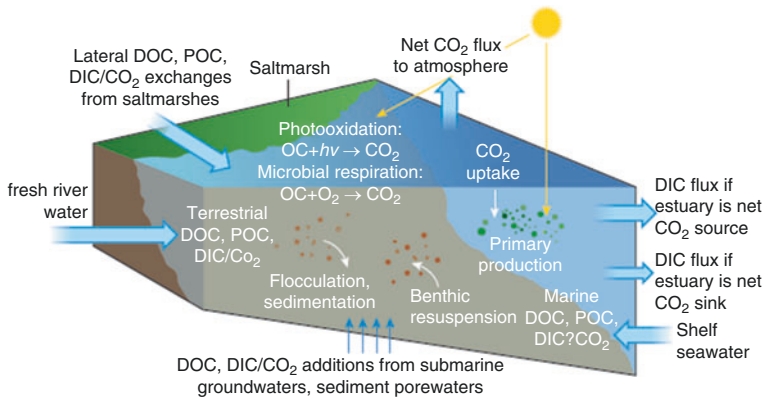
Optical properties (absorbance and fluorescence) have proven to be extremely useful tools for interrogating the composition of dissolved organic carbon in freshwater and marine systems (Cory and McKnight 2005; Jaffe et al. 2008; Komada et al. 2002; Stedmon et al. 2007). Advanced 3D excitation-emission matrix fluorescence spectroscopy (EEMs) is a nondestructive technique that distinguishes terrestrial and marine components, as well as aromatic and protein-like components in dissolved organic carbon (e.g., Coble 2007; Fellman et al. 2010).

Transformation of Organic Matter Across the Terrestrial-Ocean Transition

Export of organic carbon by rivers is positively related to the yield of suspended sediment, meaning that POM export is mostly controlled by physical erosion (Galy et al. 2015; Lyons et al. 2002). Globally ½ to ¾ of the terrestrial organic matter delivered to the ocean is remineralized along continental margins (Burdige 2005). Of the terrestrial organic matter that survives and makes it to the marine environment, ~90% of is buried in slope and shelf sediments with about 50%, focused into deltaic depocenters (Berner 1982; Blair and Aller 2012; Burdige 2005; Hedges and Keil 1995). The storage of organic carbon in terrestrial environments before delivery to the coastal ocean results in the common occurrence of pre-aged organic carbon in continental margin surface sediments (Bao et al. 2016). The mineral matrices are typically invoked as the primary mode of stabilization and sequestration of organic matter in sediments (Keil et al. 1994; Kennedy and Wagner 2011). This organic matter can be subject to further resuspension-deposition during which it is modified (Sun et al. 2002) and ages further (Bao et al. 2016).

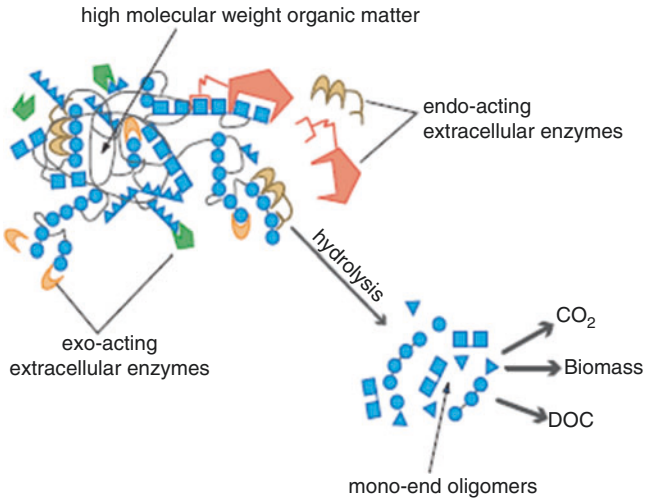
The land-ocean interface and the coastal ocean are tremendously variable and dynamic. The rates of organic carbon burial and oxidation are influenced by terrigenous inputs, sediment transport processes, depositional conditions, oxygen levels, and marine productivity with these processes occuring over broad spatial and temporal scales (Bauer et al. 2013; Bianchi et al. 2016) Fig. 1. Anthropogenic impacts that affect watersheds also impact the coastal ocean and these influences can cause coastal eutrophication and changes in the supply of terrestrial sediment. Eutrophication drives bottom-water hypoxia, the areas of which have expanded during the twentieth century (Altieri and Gedan 2015). The change to greater anoxia has largely increased the preservation of organic carbon in estuaries and continental shelves (Bauer et al. 2013; Bianchi et al. 2016).

An important conduit for terrestrial organic carbon to the coastal ocean is through estuaries. Estuaries are recognized as a complex component of the global carbon cycle that regulate the delivery of land-derived sediment and transform the amount and composition of organic carbon from rivers



Organics: Sources and Depositional Environments, Fig. 1 Major processes affecting carbon sources and fluxes in estuaries. Estuaries contain a mixture of organic carbon sources derived from terrestrial materials carried by rivers, local inputs from marshes and primary production and marine inputs. Organic carbon is lost owing to salinity-induced flocculation, sedimentation, microbial respiration and photooxidation. These processes cause estuaries to be important zones of transformation in the export of organic carbon to the ocean (Bianchi et al. 2011)

O



Organics: Sources and Depositional Environments, Fig. 2 Microbes can hydrolize high moleculare weight OM using extracellular enzymes. This produces smaller monomers. The structures of the initial and resulting molecules are not known. Overall many of the factors in the early steps of carbon transformations in aquatic and marine systems remain unknown (Arnosti 2011; Bianchi 2011)

through a wide array of degradation processes (Fig. 1). By being productive in their own right, estuaries add a complex mix of marine and marsh derived organic matter to the system (Abril et al. 2002; Bruesewitz et al. 2013; Canuel and Zimmerman 2006; Cole et al. 2007; Hermes and Sikes 2016; Mannino and Harvey 2000; Medeiros et al. 2012). The biogeochemical fate of organic matter in estuaries remains poorly quantified leading to continuing uncertainty with respect to the role of estuaries and coastal oceans in regulating atmospheric CO_2 (Bauer et al. 2013).

The transformation of organic matter can be biologically mediated or abiotic. For example, photooxidation alters and removes DOM from surface waters (Fig. 2) (Amon and Benner 1996; Benner and Opsahl 2001; Gonsior et al. 2009; Helms et al. 2013) and studies show that terrestrial and plankton-derived organic carbon exhibit different degrees of photochemical lability (Hernes and Benner 2003; Obernosterer and Benner 2004; Rontani et al. 2012). Microbial degradation consumes both dissolved and particulate organic matter and this process is also a source of modified organic matter (Figure 2) (Arnosti 2011; Komada et al. 2002; McCallister et al. 2004; Sun et al. 2002; Tremblay et al. 2007; Ziervogel and Arnosti 2009; Zimmerman and Canuel 2001). Notably, the interaction of biotic and abiotic transformations can affect organic carbon reactivity. The concept of priming – that fresh, labile carbon may enhance the reactivity of semi-labile and recalcitrant carbon – has long existed in the soils literature (Bingeman et al. 1953; Hamer et al. 2004; Kuzyakov et al. 2000) and has recently been advocated as an important factor in the degradation of terrestrial organic carbon in aquatic and marine systems (Aller and Blair 2006; Bianchi 2011; Blair and Aller 2012).

Overall, the biogeochemical transformation of organic matter as it moves from terrestrial source to marine sink remains only roughly characterized. Characterization requires multiproxy approaches that combine multi-isotopic and biomarker techniques (Blair et al. 2004; Goñi et al. 1997, 1998, 2006, 2008; Gordon and Goñi 2003; McCallister and del Giorgio 2008; Onstad et al. 2000; Sikes et al. 2009). Riverine multitracer studies have demonstrated that preaged terrestrial and recycled fossil organic matter is a significant component of the carbon mobilized and delivered to marine sediments (e.g., Drenzek et al. 2007, 2009; Goñi et al. 1997, 2006, 2008; Leithold et al. 2006; Pearson and Eglinton 2000; Pearson et al. 2001). Bulk organic carbon stable isotope and radiocarbon compositions reveal the diversity and complexity characteristic of organic carbon buried in marginal seas. This primarily relates to differences in marine and terrestrial inputs, the composition of the terrestrial component (e.g., vascular plant OM, soil, and petrogenic OM inputs), and processes modulating the fate of organic carbon within the marine environment (e.g., priming). This widely contrasting behavior of OM among these systems illustrates that the reactivity of organic carbon is a product of its chemical composition and regional conditions (Bianchi et al. 2017).

Fate of Organic Matter: The Ocean

The source and make-up of organic matter influences the fate of organic carbon in soils as well as marine sediments. Several mechanisms suggested to be responsible for the preservation are based upon the assumption that preservation, i.e., persistence, is related to chemical structure and or physical environment. (1) Recalcitrant organic matter may occur as biologically produced resistant macromolecules such as lignin, peptidoglycan, algenans, or pyrogenic carbon (Dickens et al. 2004) which may be selectively preserved within soils and sediments. (2) Rapid burial spatially protects organic matter from decomposition via reduced access to microorganisms, and their hydrolyzing enzymes, and restricts diffusion of oxygen reducing aerobic decomposition. (3) The redox state of the environment is a fundamental control with preservation in anoxic environments substantially higher than in oxic environments.

In the open ocean, about 90% of the organic matter produced by phytoplankton in the surface photic zone is consumed by zooplankton and microbial heterotrophs leaving only a few percent to sink out as particulate matter which in turn is further altered and consumed as it falls through the water column affecting the quality and reducing the quantity that finally reaches the depositional environment of the deep sea floor (Lee and Wakeham 1988). As particulate matter sinks, heterotrophic activity preferentially removes the more

labile compounds such as proteins and carbohydrates and the remaining fraction becomes more refractory and enriched in lipids such as sterols and long chain alkanes and alkenones (Wakeham and Lee 1993). Overall the fraction organic carbon that can be identified as the major biochemicals diminishes with time in favor of macromolecular composites such as humic substances and kerogen which comprise most of sedimentary organic matter (Hatcher et al. 1983; Hedges et al. 2000).

In general, there is a correspondence between the amount of organic matter in the sediments, the overlying productivity, and the rate of sedimentation (Emerson 1985). Reactivity of organic matter is conditional. Organic material may be reactive in one environment, such as aerobic soils, but relatively stable in another such as in anoxic sediments. The role of oxygen in controlling both the amount and type of preservation the sediments is fundamental with the length of oxygen–exposure time being an important controlling variable (Hartnett et al. 1998). In all likelihood, there is a continuum of reactivities defined by source materials and ecosystem properties (Bianchi et al. 2017; Blair and Aller 2012).

Summary

The fixation of organic matter converts CO_2 to reduced carbon removing it from the atmosphere and marine environment. The breakdown, and eventual remineralization back to CO_2 of this OM are important processes in the global carbon and oxygen cycles. Natural organic matter is the largest reactive reservoir of reduced carbon on Earth. If we consider autotrophy the initial source of all organics, then the ocean and its sedimentary environments are the ultimate sink. Knowledge of the diverse sources of organics outstrips our understanding of the complex interactions of detrital organics within the global carbon cycle. In particular, the carbon cycle of the coastal ocean is a dynamic component of the global carbon budget that remains poorly understood. Understanding the alteration of organic material flowing from rivers to the ocean and carbon fluxes within and between coastal subsystems is becoming an increasing area of research over the past few decades because the alteration by climate and anthropogenic changes within these systems are substantial. Understanding and accurately accounting for the factors regulating the organic and inorganic carbon fluxes between and within terrestrial and marine systems is important for achieving closure of the global carbon budget (Fig. 1).

Osmium

Richard J. Walker
Department of Geology, University of Maryland, College Park, MD, USA

Element Data
Atomic Symbol: **Os**
Atomic Number: **76**
Atomic Weight: 190.2
Isotopes and Abundances:
184: 0.0174%
186: 1.5935%
187: 1.5129%
188: 13.296%
189: 16.217%
190: 26.376%
192: 40.988%
1 Atm Melting Point: 3030 °C
1 Atm Boiling Point: 5010 °C
Common Valences: 0, +3, +4, +8
Ionic Radii: 53–77 pm
Pauling Electronegativity: 2.2
First Ionization Potential: 8.44 eV
Chondritic (CI) Abundance: 490 ppb
Silicate Earth Abundance: 3.9 ppb
Crustal Abundance: 0.031 ppb (continental), 0.055 (oceanic)
Seawater Abundance: 10 pg/L
Core Abundance: 2800 ppb

Properties

Osmium is a highly refractory, bluish-white metal (hexagonal close packed). It is hard and brittle and has a density of 22,600 kg/m^3, the highest of any element. Osmium is not a

structural constituent of any mineral, but it alloys with iridium and ruthenium and is also found in high abundance in some sulfide minerals, such as laurite (RuS_2). Osmium has oxidation states ranging from 0 to +8, but in nature 0, +3, +4, and +8 probably predominate.

History and Use

Osmium was discovered by Smithson Tennant in 1804. The element has two major commercial uses. Because of its hardness, it has been used in fountain pen nibs, and it remains commonly used for staining biological tissues for microscopy.

Geochemical Behavior

Osmium is one of the six platinum-group elements (PGE; Os, Ir, Ru, Pt, Rh, Pd). It is geochemically termed "siderophile" because it has a strong propensity to partition into metallic iron, rather than silicates (Goldschmidt 1937). As such, most of Earth's Os is contained in the core. Osmium also has a tendency to partition into sulfide melts and some sulfide minerals, so it is also referred to as a "chalcophile" element.

Osmium isotopic abundances vary in nature due to the radioactive decay of other elements: ^{187}Re decays to ^{187}Os by β^- emission (2.3 keV maximum β^- energy, half-life 4.16×10^{10} years) and is the basis for the Re-Os method of geochronology; ^{190}Pt forms ^{186}Os by α decay (α energy 3.19 MeV, half-life $\sim 4.50 \times 10^{11}$ years), which forms the basis of the Pt-Os system. Variations in the abundance of ^{186}Os are measurable only in Pt-rich materials because of the long half-life and very low isotopic abundance of ^{190}Pt (0.0129%).

Cosmochemistry

The solar abundance is 0.675 atoms Os per 10^6 atoms Si, corresponding to an average concentration of Os in CI chondrities of ~490 ppb (Anders and Grevesse 1989). Osmium, along with the other PGE, is concentrated in planetary cores. It is typically enriched, relative to chondritic meteorites, in most iron meteorites that sample asteroidal cores. By contrast, Os abundances in unbrecciated basaltic achondrites, such as angrites and eucrites, can be very low (<0.01 ppb) (Dale et al. 2012).

The chondritic relative abundances of the PGE in Earth's mantle has led to the conclusion that core formation in the early Earth strongly depleted the silicate mantle of these elements, and their present abundances are likely the result of a late influx of meteoritic material (Chou 1978).

Igneous and Metamorphic Rocks

The bulk silicate Earth concentration of Os is ~3.9 ppb Os, as estimated from variably melt-depleted mantle peridotites (Fischer-Gödde et al. 2011). During basalt formation by partial melting of the mantle, Os behaves as a strongly compatible element and remains predominantly in the residual peridotite. As a consequence of its compatibility, its abundance in the oceanic crust is very low, ~0.055 ppb (Peucker-Ehrenbrink et al. 2012). The concentration of Os in the continental crust is similar, averaging ~0.031 ppb Os (Rudnick and Gao 2003). Ocean island basalts tend to have higher abundances, ranging up to 0.5 ppb (Day 2013), and high MgO volcanic rocks, such as komatiites, can have abundances >3 ppb (Puchtel et al. 2009). The concentration of Os in metamorphic rocks has been little explored. Limited data suggest concentrations broadly follow those of igneous or sedimentary precursors (Penniston-Dorland et al. 2012).

Sedimentary Rocks

Because Os^{4+} is probably hydrolyzed and scavenged from seawater as $OsO_2 \cdot xH_2O$, the residence time of Os in the ocean is short ($<10^3$ years) and the abundance very low (~10 pg/L) (Chen and Sharma 2009). In oxidized sediments, cosmic influx may have slightly enhanced the observed abundances of Os: shales 0.05–0.45 ppb and quartz-rich sandstones 0.06–0.08 ppb (Koeberl et al. 1994). Osmium concentrations are typically higher in sedimentary rocks formed under reducing conditions, e.g., 0.2–0.7 ppb in Black Sea sediments (Ravizza et al. 1991), 0.9–4 ppb in black shales (Kendall et al. 2009), and >200 ppb in some mineralized black shales (Horan et al. 1994). In black shales and hydrocarbon deposits, much of the Os is radiogenic ^{187}Os from the decay of ^{187}Re. The Re-Os isotope system can therefore be used for dating these materials (Selby and Creaser 2005; Kendall et al. 2009).

Biological Utilization and Toxicity

Osmium has no known biological role. While Os metal is not toxic, osmium tetraoxide (OsO_4) is volatile and highly toxic, causing lung, skin, and eye damage and has a US NIOSH exposure limit of 0.2 ppb or 0.0016 $mg.m^3$. Given its low natural abundance, however, exposures at these levels are extremely rare.

Definition

The Re-Os system is a long-lived radiogenic isotope system system based on two siderophile (iron-loving) elements. With a ^{187}Re half-life of ~42 Ga, the system can potentially be used for dating rocks and minerals ranging from the age of the solar system to high Re/Os minerals <1 Ma. Because of the highly variable Re/Os ratios in different types of rocks, the system is also valuable for tracing crustal recycling into the mantle, and anthropogenic contributions of heavy metals to waterways, among numerous other applications.

Introduction

The ^{187}Re-^{187}Os system has relevance to a wide range of cosmochemical and geochemical applications. The isotope ^{187}Re decays by β^- emission to ^{187}Os with a decay constant of 1.67×10^{-11}year^{-1} ($t_{½} = 41.6 \times 10^9$ years), with an approximately ±1% uncertainty (Smoliar et al. 1996). Both Re and Os are highly siderophile and under some conditions also chalcophile. The system has been used as a tracer to study the effects of planetary core formation (Righter and Drake 1997), as well as subsequent accretion of planetesimals to planetary mantles after cessation of core formation (Morgan 1985). The system has also been commonly applied to the study of the timing of mantle melting, particularly in the subcontinental lithospheric mantle (SCLM) (Pearson et al. 1995), as well as diverse chronologic applications ranging from dating iron meteorites (Luck et al. 1980) to constraining the timing of petroleum emplacement in oil sand deposits (Selby and Creaser 2005). When applied as a tracer, Os isotopes have been used to assess crustal recycling into the mantle sources of ocean island basalts (Day 2013), for determining the changing contributions of Os from mantle, continental crustal, and organic-rich sedimentary sources to the oceans (Peucker-Ehrenbrink and Ravizza 2000) and for tracking anthropogenic heavy metal contributions to freshwater and marine sediments (Turekian et al. 2007).

Overview of the Geochemistry of Re and Os

In nature, Re is comprised of two isotopes, ^{185}Re (37.40 at.%) and ^{187}Re (62.60 at.%), and has an atomic weight of 186.207 (Gramlich et al. 1973). Osmium is made up of seven stable isotopes: ^{184}Os, ^{186}Os, ^{187}Os, ^{188}Os, ^{189}Os, ^{190}Os, and ^{192}Os. In addition to the production of ^{187}Os from the decay of ^{187}Re, ^{186}Os is produced from ^{190}Pt by α emission, with a decay constant of $\sim 1.5 \times 10^{-12}$year^{-1} (Walker et al. 1997). Therefore, the absolute abundances of Os isotopes and the atomic weight of Os vary in nature because both ^{186}Os and ^{187}Os are radioactive decay products. Isotopic ratios and atomic percentages for the University of Maryland interlaboratory reference material are provided in Table 1.

Osmium Isotopes, Table 1 Isotopic composition of the University of Maryland *Johnson-Matthey* interlaboratory reference material

Isotopic ratio	Measured ratio	2a uncertainty	Isotope	Percentage composition	Atomic weight
$^{184}Os/^{188}Os$	0.0013037	4	^{184}Os	0.0173%	190.240
$^{186}Os/^{188}Os$	0.119850	4	^{186}Os	1.5935%	
$^{187}Os/^{188}Os$	0.113787	9	^{187}Os	1.5129%

$^{192}Os/^{188}Os$	*3.08271*		^{190}Os	26.376%	
			^{192}Os	40.988%	

Measurement of the System

Early studies of the Re-Os isotope system were hindered by the lack of sensitive and precise mass spectrometric methods. Techniques such as secondary ionization mass spectrometry and resonance ionization mass spectrometry were initially employed to measure Os isotopes, but these techniques yielded relatively imprecise results (Luck et al. 1980). In the early 1990s, it was recognized that Os and Re were amenable to negative thermal ionization mass spectrometry (NTIMS), as negatively charged tri- and tetra-oxide species, respectively (Creaser et al. 1991). This discovery led to a revolution in the sensitivity and precision of measurements of these elements, as well as ushering in a much broader range of applications. Inductively coupled plasma mass spectrometry (ICP-MS) is now also commonly used to measure the isotopic compositions of Re and Os (Nowell et al. 2008).

Both acid and fusion digestions are used to dissolve phases and equilibrate enriched isotopes (spikes) with sample. The latter aspect is especially critical because of the numerous oxidation states and species possible for each element. At present, there is no one technique that is equally applicable to all matrices. Low-temperature (<150 °C) acid-based digestion techniques under reducing conditions (Birck et al. 1997) typically have low blanks but can have limitations in the dissolution of acid-resistant phases. High-temperature (>200 °C) oxidizing digestions achieved with, for example, *aqua regia* can lead to the production of volatile species of each element, so oxidizing digestions are normally done in closed vessels (Shirey and Walker 1995). Unlike lower-temperature digestions, high-temperature oxidative digestions can dissolve acid-resistant phases, such as chromite and noble metal alloys, but they leave most silicates partially or completely undigested. This may not be problematic for most rocks, because Re and Os are primarily concentrated in sulfides, alloys, and oxides, and excluded from for the structures of silicates, although there are some exceptions (Ishikawa et al. 2014). Fusion techniques include nickel sulfide fire-assay (Hoffman et al. 1978) and sodium-peroxide digestion (Morgan and Walker 1989). Fusions result in the complete digestion of all phases but are normally characterized by higher blanks.

Once sample digestion and equilibration is achieved, Os can be separated from a rock matrix by distillation (b.p. for OsO_4 is 105 °C) (Walker 1988) or solvent extraction (Cohen and Waters 1996; Birck et al. 1997). Rhenium is separated using anion exchange chromatography (Morgan and Walker 1989).

Geochronologic Applications

Dating rocks or minerals using the Re-Os system is either done by conventional isochron methods, or by model age calculations, usually assuming derivation of the material to be dated from a reservoir that had previously evolved with chondritic Re/Os. Rhenium-Os isochron dating has most commonly been applied to iron meteorites and some terrestrial igneous and sedimentary systems. For the system to be useful, geochemical processes must lead to sufficient variation in Re/Os. For example, organic-rich sedimentary rocks, such as black shales, are one type of rock commonly dated by Re-Os isochrons (Ravizza and Turekian 1989). They are usually characterized by high and variable Re/Os, but for precise age determination, it may be necessary to selectively analyze only the hydrogenous component of the rock (Selby and Creaser 2003).

The system can also be used to date single minerals. For example, molybdenite (MoS_2) has been shown to be a particularly robust mineral for achieving high precision Re-Os geochronology of some rocks (Stein et al. 2001). The system has also been used to date single sulfide grains incorporated in diamond (Pearson et al. 1998).

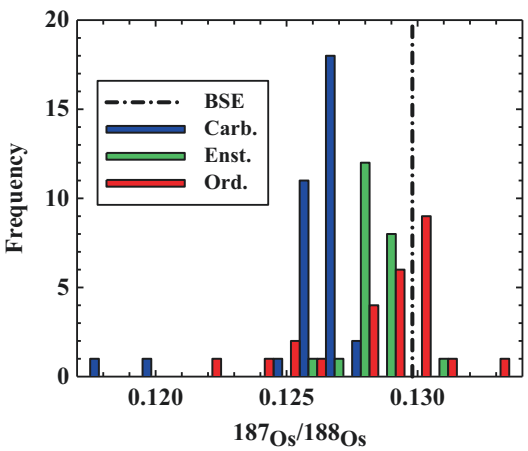
Cosmochemical Applications

Rhenium and Os are among the most refractory elements and were therefore among the first elements to condense from the solar nebula. As highly siderophile elements (HSE), they were primarily incorporated into metal during subsequent accretion and melting events, so the system is useful in the study of metals present in chondrites, stony irons, and iron meteorites. To date, the system primarily has been used to determine the ages of iron meteorites (Smoliar et al. 1996) and for characterizing the origins of materials added to the terrestrial planets through late accretion (Morgan 1985; Meisel et al. 2001). Some iron meteorites, as well as bulk chondrites, do not plot within analytical uncertainties of a primordial reference isochron, and the deviations have been interpreted to reflect open-system behavior long after the parent bodies formed.

The Re-Os System in the Earth's Mantle

Because of the limited removal of Re and especially Os from the mantle by partial melting processes, the vast proportion of Re and Os in the silicate Earth are retained in the mantle. Attempts to determine the bulk silicate Earth (BSE) concentrations of Re and Os and $^{187}Os/^{188}Os$ have largely been conducted by projecting data for variably melt-depleted mantle peridotites to fertile Lu, Al_2O_3, or MgO compositions (e.g., Meisel et al. 2001). The $^{187}Os/^{188}Os$ of the BSE averages ~0.129 (Meisel et al. 2001). This ratio is within the range of bulk chondrites and provides strong evidence that the HSE were added to the mantle after cessation of core formation by a process termed late accretion, or late veneer (Morgan 1985). The ratio is also noteworthy in that it is substantially higher than ratios observed in bulk samples of carbonaceous chondrites, but overlaps with ratios common for bulk enstatite and ordinary chondrites (Fig. 1). This indicates that late-accreted materials were more like ordinary or enstatite chondrites, rather than volatile-rich carbonaceous chondrites (Walker 2009).

Determination of the Os isotopic composition of the oceanic mantle has been difficult. In particular, the study of the system in mid-ocean ridge basalts (MORB), which are commonly used to provide averaged chemical and isotopic snapshots of different portions of the oceanic mantle, has been challenging due to the very low concentration of Os in MORB (Gannoun et al. 2007). Low Os concentrations make the Os isotopic compositions of basalts subject to modification as a result of contamination with oceanic crust and seawater. Most studies of the Os isotopic composition of MORB (e.g., Gannoun et al. 2007) have reported generally similar $^{187}Os/^{188}Os$ ratios ranging from chondritic (~0.126) to considerably suprachondritic (>0.15).



Osmium Isotopes, Fig. 1 Histogram plot showing estimate of the $^{187}Os/^{188}Os$ of the bulk silicate Earth (BSE) versus data for bulk samples of carbonaceous, enstatite, and ordinary chondrites (Figure modified from Walker 2009)

Other sources of information about the Os isotopic composition of the oceanic mantle are oceanic peridotites, also known as abyssal peridotites. The $^{187}Os/^{188}Os$ ratios for abyssal peridotites are much more restricted in range than for MORB and average approximately 0.125 (e.g., Lassiter et al. 2014). Limited isotopic overlap between MORB and abyssal peridotites may reflect lithospheric contamination of MORB, isotopic overprinting of abyssal peridotites resulting from mantle metasomatism, or the sampling of different materials in the oceanic mantle.

Osmium isotopes are useful for determining the timing of SCLM formation because mantle melting leads to the removal of some or all Re from the residues of melting that become SCLM (Pearson et al. 1995). Osmium model ages for peridotites with chemical evidence for strong melt depletion are calculated by comparing the measured isotopic composition with a reference growth model (chondritic) for the ambient mantle. A major contribution of Os isotopes to solid Earth geochemistry was the discovery that most ancient cratons are underlain by SCLM of approximately the same age as the overlying craton, suggesting that the creation of craton and underlying lithospheric mantle is intimately related (Pearson et al. 1995). By contrast, in some locations, such as the North China Craton, Os isotopes have provided chronological evidence that ancient SCLM underlying Archean craton has been removed, perhaps through lithospheric delamination (Gao et al. 2002).

Ocean island basalts (OIB) and related rocks are the surface manifestations of intraplate volcanism. Osmium isotopic data for OIB are commonly filtered for samples with very low Os abundances (e.g., < 50 pg/g), as these samples are susceptible to contamination through interactions with crustal or seawater Os. The $^{187}Os/^{188}Os$ ratios of OIB lavas with comparatively high Os concentrations generally range from that of the average oceanic mantle (0.125) to 20–30% percent higher (Day 2013). Osmium isotopic heterogeneity observed in OIB is mainly attributed to the incorporation of diverse recycled crustal components in their mantle sources (Day 2013).

The Re-Os System in the Earth's Crust and Hydrosphere

All of Earth's crust was extracted from the mantle at some point in Earth history. The tendency of Os to be strongly compatible and Re to be mildly incompatible during mantle melting means that both oceanic and continental crust are characterized by Re concentrations that are only slightly higher, and Os concentrations that are much lower, than mantle concentrations. Both oceanic and continental crusts are, therefore, characterized by high Re/Os, and even oceanic or continental crust of moderate age can have a very high $^{187}Os/^{188}Os$.

The Re-Os systematics of oceanic crust in the form of MORB is well studied. Less is currently known about the system in the continental crust and the arc lavas that are an important building block of it. The study of the Re-Os isotopic systematics of arc lavas has faced many of the same problems as studies of MORB and OIB. Low initial concentrations of Os leave them susceptible to contamination with radiogenic Os from crustal rocks or fluids. Arc lavas have $^{187}Os/^{188}Os$ ratios ranging from chondritic to >1, although most are within the chondritic range (Alves et al. 2002). This suggests that at least some continental crust originated with mantle-like $^{187}Os/^{188}Os$.

The average $^{187}Os/^{188}Os$ ratio of the upper continental crust has been estimated through studies of loess (Peucker-Ehrenbrink and Jahn 2001) and river waters and sediments (Sharma et al. 1999). The $^{187}Os/^{188}Os$ of these materials is typically >1. The high average $^{187}Os/^{188}Os$ ratio of the continental crust that is currently being eroded is also indicated by the $^{187}Os/^{188}Os$ of modern seawater to be approximately 1.05 (Chen and Sharma 2009). This ratio, however, has greatly varied over the past 100 Ma as a result of variable input of Os to the oceans from crustal versus mantle sources, as well as a result of substantial contributions of non-radiogenic Os to the oceans at 65 Ma, from the Chicxulub impactor, the Deccan Traps, or a combination (Peucker-Ehrenbrink and Ravizza 2000).

Most Os that is produced for industrial use, such as for biological tissue staining, or is produced as an ancillary product in the extraction and purification of other heavy metals, comes from platinum-group element-rich deposits, such as the Bushveld Complex, in South Africa, and is characterized by low, generally mantle-like $^{187}Os/^{188}Os$ ratios. Because of the isotopic contrast between such materials and crustal Os, Os isotopes have also been used in the tracing of anthropogenic contaminants to surface waters (Turekian et al. 2007; Chen et al. 2009).

Summary

The Re-Os isotopic system is widely used for dating a variety of cosmo- and geochemical systems including iron meteorites, organic-rich sedimentary rocks, molybdenites, and sulfide inclusions in diamonds. The system also serves as an important tracer of late-accreted materials to the Earth, recycled crustal components in the mantle, and crustal contributions to the oceans.

Eh-pH diagrams; Redox; pε-pH Diagrams

Definition

Oxidation-reduction (redox) reactions are those in which electrons are transferred between atoms resulting in a consequent change in the valence state of those atoms. Atoms losing electrons are said to be oxidized, and those gaining electrons are said to be reduced in such reactions. E_h, the hydrogen-electrode-scale electric potential, is a measure of the oxidation state of a system at equilibrium relative to a hydrogen electrode and can be combined with pH to produce diagrams that show which species will predominate among a chosen set in aqueous solution for a given oxidation state and acidity. The variable pε, which is the negative log of the chemical activity of electrons in solution, is directly related to, and sometimes used in place of, E_h.

The Hydrogen Electrode and the Table of Thermodynamic Values

The modern thermodynamic framework of the geochemistry of oxidation and reduction can be traced back to experiments in G. N. Lewis's era in the early twentieth century and perhaps even further to Humphrey Davy in the early nineteenth century, whereby electrochemical cells were constructed to transform matter and isolate new elements. In these cells, the potential for transferring electrons between two materials was measured. The simplest and most relevant example is the conversion of iron species ($FeCl_2$ and $FeCl_3$ electrolytes) coupled to a hydrogen electrode, whereby $H_2(g)$ is oxidized to two hydrogen ions (H^+):

$$H_2(g) + 2\,FeCl_3(aq) = 2\,HCl(aq) + 2\,FeCl_2(aq) \quad (1)$$

If the components are in their standard states, that is, $pH_2(g) = 1$ atm, $[HCl(aq)] = [FeCl_2] = [FeCl_3] = 1$ m, 0.77 V is the electric potential, or voltage (E°) measured by this constructed cell. At this point, a decision was made to pin the thermodynamic table of energies (Table 1) to the hydrogen electrode, that is, one half of the above cell:

$$2\,e^- + 2\,H^+(aq) = H_2(g) \quad (2)$$

defined to have $E^\circ = 0.0$ V if the constituents are in their standard states. This arbitrary decision means that the entire measured voltage, 0.77 V, is assigned to only one half of the reaction:

$$Fe^{3+}(aq) + e^- = Fe^{2+}(aq); E^\circ = 0.77\ V \quad (3)$$

It is for this reason that the Gibbs energy for $H^+(aq)$, the electron (e^-), and $H_2(g) = 0.0$ kJ mol^{-1} – they are *defined* to be so. There is, of course, no such thing as a pure half reaction, like Eqs. (2) or (3). They are all equations like (1) but referenced to a choice that Eq. (2) is set to zero volts, which means that there exists an offset for the energy scales for the standard hydrogen electrode (SHE) and the absolute vacuum

O

Oxidation-Reduction Reactions and E_h-pH (Pourbaix) Diagrams, Table 1 Some standard reduction potentials in water at 25° (Adapted from Rock 1983)

Half-reaction	E°/Volts
$Ca^{2+}(aq) + 2\ e^- = Ca^\circ(s)$	−2.866
$Mg^{2+}(aq) + 2\ e^- = Mg^\circ(s)$	−2.363
$Pu^{3+}(aq) + 3\ e^- = Pu^\circ(s)$	−2.031
$Fe^{2+}(aq) + 2\ e^- = Fe^\circ(s)$	−0.440
$Sn^{2+}(aq) + 2\ e^- = Sn^\circ(s)$	−0.14
$Pb^{2+}(aq) + 2\ e^- = Pb^\circ(s)$	−0.126
$2H^+(aq) + 2\ e^- = H_2^\circ(g)$	0.0
$Ag^+(aq) + e^- = Ag^\circ(s)$	+0.799
$O_2(g) + 2H^+(aq) + 2\ e^- = H_2O_2(aq)$	+0.682
$MnO_2(s) + 4\ H^+ + 2\ e^- = Mn^{2+}(aq) + 2\ H_2O(l)$	+1.23
$PbO_2(s) + 4\ H^+ + 2\ e^- = Pb^{2+}(aq) + 4\ H_2O(l)$	+1.455
$Co^{3+}(aq) + e^- = Co^{2+}(aq)$	+1.808

scale (AVS), where the energy corresponds to that required to separate the electron and the proton in a vacuum to infinite distance (see Xu and Schoonen 2000).

The Nernst Expression

The Nernst relation relates the voltages measured in a glass cell to the standard-state Gibbs energies, G°, that are tabulated:

$$-nFE^\circ = G^\circ \tag{4}$$

and this version requires that the electron be written on the left-hand side of the reaction, such as Eq. (3). F is the Faraday constant, whose value is 96,485 Coulombs per mole, and n is the number of transferred electrons in the reaction.

For reactions that are not at standard-state conditions, the Nernst expression is expanded, and here we express it using individual ions rather than electrolytes, which is not essential. Complete electrolytes are often used (e.g., Rock et al. 1994; Casey et al. 1996) because the activity coefficients are measured and thus without extra thermodynamic assumptions.

$$\begin{aligned} E_h &= E^\circ - \frac{2.303RT}{nF}\log\left(\frac{a_{Fe^{2+}}}{a_{Fe^{3+}}}\right) \\ &= 0.77V - \frac{2.303RT}{nF}\log\left(\frac{a_{Fe^{2+}}}{a_{Fe^{3+}}}\right) \end{aligned} \tag{5}$$

E_h is known as the redox or hydrogen scale potential; R is the gas constant and T is thermodynamic, or absolute, temperature; and a is the chemical activity of the species. There are several more points worth mentioning about this form of the Nernst expression or "Eh" equation. First, the subscript to the measured voltage, E_h, arises because this refers always to the standard hydrogen electrode (Eq. 2), which is implicit. Secondly, this expression requires that the electron appear on the left side of the half reaction (e.g., Eq. 3) and "n" electrons are transferred. Thirdly, one can view the activity of the electron in Eq. (3) as being converted to the voltage, E_h. Finally, the factor of 2.303 arises because the conventional equilibrium expression is in terms of Napierian logarithms, ($RT \ln K = -\Delta G_{rxn}^\circ$), but Eq. (5) relates the logarithm of activities in base-ten logarithms to voltages, $2.303 \log(x) = \ln(x)$. The parameters K and ΔG_{rxn}° are the equilibrium constant for the reaction and the standard-state Gibbs energy of reaction, respectively. The assembly of constants before the logarithm $\frac{2.303RT}{F}$ comes out to 0.05941 V/log unit at ambient conditions, which is why a typical glass electrode changes its voltage by 59.4 mV for every unit change in pH at room temperature.

The Pe Scale

One could formally define an equilibrium half reaction for iron reduction, remembering that the hydrogen half reaction is always implied:

$$K = \left(\frac{a_{Fe^{2+}}}{a_{Fe^{3+}}a_{e^-}}\right) \text{ and } pe = pe^o - \log\left(\frac{a_{Fe^{2+}}}{a_{Fe^{3+}}}\right) \tag{6}$$

which establishes the activity of the electron in solution, a fictitious quantity, but one that emphasizes the similarity to pH. The E_h scale arose from electrochemistry where voltages are independently controlled, but the pe scale is often more intuitive for geochemists in thermodynamic calculations. Both E_h and pe can be interconverted easily, and both are intensive state functions of the system:

$$\begin{aligned} pe^\circ &= \frac{-\Delta G_{rxn}^\circ}{2.303 \cdot nRT} = \frac{FE_h^\circ}{2.303RT} = 16.9E_h^\circ; \\ pe &= \frac{-\Delta G_{rxn}}{2.303 \cdot nRT} = \frac{FE}{2.303RT} = 16.9E; \end{aligned} \tag{7}$$

Electron-Exchange Reactions that Also Involve Proton Exchanges

At the most fundamental level, there are two classes of chemical reactions in aqueous solutions: (i) ligand-exchange reactions and (ii) electron-exchange reactions. Reaction (3) is a purely electron-exchange reactions. If, however, the electron was transferred to a partly hydrolyzed ion, electron exchange is associated with a simultaneous proton transfer, as in Reaction (2). For example, Fe(III) in solution hydrolyzes more extensively than Fe(II). So a reaction to reduce ferric iron to ferrous iron could affect a partly hydrolyzed species:

$$\mathrm{FeOH^{2+}(aq) + H^+ + e^- = Fe^{2+}(aq) + H_2O;} \quad E^o = 0.91\ \mathrm{V} \tag{8}$$

$$\text{with a } \Delta G_{rxn}{}^{\circ} = -87.7\ \mathrm{kJ\ mol^{-1}} \quad \text{and } E^{\circ} = \frac{87.7\ \mathrm{kJ \cdot mol^{-1}}}{1 \cdot 96.4\mathrm{kJ \cdot mol^{-1} \cdot V^{-1}}} = 0.91\ \mathrm{V} \tag{9}$$

or:

$$E_h = 0.91\ \mathrm{V} - \frac{2.303RT}{F}\log\frac{a_{\mathrm{Fe^{2+}}}a_{\mathrm{H_2O}}}{a_{\mathrm{FeOH^{2+}}}a_{\mathrm{H^+}}} \tag{10}$$

By convention, the activity of water is taken as unity because it is on the Raoult's law scale and virtually all aqueous solutions have a mole fraction of water near unity. Evaluating the constants at 298 K, remembering that $\mathrm{pH} = -\log(a_{\mathrm{H^+}})$and separating the terms leads to an expression that varies both with E_h and pH:

$$E_h = 0.91\ \mathrm{V} - 0.0592\log\frac{a_{\mathrm{Fe^{2+}}}}{a_{\mathrm{FeOH^{2+}}}} - 0.0592\mathrm{pH} \tag{11}$$

The equation relating measured redox potential (E_h) to solute activities at nonstandard-state conditions now includes pH as an essential variable.

Pourbaix (eh-pH) Diagrams

Garrels and Christ (1962) made popular an approach to organizing redox reactions in mineral reactions that developed in the early twentieth century by other workers. In particular, Pourbaix (1976) compiled an atlas of diagrams that show the predominant aqueous species that exists at various conditions of redox potential (E_h) and pH, with a goal to understanding metal corrosion (see Bunker and Casey 2016). These diagrams have proven to be enormously useful in interpreting corrosion reactions and for understanding the phase transformations in rocks and soil. Other compilations have been made (Brookins 1988; Schweitzer and Pesterfield 2010), and web utilities now exist to make diagrams (see, e.g., Inorganic Chemistry Royal Institute of Technology, KTH, SE-100 44, Stockholm, Sweden; https://www.kth.se/en/che/medusa/downloads-1.386254). The central assumption is that redox potential and hydrogen-ion activity can serve as master variables to control the valence states of elements (E_h) and the acid-base chemistry (pH).

The idea is that a line can be assigned to the boundary between the species in aqueous solution. For Eq. (5), a horizontal line can be assigned as the boundary where the activities of the two species are equal, i.e., $a_{\mathrm{Fe^{2+}}} = a_{\mathrm{Fe^{3+}}}$ and $E_h = 0.77V$. Unlike a phase diagram, species persist on both sides of the line, but the labeled species is the predominant one. Hence, these diagrams are *predominance* diagrams. The line is horizontal because Eq. (5) is purely an electron-exchange reaction. Similarly, a vertical line can be assigned to purely proton-exchange or acid-base reactions. Thus the reaction $\mathrm{Fe^{3+}(aq) + H_2O = FeOH^{2+}(aq) + H^+(aq)}$ does not depend upon E_h because iron does not change valence state. The equilibrium constant $K_1 = 10^{-2.19} = \frac{a_{\mathrm{FeOH^{2+}}}a_{\mathrm{H^+}}}{a_{\mathrm{Fe^{3+}}}a_{\mathrm{H_2O}}}$ fixes that vertical line at pH = 2.19 when $a_{\mathrm{Fe^{3+}}} = a_{\mathrm{FeOH^{2+}}}$and, as usual, $a_{\mathrm{H_2O}} = 1$. So, vertical lines correspond to acid-base reactions, like hydrolysis, and horizontal lines correspond to purely electron-exchange reactions.

Reactions like Eq. (8) that involve both proton and electron exchanges are slopes in both E_h and pH. Again, setting equal the activities of the two species in the reaction, $a_{\mathrm{Fe^{2+}}} = a_{\mathrm{FeOH^{2+}}}$, the Nernst equation yields a line in the predominance diagram with an appreciable slope: $E_h = 0.91\ \mathrm{V} - 0.0592\mathrm{pH}$. Similarly, one can choose to include solids in the Pourbaix diagram, although now one must also choose a total dissolved concentration of the metal. For example, an acid-base reaction can be written to include hematite (α-Fe_2O_3(s)):

$$\mathrm{Fe_2O_3}(s) + 6\ \mathrm{H^+}(aq) = 2\ \mathrm{Fe^{3+}}(aq) + 3\ \mathrm{H_2O}(l), \quad \Delta G_{rxn}{}^{o} = +8.2\ \mathrm{kJ\ mol^{-1}} \tag{12}$$

yielding an equilibrium constant that depends only on pH, as expected, but one must specify a value for $a_{\mathrm{Fe^{3+}}}$ in order to make the diagram:

$$K = 10^{-1.45} = \frac{a^2_{\mathrm{Fe^{3+}}}a^3_{\mathrm{H_2O}}}{a^6_{\mathrm{H^+}}a_{\mathrm{Fe_2O_3}}} \approx \frac{a^2_{\mathrm{Fe^{3+}}}}{a^6_{\mathrm{H^+}}} \tag{13}$$

Similar lines must be drawn to make the various hydrolysis products of Fe(III) (e.g., $\mathrm{FeOH^{2+}}$(aq)), giving rise to sets of vertical lines.

Or, the reaction could be written to involve an electron-exchange step as well, describing the reductive dissolution of hematite so that one achieves a line with both pH and E_h as key variables:

$$\mathrm{Fe_2O_3}(s) + 6\ \mathrm{H^+}(aq) + 2\ e^- = 2\ \mathrm{Fe^{2+}}(aq) + 3\ \mathrm{H_2O}(l), \quad \Delta G_{rxn}{}^{o} = -153.6\ \mathrm{kJ\ mol^{-1}} \tag{14}$$

$$E_h = 0.80\ \mathrm{V} - \frac{0.0592}{2}\log\frac{a^2_{\mathrm{Fe^{2+}}}}{a^6_{\mathrm{H^+}}} \tag{15}$$

that simplifies to a line on the Pourbaix diagram with both pH and E_h as key variables, once a value for $a_{\mathrm{Fe^{3+}}}$ is chosen:

$$E_h = 0.80\ \mathrm{V} - 0.0592 \cdot \log(a_{\mathrm{Fe^{2+}}}) - 0.177\mathrm{pH} \tag{16}$$

The boundaries of the Pourbaix diagram for most geochemists is given by the stability field of water. The upper

O

stability field is given by the oxidation of water to O_2 to exceed the confining pressure (1 atm) and so that O_2 comes boiling out solution:

$$E_h = 1.23\ \text{V} - 0.0592 \cdot pH \tag{17}$$

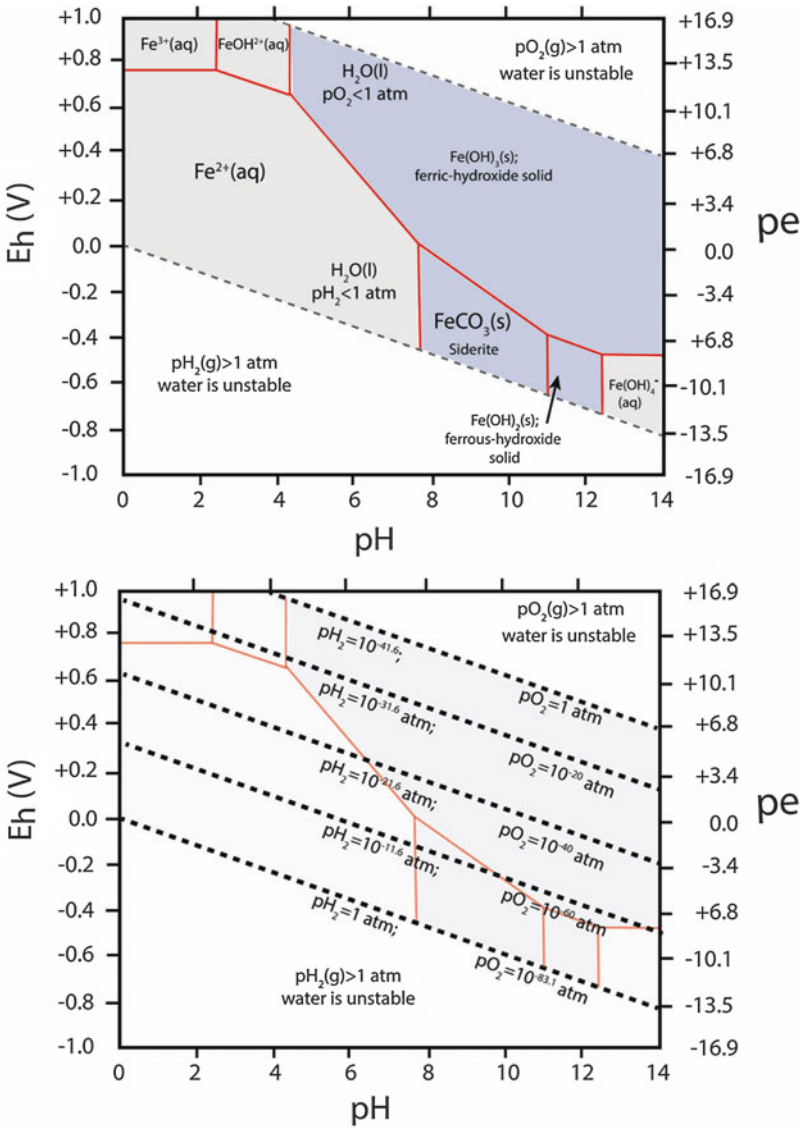
and the lower boundary is the corresponding potential where water (or actually protons) are reduced to make H_2(g) boil out of solution at pressures of 1 atm:

$$E_h = 0.0\ \text{V} - 0.0592 \cdot pH \tag{18}$$

All of these features are illustrated in Fig. 1, which shows a particularly simple Pourbaix diagram for iron in water in the topmost figure. Here the dashed lines give the stability fields of water, the vertical lines denote the acid-base reactions, the horizontal lines denote purely redox reactions, and the sloped lines indicate reactions that require both electron and proton transfers. In the bottom figure, the corresponding partial pressures of O_2 and H_2 are given, as the redox equilibrium could be equivalently expressed as the partial pressures (or actually fugacities) of these gases. These are redox-active gases because of the equilibrium, 2 H_2(g) + O_2(g) = 2 H_2O(l), which can be interconverted to a voltage (E_h) via the hydrogen electrode (Eq. 2).

The Perils of E_h as a Master Variable

Many of the problems in environmental geochemistry depended very sensitively on the redox state of the metal, so the promise of a master variable to control the valence states was profound. The solubilities of minerals formed by precipitation of metals vary by many, many orders of magnitude depending upon the valence state. For the iron system, at pH = 7, the solubility of $Fe(OH)_2$(s) is $\sim 10^{12}$ greater than



Oxidation-Reduction Reactions and E_h-pH (Pourbaix) Diagrams, Fig. 1 (*top*) The Eh-pH (Pourbaix) diagram for 10^{-4} m total dissolved iron and 10^{-2} m total dissolved carbonate species, with the stability fields of water under electrolysis shown as dashed lines and the stability fields between solutes and solids shown as *red lines* (Adapted from Garrels and Christ 1962; Bunker and Casey 2016). Conditions where solutes predominate are colored *gray*. Conditions where a solid predominates are shown in *blue*. (*bottom*) The calculated partial pressures of the redox-active gases O_2(g) and H_2(g) superimposed on the Pourbaix diagram at various values of E_h and pH

α-FeOOH(s) (Baes and Mesmer 1976). An active and urgent area of research is the redox state of radioactive transuranic elements. Considering plutonium as one example, it can exist in valence states of Pu(III), Pu(IV), Pu(V), and Pu(VI) in water and in the existence of strongly ligated complexes (see Neck et al. 2007). The solubilities vary by many orders of magnitude, and these, of course, determine the rate of migration through geological media as ions and to the biosphere.It made sense when Baas-Becking and colleagues (1960) showed that different environments at the Earth's surface had characteristic voltages relative to a hydrogen electrode, that is, E_h values, and electrochemists can define a system potential using electrodes. Thus, common codes for predicting chemical speciation in water require both pH and E_h to make predictions of mineral solubilities, aqueous complexation, gas fugacities, etc. What was promised by E_h is another master variable that could accurately predict the redox state of all metals dissolved in solution, just as pH could be used as a master variable to predict the protonation states of various molecules. One could either measure E_h and calculate the ratio of activities valence states for metals or alternatively assess a ratio of activities (e.g., $\frac{a_{Fe^{2+}}}{a_{Fe^{3+}}}$ in Eq. (5)) and get the "master variable," E_h, directly.

The approach failed, and for several reasons, that were not the fault of Baas-Becking. When the E_h values measured from redox couples in deep, old aquifers were compared with the results of direct voltage measurements, there was profound disagreement. Groundwaters that were inferred to have been stable since the last Ice Age had redox couples in profound disequilibrium (see Lindberg and Runnells 1984). One reason is that rates of many electron exchanges among solutes, particularly for multiple electrons, are slow unless catalyzed by biota and enzymes. Sulfate reduction to sulfide, for example, is an eight-electron step. It proceeds rapidly at the Earth surface when heterotrophic bacteria couple the reaction to enzymatic oxidation of organic matter, but without the catalysts, it is very slow. Similarly, measured methane concentrations are in disequilibrium with dissolved carbonate concentrations because it is a slow multiple-electron reaction and doesn't respond to the measured E_h value. Single-electron reactions are sometimes fast, such as Eq. (3), but this is a thin filament upon which to hang all thermodynamic equilibrium calculations.

These diagrams, of course, assume equilibrium. It also should be remembered that one chooses the species to be included in the diagram, including whether to include metastable species. The diagrams emphasize the presence of the dominant species, meaning the one that accounts for most of the concentration, but all other species are copresent. Depending upon the stoichiometry of the reaction, a small error in E_h leads to a large error in the ratio of stable species activities in solution, since voltages are linear but the activities are logarithmic.

There are experimental problems – the E_h measurement in the field is via a platinum electrode that doesn't respond reversibly at all conditions and can be easily poisoned so that it responds unequally to some reactions. Some reactions are fast in one direction but slow in reverse. Thus, the field E_h measurement cannot be trusted. Finally, there is a problem with the very meaning of E_h as a master variable. When one measures a solution pH, there is a real meaning – it is the negative logarithm of the concentration of protons, and this is an appreciable number. At pH = 7, the hydrogen-ion concentration, or equivalently the hydronium-ion concentration, is about 10^{-7} m. Water molecules provide a "bank" for protons. An oxygen that needed a proton can find one in the solvent. Similarly a hyperprotonated functional group can transfer the proton to the "bank" that is the bulk solvent. Because it is a solvent property, pH has meaning.

Not so for dissolved electrons. Save for highly radiolyzed solutions, the concentration of solvated electrons in water is negligible. There is no "bank" of electrons unless one has a reactive electrode, like a charged mercury drop, placed in the solution and interacting with the solutes. This means that E_h is a property of the *solutes* not the *solvent*. Whether an electron-exchange reaction proceeds depends upon an electron donor (e.g., Co^{2+}(aq)) actually colliding with an electron acceptor (e.g., SO_4^{2-}) and both having an appropriate molecular-orbital configuration to allow the reaction to proceed. There is no master variable for redox reactions in natural waters, or, stated differently, in the absence of an electrode driving processes, the E_h is a property of the solutes not the solvent.

O

The Practical use of Redox Potential

The field has instead characterized sets of redox reactions that are characteristic of general environments, which can be categorized by the presence of oxidants such as O_2(aq) (see McMahon and Chappelle 2008). Thus, for example, an *oxic* environment has no measurable dissolved iron because the metal is in the oxidized ferric state and insoluble minerals form. Dissolved iron can be detected in *suboxic* environments but is usually absent in anoxic environments because of equilibrium with insoluble sulfide minerals that form as sulfate is reduced to sulfide.

The array of possible reactions is treated in most water-chemistry textbooks (e.g., Morel and Hering 1993), but these cascade in a predictable way largely because of the influence of bacteria and enzymes. Oxidation of reduced organic matter provides the electrons, and the hierarchy of electron acceptors varies according to the available energy, as different microbial communities organize themselves both spatially and temporally. Thus, O_2(aq) is removed from solution first, followed by NO_3^-, chlorinated hydrocarbons, Mn(IV), Fe(III), SO_4^{2-}, and finally CO_2, making water, N_2, chloride ion, Mn(II), Fe

(II), H_2S, and CH_4, respectively. The cascade corresponds to energy available for the microbial community.

Summary

Redox potential, or Eh, is one master variable that is used to calculate the valence states of solutes in aqueous solutions. It refers to the voltage of the solution relative to the standard hydrogen electrode and derives from electrochemistry, where the potential is controlled by a working electrode. It is enormously useful as a means of estimating the speciation of aqueous solutions and is one variable, along with pH, in the Eh-pH diagrams known as Pourbaix diagrams. These diagrams identify the predominant aqueous complex, gas, or solid at given conditions. Problems arise when applying it to natural waters where there is no working electrode because of slow electron-exchange rates, unequal electrode responses, and the nature of Eh as reflecting the properties of solutes.

Synonyms

Oxide minerals; Oxides

Definition

Oxide minerals are inorganic compounds in which positively charged ions of metals or transition elements bond to negatively charged oxygen, O^{2-}. Oxide minerals are classified into simple and complex oxides and are commonly distinguished from other oxygen-bearing minerals such as silicates, sulfates, borates, phosphates, and carbonates. Hydroxide minerals, which contain a hydroxyl group (OH^{1-}) instead of O^{2-}, and oxyhydroxides, which comprise both hydroxyl group and oxygen, are often included in the group of oxide minerals (Deer et al. 2013, 2011; Dyar et al. 2008; Gaines et al. 1997; Klein and Dutrow 2007; Wenk and Bulakh 2004). Oxides are generally harder and denser than hydroxides. The latter predominantly occur as secondary alteration and weathering products (Klein and Dutrow 2007). Ice (H_2O) is considered a simple oxide in which hydrogen is the cation. The International Mineralogy Association (IMA) lists over 1000 approved oxide and hydroxide minerals (http://rruff.info/ima/; Back 2014).

Mineralogy

More than 40 elements are found to form oxides and more than 25 elements are known to form hydroxides in nature (Back 2014; Deer et al. 2013; Klein and Dutrow 2007; Wenk and Bulakh 2004). Table 1 lists 23 common and other important oxides and hydroxides.

Oxide minerals can be divided into classes and groups based on their crystal structure and cation site distribution. Several classification schemes exist: Nickel-Strunz (Strunz and Nickel 2001), IMA (Mills et al. 2009), and Dana (Gaines et al. 1997; Klein and Dutrow 2007). The main classes are simple oxides (XO, X_2O, XO_2, and X_2O_3), complex or multiple oxides (XY_2O_4), and hydroxides (OH^{1-}) (Deer et al. 2013; Dyar et al. 2008; Wenk and Bulakh 2004). These classes can be further subdivided into six groups: (1) periclase group, (2) zincite group, (3) hematite group, (4) rutile group, (5) spinel group, and (6) goethite group (Table 1) (Deer et al. 2013; Dyar et al. 2008; Gaines et al. 1997; Klein and Dutrow 2007; Wenk and Bulakh 2004).

Oxide Minerals, Table 1 List of common and other important oxides and hydroxides and their diagnostic properties. Crystal family—Iso: isometric (cubic), Hexag.: hexagonal, Tetrag.: tetragonal, Ortho.: orthorhombic, Monocl.: monoclinic, Tricl.: triclinic. H: Mohs hardness. Compiled using the following references: (Back 2014; Deer et al. 2011; Dyar et al. 2008; Klein and Dutrow 2007; Mills et al. 2009; Smyth and McCormick 1995; Wenk and Bulakh 2004)

Oxide class	Oxide group	Mineral, Formula	Crystal family	Occurrence	Color	H
XO	Periclase group	Periclase, MgO	Iso.	Metamorphosed limestones and dolomites	Various colors or colorless	$5^{1/2}$
	Zincite group	Zincite, (Zn, Mn)O	Hexag.	Weathering product, metamorphic rocks	Yellow to red	4–5
X_2O		Cuprite, Cu_2O	Iso.	Alteration product, secondary	Red	$3^{1/2}$–4
		Ice, H_2O	Hexag.	Snow, ice	White or colorless	$2^{1/2}$
XO_2	Rutile group	Rutile, TiO_2	Tetrag.	Granites, pegmatites, metamorphic rocks, detrital	Red-brown-black	$6–6^{1/2}$
		Pyrolusite, MnO_2		Sedimentary, hydrothermal, secondary	Grey	$6–6^{1/2}$
		Cassiterite, SnO_2		Granites, pegmatites and greisen; mainly hydrothermal	Reddish brown to black	6–7
		Uraninite, UO_2	Iso.	Granites, syenite pegmatites, high-T hydrothermal	Brown-black, grey	5–6
X_2O_3	Hematite group	Hematite, Fe_2O_3	Hexag.	Sedimentary and metamorphic rocks, BIFs, rarely magmatic	Reddish brown	$5–6^{1/2}$
		Corundum, Al_2O_3		Aluminous igneous and metamorphic rocks	Various colors or colorless	9
		Ilmenite, $FeTiO_3$		Igneous and metamorphic rocks, beach sands	Black	5–6
XY_2O_4	Spinel group	Spinel, $MgAl_2O_4$	Iso.	Igneous and metamorphic rocks, sediments	Various	$7^{1/2}$–8
		Magnetite, Fe_3O_4		Igneous and metamorphic rocks, sediments, BIFs	Black	$5–6^{1/2}$
		Chromite, $FeCr_2O_4$		Ultrabasic rocks, serpentinites	Black	$5^{1/2}$
		Franklinite, (Zn, Fe, Mn) $(Fe,Mn)_2O_4$		Metamorphic rocks, hydrothermal	Red, black	6
		Gahnite, $ZnAl_2O_4$		Granitic pegmatites, metamorphic rocks, hydrothermal	Dark green	$7^{1/2}$–8
		Chrysoberyl, $BeAl_2O_4$	Ortho.	Rare, granitic rocks, pegmatites, mica-schists, sediments	Yellow-green	$8^{1/2}$
		Fe-Columbite, (Fe, Mn) Nb_2O_6		Granitic rocks and pegmatites	Black	6
Hydroxides		Brucite, $mg(OH)_2$	Hexag.	Alteration mineral	Various colors	$2^{1/2}$
		Manganite, MnO(OH)	Monocl.	Low-T hydrothermal, hot springs	Brown-black	4
		Gibbsite, $al(OH)_3$		Weathering product, bauxite	Various colors	$2^{1/2}$–$3^{1/2}$
	Goethite group	Diaspore, α-AlO(OH)	Ortho.	Weathering product, bauxite	White or colorless	$6^{1/2}$–7
		Goethite, α-FeO(OH)		Alteration mineral, hot springs	Yellowish brown to red	$5–5^{1/2}$

Physical and Chemical Properties

Metal and transition element cations occupy interstices in the crystal structure. Ionic bonding is most common among oxide minerals; therefore, the ionic radii of the respective cations govern the structure and complexity of the corresponding oxide (e.g., Dyar et al. 2008; Wenk and Bulakh 2004). The ionic radii of the cations bonding with oxygen are always smaller than oxygen itself (<1.4 Å (Shannon 1976; Shannon and Prewitt 1969)). Oxides are often opaque or translucent but can exhibit various colors due to intrinsic crystallographic controls or minor and trace element substitution. As Table 1 illustrates, oxides generally have a high hardness due to the high coordination number of the ions in their crystal structure (Jaffe 1996). The presence of a hydroxyl group results in a lower hardness in hydroxides (Jaffe 1996; Nikischer 2011).

Oxygen fugacity is one of the main governing factors when considering the stability of oxide minerals in nature. A comprehensive account of the importance of oxygen fugacity can be found in the Reviews in Mineralogy volume 25 (Lindsley 1991). Oxides are inherently dependent on the oxygen fugacity conditions that prevail; however, they may exist as metastable phases even if conditions are unfavorable (Lindsley 1991). Oxygen fugacity also controls element partitioning between oxides, and between oxides and other minerals, particularly for elements with variable valency such as Fe, V, and Cr (e.g., Frost 1991; Ryabchikov and Kogarko 2006).

Several oxide minerals exhibit magnetic properties. Magnetite is a ferrimagnetic mineral, whereas a number of other Fe-oxides (e.g., hematite and goethite) have ferromagnetic properties (Banerjee 1991; Cornell and Schwertmann 2003). Chromite, franklinite, and ilmenite are also magnetic but belong to the group of paramagnetic minerals (Klein and Dutrow 2007; Lindsley 1991; Wenk and Bulakh 2004). Many oxide minerals also act as semi-conductors (Cornell and Schwertmann 2003; Wenk and Bulakh 2004).

Occurrence

Oxides are common minerals that occur as minor or accessory phases in the Earth's crust and Upper Mantle. Spinel group members, baddeleyite, rutile, and ilmenite are common minerals in the Upper Mantle (Deer et al. 2011; Dyar et al. 2008; Haggerty 1976, 1995; Klein and Dutrow 2007). In banded iron formations or chromite layers, oxides are the principal rock-forming compounds. Hydroxides are the main compounds in areas where alteration and weathering (i.e., oxidation and hydration) are pervasive such as in supergene oxidation zones, soils, and laterites (Delvigne 1998).

Oxide minerals can occur as primary (magmatic-hydrothermal) and secondary (products of mineral alteration) minerals in magmatic, volcanic, and metamorphic rocks and as resistant detrital grains in sediments (Klein and Dutrow 2007; Lindsley 1991). Biogenic oxides such as Mn (IV)-oxides, −hydroxides, and -oxyhydroxides occur where microbial activity produces mineral compounds through oxidation of bioavailable transition metals (Tebo et al. 2004).

Before the Great Oxidation Event at approximately 2.4 Ga (Holland 2006), oxides were restricted to species with a low oxidation state of the respective cation as the partial pressure of oxygen was low. The increased availability of oxygen led to an unprecedented rise in the formation of new minerals (Sverjensky and Lee 2010).

Applications and Economic Significance

Several oxide minerals are of economic significance and important sources of metals: Fe (hematite, magnetite), Cr (chromite), Mn (pyrolusite, manganite, psilomelane), Zn (zincite), Sn (cassiterite), Ti (ilmenite, rutile), and Al (bauxite) (Deer et al. 2011; Gaines et al. 1997; Ramdohr 1980). Some varieties of oxides, such as corundum (Al_2O_3), spinel ($MgAl_2O_4$), chrysoberyl ($BeAl_2O_4$), or baddeleyite (ZrO_2, cubic zirconia), are used as precious stones or gems. For example, rubies form when Cr and V substitute Al in corundum, causing an intense red color. When Fe and Ti substitute Al, a blue color is apparent and the corresponding gem is called sapphire (Deer et al. 2011).

Among the most ubiquitous oxide minerals are magnetite and hematite, which are primary iron ore minerals. Both occur in a range of host rocks and are often associated with mineral deposits such as banded iron formations, mineralized skarns, porphyry Cu-Mo-Ag-Au, and iron ore copper-gold deposits. Chromite is the primary constituent in chromite ore deposits such as the Bushveld igneous complex in South Africa. The widespread occurrence of common oxides such as Fe-Ti oxides and chromite, and their ability to incorporate a variety of foreign cations into their structure, has qualified them as petrogenetic indicators and useful tools for geochemical exploration (e.g., Dare et al. 2014; Dupuis and Beaudoin 2011; Knipping et al. 2015; Nadoll et al. 2014; Razjigaeva and Naumova 1992; Sack and Ghiorso 1991; Zack et al. 2004). Furthermore, magnetic oxides can help to target deposits or prospective areas with geomagnetic surveys (Cornell and Schwertmann 2003; Sandrin et al. 2007) and record the geomagnetic field for paleomagnetic investigations (Dyar et al. 2008).

Strategic elements such as the rare earth elements (REE) Ce, Y, and La can often be found in Ca-, Ti-, U-, Th-, or Ta-Nb-bearing oxides such as perovskite (CaTiO3) or aeschynite-(Ce) ((Ce,Ca,Fe,Th)(Ti,Nb)2(O,OH)6)), which

can be found as accessory mineral phases in granites, nepheline syenites, carbonatites, or pegmatites (Möller et al. 1989). Due to its ferroelectric and high-temperature superconducting properties, perovskite is also an important mineral for the electronic industry (Wenk and Bulakh 2004).

Due to their high affinity to heavy metals and other toxic elements, Mn- and Fe-oxides, −hydroxides, and -oxyhydroxides can directly or indirectly deactivate pollutants through surface adsorption and therefore play an important role for environmental applications (Cornell and Schwertmann 2003; Kumpiene et al. 2008; Tebo et al. 2004). On the other hand, U-oxides can pose a significant environmental hazard due to the radioactive radiation they emit.

Summary

Many fundamental aspects of mineralogy have been revealed through the detailed study of oxide minerals (e.g., Smyth et al. 2000). Their relatively simple structure and ability to incorporate a variety of foreign cations makes them primary targets for petrological and geochemical studies. Their economic and environmental significance is indisputable, and recent years have seen an increased interest in them for a variety of geological and technical applications.

Oxygen

Edward D. Young
Department of Earth, Planetary, and Space Sciences, UCLA, Los Angeles, CA, USA

Element Data
Atomic Symbol: O
Atomic Number: 8
Atomic Weight: 15.999
Isotopes and Abundances: ^{16}O, 99.763%; ^{17}O, 0.037%; ^{18}O, 0.200%
1 Atm Melting Point: −218.79 °C
1 Atm Boiling Point: −182.96 °C
Common Valences: 2, 1, −1, −2
Ionic Radii: 136 pm (threefold coordination), 138 pm (fourfold coordination), 140 pm (sixfold coordination)
Pauling Electronegativity: 3.44
First Ionization Energy: 1313.9 kJ/mol
Chondritic (CI) Abundance: 0.46 mass fraction
Silicate Earth Abundance: 0.44 mass fraction
Crustal Abundance: 0.47 mass fraction
Seawater Abundance: 0.89 mass fraction
Core Abundance: 0.005–0.05 mass fraction

Properties

Oxygen is distinguished from virtually all other elements by its extraordinary electronegativity. It is surpassed in its affinity for electrons only by fluorine. For this reason, concentrations of oxygen play a critical role in many geochemical cycles and in the basic structures of rocky planets. The multiple valence states of numerous geochemically relevant elements are linked to the availability of oxygen.

Oxygen is also distinctive in being a major component of not only rock, but also of volatile components in planetary bodies. The oxygen-bearing volatiles include H_2O, CO_2, and SO_2.

The electronic configuration $1s^2\ 2s^2\ 2p^4$ lends itself to forming covalent bonds with other oxygen atoms. The dioxygen molecule, O_2, is a colorless and odorless gas comprising 21% of Earth's atmosphere. Oxygen is classified as a lithophile element and occurs mainly in the crust and mantle of rocky planets. Bonding between Si and O is approximately 50% covalent and 50% ionic (Pauling 1980). Silicon is coordinated by four oxygen atoms forming the $[SiO_4]^{4-}$ group that polymerizes to varying degrees to form the basis for the crystal structures of silicates, the most common rock-forming minerals.

Because oxygen has ionic radii of several times those of the cations it bonds to (Shannon 1976), the crystal structures of rock-forming oxide and silicate minerals can be described as tightly packed oxygen atoms with cations occupying the interstices of the oxygen atoms. Oxygen therefore constitutes about 90% of the volume and about half the mass of typical rocks.

There are three stable isotopes of oxygen: ^{16}O, ^{17}O, and ^{18}O. These isotopes are especially useful as tracers in geochemical reactions because the mass differences are relatively large compared with the average atomic mass of oxygen, resulting in readily measurable partitioning of isotopes between phases, and because oxygen occurs in great abundance in rock, water, and air.

History

Three people are variously credited with the discovery of dioxygen gas in the eighteenth century. Swedish apothecary Karl Wilhelm Scheele in 1771 discovered the gas as a product of heating mercuric oxide, magnesium nitrate, potassium nitrate, and silver carbonate. He referred to this emitted gas as "fire air," a reference to the fact that the gas ignited charcoal dust. He published the result in 1777 (Scheele 1777). His discovery predates those of Antoine Laurent de Lavoisier and Joseph Priestly, but his publication postdated these works.

Lavoisier, a French chemist, explored the properties of air as a reagent for combustion beginning in 1772 (Guerlac 1961). He gave oxygen its name in 1779 and recognized that reactions with oxygen were responsible for combustion. Prior to Lavoisier's insight, combustion was thought to release the fictive, ethereal substance referred to as "phlogiston." Lavoisier discovered that phosphorous and sulfur gained weight when combined with air rather than losing weight as predicted by the phlogiston theory. He also showed that air is ~20% oxygen (on a molecular basis).

During this same period, British clergyman and natural philosopher Joseph Priestley conducted experiments in 1771 and 1772 showing that plants emit a gaseous component found in air that is in turn consumed by animals, foreshadowing the discoveries of photosynthesis and respiration, processes that produce and consume oxygen in air, respectively. He further recognized the liberation of oxygen from heated mercuric oxide in 1774 (West 2014) and published his result in 1775 (Priestley 1775). Priestly mistakenly believed that the gas that would be named oxygen by Lavoisier was a "dephlogisticated air." Because Priestly published first, his discovery of oxygen is often given priority.

Stellar Origins

Oxygen is the third most abundant element in the Galaxy, superseded only by H and He (Lodders 2003). The lightest and most abundant isotope of oxygen, ^{16}O, is produced by helium fusion (He burning) mainly in large stars that are at least ten times the mass of the Sun. It is the most abundant nuclide synthesized in stars (Clayton 2003). ^{16}O created in stars is ejected into the interstellar medium by the explosion of Type II supernovae where it is then available for incorporation into the next generation of stars. Because it is a product of He burning, the synthesis of ^{16}O is not dependent on the existence of other "metals" (metals is the term used for elements heavier than H and He in astronomy). It is therefore a primary nuclide.

The stellar nucleosynthesis of the two heavier isotopes of oxygen, ^{17}O and ^{18}O, relies on the prior existence of ^{16}O, ^{12}C, and ^{14}N; stars with no "metals" cannot produce these isotopes of oxygen. ^{17}O and ^{18}O are therefore secondary nuclides and are rare compared with ^{16}O. ^{17}O is produced in lower mass stars in their red giant phase or from novae (Clayton 2003). It is made from H and ^{16}O during hydrogen fusion (H burning) in the CNO cycle. ^{18}O is synthesized during He burning in massive stars using ^{14}N as a reactant (Clayton 2003). Novae and ejecta from red giant stars disperse ^{17}O to the interstellar medium while ^{18}O is scattered by Type II supernovae.

As stars produce more "metals," the secondary ^{17}O and ^{18}O nuclides grow in abundance with the square of time while the amount of ^{16}O grows linearly with time. The overall $^{17}O/^{16}O$ and $^{18}O/^{16}O$ isotopic ratios are therefore expected to have grown approximately linearly with time in the Milky Way Galaxy in a process known as Galactic chemical evolution (Tinsley and Cameron 1974; Young et al. 2011).

Cosmochemical Significance

The nonideal partial pressure of oxygen, oxygen fugacity, is a thermodynamic quantity that characterizes the level of oxidation for a system. The fugacity, f_{O_2}, is meant to correct the pressure of O_2 in a system from a standard state of one bar and from a mole fraction in the gas of unity. The f_{O_2} symbol is therefore usually an abbreviated way of writing f_{O_2}/P_{O_2} where the denominator pressure P_{O_2} is understood to be unity (pure O_2 at one bar); oxygen fugacity is a measure of the activity, or nonideal concentration, of O_2. It can always be defined thermodynamically to measure the degree of oxidation even in circumstances where the quantity of free dioxygen is for all practical purposes indistinguishable from zero. The parameter $\Delta IW = \log(f_{O_2}) - \log(f_{O_2})_{IW}$, quantifies the difference in oxygen fugacity at a given temperature from that defined by the equilibrium reaction Fe (Iron) + ½O_2 = FeO (Wüstite), the IW reaction. The oxygen fugacity of a planet or planetesimal can be calculated relative to the IW reference using corrections for the concentrations of FeO in the bulk silicate portion and Fe in the metal core:

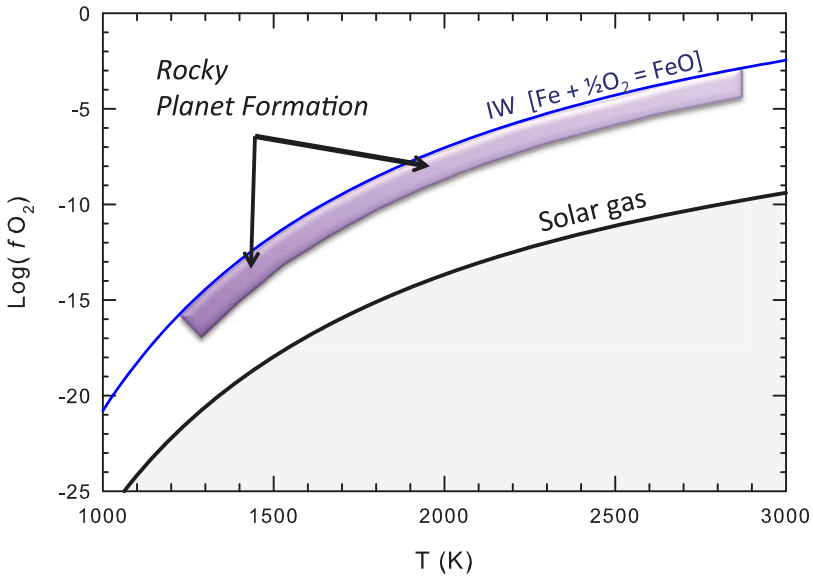
$$\Delta IW = 2\log\left(\frac{x_{FeO}^{silicate}}{x_{Fe}^{metal}}\right) + 2\log\left(\frac{\gamma_{FeO}^{silicate}}{\gamma_{Fe}^{metal}}\right),$$

where x are mole fractions of the species indicated and γ are activity coefficients that correct for nonideal mixing. The intrinsic oxygen fugacity of the Earth is constrained by the 8 weight percent FeO in the mantle and its Fe-rich core to a ΔIW value of -1 using nonideal mixing or -2 based on the assumption of ideal mixing. Estimates of the amount of oxygen in Earth's core vary from approximately 0.5% by mass to as much as 5% by mass (Huang et al. 2011; Badro et al. 2015; Rubie et al. 2015).

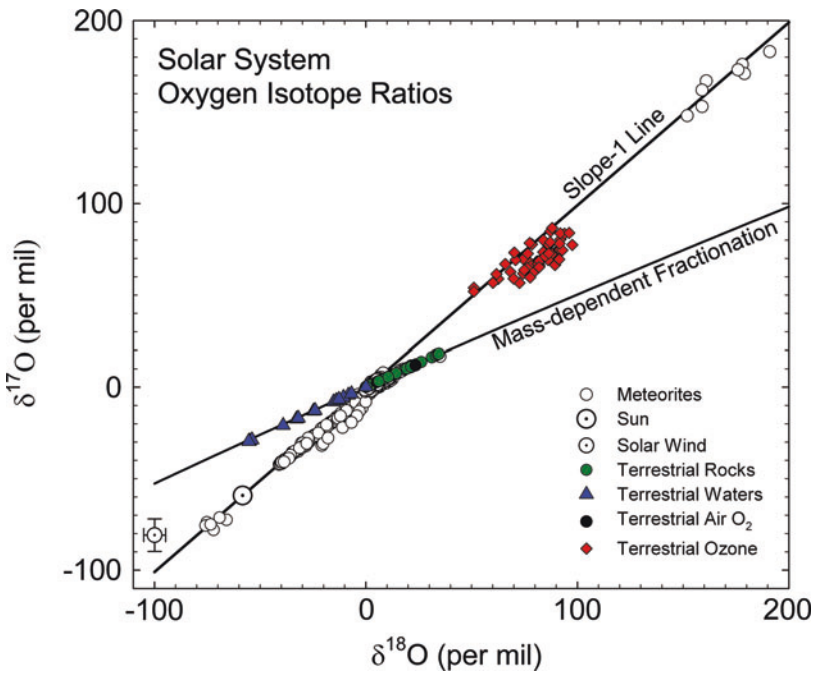
Studies of meteorites reveal that, like the Earth, most rocky bodies in the solar system formed with oxygen fugacities approximately five orders of magnitude higher than that defined by a hydrogen-rich gas of solar composition (Fig. 1). The presence of significant amounts of iron bonded to oxygen in silicates in chondrite meteorites testifies to this relatively high oxygen fugacity during rock formation in the early solar system (Grossman et al. 2012).

The fugacity of oxygen in the protoplanetary gas was controlled by the reaction H_2 + ½O_2 = H_2O (Krot et al. 2000). In order to form rocks like those comprising the Earth, the ratio of H_2O/H_2 must have increased by a factor of nearly 400 relative to the solar value. The relative abundances of water ice and H_2 gas were, therefore, the first-order controls on the fugacity of oxygen and the oxidation state of the elements comprising rocky planets.

The distribution of the three isotopes of oxygen among planets and asteroids constitutes one of the most distinctive and mysterious chemical features of the solar system (Clayton et al. 1973). In general, for the great majority of physicochemical processes, kinetic and equilibrium variations in $^{18}O/^{16}O$ ratios should be approximately twice those for



Oxygen, Fig. 1 Plot of the logarithm of oxygen fugacity versus temperature (K) for a gas of solar composition and for the equilibrium Fe (Iron) + ½O_2 = FeO (Wüstite) (IW). The conditions corresponding to rock formation in the early solar system are indicated



Oxygen, Fig. 2 Plot of oxygen isotope ratios for solar system materials. The ratios $^{17}O/^{16}O$ and $^{18}O/^{16}O$ are represented as per mil deviations from Vienna Standard Mean Ocean Water (VSMOW) such that for reservoir i $\delta^{17}O = 1000[(^{17}O/^{16}O)_i/(^{17}O/^{16}O)_{VSMOW} - 1]$ (and similar for $\delta^{18}O$). The slope-1 line that characterizes the solar system is shown for reference. The mass-dependent fractionation line represents fractionation of oxygen relative to Earth's mantle

$^{17}O/^{16}O$ ratios because of the 2:1 ratio in the mass differences involved (18 − 16 = 2 vs. 17 − 16 = 1). In other words, the fractionations are mass dependent. However, the dominant trend exhibited by minerals in meteorites that come from a variety of asteroid types is one in which $^{18}O/^{16}O$ ratios vary by about the same magnitude as $^{17}O/^{16}O$ ratios. This mass-independent ~1:1 relationship between oxygen isotope ratios includes the terrestrial planets and the Sun (McKeegan et al. 2011). The ^{16}O-rich and ^{16}O-poor ends of the array of solar system oxygen isotope ratios are evidently anchored by the Sun and pristine waters, respectively (Young 2007) (Fig. 2).

Explanations for this enigmatic trend include the residual effects of Galactic chemical evolution, intramolecular disequilibrium during oxidation reactions, and CO photochemistry (Young et al. 2008). In the case of CO photochemistry, the 1:1 relationship between the two oxygen isotope ratios arises because of the effect of CO self shielding whereby abundant $C^{16}O$ shields ultraviolet (UV) light that would otherwise liberate oxygen by the reaction $C^{16}O + UV \rightarrow C + {}^{16}O$, depriving the ensuing reservoir of liberated oxygen of ^{16}O. Atomic oxygen reacts with hydrogen to produce water, thus a paucity of atomic ^{16}O causes a paucity of ^{16}O in water, simultaneously increasing $^{18}O/^{16}O$ and $^{17}O/^{16}O$ in the water

(Yurimoto and Kuramoto 2004; Lyons and Young 2005). Any explanation for the oxygen isotope distributions in the solar system must account for the fact that all evidence points toward water having high $^{18}O/^{16}O$ and $^{17}O/^{16}O$ compared with rocks in the early solar system.

The apparent excess of $^{17}O/^{16}O$ relative to $^{18}O/^{16}O$ compared with expectations from normal "mass-dependent" isotope partitioning is expressed as the $\Delta^{17}O$ value (usually in per mil). This iconic parameter appears to be a fingerprint-like characteristic for each body formed in the solar system. Two important exceptions are the Earth and Moon, which stand out in having identical $\Delta^{17}O$ values that signify extensive intermingling of the proto-Earth and proto-lunar reservoirs (Wiechert et al. 2001; Young et al. 2016). The intermingling is most often attributed to the giant impact that evidently formed the Moon.

Applications of Oxygen Isotopes in Geochemistry

Shifts in the oxygen isotopic compositions of waters and rocks are used as records of water-rock interactions. Under hydrothermal conditions, exchange of oxygen between water and rock at temperatures greater than ~300 °C decreases $^{18}O/^{16}O$ in the rock. These signatures can be used for identifying regions that are likely to host mineralization (Taylor 1974).

Differences in oxygen isotope ratios between minerals formed at thermodynamic equilibrium can be used as geothermometers, providing estimates of equilibration temperatures in igneous and metamorphic rocks. Minerals with different structures, and therefore different bond strengths involving oxygen, make the best thermometers (e.g., quartz formed in equilibrium with magnetite).

Isotopes of oxygen are also used to trace reactions between water and rock on a global scale. An important example is the oxygen isotopic composition of ocean water over geological timescales. New oceanic crust formed at midocean ridges experiences ingress of seawater that reacts with rock at high temperatures near 300 °C. Far from the ridges, older ocean crust is infiltrated by cool water resulting in submarine weathering. At high temperatures, reactions with basalt increase the $^{18}O/^{16}O$ of the water. At low temperatures, reactions with basalt decrease the $^{18}O/^{16}O$ of the water. The relative rates of these two opposing reactions serves as a buffer for the oxygen isotopic composition of Earth's oceans (Muehlenbachs and Clayton 1976).

Harold Urey first pointed out that the temperature-dependent $^{18}O/^{16}O$ partitioning between calcite and water in the oceans could be used to reconstruct the temperatures of the oceans with time (Urey 1948). Since that original suggestion, the calcite-water oxygen isotopic paleothermometer has been a mainstay of paleoclimate reconstruction. The pattern of glacial-interglacial cycles over the last 600,000 years was enabled by this method, for example. Subsequent refinements dealt with the effect of sequestration of light oxygen isotopes in ices on ocean water $^{18}O/^{16}O$ (Shackleton and Opdyke 1973), confounding the temperature isotopic signals in the carbonate grown in the water. More recently, the uncertainties associated with the convolution of the isotopic effects of temperature and ice volume have been circumvented by the use of the relative abundances of $^{13}C{-}^{18}O$ bonds in carbonate. The concentrations of these heavy isotope bond pairs provide an intramineral isotope thermometer that is independent of the isotopic composition of the water and thus of ice volume (Gosh et al. 2004).

Oxygen in the Atmosphere

Twenty one percent of the molecules in Earth's air are O_2 (more precisely, the molecular mixing ratio of O_2 in air is 21%). The concentration of dioxygen in air is the result of two cycles operating on disparate timescales. On shorter timescales of about a 1,000 years (Bender et al. 1994), the concentration of O_2 in air is a balance between the global rate of O_2 production by photosynthesis and the global rate of O_2 uptake by aerobic respiration. Oxygen generated by photosynthesis comes ultimately from the oxygen comprising water. On longer geological timescales, O_2 uptake by weathering and the effective oxygen production by carbon burial (or rather, the absence of a long-term sink in the form of carbon oxidation) control the amount of O_2 in air over hundreds of thousands to millions of years (Lasaga and Ohmoto 2002). Short-term variations in O_2 abundance in air arise from variations in the rates of photosynthesis and respiration, while the long-term cycle of weathering and carbon burial governs the permissible amount of oxygen in Earth's atmosphere over geological time. The first appearance of significant levels of atmospheric dioxygen appeared during the Great Oxygenation Event (GOE) about 2.4 billion years before present in the Paleoproterozoic Era (Holland 2006). The possibility that there were multiple "whiffs" of O_2 prior to the GOE and marked decreases in O_2 after the GOE is debated (Lyons and Reinhard 2009). Regardless, atmospheric O_2 levels rose from maximal values of just 1–3% after the GOE to nearer to present-day levels of more than 5–18% in the Neoproterozoic. Widespread carbon deposition in the Carboniferous Period led to still higher concentrations of atmospheric O_2 (Catling and Claire 2005).

Molecular oxygen in Earth's atmosphere is not in oxygen isotopic equilibrium with the oceans. The $^{18}O/^{16}O$ ratio of atmospheric O_2 is greater than that of ocean water by about 2.3–2.4%, a value that is several times greater than that dictated by thermodynamic equilibrium. The high $^{18}O/^{16}O$ in air is referred to as the Dole effect (Dole 1935) and reflects the kinetic isotope effect of respiration and the lack of a significant isotope effect associated with photosynthesis.

In the stratosphere, O_2 photolysis by ultraviolet light (wavelengths $\leq$ 240 nm) liberates atomic oxygen that reacts to form ozone that in turn reacts with atomic oxygen or is photolyzed ($\lambda < 340$ nm) to form dioxygen. This Chapman cycle, named for its discoverer (Chapman 1930), can be described by the reactions

$$\begin{aligned}
&O_2 + h\nu \rightarrow O + O \\
&O + O_2 \xrightarrow{M} O_3 \\
&O_3 + h\nu \rightarrow O_2 + O \\
&O_3 + h\nu_{(\lambda<306\text{nm})} \rightarrow O_2 + O(^1D), \\
&O(^1D) \xrightarrow{M} O \\
&O_3 + O \rightarrow O_2 + O_2
\end{aligned}$$

where M signifies a collision partner (mainly N_2), $O(^1D)$ is the excited singlet state of oxygen, and $h\nu$ refers to the energy of the UV light. The actinic flux of UV light (i.e., the integrated flux from the top of the atmosphere) and the number density of oxygen molecules conspire to produce a peak in the rate of ozone production at an altitude of approximately 25 km. The reaction that produces ozone (O_3) causes a large mass-independent oxygen isotope effect of several per cent (tens of per mil) (Thiemens and Heidenreich 1983).

Dioxygen in air is anomalously low in ^{17}O relative to Earth's rocks and waters by 0.4 per mil ($\Delta^{17}O = 0.04\%$). Approximately 60% of this deficit is another manifestation of the Dole effect, 30% balances an excess in ^{17}O carried by $O(^1D)$ in the stratosphere caused by the mass independent fractionation associated with ozone formation, and 10% is due to evaporation and transpiration (evapotranspiration) of the water that provides the oxygen produced by photosynthesis (Young et al. 2014).

The ^{17}O deficit in dioxygen in air depends on the rate of O_2 turnover by photosynthesis, the concentration of O_2 determined by the balance between photosynthesis and respiration, and the concentration of CO_2. Carbon dioxide enters the budget because $O(^1D)$ transfers excess ^{17}O imparted by ozone photolysis to CO_2. Carbon dioxide mixes from the stratosphere to the troposphere where it exchanges oxygen isotopes with water at ground level. Water is in effect an infinite reservoir of oxygen so that exchange between CO_2 and H_2O creates a sink for ^{17}O. The greater the concentration of CO_2, the more ^{17}O is lost from the atmosphere.

Because biological processing of oxygen removes the stratospheric-induced ^{17}O deficit caused by the flux of CO_2 from the stratosphere to ground level, differences in $\Delta^{17}O$ in atmospheric O_2 have been used as a monitor of gross primary productivity (Luz et al. 1999; Blunier et al. 2002). Disambiguating the effects of changing CO_2 concentration and biological productivity is a challenge (Young et al. 2014). $\Delta^{17}O$ values in Neoproterozoic sulfates in the so-called cap carbonates have been used as evidence for high CO_2 concentrations in the waning stages of the Neoproterozoic global glaciation (snowball Earth) (Bao et al. 2008).

The concentration of the doubly substituted dioxygen isotopologue $^{18}O^{18}O$ in the atmosphere can be used as another measure of biological productivity. This is because the abundance of $^{18}O^{18}O$ is driven toward thermodynamic equilibrium by isotope exchange reactions with atomic oxygen in air, causing an excess of $^{18}O^{18}O$ relative to the purely random distribution, but this isotopic species is depleted by photosynthesis (Yeung et al. 2015).

Biological Utilization and Toxicity

Free dioxygen in Earth's atmosphere is a consequence of photosynthesis and thus is an important biosignature in the search for extraterrestrial life. Consumption of oxygen by aerobic respiration provides the energy for all higher organisms.

Summary

Oxygen is the third most abundant element in the solar system and the most abundant element synthesized in stars. The electronegativity of oxygen influences the size of a planet's metallic core and is a key ingredient for the diversity of life. The three stable isotopes of oxygen are powerful tracers of cosmochemical, geochemical, and biogeochemical processes.

Oxygen Isotopes

Hisayoshi Yurimoto
Natural History Sciences, Hokkaido University, Sapporo, Japan

Definition

Natural oxygen is a mixture of three stable isotopes ^{16}O (99.762%), ^{17}O (0.038%), and ^{18}O (0.200%). Isotope ratios of $^{17}O/^{16}O$ and $^{18}O/^{16}O$ normally vary in natural

materials by up to 5% and 10%, respectively, which are mass-dependent isotope fractionation. Mass-independent isotope fractionations also occur in oxygen for extraterrestrial materials and atmospheric molecules. These isotope fractionations are useful as tracers in geochemical and cosmochemical reactions and are applied to diverse geochemical topics as the origin of the solar system and the evolution of the atmosphere, hydrosphere, and lithosphere and paleoclimate.

Introduction

Oxygen is the third most abundant element in the universe and the most abundant element of the terrestrial planets. The presence of oxygen in both gaseous and solid phases makes oxygen isotopes (terrestrial relative abundances: $^{16}O = 99.762\%$, $^{17}O = 0.038\%$, and $^{18}O = 0.200\%$) important tracers of various fractionation processes in the solar nebula, which are essential for understanding the evolution of gaseous, liquid, and solid phases in geochemistry and cosmochemistry.

The ^{16}O is produced by helium burning mainly in massive stars (Clayton 2003). The synthesis of ^{16}O is not dependent on the existence of other elements heavier than He. ^{16}O is a primary nuclide.

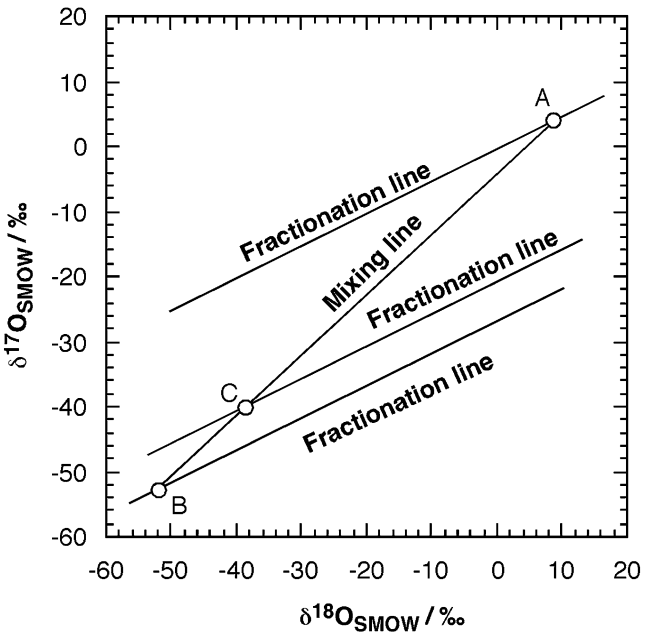
On the other hand, stellar nuclide synthesis of ^{17}O and ^{18}O need the prior existence of ^{16}O, ^{12}C, and ^{14}N. Therefore, these isotopes are secondary nuclides. ^{17}O is produced from H and ^{16}O by hydrogen burning in the CNO cycle of lower mass stars in their red giant phase or from novae (Clayton 2003). ^{17}O is produced from ^{14}N as a reactant by He burning in massive stars (Clayton 2003).

Nomenclature of Oxygen Isotope Ratios and Standardization of δ-Values

Oxygen isotope ratios are normally expressed in δ units, which are deviations in part per thousand (permil, ‰) in the $^{17}O/^{16}O$ and $^{18}O/^{16}O$ ratios from Standard Mean Ocean Water (SMOW; also referred to as VSMOW; Gröning et al. 2007) with $^{17}O/^{16}O = 0.0003829$ and $^{18}O/^{16}O = 0.0020052$ (McKeegan and Leshin 2001):

$$\delta^{17,18}O_{SMOW} = \left[\left(^{17,18}O/^{16}O\right)_{sample} / \left(^{17,18}O/^{16}O\right)_{SMOW} - 1\right] \times 1000.$$

On a three-isotope diagram of $\delta^{18}O$ versus $\delta^{17}O$, compositions of nearly all terrestrial samples plot along a single line of slope 0.52 called the terrestrial fractionation (TF) line. This line reflects mass-dependent fractionation from a single homogeneous source during chemical and physical processes that results from differences in the masses of the oxygen isotopes (Fig. 1). The slope 0.52 results from changes in $^{17}O/^{16}O$ that are nearly half those in $^{18}O/^{16}O$ because of isotopic mass differences; the precise value of the slope depends on the nature of the isotopic species or isotopologues (e.g., Thiemens 2006). This is a mass fractionation line. In contrast, O-isotopic compositions of the vast majority of extraterrestrial samples, including primitive (chondrites) and differentiated (achondrites) meteorites, deviate from the terrestrial fractionation line, reflecting mass-independent fractionation processes. The deviation from the terrestrial fractionation line is commonly expressed as:



Oxygen Isotopes, Fig. 1 Relationship between mass-dependent isotope fractionation lines and mixing lines on the three-oxygen isotope diagram. Point C is a result of mixing between points A and B

$$\Delta^{17}O_{SMOW} = \delta^{17}O_{SMOW} - 0.52\,\delta^{18}O_{SMOW}.$$

For carbonate minerals, the reporting standard may be PDB (belemnite from the Peedee formation, South Carolina) or VPDB. The relation between scales of PDB and SMOW is (Coplen et al. 1983):

$$\delta^{18}O_{SMOW} = 1.03091\,\delta^{18}O_{PDB} + 30.91.$$

Analytical Methods

Conventionally, oxygen isotope ratios are measured on CO_2 or O_2 gas by isotope ratio mass spectrometry (IRMS; Nier 1940). A dual inlet system is used for precise determination of

isotope ratios. Recently a continuous flow inlet system coupled with gas chromatograph (CF-IRMS) was developed for rapid and small sample analyses (Komatsu et al. 2008). For in situ small quantity sampling from minerals, a laser ablation method with fluorination technique is useful to measure O isotopes (Young et al. 1998).

An alternative approach for measuring O isotopes of gas molecules is by laser absorption spectroscopy. Cavity ring-down spectroscopy and off-axis spectroscopy have made major advances toward precise compound-specific measurements of three O isotopes (Johnson et al. 2011; Steig et al. 2014). The precision of oxygen isotope ratios measured by this method becomes competitive with conventional IRMS methods.

Secondary ion mass spectroscopy (SIMS) has been applied to in situ microanalysis of three oxygen isotopes of minerals (Yurimoto et al. 1994). The spatial resolution becomes down to 1 μm with precision of several permil (Yurimoto et al. 1998) and 8 μm with precision of smaller than one permil (Yurimoto et al. 2011). Oxygen isotope ratio imaging is available by SIMS with micrometer resolution and several permil in precision (Yurimoto et al. 2003).

Mass-Dependent Fractionation Relations and Geothermometers

Isotope fractionation between phases depends on differences in the thermodynamic free energies of the isotopically substituted compounds. Equilibrium fractionation factor, α, of oxygen isotopes between two phases (X and Y) is expressed as:

$$\alpha_{X-Y} = \left({}^{18}\mathrm{O}/{}^{16}\mathrm{O}\right)_X / \left({}^{18}\mathrm{O}/{}^{16}\mathrm{O}\right)_Y = \left[1 + \left(\delta^{18}\mathrm{O}_{\mathrm{SMOW}}\right)_X/1000\right] / \left[1 + \left(\delta^{18}\mathrm{O}_{\mathrm{SMOW}}\right)_Y/1000\right].$$

Fractionation factors often are reported as:

$$1000 \ln \alpha_{X-Y} \approx 1000\,(\alpha_{X-Y} - 1) \approx \left(\delta^{18}\mathrm{O}_{\mathrm{SMOW}}\right)_X - \left(\delta^{18}\mathrm{O}_{\mathrm{SMOW}}\right)_Y$$

when the isotope ratios of samples are similar to that of the reference.

The isotopic fractionation between phases generally decreases with increasing temperature, with 1000 ln α_{X-Y} approaching 0 at high temperature. This relation is typically expressed as:

$$1000 \ln \alpha_{X-Y} = A\left(10^6 T^{-2}\right) - B$$

where A and B are constants, and T is temperature in K. Temperature dependences of mineral–water and mineral–mineral ^{18}O fractionation factors serve as geothermometers virtually independent of pressure (Fig. 2).

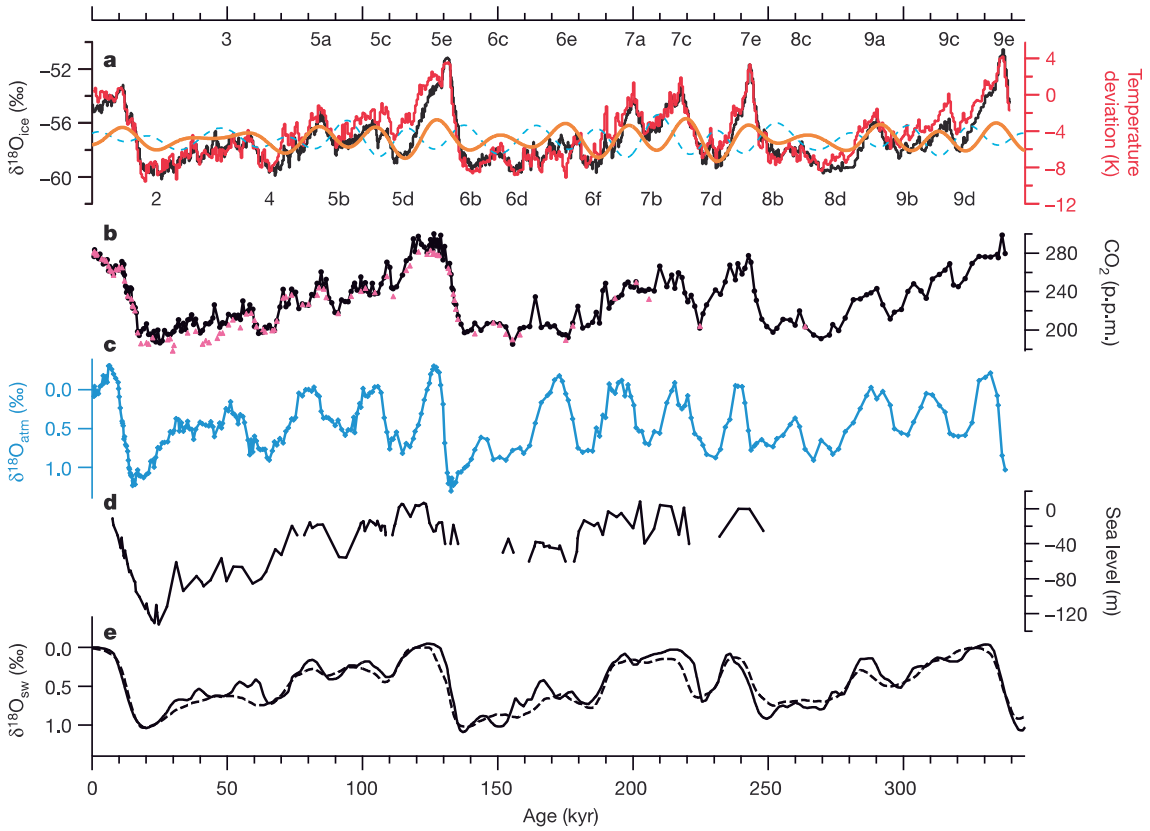
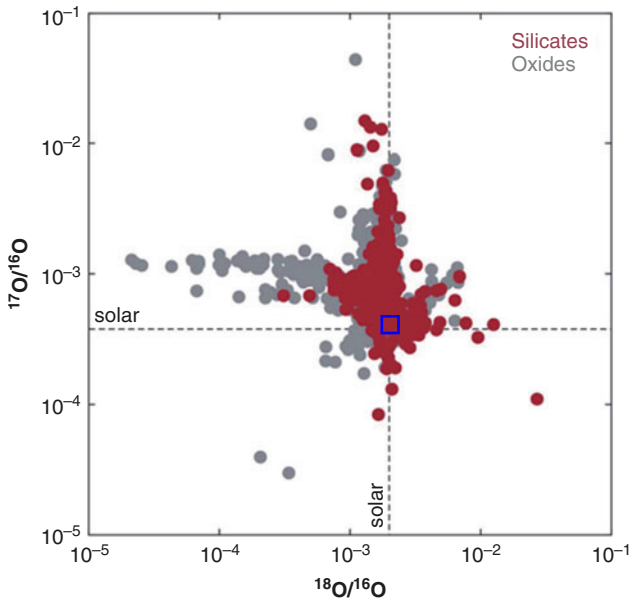
Global climate results from heat transfer between the equator and the polar areas induced by the unequal solar energy flux to the Earth. This heat transfer drives global circulation of water, i.e., evaporation of ocean water, convection, and condensation/precipitation of water vapor. As a result, oxygen isotope fractionations record thermodynamic processes in the atmosphere–ice sheet–ocean system. Therefore, oxygen isotope measurements of ice sheet and marine sediments yield global climate records (Fig. 3). Chronological variations of oxygen isotope ratios correlate between ice sheets, atmosphere, and seawater over the past 360,000 years, supporting the Milankovitch theory for glacial–interglacial cycles (Hays et al. 1976).

Oxygen Isotope Distribution of the Galaxy and the Solar System

Oxygen isotope composition of universe changes with time by stellar nucleosynthesis known as galactic chemical evolution (Tinsley and Cameron 1974; Clayton 2003). Part of this oxygen isotope evolution of the galaxy is observed in presolar grains surviving in extraterrestrial materials, e.g., a comet, interplanetary dust particles, and chondrites (Zinner 2014). The oxygen isotope ratios distribute from 2×10^{-5} to 5×10^{-2} for $^{17}O/^{16}O$ (−950 to 130000 ‰ for $\delta^{17}O_{SMOW}$) and from 2×10^{-5} to 2×10^{-2} for $^{18}O/^{16}O$ (−990 to 9000‰ for $\delta^{18}O_{SMOW}$). The distribution is far larger than those observed among materials formed in the solar system



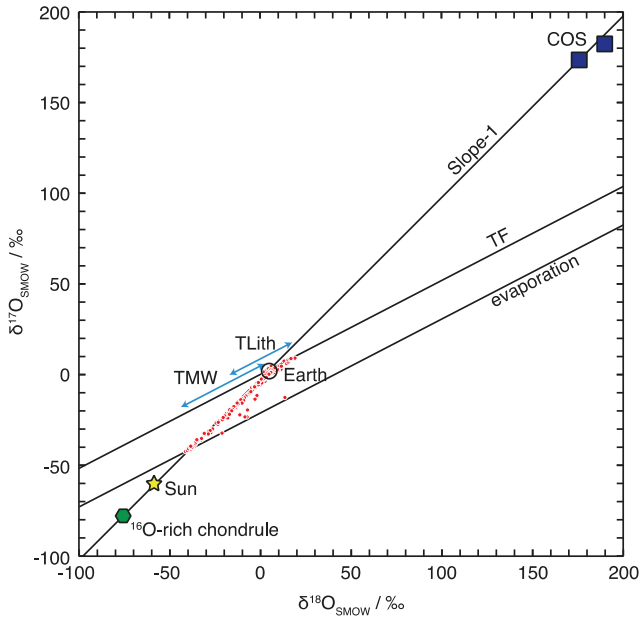
Oxygen Isotopes, Fig. 3 Chronological variation of oxygen isotopes recording global climate change (from Kawamura et al. 2007). (**a**) $\delta^{18}O$ of ice core of Dome Fuji, Antarctica (black), and temperature deviation (red), (**b**) atmospheric CO_2 concentration from the Dome Fuji core, (**c**) $\delta^{18}O$ of atmospheric O_2 from the Dome Fuji core, (**d**) sea level change, and (**e**) $\delta^{18}O$ of seawater



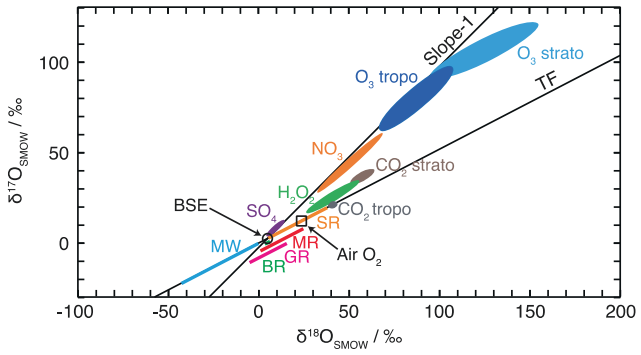
Oxygen Isotopes, Fig. 4 Oxygen isotope distribution in the galaxy. Red circle, presolar silicate grains; gray circle, presolar oxide grains (from Floss and Haenecour 2016). Oxygen isotope ratios reported from materials formed in the solar system are plotted in the blue square around the solar value, corresponding to Fig. 5

(Fig. 4). The diverse nucleosynthetic production of isotopes of elements including oxygen was mixed during formation of the solar system, but small isotopic heterogenic distribution between carbonaceous and noncarbonaceous meteorites has remained for oxygen with other elements due to incomplete mixing of their presolar feedstock (Warren 2011).

Mass-independent distribution of oxygen isotope in the solar system was found in 1973 in meteorites (Clayton et al. 1973). After the discovery, our meteorite collection has been largely developed mainly by new finds from Antarctica and African desert areas and new analytical techniques, mainly SIMS, applied to measure oxygen isotopes of the classic and new meteorite collections (Clayton 1993; Yurimoto et al. 2008). The oxygen isotope compositions in the solar system distribute essentially along slope-1 line on the three-oxygen isotope diagram (Fig. 5). The end members represent ~−100‰ for the ^{16}O-rich end and ~ + 200‰ for the ^{16}O-poor end. The oxygen isotope distribution in the solar system is quite different systematics from those in the galaxy, indicating that the oxygen isotope distribution in the solar system did not originate by nucleosynthesis but plausibly by photochemical processes (Yurimoto et al. 2007).



Oxygen Isotopes, Fig. 5 Oxygen isotope distribution in the solar system. Red circle, meteorites (from frontispiece of Rev. Mineral Geochem. 68, 2008); Earth, bulk silicate earth; Sun, solar value (McKeegan et al. 2011); COS, cosmic symplectite (Sakamoto et al. 2007); ^{16}O-rich chondrule, an extreme ^{16}O-rich chondrule (Kobayashi et al. 2003); TLith, terrestrial lithosphere which distributes on the TF line (Farquhar and Johnston 2008); TMW, terrestrial metric water which distributes on the TF line (Farquhar and Johnston 2008); TF, terrestrial fractionation line; Slope-1, slope one line; evaporation, fractionation line by evaporation and condensation



Oxygen Isotopes, Fig. 6 Oxygen isotope distribution on the Earth (Data from Hoefs 2004; Thiemens 2006). Circle, bulk silicate earth (BSE); square, atmospheric oxygen (Air O_2); BR, basaltic rock which distributes on the TF (terrestrial fractionation) line; GR, granitic rock which distributes on the TF line; MR, metamorphic rock which distributes on the TF line; SR, sedimentary rock; MW, meteoric water; CO_2 tropo, tropospheric CO_2; CO_2 strato, stratospheric CO_2; O_3 tropo, tropospheric O_3; O_3 strato, stratospheric O_3. Other symbols correspond to atmospheric molecules indicated. Note that plots of BR, GR, and MR are shifted downward in order to avoid overlap their lines

Oxygen Isotope Distribution of the Earth

Oxygen isotopes on the Earth basically distribute under control of thermodynamic processes along mass-dependent fractionation line, i.e., terrestrial mass fractionation line, on the three-oxygen isotope diagram (Fig. 6). Some atmospheric compounds exhibit a mass independently distribution as a result of photochemical processes.

Ocean water is the oxygen isotope standard (SMOW) and hence by definition has $\delta^{17,18}O_{SMOW} = 0‰$, but small variations in seawater of $\delta^{18}O_{SMOW}$ (±1‰) occur and correlate with salinity variations associated with evaporation or precipitation and mixing with meteoritic water. Meteoritic water is ultimately derived from the evaporation of seawater and hence has negative $\delta^{18}O_{SMOW}$ values as a consequence of Rayleigh distillation processes which deplete meteoritic water in ^{18}O (Gat and Gonfiantini 1981). The oxygen isotope changes correlate with mean annual temperature and with hydrogen isotopes, which correlation is termed the meteoric water line (MWL).

The average composition of the Earth is inferred $\delta^{18}O_{SMOW} = 5.7 \pm 0.5‰$ by a narrow ^{18}O range of mid-ocean ridge basalts (MORB) and fresh ultramafic rocks from upper mantle, but small variations in oxygen isotopes in mantle rocks are observed resulting of subduction and recycling surface materials to the mantle. Fresh igneous rocks have similar $\delta^{18}O$ values to mid-ocean ridge basalts (MORB) (Eiler 2001). Compared to basalts, granitic rocks show large $\delta^{18}O$ variation because of enhanced potential for hydrothermal alterations and crustal contaminations.

Original oxygen isotopic compositions of authigenic minerals in sedimentary rocks reflect the isotope fractionation between the mineral and the water which the mineral formed. Therefore, they are valuable paleoenvironmental indicators, recording temperature and water $\delta^{18}O$ (Urey 1948). This is particularly useful for carbonate sediments. $\delta^{18}O$ values are generally between −3 and +1‰ for aragonite and calcite, equivalent to paleothermometers of roughly 10–25 °C (Hudson and Anderson 1989).

The conventional $\delta^{18}O$ paleothermometers often need to assume the ^{18}O ratio in water to calculate paleotemperatures. This assumption is not necessary if clumped isotopes are used for paleothermometers. The clumped isotopes are heavy isotopes that are bonded to other heavy isotopes. The clumped-isotope thermometer of carbonate is defined as ^{13}C–^{18}O order/disorder of the crystal lattice, i.e., an intra-mineral isotope thermometer basing on the temperature dependence of the clumping of ^{13}C and ^{18}O into bonds within the carbonate mineral lattice that is independent of the isotopic composition of the water (Ghosh et al. 2006; Eiler 2007).

Oxygen isotopic compositions of metamorphic rocks reflect fluid–rock interaction during metamorphism. Thus the $\delta^{18}O$ of metamorphic rocks distribute widely over those of granitic rock and sedimentary rock.

In the atmosphere, mass-dependent fractionation behavior for oxygen isotopes is observed between meteoric

water molecular oxygen and tropospheric carbon dioxide. On the other hand, mass-independent fractionation effects are observed in atmospheric ozone, nitrate, sulfate, carbon monoxide, hydrogen peroxide, nitrogen dioxide, and, to lesser extent, molecular oxide and carbon dioxide (Thiemens 2006; Farquhar and Johnston 2008).

Summary

Natural oxygen is a mixture of three stable isotopes ^{16}O, ^{17}O, and ^{18}O. Mass-dependent and mass-independent isotope fractionations are observed in nature. Oxygen isotopes are useful tracers to determine the origin of natural materials and molecule, and cosmochemical and geochemical processes.

Definition

The stratosphere is the atmospheric layer comprised between 8–18 km for at its lowest altitudes and 40–60 km at its highest altitudes, which correspond more or less to the stratospheric ozone layer thickness. In this part of the atmosphere, intense UV radiation from the Sun fuels an active and energetic photochemical reactor leading to the formation of two important by-products: the ozone molecule (O_3), an oxygen allotrope, and heat that mostly originates from absorption of UV radiation by ozone. While heat causes a strong vertical stability of the air mass in the stratosphere (stratified atmosphere), large concentrations of ozone form a UV-protective shield allowing the development of life on the Earth's surface. The intense UV radiations combined with the ozone concentration generate a distinct stratospheric chemistry where nitrogen, oxygen, and halogen compounds are highly coupled in cycles that maintain the chemical stability of this UV-protective atmospheric layer (UVs break down atmospheric molecular oxygen, leading to the formation of ozone that better absorb UV radiations than the parent molecules). In the industrialized era, emissions of halogenated compounds have destabilized this fragile chemical stability by creating "ozone-killer" molecules, reducing the thickness of the ozone layer and allowing harmful UV radiations to reach the ground. The stratosphere is also a key atmospheric compartment for the stability of the radiative budget of the Earth and thus its climate. The presence of tiny droplets of sulfuric acid in the stratosphere acts as an aerosol layer that reflects incoming solar radiation, thus cooling the Earth's ground temperature; it also plays a significant role in the ozone budget by providing surfaces where heterogeneous chemistry can generate ozone-destroying radical species. This acid cloud layer is exacerbated during powerful volcanic eruptions where megatons of sulfur are directly injected into the stratosphere.

Ozone Stratospheric Chemistry

Ozone

This chapter introduces the main concepts about the stratospheric ozone chemistry and budget. We start by recalling briefly the history of ozone research. Then, we describe the main features of ozone distribution. The next section reviews the basic chemistry of stratospheric ozone. An analysis of the phenomenon of the so-called "ozone hole" is presented in the fourth section. The last section is devoted to the overall perturbation of stratospheric ozone by the emissions of ozone-destroying substances and the interactions with climate change.

Historical Perspectives and Background

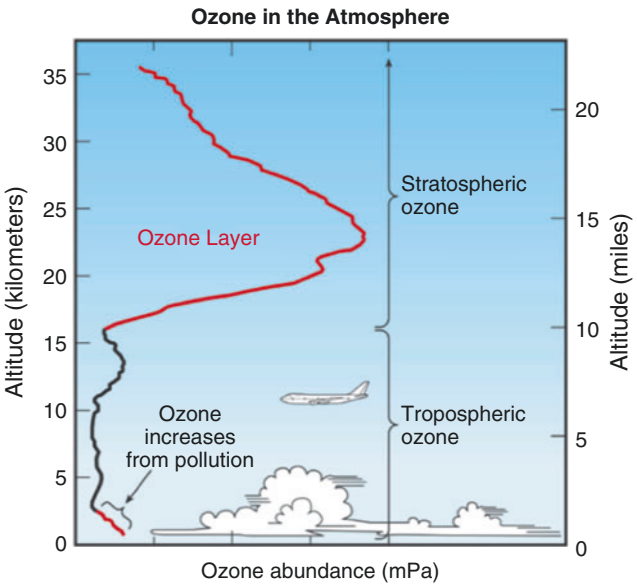
Ozone (trioxygen O_3) was first identified at Basel in 1840 by German chemist C.F. Schöenbein from its pronounced smell following electrical discharges in the air (Schöenbein 1840). The same particular smell, characteristic of ozone, can be found near photocopy machines when it has been used intensively. Schöenbein named this gas "ozone" from the Greek word "ozein" meaning "to smell." The chemical nature of ozone was determined from extensive laboratory studies

initiated by M. De la Rive and C. Marignac in Geneva in 1845. A. Houzeau then detected ozone in the atmosphere in 1858 after performing the first atmospheric measurements at Rouen, France. French chemist Albert Levy conducted systematic measurements of atmospheric ozone in Paris during 30 years in the late nineteenth century. A range of scientists investigated the absorption radiative properties of ozone. The important finding was that the quasi-absence of solar UV radiation (below about 300 nm) at the surface must have been due to absorption of UV by atmospheric ozone, notably the Hartley band (Cornu 1879; Hartley 1881). Using ozone absorption properties, French physicists H. Buisson and C. Fabry then designed a spectrograph and made the first measurements of the thickness of the ozone layer (i.e., ozone column corresponding to the vertically integrated ozone concentration) in 1913. Based on Buisson and Fabry spectrograph, the British scientist G.M.B. Dobson developed in Oxford, UK, in 1920 a spectrophotometer, which is still used nowadays to measure the ozone column (Dobson and Harrison 1926). The first successful attempt to measure the vertical profile of ozone was led by Swiss scientist F.W.P. Götz at the start of the 1930s (Götz et al. 1934). Later, German physicists V. H. Regener started making measurements from balloons (Regener 1964). These height-resolved ozone observations showed that the ozone concentration was peaking in the lower stratosphere, at 20–25 km. Since the late 1970s, the global distribution of atmospheric ozone has been extensively monitored with instruments on board satellites.

Although in relatively low concentration of a few molecules per million air molecules, atmospheric ozone is essential to sustaining life on the Earth's surface. Indeed, by absorbing solar radiation between 240 and 320 nm, it shields living organisms including humans from the very harmful ultraviolet radiation UV-B. About 90% of the ozone resides in the stratosphere, the region that extends from the tropopause, whose altitude ranges from 8 km at the poles to 18 km in the tropics, to the stratopause located at about 50 km altitude (Brasseur and Solomon 2005). Stratospheric ozone is communally referred as the "ozone layer." The remaining 10% of the ozone is found in the troposphere, the region that extends from the surface to the tropopause. Tropospheric ozone is a major pollutant near the surface. Ozone also reacts with a number of other gases and is the main source of the hydroxyl radical, OH, that is responsible for the oxidation and removal of most trace gases including pollutants in the atmosphere. Finally, ozone absorbs not only solar radiation but also outgoing infrared radiation and so plays a significant and complex role in the Earth's energy budget. For all these reasons, ozone is considered as one of the key species for the chemistry and radiative balance of the atmosphere (Jacob 1999; Brasseur and Solomon 2005).

Unlike the major atmospheric constituents, such as nitrogen, molecular oxygen, carbon dioxide, or methane, the ozone vertical profile does not exhibit a maximum at the Earth's surface and then a uniform decrease with height. The ozone concentration is low in the troposphere except near the surface where it is formed in air polluted by human activities. Then its concentration increases sharply from the tropopause to reach a maximum in the lower stratosphere, between 15 and 20 km at high latitude winter and between 25 and 30 km in the tropics (Fig. 1). Above 30 km, the ozone concentration decreases rapidly with height. Its particular vertical distribution results from the existence of a strong source of ozone in the stratosphere and not at ground level.

The absorption efficiency of solar ultraviolet radiation (240–320 nm) during its passage through the atmosphere depends on the total number of ozone molecules along the path of the sunrays. This represents the total amount of ozone in a column of air extending from the surface to the top of the atmosphere. It is calculated by integrating vertically the altitude-dependent local concentration and is commonly referred to as the thickness of the ozone layer or ozone column, often expressed in Dobson unit (Schwartz and Warneck 1995). The bulk of the ozone column is found in the lower stratosphere, between 15 and 30 km (see Fig. 1). The ozone column varies from region to region and season



Ozone and Stratospheric Chemistry, Fig. 1 Typical vertical profile of ozone concentration (in ozone partial pressure in mPa). About 90% of ozone resides in the stratosphere and is commonly referred as the stratospheric ozone layer. The vertical extent or thickness of the layer varies from region to region and with season. Note that in the troposphere, notably near the surface, ozone is also produced by the oxidation of hydrocarbons in the presence of high levels of nitrogen oxides; this so-called "smog" photochemistry is typical of polluted air and explained the enhanced levels of ozone found near the ground in some areas (Hegglin et al. 2014)

over the globe. On average, the total column ozone is about 300 DU, which is equivalent to a 3 mm ozone-pure thick layer if all the ozone molecules were brought down to Earth's surface and uniformly distributed over the globe (Brasseur and Solomon 2005).

Chapman Cycle: Ozone Chemistry in a Pure Oxygen Atmosphere

In 1930, the physicist Sydney Chapman proposed a theory that considers the balance between the formation and destruction of ozone from oxygen radicals only (Chapman 1930). It lays the foundation of stratospheric ozone photochemistry. The sequence of selected reactions constitutes a cycle that allows developing a simple theory of stratospheric ozone in a pure oxygen atmosphere (Bekki and Lefevre 2009).

The formation of stratospheric ozone occurs naturally by chemical reactions involving solar ultraviolet radiation (sunlight) and oxygen molecules, which make up about 21% of the atmosphere. The production of ozone is a two-step mechanism:

$$O_2 + h\nu \rightarrow O + O;\ \lambda < 242\ \text{nm} \quad J_1 \qquad \text{(R1)}$$

$$O + O_2 \rightarrow O_3^* + M \rightarrow O_3 + M^* \quad k_2 \qquad \text{(R2)}$$

The photolysis of molecular oxygen (R1) occurs only for photons at wavelengths below 242 nm, which explains why this source is mostly present in the middle and upper atmosphere. Ozone is then produced by the recombination of oxygen atoms with molecular oxygen following the three-body reaction (R2) where M, a third body (nitrogen (N_2) or oxygen (O_2)), acts as a stabilizing partner, absorbing the excess of energy produced during the formation of the metastable ozone, O_3^* (Lin and Leu 1982). This reaction is very fast and requires only a fraction of second in the stratosphere. It also causes a release of 24 kcal of heat per mole of ozone formed. This exothermic reaction explains the positive gradient temperature observed in the stratosphere.

Like molecular oxygen, ozone is a strong absorber of solar radiation and can dissociate:

$$O_3 + h\nu \rightarrow O_2 + O \quad J_3 \qquad \text{(R3)}$$

At wavelengths above 310 nm, the photolysis of ozone leads to the direct production of $O(^3P)$, referred as O to simplify the notations. At wavelengths below about 310 nm, the photolysis of ozone produces oxygen atom in the excited state $O(^1D)$, a very reactive form of oxygen atom that decays to $O(^3P)$, the ground state of oxygen atom. The oxygen atoms excited $O(^1D)$ produced by R3 is almost instantly deactivated back to its fundamental level $O(^3P)$ by collision. Although this channel is not treated explicitly here, J_3 corresponds to the total photolysis rate of ozone including the excited state channel.

Finally, ozone and atomic oxygen are destroyed simultaneously by the reaction:

$$O + O_3 \rightarrow 2\ O_2 \quad k_4 \qquad \text{(R4)}$$

It is possible to establish the balance of ozone and atomic oxygen in the stratosphere from the four reactions above, considering only the oxygen species. Ignoring transport processes, the continuity equations (i.e., the time-dependent concentration change due to the sum of production and destruction terms for the species considered) describing the evolution of the O and O_3 concentration are expressed by:

$$\frac{d[O]}{dt} = 2J_1[O_2] + J_3[O_3] - k_2[O_2][O][M] - k_4[O_3][O] \qquad (1)$$

$$\frac{d[O_3]}{dt} = k_2[O][O_2][M] - k_4[O][O_3] - J_3[O_3] \qquad (2)$$

It is worth pointing out that the photolysis of ozone (R3) does not lead to a net loss of it. Indeed, the produced oxygen atom reacts immediately with O_2 to reform ozone via reaction R2.

The rapid exchange between O_3 and O operates via R2 and R3 throughout the troposphere and the stratosphere. Because of its short lifetime, the oxygen atom O is always in photochemical equilibrium with ozone and molecular oxygen. The assumption of steady-state for O (i.e., $d[O]/dt = 0$ meaning production rate = destruction rate) allows us to derive the abundance ratio between O and O_3 using Eq. 1,

$$\frac{[O]}{[O_3]} = \frac{\left(2J_1\frac{[O_2]}{[O_3]} + J_3\right)}{k_2[O_2][M] + k_4[O_3]} \simeq \frac{J_3}{k_2[O_2][M]} \qquad (3)$$

The abundance ratio between O and O_3 can be simplified because the photolysis of O_3 (J_3) is so much faster than photolysis of O_2 (i.e., $J_3 >> 2J_1[O_2]/[O_3]$) and the rate of (R4) is several orders of magnitude slower than the rate of (R2).

The relative abundance of O compared to O_3 increases rapidly with altitude. It is, however, only above about 60 km that the ratio $[O]/[O_3]$ becomes greater than 1. Below 60 km, the concentration of O_3 is greater than that of O by several orders of magnitude. In these circumstances, it is useful to combine O and O_3 to define a hypothetical species O_x, called the odd oxygen family, with $O_x = O + O_3$.

Since $[O] << [O_3]$ in the troposphere and stratosphere, $[O_x] \sim [O_3]$ and the evolution equation of O_3 can simply be derived by summing Eqs. 1 and 2 in conjunction with Eq. 3:

$$\frac{d[O_3]}{dt} + \frac{d[O]}{dt} \approx \frac{d[O_3]}{dt} = 2J_1[O_2] - 2k_4[O][O_3] = 2\left(J_1[O_2] - \frac{k_4 J_3 [O_3]^2}{k_2[O_2][M]}\right) \quad (4)$$

The steady-state ozone concentration ($\frac{d[O_3]}{dt} = 0$) can then be derived from Eq. 4,

$$[O_3] = [O_2]\left(\frac{k_2[M]J_1}{k_4 J_3}\right)^{\frac{1}{2}} = x_{O_2}[M]\left(\frac{k_2 J_1[M]}{k_4 J_3}\right)^{\frac{1}{2}} \text{ with } x_{O_2} = \frac{[O_2]}{[M]} \quad (5)$$

The rate of molecular oxygen photolysis (i.e., J_1) increases with altitude, while $[M]$ decreases at the same time. As a result, the ozone concentration profile calculated from Eq. 5 shows a maximum in the stratosphere, which is consistent with observations.

Global Stratospheric Ozone Chemistry

Although, the Chapman Theory gives approximately the correct altitude distribution, Eq. 5 overestimates observed ozone concentrations by a factor of 2. Note that transport only redistribute the ozone spatially, it is neither a sink nor a source of ozone. Indeed, global mass balance budgets of ozone have shown that loss processes do not balance the production rate, so there should be missing loss processes not taken into account in the chapman model (Johnston 1975). This discrepancy is the most compelling argument to expend the chapman reaction scheme, involving other trace constituents that act as ozone destroyer, notably hydrogen radicals (Bates and Nicolet 1950; Hampson 1964), nitrogen oxides (Crutzen 1970; Johnston 1971), and chlorine radicals (Stolarski and Cicerone 1974; Molina and Rowland 1987). Note that P.J. Crutzen, M. Molina, and F.S. Rowland were awarded the Nobel Prize in 1995 "*for their work in atmospheric chemistry, particularly concerning the formation and decomposition of ozone.*"

These radicals destroy ozone via chemical catalytic cycles. The simplest catalytic cycles are of the form:

Cycle X

$$X + O_3 \rightarrow XO + O_2 \quad k_5 \quad (R5)$$

$$XO + O \rightarrow X + O_2 \quad k_6 \quad (R6)$$

$$\text{net} : O + O_3 \rightarrow 2\,O_2$$

where X is the minor constituent that is the catalyst of the cycle of reactions.

The net overall reaction, reflecting the simultaneous disappearance of odd oxygen pairs, is equivalent to the reaction R4. However, the reactions involved in the cycle above are faster and are initiated by a catalyst, which, by definition, is not consumed in the process. One can then understand how a radical X with a concentration much lower than that of ozone (in practice, up to a million times less) can destroy a large number of O_3 molecules until the radical is converted into less reactive molecules. The rate of destruction of O_3 by the cycle X is determined by the rate of reaction XO + O. Indeed, it is much slower that the reaction X + O_3, which reform XO very quickly. The destruction rate of ozone by the cycle above can be written as:

$$\frac{d[O_x]}{dt} = -2k_6[XO][O] \quad (6)$$

where k_6 is the rate of the reaction between XO and O.

The factor 2 stems from the fact that two molecules of O_3 are destroyed at each pass through the cycle. In the stratosphere, X corresponds to H, OH, NO, Cl, or Br. The relative importance of these species depends on their concentrations and the reaction rates of their specific catalytic cycles. Whatever the catalyst X involved, it can be noted that the general cycle above requires the presence of atomic oxygen O. Therefore, this type of process is very effective above 30 km altitude, when the concentration of O becomes sufficient. At lower altitudes, the destruction of odd oxygen also occurs through other types of catalytic cycles, which do not require atomic oxygen. For example, one of the most effective catalytic cycles in the lower stratosphere involves a coupling bromine and chlorine radicals.

The ozone-destroying radicals mainly originate from the stratospheric oxidation of source gases emitted at the Earth's surface. Most trace gases are quickly destroyed in the troposphere by oxidation and/or dissolution in clouds. However, certain gases have sufficiently long lifetimes in the troposphere (i.e., removed very slowly in the troposphere) for them to be transported in significant quantities into the stratosphere through air motions. The sources of stratospheric ozone-destroying hydrogen radicals (OH, HO_2) are water vapor and methane emitted at the surface. The source of stratospheric nitrogen oxides radicals (NO, NO_2) is the oxidation of nitrous oxide (N_2O) emitted at ground level by biological processes or linked to human activities. The only significant natural source of stratospheric chlorine is the oxidation of a chlorinated organic compound, methyl chloride CH_3Cl, which is emitted by the oceans. On the top of this natural source, there have been industrial sources of chlorinated organic compounds, typically chlorofluorocarbons (CFCs), for over 50 years. Almost all of these industrial compounds emitted at the surface enter the stratosphere because their lack of chemical reactivity results in very long

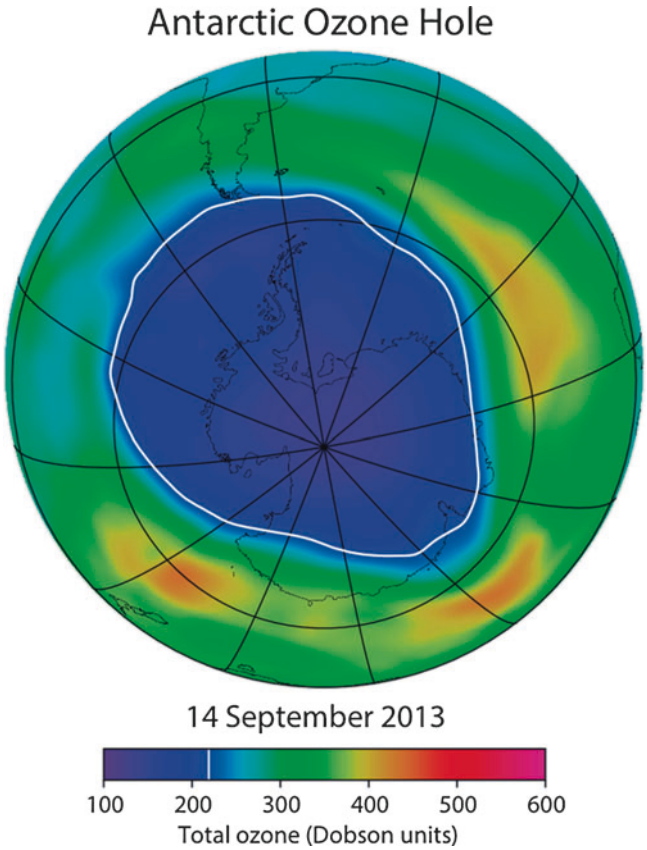
lifetimes in the troposphere, up to 100 years (Brasseur and Solomon 2005).

Polar Ozone

The total column ozone has been regularly measured for over half a century in the polar regions. In Antarctica, the observations until the late 1970s show an austral spring maximum, with an average over the month of October of about 350 Dobson Units (DU). From the early 1980s, a rapid and continuous decline in total column ozone is observed every spring above Antarctica. The Antarctic monthly mean thickness of the ozone layer in October is currently close to 200 DU. Local minima below even 100 DU have sometimes been seen since the late 1990s, which represents a decrease of nearly 70% of the total ozone column compared with measurements taken twenty years earlier. The analysis of individual vertical ozone profiles (Fig. 1) shows a destruction even more pronounced with often an almost complete disappearance of ozone in the lower polar stratosphere, between around 15 and 20 km (Brasseur and Solomon 2005).

Satellite measurements have revealed the geographical extension of this phenomenon, known as the "ozone hole," with the reduction in ozone taking place over a wide circular area centered on the South Pole (Fig. 2). This area indicates the polar vortex, an enormous ring of circling fast-moving air. Although of large magnitude, it is important to note that this now recurring feature of the southern Antarctic spring remains a seasonal phenomenon. The ozone destruction indeed starts at the end of August, when sunlight comes back on the edge of the polar vortex after the winter polar night. The rate of ozone decrease peaks in September and minimum values for total column are usually reached in October. Antarctic ozone columns remain low in November. Then, they quickly recover values close to 1970s climatology at the end of December.

When the ozone hole was discovered by a team from the British Antarctic Survey in 1987 (Farman et al. 1985), a rise in atmospheric chlorine content was proposed in an attempt to explain a phenomenon that, at that time, was totally unexpected. Indeed, as a result of human activities, the atmospheric concentration of chlorine has grown almost exponentially since the mid-twentieth century, resulting in 5-fold increase compared to preindustrial values. However, the large spring polar ozone depletion cannot be accounted for by the catalytic cycles of destruction discussed previously because they are not effective enough in the lower stratosphere due to the lack of atomic oxygen. An unusual chemistry operates in the polar regions, during winter and spring, that makes ozone very sensitive to the atmospheric chlorine content. This particular chemistry is linked to the existence of chemical reactions occurring on the surface of clouds that form during winter and beginning of spring in the Antarctic lower stratosphere. This heterogeneous chemistry on polar



Ozone and Stratospheric Chemistry, Fig. 2 Total ozone values are for high southern latitudes on 14 September 2013 as measured by a satellite instrument. The *dark blue* and *purple* regions over the Antarctic continent show the severe ozone depletion or "ozone hole" now found during every austral spring. The ozone hole area is usually defined as the geographical area within the 220-DU contour (see *white line*) on total ozone maps (Hegglin et al., 2014)

stratospheric clouds converts chlorine compounds, communally called reservoir species (HCl, $ClONO_2$), into ozone-destroying chlorine radicals such as the chlorine monoxide (ClO) (McElroy et al. 1986; Solomon et al. 1986). The resulting high levels of chlorine radicals greatly increase the probability that ClO reacts with itself to form a complex, the dimer Cl_2O_2 (Molina and Molina 1987). This three body reaction initiates a powerful ozone-destroying catalytic cycle in the winter polar regions that is responsible for 50–70% of the observed ozone destruction:

Cycle dimer ClO

$$\mathrm{ClO} + \mathrm{ClO} + M \rightarrow \mathrm{Cl_2O_2} + M \quad k_7 \qquad \text{(R7)}$$

$$\mathrm{Cl_2O_2} + h\nu \rightarrow \mathrm{Cl} + \mathrm{ClO_2} \quad J_8 \qquad \text{(R8)}$$

$$\mathrm{ClO_2} + M \rightarrow \mathrm{Cl} + \mathrm{O_2} + M \quad k_9 \qquad \text{(R9)}$$

$$2(\mathrm{Cl} + \mathrm{O_3} \rightarrow \mathrm{ClO} + \mathrm{O_2}) \quad k_{10} \qquad \text{(R10)}$$

O

$$\text{net}: \ 2O_3 \rightarrow 3O_2$$

No atomic oxygen is involved in this cycle, and it needs little sunlight to operate effectively because the photolysis of the chlorine dimer (Cl_2O_2), its rate-limiting step, is fast. The chlorine dimer may also be thermally decomposed to give back ClO. However, at the low temperatures encountered in the polar vortex, the thermal decomposition of Cl_2O_2 can usually be neglected against its photolysis. Assuming quasi-steady state for Cl_2O_2 (destruction = production), the rate of ozone destruction can be expressed:

$$\frac{d[O_3]}{dt} = -2J_8[Cl_2O_2] = -2k_7[ClO][ClO][M] \qquad (7)$$

where the factor 2 is explained by the number of ozone molecules destroyed for each molecule of Cl_2O_2 photolyzed.

This expression shows that the rate of ozone destruction is proportional to the square of the concentration of chlorine. It is estimated that the levels of chlorine in the stratosphere have tripled since the 1960s, resulting in a factor 9 increase in polar ozone destruction rate by the ClO dimer cycle. This quadratic dependence largely explains the relatively sudden appearance of the phenomenon of the ozone hole. Due to the large increase in ClO levels, the cycle that couples ClO and BrO becomes important in the polar regions. This cycle is responsible for 30–50% of the overall seasonal polar ozone destruction (Bekki and Lefevre 2009). Along with the increase in atmospheric chlorine content, its role has also risen rapidly in recent decades as a result of increasing emissions of long-lived anthropogenic bromine-carrying compounds into the atmosphere. The destruction of polar ozone described above continues until the warming of the polar vortex during spring which leads to the evaporation of polar stratospheric clouds and hence disappearance of heterogeneous chemistry. Without it, chlorine radicals are converted back into reservoirs species during spring.

Past and Future Evolution of Ozone at Global Scale

The balance of stratospheric ozone is controlled by hydrogen, nitrogen, chlorine, and bromine radicals, whose levels in the stratosphere are themselves determined by the levels of gas sources emitted at ground level. The main gas sources are water vapor and methane (CH_4) for hydrogen compounds, nitrous oxide (N_2O) for nitrogen compounds, chlorofluorocarbons (CFCs) for chlorinated compounds, and methyl bromide (CH_3Br) and halons for brominated compounds. The most significant factor for the evolution of the ozone layer during the last century has been the considerable increase in industrial emissions of long-lived chlorine and bromine compounds. These gases are decomposed in the stratosphere under the influence of intense ultraviolet radiation, releasing the atoms of chlorine and bromine that destroys ozone through catalytic cycles. Because of the widespread use of chlorofluorocarbons in the industry, the stratospheric chlorine content has risen almost exponentially since the 1960s. As a result of growing emissions of halons, the stratospheric bromine content has also increased during the recent decades, although to a lesser extent than the chlorine content (Brasseur and Solomon 2005; WMO 2014).

The measurements unambiguously show that the change in atmospheric composition since the 1980s has led to a reduction in global stratospheric ozone. The decline in total column averaged over the year has reached about 3–4%, a value far greater than the 1% natural variations of ozone. The amplitude of long-term changes in the ozone layer varies with latitude and season. The greatest reduction in the total ozone column occurs at high latitudes in the southern hemisphere (−15 to −25% on annual averages) as a result of the Antarctic ozone hole that forms each austral spring. In the northern hemisphere, the decrease is also the most pronounced at high latitudes (−4% to −6% on annual averages) and again mostly by some ozone depletion inside the arctic polar vortex during winter and spring. The ozone decrease observed at mid-latitudes largely results from transport of ozone-depleted air from polar regions, as well as direct destruction of ozone by global catalytic cycles that do not require heterogeneous chemistry on polar stratospheric clouds, Finally, ozone has not changed significantly in tropical regions.

Concerns arising from the discovery of the Antarctic ozone hole in 1985 and from a possible alteration of the stratospheric ozone layer by human activities have led to a process of regulating the production and emission of long-lived compounds that are sources of chlorine and bromine in the stratosphere. The Montreal Protocol (1987) was negotiated and ratified by producing countries to conduct a concerted reduction in emissions that would ultimately lead to elimination of these products in the industry. The protocol has been amended several times since 1987 by adopting increasingly stringent measures and extending its scope to a larger number of chlorine and bromine-carrying gases. Developed countries have halted production of halons in 1994 and of the most dangerous chlorinated compounds (CFCs, methyl chloroform CH_3CCl_3, and carbon tetrachloride CCl_4) in 1996. In most applications, CFCs are now replaced by hydrochlorofluorocarbons (HCFCs) that have much shorter lifetimes in the lower atmosphere or hydrofluorocarbons (HFCs) that contain no more chlorine atoms. Implementation of the Montreal Protocol has led to a stabilization of total chlorine content since mid-1990s. The effectiveness of the Montreal Protocol is now well established with the atmospheric burden of CFC-11 (lifetime of about 45 years) declining since 1996, while that the burden of CFC-12 (lifetime of 100 years) has stabilized. Given these findings and the most probable scenarios of production, the most likely return to the atmospheric chlorine contents to levels comparable to those that preceded

the appearance of the ozone hole is not expected to occur before the middle of this century (WMO 2014).

The slow decay of stratospheric halogen levels should lead to a gradual reduction of the large polar ozone losses and an overall increase in the thickness of the ozone layer. It is worth pointing out that although the chlorine content by the end of the century is expected to be comparable to that of 1960s, before the appearance of the ozone hole, the atmospheric composition will nevertheless be very different from that of 1960s. Indeed, human activities since 1960s have led to an important increase in the concentrations of greenhouse gases such as CO_2, CH_4, and N_2O, which will carry on during this century. Although the magnitude of this future increase is now difficult to quantify, it is already well established that the growing emissions of greenhouse gases has led to a warming of the Earth's surface and the lower atmosphere, accompanied by a cooling of the stratosphere. In the upper stratosphere, this cooling should result in increase in ozone levels because the efficiency of the catalytic ozone destruction decreases when the temperature decreases. In the lower stratosphere, on the contrary, lower temperatures will promote more frequent formation of stratospheric clouds and therefore will tend to counteract the effects of the chlorine reduction on the destruction of polar ozone in winter and spring. Our ability to predict the long-term evolution of temperature in the stratosphere has therefore become a key factor in determining the future of the ozone layer. In a sense, the issue of stratospheric ozone will be increasingly linked in the coming years with the issue of greenhouse gases emissions and climate change (Brasseur and Solomon 2005; Bekki and Lefevre 2009; WMO 2014).

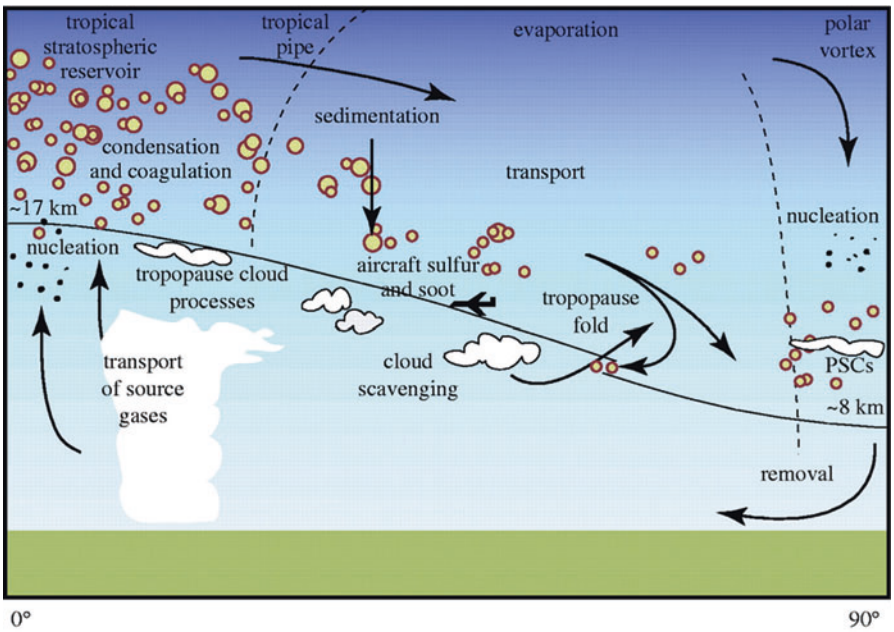
Stratospheric Sulfur Chemistry

This section is devoted to the sulfur cycle and budget in the stratosphere, notably focusing on stratospheric aerosol particles because they play a very significant role in stratospheric ozone chemistry and in the radiative balance of the atmosphere, especially after large volcanic eruptions (Hamill et al. 1997; Brasseur and Solomon 2005; SPARC 2006). The first section introduces the life cycle of stratospheric sulfur. We then review stratospheric sulfur oxidation chemistry and key aerosol microphysical processes. The next section presents the perturbations of the stratospheric aerosol layer by large volcanic eruptions and the effects on ozone and climate. The last section is devoted to the possibility of cooling the climate intentionally through deliberate sulfur injections in the stratosphere in order to counteract the climate warming from increasing concentrations of GHGs (the so-called sulfur geo-engineering).

Sulfur Life Cycle

Elevated concentrations of aerosol particles are found all over the globe in the lower stratosphere, between about 10 and 35 km. It was first discovered in 1961 by Junge et al. (1961) who noted that, as balloon-borne instruments rose into the stratosphere, they registered an increase in the concentration of large particles (Hamill et al. 1997). Further measurements have shown that stratospheric aerosols consisted primarily of submicron liquid (super-cooled) sulfate aerosols.

Figure 3 illustrates the processes that govern the stratospheric aerosol life cycle and global distribution. Most of the sulfur enters the stratosphere under the form of gases through the tropical tropopause (around 17 km in the tropics and 8 km in the polar regions). The source gases originate from



Ozone and Stratospheric Chemistry, Fig. 3 Schematic of the stratospheric aerosol life cycle (SPARC 2006 adapted from Hamill et al. 1997)

emissions at the Earth's surface or even direct injections by large volcanic eruptions. Once in the tropical stratosphere, they are transported throughout the stratosphere by the Brewer-Dobson circulation (ascending in the tropics and descending in the subtropics). During their stratospheric transit, they are oxidized and converted into sulfuric acid (H_2SO_4). Gaseous H_2SO_4 either combines with water vapor to nucleate and form new very small sulfate aerosols or condenses on pre-existing aerosol particles. Once formed, sulfate particles evolve under the action of several microphysical processes (condensation/evaporation, coagulation, sedimentation (Seinfeld and Pandis 1998)). Particles grow by coagulation and by co-condensation of H_2O and H_2SO_4, which is produced by the oxidation of sulfur gases. Sulfate aerosol particles evaporate completely above 35 km because of the increase of the temperatures in this region of the atmosphere. In the end, aerosols are removed from the stratosohere by their gravitational sedimentation. Once in the troposphere, they are then removed by wet (i.e., precipitating clouds) and dry (i.e., sticking to the earth's surface) deposition.

Conversion of Reduced Sulfur Gases into Sulfate

During nonvolcanic (also called background) conditions, the main precursor of stratospheric aerosol particles is thought to be carbonyl sulfide (OCS), the only long-lived sulfur species (Crutzen 1976). Apart OCS, all the reduced sulfur compounds are rapidly oxidized in the troposphere and thus, once emitted at the surface, they have little time to reach the stratosphere before being removed. In contrast, the vast majority of OCS emitted at the surface, predominantly from natural sources, reaches the stratosphere. It is worth pointing out that other nonvolcanic sulfur dioxide (SO_2) sources and tropospheric sulfate particles might also be important (Brock et al. 1995; Sheng et al. 2015), especially in the tropics where the vertical transport of air from the surface to the tropical tropopause can be rapid. Once it is in the stratosphere, OCS is photolyzed to give SO_2:

$$OCS + h\nu \rightarrow S + CO \quad J_{11} \qquad \text{(R11)}$$

$$S + O_2 \rightarrow SO_2 \quad k_{12} \qquad \text{(R12)}$$

Then the oxidation of SO_2 is initiated by the hydroxyl radical OH

$$SO_2 + OH + M \rightarrow HSO_3 + M \quad k_{13} \qquad \text{(R13)}$$

with M being an air molecule.

R15 is very rapidly followed by the following reactions:

$$HSO_3 + O_2 \rightarrow SO_3 + HO_2 \quad k_{14} \qquad \text{(R14)}$$

$$SO_3 + H_2O \rightarrow H_2SO_4 \quad k_{15} \qquad \text{(R15)}$$

The limiting step in the SO_2 oxidation sequence R13–R14–R15 is the reaction with OH (R13). The e-folding lifetime of SO_2 in the stratosphere is about 1 or 2 months. The net effect of the sequence can be summarized by Bekki (1995),

$$\text{Net}: SO_2 + OH + O_2 + H_2O \rightarrow H_2SO_4 + HO_2$$

The sequence converts OH into HO_2 and consumes one molecule of H_2O. When SO_2 levels are high, for instance following an injection of SO_2 by a volcanic eruption, SO_2 conversion to sulfate particles is expected to reduce levels of OH, the main atmospheric oxidant.

As gaseous H_2SO_4, the end oxidation product, has a very low saturation vapor pressure at the temperatures prevailing in the lower stratosphere, it quickly combines with H_2O to form new very small sulfate particles via binary homogeneous nucleation, typically at the tropical tropopause or in the polar regions. However, in most of the lower stratosphere, where there are quite a few particles available, gaseous H_2SO_4 tends to co-condense with H_2O on pre-existing particles and make them grow. The average composition of stratospheric sulfate aerosols is about 75% by weight of H_2SO_4, which is roughly equivalent to a molecular composition of one molecule of H_2SO_4 for two molecules of H_2O. As the result, the H_2SO_4 conversion into sulfate can be expressed by,

$$H_2SO_4 + 2H_2O \rightarrow \text{Sulphate}$$

Aerosols also grow via coagulation. Coagulation is the process of two aerosols of various sizes colliding with each other and combining into a single larger particle (Kremser et al. 2016). Finally, sulfate particles are mostly removed from the stratosphere by gravitational sedimentation. The sedimentation velocity of a particle is very strongly dependent on its size. When the sedimentation of a population of particles is considered, the critical characteristic is the particle size distribution, i.e., concentration of particles as a function of size. Size distribution is also critical for a range of properties such as the amount of surface area available for heterogeneous chemical reactions or for their scattering efficiency of sunlight (a key property for their cooling effect on climate; (Seinfeld and Pandis 1998; Jacob 1999; SPARC 2006)).

At the top of the stratospheric aerosol layer (~30-35 km), sulfate aerosols also evaporate and release H_2SO_4 in the gas-phase. There are indications that H_2SO_4 can then be photolyzed by visible sunlight to give SO_3, which in turn is also subject to photolysis and give back SO_2 (Kremser et al. 2016).

$$H_2SO_4 + h\nu \rightarrow SO_3 + H_2O \quad J_{16} \qquad \text{(R16)}$$

$$SO_3 + h\nu \rightarrow SO_2 + O \quad J_{17} \qquad \text{(R17)}$$

As the result, the dominant sulfur species above the stratospheric aerosol layer is SO_2.

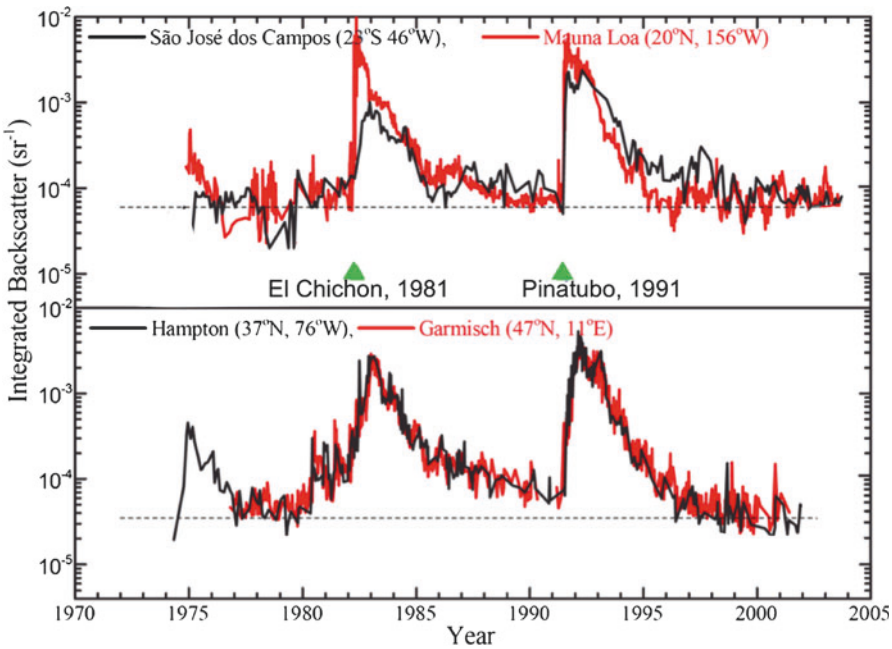
Impacts of Volcanic Eruptions

Although rare, major volcanic eruptions have an important impact on the stratospheric aerosol levels and loading, as illustrated by satellite data for the last 30 years (Fig. 4). They inject massive amount of sulfur, mostly under the form of SO_2, directly into the stratosphere, resulting in very large enhancements in sulfate aerosol levels lasting up to several years. For example, the largest volcanic eruption of the last 50 years is the eruption of Mount Pinatubo, Philippines, in June 1991. It injected about 15–20 Mega-tons of sulfur into the stratosphere, which is more than an order of magnitude greater than the annual stratospheric sulfur mass flux into the stratosphere from tropospheric surface sources during a nonvolcanic period.

The drastic increases in stratospheric aerosol loading impact stratospheric ozone and climate. They influence ozone because large volcanic sulfate aerosol particles act as sites for heterogeneous reactions that lead to ozone destruction when the atmospheric levels of halogens (chlorine, bromine) are high (see ozone section). They also impact climate because sulfate aerosols scatter the incoming sunlight back to space and hence cool the surface. To illustrate these effects, let us consider the Mount Pinatubo eruption. The injection of SO_2 and conversion into sulfate led to stratospheric sulfate aerosol loadings and surface area densities (aerosol surface available for heterogeneous chemical reactions) enhanced by up two orders of magnitude, resulting in enhanced heterogeneous chemistry that converts chlorine- and bromine-containing reservoir species such $ClONO_2$ and $BrONO_2$ into ozone-destroying radicals. Global stratospheric ozone dropped by several percentages after the Mt. Pinatubo eruption (WMO 2010). Stratospheric aerosol optical depth increased by almost two orders of magnitude (Fig. 4, bottom), enhancing the planetary albedo and hence cooling the Earth's surface by about half degree (Kremser et al. 2016). The volcanic forcing of climate represents one of the two major natural external climate forcers; the other one is the solar variability.

Geo-Engineering

Actual mitigation efforts to reduce global warming are already falling far short of what many analysts think is needed to avoid dangerous changes in climate. These failings arise from a political logic that will soon be difficult to rectify. Deep cuts may be too costly and thus politically difficult to



Ozone and Stratospheric Chemistry, Fig. 4 History of integrated backscatter from two tropical sites (São José dos Campos and Mauna Loa) and two mid-latitude sites (Hampton and Garmisch). Integrated backscattering indicates the aerosol load of the stratosphere. The *dashed horizontal lines* are meant only to aid the reader. The times of the most significant volcanic eruptions during the period are indicated in the *top panel* with the *green triangles* (El Chichon 1981, Mexico and Pinatubo 1991, Philippines). It can clearly be seen that these two major stratospheric eruptions are responsible for the large increase of the optical opacity of the stratosphere at the global scale, induced by the formation of sulfuric acid aerosols (Adapted from SPARC, 2006)

O

implement, organize, and sustain; they imply radical change in energy systems that will be difficult to implement and manage effectively in many countries even if they could gain the needed political support. More importantly, it has been proven extremely difficult to design competent international institutions for coordinating and enforcing worldwide efforts to mitigate emissions (e.g., the Kyoto protocol, COP21). As a result, the possibility of modifying the climate intentionally through large-scale technical schemes (also called geo-engineering) in order to counteract the warming effect of greenhouse gases (GHGs) has started to be considered more seriously, even by prominent scientists (Crutzen 2006; Wigley 2006; Lenton and Vaughan 2009).

Climate geo-engineering is a large-scale engineering of our environment in order to counteract the effect of changes in atmospheric composition due to human activities, in particular the increase of GHGs. Most of the proposed schemes are based on the decrease of solar flux reaching the surface to balance the increase in thermal infrared radiation reaching the surface from increasing GHG concentrations. They are based on injection of gases or particles to increase the albedo (i.e., the reflectivity) of the Earth atmosphere and clouds. By analogy with the global cooling observed after volcanic emissions of sulfur in the stratosphere, it has been proposed to inject sulfur in the stratosphere in order to enhance the stratospheric aerosol loading and hence the scattering back to space of the incoming solar radiation. According to the literature review, at least mega-tons of sulfur appears to be necessary for counteracting significantly the climate warming driven by increasing GHGs with highly uncertain costs, results, and consequences, notably on stratospheric ozone (e.g., Robock et al. 2009). Geo-engineering can certainly not be considered as a long-term solution to the climate change problem and any induced perturbation in the Earth's climate system may have unwanted consequences that should be carefully evaluated before any implementation.

Conclusions

While making only ≈10% of the mass of the atmosphere, the stratosphere plays a crucial role for the stability of the chemical and radiative balance of the Earth. The presence of a rich layer of ozone protects the Earth's ground from harmful UV radiations that otherwise would prevent the development of life on the Earth's surface. In return, by absorbing UV radiations this ozone layer generates a temperature inversion that makes the stratosphere particularly stable dynamically in comparison of the troposphere. In some way, the ozone stratospheric layer creates its own living conditions. However, the stability of the ozone layer has been drastically challenged by emissions of human manufactured halogenated species, which can cross the tropopause barrier and result in catalytic destruction of ozone. Equally, during powerful volcanic eruptions, the formation of a highly enhanced sulfate aerosol layer in the stratosphere strongly disturbs the energy and chemical balance of the stratosphere, leading to significant decreases in stratospheric ozone concentrations. In this regard, given the importance of stratospheric ozone for climate, chemistry, and life on Earth, any geo-engineering actions that would lead to change the radiative properties of the stratosphere in order to balance global warming should be viewed with a lot of caution, at minimum with distrust and critical analysis.

Paleoclimatology

Larry C. Peterson
Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, USA

Definition

Paleoclimatology is the study of past climates and their causes and effects on the timescale of Earth history. A key motivation for the study of past climates comes from the fact that modern instrumental records are limited in duration and fail to capture the full range of natural variability in the climate system. As paleoclimatology has matured as a discipline, it has contributed critical insights into the nature of past climate change over a broad range of timescales. Furthermore, paleoclimate reconstructions provide critical validation for numerical climate models that are usually tuned to reproduce the state of present-day climates. The ability of models to reproduce past climates as they are depicted in the paleoclimate record lends greater confidence in their capacity to forecast future climate developments.

A vast wealth of information about past changes in the Earth's climate is recorded in archives as diverse as tree rings, ice, cave deposits, and rocks and sediments that have formed in both marine and terrestrial settings. To use these resources, one must be able to extract information on past climate conditions from the physical, chemical, and biological components preserved in the geologic record. Such information comes almost entirely from indirect measures, known as *proxies*, that can be calibrated in some way to key climate variables. Fortunately, a diverse array of proxy types is available to choose from, many of them geochemical in nature.

Paleoclimatology had its beginnings in the mid-nineteenth century when observations of the wide distribution of glacial deposits led to realization that Earth had experienced a series of ice ages in the recent past that involved the growth and disappearance of massive ice sheets in the Northern Hemisphere. A key limitation of glacial deposits on land, however, is that the stratigraphic record is often incomplete, with more recent ice advances obliterating evidence of earlier advances. The accurate dating of glacial deposits is also an issue and generally limited to the age range (<40 Kyr) dateable using radiocarbon methods. Indeed, as late as the early 1960s, it was believed by many that the most recent series of ice ages totaled only four in number.

Paleoclimatology took a major step forward with work on deep-sea sediments that began in earnest in the 1950s with the introduction of coring methods that allowed recovery of a few tens of meters of sediment. This led to concerted study of glacial-interglacial cycles in the Quaternary and spurred the development of many of the climate proxies we use today. With the advent of the Deep Sea Drilling Project (DSDP) in the late 1960s, and the refinement of drilling technology by DSDP and successor programs that continue today, new opportunities arose to extend paleoclimate studies back well in excess of 100 Myrs. Much older rock sequences on the continents provide climate records that extend back to early Earth history. Excellent general introductions to the broad field of paleoclimatology can be found in the books by Cronin (2010) and Ruddiman (2013).

Climate Proxies

The development of proxies and refinement of analytical techniques applied to geologic archives have exploded in recent decades and have greatly enhanced our abilities to reconstruct a wide spectrum of climate and ocean parameters from the geologic record. Proxies can be divided into several categories based on the type of measurement. A review of some of the most widely used proxies is given here, together with brief descriptions of the main variables of interest associated with each. More comprehensive reviews of climate proxies are given by Henderson (2002), Katz et al. (2010),

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

and Lea (2014). Additional information can be found in cross-referenced articles cited at the end.

Fossil assemblages: The relative abundance of skeletal-producing microorganisms in marine sediments can be used to estimate past ocean temperatures, productivity, and sea ice distribution, among other properties. Foraminifera, an extremely diverse group of unicellular protists, have proven the most useful microfossil group for paleoclimate studies. They produce a calcium carbonate shell, or "test," a few hundred microns in size, and live in surface waters and the upper water column as an important group of zooplankton, as well as on the seafloor itself. The distribution of planktic species in the modern ocean correlates strongly with sea surface temperature (SST, e.g., Rutherford et al. 1999) and can be used to estimate SSTs using the transfer function technique of Imbrie and Kipp (1971). Transfer functions are a category of regression models and can be derived for any fossil group for which modern relationships to variables like SST or salinity are known. The technique is not without limitations because of the potential for secondary controls on the assemblage makeup, such as productivity changes, or no-analog situations where faunas/floras in the sediments have no modern counterpart in the calibration dataset. Transfer functions also have temporal limitations because many of the species that comprise older assemblages are extinct.

On land, pollen grains and spores that accumulate in lakes and bogs provide a record of past vegetation in an area. Studies of modern pollen rain and vegetation patterns indicate a good spatial correspondence between them. Pollen data are typically corrected for differences in pollen and spore production rate, as well as for differing rates of preservation and dispersal, but generally yield reliable estimates of the composition of the surrounding vegetation (Overpeck et al. 1985). While vegetation reconstructions are relatively straightforward, the climatic inferences that can be drawn are often qualitative, with changes interpreted in terms of wetter/drier or warmer/colder conditions.

Tree rings have long been recognized as a major source of both chronologic and climatic information (Cook and Kairiukstis 1990). The mean width of a ring in any one tree is a function of many variables, including the tree species and age, the availability of stored nutrients in the tree and soil, and a host of other climate variables, including temperature, precipitation, and sunlight. Tree ring studies have become very sophisticated and involve careful cross-dating (dendrochronology), standardization, and analysis techniques. Although climate information has most often been gleaned from tree ring width, variations in tree ring density and in the isotopic composition of the wood itself have proven useful as well.

Stable isotopes: Measurement of the stable isotope ratios of oxygen ($^{18}O/^{16}O$) and carbon ($^{13}C/^{12}C$) in the calcium carbonate ($CaCO_3$) skeletons of fossil foraminifera from marine sediments is one of the most powerful and widely used tool sets in the arsenal of the paleoclimatologist. Oxygen isotope records can be used to estimate past water temperatures, the size of ice sheets, and local salinity variations, while carbon isotope records can be used to infer deep-ocean circulation patterns and provide estimates of past oceanic nutrient levels and carbon cycling. Isotope ratios for each system are expressed in delta (δ) notation, which relates the isotopic composition of a sample to the known isotopic ratio of a standard. For oxygen isotopes,

$$\delta^{18}O = \left[\frac{\left(\frac{^{18}O}{^{16}O}\right)_{sample} - \left(\frac{^{18}O}{^{16}O}\right)_{std}}{\left(\frac{^{18}O}{^{16}O}\right)_{std}} \right] \times 1000 \qquad (1)$$

with units of parts per thousand (‰). Carbon isotope values, $\delta^{13}C$, are calculated and reported in the same form.

The use of $\delta^{18}O$ ratios as a proxy for paleotemperature began in the late 1940s with Harold Urey's observation (Urey 1947) that the $^{18}O/^{16}O$ composition of calcite should vary as a function of the temperature at which the mineral precipitated. Experimental studies confirmed this prediction and led to the development of the first paleotemperature equation (Epstein et al. 1953) with the form

$$T = 16.5 - 4.3 \times \left(\delta^{18}O_{calcite} - \delta^{18}O_{water}\right) + 0.14 \times \left(\delta^{18}O_{calcite} - \delta^{18}O_{water}\right)^2 \qquad (2)$$

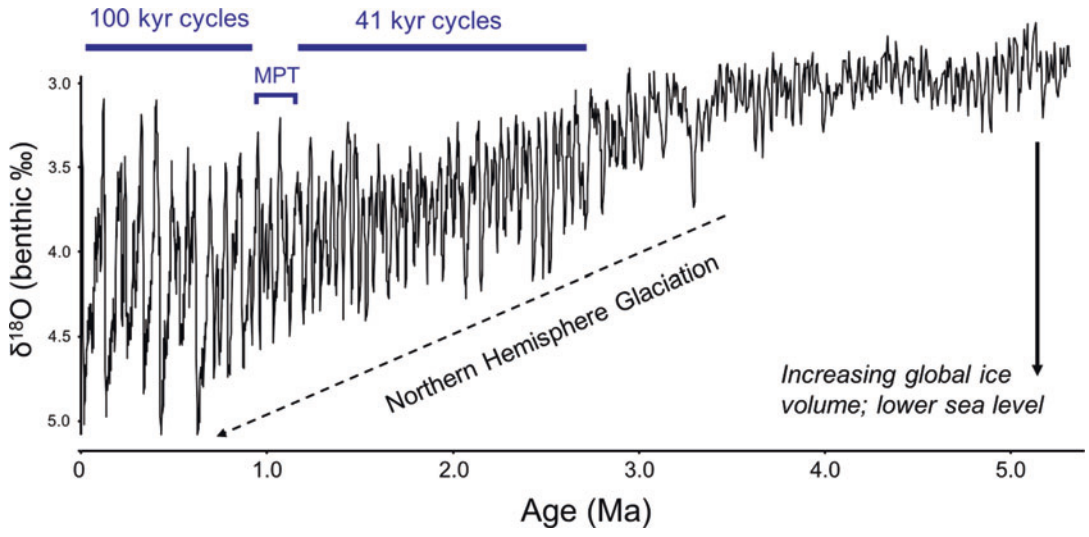
where T and $\delta^{18}O_{water}$ are the temperature (°C) and oxygen isotope value of the water in which the organism lived and $\delta^{18}O_{calcite}$ is the measured oxygen isotope value of the calcite. Analysis of this calcite yielded a paleotemperature equation with a sensitivity of approximately −0.24‰ change in $\delta^{18}O$ per 1 °C increase in temperature. Cesare Emiliani, a doctoral student working with Urey, exploited the new $\delta^{18}O$ paleothermometer by measuring planktic foraminifera in sediment cores from the Caribbean and equatorial Atlantic and documented regular cyclic variations in their isotopic composition that he interpreted as glacial-interglacial cycles (Emiliani 1955). Though Emiliani acknowledged that small variations in the isotopic composition of seawater were likely, he interpreted the bulk of the $\delta^{18}O$ signal as evidence that tropical surface waters cooled by as much as 6–8 °C during the recurring ice ages.

A significant paradigm shift came with the first $\delta^{18}O$ measurements of benthic (seafloor dwelling) foraminifera from downcore samples for which planktic $\delta^{18}O$ data were also available (Shackleton 1967). Nicholas Shackleton found that the magnitude of observed benthic variations was nearly the same as those of the planktic's and argued that benthic foraminifera could not be recording a temperature signal since the bottom waters they inhabited were already close to

freezing. Hence, the dominant component of the isotopic signal recorded by both planktic and benthic foraminifera must reflect variations in the oxygen isotopic composition of the ocean due to what is now called the "ice volume effect." A common feature of stable isotope behavior in nature is that of Rayleigh fractionation which occurs as isotopes move between gaseous and liquid reservoirs. As water evaporates, molecules containing the heavier ^{18}O isotope evaporate less readily than those containing the lighter ^{16}O isotope. Conversely, fractionation during condensation concentrates the heavier isotope in the precipitation (rain or snow), further enriching the clouds (water vapor) in the lighter $H_2{}^{16}O$ molecules. In the modern hydrologic cycle, water evaporated from the ocean returns there relatively quickly through precipitation, summer melting of snow/ice, and continental runoff. During glacial periods, however, when extensive ice sheets grow on land, the oceans become enriched in the heavier $H_2{}^{18}O$ molecules at the expense of $H_2{}^{16}O$ molecules, which are preferentially stored in the ice sheets. An important consequence of this observation is that the growth and melting of continental ice sheets create a whole-ocean $\delta^{18}O$ signal that provides a chronostratigraphic framework for making global correlations based on $\delta^{18}O$ variations in the sediment record. A standard oxygen isotope stratigraphy for the late Pliocene-Pleistocene is now well established as represented by the composite $\delta^{18}O$ record of Fig. 1 (Lisiecki and Raymo 2005).

As with oxygen isotopes, variations in $\delta^{13}C$ result from fractionation of ^{13}C and ^{12}C by physical or chemical processes. In the ocean, the $\delta^{13}C$ of the dissolved inorganic carbon reservoir ($\delta^{13}C_{DIC}$) largely reflects the utilization and remineralization of the carbon in organic matter. Phytoplankton in the surface ocean preferentially utilize the isotopically light ^{12}C to build soft tissue during photosynthesis. The breakdown or remineralization of this soft tissue as the organic remains settle through the water column after death puts nutrients and CO_2 with more negative $\delta^{13}C$ values (~ −25‰ today) back into the ocean at depth. In the deep ocean, waters longer isolated from the surface typically exhibit higher concentrations of nutrients and more negative $\delta^{13}C_{DIC}$ values because of their steady accumulation over time. Consequently, a deepwater mass close to its source region is likely to have more positive $\delta^{13}C_{DIC}$ values and low nutrient levels, whereas an "older" water mass more distant from its formation area will have more negative $\delta^{13}C_{DIC}$ values and higher nutrient levels. The distinct $\delta^{13}C$ characteristics of different deepwater masses can therefore be exploited to reconstruct circulation patterns (e.g., Lynch-Stieglitz and Fairbanks 1994). On timescales longer than the residence time of carbon in the oceans, the average $\delta^{13}C$ of the ocean's DIC reservoir is controlled by the $\delta^{13}C$ signatures and fluxes of carbon sources and sinks. Carbon is supplied to the ocean from the chemical weathering of continental rocks and by hydrothermal/volcanic outgassing, while carbon is removed from the ocean through deposition of carbonate and organic carbon in marine sediments. Changes in carbon isotopes of marine carbonates and organic matter through time hence serve as archives of changes in carbon sources and sinks (Kump and Arthur 1999).

Two other isotope systems finding increased application in marine sediments involve the stable isotopes of nitrogen and boron. Sedimentary nitrogen isotopes are one of the primary tools for studying past changes in the nitrogen cycle (Sigman et al. 2009). In the ocean, relatively little isotopic fractionation



Paleoclimatology, Fig. 1 Averaged record of globally distributed oxygen isotope ratios ($\delta^{18}O$) from benthic foraminifera showing the pattern of climate variability over the past 5 Myr (Data from Lisiecki and Raymo 2005). More positive values indicate more ice and colder temperatures though the ice effect dominates over this timescale. Increasing $\delta^{18}O$ after 3 Ma records the onset and evolution of Northern Hemisphere glaciation. Label "MPT" marks the Mid-Pleistocene Transition

occurs during N_2 fixation by cyanobacteria, resulting in newly fixed nitrogen with a signature like that of air (0‰). In contrast, there is a large fractionation (ε = 20–30‰) associated with water column denitrification as well as fractionation associated with biological uptake (ε = 2.5–6‰). The $\delta^{15}N$ of sinking organic matter thus has the potential to record changes in inputs, outputs, and utilization of biologically available nitrogen (NO_3^-).

Ocean pH is an important component of the ocean carbonate system and is controlled by the ratio of alkalinity to dissolved inorganic carbon (DIC). The reconstruction of past ocean pH is possible because boron occurs as two species in seawater whose relative concentrations are pH-dependent (Foster and Rae 2016). Boron is present in seawater primarily as the trigonal $B(OH)_3$ species (boric acid) and the tetrahedral $B(OH)_4^-$ species (borate), the latter of which has an isotopic composition approximately 20‰ more negative than B $(OH)_3$. Since only $B(OH)_4^-$ is incorporated into marine carbonate, the $\delta^{11}B$ of carbonates changes with B speciation and therefore with pH. Knowledge of ocean pH, in turn, gained from fossil marine carbonates is valuable as it can be used to investigate past changes in atmospheric pCO_2. Paleo-pH values do not uniquely constrain pCO_2 but can be used to calculate it if assumptions about past ocean alkalinity and DIC are made. Using this methodology, atmospheric pCO_2 values up to ten times present levels have been measured for the earliest Cenozoic (~60 Ma).

Elements: The oceanic distribution of certain trace elements reflects processes of climatic interest, and many of these elements substitute for calcium in carbonate shell material. One of the most valuable proxies for seawater temperature is based on the substitution of magnesium into biogenic calcite. It has long been known that calcitic shells of marine organisms in the tropics contain more magnesium than subpolar shells, but it wasn't until the 1990s that species-specific calibrations of Mg/Ca to temperature were developed for foraminifera. Since then, the application of the technique has proceeded rapidly (Lea et al. 1999; Allen et al. 2016). Mg/Ca thermometry has some distinct advantages over other temperature proxies. First, the oceanic residence times for Ca and Mg are relatively long (10^6 and 10^7 years, respectively) which means that the Mg/Ca ratio of seawater may be assumed constant over glacial/interglacial timescales, in contrast to oceanic $\delta^{18}O$ which is influenced by changes in global ice volume. Second, because Mg/Ca and $\delta^{18}O$ can be measured in the same foraminiferal calcite, the temperatures obtained from Mg/Ca can be used in combination with $\delta^{18}O$ to reconstruct variations in the isotopic composition of seawater ($\delta^{18}O_{water}$), which provides an indirect measure of salinity (Schmidt et al. 2006). The biggest limitation to Mg/Ca paleothermometry is that dissolution can preferentially remove the more soluble Mg-enriched portions of the calcitic shells (Brown and Elderfield 1996).

In corals, the ratio of strontium to calcium (Sr/Ca) is temperature dependent (Beck et al. 1992), though non-environmental factors can have an influence as well. Measurements of Sr/Ca in corals capture the annual temperature cycle and allow for collection of high-resolution temperature time series in the tropical ocean. Studies of coral Sr/Ca have proven particularly useful for studying the past behavior of the El Niño-Southern Oscillation (ENSO) system in the tropical Pacific (Gagan et al. 1998).

Variations in the ratio of cadmium to calcium (Cd/Ca) in benthic foraminifera have provided important evidence for reorganization of deepwater circulation patterns during Pleistocene glacial-interglacial cycles. In the present ocean, Cd concentrations closely resemble those of the nutrient phosphorus (Boyle 1988), which increases with water mass age because of the steady rain of organic matter from the surface ocean to the deep sea and its subsequent remineralization. Changes in Cd/Ca concentration in benthic foraminiferal shells thus reflect changes in the age of a water mass, in a manner generally consistent with $\delta^{13}C$. Foraminiferal Cd/Ca and $\delta^{13}C$ measured together in sediment cores from the Atlantic were among the first data to suggest that production rates of North Atlantic Deep Water (NADW) were greatly reduced during the last glacial (Boyle and Keigwin 1982).

Biomarkers: Biomarkers are organic molecules unique to a specific organism or group of organisms. They are typically resistant to degradation and preserved in sediments and rocks after all other traces of the organism have disappeared. Some of the most useful biomarkers can be used to reconstruct physical parameters such as temperature. Alkenones are a group of long-chained organic molecules ($C_{37–39}$) produced by only a few predominantly marine phytoplankton, including the widespread coccolithophore *Emiliania huxleyi* and related species. The alkenones produced can have two or three double bonds in their structure with the degree of unsaturation responding linearly to water temperature (Prahl and Wakeham 1987). For temperature estimation, this is written as the $U^{K'}_{37}$ ratio, the amount of di-unsaturated to the total of the di- and tri-unsaturated C_{37} alkenones ((37:2)/(37:2 + 37:3)). The $U^{K'}_{37}$ index has been calibrated to sea surface temperature using a global set of modern surface sediments (e.g., Conte et al. 2006). One limitation of the $U^{K'}_{37}$ proxy is that there is an upper temperature limit (~29 °C) that can be reconstructed. A second is that the relevant coccolithophorids don't grow in polar waters, which also precludes their use at the coldest temperatures. Nonetheless, advantages include that alkenone temperatures obtained reflect near-surface temperatures since the alkenone producers are phytoplankton and therefore live in the uppermost photic zone.

A newer biomarker proxy for measuring sea surface temperature is TEX_{86} (Schouten et al. 2002), a method based on compounds known as C_{86} glycerol tetraethers (GDGTs). These are membrane lipids synthesized in the water column by another

group of microorganisms, the Thaumarchaeota, and come with variable numbers of cyclopentane structures. The proportions of these different GDGTs produced by the Thaumarchaeota vary with temperature, according to the formula:

$$T = 56.2 \times TEX_{86} - 10.78 \quad (3)$$

where T is the temperature in °C and TEX_{86} is defined as the ratio of the sum of the quantities of GDGTs 2, 3, and 4′ to the sum of the quantities of GDGTs 1, 2, 3, and 4′. Below about 5 °C, the variation in TEX_{86} becomes negligible, so this proxy also has limitations in the coldest waters. Like alkenones, GDGTs are resistant to postdepositional processes that destroy most organic compounds and can be found in marine sediments up to Jurassic in age. The TEX_{86} method for temperature can also be applied in lacustrine settings.

An important group of terrestrial biomarkers come from the waxes that coat the leaves of vascular plants. These are long-chain n-alkyl compounds associated with cuticle, a multilayered waxy structure on the exterior of leaves and fruits. Cuticle has multiple functions, but one of its primary roles is to protect against moisture loss. Leaf wax compounds and their stable carbon ($\delta^{13}C$) and deuterium/hydrogen (δD) isotopic composition can provide valuable information about changes in vegetation and water availability (e.g., Hughen et al. 2004; Schefuß et al. 2005). The stable $\delta^{13}C$ from these compounds varies among vegetation types that utilize either the C3 (woody trees) or C4 (grasses, shrubs) photosynthetic pathways and can be used as an indicator of the relative contributions of these two types of vegetation. The hydrogen isotopic composition (δD) encoded in plant wax compounds can be used to infer the isotopic composition of the source water, usually precipitation, and is commonly used to reconstruct past hydrologic conditions (Tierney et al. 2013). Leaf waxes can be found in both terrestrial and marine sediment sequences, the latter where input occurs by rivers or wind.

Other isotope systems: Two other isotopic proxies have found increasing use in tracing past ocean circulation. One of the more promising is the isotopic composition of dissolved neodymium (Nd), specifically the $^{143}Nd/^{144}Nd$ isotope ratio, expressed as ε_{Nd} (Rutberg et al. 2000). Seawater Nd isotopes are dominated by continental inputs that enter the oceans through rivers and atmospheric deposition. ε_{Nd} values of different water masses thus reflect the geology of surrounding terranes relative to the location where deepwater masses form. They can be used to track changes in ocean circulation because Nd has a short residence time (~500–1000 years) relative to the timescale of ocean mixing (~1500 years) (Goldstein and Hemming 2003) and because fossil fish teeth and Fe-Mn coatings on sediment grains preserve a record of seawater ε_{Nd} (Palmer and Elderfield 1986). The most extreme end-members in the modern ocean are the deep North Atlantic (where NADW is formed with low ε_{Nd} values derived from old continental crust) and the deep North Pacific (where older deep waters are found with high ε_{Nd} values acquired from young volcanic arcs). In theory, changes in ε_{Nd} can be used as a water mass tracer so long as the assumption of constant end-member compositions is valid.

Another proxy that can provide information about the strength of the ocean's large-scale overturning circulation is based on protactinium (Pa) and thorium (Th). ^{231}Pa and ^{230}Th are both insoluble products formed by the natural decay of dissolved uranium (U) in the water column (Marchal et al. 2000). As U has a constant concentration in seawater, these nuclides are created uniformly at a known rate, but they are scavenged by sinking particles at unequal rates, with ^{230}Th remaining in the water for only a few tens of years before being incorporated into the underlying sediments, while ^{231}Pa is supported in the water column for ~100–200 years. In today's Atlantic Ocean, with its overturning circulation driven by formation of NADW, ^{230}Th transport to the Southern Ocean is minimal due to its short residence time and ^{231}Pa transport is high. This results in relatively low $^{231}Pa/^{230}Th$ ratios in the underlying sediment. However, as found by McManus et al. (2004), when the Atlantic's overturning circulation slows or shuts down (as hypothesized) during glacial periods, the $^{231}Pa/^{230}Th$ ratio in sediments becomes elevated as there is less removal of ^{231}Pa to the Southern Ocean. Subsequent work has shown that the use of $^{231}Pa/^{230}Th$ as a physical circulation proxy must be applied with caution since ^{231}Pa and ^{230}Th removal from seawater can be influenced by the composition of sinking particles, with ^{231}Pa having an affinity for biogenic silica (Lippold et al. 2009).

As this review suggests, there is no one perfect proxy for past climates. But as new proxies have developed, the increasing availability of overlapping proxies based on completely different chemical or physical systems provides for multiple validations of primary climate signals. For example, past sea surface temperatures can now be determined by faunal transfer functions, oxygen isotopes, foraminiferal Mg/Ca, and alkenone undersaturation in the same deep-sea sediment core and often the same samples. Similarly, inferences about past ocean circulation patterns can come from $\delta^{13}C$ and Cd/Ca in benthic foraminifers, as well as from Nd isotopes in diagenetic coatings and $^{231}Pa/^{230}Th$ in bulk sediment.

The Climate System and Timescales of Change

Earth's climate system can be divided into five major components: the lithosphere, the hydrosphere (oceans, lakes and rivers, groundwater), the cryosphere (ice sheets, glaciers, and sea ice), the atmosphere, and the biosphere. Climate involves a myriad of interactions among these components over timescales ranging from seconds to millions of years. At the most basic level, paleoclimatology involves trying to

understand the causes (forcing) and effects (the response) of climate change. Paleoclimate records provide the direct evidence of how climate has responded as deciphered from our toolbox of proxies, while the nature of the forcing and the various interactions between components must be inferred and understood from modern observations, first principles, and modeling.

Three fundamental kinds of climate forcing have been identified that impact Earth's climate system. These can be summarized as:

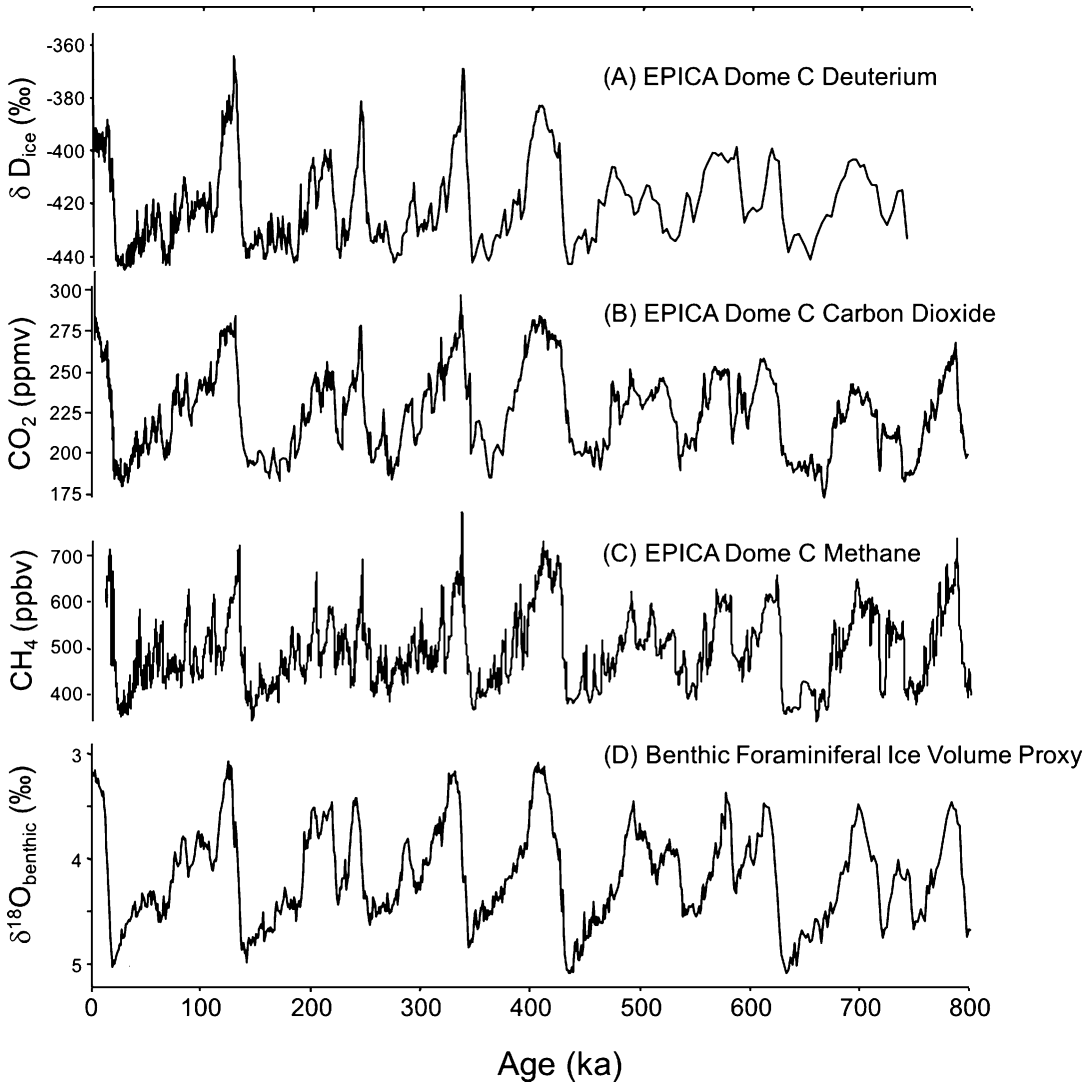
Tectonic forcing: The slow reshaping of the Earth's surface by plate tectonics is driven by the internal heat generated deep in the Earth by radioactive decay. As tectonic plates move, so do the continents, and this redistribution has an important effect on the spatial heterogeneity of the Earth's energy balance via differences in the albedos (reflectivity) and thermal properties of land versus ocean. The collision of continents, the uplift of mountains and their subsequent erosion, and the volcanism associated with mid-ocean ridges and trenches where ocean lithosphere is created and recycled impact climate over very long timescales (10–100 Myrs). Similarly, the opening and closing of ocean basins and critical gateways drive changes in ocean circulation, which can modify the distribution of heat and salt and influence marine primary productivity, as well as conditions on the adjacent continents. Tectonic processes have important geochemical impacts on climate because on long timescales, the global carbon cycle is characterized by the involvement of rocks, which contain more CO_2 than all other reservoirs on Earth combined. Atmospheric CO_2 levels reflect the balance between inputs and outputs, and CO_2 on tectonic timescales is added via volcanic outgassing, metamorphism, and diagenesis and removed via silicate weathering and storage in rock and sediment as carbonate and organic carbon (Berner et al. 1983; Kump et al. 2000). Recycling of oceanic crust at subduction zones returns the CO_2, stored in carbonates and organic carbon, back to the mantle, where the cycle is completed. Variability in the relative rates of these processes on tectonic timescales is what controls the long-term oscillations between what have come to be called greenhouse and icehouse worlds.

Astronomical forcing: On timescales of 10^4–10^5 years, climate variability is largely driven by changes in the Earth's orbit with respect to the Sun. These changes affect climate by altering the amount of solar insolation received by season and latitude. For any position on the Earth's surface, the insolation received at the top of the atmosphere is a function of the solar constant and the effects of three distinct orbital elements: obliquity, eccentricity, and precession (Berger 1988). Each operates with a characteristic periodicity and impacts climate in a different way. Changes in obliquity, or the degree to which the Earth's axis is tilted with respect to the plane of solar orbit, affect the intensity of seasons and the amount of sunlight each hemisphere receives during the year. The present angle of tilt is 23.5°, but over a period of 41 Kyr, it varies between about 21.5° and 24.5°. The shape of Earth's orbit around the Sun also varies through time, ranging from nearly circular to slightly (~5%) elliptical or eccentric. Changes in the eccentricity of Earth's orbit alter the Earth-Sun distance, subsequently reducing or increasing the amount of radiation received at the Earth's surface in different seasons. There are both 100 and 413 Kyr cycles associated with eccentricity. Finally, precession refers to the slow turning of the Earth's axis of rotation through a circular path, like the motion of a wobbling top, completing a full 360° rotation in a cycle that takes about 23 Kyr. Because the direction of the Earth's axis of rotation determines at which point in the Earth's orbit the seasons will occur, precession also plays a role in the timing and intensity of seasons.

In the early twentieth century, the Serbian mathematician Milutin Milankovitch proposed that recent ice ages affecting the Northern Hemisphere began when the three orbital cycles align to favor an extended period of more solar radiation in the winter and less in the summer at high northern latitudes (~65°N). These conditions would favor higher winter temperatures, but also more water vapor in the air, leading to greater snowfall. More importantly, reduced summer insolation would lead to cooler summers that favor less melting of winter snow and gradual glacier formation. Milankovitch developed the mathematical basis for calculating the insolation values for a given latitude and season (Milankovitch 1941), and his insolation curves, meticulously calculated by hand, formed the basis for early attempts to compare the timing of insolation minima to the ages of glacial deposits on land. Milankovitch's "orbital theory" fell into disfavor in the late 1946s as radiocarbon dating of glacial deposits on the continents revealed their incompleteness and internal complexity. However, as noted already, a fundamental shift in the study of paleoclimates occurred with the advent of coring methods that made possible the collection of more continuous deep-sea records, and the work of pioneers like Emiliani and Shackleton led to development of the $\delta^{18}O$ proxy that initiated the field of paleoceanography. Hays et al. (1976) later provided the first clear evidence that the orbital changes postulated by Milankovitch played a key role in driving the late Quaternary ice age cycles, serving as a "pacemaker" that determines their timing. Since then, the Milankovitch periodicities have been found in varying significance in most climate records of sufficient length and resolution. Climate variability on orbital timescales is largely superimposed on longer-term, tectonic-scale climate variability and is most characteristic of "icehouse" worlds where large ice sheets and their highly reflective nature provide feedbacks that amplify the relatively weak insolation changes. Evidence for the orbital forcing of climate has been found as far back as 1.4 billion years ago, in the Proterozoic Eon.

Radiative/atmospheric forcing: Forcing that arises from changes in the concentration of radiatively active trace gases in the atmosphere is a critical component of the climate system. Changes in concentration of the so-called greenhouse gases (e.g., carbon dioxide, methane, nitrous oxide) come about when the atmosphere is no longer in equilibrium with the sources and sinks of the gas. Though water vapor is the single most important greenhouse gas, changes in its tropospheric concentration are largely a natural consequence of temperature change (i.e., warm air holds more moisture) and therefore are usually treated as a feedback in climate models. Atmospheric CO_2 is the greenhouse gas with the most impact on climate, and there is abundant evidence from the geologic past for this connection on timescales ranging from orbital to tectonic.

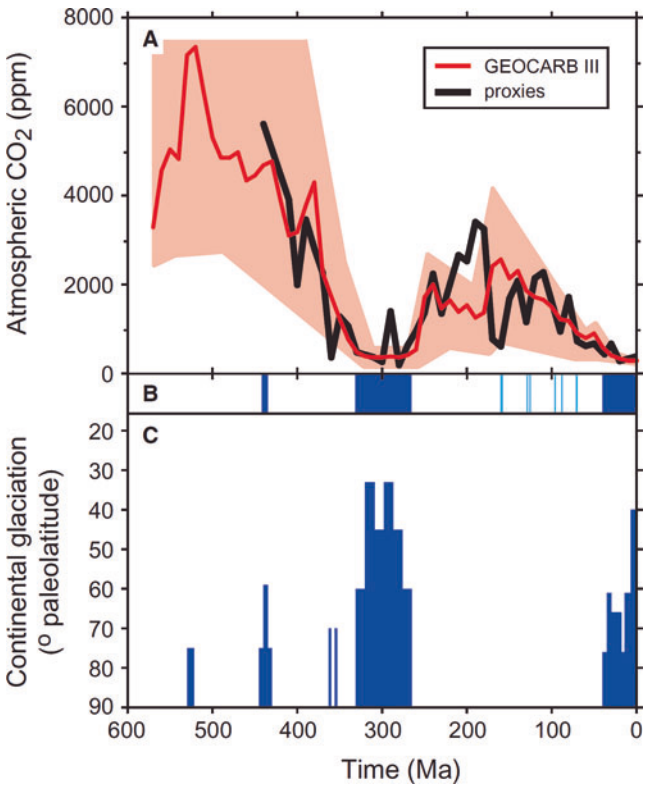
Variations in past atmospheric CO_2 levels on orbital timescales are best documented in ice cores drilled from the modern ice caps in Greenland and the Antarctic, from which gases extracted from bubbles in the ice have provided time series of changes in atmospheric composition. The oldest continuous ice core records recovered to date extend back 800 Kyrs in Antarctica. Over the last 800 Kyrs (Fig. 2), atmospheric CO_2 levels have fluctuated between about 180 and 300 parts per million by volume (ppmv), corresponding closely with glacial and interglacial climates. The complex reasons for these CO_2 changes have yet to be fully worked out. Glacial cooling of ocean surface waters can explain some small portion of the CO_2 decrease by its effect on gas solubility (cold water holds more dissolved gas);



Paleoclimatology, Fig. 2 Comparison of ice core records of temperature and atmospheric greenhouse gases to global ice volume for the last 800 Kyr. (**a**) Deuterium isotopes, a proxy for air temperature, from the EPICA Dome C ice core, Antarctica (Jouzel et al. 2007); (**b**) atmospheric CO_2 (ppmv) from ice core air bubbles, EPICA Dome C, Antarctica (Luthi et al. 2008); (**c**) atmospheric methane (CH_4; ppbv), EPICA Dome C, Antarctica (Loulergue et al. 2008); (**d**) deep-sea benthic foraminiferal $\delta^{18}O$, a proxy for global ice volume (Lisiecki and Raymo 2005)

however, most of the explanation for lowered glacial CO_2 appears tied to the transfer and storage of carbon into the deep ocean (Sigman et al. 2010). This may have come about through higher rates of photosynthesis and biologic productivity, leading to more carbon export into the deep ocean, or by changing patterns of deep-ocean overturning that allowed CO_2 to accumulate in bottom waters. Regardless of mechanism, it is evident that carbon cycling is intrinsically related to climate change over glacial-interglacial cycles and that the ocean is involved since it contains the largest source of readily exchangeable carbon. Methane concentrations also track the glacial-interglacial changes (Fig. 2), probably because there were fewer wetlands in the colder, drier glacial periods.

Reconstructed atmospheric CO_2 concentrations for the Phanerozoic are shown in Fig. 3 and include measurements based on multiple paleo-CO_2 proxies and estimates derived independently from geochemical modeling (e.g., Berner and Kothavala 2001). Though measurements and models show considerable uncertainty and variation over these long timescales, both point to atmospheric CO_2 levels in the past at times much higher than present and corresponding to periods of well-documented global warmth. A strong first-order correlation also exists between periods of low CO_2 and the presence of long-lived, aerially extensive continental glaciations. This comparison builds confidence in the validity of the simulated and reconstructed CO_2 history as well as the long-term relationship between CO_2 and climate, though keeping in mind that the link between CO_2 and global temperature cannot, on its own, explain all past climate variations.



Paleoclimatology, Fig. 3 Comparison of atmospheric CO_2 and climate from Royer et al. (2004) for the Phanerozoic, the time interval since the first appearance of multicellular life with skeletal hard parts at the base of the Cambrian Period. (**a**): Comparison of model predictions (GEOCARB III; shaded area shows error range) with estimated CO_2 levels based on multiple proxy lines of evidence. Both curves use 10 Myr time steps. Other factors can alter the radiative balance of the planet besides the concentrations of greenhouse gases. The luminosity, or brightness, of the Sun provides the energy to drive atmospheric circulation and constitutes the input for Earth's surface heat budget. Radiative energy from the Sun is variable at very small timescales, owing to solar storms and other disturbances, but variations in solar activity, particularly the frequency of sunspots, are also documented at decadal to millennial timescales. When viewed over the entire span of Earth history, the output from the Sun has increased steadily since its formation. Low solar luminosity during Precambrian time underlies the "Faint Young Sun Paradox" (Güdel 2011), the paradox being that a Sun only 70% as strong as today would yield a frozen world with no possibility of liquid water or the emergence of life, and yet both were present. The solution to this mystery is generally attributed to an early atmosphere loaded with high levels of CO_2 and perhaps methane because of increased volcanic activity.

Another critical factor is albedo, the extent to which the atmosphere and Earth's surface reflect the incoming solar radiation back to space. The albedo of the Earth's surface can be affected by land surface changes, such as desertification, but the largest changes are related to the presence of snow and the waxing and waning of ice sheets and sea ice. Fresh snow has an albedo of 0.8–0.9 which means that 80–90% of the incoming solar radiation is reflected. As ice sheets grow, the area of high albedo increases, further reducing the solar energy absorbed and leading to more cooling. Conversely, warming decreases ice cover and hence the albedo, increasing the amount of solar energy absorbed, leading to more warming. The planetary albedo can also be altered by the amount of aerosol particles in the atmosphere. In the stratosphere, the dominant aerosol source is from volcanic eruptions, while in the lower troposphere, the source can be either natural or man-made (e.g., pollutants).

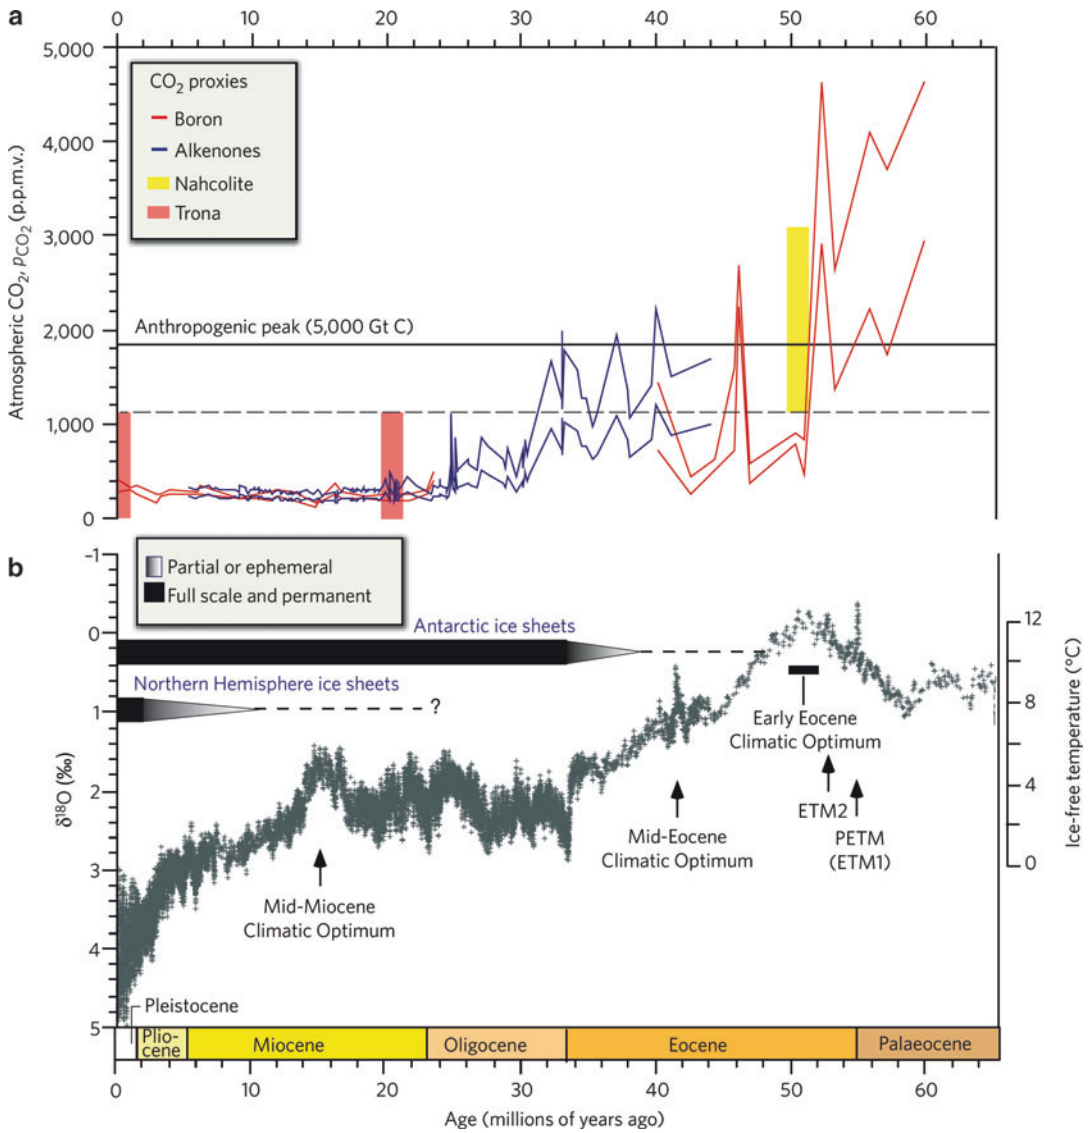
Cenozoic Climate History

Paleoclimate studies over the last half century have yielded an increasingly detailed view of how climate has changed over Earth history, ranging from climate states much warmer to

much colder than present. A review of climate for the Cenozoic (the last 66 Myrs) highlights some of the changes that have occurred and insights that have been gained. The Cenozoic, though it represents only a small fraction of Earth's existence, is the time interval best known because of the availability of well-preserved paleoclimate archives, such as deep-sea benthic foraminiferal oxygen isotope ($\delta^{18}O$) records (e.g., Zachos et al. 2001, 2008).

The asteroid impact associated with the mass extinction marking the end of the Cretaceous Period (66 Ma) came at a time of extreme greenhouse climates, which continued into the early Cenozoic (Fig. 4). This high-CO_2 world (~2000–4000 ppmv) is thought to have been driven by faster rates of seafloor spreading and volcanic emissions and by subduction and recycling of the carbonate-rich tropical Tethyan Seaway in the early Cenozoic. Tropical and subtropical floras and faunas occurred at high latitudes until at least 40 Ma, and geochemical proxies from marine sediments indicate the presence of warm oceans at all depths.

The highest known global temperatures of the Cenozoic occurred during a geologically brief interval spanning the Paleocene-Eocene boundary (Fig. 4). This "hyperthermal" event, the Paleocene-Eocene Thermal Maximum (PETM), began rapidly about 55.5 Ma and lasted approximately



Paleoclimatology, Fig. 4 Evolution of atmospheric CO_2 levels and global climate over the course of the Cenozoic. (**a**) Atmospheric CO_2 from a compilation of marine and lacustrine proxy records. The vertical distance between the upper and lower colored lines shows the range of uncertainty for the alkenone and boron pCO_2 proxies. (**b**) Cenozoic climate as recorded by deep-sea benthic foraminiferal $\delta^{18}O$ time series from Deep Sea Drilling Project and Ocean Drilling Program sites. The $\delta^{18}O$ temperature scale on the right axis is computed on the assumption of an ice-free world; it therefore applies only to the time preceding the onset of large-scale glaciation on Antarctica (about 34 Ma) (Reprinted by permission from Macmillan Publishers Ltd.: Nature; Zachos et al. (2008))

170 Kyr. Its onset was marked by repeated, rapid, and massive releases of isotopically light fossil carbon, as indicated by carbon isotopes in such diverse materials as marine foraminifera, organic carbon, and soil carbonates on land. Sea surface and continental air temperatures increased by more than 5 °C (9 °F) during the transition into the PETM, while SSTs in the high-latitude Arctic may have been as warm as 23 °C (73 °F), comparable to modern subtropical and warm-temperate seas. The extreme warming was accompanied by widespread extinctions in both marine and terrestrial ecosystems, deep-ocean acidification, and expanded low-oxygen conditions in the water column.

The enormous source of fossil carbon that led to the PETM is still unclear (Thomas et al. 2002; Dickens 2003). The most widely cited candidate is carbon sourced from frozen methane hydrates that may have dissociated (melted) as their stability field crossed a threshold triggered by the warming of the late Paleocene. Other suggested sources include the large-scale combustion of terrestrial peat sequences, the desiccation and oxidation of organic matter in large epicontinental seaways, the impact of a volatile-rich comet, and the intrusion of igneous bodies into organic-rich sediments during the opening of the North Atlantic that released thermogenic methane and CO_2 through contact metamorphism. Problems exist with each of these hypotheses, however, and to date, no single explanation fully satisfies the evidence. Multiple sources of carbon release may well be required to explain this event.

Following the PETM, global temperatures declined but then gradually increased again to near-PETM levels during a period known as the Early Eocene Climatic Optimum (Fig. 4). This temperature maximum was followed by a steady decline in global temperatures toward the Eocene-Oligocene boundary. The global cooling is reflected in marine sediments and paleontological records from the continents by gradual shifts in faunal and floral assemblages toward the equator. Uplift of the Himalayas and Tibetan Plateau caused by the collision of the Indian subcontinent with Asia beginning about 40 Ma likely contributed to late Cenozoic cooling through erosion and the drawdown of CO_2 via enhanced weathering of silicate minerals (Archer 2009). As this uplift has continued until the present day, it has influenced and strengthened the monsoon circulation in these regions.

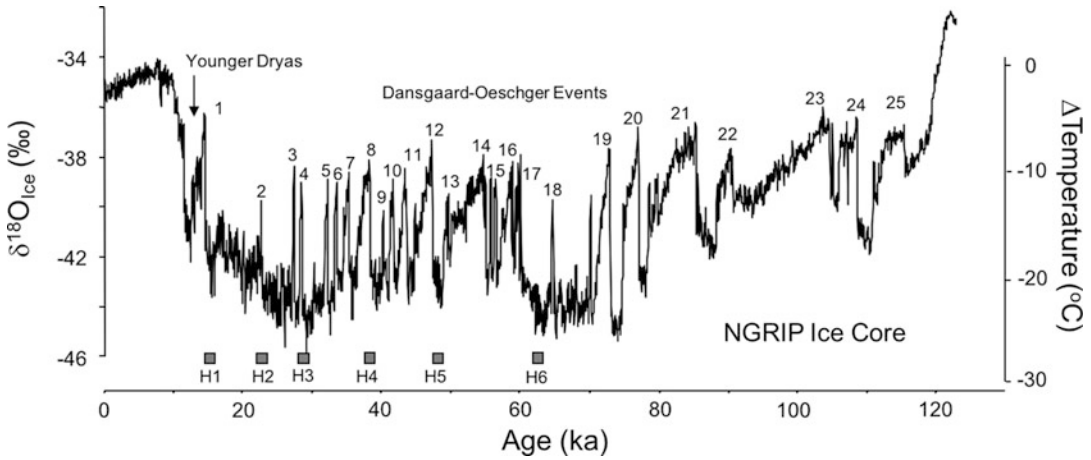
The cooling trend of the late Eocene was punctuated about 34 Ma by a rapid positive shift of more than 1.5‰ in deep-sea benthic $\delta^{18}O$ values that occurred over just a few hundred thousand years. Though some of this $\delta^{18}O$ change near the Eocene-Oligocene boundary can be attributed to deep-ocean cooling, the bulk of the signal reflects the initial growth of a permanent continent-sized ice sheet in Antarctica (Lear et al. 2008). Physical evidence for an ice sheet close to present size comes from ice-rafted materials in Southern Ocean sediments that date to this time, indicating the calving of icebergs from ice that reached the ocean's edge. The climatic stresses triggered by this pronounced transition from the early Cenozoic greenhouse world to the glaciated icehouse world of today drove significant extinction of animals and plants, both on the continents and in the ocean (Prothero 1994).

Conditions allowing rapid ice growth on Antarctica at the Eocene-Oligocene transition are thought to have been reached through a combination of declining CO_2 levels and orbitally driven changes in summer insolation (DeConto and Pollard 2003). However, it is likely that tectonics also played an important role. This period saw the gradual opening of the ocean passage between Tasmania and Antarctica, followed by the opening of the Drake Passage between South America and Antarctica. The latter, which left Antarctica thermally isolated within a cold polar sea, produced global effects on atmospheric and oceanic circulation (Barker et al. 2007).

An ice sheet in Antarctica persisted during the Oligocene, and global climate was cooler and drier, with a major expansion of grasslands and a retreat of tropical forests toward the equator. The late Oligocene and early to middle Miocene were warmer, though not nearly as warm as the Eocene, and the Antarctic ice sheet was diminished in size but still present. After a period of global warmth known as the Mid-Miocene Climatic Optimum (Fig. 4), cooling resumed about 14 Ma, and the Antarctic ice sheet expanded again to cover much of the continent. This cooling continued through the late Miocene and accelerated into the early Pliocene. During this period, the Northern Hemisphere remained ice-free, and studies of fossil pollen show cool-temperate Pliocene floras at high latitudes on Greenland and the Arctic Archipelago.

One of the most important analogs for a future high CO_2 world is the time interval between about 3.3 and 3.0 Ma in the late Pliocene. This relatively recent interval had continent-ocean configurations, ecosystems, and bipolar ice sheet extents similar to today. More importantly, the orbital configuration was nearly identical, while proxy CO_2 estimates from sediment cores in a range of ocean basins indicate peak Pliocene CO_2 values comparable to present-day values of ~400 ppmv. This Pliocene analog thus allows the study of the effects of higher CO_2 levels, while other large-scale boundary conditions were close to modern. Although the high latitudes were significantly warmer, tropical sea surface and air temperatures were comparable to today. Both drill core data and ice sheet simulations show complete deglaciation of the Greenland and West Antarctic ice sheets with global sea levels up to 20 m higher than present (Raymo et al. 2011).

The record of benthic foraminiferal $\delta^{18}O$ shows that Northern Hemisphere glaciation began about 3 Ma (Fig. 1). Several mechanisms have been proposed to explain the conditions that led to Northern Hemisphere ice growth including tectonic closure of the Panamanian seaway and its effect on ocean circulation, mountain uplift that altered the path of



Paleoclimatology, Fig. 5 High-resolution $\delta^{18}O$ measurements of ice from the NGRIP ice core in Greenland (North Greenland Ice Core Project Members 2004). The $\delta^{18}O$ of ice records air temperature (expressed in terms of temperature anomaly on the right axis) and reveals pervasive century- to millennial-scale variability. The abrupt cooling of the Younger Dryas and the rapid warmings that characterize Dansgaard-Oeschger interstadial events are numbered. Heinrich events (labeled H1–H6) are discrete layers of ice-rafted debris found in sediment cores from a wide swath of the subpolar North Atlantic

the jet stream, and decreasing atmospheric CO_2 levels (Ruddiman 2013). The gradual cooling at high latitudes that followed, and the increasing ice sheet extent recorded by $\delta^{18}O$ and other proxies, led to a period of low-amplitude climate oscillations characterized by the 41 Kyr period of Earth's obliquity, consistent with the orbital pacing predicted by Milankovitch theory. Then, in one of the most puzzling climate events of the late Cenozoic, known as the Mid-Pleistocene Transition (MPT, ~1250–700 Ka), the dominant periodicity of Earth's climate cycles inexplicably changed from 41 Kyr to 100 Kyr (Fig. 1), resulting in cold glacial intervals of increased severity and duration. This reorganization took place in the absence of any change in the underlying orbital forcing, suggesting a fundamental shift internal to the climate system (e.g., Elderfield et al. 2012). Furthermore, of the three orbital parameters that affect climate, the 100 Kyr eccentricity cycle has the least impact on insolation, so the sudden dominance of this periodicity in climate records after the MPT implies increasing nonlinearity in the climate response. This is referred to as the 100,000-year problem and serves as a reminder that our understanding of long-term climatic change is far from complete.

During the Last Glacial Maximum (LGM), from ~26.5 to 20 Kyr, the ice sheets in the Northern Hemisphere reached their maximum size with twice the volume of ice currently found in Antarctica. The massive ice sheets locked away water and lowered sea level by about 120 m (~400 ft.), which exposed the continental shelves, joining land masses together in some places and creating such features as the Bering Land Bridge and more extensive coastal plains. Much of the world was colder, drier, and dustier, the latter indicated by dust levels in ice cores that were as much as 25 times greater than now (Lambert et al. 2008).

One of the most surprising discoveries to come from the paleoclimate record is the rapidity with which large magnitude changes can occur. The most dramatic insights into this behavior first came from ice core studies in Greenland in the 1980s which showed that significant changes in regional temperature occurred in the past over timescales of a few years to decades at most. The best studied of these events is the Younger Dryas, an abrupt return to near-glacial temperatures in the high-latitude North Atlantic lasting roughly a millennium during the last deglaciation (Fig. 5). Rapid temperature excursions were subsequently found to be a characteristic feature of Greenland climate during the last glacial period. These excursions, known as Dansgaard-Oeschger or D-O events, recurred roughly every 1500 years and show up as abrupt warmings over Greenland of as much as 10–12 °C followed by a more gradual return to cold glacial conditions. Later studies showed that D-O events in Greenland are closely matched by SST changes recorded in high-accumulation-rate sediments in the North Atlantic (Bond et al. 1993). In addition, discrete layers of ice-rafted debris found in subpolar North Atlantic sediments, called Heinrich events, were deposited periodically during the coldest phases of the D-O cycles (Fig. 5) and are thought to have originated from icebergs that came out of the Hudson Strait, dropping their detrital load as they melted while being carried by currents across the North Atlantic (Hemming 2004). Though these abrupt climate events are best defined in Greenland ice for the last glacial period, many records from around the world, and from earlier glacials as well, have now been found that show evidence of large and rapid climate events with similar temporal behavior (see review in Clement and Peterson 2008). These events are of considerable interest and concern because they involve sudden shifts of Earth's climate

system from one stable equilibrium state to another, implying "tipping points" where small, gradual changes in one component of the system can lead to a large change in the entire system through feedbacks.

At present, the favored explanation for the abrupt climate events seen in ice cores and elsewhere centers on freshwater input to the high-latitude North Atlantic and its effect on heat transport into the region via disruption of the Atlantic's meridional overturning circulation (MOC). It is argued that freshwater discharges into the North Atlantic Ocean from the surrounding landmasses abruptly weaken the MOC in the Atlantic by reducing salinity and increasing stratification in the areas of modern deepwater formation. The reduction in sinking disrupts the delivery of heat from the tropics via surface currents, causing cold events in Greenland and related events around the globe, such as a southward shift in the tropical rain belts. Periodic releases of meltwater from the surrounding ice sheets seem a likely culprit, an observation consistent with the primary association of these events with glacial times. Though it is now reasonably well established that variations in the MOC accompanied the Younger Dryas and most of the abrupt D-O events recorded in Greenland (Henry et al. 2016), many questions remain, and the ultimate climate driver for these rapid excursions is not fully understood.

Summary

In 1895, the Swedish scientist Svante Arrhenius proposed that the cooling that led to the ice ages could have been produced by a drop in the concentration of atmospheric CO_2 relative to then-current levels. He further proposed that industrial emissions could potentially raise Earth's temperature in the coming centuries. As we ponder a climate future now undeniably impacted by human activities, the need to understand Earth's climate history and the full range of natural mechanisms and past variability has taken on greater importance. Paleoclimatology provides that retrospective view and has evolved into a mature and exciting discipline. The discussion in this entry barely scratches the surface of our growing knowledge of Earth's climate past, and the reader is encouraged to consult cited sources and cross-references for additional information.

Paleoenvironments

B. D. A Naafs and R. D. Pancost
Organic Geochemistry Unit, School of Chemistry, University of Bristol and Cabot Institute, Bristol, UK

Definition

A paleoenvironment is an environment that has been preserved in a natural archive, such as marine sediments and rocks, at some time in the past. However, most paleoenvironments are not preserved, and therefore, a major question is how to decipher these ancient environments using the limited archives that remain. Using a range of (geochemical but also sedimentological and biological) techniques, we can use natural archives to reconstruct not just climatological parameters such as the temperature or precipitation but also a wide variety of environmental parameters such as oxygen content of the atmosphere or pH of seawater. Over the last 40 years, scientists have been able to provide detailed reconstructions of the paleoenvironment on earth ranging from the more recent Pleistocene ice ages to the early Paleozoic and even Precambrian.

Introduction

Paleoenvironments that are commonly studied from a geochemical perspective include a wide variety of marine, lacustrine, and freshwater systems. Material can be obtained from fieldwork and using rock outcrops, which provide valuable information of ancient paleoenvironments throughout the Phanerozoic (e.g., Song et al. 2013) and Proterozoic (e.g., Arnold et al. 2004). For continuous high-resolution records from the late Cretaceous and Cenozoic, material obtained by the Integrated Ocean Discovery Project (IODP) is often used to provide a detailed insight into ancient marine environments (e.g., Zachos et al. 2001) but also terrestrial environments via geochemical signals delivered to these marine archives (e.g., de Menocal 1995; Peterson et al. 2000). Although often more challenging to exploit due to the difficulty in developing age models, terrestrial archives are also incredibly useful and include sabkhas (McKenzie 1981), paleosols (Quade et al. 2013), peat (Barber et al. 2003), and loess deposits (Zhisheng et al. 2005).

Geochemists evaluate the distributions and isotopic compositions of bulk samples as well as that of major, minor, and trace elements (e.g., S, B, Li, Cu, Ca) in these samples. More recently the distribution and especially the carbon and increasingly hydrogen isotopic compositions of organic lipids are determined in natural archives. These distributions are then compared with those observed in modern systems to reconstruct key environmental parameters. Examples are the various organic and inorganic proxies used to reconstruct atmospheric CO_2 levels (Freeman and Hayes 1992; Jasper et al. 1994; Foster 2008; Bolton et al. 2016), sea surface temperatures (Brassell et al. 1986; Elderfield and Ganssen 2000; Ghosh et al. 2006), hydrological cycle (Kohn and Law 2006; Sachse et al. 2012), global ice volume (Hays et al. 1976; Elderfield et al. 2012), dominant vegetation type (Cerling et al. 1997), and oceanic anoxia (Summons and Powell 1986; Emerson and Huested 1991; Wilkin et al. 1996).

For many parameters, a range of complimentary proxies exist. For example, the state of oceanic anoxia can be inferred by studying sulfur speciation, trace metal abundance, and isotope ratios, as well as through the presence of diagnostic biomarkers such as lycopene and isorenieratane. Together these allow geochemist to carefully reconstruct changes in the state of oxygenation of the ocean during the geological past.

Over the last 40 years, geochemists have generated a wide range of paleoenvironmental reconstructions, providing insight into specific ancient depositional environments, better understanding of the causes and consequences of biotic events in Earth history, and a better understanding about the interactions and feedbacks in the Earth system. In addition, a thorough understanding of the paleoenvironment enhances our ability to recover valuable resources. In particular, paleoenvironmental reconstructions have been an essential component in our exploration for fossil fuels and understanding of conditions leading to fossil fuel formation (Bechtel et al. 2012; Fustic et al. 2012). The conditions under which the source organic matter was deposited and the fuels were generated are largely defined by geochemical parameters. Similarly, some types of ore deposits arise from post-depositional alteration of material deposited in a particular

depositional environment or under particular environmental conditions such as an anoxic water column (Southam and Beveridge 1994; Spirakis 1996).

Complicating Factors

Fully characterizing a particular paleoenvironment, however, from the data available in the sediments is not a simple task. Geochemical parameters can be altered by secondary (postdepositional) processes during diagenesis, such as selective preservation (Zonneveld et al. 2010) in the case of lipid biomarkers or recrystallization of calcite (Fantle and DePaolo 2007), that biases the information preserved in the geological record. For example, the lipid distribution and its isotopic composition in sediments and rocks can be altered upon burial due diagenesis and thermal maturation (Seifert and Moldowan 1980; Schimmelmann et al. 2006). In addition, unique and complex conditions during deposition that have no obvious modern analogue can also contribute to the difficulty of deciphering the significance and meaning of the geochemical signatures in the rock record. For example, sea surface and terrestrial temperatures during greenhouse periods in the geological past were likely higher than any were on earth at present, and tropical temperatures persisted far into the high latitudes (e.g., Bijl et al. 2009; Pross et al. 2012; Naafs and Pancost 2016). These paleoenvironments lack a modern analogue.

In addition, the chemical composition of seawater has a strong influence on many inorganic (calcite-based) proxies such as $\delta^{18}O$, Mg/Ca, and B isotopes. However the seawater composition has changed over (geological) time (Ridgwell 2005; Coggon et al. 2010). As the exact chemistry of past seawater at a particular point in the geological past is poorly constrained beyond the Neogene (~20 Myr), it becomes difficult to interpret these proxy estimates in deep time, and assumptions have to be made regarding the composition of past seawater.

Another problem is the complexity of the geochemical signature in the rock record. The mixing of sediments and source materials in any environment produces a complex geochemical signature, making it difficult to tease apart individual parameters.

Recent Developments

Recent developments include new geochemical approaches to reconstruct marine and terrestrial temperatures using both organic and inorganic proxies. The organic TEX_{86} and MBT/CBT paleothermometers are based on the distribution of archaeal and bacterial membrane lipids and can provide information about past sea surface temperatures, past mineral soil and peat pH, and overlying mean annual temperature during the last ~200 million years (Weijers et al. 2007; Schouten et al. 2013; Naafs et al. 2017; Robinson et al. 2017). In addition, the clumped isotope composition (Δ_{47}) of biogenic calcite and soil carbonates (Quade et al. 2013) is increasingly used to reconstruct both ocean and soil temperature in the geological past. Together these proxies demonstrate that during the early Eocene, a period characterized by high pCO_2, the mid- and high latitudes were characterized by a subtropical climate with temperatures and vegetation currently only found at the low latitudes (Keating-Bitonti et al. 2011; Pross et al. 2012).

The ongoing development of the boron isotope-pH proxy (Foster and Rae 2015), which can be used to reconstruct pCO_2 if other variables can be constrained, led to detailed reconstructions of atmospheric CO_2 during key periods of the Cenozoic such as the late Pliocene/early Pleistocene (Martinez-Boti et al. 2015).

Over the last few years, a number of studies used a range of geochemical proxies such as calcium, lithium, and osmium stable isotopes to reconstruct terrestrial weathering rates during key events of the Mesozoic and Cenozoic such as the Cretaceous oceanic anoxic events (Blättler et al. 2011; Pogge von Strandmann et al. 2013) or Paleocene/Eocene thermal maximum (Dickson et al. 2015).

In addition, integration of geochemical analyses and results from climate and/or biogeochemical modeling experiments has greatly advanced our understanding of the paleoenvironment. The proxy record has often poor spatial coverage but can provide crucial constrains for global or regional high-resolution climate and biogeochemical computer models. Examples are the Cretaceous oceanic anoxic events where geochemical proxy data of oceanic anoxia was used to constrain biogeochemical model results and provided novel insights into the extent of bottom water anoxia during these events (Monteiro et al. 2012) or the early Eocene where geochemical temperature proxy data was used to constrain general circulation models (Lunt et al. 2012).

Summary

Using a wide range of inorganic and organic geochemical techniques, scientists have been able to reconstruct the paleoenvironment of a large part of the Phanerozoic. These geochemical studies in a wide variety of paleoenvironments provide important information about the processes and mechanisms that operate in Earth's climate system, which is vital for the petroleum and mining industries.

Paleoproductivity

Gerold Wefer
MARUM – Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany

Definition

Two factors are important in the reconstruction of past productivity:

1. The biogenic flux (organic and inorganic biogenic material formed at the surface that sinks to the deep ocean)
2. The availability of nutrients, especially phosphate and nitrogen

Various methods are employed for reconstructing past productivity in the ocean. Paleoproductivity is not directly measureable so it has to be derived from "surrogate data" that are closely related to the environmental parameters. These are thus referred to as proxy variables or, for short, proxies (see Wefer et al. 1999 for a review). A proxy is a measureable parameter for variables that were observable in the past (but no longer are today). As a general rule, paleoproductivity proxies record conditions in the sunlit surface waters. There is, however, another approach for estimating productivity in surface waters from material produced on the seafloor. Herguera and Berger (1994) used the abundance of benthic foraminifera in sediments as a measure of productivity because their abundance is related to food supply, which is the amount of organic substance on the seafloor.

The first paleoproductivity reconstructions were made using the accumulation rates of organic substances in sediments (Müller and Suess 1979). Since other fluxes have also been applied, including opal, carbonate, and particulate barite, assemblages of planktonic and benthic organisms are also useful for reconstructing productivity conditions because some species occur preferentially in high-productivity conditions. Various isotope and element ratios are used for reconstructions of past primary productivity or for the availability of nutrients. These include the stable carbon isotopic composition of dissolved inorganic carbon in the water column (13C/12C, expressed as δ13C). In the present-day ocean, the δ13C values of inorganic carbon are negatively correlated with nitrate and phosphate. The ratio of cadmium to calcium is used as a tracer for the phosphate content of surface waters. The nitrogen isotopes, 15 N/14 N, are also employed. These document the utilization of nitrate relative to its availability.

High-productivity regions in today's ocean are mainly located in the temperate to high-latitude regions. Wind-driven mixing, and thus the supply of nutrients from deeper waters into the surface layer, is greatest in these regions. Other high-productivity areas include the equatorial and coastal upwelling regions, where divergence also leads to the injection of deeper, more nutrient-rich waters. The upper continental margins record the highest deposition of organic carbon. Conditions there are favorable for incorporating organic material quickly into the sediment, and these regions often have low oxygen content.

Proxies

Deposition of organic material and other biogenic sediment components.

The accumulation of any sedimentary component of biogenic origin reflects a balance between production in surface waters, dilution by other sedimentary components, and dissolution/degradation both during export through the water column and in shallow sediments. There is a general relationship between productivity in the surface waters and the deposition and accumulation of organic carbon in the underlying sediments. This relationship, however, is influenced by a number of other factors and thus is not a quantitative measure. For example, organic materials can also be introduced from the land through dust or rivers. The distinction between marine and terrestrial material can be determined using carbon isotope ratios or biomarkers. The accumulation of organic material is influenced by differing decomposition rates of organic material on the way from the surface down to the sediments. Substantial changes also occur at the sediment surface. Accumulation is also affected by oxygen content and horizontal transport. As an order of magnitude, it can be assumed that only 10% of the surface production reaches the sediments, and of that amount only 10% is preserved. Because of its long residence time at the sediment surface, a large proportion of the organic carbon is broken down by bacteria. This is initially accomplished using free oxygen, and later by the reduction of nitrate, manganese and iron oxides, and dissolved sulfate.

Organism Assemblages

A number of different organism assemblages (i.e., the relative abundances of certain species within a population of one type of organism) are employed to reconstruct past productivity. Sediment traps may be used to establish correlations between the flux of organic carbon and assemblages of particular groups of organisms (e.g., phytoplankton or zooplankton). Isotope tracers such as 230Th and 210Pb are used to normalize the particle flux. Opaline siliceous fossil assemblages are often used, as they occur predominantly in high-productivity regions. These include the skeletons of diatoms, radiolarians, and silicoflagellates. The most bountiful depositional region for oceanic opal is in the Southern Ocean. When using opaline shells, we must keep in mind that they are individual proxies for the productivity of diatoms, radiolarians, or silicoflagellates and not necessarily for the total paleoproductivity. A number of transfer functions have been applied to the reconstruction of paleoproductivity using calcareous microfossil assemblages, and these are particular applicable in tropical and subtropical areas.

Stable Isotopes

The ratios of stable carbon and nitrogen isotopes are proxies for nutrients. Nutrient content is deduced from the difference in δ13C between shallow-living versus deep-living planktonic foraminifera in the surface waters and between planktonic and benthic foraminifera. Reconstructions based on δ13C values from foraminifera require additional information, for example, the calcification depths of planktonic foraminifera or the depth of living benthic foraminifera within the sediments or on the sediment surface. For the nitrogen isotopes, fractionation occurs during the uptake of nitrogen by phytoplankton, whereby 14 N is preferentially incorporated. The methodology is being constantly improved. For the study of nitrogen isotopes, not only is the total organic material analyzed, but also individual products of organisms, for example, of diatoms (Studer et al. 2015).

Trace Elements

Selected trace elements, including uranium, vanadium, and molybdenum, as well as cadmium and barium, are also used as paleoproductivity proxies. In order to apply these, their properties must be very well understood, for example, their dissolution properties under oxidizing and reducing conditions.

Reconstructions

It is difficult to make general statements about productivity in the past. The system is extremely complex, and different parts of the oceans react differently to climate and circulation changes. This is also because there is no single proxy that can be used to directly determine paleoproductivity. It is always necessary to use a number of different proxies together, which are sometimes not in agreement with each other, in order to make a statement. For example, during the glacials, high amounts of organic material are also deposited off Angola and Namibia, but with less opal than in warmer periods. This is explained by a nutrient change in upwelled waters, between glacial and interglacial periods. Changes in the (sub)antarctic silica distribution system seem to be involved (Berger et al. 2010).

Throughout Earth's history, there have been many high-productivity events that have been viewed in connection with the development of CO_2 in the atmosphere. A conspicuous example is seen in the oceanic anoxic events (OAE) of the Cretaceous, documented by alternating organic-rich and carbonate-rich facies (Arthur et al. 1985). These have a connection to orbital cycles. The high rates of deposition for organic material during the OAEs, however, are also related to low oxygen conditions in the deep water. A possible relationship to increased volcanic activity is also being debated.

There is also presently an intensive debate over the possibility of a connection between the low CO_2 content of the atmosphere and increased productivity during more recent Pleistocene glacial periods. In some regions, higher productivity observed during glacial periods has been explained by stronger trade winds. Other factors, however, have to be

considered for these productivity changes, including increased nutrient input from remote regions via ocean circulation (Jakob et al. 2016). The Antarctic, one of the most productive areas in the ocean, is viewed as a key region. Not all of the available macronutrients are being used there today. It has been suggested that this may be due to a lack of trace element micronutrients essential for phytoplankton growth (iron hypothesis, Martin 1990). This hypothesis has been resurrected by Abelmann et al. (2015) who, based on sediment-core data from the Atlantic sector of the Southern Ocean, inferred a seasonal sea-ice zone with a highly productive system for the glacials, characterized by diatoms and a high proportion of organic substance sinking into deeper water. In this hypothesis, iron is enriched by dust input on the ice surface during periods of ice cover and is released when it melts into the stratified surface waters.

A further question is how the productivity of the ocean reacts to global warming. Based on observation data, Bakun (1990) suggests that global upwelling intensifies with warming, resulting in fertility increases. This has been confirmed off northwest Africa, for example (McGregor et al. 2007). But when different regions are compared, there is often no recognizable common pattern. Narayan et al. (2010), for example, identified linear trends of upwelling intensity occurring from 1960 to 2012 in the four important regions off the coasts of NW Africa, Namibia, California, and Peru. Their results support the hypothesis of Bakun (1990) that coastal upwelling intensity has strengthened since 1960 in line with increasing atmospheric CO_2 values. They also indicate, however, that different datasets produce different results. More recent modeling studies provide evidence that by the end of this century, coastal upwelling will begin earlier and be more intense in the high but not in low latitudes (Wang et al. 2015).

Summary

Paleoproductivity describes fluctuations in biological productivity in the geological past, which can be qualitatively and semiquantitatively reconstructed using information gleaned from marine sediment archives. Knowledge of past biological productivity in the oceans is of great interest because it exhibits (proxy variables, short proxy) close ties to modern productivity (ecosystems in the ocean), to oceanic circulation with respect to the availability of nutrients, and to the carbon cycle vis-a-vis the removal of CO_2 from surface waters (and therefore from the atmosphere). Furthermore, organic matter deposited in the sediments is the origin of hydrocarbons. This entry gives an overview on proxies used for reconstructions and examples of paleoproductivity patterns in the past.

Definition

A paleotemperature is the temperature of a location, either on land or in the ocean, at a specific time in the geologic past. Scientists use paleothermometers to reconstruct past temperature records from archives – natural features of the Earth that preserve clues about past climate and environmental change. Examples of archives include marine and lacustrine sediment, glacial ice, and corals. Paleothermometers are often referred to as temperature proxies, which are measurable physical, geological, geochemical, or biological characteristics that get preserved in archives, standing in for instrumental measurements. Each proxy is associated with a calibration that transforms the proxy measurements into the parameter of interest, which in this case is temperature.

Scientists rely on proxy measurements from archives because direct observations of temperature extend back only as far as the middle of the nineteenth century (Smith et al. 2008). Direct temperature measurements of the ocean extend back even less. These limits to the length of instrumental records make it difficult to constrain the range of natural climate variability, the degree of twentieth century warming, and climate sensitivity to greenhouse gas forcing. Accurate paleotemperature reconstructions are the only way to extend the short observational period farther into the past.

This entry describes paleotemperature proxies from marine and terrestrial archives. The paleotemperature proxies presented here are by no means an exhaustive list, but instead highlight the geochemical proxies that are used most frequently for paleotemperature reconstructions.

Assemblages of Planktonic Foraminifera

Foraminifera are marine protozoa (unicellular zooplankton) that can either be found free-floating in the open, upper layers of the ocean (planktonic), or living on or in seafloor sediment (benthic). They secrete characteristic tests, or shells, often composed of calcium carbonate (calcite, $CaCO_3$), that accumulate on the seafloor after death. There are ~50 living species of planktonic foraminifera in the modern oceans, and they are found in diverse oceanic regions from the warm tropics to cold polar waters (Kucera 2007). The greatest planktonic species diversity can be found in the tropics, with diversity generally decreasing with increasing latitude. Differences in the species composition, or assemblage, of planktonic foraminifera contain information about the temperature of the waters they inhabit (Murray 1897). Statistical techniques can be used to determine sea surface temperature (SST) from assemblages, including transfer functions (Imbrie and Kipp 1971) and the modern analog technique (Hutson 1980; Howard and Prell 1992). Studies comparing both methods find little difference between them (Ortiz and Mix 1997), but there are limitations to the overall approach. Both methods are based on the assumption that temperature is the main control on the assemblages; other factors, such as food availability, light requirements, and ocean circulation changes can also alter species distributions (Wefer et al. 1999). Finally, there is uncertainty in relating habitat (depth and seasonal) to SST at a certain time of the year.

Mg/Ca Ratios

Mg/Ca ratios in benthic and planktonic foraminifera have become widely used proxies for reconstructing bottom and upper water column paleotemperatures, respectively. The underlying basis for Mg/Ca paleothermometry is that the substitution of Mg^{2+} for Ca^{2+} in calcite is endothermic and therefore favored at higher temperatures. As a result, the Mg/Ca ratio of foraminiferal calcite increases with increasing temperature.

The temperature dependence on Mg uptake into planktonic foraminiferal tests has been determined using culture-based, sediment trap, and core-top calibrations. Culture-based calibrations rely on growing planktonic foraminifera under controlled laboratory conditions in which the temperature is fixed independently of other environmental parameters (e.g., Nürnberg et al. 1996; Lea et al. 1999; Russell et al. 2004; Allen et al. 2016). Sediment trap calibrations measure planktonic foraminifera collected in sediment trap time series from regions with high seasonal temperature variability (e.g., Anand et al. 2003). Core-top calibrations measure Mg/Ca ratios of modern or recently deposited planktonic foraminifera from the seafloor and then calibrate the ratios against the water column temperature overlying the sediment core site based on the foraminifera's preferred depth habitat (e.g., Lea et al. 2000; Dekens et al. 2002). Core-top calibrations are used most often to determine the relationship between Mg/Ca ratios in benthic foraminifera and bottom water temperature (Rosenthal et al. 1997; Lear et al. 2002; Bryan and Marchitto 2008).

Despite differences between calibration methods, studies show that most species of planktonic foraminifera have a temperature sensitivity of a ~9–10% exponential increase in Mg/Ca per degree Celsius (Lea et al. 1999; Elderfield and

Ganssen 2000; Dekens et al. 2002; Anand et al. 2003). Culturing studies find that salinity also influences the uptake of Mg into planktonic foraminiferal tests, with Mg/Ca ratios increasing by 3–8% per salinity unit increase (Nürnberg et al. 1996; Lea et al. 1999; Hertzberg and Schmidt 2013; Hönisch et al. 2013; Allen et al. 2016). In contrast, the sensitivity of Mg/Ca to temperature in benthic foraminifera is more variable between species and may be influenced by other factors, including bottom water carbonate ion concentration (Lear et al. 2002; Elderfield et al. 2006; Bryan and Marchitto 2008). As benthic foraminifera dwell on the bottom of the ocean, where temperatures are lower than at the sea surface, their Mg/Ca ratios tend to fall on the lower end of the exponential relationship with temperature. Thus, the Mg/Ca paleothermometer for benthic foraminifera is less sensitive than for planktonic foraminifera, often making bottom water Mg/Ca-temperature estimates more difficult.

Postdepositional processes can alter Mg/Ca ratios in planktonic foraminifera because saturation with respect to calcite decreases in the ocean with increasing depth. Depth transect studies show that, in general, Mg/Ca ratios decrease with increasing water depth, especially below the regional lysocline (Brown and Elderfield 1996; Lea et al. 2000; Dekens et al. 2002; Regenberg et al. 2014). Partial dissolution of foraminifera tests can bias Mg/Ca ratios due to the heterogeneous distribution of Mg within the test and the higher solubility of Mg-rich calcite (Brown and Elderfield 1996; Dekens et al. 2002). However, methods have been developed to account for this effect (Rosenthal and Lohmann 2002; Dekens et al. 2002; Regenberg et al. 2014).

Recent advances in Mg/Ca paleothermometry include the analysis of multiple planktonic species that live at a range of depths and the analysis of individual foraminiferal tests from the same stratigraphic interval. By analyzing species with a range of depth habitats, scientists can reconstruct past changes in the vertical temperature profile of the ocean (Schmidt et al. 2012; Parker et al. 2015). To gain insight into short-term variability at times in the past, scientists are now using individual planktonic foraminifera Mg/Ca analyses from a single depth horizon in a sediment core (Ford et al. 2015). This approach allows scientist to reconstruct past changes in overall temperature variability and has provided insight into past changes in seasonality and El Niño Southern Oscillation variability.

Mg/Ca ratios in ostracods can be also used to reconstruct bottom water temperatures (e.g., Cronin et al. 2000). Ostracods are benthic bivalved Crustacea that secrete calcite shells during molting. Similar to foraminifera, the amount of magnesium in the calcite shells is largely controlled by the water temperature in which the organism secreted the shell (Dwyer et al. 2002). A positive correlation between water temperature and Mg/Ca in ostracods has been observed, although postdepositional processes such as dissolution also impact Mg/Ca ratios (Cronin et al. 2000). The main difference between foraminifera and ostracod Mg/Ca paleothermometry is that the calibration between temperature and Mg/Ca in ostracods is linear, as opposed to exponential for foraminifera.

Oxygen Isotopic Composition of Foraminifera

The oxygen isotopic composition of both planktonic and benthic foraminiferal calcite has been used for decades as a proxy for reconstructing past SSTs (Emiliani 1955). It is expressed as $\delta^{18}O_{Calcite}$ ($\delta^{18}O_C$), the deviation of the $^{18}O/^{16}O$ ratio relative to the VPDB standard in per mil (‰). Based on laboratory and natural experiments, a number of general and species-specific foraminiferal relationships between SST and $\delta^{18}O_C$ have been published (Epstein et al. 1953; Shackleton 1974; Erez and Luz 1983; Kim and O'Neil 1997; Bemis et al. 1998; Marchitto et al. 2014). In general, $\delta^{18}O_C$ decreases by ~0.21–0.23 ‰ for a 1 °C increase in temperature (Ravelo and Hillaire-Marcel 2007). However, foraminiferal $\delta^{18}O_C$ values are a function of both temperature and the oxygen isotopic composition of the seawater ($\delta^{18}O_{SW}$) in which they grow. Furthermore, $\delta^{18}O_{SW}$ varies with changes in salinity, as evaporation and precipitation cause local $\delta^{18}O_{SW}$ to increase and decrease, respectively. On longer timescales, changes in continental ice volume cause $\delta^{18}O_{SW}$ to decrease globally with melting of ice and increase globally with ice sheet growth. Mixing of water masses with different $\delta^{18}O_{SW}$ values can also influence local $\delta^{18}O_{SW}$. Thus, only if $\delta^{18}O_{SW}$ is known (or at least constrained) can $\delta^{18}O_C$ provide unique paleotemperatures. Other limitations to the $\delta^{18}O_C$ temperature proxy are vital effects such as photosynthetic activity of algal symbionts (Duplessy et al. 1970; Bemis et al. 1998), changing depth habitats of planktonic foraminifera, and the carbonate ion concentration of seawater (Spero et al. 1997).

Because $\delta^{18}O_C$ is a function of both temperature and $\delta^{18}O_{SW}$, researchers developed a method using paired Mg/Ca temperatures and $\delta^{18}O_C$ measurements on foraminifera to reconstruct past $\delta^{18}O_{SW}$ variability. When applied to surface-dwelling planktonic foraminifera, this method has been shown to be a robust proxy for reconstructing sea surface salinity variability once changes in continental ice volume are taken into account (Schmidt et al. 2006; Schmidt and Lynch-Stieglitz 2011). Researchers have also used this method with benthic foraminifera to reconstruct bottom water $\delta^{18}O_{SW}$ change as a proxy for continental ice volume variability over the past 1.5 Ma (Elderfield et al. 2012). The most significant advantage of this approach to calculate $\delta^{18}O_{SW}$ variability is that Mg/Ca can be measured on the same shells that carry $\delta^{18}O_C$ information, so there is no ambiguity in timing between the signals.

Clumped Isotopes in Carbonates

Recently, a considerable amount of interest has been invested in the development of a paleothermometer based on clumped stable isotope analyses of $CaCO_3$. Although the multiply substituted isotopologue ($^{13}C^{16}O^{18}O$) is rare and difficult to measure, the approach is based on the thermodynamic prediction that the abundance of multiple isotope substitutions in $CaCO_3$ increases as temperature decreases (Schauble et al. 2006; Passey et al. 2010). Therefore, unlike for temperature reconstructions based on $\delta^{18}O$ values, temperature reconstructions based on this method are not influenced by changes in the $^{18}O/^{16}O$ ratio of the water from which the mineral was precipitated. Initially, synthetically grown carbonates were used to identify the relationship between temperature and Δ_{47} values (Ghosh et al. 2006). Since then, calibration efforts have extended to shallow and deepwater corals, mollusks, and fish otoliths (Ghosh et al. 2006, 2007; Came et al. 2007; Thiagarajan et al. 2011). In addition, recent work has included the initial development of clumped isotopes in foraminifera and coccolithophores (Tripati et al. 2010, 2014). The resulting relationship for both inorganic and organic calcite shows a sensitivity of ~0.004–0.005 ‰ per °C.

Although clumped isotopes are becoming a more widely applied tool for geosciences, its application to the field of paleoceanography has been somewhat limited because of several factors. First, large sample sizes are required for a single analysis (in the range of 3–8 mg $CaCO_3$). Second, because the measurement of Δ_{47} is analytically challenging, it is necessary to replicate each measurement three to five times in order to reduce the standard error to less than ±2 °C. Third, only limited calibration data is available, especially for temperatures below 15 °C.

The abundance of ^{13}C–^{18}O bonds in a $CaCO_3$ sample is measured on the CO_2 liberated from the sample in phosphoric acid using gas source mass spectrometry (Ghosh et al. 2006; Guo et al. 2009). This allows for both Δ_{47} and $\delta^{18}O$ analysis on the same sample, resulting in the determination of both calcification temperature and the $\delta^{18}O$ value of the water from which the mineral precipitated. Therefore, as analytical methods continue to improve, this technique has considerable potential for becoming an important paleothermometer for future paleoceangraphic studies.

Biomarker Proxies: Alkenones and TEX_{86}

Although the Mg/Ca paleothermometer has advantages compared with the $\delta^{18}O_C$ proxy, it also has limitations including the influences of dissolution, calibrations based only on modern species, geographic limitations to regions inhabited by foraminifera, and temporal variability in seawater Mg/Ca ratios over millions of years. Biomarker-based SST proxies, such as the alkenone $U^{k'}_{37}$ (Brassell et al. 1986; Prahl and Wakeham 1987) and TEX_{86} (Schouten et al. 2002) indices, can overcome some of these limitations due to the ubiquitous appearance of the associated biomarkers in marine sediments temporally and spatially, especially during times and in regions where foraminifera do not exist. Similar to foraminifera-based proxies, the carriers of biomarkers accumulate and get preserved on the seafloor and can be sampled and extracted from sediment cores.

Alkenones are long-chain organic compounds produced by marine haptophyte algae (phytoplankton) known as coccolithophores. Because algae require sunlight to perform photosynthesis, they reside at or near the sea surface, making them a useful tool for reconstructing SST. The $U^{k'}_{37}$ index is based on the proportions of di- and tri-unsaturated ketones within the alkenones and varies positively with growth temperature. A decrease in temperature leads to an increase in the degree of unsaturation. Prahl and Wakeham (1987) and Prahl et al. (1988) developed the first quantitative calibration of alkenone unsaturation to growth temperature based on coccolithophores grown in the laboratory at known temperatures, and it appeared to reliably estimate SST based on samples collected from the ocean. Since then, large datasets of core-top $U^{k'}_{37}$ SST calibrations have been developed and show strong convergence with the original laboratory based calibration (Conte et al. 2006). Unfortunately, one of the main drawbacks to the $U^{k'}_{37}$ paleotemperature proxy is that it has an upper temperature limit of ~28 °C and a lower limit of ~1 °C (Herbert 2014). This precludes SST reconstructions based on the $U^{k'}_{37}$ index from the coldest and warmest regions of the ocean and from exceptionally warm periods in Earth's history.

Other ambiguities related to the alkenone paleotemperature proxy are depth and seasonal variations of alkenone-producing species in the ocean (Herbert 2014) and the potential for postdepositional transport of fine-grained alkenone carriers (Ohkouchi et al. 2002). Sunlight can penetrate to depths below the sea surface; thus, alkenones can be produced at a range of depths as long as light is sufficient for photosynthesis. Another drawback to this proxy is that phytoplankton production is seasonal in most ocean locations, so the $U^{k'}_{37}$ temperatures can be biased to the season of maximum production.

The TEX_{86} paleothermometer is another biomarker-based proxy developed more recently and holds promise for overcoming the temperature limitations of the alkenone temperature proxy. The TEX_{86} (TetraEther indeX of 86 carbons) index is based on the number of cyclopentane rings in membrane lipids, known as glycerol dialkyl glycerol tetraethers (GDGTs), which are produced by marine Thaumarchaeota (Schouten et al. 2002). The TEX_{86} paleothermometer is based on observations from culturing and mesocosm experiments that the number of cyclopentane rings in GDGTs

increases with increasing growth temperature (Wuchter et al. 2004). Schouten et al. (2002) noted a relationship between the number of rings in the GDGTS in marine surface samples and overlying SST and developed the first TEX_{86} temperature calibration based on 40-sediment core-top samples from 15 locations. Subsequent calibrations involving the addition of hundreds of core-top samples all note the highest correlation between the TEX_{86} index and SST (Kim et al. 2010). However, other studies have noted a bias in TEX_{86} temperatures where they are representative of subsurface rather than sea surface temperatures (Hertzberg et al. 2016). Unlike coccolithophorids that live near the sea surface, archaea live throughout the water column, which may help explain the subsurface signal (Schouten et al. 2002). While the exact cause of the subsurface bias is still unknown, a new calibration to subsurface temperature has been developed (Tierney and Tingley 2015). Despite this uncertainty, the TEX_{86} temperature proxy, which can reconstruct warmer temperatures than the alkenone SST proxy, has been used to reconstruct SSTs from the early Eocene when atmospheric pCO_2 levels may have reached ~2000 ppmv (Bijl et al. 2009).

The TEX_{86} paleothermometer can also be applied to lacustrine sediments for reconstructions of terrestrial temperatures, as GDGT-producing Thaumarchaeota also exist in lakes (Powers et al. 2004). The mechanistic basis of the proxy is the same in these systems, although separate calibrations are necessary (Tierney et al. 2010). In addition, soil GDGTs and methanogenic archaea can potentially complicate TEX_{86} in lakes, but these effects do not appear to be systematic (Tierney 2014). Nevertheless, the lacustrine TEX_{86} paleothermometer has been applied to a number of lakes, in, for example, Africa (Tierney et al. 2008).

Sr/Ca Ratios in Corals

Corals associated with reefs (as opposed to deep-sea corals) grow in regions of warm SST making them a useful archive for tropical SST reconstructions. These corals secrete aragonite in annual bands, so high-resolution paleotemperature reconstructions are possible. Sr^{2+} substitution in corals has inverse temperature dependence due to the exothermic nature of the reaction in which Sr^{2+} substitutes for Ca^{2+} in aragonite. Typically, Sr/Ca ratios are first calibrated with modern instrumental SST records to establish a coral-specific Sr/Ca-temperature relationship, which is then applied to the older skeleton of the same coral, or to fossil corals for reconstructions past SST (e.g., Felis et al. 2009; Hereid et al. 2013).

Coral Sr/Ca ratios appear to also be strongly influenced by vital effects (Alpert et al. 2016). Growth rate and symbiotic activity have a marked influence on coral Sr/Ca, and culture studies have shown that coral Sr/Ca responds to changes in seawater pH and light. Researchers have also noted offsets in temperature sensitivity and mean Sr/Ca ratios in neighboring colonies collected from the same reef (Goodkin et al. 2005; Alpert et al. 2016). A potential explanation for these vital effects is that corals accrete their skeleton within an isolated calcifying fluid that is continuously depleted in Sr/Ca as aragonite precipitation proceeds (Cohen et al. 2006). Changes in the carbonate ion concentration of the calcifying fluid can drive variations in the amount of aragonite precipitation and cause variations in the magnitude of calcifying fluid Sr/Ca depletion. DeCarlo et al. (2016) developed a method to account for these vital effects by combining Sr/Ca with U/Ca ratios, which decrease as carbonate ion concentrations increase. This new method, termed coral Sr-U thermometry, has the potential to offer significantly improved reliability for reconstructing past ocean temperatures from corals.

Terrestrial Temperature Proxies

Terrestrial temperature proxies provide information on Earth's surface air temperature. Geochemical proxies such as oxygen ($\delta^{18}O$) and deuterium (δD) isotopic values of glacial ice, and nitrogen and argon isotopic ratios of air bubbles trapped in ice, can be used to estimate past atmospheric temperatures.

Ice cores are a valuable paleoclimate archive because of the large number of variables that can be derived from both the ice and the air that is trapped within the ice as it forms. In addition to temperature, ice cores are used for reconstructions of atmospheric CO_2 and CH_4 concentrations, dust, and concentrations of salts, to name a few. Ice cores can be drilled from the polar regions of Greenland and Antarctica and from high-altitude tropical and subtropical locations. Oxygen and deuterium isotopes measured in ice can be used as a temperature proxy because isotopic fractions of the heavier ^{18}O and ^{2}H in snowfall are temperature dependent, and there is a strong spatial correlation between mean annual temperature and the mean isotopic fraction of ^{18}O or ^{2}H in precipitation (Dansgaard et al. 1993; Grootes et al. 1993). Evaporation fractionation, which depends on surface conditions (e.g., SST, wind speed, relative humidity), controls the isotopic composition of atmospheric water vapor. Fractionation occurs as an air mass moves poleward, cooling and condensing, which leads to fractionation as the air mass progressively loses heavy isotopes from the water vapor. As a result of this process, known as Rayleigh distillation, the predominant control on the polar isotopic composition of water vapor is the temperature difference between the evaporative source and the final region of deposition (Masson-Delmotte, et al. 2006). Thus, past changes in evaporation conditions or

atmospheric transport can induce biases in temperature reconstructions based on $\delta^{18}O$ or δD. A parameter known as deuterium excess ($d = \delta D - 8(\delta^{18}O)$) takes advantage of the combined measurements of $\delta^{18}O$ and δD to correct past temperature reconstructions from changes in evaporation conditions (Cuffey and Vimeux 2001). Prominent ice core temperature records from Greenland include GRIP (Greenland Ice-core Project Members 1993; Dansgaard et al. 1993), GISP2 (Grootes et al. 1993), and NGRIP (North Greenland Ice Core Project members 2004) and from Antarctica include Vostok (Petit et al. 1999), EPICA Dome C (EPICA community members 2004), and WAIS Divide (WAIS Divide Project Members 2013). Note that this is not a complete list of all available ice core records.

Measurements of the $\delta^{15}N$ and $\delta^{40}Ar$ of air bubbles trapped in ice cores can be used for temperature reconstructions during periods of abrupt temperature change. When rapid temperature change occurs, a transient temperature gradient is established in the firn (the region of partially compacted snow) until a stable depth temperature gradient in the upper part of the ice is restored. Under a vertical temperature gradient, the gases in the firn undergo a thermal fractionation, with the heaviest species being concentrated at the coldest end (Masson-Delmotte et al. 2006). Analyses of $\delta^{15}N$ and $\delta^{40}Ar$ in ice core air bubbles, which are constant in the atmosphere over long timescales, can be combined with firn modeling to provide estimates of past abrupt temperature changes (Severinghaus et al. 1998). This method has proven especially useful for reconstructing temperature changes from Greenland ice cores across abrupt climate change intervals such as Dansgaard-Oeschger events of the last glacial period and the millennial-scale events of the last deglaciation (Severinghaus and Brook 1999; Landais et al. 2004).

Conclusions

Each paleotemperature proxy has a unique set of advantages and disadvantages. Depending on the location and time period of interest, scientists will use the proxies that best suit their needs. Often, reconstructing temperature using two or more proxies can help to make climate records more robust. If the paleotemperatures measured using multiple proxies disagree, it may indicate an environmental control on the proxy unrelated to temperature. Finally, robust and reliable age models are key to any paleotemperature reconstruction. Temperature proxies also continue to undergo refinement as new discoveries are made and better technologies and methods are made available for measurements. The geochemical paleotemperature proxies discussed in this entry are by no means an exhaustive list, and the reader is encouraged to consult the references for more details.

Palladium

James M. Brenan
Department of Earth Sciences, Dalhousie University, Halifax, NS, Canada

Element Data
Atomic Symbol: **Pd**
Atomic Number: **46**
Atomic Weight: 106.42

(*continued*)

Isotopes and Abundances: ^{102}Pd 1.02%, ^{104}Pd 11.14%, ^{105}Pd 22.33%, ^{106}Pd 27.33%, ^{108}Pd 26.46%, ^{110}Pd 11.72%
0.1 MPa Melting Point: 1554.9 °C
0.1 MPa Boiling Point: 2990 °C
Common Valences: +2, +4
Ionic Radii: 4-fold: 64 pm (+2); 6-fold: 86 pm (+2), 61.5 pm (+4)
Pauling Electronegativity: 2.2
First Ionization Energy: 804.39 kJ/mol
Chondritic (CI) Abundance: 574 ng/g
Silicate Earth Abundance: 7.1 ng/g
Crustal Abundance: 1.5 ng/g
Seawater Abundance: 0.2–0.7 pmol/kg
Core Abundance: 3100 ng/g

Definition

Atomic number 46 is a dense, moderately refractory, precious metal with a bright silvery-white luster. Discovered in 1804, and named for the Pallas asteroid detected 2 years earlier, it is widely used for automobile catalysts as well as electrical components, jewelry, dental restoration, and hydrogen purification.

History and Uses

William Wollaston reported the discovery of palladium in 1804 (Wollaston 1804), which was purified from the aqua regia solution he used to dissolve naturally occurring platinum alloy (at the time known as platina; see entry for ▶ "Platinum"). This was the material likely derived from placer deposits of the Choco District of Columbia, which had been exploited by the pre-Hispanic aboriginals to produce jewelry and useful objects (fishing hooks, sewing needles, awls, tweezers). In his report to the Royal Society of London, Wollaston proposed the name palladium ". . .from the planet that had been discovered nearly at the same time by Dr. Olbers," referring to the discovery of the Pallas asteroid (originally considered to be a planet) by the German astronomer Heinrich Olbers on March 28, 1802. Palladium is principally used in automobile catalytic converters for engine emission control but is also employed in the industrial sector for electrical components, is alloyed with gold for use in dental restorations, and also to produce "white gold" for jewelry. Palladium has a significant solubility and selective permeability for hydrogen, at the exclusion of other gases, the latter enhanced by alloying with silver, or certain rare-earth elements. These unique characteristics are exploited for the commercial production of high purity hydrogen. A detailed account of the history of palladium, including important discoveries and scientific work, can be found in the book "*History of Platinum and its Allied Metals*" by McDonald and Hunt (1982).

Elemental and Physical Properties

Palladium has an atomic weight of 106.42[1], ground state electron configuration of [Kr]4d^{10}, with melting and boiling points at 0.1 MPa of 1554.9 °C and 2990 °C, respectively (Arblaster 2007). Palladium is a relatively dense metal (12,023 kg/m^3), similar to lead (11,340 kg/m^3). Palladium is considered to be moderately volatile, with a 50% condensation temperature of 1051 °C (Lodders 2003). Palladium has six stable isotopes: 102 (1.02[1]%), 104 (11.14[8]%), 105 (22.33[8]%), 106 (27.33[3]%), 108 (26.46[9]%), 110 (11.72[9]), as well as the now-extinct radioactive ^{107}Pd, which undergoes beta-decay to ^{107}Ag, with a half-life of 6.5×10^6 years. In addition to the neutral metal, the common oxidation states are 2+ and 4+. The radius of the neutral atom is 169 pm (Clementi et al. 1967), and Pd crystallizes in the cubic close-packed structure (space group Fm-3 m) with a metallic radius of 135.7 pm (Rao and Rao 1964). The size of the cation varies as follows (from Shannon 1976): 59 pm (+1, II-fold), 64 pm (+2, IV-fold, square planar), 86 pm (+2, VI-fold), 76 pm (+3, VI-fold), and 61.5 pm (+4, VI-fold). Useful texts that provide synopses of the chemical properties of Pd can be found in Cotton (1997) and in a compendium of papers edited by Hartley (1991).

Geochemical Behavior and Reservoir Abundance

Palladium is both highly siderophile and strongly chalcophile and is grouped with other 5th and 6th row transition metals having similar chemical properties: Pt, Rh, Ru, Os, and Ir; see entries for ▶ "Platinum Group Elements" (PGE) and ▶ "Siderophile Elements". Owing to its large ionic radius, Pd does not readily dissolve into rock-forming minerals, such as olivine and chromite (Brenan et al. 2016), but instead concentrates in base metal sulfides or forms accessory minerals. In terms of the latter, merenskyite ($PdTe_2$), stibiopalladinite (Pd_5Sb_2), arsenopalladinite ($Pd_8(As_{2.5},Sb_{0.5})_3$), atokite ($Pd_3Sn$), sobolevskite (PdBi), and Pd-bearing isoferroplatinum ($(Pt,Pd)_3(Fe,Cu)$) are some of the more common varieties found at world-class Pd deposits, such as Noril'sk, in Russia (see below; Kozyrev et al. 2002). An extensive compilation of palladium-bearing minerals is provided in Cabri (2002).

The abundance of Pd in the carbonaceous chondrite Orgueil is 574 ng/g (Horan et al. 2003), taken as similar to

the bulk earth concentration, which has now been highly fractionated between the core (3100 ng/g; McDonough 2003), upper mantle (7.1[1.3] ng/g; Becker et al. 2006), and crust (continental: 1.5 ng/g; Rudnick and Gao 2003; oceanic: 2.122 ng/g; Peucker-Ehrenbrink et al. 2012). The relative proportions of the PGE are close to chondritic in the upper mantle, although Pd is in slight excess to the others (Becker et al. 2006), with a relative fractionation similar to impact breccias on the lunar surface (Puchtel et al. 2008). The abundance of Pd in the upper mantle is also much higher and relatively unfractionated than expected for equilibrium between metal and silicate (Mann et al. 2012). Many believe this is the result of late accretion of chondritic material following core formation. The palladium content of seawater (0.2–0.7 pmol/kg) is similar to the heavy rare-earth elements (Bruland and Lohan 2003), although the crustal abundance of Pd is >100x lower. Calculations indicate that the dominant Pd species in seawater is $[PdCl_4]^{2-}$ at 25 °C, pH 8.2, 0.1 MPa (Byrne et al. 1988).

The existence of live ^{107}Pd in the early solar system was first documented by Kelly and Wasserburg (1978) by detection of excess ^{107}Ag in the Santa Clara iron meteorite. Since then, several studies have used this isotopic system to date the crystallization of iron meteorites, as large differences in Pd/Ag occur by metal-sulfide fractionation (e.g., Carlson and Hauri 2001; Chen and Wasserburg 1990). Whereas Ag is more volatile than Pd, differences in Pd/Ag can also arise due to evaporation and condensation processes acting in the early solar nebula. This has given rise to variation in the ^{107}Ag/^{109}Ag in chondritic meteorites, which has been used to establish the source and timing of addition of volatile-bearing materials to the Earth-Moon system (Schönbächler et al. 2010). Carlson et al. (2008) provided an overview of the applications of PGE isotopic systems, including Pd/Ag, in geo- and cosmochemistry.

Economic concentrations of Pd require >10,000-fold enrichment relative to crustal background values. This can occur when mantle-derived magmas reach saturation in immiscible sulfide liquid. The largest Pd deposits are found at Noril'sk (Russia), concentrated in massive sulfides formed within the magmatic conduit system of the 250 Ma Siberian Traps. Other significant deposits are associated with the Bushveld Igneous Complex of South Africa, as well as Sudbury (Canada) and Stillwater (USA). Global production in 2015 was ~180,000 kg, at an average market price of ~ $26,000/kg. The reader is referred to *Platinum Metals Review*, which provides a range of technical and historical information on the allied platinum group metals.

Summary

Palladium is a bright, silvery-white precious metal characterized by high density and moderately high melting temperature and unique surface catalytic properties. The principal uses of palladium are for automobile catalytic converters as well as electrical components, jewelry, dental restoration, and hydrogen purification. Palladium is highly siderophile, as well as chalcophile, and is therefore concentrated in Earth's core, with complementary depletions in the silicate mantle, crust, and surface reservoirs. Palladium has one extinct isotope ($t_{1/2}$ = 6.5 Ma), that was present in the early solar system, decaying to the more volatile ^{107}Ag. This isotopic system has been used to establish early solar system chronology and to establish the source and timing of addition of volatile-bearing materials to the Earth-Moon system. Extreme concentration of Pd relative to crustal background values is needed to produce minable terrestrial deposits, requiring the massive extraction capacity of immiscible sulfide melts that form in silicate magmas.

Paragenesis

Denton S. Ebel[1] and Robert J. Kamilli[2]
[1]Department of Earth and Environmental Sciences, Columbia University, New York, NY, USA
[2]Tucson Office – Geology, Minerals, Energy and Geophysics Science Center, U.S. Geological Survey, Tucson, Arizona, USA

Definition

Paragenesis is the sequence of formation of associated minerals in rocks and rock suites (Craig and Vaughan 1994, p. 164). The concept of mineral paragenesis, *sensu stricto*, applies to the characteristics of mineral associations that connote contemporaneous formation, presumably in chemical equilibrium. The word paragenesis comes from the Greek, meaning "born beside."

The classical usage of paragenesis is to describe the temporal order of mineral deposition in an ore deposit, or paragenetic sequence, for example, in the Stassfurt salt deposits (Clarke 1911; Warren 2006). Mineral paragenesis is closely related to the concept of mineral zoning, where the variation occurs in space, rather than time. In its broadest sense, the term can be applied to any sequence or assemblage of minerals related by common formation conditions. Recent conceptual developments in mineralogy frame paragenesis from stellar atmospheres, to protoplanetary disks, to planets, to plate tectonics, and to the evolution of life (Hazen et al. 2008).

History

The concept of paragenesis was introduced by the Russian Academician V. M. Severgin (1816) and developed by distinguished German mineralogist and crystallographer Johann Friedrich August Breithaupt (1849). The study of mineral paragenesis was developed in the late nineteenth century following the development of the petrographic microscope. Efforts to understand the distribution of the elements using paragenetic concepts began in the twentieth century (Vernadsky 1910; Goldschmidt 1937), and experimental petrology and theoretical geochemistry were applied to quantitative petrogenetic studies (Clarke 1911; Korzhinskii 1959; Thompson 1970; Winkler 1979). The second half of the twentieth century saw an emphasis on geologic context, with detailed mapping and attention to cross-cutting features, especially of mineral deposits. This became essential to the understanding of the time and space relationships of geological entities. The recent revolution in our understanding of meteorites, stellar environments, and the rocky planets and

moons has allowed extension of paragenetic concepts beyond the Earth.

Paragenesis of Stellar and Nebular Rocks

The very first minerals formed in the atmospheres of giant stars. A suite of ~15 minerals in micron to submicron grains is present in the "presolar" fraction isolated from primitive chondritic meteorites of age 4.5678 Ga (Davis 2011). These minerals, and micron-scale rocks, are associated by occurrence and formation history. They record their source star type, and galactic chemical evolution in their isotopes. Thus they constitute the most primitive paragenetic mineral sequences: oxides (hibonite, spinel) formed in O-rich stellar environments and carbides formed in C-rich ones (diamond, SiC, TiC).

The high-temperature minerals formed in our own Solar Nebula, prior to planetary differentiation, include three paragenetic groups with distinct chemical affinities. Refractory Ca- and Al-rich inclusions (CAIs) form distinct objects with ~10 primary minerals, often in distinct layers. Glassy Mg-silicate-rich chondrules, partially or fully melted in space, constitute the volumetric majority of chondrites. Metal-sulfide nodules or metal grains are a distinct component of most chondrites. These three paragenetic mineral groups characterize the primary variability among primitive meteorites (Grossman 1996; Weisberg et al. 2006). While they differ in terms of volatility, as a condensation sequence (Ebel 2006), great controversy surrounds the timing and formation mechanism, the parageneses, of these mostly submillimeter, high-temperature planetary precursors.

The aqueous and thermal alteration of primitive chondrite parent bodies forms paragenetic groups including nepheline, grossularite, and sodalite (from CAIs); clays and other phyllosilicates (in chondrules); and phosphates (from P-bearing metal). Accretion by impacts forms high-pressure, shock-formed minerals (e.g., maskelynite, majorite), which with their parent minerals constitute unique paragenetic sequences (Sharp and DeCarli 2006). Alteration and shock expand the suite of mineral species that occur in chondrites to about 250 (Rubin 1997). Incorporated ices were the source of water for aqueous alteration, although ices are not preserved in the meteoritic record. The associations and formation sequences of ices (cryominerals), for example, their parageneses on Titan and Pluto, are active fields of planetary science research.

Paragenesis of Planetary Bodies

Accretion into larger bodies induces melting and core-mantle differentiation, recorded by the achondrite meteorites (primarily basalts, irons, and stony irons). Sulfide nodules in iron meteorites contain a distinct paragenetic suite including carbides, nitrides, and sulfides derived from trace constituents originally dissolved in molten iron, and immiscible in slowly cooled subsolidus iron in early planetesimal cores. The basaltic achondrite meteorites record paragenetic sequences of early mantle formation on dry (e.g., Vesta) and wet (e.g., Mars) planetary bodies, the latter likely similar to Earth's Hadean Eon (> 4.03 Ga). Hazen (2013) lists about 420 mineral species likely formed during this period of mineral evolution.

Post-Hadean terrestrial processes such as plate tectonics, subduction-related volcanism and high-pressure metamorphism, continent formation, fluid-rock interactions, differentiation of high-silica magmas, and massive sulfide formation are all recorded in paragenetic sequences. Advanced geological processes and the evolution of life and an oxidizing atmosphere are responsible for much of the vast terrestrial mineral kingdom, with about 5100 species (NRMIMA 2016). Detailed study of the paragenetic associations among mineral species offers important clues to each of many terrestrial geological processes.

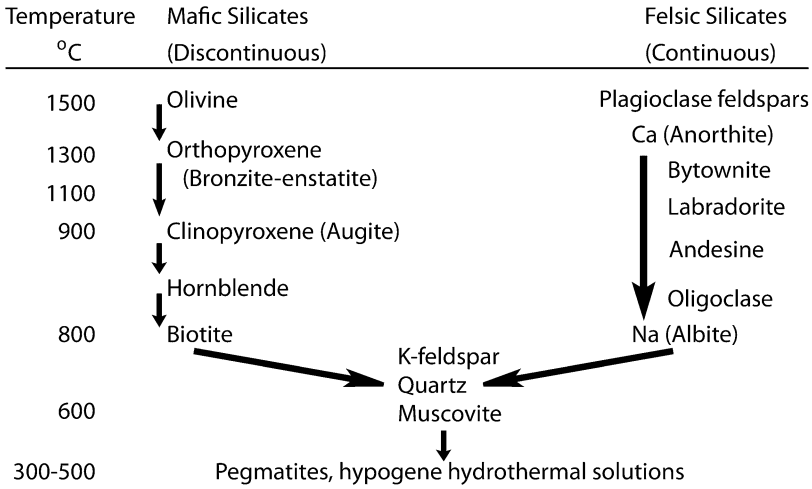
Paragenetic Models

Studies of the genesis of all kinds of rocks have consistently yielded similar sequences of mineral formation in similar environments, leading to generalized models of mineral formation. Paragenetic models often involve graphical representations of time, space, parent or bulk composition, introduction or loss of chemical constituents, physicochemical environment, and kinetics. Any single-rock body will generally show only a small part of any generalized model.

Bowen's Reaction Series

The most famous paragenetic model is known as Bowen's reaction series (Bowen 1928; Fig. 1), developed to describe the evolution or differentiation of igneous rocks by the process of fractionation. Bowen realized that since minerals that crystallize from a magma have a different composition from the magma, if reaction of the early formed minerals with the magma were somehow impeded and/or the magma and crystals were separated, rocks could be produced of different compositions from that of the parent magma.

Bowen described two separate reaction series. In the continuous series, plagioclase feldspar crystallizing from a magma is more calcium rich than the magma itself, but it reacts continuously with the magma to become more sodium rich. If the early, calcium-rich plagioclase is removed from the magma, the magma becomes richer in sodium, thereby crystallizing more sodium-rich plagioclase. Mafic minerals rich in magnesium and iron form the discontinuous series. Early



Paragenesis, Fig. 1 Bowen's reaction series describing the mineral and genetic interrelationships of plutonic rocks

formed olivine in a magma is converted to pyroxene by reaction with the magma. Similarly, pyroxene is converted to amphibole and amphibole to biotite. The separation of crystals from magma will produce a crystal fraction that is more mafic than the remaining magma. Through these two parallel series, a basaltic magma can differentiate by fractional crystallization. On Earth, differentiation can proceed to low-temperature granitic compositions of potassium feldspar, muscovite mica, and quartz. Examples of complete igneous sequences from basalt to granite are rare, and we now know that other mechanisms produce differentiation sequences. Nevertheless, Bowen's reaction series remains a useful, simple model for observed parageneses of igneous rocks on all the terrestrial planets.

Emmons' Zoning Model

As a magma differentiates, the concentration of constituents incompatible with mineral structures, such as water, carbon dioxide, fluorine, copper, lead, and zinc, will commonly increase in the residual magma. At some point late in magma crystallization, a water-rich phase may physically separate from the magma. This process leads to the formation of many types of hydrothermal mineral deposit, resulting in a typical paragenetic sequence often systematically distributed in space, time, or both. An empirical paragenetic sequence can be thought of as varying from high temperature to low, deep to shallow, or early to late. No single mineral deposit contains all these assemblages, but many show several intervals in the order given. Generalized zoning and paragenetic sequences for mineral deposits (modified from Guilbert and Park 1986, after Emmons 1936) are:

1. *Barren or low grade*: Quartz, potassium feldspar, biotite, chalcopyrite, molybdenite, trace pyrite, carbonates, and anhydrite. Potassic alteration
2. *Molybdenum-tungsten*: Quartz, wolframite, scheelite, molybdenite, and cassiterite. Potassic or no alteration
3. *Copper*: Chalcopyrite, quartz, pyrite or pyrrhotite, tennantite, bornite, chalcocite, and enargite. Quartz-sericite-pyrite alteration
4. *Copper*: Tennantite, tetrahedrite, chalcopyrite, quartz, and pyrite. Sericitic, argillic, and propylitic alteration
5. *Zinc*: Quartz, sphalerite, galena, chalcopyrite, tennantite-tetrahedrite, Ca-Fe-Mn carbonates, and sparse pyrite
6. *Lead*: Quartz, argentiferous galena, sphalerite, rhodochrosite, rhodonite, and sparse pyrite
7. *Silver-manganese*: Quartz, calcite, siderite, rhodochrosite, silver sulfosalts, and sparse pyrite. Sericitic-argillic-propylitic alteration
8. S. *Barren interval*: Most commonly occurring barren zone. Quartz, carbonates, and small amounts of pyrite, chalcopyrite, sphalerite, and galena
9. *Gold-silver*: Bonanza gold and silver, quartz, chalcedony, amethyst, adularia, alunite, silver sulfosalts, tellurides and selenides, rhodochrosite, and other carbonates. Some potassic, some sericitic, and some propylitic alteration
10. *Antimony*: Stibnite, quartz, lead-antimony sulfosalts, and galena
11. *Mercury*: Cinnabar, chalcedony, quartz, barite, fluorite, and carbonates
12. *Barren*: Chalcedony, quartz, barite, fluorite, carbonates, small amounts of mercury, antimony, or arsenic minerals

Determination of Paragenetic Sequences in Ore Deposits

Paragenetic sequences must be determined by documentation and interpretation of geochemical, spatial, and textural relationships among mineral phases (Ramdohr 1980). Criteria used are mutual growth relationships, layering, vertical and

horizontal separation, cross-cutting and offsetting relationships, and alteration and replacement textures (e.g., Foley et al. 1993). A common challenge is to decipher whether minerals in contact with or close to each other actually formed at the same time and in chemical equilibrium. Time relationships are based on individual crystal growth habits and growth textures between minerals that result from contemporaneous crystallization. It is generally easier to show that minerals did not form in equilibrium rather than the reverse. Alteration and replacement textures indicate the preserved process of one mineral changing to another.

The most common criterion for determining relative ages is contact relationships between minerals or veins that contain them. Usually the younger mineral is molded around the other. Early formed minerals tend to be euhedral, whereas later minerals will conform to the remaining spaces between the euhedral minerals and be either subhedral or anhedral. However, it is possible for a euhedral mineral to be younger than surrounding minerals if it was formed by replacement: this can be recognized by the presence of inclusions of the replaced mineral. Sometimes the replacing mineral will inherit a texture or morphology that is a characteristic of the replaced mineral. This phenomenon is called pseudomorphism.

Cross-cutting veins, especially where the older vein is offset by the younger, offer indisputable proof of relative ages of the minerals in ore deposits that contain multiple veins of differing ages and mineral assemblages. It is possible, however, that a mineral in an early vein might be replaced by a mineral formed by a younger event. This could yield an incorrect relative age if macroscopic relationships are not complemented by microscopic interpretation of replacement textures.

A common complication in studying an ore deposit is that the paragenetic sequence apparently violates itself due to cyclic processes. For example, if a deposit contains early veins and late veins, but "early" veins are observed to cut "late" veins, it can be inferred that more than one cycle of mineralization must have occurred. The identification of the paragenetic sequence requires an identification of distinguishing mineralogical or textural characteristics of each vein generation. One can then sequentially "strip out" each generation of veins, starting with the latest until the earliest vein is identified. Similar difficulties occur in metamorphic rocks, where prograde metamorphic minerals formed at extreme temperature and pressure may be replaced by retrograde minerals during cooling and decompression.

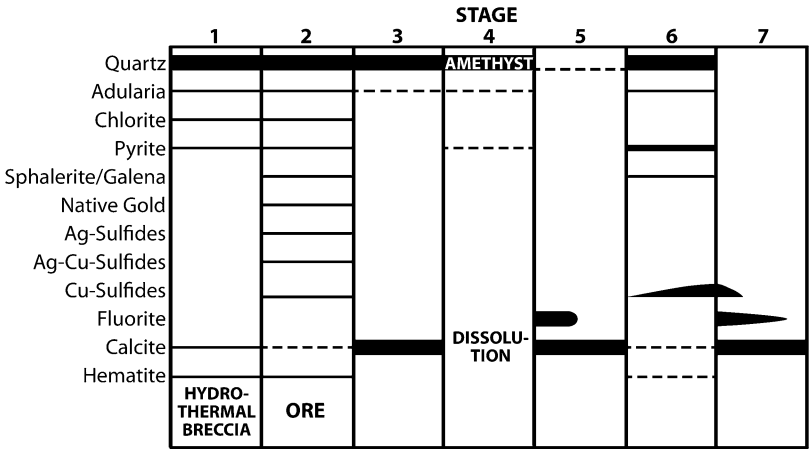
A paragenetic sequence may also vary in different parts of a large ore body, due to isolation of fluids, varying chemical parameters within the ore body and other factors. For example, particularly in epithermal ore deposits, some minerals, once deposited, will dissolve when the hydrothermal fluid becomes undersaturated with respect to that mineral. This is especially common with barite and calcite. The former existence of minerals can sometimes be identified by the presence of euhedral holes (casts) that have the crystal form of the missing mineral.

The interpretation of a paragenetic sequence requires careful, time-consuming study on both macroscopic and microscopic scales. Without a thorough understanding of the time-space relationships of a rock or geologic body, the interpretation of geochemical and other data is often ambiguous and misleading.

Example Paragenetic Diagram

Figure 2 is an example of a paragenetic diagram that is complex due to repeated episodes or cycles of faulting, hydrothermal brecciation, and mineralization. From oldest to youngest, the stages occurred as follows:

1. Hydrothermal brecciation and deposition of minerals that form the breccia matrix.
2. Main ore-depositing stage.
3. Deposition of coarse quartz and white, lamellar calcite intergrowths.



Paragenesis, Fig. 2 Paragenetic diagram illustrating mineralization in the Mogollon District, New Mexico (after Kamilli and Ratté 1995). Line width gives qualitative expression of mineral abundance. *Dashed lines* show minerals that are sporadic in occurrence

4. Partial-to-complete dissolution of calcite and concomitant replacement by quartz.
5. Deposition of fluorite and calcite.
6. A stage possibly contemporaneous with stage 2, but distinguished by the abundance of copper-bearing minerals.
7. Deposition primarily of black calcite.

The most important inference about the mineralization shown in the diagram is that it involved a repetition of all or parts of stages 1–5 at least twice and probably many times in different parts of the hydrothermal system. Compare this interpretation to intervals 8, 9, and 12 above.

Paragenetic Research Using Fluid Inclusions

Fluid inclusions are small quantities of fluid, generally water-rich, trapped within minerals. They are extremely valuable in interpreting the physicochemical history of the enclosing mineral (Roedder 1984; Goldstein and Reynolds 1994). Fluid inclusions may be primary (formed with the enclosing mineral) or secondary (formed after the enclosing mineral crystallized). Primary inclusions are identified by their relationship to the crystal habit of the enclosing mineral. Secondary inclusions form when a mineral grain fractures, allowing fluid to flow in and subsequently recrystallize the walls of the fracture to form an undulating plane of inclusions. Secondary inclusions record the history of fluids that a mineral experienced after it formed. These secondary fluid inclusion planes are analogous to cross-cutting veins in a mineral deposit. Careful study and identification of fluid inclusion paragenesis and recognition of the paragenetic sequence of secondary inclusions are essential to any study using fluid inclusions to interpret the geologic history of the enclosing rock.

Summary

Mineral paragenesis describes sequences or assemblages of minerals related by common formation conditions. Although most fully developed for ore deposits, the concept of paragenesis can be applied to all rock-forming environments including stellar atmospheres, disks around young stars, and planetary bodies. The most evolved planetary bodies, such as the Earth, host the most complex paragenetic mineral associations.

Definition

Partial melting is the transformation of some fraction of the mass of a solid rock into a liquid as a result of decompression, heat input, or addition of a flux. The resulting liquid is called magma and becomes lava if it erupts from a volcano. The understanding that partial, rather than complete, melting is the norm in natural systems is essential to appreciating the geochemical importance of melting in the Earth and planets. During partial melting, the liquid differs from the source rock and from coexisting residual minerals in composition and in physical properties such as density and viscosity. The low viscosity, low density (usually), and interconnected texture of the liquid during partial melting allow the melt to migrate from the source and thereby trigger physical phenomena like volcanism as well as chemical segregation of the Earth, Moon, and meteorite parent bodies into distinctive layers such as crust, mantle, and core. The elements that concentrate into the crust, for example, are not the lightest elements but rather those with the strongest chemical preference to dissolve in magma, which carries them upwards. At the present day, most of the Earth's crust is too cold and the mantle at too high a pressure for partial melting to occur. Therefore, regions of volcanic activity are not simply areas where magma is tapped, but rather they overlie areas where magma is being created by partial melting of previously solid rocks and then migrating to the surface.

Mechanisms of Partial Melting

Melting, as taught in basic physical science classes, occurs when the temperature of a solid material is increased to its melting point, followed by the addition of latent heat to transform the solid into a liquid. It is usually discussed only in the case of a pure material that melts completely at a single temperature. This leads to the intuitions that melting of rocks should be associated with increasing the temperature of the source rocks and that complete melting should be common. The phase relations of rocks, however, are more complicated than those of a pure substance at constant ambient pressure in ways that combine to mean melting can occur without temperature increase and to make partial melting much more common than complete melting.

Natural rocks are typically mechanical mixtures of several minerals, and many of those minerals are solid solutions of more than one chemical component. Both of these features cause melting to begin at a temperature called the solidus and end at a temperature called the liquidus, with an interval of coexisting solids and liquid or partial melting, in between. Only for a pure substance are the solidus and liquidus the same. Both the solidus and liquidus temperatures are functions of pressure; for most substances, the melting temperatures increase with pressure.

Furthermore, in the solid Earth, change of the temperature of large rock masses due to conduction of heat is a slow and inefficient process. This means that there is rarely an external heat source to provide the latent heat to drive complete melting. Instead, the main melting processes in the solid Earth are decompression melting, in which rocks are transported to lower pressure and this brings them into the partial melting interval, and flux melting, in which fluid components that lower the solidus temperature migrate into a source region and bring about partial melting. In the absence of an external heat source, melting is generally accompanied, surprisingly, by decreasing rather than increasing temperature. An important limiting case of decompression melting is adiabatic

melting, which is the behavior that results when there is no conduction of heat at all.

Decompression Melting

Decompression melting is the main mechanism for formation of basaltic magma on Earth in settings such as mid-ocean ridges, hotspots, continental rifts, and back-arc basins. It is also probably important on other terrestrial planets, but the rate of decompression depends on the acceleration due to gravity, which can lead to distinctive processes on different worlds. The importance of this mechanism is a natural result of plate tectonics and mantle convection, which produce upwelling flow fast enough to transport hot rock towards the surface and reduce the pressure on it nearly adiabatically, i.e., without significant loss of heat by conduction. Adiabatic decompression causes cooling of only about 10 K GPa^{-1}, whereas the solidus temperature of mantle rocks decreases with decreasing pressure by about 130 K GPa^{-1}. Hence, if solid mantle is drawn upwards by plate tectonic flow or its own convective buoyancy, it may intersect its solidus and begin melting (McKenzie and Bickle 1988).

With continued upwelling and pressure decrease, the extent of partial melting and the volume of melt generated increases. This is what happens at mid-ocean ridges, where steady plate separation causes hot mantle rock to continuously rise to low pressure and undergo decompression melting. This is inherently a partial melting process due to the limited availability of latent heat. This partial melting causes an ultramafic peridotite source to be separated into a mafic, basaltic magma (a liquid) and a solid residue, accompanied by fractionation of each major and trace element into the liquid or the solid residue according to its geochemical behavior. The liquid segregates and ascends to form the oceanic crust. In turn, this explains the compositional, mineralogical, and seismological differences between, for example, oceanic crust and mantle.

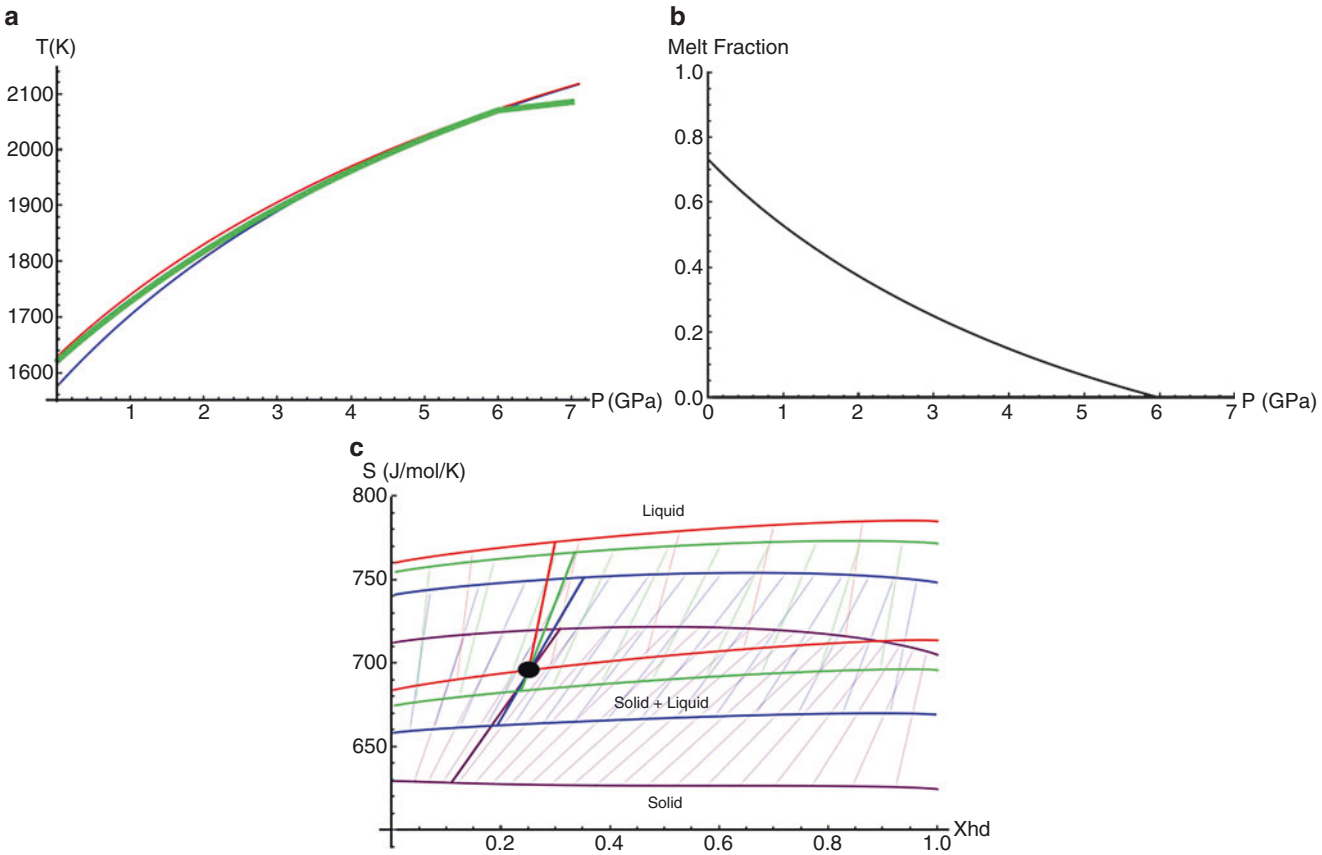
Away from mid-ocean ridges, however, the crust and the uppermost mantle are too cold and therefore rigid to flow upwards or melt by this decompression mechanism. This cold layer is called the lithosphere. Beneath the lithosphere lies the asthenosphere, which is hot enough to flow in response to motions of the overlying lithosphere and is hot enough to undergo partial melting if it flows upwards to low enough pressure. Therefore, partial melting and generation of basaltic magma can begin in response to horizontal extension that thins the lithosphere and allows the asthenosphere to move upward, such as in well-developed continental rifts. Beneath thick old lithosphere that is not thinned by extension, intersection of the solidus by decompression requires either unusually hot mantle temperatures or unusually low solidus temperatures due to volatile components or recycled crust, which explains the attention to these factors in explaining intra-plate hotspot volcanoes and continental flood basalts (Maclennan et al. 2001; Pertermann and Hirschmann 2003; Asimow et al. 2004; Herzberg et al. 2007).

As decompression continues beyond the initial intersection with the solidus, the system reaches higher extents of melting. The further it can ascend, a function of the depth where it crosses the solidus and the thickness of the lithosphere above, the more melt will be generated (Langmuir et al. 1992). Figure 1 introduces a series of phase diagrams for a two-component model chemical system that illustrate the progress of such decompression melting. We consider, as is usually done for convecting systems, that the process is slow enough to be approximated as reversible, because mantle flow is a creeping flow without turbulence. On the other hand, we consider that the flow is fast enough that heat transport is dominated by advection, with a negligible role for conduction, which means it is approximately adiabatic ($Q = 0$, where Q is conductive heat flow into a mantle parcel). The second law of thermodynamics ($dS = Q/T + \sigma$, where dS is the change in entropy, T is absolute temperature, and σ is irreversible entropy production) then indicates that we can approximate such decompression as a constant entropy process, $dS = 0$ (Asimow et al. 1997). Note that some authors consider conservation of enthalpy to be a better approximation (Ganguly 2005).

Flux Melting

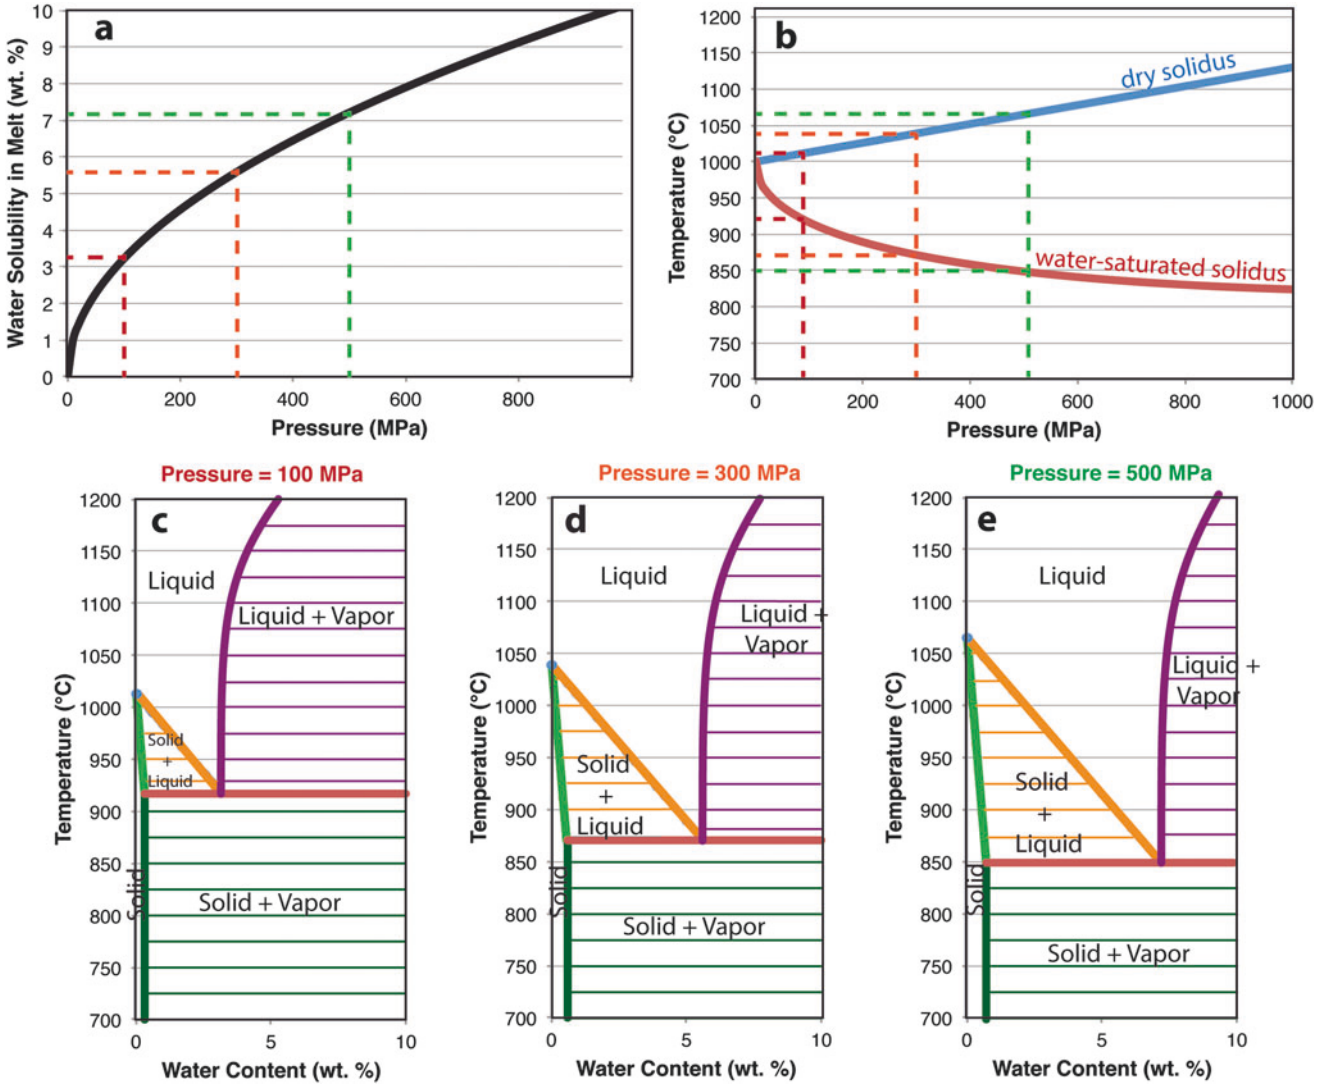
Many of Earth's most dramatic and hazardous volcanoes and most of the addition of juvenile magmatic material to the continents occur above subduction zones. This is surprising from the decompression perspective discussed above because subduction is a downwards flow of cold material – the opposite of the upwards flow of hot material that promotes decompression melting. There must be a different mechanism of partial melting at work.

Partial melting in the subduction zone environment results from the introduction of water, which can be derived from the oceanic sediments, altered oceanic crust, and perhaps serpentinized mantle of the subducting slab (Grove et al. 2006). At high pressures, where water can readily dissolve in magma, it acts as a flux (a chemical agent that promotes melting at lower temperature); Fig. 2 demonstrates the origin of such solidus depression in a model two-component rock-water system. The diagrams illustrate that, depending on how much water is added, melting may begin at temperatures intermediate between the dry solidus and the water-saturated solidus. The addition of water and other chemical components to a rock at conditions where it was solid to begin with, but partially molten as a result of the change in composition, is flux melting. This is the second most efficient source of magmatism, by volume, on Earth.



Partial Melting, Fig. 1 The use of phase diagrams and thermodynamics to analyze the progress of decompression melting in a simplified two-component chemical system. The system is $CaMgSi_2O_6$ (diopside) – $CaFeSi_2O_6$ (hedenbergite) and composition is expressed by mole fraction of the hedenbergite component, X_{hd}. (**a**) A pressure-temperature plot showing the solidus (*blue*) and liquidus (*red*) of the composition $X_{hd} = 0.25$ as well as a constant entropy decompression path (heavy *green*) that intersects the solidus at 6 GPa pressure and continues partial melting all the way to zero pressure. It is not possible to predict just by inspection of this diagram how rapidly melting will proceed or what the P-T path will be. (**b**) The extent of melting, or mass fraction of liquid, at equilibrium along the selected constant entropy decompression path; melting begins at 6 GPa and gradually increases as pressure drops, reaching 73% melting at zero pressure. (**c**) The results shown in (**a**) and (**b**) can actually be calculated directly by inspection of this diagram, which shows four constant pressure snapshots of the Entropy (S) – Composition (X_{hd}) phase diagram, at 6 GPa (*red*), 4 GPa (*green*), 2 GPa (*blue*), and zero pressure (*purple*). At each pressure, the solidus is the lower heavy curve, the liquidus is the upper heavy *curve*, and *light lines* are representative *tie-lines* connecting coexisting solids and liquids. The large *black circle* indicates the fixed total entropy and bulk composition of the system. At each pressure, the composition and entropy of the coexisting solid and liquid and the mass fraction of liquid can be found by examining the endpoints of the *tie-line* that passes through the *center* of the *black circle* and applying the lever rule. Since entropy and composition are the conserved quantities in isentropic decompression batch melting, this is the best set of variables to plot in order to visualize the partial melting process directly

The details of flux melting at subduction zones are complex and a matter of active debate in the scientific literature (Grove et al. 2009). The importance of sediment melting, basalt dehydration, basalt melting, and serpentinite dehydration in various layers of the slab are probably variable among subduction zones and through time. One view holds that only under special circumstances in the modern world and perhaps more commonly in the Archean, the hydrated, basaltic part of the subducting oceanic crust heats up enough by conduction to reach its solidus and melt directly. In this view, it is much more common for the hydrated basalt to cross dehydration boundaries and lose its water, which greatly increases its solidus temperature, before melting (Hacker et al. 2003). In this case, the partial melting that drives subduction-related volcanoes occurs instead above the subducting slab but beneath the overriding lithosphere, in the area known as the mantle wedge. The contrary view emphasizes the role of direct slab melting (Drummond et al. 1996; Kogiso et al. 2009) as the most efficient way to transfer water and other components from the subducting slab to the overlying volcanic arc (Turner and Langmuir 2015). Also, the physical pathways for flux components from their source in the slab to the melting regions in



Partial Melting, Fig. 2 An interconnected series of diagrams that demonstrate the mechanism of flux melting of rock by addition of water, at pressure-temperature conditions where the rock would otherwise be solid. (**a**) The solubility of water in basaltic liquid, i.e., the maximum amount of water that can be dissolved before saturation with a separate vapor phase occurs, increases approximately as the square root of total pressure. The solubilities at three pressures (100 MPa, 300 MPa, and 500 MPa) are illustrated by the *dashed, colored lines*. (**b**) The solidus (lowest temperature where melt occurs) of most rocks, in the absence of water, increases with increasing pressure (*blue line* labeled "dry solidus"). However, the water-saturated solidus temperature (*red curve*), along which the rock coexists with vapor and the water concentration in the liquid equals the solubility, decreases with increasing pressure. With intermediate water contents, melting might begin anywhere between these two limits. The reason for this "solidus depression" effect is seen in the lower three panels. Each of these is a temperature vs. water content phase diagram drawn at constant total pressure of (**c**) 100 MPa, (**d**) 300 MPa, and (**e**) 500 MPa. The space is divided into fields where one phase (*solid* or *liquid*) exists alone (the vapor field is off-scale to the *right*) and fields where two phases coexist and their compositions are fixed to the boundaries of the field, at either end of the light *horizontal tie-lines*. The form of these diagrams results from three physical assumptions: (1) water is incompatible in the solid and partitions strongly into the liquid; the ratio of water content along the *light green line* to that along the *orange line* shows the partition coefficient; (2) the amount of freezing point depression is proportional to the concentration of water in the liquid, as expected for addition of a small amount of any incompatible solute to a solution, so that the *orange lines* beginning from the *blue dots* indicating dry solidus temperatures are *straight* and have about the same negative slope on each diagram; and (3) the lowering of the melting point is limited by the solubility of water in the liquid, which determines the locations of the red lines indicating water saturated solidus temperatures

shallower layers of the slab or in the mantle wedge are an area of active research. Hydrous components may be immobile in peridotite close to the cold slab and may initially freeze and generate an enriched, hydrated mantle source. Either by transport to high pressure where hydrous minerals decompose or by migration horizontally or vertically into the hot interior of the mantle wedge, the flux may reach sources at conditions that are above their

P

hydrated solidus and there drive partial melting and generation of magma to feed the overlying volcanic arc.

Heating by Conduction

Although decompression and flux addition are the fastest ways to generate partial melting, there are volcanoes that cannot be explained by either of these mechanisms. These include large rhyolitic caldera-forming systems in continental interiors, such as Yellowstone (Huang et al. 2015) and Long Valley (Simon et al. 2014), in North America. The continental crust and lithosphere, along a typical conductive geotherm, are colder everywhere than even the water-saturated solidus of the most easily melting rocks. The lithosphere being too rigid to flow and undergo decompression melting, upwards transport of heat by emplacement of melts from below or by heat conduction is needed. Both of these are likely to be concentrated above areas of melt generation in the underlying mantle. Hence, although the main source of mass in a large rhyolite volcano may be within the crust, one expects to find a mantle component (Wotzlaw et al. 2013). When rising basalt magma encounters the base of the continental crust, their relative buoyancy and contrast in temperatures promote magma ponding and crystallization. The latent heat release and perturbation of the geotherm provide the relatively focused heat source needed to promote hydrous melting of overlying crustal rocks (Annen et al. 2006). The granitic magmas that dominate the upper crust may then be derived from various combinations of material derived from differentiation of the basaltic underplate and from partial melting of the overlying crust; different authors have emphasized the relative roles of these contributions at various places and times in the evolution of the continental crust (Bonin 2004). Crustal partial melting is not necessarily related to such mantle-derived heat sources, though. Overthickened crust in a collisional orogen may gradually heat up to its solidus from radiogenic heat (Clark et al. 2011).

Summary

Magma, under almost all natural circumstances on terrestrial planets and meteorite parent bodies, is generated by a process of partial melting. Hence volcanism and magmatic activity are inevitably coupled to chemical and physical segregation of molten components from residual solid components, which explains much about the typical compositions of igneous rocks as well as the differentiation of planets into layers at various scales. Partial melting processes can be understood and classified into those associated with lowering of pressure, addition of low-melting point components, and conduction of heat into the source area.

Particle-Induced X-Ray Emission (PIXE)

Masanori Kurosawa
Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan

Definition

Particle-induced X-ray emission (PIXE) is a nondestructive method for analyzing many elements simultaneously by measuring the characteristic X-rays induced by a high-energy ion beam directed onto specimens. For high-sensitivity trace-element analyses, a proton beam accelerated with 2–3 MeV of energy by a small accelerator is normally used as the ion beam. For this reason, the method is sometimes called proton-induced X-ray emission. The proton beam used for measurements is typically focused onto a spot ranging in size from 0.1 μm to several tens of micrometers, so the analytical instrument is also referred to as a proton (or nuclear) microprobe, by analogy with the electron microprobe.

Analytical Features

The use of an energy-dispersive spectrometer (EDS) such as a Li- or Si-drifted silicon detector to measure the characteristic X-rays makes simultaneous multi-elemental analysis possible. Usually, elements heavier than sodium can be analyzed. Micro-PIXE, that is, PIXE measurements made with a microbeam, uses the same X-ray detection method as a scanning electron microscope equipped with an EDS, but the background of micro-PIXE measurements is greatly reduced; consequently, elements present at levels of just a few ppm can be detected (Ryan et al. 1990; Czamanske et al. 1993). Micro-PIXE scanning with a submicrometer-sized beam is often used for trace-element mapping of various types of samples (Watt and Grime 1995; Fraser 1995). A 2–3-MeV proton beam can penetrate silicate samples to a depth of several tens of micrometers, which exceeds the penetration depth of an electron beam. The horizontal spread of the X-ray generating region induced by the proton beam, however, is much smaller than that induced by an electron beam. The deep penetration of the proton beam and its ability to generate X-rays from deep within a sample make the PIXE method suitable for elemental analyses of single fluid inclusions inside a host mineral (Kurosawa et al. 2003).

PIXE has a great analytical advantage in that it can be used to detect trace amounts of heavy elements in matrices composed of light elements because of the low X-ray background. Therefore, it is commonly used for trace-element analyses of silicate and carbonate minerals, glasses, aerosols, dried biological materials, and semiconductors. Rock thin sections, thin films, and powder-form samples supported by organic thin films are usually analyzed in a vacuum sample chamber, but it is also possible to analyze samples in ambient air (external-PIXE). Although the flight distance (range) of a 2–3-MeV ion beam in air is short (several centimeters), the beam can be extracted from a vacuum beam line to the air near the sample through a thin foil. Thus, it is also possible to analyze liquid or gaseous specimens and biological bodies, as well as large archeological objects and precious art or craft items, that cannot be inserted into a vacuum chamber. External-PIXE is used mainly for qualitative analyses of major and minor elements in such samples.

Quantitative Analysis

The calculations for quantification of PIXE analysis results use experimentally determined and fundamental physical parameters such as the X-ray generation conditions, detector solid angle and sensitivity, ion beam energy loss in the samples, X-ray self-absorption, and beam irradiation magnitudes (Reuter et al. 1975; Campbell 1995). The calculations to correct for energy loss, X-ray absorption, and secondary fluorescence effects are very similar to the ZAF correction of electron probe microanalysis. Software packages have also been developed for quantification of PIXE results (e.g., Campbell et al. 2010). The analytical error is usually better

than 10–15% for ppm concentration ranges (Czamanske et al. 1993). Detection limits of PIXE analyses depend on the atomic numbers of the elements being measured, the energy and total irradiation of the ion beam, and the bulk composition of the sample, all of which affect the generation of X-rays by the ion beam and the degree of self-absorption of the X-rays (Johansson and Johansson 1976; Sie et al. 1991; Campbell 1995). For optimal detection limits, K X-ray peaks are generally measured for elements with atomic numbers smaller than about 45, and L X-ray peaks are measured for heavy elements with atomic numbers greater than 45. The absolute detection limits are on the order of 10^{-13} g for microbeam analyses of transition-metal elements in fluid inclusions (Kurosawa et al. 2003). With micro-PIXE, it is theoretically possible to detect trace elements at levels of 10^{-15} to 10^{-16} g in thin organic films (Johansson 1995).

Future Work

Most PIXE analyses are performed at accelerator facilities, but a portable PIXE system that uses an alpha emission source (^{210}Po) is available for outdoor measurements of major and trace element compositions and for identification of minerals and pigments (Pappalardo et al. 2004). Since the portable PIXE demonstrates a strength of the higher sensitive analyses under a vacuum condition, it is suitable for in situ elemental analysis of samples on lunar and planetary surfaces. Thus, the instrument combined with an X-ray fluorescence analytical system has also been developed for the Mars exploration rover (Gellert et al. 2015).

Partitioning and Partition Coefficients

Chenguang Sun
Department of Earth, Environmental and Planetary Sciences, Rice University, Houston, TX, USA

Definition

Partitioning is used in geochemistry to describe the equilibrium distribution of a chemical species between two coexisting phases. The concentration ratio of this species between the two phases (α and β) is defined as the **partition coefficient** (D) to quantitatively measure the equilibrium fractionation,

$$D_i^{\alpha/\beta} = C_i^{\alpha}/C_i^{\beta}, \quad (1)$$

where C denotes the concentration of species i in each phase. The species could be a cation, anion, or chemical compound, while the coexisting phases may be present as solids, liquids, or vapors. According to different forms of concentration, the partition coefficient can be defined by weight fractions, molar contents, and volume percentages of the species.

Different species may behave in distinct manners with a wide spectrum of partition coefficients. Depending on its

relative affinity with the reference phase α, a species is classified as compatible when $D^{\alpha/\beta} > 1$ or incompatible when $D^{\alpha/\beta} < 1$. When the species is a fundamental constitution of phase β, the partition coefficient is then named as the solubility of this species in phase α. The partitioning concept is also applicable to measure the fractionation of two similar species between equilibrium phases. The corresponding "partition coefficient" is usually called the exchange coefficient.

History and Use

Earth's interior has two major compositional layers: a metallic core overlaid by a silicate mantle and crust. In the silicate Earth, magmatic processes along with plate tectonics play a major role in modulating chemical differentiation. An initial interest of partitioning studies in geochemistry is to understand magmatic processes using fractionation of trace element (<0.1 wt%) between crystals and melts. Relative partition coefficients of trace elements were qualitatively estimated using **Goldschmidt's rules** i.e., the size and charge of an ion determines its partitioning behaviors in various minerals (Goldschmidt 1937). Since the Apollo missions, planetary differentiation became one of the main themes in geochemistry, which also demands knowledge of element partitioning in systems relevant to core formation, such as metal-silicate and sulfide-silicate melts.

Prior to the advancement of experimental partitioning studies, bulk chemical analyses of mineral separates and matrices from quenched volcanic lavas have been used to quantitatively determine crystal-melt partition coefficients for trace elements by assuming chemical equilibrium. Using this phenocryst-matrix approach, Onuma et al. (1968) made a fundamental observation that isovalent trace element partition coefficients vary parabolically with their ionic radii in a semi-log graph. This type of graphs was later named as Onuma diagrams (see ▶ "Onuma Diagrams"), which have been widely used to investigate partitioning behaviors of trace elements in a specific mineral. The main challenges of this phenocryst-matrix approach include (1) distinguishing phenocrysts from xenocrysts that are not in equilibrium with glass matrices and (2) identifying phenocrysts without mineral or melt inclusions. The former may be prevented by careful petrographic studies or using well-constrained laboratory experiments, while the latter can be overcome by recently developed in situ analytical methods. For these reasons, the methods used in partitioning studies gradually changed to a combination of high temperature experiments and in situ chemical analyses, while the phenocryst-matrix approach is still actively used in recent literature (e.g., Mollo et al. 2017).

Due to the lack of partitioning data, trace element partition coefficients were previously considered as constant. However, later experimental partitioning studies demonstrated that trace element partition coefficients could vary by orders of magnitude, depending on temperature, pressure, composition, and/or redox condition. The variable partitioning data further motivated geochemists to develop quantitative understanding of trace element partitioning behaviors in various systems using new thermodynamic theories and experimental measurements.

Thermodynamic Basis

The theoretical basis of partitioning is the exchange reaction of a chemical species between two equilibrium phases. The exchange reaction varies with the valence states of this species and the major compositions of the phases. Following is a brief overview of thermodynamic principles (see ▶ "Geochemical Thermodynamics") for three major systems (i.e., mineral-melt, metal-silicate melts, and sulfide-silicate melts) relevant to high-temperature planetary processes.

Mineral-Melt Systems

The equilibrium exchange of a chemical species [i] between a crystal and a silicate melt can be described using the following reaction (e.g., Wood and Blundy 2003)

$$[i^{n+}]_{\text{melt}} = [i^{n+}]_{\text{crystal}}, \tag{2}$$

where n denotes the valence state of the species. The equilibrium constant (K) (see ▶ "Equilibrium Constant") can be expressed as

$$\begin{aligned} \ln K_i &= \ln\left(\frac{a_i^{\text{crystal}}}{a_i^{\text{melt}}}\right) = \ln\left(\frac{C_i^{\text{crystal}}\gamma_i^{\text{crystal}}}{C_i^{\text{melt}}\gamma_i^{\text{melt}}}\right) = -\frac{\Delta G}{RT} \\ &= -\frac{\Delta H}{RT} + \frac{\Delta S}{R} - \frac{P\Delta V}{RT}, \end{aligned} \tag{3}$$

where a, and γ are thermodynamic activity, and activity coefficient of species [i] (see ▶ "Activity and Activity Coefficients"), respectively; ΔG, ΔH, ΔS, and ΔV are the changes of Gibbs free energy, enthalpy, entropy, and volume for the exchange reaction, respectively; and R is the gas constant. Simply combining Eq. 3 with Eq. 1 gives rise to the generic thermodynamic expression for the partition coefficient of species [i] between a crystal and a melt,

$$\begin{aligned} \ln D &= \ln K_i - \ln\left(\frac{\gamma_i^{\text{crystal}}}{\gamma_i^{\text{melt}}}\right) \\ &= -\frac{\Delta H}{RT} + \frac{\Delta S}{R} - \frac{P\Delta V}{RT} - \ln\left(\frac{\gamma_i^{\text{crystal}}}{\gamma_i^{\text{melt}}}\right). \end{aligned} \tag{4}$$

In general, the activity coefficient of the chemical species varies with its concentration at a given temperature but

approaches a constant at a low concentration level according to Henry's law (see ▶ "Henry's Law").

The Lattice Strain Model

In ionic crystals, substitution of a cation into the lattice site has to overcome the strain energy change (ΔG_{strain}), which depends on the elastic property (i.e., Young's modulus, E) of the specific lattice site and the relative size differences between the cation (r_i) and the strain-free lattice site (r_0) (Brice 1975; see Fig. 1a–c). The Gibbs free energy change can be written as,

$$\Delta G = \Delta G_0 - \Delta G_{strain}^{crystal} + \Delta G_{strain}^{melt}, \tag{5a}$$

$$\Delta G_{strain}^{crystal} = 4\pi E N_A \left[\frac{r_0}{2}(r_0 - r_i)^2 - \frac{1}{3}(r_0 - r_i)^3\right], \tag{5b}$$

where ΔG_0 is the change of Gibbs free energy for strain-free exchange of an ideal cation with the same charge between the crystal and melt, and N_A is Avogadro's number. In the liquid phase, the Young's modulus and hence the strain energy change are negligible. Accordingly, the partition coefficient of a trace element has the following expression,

$$D_i = D_0 \exp\left\{-\frac{4\pi E N_A}{RT}\left[\frac{r_0}{2}(r_0 - r_i)^2 - \frac{1}{3}(r_0 - r_i)^3\right]\right\}, \tag{6a}$$

$$\ln D_0 = -\frac{\Delta H_0}{RT} + \frac{\Delta S_0}{R} - \frac{P\Delta V_0}{RT} - \ln\left(\frac{\gamma_0^{crystal}}{\gamma_0^{melt}}\right), \tag{6b}$$

where D_0 is the strain-free partition coefficient of the ideal cation, determining the maximum partition coefficients of the parabola in Onuma diagrams (see Fig. 1c).

Initially presented in Brice (1975), Eq. 6a has been well known as the **Brice equation** or the **lattice strain model**. Interestingly, prior to Brice (1975), Nagasawa (1966) had already developed a similar equation, which was used by Onuma et al. (1968) and Beattie (1994) to demonstrate the parabolic relationship between partition coefficients and ionic radii. Because Brice's equation is more straightforward and easier to use, since the first experimental test by Blundy and Wood (1994), it became popularized in geochemistry and widely used for modeling the partitioning of isovalent trace element cations between minerals and melts. The most successful application of the lattice strain model in crystal-melt systems is on rare earth elements (REE; see ▶ "Lanthanide Rare Earths") that are typically present as trivalent cations with similar ionic radii. The challenges for other isovalent cations include multiple site occupancies (e.g., Zr and Hf in garnet; van Westrenen et al. 2001a), multiple valence states (e.g., V, Cr, and Co), and crystal field effects (e.g., V, Cr, Mn, Fe, Co, and Ni).

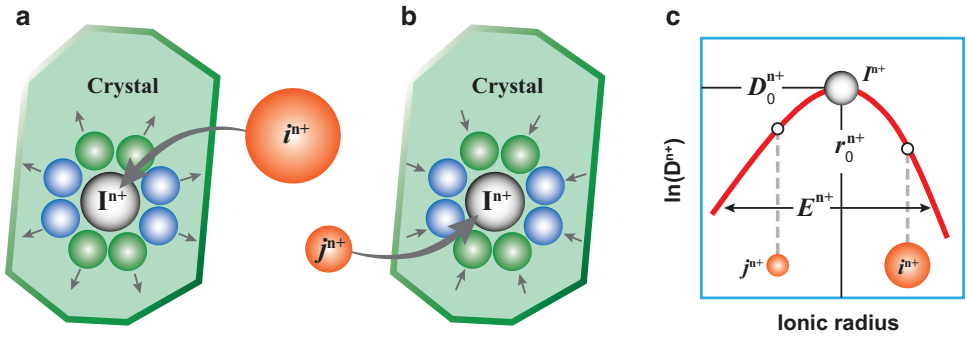
The Electrostatic Model

Inverted from the experimentally determined partitioning data, the lattice strain parameters (D_0, E, and r_0) of heterovalent cations in the same lattice site vary systematically with the cation charge. The strain-free partition coefficients (D_0) and the cation charge follow a parabolic relationship (Fig. 2a), which could be well explained by the **electrostatic model** of Wood and Blundy (2003),

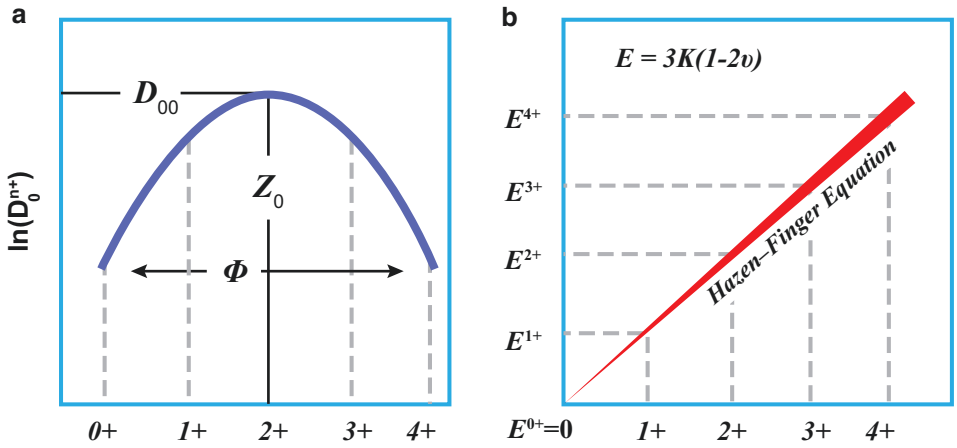
$$D_0^{Z+} = D_{00} \exp\left[\frac{-\Phi}{RT}(Z - Z_0)^2\right], \tag{7}$$

where Φ is a constant factor for the electrostatic work, controlling the opening of the parabola; Z is the charge of the ideal cation; Z_0 is the charge of major cations in the lattice site; and D_{00} is the strain-free partition coefficients for cations of charge Z_0.

The strain-free lattice size (r_0) displays a week correlation with the cation charge; however, the Young's modulus (E) shows a strong positive correlation with the cation charge, which agrees well with the Hazen–Finger equation (Hazen and Finger 1979) parameterized for homogeneous isotropic materials (Fig. 2b). A striking feature of the electrostatic model (Eq. 7) is that it allows estimation of the poorly constrained **noble gas** (see ▶ "Noble Gases") partition coefficients. Because the Young's modulus of noble gases (0+) in the lattice site is negligible according to the Hazen–Finger



Partitioning and Partition Coefficients, Fig. 1 Cartoon drawings showing cation substitution into the crystal lattice site (**a** and **b**), and a schematic Onuma diagram showing their crystal-melt partitions (**c**). i^{n+} indicates a lager cation, j^{n+} denotes a smaller one, and I^{n+} represents the strain-free cation in the lattice site



Partitioning and Partition Coefficients, Fig. 2 Illustrations of the parabolic relationship between the strain-free partition coefficients (D_0) with cation charges (**a**) and the positive relationship between the Young's moduli (E) and cation charges (**b**). Z_0 in (**a**) indicates the major cation charge in the lattice site. Equation inset in (**b**) shows the relation between Young's modulus (E) and bulk modulus (K), in which υ is the Poisson's ratio of the material (Wood and Blundy 2003)

equation, the noble gas partition coefficients can be directly calculated using Eq. 7, when the strain-free partition coefficients are available for monovalent, divalent, and trivalent cations in the same lattice site.

Metal-Silicate Systems

The equilibrium exchange of a chemical species [i] between a liquid metal alloy and a silicate melt can take place through the following reaction (e.g., Righter and Drake 2003),

$$[i^{n+}]_{\text{silicate}} + \frac{n}{2}[O^{2-}]_{\text{silicate}} = [i]_{\text{metal}} + \frac{n}{4}[O_2]_{\text{gas}}, \quad (8)$$

The equilibrium constant (K) can be expressed as

$$\begin{aligned} \ln K_i &= \ln\left(\frac{a_i^{\text{metal}}(fO_2)^{n/4}}{a_i^{\text{silicate}}\left(a_{O^{2-}}^{\text{silicate}}\right)^{n/2}}\right) \\ &= \ln\left(\frac{C_i^{\text{metal}}\gamma_i^{\text{metal}}}{C_i^{\text{silicate}}\gamma_i^{\text{silicate}}}\right) - \frac{n}{2}\ln a_{O^{2-}}^{\text{silicate}} + \frac{n}{4}\ln fO_2 \\ &= -\frac{\Delta G}{RT}. \end{aligned} \quad (9)$$

Note that this equilibrium constant is distinct from that in a mineral-melt system (Eq. 3) because this metal-silicate exchange reaction requires the change of oxidation states (fO_2). Accordingly, the metal-silicate partition coefficient has the following thermodynamic expression,

$$\begin{aligned} \ln D_i^{\text{metal/silicate}} = &-\frac{\Delta H}{RT} + \frac{\Delta S}{R} - \frac{P\Delta V}{RT} - \ln\left(\frac{\gamma_i^{\text{metal}}}{\gamma_i^{\text{silicate}}}\right) \\ &+ \frac{n}{2}\ln a_{O^{2-}}^{\text{silicate}} - \frac{n}{4}\ln fO_2. \end{aligned} \quad (10)$$

Although trace elements in a silicate melt may obey Henry's law and have constant activity coefficients, the activity of O^{2-} in the silicate melt strongly depends on the melt compositions. As well known in material science, trace elements in liquid metal alloys also have composition-dependent activity coefficients due to their strong interactions with the major constitutions (e.g., Fe, C, S, and Si) in the alloy (e.g., Ma 2001).

The metal-silicate partitioning of a chemical species could also be described through an alternative reaction by coupling Fe exchange with the species of interest (e.g., Wade and Wood 2005),

$$[i\,O_{n/2}]_{\text{silicate}} + \frac{n}{2}[Fe]_{\text{metal}} = [i]_{\text{metal}} + \frac{n}{2}[FeO]_{\text{silicate}}. \quad (11)$$

This reaction has a different thermodynamic expression for the partition coefficient,

$$\begin{aligned} \ln D_i = &-\frac{\Delta H}{RT} + \frac{\Delta S}{R} - \frac{P\Delta V}{RT} - \ln\left(\frac{\gamma_i^{\text{metal}}}{\gamma_i^{\text{silicate}}}\right) \\ &- \frac{n}{2}\ln a_{FeO}^{\text{silicate}} + \frac{n}{2}\ln a_{Fe}^{\text{metal}}. \end{aligned} \quad (12)$$

An advantage of this treatment is that it could avoid the use of oxygen fugacity, which may not be straightforward to constrain in high-pressure experiments or during planetary processes. However, this does not imply a negligible effect of oxygen fugacity on metal-silicate partitioning, as the oxygen fugacity controls FeO activity in a metal-saturated silicate melt.

The metal-silicate partitioning for anion species may follow different reactions. For instance, Tsuno et al. (2013) considered oxygen as free atoms in liquid metal alloys ($[FeO]_{\text{silicate}} = [Fe]_{\text{metal}} + [O]_{\text{metal}}$), while Boujibar et al. (2014) regarded sulfur as S^{2-} both in liquid metal alloys and silicate melts ($[Fe^{2+}]_{\text{silicate}}+[S^{2-}]_{\text{silicate}}=[FeS]_{\text{metal}}$; from the combination of their Eqs. 4 and 7). However, the thermodynamic expressions of the anion partition coefficients are similar to Eq. 12, supporting the effects of temperature, pressure, composition, and/or redox condition.

Sulfide-Silicate Systems

The equilibrium exchange of a chemical species between a sulfide melt and a silicate liquid does not require the valence change of the chemical species. Simply, the exchange reaction could be written as the same form of Eq. 2, rendering a thermodynamic expression of sulfide-silicate partition coefficients similar to Eq. 4. However, the stabilization of sulfide liquids in a silicate melt is determined by the reaction (e.g., Fincham and Richardson 1954),

$$\left[O^{2-}\right]_{\text{silicate}} + \frac{1}{2}[S_2]_{\text{gas}} = \left[S^{2-}\right]_{\text{sulfide}} + \frac{1}{2}[O_2]_{\text{gas}}, \quad (13)$$

where ½S_2 may be replaced by SO_2 with one additional O_2 on the right hand side. Taking account of sulfide saturation in the silicate melt, the sulfide-silicate chemical exchange could be described as (e.g., Gaetani and Grove 1997)

$$\left[i\ O_{n/2}\right]_{\text{silicate}} + \frac{n}{4}[S_2]_{\text{gas}} = \left[i\ S_{n/2}\right]_{\text{sulfide}} + \frac{n}{4}[O_2]_{\text{gas}}. \quad (14a)$$

This exchange reaction can be well characterized under controlled low-pressure laboratory conditions but introduces an extra term fS_2, a poorly constrained intensive parameter in planetary interiors.

At the saturation of FeS, a dominant component in sulfide melts, the exchange of a minor or trace element cation between sulfide and silicate melts could also be considered through a reaction coupled with Fe^{2+} exchange (e.g., Kiseeva and Wood 2013),

$$\left[i\ O_{n/2}\right]_{\text{silicate}} + \frac{n}{2}[FeS]_{\text{sulfide}} = \left[i\ S_{n/2}\right]_{\text{sulfide}} + \frac{n}{2}[FeO]_{\text{silicate}}. \quad (14b)$$

Accordingly, the sulfide-silicate partition coefficient has the following thermodynamic expression,

$$\ln D_i = -\frac{\Delta H}{RT} + \frac{\Delta S}{R} - \frac{P\Delta V}{RT} - \ln\left(\frac{\gamma_i^{\text{sulfide}}}{\gamma_i^{\text{silicate}}}\right) - \frac{n}{2}\ln a_{\text{FeO}}^{\text{silicate}} + \frac{n}{2}\ln a_{\text{FeS}}^{\text{sulfide}}. \quad (15)$$

Similar to those for mineral-melt (Eqs. 6a, b) and metal-silicate (Eq. 12) systems, sulfide-silicate partition coefficients, as shown in Eq. 15, are also a function of temperature, pressure, composition, and/or redox condition.

Mineral-Melt Partition Coefficients

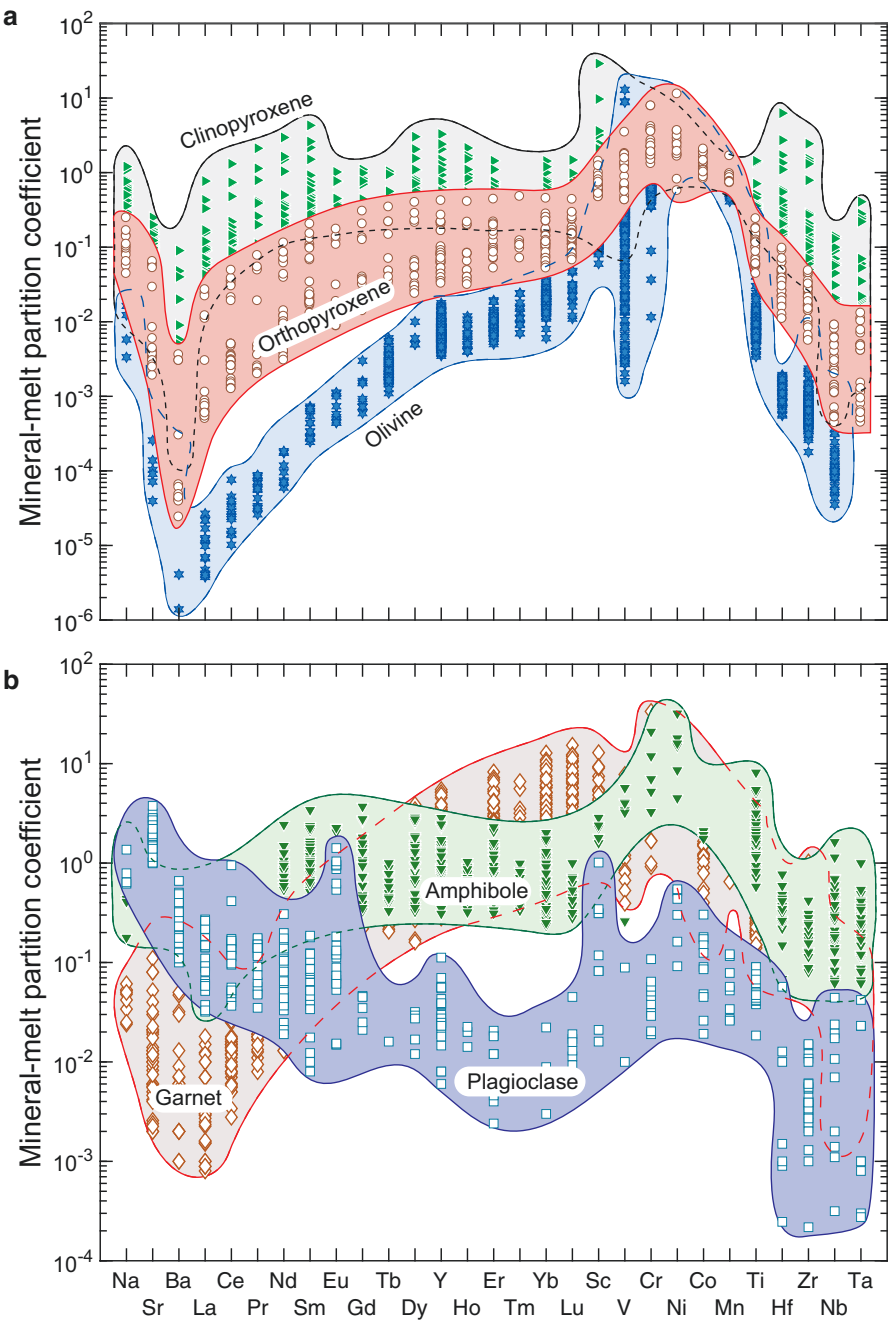
Mineral-melt partition coefficients are widely used to track high-temperature magmatic processes through igneous rocks. Specific applications include, but not limited to, (1) modeling chemical differentiation during mantle melting or magma crystallization (e.g., Shaw 2000; Liang 2008; Dasgupta et al. 2009a; see ▶ "Magmatic Process Modeling"), (2) constraints on the composition and redox conditions of parental melts and/or mantle sources (e.g., Papike 1996; Lee et al. 2010; Le Roux et al. 2011; Trail et al. 2011), and (3) development of geothermometers and geobarometers (e.g., Watson et al. 2006; Liang et al. 2013; Sun and Liang 2015, 2017). As major rock-forming minerals in the upper mantle and lower crust, olivine, pyroxene, garnet, plagioclase, and amphibole have been systematically investigated for partitioning behaviors of trace elements through high-temperature experiments.

Olivine

The general formula for olivine crystals is M_2TO_4, in which M indicates the octahedral site and T denotes the tetrahedral site. The M site mainly contains Mg^{2+} and Fe^{2+} in VI-fold coordination with ionic radii (see ▶ "Ionic Radii") of 0.72 and 0.78 Å, respectively (Shannon 1976), while the T site is primarily composed of Si^{4+} in IV-fold coordination ($^{IV}Si^{4+}$: 0.26 Å). Impurities of minor or trace elements, if any, are mainly incorporated into the larger M site. Because small divalent cations, e.g., Ni^{2+} (0.69 Å; VI-fold), Co^{2+} (0.745 Å), and Mn^{2+} (0.83 Å), have ionic radii similar to Mg^{2+} and Fe^{2+}, they are generally compatible in olivine ($D \geq 1$; Fig. 3a). Large divalent cations, e.g., Sr^{2+} (1.18 Å) and Ba^{2+} (1.35 Å), however, are difficult to fit into the M site due to the lattice strain energy (cf. Eq. 6a) and thus are incompatible in olivine ($D < 1$; Fig. 3a).

For cations with 1+, 3+, 4+, and 5+ charges, the substitution involves the replacement of Mg^{2+}, Fe^{2+}, or Si^{4+} by other cations (e.g., Al^{3+} or Fe^{3+}) (i.e., **coupled substitution**) for charge balance, which leads to strong compositional dependence of trace element partitioning. Substitution of these cations into the divalent M site has to overcome the electrostatic work (Eq. 7) in addition to the lattice strain energy. For instance, although the ionic radii of pentavalent cations, e.g., Nb^{5+} and Ta^{5+} (0.64 Å), are close to major cations in the M site, the excess electrostatic work prevents the partitioning of these cations in olivine. This is also the case for the partitioning of tetravalent cations, e.g., Ti^{4+} (0.605 Å), Hf^{4+} (0.71 Å), and Zr^{4+} (0.72 Å), in olivine. Due to the larger deviation of their valence from that (2+) of major cations in the M site, pentavalent cations appear to be more incompatible than tetravalent cations and monovalent cations (e.g., Na^{+}).

Small trivalent cations, e.g., Sc^{3+} (0.745 Å), V^{3+} (0.64 Å), and Cr^{3+} (0.615 Å), have ionic radii close to major cations in the M site and in turn are moderately compatible in olivine ($D = \sim 0.05–5$). Given their variable valence states in response to redox conditions, V and Cr have a wide range of partition coefficients. As REE have significantly larger ionic radii



Partitioning and Partition Coefficients, Fig. 3 Spider diagrams showing the experimentally determined partition coefficients of trace elements in olivine-melt, clinopyroxene-melt, orthopyroxene-melt, garnet-melt, plagioclase-melt, and amphibole-melt systems. Data sources can be found in Sun and Liang (2012, 2013a), Yao et al. (2012), Sun et al. (2017), and Shimizu et al. (2017). Note the different scales along Y-axes in (**a**) and (**b**)

(i.e., 0.861–1.032 Å), their partition coefficients are overall smaller than those of Sc^{3+}. With the increase of ionic radii from Lu to La, REE become highly incompatible in olivine.

Notably, for a given trace element, the experimentally determined olivine-melt partition coefficient also varies by one to four orders of magnitude due to the effects of temperature, pressure, and composition (and fO_2 for multivalent cations; e.g., V), which complicate the direct use of partition coefficients. Several predictive models have been developed using experimental partitioning data for calculating olivine-melt partition coefficients of individual trace elements (e.g., Beattie et al. 1991; Evans et al. 2008; Mallmann and O'Neill 2013; Matzen et al. 2017). In particular for REE, a generalized lattice strain model is available in Sun and Liang (2013a). However, the accuracy of these models is not uniform, which demands special attention for geological applications.

Pyroxene

The general formula for pyroxene crystals is XYT_2O_6. The *T* site could accommodate tetrahedrally coordinated Si^{4+} and Al^{3+} ($^{IV}Al^{3+}$: 0.39 Å), whereas *X* and *Y* denote two octahedral sites, a larger *M2* site and a smaller *M1* site. The *M1* site is

occupied by small cations in VI-fold coordination, including Mg^{2+}, Fe^{2+}, and Al^{3+} ($^{VI}Al^{3+}$: 0.535 Å); in addition to Mg^{2+} and Fe^{2+}, the *M2* site could also hold larger cations, Ca^{2+}, Na^{+}, and K^{+}. The *M2* coordination number increases from VI-fold to VIII-fold with the enrichment of large cations (e.g., Ca^{2+}) on the site (Cameron and Papike 1981). Practically, VI-fold and VIII-fold are applied to cations in the *M2* sites of orthopyroxene and clinopyroxene, respectively. Because ionic radii of cations become larger for greater coordination numbers, the same cations in clinopyroxene *M2* site are effectively bigger than those in orthopyroxene *M2* site (e.g., $^{VIII}Ca^{2+}$–1.12 Å vs. $^{VI}Ca^{2+}$–1.0 Å, $^{VIII}Mg^{2+}$–0.89 Å vs. $^{VI}Mg^{2+}$–0.72 Å, and $^{VIII}Fe^{2+}$–0.92 Å vs. $^{VI}Fe^{2+}$–0.78 Å). Overall, with higher Ca contents, the *M2* site in clinopyroxene is larger than that in orthopyroxene. This enables clinopyroxene to accommodate trace element cations with large ionic radii (e.g., REE^{3+}, Sr^{2+}, Ba^{2+}, Na^{+}) and in turn results in greater partition coefficients of these cations in clinopyroxene (Fig. 3a).

Small divalent cations (e.g., Ni^{2+} and Co^{2+}) with ionic radii similar to $^{VI}Mg^{2+}$ and $^{VI}Fe^{2+}$ preferentially enter the *M1* site in pyroxenes. The slightly larger divalent cation, Mn^{2+}, could freely go to both *M2* and *M1* sites. All three are generally compatible in pyroxenes and have partition coefficients comparable to those in olivine. Similar to Ni^{2+} and Co^{2+}, small tetravalent and pentavalent cations (e.g., Ti^{4+}, Hf^{4+}, Zr^{4+}, Nb^{5+}, and Ta^{5+}) also go to the *M1* site, but their partition coefficients are about one to three orders of magnitude greater that those in olivine. This can be attributed to their different crystal structures. As partitioning of 3+, 4+, and 5+ cations into divalent cation sites requires coupled substitution with trivalent cations (e.g., Al^{3+}) for charge balance (e.g., Gaetani and Grove 1995; Lundstrom et al. 1998), Al-enriched pyroxenes tend to have higher affinity with these high-valent cations. An extreme example can be found in Blundy et al. (1998), in which heavy REE becomes compatible in high-Al clinopyroxenes.

The effects of temperature, pressure, and composition result in one to three orders of magnitude variations in experimentally determined pyroxene-melt trace element partition coefficients (Fig. 3a). However, selection of partition coefficients for relevant geological settings could be readily achieved using thermodynamic-based predictive models calibrated against experimental data (e.g., Gaetani and Grove 1995; Salters et al. 2002). Particularly, generalized lattice strain models are also available for the partitioning of REE (Wood and Blundy 1997; Sun and Liang 2012; Yao et al. 2012) and Ti, Hf and Zr (Hill et al. 2011; Sun and Liang 2013b).

Garnet

The general formula for garnet is $X_3Y_2T_3O_{12}$, in which *X*, *Y*, and *T* indicate the dodecahedral, octahedral, and tetrahedral sites, respectively. The *X* site is controlled by VIII-fold coordinated divalent cations, Ca^{2+}, Fe^{2+}, Mg^{2+}, and Mn^{2+}, while the *Y* site is governed by VI-fold coordinated small trivalent cations, Al^{3+}, Cr^{3+}, and Fe^{3+}. Tetrahedrally coordinated Si^{4+} dominates the *T* site. With increasing pressure, the garnet structure favors the replacement of small trivalent cations in the *Y* site by Si^{4+} and Mg^{2+}, leading to the Mg- and Si-rich end-member garnet, majorite. In general, the *X* and *Y* sites are the major locations in the garnet lattice to incorporate trace element cations. Large cations, e.g., REE^{2+}, Sr^{2+}, Ba^{2+}, Na^{+}, favor the *X* site, small cations, e.g., Cr^{3+}, V^{3+}, and Ti^{5+} (and perhaps Nb^{5+} and Ta^{5+}), preferentially enter the less spacious *Y* site, whereas intermediate cations, e.g., Ni^{2+}, Co^{2+}, Sc^{3+}, Zr^{4+}, and Hf^{4+}, may occupy both *X* and *Y* sites. With increasing Ca content, the *X* site in garnet becomes bigger, which enhances the substitution of larger cations.

The partition coefficients of trace elements in garnet are overall comparable to those in pyroxenes, except for REE. Similar to those in olivine and pyroxene, heavy REE have ionic radii closer to the major cations in garnet *X* site and thus are easier to substitute into the lattice site than the larger light REE. The relatively more rigid structure of garnet, however, determines a tighter parabola for REE in Onuma diagrams. This gives rise to an important characteristic of REE partitioning in garnet, i.e., heavy REE are generally compatible in garnet while light REE are incompatible (Fig. 3b). The relative differences between light- and heavy-REE partition coefficients in garnet are comparable to those in olivine despite that all REE are incompatible in olivine (Fig. 3a). In high-temperature geochemistry, this special feature of REE partitioning in garnet has been widely used as a geochemical indicator for assessing the presence of garnet in magma sources.

As a minor cation in garnet *Y* site, Cr^{3+} appears to be more compatible than other trace element cations in garnet (Fig. 3b). With a slightly larger ionic radius, V^{3+} has to overcome the lattice strain energy for substitution into the *Y* site, determining its smaller partition coefficients. Because of its excess electrostatic energy and smaller ionic radii, Ti^{5+} is less compatible in garnet than V^{3+}. Due to the multiple-site occupancies, the intermediate cations are difficult to understand solely based on the charge and site. As shown in van Westrenen et al. (2001a), the relative compatibilities of Zr and Hf may overturn, depending upon the major element composition of garnet.

Several models have been constructed to explain the large variation of experimentally determined trace element partition coefficients between garnet and silicate melts (e.g., van Westrenen et al. 2001b; Salters et al. 2002; van Westrenen and Draper 2007; Sun and Liang 2013a). Salters et al.'s models were calibrated for individual trace elements based on the thermodynamic expression of Eq. 4, whereas others are generalized lattice strain models but only for REE.

Plagioclase

The plagioclase structure follows a general formula MT_4O_8. The *T* site is occupied by tetrahedrally coordinated smaller cations, Si^{4+} and Al^{3+}, whereas the *M* site holds larger cations, Ca^{2+}, Na^{+}, and K^{+} in VII- to IX-fold coordination, and thus is the major place to incorporate trace element cations. Monovalent and divalent cations can enter the *M* site by replacing Na^{+} and Ca^{2+}, respectively. Large high-valent cations (e.g., REE^{3+}, U^{5+}, and Th^{5+}) require coupled substitution mechanisms for charge balance. For instance, the substitution of REE^{3+} for Ca^{2+} is coupled with Na^{+} replacing Ca^{2+}. However, it remains unclear which site (*M* or *T*) smaller high-valent cations (e.g., Ti^{4+}, Hf^{4+}, and Zr^{4+}) may occupy (e.g., Peters et al. 1995; de Vries et al. 2012).

Given the large ionic radii of Ca^{2+} ($^{VIII}Ca^{2+}$: 1.12 Å) and Na^{+} ($^{VIII}Na^{+}$: 1.18 Å), the *M* site is significantly more spacious than the cation sites in olivine (*M* site), pyroxenes (*M1* and *M2* sites), and garnet (*X* and *Y* sites). This effectively makes plagioclase favor larger cations (e.g., Sr^{2+}, Ba^{2+}, and light REE^{3+}) in the *M* site than smaller ones (e.g., Ni^{2+}, Co^{2+}, and heavy REE^{3+}). As shown in Fig. 3b, the larger cations are relatively more compatible in plagioclase than the smaller ones. Because the ionic radii of Sr^{2+} (1.26 Å) and Eu^{2+} (1.25 Å) are very similar to that of Ca^{2+}, they are the most compatible trace elements in plagioclase. Due to the presence of highly incompatible Eu^{3+} at relatively oxidized conditions, Eu partition coefficients appear to have a large variation bounded by the partition coefficients of Eu^{2+} and Eu^{3+} (Fig. 3b).

A notable feature of plagioclase-melt trace element partition coefficients is their strong dependence upon plagioclase anorthite contents in addition to temperature. Using a simple linear relation between $RT\ln(D)$ and plagioclase anorthite contents, several models have been developed to describe the partition coefficients of individual trace elements (e.g., Blundy and Wood 1991; Bindeman et al. 1998; Tepley et al. 2010). Generalized lattice strain models are also available in Wood and Blundy (2003) and Dohmen and Blundy (2014). A most recent calibration of the lattice strain model can be found in Sun et al. (2017) for plagioclase-melt partition coefficients of monovalent, divalent, and trivalent cations.

Amphibole

The chemical formula of amphibole crystals is more complex than those of olivine, pyroxene, garnet, and plagioclase. Conventionally, the amphibole formula is written as $AB_2C_5T_8O_{22}(OH)_2$. According to the nomenclature of amphibole subgroups (Hawthorne et al. 2012), here *A* denotes a large vacancy site partially filled by Li^{+} and large cations, Na^{+}, K^{+}, Ca^{2+}, and Pb^{2+}; *B* indicates the *M4* site holding Li^{+} and large cations, Ca^{2+}, Na^{+}, Fe^{2+}, Mg^{2+}, and Mn^{2+}; *C* includes the medium (*M1* and *M3*) and small (*M2*) octahedral sites occupied by Fe^{2+}, Mg^{2+}, Mn^{2+}, Al^{3+}, Cr^{3+}, Fe^{3+}, Ti^{4+}, and Li^{+}; *T* is the tetrahedral site dominated by Si^{4+} and Al^{3+} (and very rarely Ti^{4+}); and OH shows the anion site for OH^{-}, F^{-}, Cl^{-}, and O^{2-}.

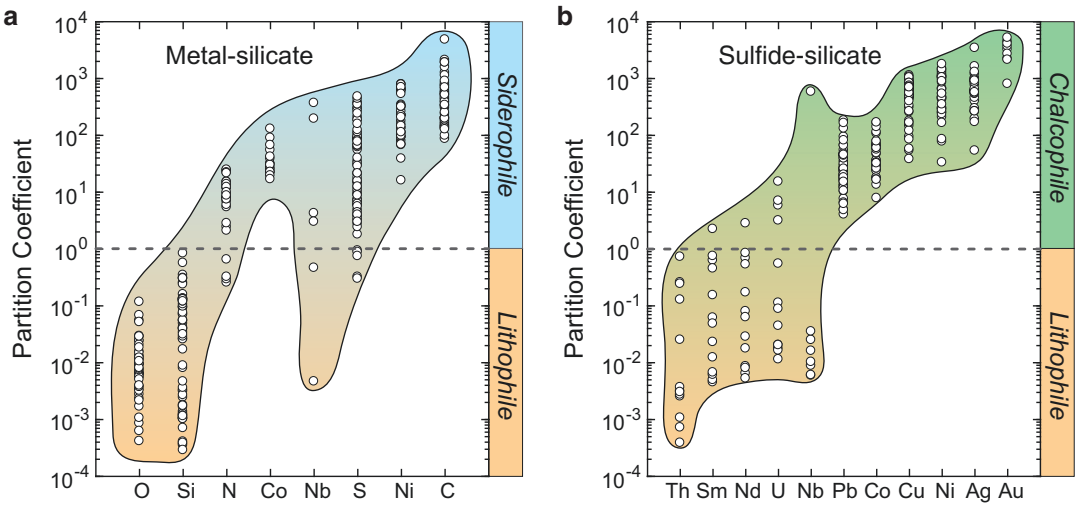
The large number of cation sites in amphibole results in flexible substitution of trace elements, with variable charges and sizes, for the major cations. The large divalent cations, Sr^{2+} and Ba^{2+}, may substitute Ca^{2+} in both *A* and *B* sites. Small cations, e.g., Ni^{2+}, Co^{2+}, Sc^{3+}, V^{3+}, Zr^{4+}, and Hf^{4+}, likely behave similar as Cr^{3+} entering the *C* sites. With ionic radii nearly identical to that of Ti^{4+} (IV–0.42 Å and VI–0.605 Å), small pentavalent cations, Nb^{5+} and Ta^{5+} (IV–0.48 Å, VI–0.64 Å), may also enter the *C* site. Large trivalent cations, REE^{3+}, are believed to occupy the *B* sites, which may be split into two distinct M4 sites (e.g., Tiepolo et al. 2007). In addition, the spacious *A* site may also hold some REE, especially light REE, as those in plagioclase *M* site.

The partition coefficients of trace elements between amphibole and silicate melts vary by about one order of magnitude as a function of temperature, pressure, and composition (Fig. 3b). The absolute values and overall variations are similar to those for clinopyroxene. Exceptions are the large divalent cations (Sr^{2+} and Ba^{2+}) and the small high-valent cations (Ti^{4+}, Nb^{5+}, and Ta^{5+}), which appear to be relatively more compatible in amphibole. Their partition coefficients in amphibole are about one order of magnitude greater than those in clinopyroxene. Predictive models have been calibrated against experimentally determined amphibole-melt partition coefficients for a comprehensive list of trace elements (Tiepolo et al. 2007). A generalized lattice strain model is also available in Shimizu et al. (2017) for REE.

Metal-Silicate Partition Coefficients

Metal-silicate partition coefficients are used to constrain the composition and formation of metallic cores of terrestrial planets (see ▶ "Earth's Core"), which have great implications for planetary formation and differentiation (e.g., Wood et al. 2006). Two fundamental observations that motivate metal-silicate partitioning studies are (1) density deficit of the Earth core with respect to pure iron (e.g., Birch 1952) and (2) apparent anomalies of certain trace elements in Earth's mantle (e.g., Ringwood 1966). The elements of interest for the former are mainly centered on light elements such as Si, O, S, and C, while those for the latter mainly include excess siderophile elements (e.g., Ni and Co; see ▶ "Siderophile Elements") and missing lithophile (e.g., Nb; see ▶ "Lithophile Elements") and volatile elements (e.g., N).

Existing experimental partitioning studies have shown that metal-silicate partition coefficients of these elements also vary over orders of magnitude as a function of temperature, pressure, composition, and oxidation state (Fig. 4a). The moderately siderophile elements Ni and Co become less siderophile at elevated pressures, and therefore, the apparent excess of Ni



Partitioning and Partition Coefficients, Fig. 4 Spider diagram showing the experimentally determined partition coefficients of trace elements between liquid metal alloys and silicate melts (**a**) and between sulfide liquids and silicate melts (**b**). The metal-silicate partitioning data are from Li and Agee (2001), Wade and Wood (2001), Tsuno et al. (2013), Boujibar et al. (2014), Li et al. (2016) and Dalou et al. (2017). The sulfide-silicate partitioning data are from Gaetani and Grove (1997), Ripley et al. (2002), Li and Audétat (2012), Kiseeva and Wood (2013), Wood and Kiseeva (2015), Wohlers and Wood (2015), and Hart and Gaetani (2016)

and Co in Earth's mantle is likely artificial due to the applications of low-P partitioning data. In particular, the Ni and Co partitioning data indicate a core-mantle equilibrium pressure in the Earth upper mantle (~50 GPa), likely the magma ocean depth during planetary accretion (Li and Agee 2001). At high pressures and temperatures (e.g., P > 25 GPa, and T > 2700 °C), conventional lithophile elements, Si and O, behave close to siderophile, supporting the incorporation of a substantial amount of Si and O in the core for explaining the density deficit (Tsuno et al. 2013). Another lithophile element Nb may become highly siderophile at low oxidation states and high pressures (>23 GPa), making the core a potential "reservoir" for the Earth's missing Nb (Wade and Wood 2001).

The volatile elements C, S, and N appear to have distinct metal-silicate partition coefficients (e.g., Boujibar et al. 2014; Chi et al. 2014; Li et al. 2016; Dalou et al. 2017). C remains highly siderophile for a wide range of experimental conditions, while S and N behave generally as moderately siderophile elements but becomes more lithophile under relatively more reduced conditions. However, their differential partitioning behaviors pose a challenge for the single-stage core formation model that should have produced a more C-depleted primitive Earth's mantle.

Predictive models have also been experimentally calibrated for individual trace elements based on the thermodynamic expressions of metal-silicate partitioning (Eqs. 10 or 12). Interested readers are referred to the aforementioned studies for representative models. With the expanding experimental measurements, these models are continuously updated for additional elements or a broader range of pressures, temperatures, compositions, and/or redox conditions.

Sulfide-Silicate Partition Coefficients

Sulfide is present as immiscible droplets during magmatic processes at various geological settings (e.g., Lee et al. 2012) and is also considered significant for core formation and planetary accretion (e.g., Gaetani and Grove 1997; Dasgupta et al. 2009b; Wohlers and Wood 2015; Li et al. 2016). The elements of interest for sulfide-silicate partitioning studies mostly include chalcophile (sulfide-loving) elements (see ▶ "Chalcophile Elements"), siderophile elements, and more recently lithophile elements (e.g., REE, Nb, U, and Th). Similar to those in mineral-melt and metal-silicate systems, experimentally determined sulfide-silicate partition coefficients of trace elements also display considerable variations in response to changes in temperature, pressure, composition, and redox condition (Fig. 4b).

Chalcophile (e.g., Cu, Ag, and Pb) and siderophile elements (e.g., Au, Ni, Co) are highly compatible in sulfide, indicating the importance of sulfide for modulating the compositions of these elements in planetary interiors. Among those, Au appears to be the most sulfide-loving element with partition coefficients in the range of 800–5000. Cu, Ni, and Ag show similar compatibilities in sulfide (D = ~30–1800), but both are slightly less chalcophile than Au. Pb and Co are moderately chalcophile with similar affinities for sulfide (D = ~4–180). As a major host of precious metals such as Au and Ag, sulfide also bears economic implications for metal ores (see ▶ "Ore Deposits"). Generalized thermodynamic models are available in Kiseeva and Wood (2013) for chalcophile and siderophile element partitioning between sulfide and silicate melts.

The partition coefficients of lithophile elements such as REE, Nb, U, and Th vary by about three to five orders of magnitude, much greater than those of chalcophile and siderophile elements. When the silicate melts are depleted in FeO, these conventional lithophile elements become weakly chalcophile in sulfide-silicate systems (e.g., Wohlers and Wood 2015). As an extreme example, Nb highly favors the sulfide liquid with a partition coefficient of >600 when FeO becomes a minor or trace component in the coexisting silicate melt (<1 wt%; Wood and Kiseeva 2015). In addition, U and Nd appear to be relatively more compatible than Th and Sm in sulfide, respectively, underscoring the potential role of sulfide in fractionating lithophile elements during magmatic processes and planetary accretion. However, due to the lack of experimental data, generalized predictive models have not been developed for lithophile elements.

Summary

Element partitioning determines the chemical fractionation between coexisting equilibrium phases during various planetary processes. As a quantitative measure of partitioning, the partition coefficient enables geochemists to track ancient or ongoing geological processes through the chemical compositions of minerals and rocks from the planetary interior. However, the partition coefficient of a given element exhibits considerable variations with changes in temperature, pressure, redox condition, and phase compositions, which may even alter the conventional geochemical classification of elements (see ▶ "Geochemical Classification of Elements") to various extents. Thus, constant partition coefficients must be used with caution. The large variations of partition coefficients can be generally understood through thermodynamic models, but for quantitative understanding of specific geological processes, these models have to be calibrated using experimental measurements under relevant conditions.

Peat

Thomas J. Kelly[1], Ian T. Lawson[2] and Lydia E. S. Cole[3]
[1]School of Geography, University of Leeds, Leeds, UK
[2]Department of Geography and Sustainable Development, University of St Andrews, Edinburg, Scotland, UK
[3]Department of Zoology, Biodiversity Institute, University of Oxford, Oxford, UK

Definition

Peat is an organic soil composed of partially decomposed plant and, to a lesser extent, animal remains. Precise definitions of "peat" vary but are mostly based on a combination of thickness (typically >30 cm) and organic matter content (typically >50–65%; e.g., Wüst et al. 2003; Page et al. 2011; Dargie et al. 2017). Their high organic matter content means that peats have a high carbon concentration, up to 48–60 wt% in very pure peats (Shimada et al. 2001; Loisel et al. 2014; Lawson et al. 2015). The term "histosol," used in the FAO and USDA soil taxonomies, includes peats.

Peat Formation, Peatlands, and Peatland Classification

Peat has a long geological history dating back to the Late Devonian (Greb et al. 2006). Burial and heating slowly transform ancient peat deposits into extensive coal and lignite deposits, which are economically important; some modern peat accumulating environments can therefore be used as analogues to understand coal formation (Phillips and Bustin 1998). Peat accumulations are found on every continent, from Antarctica, the lowland and montane tropical peatlands of Africa, South America, and Southeast Asia, to the vast peatlands of the temperate, boreal, and arctic regions of North America and Eurasia (e.g., Fenton 1980; Gorham 1991; Page et al. 2011). Most modern peatlands are Holocene in age (Yu 2012). Although older sites are known – for example, the exceptional 1.35 million year peat sequence at Tenaghi Phillipon in Greece (Tzedakis et al. 2006) – peat formation appears to have been relatively limited during the globally cold/dry glacial intervals of the Quaternary.

Peat accumulation is relatively slow; long-term accumulation rates vary between different peatland environments but are typically less than 1 mm/yr. (e.g., Barber et al. 1994; Arlen-Pouliot and Bhiry 2005), with some higher accumulation rates recorded in the tropics (e.g., Lähteenoja et al. 2012). In general, peat accumulates when the rate of production of plant litter – including roots, stems, wood, and leaves – exceeds the rate of decomposition and other losses (e.g., fire). In most terrestrial environments, litter decomposition by microbes and invertebrates can easily keep pace with litter supply. In saturated conditions, waterlogging slows the rate of oxygen diffusion from the surface into the litter and soil. Year-round waterlogging can result in permanently anoxic conditions, which exclude most invertebrates and many microbes, severely reducing the rate of litter decay. Other factors such as low pH and low nutrient status may also play a role in inhibiting litter decomposition (Clymo 1984).

Peat can therefore accumulate in a wide variety of situations, typically wherever the substrate is wet for most of the year. Peatland settings include moss banks (Fenton 1980), palsa mires in permafrost areas (Christensen et al. 2012), floating islands or rafts on lakes and rivers (Zaccone et al. 2017), blanket peat in wet upland areas (Tipping 2008), coastal mangroves or marshes (Orson et al. 1987; Ezcurra et al. 2016), depressions in formerly glaciated areas (Ireland and Booth 2011), and abandoned river channels (Lähteenoja et al. 2009) (Fig. 1). Modern-day peatlands are usually classified on the basis of their vegetation and/or geochemistry (Wheeler and Proctor 2000). Vegetation and geochemistry are likely to share a causal connection: environmental gradients described by pH and basic cations (e.g., Ca^{2+}) appear to be important in determining vegetation composition in northern

Peat, Fig. 1 Geographically and geochemically diverse types of peatland: (**a**) Quistococha peatland palm swamp in the Peruvian Amazon; (**b**) intact blanket peatland with hummock and hollow microtopography at Slieveanora, Northern Ireland, UK; (**c**) palsa peatland in Stordalen, within the Swedish subarctic; and (**d**) degraded upland blanket bog in Northern Ireland, UK (Credit to T.J.K. (**a**–**c**) and L.E.S.C. (**d**))

peatlands (Wells 1996; Wheeler and Proctor 2000). Peatlands may be classified as ombrotrophic (purely rain-fed) or minerotrophic (largely groundwater-fed), but this classification can be problematic if only because many nutrient-poor groundwater-fed fens have similar vegetation communities to ombrotrophic peatlands (Wheeler and Proctor 2000). Northern peatlands can perhaps be more securely divided into "bogs," with pH $<$ 5.5 and low Ca^{2+} concentrations, and "fens" which have pH $>$ 5.5 and higher Ca^{2+} concentrations (Wheeler and Proctor 2000). There are cases where this classification may prove inadequate such as in the "iron fens" of Colorado, some of which have both low pH ($<$4.5) and high Ca^{2+} concentration (e.g., Cooper et al. 2002; Chimner et al. 2010), and within the broad division between bog and fen, there is substantial variation in peatland vegetation associations (Hájek et al. 2006). Nevertheless, this division is generally found to be a useful one in northern peatlands, and a strong contrast between "bog" and "fen" vegetation also appears to hold in some parts of the tropics (e.g., Lähteenoja et al. 2009).

Other environmental gradients are also important in peatlands, in particular water table depth and the availability of nutrients other than calcium (Wheeler and Proctor 2000). For example, in some tropical and subtropical systems, nitrogen (N) and phosphorus (P) may be more critical in controlling plant communities than pH and the quantity of basic cations such as Ca^{2+} (e.g., Bridgham and Richardson 1993; Sjögersten et al. 2011).

Significance

Although they cover only c. 3% of the Earth's surface, peatlands play a disproportionately large role in the global carbon cycle due to their high carbon density per area and their ability to act as long-term stores of atmospheric CO2 (Gorham 1991; Rydin and Jeglum 2006). In some parts of the world, such as Finland and the Congo Basin, the soil carbon stored in peatlands either equals or exceeds that in the aboveground biomass of vegetation across the region as a whole

(Turunen et al. 2002; Dargie et al. 2017). There is some uncertainty as to the total amount of carbon stored in peatlands, but a review of the available data places the value at c. 600 GtC (Page et al. 2011), approaching that held in the atmospheric pool (c. 850 GtC; IPCC 2013). Most peat carbon is stored in temperate and boreal peatlands (517–526 GtC; Page et al. 2011), with a smaller amount in the tropics (70–130 GtC; Dargie et al. 2017).

Carbon losses from peatlands are a particular concern due to their contribution to atmospheric greenhouse gas emissions, and hence to climate change. Some of the main pathways include gaseous losses resulting from decomposition (CO_2 and CH_4), water-borne losses (e.g., dissolved organic carbon), and losses due to burning (CO_2, CO, and CH_4). Gaseous losses have been a particular focus for research, as the anaerobic conditions found in peatlands result in the production of methane, which is a more potent greenhouse gas than carbon dioxide (Christensen et al. 2012; Bridgham et al. 2013). Annual methane emissions from northern peatlands alone have been estimated at around 0.046 Gt CH_4-C (Gorham 1991).

Water-borne losses of carbon from peatlands occur in the form of dissolved organic carbon (DOC) and particulate organic carbon (POC). DOC forms as peat decomposes and builds up in the pore waters within the peat matrix until it is flushed out by water passing through (Holden 2005; Limpens et al. 2008). POC usually results from peatland erosion, which can occur at the margins of peatlands (e.g., in proximity to a river channel), or below the surface (Holden 2005). In temperate peatlands, DOC may account for around 10% of peatland carbon losses, with a similar loss occurring as POC (Holden 2005), although there is substantial variation (Yu 2012). DOC and POC losses are often greater in degraded areas, such as deforested peatlands in the tropics (Moore et al. 2013).

Under natural conditions, peatlands are generally too wet to burn, but peat surface layers can ignite during dry weather. When artificially drained, unnaturally dry conditions are created, making peatlands very vulnerable to fire (Turetsky et al. 2014). Recent losses of carbon from fires in disturbed tropical peatlands have been particularly significant. Peatland fires in SE Asia in 1997, a particularly severe episode, are thought to have released 2.97–9.42 Gt CO_2, equivalent to 13–40% of the global anthropogenic greenhouse gas emissions for that year (Page et al. 2002).

Peatlands therefore require careful management in order to avoid unintentional carbon emissions, and considerable effort has been invested in restoring degraded peatland areas (Chimner et al. 2017). Peat is economically important, as a fuel and as a horticultural substrate and soil improver (Schilstra 2001; Chimner et al. 2017). Peatlands and their distinctive landscapes can be culturally important, not least for the whisky industry, and they are important habitats for often highly specialized plants and animals. They are scientifically important, particularly for paleoecological research: the botanical composition of the peat and other less obvious characteristics, such as its microfossil assemblages, make it possible to reconstruct the development of a peatland in great detail over thousands of years (Chambers and Charman 2004). Peatlands, and their globally significant carbon stocks, are also highly vulnerable to mismanagement and, in some instances, to future climate change. More research is needed to fully understand the processes that lead to peat formation around the world and to predict the impact of future changes in climate and land use on peatland carbon storage.

Summary

Peat accumulates in a wide range of different waterlogged environments, and its high carbon concentration means that although peatland areas cover only a small fraction of the earth's surface, they play a large role in the global carbon cycle. Greenhouse gas emissions from some disturbed peatlands have been particularly large in recent years. Peatlands are also culturally important, home to a range of unique plants and animals, and act as archives of paleoenvironmental information which has enabled an increased understanding of past environmental and climatic changes.

Periodic chart

Introduction and Definition

The modern periodic table is a schematic arrangement of all known elements, in order of increasing atomic number (i.e., number of protons in an element, its defining characteristic; Fig. 1) and hence their mass. The elegance of the periodic table is that the two-dimensional layout conveys far more than just atomic number and mass. Incorporated into the design is information about how electrons are arranged around the nucleus, the reactivities of elements, and patterns in the elements' chemical properties. If one understands these aspects of the periodic table, it can also provide insight into how elements behave in Earth's geochemical systems.

History

Even by the mid-1800s, it was common knowledge among scientists that many of the approximately 50 elements that had been identified at the time could be grouped into subsets sharing similar chemical behavior. Alexandre-Emile Béguyer de Chancourtois (France; 1820–1886), John Newlands (U.K.; 1837–1898), Lothar Meyer (Germany; 1830–1895), and Dmitri Mendeleev (Russia; 1834–1907) were among researchers who independently came to the critical conclusion that the periodicity of chemical behavior was a function of elements' atomic numbers and masses.

Not all proposals for what ultimately became the periodic table met with immediate acceptance in the scientific community. For instance, De Chancourtois (the only geologist of the group) designed a cylindrical chart, arranging the elements in a spiral so that similar elements were aligned in a column (the Telluric Helix). Unfortunately, because his publisher did not include the complex graphic in the original paper, de Chancourtois only received delayed credit for his ideas (Scerri 2006). Shortly thereafter, Newlands proposed the Law of Octaves, noting that the atomic numbers of elements with similar chemical behavior "generally differ either by 7 or by some multiple of seven; in other words, members of the same group stand to each other in the same relation as the extremities of one or more octaves in music" (Newlands 1865). It appears as though the Chemical Society of London did not take to his musical analogy, however, and they rejected his paper (Kean 2010).

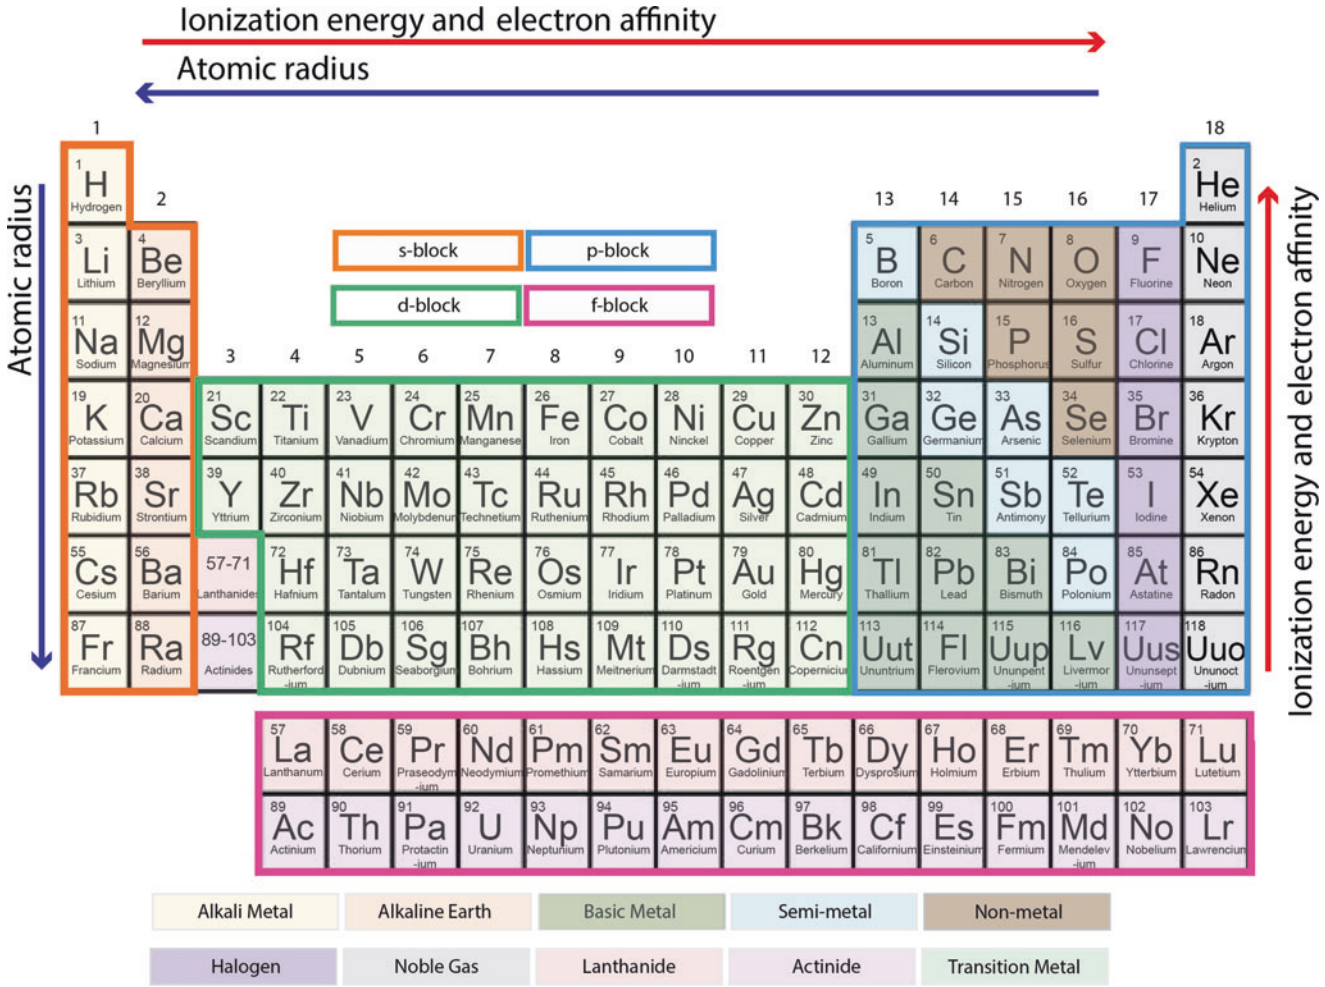
Meyer and Mendeleev published their periodic tables of the elements at nearly the same time, ultimately sharing the Davy Medal for their discoveries in 1882 (Newlands subsequently received a Davy Medal 5 years later). Both scientists left gaps in the table where no elements existed at the time, but Mendeleev actually predicted that new ones would be found (Fig. 2). His estimates of their densities and atomic weights proved quite accurate, cementing his position as the father of the modern periodic table.

Guide to the Periodic Table

Most periodic tables include every element's symbols, name, atomic number, and atomic mass. The *atomic number* of an element is the same as the number of protons and electrons in a neutral atom. *Atomic mass* is an average of the masses of all the element's isotopes, weighted according to their abundance on Earth. Elements are organized in order of increasing atomic number. Hydrogen, the lightest element, has one proton and sits in the uppermost corner of the periodic table; uranium, the heaviest naturally occurring element, has 92 protons and is found near the very bottom of the table.

As one moves left to right across the periodic table, the number of protons in the elements' nuclei and the number of electrons around a neutral atom increase systematically, one by one. As atomic number increases, the accompanying electrons are arranged in a sequence of structured shells around the nucleus. Each shell is able to accommodate a limited quantity of electrons, a number that increases as the atoms get larger. Specifically, the first shell can only hold 2, the second can manage 8, the third can accommodate 18, and the fourth houses up to 32 electrons. Elements in the same period, or row, have their electrons stored in the same number and type of shells.

Within each shell, electrons occupy subshells, which in turn host atomic orbitals. There are several types of subshells, each with a limited capacity for electrons: s subshells host a maximum of 2 electrons, p subshells hold up to 6, d can accommodate 10 electrons, and f subshells hold up to 18 electrons. Elements in the first row in the periodic table only have a 1s subshell, with a capacity of 2 electrons. Consequently, the first row of the table consists of only 2 elements, hydrogen and helium (Fig. 1). The second and third row elements have an outer electron shell with an s and a p subshell, giving them the capacity for 8 electrons, thus there are 8 elements in the second and third rows of the periodic table. The fourth and fifth period elements also have d subshells, allowing an additional 10 elements into each row. The sixth and seventh



Periodic Table, Fig. 1 Periodic table of the elements. Atomic numbers are in the *upper left* corner of each element's box; atomic weights are not shown. Group numbers are located *above* each column of elements. Non-metallic character increases from the *bottom left* of the table to the *upper right*; metallic character increases in the opposite direction, from lowest in the *upper right* corner to highest in the *lower left* corner. Blue and red arrows indicate directions of increasing ionization energy, electron affinity, and atomic energy. Electron affinity is the amount of energy released when an electron is added to the neutral atom; electronegativity is a measure of an atom's ability to attract electrons

periods include f subshells and therefore 14 additional elements.

Another way to look at the periodic table is to categorize elements according to the subshells being filled, in blocks (Fig. 1). For instance, because s-orbitals can only manage 2 electrons, the s-block elements are in the first two columns on the left side of the periodic table (Groups 1 and 2; Fig. 1). Elements in which the new electrons are filling p subshells are in the p-block; because p-orbitals have the capacity for 6 electrons, there are six columns in the p-block (Groups 13 through 18). The d-block, with its 10-electron capacity, consists of Groups 3 through 12, and includes the transition metals. The f-block's 14 spaces are usually displayed at the bottom of the periodic table and are made up of the lanthanide and actinide elements (the f-block really belongs in the sixth row, but they have been shifted to the lower part of most periodic tables to keep the tables more compact).

For the most part, this process works in a straightforward way: the larger the atomic number, the larger the atom. A subtlety arises, however, involving the d- and f-orbitals. Instead of housing their electrons around the periphery of the atom, as with the s- and p-orbitals, the d- and f-orbitals are embedded deep within the electron cloud. As most beginning chemistry students will attest, this phenomenon poses a challenge when learning how to arrange electrons around atoms properly. Several alternative versions of the periodic table have been designed to mitigate this problem inherent in the electron configuration system. In 1929, Charles Janet published an extended version of the periodic table (the left-step periodic table; Fig. 3), which laid the atoms out in a step-wise pattern; one simply starts at hydrogen and moves along from left to right

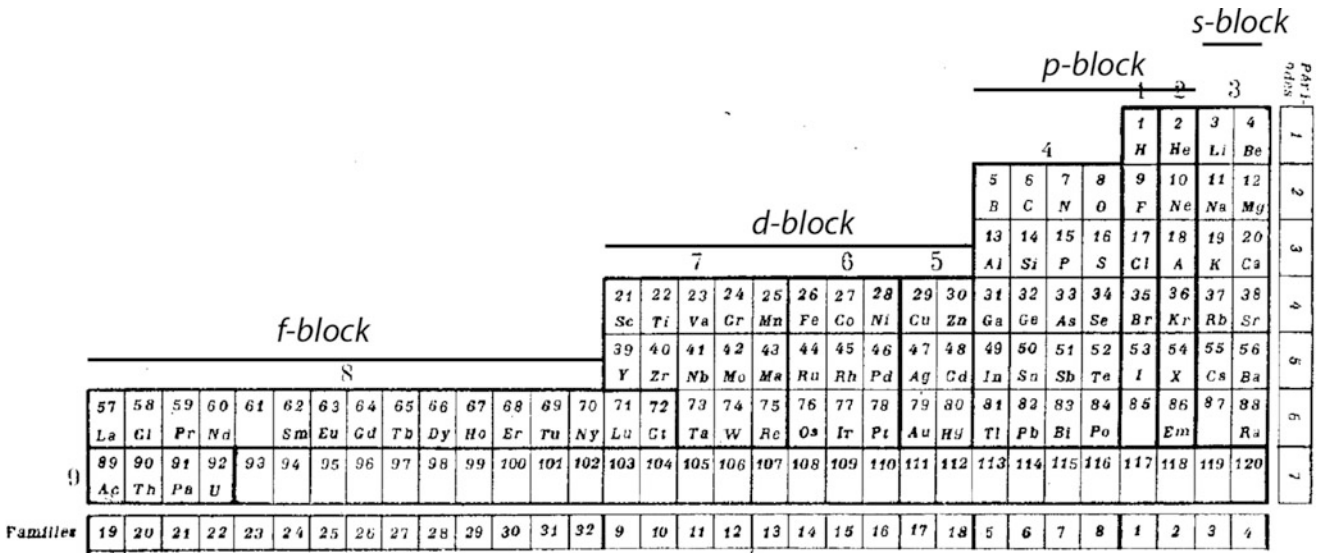
Periodic Table, Fig. 2 One of Mendeleev's first periodic tables (1871). The *dashes* indicate positions where Mendeleev predicted new elements would be discovered (From https://en.wikipedia.org/wiki/File:Mendeleev%27s_1871_periodic_table.jpg)

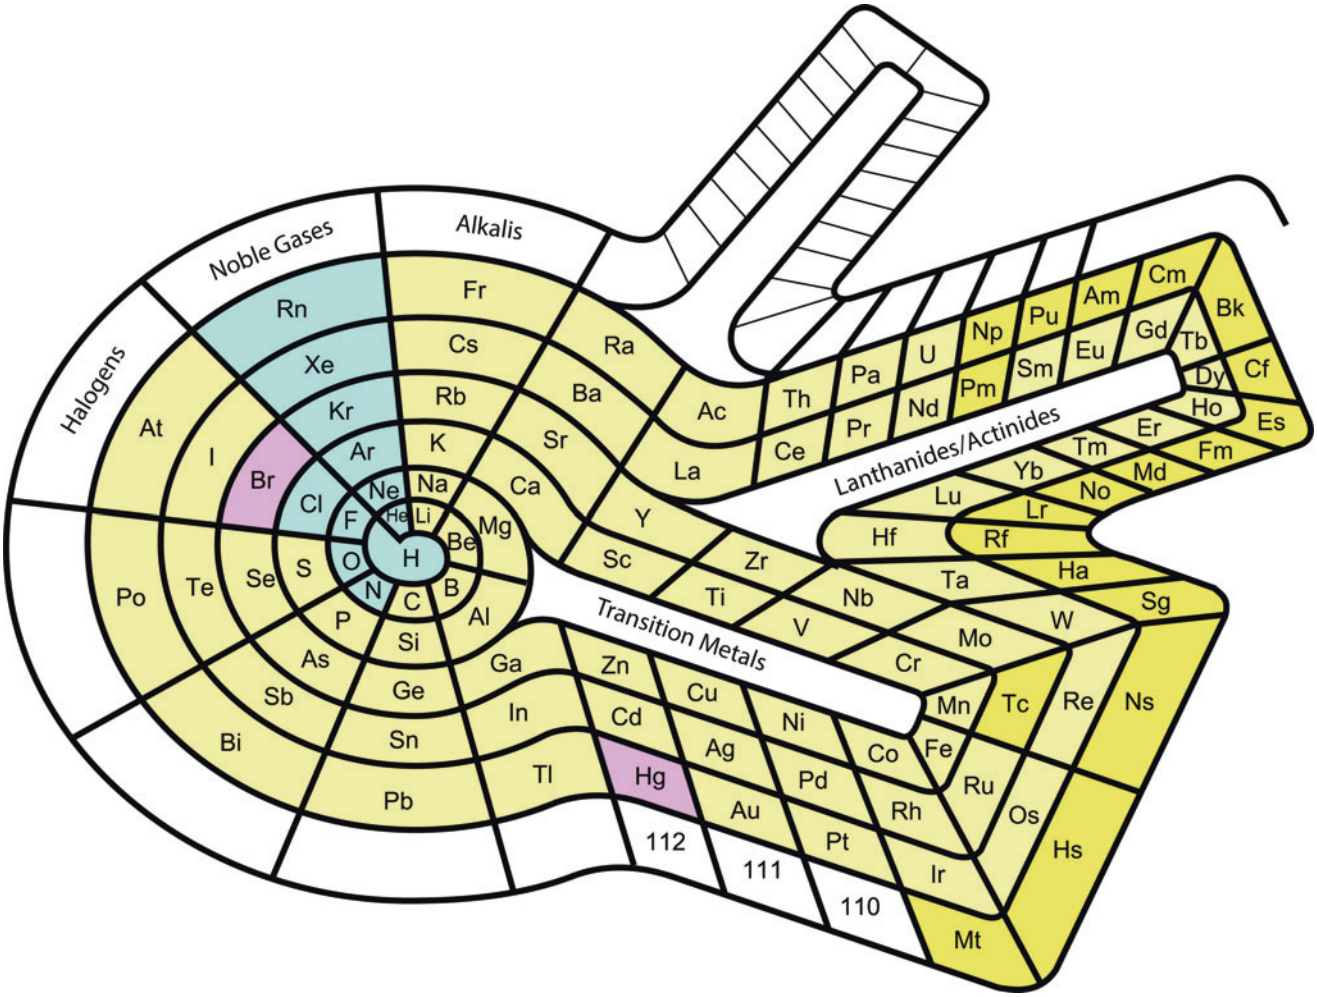


Periodic Table, Fig. 3 A version of the Janet left-step periodic table (1929). Atomic numbers and element symbols are displayed in each box for elements that existed at the time of the table's design. The indications for the orbital blocks are an addition to his table, and were not part of the original annotations. Note that H and He should sit in the s-block according to our current understanding of electron configurations (Modified from Janet (1929))

adding electrons in the appropriate blocks. Theodor Benfey designed a spiral periodic table (Seaborg 1964; Fig. 4), in which the smallest atom, hydrogen, is at the center, and the progressively larger atoms are built by following the serpent-like spiral. The d-block is the transition metal peninsula, and the f-block is the lanthanide and actinide peninsula in the table.

Periodicity

The notion of chemical periodicity is where the elegance of the periodic table begins to emerge. The arrangement of the table conveys important information about the structure, and therefore the reactivity, of atoms.



Periodic Table, Fig. 4 Version of the Benfey spiral periodic table (1964). Note that the blank "peninsula" is intended to be predictive for heavier elements that may be discovered in the future (the "super-actinides"). *Blue*: Gases (at room temperature); *Pink*: Liquids at room temperature; *Pale yellow*: Solids; *Dark yellow*: Experimentally produced elements (Modified from https://commons.wikimedia.org/wiki/File:Periodic_system_Benfey_format.svg)

An atom is at its most stable when it has a filled outer electron shell, or valence shell. The chemical behavior of an element is dictated by a fundamental objective: to fill its outer electron shell, or valence shell, completely. Because elements within a vertical group have the same outer electron configurations, they will share physicochemical characteristics as well.

Elements with nearly full electron shells are on a mission to obtain those last few electrons necessary to reach full orbital occupancy. The most extreme set of elements in this category are the halogens, the second-to-last column on the right, Group 17 (Fig. 1). These elements reside in the p-block and have 7 electrons in their valence shell, in desperate need of only one additional electron. Consequently, they have high electronegativity (the tendency to take an electron from other atoms; fluorine has the highest electronegativity of any element, at 4.0) and high-ionization energies (the energy required to remove an electron from an atom). The halogens therefore tend to form anions with −1 charges.

In contrast, elements in Group 1, the alkalis, are generally found in a +1 valence state and have a habit of reacting energetically to achieve that condition (e.g., the reaction of sodium metal, Na, with water to make Na^+ is strongly exothermic, often dangerously so). All the alkalis have one extra electron that they strive to lose.

Elements with completely filled electron shells are in the last group to the far right on the table, the noble gases. These elements have electron shells that are filled to capacity. This is where they get their other common name, the inert gases; they are unlikely to either donate or acquire electrons in chemical reactions and are fundamentally unreactive.

Within a group, several additional patterns emerge. From top to bottom, atomic radii increase, and the outermost electrons are found progressively farther from the nucleus

(Fig. 1). This in turn makes it easier to remove electrons from an atom, resulting in decreasing ionization energy and electronegativity from top to bottom in a group, with only a few exceptions.

In the other dimension, horizontal rows are referred to as *periods*. Moving from left to right along a period, atomic radius generally decreases, as the electron cloud is drawn closer to the more positively charged nucleus. Consequently, electrons are held tighter within the atom, causing ionization energy and electronegativity to increase from left to right along a row. This phenomenon is particularly apparent in the lanthanide and actinide elements (known collectively as the rare earth elements; Fig. 1), which make up the f-block relegated to the bottom of the periodic table. Electrons in these nuclei are housed as much as two energy levels below the outer electron shell, which causes two phenomena unique to the rare earth elements. First, the addition of more electrons and protons to each element in the rows increases the electrostatic forces holding the atoms together, resulting in a larger than expected decrease in ionic radii from left to right across the periodic table. This phenomenon was named the "lanthanide contraction" by Goldschmidt in 1925. Second, because the outer electron shells of the rare earth elements are identical, all of the elements in the suite behave the same way chemically (with a few exceptions), making them quite useful in geochemical applications (see ▶ "Lanthanide Rare Earths") but particularly troublesome to purify. According to Sam Kean (2010), a chemist determined to isolate thulium from the other lanthanides began with hundreds of kilograms of ore, from which he removed tiny amounts of thulium. He had to perform the process over 15,000 times to extract a few grams of the element (and even then, the thulium was still a bit contaminated by other lanthanides, because, as Kean writes, "there just wasn't enough of a chemical handle to grasp them and pull them out").

Elemental Abundances

The abundance of elements in nature is not included in the traditional periodic table. Nevertheless, it is possible to extract some insight from information that is available on every periodic table: the atomic numbers.

Early investigations into elemental abundances revealed important perspectives on the formation of elements in stars (see ▶ "Nucleosynthesis"). Two scientists, Giuseppe Oddo in 1914 and William Harkins in 1917, noted that elements with even atomic numbers were more abundant than their odd-numbered neighbors on the periodic table. What is now known as the Oddo-Harkins Rule postulates that during nucleosynthesis, nuclei with odd numbers of protons are more likely to capture other odd-numbered nuclei, fusing to form a new atom with an even number of protons (see ▶ "Atomic Number, Mass Number, and Isotopes"). In contrast, elements with even atomic numbers are more stable, making it less likely that they will undergo fusion to form larger elements. Nuclei with an even number of protons and an even number of neutrons have higher binding energies and are therefore more stable than ones with odd numbers of either protons or neutrons. The abundances of the lanthanides in the solar system exhibit the Oddo-Harkins effect clearly (see ▶ "Lanthanide Rare Earths").

Geochemical Affinity and Periodicity

The abundances of elements in Earth's major reservoirs (its core, silicate mantle, atmosphere, hydrosphere, and crust), however, do not mirror the composition of the solar system. When the major Earth reservoirs formed, elements were rearranged ("differentiated") according to their behavior under varying physiochemical conditions, much of which can be explained in the context of elemental abundance in the major Earth reservoirs.

Victor Goldschmidt, one of the most important pioneers of modern geochemistry, was a Swiss-born mineralogist who moved to Norway, where he published a series of works entitled *Geochemische Verteilungsgesetze der Elemente* in 1926. In this work (and subsequent; Goldschmidt 1937), he classified the known chemical elements according to where they were found in nature, primarily (see ▶ "Geochemical Classification of Elements"). He defined four main categories for elemental behavior: (a) Lithophile (rock-loving); (b) Atmophile (gas-loving); (c) Chalcophile (ore- or chalcogen-loving, i.e., elements from the oxygen family, mostly sulfur, and oxygen excepted); and (d) Siderophile (iron-loving).

The group (or groups) to which an element belongs is dictated by its chemical properties. Lithophile elements are cations predominantly from the s- and f-blocks (Fig. 1) that combine readily with oxygen, and thus are strongly enriched in Earth's crust, mostly in silicate phases. They tend to form stable ions (e.g., the alkali and alkali earth elements, Groups 1 and 2) or strong covalent bonds (e.g., silicon, phosphorus) and have extreme electronegativities (high or low). Atmophile elements are volatile, meaning they evaporate easily and exist on Earth mostly in either liquid or gas phases. Consequently, the Earth is strongly depleted in atmophile elements compared to the solar system, which were lost during the early stages of Earth's formation. Atmophiles are noble gases, atoms that form strong, covalently bonded molecules (e.g., N_2, O_2), or ones that form stable molecules with oxygen (e.g., H as H_2O and C as CO_2).

Chalcophile elements form strong bonds primarily with sulfur, often as sulfides. They range from transition metals to heavy nonmetals, primarily from Groups 11, 12, and the

heavier elements from Groups 13 through 16, and tend to form covalent or metallic bonds owing to their intermediate electronegativities (Fig. 1). These elements are depleted in the Earth's crust and presumably concentrated in the core, and their ores are sources of many commercially important metals. The chalcophiles share some common characteristics with siderophile elements. Siderophiles are transition metals from the d-block that tend to be soluble in iron in solid or molten states. Because they do not form strong bonds with oxygen, they are predominantly concentrated in Earth's core and are relatively rare in the crust, making them precious metals from an economic perspective.

The periodic table provides further insight into the geochemical behavior of elements concentrated in Earth's silicate reservoir, the mantle and crust. The primary upper mantle minerals (olivine, pyroxene, plagioclase, garnet, and spinel) are made of a small number of elements, primarily Si, Mg, Fe, Al, and Ca; these are also the major elements in the Earth, owing to their abundance and prevalence in common minerals. If the crust is also considered, Ti, K, P, and Mn are also major elements for the same reason. Elements that do not constitute a stoichiometric or lattice-building component of these minerals are referred to as trace elements.

If a trace element has a similar ionic radius and charge to the lattice-building elements in a mineral, it is able to fit into the mineral's crystal structure and is therefore deemed a "compatible" element. Those with either ionic radii or charges that are inconsistent with the lattice builders will not be incorporated easily into the structures and are "incompatible" elements. When a mineral melts, the incompatible elements move preferentially into the liquid phase, owing to their less-stable configurations within the solid minerals; in contrast, compatible elements remain in the residual solid during melting. Whether an element behaves compatibly or incompatibly in the mantle or crust can be determined by examining periodic table trends. Most compatible elements reside in the same column on the periodic table as the major element it is replacing, or for the transition metals in the same row.

Elements with ionic radii too large to fit into most silicate minerals are classified as Large Ion Lithophiles (LIL) and are primarily the heavier elements from the first two columns in the periodic table (Groups 1 and 2, the alkalis and alkali earths; Fig. 1). Because their large volume distorts the lattices of common mantle minerals, these elements are highly incompatible and strongly enriched in the Earth's crust.

A second set of trace elements is incompatible in mantle minerals not because of their ionic size but owing to their high ionic charges (>3+). Substitution of an ion with a mismatched charge in a lattice site necessitates that charge balance be maintained by a coupled substitution, an energetically unfavorable event (i.e., if Ta^{5+} substitutes into a site that normally takes a trivalent cation, another +3 site must be occupied by an ion with only a +1 charge). Elements with the highest ionic charges are in the left columns of the d-block, among the transition metals, and are known as the High-Field-Strength elements. Even though ions such as Zr^{+4}, Hf^{+4}, Ta^{+5}, and Nb^{+5} have ionic radii that fit comfortably into most mantle and crust mineral, their excessive charges cause them to be highly incompatible and concentrated strongly in Earth's crust.

Conclusions

Despite its deceptively simple appearance, the periodic table encapsulates a remarkable wealth of information about the fundamental building blocks of matter.

Its systematic organization makes it possible to predict an element's chemical behavior, physical properties, and geochemical affinities, making it one of the most important reference tools for earth scientists.

Additional Resources

There are many useful and creative versions of the periodic table available online. Just a few of them are listed below:

1. The Royal Society of Chemistry has an interactive periodic table, with historical perspectives, videos, and a set of original artistic representations of the elements: http://www.rsc.org/periodic-table
2. A periodic table incorporating photographs of all the elements can be found here: http://periodictable.com/
3. The University of Nottingham hosts a website that includes videos about most of the elements: http://www.periodicvideos.com/
4. WebElements includes geochemically relevant information in a periodic table, such as elemental abundances in different environments: http://www.webelements.com/geology.html
5. In 1959, Green produced a version of the periodic table for geochemists, which included elemental abundances in different rock types, seawater, meteorites, and the universe, as well as their abundances in common minerals. More recently, Railsback (2003) compiled a complex but comprehensive periodic table for earth scientists, organized by ionic charge, and intended to convey interrelationships among elements in different geochemical settings (Railsback 2003): http://www.gly.uga.edu/railsback/PT.html
6. In the category of not particularly useful but fun, a periodic table anagram won the Special Category Prize in 1999 at Anagrammy.com (http://www.anagrammy.com/winners/Mike%20Keith). Exactly the same letters are on each side of the equation, arranged differently. The most

intriguing part is that if you replace the element names with their atomic numbers, those add up as well (Michael Keith)
7. Finally, no overview of the periodic table is complete without the Elements Song, written in 1959 by Tom Lehrer, who also performs it in the video: https://www.youtube.com/watch?v=DYW50F42ss8

Petroleum

Philippe Ungerer
Materials Design S.A.R.L., Montrouge, France

P

Definition

Petroleum, from greek *petra* (rock) and latin *oleum* (oil), is a mixture of natural origin, made of numerous organic molecules, mostly hydrocarbons, from 1 to 80 carbon atoms. Petroleum is found as a liquid phase (oil), a gaseous phase (▶ *Natural Gas*), or a solid-like phase (bitumen) in the porosity and cracks of reservoir rocks where it has accumulated. These different forms result from a common origin, as petroleum is the product of the thermal or bacterial degradation of sedimentary organic matter in deep strata of sedimentary basins. The range of conditions produces a continuum of compositions between natural gas, oil, and bitumen.

History

Natural ▶ *Oil-seeps* have been used as sealing agent, adhesive, cosmetics, and fuel in oil lamps, from three millennia before BC in Ancient Egypt and the Middle East. *Biomarker*

analysis has allowed to trace back the origin of these bitumen (Connan 1999). In Asia, hand-dug wells were used to produce petroleum from 900 BC (Hunt 1995; Thornton 2015). In Europe, petroleum was also mined locally (e.g., in Pechelbronn, France) in the seventeenth century. The industrial production of oil by drilling wells – instead of mining – and processing oil in refineries appeared in 1857 in Ploiesti (Romania) and in 1859 in Titusville (Pennsylvania, USA). The increase of oil and gas production during the twentieth century was made possible by the discovery of new accumulations, particularly in the Middle East where the largest fields of oil (Ghawar, Saudi Arabia) and of natural gas (North Dome – South Pars, Qatar, and Iran) of the world were discovered in the 1948 and 1971, respectively. In the second half of the twentieth century, exploration was also successful in offshore continental margins (North Sea, Gulf of Mexico, Alaska, among others). Since 2000, exploration has extended to offshore areas with water depths of 1–3 km (e.g., S. Atlantic, W. Mediterranean sea) and arctic regions. According to Campbell and Laherrère (1998), the rate of new discoveries should not compensate for the production from conventional reservoirs (i.e., allowing economic production rates with the original reservoir permeability). The oil and gas industry is indeed producing an increasing volume of unconventional resources which need specific technologies to increase production rates. These are mainly extraheavy oils and bitumen (e.g., W. Canada), shale gas (e.g., Barnett formation, USA), and shale oil (e.g., Bakken formation, USA).

Distribution of Petroleum Reserves

A summary of oil and gas reserves and distribution is given in Table 1. Estimates of reserves are subject to significant uncertainties (10–20%) and their precise definition may change according to the data source. The percentage of oil in place that can be produced economically with current technology (i.e., the recovery factor) is approximately 35% (world average) for conventional oil reservoirs and approach 80% for natural gas (IFPEN 2017). There are important variations depending on reservoir characteristics. The resources of extraheavy oils and bitumen have been shown separately in Table 1 because they involve important volumes of oil in place (747 Gt) and low recovery factors (<10%) in current estimates. The possible resources of shale oil (US DOE-EIA 2013) are not shown in Table 1, as it is uncertain whether their production will be economic on a significant basis. Until 2016, the cumulated amount of oil and natural gas liquids produced worldwide is estimated to 200 Gt (IFPEN 2017). This is larger than the remaining reserves of conventional oil (178 Gt in Table 1).

Petroleum Composition

Petroleum composition is highly variable, as it results from a series of complex transformations involving chemical reactions and basin-scale migration (see below section on "Origin" and "Petroleum Migration"). In addition to its variability, petroleum composition is delicate to understand because it cannot be preserved in its original phase state when brought in surface conditions. For instance, the low molecular weight components e.g., (methane, C_2–C_4 alkanes, CO_2, H_2S) are gaseous in surface conditions and they may be dissolved in a liquid phase due to the high pressure prevailing in reservoir conditions. As another example, a methane-rich natural gas often contains significant concentrations of gasoline-range and gas-oil range hydrocarbons, which are dissolved in the gas phase in reservoir conditions, and liquid in surface conditions (Pedersen et al. 2014).

Finally, petroleum contains dissolved organic compounds of high molecular weight (asphaltenes, waxes). The abundance of these compounds in bitumen or in high wax oils explains their solid-like behavior, and their presence in

Petroleum, Table 1 Distribution of proven reserves, original oil in place (OOIP), and natural gas reserves on a global basis. Conventional oil reserves include natural gas liquids, i.e., hydrocarbons of natural gas collected in a liquid state by processing in surface conditions. Extraheavy oils reserves (including "bitumen" and "tar sands") are taken from the same source as a conventional oil (BP 2017) and the corresponding OOIP are taken from Total (2006). Oil reserves are expressed in billion tons (Gt) assuming average densities of 1000 kg/m^3 for extraheavy oils for volume/mass conversions. Natural gas reserves (source: BP 2017) are expressed in Tm^3 (10^{12}) in standard surface conditions

	Conventional (crude oil and Natural gas liquids)	Extraheavy oils		Natural gas (Tm^3)
Region	Proven reserves (2016), Gt	Estimated reserves (2016), Gt	Estimated OOIP, Gt	Proven reserves (2016)
North America	7.6	26.9	318	11.1
South America	15.1	35.7	207	7.6
Europe-Eurasia	21.8	–	222	56.7
Middle-east	110.1	–		79.4
Africa	16.9	–		14.3
Asia-Pacific	6.4	–		17.5
Total world	178	62.6	747	186.6

Petroleum, Table 2 Main petroleum fractions ranked by normal boiling temperature (Tb) and economic use. Direct use refers to fractions or compounds obtained by distillation or more specific separations, and conversion refers to chemical transformations by specific processes (thermal or catalytic) in refineries

Fraction	Tb, °C	Standard state at 25 °C, 1 atm	Carbon number range	Main direct use (products obtained by distillation or separations)	Main conversion products (obtained by chemical transformation)
Methane	−162	Gas	1	Distribution gas	Methanol, H_2
Other gases (C_2-C_4 alkanes, CO_2, H_2S)	−89 to 0	Gas	0–4	LPG fuel	Light olefins (ethylene, propylene), ethers
Gasoline (alkanes, cycloalkanes, aromatics)	0–204	Liquid	4–11	Fuel, chemicals	Light aromatics and olefins (e.g., paraxylene, ethylene)
Gas oil	204–315	Liquid	11–18	Diesel fuel, jet fuel	
Atmospheric and vacuum gas oil (AGO- VGO)	315–538	Liquid	14–40	Fuel oil, lubricant bases, waxes	Gasoline and diesel fuel
Vacuum residue (mostly polyaromatics)	>538	Amorphous solid	22–100[a]	Road asphalt, roof sealing	Gasoline and diesel fuel, coke

[a]Indicative maximum number of carbons of crude oil asphaltenes.

reservoir oils may also cause solid deposits when brought to surface conditions.

Whether petroleum is a natural gas, a reservoir oil, or a bitumen, its composition is first described by its main boiling point fractions (Table 2). It is worth noting that some families are systematically absent from natural petroleum: this is particularly the case of alkenes (also named olefins) of linear, branched, or cyclic structure. Similarly, three- and four-membered saturated cycles are marginal building units in petroleum hydrocarbons, their absence being explained by the lower stability of these small cycles compared with five-and six-membered cycles. A common characteristic of all petroleum fractions is the absence of the radioactive ^{14}C isotope of carbon, as a consequence of residence time of organic matter and petroleum $>10^6$ years in the subsurface. Petroleum fractions are also displaying a lighter ^{13}C composition than standard ($\delta^{13}C = -25$ to -100‰ for methane, usually -25‰ to -35‰ for other fractions) which is caused by the isotopically lighter carbon of living organisms and hence of sedimentary organic matter. Deuterium is also displaying lighter than average concentrations (Schoell 1980).

Light hydrocarbons (1–4 carbon atoms) are the major compounds of natural gas, and they are also found dissolved in reservoir oils. Methane represents generally 60–95% of natural gas and 0–50% of reservoir oil on a molar basis.

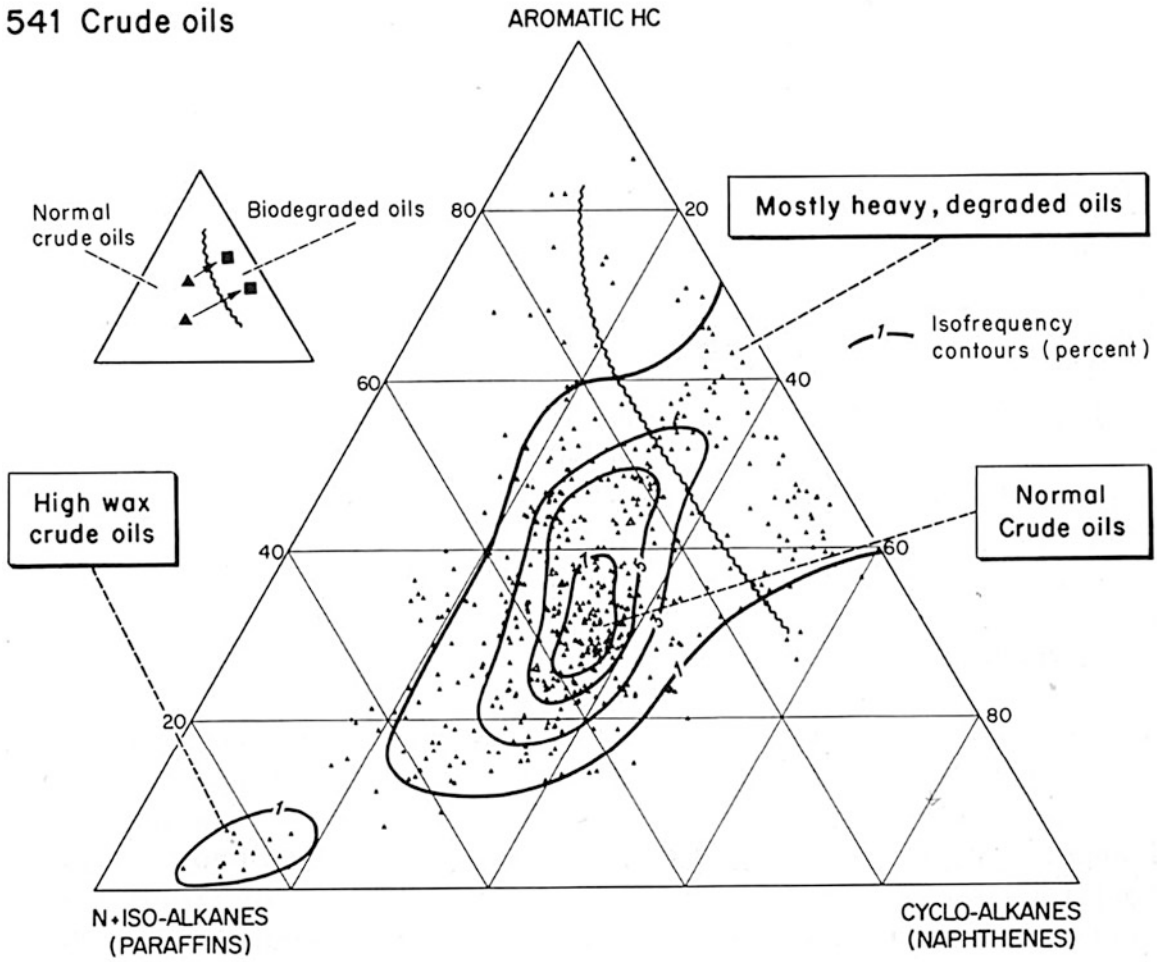
Nonhydrocarbon compounds of low molecular weight (CO_2, H_2S, N_2) show variable concentrations: 70% of natural gas reserves are reported to contain molar fractions of CO_2 lower than 2% vol and H_2S contents lower than 1% vol (Rojey et al. 1997). Occasional CO_2 contents of 10% and higher have been reported, possibly linked with magmatic contribution (e.g., 8–18% in Lula field offshore Brazil). H_2S concentrations in excess of 10% are also found in some deep reservoirs (e.g., 15.3% H_2S in Lacq field, France). Nitrogen content is generally low in natural gas and associated gas (0–3%) but may be higher in deep gas reservoirs (e.g., 14% in Groningen field, Netherlands).

The gasoline fraction usually contains linear and branched alkanes, monocyclic alkanes (alkylcyclopentanes, alkylcyclohexanes), and light aromatics (benzene, toluene, xylene isomers, and other alkylbenzenes). Among cyclic hydrocarbons, the unsubstituted end-members (cyclopentane, cyclohexane, benzene) are generally less abundant than the methyl-, dimethyl-, or ethyl- bearing compounds of the same families. Compared with heavier fractions, the composition of gasoline-range hydrocarbons is more delicate to sample because of possible evaporation of volatile compounds. It is also less specific of petroleum origin. It provides, however, useful indications of possible compositional variations revealing different blocks in a given reservoir.

The gasoil and intermediate distillate fractions contain linear and branched alkanes, naphthenes (i.e., cyclic alkanes), and aromatic hydrocarbons (Fig. 1). On average, these fractions display comparable mass fractions. The distribution of linear alkanes generally displays a broad distribution providing some insight in petroleum origin: a distribution showing a clear maximum above C_{20} and significant odd/even preference is an indication of a low degree of secondary reactions and an exponentially decreasing tail is an indication of more transformations. The absence of n-alkanes is an indication of oil biodegradation.

With the exception of isoprenoids, branched alkanes (alkanes bearing a branched methyl group every fourth carbon) are more difficult to identify because of the very large number of isomers. Among isoprenoids, pristane and phytane display comparable abundance to linear alkanes of similar molecular weight (Fig. 2).

Cyclic hydrocarbons in the gasoil fraction and vacuum gasoil fraction are either fully saturated (naphthenes with

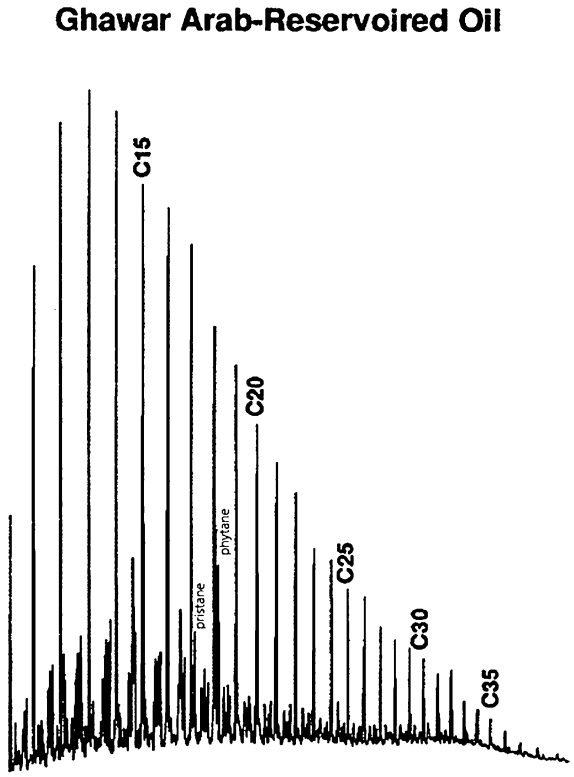


Petroleum, Fig. 1 Distribution of the oil fraction boiling above 210 °C in a ternary diagram (n + iso alkanes, naphthenes, aromatics) (After Tissot and Welte 1984)

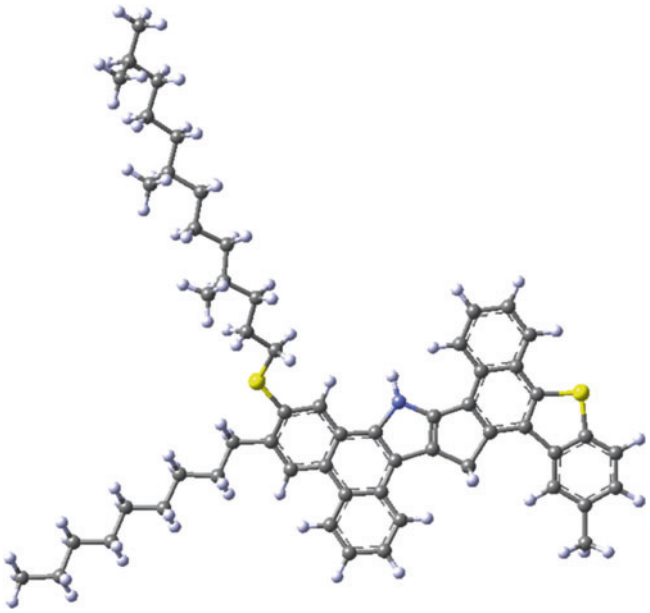
1–5 condensed cycles), aromatic (1–5 cycles), or mixed (naphthenoaromatics). In these fractions, polycyclic naphthenes comprise several families of biomarkers analyzed by ▶ GC-MS to trace oil origin: steranes (four condensed cycles), hopanes, gammacerane, and oleananes (five condensed cycles), among others. Among polycyclic hydrocarbons, alkyl-substituted molecules (e.g., methylnaphthalenes, dimethylnaphthalenes) are more abundant than the condensed molecule (e.g., naphthalene). In gasoil and vacuum gasoil fractions, the structure of polyaromatic molecules and the decrease of alkyl substituents are often linked with the aromatization of polycyclic naphthenes at advanced stages of thermal degradation.

The heavy molecular weight compounds of crude oils present in vacuum residue are defined as solubility classes: resins are soluble in light alkanes, and asphaltenes are not. The presence of polyaromatic nuclei in asphaltenes (Fig. 3) explains why they can aggregate by stacking and segregate if aggregates are large enough (Mullins et al. 2012). Their elemental analysis (atomic H/C = 0.9–1.25 according to Rogel et al. 2012, 2013) and their investigation by Atomic force microscopy (Schuler et al. 2015) reveal important variations in structure and molecular weight. Resins and asphaltenes commonly display significant contents in sulfur, nitrogen, and oxygen.

Although dominated by hydrocarbons, petroleum contains also organic compounds including sulfur, oxygen, or nitrogen in functional groups or embedded in chains and cycles. These are mostly sulfur-bearing (thiols R-SH, alkylsulfides, thiophene derivatives), nitrogen-bearing (e.g., amines, pyrole derivatives), oxygen-containing compounds (e.g., alkanols, carboxylic acids), and organometallic compounds (Filby and Branthaver 1987). Ni- and VO-▶ *Porphyrins* are typical examples. As a general rule, the percentage of non-hydrocarbon compounds is small for light fractions and increases with molecular weight. Crude oils may contain up to 7% wt sulfur (average < 1%), up to 200 ppm of Nickel and up to 1500 ppm of Vanadium.



Petroleum, Fig. 2 C15+ chromatogram of a representative sample of Ghawar reservoired oil (After Carrigan et al. 1995)



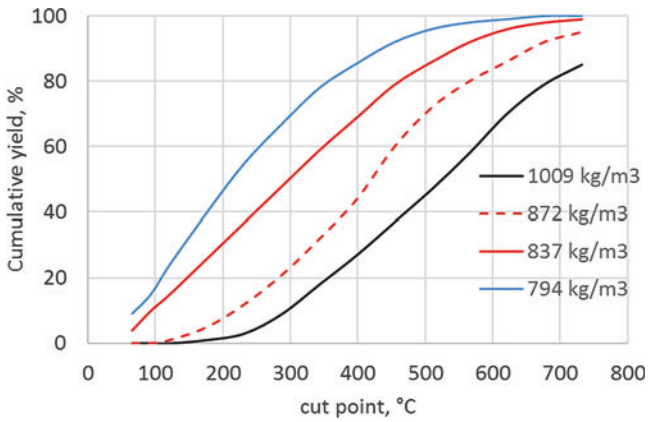
Petroleum, Fig. 3 Example of molecular structure of asphaltene ($C_{59}H_{71}NS_2$) in which the polyaromatic nucleus is derived from Atomic force microscopy data (Schuler 2015). Alkyl chains and functional groups containing nitrogen (blue) and sulfur (yellow) are included to approach the average composition of asphaltenes from heavy oils. This is just one out of many possible structures of asphaltenes

Among the average properties that serve to characterize the composition of petroleum, gas-oil ratio, and oil density are of particular importance. Both properties are measured after liquid-vapor separation in standard surface conditions. The gas-oil ratio (or GOR) is the volume ratio of vapor to liquid, expressed in std. m^3 of gas per m^3 of oil. Oil density defines the main categories of reported petroleum resources: light oils (less than 870 kg/m^3), medium and heavy oils (870–1000 kg/m^3), and extraheavy oils (>1000 kg/m^3). High density is generally associated with a high content of high boiling point fractions, as illustrated in Fig. 4.

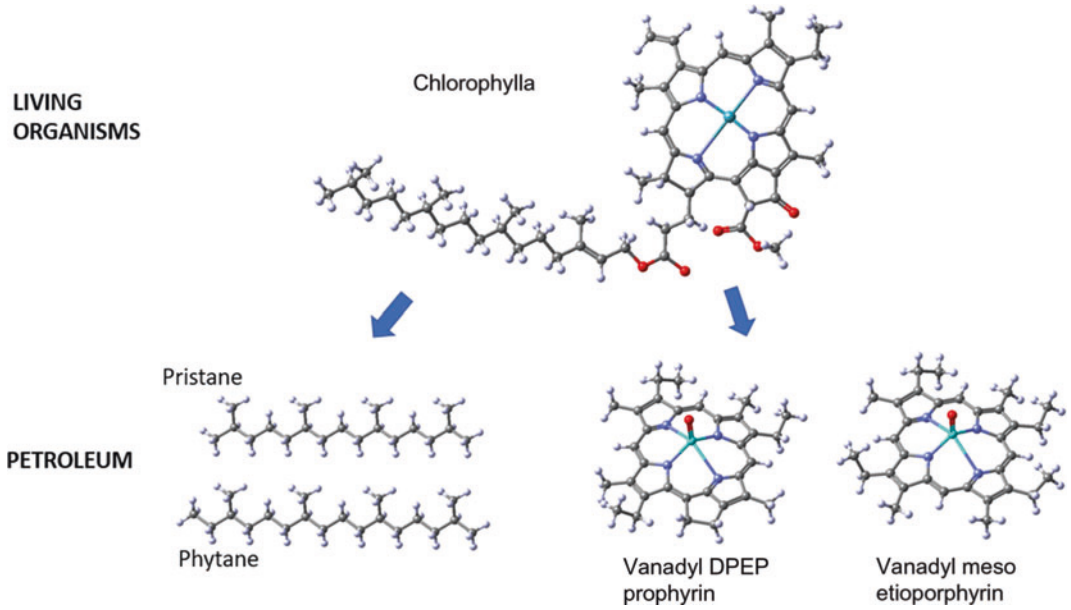
Origin

Petroleum is the byproduct of the thermal evolution of ▶ *Kerogen*, the organic matter contained in fine-grained sediments, called source rocks. In 1934, Treibs attributed the origin of petroleum ▶ *Porphyrins* (Treibs 1934) to parent molecules of living organisms like chlorophyll (Fig. 5). Now there is no doubt that petroleum is dominantly issued from the transformation of biogenic material. The investigation of petroleum *biomarkers* and their origin in living microbial, vegetal, or animal organisms has become an important branch of ▶ *Organic Geochemistry*, based on ▶ *Gas Chromatography-mass Spectrometry (GC-MS)* among other techniques. The biogenic origin of petroleum is also supported by its negative $\delta^{13}C$, because carbon produced by photosynthesis is isotopically lighter than the atmospheric CO_2 source (see ▶ "Carbon Isotopes").

The deposition of organic-rich source rocks occurs in specific sedimentary environments in which a fair organic productivity and good preservation conditions prevail (see ▶ "Organic Matter Degradation and Preservation"). Preservation requires anoxic conditions (i.e., a very low ▶ *Fugacity* of oxygen). The Black Sea and Great African lakes are contemporary examples. Analyzing preservation



Petroleum, Fig. 4 Boiling point distribution of two light oils (std density 794 and 837 kg/m^3), an intermediate oil (872 kg/m^3), and an extraheavy oil (1009 kg/m^3) (Redrawn from Boduszynski et al. 1998)



Petroleum, Fig. 5 Example of common petroleum *biomarkers* (vanadyl ▶ *Porphyrins*, pristane, phytane) and typical precursor (chlorophyll *a*). Chlorophyll *a* is a universal Mg-porphyrin involved in photosynthesis in living plants (color code as Fig. 3 for C, H, N, and oxygen in red). Arrows summarize a multistage diagenetic process involving the rupture of the alkyl chain and the exchange (▶ *Chelation*) of Mg^{2+} ion (emerald blue) by the vanadyl group $(VO)^{2+}$

conditions in the context of plate tectonics, as initiated by Tissot and Welte (1984), helps understanding the occurrence of organic-rich sediments. For instance, good source rocks deposited in the early phases of opening of the Atlantic ocean during Lower Cretaceous: the Bucomazi formation, Congo coastal basin (Burwood et al. 1995), the La Luna and Querequal formations in Venezuela (Talwani 2002), and the Lagoa Feia formation in Campos basin, offshore Brazil (Trindade et al. 1995). This helped exploration to find large accumulations in the Southern Atlantic presalt units.

Building upon the findings of ▶ *Coal* science (van Krevelen 1993), it has been recognized in the 1970s that different types of kerogen could be identified and that their composition followed systematic paths with increasing depth in a given basin (Tissot et al. 1974). The van Krevelen diagram (H/C vs O/C) allows to identify three main types, corresponding to different types of sedimentary environment (Fig. 6): type I kerogen, deposited in confined anoxic lakes such as the Green River Shales (Uinta basin, USA) is characterized by high H/C (1.35–1.55) at low depths of burial; type II kerogen, deposited in anoxic marine environments such as the Lower Torcian shales (Paris Basin, France) or the Upper Jurassic Kimmeridge Clay (North Sea) is displaying slightly lower H/C (1.2–1.3) at low depth; it is the most common form of organic matter in prolific source rocks; type III kerogen, originated from higher plants, is found in organic-rich shales or coals in deltaic environments like the Mahakam Delta (Indonesia). It displays a higher initial oxygen content (O/C = 0.1–0.3) and lower hydrogen content (H/C = 0.8–1.0).

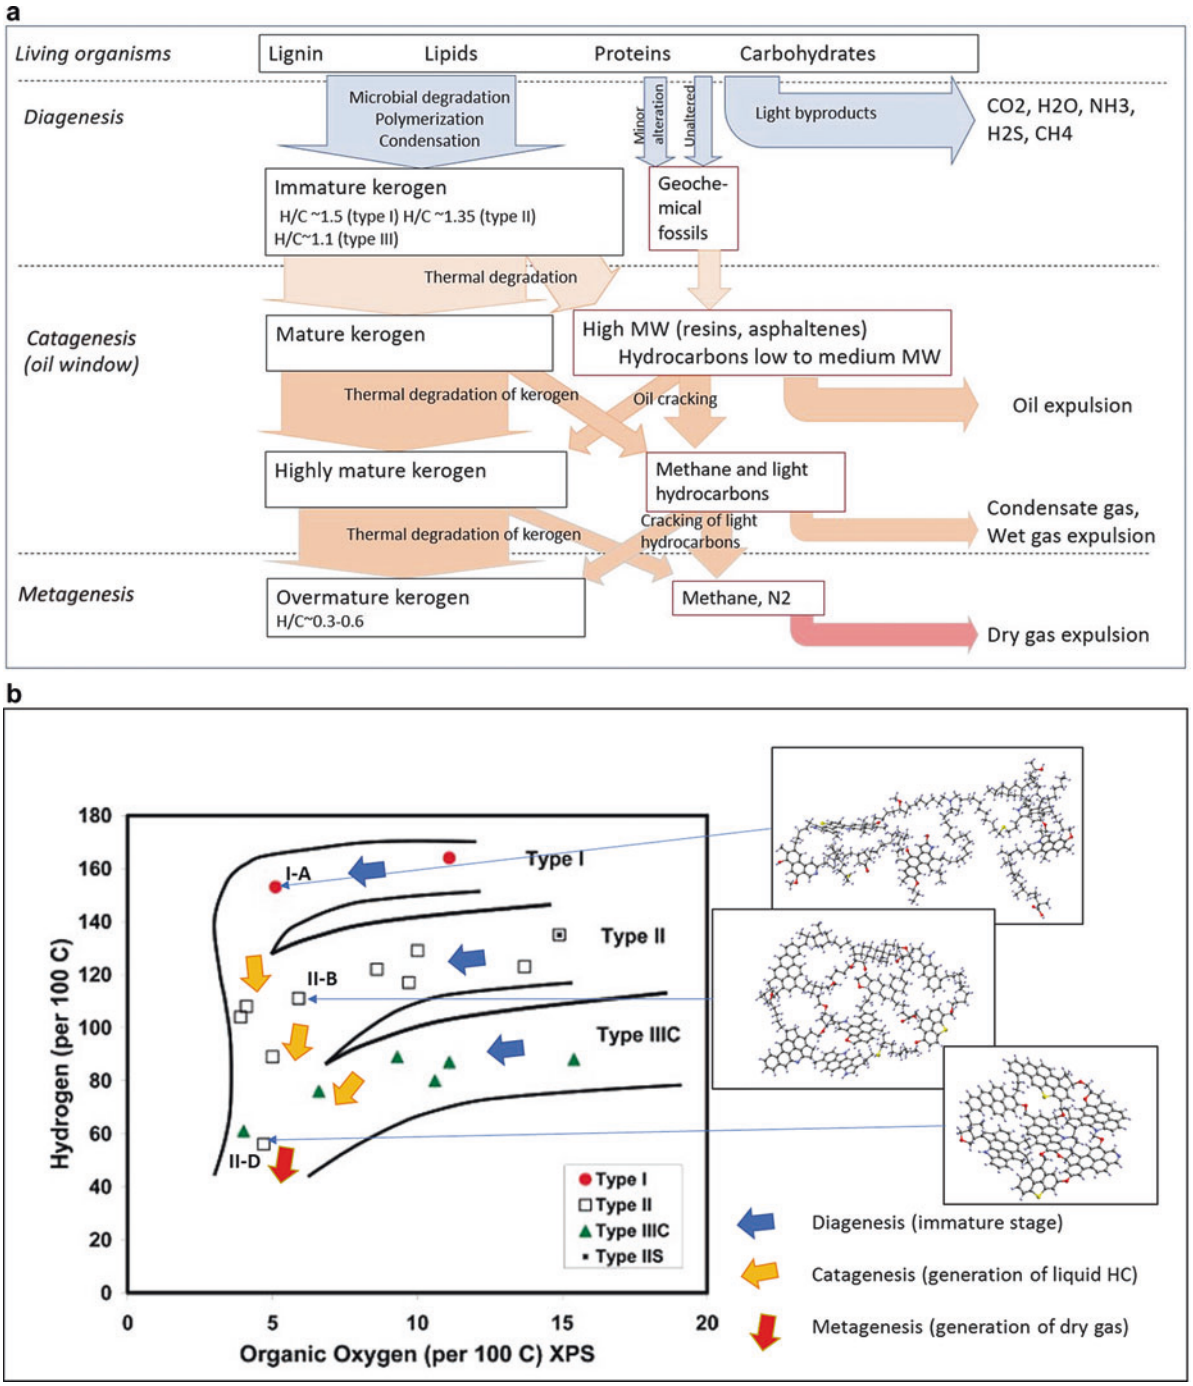
In a given area with continuous sedimentation, three successive stages are observed with increasing depth (Fig. 6).

During the immature stage (organic diagenesis), petroleum formation has not significantly started and only small quantities of biomarkers are present. This stage is characterized by the degradation of labile functional groups of kerogen, such as amines, carboxylic acid, carbonyl, and hydroxyl. It results in the loss of CO_2 and H_2O.

The mature stage (also called "catagenesis" or "oil window"), starting below depths of 2–3 km, is characterized by the maximum amount of petroleum amount in organic-rich rocks. High molecular weight compounds are generated first, then augmented with larger amounts of gasoil- and gasoline-range hydrocarbons; these fractions decrease in their turn while light C_1–C_4 hydrocarbons increase, so that the content of liquid-behaving compounds shows a maximum (peak oil generation).

The overmature stage (metagenesis), below 3.5–5 km, is characterized by the final stages of the thermal degradation responsible for the decrease of gasoline-range and heavier fractions. Most C_2+ alkanes are then degraded into methane and polyaromatic solids (pyrobitumen).

The thermal degradation process described above is named *maturation*. There is, however, no universal maturity indicator to quantify maturation. In addition to the position in the van Krevelen diagram (Fig. 6b), the main maturity indicators measured on organic matter samples are the vitrinite



Petroleum, Fig. 6 (a) Schematic diagram indicating the successive stages of petroleum formation in a basin with continuous sedimentation, adapted from a diagram of Tissot and Welte (1984). (b) van Krevelen diagram illustrating the change of atomic composition and schematic molecular structure of kerogen with organic type and maturity (Adapted from Kelemen et al. 2007 and Ungerer et al. 2015)

reflectance, obtained from optical reflectivity measurements of specific components of kerogen, and the peak temperature Tmax measured in programmed temperature pyrolysis. Maturity indicators are also defined to estimate the thermal degradation of oils from their composition (Radke and Welte 1981; Mackenzie and McKenzie 1983). These are based on the dilution or degradation of biomarkers (e.g., pristane/n-alkane, sterane isomerization) or on the dealkylation of polyaromatic structures (e.g., methylphenanthrene index), among other examples.

The isotopic composition carbon is providing indications of petroleum origin: thermogenic gas displays ^{13}C content similar to oil (usually $\delta^{13}C = -30$ to $-40‰$), and biogenic methane generated at temperatures lower than 80 °C displays

lighter isotopic composition ($\delta^{13}C = -50$ to -100‰). The presence of C_2+ hydrocarbons in gas is another marker of thermogenic origin, as opposed to biogenic gas in which C_2+ hydrocarbons are absent.

When source rocks are buried under a column of sediments, temperature increases due to the local geothermal gradient (generally 20–30 °C/km, with important variations and extreme values reaching 80 or 90 °C/km). This is the main factor of organic matter thermal degradation and petroleum formation. When maturation progresses, the remaining kerogen is more aromatic and its hydrogen content decreases as a result of the release of hydrocarbons (Tissot et al. 1974).

Thermal degradation is controlled by chemical *kinetics* at moderate temperatures in sedimentary basins (typically 70–150 °C) where source rocks are submitted to long heating times (1–100 Myr, i.e., 3×10^{13} to 3×10^{15} s). Petroleum formation can be simulated by pyrolysis in the laboratory, where higher temperatures (300–500 °C) compensate for shorter heating time (1–10^7 s). This has provided the basis of *Rock-Eval pyrolysis*, a standard thermal analysis under inert gas flow specifically designed to characterize the petroleum generation potential and kerogen maturity of large series of source rock samples (Espitalié et al. 1985/1986). Alternative methods of pyrolysis in high pressure vessels allow investigation of secondary reactions (Lewan 1985; Behar et al. 1997). Being kinetically controlled, thermal degradation explores lower free energy conformations of the kerogen + petroleum system, and it is thus essentially irreversible. The role of liquid water and natural catalysts (clay minerals) does not appear necessary to explain the main aspects of petroleum formation. The main influence of minerals is more likely to adsorb preferentially the polar and aromatic compounds, compared with the alkanes. Reservoir oils are indeed richer in alkanes than source rock extracts (Vandenbroucke 1993).

The *kinetics* of petroleum formation and cracking are generally modelled by first order reactions:

$$dx/dt = Kx$$

where x is the initial petroleum and generation potential and K is the rate constant (1/s) that changes with temperature according to Arrhenius law:

$$K = A \exp(-E/RT)$$

where A a prefactor, E an apparent activation energy, R universal gas constant (8.3145 J/mol/K), and T absolute temperature (K). In order to address a large range of conditions and kerogen types, several parallel and successive reactions are included, with activation energies in the range 190–250 kJ/mol (Tissot et al. 1987; Burnham et al. 1987; Ungerer 1990; Behar et al. 1997). Based on ▶ Paleotemperature reconstructions, these models allow to understand the timing and spatial distribution of petroleum formation in a given basin. These models account for the differences in petroleum potential between major ▶ *Kerogen* types: type I kerogen, generates 600–800 mg of *hydrocarbons and NSO compounds* per g of initial total organic carbon (TOC); type II kerogen, generates 400–600 mg/g TOC; and type III kerogen issued from higher plants generates 100–300 mg/g TOC. Type III kerogen generates mostly methane and C_2–C_4 hydrocarbons, but hydrogen-rich type III containing long alkyl chains are also considered to generate significant gasoline-range hydrocarbons and heavier fractions.

The role of pressure in petroleum formation *kinetics* is modest compared to temperature. Detailed kinetic models, based on free radical mechanisms, explain why natural petroleum does not contain linear alkenes, which are important products in low pressure pyrolysis (Enguehard et al. 1990). Detailed kinetic models are also useful in understanding the role of high pressure conditions (20–120 MPa) and hydrocarbon structure on the rates of thermal degradation (Dominé et al. 1991, 2002; Burklé-Vitzthum et al. 2011).

Petroleum Migration

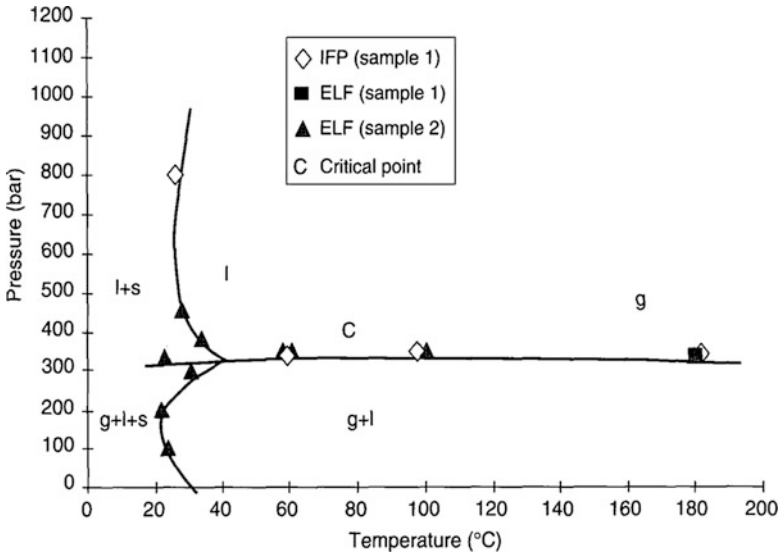
Petroleum migration is an essential step of petroleum formation and accumulation, involving important changes of composition. The understanding of migration is primarily based on the possible phase state and properties of petroleum in the conditions prevailing in sedimentary basins. The water solubility of hydrocarbons is lower than a few ppm in diesel-range fractions and above (McAuliffe 1966). As a result, petroleum forms a separate phase from pore water. At very high pressure ($P > 35$ MPa), petroleum is most often forming a single phase even when it contains a high percentage of methane (Fig. 7).

Another important property for petroleum migration is its viscosity (μ_i), which controls flow rates in porous media through the two-phase Darcy's law:

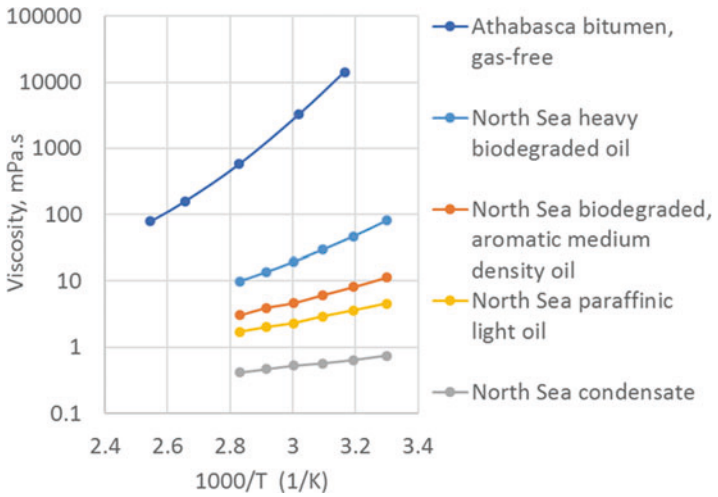
$$u_i = -\frac{K}{\mu_i} k_{r\,i}(\nabla P_i - \rho_i g)$$

Viscosity changes by several orders of magnitude with petroleum composition and local conditions: it is lower than 0.1 mPa.s for natural gas, 1–100 mPa.s for most oils. It reaches 100 Pa.s for bitumen at low temperature (Fig. 8). This is why bitumen appears solid at human timescale although it is a complex fluid.

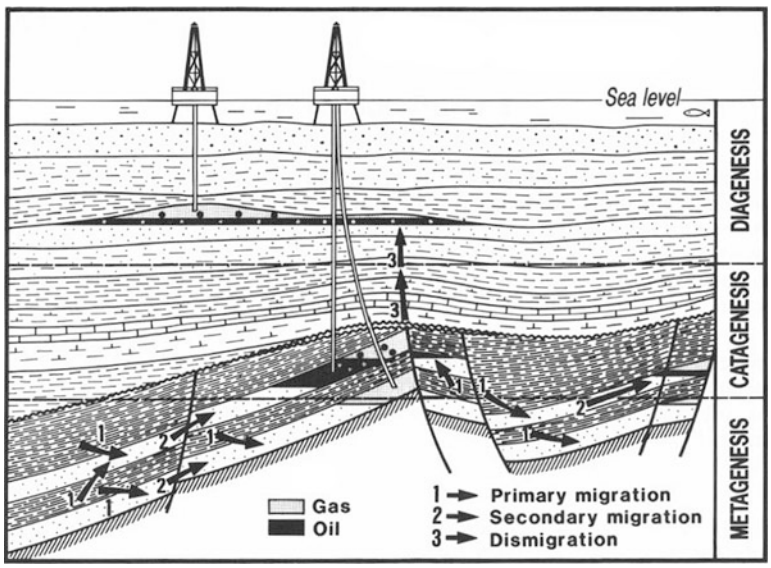
Petroleum migration is generally described with the main steps illustrated in Fig. 9.



Petroleum, Fig. 7 P, T phase diagram of a methane-rich petroleum fluid (Ungerer et al. 1995) showing gas + liquid (g + l) phase split below 310 bar, and a monophasic region for higher pressure, either vapor (g) above 80 °C or liquid (l) below 80 °C. Wax crystallization below 20–30 °C results in three phases (g + l + s) below 310 bar and two phases (l + s) above 310 bar



Petroleum, Fig. 8 Viscosity of Athabasca bitumen (Data from Mehrotra and Svrcek 1986) and of selected oils from North Sea Viking graben (Data from Roenningsen et al. 1991) as a function of inverse temperature at ambient pressure (P = 1 atm)



Petroleum, Fig. 9 Schematic cross-section illustrating primary migration and secondary migration, inspired by the case studies of the North sea Viking graben (reprinted from Durand 1988, with permission)

P

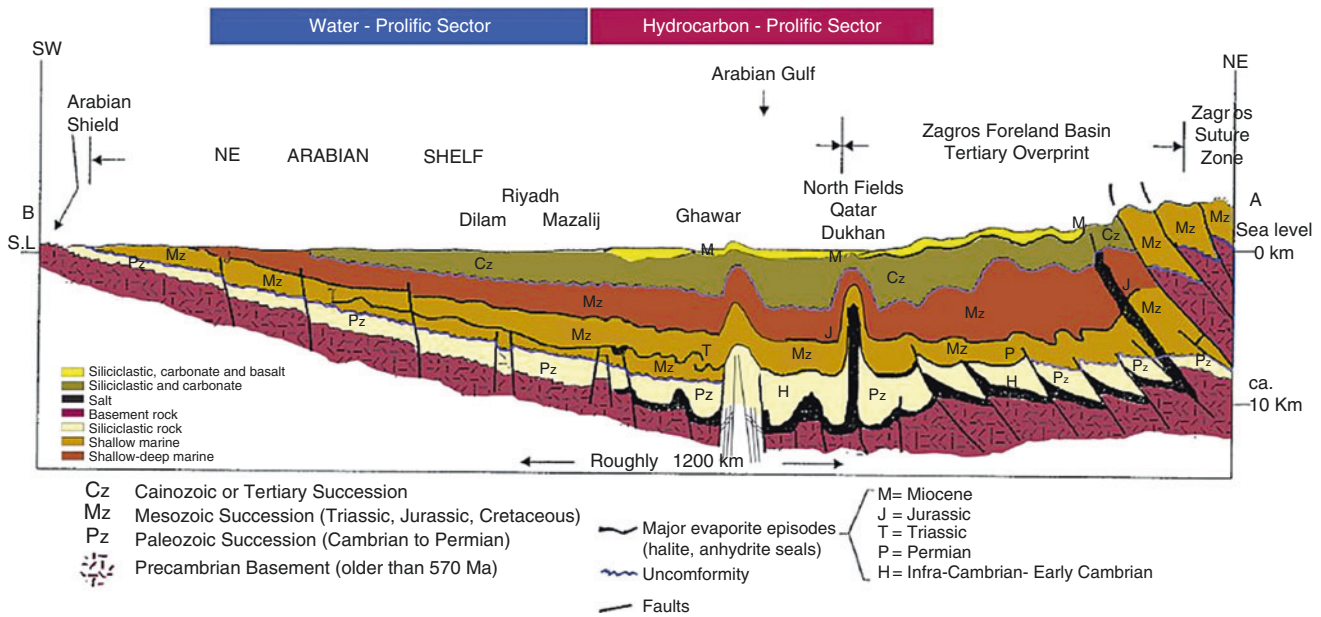
Primary migration refers to the expulsion of petroleum from source rocks, i.e., from low porosity shales with permeability (K in Darcy's law) as low as 1 nanodarcy (10^{-21} m^2), toward surrounding carrier beds. This process is considered to be controlled mostly by fluid pressure build-up, molecular scale transport (Collell et al. 2014) and compaction. Expulsion occurs when a sufficient amount of petroleum has been generated, creating a continuous path of saturated pores or microfractures (Vandenbroucke 1993). It is considered to require a total organic carbon content (TOC) of 0.5%wt at least for type II organic matter.

Secondary migration, in which petroleum flows inside more permeable units or faults, is a process dominated by gravity, capillary forces, and phase behavior. In this process, low permeability strata (called caprocks) plays an essential role in favoring horizontal migration. Caprocks may be ▶ *Evaporites* (halite, anhydrite) or shales. Migration follows the top of permeable units until it faces other obstacles (anticline, fault, pinch-out) where petroleum may eventually get trapped. Secondary migration is often associated with a liquid-gas phase split in the reservoir, as a result of pressure decrease along migration path. The consequences of phase split with decreasing reservoir pressure are the following: accelerated migration of the gas phase due to its lower viscosity and lower density; decreasing GOR of reservoir oil; decreasing condensate content of the gas and molecular fractionation (Carpentier et al. 1996). When a deep gas migrates into a shallower reservoir, the liquid dropout may generate light oil accumulations (oil rim) below the gas accumulation.

The distances covered during secondary migration are commonly a few hundred meters to a few km vertically, a few km to several hundreds of km horizontally. Together with prolific source rock deposition and maturation conditions, favorable structure to long-distance migration explains the size of the Middle East accumulations, as illustrated in Fig. 10.

The composition of the oil in a given trap results from the mixing of areas with different maturity, the less mature providing more heavy compounds (resins, asphaltenes) and the more mature providing lighter ▶ *Hydrocarbons* and gas. It is generally considered that diffusivity and thermally driven natural convection in the reservoir are sufficient to equilibrate petroleum composition vertically. Significant differences in composition persist horizontally when permeability barriers or large horizontal distances prevent petroleum from homogenizing. The mixing of light oil or gas with a heavy oil may cause the segregation of highly viscous oil (tar mats) near the oil-water contact.

A third stage of migration may be defined to address the leakage of accumulations (Fig. 9). On a geological timescale, an accumulation of petroleum may lose ▶ *Hydrocarbons* in various ways: erosion of caprock; differential subsidence reducing trap volume; growth of gas cap causing spill-over of oil; leakage through fractures; aerobic and anaerobic



Petroleum, Fig. 10 SW-NE cross-section across Saudi Arabia, Qatar, and Iran showing the geological context of major Middle East petroleum accumulations (reprinted from Jagu et al. 2016, with permission). Prolific source rocks are Upper Jurassic Tuwaiq mountain and Hanifa formations (Carrigan et al. 1995), which have sourced the Jurassic reservoirs; paleozoic Silurian intervals that have sourced Permian and Ordovician accumulations (Konert et al. 2001). Several basin-wide evaporitic episodes have provided efficient caprocks allowing long-distance horizontal migration and preservation of major oil fields (e.g., Ghawar) and *natural gas* fields (South Pars, North Dome) on the Arabian platform as well as large accumulations in the Zagros thrustbelt and its foreland

biodegradation of petroleum, which may occur up to 80 °C (Connan et al. 1997; Aitken et al. 2004); and thermal cracking of gasoline-range and heavier fractions of oil into lighter alkanes (mostly methane) and pyrobitumen in high temperature reservoirs. Thermal cracking of oil into gas occurs mainly at temperatures above 150 °C, and some deep reservoir fluids are still containing significant concentrations of gasoline-range and gasoil-range hydrocarbons although the reservoir temperature is 190 °C (Ungerer et al. 1995). Biodegradation is specific as light linear alkanes and saturated ▶ *Hydrocarbons* are preferentially degraded. It results in a significant increase in density and viscosity, and also higher concentrations in sulfur and metals (Huc 2010). Biodegradation in shallow reservoirs explains the origin of extraheavy oils and bitumen in Western Canada (Fig. 11) and Venezuela (Eschard and Huc 2008; Talwani 2002).

Interactions with Mineral Diagenesis

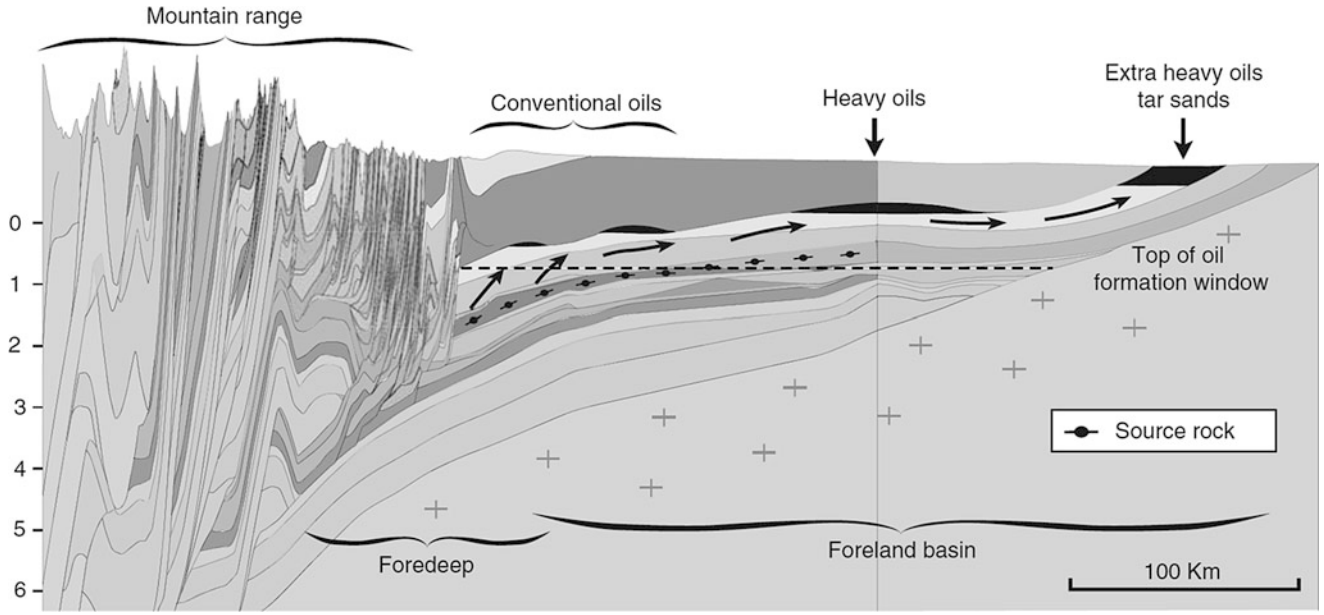
In an oil-saturated reservoir rock, mineral ▶ *Diagenesis* is considerably slowed down as it requires a continuous ▶ *Water* phase. Pore filling with oil or gas interrupts the growth of diagenetic minerals (e.g., clay minerals) and also the porosity reduction by pressure solution, which is the dominant mode of compaction (Gratier et al. 2013). In the example of the Ekofisk field (Norwegian North Sea), a high porosity (up to 35%) is preserved in the oil-saturated zone while porosity is reduced to a few % in the water-saturated zone of the same chalk reservoir (Van den Bark and Thomas 1981). The unconsolidated nature of oil sands in W. Canada and in Venezuela is probably also caused by an early migration of oil in the reservoir. This may have important effects on oil production such as producing loose sand together with extraheavy oils (Tremblay et al. 1997). It may also cause significant surface subsidence when petroleum is replaced by injected water (Doornhof et al. 2006).

In evaporitic series, thermal sulfate reduction (TSR) of calcium sulfate (e.g., anhydrite) by *hydrocarbons* may generate important amounts of H_2S and other reduced form of sulfur, together with CO_2, at temperatures in the range 100–140 °C mainly (Machel 2001). These reactions are responsible for high H_2S contents in ▶ *Natural Gas* and associated gases in SW France, Western Canada, and the Middle East, among other regions (see ▶ "Sulfur Cycle").

Petroleum in the Global Carbon Cycle

According to BP statistical review (2017), the global production of oil was 4.6 Gt/yr. (i.e., ~4 Gt of carbon) and the production of natural gas was 3.55 Tm3/yr. (i.e., ~2 Gt of carbon) in 2016. The total flux (6 Gt of carbon/yr) represents 10% and 5% of the yearly fluxes of carbon between ocean/atmosphere and atmosphere/continent, which are estimated to ~60 GtC per year and 120 GtC/yr., respectively (IPCC 2013).

Based on reserve estimates of Table 1, average recovery factors, and other sources (e.g., shale oil estimates from US DOE-EIA 2013), the overall amount of petroleum in the subsurface may be roughly estimated to 2720 Gt (~900 Gt in conventional reservoirs, 750 Gt in extraheavy oil and bitumen reservoirs, 900 Gt of shale oil, and 175 Gt in natural



Petroleum, Fig. 11 Schematic geological cross-section of foreland basin showing the location of conventional oils, heavy oils, and extra-heavy oils as a result of petroleum generation in deep source rocks, migration along carrier beds, and biodegradation in shallow reservoirs (reprinted from Eschard and Huc 2008 with permission)

gas accumulations, excluding natural gas hydrates). A small fraction of this amount (<10%) appears as technically recoverable.

Summary

Petroleum composition is highly variable and complex, as a consequence of the large range of conditions during its formation and accumulation along geologic time. The origin of petroleum by thermal degradation of the sedimentary organic matter is the dominant process, bacterial degradation playing a significant role in methane generation and oil biodegradation. The influence of phase equilibria and petroleum migration on the distribution and composition of petroleum accumulations is also reasonably understood.

This knowledge has contributed to the success of oil and gas exploration. However, the rate of new significant discoveries slows down because fewer regions are still unexplored. Conventional petroleum accumulations appear as a finite resource from which more than 50% has been produced. In the long range, petroleum production will rely increasingly on the production of unconventional resources (particularly extraheavy oils and bitumen).

Phase Equilibria

Robert W. Luth
Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada

Definition

Phase equilibria is the application of the principles of thermodynamics to the study of equilibrium relationships within or between phases, corresponding to homogeneous and heterogeneous phase equilibria, respectively. These phases may be minerals within a rock, a fluid percolating through the pore space of a sediment, a gas, or a combination of these. The study of phase equilibria is used to constrain the stability of individual minerals and assemblages of minerals in pressure-temperature-composition space, to obtain estimates of pressure or temperature of equilibration of metamorphic and igneous rocks and to evaluate conditions of origin of various magmas.

Introduction

The study of phase equilibria is firmly rooted in thermodynamics as formulated by J.W. Gibbs in the late nineteenth century (Gibbs 1961). In phase equilibria, the problem is to determine the conditions at which a given portion of the universe – a system – is at equilibrium, with minimum energy. If the thermodynamic properties of the system, including the Gibbs free energy, enthalpy, entropy, molar volume, heat capacity, isothermal compressibility, thermal expansivity, and the activity-composition relationships for all multicomponent phases in the system, are all known, then the phase equilibria may be calculated. In practice, however, some of this information is usually lacking, and so techniques for the graphical analysis of phase equilibria have been developed to allow evaluation of heterogeneous equilibria based on limited experimental data. Here, we shall first define some terms to provide a common terminology. Second, we shall look at the fundamental constraints on phase equilibria provided by thermodynamics by applying the phase rule and by looking at the inter-relationship of free energy, pressure, temperature, and composition that gives rise to phase diagrams. Finally, we will examine graphical analysis of phase equilibria, concentrating on Schreinemakers' analysis of the arrangement of univariant curves about an invariant point (Schreinemakers 1965).

Definitions

System

The portion of the universe under consideration. The choice of how the system is defined is the observer's choice. Several types of systems are commonly defined. An isolated system is one in which no energy or matter is transferred into or out of the system. A closed system is one in which energy but no matter may be transferred into or out of the system. An open system is one in which both energy and matter may be transferred into or out of the system.

Component (c)

Components make up the minimum set of chemical constituents necessary to describe the chemical variation in the system. These constituents need not correspond to physical entities such as mineral endmembers. The selection of components must allow for all possible chemical variations in phases in the system. For example, if the system is a crystal of potassium feldspar, $KAlSi_3O_8$, at atmospheric pressure, then one component ($c = 1$) will suffice if temperatures are less than ~ll50°C. At ~l150 °C, the crystal will melt incongruently to a SiO_2-enriched liquid and crystalline leucite ($KAlSi_2O_6$). At this point, two components (c = 2) are necessary to describe the chemical variation in the system. These two components could be $KAlSi_2O_6$ and SiO_2; $KAlO_2$ and SiO_2; $KAlO_2$ and $Si(KAl)_{-1;}$ or $KAlSi_3O_8$ and either $KAlO_2$ or SiO_2, or any other combination that encompasses the chemical variability present in the system.

Phase (p)

A chemically homogeneous, uniform portion of the system that is mechanically separable from the rest of the system, at least in principle. Each phase is bounded by physical interfaces. Each phase may occur in different places in a system. For example, if the system is a rock containing quartz and feldspar crystals, all of the quartz crystals constitute a single phase. If all the feldspar crystals have the same composition, they too would be a single phase. Another example is a mixture of oil and water at room temperature, two liquids that do not intermix but rather remain immiscible, although the scale of physical domains may be small. All the droplets of oil are the same phase, as is all of the surrounding water phase.

State Variable

A property of a system that has a fixed value at equilibrium. Extensive state variables are those that depend on the amount of matter in the system, such as volume and total internal

energy. Intensive state variables are those that are independent of the amount of matter and include density, temperature, pressure, and concentration, among others. Extensive state variables may be converted to intensive state variables by dividing by the number of moles (or grams) of material, to calculate molar (or specific) volume from total volume, for example.

Variance or Degrees of Freedom (f)

The number of independent intensive variables that must be fixed to define uniquely the equilibrium state. If a system has no degrees of freedom ($f = 0$), it is invariant; if it has one degree of freedom ($f = 1$), it is univariant; and if it has two degrees of freedom ($f = 2$), it is divariant or bivariant.

Gibbs Phase Rule

The phase rule is an elegant, simple equation that results from the conditions of equilibrium between phases in a system. The phase rule may be expressed as:

$$f + p = c + 2. \quad \text{(l)}$$

Clear derivations of the phase rule are given in Ricci (1951), Prigogine and Defay (1954), Morse (1980), Spear (1993), and Anderson and Crerar (1993).

Homogeneous Phase Equilibria

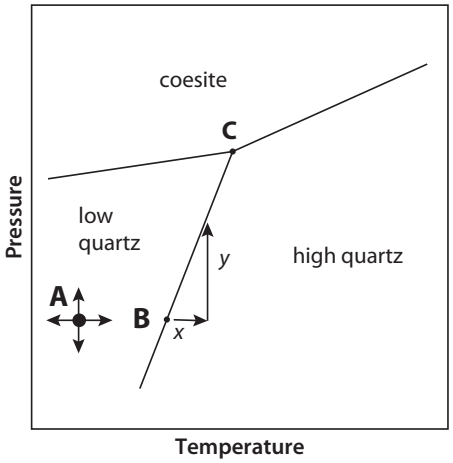
Equilibria within single phases involves the thermodynamic requirements for equilibrium, which are that the pressure and temperature must be uniform throughout the phase, and the free energy of the phase must be at a minimum. To formulate the free energy for the phase as a function of composition, pressure, and temperature, a model for the activities of the components of the phase must be formulated. Different aspects of homogeneous phase equilibria are considered in the entries under ▶ "Activity and Activity Coefficients," ▶ "Aqueous Solutions," and ▶ "Equilibrium."

Heterogeneous Phase Equilibria

Equilibria between phases is the realm of heterogeneous phase equilibria, and phase relationships in systems of increasing complexity will be considered in turn.

One-Component Systems

From the phase rule, a one-component system may contain one, two, or three coexisting phases, with variances of two, one, and zero, respectively. As an example, consider the system with the single component SiO_2 (Fig. 1). The *P-T* diagram consists of three fields, labeled coesite, low quartz, and high quartz, respectively, which represent the stability fields of these three polymorphs of SiO_2. Application of the phase rule to these fields, with c = 1 and p = I, yields a variance of two, which requires that both the intensive variables such as pressure and temperature be specified to determine the state of the system. Graphically, this may be visualized by looking at point A (Fig. 1), which is located in the divariant low quartz field. From A, both pressure and temperature may be varied independently (as shown by the arrows) and the system would remain single phase, with only low quartz present. In order to know exactly where A is requires both pressure and temperature to be specified.



Phase Equilibria, Fig. 1 Schematic pressure-temperature projection of phase relations in the system SiO_2. Points A, B, and C are discussed in the text

In contrast, along the curve separating the fields of low quartz and high quartz, these two phases coexist. Therefore, this curve represents the conditions of pressure and temperature at which these two phases are in equilibrium. Application of the phase rule with $c = 1$ and $p = 2$ yields a variance of one, which means that only one intensive variable needs to be specified to define the system of coexisting low quartz and high quartz completely. This situation may be illustrated graphically by considering the point B on the univariant curve (Fig. 1). A change in T of x requires a corresponding change in P of y to remain on the equilibrium boundary as required to preserve the coexistence of low quartz and high quartz. Therefore, only one of the intensive variables is independent, with the other being a dependent variable.

For the system to be invariant ($f = 0$) requires three phases coexisting in equilibrium. Such a situation exists at point C (Fig. 1), where low quartz, high quartz, and coesite all coexist. In this situation, neither pressure nor temperature may be specified independently; they are dictated by the pressure and temperature of the unique point on the *P-T* diagram where the system of three phases can exist.

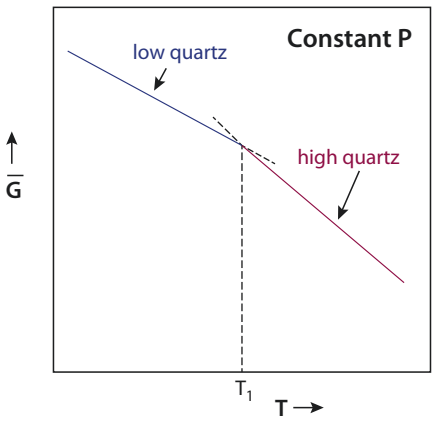
Free Energy Diagrams in One-Component Systems

A one-component system such as that shown in Fig. 1 may be used to illustrate the inter-relationship between the state variables P, T, $\overline{G}$ (molar Gibbs free energy), $\overline{S}$ (molar entropy), and $\overline{V}$ (molar volume). For clarity, consider only the phases low quartz and high quartz. The functional relationships of $\overline{G}_{low\ quartz}$ and $\overline{G}_{high\ quartz}$ to T at constant pressure are illustrated in Fig. 2. Because $(\partial G/\partial T)_P = -\overline{S}$, and because entropy is positive, the slopes of the curves in G-T space are negative. Similarly, the relationship $\partial G/\partial P)_T = \overline{V}$, and the requirement of positive molar volumes (nonnegative densities) leads to positive slopes in isothermal (constant T) G-P diagrams (Fig. 3).

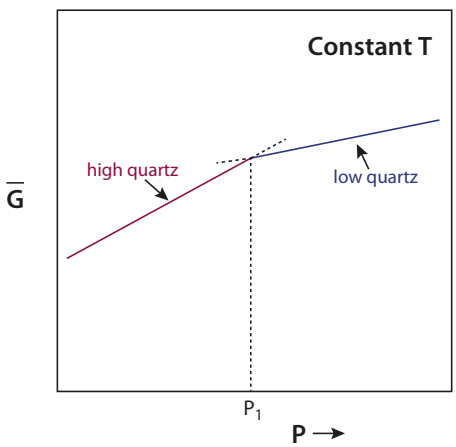
The temperature T_1 (Fig. 2), where $\overline{G}_{low\ quartz} = \overline{G}_{\text{high quartz}}$, represents the temperature at which low quartz and high quartz coexist, corresponding to the temperature of the univariant curve at this pressure. The pressure P_1 (Fig. 3), where the $\overline{G}$ curves for low quartz and high quartz intersect, represents the pressure at which these two phases coexist at this temperature, which would correspond to a point on the univariant curve (Fig. 1) in P-T space.

From Figs. 2 and 3, information regarding the relative stability of the two phases at differing P, T conditions may be inferred. The stable phase is that with the lowest $\overline{G}$, which is low quartz at low T (Fig. 2) and high P (Fig. 3). The P-T phase diagram (Fig. 1) shows the same information in a different format. Starting at point B, low quartz is stable at lower T and at higher P relative to high quartz.

All of these diagrams may be related in a three-dimensional $\overline{G}$-T-P diagram (Fig. 4). The bottom face of this diagram corresponds to Fig. 2, where a slice at constant P has been taken through the diagram. The left-hand face of the diagram corresponds to Fig. 3, where T has been held constant. On a P-T diagram (Fig. 1), the univariant curve where low quartz and high quartz coexist corresponds to a projection of the line of intersection (I in Fig. 4) of the $\overline{G}_{\text{low quartz}}$ and $\overline{G}_{\text{high quartz}}$ planes onto the P-T face. Unlike the $\overline{G}$-T and $\overline{G}$-P sections, where one intensive variable is held fixed (P and T, respectively, in Figs. 2 and 3), the P-T projection does not hold $\overline{G}$ fixed, but rather represents the locus of points at which $\overline{G}_{\text{low quartz}} = \overline{G}_{\text{high quartz}}$.



Phase Equilibria, Fig. 2 Schematic molar Gibbs free energy ($\overline{G}$)-temperature (T) section at constant pressure for a portion of the system SiO_2



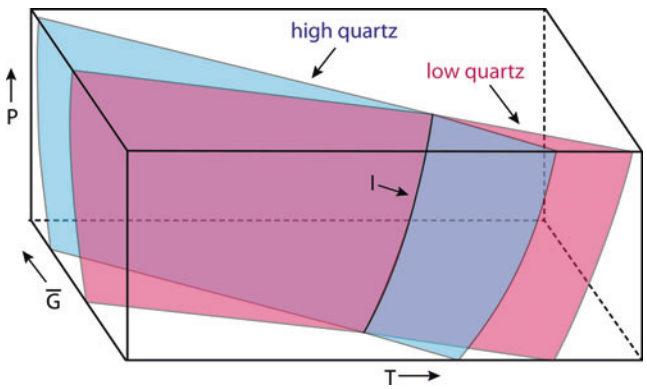
Phase Equilibria, Fig. 3 Schematic molar Gibbs free energy ($\overline{G}$)-pressure (P) section at constant T for phases in the system SiO_2

Two-Component (Binary) Systems

Systems with two components introduce composition as a variable, with the compositions of all phases constrained to be colinear in composition space. Phases may either have fixed composition (e.g., quartz SiO_2) or variable composition (e.g., plagioclase, with composition between $NaAlSi_3O_8$ and $CaAl_2Si_2O_8$). Three dimensions are required to illustrate the phase relationships in terms of P, T, and X (composition).

Application of the phase rule leads to four possible situations:

- $f = 0$ (invariant), with four phases coexisting
- $f = 1$ (univariant), with three phases coexisting
- $f = 2$ (divariant), with two phases coexisting
- $f = 3$, with one phase present



Phase Equilibria, Fig. 4 Schematic $\overline{G}$-T-P diagram illustrating the relationship between the $\overline{G}$ surfaces for low quartz and high quartz

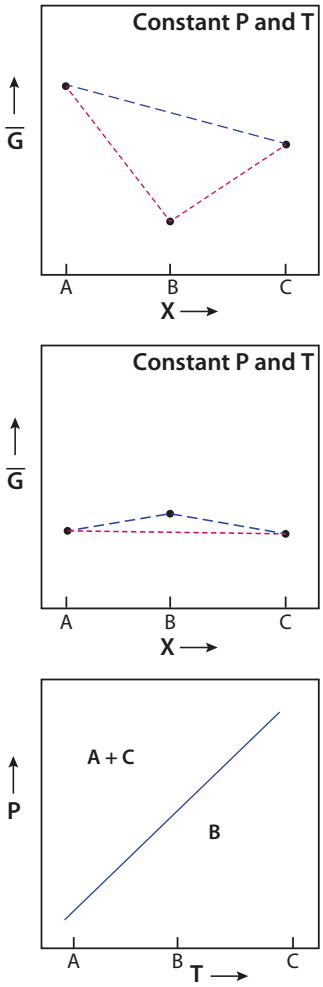
Analogous to the one-component case, invariant situations plot as points on *P-T* projections, univariant situations as lines, and $f \geq 2$ as fields.

Free Energy Diagrams in Two-Component Systems

Graphical depictions of possible relationships between the compositions of the phases and *P, T,* and *G* are shown in Figs. 5 and 6. These *G-X* diagrams illustrate graphically the principles of equilibrium between phases (see ▶ "Equilibrium"). Considering first phases with fixed compositions, the free energies of three phases (A, B, and C) in a binary system are illustrated in Fig. 5a and b. In the first diagram, the equilibrium assemblages (those with the lowest free energies) are A + B and B + C. Any mixture of A + C would plot along the short-dashed line in Fig. 5a, and could reduce its energy by reacting to form either A + B or B + C, depending on the bulk composition. Bulk compositions to the left of the composition of the B phase (Fig. 5a) would break down to A + B, and those to the right would react to form B + C. At different conditions of *P* and *T* (Fig. 5b), the assemblage A + C (represented by any point on the long-dashed line connecting A to C) is stable relative to assemblages of A + B or B + C.

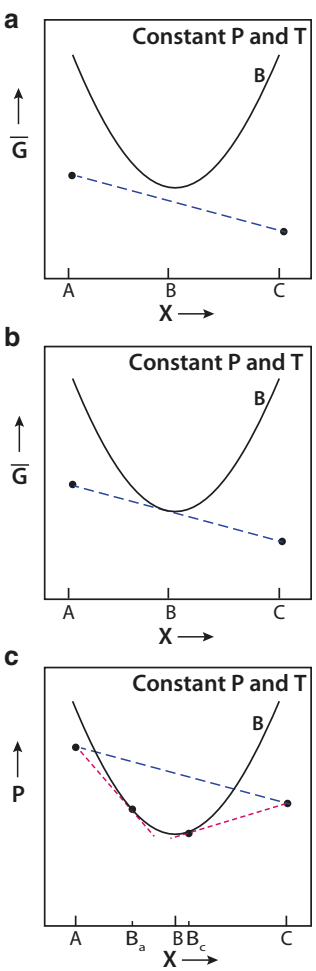
Relating these two diagrams (Figs. 5a, b) to a *P-T* projection (Fig. 5c), the field labeled B represents the situation in Fig. 5a, and the field labeled A + C represents the situation in Fig. Pl6b. Even though the high-*T*, low-*P* field in Fig. 5c is labeled B, comparison with Fig. 5a illustrates that the divariant assemblages A + B and B + C are stable in this field as well as the trivariant assemblage of B alone. At a *P* and *T* along the univariant reaction curve separating these two fields, the free energies of the three phases would be colinear in a $\overline{G}$-X diagram.

If one (or more) of the phases in the system has a variable composition, the situation is more complex (Fig. 6). The free energy for the phase of variable composition is a curve in $\overline{G}$-X space. At conditions of *P* and *T* where the assemblage A + C is



Phase Equilibria, Fig. 5 (**a**) Schematic $\overline{G}$-composition *(X)* section at constant *P* and *T* for three phases of fixed composition in a binary system at conditions where phase B is stable. See text for discussion. (**b**) Schematic $\overline{G}$-*X* section at constant *P* and *T* for three phases of fixed composition in a binary system at conditions where phase B is metastable relative to A + C. (c) Schematic *P-T* projection of the binary system illustrated in (**a**) and (**b**). Field labeled B corresponds to section in (**a**). Field labeled A+ C corresponds to section in (**b**)

Phase Equilibria, Fig. 6 Schematic $\overline{G}$-*X* sections at different conditions of *P* and *T* for a binary system wherein one phase (B) has variable composition. (**a**) Phase B is metastable relative to A+ C at the *P, T* conditions of this section. (**b**) Phase B is in equilibrium with A + C at the *P, T* conditions of this section. (**c**) The assemblage A + C is metastable relative to B-containing assemblages at the *P, T* conditions of this section



stable relative to B-containing assemblages, the relative free energies are as illustrated in Fig. 6a. At conditions along the univariant reaction, the line connecting A and C in $\overline{G}$-X space is tangential to the curve representing the free energy of solution B (Fig. 6b). At conditions in the B stability field, the situation is as shown in Fig. 6c. Note that the compositions of the solution B that coexist with phase A and with phase C are different (denoted B_a and B_c, respectively, in Fig. 6c). At the P and T illustrated in Fig. 6c, the assemblage present depends on bulk composition: the divariant assemblage A + B_a for bulk compositions between those two compositions; the trivariant assemblage B (with varying composition) for bulk compositions between B_a and B_c; and the divariant assemblage B_c + C for bulk compositions between Be and C. The P-T projection of these phase relationships would be similar to that in Fig. 5c, with the univariant curve representing the locus of P, T points for which the schematic $\overline{G}$-X relationships in Fig. 6b hold.

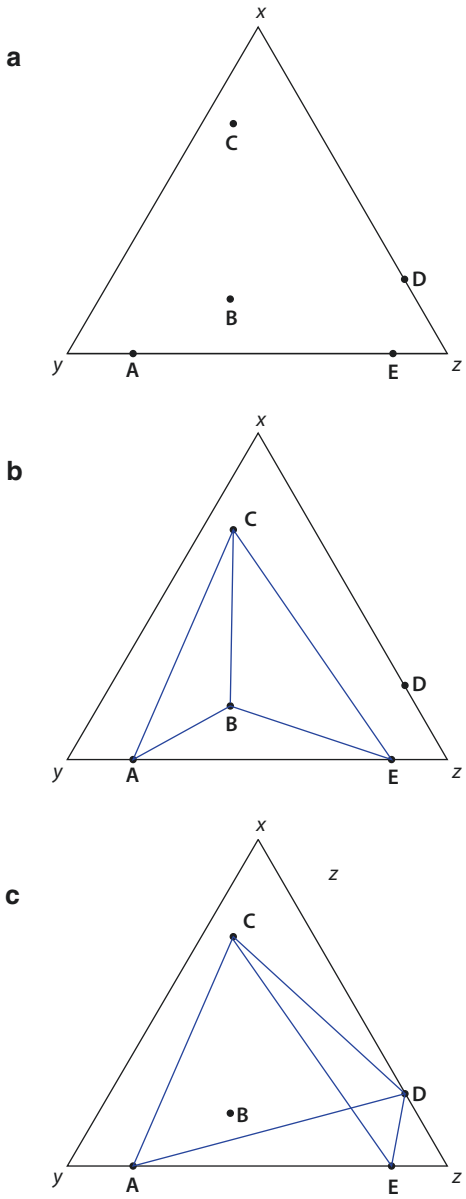
Three-Component (Ternary) Systems

Systems with three components introduce another compositional variable. The compositions of all phases, either fixed or variable in composition, must be coplanar in a three-component composition space. It is customary to illustrate these compositional relationships in an equilateral triangle, with each component occupying an apex (Fig. 7a). Because of the added compositional variable, four dimensions are required to illustrate the phase relationships in terms of *P*, *T*, and composition. Projections and sections of the phase relationships into three or two dimensions are therefore customary.

Application of the phase rule leads to five possible situations:

- $f = 0$ (invariant), with five phases coexisting
- $f = 1$ (univariant), with four phases coexisting
- $f = 2$ (divariant), with three phases coexisting
- $f = 3$, with two phases present
- $f = 4$, with one phase present

In *P-T* projection, invariant situations plot as points on P-T projections, univariant reactions as lines, and $f \geq 2$ as fields. The possible univariant reactions are of two types, depending on the compositions of the phases involved. The first type is a eutectic-like reaction (also called a terminal stability reaction) such as: A + C + E = B (Fig. 7b). In this type of reaction, the composition of the terminal phase (B) lies in the interior of the triangle defined by the compositions of the other three phases. The other type of reaction is a join-crossing reaction such as: A+ D = C + E (Fig. 7c). In this reaction, the composition of the fourth phase lies exterior to the triangle formed by the other three phases.



Phase Equilibria, Fig. 7 (**a**) Ternary composition space represented with an equilateral triangle. Components of the system are *x, y,* and *z*. Phases present are A, B, C, D, and E. (**b**) Tie-lines for the eutectic-like ternary reaction A + C + E = B in the system *x, y, z*. (**c**) Tie-lines for the join-crossing ternary reaction A+ D = C + E in the system *x, y, z*

Free Energy Diagrams in Three-Component Systems

Three dimensions are required to illustrate the $\overline{G}$-X relationships for ternary systems. By analogy with the binary case, equilibrium between phases is achieved in ternary systems when the free energies of the phases are coplanar in $\overline{G}$-*X* space. If one or more phases have variable compositions (solid or liquid solutions), the equilibrium case occurs when the planes defined by the free energies of the phases of fixed composition are tangential to the curved surfaces representing the free energies of the variable composition phases.

Systems with Four or More Components

Four components require three dimensions (and considerable artistic talent) to portray the compositional relationships alone. It is customary to represent the composition space with a tetrahedron, with each component represented at an apex. Often, the compositions will be projected from one component apex onto an equilateral triangle to facilitate representation in two dimensions. From the phase rule, six phases coexist at an invariant point, and five phases are involved in univariant reactions.

The two types of univariant reactions discussed above for ternary systems have analogs in quaternary systems. The eutectic-like reaction has the composition of the fifth phase interior to the polyhedron whose apices are the compositions of the other four phases. Algebraically, this type of reaction would be expressed: A + B + C + D = E. The join-crossing reaction would have the composition of the fifth phase exterior to the polyhedron whose apices are the compositions of the other four phases. Algebraically, the reaction stoichiometry would be A+ B + C = D + E. Because one join that is being crossed is a three-phase join (A+ B + C in the example above; geometrically a plane) this type of reaction is referred to as a plane-piercing reaction.

The principles outlined in the previous sections hold equally well for systems with more components, with the added complexity in illustrating or conceptualizing the relationships between phases. For these reasons, algebraic or analytical techniques, rather than graphical, are used for these systems.

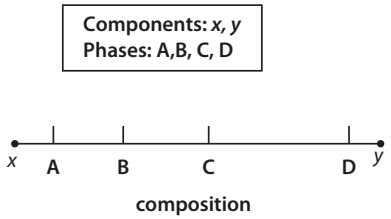
The Arrangement of Univariant Curves About an Invariant Point

For a system of c components, $c + 2$ phases coexist at an invariant point. From this point, $c + 2$ univariant curves radiate outward in variable space. F.A. Schreinemakers, in a series of articles from 1915 to 1925, developed a method for determining systematically the arrangement of these univariant curves requiring only the compositions of the $c + 2$ phases coexisting at the invariant point (Schreinemakers 1965).

Terminology

Each univariant reaction is denoted by the phase not participating in the reaction, surrounded by parentheses. In a similar fashion, divariant fields are denoted by the phases not present. For example, in the binary system illustrated in Fig. 8, the reaction A + C = B would be denoted (D), and the divariant assemblage A + C would be denoted by (B, D).

The number of assemblages of a given variance may be determined by application of the combinatorial formula (Zen 1966):



Phase Equilibria, Fig. 8 The binary system x, y with the compositions of phases A, B, C, and D plotted. See text for discussion

$$M(c+2,p) = \frac{(c+2)!}{p!(c+2-p)!} \tag{1}$$

where $M(c + 2, p)$ is the number of combinations of $c + 2$ possible phases (the number of phases that coexist at the invariant point, where c is the number of components in the system) and p is the number of phases in the assemblage of interest. For the binary example (Fig. 8), application of this formula yields four univariant curves [4!/((3!)(1!))] and six divariant assemblages [4!/((2!)(2!))].

These univariant curves would represent the reactions:

$$\mathrm{B} + \mathrm{D} = \mathrm{C} \qquad (\mathrm{A})$$

$$\mathrm{A} + \mathrm{D} = \mathrm{C} \qquad (\mathrm{B})$$

$$\mathrm{A} + \mathrm{D} = \mathrm{B} \qquad (\mathrm{C})$$

$$\mathrm{A} + \mathrm{C} = \mathrm{B} \qquad (\mathrm{D})$$

and the divariant assemblages would be:

$$\mathrm{A} + \mathrm{B} \qquad (\mathrm{A}, \mathrm{D})$$

$$\mathrm{A} + \mathrm{C} \qquad (\mathrm{B}, \mathrm{D})$$

$$\mathrm{A} + \mathrm{D} \qquad (\mathrm{B}, \mathrm{C})$$

$$\mathrm{B} + \mathrm{C} \qquad (\mathrm{A}, \mathrm{D})$$

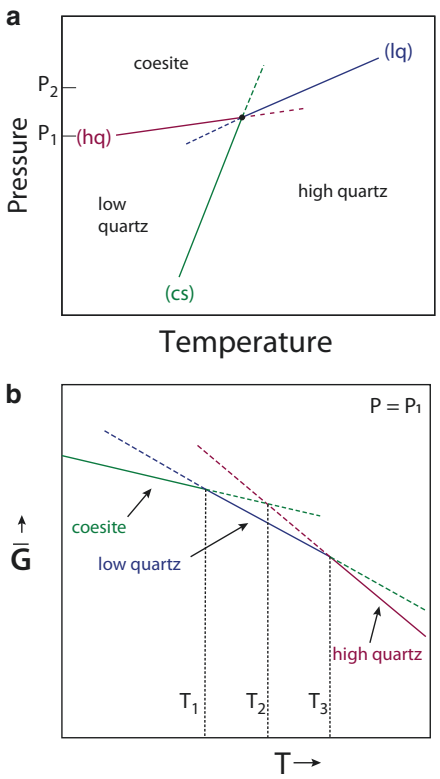
$$\mathrm{B} + \mathrm{D} \qquad (\mathrm{A}, \mathrm{C})$$

$$\mathrm{C} + \mathrm{D} \qquad (\mathrm{A}, \mathrm{B})$$

Several rules summarize Schreinemakers' method.

Rule 1 (The Fundamental Postulate)

A univariant curve, either stable or metastable, separates two divariant assemblages. On one side of this curve, one of the two divariant assemblages is more stable than the other assemblage. On the other side of the curve, the relative stabilities of the two assemblages are reversed.



Phase Equilibria, Fig. 9 (**a**) Schematic *P-T* projection for the system SiO_2. The univariant reactions have been labeled with the "missing-phase" notation. (**b**) Schematic $\overline{G}$-*T* diagram corresponding to pressure P_1 of (**a**)

This rule may be understood readily by considering the free energy surfaces (or curves) for the divariant assemblages. Returning to the simple one-component case of SiO_2 (Fig. 9a), three univariant reactions are labeled (cs), (lq), and (hq), which represent coesite, low quartz, and high quartz, respectively. The reaction (hq) separates the divariant assemblages of coesite and low quartz. In the missing-phase notation, these divariant assemblages are (lq, hq) and (hq, cs), respectively. At P_1 (Fig. 9b), coesite is more stable (i.e., has a lower free energy) than is low quartz at $T < T_1$. At $T > T_1$, the relative stabilities are reversed.

The logic applies equally well to metastable reactions. Consider the reaction (lq), coesite = high quartz, which is metastable at P_1. Coesite is more stable (less metastable) than is high quartz at $T < T_2$, and high quartz is more stable (less metastable) than is coesite at $T > T_2$. In both situations, both coesite and high quartz are metastable relative to low quartz.

Rule 2

A divariant assemblage **(**A, B**)** occurs in a region of $<180°$ about the invariant point between the univariant curves **(**A**)** and **(**B**).** The consequence of this rule is that the angle between neighboring stable univariant curves is $<180°$. This rule is used extensively to determine the stable fields of divariant assemblages.

Rule 3

Any divariant assemblage that extends across the univariant curve (X) contains the phase X. This rule holds for both stable curve (X) contains the phase X. This rule holds for both stable and metastable curves.

Use of Schreinemakers' Analysis in Arranging Univariant Curves

An extremely powerful method for quickly and accurately deriving the arrangement of univariant curves about an invariant point uses Schreinemakers' system of notation that capitalizes on the correspondence between the stoichiometry of the univariant reactions and the arrangement of the corresponding univariant curves. This point is best illustrated by example. In the binary system *x-y* (Fig. 8a), the reaction (D) may be written A + C = B. According to Schreinemakers' univariant scheme (Zen 1966) there is a corresponding arrangement of univariant curves, such that univariant curves (A) and (C) are on one side of (D) and univariant curve (B) is on the other. This topology may be written concisely in a form that parallels the reaction:

$$(\mathrm{A})(\mathrm{C}) \mid (\mathrm{D}) \mid (\mathrm{B})$$

where the univariant curve (D) is set off by vertical lines to illustrate that this is the curve about which (A), (C), and (B) are arrayed.

Once any reaction is written with positive stoichiometric coefficients, the corresponding arrangement of the other univariant curves may be determined immediately. This procedure works independent of the complexity of the system, including for multicomponent systems that are difficult or impossible to illustrate in two or three dimensions.

The steps of the procedure for determining the arrangement of univariant reactions about an invariant point may be illustrated for a binary system. The same procedure applies to systems with more components.

1. Write the reactions and the corresponding univariant schemes. From Fig. 8, we see that the reactions are:

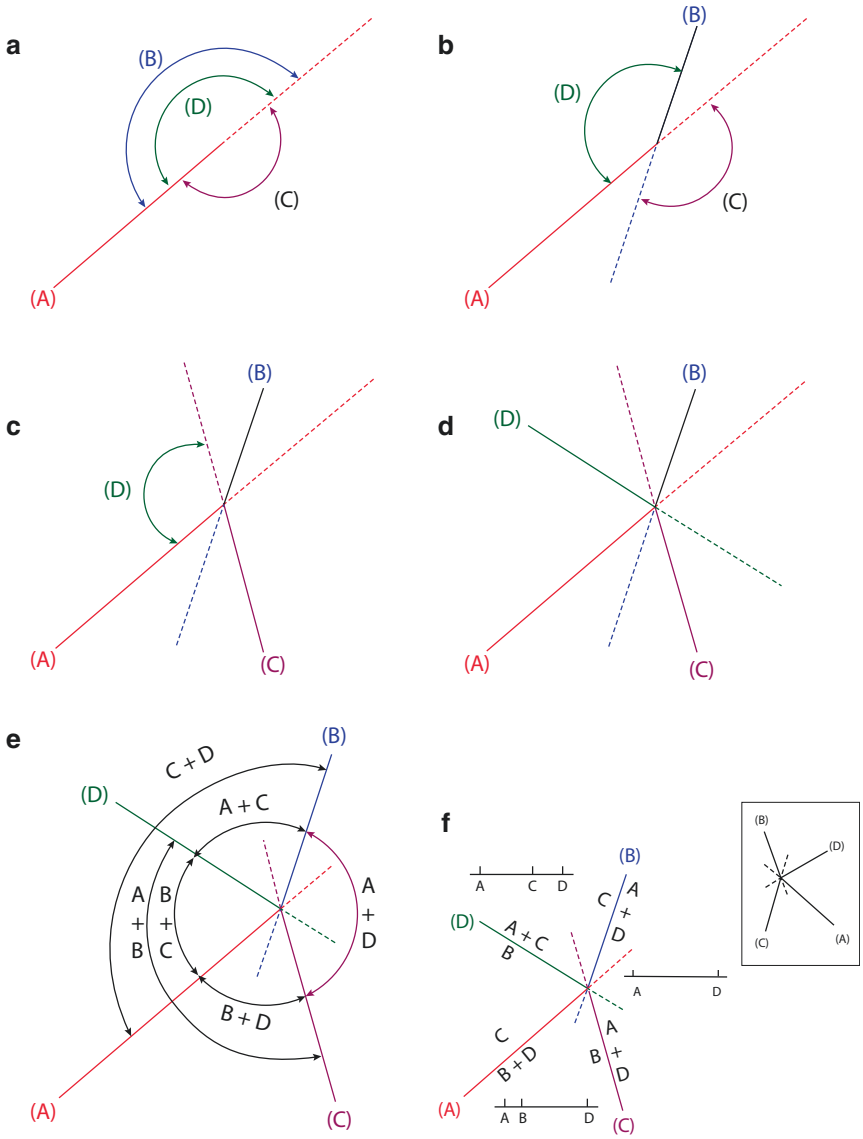
$$\mathrm{B} + \mathrm{D} = \mathrm{C}$$

$$\mathrm{A} + \mathrm{D} = \mathrm{C}$$

$$\mathrm{A} + \mathrm{D} = \mathrm{B}$$

$$\mathrm{A} + \mathrm{C} = \mathrm{B}$$

and the corresponding univariant schemes are:



Phase Equilibria, Fig. 10 Construction of univariant curves about an invariant point for a binary system. See text for discussion

(B)(D)|(A)|(C)

(A)(D)|(B)|(C)

(A)(D)|(C)|(B)

(A)(C)|(D)|(B)

2. Begin by drawing (A), and indicate allowable locations for (B), (D), and (C) as shown by the arcs in Fig. 10a.
3. Draw **(B)** in its permissible sector (Fig. 10b). Using the univariant scheme for **(B),** narrow down the allowable locations for (C) and (D).
4. Draw (C) in its permissible sector (Fig. 10c), between the metastable extensions of (A) and (B). Using the univariant scheme for (C), narrow down the allowable sector for to between the stable part of (A) and the metastable extension of (C).
5. Draw (D) (Fig. 10d).
6. Indicate the fields of stability for the six divariant assemblages:

Assemblage	Missing-phase notation	Stable between univariant curves
A + B	(C, D)	(C), (D)
A + C	(B, D)	(B), (D)
A + D	(B, C)	(B), (C)
B + C	(A, D)	(A), (D)
B + D	(A, C)	(A), (C)
C + D	(A, B)	(A), (B)

as shown in Fig. 10e.

Labeling the univariant curves with the appropriate reactions is now straightforward, because the divariant (two-phase) assemblage involved in each reaction is stable only on one side of the reaction. This labeling, and the use of the compositional join rather than arrows to represent permissible divariant assemblages, cleans up the diagram and yields the finished product (Fig. 10f). Note that two mirror image (enantiomorphic) possibilities exist (Fig. 10f and inset), and selection of the correct one, as well as the correct orientation in *P-T* space, requires additional information.

Application of Schreinemakers' Analysis to One-Component Systems

Returning again to the SiO_2 system (Fig. 9a), the three reactions may be written:

$$l_q = h_q \qquad (cs)$$

$$c_s = l_q \qquad (hq)$$

$$c_s = h_q \qquad (lq)$$

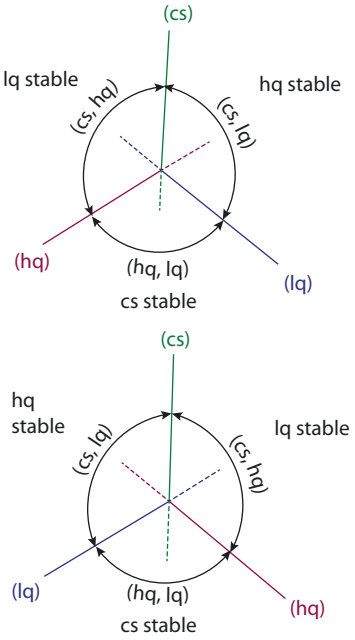
where lq = low quartz, hq = high quartz, and cs = coesite. There are three divariant assemblages:

$$l_q \qquad (hq, cs)$$

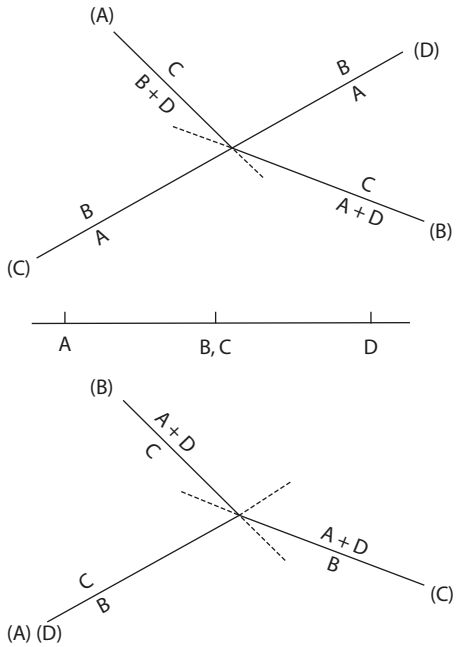
$$h_q \qquad (lq, cs)$$

$$c_s \qquad (lq, hq)$$

Application of rule 2 generates two possible enantiomorphic versions of the *P-T* projection (Fig. 11). As discussed above, additional information (e.g., relative densities or experimental constraints on phase equilibria) is required to decide between these two enantiomorphs and to orient the phase diagram properly with respect to the pressure and temperature axes.



Phase Equilibria, Fig. 11 Enantiomorphic pair of possible arrangements of univariant curves about the invariant point where coesite + high quartz + low quartz coexist. *Arrows* indicate stability fields for divariant assemblages labeled with "missing-phase" notation. See text for discussion



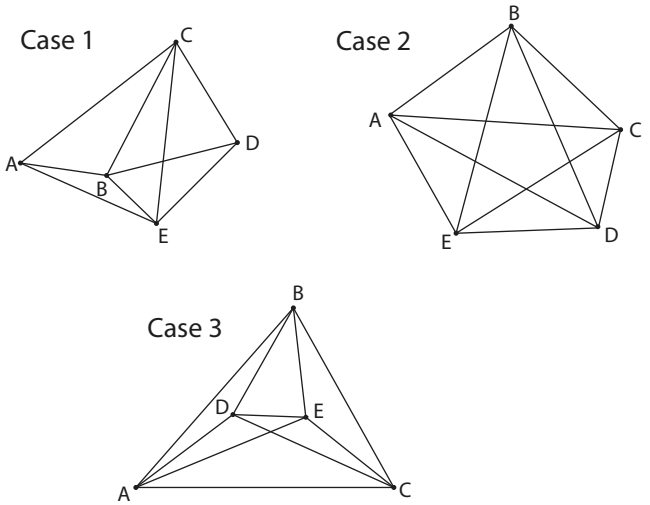
Phase Equilibria, Fig. 12 Two possible configurations of univariant curves about invariant points in binary systems, illustrating the effect of compositional degeneracy (polymorphism)

Application of Schreinemakers' Analysis to Binary Systems

The example worked above illustrates the principles of the application of this method to binary systems. A complication is introduced by degeneracy, where the compositions of two of the phases are the same. The logic outlined above still applies, but two of the univariant reactions overlap in either their stable portions, or such that the stable portion of one overlaps with the metastable extension of the other. Two examples of such degenerate situations are illustrated in Fig. 12.

Applications of Schreinemakers' Analysis to Ternary Systems

In a ternary system, the five phases that coexist at the invariant point are coplanar in composition space (Fig. 7a). In the general case, the system is defined by three components *x, y,* and *z* and contains phases A, B, C, D, and E, all with differing *x/y* or *x/z*. From the invariant point at which A + B + C + D + E coexist, five univariant reactions, each involving four phases, will radiate.



Phase Equilibria, Fig. 13 Ternary composition space, illustrating the three possible (nondegenerate) arrangements of *five* phases that coexist at an invariant point

In general, there are three possible (nondegenerate) compositional arrays of five phases (Fig. 13). Each of these arrays generates a different arrangement of univariant reactions about the invariant point (Fig. 14). In each case, only one of the enantiomorphic pairs is illustrated.

Degeneracy of two types is possible in ternary (and higher-order) systems. One type, polymorphism, is analogous to the case considered for the binary system (Fig. 12). The other type is generated when the compositions of three (or more) of the phases involved in the invariant point are colinear. This colinearity means that these three phases are a binary subsystem within the ternary. Degeneracy of either type leads to coincidence of two, or more, of the univariant reactions, which then coincide, superimposing either stable portions (analogous to the binary case illustrated in Fig. 12b), or the stable portion of one overlapping the metastable portion of the other (Fig. 12a). The "cookbook" approach outlined above works equally well for degenerate situations as for nondegenerate ones, as long as the coincidence of some of the univariant curves is borne in mind. This coincidence is obvious immediately upon writing the reactions. For the example shown in (Fig. 15), the reactions are:

$$\mathrm{B} + \mathrm{D} = \mathrm{C} + \mathrm{E}$$

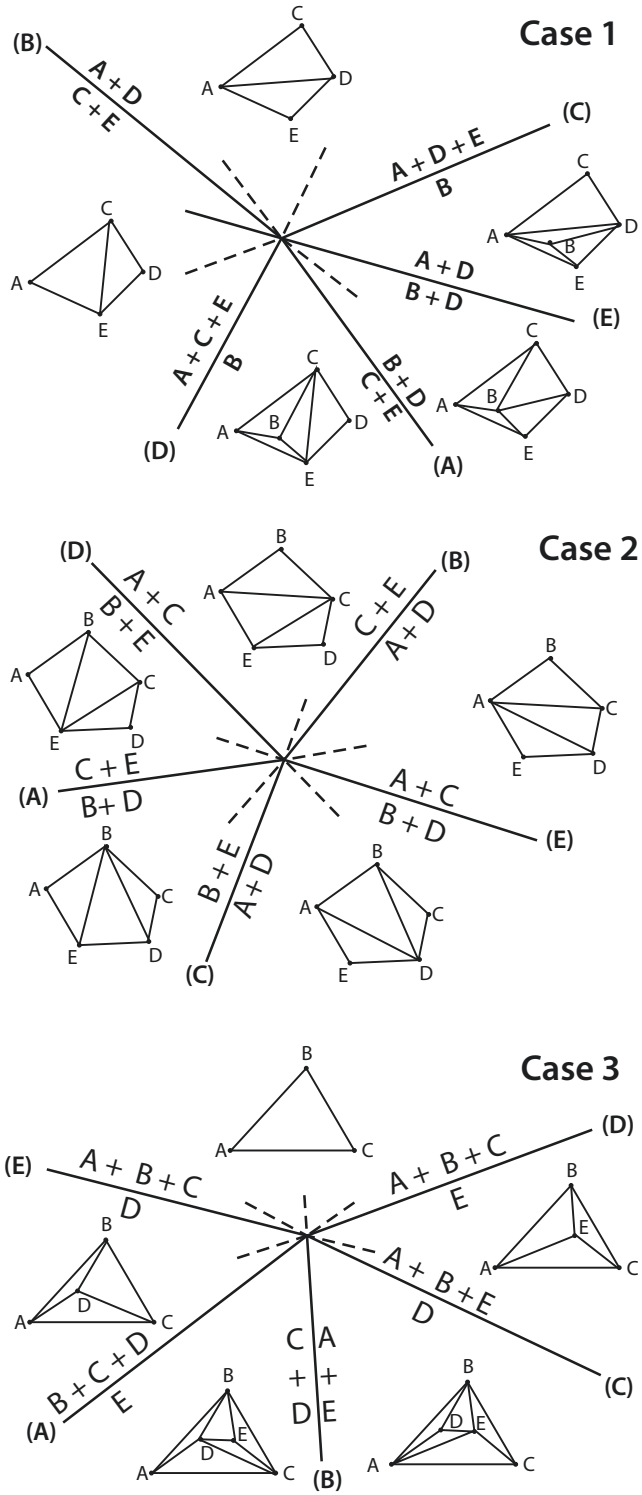
$$\mathrm{A} + \mathrm{C} + \mathrm{D} = \mathrm{E}$$

$$\mathrm{A} + \mathrm{B} + \mathrm{D} = \mathrm{E}$$

$$\mathrm{A} + \mathrm{C} = \mathrm{B}$$

$$\mathrm{A} + \mathrm{C} = \mathrm{B}$$

This list illustrates two points: (D) and (E) are the same, and they are binary univariant reactions involving three phases; they are univariant by restriction in the ternary case, where the restriction is the compositional colinearity.



Phase Equilibria, Fig. 14 Arrangements of univariant curves about invariant points corresponding to the three different compositional situations in nnn 13. Only one of each enantiomorphic pair is illustrated for each case

P
