Many workers have cited the similarity between the trace element composition of the continental crust and convergent margin magmas, such as the significant depletions in Nb and Ta relative to La (Fig. 2 the elements are plotted on this figure in order of bulk partition coefficients during adiabatic mantle melting) and enrichments in Pb relative to neighboring elements, as evidence that most continental crust formed above subduction zones (e.g., Barth et al. 2000; Hawkesworth and Kemp 2006; Kelemen 1995; Rudnick 1995). Such anomalies in multielement plots are iconic features of convergent margin magmas and are attributed to retention of Nb and Ta in the slab (possibly due to the presence of a Ti-bearing phase such as rutile) and enrichment of more soluble elements such as Pb and Sr in slab fluids and/or melts (Elliott 2003; Kelemen et al. 2003b). Using the magnitude of Nb depletion relative to La, mass balance between different end-member compositions have been used to suggest that 80–95% of the present continental crust formed in subduction zones (Barth et al. 2000; Hawkesworth and Kemp 2006).

Earth's Continental Crust, Table 6 Estimates of the amount of lower continental crust recycled into the mantle

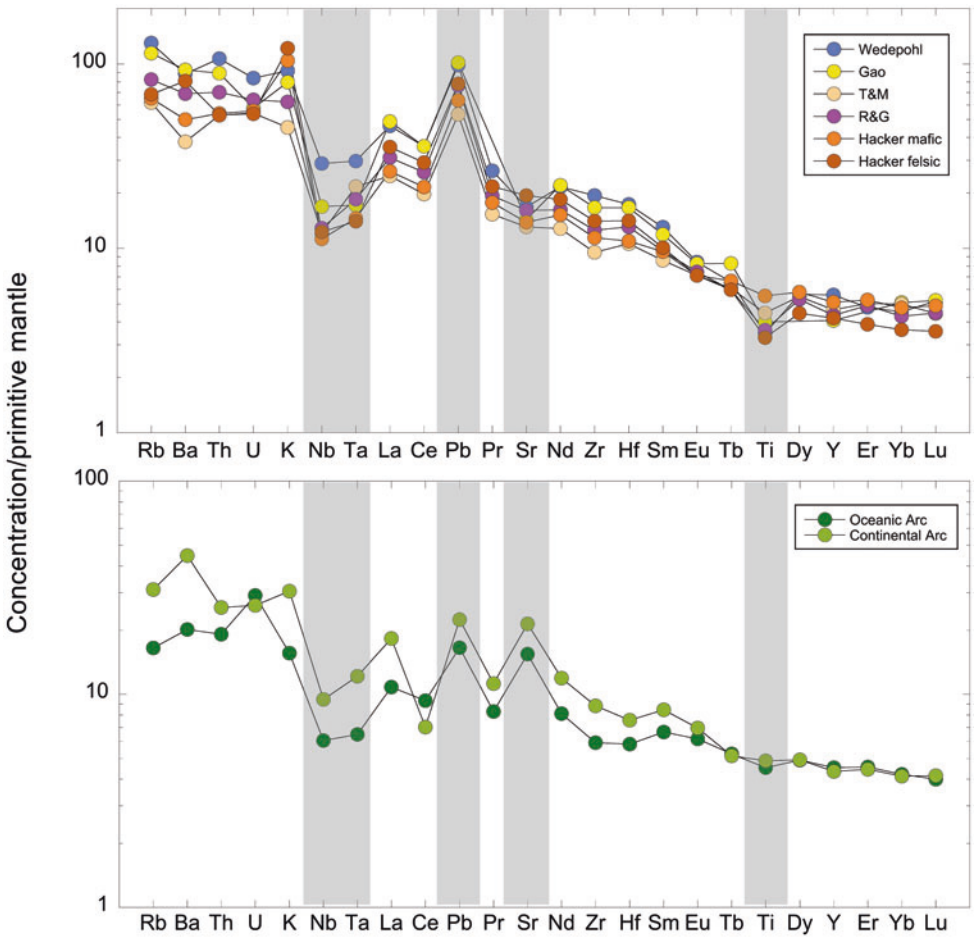
[a]Minimum estimate
[b]For orogenic plateaus only and assuming crust formation for the past 2.5 to 4.5 Ga, density of foundered crust = 3200 kg/m^3, and mass of present-day crust is 2.06 × 10^{22} kg (Huang et al. 2013)



Earth's Continental Crust, Fig. 2 Primitive mantle-normalized trace element abundances of (**a**) different compositional models of the bulk continental crust (Wedepohl 1995; Gao et al. 1998; Taylor and McLennan 1985; Rudnick and Gao 2003; Hacker et al. 2015 showing the mafic and felsic end-members). (**b**) Average primitive arc lavas from oceanic and continental settings (From Kelemen et al. 2003b). Vertical *gray bars* highlight, from *left* to *right*: Nb and Ta (depleted in continental crust and arc lavas), Pb (enriched in both), Sr (enriched in arcs but not bulk crust), and Ti (depleted in bulk crust and variable in arc lavas). Mantle-normalizing values are from McDonough and Sun (1995)

By contrast, Albarède (1998) and Stein and Hofmann (1994), citing the apparent episodicity in crustal growth (discussed below), suggest that much of the continental crust formed in intraplate settings by "superplume" or "mantle overturn" events, respectively. They explained the similarities between the trace element composition of the continental crust and convergent margin magmas as being due to later reprocessing of original plume-generated crust in subduction zones. A more recent hypothesis regarding the role of plumes in generating episodic continental crustal

growth was proposed by Arndt and Davaille (2013) whereby large mantle plumes displaced material from the upper mantle and accelerated subduction to generate new crust.

It is worth noting that estimates of the trace element composition of the bulk continental crust, while similar to one another and to convergent margin magmas, also show differences with the latter. For example, subduction zone magmas are typically enriched in Sr relative to Nd (also attributed to slab fluids and/or melts), yet the bulk continental crust does not show such an enrichment (Fig. 2). This lack of Sr enrichment, and perhaps even Sr depletion, in the continental crust may be due, in part, to chemical weathering, as Sr is highly soluble and is preferentially lost from the continents (e.g., Gaschnig et al. 2016; Goldstein 1989; Rudnick 1995). Strontium depletion may also be generated by removal of plagioclase-bearing residues or cumulates from the base of the crust, as plagioclase incorporates Sr relative to Nd. Indeed, Tang et al. (2015) presented evidence that the bulk continental crust possesses a negative Eu anomaly (Eu/Eu*) ("Eu/Eu* = $Eu_N/(Sm_N*Gd_N)^{1/2}$, where "N" signifies concentrations normalized to chondrite"), which they attributed to this process. In addition, Plank (2005) noted that the high Th/La ratio seen in arc lavas is inherited from subducted terrigenous sediments and is not generated through subduction. She suggested that the continental crust attained a high Th/La due to intracrustal melting, followed by removal of the low Th/La residue. So, whereas the overall pattern of trace elements within the continental crust is similar to that of convergent margin magmas, there are also notable differences that must relate to the signature of crustal recycling superimposed on the original igneous composition, just as the major element composition of the bulk crust requires return of mafic materials to the mantle.

Finally, it is also worth noting that arc-like trace element signatures (light rare earth element (LREE) enrichment, Nb and Ta depletion, Sr and Pb enrichment) can also be generated in intraplate settings by melting of thickened mafic crust. An example of such magmas has been documented in Iceland (Willbold et al. 2009) and may be an analogy for crust formation during the Archean. Indeed, if most of the continental crust formed in the Archean (see below), modern plate tectonic settings may bear little relevance to the environment in which much of the continental crust formed, as discussed in the next section.

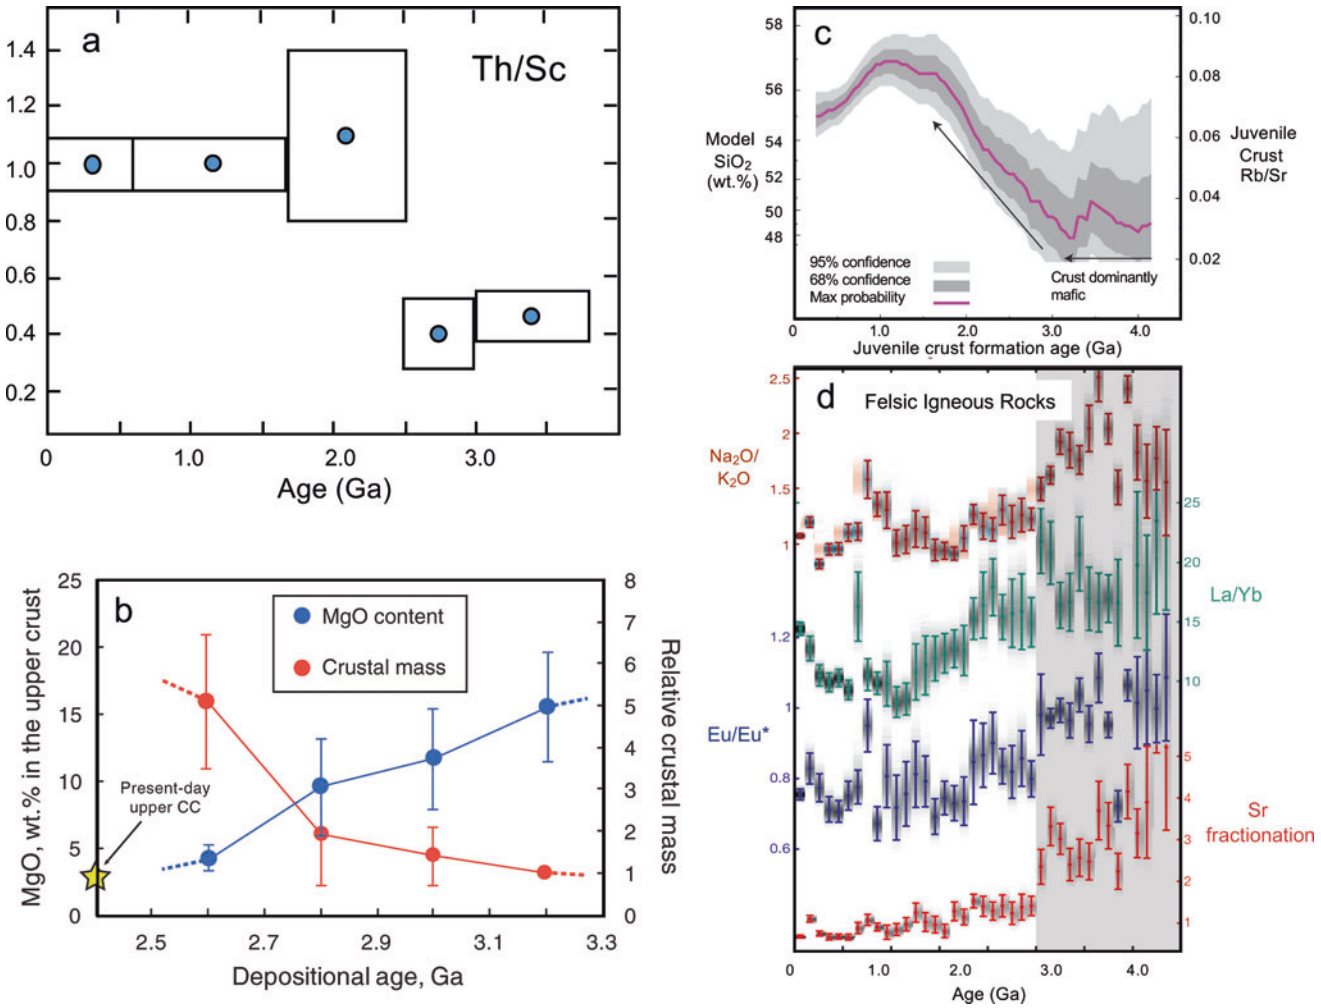
Temporal Evolution of the Continental Crust

The continental crust today is the product of billions of years of evolution involving mantle melting, igneous differentiation (e.g., crystal fractionation, crustal melting, and crustal assimilation), fluid and melt transfer in subduction zones, weathering, metamorphism, and crustal recycling, which may occur via both subduction and foundering, as described above. A number of lines of evidence point to a fundamental change in the composition of the upper continental crust at the Archean-Proterozoic (A-P) boundary (i.e., 2500 Ma) (Fig. 3), which may signal a shift in the processes by which continental crust formed. Evidence for this change is seen in the compositions of fine-grained terrigenous sedimentary rocks (Fig. 3a, b), in the composition of Archean chemical sediments, and the composition of magmatic rocks (Fig. 3c, d), and surface exposures of igneous rocks, as discussed below.

Taylor and McLennan (1985) summarized the evidence for crustal compositional change contained within the insoluble trace element concentrations in fine-grained terrigenous sedimentary rocks such as shales, mudstones, and their metamorphosed equivalents. This includes a decrease in first-row transition elements (e.g., Sc, Cr, Co, Ni) and an increase in incompatible element concentrations (e.g., Th, La) as well as Eu anomalies of shales at the A-P boundary. Figure 3a shows how Th/Sc increases in fine-grained terrigenous sedimentary rocks across the A-P boundary, which is due to both an increase in Th and a decrease in Sc concentrations. Th is a highly incompatible trace element while Sc is a compatible trace element, so this change reflects a change from relatively mafic to felsic crust across the A-P boundary. Later studies of shales and glacial diamictites have confirmed these compositional changes (e.g., Condie 1993; Gaschnig et al. 2016; McLennan and Taylor 1991; Tang et al. 2016).

The composition of chemical sedimentary rocks (banded iron formations, carbonates, and cherts) provide insights into the chemical composition of the ancient oceans, which, like the modern ocean, reflect a mixture of inputs from continental weathering (rivers) and hydrothermal vents, and outputs through exchange with oceanic crust. Veizer and Compston (1976) noted that the $^{87}Sr/^{86}Sr$ ratio of Archean carbonates are similar to values expected for the Archean mantle and suggested that this low ratio arose from weathering of an Archean continental crust that was dominated by greenstone belt basalts. Later studies attributed the low $^{87}Sr/^{86}Sr$ in Archean carbonates to the influence of hydrothermal vents. However, Kamber (2010) suggested that the observed Sr and Eu concentrations and Nd isotopes observed in Archean chemical sediments do not match those expected from mixing between hydrothermal vents and rivers draining evolved continents. He instead suggested that these rather enigmatic compositions reflect the weathering of widespread mafic to ultramafic volcanic surfaces on subaerial oceanic plateaus.

Studies of surface exposures of igneous rocks also suggest a compositional change of the upper continental crust at the A-P boundary. Using geologic maps and measured stratigraphic sections, Condie (1993) observed that greenstone belts show an increase in the proportion of felsic volcanic rocks and graywackes, whereas komatiites drop to almost zero at the A-P boundary. He also observed a systematic



Earth's Continental Crust, Fig. 3 Illustration of various lines of evidence for a compositional change in the composition of the continental crust across the Archean-Proterozoic (A-P) boundary. (**a**) Average Th/Sc ratio in fine-grained sedimentary rocks (Modified from Taylor and McLennan 1985). Because both Th and Sc are insoluble elements, the values reflect the average composition of the crust exposed to weathering and erosion for a given time period. Boxes represent time interval under consideration and 95% confidence interval of mean. (**b**) Changing average MgO concentration of upper continental crust as a function of time, inferred from Ni/Co and Cr/Zn ratios in fine-grained sedimentary rocks. Also shown is inferred change in crustal mass based on addition of TTGs to original mafic crust (From Tang et al. (2016). (**c**) Changing Rb/Sr ratio of juvenile crust and correlated SiO_2 as a function of time based on data for over 13,000 igneous rocks (Modified from Dhuime et al. 2015). (**d**) Changes in the geochemistry of felsic igneous rocks as a function of time, based on data for over 70,000 igneous rocks (Modified from Keller and Schoene 2012)

change during the Archean, with Late Archean upper crust having lower Mg, Cr, Ni, Co, and Eu/Eu* and higher K, Rb, Ba, Th, U, and HREE compared to that of the Early Archean. These findings are consistent with a shift from more mafic to more felsic crust within the Archean and across the A-P boundary. Comparing shales to surface exposures of igneous rocks in the Archean, he found that the shales, on average, lack HREE depletion and are more enriched in Fe, V, and Sc compared to the surface exposures and hypothesized that the source of the shales, which had since eroded away, was dominated by basalt and komatiite with little HREE-depleted TTGs. This finding is supported by an inferred drop in average upper crustal MgO content from ~15 wt.% in the Early Archean, to ~4 wt.% in the Late Archean based on transition metal ratios in fine-grained sedimentary rocks (Tang et al. 2016, Fig. 3b). It remains an open question whether this change in MgO reflects a vertical or temporal change in upper crust composition.

Dhuime et al. (2015) used initial Sr isotope ratios and Nd model ages of igneous rocks to calculate the Rb/Sr ratio of juvenile crust at the time of mantle extraction. Because Rb/Sr ratio increases systematically with SiO_2 concentration, they used these results to estimate the average SiO_2 concentration of newly generated continental crust over time (Fig. 3c). They found that both Rb/Sr and SiO_2 increased dramatically around 3.0 Ga, which they attributed to the start of plate tectonics.

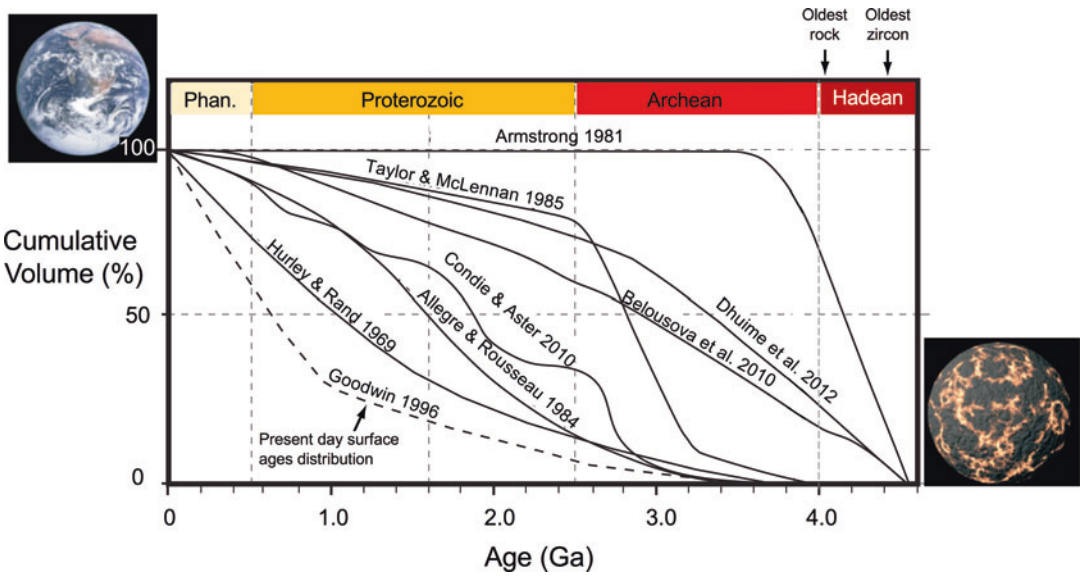
Keller and Schoene (2012) used statistical sampling of over 70,000 dated igneous rocks compiled from geochemical databases and other sources to examine secular trends in the compositional data. They found that continental basalt compositions record a gradual decrease in mantle melt fraction but with an abrupt change occurring at the A-P boundary. Likewise, felsic igneous rocks also show a rather abrupt change in composition at the A-P boundary from high Na/K, La/Yb, Eu/Eu* (typical of TTGs) to lower ratios (Fig. 3d). Keller and Schoene attributed these changes to decreasing mantle temperature and changing continental crustal thickness at the A-P boundary and inferred that the Archean crust was originally thick and mafic. Melting in its deeper sections produced TTGs followed by recycling of the residues to leave a relatively thin and felsic crust in Archean regions today. Keller and Schoene's interpretations suggest that the deep continental crust, as well as the upper continental crust, was more mafic in the Archean than in the post-Archean.

Most recently, Lee et al. (2016) suggested that the first significant peak seen in detrital zircon dates, at ~2.8 Ga (see next section), may reflect the transition from a mafic crust where the magmas are not generally saturated in zircon, to a felsic crust that grew abundant zircon. Because production of copious amounts of felsic magmas requires water (e.g., Arndt 2013; Campbell and Taylor 1985), they also suggested that this transition may mark the evolution from stagnant lid tectonics to plate tectonics, which provides a ready mechanism by which to carry water to depth.

Crustal Growth

One of the most persistent debates concerning the continental crust is the question of how the volume of the crust may have changed through time. Did continents form early and remain more or less in steady state as new additions were balanced by subtraction due to recycling (e.g., Armstrong 1981, 1991)? Or has the volume of continental crust increased over Earth history (e.g., Dhuime et al. 2012; McCulloch and Bennett 1994; Taylor and McLennan 1985)? If the latter, what is the shape of the growth curve? Fig. 4 shows a recent compilation of crustal growth curves by Cawood et al. (2013). While there is far from a consensus on this topic, the burgeoning information being gleaned from zircons, particularly detrital zircons harvested from terrigenous sedimentary rocks, points to significant generation of felsic continental crust in the mid- to Late Archean.

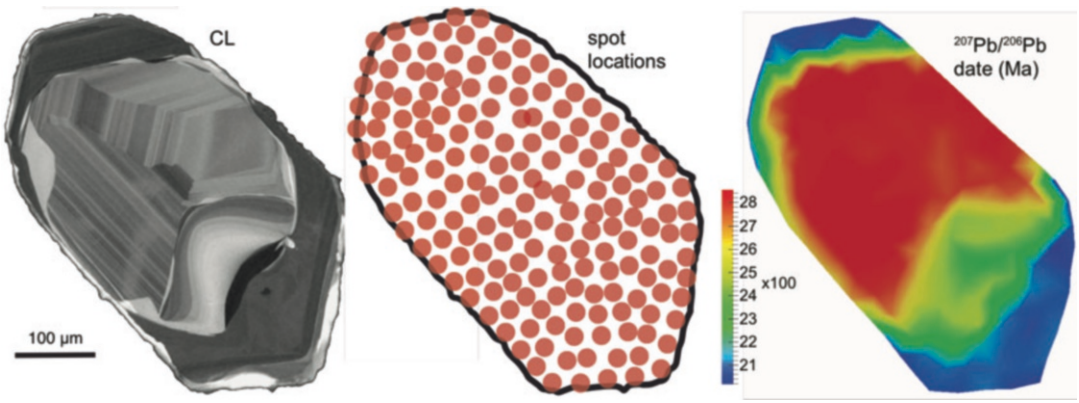
Zircons are particularly powerful recorders of geologic history because their crystallization age can be determined precisely via U-Pb dating (see reviews by Scherer et al. 2007; Schoene 2014), and they contain relatively high concentrations of Hf. Decay of ^{176}Lu to ^{176}Hf (half-life = ~37.5 Ga,



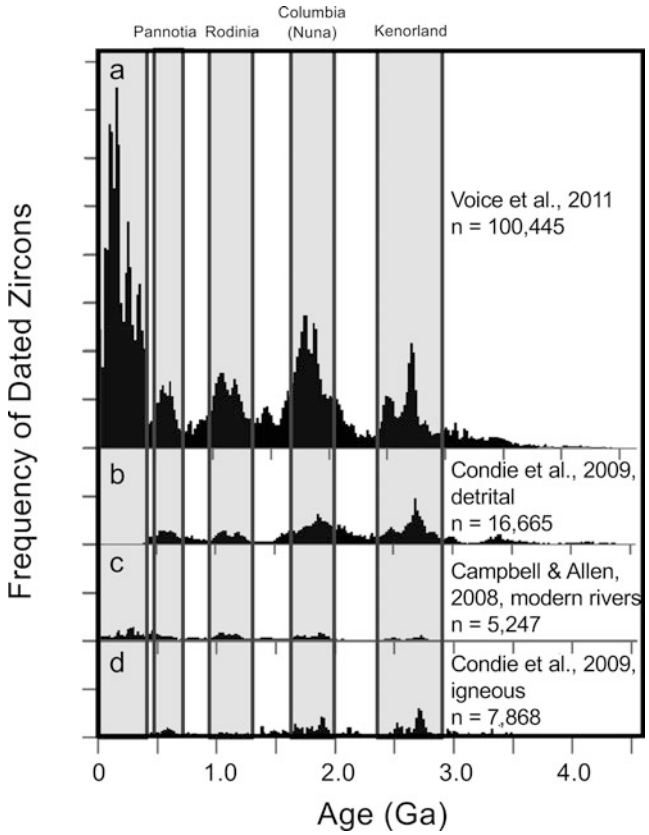
Earth's Continental Crust, Fig. 4 A selection of continental crustal growth or preservation curves, compiled by Cawood et al. (2013). The curves of Goodwin (1996) and Hurley and Rand (1969) are based on the present-day surface Rb-Sr and K-Ar dates and represent minima, as they do not take into consideration isotopic resetting due to metamorphism. The curve of Condie and Aster (2010) is based on a combination of U-Pb dates of zircons from both orogenic granites for which Nd whole rock data exist and U-Pb dates of detrital zircons for which Hf isotope data exist, as well as map distributions of dated rocks. The Allègre and Rousseau (1984) curve is based on Sm-Nd model ages in shales, while the curves of Belousova et al. (2010) and Dhuime et al. (2012) are different takes on Lu-Hf model ages of detrital zircons. The remaining curves (Armstrong 1981; Taylor and McLennan 1985) are based on concepts about how the crust may have grown (Modified from Cawood et al. 2013)

Scherer et al. 2001; Söderlund et al. 2004) and the relatively low Lu/Hf ratio of zircon means that mantle derivation ages (or model ages) can be determined for each zircon, provided that the Lu/Hf ratio of the pre-existing crustal reservoir and the Hf isotope mantle evolution curve can be approximated (see Kemp and Hawkesworth 2014; Payne et al. 2016; Vervoort and Kemp 2016 for recent reviews of the methods and potential pitfalls involved). In particular, with the widespread application of in situ analytical methods such as secondary ion mass spectrometry (SIMS) and laser ablation inductively coupled multi-collector plasma mass spectrometry (LA-MC-ICP-MS), both U-Pb dates and Hf isotopes can be determined for the same zone within a given zircon (zircons frequently contain different domains grown at different times, Fig. 5), or even for the same volume (e.g., employing laser ablation split-stream methods, Fisher et al. 2014; Kylander-Clark et al. 2013; Yuan et al. 2008) to ensure a direct match between U-Pb date and Hf isotope model age. Finally, oxygen isotopes of the zircons can be used to identify zircons derived, in part or in whole, from pre-existing crust, which will generally have non-mantle-like $\delta^{18}O$ values. In this way, zircons that crystallized from magmas that contain components of older continental crust can be identified, in order to infer the proportions of juvenile to pre-existing crust and define crustal growth curves (Kemp et al. 2006). The results from analyses of thousands of zircons suggest that most (~60–75%) of the continental crust formed by the end of the Archean, possibly by processes other than subduction zone magmatism. Assuming that it is difficult for the zircon record to be completely obliterated by crustal recycling because weathering and erosion disperse detrital zircons, the results also suggest that only a small fraction of present-day continental crust (20–25%) was present at the start of the Archean at about 3.8 Ga. In these discussions, it is important to note, as pointed out by Lee et al. (2016) that the U-Pb zircon record is mostly a record of felsic crust, as zircon is not saturated in mafic melts. In addition, detrital zircons (and their associated sedimentary rocks) can only be generated if crust is exposed above sea level. It is conceivable that evolved crust submerged below the oceans could have been efficiently recycled in the Hadean without leaving a trace. However, based on the evidence for dominantly mafic crust in the Archean cited above, this scenario is unlikely.

A striking feature of the age distribution of continental crust is the well-defined peaks in U-Pb zircon dates (Fig. 6). These peaks appear in zircons from both terrigenous sediments and igneous rocks and are found on all continents. Given the very large number of near-concordant U-Pb dates for zircons from the continental crust (several hundred thousand), the peaks appear to be robust and are unlikely to be an artifact of incomplete sampling. Yet the significance of these peaks is debated. One school of thought interprets the peaks as episodes of enhanced crustal growth, possibly driven by superplume events or slab avalanches in the mantle (Arndt and Davaille 2013; Condie 1998; Parman 2015). This interpretation is supported by peaks at similar time intervals in Os model ages in mantle peridotites and platinum-group alloy grains from ophiolites, which may date continental crust extraction events (Pearson et al. 2007). An alternative interpretation suggests that crustal preservation may be uneven (Gurnis and Davies 1986) and that the U-Pb peaks may represent zircon growth and preservation during supercontinent formation (Condie and Aster 2010; Hawkesworth et al. 2010, 2013; Kemp et al. 2006). This interpretation is supported by the apparent absence of corresponding peaks in Lu-Hf model ages from the same zircons (Voice et al. 2011), including those that have been filtered using oxygen isotopes to identify only zircons from juvenile crustal additions (Dhuime et al. 2012; Kemp et al. 2006). If the Lu-Hf model age distributions prove robust (see caveats in Payne



Earth's Continental Crust, Fig. 5 Example of a complexly zoned zircon crystal from a granite from Cameroon. *Left*: cathodoluminescence image, *right*: $^{207}Pb/^{206}Pb$ age map; *center* panel shows the position of the individual laser spot analyses that were used to create the map on the right. The analyses reveal a ~2.8 Ga igneous core with oscillatory zoning that was partially resorbed and overgrown in the latest Archean, earliest Paleoproterozoic. The outer rim grew around 2.1 Ga (Modified from Cottle and Stearns 2017)



Earth's Continental Crust, Fig. 6 U-Pb dates of zircons from detrital terrigenous sedimentary rocks and granites. (**a**) Detrital zircons that are less than 5% discordant, from Voice et al. (2011); (**b**) detrital zircons <10% discordant, from Condie et al. (2009); (**c**) detrital zircons from global modern river sediments, from Campbell and Allen (2008); (**d**) zircons for orogenic granites that are <5% discordant, from Condie et al. (2009). Vertical *gray bars* delineate the statistically significant peaks and proposed times of supercontinent formation (labels at *top*) (Modified from Voice et al. 2011)

et al. 2016), they indicate that crustal growth was a far more continuous process than the U-Pb zircon age peaks suggest.

Earth's Earliest Crust

The oldest known indigenous minerals found on Earth are Hadean detrital zircons from Mt. Narryer and the Jack Hills, Western Australia (Compston and Pidgeon 1986; Froude et al. 1983), which date back to 4.4 Ga (Wilde et al. 2001). Since their discovery, these tiny grains have been the subject of intense scientific scrutiny in order to divine the nature of the Hadean Earth, for which we have no rock record (see review by Harrison 2009). Key features suggest that these zircons crystallized from hydrous, relatively low-temperature granitic melts: encapsulation of mineral inclusions of typical granitic composition (e.g., quartz, muscovite, K-feldspar, hornblende, Hopkins et al. 2008; Maas et al. 1992), fractionated oxygen isotopes, indicating incorporation of materials that experienced low temperature alteration in the presence of liquid water (Mojzsis et al. 2001; Wilde et al. 2001), and low Ti-in-zircon temperatures indicative of relatively evolved melt compositions (Fu et al. 2008; Watson and Harrison 2005). These results have been interpreted to suggest that the Hadean Earth was temperate, with liquid water, and possibly also widespread continents created by plate tectonics (Harrison 2009; Mojzsis et al. 2001; Wilde et al. 2001). Most recently, isotopically light carbon isotopes measured in graphite contained within a 4.1 Ga zircon suggests the possibility of a biosphere at this time (Bell et al. 2015), and remnant magnetism has even been detected in the Hadean zircons, leading to the suggestion that the Hadean Earth possessed a magnetic field (Tarduno et al. 2015), though debate exists regarding the veracity of this signal (cf. Cottrell et al. 2016; Weiss et al. 2015).

Origins alternative to a wet granite source for the zircons have also been proposed. For example, the zircons may have crystallized during differentiation of impact melts, as zircons from the Sudbury impact melt sheet also record low Ti-in-zircon temperatures (e.g., Darling et al. 2009; Kenny et al. 2016). Or the Hadean zircons may have crystallized during the final stages of differentiation of basaltic melts (e.g., Rollinson 2008). Various lines of argument have been mustered to counter these arguments. Perhaps the most compelling evidence lies in the presence of muscovite inclusions, which, after quartz, are the second most abundant inclusion observed (Hopkins et al. 2008). Muscovite does not crystallize during basalt differentiation and has not been recognized in impact melts. Moreover, the trace element compositions of the zircons are distinct from those formed in late-stage differentiates of basalt (Grimes et al. 2007).

Although the weight of evidence supports crystallization of the Jack Hills zircons from hydrous granitic melts, the degree to which these rare crystals indicate the presence of widespread continental crust and the operation of plate tectonics is open to debate. Harrison (2009) made the case that the inferred low geotherm determined from thermobarometry of the mineral inclusions (Hopkins et al. 2008) could only reasonably exist on a hotter Hadean Earth if there were subduction zones, which are characterized by exceedingly low temperatures in the modern Earth and, by analogy, the Hadean Earth. However, others have suggested that it is unlikely that widespread Hadean continental crust could be obliterated with nary a trace. For example, the rarity of detrital zircons having Hadean U-Pb ages is hard to explain if such widespread felsic crust existed (Belousova et al. 2010; Voice et al. 2011). Moreover, Lu-Hf model ages for the most ancient zircons typically fail to exhibit evidence for significant volumes of Hadean continental crust (Kemp et al. 2010, 2015; Vervoort et al. 1996). In addition, the evidence reviewed above for a dominantly mafic crust in the Archean does not

support the presence of widespread granitic crust in the Archean or Hadean. Finally, one of Armstrong's (1991) strongest arguments for very early differentiation of Earth's crust is the comparison with other rocky planets in our solar system, all of which show evidence of early crust formation (e.g., Taylor and McLennan 2009). It is indeed quite likely that such differentiation occurred on Earth but that the earliest crust was dominated by basalts and komatiites, consistent with the higher mantle temperatures at that time, and with the basaltic compositions of other ancient planetary crusts (Taylor and McLennan 2009).

In addition to the Hadean zircons, evidence for the nature of the earliest crust comes from some of the oldest rocks on Earth: the 4.0 Ga Acasta gneisses in the Great Slave Craton, Canada, the 3.8-3.9 Ga rocks of southwest Greenland, and unusual, ~3.8 Ga ortho-amphibole-bearing amphibolites and associated TTGs of the Nuvvuagittuq Greenstone Belt, Canada.

The oldest dated rocks are tonalitic gneisses – the Acasta gneisses from the Slave Craton, Northwest Territories, Canada, which have U-Pb zircon ages dating back to 4.03 Ga (Bowring and Williams 1999). Several lines of evidence suggest that the original tonalitic magmas derived from pre-existing mafic to ultramafic crust. Whole rock ^{142}Nd isotope data for the Acasta gneisses that deviate from that of the bulk Earth have been interpreted to reflect their derivation from a ~4.3 Ga precursor mafic crust (Roth et al. 2014 and references therein). Likewise, Hf isotope compositions of zircons from a 4.02 Ga Acasta gneiss indicate its derivation from mafic to ultramafic crust, with no evidence for earlier granitic continental crust (Reimink et al. 2016).

The Itsaq gneiss complex and Isua supracrustal belt in southwestern Greenland were recognized early on as containing some of Earth's most ancient rocks, dating to at least 3.7 Ga (Moorbath et al. 1972, 1973). They form the largest continuous track of early Archean rocks yet recognized. More recent work shows these rocks to have formed as far back as ~3.9 Ga (Nutman et al. 1996, 1997). The Itsaq gneisses are highly deformed amphibolite facies rocks comprised of ~80% gray gneisses dating to >3.8 Ga, 10% supracrustal, mafic, and ultramafic rocks formed at ≥3.87 to 3.6 Ga and 10% somewhat younger (≤3.65 Ga) granites (Nutman et al. 1997). By contrast, the Isua supracrustal belt is comprised of less deformed amphibolite-facies chemical (BIF, cherts, and carbonates) and clastic sedimentary rocks interbedded with bimodal (mafic-felsic) volcanic rocks that form a least two distinct stratigraphic units dating to 3.7 Ga and ≥3.8 Ga (Nutman et al. 1997) and contain what may be the oldest microbial mats (Nutman et al. 2016). The SW Greenland rocks record both positive (Boyet et al. 2003; Caro et al. 2003; Harper and Jacobsen 1992) and negative ^{142}Nd isotopic anomalies (Rizo et al. 2012), indicating their derivation from rocks that originally differentiated in the Hadean.

The most recently recognized ancient crust occurs in the Nuvvuagittuq Greenstone Belt, in the Minto Block of the northern Superior Province, which crops out on the eastern shore of Hudson Bay in northern Quebec. The lithological assembly comprises chemical sedimentary rocks (quartz-magnetite rocks, ferruginous quartz-pyroxene rocks), quartz-biotite schists containing clasts of quartzite and mafic rocks (Cates and Mojzsis 2007), ultramafic sills, as well as unusual cummingtonite-bearing amphibolites (O'Neil et al. 2008). The oldest dated rocks in the assemblage are felsic schists, interpreted to be volcanic in origin with U-Pb zircon dates of 3.77 (Augland and David 2015) to 3.82 Ga (David et al. 2009). The amphibolites generally have lower ^{142}Nd/^{144}Nd than bulk Earth and correlate with Sm/Nd ratios to yield an isochron of 4280 Ma (O'Neil et al. 2008), which has been interpreted, with some controversy (e.g., Roth et al. 2013), to represent the age of the belt. Irrespective of this debate, multiple lines of evidence suggest the derivation of the Nuvvuagittuq igneous rocks from mantle that experienced melt depletion early in the Hadean (Roth et al. 2013; O'Neil et al. 2016). Most recently, coupled ^{142}Nd and ^{143}Nd isotopic studies of much younger granitoids in the region point to their derivation from extensive Hadean mafic crust (O'Neil and Carlson 2017).

Summary

Earth is the only planet in our solar system that has a compositionally highly evolved crust – the continental crust – that contains a significant fraction of Earth's most strongly incompatible elements, including the heat-producing elements K, Th, and U. All estimates agree that the present-day continental crust has an average "andesite" composition and is vertically stratified. The upper continental crust is evolved (66–70 wt.% SiO_2), and its composition is the best constrained of any portion of the crust, with average estimates for major element concentrations falling within 70% of one another and most trace element concentration estimates falling within a factor of two. The average compositions of the middle and lower crust are much less constrained and the subject of debate (mafic or intermediate?), but surface heat flow observations require they be depleted in heat-producing elements. An average andesitic crust composition cannot be generated by single-stage melting of mantle peridotite. Multiple processes likely helped to transform original basaltic crust to the crust present today, including weathering and erosion, melting of subducted or foundered basaltic rocks, and density foundering and/or "relamination."

A number of lines of evidence point to a fundamental change in the bulk continental crust composition in the Late Archean from dominantly mafic to felsic by 2.5 Ga. Such a transformation may signal the onset of widespread plate

tectonics as a ready means to generate voluminous granitic magmas, though hydrous, K-rich granites existed in the Hadean, as inferred from Hadean-aged detrital zircons. The timing of growth of the continental crust is a topic of major debate. Early crust formation must have occurred in response to a cooling Earth, but it is likely that this crust was dominantly basaltic, with minor TTGs, but thick enough to rise above sea level locally. Growth of volumetrically significant felsic continental crust likely occurred in the Late Archean. Prominent peaks in U-Pb zircon dates are observed on all continents, but the interpretation of these peaks is uncertain: they may represent periods of enhanced crust formation or preservation.

Acknowledgments Peter van Keken, Gray Bebout, Ralf Halama, and Sujoy Mukhopadhyay all provided help in tracking down compositional estimates for the continental crust or other data. John Cottle kindly provided the beautiful zircon images in Fig. 5. Mike Free, Allison Greaney, and Ming Tang provided comments that helped me to clarify different parts of the original manuscript. I appreciate review comments from Kent Condie, Bruno Dhuime, Brad Hacker, Chris Hawkesworth, and Scott McLennan. I am grateful for support of my research from the National Science Foundation over the past two decades. Finally, I thank Bill White for being exceedingly patient while the writing of this entry was delayed due to my move across a continent.

Earth's Core

William F. McDonough
Department of Geology, University of Maryland, College Park, MD, USA

Definition

The composition of the Earth's core is essentially 85% Fe, 5% Ni, and ~10% other, by weight. The details are more complicated, with the "other" being a light element component, which results in the core having on average a lower mean atomic number than that of iron. Birch (1952, 1964) recognized a 10% difference in the density of the outer core relative to an iron-nickel alloy at core pressure and temperature conditions. Anderson and Isaak (2002) recommend that the core density deficit is between 3% and 7%. Both the liquid outer core (~95% by mass) and solid inner core (~5%) contain a fraction of a light element (nominally in a ~2/1 proportion, respectively).

Properties

For more than a century the Earth has been described as having a metallic core surrounded by a silicate shell. A brief history of this topic is given in McDonough (2014). Emil Wiechert in 1897 first subdivided the Earth's interior into these two main components and later, his graduate student Beno Gutenberg, using seismological data, established the core-mantle boundary (CMB) at 2900 km depth, which is within uncertainty the accepted depth for the boundary. First-order physical aspects of the core are listed in Table 1 and are based on fundamental constraints derived from seismology, geodetics of the planets, mineral physics, and experimental studies, with limited additional constraints from geochemistry and cosmochemistry. Seismology reveals that the CMB is more than half an Earth's radius. The outer core (OC) is liquid (absence of a shear-wave) and the inner core (IC) is solid (given observation of PKJKP waves (i.e., P-waves in mantle and OC that converts to an S-wave in IC then back to P-wave as it leaves the IC). Geodesy documents the coefficient of the planet's moment of inertia (i.e., a dense core surrounds a less dense silicate shell) and libration confirms the liquid state of the outer core. Thermodynamic analysis and experimental studies document the conditions of melting and crystallization of Fe-Ni alloys at core conditions and set the upper temperature limits at the inner-outer core boundary. Meteorites confirm that Fe and Ni are chemical partners and their ratios

Earth's Core, Table 1 Physical properties of the Earth's core

Mass	Value (±)	Units	Ref	(% Planet)
Earth	5. 97218(60) × 10^{24}	kg	Chambat et al. (2010)	100%
Inner core	9.68 × 10^{22}	kg	Yoder (1995)	1.6%
Outer core	1.84 × 10^{24}	kg	Yoder (1995)	30.7%
Core	1.93 × 10^{24}	kg	Yoder (1995)	32.3%
Mantle	4.015 × 10^{24}	kg	Chambat et al. (2010), Yoder (1995), Huang et al. (2013)	67.7%
Crust (ocean + continental)	2.73(48) × 10^{22}	kg	Huang et al. (2013)	0.46%
Inner core to core (%)				5.0%
Radius				
Inner-outer core boundary	1220 ± 10	km	Masters and Shearer (1995)	19%
Core-mantle boundary	3483 ± 5	km	Masters and Shearer (1995)	55%
Mean radius of the Earth	6371.23 (0.01)	km	Chambat et al. (2010)	100%
Volume				
Inner core	7.61 × 10^{9}	km^3		0.7%
Outer core	1.69 × 10^{11}	km^3		16%
Bulk core	1.77 × 10^{11}	km^3		16%
Silicate Earth	9.14 × 10^{11}	km^3		84%
Earth	1.083 × 10^{12}	km^3		100%
Density				
Outermost inner core (solid)	12,830	kg/m^3	Masters and Gubbins (2003)	
Innermost outer core (liquid)	12,010	kg/m^3	Masters and Gubbins (2003)	
Inner-outer core Δ density	820 (180)	kg/m^3	Masters and Gubbins (2003)	
Average outer core density	11,160 (60)	kg/m^3	Masters and Gubbins (2003)	
Average inner core density	13,070 (260)	kg = m^3	Masters and Gubbins (2003)	
CMB (Core-mantle boundary)				
Peak-to-peak topography	<3	km	Sze and van der Hilst (2003)	
CMB ellipticity	~0.2	km	Sze and van der Hilst (2003)	
Thermal and pressure data				
Top of outer core	4000 ± 500	K	Tsuchiya et al. (2016), Fischer (2016)	137 GPa
Top of inner core	5700 ± 550	K	Tsuchiya et al. (2016), Fischer (2016)	330 GPa
Outer core adiabatic gradient	0.55 (0.1)	K/km	Tsuchiya et al. (2016)	
Heat flow across CMB	5–15	TW	Tsuchiya et al. (2016)	
Moment of inertia constants				
Equatorial moment of inertia (I)	0.3299765	Ma^2	Yoder (1995)	
Mean moment of inertia (I)	0.330690 (9)	MR^2_0	Chambat et al. (2010)	

in primitive and iron meteorites inform us of their initial proportions in the Earth.

The maximum in the Earth's gravitational acceleration occurs at just above the CMB, where being close to the high density core has its greatest effect on the gravity field. Consequently, "g" (i.e., acceleration of gravity) increases in roughly linear fashion from center to CMB (i.e., approximately a uniform density sphere) and then remains between 9.8 and 10.5 m/s^2 from the surface to the CMB. The Earth's dynamic figure for the gravitational field is known to six significant figures and in combination with seismological constraints indicates that the excess ellipticity of the CMB is slight (~0.2 km) and that the CMB surface topography is smooth at long-wavelength being on the order of 1–3 km of peak-to-peak topographic amplitude (Table 1).

Formation

The core's origin dates back to the formation of the planet, with planet accretion occurring via accumulation and agglomeration of increasing size of particles and later planetesimals. Our solar system owes it origin to a supernova (or multiple supernovae) where the mass and momenta of the supernova combined with a fragment of an interstellar gas-dust cloud to rotate, collapse, condense, and centrally concentrate mass, internally controlled by a balance of gravitational and centripetal forces. Because of its mass the Sun, and to a lesser extent Jupiter, dominated accretion and condensation of the inner rocky planets, which formed relatively early (a few 10^6 years) and grew by the accretion of material flowing into and less so out of their respective feeding zone (first few AU surrounding the Sun).

Growth by accretion of a planet does not require differentiation of the body into a core and mantle, although differentiation likely occurred in stages during growth and included accretion of predifferentiated planetismals. For the Earth, it is likely that as accretion progressed the proto-Earth at some point reach melting temperatures for metallic liquids (lower than that for silicate liquids) and because of the large density contrasts (i.e., silicates being ~3000 and iron metal being ~7900 kg/m^3 at surface conditions) gravitational separation of a metallic core quickly ensued. The mean time of formation of the bulk of the Earth's core is, however, an open question with best estimates being between 30 and 60 Ma (million years) after the formation of the solar system (an age established by the oldest dated materials in the solar system, Hf-W isotope systematics of iron meteorites, and the age of Moon formation; more about this topic later). Note, timing of core formation can be considered as the mean age (or mean lifetime), which is a scaling time reflecting when much of the mass of metallic atoms were separated. The initial mass associated with core formation was likely significant and rapidly separated. Subsequent additions to the core might have followed some exponentially decreasing mass versus time function.

A second constraint on the time of core formation comes from understanding the origin of the Moon and the dating of its oldest rocks. This constraint is based on the fact that the Moon possesses a bulk composition that approximates that of the Earth's mantle (i.e., they share the same oxygen isotopic composition to six significant figures), with a bit more iron in the Moon (Young et al. 2016). The Moon's origin is often ascribed to being due to a giant impact (collision) between a nearly completely formed Earth and a Mars sized impactor (Mars is ~10% by mass the size of the Earth, whereas the Moon's mass is 7.346×10^{22} kg, which is 1.2% of the mass of the Earth) (Canup 2012; Cuk and Stewart 2012). Alternative scenarios for the moon-forming event(s) allow for a series of lesser, but still substantial, impacts that also satisfy the observational constraints (Cuk et al. 2016). The material ejected during this event coalesced into a corotating accretion disk around the Earth, possessed only a small fraction of metal from the Earth's core or the impactor, and subsequently accreted to form the Moon. The general features of this model (Canup 2012; Cuk and Stewart 2012; Cuk et al. 2016) are consistent with hydrodynamic models of accretion that seek to reconcile the angular momentum of the Earth-Moon system and isotopic constraints.

Major questions about the composition of the Earth's core, its age, the age of the inner core, present conditions, and dynamics of its formation remain unresolved. Debate focuses on the following questions for which we have limited observational constraints:

Formation Conditions and Composition

- What was the integrated composition of material feeding the Earth (i.e., chondrites)?
- What is the temperature and pressure evolution of planet growth and core formations?
- What was the integrated fO_2, fH_2, and fS_2 (gas fugacity) of core formation?
- How did the redox state of core formation evolve (early to late evolution)?
- Was segregation and sinking of metal from silicate an equilibrium process throughout the mantle or only for a portion thereof?
- Was core separation accomplished in the presence a magma ocean or not?
- Did the process of giant impact collision coalesce and emulsify the cores of the Earth and its impactor and re-establish metal-silicate equilibrium?
- What is the duration and timing of core formation (e.g., ^{182}Hf-^{182}W. isotope system)?
- How much S, C, N, and H (i.e., volatile elements) are in core?
- How much O, Si, and Mg (i.e., major elements) are in core?
- Are there radioactive elements in the core and if so, how much?

Inner-Outer Core

- When did the inner core start to form?
- What is the crystal structure of the inner core?
- How much and what is (are) the light element(s) in the inner core?
- How much and what is (are) the light element(s) in the outer core?
- Does enrichment of buoyant, light-element-rich liquids, produced at the inner-outer core boundary, drive compositional convection and the geodynamo?
- To what degree does crystallization of the inner core drive compositional convection?

Many unknowns remain and detailed constraints on the core's composition come almost exclusively from the chemical and isotopic composition of the silicate Earth and meteorites.

Building Compositional Models of the Planet and Core

Our view of planetary compositional modeling is explicitly informed by the compositions of chondrites, the most primitive rocks of the solar system. Chondritic meteorites, which make up the bulk of the meteoritic material (~95% of the falls), fell to the Earth during historical times and thus shape our view of the building blocks of the planets (Engel and

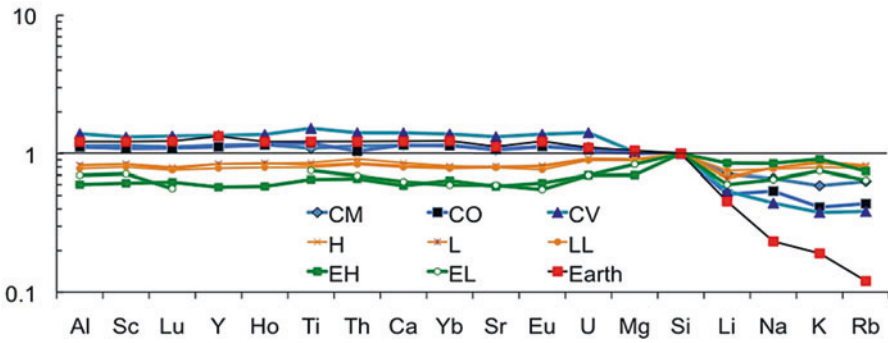
McDonough 2016). CI1 carbonaceous chondrites have the most primitive composition of the various chondrites and closely match the spectroscopically derived composition of the solar photosphere for all but H, C, N, O, and the noble gases (McDonough 2016). [Note, that the chondrite type is CI and the metamorphic grade is 1, hence CI1.] The element abundance curve for the solar photosphere, for at least the dozen most abundant elements, is the same as that for other stars in the galaxy and nearby galaxies. Thus, the principles developed below are applicable for exoplanet building too.

As building blocks, chondrites provide the basis for compositional models that can plausibly describe what is in the Earth's core. Some proposed models of the Earth's composition fall outside of the observed range for chondrites, with enrichments in refractory elements and stronger depletions in volatile element abundances than seen in chondrites (Fig. 1) (McDonough 2014). Element classification (i.e., volatile versus refractory) is defined in terms of half-mass condensation temperatures of an element during cooling of a nebular accretion disk and precipitation into common mineral phases. Given the plausible range of volatile and refractory element abundances in different groups of chondrites that accreted to form the Earth, it is not possible to uniquely define the planet's composition. Moreover, while chondrites represent a compositional guide, the Earth is unlikely to match the composition of any specific, single chondrite. The standard rules for planet building are as follows:

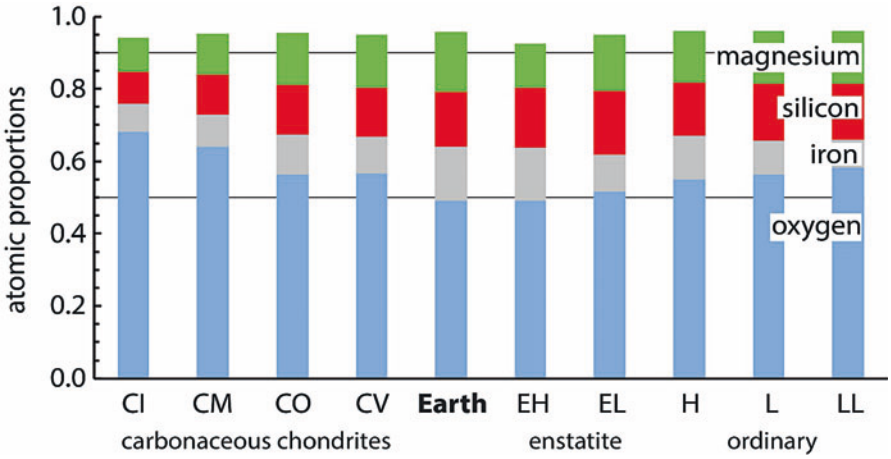
- Use orbital and seismic constraints, if available, to define the physical state
- Use chemical and isotopic data from chondritic (i.e., primitive) meteorites and the solar photosphere
- Assume chondritic proportions for the refractory elements and model their absolute abundances based on chemical trends observed for mantle samples (basalts and peridotites),
- Model the absolute abundances of Mg, Fe, Si, and O; these are the major elements, which are nonrefractory elements, and constitute >90% by mass of the rocky planets
- Recognize a chemical gradient in solar system (e.g., rocky planets versus the gas giants)
- Model the relative and absolute abundances of the nonrefractory elements in the planet

Model core compositions are estimated by subtracting the composition of the silicate Earth from the composition of the bulk planet. The relative distribution of lithophile elements (those that tend to bond with oxygen and are excluded from the core) versus siderophile elements (those that tend to bond with iron and are dominantly stored in the core) in the crust and mantle define the composition of the silicate Earth. For refractory elements, including lithophile and siderophile, their relative proportions in the planet are the same as in chondrites (i.e., the lithophiles have constant ratios at ±10% or better, constant ratios of siderophiles are at ±15% or better, and ratios of lithophile to siderophile have uncertainties at circa ±25%, with the greater difference for the latter being due to variations in the proportion of metal to silicate in chondrites). Therefore, if we can predict the abundance of one refractory element in the Earth, we can predict the planetary inventory of all 37 refractory elements, which include: Be, Al, Ca, Sc, Ti, V, Sr, Y, Zr, Nb, Ba, REE, Hf, Ta, Th, and U (these are the lithophiles); and Mo, Ru, Rh, W, Re, Os, Ir, and Pt (these are the siderophiles, with V showing both behavior). How and why elements are distributed between the core (mostly siderophile) and the surrounding silicate shell (lithophile) depends on the conditions of pressure, temperature, and redox state during core formation. The conditions of core formation are critical to establishing its final composition.

Among the dozen most common elements in the solar system, the rocky planets are variably depleted in the most

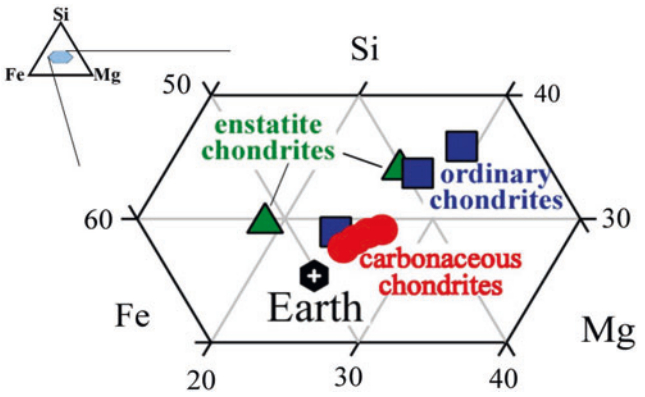


Earth's Core, Fig. 1 Chondrite normalize compositions for carbonaceous chondrites (CM, CO, CV subtypes), ordinary chondrites (H, L, and LL subgroups), enstatite chondrites (EH and EL subgroups) and the Earth. The figure is double normalized with all compositional models plotted as having the same Si content, which corrects for differing amounts of highly volatile element contents (i.e., H, C, N, O). Normalizing reference frame assumes a CI1 chondrites composition. Data for the chondrites are from Wasson and Kallemeyn (1988) and McDonough (2014)



Earth's Core, Fig. 2 Atomic proportions of O, Fe, Si, and Mg in chondrites and the Earth. Data sources listed in Fig. 1. The O context is ≥50% in the chondrites and the total atomic fraction for these four elements in all of these materials adds up to >90%

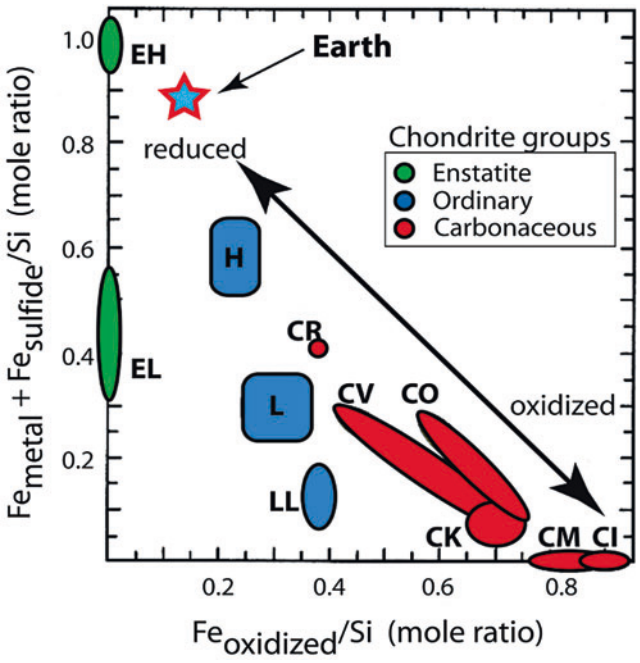
volatile constituents (i.e., the gases: H, He, C, N, O, Ne, Ar). The remaining common elements are O, Fe, Si, and Mg, which constitute between 90% and 95% the mass of the Earth, Mars, and Venus roughly in the mass proportion 30:30:20:20 (or in the approximate atomic proportions of 50:15:15:15), respectively (Fig. 2). The high density and small radius of Mercury indicates that it likely has a much higher proportion of iron than the other rocky planets. Compositional models for the Earth, other terrestrial planets, and exoplanets with bulk density in the range 3000–6000 kg/m^3 will be dictated by mixtures of metal and silicate. The silicates are predominately a bimineralic mix of olivine and pyroxene at pressures equivalent to the Earth's upper mantle. At the seismically define base of the Transition Zone (i.e., 660 km depth, ~22 GPa), olivine disproportionates into bridgmanite (Mg-Fe silicate perovskite) and ferro-periclase, whereas the pyroxene component (which in the upper mantle has gradually dissolved into a majoritic garnet) converts to bridgmanite and Ca perovskite over a broader range of pressures (i.e, ~19–24 GPa).



Earth's Core, Fig. 3 The compositional space for the chondrites and the Earth in a tetrahedral volume plotted from the apices of Si, Mg, Fe, and O, with the data plotted onto the surface of the Si-Fe-Mg plane. Data sources listed in Fig. 1. The Earth's composition falls outside of the field of the known chondrites. This model composition for the Earth is acceptable given observations of the spatial variations in rates of olivine to pyroxene crystallization in accretion disks (See text for further details)

A big unknown in predicting the bulk composition of a planet is establishing the proportion of olivine to pyroxene accreted by the body, which is indicated by its Mg/Si ratio. There is no fixed Mg/Si ratio for chondrites and thus there is no chondritic constraint (Fig. 3). Olivine has a 2:1 molar Mg/Si content, whereas pyroxene's molar ratio is 1:1. Astromineralogical observations of accretion disks reveal radial variations in the proportion of olivine to pyroxene, some with inner disk regions being richer in olivine relative to the disk wide composition (van Boekel et al. 2004), whereas other have more olivine in the outer part of the circumstellar disk; differences in disk mineralogy may relate to type of star (e.g., T Tauri vs. Herbig Ae/Be stars) (Bouwman et al. 2010). Likewise, one can also envisage disk evolution in time with temperature decreasing as the disk cools leading to decreasing Mg/Si (less olivine ppt with time). Moreover, crystallinity scales radially, with inner disk regions (a few AU) having higher abundances of large grains and generally higher crystallinity as compared to outer disk regions, suggesting grain growth occurs more rapidly in the inner disk regions (D'Alessio et al. 2005; Sargent et al. 2009). Thus, planetary modelers must acknowledge that there is no fixed Mg/Si value for a planet.

After O, Fe, Si, and Mg, the next most abundant elements in chondrites and rocky planets are Al, Ca, and Ni and together these seven elements, plus S, make up >98% by mass of these solid bodies. Both Ca and Al are refractory elements, and their planetary weight ratio is 1.1 (atomic ratio is 0.72), equal to that of chondrites, but their absolute abundances in the Earth are model dependent; these elements are exclusively lithophile and thus concentrate in only the silicate portion of the Earth. Nickel and sulfur are both nonrefractory elements and are partitioned into both the core and mantle, with Ni being dominantly siderophile (>90% of the Earth's



Earth's Core, Fig. 4 A plot of the oxidized iron to Si content of chondrites versus the metallic and sulfur-bearing content to Si content of chondrites. This diagram is also referred to as a Urey-Craig diagram. The Earth plots intermediate to the highly reduced enstatite chondrites and the less reduced ordinary chondrites. The CM and CI chondrites have nearly (or all) iron as oxidized, with no metallic iron

Ni is hosted in the core) and sulfur is the definition of what is a chalcophile element (>95% of the Earth's sulfur is in the core) (McDonough 2014).

The ratio of metals to oxides is a basic feature used to classify chondrites. The chondrites, carbonaceous (highly oxidized), ordinary (an intermediate redox state), and enstatite (highly reduced state) can be divided into subgroups of high, low, and low-low iron contents. Therefore, the amount of Fe relative to O, Si, and Mg in chondrites and planets can vary considerably. The redox state of a planet can be readily established by determining the Mg # (atomic Mg/(Mg + Fe)) of mantle silicates in combination with a value for the mass proportion of metallic to silicate shells. The Earth with 90% of its iron in metallic state is a reduced body with a redox state intermediate between ordinary and enstatite chondrites (Fig. 4).

Importantly, there are a number of critical element ratios for the nonrefractory elements that are relatively constant in chondrites and, if these element pairs have similar condensation temperatures, then these fixed ratios can be used to place compositional constraints on the bulk planet. The fixed chondritic ratios of Fe/Ni (17.4 ± 0.5) and Ni/Co (20.5 ± 0.6) constrains the planetary and core abundances of Ni and Co, given well established values for the mantle. To this end, a major advance was made when Thibault and Walter (1995) and Li and Agee (1996) identified the pressure dependence partitioning of Ni relative to Co and found that at mid-mantle conditions the relative partitioning of these two elements approached 1, with both the core and mantle having chondritic Ni/Co values. This finding was fundamental as the silicate Earth and core are assumed to have a mass balance in these ratios.

The initial growth of Earth and core-mantle segregation is often consider in terms of occurring under conditions of homogeneous or heterogeneous accretion, with the former model assuming that the accreting materials had a fixed, constant composition throughout planetary growth, while latter model models envisages significant changes in the composition of material that accretes to the Earth as it grew (see also discussion in McDonough (2014)). These different models seek to explain the siderophile element composition of the mantle. For the most part models of homogeneous accretion require a continuous and restricted set of physical and chemical conditions to achieve the present composition of the core and mantle, whereas heterogeneous accretion models allow for a range of probable conditions envisaged in an evolving proto-planetary disk, including temporal variations in redox conditions and the relative proportions of volatile to refractory materials.

Given an average condition for temperature, pressure, and oxygen fugacity of core formation we can construct models for the core that fit the existing constraints and match compositional models of the silicate Earth and chondrites. The abundance, absolute and relative, of various redox sensitive siderophile elements (e.g., W, V, Cr, Nb, Mn, Mo, and others) in the silicate Earth further define the relative silicate-metal partitioning of elements during core formation (Badro et al. 2015; Badro et al. 2014; Corgne et al. 2008; Fischer et al. 2015; Rubie et al. 2015). At this stage there remains one further consideration before estimating the composition of the core, and that is identifying the chemical identity of the element(s) accounting for its density deficit.

Finally, an important constraint on core formation came from the observation that the primitive mantle abundances of the highly siderophile elements (i.e., those with metal/silicate partition coefficients of 10^4 and greater and include the platinum group metals (Ru, Rh, Pd, Os, Ir, Pt), Re and Au) are in chondritic proportions and are enriched in the mantle at concentration levels well beyond that expected for their known metal/silicate partition coefficients (Kimura et al. 1974). Following a range of experimental studies it has been demonstrated that that the relative metal/silicate partitioning behavior of the highly siderophile elements are 10^4 and greater and that the relative differences between different member of this element group would result in grossly non-chondritic ratios for the Re-Os-Pt isotope system, which is not observed (Brenan et al. 2016; Day et al. 2016). Thus, the mantle signature requires the addition of a late veneer of

added chondritic material, with a mass contribution equivalent to about 0.5% to <1% the mass of the mantle (Day et al. 2016).

Core Composition and Its "Light Element(s)"

Table 2 presents a model for the composition of the Earth, its core, and the silicate Earth. The core model was constructed as the difference based on estimates of the bulk silicate Earth and the bulk planet compositions. The core composition proposed here has a mixture of O, Si, and S that accounts for the density deficit (3–7%). The relative proportions of O and Si in the core were established by metal/silicate partitioning (Badro et al. 2015; Fischer et al. 2015; Rubie et al. 2011). Assuming the core's mean atomic number to be 23 (Birch 1964), the absolute proportions of O and Si is then fixed. By way of comparison, McDonough (2014) proposed two end-member models, with one model containing Si and S and no O as the light elements and the other model contains O and S and no Si. Other compositional models are presented for comparison in Table 1 in Hirose et al. (2013), where they have sorted the different models in terms of simple single light element versus multiply, mixed light element models. One should view all of these models as acceptable, given the available constraints.

Let me start by saying that I do not know what is (are) the light element(s) in the core. The issue has dogged our science for half of a century and will continue to do so for some time. Words of caution are needed before discussing further the composition of the core. My bias as a geochemist states that observations on the composition of the silicate Earth and the range of compositions in chondrites defines the recipe that must be matched by experimental studies to define the P-T-fO_2-Xi (i.e., pressure, temperature, oxygen fugacity, and compositional) space for metal-silicate equilibrium during core formation. Models describing the dynamics of core formation and its final composition are probability positions and need to be recognized as such. As a second cautionary note, the periodic table is not a one-stop shopping table, if it is argued that a minor or trace element is in the core, then other elements in the same column are likely there too in some proportional relationship (e.g., Cr: Mo and W, Mn: Re, V: Nb and Ta). This principle is fundamental chemistry reflecting the importance of outer orbital electrons in controlling the partitioning behavior of elements. Thirdly, all partition coefficients (D-values) go to 1 as temperature goes to infinity and thus metal-silicate fractionation becomes muted at higher temperature conditions. Finally, appeals to adding specific elements into the core are also understandably done so to explain the power driving the geodynamo; resolving the energy equation for the geodynamo is intractable and will be so for some time.

The identity of the light element(s) in the core is elusive. Many suggestions have been published over the decades (e.g., H, C, N, O, Mg, Si, S). In general, any element with a lower atomic number than $_{26}$Fe is a likely candidate. Assuming Birch's law

$$V_\phi = \left(\frac{K}{\rho}\right)^{0.5}; \; V_p = M_\rho + B + A(T - T_0)(\rho - \rho^*) \quad (1)$$

where Vϕ is hydrodynamic or bulk sound velocity, V_P is compressional wave velocity, κ is bulk modulus, ρ is density, M and B are room temperature coefficients of Birch's law, and A and ρ^* account for its temperature dependence (see also Sakamaki et al. (2016))], one can predict the mean atomic weight of the mantle or core. Recently, Helffrich (2015) reported a similar relationship between sound speed and molecular weight using a hard sphere model for liquids. In addition, Poirier (1994), Anderson and Isaak (2002) and Badro et al. (2014) present simple graphical models to determine the amount (in wt%) of light element mixture in the core that scales as a function of core temperature. The model presented in Table 2 uses these principles to constrain the proportion of O and Si in the core. The S content of the core is established on cosmochemical grounds (Dreibus and Palme 1996) and constraints from the modeling of the bulk silicate Earth (McDonough and Sun 1995).

Chemical and physical observations are useful for developing plausible models for the nature and amount of a light element(s) in the core. Lithophile elements like O, Si, and Mg, in addition to Fe, are the most abundant elements in the Earth and can be readily defended as being dissolved in a core forming metallic liquid. Likewise, the gases of H-C-N-O are abundant in the solar system and would have been abundant in the nebular disk. The rocky planets might have had a dense surrounding atmosphere, particularly early in their evolution, which increases the solubility of these gases in a magma ocean and the potential for partitioning these elements into a core forming metallic melt. Thus, models invoking H, C, and/or N as constituents of the core cannot be dismissed. On the other hand, however, the Earth, and potentially the rest of the terrestrial planets in the solar system, is volatile depleted, as documented by its Rb-Sr, K-Ar, K-U, and He-Ne-Ar isotopic systems and total radiogenic heat production. Therefore, the Earth's volatile depletion curve establishes the limit of 2% (by mass) of sulfur in the core. Overall, chemistry offers guidelines, but a few constraints in eliminating competing core compositional models. Physical observations provide the best limits on acceptable core models.

The small addition of the lightest elements (e.g., H and C) is appealing because they offer considerable leverage in lowering the mean atomic weight of the core. It is noteworthy that the core composition reported in Table 2 posits significant amounts of C and H in the core given the Earth's volatility

Earth's Core, Table 2 Composition of the Earth, silicate Earth, and core in weight percent and atomic proportions

wt%	Earth	Silicate Earth	Core	Atomic prop.	Earth	Silicate Earth	Core

Absolute and relative proportions of O and Si in the core were established by metal/silicate partitioning and fixing the core's mean atomic number to 22.9 (c.f. Birch 1964)

curve (McDonough 2014). However, their appeal is diminished if their addition to the core also comes with consequences for the mantle (e.g., limited metal-silicate fractionation for H and C during core formation). Compositional models for the mantle have proposed a range of H and C abundances (Dasgupta and Hirschmann 2010; Halliday 2013; Marty 2012) and variable estimates for the contents of H and C in the core and some model compositions proposed for the Earth's core suggest abundant carbon (Wood 1993) or hydrogen (Williams and Hemley 2001) for consideration.

Considerable attention has been paid to models with O, Si, or both as likely light element candidates (Badro et al. 2015; Fischer et al. 2015; Li and Fei 2014; Ringwood 1984). Based on the differences in the silicon isotopic composition of chondrites and the Earth, Fitoussi and Bourdon (2012) and Fitoussi et al. (2016) proposed that the Earth core contains some 4–7 wt% Si, with the range taking into account metal-silicate isotopic fractionation at presumed core separation temperatures. Initially, the presence of silicon and oxygen in the core was considered an either or condition, whereas today many have found a range of acceptable conditions of core formation that result in iron alloys with mixed amounts of silicon and oxygen. More recent models suggest that Mg may have once been present as a light element in the core (Badro et al. 2016; O'Rourke and Stevenson 2016). This suggestion is permitted given that Mg is one of the four most abundant elements in the Earth. Moreover, these authors note that as the core cools down it exsolves MgO (or Mg silicate) and this reaction is exothermic and thus provides a power source for driving the geodynamo. Alternatively, Hirose et al. (2017) have suggested that exsolution of SiO_2 from the outer core is another potential power source for the geodynamo. The present-day situation we face is that there are many competing models to explain the core composition and potentially also energy sources for driving the core's dynamo.

Power to Drive the Geodynamo and Radioactive Elements in the Core

The geodynamo is produced in the outer core and demands power for its operation. Several papers have considered the presence of radioactive, heat producing elements (i.e., HPE = K, Th, and U) in the Earth's core, as they provide power to drive the core's dynamo. There is no compelling experimental or geochemical constraint that requires HPE in the core. Moreover, doing so often requires incorporation of other lithophile elements for which there is no supporting evidence for their depletion in the silicate Earth.

The energy budget of the core does not require HPE, as alternative energy sources (e.g., oxide exsolution, see above) may also provide the needed power. In addition, unknowns in understanding the generation and maintenance of a geodynamo are great, which includes being able to describe accurately the core's energy equation.

As is the case with the discussion of the light element in the core, so too for the presence of radioactive elements in the core: there are big unknowns. Thus, one should not confuse the conditions of what is plausible and what is needed.

Potassium: Incorporation of K in the core has been considered by numerous workers (Corgne et al. 2007; Li and Fei 2014; Watanabe et al. 2014) and generally found that a few to a couple tens of μ g/g of K, or less, can be accommodated in the core. Using ab initio calculations Lee et al. (2004)

suggested that the metallization of potassium at pressure, due to s-to d-orbital transitions, as a mechanism for alloying potassium with Fe. Both Cs and Rb, larger alkali metals, would undergo similar orbital transitions, but at lower pressures. There is no evidence, however, that Rb is anomalously depleted in the mantle with respect to the planetary volatility curve, contrary to an expectation from the pressure-dependent metallization process.

Uranium and thorium: Wheeler et al. (2006) and Malavergne et al. (2007) show that under core segregation conditions U remains strongly lithophile and is for the most part excluded from the core. Similarly, thorium has not been found to partition into a core forming metal phase; it is understood to be wholly lithophile. An additional constraint on the abundance and relative distribution of Th and U in the bulk silicate Earth comes from Pb isotope studies. The κ_{Pb} ratio (i.e., the time integrated Th/U ratio derived from the $^{208*}Pb/^{206*}Pb$ ratio) of the silicate Earth is comparable to that of chondrites at ±25% (Andersen et al. 2015; Castillo 2016; Elliott et al. 1999; Galer and O'Nions 1985; Kumari et al. 2016; Paul et al. 2003), consistent with negligible amounts of Th and U in the Earth's core. Studies on the partitioning of thorium between metal and silicate demonstrate that it is wholly lithophile in its behavior.

The Age of Core-Mantle Separation

Age of core formation is constrained by the ^{182}Hf-^{182}W isotope system ($t_{1/2}$ of 9 Ma) and known to be on the order of 30–150 million years after the age of solar system formation (Kleine et al. 2002; Kleine et al. 2009; Yin et al. 2002). The solar system formation age ($t_0 = 4568$ Ga) is established mostly from the absolute system, U-Pb isotopes, and the relative system $^{26}Al/^{26}Mg$ isotopes ($t_{1/2}$ of 0.7 Ma), as applied to the earliest condensates, which are high temperature, refractory materials (i.e., CAIs, calcium alumina inclusions) found as inclusions in chondritic meteorites (Brennecka et al. 2015; Connelly et al. 2012; MacPherson et al. 2012). Together these isotopic systems indicate that the bulk of Earth's accretion occurred some 10^6–10^7 years after t_0 and core formation followed as accretion progressed, including some modification during and following the Moon-forming impact event.

The current core formation paradigm posits segregation of sinking metal diapirs that chemically interact with the immediately surrounding silicate (liquid or solid) during or following a magma ocean(s) environment of the early Earth. The degree of metal-silicate equilibrium occurring during descent of these diapirs is unknown. However, as metal aggregates ponds and then begin to sink the potential for chemical exchange becomes less efficient as the length scale increases. Chemical consequences of a large Moon-forming impact event introduces other unknowns, for which we do not know whether or not the impactor's core merged, emulsified in the mantle, or otherwise superimposed additional complications on the core's composition (Nakajima and Stevenson 2015).

Hafnium and tungsten readily and effectively separate between the metallic (core) and silicate Earth (planet minus the core), with Hf hosted nearly exclusively in the silicate Earth and W almost wholly (90%) in the core. Due to the solar system initiating supernova, the solar system (and hence the Earth) inherited a fraction of live ^{182}Hf (Lugaro et al. 2014) that decayed into ^{182}W and consequently the age of core formation reflects the competing processes of metal segregation versus ^{182}Hf decay.

Chronologically, what has been established recently is that small bodies, as represented by groups of iron meteorites, accreted and differentiated quickly (i.e., 0–5 Ma after t_0) (Kruijer et al. 2014). During the waning stages of small-body accretion (t_0 + 3–5 million years), and when radiogenic heating from the $^{26}Al/^{26}Mg$ isotope system was running out of energy, the formation of chondritic bodies occurs, which are the most primitive and undifferentiated planetesimals in the solar system. Hence, the preservation of chondritic parent bodies represents a waning stage of accretion of small bodies. It is likely that Earth's formation occurred throughout this sequence and beyond and consequently its inventory of ^{182}W was shared between the core and mantle, revealing that the amount of ^{182}W in the silicate Earth establishes a lower limit to core formation age, while the timing of Moon formation sets the upper limit. Our present estimate is the silicate Earth has a $\mu^{182}W$ isotopic composition of zero (it is the reference point for the isotope system and units are expressed as deviations in parts in 10^6), chondrites are approximately −200 and the Earth's core is slightly more negative (~−220) (Walker 2016).

Inner Core and Its Age of Crystallization

The inner core is <2% the mass of the Earth and 5% the mass of the core. It is slightly smaller than the Earth's moon and is at about the temperature of the Sun's surface. The ICB (inner-outer core boundary) surface provides a constraint for estimating the temperature at the center of the Earth. An upper temperature limit is obtained from the melting temperature of Fe at relevant temperatures and pressures (~6200 K, 330 GPa) and an assumed conductive thermal gradient (Fischer 2016). Experimental challenges associated with determining the melting curve of iron and the upper temperature limit of the ICB are formidable; there is a range of 1500 K at 330 GPa for the Fe-alloy melting curves (Fischer 2016). Nonetheless, given the potential light element candidates and their influence on melting point depression, an ICB temperature of 5700 ± 550 K covers the range of estimates (Fischer 2016).

The inner core has about half the density deficit relative to that of the outer core (Anderson and Isaak 2002; Jephcoat and Olson 1987; Masters and Gubbins 2003); proportionally, one might intuit that this translates to approximately half the amount of light element. The phase diagram dictates that the inner core crystallization temperature will be lower than that for pure iron due to freezing point depression. Thus, an estimate of the temperature of the ICB depends on one's estimate for the light element composition of the outer core, which is a concatenation of unknowns.

Compositional estimates for the inner core are not forthcoming, as the unknowns are great, and come with considerable nonuniqueness (Antonangeli et al. 2010; Badro et al. 2007; Sakamaki et al. 2016). We know that its solid, likely in an hcp (hexagonal close packed) structure, there is 820 ± 180 kg/m^3 density increase across the ICB (Masters and Gubbins 2003), it has a density deficit, and it is anisotropic (polar vs equatorial wave speed). The inner core may be undergoing thermal convection (Cottaar and Buffett 2012), which may explain its seismic anisotropy.

Solidification of the inner core produces latent heat and results in a buoyant, residual liquid enriched in light elements. The Coriolis force from the Earth's rotation, combined with a heated, compositionally buoyant fluid, gives this ascending fluid the power to generate a magnetic field. In addition, heat extracted from the core by the mantle, as the planet cools, gives rise to the core's thermal convection. In combination with rotational forces, the thermal and compositional effects are the most probable energy sources driving the geodynamo.

When did inner core crystallization begin? This question hinges greatly on understanding the thermal history of the core. There are many unknowns that contribute to this question and most are active areas of research accompanied by considerable debate, these include: the thermal and electrical conductivity of core materials (where there is an ongoing debate over the factor of 2 difference in the assumed values for these parameters), the initial and present day core temperature, heat flow across the CMB (see Table 1), and whether there are (and how much) radioactive elements in the core. Debates on these topics will continue for some time as technical and computational challenges are great, including understanding the energy budget needed to drive the geodynamo.

For about a decade there were models that proposed early inner core crystallization, as early as 4.5 Ga. Models of early inner core growth were nearly exclusively based on anomalous ^{186}Os-^{188}Os and ^{187}Os-^{188}Os isotopic compositions in basalts whose source region experience core additions; the origins of these anomalies came from decays in the Re-Os and Pt-Os isotope systems and parent daughter fractionation due to inner core crystallization (Walker 2016). More recently, however, corroborating ^{182}W isotopic evidence of this core-mantle exchange process occurring was not found in these basalts and thus the model of early inner core growth based on isotopic evidence has been abandoned (Walker 2016).

Geophysical estimates for the age of the inner core are based on a full understanding of the core's energy equation and usually includes a trade-off between internal heat production and heat dissipation across the core-mantle boundary. Labrosse et al. (2001) examined the question assuming a role for heat generation from potassium, modeling up to 200 μg/g K in the core, and showed that core crystallization might have started anytime from the Archean to nearly the present depending on how much potassium is in the core. Later, addressing this issue following the recently revised thermal and electrical conductivity values for the core, Gomi et al. (2013) and Labrosse (2015) concluded that the amount of potassium in the core plays less of a role in establishing the initiation of inner-core crystallization, but that the core cooling rate is significant. From these analyses a young age (circa ~05 Ga) for initiation of inner core is favored. Alternatively, estimates of an inner core having begun crystallization from 1.5 to 0.5 billion years ago are common (Labrosse et al. 2001). Overall, there are few constraints regarding the physical state and evolution of the core and inner core system, leaving us with open questions about when the inner core began to crystallize, the heat flux across the core-mantle boundary, and the power budget for the geodynamo.

Summary

The Earth's core comprises the innermost 3483 km of the planet. Both the inner solid core and outer liquid core consist of about 85% iron and 5% nickel with $\leq$10% other elements including lighter elements O, Si, and/or S as well as most of the inventory of highly siderophile elements such as the platinum group elements and gold. A metallic liquid core had likely formed within the first 30–60 million years of solar system history. The solid inner core has grown by crystallization of the outer core, a process that may have begun as recently as 0.5–1.5 billion years ago.

Earth's Oceanic Crust

Michael Perfit
Department of Geological Sciences, University of Florida, Gainesville, FL, USA

Definition

Oceanic crust is the outermost solid layer of the lithospheric tectonic plates under the oceans that covers much of the Earth's surface. It has a distinctive basaltic composition characterized by rocks that have relatively low concentrations of potassium and other highly incompatible trace elements (those typically excluded from minerals that comprise the mantle). Not including a sedimentary cover of variable thickness and composition, the oceanic crust consists of three layers: (1) a relatively thin uppermost volcanic layer of basaltic lavas known as mid-ocean ridge basalts (MORB) erupted on the seafloor; (2) a thicker layer of more coarsely crystalline, intrusive basaltic dikes that feed the volcanic layer; and (3) a thick lowermost layer of intrusive coarse-grained gabbros that mostly represent minerals that have settled out of slowly cooled melt bodies and lenses in a crystal mush zone below ridge crests.

Introduction

Nearly three-quarters of Earth's surface lies beneath the oceans and marginal seas where most of the oceanic crust has been formed by magmatic processes at mid-ocean ridges (MOR) and near-ridge seamounts. However, there are some regions where significant volumes of crust have formed locally such as at intraplate hotspot volcanoes, back-arc basins, and oceanic plateaus that will not be discussed here. Oceanic crust formed at MOR is primarily basaltic in composition and thin (~3–10 km thick) compared to continental crust that has an average thickness of 35–40 km and a roughly andesitic composition (Taylor and McLennan 1985; Rudnick 1995). In-situ sampling of the oceanic crust has largely been restricted to surface lava flows by dredging, drilling, remotely operated vehicles and human-occupied submersibles. Therefore, in order to estimate the bulk composition of the entire oceanic crust, these surficial samples have been augmented by dredging steep faults, several deep drill holes, investigations of ophiolite complexes (fragments of oceanic and back-arc crust and upper mantle that have been thrust upon to continents), and comparisons of the seismic structure of the oceanic crust with laboratory determinations of seismic wave velocities in known rock types. Integration of observations and analysis of oceanic rocks on the seafloor and exposed above sea level, combined with geophysical information, provides us with a reasonable view of Earth's oceanic crustal composition. Here the focus is on the composition of rocks that comprise the crust formed at MOR with the understanding that there is a range of compositions associated with other oceanic magmatic environments (e.g., intraplate hotspots, island arcs).

Seismic investigations of the seafloor have determined that the thickness of oceanic crust averages about 6–7 km at fast- and intermediate-spreading rate ridges, but typically is much thinner at slow-spreading MOR where the crust exhibits greater variation in thickness and is remarkably complex compared to crust formed at magmatically robust fast-spreading centers (Cannat 1996; Dunn and Forsyth 2007). In general, seismic layers 2a and 2b form the top 2 km of the oceanic crust and are comprised of extrusive basaltic lava flows and intrusive dikes that serve as conduits that supply the magma erupted on the seafloor. Compared to basalts erupted in other tectonic environments, mid-ocean ridge basalts (MORB) have rather limited compositions. However, they are far from being a homogeneous group, reflecting their diverse sources and melting conditions, as well as the magmatic processes that cause them to differentiate into different rock types (Melson et al. 1976; Langmuir et al. 1992; Perfit and Chadwick 1998; Arevalo and McDonough 2010; O'Neill and Jenner 2012; Gale et al. 2013). The lower and thicker part of the crust (~5 km thick) consists of a wide variety of coarse-grained plutonic rocks that range in composition from ultramafic cumulate rocks to a wide variety of cumulate and isotropic gabbros and even to silica-rich plagiogranites (Coogan 2014). Although detailed surficial sampling and mapping has been completed at a large number of MOR and some sampling has been carried out along steep escarpments and rifts in the crust (tectonic windows), only very limited direct sampling of the deep oceanic crust has been accomplished. Consequently, there are significant uncertainties about the detailed internal structure and overall composition of the crust.

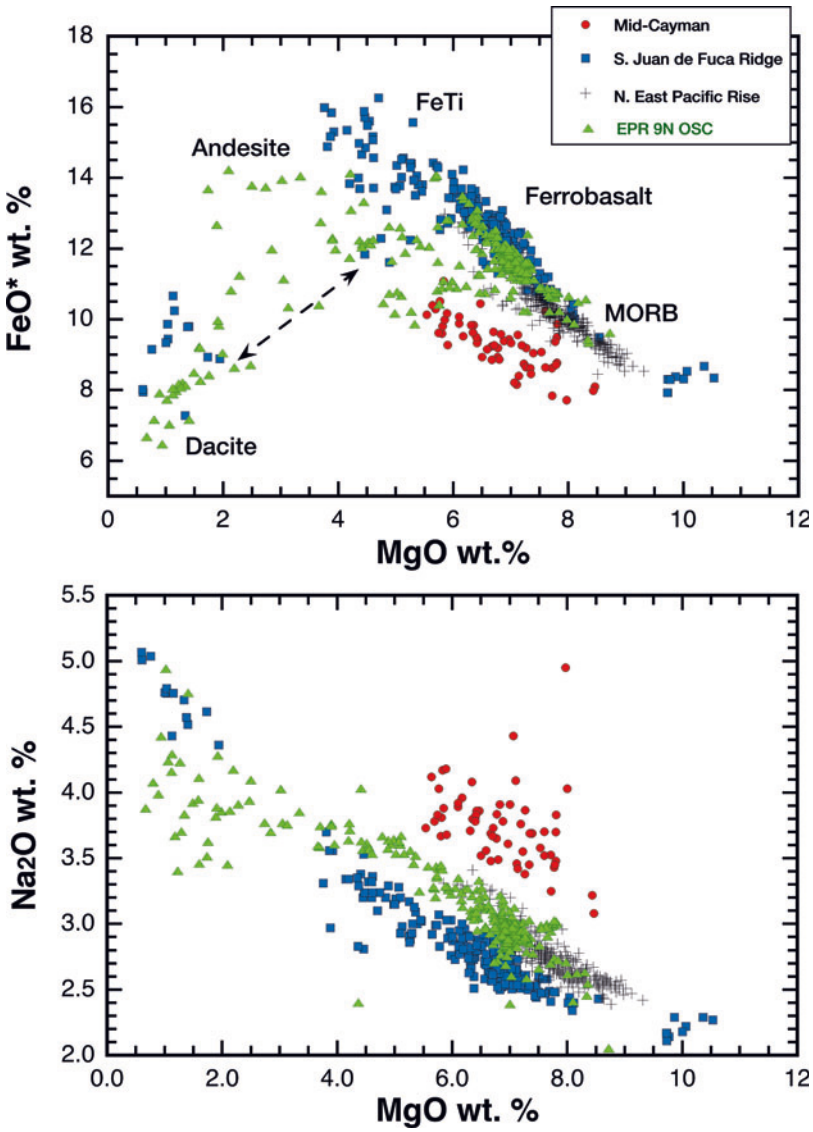
Composition of the Upper Oceanic Crust: Major Elements

The chemical characteristics of MORB provide critical information about their origin (source) and petrologic evolution (Langmuir et al. 1992; Rubin and Sinton 2007; Rubin et al. 2009). Deciphering the magmatic history of MORBMid-ocean ridge basalts (MORB) suites can be relatively straightforward and provides information about the mantle without the complexities that arise, for example, when magmas transit through thick, old continental crust or where subducted sediments contaminate mantle sources beneath island arcs. Slight differences in oceanic mantle sources and the extents and

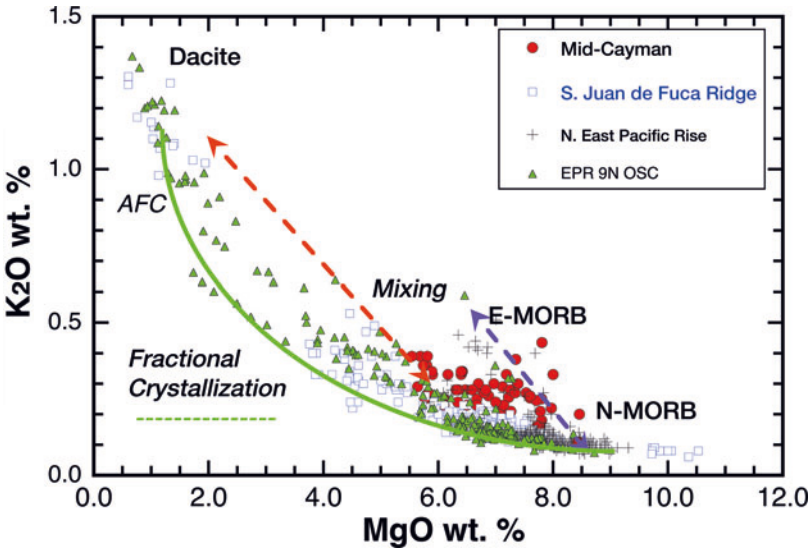
depths of melting of these sources, however, are known to generate "parental melts" with compositions that differ within individual ridge segments and relative to spreading rates (e.g., Klein and Langmuir 1987). Variations in the amounts of FeO, Na_2O (Fig. 1), and K_2O (Fig. 2) at specific MgO contents reflect the effects of source composition and/or extents and depths of mantle melting.

Although as a global rock type MOR lavas are thought to be relatively homogeneous, significant differences in major element compositions also occur on both large (ridges with different spreading rates) and small (adjacent ridge segments) spatial scales as well as over short-time intervals (decades) (Langmuir et al. 1986; Reynolds et al. 1992; Perfit et al. 1994; Perfit and Chadwick 1998; Smith et al. 2001; Rubin and Sinton 2007; Rubin et al. 2009; Goss et al. 2010). Both the most primitive (high MgO wt%) and evolved (low MgO, high SiO_2) tend to erupt at discontinuities in the linear ridge segments such as transform faults and overlapping spreading centers where magma mixing and recharge are limited.

To eliminate some of the complexities of different sources and amounts and depths of melting, Fig. 3 shows only the compositional variation of lavas (glasses) from a limited region of the northern East Pacific Rise. As observed in many other ridges, MORB can range in composition from rare picrites with high MgO contents to ferrobasalts and FeTi (iron-titanium) basalts containing lower MgO concentrations and high concentrations of FeO and TiO_2. The pronounced iron-enrichment trend with decreasing MgO contents (Fig. 3 bottom) is primarily related to fractional crystallization as magmas cool. It is this trend together with their low alkali contents that classifies MORB as belonging to what is known as the subalkaline "tholeiitic magmatic suite." Hence MORB are sometimes also known as ocean floor tholeiites. More



Earth's Oceanic Crust,
Fig. 1 Major element diagram showing the variation of MgO wt% versus FeO (total) wt% (*top*) and Na_2O wt% (*bottom*) in quenched glass from lavas from three mid-ocean ridges that have different spreading rates. Basalts from more slowly spread ridges have relatively higher Na_2O and lower FeO. Volcanic rock names are shown adjacent to their typical range of compositions in *top diagram*. The general elemental trends with decreasing MgO are primarily due to fractional crystallization for typical MORB suites. The variations in FeO and Na_2O at any given MgO reflect different extents and integrated depths of melting (Klein and Langmuir 1987; Langmuir et al. 1992; Gale et al. 2013; White and Klein, 2015)



Earth's Oceanic Crust, Fig. 2 Variations in K_2O wt% versus MgO wt % in MORB from different MOR. Differences in K_2O in lavas with high MgO (e.g., parental N-MORB vs. E-MORB) arise from differences in the K_2O in their mantle source and/or extents of melting of the source. Potassium is an incompatible element in MOR magmatic systems and as such also exhibits large increases in concentration with decreasing MgO as a consequence of fractional crystallization (typical fractional crystallization path shown as *green curve*). Dacite lava compositions reflect additional enrichments from crustal assimilation coupled with fractional crystallization (*AFC*) (Data from Wanless et al. 2010). Some variability may also be due to mixing between N- and E-MORB melts (*purple dashed line*) or between highly evolved, low-MgO magmas and evolved basalts (*red dashed line*) (Modified from Karson et al. 2015)

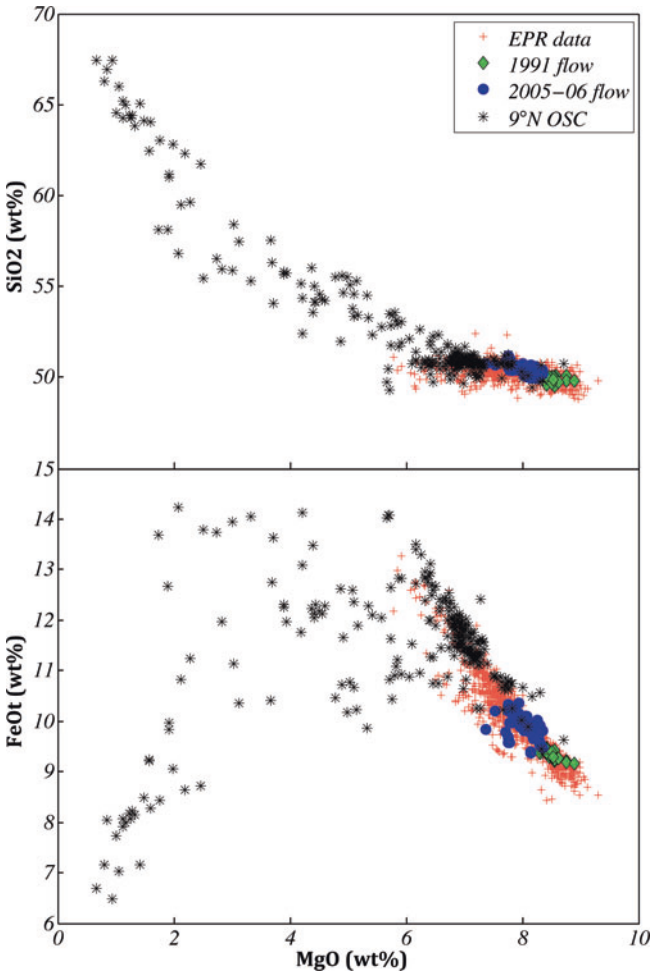
rarely, and almost exclusively, found on fast- and intermediate-spreading rate ridges, are even more differentiated, silica-enriched lavas that include low-potassium MOR basaltic andesites, andesites (icelandites), dacites, and rhyodacites. They have low MgO (<4 wt%) concentrations and SiO_2 contents that range from 52 wt% to more than 70 wt% (Fig. 3 top).

Composition of the Upper Oceanic Crust: Trace Elements

MORB are similar to tholeiitic basalts erupted on oceanic islands like Iceland, the Galápagos, and the Hawaiian Islands in that they are composed of about 50 wt% silica (SiO_2) and lesser amounts of the oxides of magnesium, iron, calcium, and aluminum. However, MORB differ from ocean island basalts (OIBOcean island basalts (OIB)) and oceanic arc basalts in their distinct trace element and isotopic chemical characteristics (Sun et al. 1979; Sun and McDonough 1989; White and Klein 2014). In comparison to other magmatic/tectonic environments, MORB contain very low abundances of K_2O and trace elements such as cesium, rubidium, barium, (large ion lithophile elements), uranium, thorium, niobium, the LREE, and volatile elements. These elements are all considered to be highly incompatible in typical mantle mineral assemblages, and their low concentrations indicate MORB mantle was depleted in these elements by previous melting events. The trace element abundances in MOR lavas relative to an accepted value of "primitive mantle" show the differences in MORB types (Fig. 4). So-called normal mid-ocean ridge basalts, or N-MORB, are those with very low concentrations of highly incompatible trace elements and consequently are characterize as "depleted" relative to basalts from continents, island arcs, or ocean islands. On normalized elemental abundance diagrams, N-MORB exhibit characteristic smooth concave-down patterns reflecting their incompatible element depleted nature. MORB containing slightly greater concentrations of highly incompatible elements, including K_2O, are termed "enriched" or E-MORB (Figs. 3 and 4). In some localities, samples have been recovered that are even more depleted than N-MORB and are consequently classified as D-MORB (Gale et al. 2013).

Differences in the absolute abundances of elements are commonly related to the amount of crystal fractionation that magmas experience during cooling. In contrast, the relative abundances of elements, reflected in the slope of the elemental patterns, are generally considered to reflect source composition and/or extents of melting of different mantle sources (or mixing between different MORB types). Relatively enriched MORB are volumetrically minor on most normal ridge segments but can comprise a significant proportion of the crust around regions influenced by plume magmatism such as the Galapagos Islands, the Azores, and Iceland (e.g., White and Schilling 1978; Schilling 1985; White et al., 1993).

Isotopic investigations have conclusively shown that values of the radiogenic isotopes of strontium, neodymium, hafnium, and lead in N-MORB are consistent with their



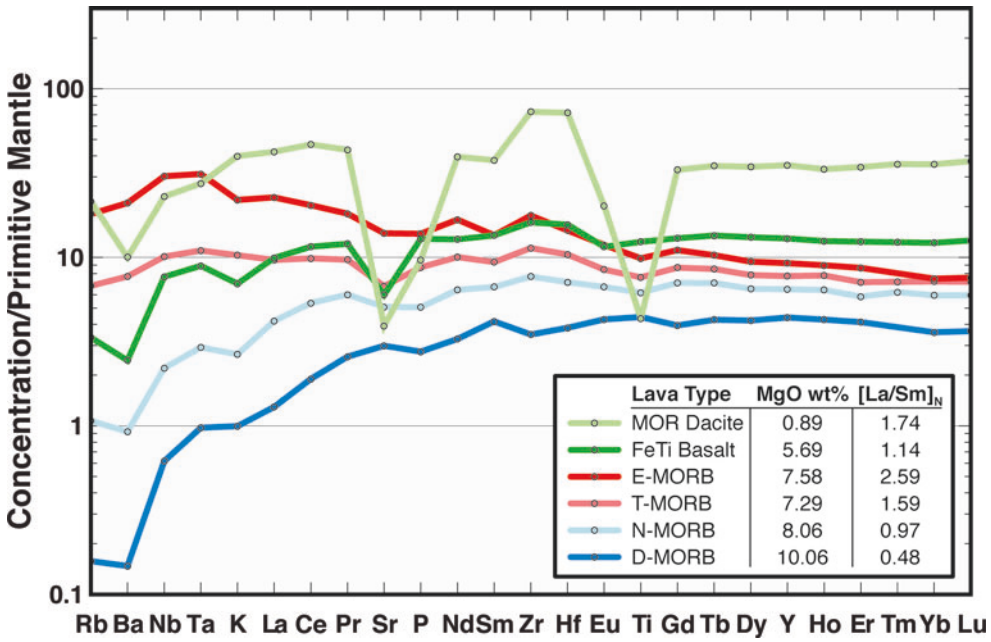
Earth's Oceanic Crust, Fig. 3 Major element variation diagrams of MORB glasses from 9 to 10° N on the East Pacific Rise (*EPR*) as an example of the range of compositions along a fast-spread MOR (Perfit et al. 2012). The plot shows the compositions in ~1600 lavas erupted between 9° 17′ N and 10° N (*red crosses*) compared to those from an Overlapping Spreading Center (OSC) at 9° N (*black asterisks*). The general compositional trends in the basalt data (MgO > ~6 wt%, SiO_2 < 52 wt%) are primarily due to the effects of low to moderate pressure fractional crystallization. Highly evolved andesites and dacites, exemplified by those erupted at around 9° N (Wanless et al. 2010; *asterisks*), are a result of extreme fractional crystallization coupled with crustal assimilation (AFC) along a propagating limb of the OSC, as well as a component of magma mixing between high-SiO_2 magmas and relatively evolved basaltic liquids. Also shown are the composition of lavas from 9° 50′ N that erupted in 1991 and again in 2005–2006 showing the relatively restricted compositional variations that characterize individual MOR eruptions. There are, however, distinct differences in the compositions of lavas erupted in 1991 (*green diamonds*) versus 2005–2006 (*blue circles*) that reflect magma cooling and mixing during the ~15 years between eruptions at the same locality (Goss et al. 2010)

incompatible element-depleted characteristics and indicate this depletion occurred via one or more episodes of partial melting of upper mantle sources beginning more than 2 billion years ago (Hart 1971; Zindler and Hart 1986; Hofmann 1988; White and Klein 2014). E-MORB, on the other hand, have obtained their geochemical characteristics from mantle that has been enriched in incompatible trace elements relatively recently in Earth history (Schilling 1985; Hofmann 1997; Stracke 2012).

The geochemical characteristics of MORB have been used to decipher the composition of their mantle source(s), how much mantle melting occurred, and at what temperatures and pressures (Langmuir et al. 1986, 1992; Putirka et al. 2011; Stracke 2012; Gale et al. 2013). It has been clearly shown that different MOR segments have distinctive chemical characteristics that can be related to differences in regional mantle sources and melting (Schilling et al. 1983; Graham et al. 1992; Michael 1995). On a much smaller scale, detailed geochemical investigations of lavas have documented the dominant effects of fractional crystallization and magma mixing on MORB geochemistry (e.g., Rhodes et al. 1979; Perfit and Fornari 1983; Perfit et al. 1983; Langmuir et al. 1992; Frey et al. 1993; Perfit and Chadwick 1998; Wanless et al. 2010; Rubin 2014). High melt supply at fast-spreading ridges leads to greater degrees of differentiation and homogenization of parental magmas in shallow magma chambers or lenses. At slower-spreading ridges where magma supply is low, episodic magma accumulation in deeper, poorly connected, and more insulated melt reservoirs produces less differentiated and more heterogeneous lavas (Rubin and Sinton 2007; Rubin et al. 2009).

Recent examinations of trace element systematics in MORB and mineralogic reactions in gabbros and xenoliths enclosed in some lavas have indicated that other magmatic processes such as reactive porous flow, in situ crystallization, and frequently replenished, open system magma chambers likely occur in the magma chambers or crystal-melt mush zones beneath ridge axes (Langmuir 1989; Ridley et al. 2006; Kvassnes and Grove 2008; Lissenberg and Dick 2008; Lissenberg et al. 2013; Coogan and O'Hara 2015). The greatest extents of chemical diversity occur at MOR discontinuities such as environments proximal to transform faults, propagating rift tips, and overlapping spreading centers where highly differentiated FeTi basalts are common and iron-rich andesites and dacites are often found (Perfit et al. 1983; Sinton et al. 1983; Rubin and Sinton 2007; Wanless et al. 2010). This is largely due to extensive fractional crystallization coupled with some crustal assimilation (AFC- assimilation fractional crystallization) in crustal magma chambers as a consequence of the relatively cooler thermal regimes and magmatic processes associated with ridge propagation and/or proximity to transform faults.

High-resolution sampling has also documented the inherent short-term and spatial variability of MOR eruptions (Perfit et al. 1996; Smith et al. 2001; Stakes et al. 2006; Bergmanis et al. 2007; Rubin and Sinton 2007; Goss et al. 2010). Significant geochemical differences in closely spaced dikes from



Earth's Oceanic Crust, Fig. 4 Incompatible trace element abundances are commonly used to chemically characterize different types of MORB and to provide information about magmatic processes and sources. Concentrations of incompatible elements (on X-axis) plotted on this primitive mantle-normalized diagram (Values from Sun and McDonough 1989) show the variations in trace element "patterns" for representative E-MORB (enriched), N-MORB (normal), and D-MORB (depleted). Transitional varieties are sometimes referred to as T-MORB. The degrees of enrichment (e.g., increased La/Sm) in MORB show good correlations with K_2O contents (see Fig. 2) and K/Ti ratios. E-MORB have strong enrichments in elements that are the most incompatible during mantle melting (elements on far *left*) relative to the middle to heavy rare earth elements and may be the result of melting enriched mantle source or smaller extents of melting. Highly differentiated N-MORB (low-MgO) FeTi and dacite lavas exhibit overall enrichments of incompatible elements but also some significant elemental depletions (e.g., Sr, P, Eu, Ti) due to their compatibility in minerals crystallizing out of more evolved magmas. All samples shown are from the 8°–10° N segment of the EPREast Pacific Rise (EPR) including the D-MORB from the Siqueiros Transform (From Karson et al. 2015)

sheeted dike complexes that presumably fed overlying lava flows are also consistent with the short-term temporal and spatial variability in ridge magmatic systems (Stewart et al. 2002, 2003; Pollock et al. 2009).

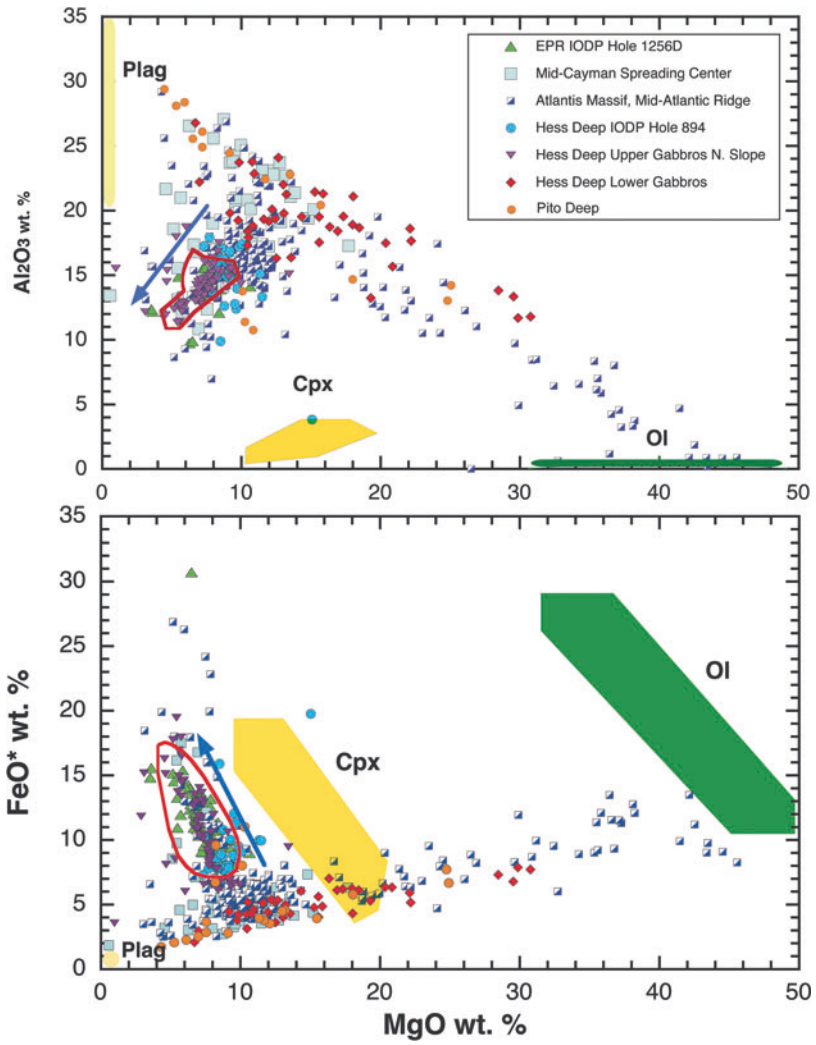
MOR Dikes

Dikes that comprise seismic layer 2b in the oceanic crust have compositions and mineralogies similar, although not identical, to the overlying MORB lavas they supply. Basaltic dikes have been recovered together with lavas at a few tectonic windows and from a few deep-drilling sites. Where unaltered, dikes have major element compositions that, for the most part, overlap the composition of spatially associated lavas (Stewart et al. 2002, 2003; Pollock et al. 2009; Sano et al. 2011). Dikes tend to have coarser textures than lavas, as a consequence of their intrusive nature where cooling rates can be much slower than magma extruded on the seafloor. Ubiquitous patchy, hydrothermal metamorphism of both the lowermost lavas in layer 2a and the sheeted dike complex complicates direct comparisons between the geochemistry of lavas and dikes in some instances.

Gabbroic Layer

The middle to lower portions of the oceanic crust (seismic layer 3) are composed of a complex and varied assemblage of coarse-grained, gabbroic, and ultramafic plutonic rocks. These materials primarily formed by slow cooling and crystallization of melts stored in mushy magma chambers or melt sills (mixtures of crystals and melt) located at depths of ~1–4 km below the seafloor. Unlike crystal-poor volcanic lavas on the seafloor, and the dikes that feed them, these plutonic rocks are comprised of crystalline minerals that reflect the physical and chemical conditions under which they formed. Mafic and ultramafic plutonic rocks constitute the bulk of the oceanic crust (>60% by volume). Most of the gabbroic rocks have mineralogies dominated by plagioclase, olivine, pyroxenes, and minor spinel (Fig. 5). In more evolved rock types, hornblende and Fe-Ti oxides are more prevalent and olivine and spinel less so.

Various magmatic processes that occur in crustal magma chambers such as fractional crystallization coupled with crystal settling and accumulation form cumulate plutonic rock types, commonly exhibiting igneous layering, such as dunites rich in accumulated olivine, anorthosites rich in plagioclase,



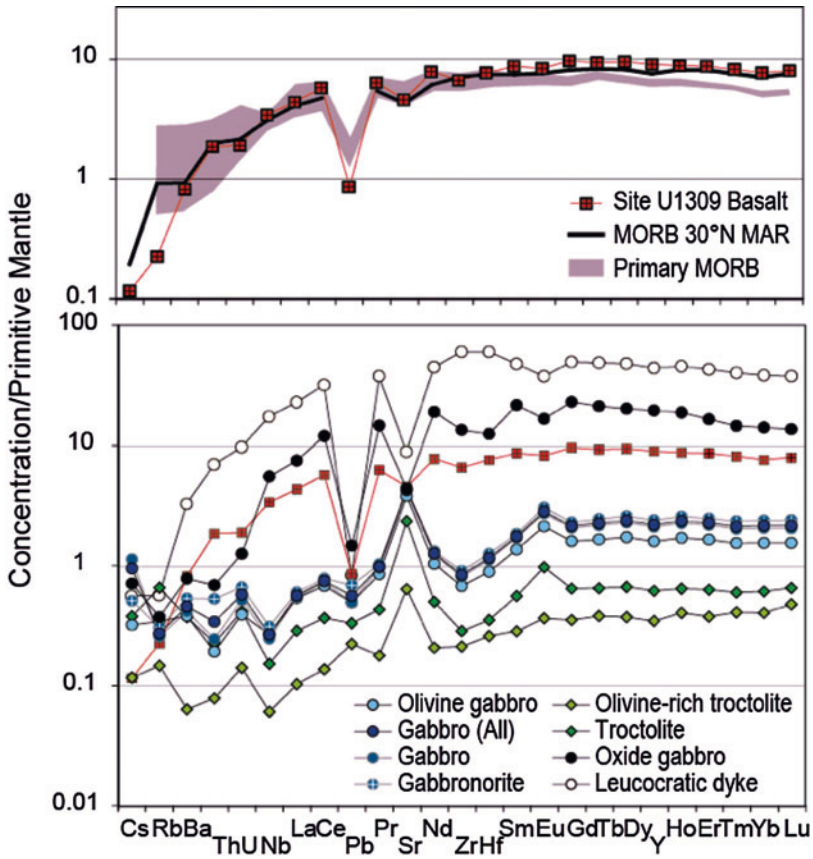
Earth's Oceanic Crust, Fig. 5 Major element variations in gabbros, from various ocean floor localities compared to lavas and dikes from Hess Deep and Pito Deep rifts in the southern Pacific. Overall, gabbros exhibit a much wider compositional range than lavas and dikes due to accumulation of crystals during their formation. MgO-rich olivine gabbros and troctolites have trends that project toward magnesian olivine (*Ol*) compositions (*green field*) whereas high Al_2O_3, low MgO gabbros project toward calcic plagioclase (*Plag*) compositions (*yellow field*). Some more evolved upper crustal gabbros (e.g., IODP Hole 894 from Hess Deep and IODP Hole 1256 from the EPR) have compositions similar to lavas and dikes from Hess Deep (*red outlined field*). These more evolved gabbros, including ferrogabbros, follow the same differentiation trends observed in the lavas and dikes (*blue arrow*) due to low-pressure fractional crystallization (Modified from Karson et al. 2015)

and pyroxenites rich in pyroxenes. Various combinations of these mineral phases form a range of rock types including troctolite, olivine-gabbro, gabbronorite, and ferrogabbros, collectively referred to as gabbroic rocks. Rare silica- and plagioclase-rich intrusive bodies, commonly found in the upper parts of layer 3, are collectively known as plagiogranites.

On the seafloor, plutonic rocks are only exposed on slow- and ultraslow-spread ridges where major faulting has removed the overlying upper crustal units exposing core complexes or where deeply rifted crustal sections provide tectonic escarpments. Along segments of the melt-poor, ultraslow-spread Southwest Indian and Gakkel ridges, serpentinized peridotites (altered mantle rocks) are exposed directly on the seafloor with minor amounts of gabbro (Dick et al. 2003; Cannat et al. 2006). Only the uppermost portions of the plutonic section, away from tectonic windows have been penetrated and sampled by crustal drilling (Coogan et al. 2002; Coogan 2014; Karson et al. 2015). Despite their abundance and importance in constructing oceanic crust, the paucity of exposures and difficulties in recovering gabbros in situ on the seafloor limit our understanding of their origins and overall compositions.

Gabbroic rocks recovered from the oceans display a much greater compositional variation than their spatially related dikes and lavas (Fig. 5). Whereas the major element trends in the lava and dike compositions primarily reflect the differentiation and evolution of primitive liquids via crystal fractionation and magma mixing, the spread in gabbro data mainly reflects crystal accumulation within MORMid-ocean ridges (MOR) magma chambers and crystal mush zones as well as the addition of melts that permeate and react with the cumulate minerals. For example, elemental trends toward high Al_2O_3 and low FeO and MgO contents in plutonic rocks reflect the accumulation of calcic plagioclase in many of the troctolites, gabbros, and anorthositic gabbros whereas more mafic samples with high MgO contents primarily show the effects of magnesian olivine accumulation (Fig. 5).

Gabbroic rocks recovered from the seafloor exhibit a large range of trace element abundances, particularly the highly



Earth's Oceanic Crust, Fig. 6 Normalized trace element concentration diagram showing the relative abundances of incompatible trace elements in gabbros (*lower plot*) from the Atlantis Massif (IODP Site U1309) relative to spatially associated MORB from the MAR (*upper diagram*). The primitive mantle-normalized values are mean values for different types of gabbroic rocks corresponding to the range of compositions shown in Fig. 5. Excluding the highly differentiated oxide gabbro and leucocratic dike, the gabbroic rocks are unlike MORB, characterized by variable but overall low abundances of incompatible trace elements and anomalously high concentrations of Sr and Eu relative to the REE indicative of their cumulate nature. Incompatible trace element pattern for a typical MORB (*red*) from the Mid-Atlantic Ridge is shown relative to the gabbros (*lower plot*) highlighting the differences between intrusive rocks and erupted basalts (From Godard et al. 2009)

incompatible elements that correspond to their varied major element compositions (Fig. 6). The trace element abundances partly reflect the concentrations in parental melts but are also largely dependent on the proportion of cumulus phases (including accessory phases) and intercumulus melts. Chondrite-normalized REE patterns vary from very LREE-depleted troctolites to slightly LREE-enriched ferrogabbros and plagiogranites (e.g., Dick et al. 2000; Coogan et al. 2002; Godard et al. 2009; Gillis et al. 2013; Coogan 2014). Relative to primitive mantle concentrations, some cumulate gabbros have low incompatible element and REE abundances with characteristic positive Sr- and Eu-anomalies – indicative of plagioclase accumulation (Fig. 6). The most evolved ferrogabbros exhibit elevated incompatible element contents and negative Sr- and Eu-anomalies indicative of plagioclase removal from evolving magmas, consistent with their relatively low Al_2O_3 contents. Relatively few gabbros have trace element patterns that mimic those in dikes and lavas. Because the compositions of gabbroic rocks reflect the variable proportions of accumulated phases and different amounts of interstitial melt, they cannot be directly related to mantle-derived melts. However, detailed mineralogic studies suggest many gabbros have experienced complex crystal-melt reactions within crystal mush zones in the lower crust (Natland and Dick 2001; Gao et al. 2007; Suhr et al. 2008; Lissenberg et al. 2013; Coogan 2014).

Bulk Composition of the Oceanic Crust

Because oceanic crust has been incompletely sampled and is heterogeneous on a small scale, it is difficult to determine its bulk chemical composition with confidence. However some estimates have recently been made of the compositions of the volcanic and plutonic layers (Arevalo and McDonough 2010; Gale et al. 2013; Coogan 2014; White and Klein 2014) that, together with their relative volumes, allow some constraints to be placed on the bulk unaltered composition of the oceanic crust. However, one needs to be aware that it is uncertain what proportion of the oceanic crust has been chemically modified by the pervasive hydrothermal alteration associated with submarine volcanism focused at the ridge crest and low-temperature submarine weathering that occurs as crust moves away from the magmatic portion of ridges (Ridley et al. 1994; Alt 1995; Alt 2004; Staudigel 2013). Basically, the interaction of seawater with oceanic igneous rocks in low-temperature (<100 °C), off-axis hydrothermal recharge environments results in increased oxidation and alkali fixation, an increase in volatiles and some large ion lithophile elements (e.g., Rb, K, Cs), and a depletion of Ca, Sr, S that is sometimes associated with depletions in Mg, Si, Co, and Ni (Alt 1995). In deeper regions of the crust where temperatures are higher (>150 °C) and fluid flow may be more restricted, there are significant gains in Na, Mg, H_2O, and CO_2 and

losses in S, Ca, Si, alkalis, and Au. Where temperatures are even higher (>350 °C), which typically occurs in focused or diffuse reaction zones in the dikes and upper gabbros beneath hydrothermal vents and stockwork zones, significant depletion of liable trace metals (e.g., Cu, Zn, Co, Fe) occurs along with the stripping of S and alkalis (Alt 1995). A study of an in situ section of crust drilled at IODP hole 1256D showed significant depletions (> ~8% relative to fresh MORB) in Au, As, Se, S, Cu, Zn, and Pb in the lower portions of the dike layer and uppermost gabbroic samples. However, the same elements are commonly enriched in altered rocks at higher levels in the crust beneath zones of high-temperature venting (Patten et al. 2016). In sections of the upper crust dominated by hydrothermal fluid-rock interactions, major element enrichments and depletions are quite variable and difficult to generalize (Ridley et al. 1994). Overall, the extent of alteration and elemental exchange in the oceanic crust can be highly variable depending on the temperature of the circulating seawater or hydrothermal fluids and the water to rock ratio. Although alteration of the upper portions of the crust clearly plays an important role in determining the bulk composition of the oceanic crust, the overall effects and volume of crust affected are uncertain.

Summary

The composition of the oceanic crust is roughly basaltic; however, an accurate estimate of the bulk composition is difficult to make for many of the reasons discussed above (also see Rubin et al. 2009). Reasonable estimates of the composition of the bulk, unaltered oceanic crust might be made by using two methods. First, one can take a mass-balance approach by determining the compositions and volumetric proportions of the various rocks that comprise the crust but the current state of our knowledge of the lower crust precludes any precision.

Alternatively, one can estimate the composition of primary, mantle-derived magmas that crystallized and differentiated to form the different crustal lithologies observed. Current estimates of primary MOR mantle melts are still somewhat speculative and debatable (Kinzler and Grove 1993). High-MgO lavas that have compositions comparable to some high-pressure melting experiments of likely mantle source rocks include rare picritic lavas and magnesian glasses that have been recovered from a few ocean floor locales (Elthon 1979; van Heerden and le Roex 1988; Natland 1989; Perfit et al. 1996; Wendt et al. 1999). MgO contents for those rocks range from ~10 wt% to over 15 wt% and could have been primary or near-primary mantle melts. But are they representative of the composition of the oceanic crust as a whole? The range of their observed compositions likely reflects variations in source composition, extents of melting, types of melting and minor effects of crustal differentiation. Consequently, the estimates are not very precise and the bulk composition of the oceanic crust remains controversial and a focus of current investigations.

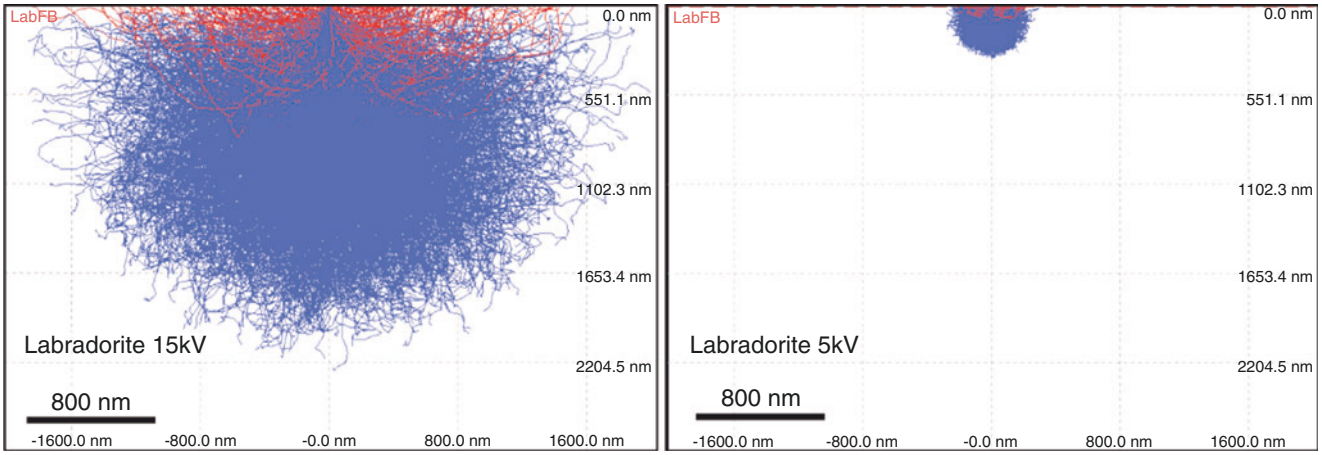
Electron Probe Microanalysis (EPMA)

Stuart Kearns
School of Earth Sciences, University of Bristol, Bristol, UK

Definition

A microanalytical technique yielding quantitative major and minor elemental analysis from solid materials using an electron source and X-ray spectrometers.

The technique of electron probe microanalysis (EPMA) was developed in the 1950s, primarily the outcome of a PhD thesis by Castaing (1951). In the following decade, it became established as the preferred method to characterize the in situ chemistry of very small volumes of mainly inorganic materials, including minerals. The instrument, often referred to as the "microprobe" or sometimes simply the "probe," works by firing a beam of electrons accelerated to high potential (1–30 kV) and focused to a small convergent spot which strikes a flat, usually polished sample. Atoms within the sample undergo inner shell ionization resulting in characteristic X-ray emission. These X-rays are detected and measured by X-ray spectrometers, and their count rates are compared to known standards to yield a primary intensity ratio – the *k*-ratio. As both the incoming electron beam and outgoing X-rays are subject to other interaction events, the *k*-ratio needs to be corrected for matrix effects to yield a quantitative analysis.



Electron Probe Microanalysis (EPMA), Fig. 1 Monte Carlo simulation for labradorite plagioclase at 15 kV and 5 kV accelerating voltage. Electron interaction volume is shown (red lines display emitted backscattered electron trajectories). Generated using Casino (Hovington et al. 1997)

Electron Source

The electron gun is supplied as one of three options –a tungsten filament, lanthanum hexaboride (LaB6), and thermal Schottky Field Emission Gun (FEG). All three sources have been used extensively in scanning electron microscopes (SEM). EPMA has traditionally utilized the tungsten filament as it offers sufficient longevity and good stability, critical for quantitative analysis. Technology advances now mean that both LaB6 and FEG can also supply a very stable beam with the benefit of higher beam brightness yielding a smaller spot size and therefore the promise of higher resolution analysis, with the FEG offering the highest. EPMA instruments include a scan generator and electron detectors such that standard SEM images can be acquired.

Analytical Resolution

The analytical resolution can be determined from Monte Carlo simulation of the electron beam interaction and X-ray emission. The volume of material excited is much greater than that for either secondary electron (SE) or backscattered electron (BSE) yields. It is strongly dependent on both the beam voltage and sample properties, importantly density (Fig. 1).

Typically silicate minerals will yield excitation volumes of several cubic micrometers using a 20 kV electron beam. At 5 kV when the beam penetration is maybe only a few hundred nanometers, submicron resolution is achievable. However, at such low voltage, only low energy X-rays, whose critical excitation potential is exceeded, can be detected.

X-ray Spectrometers

The microprobe usually consists of one Energy Dispersive Spectrometer (EDS) and multiple wavelength dispersive spectrometers (WDS) around the electron column. The EDS benefits from parallel detection of all X-rays. Contrastingly each WDS has a limited wavelength range (depending on its diffracting crystal d-spacing) but benefits from much greater resolution and better peak to background ratio (Fig. 2).

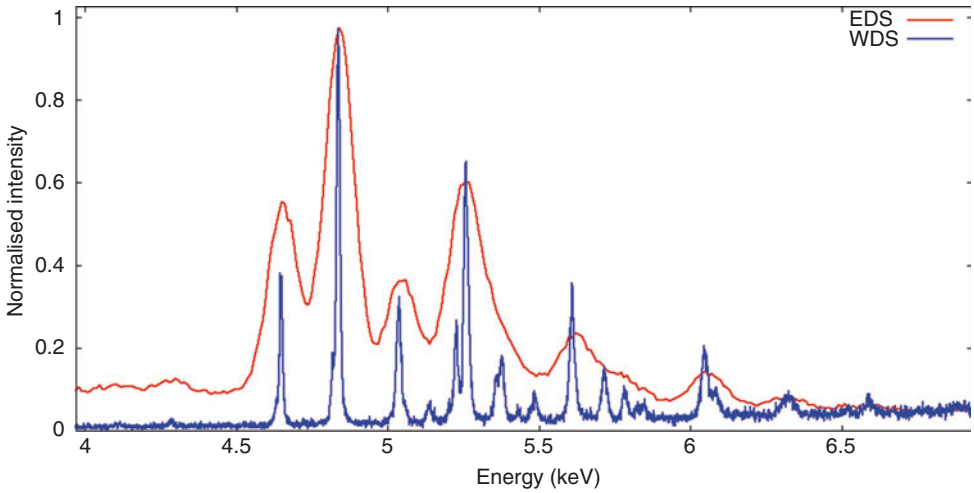
WDS operates on the basis of diffraction of X-ray photons by a crystal of known d-spacing according to Bragg's Law – as the angle of incidence changes, it detects X-rays of varying wavelengths in a serial fashion.

Today's EDS consists of a silicon drift detector (SDD) with the older Si (Li) detectors slowly being replaced. The SDD offers much higher throughput such that it can operate at high beam currents without excessive deadtime – a limitation of Si (Li) detectors. As such, SDD is an ideal accompaniment to WDS on a microprobe. Additionally, to the delight of laboratory managers, the SDD only requires Peltier cooling; the constant necessity to replenish the liquid nitrogen dewers of Si(Li) detectors is no longer needed.

A modern addition to the standard detectors is a soft X-ray emission spectrometer (Terauchi et al. 2012) based on a diffraction grating which offers spectacular resolution improvement in the <1 kV X-ray range. Other detectors usually associated with the SEM, e.g., cathodoluminescence and electron backscatter diffraction are occasionally added to microprobes.

Quantitative Analysis

The conversion of the emitted X-ray signals into a quantitative analysis requires firstly measurement of a set of primary standards containing known concentrations of each of the elements of interest. The derived *k*-ratio from the unknown is then subject to an iterative matrix correction algorithm to take account of the effects of Rayleigh scattering, Compton scattering, and photoelectric absorption. The relationship



Electron Probe Microanalysis (EPMA), Fig. 2 Comparison of Energy dispersive (red) and wavelength dispersive (blue) spectra of LREEs from a monazite recorded under identical operating conditions

between the X-ray intensity and the elemental composition is established using the phi-rho-z method – an integral as a function of mass depth provided the depth distribution of ionizations is known. Several models to predict this function are available, e.g., the double Gaussian model, X-Phi (Merlet 1994). The calculation is performed online and yields a quantitative analysis with elemental concentrations expressed as atomic or weight percents. We would expect an accuracy of better than 2% on samples of known concentration.

As the wavelengths of X-rays increase so the uncertainty becomes greater; absorption effects are larger for "soft" X-rays and the correction factors increase. Consequently at low accelerating potentials, selection of primary standard materials as compositionally similar to the unknowns as possible, and measured under the same operating conditions, is required to yield the best quantitative results (Bastin and Heijligers 2004). Routinely in earth sciences, oxygen is assumed to have a fixed stoichiometry and is rarely analyzed directly – EPMA cannot readily distinguish between varying valence states.

The X-ray spectrum includes a continuum of "*bremsstrahlung*" – literally a braking radiation which forms a background of variable intensity. This must be measured and subtracted from the characteristic peak intensity. The detection limits of EPMA may be defined as 3 standard deviations of the background count rate. Typically, minimum detection limits are in the range 100–500 ppm but in cases where multiple WD spectrometers are assigned to a single element and long count times and high beam currents are employed, less than 10 ppm of some elements may be detectable (e.g., analysis of Ti in quartz, Wark and Watson 2006).

X-ray Mapping

If the beam is scanned across a sample surface, and spectrometers record the X-ray intensity as the scan progresses, a map of that X-ray, and therefore element distribution, can be collected (Wuhrer and Moran 2014). The X-ray signal is subject to the same matrix effects as with spot analyses, but quantitative element maps can be produced. Using EDS, it is now commonplace to acquire a full ED spectrum for each pixel on an image permitting complex phase mapping. As WDS signals are serially collected, a single element is mapped on each spectrometer. As with quantitative analysis the background intensity needs to be subtracted especially when mapping multiphase samples. This can either be measured directly or estimated using a mean atomic number calculation (Donovan and Tingle 1996).

Sample Preparation and Materials

It is imperative that samples are clean, flat, and polished and, as most earth science materials are dielectric, are rendered conductive by application of a coating of conductive material, typically carbon or alternatively, gold, silver, or aluminum. Many materials (especially those containing water or hydroxyl) suffer from beam damage, often a result of phonon excitation. For this reason, a range of optimal operating conditions exist depending upon the task in question. For example, rhyolitic glasses suffer from alkali migration during beam exposure; this is mitigated by using a defocused beam and low beam currents (2–5 nA) (Morgan and London 2005). Time-dependent intensity calculation can be used to restore the intensity back to that expected at $t = 0$ (e.g., halogen analysis in apatites, Goldoff et al. 2012).

Conclusions

Since the 1950s, EPMA has developed into a mature technique and continues to play an important role in the chemical characterization of minerals and glasses. Modern advances offer the prospect of better light element analysis,

quantification of smaller volumes of material, and improved X-ray mapping systems. EPMA occupies a unique analytical niche and compliments many other techniques such as XRF, XRD, SEM, SIMS, LA-ICPMS.

Electronegativity

Barry R. Bickmore and Matthew C. F. Wander
Department of Geological Sciences, Brigham Young University, Provo, UT, USA

Definition

Electronegativity is a measure of the electron attracting power of an atom, or group of atoms, in a molecule. Several electronegativity scales exist, based on different physical properties, but all of them are highly correlated. Electronegativity is used for a variety of purposes in chemistry, providing both an intuitive concept with which to rationalize chemical trends and values that are highly correlated with a number of chemical and physical properties.

Introduction

Electronegativity is one of the most ambiguously defined but useful concepts commonly employed in chemistry. In 1806, Humphry Davy posited that the chemical affinity between two substances was related to the degree of difference in their electrical properties, i.e., their ability to obtain and hold positive or negative charge. Avogadro expanded upon it and gave similar suggestions in 1809, when he envisioned a relative scale on which all simple substances could be ranked, calling it the scale of "oxygenicity." Over the next few years, Jacob Berzelius constructed a similar ranking, calling it the scale of "electronegativity." As theories of atomic structure progressed, the term came to mean the ability of an atom to attract and hold electrons (Jensen 1996). Linus Pauling was the first to create a quantitative scale of electronegativity, based on thermochemical data (Pauling 1932). Since then, a number of electronegativity scales have been proposed, with precise definitions based on various types of chemical and spectroscopic data, and the concept has been extended to encompass groups of atoms or even entire molecules. The fact that there is no unique definition of electronegativity has caused some to question the usefulness of the concept (Bergmann and Hinze 1996), but all these scales are highly correlated, implying they all are based on a fundamental atomic characteristic.

In this entry, we explore the origin of some of the most commonly used electronegativity scales and their applications.

Electronegativity Scales

Pauling (1932) created the first numerical electronegativity scale based on the dissociation energies of single bonds. He noted that there was considerable evidence for the proposition that the energies of normal covalent, single bonds are additive. In other words, if there are two molecules A_2 and B_2, internally held together by covalent single bonds, the dissociation energy of the molecule AB (E_{AB}) will be approximately equal to the mean of the dissociation energies of A_2 and B_2 (E_{AA} and E_{BB}). However, this is not the case when AB is ionically bonded; instead, the dissociation energy of AB is larger than the average of the other two by some amount Δ_{AB}. Pauling represented this using Eq. 1.

$$E_{AB} = \frac{E_{AA} + E_{BB}}{2} + \Delta_{AB} \tag{1}$$

Pauling constructed his electronegativity scale to follow the definition in Eq. 2, where χ_A and χ_B represent the electronegativity values of elements A and B, respectively.

$$\Delta_{AB} = (\chi_A - \chi_B)^2 \tag{2}$$

Thus, the difference in electronegativity values is related to the polarity of the bond between the two atoms, with the more electronegative atom attracting the bonding electrons to a greater extent than the other. Pauling rationalized bond polarity in terms of his valence-bond theory, in particular the resonance between the states AB, A^-B^+, and A^+B^-. That is, the relative electronegativity of the two atoms determines the degree to which some resonance states are favored over the others in the molecule. The calibration of the Pauling electronegativity scale is somewhat arbitrary, in that it is based on the assignment of $\chi = 4.0$ for F (Malito 1995). The scale has since been updated and expanded several times, based on larger sets of thermochemical data (e.g., Allred 1961).

In the Pauling definition, electronegativity is conceived as an intrinsic property of an atom, but its definition is tied to the energies of bonds between atoms. Allred and Rochow (1958), in contrast, developed an alternative scale in which electronegativity is more closely tied to a physical, though oversimplified, picture of the atom itself. Here, electronegativity is conceived as the electric force experienced by an electron on the "surface" of an atom, proportional to the force of attraction between an atomic core (nucleus + core electrons) and a valence electron in terms of a simple Coulomb's Law calculation. Specifically, the Allred-Rochow electronegativity (χ_{AR}) is proportional to the effective nuclear charge (Z_{eff}), obtained by applying Slater's rules (Slater 1930), and inversely proportional to the squared covalent radius (r_{cov}), as shown in Eq. 3, where e is the charge on an electron. The values obtained are then scaled to be comparable to the 4-point Pauling scale (Malito 1995).

$$\chi_{AR} \propto \frac{Z_{eff}e}{r_{cov}^2} \tag{3}$$

This physical picture is oversimplified, in that r_{cov} is a very rough approximation of the distance of valence electrons from the nucleus, and orbital shapes are not taken into account. Furthermore, Allred-Rochow electronegativity values can be problematic, due to the difficulty in obtaining accurate Z_{eff} and the fact that the covalent radii of transition metals lead to lower electronegativity values than other scales.

Although the Allred-Rochow scale is based on an oversimplified physical depiction of the atom, one of its advantages is that it makes a very direct link between electronegativity and its definition as the relative ability of an atom to attract electrons. The Pauling scale, in contrast, is linked to the definition more indirectly via bond dissociation energies. Another scale, the Mulliken-Jaffe electronegativity scale is similar to the Allred-Rochow scale, in that it has a direct connection to the ability of an atom to attract electrons, but the former has the advantage of being based on precisely measurable quantities. Mulliken-Jaffe electronegativity values (χ_{MJ}) are calculated by taking the arithmetic mean of an atom's first ionization energy (the energy required to remove the most loosely bound electron from the neutral atom to make a positively charged ion) and its electron affinity (the energy released when the neutral atom captures one extra electron to make a negatively charged ion). This produces a value in energy units, which is often subsequently scaled to be comparable to Pauling electronegativity values (Malito 1995).

Several other electronegativity scales are commonly used, but all of them are highly correlated with one another, especially among main group elements. Certainly this indicates that all of the precise definitions used are based on highly related atomic and molecular characteristics, but the particular definition employed determines how useful electronegativity values will be for a given application.

Electronegativity and Chemical Context

If the purpose of an electronegativity scale is to provide insight about trends in chemical reactivity, then viewing electronegativity as an intrinsic property of a certain element, rather than a property of an atom in a particular chemical environment, may prove too inflexible for some purposes.

One obvious deficiency is that electronegativity values are often presented as an unchanging property of a given element, when in fact the relative attraction of an atom for electrons should depend strongly on the oxidation state. Electronegativity values for individual oxidation states of some elements have been reported, and, at least for some definitions, there is no a priori reason why they should not be. The main obstacle, in these cases, is usually a paucity of available data for the less common oxidation states (Malito 1995).

Even for a given oxidation state of an element, electronegativity should vary somewhat with chemical context, due to the competition for electrons among all the atoms in a particular neighborhood. For example, all else being equal, the carbon atom in a trifluoromethyl group ($R–CF_3$) must hold its electrons more tightly, with respect to the rest of the molecule, than that in a methyl group ($R–CH_3$), because its association with fluorine would decrease its polarizability. Organic chemists, therefore, commonly assign "group electronegativity" values based on several methods (Mullay 1987).

Finally, the assignment of electronegativity scales to the noble gases has been particularly difficult. For those scales that attempt it, widely varying answers are obtained. While these elements are able to undergo chemical reactivity, their special natures make them difficult to analyze with such a simple model.

Electronegativity Equalization

Some of these methods for calculating group electronegativity rely on the principle of "electronegativity equalization," which

has received strong support from density functional theory (Mullay 1987). That is, as atoms come together and electron density is redistributed toward the more electronegative elements, the electronegativity values of the atoms change with their atomic charge, until all the atoms in a system have equal electronegativity values. In Sanderson's electronegativity equalization method, for example, the final electronegativity of all atoms is taken as the geometric mean of the atomic electronegativity values, and atomic partial charges are assumed to vary linearly with electronegativity (Sanderson 1983).

Sanderson was able to accurately calculate many bond dissociation energies with this method, but it presents certain problems for large molecules and condensed phases. If all atoms in a molecule have the same electronegativity value, for example, and partial charge on atoms of the same element is linked only to their electronegativity, then it follows that all atoms of the same element in a system must have the same partial charge. This contradicts the argument presented above about the behavior of methyl and trifluoromethyl groups, at least if they exist in the same molecule. Therefore, others have developed partial equilibration schemes to more adequately deal with proximity effects (Mullay 1987). Several of these schemes have been implemented to estimate partial charges in molecular mechanics calculations (Oliferenko et al. 2006).

Applications

The utility of the electronegativity concept is that it condenses complex atomic characteristics in a way that correlates with important chemical properties in an intuitively understandable manner. One can readily imagine how a property like electronegativity would affect the behavior of atoms in a molecule, so a model meant to predict some chemical behavior based on correlation with a quantity derived from electronegativity values often also provides a simple, intuitive rationale for that behavior. For instance, the distribution of charge around the atoms in a compound would obviously affect the energies of available orbitals, so it is no surprise that atomic charges calculated from electronegativity equalization correlate well with chemical shifts in X-ray photoelectron spectroscopy data (Bergmann and Hinze 1996). Charge distribution obviously affects bond energies (Pauling 1932), so it is no surprise that the ionic character of a bond is an important predictor of equilibrium constants for acid dissociation reactions (Li 2000; Bickmore et al. 2004). Similar arguments can be made for the relationships between electronegativity and stretching force constants, bond lengths, and many other properties (Bergmann and Hinze 1996).

Summary and Conclusions

The definition of electronegativity, the power of an atom to attract electrons, may be somewhat vague, but it has nevertheless proven to be an extremely useful concept in chemistry and geochemistry. Certainly we have available more rigorous theoretical constructs, like quantum mechanics, but given the difficulty in applying rigorous theory in some contexts, simpler, more intuitive constructs are warranted for creating models of chemical behavior. Furthermore, intuitive concepts like electronegativity are useful as a means to facilitate fluent thinking about chemical problems (Brown 2003).

Although electronegativity is usually presented as an invariant atomic property, it nevertheless depends strongly on the chemical context. Oxidation state and the electronegativity of surrounding atoms, for instance, both affect the attraction of a particular atom for electrons. In fact, it has been shown that the electronegativity values of atoms in a compound at least partially equilibrate with one another, and several electronegativity equilibration schemes have proven useful for calculating on-the-fly atomic charges for molecular simulations.

Elements: Metalloids

David A. Dixon and Monica Vasiliu
Department of Chemistry, University of Alabama, Tuscaloosa, AL, USA

Definition

The metalloids comprise a group of main group elements found along the stair-step line that divides metals (transition metals and other metals) and the nonmetals. The metalloids usually include B (Group 13) in the first row, Si (Group 14) in the second row, Ge (Group 14) and As (Group 15) in the third row, Sb (Group 15) and Te (Group 16) in the fourth row, and At (Group 17) in the fifth row.

Overview

The metalloid are main group elements that are at the border of solids that are metallic (itinerate electrons that are shared freely among the atoms) in contrast to those that are covalent with chemical bonds. Note that as one proceeds down the Periodic Table, the metalloids move to the right in the Table.

The metalloids exhibit mixed properties as they are solids and may even look metallic but may not conduct electricity and heat in the same way as a metal. For example, silicon looks like a metal as it is shiny, but it is not malleable like a metal, and is a poor conductor of heat and electricity. The metalloids can exhibit different crystal structures. For example, white tin is a metallic conductor with a tetragonal crystal structure, whereas below 13 °C, it is known as gray tin and forms a powder with the diamond crystal structure and is a poor conductor. A number of the metalloids are semiconductors as they have intermediate conductivity which is temperature dependent. The ability of the metalloids to conduct electricity and heat is far better than the nonmetals, for example, diamond, which are insulators. As such, the metalloids play a major role in the electronics industry, and modern society is built around the properties of the metalloids and their compounds.

These elements can be quite toxic and are associated with ore formation and hydrothermal chemistry. Thus, compounds of the metalloids play an important role in geochemistry as their compounds make up much of the Earth's surface, for example, the critical role of silicon oxides in geochemical systems. As another example, there is an important role for boron in geochemical systems, and boron isotope fractionation factors play an important role in understanding paleoclimates as the equilibrium constant for the isotope exchange reaction

$$^{10}B(OH)_3(aq) + {}^{11}B(OH)_4^-(aq) \leftrightarrow {}^{11}B(OH)_3(aq) + {}^{10}B(OH)_4^-(aq)$$

is the basis for a method commonly used to infer the pH of the ancient oceans and, hence, the PCO_2 of the ancient atmosphere (Hemming and Hanson 1992; Spivack et al. 1993; Sanyal et al. 1995; Rustad et al. 2010).

Silicon is the most abundant of the metalloids on Earth, and it is the second most abundant element in the Earth's crust after oxygen. Tellurium is the least abundant among the nonradioactive metalloids, and it is one of the rarest stable elements on Earth with an abundance similar to platinum.

Because the metalloid elements are in different columns in the Periodic Table, the properties and reactivity of these elements are quite different from each other due to having different numbers of valence electrons. Boron with three valence electrons forms trivalent molecules with an empty 2p orbital which often makes its compounds good Lewis acids, electron pair acceptors. Boron also forms electron-deficient bonds in compounds such as the boron hydrides. Silicon with four valence electrons forms tetravalent compounds but can expand its valency up to six, for example, SiF_6^{2-} which is important in the fluoridation of water (Jagtap et al. 2012; Urbansky 2002). Germanium with four valence electrons is also tetravalent and like silicon can expand its valency up to six. Arsenic with five valence electrons forms both trivalent and pentavalent compounds as does antimony. The pentafluorides of As (AsF_5) and Sb (SbF_5) are very strong Lewis acids (Christe et al. 2000; Dagani 2003), and SbF_5 with FSO_3H is the basis of magic acid, a super Brönsted acid (Olah et al. 2009). Tellurium can form divalent, tetravalent, and hexavalent compounds. Little is known about the chemistry of astatine, but as it is in the halogen column with seven valence electrons, it would be expected to be able to form mono-, tri-, penta-, and heptavalent compounds.

Conclusions

Metalloids have properties of both metals and nonmetals. Metalloids are solids under standard conditions and can appear to be metallic in appearance, but they are brittle and generally form alloys with metals. They usually do not conduct heat or electricity that well in many forms. Some of the metalloids (silicon and germanium) are semiconductors making them useful in chips for the semiconductor industry. Other metalloids are often used as dopants for semiconductor manufacturing. Because of the variation in the number of valence electrons, the chemistry of these elements can be very different. Overall compounds containing the metalloids are mostly nonmetallic in their properties.

Enthalpy

Carl O. Moses
Provost and Vice President for Academic Affairs, Grand View University, Des Moines, IA, USA

Enthalpy (from the Greek root for "heat"), H, is a thermodynamic function that provides a measure of the energy in a system. Enthalpy is fundamentally important to geochemistry owing to its relationship to heat capacity (see ▶ Geochemical Thermodynamics), its role in defining and giving the temperature dependence of free energy (see ▶ Free Energy), and its relationship to the entropy of the system's surroundings (see ▶ Entropy). The conditions under which H represents a system's energy are different from those under which internal energy, U (see ▶ Geochemical Thermodynamics), represents the energy of the same system. In fact, U is the basis for the definition of enthalpy, $H \And \equiv 6; U + PV$, so a brief background discussion of U is warranted.

The first law of thermodynamics (Eq. 1), in which q is heat and w is work, is the basis for measuring energy changes.

$$\Delta U = q + w \tag{1}$$

Measuring changes in U entails partitioning the work term into P-V (pressure-volume) work ($w = -P\,\mathrm{d}\,V$) and another form of work (e.g., electrical work, w_e) that can be measured to give the energy change for the process in question (Eq. 2).

$$\Delta U = q + w_e - \int P\,\mathrm{d}V \tag{2}$$

Because q cannot be measured, calorimeters are well insulated so that processes are as adiabatic as possible ($q \to 0$). In principle, one could measure $\int P\,\mathrm{d}V$, but it is generally more practical to make $\mathrm{d}V = 0$ (i.e., a constant volume process) so that Eq. 2 yields $\Delta U = w_e$. Such measurements are called constant volume calorimetry (see ▶ Calorimetry).

An alternative measurement of the energy in a system is obtained if P is held constant. In the adiabatic limit, Eq. 2 gives, under constant pressure conditions,

$$\begin{aligned} \Delta U &= w_e - P\Delta V \\ &= w_e - \left(PV_f - PV_i\right), \end{aligned} \tag{3}$$

where the subscripts f and i denote the final and initial states, respectively, of the system. Because V is a state function, the potentials PV_f and PV_i depend only on the states and are independent of the means by which the system is transformed from initial to final state. Similarly, $\Delta U = U_f - U_i$, and rearranging Eq. 3 gives $(U_f + PV_f) - (U_i + PV_i) = w_e$. Thus, the constant pressure calorimetric measurement is $w_e = \Delta(U + PV)$ or $w_e = \Delta H$. Because the difference between constant volume and constant pressure conditions is so fundamental, it is convenient to use U and $H = U + PV$ to obtain different measures of energy in the system. In general, the enthalpy function is more relevant to geochemical processes than internal energy because very few natural systems operate at constant volume.

Differentiating the definition of enthalpy gives

$$\mathrm{d}H = \mathrm{d}U + P\,\mathrm{d}V + V\,\mathrm{d}P. \tag{4}$$

Equation 1 can be written $\mathrm{d}U = q - P\,\mathrm{d}V$, excluding all forms of work besides P-V work, so Eq. 4 can be rewritten as $\mathrm{d}H = q + V\,\mathrm{d}P$, an alternative statement of the first law. Another first law statement is obtained from Eq. 4 when the state function entropy, S, is introduced (see ▶ Entropy), and Eq. 1 written $\mathrm{d}U = T\,\mathrm{d}S - P\,\mathrm{d}V$: $\mathrm{d}H = T\,\mathrm{d}S + V\,\mathrm{d}P$.

By convention, the enthalpy of elements in the standard state (usually 298 K, 1 bar) is 0. For compounds or elements in a state other than the standard state, the standard state enthalpy of formation (from the standard state elements), Δ^0_f, represents the energy of making the bonds of the compound and, therefore, stored in those bonds. For example, graphite, the standard state form of elemental carbon, has

Originally published in: Marshall CP, Fairbridge RW (eds) Encyclopedia of Geochemistry, Springer Netherlands, 1999

$\Delta H^0_f = 0$, while for diamond, $\Delta H^0_f = 1.9$ kJ/mol, indicating that converting the planar trigonal bonds of a mole of graphite into the tetrahedral bonds of diamond requires 1.9 kJ. Thus, the diamond bonds are "stronger" than those of graphite by that amount. Note that, although diamond is a polymorph of elemental carbon, it is not the standard state form, so its ΔH^0_f is nonzero.

Generally, a convenient notation includes a subscript on ΔH^0, where the superscript 0 denotes standard state, which indicates the process (e.g., chemical reaction, phase transition) for which the enthalpy change is calculated:

$$\Delta H^0_{\text{process}} = \sum \nu_i \Delta H^0_{f,i},$$

where the ν_i are the stoichiometric coefficients of the constituents of the system in the final state (e.g., reaction products, $\nu_i > 0$) or the initial state (e.g., reactants, $\nu_i < 0$). For example, the evaporation of liquid water, $H_2O_{(l)} = H_2O_{(g)}$, involves an enthalpy change given by $\Delta H^0_{\text{evap}} = \Delta H^0_{f,} H_2O_{(g)} - \Delta H^0_{f,H\ 2}O_{(l)} = (-241.8) - (-285.8) = 44$ kJ/mol at 298 K. Because $\Delta H^0_{\text{evap}} > 0$, it is said to be an endothermic process, one in which the final state (water vapor) has greater energy than the initial state. Equation 4 shows that, at constant pressure, this energy must be in the form of heat. Another example: the enthalpy change for the quartz-fayalite-magnetite O_2-buffer reaction, $3Fe_2SiO_{4(fay)} + O_2(g) = 2Fe_3O_{4(mag)} + 3SiO_{2(qtz)}$ is given by

$$\Delta H^0_{\text{QFM}} = \left(2\Delta H^0_{f,\text{mag}} + 3\Delta H^0_{f,\text{qtz}}\right) - \left(3\Delta H^0_{f,\text{fay}} + 0\right) = -529.9\,\text{kJ/mol}$$

at 298 K. For this reaction, $\Delta H^0_{\text{QFM}} < 0$, indicating an exothermic process that releases energy to the surroundings (as heat at constant pressure) and yielding a final state with less energy than the initial state.

Like most properties of condensed phases (solids and liquids), enthalpy has only a weak pressure dependence, but the pressure dependence for gases can be quite strong. The differential expression of the isothermal pressure dependence of enthalpy, $(\partial H/\partial P)_T$ can be inverted to give $-(\partial T/\partial P)_H(\partial H/\partial T)_P$. At constant pressure, Eq. 4 shows that $dH = q$ or $dH = dq$. Because constant pressure heat capacity is defined as $C_P = (\partial q/\partial T)_P$ (see ▶ Geochemical Thermodynamics), we have the isobaric (constant pressure) temperature dependence of enthalpy: $(\partial H/\partial T)_P = C_P$. Thus the isothermal pressure dependence of enthalpy becomes $-(\partial H/\partial P)_H C_P$. Finally, the isenthalpic pressure dependence of temperature, $(\partial T/\partial P)_H$, is known as the Joule-Thomson coefficient, μ_{JT}, so we have $(\partial H/\partial P)_T = -\mu_{JT} C_p$.

Enthalpy is temperature dependent in both gases and condensed phases. If C_p is independent of T over the temperature range of interest, i.e., $C_p \neq f(T)$), integration of $(\partial H/\partial T)_P = C_p$ gives the simple relationship $\Delta H = C_P \Delta T$ or $H_{T2} = H_{T1} + C_P \Delta T$. If, however, $C_p = f(T)$, an analytical function for the T dependence of C_p must be substituted and integrated.

Another important relationship can be derived for the temperature dependence of enthalpy, this one for isochoric (constant volume) temperature dependence, $(\partial H/\partial T)_V$; although we will not pursue the complete derivation here. The isobaric thermal expansivity, α, is given by $(1/V)(\partial V/\partial T)_P$, and the isothermal compressibility, k, is given by $-(1/V)(\partial V/\partial T)_T$. If we begin by writing a total differential for $H = f(T, P)$, $dH = (\partial H/\partial P)_T\, dP + (\partial H/\partial T)_P\, dT$, we can derive $(\partial H/\partial T)_V = [1 - (\alpha\mu_{JT}/k)]C_p$.

Introduction and Definition

The Greek word εντροπε refers to a property that indicates the direction of change. In thermodynamics, the entropy function, *S,* provides the criteria for predicting the direction

Originally published in: Marshall CP, Fairbridge RW (eds) Encyclopedia of Geochemistry, Springer Netherlands, 1999

of spontaneous natural processes and the equilibrium state of a system. Entropy is a state function, which means that its value is determined by the state of a system and is independent of the process or path by which the system arrived at its state.

Background and Framework

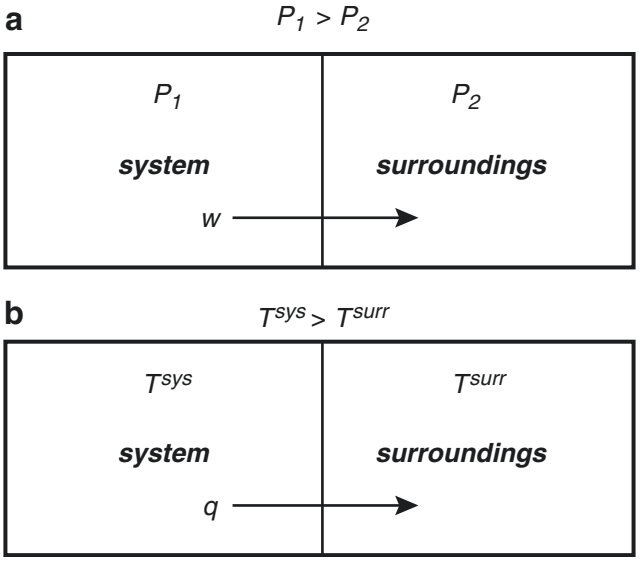
The need for a function such as entropy arises from the fact that the zeroth and first laws of thermodynamics (see ▶ "Geochemical Thermodynamics") fail to explain the direction of natural processes. The zeroth law introduces the concept of thermal equilibrium and provides a basis for temperature measurements, while the first law is a statement of the conservation of energy principle and the interconvertibility of heat (q) and work (w). Heat exchange and work contribute to changes in the internal energy (U) of a system. The first law gives us a tool for meeting one of the principal objectives of thermodynamics: keeping track of energy changes in a system (Eq. 1).

$$\Delta U = q + w \tag{1}$$

A system is a region whose boundaries can be specified. A system's surroundings only include those entities with which it actually interacts, and we define the sum of the system and its surroundings as a thermodynamic universe (not the same as the cosmologic Universe; thermodynamics does not presume to apply on such vast scales). Accordingly, a universe is itself an isolated system (one that does not interact with its surroundings). We can quantify an extensive property (one that depends on the amount of substance present) of a universe by adding the contribution from the system of interest and the contribution from the system's surroundings. For example, $\sum S = S^{\text{univ}} = S^{\text{sys}} + S^{\text{surr}}$.

The Thermodynamic Concept of Entropy

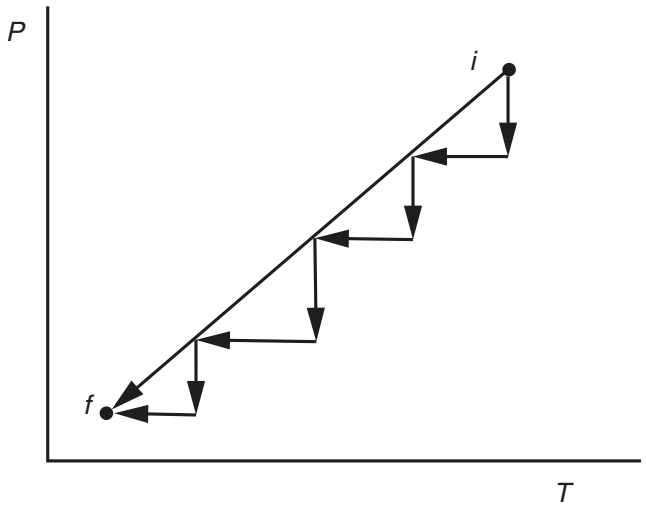
As important as it is to quantify the conservation of energy principle, the first law cannot explain why natural processes proceed spontaneously in one direction only. For example, why is heat spontaneously transferred from a warm object to a colder object, and why do we never observe the cold object to transfer some of its heat spontaneously to the warmer object? One of the earliest statements of the second law, attributed to Rudolph Clausius, holds that there exists no process in which the sole result is the transfer of heat from a cooler to a hotter body. Another early statement, attributed to William Thomson, Lord Kelvin, holds that there exists no process in which the sole result is the complete conversion of heat absorbed by a system into work. Clausius' statement emphasizes the unidirectional nature of natural spontaneous processes while Kelvin's emphasizes the idea that energy is degraded when it is transferred as heat, so not all of the absorbed heat is available for work. The interconvertibility of heat and work is thus asymmetrical. Because energy is conserved. Kelvin's degradation of energy requires a quantity (a potential) into which energy can be converted but not recovered, which is Clausius' unidirectional change.



Entropy, Fig. 1 (**a**) In response to a pressure gradient, the system transfers energy to its surroundings by expanding and, thereby, doing work on the surroundings. The heavy line encloses a universe, and the system is separated from its surroundings by a movable or deformable partition. (**b**) In response to a temperature gradient, the system transfers energy to its surroundings as heat. As in (**a**), the heavy line encloses a universe, but here the system is separated from its surroundings by a rigid, unmovable wall

Consider a mechanical analog that provides a basis for analyzing the second law (Fig. 1a). The apparatus is enclosed by rigid unmovable walls and is well insulated, so it is a universe. Energy will be transferred from the system to its surroundings as the system's volume expands against the lower pressure of the surroundings. The amount of work done by the system on its surroundings is proportional to the change in volume of the system: $w \propto -\Delta V$. Pressure gives the magnitude of the proportionality (higher pressure yields greater work for a given volume change), hence $w = -P\Delta V$.

Decompression may be carried out reversibly or irreversibly (Fig. 2). The irreversible process takes place by, for example, a combination of isothermal and isobaric steps. The changes in P, T, and V are finite, and derivatives relating P, T, V, and U (e.g., dP/dT) are undefined. ΔV or ΔU can be calculated from the P and T coordinates of any pair of intermediate states along the path using an equation of state, relying on the fact that V and U are state functions and $\Delta V = V_f - V_i$ and $\Delta U = U_f - U_i$, regardless of the sequence of



Entropy, Fig. 2 Decompression of the system in Fig. 1a, from initial state *i* to final state *f,* in *P-T* coordinates. There is one reversible path (*the diagonal arrow*); an irreversible path, comprising one set of the infinite number of irreversible steps between *i* and *f,* is also shown

steps (*f* and *i* denote final and initial states, respectively). During an isothermal decompression step, the system must absorb heat from the surroundings ($q^{sys} > 0$), while during an isobaric cooling step, the system must transfer heat to the surroundings ($q^{sys} < 0$). For irreversible processes, $w = \Delta U - q$ depends on the net heat exchange between system and surroundings, so the work depends on the character of the path rather than the change in state of the system. Because we can know ΔV_j and P_j for each j step of the irreversible process, we can calculate w_j for each step, and the total work is given by $w_{irrev} = -\Sigma P_j \Delta V_j$.

If we make the isothermal and isobaric steps increasingly smaller, $\Delta P \rightarrow dP$, $\Delta T \rightarrow dT$ (accordingly, $\Delta V \rightarrow dV$ and $\Delta U \rightarrow dU$, the behavior of the system approaches reversibility. The reversible process is continuous, and derivatives like dP/dT are defined. As a consequence of the infinitesimal size of the steps, $q \rightarrow 0$. The reversible behavior of the system is singular, because there can be only one path in which the steps are infinitely small. Now, $w_{rev} = \Delta U$ because no heat is exchanged between system and surroundings, but w is no less dependent on path than before because we have stipulated a very specific path. As the steps become infinitesimal, the summation used for the total work becomes an integral, so $w_{rev} = -\int_i^f P\, dV$, and $dw_{rev} = -P dV$. Because no heat is exchanged, all of the energy of the system is available for work, so $w_{max} = w_{rev}$ and for any arbitrary process, $w \leq w_{rev}$.

Now consider a universe in which the system is separated from its surroundings by a unmovable diathermal wall (one that readily permits heat exchanges but does not permit work; Fig. 1b). If heat is transferred in infinitesimal increments (dq) by allowing the temperature of the system and its surroundings to differ only very slightly, the heat transfer can be made reversible. This energy transfer is completely analogous to the case of the pressure gradient, but now energy is transferred down the gradient as heat rather than work, entropy change is the quantity analogous to volume change, and in place of $w \propto -\Delta V$, we have $q_{rev}^{sys} \pi \Delta S^{sys}$. Because higher temperatures yield greater heat transfer for a given entropy change, T determines the magnitude of the proportionality between the heat transfer and the entropy change, and $dq_{rev}^{sys} = T\, dS^{sys}$. Whether applied to the system or to the surroundings, the defining expression for entropy holds that entropy is the state function whose differential is given by the reversible transfer of heat divided by temperature (Eq. 2).

$$dS = \frac{dq_{rev}}{T} \tag{2}$$

We might similarly say that volume is the state function whose differential is given by work divided by pressure [$dV = (-dw_{rev}/P$]. Both expressions emphasize the relationships between energy changes as work or heat and corresponding changes in volume (energy/pressure) or entropy (energy/temperature). A given amount of work (heat) creates a larger volume (entropy) change in a system of lower pressure (temperature).

Because work and heat are both potentials, dw and dq correspond to the potential gradients P dV and T d*S,* and PV and TS are potentials. With entropy defined and work restricted to volume changes, the first law may be written as $dU = T\, dS - P\, dV$ (each of *U, S,* and *V* is measured for the system), a form that is sometimes called the first part of the second law of thermodynamics.

The Clausius Inequality

Reversibility means that a transfer of energy between the system and its surroundings can be reversed without changing the state of the surroundings. At every stage of the process, the system and its surroundings are in equilibrium. Reversibility is an idealization, but one that can be approached very closely in many systems often well within the limits of measurement error; it is a pragmatically viable concept. In the reversible heat transfer example above, the heat transferred from the system to the surroundings was exactly balanced by the heat gain in the surroundings. We can write $dq_{rev}^{sys} = -dq_{rev}^{surr}$ or $dq_{rev}^{sys}/T = -dq_{rev}^{surr}/T$, so $dS^{sys} = -dS^{surr}$. We conclude that $dS^{univ} = dS^{sys} + dS^{surr} = 0$ for a reversible process.

What if we carry out the heat transfer irreversibly? In this case, the process could not be reversed without causing a definite change in the state of the surroundings. Because no change results to the state of the surroundings in a reversible process, the change in the state of the surroundings must be larger for an irreversible process than for a reversible one.

From the point of view of the system, therefore, $dq^{sys}_{irrev} < dq^{sys}_{rev}$ (generally, $dq^{sys} \leq dq^{sys}_{rev}$, just as we concluded for work in the previous section), which means that $dq^{sys}_{irrev}/T < dq^{sys}_{rev}/T$ and $dq^{sys}_{irrev}/T < dS^{sys}$. Generally, $dq^{sys}/T \leq dS^{sys}$; the "<" condition applies to irreversible processes, while the "=" condition applies to reversible processes. Because S is a state function, $\oint dS^{sys} = 0$, where the $\oint$ denotes a loop integral and implies a path from state A to state B to state A (i.e., a cycle in which the final state is congruent with the initial state). Accordingly, $\oint dq^{sys}_{rev}/T = 0$, but generally,

$$\oint \frac{dq^{sys}}{T} \leq 0. \tag{3}$$

If we take a system from an initial state i to a final state f by an arbitrary process, which may be reversible or irreversible, and then return it to i by a reversible process, we can write:

$$\oint \frac{dq^{sys}}{T} = \int_i^f \frac{dq^{sys}}{T} + \int_f^i \frac{dq^{sys}_{rev}}{T}.$$

The second term on the right hand side is equivalent to $-\int_i^f dS^{sys} = -\Delta S^{sys}$ (switching the limits of integration while changing the sign is legitimate only for a state function), so:

$$\oint \frac{dq^{sys}}{T} = \oint_i^f \frac{dq^{sys}}{T} - \Delta S^{sys}. \tag{4}$$

By combining Eqs. 3 and 4,

$$0 \geq \int_i^f \frac{dq^{sys}}{T} - \Delta S^{sys},$$

or

$$\Delta S^{sys} \geq \int_i^f \frac{dq^{sys}}{T}, \tag{5}$$

which is the Clausius, or fundamental, inequality. In an isolated system, $dq^{sys} = 0$ always, and because an isolated system is the same as a universe, the Clausius inequality leads to $\Delta S^{univ} \geq 0$, which is the second part of the second law. A spontaneous process in a universe must be irreversible (i.e., caused by an internal potential gradient), so $\Delta S^{univ} > 0$. For a universe at equilibrium (no internal gradients), $\Delta S^{univ} = 0$. The second part of the second law provides the criterion for the direction of spontaneous processes (the direction that yields an increase in the entropy of a universe) and the criterion for equilibrium (the state in which the entropy of a universe remains constant). There are no known processes that cause a decrease in the entropy of a universe. Energy must be conserved, but S^{univ} is a very different sort of function because it is conserved only under the special conditions of the equilibrium state; if there are internal gradients, entropy will be generated!

Using the Second Law Entropy Criteria for Direction and Equilibrium

Only the sum of ΔS^{sys} and ΔS^{surr} must be ≥ 0, so it is possible for $dS^{sys} \leq 0$. For a spontaneous process, any decrease in S^{sys} must be accompanied by an offsetting increase in S^{surr}, and at equilibrium, where $dS^{univ} = 0$, $dS^{sys} = -dS^{surr}$ (including the possibility that both dS^{sys} and dS^{surr} are zero). Because the second law criteria for direction and equilibrium are expressed only in terms of dS^{univ}, it seems that we need to know something about both dS^{surr} and dS^{sys} in order to use those criteria.

Because TS^{sys} represents a potential quantity unavailable for doing work, we define free energy as the net energy available for doing work. With two measures of the total energy in a system (internal energy, U, and enthalpy, H; see ▶ "Enthalpy"), there are two measures of free energy: $A \equiv U - TS^{sys}$ and $G \equiv H - TS^{sys}$ (see ▶ "Free Energy"). For our present purposes, we will concentrate on G, which is called Gibbs free energy. In differential form and under isothermal conditions ($dT = 0$),

$$dG = dH - T\,dS^{sys}. \tag{6}$$

Each quantity in Eq. 6 is a property of the system. Is there a way to use free energy to determine the direction of spontaneous processes or equilibrium?

For an arbitrary (reversible or irreversible) isothermal process, $dS^{surr} = dq^{surr}/T = -dq^{sys}/T$. Summing the contributions to dS^{univ} from the system and the surroundings and referring to the second part of the second law,

$$dS^{univ} = dS^{sys} - \frac{dq^{sys}}{T} \geq 0. \tag{7}$$

With Eq. 7 we can express dS^{univ} in terms of quantities measured for the system, but we need a proxy for dq^{sys} because we cannot measure q. Under constant pressure conditions, $dq^{sys} = dH$, so we can write $dS^{sys} - dH/T \geq 0$, identifying $-dH/T$ with dq^{surr} and dS^{surr}. With this identity and the result of dividing Eq. 6 by $-T$, we have an expression that is congruent with $dS^{univ} = dS^{surr} + dS^{sys}$ (Eq. 8; an analogous expression can be established for A and U).

$$\frac{-dG}{T} = \frac{-dH}{T} + dS \tag{8}$$

Equation 8, in which G, H, and S are all properties of the system, is one of the most important equations in chemical thermodynamics, and it allows us to translate the second law criteria for direction and equilibrium into free energy terms: $-\mathrm{d}G/T \geq 0$. Spontaneous processes lead to minimizing G ($\mathrm{d}G < 0$), and at equilibrium, $\mathrm{d}G = 0$.

Measuring Entropy

For entropy to be a useful function, we need a way to measure it. From Eq. 2, a system heated from an initial temperature T_i to a final temperature T_f, must undergo an entropy change given by:

$$\Delta S^{\mathrm{sys}} = \int_{T_i}^{T_f} \frac{\mathrm{d}q_{\mathrm{rev}}^{\mathrm{sys}}}{T}.$$

If we treat T_i as a reference temperature (T_{ref}), we define a scale of entropy measurements, and for any T,

$$S_T^{\mathrm{sys}} = S_{T_{\mathrm{ref}}}^{\mathrm{sys}} + \int_{T_{\mathrm{ref}}}^{T} \frac{\mathrm{d}q_{\mathrm{rev}}^{\mathrm{sys}}}{T}.$$

Given that constant pressure heat capacity C_p is defined as $(\partial q/\partial T)_{\mathrm{P}}$ (see ▶ "Heat Capacity"), we have:

$$S_T^{\mathrm{sys}} = S_{T_{\mathrm{ref}}}^{\mathrm{sys}} + \int_{T_{\mathrm{ref}}}^{T} \frac{C_P \mathrm{d}T}{T}. \tag{9}$$

If $C_p \neq f(T)$, Eq. 9 gives $S_T^{\mathrm{sys}} = S_T^{\mathrm{sys}} + C_p \ln(T/T_{\mathrm{ref}})$. Over temperature ranges for which $C_p = f(T)$, we need at temperature-dependent expression for C_p that is integrated in Eq. 9. If the temperature range spans a phase transition, an entropy change $\Delta S_{\mathrm{trans}}^{\mathrm{sys}} = \Delta H_{\mathrm{trans}}/T_{\mathrm{trans}}$ must be added to Eq. 9. A rational choice for T_{ref} is 0 K, so a complete expression for the entropy of a gas (i.e., $T > T_{\mathrm{boil}}$) is:

$$S_T^{\mathrm{sys}} = S_0^{\mathrm{sys}} + \int_0^{T_{\mathrm{melt}}} \frac{C_P^{\mathrm{solid}} \mathrm{d}T}{T} + \frac{\Delta H_{\mathrm{melt}}}{T_{\mathrm{melt}}} + \int_{T_{\mathrm{melt}}}^{T_{\mathrm{boil}}} \frac{C_P^{\mathrm{liquid}} \mathrm{d}T}{T} + \frac{\Delta H_{\mathrm{vap}}}{T_{\mathrm{boil}}} + \int_{T_{\mathrm{boil}}}^{T} \frac{C_P^{\mathrm{gas}} \mathrm{d}T}{T}$$

For a liquid ($T_{\mathrm{melt}} < T < T_{\mathrm{boil}}$), the last two terms are not needed, and the second integration is carried from T_{melt} to T; for a solid ($T < T_{\mathrm{melt}}$), the last four terms are not needed, and the first integration is carried from 0 to T. In practice, C_p data for the lowest temperatures ($<\sim$10 K) are extrapolated from a function like aT^3, which is fitted to C_p data for temperatures up to ~50 K.

The third law of thermodynamics holds that all pure substances have the same entropy at $T = 0$ K. Thus, for all pure substances, S_0^{sys}, the reference entropy, is the same. For convenience, we use $S_0^{\mathrm{sys}} = 0$. The so-called absolute entropies of substances, S_T^{sys}, are given the symbol S_T^0 and have units of energy/temperature/amount (e.g., J/K/mol).

Values of S_T^0, based on calorimetric and heat capacity measurements, are tabulated and can be used to calculate standard state entropy changes, ΔS_R^0, for reactions. Entropy changes in processes are calculated from:

$$\Delta S_{\mathrm{process}}^0 = \sum \nu_j \Delta S_{T,j}^0,$$

where the ν_j are the stoichiometric coefficients of the constituents of the system in the final state (e.g., reaction products, $\nu_j > 0$) or the initial state (e.g., reactants, $\nu_j < 0$). The subscript R may be substituted by a more informative subscript denoting the specific process in question (e.g., melt or boil). Note that S_T^0 is not the same as $\Delta S_f{}^0$. By convention, the ΔG_f^0 for an element in the standard state (usually 298 K, 1 bar) is 0, as are ΔH_f^0 and ΔS_f^0. Absolute entropy gives the entropy change for a substance from 0 K to T, so $S_T^0 > 0$. Furthermore, for a nonelement, S_T^0 includes the entropy of formation, ΔS_f^0, of that substance plus the absolute entropies of its constituent elements. For example, at 298 K, graphite, the standard state form of elemental carbon, has $\Delta H_f^0 = \Delta G_f^0 = \Delta S_f^0 = 0$, while for diamond, $\Delta H_{f,\mathrm{dia}}^0 = 1.9$ kJ/mol and $\Delta G_{f,\mathrm{dia}}^0 = 2.9$ kJ/mol. The difference, 1 kJ/mol, is the potential $-T\Delta S_{f,\mathrm{dia}}^0$, so $\Delta S_{f,\mathrm{dia}}^0 = -3.36$ J/mol/K. Note that $\Delta S_{f,\mathrm{dia}}^0 = S_{\mathrm{dia}}^0 - S_{\mathrm{gra}}^0 = (2.38 - 5.74)$ J/mol/K. Values of ΔS_f^0 are not usually tabulated. In calculating ΔS_R^0, this distinction is transparent. For the graphite = diamond transition,

$$\begin{aligned}\Delta S_R^0 &= S_{\mathrm{dia}}^0 - S_{\mathrm{gra}}^0 = (2.38 - 5.74)\,\mathrm{J/mol/K} \\ &= \Delta S_{f,\,\mathrm{dia}}^0 - \Delta S_{f,\,\mathrm{gra}}^0 = -3.36 - 0\,\mathrm{J/mol/K}\end{aligned}$$

It is important to recognize, however, that the distinction matters in calculations of ΔS_f^0 for nonelements, which are in turn required with values ΔH_f^0 of in calculations of ΔG_f^0.

Clapeyron Equation

Entropy has practical utility beyond providing criteria for the direction of spontaneous change and equilibria. If we remove the isothermal constraint used in deriving Eq. 6 and substitute $\mathrm{d}H = T\,\mathrm{d}S + V\,\mathrm{d}P$, we have:

$$\mathrm{d}G = V\,\mathrm{d}P - S\,\mathrm{d}T \tag{10}$$

(see ▶ "Free Energy" for more discussion of the derivation of Eq. 10). Then, if we define chemical potential, μ, as the partial molar Gibbs free energy of a substance j, $\mu_j = (\delta G/\delta n_j)_{T,P,nk \neq j}$ (the subscripts denote constant pressure, temperature, and composition; see ▶ "Free Energy"

and ▶ Geochemical thermodynamics), Eq. 10 can be rewritten in terms of $\mu(P,T)$: $\mu_j = \overline{V}_j^0\,dP - \overline{S}_j^0\,dT$, where the overbar on $\overline{V}_j$ and $\overline{S}_j^0$ denotes a molar quantity. At equilibrium, two coexisting phases (A and B) must have the same μ. Accordingly, $\mu_A = \mu_B$, and $\overline{V}_A^0\,dP - \overline{S}_A^0\,dT = \overline{V}_B^0\,dP - \overline{S}_B^0\,dT$. After collecting like terms, we have:

$$\frac{dP}{dT} = \frac{\Delta S_R^0}{\Delta V_R^0} \tag{11}$$

Equation 12 is the Clapeyron equation, which is the basis for deriving the equations for phase boundaries in P-T coordinates ($P = f(T)$). Note that ΔS_R^0 and ΔV_R^0 are taken to be molar quantities. No assumptions or approximations are involved in the derivation of Eq. 12, so it is exact and applies to all phase changes (see section "Clapeyron Equation").

The Molecular Basis of Entropy

From the thermodynamic point of view, there is no need to establish a molecular basis for any process; all that is necessary is to account for the energy changes. From this perspective, the idea that entropy is the state function given by Eq. 2 is sufficiently powerful and leads to many other useful relationships. A somewhat deeper measure of understanding can, however, be acquired by inquiring into the molecular basis of entropy.

The fundamental proposition of statistical thermodynamics is that a system contains a very large number of molecules, the average properties of which determine the behavior or state of the system. The goal, then, is to calculate the average properties. The most basic property of a molecular system is the distribution of molecules among the system's energy levels, which are quantized according to the rules of quantum mechanics. The lowest energy level is the ground state of a molecule; all other states have higher energy. The configuration of a system expresses how many molecules are in each state. There are W different ways to organize N molecules into a given configuration:

$$W = \frac{N!}{n_0!n_1!n_2!\ldots},$$

where n_j represents the number of molecules in state j, and $j = 0$ represents the ground state. The most probable configuration of a system is the one with the largest W subject to the constraints $\Sigma n_j = N$ and $\Sigma n_j \varepsilon_j = E$ (ε_j is the energy of state j) so that the number of molecules N and the total energy E of the system are fixed. For the most probable configuration, W is denoted by W^* and each n_j by n_j^*. The Boltzmann distribution gives the ratio of each n_j^* to N as a function of the discrete (quantized) ε_j :

$$\frac{n_j^*}{N} = \frac{\exp(-\varepsilon_j/kT)}{q},$$

where k is the Boltzmann constant (1.381×10^{-23}J/K), and q is the molecular partition function, $\Sigma_j \exp(-\varepsilon_j/kT)$. Deriving and interpreting partition functions for different modes of molecular motion and different systems is one of the principal tasks of statistical thermodynamics.

For the sake of brevity, we will assume that macroscopic thermodynamic systems are ergodic (properties averaged over a very large number of identical systems are the same as the properties of one such system averaged over a long period of time) and bypass the development of canonical ensembles, but the reader is cautioned that the ergodic hypothesis and our assumption are untested. The total energy term, E, used above is the difference between the internal energy of a system at T and U_0, the system's internal energy at $T = 0$, so the most probable configuration gives $U - U_0 = n_j^* \varepsilon_j$. By differentiation, we obtain an expression for changes in U with contributions from changes in U_0, changes in the energy states of the system, and changes in the distribution of molecules among the energy states (Eq. 12).

$$dU = dU_0 + \sum n_j^*\,d\varepsilon_j + \sum \varepsilon_j\,dn_j \tag{12}$$

We observe that reversible work changes internal energy by altering the energy levels of a system but does not alter the n_j^* distribution of molecules in the levels, so we identify $dw_{rev} = dU_0 + \sum n_j^*\,d\varepsilon_j$. On the other hand, reversible heat transfers change the distribution without altering the levels, so we identify $dq_{rev}^{sys} = T dS^{sys} = \Sigma \varepsilon_j\,dn_j$, or:

$$dS^{sys} = \left(\frac{1}{T}\right)\sum \varepsilon_j\,dn_j. \tag{13}$$

Under isothermal conditions, N is fixed, so $\Sigma dn = 0$ on its own. If molecules shift from low energy levels ε_{low} to high energy levels ε_{high}, however, and $dn_{low} < 0$ and $dn_{high} > 0$ (in fact, $dn_{low} = -dn_{high}$). Accordingly, $\varepsilon_{low} dn_{low} < 0$ and $\varepsilon_{high} dn_{high} > 0$. Because of the energy difference, $|\varepsilon_{low}\,dn_{low}| < |\varepsilon_{high}\,dn_{high}|$ so $\Sigma \varepsilon_j\,dn_j > 0$ and $T dS^{sys} > 0$. If we define entropy as being proportional to W^*,

$$S = k \ln W^*, \tag{14}$$

we can derive the established identity (Eq. 13) by another route beginning with Eq. 14. That derivation is beyond the scope of this article, but we conclude that it validates the definition in Eq. 14. If we increase the temperature of

the system, more energy levels become accessible, so the number of ways to distribute molecules among those energy levels and still satisfy the constraints increases. Accordingly, W^* and S also increase. Decreasing temperature yields lower values of W^* and S. In the limit of $T \rightarrow 0$ K, the only accessible energy level is the ground state, so $\lim_{T \rightarrow 0} W^* = 1$. It follows that $\lim_{T \rightarrow 0} S = 0$, which is consistent with our earlier discussion of the third law and absolute entropies.

Epigenesis

Jamie J. Wilkinson
Department of Earth Sciences, Natural History Museum, London, UK
Department of Earth Science and Engineering, Imperial College, London, UK

Definition

Epigenesis is a term derived from the Greek (epi+genesis = after formation) that is primarily used to describe a geological process involving the addition, modification, and/or removal of minerals from a rock subsequent to its formation. It typically refers to a *metasomatic* process that has, as well as transforming the mineral assemblage, modified the chemical composition and even textural properties of the bulk rock via the addition or removal of elements. The term may be applied in geomorphology to the formation of glacial valleys, in soil science to soil formation, and in sedimentology to the process of formation of a mineral, texture, or structure subsequent to compaction – thus partly synonymous with *diagenesis*. However, it is most commonly used in geochemistry in relation to the formation of mineral deposits – in particular those formed from *hydrothermal solutions* such as sediment-hosted mineral deposits (Brown 2014; Ramanaidou and Wells 2014; Wilkinson 2014) and volcanogenic massive sulfide deposits (Franklin et al. 1981).

Epigenetic Mineral Deposits

The early subdivision of mineral deposits into those that formed by *syngenesis* (process of formation similar to that which formed the enclosing rock and, in modern usage, also implying a temporal connection) and *epigenesis* (introduced into a preexisting rock) recognized the fundamental difference in mineral deposit morphology that can result from these end-member processes (Lindgren 1913). The morphology is important for mineral exploration and mining because different methods are used to recognize and mine ore from *syngenetic* deposits that are lenticular and conformable with stratigraphic units (described as *stratiform*) and *epigenetic* deposits that may have tabular, pipelike, or irregular geometries that are contained within specific stratigraphic units (*stratabound)* or crosscut stratigraphy. In sedimentary ore systems, there is overlap in the usage of terms, with *syngenesis* often considered synonymous with *early diagenesis* and *epigenesis* with *late diagenesis* (or *epidiagenesis*; particularly in the USA). *Syndiagenesis* has been used as a term by economic geologists to separate the stages of syngenesis and epigenesis (e.g., Bartholomé et al. 1972; Boast et al. 1981). In carbonate sedimentology, *syndiagenesis* is broadly synonymous with *eogenesis*.

Epigenetic deposits may form in two general ways: either by infiltration of fluids into intergranular porosity with precipitation of ore and gangue minerals in pore space and by replacement of existing grains or by infiltration of fluids along fracture permeability or brecciated zones with precipitation of minerals to form veins or breccia cements. Gradations between the two end-members frequently occur, where mineralization spreads into the wall rocks surrounding vein systems or into breccia clasts. Replacement can be either highly selective, preserving primary rock components such as fossils or primary rock-forming minerals and textures, or may be texturally destructive so that primary features are obscured.

Controversy Regarding the Syngenetic or Epigenetic Origin of Mineral Deposits

The distinction between syngenesis and epigenesis is not straightforward and has led to extensive debate in the literature surrounding the processes responsible for the formation of certain types of mineral deposits, such as sediment-hosted Pb-Zn deposits (e.g., Leach et al. 2005). *Syngenesis*, as applied to sediment-hosted or volcanogenic massive sulfide deposits, implies that ore-forming processes occurred near the water-sediment interface, effectively in connection with the hydrosphere and biosphere. By contrast, *epigenesis* can have occurred tens or hundreds of millions of years after rock lithification, potentially at significant burial depths, and possibly at high temperatures. Clearly, the processes involved in the transport and precipitation of ore-forming elements in such contrasting regimes are very different. The relative timing of ore formation also has major implications for mineral exploration: syngenetic deposits are likely to be found in a specific stratigraphic interval in a particular terrane, whereas epigenetic deposits could be found in any suitably receptive rocks that are older than the hydrothermal system involved. In a number of cases, both genetic models have been proposed for the same ore deposits, with perhaps the best-known examples being the Proterozoic sediment-hosted Zn-Pb deposits of the McArthur Basin in Australia (Large et al. 1998; Perkins and Bell 1998) and the Carboniferous deposits of the Irish Midlands orefield (Hitzman and Beaty 1996; Wilkinson et al. 2005). The principal arguments for the timing of mineralization are based on geological relationships and textural observations – whether the ore minerals form stratigraphically conformable sedimentary layers that can be accounted for by deposition from suspension in water or if they can be shown to transgress stratigraphic contacts and replace preexisting minerals in the rock. Unfortunately, where a mineral deposit is subject to post-formation diagenetic, tectonic, or metamorphic overprinting, remobilization of minerals can obscure primary depositional textures and generate secondary "epigenetic" characteristics. Thus, because of the ambiguity often present in such observations, research efforts increasingly utilize isotope geochemistry or geochronology to distinguish between syngenesis and epigenesis (e.g., Hnatyshin et al. 2015).

Mineral Systems with Syngenetic and Epigenetic Components

Other complications include the fact that syngenetic deposits can also have epigenetic components in the form of vein, breccia, and/or alteration "feeder" zones that underlie the main deposit, such as in sedimentary-exhalative (SEDEX) deposits (Leach et al. 2005) or volcanic-hosted massive sulfide deposits (Franklin et al. 1981). These reflect the upward passage of buoyant hydrothermal fluids into the ore-forming environment and so are an intrinsic part of the overall hydrothermal system. The temporal relationship between the metasomatic process and rock lithification implicit in the term *epigenesis* is also subject to ambiguity when the host rocks are carbonate rich. Such rocks lithify very quickly, potentially at the seafloor (Bathurst 1970); as a result, strictly epigenetic processes and textures can be generated, although the processes are effectively operating within the syngenetic domain (e.g., Wilkinson and Hitzman 2014).

Summary

Epigenesis has wide usage in the geoscience literature but is most commonly applied in the description of mineral deposits. Because it describes a genetic process that may not be easily constrained from the rock record, and because it also represents an "end-member" of a spectrum of linked processes, its usage is quite commonly controversial. For more details on distinctions between the usage of "epigenesis," "diagenesis," and "syngenesis" in the context of mineral deposits, see Misra (2000).

Equilibrium

Heinz Gamsjäger
Leoben, Austria

Definition

Equilibrim is the condition toward which a system will change in the absence of constraints. In a chemical system it is the state with the minimum Gibbs Free Energy.

The state of equilibrium is a common feature of all branches of physical science. It plays an important role when either chemical, mechanical, or electromagnetic phenomena are described. Three examples emphasizing chemical applications must suffice. Analytical and preparative chemists use equilibrium considerations to select the temperature and concentration ranges best suited for their work. Chemical and metallurgical processes are often designed on the basis of equilibrium calculations. Moreover, equilibrium models for the distribution of species in natural waters are frequently applied by geochemists.

Heinz Gamsjager is deceased.
Originally published in: Marshall CP, Fairbridge RW (eds) Encyclopedia of Geochemistry, Springer Netherlands, 1999

As originally demonstrated by Gibbs, the concept of equilibrium is described in an entirely general way by classical thermodynamics (Gibbs 1875). Let us consider the contemporary treatment also based on the second law and using modern nomenclature given by McGlashan (1979):

> If a spontaneous process occurs in an isolated system (L) consisting of one or more phases α, β, ..., the entropy S^{Σ} of the system increases. If nothing is happening, the entropy remains constant and the isolated system is said to be in a state of equilibrium.

In an isolated system the quantities internal energy U^{Σ}, volume V^{Σ} and the total amount of substance n^{Σ} are kept constant. Expressing the entropy variation by its time derivative $\partial S/\partial t$, the statement can be cast into a mathematical relation where the inequality and equality signs refer to spontaneous process and equilibrium respectively:

$$\left(\partial S^{\Sigma}/\partial t\right)_{U^{\Sigma},V^{\Sigma},n^{\Sigma}} \geqslant 0 \tag{1}$$

The definition $\partial S^{\Sigma}/\partial t = 0$ includes metastable equilibria, provided no change is detected during the period and with the instruments of observation. Thus, a mixture of methane and air at ambient temperatures is metastable unless it is lighted, whereupon it burns and transforms into the even more stable state of flue gas.

Other, sometimes more convenient, sets of independent variables are obtained from Eq. 1 simply by applying the rules of differentiation. By this method, the extensive quantity U is successively transformed into the likewise extensive quantities H (enthalpy), A (Helmholtz function), and G (Gibbs function). Now, the conditions for chemical as well as thermal, hydrostatic, diffusive, etc. equilibrium can be derived from Eq. 1 or one of its alternative forms (McGlashan 1979). It is easy to carry out and study chemical reactions at constant thermodynamic temperature T and pressure p; consequently, Eq. 2 is the most important from the viewpoint of chemistry.

$$\left(\partial G^{\Sigma}/\partial t\right)_{T,p,n^{\Sigma}} \leqslant 0 \tag{2}$$

It can be shown that the general homogeneous reaction:

$$aA + bB \rightleftharpoons cC + dD \tag{3}$$

is in a state of equilibrium when the chemical potentials μ satisfy the following equation:

$$c\mu_C + d\mu_D - a\mu_A - b\mu_B = 0 \tag{4}$$

This result can easily be generalized to systems, composed of more than one phase, in which two or more simultaneous reactions occur.

Once a system has attained chemical equilibrium the concentrations of the chemical species involved no longer change, on a macroscopic level it has chemically come to a rest. On the molecular level, the reactions are still going on, however, as can be demonstrated by spiking an equilibrated system with an isotopic tracer.

Equilibrium Constant

Erich Königsberger
Chemical and Metallurgical Engineering and Chemistry, School of Engineering and Information Technology, Murdoch University, Murdoch, WA, Australia

Definition

The *standard equilibrium constant*, $K^{\ominus}(T)$, for a chemical reaction is a dimensionless quantity defined by

$$K^{\ominus}(T) = \exp\{-\Delta_r G^{\ominus}(T)/RT\},$$

where $\Delta_r G^{\ominus}(T)$ is the change in the standard molar Gibbs energy due to the reaction. The value of $K^{\ominus}(T)$ depends on the choice of the standard state, which must be specified. The standard equilibrium constant is, like all standard thermodynamic quantities, independent of pressure and composition (Ewing et al. 1994; Cohen et al. 2008).

Introduction

The following definitions and examples are based on recommendations by the Commission on Thermodynamics of the International Union of Pure and Applied Chemistry (Ewing et al. 1994), cf. also the recommendations given in IUPAC's *Green Book* (Cohen et al. 2008). Further details can be found in textbooks on Chemical Thermodynamics (e.g., McGlashan 1979).

According to IUPAC, *all* standard chemical potentials and standard equilibrium constants are defined in terms of an arbitrarily chosen standard pressure. Alternative definitions with explicit pressure dependencies of these quantities are possible for reactions in *condensed* phases (e.g., Wood and Battino 1990). This, however, requires different relationships for reactions in condensed and gaseous phases, because for the latter the standard thermodynamic quantities are usually defined for a standard pressure of 1 bar.

It should be emphasized that other choices can be made as well. For instance, fixed-temperature and fixed-pressure standard states have been proposed for aqueous solutions (Nordstrom and Munoz 1986, p. 186).

Equilibrium Condition

Consider a chemical reaction written as

$$\sum_{\mathrm{B}} \nu_{\mathrm{B}} \mathrm{B} = 0, \tag{1}$$

where each ν_{B} represents the stoichiometric coefficient of the substance B in the balanced reaction; the sign is positive for products and negative for reactants.

The Gibbs energy, $G(T,p,\xi)$, of the reacting system (1) is defined as

$$G(T,p,\xi) = \sum_{\mathrm{B}} n_{\mathrm{B}}(\xi)\mu_{\mathrm{B}}(T,p,\xi),$$

where $n_{\mathrm{B}}(\xi)$ is the amount of substance B and $\mu_{\mathrm{B}}(T,p,\xi)$ denotes the chemical potential of substance B which depends on temperature, pressure, and the extent of reaction, ξ. Chemical equilibrium will be attained when G assumes a minimum

with respect to ξ at constants T and p. The extent of reaction is defined by

$$n_{\mathrm{B}}(\xi) = n_{\mathrm{B}}(0) + \nu_{\mathrm{B}}\xi, \tag{2}$$

where $n_{\mathrm{B}}(0)$ denotes the initial amount of substance B. Hence, the condition of equilibrium for reaction (1) is given by

$$\frac{\partial G}{\partial \xi} = \sum_{\mathrm{B}} \frac{\partial n_{\mathrm{B}}}{\partial \xi}\mu_{\mathrm{B}} + \sum_{\mathrm{B}} n_{\mathrm{B}}\frac{\partial \mu_{\mathrm{B}}}{\partial \xi} = 0. \tag{3}$$

According to the Gibbs-Duhem equation, the second sum in Eq. 3 is identically equal to zero. Consequently, by the use of Eq. 2,

$$\sum_{\mathrm{B}} \nu_{\mathrm{B}}\mu_{\mathrm{B}}(T, p, \xi^{\mathrm{eq}}) = 0, \tag{4}$$

where ξ^{eq} denotes the extent of reaction at chemical equilibrium.

Standard Equilibrium Constant

The standard equilibrium constant $K^{\ominus}(T)$ for reaction (1) is a dimensionless quantity defined by

$$RT\ln K^{\ominus}(T) = -\sum_{\mathrm{B}} \nu_{\mathrm{B}}\mu_{\mathrm{B}}^{\ominus}(T) = -\Delta_{\mathrm{r}}G^{\ominus}(T) \tag{5}$$

where $\mu_{\mathrm{B}}^{\ominus}(T)$ denotes the standard chemical potential of substance B and $\Delta_{\mathrm{r}}G^{\ominus}(T)$ is the standard Gibbs energy of reaction (1).

Combination of Eqs. 4 and 5 yields

$$RT\ln K^{\ominus}(T) = \sum_{\mathrm{B}} \nu_{\mathrm{B}}\left\{\mu_{\mathrm{B}}(T, p, \xi^{\mathrm{eq}}) - \mu_{\mathrm{B}}^{\ominus}(T)\right\}. \tag{6}$$

Evaluation of the differences

$$\left\{\mu_{\mathrm{B}}(T, p, \xi) - \mu_{\mathrm{B}}^{\ominus}(T)\right\}$$

between the chemical potential of substance B and its standard chemical potential for the same temperature and state of aggregation will be discussed below.

Standard Chemical Potential

Since a variation of temperature, pressure, or composition changes the values of thermodynamic quantities, it is important to define a reference value of each quantity to which such changes, which can be measured or calculated easily, may be referred. Suitable reference values, known as standard thermodynamic quantities, can be obtained from the standard chemical potential by the usual mathematical operations (cf., e.g., McGlashan 1979).

The standard chemical potential is defined in terms of a specified state of aggregation, a specified temperature, and an arbitrarily chosen but specified standard pressure. For a solute substance in a solution, an arbitrarily chosen but specified standard molality is required too. Consequently, all standard thermodynamic quantities, including standard equilibrium constants, are independent of pressure and composition, but they remain functions of temperature.

The recommended value of the standard pressure $p^{\ominus}$ is 10^5 Pa (1 bar). If the value of $p^{\ominus}$ changes from $p_1^{\ominus}$ to $p_2^{\ominus}$, then the change in the standard chemical potential is given by one of the following three equations:

1. For a gaseous substance B, whether pure or mixed,

$$\mu_{\mathrm{B}}^{\ominus}(\mathrm{g}, T, p_2^{\ominus}) - \mu_{\mathrm{B}}^{\ominus}(g, T, p_1^{\ominus}) = RT\ln\left(p_2^{\ominus}/p_1^{\ominus}\right).$$

2. For a substance B in a condensed phase (cd), whether pure or mixed, or for a solvent substance B in a solution

$$\mu_{\mathrm{B}}^{\ominus}(\mathrm{cd}, T, p_2^{\ominus}) - \mu_{\mathrm{B}}^{\ominus}(\mathrm{cd}, T, p_1^{\ominus}) = \int_{p_1^{\ominus}}^{p_2^{\ominus}} V_{\mathrm{B}}^{*}(\mathrm{cd}, T, p)\,\mathrm{d}p,$$

where $V_{\mathrm{B}}^{*}(\mathrm{cd}, T, p)$ is the molar volume of the pure substance B.

3. For a solute substance B in a solution

$$\mu_{\mathrm{B}}^{\ominus}(\mathrm{solute}, T, p_2^{\ominus}) - \mu_{\mathrm{B}}^{\ominus}(\mathrm{solute}, T, p_1^{\ominus}) = \int_{p_1^{\ominus}}^{p_2^{\ominus}} V_{\mathrm{B}}^{\infty}(\mathrm{solute}, T, p)\,\mathrm{d}p,$$

where $V_{\mathrm{B}}^{\infty}(\mathrm{solute}, T, p)$ is the partial molar volume of the solute B at infinite dilution.

For example, if $p^{\ominus}$ increases from 10^5 Pa to 101,325 Pa (1 atm), then, for a gaseous substance, the standard chemical potential increases by about 0.013 RT and the standard molar entropy decreases by about 0.013 R. For condensed phases, however, the same variation in the standard pressure will result in a negligible difference in the standard thermodynamic quantities compared with the current uncertainties in these data.

The recommended value of the standard molality $m^{\ominus}$ is 1 mol kg^{-1}.

In the following three sections, definitions are given for the standard chemical potential of a substance B in the following states of aggregation: pure or mixed gas phase, pure or mixed condensed phase or solvent substance in a solution, and solute substance in a solution. Using these definitions, methods for the calculation and measurement of the differences

$\{\mu_B(T,p,\xi) - \mu_B^{\ominus}(T)\}$, and hence of the standard equilibrium constant, can be derived.

Gaseous Systems

The standard chemical potential of a gaseous substance B, whether pure or mixed, is defined by the relation

$$\mu_B(g,T,p,x) - \mu_B^{\ominus}(g,T) = RT\ln(f_B/p^{\ominus}), \tag{7}$$

where x denotes the set of mole fractions x_B, x_C, $\cdots$ of B, C, $\cdots$ and f_B is the fugacity of B defined by

$$f_B = (x_B p)\exp\left\{\int_0^p \left(\frac{V_B}{RT} - \frac{1}{p}\right) dp\right\}, \tag{8}$$

where $V_B = V_B(g, T, p, x)$ is the (partial) molar volume of B. Consequently, the fugacity has the same dimension as pressure. Since the integral in Eq. 8 vanishes for a perfect gas, the fugacity is sometimes used as a measure of the deviation of the gas or gaseous mixture from perfection. For an expression of the fugacity in terms of the virial equation of state see, e.g., Ewing et al. (1994) or McGlashan (1979). As the symbol f_B is also used for the activity coefficient of substance B referenced to Raoult's law, the fugacity is sometimes denoted as $\tilde{p}_B$ (Cohen et al. 2008).

The standard equilibrium constant for a reaction in the gas phase is derived by combining Eqs. 6 and 7:

$$K^{\ominus}(g,T) = \prod_B (f_B/p^{\ominus})^{\nu_B} = \lim_{p\to 0} \prod_B (x_B p/p^{\ominus})^{\nu_B}.$$

The second form of this equation, which follows from Eq. 8, provides the most direct method of determining $K^{\ominus}(g, T)$ experimentally and is useful when the partial molar volumes $V_B(g, T, p, x)$ are not known. At least at low to moderate pressures, the extrapolation to zero pressure is often not necessary. In practice the quantity

$$K_p(g,T,p,x) = \prod_B (x_B p)^{\nu_B}$$

which has the dimension of $(\text{pressure})^{\Sigma_B \nu_B}$ is often used. However, K_p varies with pressure and composition and should be clearly distinguished from the dimensionless standard equilibrium constant $K^{\ominus}(g, T)$.

Condensed Phases

The standard chemical potential of a substance B in a condensed phase, whether pure or mixed, is defined by the relation

$$\mu_B^{\ominus}(cd,T) = \mu_B^*(cd,T,p) + \int_p^{p^{\ominus}} V_B^* \, dp, \tag{9}$$

where $\mu_B^*(cd,T,p)$ and $V_B^*(cd,T,p)$ are the chemical potential and the molar volume of the pure substance B, respectively.

The activity coefficient f_B of a substance B in a liquid or solid mixture is a dimensionless quantity defined by

$$\mu_B(cd,T,p,x) - \mu_B^{\ominus}(cd,T) = RT\ln(x_B f_B) - \int_p^{p^{\ominus}} V_B^* \, dp, \tag{10}$$

where x denotes the set of mole fractions x_B, x_C, $\cdots$ of B, C, $\cdots$ in the mixture. The (relative) activity of B in a mixture is a dimensionless quantity given by

$$a_B = x_B f_B. \tag{11}$$

It follows from the definitions of a_B and f_B that

$$\lim_{x_B\to 1} a_B = \lim_{x_B\to 1} f_B = 1.$$

A mixture of substances B, C, $\cdots$ is called an ideal mixture when $a_B = x_B$, $a_C = x_C$, $\cdots$ or $f_B = 1, f_C = 1, \cdots$.

The standard equilibrium constant for a reaction in a condensed phase is given by

$$K^{\ominus}(cd,T) = \prod_B (x_B f_B)^{\nu_B} \exp\left[-\int_p^{p^{\ominus}} \sum_B \frac{\nu_B V_B^*}{RT} dp\right]. \tag{12}$$

The pressure integral in Eq. 12 is often neglected, especially when $p \approx p^{\ominus}$. Then, the quantity

$$K_{xf}(cd,T,p) = \prod_B (x_B f_B)^{\nu_B}$$

is a good approximation to $K^{\ominus}(cd, T)$, whereas the quantity

$$K_x(cd,T,p,x) = \prod_B (x_B)^{\nu_B}$$

usually varies strongly with composition and is therefore a poor approximation to $K^{\ominus}(cd, T)$ because only few real mixtures are even approximately ideal.

Solutions

A solution is a special description of a mixture for which it is convenient to distinguish between the solvent A, usually present in excess, and the solutes B, C, $\cdots$.

The standard chemical potential $\mu_B^{\ominus}$ of a solute substance B in a solution of B, C, $\cdots$ in a solvent substance A is defined by

$$\mu_B^{\ominus}(\text{solute}, T) = \{\mu_B(\text{solute}, T, p, m) - RT \ln (m_B/m^{\ominus})\}^{\infty} + \int_p^{p^{\ominus}} V_B^{\infty} \, dp, \tag{13}$$

where m denotes the set of molalities m_B, m_C, $\cdots$ of B, C, $\cdots$ in the solvent A, $m^{\ominus}$ is the standard molality, $V_B^{\infty} = V_B^{\infty}(\text{solute}, T, p)$ is the partial molar volume of B at infinite dilution, and ∞ denotes the limit at infinite dilution, i.e., $\sum_B m_B \to 0$. In Eq. 13, both terms inside $\{\cdots\}^{\infty}$ diverge as $m_B \to 0$, but their difference remains finite.

The activity coefficient $\gamma_{m,B}$ of a solute B in a solution is a dimensionless quantity given by

$$\mu_B(\text{solute}, T, p, m) - \mu_B^{\ominus}(\text{solute}, T) = RT \ln\left(m_B \gamma_{m,B}/m^{\ominus}\right) - \int_p^{p^{\ominus}} V_B^{\infty} \, dp.$$

The (relative) activity a_B of a solute B in a solution is a dimensionless quantity given by

$$a_B = m_B \gamma_{m,B}/m^{\ominus}.$$

It follows from the definitions of a_B and $\gamma_{m,B}$ that

$$(a_B m^{\ominus}/m_B)^{\infty} = \lim_{\Sigma_B m_B \to 0} \gamma_{m,B} = 1.$$

A solution of solutes B, C, $\cdots$ in a solvent A is called an ideal-dilute solution when $a_B = m_B/m^{\ominus}$, $a_C = m_C/m^{\ominus}$, $\cdots$ or $\gamma_{m,B} = 1$, $\gamma_{m,C} = 1$, $\cdots$.

The definition of the standard chemical potential of the solvent A in a solution is identical with the definition (9) of the standard chemical potential of any substance B in a condensed phase. The activity a_A of the solvent A is defined by relations analogous to Eqs. 10 and 11.

Since the solvent A is treated differently from the solutes B, C, $\cdots$, the expression for a chemical reaction in a solution may be written in the form

$$\nu_A A + \sum_B \nu_B B = 0.$$

The standard equilibrium constant then takes the form

$$K^{\ominus}(\text{solution}, T) = (a_A)^{\nu_A} \prod_B (a_B)^{\nu_B} \exp\left[-\int_p^{p^{\ominus}} \frac{\nu_A V_A^* + \Sigma_B \nu_B V_B^{\infty}}{RT} dp\right]. \tag{14}$$

The pressure integral in Eq. 14 is often neglected, especially when $p \approx p^{\ominus}$. Then, the quantity

$$K_a(\text{solution}, T, p) = (a_A)^{\nu_A} \prod_B (a_B)^{\nu_B}$$

varies with pressure but may still be a good approximation to $K^{\ominus}$. The solvent term, which is close to unity for sufficiently dilute solutions, is also often omitted. Then, the quantity

$$K_{m\gamma}(\text{solution}, T, p, m) = \prod_B \left(m_B \gamma_{m,B}/m^{\ominus}\right)^{\nu_B}$$

varies with composition but may still be a good approximation to $K^{\ominus}$. The quantity

$$K_m(\text{solution}, T, p, m) = \prod_B (m_B)^{\nu_B},$$

which has the dimension of $(\text{molality})^{\Sigma_B \nu_B}$, is sometimes used in practice; however, it should be clearly distinguished from the dimensionless quantity $K^{\ominus}$ (solution, T). The dependence of K_m on solution composition may be severe, especially for aqueous electrolyte solutions.

In many experimental studies on complex formation and solubility, the solution composition has been kept essentially constant by adding an "inert" electrolyte (constant ionic medium method). Also, some natural waters maintain a rather constant composition, such as surface seawater. For reactions involving minor species B at $p = p^{\ominus}$, a so-called stoichiometric equilibrium constant may be defined as

$$K_{st}(\text{solution}, T, m_C) = \lim_{\Sigma_B m_B \to 0} \prod_B (m_B)^{\nu_B}, \quad m_{C \neq B} = \text{constant}.$$

The quantity K_{st}, which has the dimension of $(\text{molality})^{\Sigma_B \nu_B}$, varies with solution composition and is only valid for a particular set of $m_{C \neq B}$.

For any solution at $p = p^{\ominus}$, Eq. 14 can be written in the form

$$K^{\ominus}(\text{solution}, T) = \lim_{\Sigma_B m_B \to 0} \prod_B (m_B/m^{\ominus})^{\nu_B}.$$

This equation provides the most direct method of determining $K^{\ominus}$ (solution, T) experimentally and is useful when the activity a_A for the solvent and the activity coefficients $\gamma_{m,B}$, $\gamma_{m,C}$, $\cdots$ for the solutes are not known.

E

Effect of Temperature on the Equilibrium Constant

The standard molar enthalpy of substance B, $H_B^\ominus$, is given by the Gibbs-Helmholtz equation:

$$H_B^\ominus = \mu_B^\ominus - T\mathrm{d}\mu_B^\ominus/\mathrm{d}T = -RT^2\mathrm{d}(\mu_B^\ominus/RT)/\mathrm{d}T.$$

(cf. McGlashan 1979). Remember that all standard quantities are functions of temperature only. Then, by the use of Eq. 5, van't Hoff's Eq. 15 is obtained:

$$\mathrm{d}\ln K^\ominus/\mathrm{d}T = \sum_B \nu_B H_B^\ominus/RT^2 = \Delta_r H^\ominus/RT^2. \quad (15)$$

Integration of Eq. 15 yields

$$\ln K^\ominus(T_2) - \ln K^\ominus(T_1) = \int_{T_1}^{T_2} \left\{\Delta_r H^\ominus(T)/RT^2\right\}\mathrm{d}T. \quad (16)$$

Thus, if the value of $K^\ominus$ is known for a temperature T_1, its value at another temperature T_2 can be calculated, provided that the standard enthalpy of reaction, $\Delta_r H^\ominus(T)$, is known over the temperature range T_1 to T_2. Usually, the standard molar heat capacities at constant pressure, $C_{p,B}^\ominus$, have been measured and tabulated (e.g., as coefficients of a power series in T), and $\Delta_r H^\ominus(T_0)$ is known at some reference temperature T_0 (which may be outside the range T_1 to T_2). Since

$$\Delta_r H^\ominus(T) - \Delta_r H^\ominus(T_0) = \int_{T_0}^{T} \sum_B \nu_B C_{p,B}^\ominus(T)\,\mathrm{d}T,$$

Eq. 16 can be rewritten as

$$\ln K^\ominus(T_2) - \ln K^\ominus(T_1) = \Delta_r H^\ominus(T_0)(T_2 - T_1)/RT_1T_2 + \int_{T_1}^{T_2}\left\{\int_{T_0}^{T}\sum_B \nu_B C_{p,B}^\ominus(T)\mathrm{d}T\right\}\left(1/RT^2\right)\mathrm{d}T.$$

Examples

In practice, many chemical reactions involve more than one phase. Then, the expressions for the standard equilibrium constant are appropriate combinations of those given above for reactions in a single phase (an illustrative example is presented by Ewing et al. 1994).

Standard equilibrium constants can be defined and also determined experimentally for electron-transfer reactions, proton-transfer reactions (e.g., standard acidity constant, $K_A^\ominus$), water dissociation (standard ionization constant, $K_w^\ominus$), complex formation (standard stability constant), dissolution of solid electrolytes (standard solubility product, $K_s^\ominus$), etc. (cf. McGlashan 1979).

Element Data

Atomic Symbol: Er
Atomic Number: 68
Atomic Weight: 167.259(3)
Isotopes and Abundances: ^{162}Er, 0.139(5)%; ^{164}Er, 1.601(3)%; ^{166}Er, 33.503(36)%; ^{167}Er, 22.869(9)%; ^{168}Er, 26.978(18)%; and ^{170}Er, 14.910(36)%
1 Atm Melting Point: 1529 °C
1 Atm Boiling Point: 2868 °C
Common Valences: +3
Ionic Radii: 89.0 pm (CN6), 100.4 pm (CN8), and 121.4 pm (CN12)
Pauling Electronegativity: 1.24
First Ionization Energy: 589.30 kJ mol^{-1}
Chondritic (CI) Abundance: 0.166 ppm
Silicate Earth Abundance: 0.370 ppm
Crustal Abundance: 2.2 ppm
Seawater Abundance: 1.09 ppt
Core Abundance: ~0

Properties

Erbium (Er), named after the Swedish village of Ytterby, is a soft, malleable, dense (9.066 g cm^{-3}), bright silvery-white metal. Its electronic configuration is $[Xe]4f^{12}6s^2$. It is stable at room temperature and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE). In geochemical terminology, it is grouped with heavy rare earth elements (HREE; Gd-Lu). Erbium has six natural, stable isotopes, listed above with their abundances.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Er as a major component are restricted to Y and HREE varieties, such as xenotime [$Y(PO_4)$], bastnäsite [$REE(CO_3)F$], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+},Fe^{3+})_3(SiO_4)_3(OH)$], and britholite [$(REE,Ca)_5(SiO_4,PO_4)_3(OH,F)$]. In addition, Er may be enriched in ion adsorption lateritic kaolinite-halloysite clay deposits that are mined for REE.

Details of properties, mineralogy, history, and uses of Er were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner (2016), Hammond (2016), and Meija et al. (2016a, b).

History and Use

Erbium was discovered in 1843 by Carl Gustaf Mosander, but early naming is somewhat confused as the names erbium and terbium were switched in 1864; it was first isolated as a metal in 1934. Erbium oxide has a distinctive pink color and so is used as a colorization additive to glass, cubic zirconia jewelry, and glazes on ceramics. Due to the Er ion 2940 nm emission, it is also used to produce Er:YAG lasers, commonly used for certain types of cosmetic and dental surgeries. Erbium-doped fiber amplifiers (EDFA) can be used to amplify modulated laser beams and accordingly are used in fiber-optic systems.

Geochemical Behavior

The fundamental importance of Er in geochemistry is that it is one of the small trivalent rare earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction."

Erbium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element, with a 50% $T_{condensation}$ of 1659 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Er is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Er normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Er contents of clastic sediments typically reflect their average provenance.

In seawater, Er has very low concentrations (~ppt) and residence times (~2420 year) with speciation dominated by Er^{3+}, $ErCO_3^+$, and $Er(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Er can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration and residence time data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Er, but in China REE have been added to fertilizers and to stock feed to promote growth. REE (including Er^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Er) in human tissues and fluids are very low (tens of ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Europium

Matthias Willbold
School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Manchester, UK

Element Data
Atomic Symbol: Eu
Atomic Number: 63
Atomic Weight: 151.965 g/mol
Isotopes and Abundances: ^{151}Eu 47.8%, ^{153}Eu 52.2%
1 Atm Melting Point: 822 °C
1 Atm Boiling Point: 1529 °C
Common Valences: 3+, 2+
Ionic Radii: Eu $^{3+}$ 109 pm (sixfold), 121 pm (eightfold); Eu $^{2+}$ 131 pm (sixfold), 139 pm (eightfold)
Pauling Electronegativity: 1.2
First Ionization Potential: 5.6704 eV
Chondritic (CI) Abundance: 0.056 µg/g
Silicate Earth Abundance: 0.166 µg/g
Crustal Abundance: 1.1 µg/g
Seawater Abundance: <~0.3 pg/g
Core Abundance: ~0

Properties

Europium is a silvery-white rare-earth element with a pale yellow tint (Greenwood and Earshaw 1997). It is a ductile metal and has the second lowest melting point and the lowest density of all rare-earth elements (Haynes 2016). Europium metal is commercially produced by isolation from rare-earth element-bearing minerals such as bastnäsite and more rarely monazite. Currently, the Bayan Obo iron ore deposit (China) is one of the most important sources of bastnäsite worldwide (Wu 2008).

Europium is the most reactive element of all rare-earth elements, and it readily oxidizes in air and water to form colorful Eu(III) compounds. Although predominantly occurring in the trivalent state, it is the only rare-earth element that occurs in the divalent state under reducing conditions. Divalent Eu is highly reducing and has an ionic radius and coordination number similar to that of Ca^{2+} (calcium), Sr^{2+} (strontium), and Ba^{2+} (barium). Many Eu compounds exhibit phosphorescence properties.

History and Use

Europium was discovered in 1890 by Paul Émile Lecoq de Boisbaudran. It was first isolated in 1901 by Eugène-Anatole Demarçay who named it after Europe. Commercial use of Eu is limited and centered on its phosphorescence characteristics. Europium has been used as a dopant in laser crystals and as a fluorescent material in cathode ray tube television sets and fluorescent lamps.

Geochemical Behavior

Europium is a refractory, lithophile element (Goldschmidt 1930; Lodders 2003) and is concentrated in the silicate fraction of terrestrial planets, i.e., the Earth's mantle and crust. It is classified as a trace element. The redox-sensitive property of Eu makes it a useful geochemical tracer. In oxidized magmatic systems, it exists – like most other rare-earth elements – as a trivalent ion rendering it incompatible in rock-forming minerals. Under reducing magmatic conditions, Eu is compatible in feldspar because Eu $^{2+}$ can substitute for divalent alkaline earth elements in its crystal lattice. This geochemical characteristic can lead to relative enrichment of Eu in feldspar-rich rocks. When compared to other rare-earth elements of similar geochemical properties (samarium and gadolinium), rocks with an overabundance of Eu relative to a reference material (most commonly a chondritic meteorite or an average mid-ocean ridge basalts composition) are said to have a positive Eu anomaly, while those with a deficiency are referred to as having a negative Eu anomaly.

Being an important rock-forming mineral in crustal lithologies, fractional crystallization of feldspar in magmatic systems has a significant effect on the distribution of Eu within the crust of the Earth, the Moon, and other planetary bodies. Feldspar-rich lithologies and geochemical reservoirs, such as the lower continental crust on Earth or the lunar highland terrains, exhibit large positive Eu

anomalies, while the Earth's upper continental crust and the lunar mare basalts comprise complementary negative Eu anomalies (Rudnick and Gao 2014; Taylor and McLennan 2010). This makes Eu the most heterogeneously distributed rare-earth element within the crust. The dichotomy of Eu distribution in the Earth's continental crust has recently been used to trace recycled upper and lower continental crust materials in enriched mantle reservoirs (Willbold and Stracke 2010).

In chondritic meteorites, negative Eu anomalies have been measured in some chondrules and interpreted as the result of rare-earth element gas-solid fractionation at reducing conditions within the solar nebula (Pack et al. 2004).

In aquatic environments, enrichment of Eu relative to other rare-earth elements can only occur in reduced hydrothermal systems (Klinkhammer et al. 1994; Olivarez and Owen 1991). Experimental data suggest that in hydrothermal fluids Eu exists in the divalent form, which exhibits higher solubility than trivalent rare-earth elements (Bau 1991; Haas et al. 1995).

In seawater, Eu only occurs in trivalent form (Goldstein and Hemming 2014; Piper and Bau 2013). Like other rare-earth elements, Eu complexes have a low solubility in seawater. Europium has an average residence time in the oceans of up to 820 years (Alibo and Nozaki 1999; Li 1982).

Both naturally occurring isotopes of Eu can be regarded as stable. ^{151}Eu has recently been found to undergo α-decay to ^{147}Pm, albeit with an extremely long half-life of 4.6×10^{18} years (Casali et al. 2014). Natural mass-dependent variations of Eu isotopes have so far only been reported for two calcium-aluminum inclusions from a carbonaceous chondrite (Moynier et al. 2006).

Biological Utilization and Toxicity

Europium is not known to have a biological role and is not classified as a toxic or harmful element in the environment. Owing to its susceptibility to oxidation, metal powder of Eu can ignite in air at temperatures >150 °C and may thus present a fire and explosion hazard.

Summary

The unique geochemical property of Eu to change valence state depending on ambient redox conditions can be used to understand the magmatic history of igneous rocks and meteoritic components, investigate crustal evolution and mantle recycling models, constrain the sources of sedimentary rocks and water masses, as well as to study hydrothermal systems and their deposits.

Evaporites

John Warren
Petroleum Geoscience Prog., Chulalongkorn University, Bangkok, Thailand

Synonyms

Bittern salts; Marine salts

Definition

A widely accepted definition of an evaporite is "A salt rock originally precipitated from a saturated surface or near-surface brine in hydrologies driven by solar evaporation" (Warren 2016).

How Evaporite Salts Form

Evaporites are the resultant mineral precipitates accumulating in and around an increasingly saline residual brine undergoing evaporation, which has reached a state of supersaturation with respect to a particular mineral salt or salts. This simple definition encompasses a broad range of naturally precipitated salts and includes alkali earth carbonates as well as some halide salts (see also halide salts).

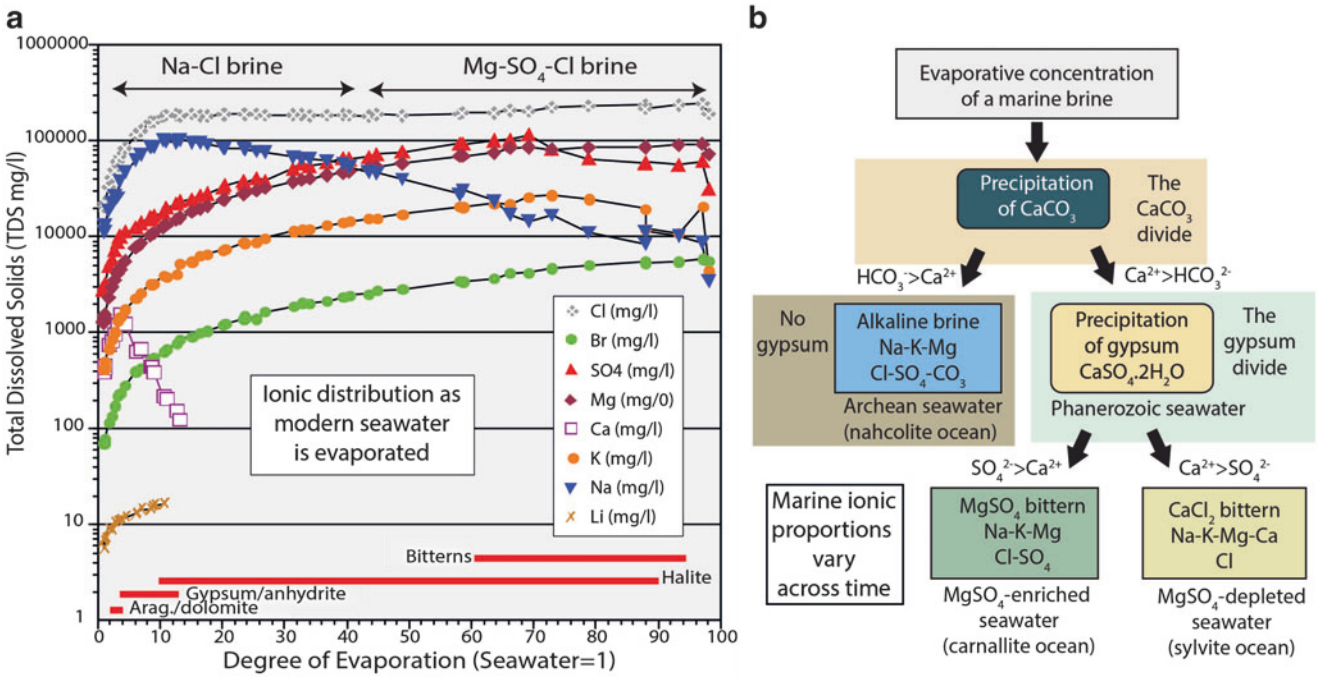
Brine Chemistry and Evolution

The mother brine that precipitates a suite of evaporite salts can be either marine or nonmarine. Sometimes the source of an ancient evaporite salt can be inferred from the chemical proportions of the ions in the deposited salt sequence (Figs. 1 and 2).

Marine Brine

When seawater evaporates, a predictable suite of primary evaporite salts crystallizes from increasingly concentrated hypersaline waters (Fig. 1). Today, the chemical makeup and the proportion of the major ions in seawater are near constant in all the world's oceans and are dominated by Na and Cl, with lesser amounts of SO_4, Mg, Ca, K, CO_3, and HCO_3 (Fig. 1a). Using the brine classification of Eugster and Hardie (1978), modern seawater is a Na–(Mg)–Cl–(SO_4) solution, with a density of ~1.03 g/cc and a salinity around 35 ‰. By the time a modern seawater brine attains the bittern stage (defined by the onset of the potassium and magnesium salts), it has become a Mg–SO_4–Cl brine (Fig. 1a). The first mineral to precipitate in the seawater evaporation series is $CaCO_3$, usually as aragonite. This begins in mesohaline waters when the brine reaches twice the concentration of seawater (40–60 ‰) and achieves a density ≈1.10 g/cc. As the brine continues to concentrate and approaches four to five times the concentration of seawater, that is 130–160 ‰, gypsum precipitates from penesaline waters, with densities around 1.13 g/cc. At 10–12 times the original seawater concentration (340–360 ‰) and densities around 1.22 g/cc, halite drops out of supersaline marine waters.

After halite, the bittern salts (potassium or magnesium sulfates/chlorides) precipitate from supersaline waters with concentrations more than 70–90 times that of the original seawater. Brine density by this stage is more than 1.30 g/cc, while brine viscosity and feel approach that of olive oil. Because magnesium and sulfate, along with chloride, are the major ionic components of a modern seawater bittern, carnallite ($KMgCl_3 \cdot 6(H_2O)$) and epsomite ($MgSO \cdot 7H_2O$) are the dominant bittern precipitates (Fig. 1b). In contrast, sylvite (KCl), not carnallite, was a significant primary bittern salt at different times in the Phanerozoic when seawater contained lesser amounts of dissolved Mg and SO_4. The varying proportion of magnesium relative to calcium and sulfate in Phanerozoic seawater was likely controlled by rates of rock–fluid interactions. Proportions varied according to the rate of



Evaporites, Fig. 1 Chemical evolution of marine brine. (**a**) Changes in ionic proportions due to sequential precipitation of aragonite, gypsum, halite and bittern salts as modern seawater is evaporated to 100 times its original concentration (in part, after McCaffrey et al. 1987; Warren 2016). (**b**) Chemical divides and the evolution of three major brine types in a framework of geological time (in part after Hardie 1990)

creation of newly formed oceanic crust at mid-ocean ridges or varying extents of epeiric seaways and associated rates of dolomitization (Holland et al. 1996; Lowenstein et al. 2014). Further back in time, in the early Archean, when the atmosphere was hotter, lacked oxygen, and contained high levels of CO_2 and CH_4, the typical marine evaporites were aragonite, nahcolite ($NaHCO_3$), and trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$), along with halite, with little or no primary gypsum. Given the vast age of these sediments, the chemically aggressive Archean atmosphere, and the inherent high reactivity of most mineral salts in the subsurface, only silicified or baritized pseudomorphs of Archean evaporite salts remain (Sugitani et al. 2003; Lowe and Tice 2004).

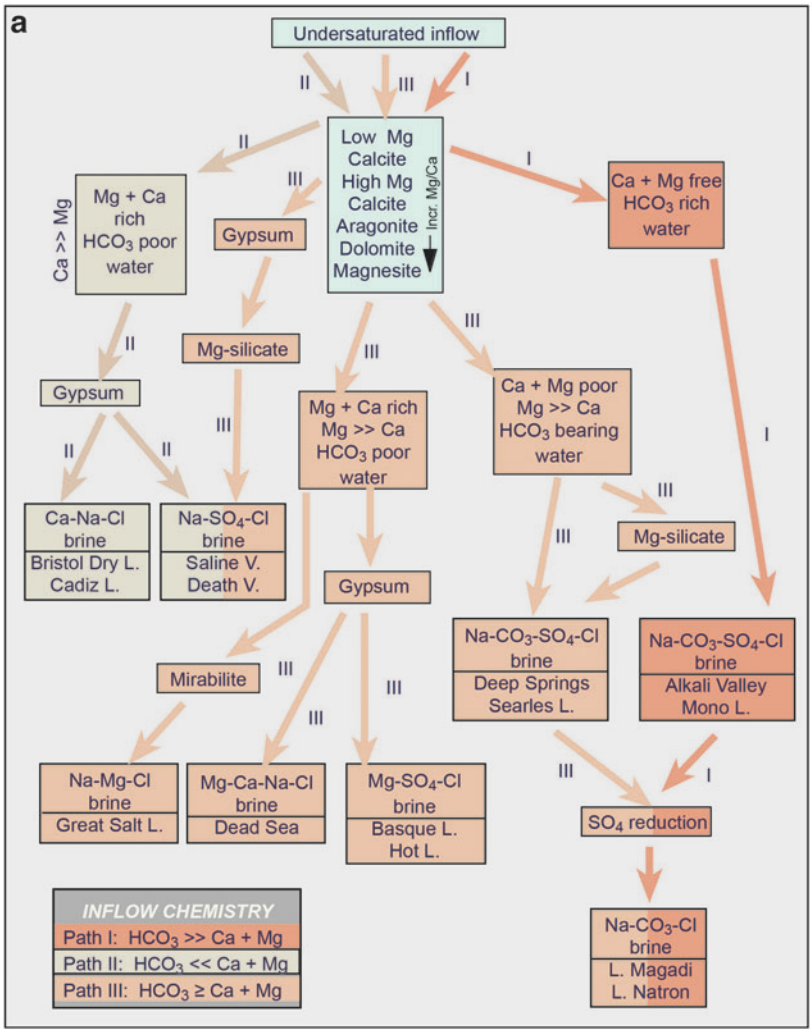
Nonmarine Brine

More diverse, less predictable suites of evaporite minerals precipitate during evaporation of continental waters. In nonmarine settings, rivers and groundwaters source most of the ions that ultimately deposit as evaporite salts. Unlike marine-derived brines, evaporating continental waters do not draw on the near-isochemical reservoir that is the ocean. So, in closed nonmarine hydrologies, the composition of nonmarine brines and the resulting evaporite suite depends on lithologies leaching in the surrounding drainage basin (Eugster and Hardie 1978; Eugster 1980). Flow through limestone aquifers in hydrologically closed basins produces inflow waters rich in Ca and HCO_3, dolomite dissolution generates more Mg, while igneous and metamorphic matrices tend to yield silica-rich Ca–Na–HCO_3 waters. Pyritic shale and other sulfide-rich sediment under today's oxidizing atmosphere contribute sulfate ions, whereas basic and ultrabasic rocks tend to produce alkaline Mg–HCO_3 mother waters. In all, Eugster and Hardie (1978) distinguished five major water types in what they termed "hydrologically closed" continental evaporite basins (Fig. 2a):

I. Ca–Mg–Na–(K)–Cl
II. Na–(Ca)–SO_4–Cl
III. Mg–Na–(Ca)–SO_4–Cl
IV. Na–CO_3–Cl
V. Na–CO_3–SO_4–Cl waters

As any one of these waters concentrates within a particular evaporite basin, it deposits a characteristic suite of evaporite minerals (Fig. 2b). Early precipitates are the alkaline earth carbonates: low-magnesian calcite, high-magnesian calcite, aragonite, and dolomite. Mineralogy of initial precipitates depends on Mg/Ca ratio in the parent brine. Subsequent evaporation pathway (types I, II, and III) of a continental brine is controlled by relative proportions of calcium, magnesium, and bicarbonate ions in inflow waters. That is, early carbonate precipitation sets up geochemical divides that then control subsequent geochemical and mineralogical (Fig. 2a).

Archean seawater, which due to much higher levels of CO_2 in the atmosphere, had a chemical makeup much like a type



b

Brine Type	Saline Mineral	
Ca-Mg-Na-(K)-Cl	Antarcticite	$CaCl_2.6H_2O$
	Bischofite	$MgCl_2.6H_2O$
	Carnallite	$MgCl_2.KCl.6H_2O$
	Halite	NaCl
	Sylvite	KCl
Na-(Ca)-SO_4-Cl	Tachyhydrite	$CaCl_2.2MgCl_2.12H_2O$
	Glauberite	$CaSO_4.Na_2SO_4$
	Gypsum	$CaSO_4.2H_2O$
	Halite	NaCl
	Mirabilite	$Na_2SO_4.10H_2O$
	Thenardite	Na_2SO_4
Mg-Na-(Ca)-SO_4-Cl	Bischofite	$MgCl_2.6H_2O$
	Bloedite	$Na_2SO_4.MgSO_4.4H_2O$
	Epsomite	$MgSO_4.7H_2O$
	Glauberite	$CaSO_4.Na_2SO_4$
	Gypsum	$CaSO_4.2H_2O$
	Halite	NaCl
	Hexahydrite	$MgSO_4.6H_2O$
	Kieserite	$MgSO_4.H_2O$
	Mirabilite	$Na_2SO_4.10H_2O$
	Thernadite	Na_2SO_4
Na-CO_3-Cl	Halite	NaCl
	Nahcolite	$NaHCO_3$
	Natron	$Na_2CO_3.10H_2O$
	Thermonatrite	$NaCO_3.H_2O$
	Trona	$NaHCO_3.Na_2CO_3$
Na-CO_3-SO_4-Cl	Burkeite	$Na_2CO_3.2Na_2SO_4$
	Halite	NaCl
	Mirabilite	$Na_2SO_4.10H_2O$
	Nahcolite	$NaHCO_3$
	Natron	$Na_2CO_3.10H_2O$
	Thernadite	Na_2SO_4
	Thermonatrite	$NaCO_3.H_2O$

Evaporites, Fig. 2 Nonmarine brine evolution pathways (After Eugster and Hardie 1978). (**a**) Hydrologic classification and brine evolution pathways of concentrating nonmarine waters (*L* lake, *V* valley). (**b**) Listing of major evaporite minerals associated with the different brine types

I brine, tended to precipitate trona and nahcolite, along with some halite but no gypsum (Lowe and Fisher-Worrell, 1999; Sugitani et al. 2003). Thermally dependent type I pathways explain widespread occurrence of nahcolite in saline lacustrine deposits of the Eocene in the USA and China. At that time, atmospheric CO_2 levels were significantly higher than today. During the Eocene climatic optimum, atmospheric CO_2 ranged between 680 and 1260 ppm, compared to current levels around 400 ppm (Jagniecki et al. 2015).

Genetic Mechanism and Salt Texture

For a water molecule to escape into the vapor phase in an evaporitic setting, and so increase the salinity of the residual brine lake, or pore water in a sabkha, the molecule must (1) absorb heat energy, (2) be located near the liquid surface, (3) be moving in the proper direction, (4) have sufficient energy to overcome liquid-phase intermolecular forces, and (5) pass through the surface tension interface.

Simple physics (rate and intensity) of molecular escape during solar evaporation largely controls the hydrological nature of the remaining brine. Brine bodies, either as perennial surface waters or as shallow capillary pore brines, are where various evaporite salts crystallize. Precipitative textures preserved in an accumulating salt bed are the result of concentration levels in the brine and its hydrological setting/stability. In combination, relative brine density and specific heat capacity of adjacent brine masses control density and thermal stratification in saline brine bodies located at or near the earth's surface. Subsequent burial and interaction with other regional shallow and deep phreatic hydrologies control later textural evolution (Warren 2016).

Specific heat, or heat capacity, is the amount of heat needed to raise 1 g of a substance by 1 °C. For a given amount of heat

input, a unit volume of hypersaline water will show a greater increase in temperature than a less saline water. Given the same degree of insolation, this means density-stratified water columns tend to be heliothermic, with the lower, denser bottom brine layer being warmer than the somewhat less saline, less dense, upper water layer (Fig. 3). The condition of a warmer lower water and a cooler upper water is known as heliothermality. The level in a water column where a marked change in temperature occurs in the water column is called the thermocline, and in a density-stratified brine, mass corresponds to the halocline, sometimes also referred to as the chemocline. The combination of high temperature, high salinity, and lowered oxygen in the lower brine mass of a heliothermal brine system means only a specialized biota can survive in these waters, often with a specialized bacterial population occurring in waters just above a saline thermocline (Warren 2011).

Holomixis allows deposition of a consistent salt layer across the whole basin floor, beneath both shallow and deep brine columns. Density stratification allows evaporitic salts to crystallize only in the upper water mass or at the brine–brine interface, so bottom nucleation tends to occur on the shallower lake floor, where it lies above the halocline. That is, long-term (ectogenic) column stratification means bottom nucleation of salts can only occur where the upper salt-saturated brine mass intersects the sediment bottom, with pelagic settling of salts occurring deeper out in the depositional basin. Bottom growth of crystals cannot occur on the deeper bottom beneath a density-stratified system as there is no mechanism to drive ongoing supersaturation in the lower water mass. For the same reason, constant brine reflux driving sinking of a dense brine into sediments below the flow of the evaporite basin can only proceed in significant volumes if the overlying brine mass is holomictic. Deposition of capillary salts (sabkha deposits) occurs in sub-aerial settings, wherever the saline capillary zone intersects the land surface.

When salts are accumulating beneath a holomictic brine mass, the nature of bottom nucleates is controlled by the stability of the overlying brine column (Fig. 3a). When the overlying column is deep (>30–100 m), then, other than areas on the deep bottom of local phreatic outflows, there is no widespread hydrochemical mechanism to drive fluctuations in bottom-brine chemistry. The resulting deep bottom precipitates tend to be monomineralogic crystal clusters, possibly encased by re-transported material washed in from the shallower surrounds (Fig. 3a). In contrast, when the overlying brine column is shallow (<30 m and typically <5–10 m), then the chemistry and stability of the brine varies on a shorter-term (daily weekly) basis, so more layered bottom nucleates can accumulate as layered to laminated salt beds. In addition, all evaporite sediments can be mechanically reworked by process sets that also typify siliciclastic and carbonate sediments (Fig. 3b).

World-Scale Depositional Associations

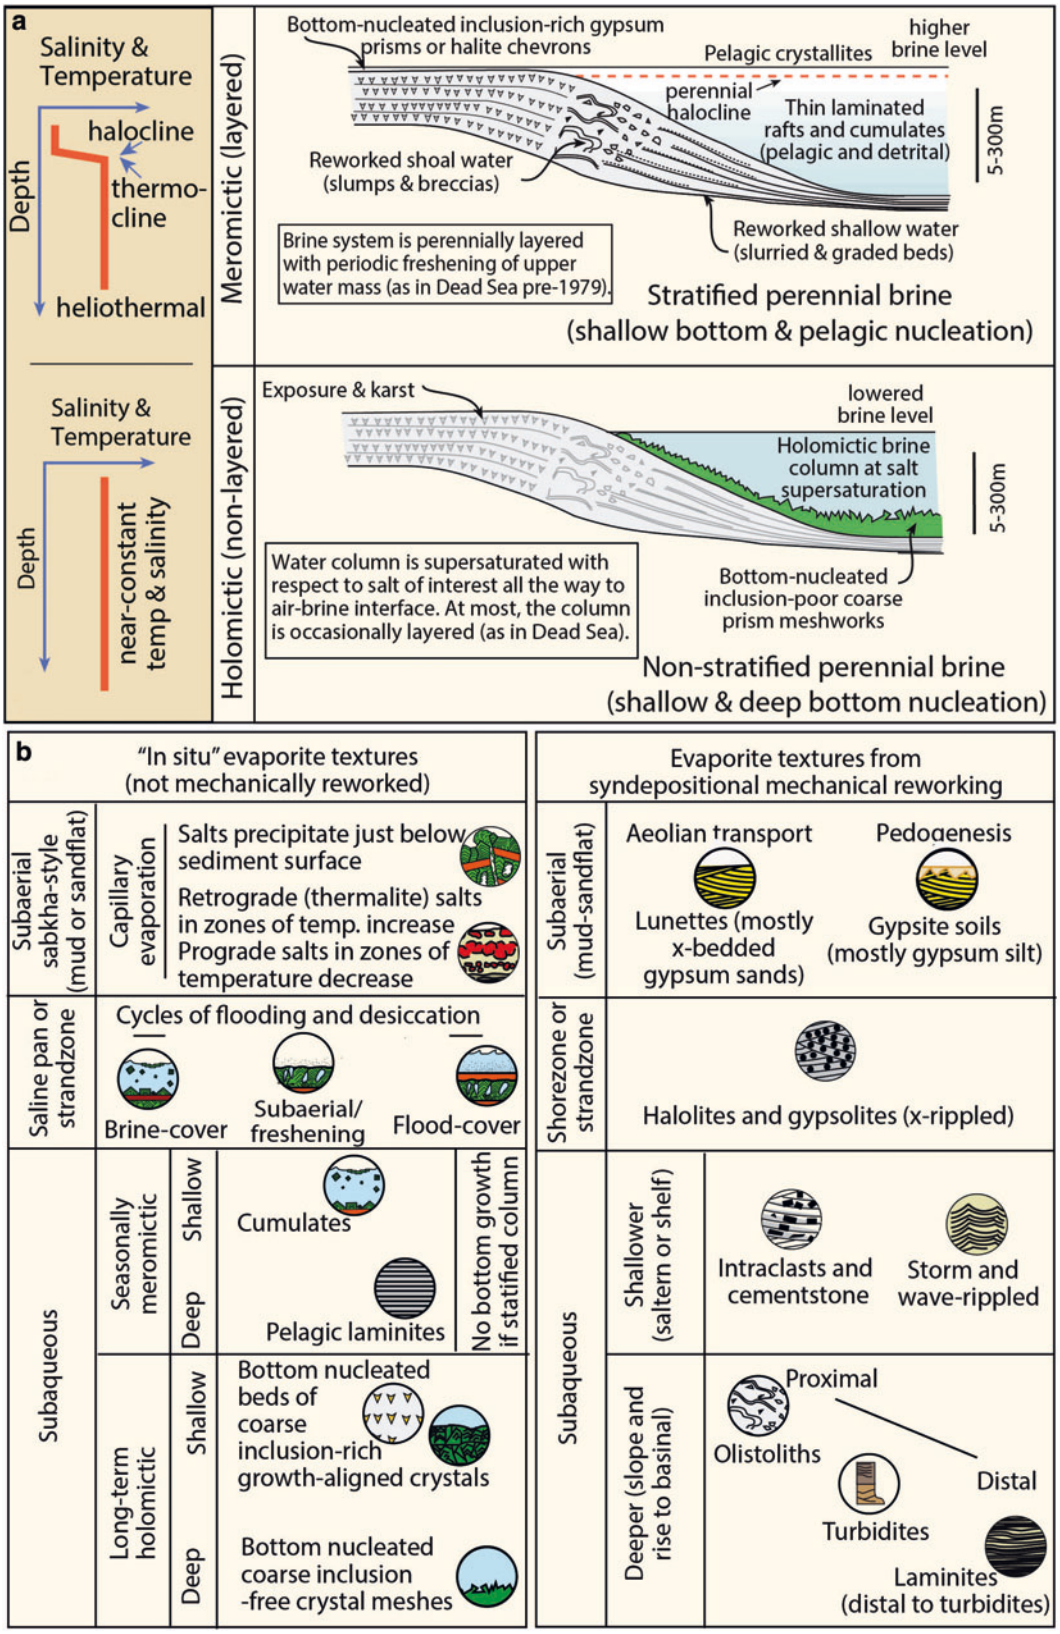
At the world scale, most ancient evaporites are marine and were deposited in either of two large-scale settings that at times merged into one another, namely, (1) platform evaporites and (2) basinwide evaporites (Fig. 4).

Platform Evaporites

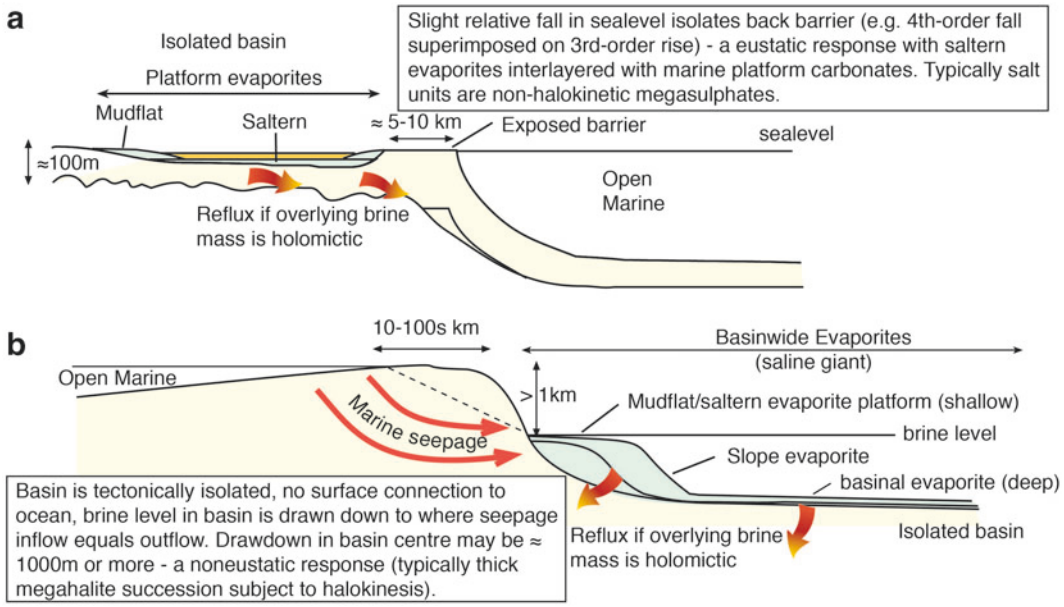
Platform evaporites are made up of stratiform beds, usually <50 m thick and composed of stacked <1–5 m thick parasequences or evaporite cycles, with a variably present restricted marine carbonate at its cycle base (Table 2). Salts were deposited as mixed evaporitic mudflat and saltern evaporites, sometimes with local accumulations of bitterns. Typically, platform salts were deposited in laterally extensive (>50–100 km wide), hydrographically isolated, subsea level marine-seepage seaways known as salterns or in evaporitic mudflats made up of a mosaic of sabkhas and salinas (Warren 2016). These regions had no same-scale modern counterparts and extended as widespread depositional sheets across large portions of marine platform areas, which passed seaward across a sub-aerial seepage barrier into open marine sediments. In marine-margin epeiric settings, such as the Jurassic Arab/Hith and Permian Khuff cycles of the Middle East or the Cretaceous Ferry Lake Anhydrite in the Gulf of Mexico, these platform evaporites are intercalated with shoalwater marine-influenced carbonate shelf/ramp sediments, which in turn pass basinward across a sub-aerial sill into open marine carbonates. Landward, they pass into arid zone continental siliciclastics or carbonate mudflats.

Platform evaporite deposition occurred in pericontinental or intracratonic (epicontinental) settings, at times of low-amplitude sea level changes, which typify greenhouse eustasy. Platform evaporites cannot survive in the high-amplitude, high-frequency sea level changes of icehouse eustasy. The 100 m + amplitude oscillations of icehouse times mean sea level falls off the shelf edge every 100,000 years, so any evaporite that had formed on the platform is sub-aerially exposed and leached. Fourth-order high-amplitude icehouse eustatic cycles also tend to prevent laterally continuous carbonate sediment barriers forming at the top of the shelf to slope break, and so icehouse evaporite systems tend not to be hydrographically isolated (drawdown) at the platform scale. Rather icehouse eustasy favors nonmarine evaporites as the dominant style, along with small ephemeral marine-margin salt bodies.

Platform evaporite successions may contain halite beds, especially in intracratonic basinwide settings, but in peri-platform settings are typically dominated by 5–40 m thick Ca-sulfate beds intercalated with normal marine platform carbonates. The lateral extent of these epeiric platform salts, like the Khuff Anhydrite with its area of 1,206,668 km^2, constitutes some of the most aerially extensive evaporite beds ever deposited.



Evaporites, Fig. 3 Textures are controlled by hydrology (After Warren 2016). (**a**) Inter-relationships between brine stratification, stability and depositional texture. (**b**) When brine column is stratified, bottom nucleation is restricted to shallower areas, when holomictic, bottom nucleated growth possible over whole basin floor



Evaporites, Fig. 4 Schematic cross sections of ancient evaporite settings that have no modern counterparts. (**a**) Platform evaporites. (**b**) Basinwide evaporites

Basinwide Evaporites

Basinwide evaporites are made up of thick evaporite units >50–100 m thick made up of varying combinations of deep-water and shallow water evaporites. They retain textural evidence of different but synchronous depositional settings, including mudflat, saltern, slope, and basin (Fig. 4). When evaporite deposition took place, the whole basin was evaporitic, holomictic, and typically saturated with the same mineral phase across vast areas of the basin floor (as when today in the Dead Sea basin, but within its more limited lateral scale, halite forms decimeter-thick chevron-dominated beds on the saline-pan floor and coarse inclusion-poor crystal meshworks on the deep basin floor). Basinwide successions are usually dominated by thick massive salt beds (generally more than 100 m thick), which are made up of stacked thick halite beds, but can also contain substantial volumes of thick-bedded Ca-sulfate and evaporitic carbonate, as in the intracratonic basinwide accumulations of the Delaware and Otto Fiord Basins.

Some basinwide systems (mostly marine-fed intracratonic) also entrain the larger accumulations of the world's potash salts, even though our only Quaternary examples of economic potash are continental systems (Warren 2010). Owing to inherent purity and thickness of the deposited halite, many halite-dominant basinwide beds are also remobilized via loading or tectonics into various halokinetic geometries (Hudec and Jackson 2007).

Basinwide evaporite deposits require tectonically and hydrologically isolated widespread subsea level depressions that are not currently present on the world's surface. They were last active in the Late Miocene, in association with soft-suture collision basins tied to the Alpine–Himalaya orogenic belt and to Middle Miocene basins developed in the early rift stages of the Red Sea. Basinwide systems will be active again in the future at sites and times of appropriate plate–plate interaction, when two continental plates are nearby and the intervening floor at or near a plate-edge rift or suture is both subsea level and hydrographically isolated.

Lacustrine (Nonmarine) Evaporites

Quaternary continental playa/lacustrine is constructed of stratiform salt units, with the greater volume of saline sediment accumulating in lower, more saline portions of the lacustrine landscape. Beds are usually dominated by nodular gypsum and displacive halite, deposited in widespread evaporitic mudflats and saltpans, rather than as bedded bottom-nucleated layers on the subaqueous floors of perennial brine lakes. In ancient counterparts, the total saline lacustrine thickness ranged from meters to hundreds of meters, with lateral extents measured in tens to hundreds of kilometers. Lacustrine salt beds are separated vertically and usually surrounded by deposits of lacustrine muds, alluvial fans, ephemeral streams, sheet floods, eolian sands, and redbeds. As today, ancient lacustrine salts accumulated in endorheic or highly restricted discharge basins, with perennial saline water masses tending to occur in the drainage sumps of steep-sided drainage basins (Warren 2010, 2016). Saline lake basins accumulating gypsum, or more saline salts like halite or glauberite, typically have a shallow water table in peripheral saline mudflat area and so are dominated by sabkha textures.

The lowermost part of the lacustrine depression or sump is typified by ephemeral ponded brine pan deposits rather than permanent saline waters with subaqueous textures lacking evidence of drawdown and exposure.

Across the Quaternary, less-saline perennial saline lake beds tend to occur during more humid periods in the same continental lacustrine depressions where saline pan beds form today (e.g., Lake Magadi, Great Salt Lake, Lake Urmia). On a smaller scale, in some modern saline lake basins, parts of the lake floor can be permanently located below sea level (Northern Basin in the Dead Sea, Lake Assal). In some modern saline sumps dominated by mudflats, a perennial saline lake water mass can be located toward the edge of a more central salt-flat zone, forming a "moat" facies (Salar de Atacama, Salar de Uyuni, Lake Magadi, Lake Natron). These permanent saline water "moat" regions are typically created where fresher inflows come in contact with saltier beds of the lake center, dissolve them, and so form water-filled peripheral depressions.

As mentioned earlier, saline lacustrine evaporite mineralogies depend on compositions of inflowing waters (Fig. 1); suitable settings can accumulate thick sequences of nonmarine salts such as trona, glauberite, and thenardite, as well as more typical sequences of halite, gypsum, and anhydrite. High-water stage perennial saline lacustrine sediments tend to be carbonate-rich or silica-rich (diatomaceous) laminites. Ancient examples of large saline lacustrine deposits include the Eocene Green River Formation of Wyoming and the Permian Pingdiquan Formation of the Junggar Basin, China. Evaporites deposited in a supra-sealevel lacustrine basin (especially Neogene deposits) have numerous same-scale quaternary analogs, unlike the more voluminous ancient marine platform and basinwide evaporites.

Summary

Evaporites are sedimentary salts precipitated at or just below the earth's surface in arid hydrologies where the concentration of the mother brine is driven by solar evaporation. Inflow brines can be either nonmarine (continental) or marine (seawater supplied). The largest modern evaporite settings are continental endorheic sumps with base levels that may be hundreds to thousands and meters above sea level. The largest ancient evaporite basins were marine, with vast expanses of bedded salt accumulating in seawater-seepage fed, sub-sealevel basins. Ancient marine evaporite basins were of two types, (a) platform evaporite systems and (b) basinwide evaporite systems. Platform evaporite systems typify epeiric and intracontinental seaways during times of basin restriction in arid settings when the earth was in greenhouse climate mode. Basinwide evaporite systems are tectonically induced and accumulated large volumes of salt at times of plate tectonic-scale continent–continent proximity in both extensional (early rift) and compressional (suture basins) plate-scale settings. Platform and basinwide settings require hydrographical isolation of the evaporite basin, that is, no long-term surface connection to waters of the open ocean, but typically had an ongoing marine seepage (drawdown) connection. Because of the continual seepage connection to the large isochemical of the ocean, volumes of salt found in ancient marine evaporite basins are much larger than any continental lacustrine evaporite system (modern or ancient). Because of the earth's current icehouse mode, and a lack of appropriate zones of continent–continent proximity, there are no regions on the earth's surface where large-scale platform or basinwide hydrologies are currently active. The last time a basinwide system was active was across the various Messinian (Late Miocene) basins of the Mediterranean, while the last time a widespread set of bedded platform evaporite salts accumulated was during the Eocene in the Middle East.

Definition

Experimental mineralogy and petrology is an Earth science discipline that models or simulates mineralogical, petrological, and geochemical processes within the laboratory in order to understand the physical and chemical properties of minerals, rocks, melts, and fluids and their interactions. For example, most of Earth's interior and that of other planets are not accessible to direct study. Thus, various types of high-pressure and high-temperature experiments are carried out in order to obtain an understanding of deep Earth and planetary structure and behavior.

History and Introduction

The field of experimental mineralogy and petrology, which constitutes a part of the geological or Earth sciences, can be traced back for at least 200 years. The Scottish geologist Sir James Hall (1761–1832) is considered to be the father of experimental petrology. His laboratory experiments on the melting and crystallization of basaltic magmas were decisive in resolving the debate between the Plutonist and Neptunist schools of geologists in the late eighteenth and early nineteenth centuries and in favor of the former. His results illustrated the power of laboratory investigations for a scientific field that was field orientated and observational. The publication of N.L. Bowen's well-known book *The Evolution of the Igneous Rocks* in 1928, which was largely based on his pioneering laboratory melting investigations on simple model silicate systems at the Geophysical Laboratory of the Carnegie Institute of Washington, D.C., proved the necessity of experimentation in understanding the diversity of igneous rocks found in Earth. It was not until the last half of the twentieth century, though, that experimental mineralogy and petrology became an integral part of geology departments at universities.

The main, but not only, goal of experimental mineralogy and petrology is to model or simulate certain conditions within the laboratory in order to understand the physical and chemical properties of minerals, rocks, melts, and fluids and their interactions. As such, it is closely linked to the field of geochemistry and also partly geophysics. Most of Earth's interior and that of other planets are not accessible to direct study. Thus, it is necessary to simulate conditions or model geochemical or geophysical processes in order to gain a more complete understanding of these bodies. In addition, experimental mineralogical studies can have technical applications relating it, in part, to the fields of inorganic and physical chemistry, solid-state physics, and materials science.

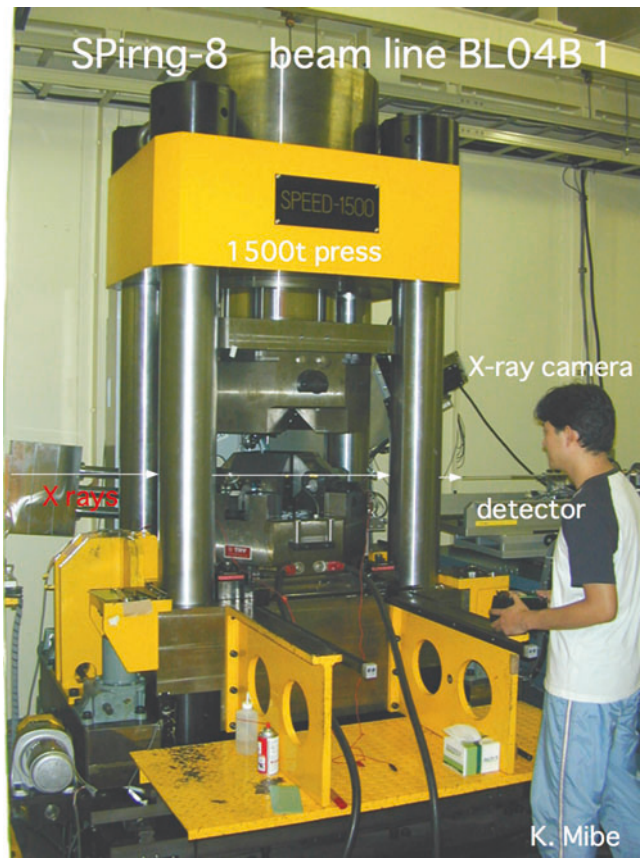
The physicist Percy Bridgman (1882–1962), a foremost scientist in high-pressure research and a Noble prize recipient, developed methods to reach conditions up to 2 GPa in 1905 while a student at Harvard University. Since then, studies have increased greatly in variety and complexity with technical advances so great and wide-ranging that it is presently possible to make experiments in the laboratory between pressures of 0.01 Pa and 100 GPa on mm-size samples using various large-volume presses (Fig. 1) and up to 500 GPa on micrometer-size samples with a small hand-sized diamond anvil cell (DAC, Fig. 2). Accessible temperatures range from those of liquid helium (~3 K) for SQUID magnetic susceptibility measurements in the DAC up to 6,000 K using focused laser heating in the same device. Hence, it is now technically possible to simulate the full range of pressure-temperature (*P-T*) conditions encountered on and within Earth, other rocky planets, and extraterrestrial bodies as well the large gaseous planets to substantial depths.

Phase Equilibrium Experiments: The Mineralogy and Petrology of the Earth

Traditionally, phase equilibrium studies have played the central role in experimental mineralogy and petrology. They normally consider the *P-T-X* stability relations, where *X* represents the composition of the system under study, namely, a mineral, mineral assemblage (i.e., rock), melt, or

fluid phase. In most experiments, a sample, either synthetic or natural in nature, is held for a certain length of time at the desired *P-T* condition in some device, quenched to ambient conditions, and the experimental products are examined. Normally, the assumption is made that chemical equilibrium was achieved at the *P* and *T* of the experiment and it is preserved in the quenched state. The chemical and structural state of the different phases from a series of experiments can then be characterized and a *P-T* phase diagram, for example, constructed. Hence, various solid-state mineral reactions, melting relations, solid phase transitions, fluid-rock interactions, or changes in chemical and physical properties can be described. In the 1980s, in situ experiments using the DAC and simple optical observation were made, which is possible because of the transparency of diamond. Intense synchrotron radiation can be used for in situ experiments using large-volume multi-anvil type (Fig. 1) or toroidal-cell-type devices, and the DAC (Fig. 2). X-ray diffraction, absorption, and fluorescence measurements are possible.

Phase equilibrium studies are coupled to the field of chemical thermodynamics. The stability of a given phase with respect to another phase or phase assemblage is a function of the *P-T-X* conditions of the system. Thermodynamic analysis enables experimental results to be extrapolated outside of the *P-T* conditions under study and also to extract thermodynamic properties of the participating phases.



Experimental Mineralogy and Petrology, Fig. 1 A large volume 1,500-ton Kawai-type multi-anvil press used in connection with synchrotron radiation at the SPring-8 facility, Japan, in order to study various processes in situ at high *P* and *T*. (Kawamoto et al. 2012, Proceedings of the National Academy of Sciences, U. S. A., 109, 18695)

Some important areas involving phase equilibrium study have involved or are:

i. The determination of phase diagrams showing *P-T* stability relations for key minerals and their reactions in Earth's crust and upper mantle. Here, cold-seal (for $P < 0.5$ GPa) and solid-media piston-cylinder (for $P < 5$ GPa) devices are often used. Various mineral geothermometers and geobarometers have also been calibrated. They can be used, as with phase diagrams, to determine paleo *P-T* conditions experienced by buried rocks, which have been returned to Earth's surface in a metamorphic cycle, for example, to understand tectonic events of the crust.

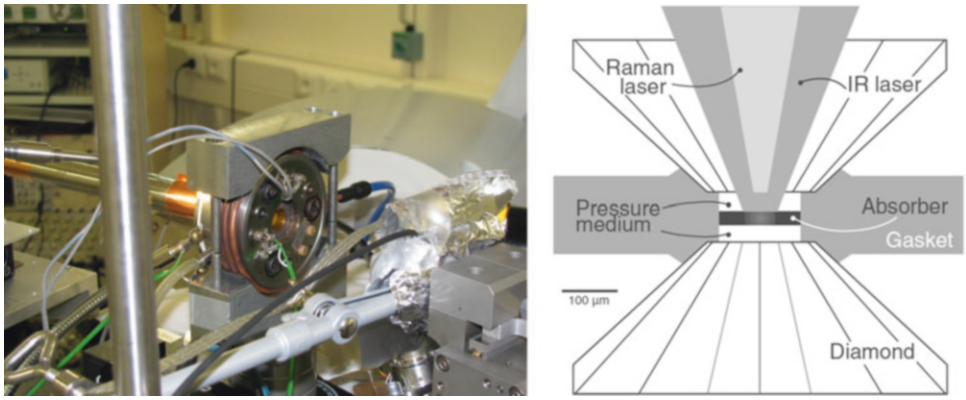
ii. In terms of igneous petrology, laboratory studies made in the 1950s at relatively low pressures and temperatures ($P < 0.5$ GPa and $T < 750$ °C) showed that most natural granitic bodies are the products of partial melting processes in the continental crust and were not formed by fluid-related metasomatic processes, as had been advanced by some field geologists.

iii. To understand the mineralogy of the deeper mantle, experiments using various multi-anvil devices and the DAC over the past 50 years have been made. They show that Earth's transition zone, located between seismic discontinuities at 400 and 670 km depth, consists largely of β-Mg_2SiO_4 (wadsleyite) or γ-Mg_2SiO_4 (ringwoodite) and a compositionally complex garnet solid solution containing a majorite component [$Mg_3(Mg,Si)Si_3O_{12}$]. The 400 km discontinuity is related to the relatively sharp phase transition of upper-mantle olivine (Mg_2SiO_4) to β-Mg_2SiO_4. Experiments using the DAC and multi-anvil devices have shown that below the 670 km discontinuity, in the lower mantle, $MgSiO_3$ bridgmanite and magnesiowüstite [(Mg,Fe)O] are stable. The former phase is considered the most abundant silicate in Earth. At even higher *P* and *T* conditions, DAC experiments led to the discovery of a new phase called post-bridgmanite, which is thought be a main constituent of the D″ layer at the mantle-core boundary.

iv. DAC experiments at extreme *P* and *T* are now being made on the system Fe–O–S with or without H, for example, in order to better understand the nature of Earth's Fe-rich outer and inner core.

Fluid, Melt, and Rheological Behavior at High Pressure and Temperature

Research has been carried out to study the phase relations and thermodynamic behavior of single or multicomponent fluids



Experimental Mineralogy and Petrology, Fig. 2 (*left*) Externally heated Bassett-type hydrothermal diamond anvil cell (DAC) setup used for high-*P* and high-*T* investigations in connection with synchrotron radiation at the Soleil facility, France. The cell size is 75 mm in diameter. (Kawamoto et al. 2014, Earth, Planets and Space, v. 66, 61). (*right*) Schematic figure showing just the two diamond anvils. Between the diamond faces, a sample is enclosed in NaCl, for example, which serves as the pressure-transmitting medium and thermal insulator. Here, focused heating is done internally using an IR laser, and Raman and synchrotron X-ray measurements can be made (Uts et al. 2013, Reviews of Scientific Instruments, v. 84, 103904)

(e.g., H_2O, H_2O–CO_2, H_2O–CO_2–CH_4). Equations of state have been developed that describe *P*-*V*(volume)-*T* relations to extreme conditions. In addition, much work over the years has been made to understand mineral or rock phase relations with fluids at high *P* and *T*. Research has showed that water is soluble in silicate melts as molecular H_2O and OH^-. Starting in the 1960s, the critical endpoints between SiO_2 and aqueous fluids were determined at 1 GPa, and it was determined that those between H_2O and various natural rocks occurred at higher pressures. The compositions of basaltic and high-Mg andesitic partial melts derived from mantle peridotite in the presence of H_2O were determined at 1 GPa in the 1990s. At pressures greater than 3 GPa, partial melts of hydrous peridotite are more mafic in composition than those obtained by anhydrous melting. Experiments also showed that the composition of aqueous fluids changes with pressure. Those coexisting with forsterite (Mg_2SiO_4) and enstatite ($MgSiO_3$) are relatively silica rich from 1 to 2 GPa, but they become more mafic than enstatite in composition at 3 GPa and are close to peridotite composition from 3 and 5 GPa. The interpretation is that the solvus between melt and aqueous fluid in the peridotite-H_2O system closes at pressures greater than 3 GPa.

More recently, the critical endpoints between various natural rock compositions and aqueous fluids have been studied in situ with multi-anvil devices using synchrotron X-ray radiography. The second critical endpoints are located at 2.5 GPa and 700 °C for pelite-H_2O, 2.9 GPa and 800 °C for high-Mg andesite-H_2O, 3.4 GPa and 900 °C for basalt-H_2O, and 3.8 GPa and 1,000 °C for peridotite-H_2O. These results are significant because beyond the endpoints, there is no phase separation between silicate melt and aqueous fluid. Only a single fluid phase exists.

The solubility of minerals in aqueous fluids has also been investigated in situ using the DAC via simple visual observation or using synchrotron X-ray fluorescence. The results agree with those obtained using the larger devices. Finally of note, the solubility of hydrogen in nominally anhydrous minerals (e.g., olivine, pyroxene, garnet, plagioclase, wadsleyite, ringwoodite, bridgmanite) coexisting with free aqueous fluids, as well as the hydrogen partitioning behavior between minerals and silicate melts, has been determined from high-*P* and high-*T* quenched experiments. It has been argued through these investigations that Earth's mantle possibly contains several "oceans of water" relative to its hydrosphere.

The physical processes governing melt generation, segregation, and extraction, from an initially solid source, are important in understanding magma genesis and transport. Experimental studies have determined the amount of melt that must be present and under which physical conditions, before it can separate from a crystalline matrix. Mg-rich silicate melts, which are difficult to quench from high *P* and *T*, can be studied using the "floating-bead method" with laser heating, with which it is possible to make forsterite (Mg_2SiO_4) glass. Laboratory measurements have shown that some silicate melts are more compressible than their equivalent crystalline materials and that at some elevated pressure, a crossover point occurs such that melts will have negative buoyancy and crystals will float even under hydrous conditions. Investigations have also focused on measuring the macroscopic physical properties, such as density and viscosity, of silicate- and oxide-based melts for both model and natural composition systems. High-pressure compression experiments on some crystalline silicates have shown that pressure-induced amorphization can be achieved without heating or melting. Hence, the realm between the amorphous state of glass, having only short-range order, and crystalline materials, having long-range translational

symmetry, may not be as widely separated as previously believed.

Rheological studies have been made on the deformational properties of Earth materials and in the presence or absence of a fluid and differential stress. Using synchrotron X-rays, deformation experiments in large-volume multi-anvil apparatus have been carried out at controlled strain rates at high-*P* and high-*T* conditions. High-pressure experiments to investigate the conversion of olivine to β-Mg_2SiO_4 have been undertaken to understand the physical properties of subducting lithosphere. The metastable persistence of olivine beyond its equilibrium pressure stability in relatively cool subducted slabs, followed by a sudden transition to β-Mg_2SiO_4, has been proposed as a mechanism for triggering deep-focus earthquakes.

Rock physics and fracture-mechanics investigations, often undertaken by the engineering community, have now also found a place within the Earth sciences. Deformation and textural studies of polymineralogic rocks, highlighting their anisotropic physical properties, are important for interpreting seismic profiles of the lower crust and upper mantle. The lattice preferred orientation of olivine is used as a hydrometer and also to determine stress conditions in the upper mantle. Fracture mechanics studies, concerning the strength and ductility of crustal rocks, are undertaken to better understand, for example, the cause of earthquakes generated in active fault zones.

Low-Temperature Mineral Solubility and Kinetic and Diffusion Studies

At low *P-T* conditions, with *T* less than roughly 300 °C, solubility measurements of minerals in H_2O can be made. The results can be used to extract thermodynamic data for phases that are not stable at high temperatures or where the kinetics of growth are slow, and, hence, thermodynamic equilibrium is not reached. These experiments are designed to understand, for example, near surface geological processes and hydrosphere-lithosphere interactions. Studies have been undertaken to model seawater-basalt interactions occurring at ocean spreading centers and to understand the processes causing submarine sulfide precipitation and ore-forming reactions.

Phase equilibrium work is complemented by atomic diffusion studies of minerals, glasses, and melts and kinetic studies of reactions. Experiments investigating the rates of cation or anion diffusion in minerals at different *P* and *T* conditions have been done and interpreted using the theory of chemical kinetics. In these studies, atomic diffusion coefficients have been determined for important rock-forming crystals such as olivine and garnet to better understand their compositional zoning. It is possible to estimate the cooling histories of some rocks and meteorites using such data.

The study of crystalline point defects in minerals is important in kinetic-related experiments, as it is in investigations of electrical and thermal conductivity behavior. Impedance spectroscopy and EMF measurements using oxygen-sensitive solid electrolytes are used in studies of point defects and electrical conductivity.

Mineral Physics and Experimental Measurement Techniques

Mineral physics is a scientific field related to experimental mineralogy and petrology that largely focuses on the physical properties of minerals often, but not only, at extreme *P-T* conditions. The fields of geophysics and mineralogy have merged, in part, creating the field of high-*P* mineral physics. Investigations employ an ever-increasing variety of techniques to study condensed matter properties. Diffraction measurements often use synchrotron radiation. In addition, infrared, Raman, Mössbauer, nuclear magnetic resonance (NMR), X-ray absorption (i.e., EXAFS and XANES), UV/VIS optical absorption, electron paramagnetic resonance, and neutron spectroscopies are being used routinely.

Magic-angle spinning NMR work has been made on glasses synthesized in the laboratory to determine their local properties such as the type of polyhedral coordination units that are present and their degree of polymerization. Some NMR measurements can even be made directly at high *T* in the stability field of the melt phase. Raman and IR spectroscopy are used in DAC experiments at high-*P* and high-*T* conditions. Inelastic synchrotron X-ray scattering measurements are made to study the electronic state of various elements and their oxygen coordination behavior at high pressures.

The determination of density and bulk modulus and its pressure derivatives (equations of state) of mantle phases and silicate melts is needed for the interpretation of seismic velocity profiles measured in Earth. They are used in models that attempt to understand early Earth differentiation and Earth structure with depth. The elastic constants at room temperature of most of the important rock-forming silicates have been measured by ultrasonic and Brillouin methods. They, together with diffraction measurements made in the DAC, allow the density and bulk moduli of minerals to be determined. X-rays at synchrotron facilities permit, further, both the *P* and *T* effects on the elastic properties and sound wave velocities to be measured. The results are important because density and sound velocity properties of minerals can be compared with geophysical seismic measurements through the whole Earth to analyze mantle structure and its mineralogical composition with depth.

Other measurement techniques that are being employed include electron back-scattered diffraction to determine

single-crystal orientations. Computer tomography is used to make nondestructive analyses of the 3D distributions of minerals, melts, and pore spaces in both natural and synthetic rocks. Very minute sections of experimental charges retrieved from laser-heated high-*P* and high-*T* DAC experiments can be excised using focused ion beams for careful transmission electron microscopy examination that indicate reaction and melting features.

Crystallographers and mineral physicists have contributed knowledge to other fields concerned with crystal chemistry and chemical bonding behavior such as inorganic and physical chemistry and solid-state physics. An emphasis is being placed on understanding the atomistic scale behavior of Earth materials (e.g., minerals, melts, fluids) and their relationship to macroscopic properties and under different, often extreme, *P-T-X* environments.

Mineral Synthesis

The discipline of mineral synthesis is also an important, but often overlooked, part of experimental mineralogy and petrology. The growth or production of single crystals, mineral assemblages, or glasses in the laboratory are invaluable for other investigations. For example, compositionally simple end-member and solid-solution minerals, which cannot be found in nature, have been synthesized for calorimetric measurements to determine their thermodynamic properties. These thermodynamic data have been used to construct geothermobarometers and calculate various *P-T* positions of mineral reactions and complement those calibrated in phase equilibrium experiments. Single crystals are grown for crystal-chemical study using different spectroscopic and diffraction techniques. Polycrystalline nano-diamonds are synthesized directly from graphite at high *P* and *T*, and they are harder than single crystal diamond. They can be used, for example, to generate the highest pressures in large-volume multi-anvil devices.

Present and Future Developments

Today, there is an extensive and impressive arsenal of experimental techniques available for investigating the chemical and physical properties of Earth and planetary materials. Traditional methods used in experimental mineralogy and petrology of just 30 years ago largely involved optical microscope examination, X-ray powder diffraction measurements, and chemical analysis using the electron microprobe. Technical developments have made it possible to make measurements on continually smaller amounts of material and at higher spatial resolutions. The development and construction of large national and international research facilities has increased. Dedicated third-generation synchrotron sources, characterized by extremely intense radiation, and advanced neutron spallation sources are permitting new condensed matter experiments unimaginable 30 years ago. Novel experiments and measurements on minerals and other materials are being made, and investigations are of increasing complexity and cost and sometimes involve teams of specialists and researchers.

Applied research, though not discussed here, is becoming more widespread, and collaborations between mineral physicists and material scientists and condensed matter physicists are increasing. Experimentalists are needed to apply their expertise to solve environmental problems in such areas as radioactive waste disposal, pollution control and cleanup and in finding ways to reduce atmospheric CO_2 by storage in underground reservoirs and through CO_2 binding by forming carbonate minerals. Here, the field of experimental mineralogy and petrology strongly overlaps that of geochemistry.

Concomitant with these experimental developments, there has been an increase in theoretical and computer studies (computational or theoretical mineralogy). Molecular dynamic simulations, empirically based static lattice energy, lattice dynamic, and ab initio quantum mechanical calculations are being applied in a variety of mineralogical, geochemical, and geophysical studies. Experimentalists can use these calculations to guide their avenues of research and to interpret their results. Calculations can be used to plan experiments and to predict certain behavior, but ultimately it is in the laboratory or in nature where they must be tested.

Summary

The field of experimental mineralogy and petrology has become extremely diverse encompassing many different approaches and areas of research. The principles of physics and chemistry are of increasing importance in many areas of the Earth sciences. Developments point to the breakdown of traditional borders both within the Earth sciences and between it and other scientific disciplines. The synergy generated by closer collaboration between different scientific disciplines is spawning new methods and types of experiments and is providing an evermore quantitative and comprehensive understanding of a variety of Earth processes.

Definition

Ferromanganese (Fe-Mn) crusts and nodules are marine sedimentary mineral deposits, composed mostly of iron and manganese oxides. They precipitate very slowly from seawater, or for nodules also from deep-sea sediment pore waters, recording the chemical signature of these source waters as they grow. Additional elements incorporate via sorption processes onto the Fe-Mn oxides, including rare and valuable metals that can reach concentrations that are economically valuable.

Introduction

Fe-Mn crusts and nodules occur throughout the global ocean, from the flanks of seamounts to the abyssal plains of the deep ocean. Unique compared to other marine rocks, Fe-Mn mineral deposits actually grow over time. They grow extremely slowly by precipitation of metals from seawater onto seamount rock outcrops for Fe-Mn crusts, and for nodules by precipitation from both seawater and bottom-sediment pore waters around nuclei at the sediment surface. Although the deposits are composed mainly of iron and manganese oxide minerals, their unique formation allows for the acquisition and concentration of numerous other elements, many of which are economically valuable, including critical metals, platinum group metals, and the rare earth elements. The concentrations of metals vary with water depth and geographic location. Fe-Mn crusts and nodules are excellent archives for paleoceanographic conditions and are used extensively to understand Earth's geologic history. The study of Fe-Mn deposits is therefore very active as scientists probe them at a molecular level for paleoceanographic and element mass-balance studies, and scientists, governments, and companies pursue them from the level of global- to local-scale distributions to understand and quantify their valuable metal contents.

Formation and Composition

Mechanism of Chemical Sedimentation

Fe oxyhydroxide and Mn oxide are the dominant minerals that compose Fe-Mn crusts and nodules, and additional metals are sorbed onto these main phases (see "Mineralogy" section below for further information). When seawater is the sole source of the metals, which is true for all crusts and some nodules, the deposit is called hydrogenetic. Elements dissolved in seawater are derived predominantly from land via rivers and wind-blown dust, which then dissolve to various degrees forming ions and complexes. Another source of elements to seawater is hydrothermal venting that occurs along the 89,000 kilometers (km) of oceanic spreading centers and volcanic arcs, which is the source of most manganese and some iron dissolved in seawater. When metals are supplied from the pore waters of seafloor sediments, the deposits are called diagenetic. Metals in the pore-fluid are derived from diagenetic oxidation-reduction (redox) reactions that occur in

Ferromanganese Crusts and Nodules: Rocks That Grow, Fig. 1 Map of global distribution of Exclusive Economic Zones (EEZ; *teal* shading), areas beyond national jurisdictions (*gray*), and global permissive areas for ferromanganese crust (*diagonal line fill*) and abyssal plain nodules (*thin outline*). Areas of high economic interest, the Clarion-Clipperton Zone, Prime Crust Zone, and Cook Islands-Penryhn Basin (CCZ, PCZ, CI-PB, respectively) are marked by unique outlines as indicated in the legend. Notes: (1) designation of an area as permissive indicates the possibility, not certainty, of economically valuable deposits (2) small patches of scattered nodules occur in regions not indicated on this figure

the sediment layers, then diffuse upward and are incorporated into the Mn and Fe minerals forming at the seabed. Only nodules have input of diagenetically produced metals, and some nodule fields receive metals predominantly from that source (i.e., Peru Basin; Fig. 1) but most have a mixed hydrogenetic and diagenetic origin. Sediment pore fluids can be the dominant source of Ni, Cu, Mn, and Li, while seawater is the dominant source of Co, Te, platinum group metals (PGM), rare earth elements plus Y (REY), and others (Hein and Koschinsky 2014).

Charged ions dissolved in seawater then sorb onto the surface of the Fe and Mn oxides according to charge as designated by a first-order electrochemical model. Cations sorb onto the Mn oxide, which has a strong negative surface charge at seawater pH. In contrast, the negative and neutral element complexes dissolved in seawater sorb onto the slightly positively charged surface of Fe oxyhydroxide (Koschinsky and Hein 2003). Elements can undergo outer-sphere (weak) sorption or inner-sphere (strong) sorption. In the latter, covalent bonds are formed that tightly hold the metals to the main Fe and Mn minerals. Many of the metals that are highly enriched in Fe-Mn deposits are oxidized to an immobile state on the surface of the Fe and Mn minerals accompanying inner-sphere sorption (Hein and Koschinsky 2014). For example, Co^{2+}, Ce^{3+}, and Tl^{+} oxidize to Co^{3+}, Ce^{4+}, and Tl^{3+}, respectively, on the surface of the Mn oxide while Te^{4+} and Pt^{2+} may oxidize to Te^{6+} and Pt^{4+} on the surface of the Fe oxyhydroxide.

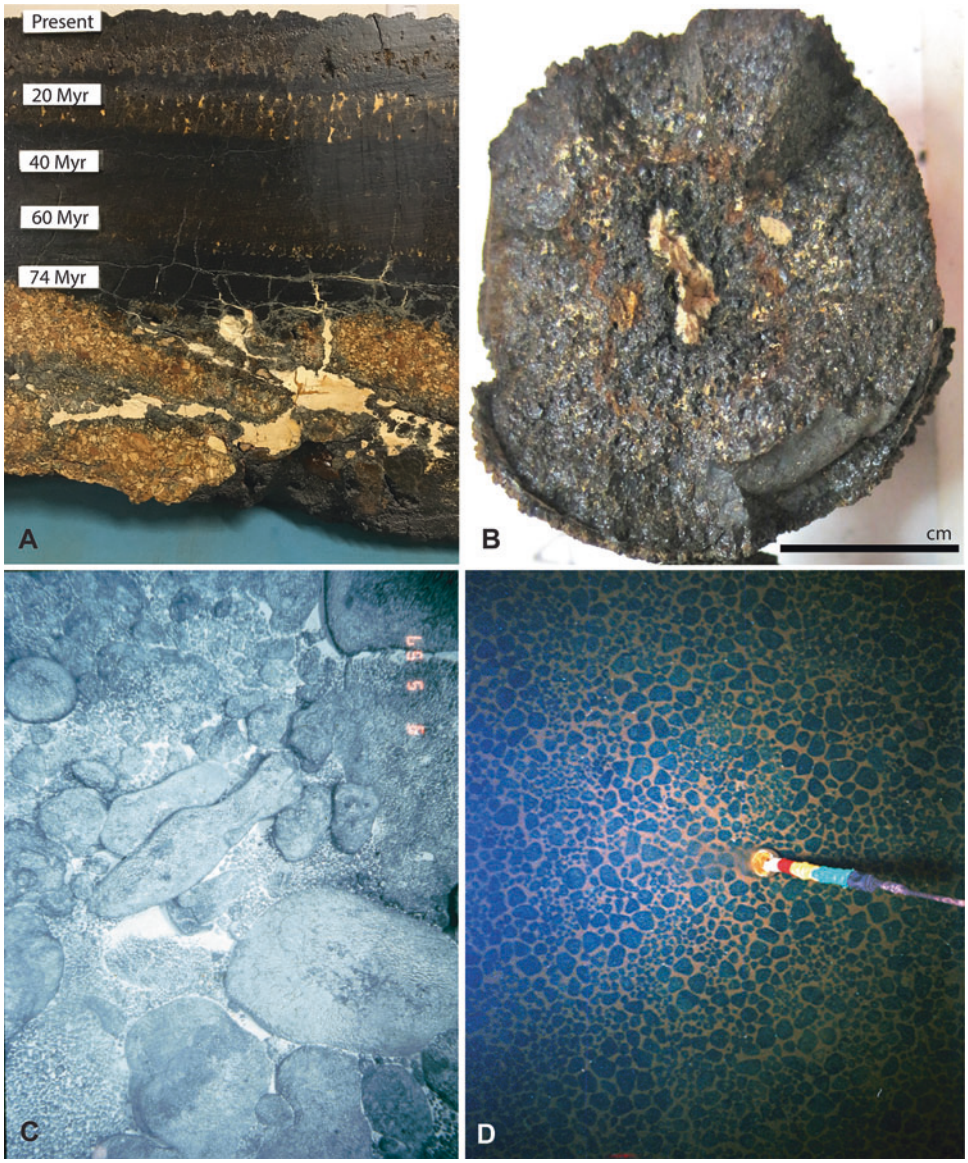
Structure and Texture

Hydrogenetic precipitation of Fe-Mn crusts produce strata (layers) with complex structures determined by changes over time in seawater composition, growth rates, bottom current activity, and location, including water depth. These layers begin at the substrate rock and stack on top of one another along a vertical growth axis. Layers have unique chemical compositions and are visually distinguishable, allowing for evaluation of crust growth through time (Fig. 2). Layers range from dense and massive to friable and loosely consolidated, and textures are most commonly laminar, columnar, and botryoidal (mamillary).

Fe-Mn nodules grow by mineral precipitation in concentric layers around a minute nucleus that is commonly composed of a fragment of an older nodule, rock fragment, or even a shark's tooth (Fig. 2). Like crusts, the layers are distinct in chemical composition, texture, and appearance, but in this case, they are aligned along the radial growth axis. Although nodules typically sit at the sediment surface and therefore grow both hydrogenetically and diagenetically, individual layers tend to be uniform around the circumference. Therefore, the nodules must rotate as they grow causing near-equal exposure to seawater and sediment pore waters.

Growth Rates

Fe-Mn crusts accrete/precipitate at average rates of 1–5 mm per million years (mm/Ma), and crusts with slower growth



Ferromanganese Crusts and Nodules: Rocks That Grow, Fig. 2 Representative photographs of ferromanganese crusts and nodules: (**a**) cross-section of crust CD29-2 collected during cruise F7-86-HW from Karin Ridge, Central Pacific (168°42′N, 168°14′W) at a water depth of 2,180 m; approximate ages for each crust layer are labeled in million years (Myr) ago (Klemm et al. 2005; Nielsen et al. 2009); (**b**) interior of a nodule from Cook Islands-Penrhyn Basin with small mudstone nucleus; scale bar represents 1 cm (sample ID: CK-76-1 STN-11 FFG-14A; Hein et al. 2015); (**c**) seafloor paved with Fe-Mn crust from Horizon Guyot in the Johnston Island EEZ, Central Pacific, 2,000 m water depth; (**d**) seafloor image of Cook Islands nodule field, 5,009 m water depth, taken during a Japanese research cruise in 2000 (Photograph 0447, JICA/MMAJ 2001)

F

rates contain higher concentrations of sorbed metals. If bottom currents do not keep the seamounts free of sediment, small amounts of sinking particles can be incorporated into the crusts. Incorporation of these particles in large enough quantities can increase the growth rates. Hydrogenetic nodules also grow remarkably slowly, at rates similar to those of Fe-Mn crusts, whereas purely diagenetic nodules grow at rates up to 250 mm/Ma. Because most nodules form by hydrogenetic and diagenetic precipitation, they grow at intermediate rates of several tens of mm/Ma (Hein and Koschinsky 2014). Despite average nodule growth rates being thousands of times slower than the average sediment accumulation rate, nodules persist at the sediment surface. There have been several proposals to describe the mechanism for keeping nodules at the seabed (e.g., Halbach et al. 1988), although the actual process remains a mystery.

Mineralogy

Fe-Mn crusts are composed predominantly of nano-structured vernadite ($MnO_{2-x}•xH_2O$; also called δ-MnO_2 and turbostratically disordered birnessite) and X-ray amorphous Fe oxyhydroxides (FeO(OH); feroxyhyte, ferrihydrite, and goethite) as determined by electron diffraction. The crusts contain minor amounts of detrital minerals, such as quartz and feldspar, that are deposited as sinking particulate from the water column. Older layers of thick crusts contain carbonate fluorapatite ($Ca_5(PO_4,CO_3)_3(F,Cl)$), a secondary phosphate mineral that formed by replacement and precipitation in crust pore spaces long after the Mn and Fe minerals precipitated from seawater. Fe-Mn nodules are also composed predominantly of hydrogenetic vernadite, as well as 10 Å manganates (todorokite, buserite, asbolan), and occasionally diagenetic birnessite, a 7 Å manganate. Mixed-origin and

diagenetic nodules contain lesser amounts of Fe oxyhydroxide, as well as minor amounts of detrital material, and authigenic minerals that formed in the sediment from alteration of other materials (alteration products of volcanic glass are particularly common). As discussed above regarding fluid source, mineral crystal structure can also influence metal concentrations. The tunnel structure of todorokite, for example, enables the acquisition of large amounts of Ni, Cu, and other diagenetic elements, such as Li, whereas the more common hydrogenetic manganese oxide, vernadite, is a phyllomanganate that has a layered structure and tends to accumulate more Co (Post 1999). Lead, which sorbs onto Fe oxyhydroxides (Koschinsky and Hein 2003), occurs in much higher concentrations in hydrogenetic deposits because the Fe minerals are much more abundant in Fe-Mn crusts than in diagenetic-influenced nodules.

Metal Concentration

In addition to the subequal iron and manganese contents, the concentrations of other metals in Fe-Mn deposits are variable based on their seawater composition, growth rates, water depth, etc., as discussed above. Mineralogy can also have an influence, as is the case for cobalt and many other rare metals that are adsorbed onto vernadite, which is more abundant in crusts than nodules (Hein and Koschinsky 2014). The rare metals Te and Pt are also more highly concentrated in crusts than nodules because they are sorbed onto and ultimately bonded to the more abundant iron oxyhydroxide in crusts. For diagenetic nodules or those of mixed origin, Mn concentrations are much higher than in crusts, and the metals of greatest economic interest are Ni, Cu, Co, Li, Mo, and REY. Additional trace elements of note for crusts and nodules can be seen in Table 1.

Geologic Setting and Distribution

Crusts

Fe-Mn crusts form pavements on rock surfaces and coat pebbles and cobbles throughout the global ocean where these substrates have been kept free of sediment for millions of years. The primary setting for crust growth is the flanks of extinct submarine volcanoes (seamounts, guyots), ridges, and plateaus, of which there are more than 100,000 throughout the global ocean. This co-occurrence with seamounts allows crusts to grow at a wide range of water depths from 400 to 7,000 meters (m), and the maximum thickness of the crust is proportional to the age of the seamount. Crust thickness varies from less than 1 mm to about 260 mm. In ocean basins that host fewer seamounts, the Atlantic and Indian Oceans, crusts are also associated with oceanic spreading centers and their accompanying hydrothermal activity. Hydrothermally influenced crusts obtain increased concentrations of Fe or Mn, mostly to the lowermost layers, which dilute the trace and rare metals. Therefore, Fe-Mn crusts of economic interest occur distant from hydrothermal sources and from continental margins. Based on these criteria, and the fact that the oldest seamounts occur in the equatorial NW Pacific, the area with the thickest and most metal-rich crusts of greatest economic interest occurs there (Fig. 1), which is called the prime crust zone (PCZ; Hein et al. 2009). However, thick and metal-rich crusts occur at other locations, including in the Atlantic Ocean

on deep-water seamounts in the marginal areas, especially east of New England, west of the Iberian Peninsula, the Rio Grande Rise, and ridges in the SE Atlantic.

Nodules

Fe-Mn nodules occur as abundant individual rocks on the surface of or partially buried in sediment that blankets abyssal plains throughout the global ocean, which occupy water depths of about 3,500 to 6,500 m. Specifically, nodules form where sedimentation rates remain less than 10 mm per thousand years (mm/ka), and abyssal plain sedimentation rates are usually low in areas distant from continents where biological productivity is low and in areas that remain below the carbonate compensation depth but also near continental margins that are bordered by a deep-sea trench, arid climate, or have a wide continental shelf. Nodules are generally golf-ball size with average diameters of 1–12 cm, but they can vary in diameter from millimeters (micronodules) to 20 cm. The size of nodules maximizes with increasing diagenetic input of metals, whereas the economic value is greatest in areas of moderate primary productivity in surface waters, which allows both hydrogenetic and diagenetic growth (ISA 2010). Therefore, despite nodule fields being vast and relatively common, nodule size, density, and metal content can vary greatly. To date, the regions confirmed to have the greatest concentrations of metal-rich nodules are: the NE Pacific Clarion Clipperton Zone (CCZ; Fig. 1) that extends from offshore Mexico to as far west as the longitude of Hawaii, the central South Pacific Penrhyn Basin, the NE Pacific Peru Basin, and the Central Indian Ocean Basin. In general, fewer large abyssal plains exist in the Atlantic and Indian Oceans compared to the Pacific because their topography is dominated by midocean ridge systems. Other areas may possess nodule fields, but more exploration is needed.

Economic Potential

Regional-Scale Metal Grade and Tonnage

Due to the high demand for metals as technology advances and population increases, the metal content in Fe-Mn deposits is attractive as a potentially minable ore. To estimate the potential economic value of Fe-Mn crust and nodule deposits, first-principle calculations are made using average element concentration data from many individual samples and estimated tonnages based on observed nodule densities and total area of the deposit. Here, one major well-known deposit for crusts (PCZ) and two for nodules (CCZ and Cook Islands-Penrhyn Basin; CI-PB) will be discussed, but numerous other studies characterize additional deposits (e.g., Sudhakar 1989).

In the CCZ, the Mn nodule field covers an area of about 9 million square km that contains on average about 6 kilograms (dry weight) of nodules per square meter (kg/m^2) of seabed but can reach up to 44 kg/m^2 (Hein et al. 2015; Fig. 1). Using these figures, it is estimated that about 21,100 million dry tonnes of nodules occur within the CCZ. That tonnage of nodules would provide nearly 6,000 million tonnes of Mn. To put this amount into perspective, it is possible to compare it with the terrestrial reserve base (TRB), which includes resources that are currently economic (reserves), marginally economic, and subeconomic (U.S. Geological Survey 2013). There is more Mn in the nodules from the CCZ than the entire TRB of Mn (Hein and Koschinsky 2014; Hein et al. 2013; Table 1). The tonnage of Ni, Co, Te, and Y in CCZ nodules exceeds that of the TRB by 2, 3, 1.4, and 4 times, respectively. Other elements add up to a significant percentage of the TRB: Mo – 63%, Li – 19%, and total REY as oxides – 11%.

The Cook Islands-Penrhyn Basin (CI-PB) nodule field hosts 8.86 million tonnes (dry weight) of nodules; this high tonnage is largely due to the high abundance of nodules which average 14.4 kg/m^2 (dry weight); the maximum nodule abundance recorded is 58 kg/m^2 (Hein et al. 2015; Fig. 1). CI-PB nodules have significantly more Co and Te than the TRB; for Te, this is true even if only the high tonnage belt (>25 kg/m^2) is considered. The CI-PB nodules also contain about 25% of the TRB of Ni, 28% of Nb, 27% of Mn, and 10–12% of REY, Mo, Ti, and V. In addition, the complement of heavy REY (Eu-Lu) of the total REY content averages 17% (maximum 24%; Hein et al. 2015), which contrasts significantly with the <1% heavy REY complement in the large land-based carbonatite-hosted REY deposits (Hein et al. 2013) – it is the heavy REY that are most needed for high-tech applications.

For Fe-Mn crusts, 7,533 million dry tonnes of crust are estimated to reside in the PCZ (Hein and Koschinsky 2014; Fig. 1). Although PCZ crusts only amount to 36% of the tonnage of CCZ nodules, they have ~1,700 times more Tl, 9 times more Te, 3.8 times more Co, and 3.4 times more Y than the TRB (Table 1). Additional metals in PCZ crusts as a percent of the total TRB are Bi 46%, Mn 33%, Ni 21%, Mo 18%, V 13%, Nb 13%, total REY as oxides 11%, W 11%, Ti 10%, Th 8%, PGM 5%, and Cu 0.7% (Hein et al. 2013; Table 1). Although calculations illustrate that significant tonnages of metals occur in marine Fe-Mn deposits, it should be noted that not all the nodules and crusts in any one deposit will be recovered, as is also true for the metals that make up the TRB.

Exploration and Mining Progress

Some Fe-Mn deposits occur relatively close to the coasts of countries and are therefore hosted within their 200 nautical mile Exclusive Economic Zone (EEZ; Fig. 1). Within these EEZs, countries have full jurisdiction over the exploration and exploitation of marine mineral deposits. An example is the CIs nodules, which encompasses 1,977,000 km^2 and is currently the only country with a public tender for exploration contracts for nodules (Hein et al. 2015).

Many Fe-Mn deposits, however, occur outside the EEZs known as the area beyond national jurisdictions, or simply "The Area" (Fig. 1). To manage this, the United Nations, through the Convention of the Law of the Sea Treaty (UNCLOS), established the International Seabed Authority (ISA) as an independent agency that would oversee development of mineral resources in The Area. The ISA has 166 member states plus the European Union and receives applications by government agencies and industry for exclusive rights for exploration in specific areas. As of May 2016, there are 17 confirmed or pending contracts for exploration areas for nodules, 16 of which are within the CCZ and 1 within the Central Indian Ocean Basin, and 5 exploration contracts for crusts, 4 in the PCZ and 1 in the SW Atlantic Ocean.

There is as yet no mining in The Area and exploration encompasses resource delineation and evaluation, baseline data collection, and study of environmental impacts; however, exploitation regulations are currently under development by the ISA. The global demand for metal continues to rise as population increases and technological needs grow while terrestrial ore grades diminish and mines are closed. The promising metals grades in Fe-Mn deposits, especially nodules which are easier to harvest at the sediment surface then are crusts, will thus continue to be evaluated for their resource potential, and the likelihood of mining them will certainly increase if environmental impacts are deemed acceptable and viable mining technologies are engineered.

Summary and Conclusions

Fe-Mn mineral deposits are extensive in the deep ocean wherever low sediment accumulation is maintained. Fe-Mn crusts grow ubiquitously on rock outcrops throughout the global ocean whereas Fe-Mn nodules are expansively developed on the abyssal plains. Both crusts and nodules are composed predominantly of Fe and Mn oxide minerals that precipitate from cold seawater and/or deep-sea sediment porewaters and acquire abundant metals and other elements via sorption on the main Fe and Mn minerals as controlled by these source waters. Both Fe-Mn deposit types record the history of the waters they precipitated from, and crusts especially serve as one of the most important records of oceanographic events that have occurred over the past 70 million years. Metals essential to many emerging technologies are enriched in these nonrenewable Fe-Mn deposits to the extent that they are considered a potential resource for mining in the near future. Twenty-two contracts for exploration for nodules and crusts have already been signed or are pending with the International Seabed Authority (ISA). A set of environmental and other exploitation regulations are currently under development by the ISA and expectations are that they will be finalized within the next 3–4 years.

Fick's Law

Isao Sakaguchi
National Institute for Materials Science, Tsukuba, Ibaraki, Japan

Definition

Fick's First Law

It is considered that the concentration gradient of elements in mineral and rock resulted from an evidence of diffusion, and the nonequilibrium state was frozen in them. The mobile element found the concentration gradient in material is useful as the tracer to estimate the timescale. The tracer diffuses in a manner to decrease the concentration gradient from the material surface. In such cases, the flux density of species, *i*, in the three dimensions is given by

$$J_i = -D_i \rho \nabla C_i \tag{1}$$

where D_i is the diffusion coefficient, ρ is the density, and ∇C_i is the mass fraction concentration gradient. In one dimension, Eq. 1 becomes

$$J_i = -D_i \rho \left(\frac{\partial C_i}{\partial x} \right) \tag{2}$$

Fick's Second Law

Equation 2 is written with the consideration of the conservation of mass. It can be shown that

$$\frac{\partial C_i}{\partial t} = \frac{\partial}{\partial x} \left(D_i \frac{\partial C_i}{\partial x} \right) \tag{3}$$

where t is time. This is known as Fick's second law. If D is independent at the position, Eq. 3 is written as

$$\frac{\partial C_i}{\partial t} = D_i \frac{\partial^2 C_i}{\partial x^2} \tag{4}$$

Equation 4 is solved with the boundary condition, and then the solution is given the concentration of tracer "species, *i*," in the solid as a function of the distance, x, and time, t. In the experiment of elemental diffusion in the solid, the following boundary conditions are considered.

Solution of Constant Concentration on the Surface

First is that the surface x = 0 is maintained at a constant concentration during the diffusion annealing.

$$C(x,t) = C_l \text{ for } 0 \le t \le \infty$$

$$C(0,t) = C_l \text{ at } t > 0$$

$$C(x,t) = C_l \text{ as } x \to \infty$$

The solution to Eq. 4 satisfying above condition is

$$C(x,t) - C_l = (C_o - C_l) erfc \left[\frac{x}{2\sqrt{Dt}} \right] \tag{5}$$

where *erfc* is the complementary error function. Above boundary condition is achieved in the diffusion experiment of gas–solid exchange at high temperature. For example, above solution is usually used to calculate the diffusion coefficient of oxygen tracer (^{18}O) in oxide materials.

Solution of Thin Film Source

Second boundary condition used a thin film as tracer source deposited on the material. Above state is the boundary condition for one of the simplest solutions to Fick's second law. If the thin film source on the material is heated so that the tracer diffuses, the tracer composition will be given by:

$$C(x,t) = \frac{\alpha}{2\sqrt{Dt}} exp \left(\frac{-x^2}{4Dt} \right) \tag{6}$$

where α is the total amount of tracer. This is called the "thin film solution" and it holds for a film thickness less than $\sqrt{Dt}$. The diffusion experiments satisfying the boundary condition are usually carried out to determine the diffusion coefficient of cation in materials.

F

Summary

Fick's law is a basic law to understand diffusion phenomena.

Fission Track Analysis

Stuart N. Thomson
Department of Geosciences, University of Arizona, Tucson, AZ, USA

Definition

Fission track analysis is the study of microscopic linear traces of radiation damage in minerals and natural glass formed by radioactive decay of the ^{238}U isotope of uranium by spontaneous fission. The constant accumulation rate of fission tracks provides a means to date geologic materials, and the gradual fading of fission tracks (annealing) at elevated temperatures over geologic time can be used to elucidate host rock thermal histories.

Introduction: What Are Fission Tracks?

Radioactive decay of natural uranium occurs by two processes: alpha and beta decay to stable isotopes of lead – the basis of U-Pb, (U-Th)/He, and U-series dating – and by natural spontaneous fission. The latter process is restricted almost exclusively to the ^{238}U isotope of uranium and occurs with a probability almost two million times lower than U to Pb alpha decay. The energy released by spontaneous fission propels two fission fragments in opposite directions, which in an insulating solid such as a crystal lattice forms a metastable linear zone of damage known as a *fission track*. The most widely accepted model for fission track formation is the ion explosion spike mechanism (Fleischer et al. 1965) whereby the positively charged fission fragments strip electrons from atoms in the lattice leaving behind a trail of positively charged ions that mutually repel one another. Newly formed fission tracks are generally assumed to have the same initial length, typically 10–20 μm long and 5–10 nm in diameter, dependent on the composition and density of the medium in which they form.

Revealing Fission Tracks

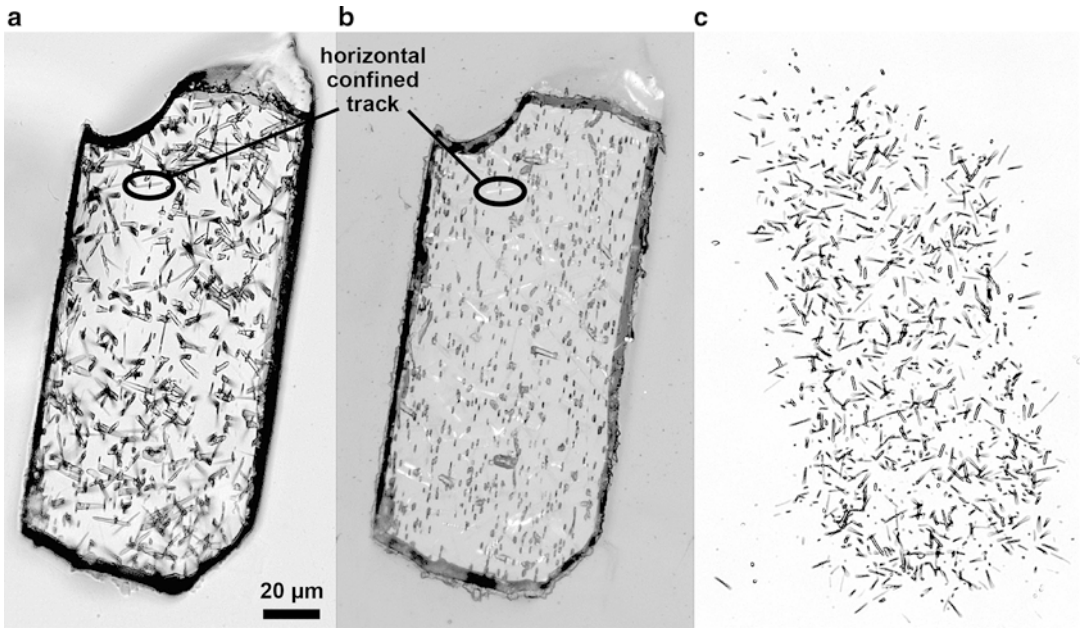
Fission tracks were first observed using transmission electron microscopy by Silk and Barnes (1959). A few years later Price and Walker (1962) discovered fission tracks could be enlarged by means of selective chemical etching, allowing routine observation using optical microscopy. Chemical etchants preferentially attack the fission track relative to the surrounding undamaged bulk material (Fleischer et al. 1975; Wagner and Van den haute 1992). To avoid externally sourced fission tracks, etching is done on the polished internal surface of mineral grains mounted in an etchant-resistant medium such as epoxy resin (apatite) or FEP Teflon (zircon).

Fission Track Dating

Spontaneous fission of ^{238}U occurs at a known constant rate, meaning fission tracks can be used to date geologic materials (Price and Walker 1963). Fission track dating was first applied successfully to natural glass (Fleischer and Price 1964) and today is most commonly applied to apatite and zircon. Fission decay follows the exponential radioactive decay law, whereby the concentration of daughter product, in this case the number of spontaneous fission tracks per unit area (track density), is dependent on (1) the time of residence of parent isotope ^{238}U in the material, (2) the concentration of ^{238}U, (3) the rate of ^{238}U radioactive decay by spontaneous fission, and (4) the assumption that fission tracks are not removed following their formation.

Track Counting and Density Measurement

Fission track densities are typically measured manually with a tally counter using an optical research microscope at around 1250x magnification under either transmitted and reflected light (Fig. 1). Recent development of automated counting systems using digital image track recognition algorithms offers potential for faster, more reliable track counting (Gleadow et al. 2009).



Fission Track Analysis, Fig. 1 (**a**) Transmitted light photomicrograph of etched spontaneous fission tracks in a polished apatite grain from the Sierra Nevada Batholith, California. A horizontal confined track is *circled* (see section "Fission Track Annealing"). (**b**) Same crystal viewed with reflected light highlighting etch pits (where tracks intersect surface). (**c**) Etched induced fission tracks in mica derived from the same apatite crystal using the external detector method

Dating Methods and Determination of ^{238}U Concentration

To measure the ^{238}U concentration for fission track dating, a sample can be exposed to a dose of thermal neutrons (neutrons with low kinetic energy) to induce fission in the rarer ^{235}U isotope of uranium (Price and Walker 1963). Since the present-day terrestrial isotopic ^{238}U/^{235}U ratio is effectively constant, then if the total thermal neutron dose is known, the concentration of ^{238}U can be determined from the density of ^{235}U-induced fission tracks. The ratio of spontaneous to induced fission track density (equivalent to the ratio of daughter to parent isotopes) can be used to calculate a fission track age, t, according to the basic fission track age equation first proposed by Fleischer and Price (1964):

$$t = \frac{1}{\lambda_D} \ln\left\{1 + \left(\frac{\lambda_D}{\lambda_f}\right)\left(\frac{\rho_s}{\rho_i}\right) I\sigma\phi_{th}QG\right\} \qquad (1)$$

where $\lambda_D = {}^{238}$U total decay constant (1.55125×10^{-10} year^{-1}), $\lambda_f = {}^{238}$U spontaneous fission decay constant (~8.46×10^{-17} year^{-1}), $I =$ isotopic ratio of ^{235}U/^{238}U = 0.00725268, $\sigma =$ thermal neutron cross section for ^{235}U (580.2×10^{-24} cm^{-2}), $\phi_{th} =$ total thermal neutron fluence (n.cm^{-2}), $Q =$ a track etching and recognition efficiency factor with a value = 1 if spontaneous and induced tracks are etched and observed under the same conditions, and $G =$ a geometry factor with ideal value of 0.5 to account for spontaneous tracks being formed on both sides of a polished internal surface, whereas induced tracks are only produced from the one side remaining after polishing.

Sample handling procedures for fission track dating fall into two broad groups (Hurford and Green 1982): (1) grain population methods, where two mineral aliquots are measured, one for spontaneous tracks and another for induced tracks, and (2) grain-by-grain methods where spontaneous and induced tracks are analyzed from the same mineral grain. Grain-by-grain methods are generally favored as they allow full assessment of age and uranium concentration variation between grains within a sample. The most popular procedure is the *external detector method*. It involves counting spontaneous tracks on the internal surface of mineral grains contained in a sample mount. An external detector (usually a low uranium mica sheet) is then placed firmly against the etched surface of the mounted grains. During neutron irradiation, induced fission fragments from the polished grain are recorded as etchable tracks in the mica. Etched induced mica tracks can be matched to each mineral grain through the use of an automated microscope stage (Fig. 1c). External mica detectors are also used to estimate total neutron fluence by measuring induced track density in a mica placed against a standard dosimeter glass with known uranium concentration. The induced track density, ρ_d, is related to the total thermal neutron fluence by the expression

$$\phi_{th} = B.\rho_d \qquad (2)$$

where B is a constant that can be evaluated by metal activation monitors (Hurford and Green 1981). One issue with the external detector method is that spontaneous and induced tracks are measured on materials with different track etching and recognition efficiencies. To minimize this difference, spontaneous tracks are only counted in crystals in the optimum orientation of minimum bulk etching rate to match the low bulk etching rate of the cleaved mica surface. In both apatite and zircon, this is the plane parallel to the crystallographic c-axis.

This issue can be avoided by using an age-standard approach known as the *zeta age calibration* (Hurford and Green 1983; Hurford 1990). This was originally motivated by uncertainties in the true value of the ^{238}U spontaneous fission decay constant and difficulties accurately measuring the neutron fluence. Instead, the constants and problematic parameters in Eq. 1 are combined in to a zeta calibration factor $\zeta = I\sigma B/\lambda_f$ (where B comes from Eq. 2). Using a suitable age standard (typically minerals from quickly cooled rocks with precise, homogeneous age determined by other dating techniques from several different laboratories, Hurford 1990), Eq. 1 can be rearranged to determine a zeta value. To account for natural statistical dispersion, at least 20–30 zeta values from different age standards and irradiations are required for a robust calibration. If the etching procedure and track recognition for the age standard and unknown are the same, the factor, Q, can be ignored. Because track recognition, Q, varies between analysts and the B value varies between different irradiation facilities, a zeta value is unique to a particular user for any specific laboratory and irradiation facility.

Laser ablation inductively coupled mass spectrometry (LA-ICP-MS) has recently emerged as an alternative method to measure ^{238}U concentration for fission track dating (Hasebe et al. 2004). Ages have been reported using both an absolute determination of ^{238}U concentration by reference to a standard glass (Gleadow and Seiler 2015) and using a modified zeta calibration approach, with reference to an age standard (Chew and Donelick 2012).

Fission Track Annealing

Fission tracks fade or anneal when heated to relatively low near-surface temperatures over geologic time (Fleischer et al. 1964). Conceptual annealing models (e.g., Green et al. 1986) and observation of unetched fission track annealing in apatite (Li et al. 2012) indicate a two-stage annealing process. In the first main phase, tracks shorten from both ends. Once the track reaches about half its original length, a secondary phase of track segmentation occurs, leaving unetchable gaps preventing full revelation. Shorter annealed tracks have less chance of intersecting any polished surface; thus annealing leads to lower track density and hence a reduction in age (Laslett et al. 1982).

Precise evaluation of fission track annealing is achieved by measuring track length reduction in so-called *confined tracks* that are within 15° of horizontal (Laslett et al. 1982). These are complete fission tracks situated fully below the polished surface that can be revealed by etching if they intersect a track or crack that penetrates the etched surface (Fig. 1). Track length reduction has been studied in numerous laboratory heating experiments resulting in a number of predictive annealing models (Laslett et al. 1987; Carlson et al. 1999; Ketcham et al. 2007 for apatite; Tagami et al. 1998; Rahn et al. 2004 for zircon). For a fixed amount of track length reduction, experimental data shows annealing has an Arrhenius relationship (a positive dependence between log time and inverse temperature) that can be extrapolated to geologic time.

Annealing rate is also correlated with several other measurable kinetic parameters. These include crystal orientation and apatite crystal chemistry (primarily Cl concentration) (Green et al. 1986), as well as apatite bulk etching characteristics, measured using the parameter *Dpar* – the diameter of a track etch-pit parallel to the c-axis (Burtner et al. 1994) – and alpha-decay radiation damage in zircon (Rahn et al. 2004). In apatite no parameter fully describes annealing rate variability, but Cl concentration or *Dpar* are effective for about 90% of commonly encountered apatite compositions (Donelick et al. 2005). These annealing models, plus data from deep boreholes (e.g., Gleadow and Duddy 1981), reveal that significant fission track annealing in apatite starts at about 60 °C, with full annealing at ca. 125 °C, although high Cl concentration or large *Dpar* apatite grains may retain tracks up to ca. 160 °C. This range of temperatures is known as the *partial annealing zone* (PAZ). Other minerals have different annealing temperatures (see Wagner and Van den haute 1992). For example, zircon shows higher annealing temperatures (ca. 180–340 °C), but this remains less well quantified owing to complexities related to variable etching and radiation damage (Rahn et al. 2004).

Thermal History Modeling

A valuable property of fission tracks is that they form continuously over time and have effectively constant initial length (ca. 16 μm and ca. 11 μm for spontaneous tracks in apatite and zircon, respectively). Thus, each track experiences its own unique annealing history dependent on when it formed during the full thermal history of its host mineral. Measuring horizontal confined track length distributions is thus a powerful interpretative tool for evaluating sample thermal histories.

Using the annealing models outlined above, computer techniques can be used to predict such fission track length distributions, as well as age, from any given thermal history (a so-called *forward* approach), allowing manual comparison to measured data (Green et al. 1989). More efficient and

statistically robust *inverse* algorithms have since been developed, whereby measured data are tested against the predictions of many computer-generated time-temperature paths, with the most likely thermal histories chosen using statistical goodness-of-fit tests. Two currently popular public-domain applications using this method are HeFTy (Ketcham 2005) and QTQt (Gallagher 2012).

Summary

Fission track analysis, coupled with more recently developed techniques such as (U-Th)/He and cosmogenic nuclide dating, has helped transform our understanding of upper crustal thermal histories and geologic processes. It has been at the forefront of understanding the erosion processes behind the shaping of mountain belts, as well as long-term landscape evolution in non-orogenic settings. Other popular applications include sedimentary basin analysis and hydrocarbon generation, the timing and rates of extensional unroofing, sedimentary provenance discrimination, and conventional dating of volcanic ash and archaeological samples. Extensive reviews of these and other applications are provided by Gallagher et al. (1998), Bernet and Spiegel (2004), Galbraith (2005), Reiners and Ehlers (2005), Braun et al. (2006), and Lisker et al. (2009).

Current progress in fission track analysis includes LA-ICP-MS and electron microprobe to determine uranium concentrations, image analysis techniques for improved track recognition, and integration with other techniques to obtain multiple dates from single mineral grains. Future perspectives include improvements to empirical annealing models, particularly for zircon, and more fully understanding the atomic-scale physical process of track formation and annealing.

Fluid Inclusions

Robert J. Bodnar
Department of Geosciences, Virginia Tech, Blacksburg, VA, USA

Definition

Fluid inclusions. Small, usually microscopic, droplets of fluid that are trapped in crystals during their initial growth or post-growth during healing of fractures in the mineral.

Introduction

Fluid inclusions are small droplets of fluid that are trapped in minerals. Those trapped during growth of the crystal are referred to as primary fluid inclusions, whereas those trapped along fractures that develop and heal long after the crystal has formed are termed secondary inclusions. Pseudo-secondary inclusions are inclusions that form along a healed fracture that develops and heals during the continued growth of the crystal.

During the past three-quarter century, fluid inclusions have evolved from being viewed as curious artifacts contained in minerals to become one of the most commonly used tools to constrain temperatures and pressures attending geologic processes, and for characterizing the compositions of fluids involved in those processes. Fluid inclusions range in size from submicron to several tens to hundreds of microns in diameter and typically contain on the order of 10^{-13}–10^{-6} g of fluid (Roedder 1984). In practice, most fluid inclusions that are studied are those that are optically resolvable using a conventional petrographic microscope, and range from a few to several tens of microns in maximum dimension.

The presence of fluid inclusions in minerals has been known for at least two millennia, as Pliny the Elder (Gaius Plinius Secundus) described features thought to be fluid inclusions in his volume *Natural History* that was written in about 75 AD. In ~400 AD, the Latin poet Claudius Claudianus wrote a poem entitled "On a crystal enclosing a drop of water" that is thought to describe a large fluid inclusion in a quartz crystal. Numerous other reports of large, macroscale fluid inclusions in minerals (today known as enhydros) appeared during the following centuries, but the first detailed scientific description of fluid (and melt) inclusions was in a classic paper by H. C. Sorby (1858). The paper was published by the Geological Society of London, and such publications were first presented as lectures in an adversarial setting with friends and opponents of the speaker lined up on opposite sides of the lecture hall. After Sorby's talk, the President of the Society at the time is reported to have commented that it was the least plausible paper he had ever heard presented – how could one understand the formation of mountains from such tiny features in the rock? Sorby responded that ". . . there is no necessary connection between the size of an object and the value of a fact, and that, though the objects I have described [fluid inclusions] are minute, the conclusions to be derived from the facts are great."

Information Available from Fluid Inclusions

Fluid inclusions have the potential to provide information concerning temperatures, pressures, compositions, and densities of fluids associated with various geological events or processes. However, certain requirements must be met for fluid inclusions to provide reliable information concerning the physical and chemical conditions of formation. These requirements, which are commonly referred to as Roedder's (or Sorby's) rules, state that (1) the fluid inclusion traps a single, homogeneous phase, (2) the inclusion represents a constant volume (isochoric) system, and (3) nothing has been added to or lost from the inclusion following trapping, i.e., it remains a closed system. Fluid inclusions that do not meet one or more of these requirements fail to

record and preserve information on original trapping conditions. Adherence to Roedder's rules is confirmed by examining a group of inclusions that were all trapped at the same time (referred to as a fluid inclusion assemblage; Goldstein and Reynolds 1994). If the inclusions were all trapped at the same time, they would have all formed at the same temperature and pressure, and all would have trapped a fluid of the same composition. As such, all inclusions in the FIA would show similar phase behavior when observed at room temperature and similar temperatures of phase changes during heating and/or cooling. A wide range in room temperature phase ratios or microthermometric behavior could result from trapping mixtures of two or more fluids, from loss (or gain) of material following inclusion formation, or a change in the fluid inclusion volume following trapping. In many cases, the cause of the variability cannot be determined, but, in all cases, the fluid inclusion data should be discarded if any of Roedder's rules are violated. Unfortunately, much of the fluid inclusion data in the literature is of questionable quality because the researchers did not follow the FIA protocol when collecting and evaluating data.

Temperature

Although many geothermometers are available to constrain temperatures of geologic processes, none of the mineralogical or isotope-based geothermometers offer the temperature or temporal resolution offered by fluid inclusions. A single fluid "event" such as the formation of a growth zone in a crystal or healing of a fracture in a mineral can often be determined to ±1–5 °C using fluid inclusions. For example, Roedder (1974, see also Roedder 1984, Fig. 15.6) examined temperature (and salinity) fluctuations during the precipitation of a single, large sphalerite (ZnS) crystal from the Creede, Colorado, mining district. He identified 21 distinct growth zones in the crystal, and the temperature of formation of each growth zone could be constrained to within ≈±1 °C by fluid inclusions, even though the entire crystal precipitated over the range 200–270 °C. Each growth zone likely took 10^2–10^3 years to precipitate – thus, fluid inclusions provide a temporal resolution that is typically 2–4 orders of magnitude better than is possible with more conventional geothermometers that constrain temperatures with a resolution of hundreds of thousands to tens of millions of years.

Pressure

Fluid inclusion microthermometric data, combined with phase equilibrium data for the fluid in the inclusion and/or an equation of state to estimate the pressure-volume-temperature-composition (PVTX) properties of the fluid, allow pressures of fluid inclusion formation to be determined (Roedder and Bodnar 1980). The most reliable pressures are obtained when fluid inclusions are trapped from boiling or immiscible fluids, as evidenced by coexisting liquid-rich and vapor-rich fluid inclusions within the same fluid inclusion assemblage. In this case, the pressure at trapping is equal to the pressure in the inclusion at the homogenization temperature, and this pressure in turn may be determined from PVTX data. Alternatively, if the fluid inclusions are trapped in a single fluid phase field, the pressure of trapping may be determined from the intersection of the isochore corresponding to the measured homogenization temperature with some other relevant phase boundary. One example is when fluid and melt inclusions are trapped simultaneously on the water-saturated solidus in a silicate melt - water system, i.e., granite water. In this case, the intersection of the fluid inclusion isochore with the H_2O-saturated solidus provides both the pressure and temperature of fluid (and melt) inclusion formation (Lecumberri-Sanchez et al. 2015).

Fluid Density

Fluid inclusions provide the only direct method to determine densities of fluids associated with ancient geologic processes. Assuming that either experimental data or an equation of state is available for the fluid composition in the inclusion, the density of the fluid may be determined using the measured homogenization temperature (and pressure). Density information obtained from fluid inclusions provide a valuable source of information to develop and test fluid flow models that simulate fluid flow in magmatic-hydrothermal systems (Weis et al. 2014).

Fluid Composition

Among the information available from fluid inclusions, and which is not available from any other source, is the composition of the fluid associated with various geological processes. Over the past half century, techniques for determining compositions of fluid inclusions have advanced significantly. In the late 1950s, it was only possible to determine bulk salinities of fluid inclusions based on microthermometry or from bulk analyses of fluid inclusion-bearing samples. While bulk analysis often provided very precise results, most natural samples contain multiple generations of primary and secondary inclusions, and each of these different generations may have contained fluids with very different compositions. Starting in the late 1970s and continuing today, various techniques were introduced that allowed analysis of individual fluid inclusions. Raman spectroscopy proved to be an important tool to determine the compositions of volatile components and daughter minerals in fluid inclusions, and today it is possible to quantitatively determine compositions of many different types of fluid inclusions by Raman analysis (Frezzotti et al. 2012).

The most significant advance in fluid inclusion research in recent decades has been the development and application of laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) to determine major, minor, and trace element

compositions of individual fluid inclusions (Günther et al. 1998). Before introduction of LA-ICP-MS analysis in fluid inclusion research, it was only possible to infer concentrations of a few major elements (such as Na, Cl, K) from phases observed in fluid inclusions at room temperature and/or from observations during heating or cooling of the inclusions. Today, it is possible to measure major, minor, and trace element abundances (representing 4–6 orders of magnitude range in concentrations) in fluid inclusions as small as 5–10 μ. These data have revolutionized our understanding of ore-forming processes by providing direct evidence on the concentrations of metals in ore-forming fluids (Roedder and Bodnar 1997). A recent review of the current status of laser ablation microanalysis to studies of hydrothermal systems is provided by Wagner et al. (2016).

Synthetic Fluid Inclusions

While the underlying physical and chemical principles that govern the interpretation of natural fluid inclusions are robust and supported by theoretical and empirical models, in many cases the assumptions involved were taken "on faith." Then, in the early 1980s, it was recognized that synthetic fluid inclusions could be trapped under carefully controlled and known experimental conditions (Sterner and Bodnar 1984), and these inclusions could then be studied to test the many assumptions involved in fluid inclusion interpretation, such as assumptions related to isochoric (constant-volume) behavior, trapping of single, homogeneous phases, etc. Moreover, because it was quickly confirmed that the synthetic fluid inclusions did indeed record and preserve the trapping conditions (temperature, pressure, fluid composition), it became apparent that synthetic fluid inclusions could be used to determine fluid PVTX properties and could be employed to examine the conditions under which fluid inclusions might violate the requirements imposed by Roedder's rules. This has led to hundreds of studies in labs worldwide and resulted in major advances in our understanding of fluid inclusion trapping and subsequent modifications and has significantly increased the amount of experimental PVTX data available to interpret results obtained from natural inclusions.

Post-Entrapment Changes

Early workers recognized that, in some cases, fluid inclusions violated one or more of Roedder's rules (Larson et al.1973), but the mechanisms responsible were poorly understood. Starting in the 1970s and continuing today, numerous workers have investigated the various types of reequilibration, and the causes, that fluid inclusions experience after trapping. A review of the various reequilibration processes associated with fluid inclusions is provided by Bodnar (2003). Bodnar et al. (1989) showed that the internal overpressure required to cause fluid inclusions in quartz to change volume is mostly a function of inclusion size and, to a lesser extent, inclusion shape, with rounded, equant inclusions less susceptible to reequilibration compared to more irregularly shaped inclusions. Sterner and Bodnar (1989) reequilibrated synthetic fluid inclusions in quartz along various PT paths simulating those followed by metamorphic rocks during exhumation. The results showed that the textures and distribution of homogenization temperatures following reequilibration showed systematic variations and characteristics that permit PT paths of natural inclusions to be inferred based on textural and microthermometric characteristics. Vityk and Bodnar (1995) similarly reequilibrated inclusions in quartz along various PT paths and observed that inclusions reequilibrated along a compressional path in which the internal pressure in the inclusion was less than the confining pressure developed an annular texture that was remarkably similar to textures of natural inclusions from the Himalayan Mountains that had been interpreted to have reequilibrated during compressional loading. Similarly, Vityk and Bodnar (1998) showed that the distribution of fluid inclusion homogenization temperatures on histograms varies in a systematic manner as a function of the mode and duration of the reequilibration event.

Experimental studies have documented the extent to which fluid inclusion compositions might change in response to a changing external physical and chemical environment. It has long been speculated that hydrogen easily diffuses out of fluid inclusions, thus changing the oxidation state in the inclusion. This process was thought to be responsible for the observation that solid phases, such as sulfides, sulfates, iron oxides, etc. that contain elements that occur in multiple oxidation states in crustal environments, often fail to dissolve when the inclusions are heated. This interpretation was supported by experimental studies in which chalcopyrite-bearing fluid inclusions were heated under pressure in the presence of a high hydrogen gas pressure, thus causing hydrogen to diffuse into the fluid inclusions (Mavrogenes and Bodnar 1994). Before the experiment the chalcopyrite phase did not dissolve during heating. However, following the experiment, the chalcopyrite did dissolve when heated and observed under the microscope because the addition of hydrogen had lowered the oxidation state of the fluid. Similarly, Hall et al. (1991) showed that diffusion of hydrogen into fluid inclusions resulted in a D/H isotopic composition that was 65‰ too low to be in isotopic equilibrium with the surrounding mineral assemblage. In addition to hydrogen, other recent experiments have documented the apparent ease with which some elements, such as Cu, Na, Li, and Ag, diffuse out of inclusions following formation (Zajacz et al. 2009). Diamond and Tarantola (2015) conducted experiments under non-

isotropic stress and found that some inclusions became dismembered and produced irregularly shaped inclusions surrounded by planar arrays of tiny inclusions. These workers observed that deformed inclusions preserve their pre-deformation concentration ratios of gases to electrolytes but have lost some H_2O. Significantly, the results suggest that the orientation of the maximum principal compressive stress at the time of deformation can be obtained from these data and that the density of newly formed inclusions records the maximum pressure during deformation.

Summary and Conclusions

During the last few decades, significant advances have been made in our ability to quantitatively analyze individual fluid inclusions by Raman spectroscopy and laser ablation ICPMS. In the next years, it is likely that much progress will be made in determining the stable and radiogenic isotopic compositions of fluids in individual fluid inclusions. This revolutionary advance will allow workers to better determine sources of fluids using, for example, D/H and $^{18}O/^{16}O$ ratios of water in fluid inclusions (Dublyanksy and Spötl 2009). Similarly, Pb and Sr isotopic compositions of individual fluid inclusions (Pettke et al. 2012) will allow determination of the "ages" of fluids and their host phases and contribute to our understanding of the timing and duration of ore-forming processes.

Fluid–Rock Interaction

William E. Glassley[1], Laura J. Crossey[2] and Isabel P. Montanez[1]

Definition

Throughout the Earth's crust there is chemical and mineralogical evidence that fluids are present as rocks evolve. Those fluids, which are mainly aqueous, chemically interact with the minerals present to modify the mineral chemistry or completely change the assemblage of minerals that compose the rock. This process is called *fluid–rock interaction* and is the subject of a broad body of research and technological development activity.

Introduction and Concepts

Fluid–rock interaction is the process in which solutions, which are usually aqueous, and the rock material with which they are in contact, chemically react to achieve a state that approaches thermodynamic equilibrium. The tendency to approach equilibrium is driven by chemical thermodynamics and is manifest as the tendency to develop assemblages of co-existing minerals and dissolved aqueous species that possess the lowest free energy for the chemical components in the total system. The rate at which equilibrium is approached is controlled by reaction kinetics. These processes occur in all regions of the Earth where aqueous solutions are found, which usually is restricted to those portions of the Earth where temperatures are between 0 °C and ~ 800 °C and pressures are between 0.1 MPa and ~ 3 GPa. To theoretically predict the products of these interactions and to quantitatively interpret the mineralogical and chemical evolution of geologic systems through time, data must be available on the thermodynamic properties of minerals and dissolved species over this range of physical conditions and on the rates at which minerals dissolve and precipitate (the rates at which speciation reactions occur in solution are usually considered to be instantaneous).

The principal mechanism whereby fluid–rock interaction takes place is dissolution and precipitation of mineral phases. Minerals with which water is in contact will dissolve, if the solution is undersaturated in the mineral phase, and minerals will precipitate if the solution is supersaturated with those phases, although the actual chemical pathway may be mediated by microbial activity at low temperature conditions. Also important in fluid–rock interaction are ion exchange processes at mineral surfaces (sorption effects), which involve exchange of ions between water and crystallographic sites in mineral structures. The rates at which these various mechanisms occur are strong functions of temperature, surface area (and number of available sites, in the case of ion exchange), pH, water composition, and ionic strength. Reaction rates are also influenced by whether the system is far from equilibrium, reaction rates being significantly higher when systems are far from equilibrium. These processes are primarily expressed on the pore scale, where the fluid and minerals are in intimate contact (Steefel et al. 2015 and other papers in that volume).

In general, rates for silicate and oxide mineral dissolution and precipitation are in the range of 10^{-10}–10^{-15} mol/cm^2 surface area/s at 25 °C. These rates are many orders of magnitude slower than other rate processes that influence water composition, such as salt dissolution or precipitation and ion exchange. Hence, for processes in which short time scales (seconds to hours) are important, silicate mineral dissolution and precipitation must be considered a second order effect in controlling water composition; ion exchange processes and salt dissolution or precipitation would be expected to control water chemistry. For longer-term concerns (months to years), the influence of silicate mineral saturation state becomes paramount.

Within the near-surface environment, fluid–rock interaction, often with the participation of microbial communities, controls the development of soils, the quality of water in streams, rivers and aquifers, and the chemistry of the oceans and ocean sediments (Holland 1984) and is thus an important influence in establishing the overall state of the environment. Soils represent the chemical products that form when minerals in igneous, metamorphic, and sedimentary rocks are hydrated, oxidized, and carbonated under low temperature conditions in which the water is in contact with atmospheric gases and influenced by diurnal and seasonal temperature cycles and biological activity. In this case, carbonates, oxides and hydroxides of iron, and clays (hydrated alumino-silicates) tend to be the thermodynamically stable reaction products. However, rigorous thermodynamic equilibrium is often not achieved due to the low temperatures, and hence low reaction

rates, characteristic of this environment. This is usually indicated by the metastable persistence of preexisting mineral phases and structural and compositional irregularities in many of the minerals that form during weathering. Those mineral phases that form during weathering often have a large capacity for exchanging ions and can readily influence the composition of water that may flow through them. The chemical compositions of waters in streams, rivers, and aquifers thus reflect both the effects of mineral dissolution and precipitation during weathering of preexisting rocks and the effects of ion exchange with the minerals that formed as a result of weathering. The chemical composition of the ocean reflects the time-integrated result of these near-surface rock–water interaction processes, modified by atmospheric interactions, the effects of seawater alteration of oceanic crust, and marine sedimentation (Holland 1984).

Interaction of fluids with rock at deeper levels in the crust is strongly influenced by the elevated temperatures and higher pressures found at depth and is an integral part of metamorphic recrystallization. As temperatures and pressures increase, reaction rates also increase, thus tending to generate mineral assemblages that are locally in chemical equilibrium. The total fluid volume present during metamorphism has been difficult to estimate but is expected to diminish as pore volumes and fracture permeability drop to very low values (ca. microdarcies) at the high pressures achieved tens of kilometers into the crust. Nevertheless, the presence of a wide variety of ore deposits, pegmatitic bodies, fluid inclusions, and mineral segregations and veins, all of which formed as a result of fluid–rock interaction (see Ilton and Eugster 1990, and other papers in that volume), requires at least the episodic presence of significant volumes of water-rich fluids at elevated temperatures and pressures.

Fluid–rock interaction associated with magmatic processes has been well documented through field and isotopic studies. In general, emplacement of magma bodies in the crust results in strong thermal gradients that drive convective flow of high temperature aqueous solutions. These fluids are a combination of solutions derived from the rocks that enclose the magma bodies and fluids derived from the crystallizing magma. Relatively rapid flow of these complex solutions around the magma body transports the fluids along temperature gradients and into other rock units. This results in extensive dissolution and precipitation, as the hot fluids interact with a range of rocks under different temperature and pressure conditions. Systems such as these tend to generate highly altered rock systems which are preserved in geologic environments as chemically evolved ("metasomatized") lithologic units in which extensive mass transfer is recorded (often called skarns) or, in those cases where active systems extend to the Earth's surface, are expressed as hot springs, geysers, and other expressions of hydrothermal and geothermal activity (Glassley 2014).

The primary methods for establishing the source regions for fluids involved in crustal processes, and their ages, is via studies of stable and radiogenic isotope systems (e.g., Craig 1963; Giggenbach 1992; Ivanovich and Harmon 1992; Seal 2006; Kennedy and van Soest 2007). Tritium, ^{3}He, ^{14}C, and ^{36}Cl are among the radiogenic isotope systems commonly used to date groundwaters or to establish the recharge rates or residence times of groundwaters. To obtain information about ion exchange, and dissolution and precipitation processes in aqueous systems, the systematics of the U-Th decay chain are often used. This system contains numerous daughter isotopes of varying half-lives and chemical properties. Disequilibrium in this decay chain can provide information about the exchange rates of ions and the chemical behavior of the local fluid–rock system. Oxygen, hydrogen, carbon, and sulfur isotope systems are often used to examine the extent to which evaporation has influenced near-surface fluid–rock systems, to determine whether biological sources played a role in the evolution of the fluid–rock system, and to determine whether mixing of fluids from different sources has occurred. Isotopic ratios involving these elements can also be used to evaluate reaction progress and the state of fluid–rock equilibrium and, in some cases, the temperature at which isotopic equilibrium was achieved, for rock systems that have experienced conditions typical of intermediate and deep crustal levels.

Practical Aspects of Fluid–Rock Interaction

Practical aspects of fluid–rock interaction include the important role these processes play in maintaining the quality of water resources (Manahan 1994). Through exchange and sorption of metals and other dissolved constituents onto their surfaces, clays and zeolites in geologic materials strongly influence overall water quality. Conversely, degradation of this capacity in aquifers that are naturally rich in clays and zeolites can result when aquifers are invaded by solutions that either diminish the abundance of these minerals or which overwhelm the available exchange sites of these minerals. Sea water incursion in regions of severe groundwater exploitation or leakage of contaminants from underground storage facilities are examples of processes that can diminish the exchange capacity of minerals that contribute to maintaining water quality.

Active Research Areas

The ability to rigorously simulate all aspects of fluid–rock interaction is a rapidly expanding field of research. Conceptual models of these processes, the mathematical constructs that rigorously describe them, and the computer codes to carry

out the calculations have rapidly evolved, although they are still limited by insufficient information about reaction mechanisms and processes that occur at mineral surfaces (Steefel et al. 2015). Nevertheless, a broad spectrum of efforts is being pursued to refine and apply existing capabilities (see papers in Lichtner et al 1996; Steefel et al. 2005). Molecular simulation of, and experiments on, interactions at mineral surfaces and within pores is an active research area. Simulations of rock–water interaction under conditions of fluid flow, often termed reactive transport, are playing a large role in establishing how mineral assemblages, individual lithologic units, and large sedimentary basins and petroleum reservoirs evolve through time. These capabilities are important because they are required for understanding the geologic and environmental consequences resulting from change due to the temporal variability of natural processes and those effects resulting from human activity such as CO_2 disposal (Al-Khoury and Bundschuh 2014).

The primary limitation in these efforts is an insufficient database for conducting the simulations. The database limitations stem from insufficient measurements of thermodynamic properties and rate constants for complex mineral phases and a dearth of experimental studies of processes at mineral surfaces and in complex isotope systems. The magnitude of this problem is greatest for conditions at high temperatures and pressures, although data at standard temperature and pressure are also inadequate.

Another area of active research is in establishing the characteristics of aqueous fluids at elevated temperatures and pressures. From theoretical considerations of the solubilities of mineral phases, it is clear that aqueous solutions with significant amounts of dissolved species should be present during recrystallization in metamorphic environments. Observations from fluid inclusion studies (e.g., Roedder 1984) document the common presence of such water-rich solutions, some of which are highly concentrated brines with total dissolved solids exceeding 40% by weight of the aqueous phase, thus supporting the theoretical considerations. However, such solutions are not miscible with fluids that are predominantly $H_2O - CO_2$ (Duan et al. 1995), which are often the two most abundant components in crustal fluids. Thus, it is expected that rock–water interaction during metamorphism may, in many cases, actually involve co-existing fluid phases, one of which is a concentrated brine, the other an $H_2O - CO_2$ solution. The relative abundances of these solutions remain unknown but can be expected to vary from region to region. The role such fluids play in mass transport in the crust, and methods for identifying their respective effects, have yet to be established.

Advances in the understanding of the role of microbial activity in subsurface environments have expanded interdisciplinary research in geomicrobiology and biogeochemistry. Genetic, geochemical, and genomic approaches have led to a greater understanding of how microbes (and microbial communities) depend on, and shape, their geochemical environments. Geomicrobiological effects on water–rock interaction include modification of chemical gradients, changes in fluid and gas composition, as well as modifying reaction rates. Early efforts focused on geochemical links to metabolic processes in hydrothermal ecosystems (Brock 1978), while more recently interdisciplinary efforts have covered a wide range of subsurface environments (Newman and Banfield 2002; Reysenbach and Shock 2002; Hinman 2013).

Summary and Conclusions

Fluid–rock interaction is a common process within the Earth that affects mineral compositions and mineral assemblages in rocks through numerous thermodynamically driven pathways. These interactions can provide a history of the diagenetic and metamorphic processes rocks experience and have an important influence on the specific mineral assemblages and mineral compositions that are stable at any given set of conditions. From a practical perspective, fluid–rock interaction can play an important role in establishing water quality in a region. Fluid–rock interaction also is important in considerations involving CO_2 disposal and contaminant transport in the subsurface. Current research areas include isotopic systematics of fluid–rock systems, computer simulations of fluid–rock interaction, and the kinetics that control the rates of these processes.

Fluorine

Kenneth T. Koga and Estelle F. Rose-Koga
Laboratoire Magmas et Volcans, Université Blaise Pascal – CNRS, Clermont-Ferrand, France

Element Data
Atomic Symbol: F
Atomic Number: 9
Atomic Weight: 18.998 g/mol
Isotopes and Abundances: ^{19}F 100%
1 Atm Melting Point: −219.67 °C
1 Atm Boiling Point: −188.11 °C
Common Valences: −1
Ionic Radii: 130 (III), 131 (IV), and 133 (VI), in pm (coordination number)
Pauling Electronegativity: 3.98
First Ionization Potential: 17.4428 eV
Chondritic (CI) Abundance: 60.7 μg.g^{-1}
Silicate Earth Abundance: two estimates – 18 ± 8 and 25 ± 10 μg.g^{-1}
(*continued*)

Continental Crust Abundance ~ 550 μg.g^{-1}
Oceanic Crust Abundance 130 ~ 1000 (est. 400) μg.g^{-1}
Seawater Abundance: 1.3 μg.g^{-1}
Core Abundance: considered as 0

Properties

In its elemental form, fluorine exists as a diatomic molecule of highly toxic, corrosive, pale yellow gas with a pungent smell in ambient conditions. As the most electronegative element, fluorine is reactive and commonly found in nature as ionic compounds bonded to metal cations or hydrogen. Fluorine can dissolve into solution forming F^- ions.

History and Use

Fluorite (CaF_2) has been known and used in the metal smelting process to lower the melting temperature of metal ores since the sixteenth century. It was then known as *fluores* or *flusse*. The element was later isolated in 1886 (Moissan 1886), 330 years after fluorite was first described by Agricola (1556). Today, 6.2 million metric tons of fluorite is mined for industrial use (British Geological Survey 2010–2014 report) in metallurgy, ceramics, and chemistry, with applications including the production of aluminum, fluorocarbons, and fluorine gas. For example, fluorine is used to separate uranium in the nuclear power industry and to produce high-performance plastics such as polytetrafluoroethylene (PTFE, commonly known as Teflon®) and the Gore-Tex® membrane.

Geochemical Behavior

Fluorine plays an important role in geochemical and biogeochemical systems, despite its relative low overall abundance on Earth and in the cosmos. For example, fluorine can exert a significant control on the behavior and composition of magmas, the composition of hydrothermal fluids, and the transport of ore metals in the crust. The distribution of fluorine in various geological samples is therefore of interest in geochemical investigations, including tracing the evolution and source of hydrothermal fluids active in ore deposit formation, metamorphism and subsolidus alteration, and tracking subduction-related mantle to crust mass transfer.

Fluorine has a strong tendency to bond with silica and other cations and is therefore considered a lithophile element. Reflecting this characteristic, a dominant fraction of F on Earth, ~99%, is estimated to exist in the solid earth. However, fluorine is also referred to as a magmatic volatile element, as it

is found as HF gas in volcanic edifices and fumaroles. A small quantity of F is found in surface waters. On the contrary, F is thought to play a role in forming ligands and increasing metal solubility in high-temperature fluids (hydrothermal fluids, diagenetic formation waters, metasomatic fluids).

Considerable effort has been put into the advancement of analytical techniques to accurately determine the fluorine content of geological materials. Such analytical techniques include anion chromatographic column, selective electrode, neutron activation, electron microprobe, ion probe (SIMS), and irradiated rare-gas analysis (Hanley and Koga in prep).

Abundances

Fluorine, having the single isotopic species $^{19}_{9}F$, was produced by nucleosynthesis in stars and supernovae predating the sun, through neutrino spallation of ^{20}Ne and hydrogen-helium burning involving ^{14}N, ^{18}F, ^{18}O, and ^{15}N (Woosley and Haxton 1988; Forestini et al. 1992). At the time of the formation of the solar system, F is considered to have been moderately volatile with a 50% condensation temperature of 734 K for fluorapatite (Lodders et al. 2009). The solar abundance has been assessed by measurements of volatile element-rich CI chondrites and spectrometry of the sun's photosphere. While heavier halogen elements tend to be less abundant, the lightest halogen, fluorine, is notably less abundant than the heavier element Cl. In addition, F is 3–4 orders of magnitude less abundant than neighboring elements, namely, C, N, O, and Ne, due to a small probability of production and its destruction in supernovae (Clayton 2003).

Meteoritic F abundances vary by a factor of 20; CI and EH chondrites show higher abundances among the different chondrite classes (i.e., CM, CO, CV, H, and L, while EL and LL show the highest abundances; Wasson and Kallemeyn 1988). Fluorine contents of the Moon, Mars, and Vesta are also reported. The Moon's mantle is reported as 5.3 ppm F, based on glass samples (approximately 30% of Earth mantle). Bulk F abundance for Mars is 21 $\pm$ 13 ppm, estimated from shergottite meteorites (Taylor 2013). The eucrite parent body, Vesta, probably contains some volatile elements since F-rich apatites have been found in this class of meteorites.

The abundance of trace elements in the Earth's mantle is commonly assessed through compositional correlations among primitive basalt, peridotite xenoliths, and chondritic meteorites. The modeled F content of the bulk silicate earth (BSE) ranges from 18 to 25 ppm, with different estimates agreeing within reported uncertainty. Mid-ocean ridge basalt (MORB) are derived from a depleted mantle source with F contents ranging from 6 to 22 ppm. Limited data on the bulk F content of mantle xenoliths shows significant variability from 7 to 400 ppm (Hanley and Koga in prep).

Laboratory experiments show that F has a stronger affinity to silicate melt than to metals, metal alloys, and sulfides (e.g., Mungall and Brenan 2003). Based on a comparison of chondritic and BSE abundances, F abundance in the core is negligible (McDonough 2003).

Seawater, representing only 0.02% of Earth's mass, is a negligible F reservoir as it contains less than 1% of the total F budget of the bulk earth. The preferred mean abundance of F in seawater is 1.3 ppm. Fluorine in river water is reported as 10–20 ppb. Formation water in sedimentary basins and well waters in crystalline basements typically ranges from 0.5 to 10 ppm (Hanley and Koga in prep). Hydrofluoric acid is present in high-temperature volcanic gases, with concentrations typically in the range of 100–300 ppm, in which F is the least abundant of the six elements (H, C, O, S, Cl, and F) constituting volcanic gas (Symonds et al. 1994).

Fluorine abundance in the bulk continental crust is estimated as 553 ppm; this value is a volumetric average of upper (611 ppm) and lower crustal (429 ppm) average abundances. The upper continental crust is enriched in fluorine, relative to the lower continental crust, by a factor of 1.4–2.3 (Rudnick and Gao 2003).

Fluorine contents in magmatic rocks are in the 100s to 1000s of ppm range. Highly fractionated peraluminous and peralkaline granitoids, and some basaltic rocks, show the highest abundances, as F is generally concentrated into magmas during crystal fractionation. In addition, F is incorporated into silicate melt by bonding to Si and Al, resulting its higher solubility in felsic than mafic melts (Dalou et al. 2015).

During the weathering of volcanic products, glass devitrification results in mobilization of F (e.g., Stix et al. 1995). F is particularly rich in phosphatic shales, caliche (nitrate) deposits (up to ~4000 ppm; Batista et al. 2005), and evaporites.

Fluorine can be locally concentrated in mantle as halides and hydroxyl minerals. Carbonatites from Ol Doinyo Lengai, Tanzania, contain between 1.2 and 3.5 wt% F, occurring as immiscible halide melt (Teague et al. 2011); halide melt inclusions in magmatic minerals are found in intrusive carbonatites (Saint-Honoré, Quebec, Canada). Furthermore, fluoride melt has been reported in peridotite xenoliths (Klemme 2004). Similarly, F-rich micas and amphiboles are reported from various mantle nodules (e.g., up to 8 wt% F for phlogopite found in peridotite nodules).

Mineralogical Hosts

There are 427 naturally occurring fluorine-hosting minerals registered in the IMA inventory, in which halides, oxyhalides, silicates, and other groups are listed. Nearly all silicate minerals with hydroxyl (OH^-) sites can potentially have F-bearing species, such as mica, amphibole, apatite, and

norbergite. Fluorite (CaF_2) contains 48.7 wt% F. Up to a few weight percent, F can be found in micas, amphiboles, and apatites (e.g., 4.5 wt% phlogopite, 4.6 wt% fluororichterite, 3.8 wt% fluorapatite). Trace quantities of F can be incorporated into minerals without crystallographic site accommodation because of its similar ionic size to oxygen. For example, olivine and orthopyroxene in mantle peridotites are reported to contain 2.9–30.3 and 12–30 ppm, respectively (Beyer et al. 2012).

Biological Utilization and Toxicity

The teeth of some sharks are enameloid (in contrast to common dentin), which consists of fluorapatite, contrary to hydroxyapatite in human teeth. The lattice parameters of enameloid are close to those of the geological fluorapatite single crystal, with enameloid F content being 3.1 wt%, similar to the F content of geological fluorapatite (3.64 wt%; Enax et al. 2012). Incorporation of F in benthic foraminifera shells ranges from 0.00016 to 0.0016 F/Ca by weight, a maximum of 650 ppm F (Rosenthal et al. 1997). Corals contain 700 ~ 1200 ppm F.

In low concentrations, fluoride (F^-) strengthens the teeth and bones of vertebrates, and less than 2 ppm is added to toothpaste and drinking water in some countries. The human body contains on average 3 mg of F^-.

Elemental fluorine is highly toxic. Studies have found that a single ingestion of just 0.1–0.3 mg F/kg (i.e., milligrams of F for every kilogram of body weight) can cause the first symptoms of poisoning, including nausea, vomiting, abdominal pain, and diarrhea. Ingested fluoride is transformed in the stomach to hydrofluoric acid, which has a corrosive effect on the epithelial lining of the gastrointestinal tract. Fluoride consumed in excess is an endocrine disruptor that can affect bones, brain, thyroid gland, pineal gland, and even blood sugar levels (Akiniwa 1997).

Formation and Evolution of the Earth

Francis Albarède
Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

Planet Earth is the largest rocky object of the inner Solar System. It formed some 4.5 billion years ago through accretion of smaller bodies, protoplanets, and planetesimals, which themselves had accreted from solids that condensed from the same nebula of gas and dust that formed the Sun. It has evolved since then through the segregation of the atmosphere, the oceans, the crust, the mantle, and the core, and, most peculiarly of all, of a biosphere.

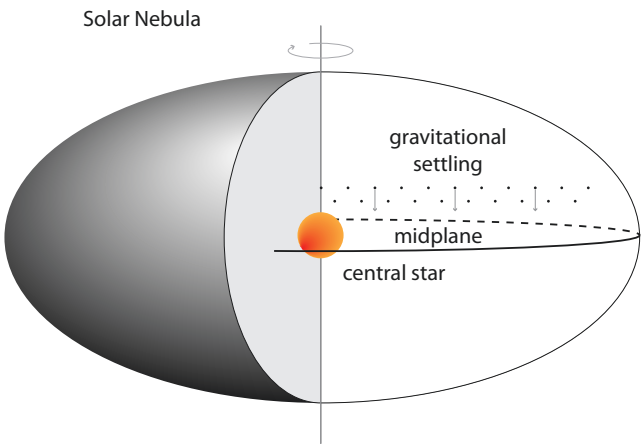
Introduction

The Earth harbors a number of familiar characteristics, obviously life, but also a conspicuous ocean and an oxygen-rich atmosphere. The strong dichotomy between ocean and subaerial continents, which allows weathering and steady fluxes of nutrients to the ocean surface, a product of plate tectonics, is another distinctive feature of our planet. Only Mercury and Venus are closer to the Sun, whereas Mars is the last stop on the way to the outer Solar System, which is dominated by gaseous planets made of elements or compounds that condense at very low temperature, such as hydrogen, helium, and methane. The purpose of this article is to summarize our current understanding of the formation of our home planet, why it is so unique, and which processes and features allowed it to evolve through time into the modern Planet Earth. A strong caveat is that the scientific fields, which deal with these topics, are still evolving very fast. New fundamental observations are made each year and new concepts keep emerging. What was considered ground truth a decade ago is now being challenged, which should invite us to be modest when it comes to assessing the present state of the art.

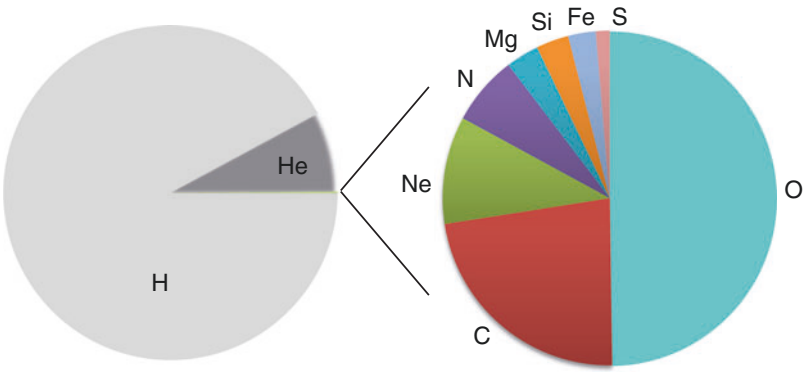
The Formation of the Solar System

The best accepted model of the Solar System is the Solar Nebula hypothesis formulated by Immanuel Kant in 1755 and formally detailed by Pierre-Simon Laplace in 1796 (Fig. 1). In the beginning, 4.68 billion years ago, was a cloud of gas and dust. This cloud can be described by its mass, chemical composition, and rotational kinetic energy, which physicists usually deal by talking of angular momentum. These quantities are referred to as "conservative": mass does not change spontaneously in a closed system, while angular moment only changes under the effect of torques, such as those provided by tides. We know that today such nebular clouds are still formed from shreds torn off from very large dying stars, called the Asymptotic Giant Branch red-giant stars, and injected with material expelled from exploding supernovae.

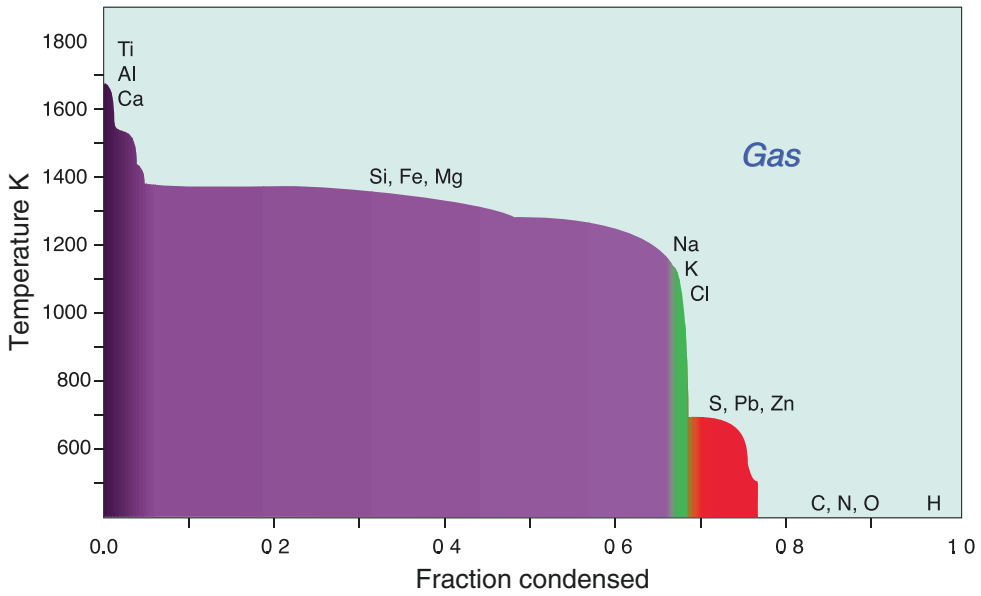
Nebular gas is dominated by hydrogen (Fig. 2), but contains minute amounts of other elements, helium as well as heavier elements produced in older stars by nucleosynthesis. Gas collapses under its own weight, attracted, not toward the center of gravity, as this would violate the principle of angular momentum conservation, but vertically onto the midplane. The center of gravity remains nevertheless the locus of maximum mass accumulation and becomes the core of the newborn star. In the process, gravitational energy is changed into thermal agitation, the contracting cloud become extremely hot. The core of the Solar Nebula becomes dense and hot, enough to beam out large amounts of energy in the form of UV and X-ray light. This energy is strong enough to blow off all the nebular hydrogen and helium and chop off the outer edge of the collapsing cloud beyond 20 AU. A star at this



Formation and Evolution of the Earth, Fig. 1 The spinning and collapsing Solar Nebula. Because orbital angular momentum is conserved, material sedimentation takes place in the midplane



Formation and Evolution of the Earth, Fig. 2 The composition of the solar photosphere is dominated by H and He. The fraction of Si in the total Sun is 3.5×10^{-5}. Material used to form rocky planets, therefore, represents a very small fraction of the total nebular gas



Formation and Evolution of the Earth, Fig. 3 Sequence of element condensation from the nebular gas as a function of the mass fraction of element condensed. Vertical segments represent condensation gaps with falling temperatures not affecting the fraction condensed. Condensation proceeds by stages separated by gaps, from ultrarefractory material (Ti, Al, Ca), planetary core and silicate mantle (Si, Fe, Mg), alkali elements (Na, K), sulfur-loving elements (S, Pb, Zn), and finally the most volatile elements, C, N, O. Hydrogen comes in at a very late stage. Planetary objects depleted in Zn and K, such as the Moon and the Earth, are therefore unlikely to have reached the condensation threshold for C, N, O, and H

stage is known by the name of the first example identified by astronomers, the star T in the Taurus constellation or T-Tauri. Further collapse of T-Tauri stars leads to the formation of a "true" star, in which central temperatures are high enough for the nuclear fusion of hydrogen into helium to be ignited. Observations of infrared radiations emitted by T-Tauri stars and blocked by the surrounding nebular disk led astronomers to conclude that this phase last less than 5 million years (Wyatt 2008).

The inner Solar System being hotter than its outer counterpart, gas and dust were lost before the primordial nebular material was fully condensed. Elements which condense at high temperatures (> 1300 K), such as aluminum, titanium, and magnesium, are called refractory, whereas those only condensing at lower temperatures (< 700 K), such as carbon, nitrogen, and hydrogen, but also sulfur and zinc, are referred to as volatiles (Fig. 3). The composition of the Solar Nebula is known in two ways, first by the spectroscopic analysis of the Sun's outer layer, the photosphere, second by measuring the elemental and isotopic abundances of the least transformed objects in the accessible Solar System. The Earth, Moon, and Mars were processed by impacts, and by internal and external geological processes, so in order to represent the nebular composition, excluding gases, cosmochemists turn to undifferentiated meteorites known as chondrites. These are aggregates of small beads of melted material (chondrules) cemented by a matrix of various fragments and debris and low-temperature condensates. Pre-solar grains may also be

present, although at < 0.1% level. Carbonaceous chondrites show evidence of a minimal deficit of the most volatile elements relative to the solar photosphere.

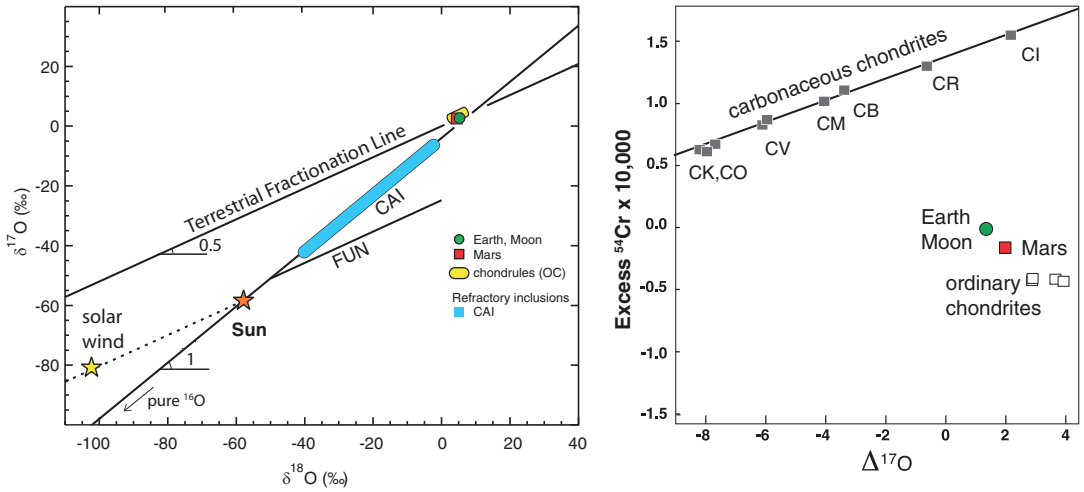
Condensation of the nebular gas to dust is probably the best understood part of Solar System history. Hydrogen makes up more than 98% of the gas, so the total pressure will be controlled by the dynamic expansion of the rotating nebular disk, its radiative cooling, and photoevaporation of the elements by stellar radiations. The rest of the elements are largely controlled by the respective thermodynamic properties of the gaseous and condensed phases. Upon cooling, condensation takes place in four stages (Fig. 3), first the ultrarefractory elements (Ti, Al, Ca), then the refractory elements, which account for most of the solid planetary interiors (Si, Fe, Mg), the moderately volatile elements, notably alkali elements (Na, K) and sulfur-loving (chalcophile) elements (Zn, S), and finally the elements involved in atmospheres and oceans (C, N, O, H). All these stages are separated by temperature intervals with little or no condensation.

The Formation of the Earth-Moon System

The standard planetary formation scenario can be divided into four main stages (Morbidelli et al. 2012). The first, and probably the least understood, stage takes the material from the dust, formed by the initial gas condensation. Dust grains can only stick together through weak van der Waals forces unless they are glued by shocks. Even objects of the size of a pebble bounce off each other upon collision. Passed this "bouncing barrier," aggregates continue to grow until they form kilometer-sized planetesimals. The myriads of planetesimals orbiting around the Sun sweep their orbit clean of dust and rocky debris; they collide and quickly form a smaller number protoplanets, with a typical size of 1000 km. This is the *runaway* growth stage. When too little material is left to sweep, planetary growth slows down and the large planetesimals gain control by perturbing the orbit of smaller objects: this is the *oligarchic* growth phase, at the end of which few protoplanets are left drifting in a medium still rich in planetesimals. The last, *chaotic* phase, lasts for a few tens of Ma: the combination of gravity fields of the Sun and Jupiter, the largest planet in the Solar System, perturbs the orbit of protoplanets and planetesimals. When a planetary object enters some resonance, i.e., when it returns to the same orbital position after an integer number of revolutions, gravitational pumping quickly builds up, orbits become increasingly elliptical, and the object is ejected from its orbit into the Sun, the inner Solar System where it can be captured by a resident planet, or lost from the Solar System. The number of planets quickly decreases to its current value and smaller objects are swept out of their original orbits over a time scale of about 150 Ma. Planetary orbits are not truly stable. Even giant planets can shift inward and then outward (the Grand Tack (Walsh et al. 2011)) and displace some large objects from their original orbit, which is a popular, yet not universally accepted, interpretation of the Late Heavy Bombardment of the inner Solar System some 700 Ma after its formation (the Nice model) (Gomes et al. 2005).

This well-structured picture has recently been blurred by new observations. First, isotopic analyses of oxygen implanted by the solar wind into metal grains at the surface of the Moon found it to be extremely enriched in the ^{16}O isotope relative to the rest of the Solar System (Hashizume and Chaussidon 2005). The difference is simply much too large relative to isotopic variations of other elements in the Solar System and cannot be explained by processes taking place within the nebula. This observation has been confirmed by the excess ^{16}O found in the solar wind implanted in material sent by NASA's Genesis mission (McKeegan et al. 2011) and by observations on a particular kind of refractory inclusions in chondrites showing FUN (Fractionation and Unknown Nuclear) effects (Krot et al. 2014) (Fig. 4). The suggestions that ^{16}O anomalies was produced by isotope-dependent photodissociation (self-shielding) of carbon monoxide generated controversy over the last 15 years (Clayton 2002; Lyons and Young 2005; Thiemens 2006). Rapid recombination of CO self-shielding products (Navon and Wasserburg 1985) led Yurimoto and Kuramoto (2004) and Lyons and Young (2005) to suggest that capture of anomalous oxygen upon freezing and transport of ice from the outer into the inner Solar System was responsible for isotopic heterogeneities. The strongly correlated concentrations of water and other volatile elements (e.g., K, Zn, Cd, Tl) in chondrites (Albarede et al. 2013) does not support a peculiar role for ice. The nucleosynthetic significance of ^{16}O anomalies became much more intelligible when they were found to correlate with nucleosynthetic excesses of some neutron-rich isotopes, notably chromium-54 and titanium-50 (Trinquier et al. 2007; Trinquier et al. 2009; Warren 2011), and even with the abundance of the stable isotopes of elements such as Cu, Zn, and Si (Fitoussi and Bourdon 2012; Luck et al. 2005; Luck et al. 2003). At least three unrelated components took part in the making of the Solar Nebula, the Sun itself, the inner Solar System, dominated by ordinary chondrites, and the outer Solar System, home of the carbonaceous chondrites and comets. Further down, we will explain how the low content of water and other volatiles in ordinary chondrites relative to carbonaceous chondrites is key to the understanding of the presence of water in the Earth.

The infant Earth drew heat from three sources of energy. First, as soon as a planet radius exceeds about 2000 km, conversion of gravitational energy by accretion of dust, asteroids, planetesimals, and planetary embryos into heat becomes very efficient, to the point that large amounts of material are molten and even vaporized. Second, internal differentiation,

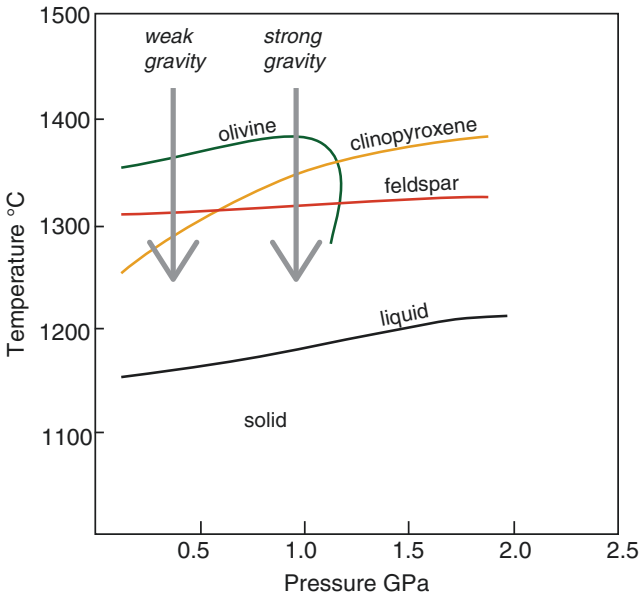


Formation and Evolution of the Earth, Fig. 4 The Solar Nebula is isotopically heterogeneous and must have formed from unrelated masses of interstellar gases. Left: oxygen isotope relationships in the inner Solar System (Krot et al. 2014). Thermodynamic processes, whether magmatic or environmental, produce an effect on the 18O/16O, which is twice the effect on 17O/16O, and hence moves oxygen isotopes on straight lines with a slope of 0.5 (Terrestrial Fractionation Line, FUN inclusions, solar wind). The elevation of a data point above the Terrestrial Fractionation Line is noted Δ17O and signals a nucleosynthetic origin different for the Earth and other material. The existence of a straight line with a slope of 1 on which the refractory calcium and aluminum-rich inclusions (CAI) found in chondrites demonstrates the existence of an excess of pure 16O in the Sun relative to the Earth. Right: the correlation of the excess of 54Cr with Δ17O in chondrites demonstrates the nucleosynthetic origin of both 16O and 54Cr excesses (Trinquier et al. 2007). Correlations of Δ17O with 65Cu/63Cu and 66Zn/64Zn in chondrites reinforce the conclusions that the Solar Nebula incorporated unrelated nucleosynthetic components

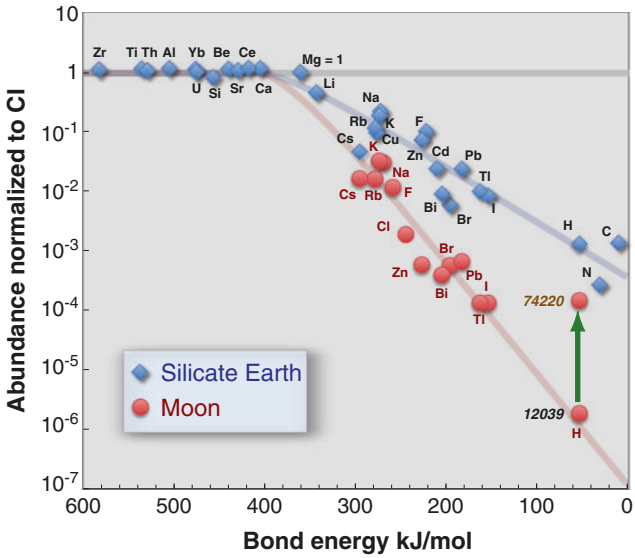
and in particular the segregation of the Earth's metallic core, liberates over the entire planet the equivalent of 2000 K heating. Third, stellar-derived short-lived aluminium-26, which decays into ^{26}Mg with a half-life of 0.7 Ma in releasing huge amounts of energy, was incorporated into the innermost regions of Solar Nebula, while the outer Solar System seems to have received only small amounts of it (van Kooten et al. 2016).

These heat sources drove melting of terrestrial planets and planetary embryos, which allowed dense iron and nickel to sink into planetary cores and left an outer shell of material known as a magma ocean. The fate of the magma ocean depends on the radius of the planet. If the planet is large, say the size of the Earth, and therefore its gravity strong, the surface of the molten layer solidifies as crystals of dense minerals, olivine and pyroxene, which quickly founders into the magma and the magma ocean crystallizes in a very short time (<1 Ma). For a small planet like the Moon, the gravity field is weak, buoyant crystals of a mineral known as plagioclase float to the surface and form as a thick blanket insulating the magma ocean from fast cooling (Fig. 5). Abundant plagioclase is responsible for the silvery shine of the lunar highlands. It is believed that under such conditions, the lunar magma ocean may have persisted for over 100–200 Ma (Elkins-Tanton et al. 2011; Nemchin et al. 2009).

The chronology of the lunar giant impact and of late accretion is not fully resolved, and as it ties into the origin



Formation and Evolution of the Earth, Fig. 5 Effect of gravity and, therefore, planetary size on the sequence of magma crystallization. At pressures in excess of 0.5 GPa (about 15 km in the Earth, and 90 km in the Moon), the first minerals to crystallize are olivine and pyroxene. These minerals are dense and sink in the magma, which keeps the magma largely exposed and causes fast cooling. In contrast, at pressures less than 0.5 GPa, plagioclase feldspar steps in at an earlier stage. This mineral is less dense than its parent melt and floats to the surface, creating an insulating blanket and slowing down magma crystallization. The lunar highlands and meteorites known as cumulate eucrites (likely from Vesta) illustrate how such a process can control the differentiation of small planets



Formation and Evolution of the Earth, Fig. 6 Abundance of elements in the Earth and Moon normalized to carbonaceous chondrites and to Mg = 1. The bond-energy scale (Luo 2007) adopted in this plot (Albarède et al. 2015) is different from the 50% condensation temperature T50 (e.g., (Lodders 2003) calculated from the standard cooling sequence of the Solar Nebula. For the Earth, T50 can be calculated in kelvins by multiplying the value of bond energy by ~3 (e.g., T50 ~ 700 K for Zn). The lack of hydrogen and helium in the gas of the lunar disk in the aftermath of the Giant Lunar Impact makes T50 irrelevant. The Moon is clearly depleted in all volatile elements except in pyroclastic glasses produced by lava fountaining, such as "orange glass" 74220

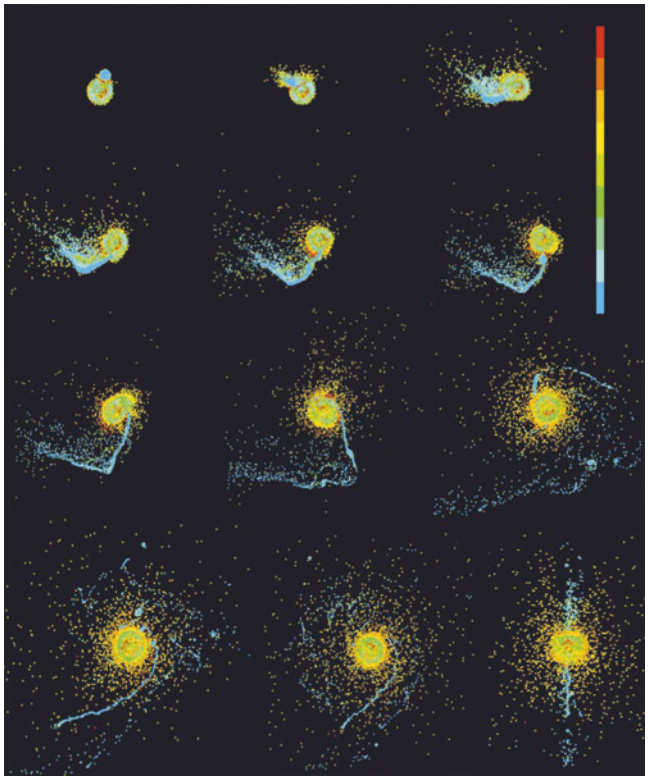
of the terrestrial ocean, neither is the origin of water and volatiles in the Earth (Fig. 6). In the legacy of Apollo missions in the 1970s was the dry character of the Moon. Beyond manifest evidence that the Moon has no ocean, common hydrous minerals (amphiboles, micas) so conspicuous in terrestrial magmas are totally absent from the lunar basalts and other rocks or subordinate (apatite). The idea of a dry Moon was recently challenged when substantial amounts of water were found in melt droplets encased in olivine crystals present in blebs of pyroclastic lavas, a form of lavas produced by lava fountains (Hauri et al. 2011).

Are those new observations enough to discard the old theory of a dry Moon? Not yet. Water is made of two elements, oxygen and hydrogen. But outside of the biological world, water does not really hold the status of a "magic" component. In all the objects of the inner Solar System, hydrogen, and therefore water, shares a common trend with other volatile elements such as C and N, but also of less volatile elements such as S, Zn, K, and Na. Clearly, the Earth is depleted in all the volatile elements and the Moon is even more depleted than the Earth. Potassium which condenses at 1000 K is three times more depleted in the Moon, zinc which condenses at 700 K about 250 times, so what should we think about water which condenses at 180 K (Albarede 2009)? If pyroclastic lunar melts contain large amounts of water and other volatile elements, this property is not common to all lunar material indiscriminately.

This problem of water in the Moon is actually tightly connected to the question of water in the Earth and we are now going to discuss why. We focus on water primarily because of the ocean and the role of aqueous chemistry in the emergence of life. As indicated before, however, hydrogen abundances are strongly correlated with the abundance of other volatile elements. The question of water in terrestrial planets can be formulated in two different ways: (1) Were volatile elements initially present in planetary material but subsequently lost by shocks and gravitational escape? Or (2) Does the depletion pattern common to all the objects in the Solar System indicate that nebular gas was blown off before it cooled down to volatile condensation temperature? Solution (1) faces a very tough challenge because volatile elements with light masses should be more depleted than their heavier counterparts. Examining families of elements with related properties provides a strong clue: alkali elements sodium (M = 23) and cesium (M = 133) are not depleted to very different extents, nor are halogens Cl (M = 35) and iodine (M = 125). In general, depletion patterns are not related to mass.

Solution (2) faces a very different problem: if potassium, an element which condenses at 1000 K, is depleted by a factor of 6 in the Earth relative to the nebular composition, what are the chances that the Earth contains any water, which condenses at 180 K, at all? Given the broad gaps in condensation temperatures indicated above, the answer is clearly "none." Most elements condense and vaporize from the cooling nebular cloud in a temperature interval smaller than 100 K (Larimer 1973) and their abundances would be expected to "toggle" between condensation to no-condensation status. The broad range of temperature inferred from the abundance of moderate volatile elements, such as Zn, Rb, Mn, Li, in the Earth (>700 K; Palme and O'Neill 2003) calls for late addition of material variably depleted in volatile elements. Water in particular must have been added after the primordial condensation was completed. A similar response can be given for other volatile elements such as S, N, and C. Although water is found on Earth in the form of a conspicuous liquid ocean, most scientists would also argue that more inconspicuous water, worth more than an oceanic mass, is also present in the mantle.

This problem is addressed with the important concept of Late Veneer. At any given point in the history of the Solar System, material is left over with orbits that will eventually cross the Earth's orbit in the form of dust and grains (the modern equivalent being the shooting stars), asteroids such as the one ramming into the Earth killing dinosaurs and most living organisms 65 million years ago, and protoplanets such as Theia, which is widely believed to have caused the Lunar Giant Impact and left the Earth and Moon close to their modern configuration (Fig. 7). Today, the Earth's



Formation and Evolution of the Earth, Fig. 7 The Lunar Giant Impact (Canup and Asphaug 2001). Theia, a Mars-size impactor (in blue in the upper left corner), obliquely collides with the proto-Earth. Scattered material is rapidly collected by the Earth or placed into orbit as a pre-lunar disk (in blue in the lower right corner). Colors refer to material temperature. Snapshots at time t = 0.3, 0.7, 1.4, 1.9, 3, 3.9, 5, 7.1, 11.6, 17, and 23 h

neighborhood is relatively clean and safe, although some resonances with Jupiter may occasionally break asteroids and send the fragments flying across the Solar System as they did 160 (Bottke et al. 2007) or 420 (Nesvorný et al. 2007) Ma ago. Observations strongly support this concept: upon core segregation, iron-loving elements (siderophile) and in particular those of the platinum group family (PGEs, such as osmium, rhodium, etc.) are completely segregated into the metal phase. The overlying mantle should be left with barely a whiff of PGEs. Observations on ultramafic rocks and basalts show, however, that platinum and its kin are present in the mantle (Morgan 1986; Walker 2009). In addition, their relative proportions coincide with chondritic proportions, whereas if PGEs had been left behind by core-mantle segregation, elements should have strongly been fractionated from each other. All these observations can be reconciled with the Earth's growth history, if 0.4% chondritic material or more was added after the last major event of metal/silicate fractionation. This last added fraction is known as the Late Veneer.

The Late Veneer hypothesis (Chou 1978) has gained momentum as the prevailing mechanism for bringing water and other volatile elements, as well as the highly siderophile elements discussed above, to the Earth. Water can therefore be seen as "extraterrestrial." The older assumption that comets were the water carrier lost favor, largely because of their excessive deuterium abundance (Owen and Bar-Nun 1995; Robert et al. 2000). The "dry" character of the Moon is in keeping with Platinum Group Elements being some 40 times less concentrated in the lunar mantle indicating a much smaller contribution of Late Veneer relative to the Earth (Day et al. 2010). The stark contrast between the amount of Late Veneer brought to the two planetary bodies suggests that the Earth acquired its water and volatile elements by collision with a single object (Bottke et al. 2010) resembling one of the Jupiter's moons, Ganymede.

What was the timing of the events? The oldest age on the Moon was found in a zircon from a breccia (**4417 ± 6 Ma)** (Nemchin et al. 2009.) Our understanding of the chronology was greatly influenced by the extinct radioactivity of the isotope 182 of hafnium, which decays to the isotope 182 of tungsten with a half-life ($T_{1/2}$) of about 9 Ma (Table 1). Upon planetary melting, tungsten is preferentially hosted in the Earth's metallic core, whereas hafnium remains in the mantle. The ^{182}Hf-^{182} W is therefore an excellent chronometer of core/mantle segregation. It has been found that the Earth's core segregated some 30 Ma after the formation of the Solar Nebula (Kleine et al. 2002; Yin et al. 2002), while the lack of a significant excess of ^{182}W in the Moon relative to the Earth suggests that the Lunar Giant Impact took place after all radioactive ^{182}W disappeared, about 40–60 Ma later (Touboul et al. 2015). Such a late formation age of the Moon is based on Hf and W abundances in the terrestrial and lunar mantles, and on how well constrained the value of 0.4% of Late Veneer may be, two assumptions that are both the subject of variable opinions in the field of planetary geochemistry. How early the Moon formed is still a subject of active discussion. Can we now date the arrival of the Late Veneer? Although some scientists still believe that water and volatiles were accreted to the Earth at a very early stage, the case for a later event is based on multiple observations. The long-lived ^{235}U-^{207}Pb, ^{238}U-^{206}Pb, and ^{87}Rb-^{87}Sr chronometers suggest major events fractionating volatiles from

refractory elements at 100–150 Ma, and it is difficult to believe that these events are disconnected from the Late Veneer imprint.

What about the terrestrial atmosphere? It has long been pointed out that the distribution of rare gases (He, Ne, Ar, Kr, Xe) in the atmosphere is very different from solar abundances, which led earlier scientists to suggest that the terrestrial atmosphere is "secondary" and cannot have been outgassed from the mantle. The relative abundances of the stable isotopes of the rare gas xenon also are different in the atmosphere and the mantle (Caffee et al. 1999; Holland and Ballentine 2006), which confirms that the atmosphere cannot be simply accounted for by outgassing or mantle volatiles (Allegre et al. 1983). Again the extinct radioactivity of iodine-129 ($T_{1/2} = 15.6$ Ma) and plutonium-244 ($T_{1/2} = 80$ Ma) as measured by the relative proportions of their daughter xenon isotopes ^{129}Xe and $^{131\text{-}136}$Xe suggest an apparent age of the atmosphere of about 100 Ma after the formation of the Solar System (Ozima and Podosek 1999). If the Earth's atmosphere built up from small planetary objects brought from the outer Solar System, an initial composition rich in carbon dioxide (now stored as carbonates) and nitrogen is expected, very similar to the atmosphere of Venus.

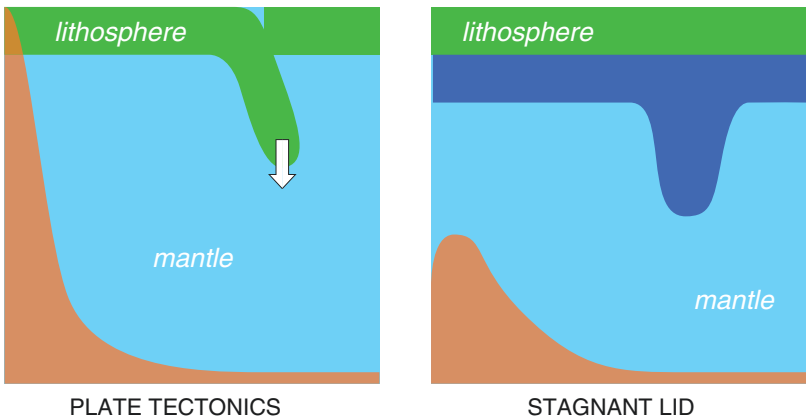
The Early Earth

After the formation of the Earth-Moon system, the Earth was left with a partially molten mantle, a magma ocean occupying the top of the mantle and possibly another ocean at the bottom (Labrosse et al. 2007). For lack of relevant observations, the thermal regime of our planet at that stage is very poorly understood. Upward crystallization of the upper magma ocean gave most of the mid-mantle the geochemical character of a solid cumulate depleted in the most fusible elements, such as alkali elements, aluminum, and titanium, but also trace elements such as rare-earth elements and heat-producing uranium and thorium. Upward segregation of a liquid enriched in incompatible elements, very similar to the lunar basalt component dubbed "KREEP" to emphasize its high abundances in potassium, rare-earth elements, and phosphorus, may have been accompanied by the formation of a buoyant crust, for the composition of which we have very little evidence. Although mass balance between the primordial mantle, the crust, and the residual mantle may be satisfactorily worked out at the first-order for most elements, the geochemical pathways and processes that severely depleted the terrestrial upper mantle in incompatible elements and heat sources over geologic times and led to continental crust segregation remain poorly understood in detail.

A related issue is why the Earth was apparently the only planet to "go plate tectonics." The two main dynamic modes of terrestrial planets are (Schubert et al. 2001) (Fig. 8):

1. The stagnant lid regime, in which steady lithosphere, unbroken, cold, and solid overlies the convective mantle (Davaille and Jaupart 1993). The solid lithosphere thermally insulates the mantle and heat produced in the planetary interior can only be lost by conduction, a very inefficient cooling mechanism.
2. Plate tectonics, in which solid lithospheric plates yield under their own weight as they cool then founder into the mantle. This process is known as subduction. New lithosphere must therefore be created by upwelling of hot and partially molten upper mantle. The site at which new crust is created is called mid-ocean ridges. This process brings very hot material at the surface and acts very efficiently to cool the mantle. Many believe that the terrestrial dynamo and its external manifestation, the terrestrial magnetic field, owe their existence to the enhanced cooling provided by plate tectonics.

To some extent, plate tectonics prevailed in the Earth due to the presence of water, which decreases the viscosity of the mantle (Hirth and Kohlstedt 1996). But the exact mechanisms

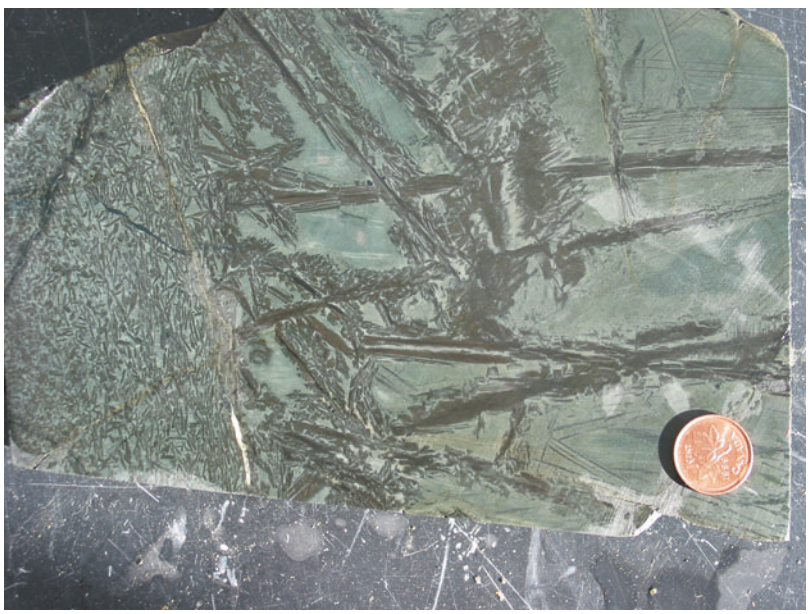


Formation and Evolution of the Earth, Fig. 8 The contrasting geodynamic regimes of Earth (left) and Mars (right). In the Earth, the abundance of water makes the lithosphere less resistant to gravitational pull and the mantle less viscous: plate tectonics is the stable regime and enhances planetary cooling. In Mars, the paucity of water and weaker gravity makes the lithosphere stable and act as a thermally insulating blanket

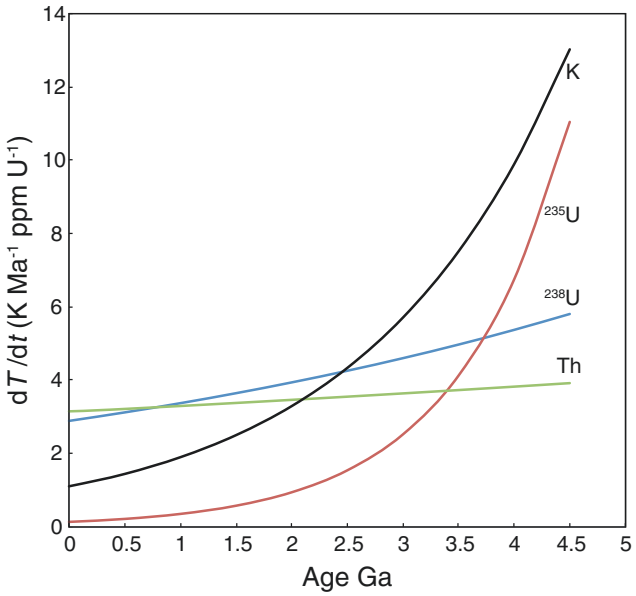
that allowed tectonic plates to form remain largely enigmatic. Two factors are thought to be primordial. First, mantle material obeys a nonlinear rheology (rocks only yield above a particular threshold). Second, by reducing grain size and damaging crystalline structures, shear helps localize deformation and cause plates to break (Bercovici and Ricard 2014).

The time at which tectonic plates appeared is better constrained thanks to the presence of very ancient granites, the hallmark of continental crust and plate tectonics. When extracted from the mantle, most primary basalts are saturated in magnesian olivine, the cardinal mantle mineral, but olivine irreversibly reacts with granitic liquids; granites cannot therefore be primary mantle melts and their presence indicates the remelting of basaltic rocks instead and the presence of water in the source. Such a process is known to take place within terrestrial subduction zones and, exceptionally, in Iceland, where the basaltic piles are hydrothermally altered upon infiltration of meteoric water. In most other oceanic islands, granites are very rare and reduced to isolated outcrops. In planetary materials such as lunar rocks, they occur as rare and small fracture-filling exudates. In contrast, granites and their metamorphic and sedimentary derivatives are major components of the continental crust. Ancient granites are best traced by zircon (zirconium silicate $ZrSiO_4$), a tiny but ubiquitous mineral, which crystallizes at high temperature and is extremely resistant to mechanical and chemical erosion. Abundant detrital zircons is a sure sign of the presence of granites in the watershed and therefore of continental crust. In addition to Zr, zircon contains substantial amounts of uranium, which makes this mineral the epitome of precise and reliable chronometers. It also hosts sizeable amounts of hafnium, a nearly perfect isomorph of zirconium, which allows the ^{176}Lu-^{176}Hf chronometer to be implemented and model ages of crustal residence to be calculated. In the Yilgarn craton, Western Australia, the ~3 Ga old Jack Hills conglomerate was found to contain a huge variety of detrital zircons, some of them as old as 4.1 Ga and up to 4.38 Ga (Harrison et al. 2005; Kemp et al. 2010; Wilde et al. 2001). Zircon crystals from Jack Hills also contain mineral inclusions that are all characteristic of granitic rocks, typically feldspars and micas. The presence of granitic rocks as early as 4.3 Ga and of a suite of granites at 4.1 Ga attests to the existence of some early form of continental crust and therefore of active plate tectonics less than 500 Ma after the formation of the Earth. Venus and its complete resurfacing about 1 Ga ago should be taken as a caveat (Phillips et al. 1992): we know very little about the geology of the first planet aeon. Although the view that plate tectonics started early in the Earth's history has gained momentum, it has also been suggested that it could have started at a much later stage.

Two unusual types of rocks are only found in the Archean crust, with rare exceptions. The first type is known as komatiites (Fig. 9), lavas that represent some sort of "superbasalts" melted at great depth in the mantle and erupted at temperatures in the order of 1500 °C, much higher than modern basalts (Arndt et al. 2008). Komatiites have been related to either mantle plumes or to subduction zones, and attest that the mantle was much hotter in the Archean than today. Such high temperatures reflect that the radioactive isotopes of potassium, uranium, and thorium were more abundant several billion years ago than today (Fig. 10). Another major group of Archean rocks, awkwardly designated as the tonalite-trondhjemite-granite or TTG assemblage (Fig. 11), has peculiar geochemical characteristics indicative of a mantle source enriched in incompatible elements. The



Formation and Evolution of the Earth, Fig. 9 Archaean komatiite from South Africa (courtesy of Nicholas T. Arndt) attest to extremely hot mantle sources. The eruption temperature of these lavas may have reached 1500 °C. Very rapid cooling rates induced the growth of long olivine crystals which gives the rock its fern-like appearance



Formation and Evolution of the Earth, Fig. 10 Contribution of naturally occurring radioactive isotopes to the radioactive heating of the Earth through time. The curves represent the rate dT/dt of heating per Ma by radioactivity for a typical terrestrial rock containing today 1 part per million of uranium and 1% potassium (K/U = 10,000)

structure of Archean continents typically show TTG nuclei stitched to each other by komatiite-rich lineaments, referred to as greenstone belts. So, although the early Earth had gone the plate-tectonics way, the differences between Archean and modern geodynamics were fairly conspicuous.

An additional characteristic of the early Earth was continental elevation above sea level. Continental crust is significantly less dense than the ambient mantle and makes continental plates thick and buoyant. The Earth is therefore characterized by a strong dichotomy of elevations: plates capped with continental crust rise like icebergs above the sea surface. Today, they emerge above sea level, in contrast with oceanic plates, such as the Pacific plate, which are submerged by deep oceans and form oceanic abyssal plains. Such a dichotomy does not exist on other terrestrial planets (the contrast between the northern and southern hemispheres of Mars is believed to be inherited from a large impact) and is a sure indication of an active plate tectonics regime. Archean subaerial sediments such as river sandbars and braided channel deposits of mud flats are very uncommon (Eriksson et al. 2005; Long 2011). Most volcanic eruptions seem to have occurred under shallow water (Arndt 1999).

How Does the Mantle-Crust System Evolve?

Before discussion starts, a caveat must be born in mind. We walk on the Earth's surface only and the geologist can only scratch the top layers of the upper crust, which is, on average,

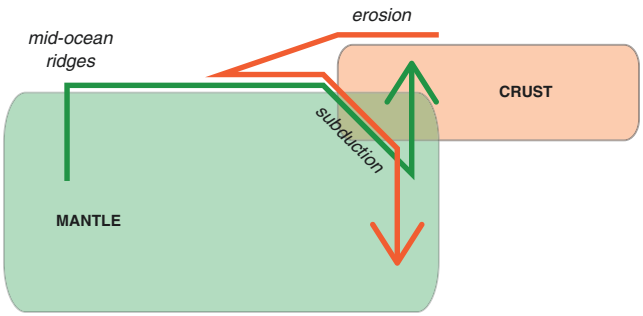
Formation and Evolution of the Earth, Fig. 11 The tonalite-trondhjemite-(TTG) granite association dominates continental crust in Archean terranes (Canada, courtesy Martin Guitreau). Here the color contrast between rocks of variable silica contents underlines the strong deformation of the whole crustal segment

35–40 km thick. Decreeing that a particular surface sample is representative of the lower crust requires detailed investigations with usually ambiguous conclusions. Volcanic eruptions raise rock fragments known as xenoliths, from the deep crust and the upper mantle to the surface. The depth at which the rock was torn off from the wall by the rising magma is usually assessed through thermodynamic models. The persistence of radiogenic isotope excesses in xenoliths (Bedini et al. 2004) indicates that, even at mantle depth, thermodynamic equilibrium may not be achieved. Faults, such as transform faults along mid-ocean ridges, exhume deep-seated material but often at the price of intense chemical and mechanical transformation. Most geologists would agree that we have a reasonably good sampling of the continental crust and the subcontinental lithospheric mantle. In contrast, we do not have access to samples from the convective mantle and we must rely on inferences from basalts and from rare samples of

intensely transformed peridotites collected along mid-ocean ridges.

For the sake of illustration, let us represent the Earth the "mantle" and the "crust" by two boxes exchanging material through magmatic activity, crustal foundering, and subduction (Fig. 12). Mantle peridotites partially melt by decompression under mid-ocean ridges. The partial melts, known as basalt, form a ~ 5 km thick oceanic crust, which, on average, remains on top of the oceanic plate for a geologically short ride of about 60 Ma. The crust and overlying sediments are sent back to the mantle at subduction zones, where they melt with partial melts being a major contributor to new continental crust and to ocean island material (Allegre et al. 1983; Hofmann and White 1982). The process is complex and involves fluxing of the subduction zone by fluids and foundering of deep crust into the mantle. The overall consequence is, however, that material extracted as basalt at mid-ocean ridges is partly allocated to the continental crust and partly returned to the mantle. Likewise, the subaerial upper crust is eroded, both chemically and mechanically with the product of erosion ending up in the oceanic crust, while some fraction of the lower crust founders into the mantle. Such a model describes well what drives the simplest model of crust formation and mantle-crust interactions.

A first major enigma is that of the initial state of the mantle-crust system. Isotopic anomalies associated with extinct radioactivities, such as that of ^{146}Sm (which produces ^{142}Nd with $T_{1/2} = 103$ Ma) and ^{182} W ($T_{1/2} = 9$ Ma), have been detected in early Archean rocks, which shows that the mantle did not start as a homogeneous medium (Caro et al. 2003; Boyet and Carlson 2006; Bennett et al. 2007; Willbold et al. 2011). The existence of a primordial crust is accepted by many, but its composition was certainly very different from the modern continents, and overall the conclusions still rest on shaky grounds. As attested to by the restriction of TTG to



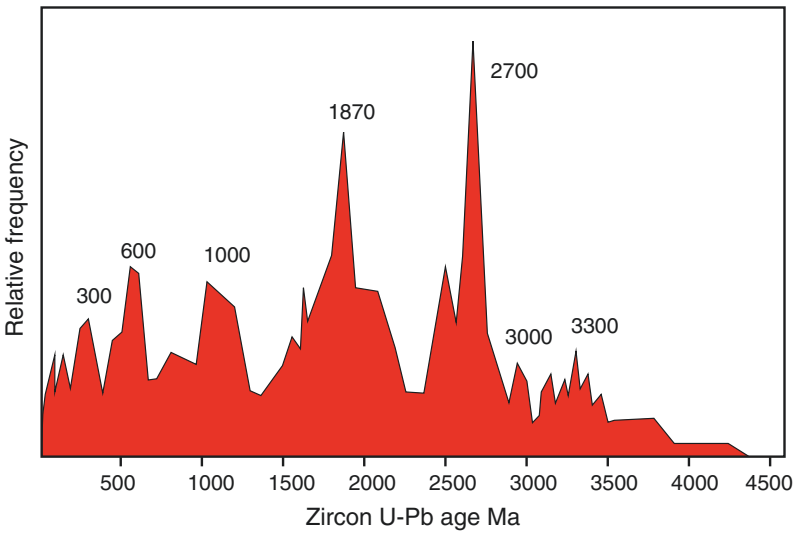
Formation and Evolution of the Earth, Fig. 12 The two-box representation of the mantle-crust system. Magmas erupted at mid-ocean ridges and oceanic islands are transported by plate tectonics to subduction zones. Erosion of continental crust, both chemical and mechanical, also brings material as sediments to the ocean floor and then to subduction zones. Both types of material are processed as orogenic magmas, which are incorporated to the crust, while the residue sinks into the mantle

Archean times, it took almost 2 billion years to remove the enrichment of the upper mantle in incompatible elements and turn it into the modern depleted upper mantle source of mid-ocean ridge and subduction zone magmas (Blichert-Toft and Albarède 2008). It took about the same time for komatiites to disappear as a prominent magma type (Arndt et al. 2008). Both the occurrence of TTG and komatiites, and their unusual compositions and geological settings relative to modern rocks attest to a particular thermal regime prevailing in the Archean. This is expressed by saying that "the Earth relaxed its initial conditions." The nature and composition of the mantle-crust system were reshaped by mantle convection, its surface expression plate tectonics, and by crustal growth.

The mantle-crust system never reached a true thermal and chemical steady-state because radioactive heat production strongly decreases through time (Fig. 9) and also because continental crust grows from the mantle. The idea that, although some crust may have existed from start, its volume increased through time and its composition evolved toward the more mature composition familiar to us is widely accepted. Many models of crustal growth still struggle with three major issues: (1) Was crustal growth continuous or episodic? The presence of very distinctive age provinces on continents, such as 3.3, 3.0, 2.7, 1.8, 1.0, 0.6, 0.3 Ga (Condie and Aster 2010; Condie and Aster 2013; Gastil 1960) (Fig. 13), suggests so, but alternative explanations have been put forward. The answer to this question has far-reaching consequences: subduction being a continuous process, episodic crustal growth would therefore call for episodic extraction of crustal material by mantle plumes rather than reprocessing of normal oceanic crust. (2) Was crustal growth faster in the past than today? It seems that, although a huge peak in crustal growth took place at about 2.7 Ga ago, continents never ceased to grow. (3) What fraction of continental crust gets recycled into the mantle? These questions are an active field of research and there is no indication that we may be nearing a consensus on any of them. We will see that the additional question of when continents rose above sea level (Flament et al. 2008) has huge consequences for rise of oxygen and the evolution of life (Campbell and Allen 2008; Pons et al. 2013).

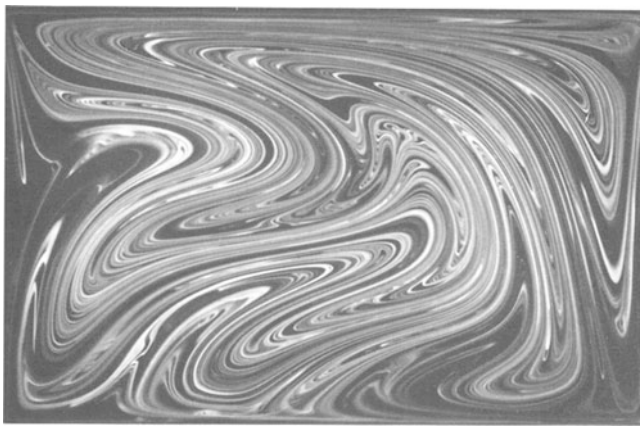
The respective role of mid-ocean ridges and subduction zone, the two sides of the interface between the mantle and the crust, appears very clearly in the trace element and isotope geochemistry of modern basalts. Elemental fractionation prevailing at mid-ocean ridge is controlled exclusively by magmatic processes, whereas dehydration at subduction zones imparts a strong signature of hydrous process to the erupting magmas and indirectly to continental crust.

So far, we have assumed that the mantle and the crust behave as homogeneous boxes with relatively uniform properties. Isotope geochemistry demonstrates that, actually, the mantle is composed of different petrological units with



Formation and Evolution of the Earth, Fig. 13 Histogram of zircon U-Pb ages (Condie and Aster 2013). The database includes several thousands of zircon crystals from granites and river sediments. Although the concept was established in 1960, this database unambiguously demonstrates that crustal growth is episodic (although some believe that preservation may still play a role (Hawkesworth et al. 2009))

identifiable properties, known as geochemical components (Hofmann 1997; White 1985; Zindler and Hart 1986). For instance, the depleted mantle, which prevails in mid-ocean ridge basalts, is largely a residue from previous episodes of upper mantle melting. In contrast, the HIMU component, frequent in some oceanic islands, betrays the recycling of ancient oceanic crust, and the rare EM2 component the presence of continental debris in the source of basaltic rocks (see entries on mantle geochemistry and oceanic island basalts). In spite of vigorous convection, the mantle is not well mixed at all scales. Mixing results from the combination of mechanical stirring, which stretches and refolds layers of different compositions, e.g., peridotites and basalt, like in a marble cake (Allègre and Turcotte 1986; Olson et al. 1984; Tackley and Xie 2002) (Fig. 14), and molecular diffusion of elements from one layer to the next (Hofmann and Hart 1978). Stirring can be undone, at least as a thought experiment, in contrast with diffusion, which spontaneously increases entropy. The mantle is stirred in two ways (Agranier et al. 2005). First, three-dimensional velocity gradients associated with chaotic mantle convection creates streaks and tendrils in the entire volume. Second, fringe velocity gradients in the mantle penetrated by subducting plates efficiently perturb the original large-scale patterns of mantle geochemistry. Oceanic crust entering the mantle at subduction zones can be seen as a steady source of heterogeneities with length scales typical of those associated with lithospheric plates, while mantle convection progressively stretches and folds these heterogeneities and decreases their length scales. In contrast to mechanical stirring, which acts over long distances (1 meter to 1000s of kilometers), diffusion only acts locally (<1 m over billions of years). At mantle temperatures, it erases the original details of petrology and keeps isotopic chronometers open, thereby obliterating most of the local information, such as ages and original equilibration temperature, pressure, and composition



Formation and Evolution of the Earth, Fig. 14 Mechanical stirring reduces initial heterogeneities by stretching and refolding without destroying them (Ottino 1989)

conditions geochemists would hope to retrieve from the study of hand samples (Bedini et al. 2004; Hofmann and Hart 1978).

One of the major challenges of geochemistry has been the faint but unmistakable evidence that some parts of the mantle are poorly mixed and keep some record of the original chemistry of the planet. Historically, the strongest case was made by rare gases, and in particular by the presence of ^{3}He and solar neon, which are still present in basalts originating at great depth, like in Hawaii and Iceland. Once helium is outgassed from a volcano, it is rapidly lost to space because it is too light to be bound to the Earth's gravity field. Helium-3 is no more "primordial" than any other stable isotope of any element, but its excesses in basalts attest to the irreversible outgassing of primordial material from the mantle by magmatic activity. Thirty-year-old evidence from ^{3}He and other rare gases that the lower mantle was poorly mixed and still

contains material that avoided processing by mid-ocean ridges over the entire geological history is extremely strong (Graham 2002). It is in particular well established that the mantle source of hot-spot basalts (Iceland, Hawaii) has been much less outgassed than the source of mid-ocean ridge basalts. Likewise, excesses of tungsten-182 have now been found in large flood basalts, which entail that some mantle domains have been preserved since the formation of the Earth (Rizo et al. 2016).

To sum up this part, the Earth still remembers its original state inherited from accretion and magma ocean differentiation, but is well on its way to some sort of steady state controlled by continental crust extraction and recycling at subduction zones.

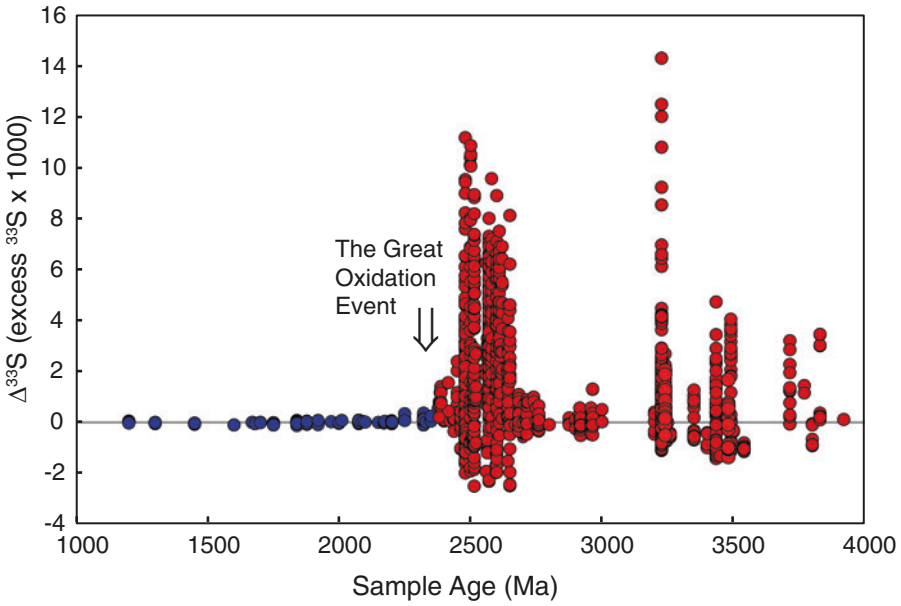
The Early Evolution of the Ocean and the Atmosphere

We will finally address how the evolution of the deep Earth affected the ocean and the atmosphere. Let us first describe their current state. An extraterrestrial traveler to Planet Earth would be first struck by the abundance of oxygen in the atmosphere and quickly conjecture that it originated from primordial CO_2 by removal of carbon and wonder where carbon went over the ages. The answer is clearly that a process known as oxygenic photosynthesis dissociates CO_2, with reduced carbon being buried in sediments and sent to the mantle by plate tectonics. Of course, would our visitor say, plankton receives light from the Sun and takes on the job. But, plankton also needs phosphate, a critical nutrient, and a lot of it, about one atom of P for 105 atoms of C: if carbon is lost to sediment, so is phosphorus (Delaney 1998). In addition, decades of careful investigations show that the oceanic crust acts as sink for phosphorus, not as a source (Wheat et al. 2003). How is the level of phosphorus maintained at the surface of the ocean? Still another miracle of plate tectonics! Water vapor produced by the ocean condenses as rain, which, combined with atmospheric CO_2, dissolves surface rocks and liberates ions, including phosphate, into the rivers. Without erosion, the terrestrial food chain as well as the marine one would collapse for lack of phosphorus. An additional effect of erosion is the control of ocean pH: reaction of rain and CO_2 with exposed crustal material liberates carbonates, while cations such as Na, Ca, and Mg are transported to the sea. The balance of negative and positive charges condition the dissolution of carbonates (HCO_3^- and CO_3^{2-}) and therefore buffer the pH of the ocean. Such conditions were never met on Mars which died a planet with a long-gone and rather acidic hydrosphere with sulfates as a prominent sediment. Although river-like morphologies show that some water was undoubtedly present at the surface of the young Mars, the paucity of hydrous minerals demonstrated by orbital spectrometers or observed in Martian meteorites is not in favor of a "wet Mars."

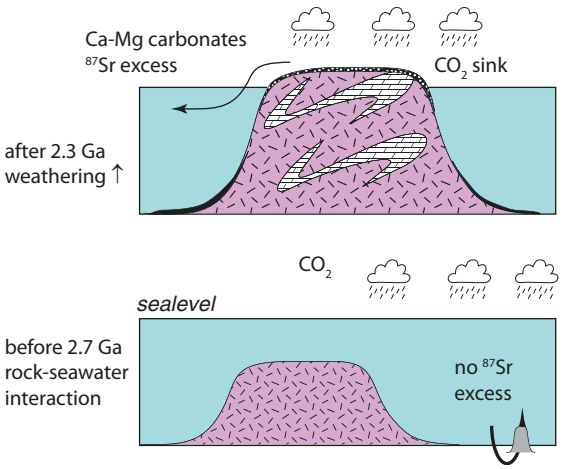
Can we try to guess how the ocean-atmosphere would function in a "water world" with very little emerged continental surface? Oceanic abysses would not be covered with as much sediments like they are today; carbonates and clays would necessarily be scarce. Planktonic life energized by sunlight could not function for lack of phosphorus replenishment and life should be segregated at the sediment-ocean interface or around hydrothermal vents, probably powered by chemotrophic organisms.

It is in this context that the Great Oxygenation Event (GOE) must be understood. By 2.4 Ga, several major changes occurred that would irreversibly change the face of the Earth. Banded iron formations formed by oxidation of dissolved ferrous iron and precipitation as ferric minerals disappeared. Minerals sensitive to atmospheric oxidation, such as uranium dioxide and pyrite, disappeared from the sedimentary record. Probably the strongest evidence of the GOE is the disappearance at 2.4 Ga of photolytic reactions between UV light and atmospheric SO_2 of volcanic origin and the rather brutal transition to the shielding of the atmosphere by the ozone layer, which itself attests to the presence of a high level of oxygen in the troposphere after that date. Evidence of photolytic reactions prior to the GOE rests on mass-independent effects (MIF = mass-independent fractionation) on sulfur isotope abundances measured by the excess of ^{33}S abundances predicted from ^{32}S and ^{34}S (Fig. 15) (Farquhar et al. 2000).

Many explanations have been claimed to account for the GOE. An internal geodynamic cause is unlikely because the event was essentially completed in less than 100 Ma. The most appealing interpretation rests on strontium isotopes (Flament et al. 2008). Radiogenic strontium-87 is produced by the slow decay of rubidium-87. The Rb/Sr is much smaller in the mantle relative to the crust, so that the apparent excess of radiogenic ^{87}Sr is also smaller in mantle material. Until 2.4 Ga, the ^{87}Sr excess of seawater recorded through time by marine carbonates is similar to that of the mantle, but suddenly increases at that time to track the ^{87}Sr excess of the crust. Such a spectacular shift signals the rise of continental crust above sea level, the onset of subaerial weathering, and the rapid drawdown of atmospheric CO_2. It seems that the GOE marked the emergence of permanently emerged continental surfaces, the beginning of a sustainable nutrient cycle, notably a rich supply of phosphates to the ocean (Pons et al. 2013). The prevalence of conditions favorable to oxygenic photosynthesis, which allowed carbon and oxygen to be dissociated, allowed organic carbon to be incorporated into seafloor sediments and subsequently dragged down to the mantle by sedimentation, leaving oxygen to accumulate in the atmosphere. By that time terrestrial atmosphere was on its way, the ocean could become oxygenated, oxygen could oxidize atmospheric methane, and the greenhouse effect be kept in check (Fig. 16).



Formation and Evolution of the Earth, Fig. 15 Sulfur isotope evidence for the end of SO_2 photolytic destruction in the atmosphere and the rise of atmospheric oxygen. Before atmosphere was protected by the ozone layer, excess ^{33}S was produced by the effect of UV on volcanic SO_2 emissions into the atmosphere (courtesy James Farquhar)



Formation and Evolution of the Earth, Fig. 16 A probable cause for the rise of atmospheric oxygen during the ~2.35-Ga-old Great Oxygenation Event (Pons et al. 2013). Release of radiogenic 87Sr into the ocean, as attested to by its capture by marine carbonates, indicates the onset of vigorous subaerial erosion of continental crust by CO2 and rainwater. The rise of continents above sea level, allowed the rapid drawdown of atmospheric CO2 and a supply of abundant phosphates to the ocean, which favored strong oxygenic photosynthesis. Sedimentation of reduced carbon on the seafloor and its subsequent removal by subduction triggered the sudden rise in atmospheric oxygen

Conclusion

Although the Earth formed under the control of physical processes common to all the terrestrial planets, it is unique with respect to multiple characters: it possesses a strong magnetic field, a prominent hydrosphere with a surface ocean, and its geodynamic regime is plate tectonics, which allowed a continent–ocean duality to emerge and a slowly evolving separation of a granitic crust from the residual upper mantle. The rather large size of our planet suppressed crystallization of a plagioclase-rich buoyant boundary layer and allowed the terrestrial magma ocean to vanish relatively fast. Water comes up as a remarkable "gift" from the outer Solar System. All these defining characters are inherited from the accretion stage and seem to have contributed to the emergence of life: the magnetic field protected the atmosphere, the hydrosphere fostered life for most of its history; plate tectonics divided the surface into subaqueous and subaerial expanses, each with a particular role with respect to life; the rise of continents allowed the rise of atmospheric oxygen.

Summary

4.56 Ga ago, Earth's material condensed from heterogeneous stellar residues, collectively known as the Solar Nebula, around the central star, our Sun. The Earth itself is the end product of very many collisions of planetesimals and protoplanets, the last of which, the Moon, accreted a few tens of Ma after condensation started. The Earth was born depleted in volatiles, which were later added to our planet by colliding water-rich bodies originating in the outer Solar System. Abundant water caused the interior of the Earth to develop a geodynamic regime of plate tectonics, leading to a strong dichotomy between continents and deep ocean basins and allowed life to appear. Oxygenation of the atmosphere some 2.4 Ga ago is attributed to thriving life and marks the rise of continents above sea level.

Fractional Crystallization and Assimilation

Frank Spera and Melissa Scruggs
Department of Earth Science, University of California Santa Barbara, Santa Barbara, CA, USA

Definitions

Fractional crystallization is one of the most important petrogenetic processes contributing to the compositional diversity of magmas and associated igneous rocks of the Earth's continental and oceanic crust. N.L. Bowen, one of the guiding lights of modern petrology, brought this mechanism to the fore in the early part of the twentieth century. A multicomponent silicate liquid (melt) undergoes fractional crystallization when crystals precipitated from the melt do not remain in equilibrium with residual melt during crystallization. This may occur, for example, by physical separation of crystals from melt (e.g., by gravitative settling or floatation of crystals) or by sluggish crystal-melt reaction kinetics (nucleation and growth) without physical separation. Fractional crystallization in multicomponent silicate liquids is complex compared to crystallization in unary systems because the composition of removed crystals is generally different than the starting liquid composition. The only exception is when the bulk composition of the system resides at a thermodynamic invariant point. Because the composition of precipitated crystals is generally different from melt, residual melt will be compositionally distinct from parental (pre-crystallization) melt. Consequently, residual melt will evolve toward one with lower concentrations of the oxide components that are removed by crystallization. A detailed example of how mid-ocean basaltic melt, the dominant melt composition on Earth, changes upon closed-system fractional crystallization is presented below using the MELTS algorithm (Ghiorso and Sack 1995; Ghiorso and Gualda 2015). Fractional crystallization also leads to the strong enrichment of the incompatible trace elements that do not partition into crystalline phases. A quantitative example is presented below. Because there are very small isotopic fractionations of high atomic mass elements such as Sr, Nd, and U during crystallization, closed-system fractional crystallization produces very small, generally negligible, isotopic fractionations. Exceptions are for light elements such as hydrogen or oxygen although the effects are relatively small especially for oxygen.

Assimilation or magma contamination is compositional modification of preexisting magma by addition of material derived from country rock surrounding the magma body. Unlike fractional crystallization that operates in closed-system magma bodies, assimilation requires a flow of material across the magma body-country rock boundary and hence constitutes prima facie evidence of open-system behavior. Since country rock is practically always at a different temperature (generally lower) than the invaded magma, assimilation implies that heat is exchanged across the country rock-magma boundary. Assimilation can proceed by the addition of initially sub-solidus roof or wall rock or by the addition of partial melt generated in the country rock with subsequent transfer of country rock partial melt (or some fraction thereof) into the magma body by porous media percolative flow and/or flow in fractures. Such country rock fractures may be preexisting or may form due to thermal stresses associated with steep thermal gradients along the magma-country rock boundary. Assimilation differs from magma mixing, which is also an open-system process leading to magma contamination, in that the energy required for heating and partial melting of country rock in assimilation derives from the latent heat of crystallization and cooling within the magma body. In contrast, when magma contamination occurs by replenishment (magma mixing), heat may be transferred from recharge to resident magma or vice versa depending on the specific enthalpy (enthalpy per unit mass) of the two mixing end-members in their initial (premixed) state.

AFC is an acronym for *assimilation and fractional crystallization*. The AFC model adopts the approximation that the heat generated by fractional crystallization (enthalpy of crystallization plus the sensible heat from magma cooling) is available to heat up and potentially melt or partially melt host country rock. To model the extent of assimilation and its geochemical implications, an energy balance is explicitly considered along with constraints from mass balance and phase equilibria. In early models of AFC, the energetic requirements were modeled using the mass ratio of fractionation products (cumulates) to assimilated country rock set ab initio to a constant, and phase equilibria was approximated using heuristics. In modern models (e.g., Bohrson et al. 2014), partial melt generation is explicitly linked at each step to production of fractionated solids (cumulates), and thermodynamic methods are used to compute phase equilibria, energy balance, and trace element partitioning self-consistently for magma treated as an open multiphase-multicomponent system that may interact by material and energy exchange with its environment.

RAFC is an acronym for recharge, assimilation, and fractional crystallization. This set of processes describes the open-system evolution of a magma body that exchanges heat and mass with its surroundings. RAFC equilibrium models are developed by adding magma replenishment or recharge to AFC models in a thermodynamically self-consistent manner. Recharge magma is in internal thermodynamic equilibrium before addition to the magma body. Typically, the elementary step of magma mixing is accomplished isobarically and isenthalpically, and the mixing magmas are brought to thermodynamic equilibrium by maximization of the system entropy. The mixing process generates a hybrid magma that represents a unique thermodynamic state in which the composition and amount of all phases in equilibrium (solids, liquids, and fluids) as well as temperature is determined. Interestingly, the postmixing temperature does not necessarily lie between the initial temperatures of the mixing magmas. There are cases, specifically when one or both of the mixing magmas are phyric, for which the final (postmixing) magma temperature is lower than either of the mixing magmas. Assimilation can also be considered an isenthalpic-isobaric process with the post-assimilation state being one that maximizes the system entropy. In contrast, during isobaric fractional crystallization when temperature is fixed, the Gibbs free energy is minimized to obtain the phase equilibria solution. A model to perform these calculations is presented elsewhere (Bohrson et al. 2014).

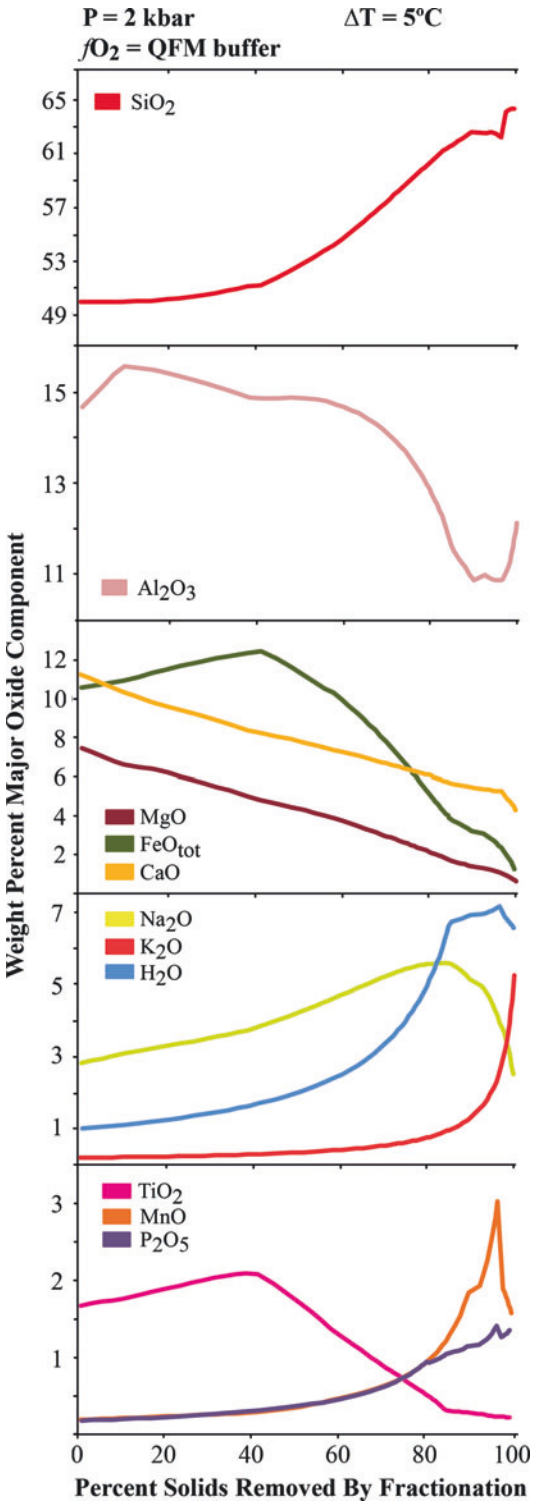
Historical Development of Fractional Crystallization

Fractional crystallization is a fundamental process by which natural silicate melts (liquids) chemically evolve from an initial parental melt to a derived melt of different composition. The use of the word "evolve" harkens back to the early part of the twentieth century when N. L. Bowen, considered by many to be the founder of modern igneous petrology, first used the term in a petrological context. Bowen was influenced by its usage in biology, specifically the concept of Darwinian evolution whereby one species descends or evolves from a pre-existing one. Even today, petrologists use the phrase "liquid line of descent" to describe the sequence of melts that arise as crystalline solids are physically or chemically segregated from parental melt by the process of closed-system fractional crystallization. N.L. Bowen uniquely and masterfully blended many years of experimental investigation based on the physical chemistry and thermodynamics of high-temperature multiphase-multicomponent silicate systems with field observations on the rocks and rock-forming minerals to provide the conceptual infrastructure for modern igneous petrogenesis. His seminal ideas have ramifications for the search for mineral deposits, for the exploitation of geothermal energy, and for the origin and evolution of Earth's oceanic and continental crust and upper mantle.

Although Bowen focused on crystal fractionation as the essential mechanism driving the compositional variety of igneous rocks, he also discussed the role of assimilation, magma mixing, liquid immiscibility, and Soret separation as additional, but secondary, effects. Nowadays, due to detailed study of the trace element and isotopic geochemistry of magmas and a more comprehensive understanding of their phase equilibria and crystallization products, it is recognized that many magma bodies do not evolve strictly as closed chemical systems. When magma bodies behave as open systems, the processes of contamination via assimilation of country rock en masse or assimilation of melt derived by partial melting of country rock and the effects of magma replenishment by addition of recharge magma must be considered. The reheating of previously crystallized magma by fresh replenishment magma recharge to generate large volumes of invariant-point like melts may also be important. RAFC processes can occur concurrently, serially, or episodically in many different combinations that are not known a priori; much of modern petrogenesis involves the use of petrological, geochemical, isotopic, and geochronological tools in combination with field observations to elucidate the relative importance of RAFC phenomena in a geologically referenced spatial and temporal context. Complicated cycles of crystallization followed reheating and partial melting, assimilation, further crystallization. and magma replenishment may be the rule rather than the simpler closed-system monotonic behavior envisioned by Bowen and his cohorts. Nevertheless, the tremendous insights illuminated by N. L. Bowen by a half-century of research stand today as both a towering achievement and pillar upon which modern petrology has been built. Every student of igneous petrology should study his famous treatise of 1928, *The Evolution of Igneous Rocks* (Bowen 1928), not only for its vast insight into the petrogenesis of igneous rocks but also as an multifaceted example of the power of both inductive and deductive scientific reasoning based on sound thermodynamic principles and what might be called petrologic common sense based on careful observation in the field and in the laboratory. The fiftieth year anniversary of his classic treatise was celebrated in a publication edited by one of the mid-century geologists whose own work was emblematic of the Bowen tradition (Yoder 1979).

Styles of Closed-System Crystallization

Crystallization occurs along a continuous spectrum from equilibrium crystallization to perfect fractional crystallization. In equilibrium crystallization (EC), residual melt and precipitated solids remain in equilibrium throughout crystallization. At fixed pressure and temperature, the state of magma (i.e., the composition and amounts of coexisting phases) is determined by minimization of the Gibbs free energy. Because equilibrium is maintained, all coexisting phases are homogeneous: crystals are not compositionally zoned since crystal-melt equilibrium is maintained as magma cools and crystallizes. In contrast, during perfect fractional crystallization (PFC), each



Fractional Crystallization and Assimilation, Fig. 1 The composition of residual melt in terms of the major oxide components SiO_2, TiO2, Al_2O_3, FeO_T, MnO, MgO, CaO, Na_2O, K_2O, P_2O_5, and H_2O versus the total (all phases) percent solids removed by fractional crystallization is portrayed in this sequence of diagrams. The starting composition is average MORB with one weight percent H_2O. Crystallization proceeds isobarically at 0.2 GPa (about 5 km depth on Earth) along the QFM oxygen buffer (see text). A few especially noteworthy features include (1) silica in the melt begins to rise significantly in concentration only after 40% crystallization; (2) The alkaline earth metal oxides MgO and CaO decrease monotonically, linearly, and similarly from high to low values; (3) the alkali oxides and water behave similarly until about 80% crystallization at which point behaviors diverge, and Na_2O increases early on because the plagioclase crystallizing is relatively calcic; (4) the minor element oxides titania, MnO, and P_2O_5 show diverse trends controlled by their degree of incompatibility with respect to specific accessory phases being removed by fractionation. No two melt chemical evolution trajectories are the same because the path depends on the initial conditions as well as the style (see text) of fractionation. Results presented here are generated using the rhyolite-MELTS algorithm (see text)

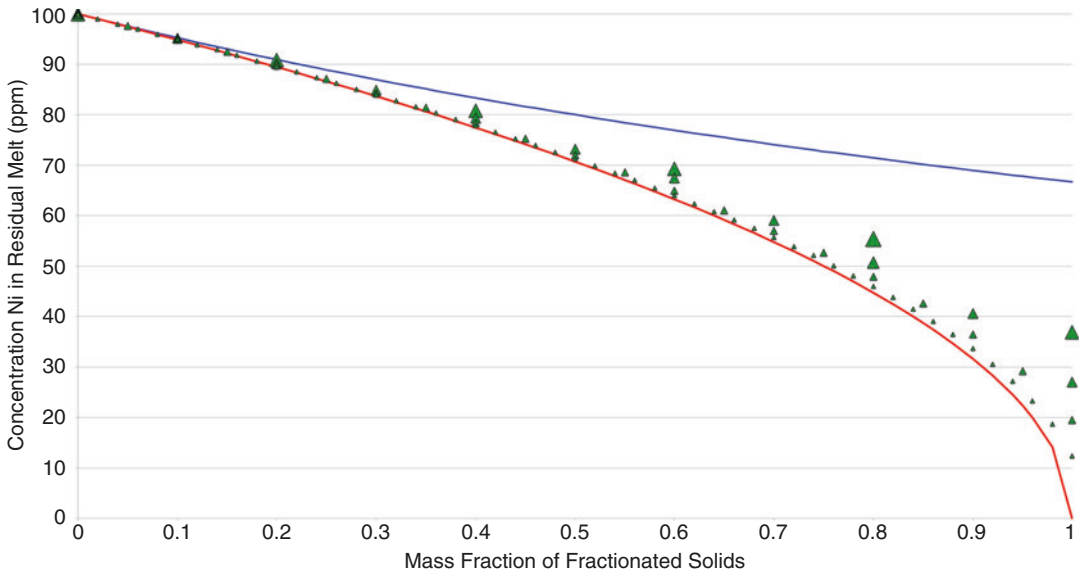
infinitesimal increment of solid that forms is immediately sequestered from the liquid: no further reaction between solid and melt occurs. In both EC and PFC, the melt changes composition as the mass of precipitated crystals increases in response to changing system conditions. However the extent of liquid compositional variation in PFC is greater than in EC because the reactive part of the system in PFC is solely the residual melt: earlier formed solids are completely removed from the liquid and hence cannot react with residual liquid. In EC by contrast, precipitated solids remain in equilibrium with liquid throughout the crystallization process.

In natural systems the style of crystallization is neither perfect fractional crystallization (PFC) nor equilibrium crystallization (EC). Perhaps the most reasonable model is one that may be termed finite-mass fractional crystallization or batch crystallization (BC). Note that PFC can be considered infinitesimal-mass fractional crystallization, an extreme form of BC. In BC, one considers the following scenario. Starting in the liquid state, a finite mass of solid forms by equilibrium crystallization (e.g., magma is cooled by extraction of heat). This finite batch of solid in equilibrium with remaining liquid is then removed (fractionated) from the system either physically (e.g., gravitative settling) or because of the inability of the precipitated solids to stay in chemical equilibrium with residual melt by reaction (e.g., slow solid-liquid reaction kinetics aided by sluggish diffusion in crystals compared to the liquid). The residual liquid then undergoes a second increment of solid removal. This crystallization-fractionation process is repeated until no liquid remains. To carry out BC one needs to specify the magnitude of the mass increment removed. As this mass increment approaches zero, BC approaches PFC. The composition of residual liquid does not continuously vary in composition during BC; instead there is a finite sequence of liquid compositions. The array of liquid compositions depends on the mass of the crystal batch removed at each step. In nature, the batch masses may vary depending on a myriad of (often covert) factors, and hence the (discontinuous) liquid line of descent will not necessarily follow a smooth trend on classical Harker diagrams.

As an illustration, Fig. 1 portrays the major element chemical evolution of melt, expressed in terms of metal oxides (e.g., SiO_2, Al_2O_3, TiO_2, etc.), for closed-system PFC of basaltic melt. This

example starts with a melt of average mid-ocean ridge basalt (MORB) composition at a pressure of 0.2 GPa and depicts how residual liquid evolves as crystals are removed. The oxygen fugacity during crystallization is fixed along an oxygen buffer defined by the assemblage quartz-fayalite and magnetite (QFM buffer) at each temperature. The state of the system is computed discretely at five-degree temperature decrements and, in this case, very closely approximates PFC.Melt composition in terms of the major oxide components is shown as a function of the total mass of removed (fractionated) crystals in the figure. The liquidus temperature at 0.2 GPa along the QFM buffer is 1170 °C where a Ca-rich monoclinic pyroxene first precipitates. This is followed by precipitation of plagioclase feldspar (An_{76} at 1148 °C), olivine (Fo_{77} at 1133 °C), cubic spinel at 1088 °C, orthorhombic pyroxene (En_{66} at 1068 °C), and the hexagonal phosphate mineral apatite at 953 °C. The melt becomes water saturated at 908 °C and the rhombohedral oxide ilmenite crystallizes at 883 °C. The magma is 99.9 wt% crystallized at 818 °C. The melt composition trajectory as a function of mass fractionated is easy to rationalize by noting the composition of the bulk solid being removed during the PFC closed-system evolution. Note that each oxide component exhibits a unique trajectory; some are monotonic, others are not. Some exhibit maxima or minima. Some vary smoothly and some more abrupt. The particular behavior of the liquid line of descent in general is a function of starting composition, pressure, oxygen buffer, and whether EC, BC, or PFC is the crystallization process. In the example shown, PFC is most applicable.

Fig. 2 shows the concentration of the trace element Ni in melt undergoing different styles of solid fractionation including equilibrium crystallization, four examples of batch crystallization each of unique mass batch decrement and perfect fractional crystallization. The partition coefficient, defined $K_{sm}^{Ni} = C_{Ni}^{solid}/C_{Ni}^{liquid}$, is treated as a constant equal to K_{sm}^{Ni}=1.5 throughout the crystallization process for all cases. In reality, the partition coefficient should be recomputed at each step to reflect the phase proportions that are being removed at each temperature. Here we neglect this to



Fractional Crystallization and Assimilation, Fig. 2 Illustrative (hypothetical) example of the effects of fractionation style on the concentration of Ni in a silicate liquid undergoing closed-system fractionation. In this example (for all cases), the partition coefficient of Ni between solid and liquid is 1.50, and the initial a concentration of Ni in the liquid is 100 parts per million (ppm). Six examples illustrating the style of fractionation are depicted. The coordinates of the plot are concentration of Ni in residual liquid (ppm) versus the mass fraction of fractionated solid. The uppermost blue curve portrays equilibrium crystallization (EC) during which, by definition, solid remains in chemical potential equilibrium with liquid during crystallization. Because the partition coefficient is > 1, Ni is concentrated in the solid relative to the liquid and hence the concentration of Ni in the liquid decreases as solid precipitates. The lower red curve pertains to perfect fractional crystallization (PFC). In PFC, solid is removed from further reaction with liquid immediately upon crystallization. Liquid undergoes rapid depletion in Ni. The triangle symbols depict four examples of batch crystallization (BC). In BC, the mass of the (constant) decrement must be specified; the liquid takes on discrete values for the concentration of Ni defined only for discrete values of the mass of solid removed. The concentrations of Ni in residual liquid for the four cases are shown as green triangles. The size of the triangle scales with the mass decrement based on the mass fraction of removed solids in the order: 0.2 (*largest triangles*), 0.1, 0.05, 0.02 (*smallest triangles*). Note that the BC model, with 50 discrete mass decrements of removed solid each equal to 0.02, comes closest to PFC whereas the BC model with only five discrete removal events is closer to the EC path. That is, as the batch mass decrement increases, the concentration of Ni in residual melt approaches the EC limit and as the batch mass decrement becomes small, PFC is approached. In all cases, note that BC generates a discrete series of liquid compositions. It would be incorrect to represent the batch models using continuous curves because the concentration of Ni in the liquid is only *defined* for discontinuous values of the mass fraction of solids removed. The values depend critically on the mass decrement

schematically illustrate how the style of FC affects the trace element composition of residual melt during closed-system FC. The concentration of Ni in the residual melt decreases as the mass fraction of solid precipitated from the liquid increases in all cases but the quantitative details vary with fractionation process. The variation in the concentration of Ni in the melt is least dependent on the fraction of solid removed for equilibrium crystallization and most dramatically different for perfect fractional crystallization. Batch crystallization closely approximates perfect fractional crystallization when the mass decrement is small, whereas batch crystallization more closely resembles equilibrium crystallization when the mass decrement is large. Because equilibrium crystallization and perfect fractional crystallization are continuous processes, concentration of Ni in residual melt varies *continuously* from its starting value of 100 ppm to its final value as solid, always enriched in Ni relative to coexisting liquid, is removed. In contrast, because batch crystallization is a discrete process, the concentration of Ni in the melt is defined at integral multiples of the mass fraction decrement. Batch crystallization and perfect fractional crystallization, which is simply batch crystallization with an infinitesimal decrement, converge as the mass decrement becomes small. The difference in melt trace element concentration between BC and PFC depends on the partition coefficient for a fixed mass decrement: the difference between the trace element concentration of residual liquid in BC relative to PFC grows as the partition coefficient increasingly deviates from unity.

Models of RAFC

The recent trend in modeling the evolution of magmatic systems is based the concept that magmas evolve during ascent and storage as open-system multicomponent-multiphase geochemical reactors. Because magmas are high-temperature systems, a reasonable approximation is to assume that chemical potential equilibrium prevails locally at the scale of decimeters subject to the global constraints imposed by the transport of heat and matter across the boundaries of the magma body by assimilation and recharge. The evolution of the magma body then depends explicitly on the flow of mass and heat across the magma body considered as one subsystem in a larger composite supersystem of country rock + recharge reservoir + magma body. By adopting a magma body-centric view, the coupling of heat and material transport between all subsystems can be defined once relative masses are specified, thereby enabling a self-consistent solution to the "magma body as open-system" problem. Recent examples of this approach include Spera and Bohrson (2004), Bohrson and Spera (2007), Smith and Asimow (2005), and Bohrson et al. (2014). These models use the MELTS computation engine developed by Ghiorso and collaborators over the past 35 years.

Summary

About 30 cubic kilometers of magma is erupted or emplaced at shallow levels in the crust or uppermost mantle each year on Earth primarily at divergent (MORB) and convergent (IAM) plate boundaries and at intraplate locations (OIB). Magma originates mainly by partial melting in the Earth's upper mantle, which is predominantly peridotitic (a mixture of olivine, orthopyroxene, clinopyroxene, and garnet) although pods of eclogite (clinopyroxene plus garnet) and perhaps even crustal sediments or associated sedimentary rocks (varying mineralogy depending on bulk composition) are involved as well. The latter two sources are delivered to the mantle by subduction. The mixing or homogenization time for the Earth's mantle taken as a whole is of the order of or exceeds the age of the Earth. This explains why parental mafic magmas erupting today vary in trace element and isotopic composition; major elements also vary but differences are subtler. Once sufficient liquid forms such that melt buoyancy overcomes viscous forces impeding melt segregation and ascent, melt begins its journey to the Earth's surface or its crustal emplacement site provided the minimum principal stress is oriented horizontally or subhorizontally. The ascent of mafic magma occurs primarily by the upward propagation of vertical or subvertical melt-filled cracks with typical widths of 1–5 m. It is during ascent and post-emplacement that recharge (mixing of different magma batches), assimilation, and crystallization – the primary means of magma evolution – takes place. These processes, sometimes encapsulated by the acronym RAFC, are prima facie evidence for magma bodies behaving as open systems subject to heat loss and matter exchange. Styles of crystallization can be modeled based on the accurate calculation of phase relations using the methods of classical macroscopic thermodynamics. In order to quantify the style, additional assumptions regarding the extent of "communication" between solids precipitated and residual liquid must be made. The end-member possibilities for crystallization are equilibrium crystallization for which precipitated solids remain in equilibrium with melt throughout the crystallization interval to perfect (infinitesimal batch) fractional crystallization such that precipitated solid is chemically isolated from residual liquid. The most realistic style generally falls between these extremes and is called batch crystallization. Batch crystallization is determined using the mass balance relations of equilibrium crystallization applied to finite-mass batch decrements of solid removal. Batch crystallization can be combined with the thermodynamics of open-system assimilation and magma mixing (recharge) to develop open-system models for the evolution of magmatic systems.

In addition to the generation of basaltic melts by partial melting of eclogitic or peridotitic mantle, partial melting of crustal rocks is also a significant petrological mechanism.

Although not well constrained, it is likely that lower continental crust is approximately mafic (gabbroic) in composition on average. Partial melting of lower crust will generate intermediate to silicic composition melts, which due to their chemical buoyancy, tend to migrate upward. Stagnation within the crust leads to cooling and fractionation of these magmas to give residual liquids that are further enriched in silica (65–75 wt%) and other light components (e.g., Al_2O_3 and the alkalis). These silicic magmas can either crystallize at depth to produce granites such as the majestic batholithic rocks of California's Sierra Nevada Range or, when crustal stress fields are suitably oriented, ascend to the surface to give rise to supervolcanoes that erupt vast quantities of very differentiated melt to form the great rhyolitic ignimbrite deposits such as at Yellowstone National Park in the USA. Finally, upper crustal magmas may also originate by partial or total melting of upper crustal rocks. The upper crust is chemically quite heterogeneous. If mantle-derived mafic liquids solidify at shallow depths, mantle-derived heat would be available to melt or partially melt upper crustal materials. There is some geochemical evidence to suggest that some especially aluminous granites called S-type granites may originate in this manner.

Free Energy

Carl O. Moses
Provost and Vice President for Academic Affairs, Grand View University, Des Moines, IA, USA

Natural processes tend to increase the amount of entropy in a universe (a thermodynamic universe is an isolated system not the cosmological universe), but they also tend to minimize the system's energy (see ▶ Geochemical Thermodynamics). Some processes can be regarded as end-members. For example, the mixing of two ideal gases is driven entirely by the maximization of entropy and entails no energy change. On the other hand, a ball rolls down a hill under the influence of energy minimization without any entropy change. If we wish to analyze processes such as chemical reactions in which both energy and entropy play a role, we need to determine how entropy maximization and energy minimization interact, and we accomplish this task by defining free energy. Free energy is the concept that embodies much of the geochemical motivation for studying thermodynamics because it provides an indication of the direction of a reaction. When used to calculate an equilibrium constant for a reaction, it also indicates the equilibrium composition of a system.

According to the second law of thermodynamics, the entropy of a system, S^{sys}, or more precisely a potential quantity, TS^{sys}, represents a dissipation of the system's energy from a form that is available for work to a form that is useless. Entropy is always produced when energy is transferred as heat, and the identity $dq_{rev}^{sys} = T dS^{sys}$ defines entropy

Originally published in: Marshall CP, Fairbridge RW (eds) Encyclopedia of Geochemistry, Springer Netherlands, 1999

(rev denotes a reversible process and sys indicates that the heat transfer dq is measured from the point of view of the system; see ▶ Entropy). The system's energy is measured as either internal energy, U, or enthalpy, H (see ▶ Enthalpy). Energy is frequently defined as the ability to work, and in the absence of entropy, U or H could be converted completely into useful work, such as the work of making and breaking bonds in a chemical reaction. A consequence of the second law, however, is that U and H are partitioned into a "lost" potential TS^{sys} and a "net" potential that is actually available for work. That net potential is called free energy, and two types of free energy are defined on the basis of the two measures of energy (Eq. 1).

$$\begin{aligned} A &\equiv U - TS^{sys}, \quad \text{Helmholtz free energy} \\ G &\equiv H - TS^{sys}, \quad \text{Gibbs free energy} \end{aligned} \tag{1}$$

Because constant pressure calorimetry is more pertinent than constant volume calorimetry to geochemical processes (most of which do not take place in rigidly confined vessels), H and G are more generally useful in geochemistry than U and A. The remainder of this entry focuses on G, but analogous expressions can be derived for A.

Gibbs free energy changes (Eq. 2) can be obtained by differentiating (1) and substituting $dH = T\,dS^{sys} + VdP$ (see ▶ Enthalpy).

$$\begin{aligned} dG &= dH - T\,dS^{sys} - S^{sys}\,dT \\ dG &= V\,dP - S^{sys}\,dT \end{aligned} \tag{2}$$

T and P are called "natural" variables of G, and we can say that G is a "characteristic" function of T and P, $G_{char} = f(T,P)$.

The second law of thermodynamics stipulates $dS^{univ} \geq 0$. Thus, S^{univ} is the basis of criteria for spontaneity or the direction of natural processes ($dS^{univ} > 0$) and for equilibrium ($dS^{univ} = 0$). No processes reduce S^{univ}; only "local" entropy changes (e.g., ΔS^{sys}) may be <0. These criteria are based on properties of a universe, but they can be translated into properties of the system of interest, yielding $\Delta G \leq 0$ (see ▶ Entropy). For all spontaneous processes, $\Delta G < 0$, corresponding to our expectations that spontaneous processes minimize energy and that the more stable of two states is the one with the lower energy. Free energy is, therefore, the appropriate system parameter for evaluating the direction of reactions or the stability of states (or phases). The equilibrium state is characterized by the absence of energy gradients, so $\Delta G = 0$.

It is frequently convenient to use the partial molar Gibbs free energy or chemical potential, μ (Eq. 3).

$$\mu_j = \left(\frac{\partial G}{\partial n_j}\right)_{T,P,n_{k\neq j}} \tag{3}$$

The chemical potential of substance j is the dependence of G for the system containing j on the amount of j (n_j, number of moles of j), with T, P, and composition (constituents k other than j) held constant.

The composition of a system, expressed in terms of activities of the constituents (see ▶ Activity and Activity Coefficients), is given by the mass-action expression Q (Eq. 4), which gives the product of each component's activity (a, raised to the power of its stoichiometric coefficient, ν; $\nu_{product} > 0$ and $V_{reactant} < 0$).

$$Q = \prod a_j^{\nu_j} \tag{4}$$

For example, the mass-action expression for the relative stability of albite and kaolinite in aqueous solution,

$$NaAlSi_3O_{8(alb)} + H^+ + \tfrac{9}{2}H_2O = \tfrac{1}{2}Al_2Si_2O_5(OH)_{4(kaol)} + Na^+ + 2H_4SiO_4^0$$

where the 0 superscript denotes an uncharged aqueous solute, would be:

$$Q = \frac{a_{kaol}^{1/2} a_{Na^+} \times a_{H_4SiO_4^0}^2}{a_{alb} a_{H^+} \times a_{H_2O}^{9/2}} \tag{5}$$

If we can assume that the solid phases are pure and that the aqueous solution is sufficiently dilute for the liquid water to behave as if it were pure, then those activities go to 1 (pure substances are in the standard state and have unit activity). With those assumptions, the mass-action expression simplifies to:

$$Q = \frac{a_{Na^+} \times a_{H_4SiO_4^0}^2}{a_{H^+}} \tag{6}$$

The free energy change of a reaction in any arbitrary state, ΔG_R, or the standard state free energy change of a reaction, $\Delta G^0{}_R$, are both molar quantities (energy/mol). The standard state is a carefully defined reference state for a substance or an assemblage of substances (a reaction system) at a given temperature, pressure, and system composition. The dependence of ΔG_R on composition (Eq. 7) uses Q as the compositional variable to correct the reference value for the actual composition of the system:

$$\Delta G_R = \Delta G_R^0 + RT \ln Q \tag{7}$$

As noted above, $\Delta G_R = 0$ at equilibrium. Also at equilibrium, the composition of the system assumes a singular mass-action ratio, whose value depends on T and P, and which is called the equilibrium constant, K. Thus, at equilibrium, Eq. 7 gives the important relationship between K and $\Delta G^0{}_R$ (Eq. 8):

F

$$\Delta G_R^0 = -RT\ln K$$
$$\Delta G_R^0 = -2.303\,RT\log K \quad (8)$$

Calculations of free energies are based on enthalpy and entropy measurements. Standard state enthalpies of formation, ΔH^0_f, and absolute entropies, S^0_T, based on calorimetric and heat capacity measurements, are tabulated and can be used to calculate standard state enthalpy changes, ΔH^0_R, and entropy changes, ΔS^0_R, for reactions. ΔG^0_R can then be calculated from $\Delta H^0_R - T\Delta S^0_R$ (Eq. 2). Similarly, $\Delta G^0_f = \Delta H^0_f - T\Delta S^0_f$, and it is more common, and usually more convenient, to calculate ΔG^0_R from tabulated values of ΔG^0_f. By convention, the ΔG^0_f for an element in the standard state (usually 298 K, 1 bar) is 0, as are ΔH^0_f and ΔS^0_f. For compounds or elements in a state other than the standard state, the standard state free energy of formation (from the standard state element), ΔG^0_f, represents the energy of making the bonds of the compound, ΔH^0_f, less the energy expended in the isothermal heat transfer accompanying the formation, $T\Delta S^0_f$. For example, at 298 K, graphite, the standard state form of elemental carbon, has $\Delta H^0_f = \Delta G^0_f = \Delta S^0_f = 0$, while for diamond, $\Delta H^0_f = 1.9$ kJ/mol and $\Delta G^0_f = 2.9$ kJ/mol. The difference, 1 kJ/mol, is the potential $-T\Delta S^0_{f,\text{dia}}$, so $\Delta S^0_{f,\text{dia}} = -3.36$ J/mol/K. Note that $\Delta S^0_{f,\text{dia}} = S^0_{\text{dia}} - S^0_{\text{gra}} = (2.38–5.84)$ J/mol/K (see ▶ Entropy for a discussion of the difference between S^0_T and ΔS^0_f).

The free energy change is calculated from:

$$\Delta G^0_{\text{process}} = \sum \nu_j \Delta G^0_{f,j}$$

where ν_j is the stoichiometric coefficient of the constituents of the system in the final state (e.g., reaction products, $\nu_j > 0$) or the initial state (e.g., reactants, $\nu_j < 0$). The subscript R may be substituted by a more informative subscript denoting the specific process in question. For example, the evaporation of liquid water, $H_2O_{(l)} = H_2O_{(g)}$, involves a free energy change given by:

$$\Delta G^0_{\text{evap}} = \Delta G^0_{f,H_2O_{(g)}} - \Delta G^0_{f,H_2O_{(l)}}$$
$$= (-228.6) - (-237.1) = 8.5\,\text{kJ/mol}$$

at 298 K. Because $\Delta G^0_{\text{evap}} > 0$, evaporation of water is not spontaneous at 298 K; $\Delta G^0_f, H_2O_{(l)} < \Delta G^0_f, H_2O_{(g)}$, so $H_2O_{(l)}$, is more stable than $H_2O_{(g)}$. The equilibrium constant for the evaporation of water at 298 K is thus:

$$\log K = \frac{-8500}{2.303(8.314)298.15} \approx -1.5 (K < 1),$$

and the equilibrium partial pressure of water vapor (i.e., the vapor pressure for water) at 298 K is ~ 32 mb.

Another example: the free energy change for the quartz-fayalite-magnetite O_2-buffer reaction, $3Fe_2SiO_{4(\text{fay})} + O_{2(g)} = 2Fe_3O_{4(\text{mag})} + 3SiO_{2(\text{qtz})}$ is given by:

$$\Delta G^0_{\text{QFM}} = \left(2\Delta G^0_{f,\text{mag}} + 3\Delta G^0_{f,\text{qtz}}\right) - \left(3\Delta G^0_{f,\text{fay}} + 0\right)$$
$$= -463.7\,\text{kJ/mol at 298 K}$$

The (fay + $O_{2(g)}$) assemblage is less stable than the (mag + qtz) assemblage, and for this reaction, $\Delta G^0_{\text{QFM}} < 0$, indicating a spontaneous process, for which we expect $K > 1$. Indeed,

$$\log K = \frac{463\,700}{2.303(8.314)298.15} \approx 81.2.$$

Accordingly, the equilibrium partial pressure of O_2 in the QFM buffer system at 298 K is $\sim 10^{-81.2}$ bar.

A total differential equation based on $G_{\text{char}} = f(T, P)$ gives:

$$dG = \left(\frac{\partial G}{\partial P}\right)_T dP + \left(\frac{\partial G}{\partial T}\right)_P dT$$

Comparison with Eq. 2 allows the immediate derivation of the isothermal pressure dependence and the isobaric (constant pressure) temperature dependence of G, respectively (Eq. 9); molar values, denoted by the overbar, are used here).

$$\left(\frac{\partial \overline{G}_i}{\partial P}\right)_T = \overline{V}_i \left(\frac{\partial \overline{G}_i}{\partial T}\right)_P = -\overline{S}_i \quad (9)$$

Accordingly, of two phases initially at equilibrium, the phase with the smaller molar volume will be more stable at higher pressures, while the phase with the larger molar entropy will be more stable at higher temperatures. The relationships in Eq. 9 apply equally well to reactions:

$$\left(\frac{\partial \Delta G^0_R}{\partial P}\right)_T = \Delta V^0_R \left(\frac{\partial \Delta G^0_R}{\partial T}\right)_P = -\Delta S^0_R \quad (10)$$

The overbar is not needed for the expressions in Eq. 10, because ΔY^0_R, where $Y = G, V, S$, is taken to be a molar quantity.

Correcting ΔG^0_R for pressure changes requires integrating the first expression in Eq. 10, giving:

$$\Delta G^0_{R,P} = \Delta G^0_{R,P_{\text{ref}}} + \Delta V^0_R (P - P_{\text{ref}}) \quad (11)$$

as long as $\Delta V^0_R \neq f(P)$. For condensed phases (solids and liquids), the pressure dependence of volume changes is usually very weak, even over large ranges of P. Clearly, however, the pressure dependence of volume is quite strong for gases. For this reason, the standard state of condensed phases is usually defined at a given temperature and pressure (i.e., both T and P are allowed to vary in the standard state), but for gases, the standard state is defined at a given temperature but for a single pressure (i.e., T may vary but P is fixed in the

standard state). All of the pressure dependence of G, and thus K, for gases is accounted for by the variation of fugacity with pressure (Eq. 12).

$$\mu_j = \mu_j^0 + RT\ln f_j \tag{12}$$

When calculating the pressure dependence of $\Delta G^0{}_R$ for a reaction in which one of the constituents is a gas, the gas itself is excluded from the calculation of $\Delta V^0{}_R$. In the QFM example above, therefore,

$$\Delta V_R^0 = \left(2\overline{V}_{\text{mag}} + 3\overline{V}_{\text{qtz}}\right) - \left(3\overline{V}_{\text{fay}}\right) = 17.9\,\text{cm}^3/\text{mol}$$

(1.79 J/bar/mol) at 298 K.

The second expression in Eq. 10 can be integrated to give the temperature dependence of $\Delta G^0{}_R$ (Eq. 13), which assumes that the temperature range between T and T_{ref} is narrow enough for $\Delta S^0{}_R$ to be effectively constant).

$$\Delta G_{R,T}^0 = \Delta G_{R,T_{\text{ref}}}^0 - \Delta S_R^0(T - T_{\text{ref}}) \tag{13}$$

In fact, the temperature dependence of the function G/T is of more interest, owing to the mathematics of deriving the temperature dependence of K. The Gibbs-Helmholtz equation gives the temperature dependence of G/T and can be applied directly to reactions (Eq. 14):

$$\left(\frac{\partial(G/T)}{\partial T}\right)_P = \frac{-H}{T^2}\left(\frac{\partial(\Delta G/T)}{\partial T}\right)_P = \frac{-\Delta H}{T^2} \tag{14}$$

From Eq. 8,

$$R\ln K = \frac{-\Delta G_R^0}{T}$$

and substituting that result into Eq. 14 gives:

$$\left(\frac{\partial \ln K}{\partial T}\right)_P = \frac{\Delta H_R^0}{RT^2}$$

the van't Hoff equation, which can be integrated to correct K for T.

The application of free energy to problems in geology and environmental science is constrained, as is the application of any thermodynamic concept, by two important considerations. First, free energy and the equilibrium constant provide no insight into the time required for a system to achieve equilibrium or the process by which equilibrium is attained. Reaction rates and reaction mechanisms fall in the domain of chemical kinetics. Second, open systems (e.g., fluid-rock systems in which fluids may be imported to or exported from the system) are not amenable to straightforward thermodynamic evaluation. Despite these important limitations, free energy has proved exceedingly useful in answering geologically relevant questions, such as whether a postulated reaction can occur (using the criterion of direction, $\Delta G^0{}_R < 0$) or determining the equilibrium composition of a system (using K, which is derived from the zero gradient equilibrium criterion, $\Delta G_R = 0$).

Fugacity

Christopher A. Colla and William H. Casey
Department of Chemistry and Department of Earth and Planetary Sciences, University of California, Davis, CA, USA

Definition

The thermodynamic pressure of a gas.

Introduction

The concept of fugacity was defined by G. N. Lewis, one of the most prominent American physical chemists in the early twentieth century (Rock 1983 and Laidler 1993). Lewis defined a ratio of fugacities to yield thermodynamic activities, and fugacity is the pressure if the gases both satisfy the ideal gas law and if the standard-state fugacity is defined for a total pressure of 1 bar (10^5 Pa). Pressure could not be used directly to define activities because some real gases deviate from behavior described by the ideal gas law. The choice of a standard-state fugacity of 1 bar total pressure, however, means that activities vary with total pressure, which is circumvented by geochemists who define standard states at elevated pressures for geochemical calculations. This concept is central to geochemistry because the conditions in the Earth deviate considerably from 1 bar (10^5 Pa) and 298 - K. Oxygen fugacities, for example, are an expression of the redox behavior of the Earth's crust and mantle (e.g., Ballhaus et al. 1990).

Elaboration

When introducing activities, it is useful to reprise the sequence employed in most introductory chemistry courses. Here, vapor-pressure measurements play a central role, and the thermodynamic activity is defined as a ratio of pressures by either Henry's law (if the component is treated as a solute) or Raoult's law (if the component is treated as a solvent): $a_i \equiv \frac{P_i}{P_i^o}$ where P_i^o is the pressure of the pure component. An ideal solution satisfies Raoult's law: $\frac{P_i}{P^o} = X_i$ where X is mole fraction. Deviations from this linear relation arise from chemical interactions among the components that cannot be treated using random-mixing statistics. These deviations indicate nonideality, interactions between components that yield an appreciable excess Gibbs energy of mixing and a pressure ratio that deviates from Raoult's Law.

In the case of Raoult's Law, P_i^o is a directly measurable quantity – it is the vapor pressure that would exist, for example, above a bottle of the pure solid or liquid purchased from a stockroom. Again using the most basic approach:

$$\mu_{\text{ideal}} - \mu^o_{\text{Henrian or Raoultian}} = RT\ln\left(\frac{P_i}{P^o_{i,\,\text{Henrian or Raoultian}}}\right) \tag{1}$$

In the case of Henry's law, the P_i^o value is not directly measurable but is estimated by extrapolating the variation of pressure with composition to the point where the solution is diluted to the extreme condition of the pure material. There is no reagent bottle that can be purchased that has this pressure over pure material. Practically this means drawing a line between P_i and X_i until the intercept is reached where $X_i = 1$. This intercept is now a *hypothetical* vapor pressure that would exist if the pure substance retained the same structure that it had at infinite dilution, when it satisfied Henry's law.

There are two simplifications that are never explained in these introductory chemistry courses. First, deviations from Raoult's law may arise because the gases do not behave ideally even at 1 bar (10^5 Pa). Thus the behavior of some compositions must be adjusted to account for interactions among the various gas molecules. The second simplification is more important to geochemists. Lewis defined the standard state, P^o, at the temperature of interest (which can vary), but only at a *total* pressure of 1 atm or 10^5 Pascals. Thus adjustments must be made if the total pressure deviates from this standard-state condition.

To accommodate the first difficulty, G. N. Lewis defined activity to be a ratio of *fugacities*, from the Latin word that means the tendency to flee (as in *tempus fugit*):

$$a_i \equiv \frac{f_i}{f_i^o}$$

with the caveat that $f_i \rightarrow P_i$ as pressure is reduced, since all gases behave ideally if the pressures are low enough. The ratio can also be derived from statistical mechanics (see Dill and Bromberg 2010, pp. 211–242). This first difficulty, the nonideality of gases, can be accounted by correcting the measured pressure using a model of interactions that recaptures the behavior of a perfect gas (see Nordstrom and Munoz 1994, pp. 131–136).

The second difficulty, the defined standard state at 1 bar pressure, can be adjusted either by allowing the activity to vary, which is illustrated in Table 1, or by moving the standard state to a new pressure, which is probably more convenient to geochemists (Lewis and Randall 1961). Chemical potentials relate to thermodynamic activities by an integration from a defined endpoint. At fixed temperature from a standard, or reference, state that is denoted by the superscript '^{o}' to another (nonstandard) state:

$$\int_{\mu_i=\mu^o}^{\mu_i} d\mu_i = \int_{a_i=a^o}^{a_i} RT\ d\ln(a_i) \tag{2}$$

Fugacity, Table 1 The vapor pressure of H_2O over the pure liquid differs with the total pressure at 298 K. These differences lead to a varying activity (column 3) even if the vapor behaves like an ideal gas because the standard state fugacity (or pressure) is defined at 1 bar total pressure (Adapted from Randall and Sosnick (1928) and Garrels and Christ (1965))

Total pressure (Pa)	Fugacity (Pa)	Activity of water
101,325	3166.41	1
1.013×10^7	3406.54	1.0757
2.027×10^7	3665.93	1.1576
3.040×10^7	3943.56	1.2454
4.053×10^7	4241.46	1.3394
5.066×10^7	4560.63	1.4402
6.080×10^7	4902.10	1.5481
7.093×10^7	5267.88	1.6637
8.106×10^7	5660.01	1.7874
9.119×10^7	6079.50	1.9200
1.013×10^8	6528.36	2.0618

or:

$$\mu_i - \mu_i^o = RT\ln\left(\frac{a_i}{a_i^o}\right) \tag{3}$$

Any fixed pressure could be used as a standard state, and activities that differ only in pressure are related by the equations:

$$\int_{\text{State1}}^{\text{State2}} d\ln(a_i) = \frac{1}{RT}\int_{P_1}^{P_2} \overline{V}_i \, \mathrm{dP} \tag{5}$$

where in general, $\overline{V}_i$ depends on both P and T. We can set $a_{i,1} = 1$ for any convenient value of P and refer all $a_{i,2}$ values to that new standard state (see Anderson and Crerar 1993).

Conclusions

The concept of fugacity is central to the use of thermodynamic activities to estimate the equilibrium state of materials in the Earth. It leads directly to definitions of standard states that are particularly important to geochemists because they treat variations in temperatures and pressures that span well beyond the range treated by most chemists.

Core Abundance: ~0

Properties

Gadolinium (Gd), named after the geologist and chemist Johan Gadolin, is a malleable, ductile, moderately dense (7.901 g cm^{-3}), bright silvery-white metal. Its electronic configuration is [Xe]4f^{7}5d^{1}6s^2. Stable in dry air at room temperature, it oxidizes at elevated relative humidity and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE). In geochemical terminology, it is grouped with heavy rare earth elements (HREE; Gd-Lu). Gadolinium has six natural, stable isotopes and one long-lived radioisotope (^{152}Gd; $t_{1/2} = 1.081 \times 10^{14}$ years; alpha decaying to ^{148}Sm) occurring in nature, listed above with their abundances. ^{157}Gd is notable in having the highest thermal neutron absorption cross section (259,000 barns) of any stable nuclide.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Gd as a major component are restricted to minerals such as gadolinite-Y [$Y_2FeBe_2(Si_2O_{10})$], xenotime [$Y(PO_4)$], bastnäsite [REE(CO_3)F], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+},Fe^{3+})_3(SiO_4)_3(OH)$], and britholite [$(REE,Ca)_5(SiO_4,PO_4)_3(OH,F)$].

Details of properties, mineralogy, history, and uses of Gd were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner (2016), Hammond (2016), and Meija et al. (2016a, b).

History and Use

Gadolinium was identified spectroscopically in the minerals gadolinite and cerite in 1880 by Jean Charles Galissard de Marignac and first isolated as a metal in 1886. Gadolinium has numerous highly specialized commercial uses. For example, due to its high neutron absorption cross section, it is used both in nuclear reactor control rods and in nuclear medicine. Gadolinium's phosphorescent properties make it useful in X-ray imaging devices, and its room temperature paramagnetic properties make it useful as a component in magnetic resonance imaging.

Geochemical Behavior

The fundamental importance of Gd in geochemistry is that it is one of the small trivalent rare earth elements, among the

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction."

Gadolinium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element, with a 50% $T_{condensation}$ of 1659 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Gd is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Gd normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Gd contents of clastic sediments typically reflect their average provenance.

In seawater, Gd has very low concentrations (~ppt) and residence times (~520 year) with speciation dominated by Gd^{3+}, $GdCO_3^+$, and $Gd(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Gd can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration and residence time data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Gd, but in China REE have been added to fertilizers and to stock feed to promote growth. REE (including Gd^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Gd) in human tissues and fluids are very low (tens of ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Seawater Abundance: ~1.2 pg/g
Core Abundance: <1 μg/g

Properties

Gallium does not occur as a native metal and forms very few minerals like gallite ($CuGaS_2$), but widely occurs in nature as

a trace constituent substituted for Al. Gallium metal is prepared as a by-product of aluminum production from bauxite ore and from Zn ores (e.g., sphalerite). Synthetically prepared metallic Ga is a soft, silvery white metal and has a melting point below human body temperature so it can be readily melted in one's hand. Liquid gallium is one of a few substances (like water) that expand on solidification. Of all elements, Ga has the largest temperature range over which it is liquid.

Gallium has two stable isotopes, ^{69}Ga and ^{71}Ga, and about 20 known radioactive isotopes (Gross and Thoennessen 2012), all of which have half-lives <80 h and have found no geochemical applications.

History and Use

Before its eventual discovery and isolation, the existence of gallium was predicted by the Russian chemist Dmitri Mendeleev as "eka-aluminium," the element below Al, in his new periodic table in 1871. It was discovered spectroscopically in 1875 by the French chemist, Paul Emile Lecoq de Boisbaudran, in a sphalerite sample and subsequently isolated by electrolysis. Lecoq de Boisbaudran named the new element from Latin *Gallia*, the land of the Gauls, i.e., France.

The low melting point (29.78 °C) for metallic Ga allows it to be liquid near room temperature, while its low first ionization potential (5.1 eV) makes it easy to ionize, so it is widely used as an ion source in Ga ion guns for focused ion beam (FIB) slicing in transmission electron microscopy and for imaging in secondary ion mass spectrometry. Gallium readily alloys with many metals, finding use in low-melting alloys like galinstan, a eutectic alloy (m.p. −19 °C) of Ga, In, and Sn used in thermometers to replace toxic mercury. It is alloyed with δ-plutonium in nuclear weapons.

Neutrinos react with ^{71}Ga to form ^{71}Ge that can be radiochemically detected. Gallium metal is used in the SAGE (http://www.inr.troitsk.ru/eng/ebno.html) neutrino detector. Gallium trichloride is used in the GALLEX (https://www.mpi-hd.mpg.de/lin/research_history.de.html) neutrino detector.

Gallium's principal use is in semiconductors as gallium arsenide (GaAs) and gallium nitride (GaN). It finds use in optoelectronics, e.g., in light-emitting diodes (LEDs), and GaN is used in 405 nm diode lasers in Blu-ray disks. Gallium also finds important applications in photovoltaic (PV) cells as Cu-In-Ga-Se (CIGS), which is a solid solution of $CuInSe_2$ and $CuGaSe_2$, with the general formula $[Cu(In_xGa_{1-x})Se_2]$. The bandgap of CIGS can be varied from 1.04 to 1.68 eV by varying the ratio of In to Ga in the solid solution, leading to some of the highest efficiency solar PV cells (http://www.solarpowerworldonline.com/2014/01/cigs-solar-cells-simplified/).

Cosmochemical Behavior

Gallium, an odd Z element, is less abundant (9.5 ppm) than the neighboring elements of Zn (312 ppm) or Ge (32.7 ppm) in type I carbonaceous chondrites (CI). The nuclear statistical equilibrium process that creates the Fe peak elements mainly produces the stable isotopes of Ga. The astrophysical s-process contributes ~5% to the abundance of Ga, with an even smaller contribution from the r-process (Clayton 2003). In the first recent study of Ga isotopic variations, Kato et al. (2014) reported variations in δ^{71}Ga of −0.27 ‰ for eight samples of chondrites relative to terrestrial samples.

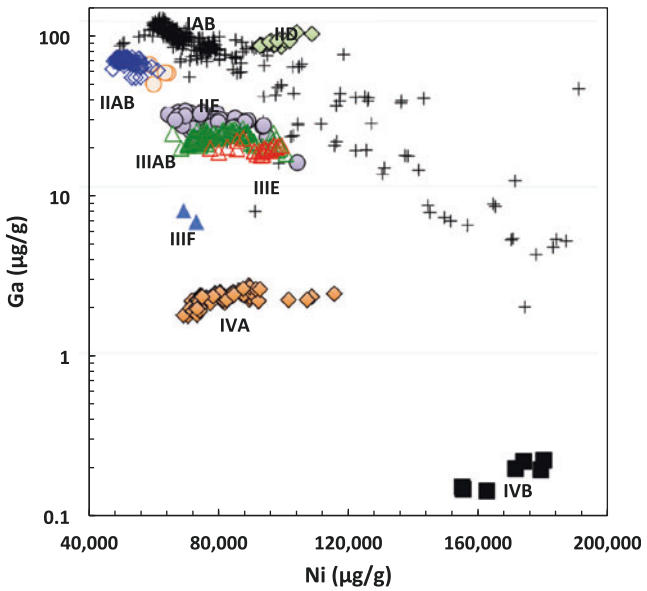
Gallium is a moderately volatile element during gas to solid or gas to liquid condensation or evaporation processes occurring in the solar nebula. While pure Ga metal has a high boiling point (2,400 °C), Ga forms volatile chlorides in a gas of solar composition. Thus, Ga condenses at 968 K (10 Pa total pressure) in Fe-Ni alloy, being more volatile than Cu or As but less volatile than Ge or Zn (Lodders 2003). As a moderately volatile element, Ga is depleted relative to CI abundances and the major elements in other chondrites and in all differentiated meteorites. In bulk chondrites, the abundances of Ga are highest in the enstatite chondrites, both EH (16 μg/g) and EL (11 μg/g) chondrites. The ordinary chondrites have a narrow range of Ga contents (5–6 ppm) independent of their metal abundances, because these chondrites are oxidized enough that much of their Ga inventory is in their silicate fraction. The depletion of Ga is evident in the successive order of Ga contents of carbonaceous chondrites: CI > CM > CO > CV > CR ~ CH > CB (Wasson and Kallemeyn 1988). The metal of CR and CB chondrites is depleted in Ga, with depletion factors relative to Ni and CI chondrites of 0.1–0.01 in CR metal (Humayun 2012). Gallium has a higher diffusivity in Fe-Ni metal than Ni (Righter et al. 2005) making it useful in determining cooling rates of metallic grains in chondrites (Humayun 2012).

Gallium is also moderately siderophile, partitioning into iron meteorites (Fig. 1) and into planetary cores. In metallic liquids, the partition coefficient of Ga between liquid Fe-FeS and solid Fe metal is close to unity, similar to that of Ge. The partition coefficient varies with increasing alloying by light elements like C, Si, P, and S driving the Ga into the solid metal. A notable exception occurs when oxygen is the alloying element, since Ga readily forms an oxide in an Fe-FeO-FeS liquid, Ga is systematically more incompatible in the solid metal with increasing mole fraction of oxygen dissolved in the metallic liquid relative to its behavior in pure Fe-FeS liquids (Chabot et al. 2015). Although Ga has chalcogenic properties, it is not detectable in meteoritic troilite, leaving metal and silicate as its major hosts.

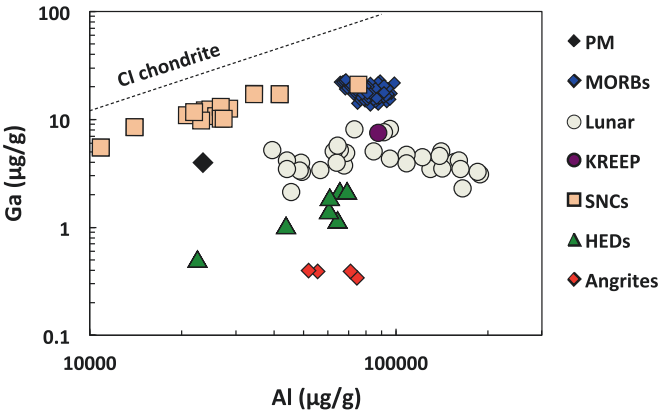
Due to its volatility, Ga content varies in the parental materials from which the iron meteorites differentiated. This makes Ga (and Ge) useful in classifying iron meteorites into

chemical groups (Goldstein et al. 2009). The Ga contents span nearly three orders of magnitude in irons, with "magmatic" irons (e.g., IIAB, IIIAB, IVA, IVB), thought to represent asteroidal cores, having small ranges of Ga and Ni and "non-magmatic" irons (e.g., IAB, IIE), thought to represent smaller pools of iron formed by incipient differentiation, having larger ranges of Ga and Ni contents (Fig. 1).

The Ga that remains in the mantle (as Ga_2O_3) behaves similarly to Al, being moderately incompatible. This aspect of Ga makes the Ga/Al ratio a useful indictor of planetary origin for basaltic meteorites. Figure 2 is a plot of Ga vs. Al for a selection of planetary and asteroidal basalts. The order of depletion (largely controlled by volatility) is Mars<Earth<Moon<4 Vesta<angrites, with about two orders of magnitude decrease in the Ga/Al ratio in angrites relative to CI chondrites. Lunar rocks exhibit a convex upward pattern with basalts being positively correlated and anorthosites being negatively correlated with Al due to the low partition coefficient of Ga in plagioclase. The Ga/Al ratio of planetary basalts is sufficiently unique to a meteorite group that it is used in identifying basaltic meteorites.



Gallium, Fig. 1 Gallium vs. Ni in iron meteorites (Campbell and Humayun 2005; Wasson et al. 2007)



Gallium, Fig. 2 Gallium vs. Al in planetary and asteroidal basaltic rocks. PM, the silicate Earth composition; MORBs, mid-ocean ridge basalts; KREEP, enriched lunar composition; SNCs, martian meteorites; HEDs, Vestan meteorites (sources: Mittlefehldt et al. 1998; McDonough and Sun 1995; Jenner and O'Neill 2012; Wänke et al. 1976; Yang et al. 2015)

Geochemical Behavior

Gallium is a volatile siderophile element. Its siderophile character is intermediate between that of Fe and that of Si, while Al is not siderophile. The fact that Ga is less siderophile than Fe forms a useful property in tracking redox variations in core formation processes. The partitioning of Ga between mantle and core is dependent on pressure, temperature, and the nature of the light element in the core. Blanchard et al. (2015) found that the abundance of Ga in the Earth's mantle could be accounted for by formation of the core in a deep (>1,300 km) magma ocean if 5% of a combination of O and Si was present in the core. This process puts very little Ga into the core in contrast to iron meteorites, which contain a significant inventory of Ga.

Gallium is concentrated in Al-rich minerals in the crust. During partial melting of the mantle, Ga, like Al, is incompatible in most phases, including garnet, but is compatible in spinel (Davis et al. 2013).

Gallium contents in soils follow those of Al, due to the low solubility of both elements. The overall average abundance of Ga in a global compilation of 1,600 soils was ~21 ppm (Bowen 1982). Bauxite deposits formed by intense weathering concentrate Ga in Al-oxide ores with a mean Ga/Al ratio 2.7×10^{-4} (Schulte and Foley 2013), similar to the crustal value. Like Ge, Ga is known to be concentrated in coals and in coal ashes perhaps due to the presence of Ga-porphyrins (Bennett and Czechowski 1980).

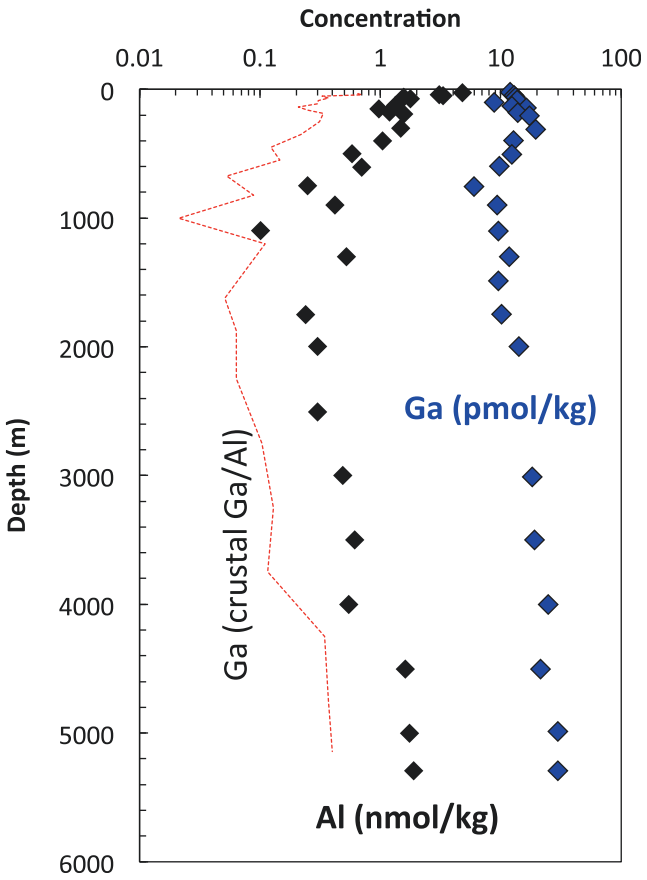
Aqueous Geochemistry

The tendency of Ga^{+3} ions to form insoluble hydroxides in solution, similar to Al, results in very low abundances of Ga in natural waters. The solution species as a function of pH and temperature have been worked out from 25°C to 300 °C, with $Ga(OH)^{+2}$ and $Ga(OH)_2^{+}$ dominating at pH < 4 and Ga $(OH)_4^{-}$ dominating in more basic solutions. Gallium solubility increases with increasing temperature. Experimental studies of Ga solubility show that it is least soluble around a pH of 4 and becomes more soluble in either acidic or basic solution

(Benezeth et al. 1997; Diakonov et al. 1997). Since seafloor hydrothermal fluids have pH ~ 4, the Ga abundances are likely to be very low, although little is known about Ga in hydrothermal fluids at present.

During chemical weathering, Ga is preferentially leached from weathering residues relative to Al so that its abundance in stream waters is an order of magnitude higher than in the source rocks (Shiller and Frilot 1996). In fresh water, like Al, Ga may be complexed by organic ligands that enhance its solubility in rivers and streams (Shiller and Frilot 1996). Since the total inventory of Ga (or Al) that is removed by weathering from soils is negligible, even intense weathering residues like laterites and bauxites, still retain a Ga/Al ratio close to that of bedrocks.

Gallium is present in seawater at average concentrations of ~17 pmol/kg (~1.2 pg/g), with a profile similar to that of Al (Johnson 2016). Net sinks include clay minerals, with a Ga/Al ratio of pelagic clays (2.40×10^{-4}) being nearly identical to those of upper continental crust (2.35×10^{-4}) and in Mn oxides that exhibit a higher Ga/Al ratio of 9.7×10^{-4}. Figure 3 shows vertical profiles for Ga and Al in the Pacific Ocean (Orians and Bruland 1988), together with a dashed curve that shows the Ga abundance expected from the Al concentration using a crustal Ga/Al ratio. The Ga/Al ratio in seawater (15×10^{-3}) is over an order of magnitude higher than the crustal ratio, implying that Ga is scavenged less efficiently than Al. While the overall profile of Ga is similar to that of Al, there are key differences including a peak at intermediate depths (100–300 m) and a flatter profile than that of Al. The peak in Ga concentration at intermediate water depths is attributed to dissolution of aeolian dust. The overall patterns of both Al and Ga are determined by aeolian dust input to the surface water followed by scavenging on particles at depth that removes Al more than Ga. Inputs from sediments at the bottom of the ocean is thought to create the increase in Ga at depth. The concentration of Ga in surface waters is variable and has a small seasonal dependence (Orians and Bruland 1988; Johnson 2016).



Gallium, Fig. 3 Vertical profiles of Ga (pmol/kg) and Al (nmol/kg) in Pacific seawater (Orians and Bruland 1988). The *dashed line* is the calculated Ga abundance from the Al profile and a crustal Ga/Al ratio

Gallium abundance in river waters is very low. A significant portion (20–90%) of the Ga transported is on Fe colloids (1–100 kDa) obtained by ultrafiltration of river water (Dupre et al. 1999). Organic colloids (including humic acids) do not appear to be important in the transport of Ga or Al. The abundance of Ga obtained in dialysis samples of river water has abundances of ~5–15 pg/g, which is higher than seawater (~1 pg/g) indicating that loss of Ga in estuaries must be significant.

Biological Utilization and Toxicity

Gallium is mainly nontoxic, but serves no essential nutrient function unlike neighboring Cu and Zn or the toxic As. Because it is not redox sensitive during biological uptake, occurring exclusively as Ga^{+3}, and insoluble like Al^{+3}, Ga^{+3} finds little function in biochemical processes. In biological systems, Ga^{+3} substitutes for Fe^{+3}-binding proteins, e.g., transferrin, lactoferrin, and bacterial siderophores. The radioisotope, ^{67}Ga (3.26 days half-life), is used in radioisotope imaging (radiopharmacology) of inflammation, tumors, and osteomyelitis. Ga^{+3} finds some use in medical applications as an antimicrobial agent where it can substitute for Fe^{+3} in some bacteria (e.g., *Pseudomonas*) shutting down microbial respiration (Chitamber 2010).

Gas Chromatography–Mass Spectrometry (GC–MS)

Patricia M. Medeiros
Department of Marine Sciences, University of Georgia, Athens, GA, USA

Definition

Gas chromatography-mass spectrometry (GC-MS) is one of the so-called hyphenated analytical techniques. It is actually two techniques that are combined to form a single method for analyzing mixtures of organic chemicals. Gas chromatography separates the components of a mixture, and mass spectrometry characterizes each of the components individually. The combination of the two techniques allows for both qualitative and quantitative evaluations of a sample containing a number of organic compounds. The uses for GC-MS are numerous, including chemical, geological, environmental, and forensic research.

Introduction

Structure elucidation of organic compounds has been carried out by organic chemists since the early 1900s.

Chromatography is an analytical technique used to separate mixtures of chemicals into individual components, and it was first employed in the separation of plant pigments (chlorophyll, carotenes, and xanthophylls) in 1901 (Ettre 2001). Chromatographic methods evolved, especially in the mid-twentieth century with the development of new techniques.

Gas chromatography (GC) was first described in 1952 with the separation of a mixture of small carboxylic acids (James and Martin 1952). A gas chromatograph uses a flow-through column, through which different chemical constituents of a sample pass in a gas stream (carrier gas, *mobile phase*) at different rates depending on their chemical and physical properties and their interaction with a specific column filling, called the *stationary phase*. The function of the stationary phase in the column is to separate different components, causing each one to exit the column at a different time. Other parameters that can be used to alter the time of retention are the carrier gas flow rate, column length, and temperature. At first, packed-columns were used; however, the power of GC was substantially improved by the introduction of wall-coated open-tubular capillary columns, initially glass but superseded by more durable fused-silica capillary columns in 1976. This was considered a major advance in the development of GC (Niessen 2001). As the chemicals exit the column, they are detected electronically.

Mass spectrometry (MS) is an analytical technique used to identify and quantify different chemicals present in a sample by measuring the mass-to-charge ratio and abundance of gas-phase ions. The history of mass spectrometry started in 1912 when the first mass spectra of compounds, such as Ne, N_2, CO_2, and $COCl_2$, were obtained (Thomson 1913). The first commercial instruments dedicated to organic analysis were built during World War II, with the major application at that time in petrochemistry (Niessen 2001).

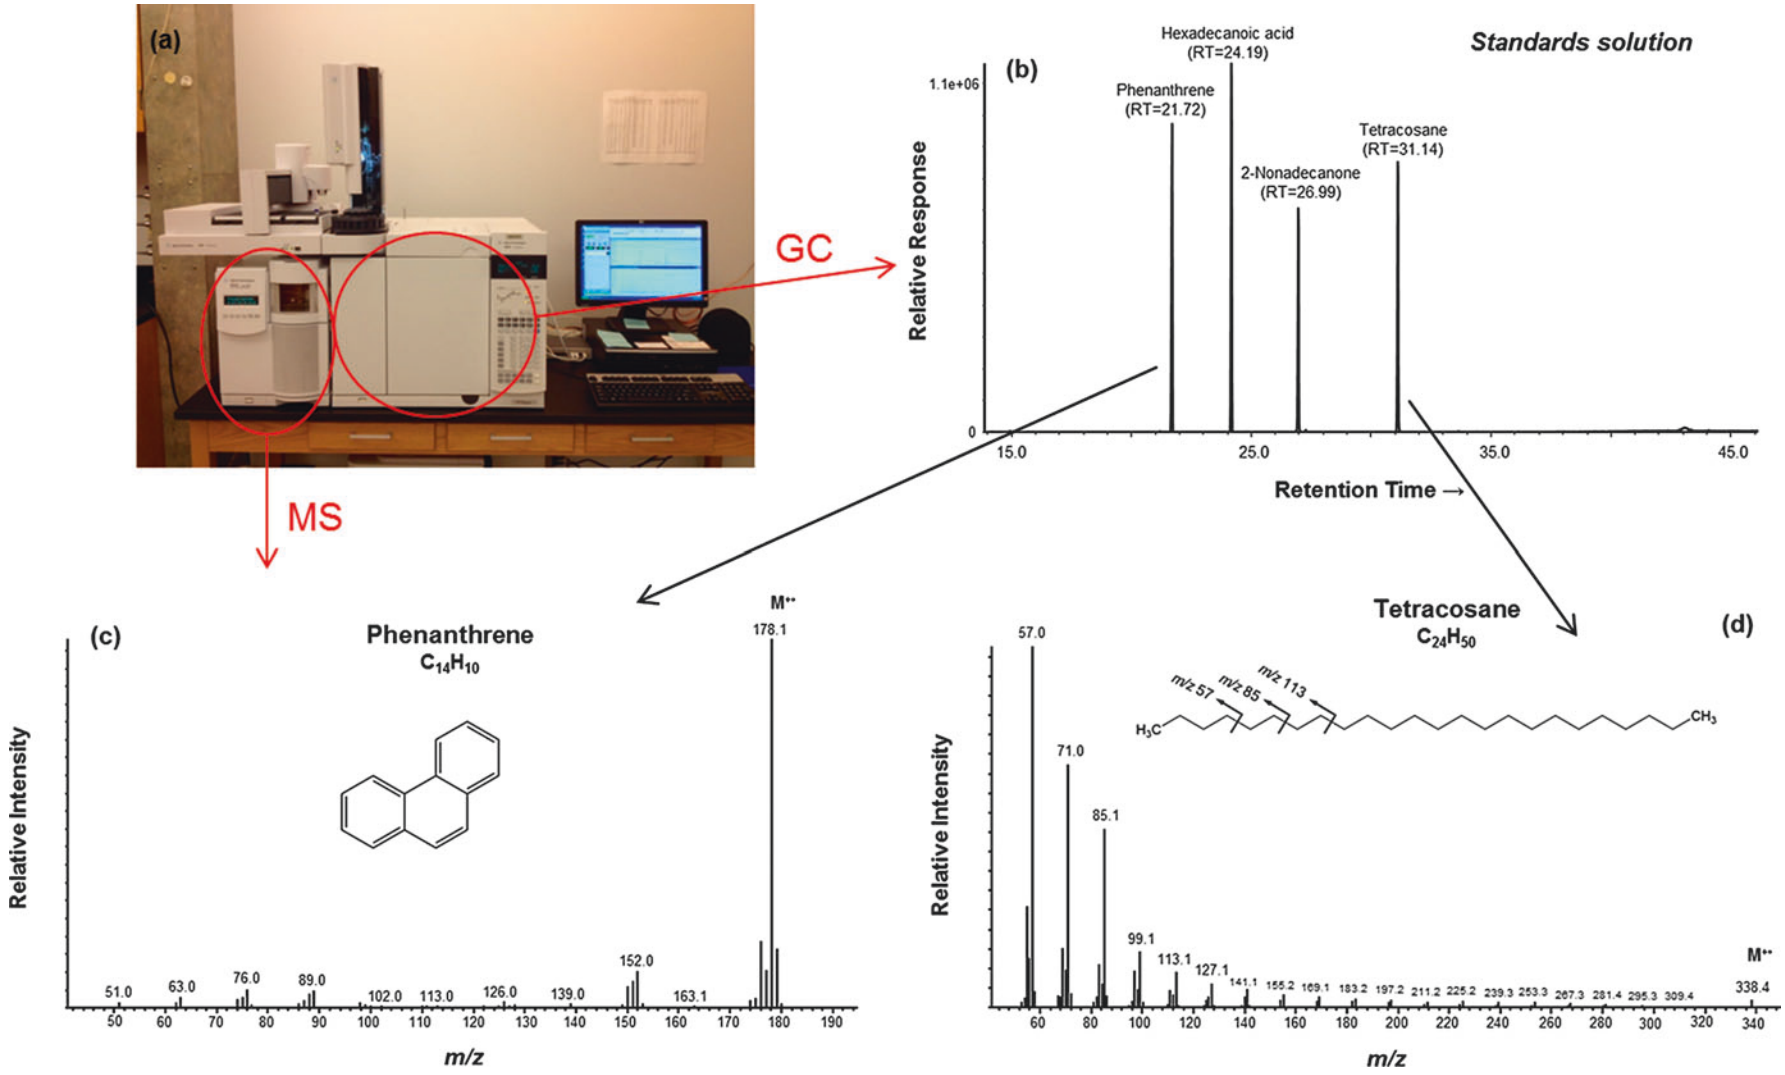
In a typical MS procedure, a sample (solid, liquid, or gas) is ionized, for example by bombarding it with electrons (electron ionization – EI). This may cause some of the sample's molecules to break into charged fragments. These ions are then separated according to their mass-to-charge ratio, typically by accelerating and subjecting them to a magnetic or electric field or measuring the time taken to reach the detector: ions of the same mass-to-charge ratio will undergo the same amount of deflection. There are currently four main types of analyzers: magnetic sector, ion trap, quadrupole (Q), and time of flight (ToF), though these are often combined into tandem configurations such as a QToF. The mass resolution (accuracy to which masses can be separated) of the analyzer types varies, generally with quadrupoles being lowest, ion traps being intermediate, and ToF and magnetic sector being the highest (4 decimal place or better). The ions are detected by a mechanism capable of recognizing charged particles. The atoms or molecules in the sample can be identified by correlating theoretical masses to the identified masses or through a characteristic fragmentation pattern.

In 1958, the first online GC-MS instruments were introduced. In the early 1960s, the development of affordable and miniaturized computers has helped in the simplification of the use of this instrument, as well as allowed for great improvements in the amount of time it took to analyze a sample. The major breakthrough in GC-MS occurred in 1968 with the introduction of the first data-processing units. In 1981, fused-silica capillary columns were first applied for GC-MS, and today, it is the most widely used column in GC-MS analysis (Fig. 1a).

GC-MS Analysis

When GC is combined with MS, a powerful analytical tool is created. The instruments are coupled using a heated transfer line which the latter part of the column passes through and ends at the entrance to the MS ion source where compounds eluting from the column are converted to ions. Complex mixtures of chemicals may be separated, identified, and quantified. This makes it ideal for the analysis of the hundreds of relatively low molecular weight compounds found in environmental and biological materials. As a gas-phase separation method, GC requires the analytes to be volatilized prior to their separation. Therefore, in order for a compound to be analyzed by GC-MS, it must be sufficiently volatile and thermally stable. Samples are usually analyzed as organic solutions, consequently solid materials of interest (e.g., soils, sediments, tissues, etc.) need to be solvent-extracted and the extract subjected to "wet chemical" procedures (e.g., fractionation, concentration, derivatization) before GC-MS analysis. Thermal extraction and pyrolysis techniques for analyzing solid samples are also commonly used in geochemical analyses, and while more often utilized with GC-FID, they can also be coupled with GC-MS for characterization of the evolved organic fractions (e.g., Horsfield et al. 2015).

For liquid sample analysis, a known volume of the analyte is injected into a heated injector port commonly at 250–300 °C (GC inlet), usually using a microsyringe. A carrier gas (usually Helium) sweeps the vaporized analyte molecules through the column. Separation occurs by a combination of kinetic, physical, and chemical interactions with the stationary phase filling, resulting in the various components eluting at different times. The time at which each component reaches the outlet, the retention time (RT), is defined as the time from when the injection is made (time zero) to when elution occurs. As the instrument runs, a computer software generates a graph called *chromatogram* (Fig. 1b). The x-axis shows the RT, and the y-axis shows the intensity (abundance) of the signal.



Gas Chromatography–Mass Spectrometry (GC–MS), Fig. 1 (**a**) GC-MS equipment in an environmental chemistry lab; **(b)** GC-MS data (chromatogram) for a standard solution containing phenanthrene ($C_{14}H_{10}$), hexadecanoic acid ($C_{16}H_{32}O_2$), 2-nonadecanone ($C_{19}H_{38}O$), and tetracosane ($C_{24}H_{50}$) with their respective retention times (RT); Mass spectra showing the molecular ion ($M^{+\cdot}$) and characteristic fragmentation patterns of **(c)** phenanthrene and **(d)** tetracosane. *m/z* = mass-to-charge ratio

The most frequently used methods for ion production are electron ionization (EI) and chemical ionization (CI). In geochemical applications, EI is primarily applied. A beam of electrons (e^-) at a known electron voltage (eV) ionizes the sample molecules resulting in the loss of one electron, producing a molecular ion represented by $M^{+\bullet}$ (a radical cation). Due to a large amount of energy imparted to the molecular ion, it usually fragments producing further smaller ions. The mass of the fragment divided by the charge is called mass-to-charge ratio (*m/z*). Since most fragments have charge of +1, the *m/z* usually represents the molecular mass of the fragment or the entire compound in the case of $M^{+\bullet}$.

Following ionization, the positively charged ions are accelerated into a mass analyzer (filter), which separates them according to their *m/z* ratios. After the ions are separated, they enter a detector where their outputs are amplified (by an electron multiplier or photomultiplier) to boost the signal. The detector sends information to a computer that records all of the data produced and converts the electrical impulses into visual displays called *mass spectrum* (Fig. 1c, d). In a mass spectrum, the x-axis represents the *m/z* ratios and the y-axis represents the signal intensity for each of the fragments detected. Because the mass spectrum produced by a given chemical at the same eV (most commonly 70 eV) is essentially the same every time and the fragmentation pattern is characteristic for that chemical, it represents the "fingerprint" for that molecular structure. This information may be then used to identify compounds of interest (often using library databases such as NIST or Wiley) and to help elucidate the structure of unknown components of mixtures. Quantification of individual compounds can be done by comparing the area of each identified peak on a given chromatogram to that of an internal standard, which is added in a known amount from a standard solution. Semiquantification can be conducted when internal standards are not present. The detection limits of GC-MS systems range from nanogram (10^{-9} g) to femtogram (10^{-15} g).

In a GC-MS, the collection of data can be performed in one of the two ways: full scan and selected ion monitoring (SIM). The full scan mode targets a broad range of mass fragments, typically from *m/z* 50 to *m/z* 600, and it is useful in determining unknown compounds in a sample. In contrast, SIM only monitors selected ions associated with a specific substance. This is a fast and efficient analysis, especially if the analyst has previous information about a sample or is only looking for a few specific substances.

GC-MS for Biomarker Elucidations

Structure elucidations of natural compounds by GC-MS were the major breakthrough in developing biomarker geochemistry, initially for petroleum exploration research and then for organic geochemistry in general. In geochemistry, biomarkers are defined as compounds derived from biological sources (i.e., plant, microbes, and animals) that retain some, if not all, of the structural characteristics of their parent precursor molecule after being preserved in the geological record or released into the environment. Hence, they can be traced back to their biological (natural) origin. Current instrumentation and derivatization methods extended the biomarker concept into other disciplines such as environmental, food, and forensic applications where natural as well as synthetic (anthropogenic) compounds are encountered.

Petroleum Exploration

In petroleum geochemistry, biomarkers or "molecular fossils" have had extensive applications as organic matter source, maturity, and alteration indicators. Whole oil screening by GC-MS is commonly undertaken to assess hydrocarbon distributions and identify samples for further more intensive geochemical investigations. Hydrocarbon profiles can be used to infer source matter, e.g., *Gloecapsomorpha prisca* in early Paleozoic oils through their distinctive odd over even *n*-alkane distributions (e.g., Reed et al. 1986; Fowler 1992), while the ratio of the isoprenoids pristane to phytane is used to infer redox conditions in the depositional environment, and the ratio of the polyaromatic hydrocarbon phenanthrene and its methyl homologues can be used as a maturity proxy (Peters et al. 2005). Due to the extremely complex nature of the biomarker distributions, the chromatographic separation can be problematic with many coelutions of diagnostic components, with tandem mass spectrometry (GC-MS/MS) being utilized for the greatest level in specificity.

Environmental Impacts and Forensic Applications

More recently, these compounds have been extensively utilized in fossil fuel pollution studies (e.g., Volkman et al. 1992; Aboul-Kassim and Simoneit 1996; Medeiros and Bícego 2004). Assessment of the environmental impact in the short- and long-term of crude oil spills such as the Exxon Valdez, MV Braer, Erika, and more recently the Deepwater Horizon relied greatly on the quantification of organic pollutants using GC-MS (e.g., Hostettler and Kvenvolden 1994; Webster et al. 1997; Rosenbauer et al. 2010; Natter et al. 2012; Babcock-Adams et al. 2017). GC-MS is also a key forensic tool in correlating sources of pollution to an incident. The Erika spill in 1999, for instance, was followed by many other oil tankers illegally cleaning their tanks at sea in the area. Through the use of GC-MS analyses, it was possible not only to differentiate numerous sources of residues in the region but also to accomplish the unambiguous correlation of residues from the Erika spill (Mazeas and Budzinski 2002).

Anthropogenic Impacts on Geological Matrices

Unfortunately for geochemical research anthropogenic contamination of geological samples, whether in the environment, during collection or in storages can overprint the indigenous biological compounds (e.g., Brocks 2011). Identification of these contaminants by GC-MS and subsequent methodologies for quantifying their pervasiveness allow more accurate determination and hence interpretation of original biomarkers from ancient materials (e.g., Brocks et al. 2008; John et al. 2017).

Paleoclimatology

Lipid biomarkers are compounds that can be traced to a particular biological source and, as such, provide numerous paleoecological and paleoclimatological proxies (Eglinton and Eglinton 2008). For example, higher plants produce high-molecular weight (C24–C36) *n*-alkanoic acids as part of their cuticular waxes, and these compounds can be preserved in sediments for thousands of years (Eglinton and Eglinton 2008; Bush and McInerney 2013). Measures such as average chain length (ACL) and carbon preference index (CPI) provide valuable information on past ecosystems, climates, and postdepositional processes (Bush and McInerney 2013). GC-MS analyses also provide a valuable screening tool prior to compound-specific isotope analysis (CSIA) of leaf wax compounds to ensure the fractionated extracts are of measurable concentration and free of coeluting compounds that could affect the isotopic value processes (Sachse et al. 2004).

Modern Environmental Studies

The application of biomarkers as tracers has been used extensively in determining sources, transport, and transformation products of organic matter in aquatic, soil, and atmospheric samples. For instance, higher plant biomarkers, such as diterpenoids and lignin phenols, have been used to trace terrestrial inputs in both coastal marine and open-ocean waters (Simoneit 1977; Goñi et al. 1997); phospholipid fatty acids (PLFA) patterns have become popular as a way of acquiring a view of the microbial community in soil samples (Medeiros et al. 2006b); biomass burning biomarkers such as levoglucosan, mannosan, and galactosan (decomposition products of burning of cellulose and hemicellulose) demonstrated their usefulness to be used as tracers of wildfires in the atmosphere (Simoneit et al. 1999; Medeiros et al. 2006a).

Conclusions

The coupling of GC and MS in the 1960s was a major development, first in the petrochemistry field and then for organic geochemistry in general. The elucidation of biomarkers allowed for their applications as molecular tracers for numerous processes in geological and environmental studies using natural and anthropogenic compounds. The number of novel compounds identified as well as the applications of biomarker tracers is expected to keep increasing. The utilities of GC-MS for contemporary interdisciplinary sciences will also continue to expand, especially as the analytical instrument capabilities develop further with increased sensitivities, ease of operation, lower maintenance, better separation technology, and improved ionization efficiencies. The current increasing use of related techniques such as GC-IRMS, GC × GC-MS, and GC-MS/MS is further advancing the utilization of hyphenated techniques.

Gas Hydrates

Rajnish Kumar[1] and Praveen Linga[2]
[1]Department of Chemical Engineering, Indian Institute of Technology, Chennai, India
[2]Department of Chemical and Biomolecular Engineering, National University of Singapore, Singapore, Singapore

Definition

Gas hydrates are nonstoichiometric crystalline compounds in which hydrogen-bonded water molecules (host) create cavities that enclose a gaseous molecule or low molecular weight hydrocarbon (guest). The guest molecule inside the cavities rotates freely as there is no chemical bonding between the host water molecules and the enclosed guest molecule. Unlike crystalline ice which exists below 0 °C, solid crystals of gas hydrate are stable above or below 0 °C. Methane (CH_4) is the most common guest molecule. Methane hydrates are found in many subsea and permafrost regions on earth. Methane hydrates represent a highly concentrated form of methane; a cubic meter of methane hydrate may contain as much as 170 m^3 of methane at standard temperature-pressure condition along with 0.84 m^3 of (potable) water. An estimated 99% of worldwide gas hydrate occurs in ocean (marine) sediments at water depths ranging from 300 m to greater that 2500 m. Key challenges in exploiting this resource are locating gas hydrate reservoirs, obtaining extensive reservoir mapping and developing viable (safe and economical) production strategies for eventual natural gas production.

Introduction

The proven hydrocarbon reserves are roughly 235,000 million tons of oil and 200 trillion cubic meters of natural gas (BP 2013). Global oil production data show that crude oil production from the existing fields has already peaked and will decline significantly in years to come. At the current level of consumption, these reserves are sufficient to meet more than 50 years of global production of oil and natural gas. Coal as a fossil fuel is undesirable in CO_2 constrained world. Natural gas is the cleanest burning fossil fuel and there is an increasing effort to locate their existence in nature for exploitation. As a result, a new solid component of gas and water has emerged in the field of unconventional energy sources and is known as clathrate of natural gas commonly called as gas hydrate (Makogon 1965; Buffett 2000).

Estimates of gas hydrate deposits vary over several orders of magnitude but the energy contained in the gas hydrate accumulations is believed to be more than that of all the fossil

fuels combined (Makogon et al. 2007). The promise of this untapped energy source is such that it is prompting many governments and industry groups to set up national gas hydrate programs with countries like the USA, Japan, India, China, and Korea largely in the mix. Most of these countries may not have conventional resources of natural gas and for these economies, investing on natural gas hydrate "resources estimation" and "production" is a key strategy.

This article discusses the origin and distribution of gas hydrate deposits around the world, takes a look at the geochemical aspects and some of the early hydrate studies working toward the development and production of gas from gas hydrate deposits. A brief discussion on natural destabilization of natural gas hydrate is also given.

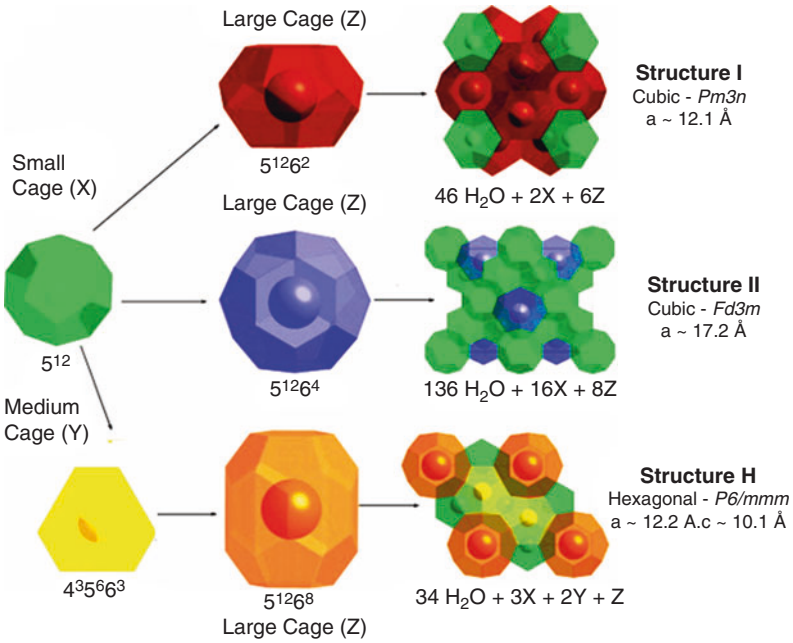
Structure and Characteristics of Gas Hydrates

Entrapment of guest molecules, such as methane or carbon dioxide by hydrogen-bonded water molecules at subambient temperature and moderate pressure, produces solid crystalline gas hydrates which physically resemble ice. Gas hydrates belong to a class of compounds known as clathrates (Davidson 1973; Englezos 1993; Sloan and Koh 2008). These are caged structures with varying sizes which further recombine to produce well-defined unit crystals as shown in Fig. 1.

Three most common structures, which have been found in nature and synthesized in laboratory setup at suitable conditions, are Structures I and II, which bear cubic symmetry and structure H which is hexagonal. Structure I typically forms by small gaseous guests molecules like CO_2, CH_4 (molecular diameter roughly 0.4–0.5 nm). Structure II type hydrates are formed by relatively larger gases or lower hydrocarbon liquids (molecular diameter roughly 0.5–0.7 nm) with water and are observed generally in areas of active hydrocarbon flux (deep-sea seeps). Structure II type hydrates are also formed by smaller gaseous molecules like H_2 and N_2 (molecular diameter roughly 0.3–0.4 nm) though at slightly higher pressure (Davidson et al. 1984). Larger hydrocarbon molecules which are too big to fit into the large cages of Structure II hydrates form Structure H type hydrates, however, not without the help of a gaseous molecule which by itself may form Structure I type hydrate. Figure 1 shows in detail the different type of cages formed for each structure, the respective number of cages per unit structure, and the number of water molecules needed for unit structure of each.

Gas Hydrate Resources

Ingredients for hydrate formation, water (host), and natural gas (guest) along with right pressure and temperature are simultaneously required for hydrate formation. Thus, unlike conventional natural gas resources, gas hydrate only occurs in sediments which exist at a suitable pressure and temperature conditions. However, gas hydrate deposits may not be always present within the gas hydrate stability zone. The key limiting factor in gas hydrate formation in most locations is the lack of adequate amounts of gas and in some cases a relative shortage of free water in sediments which limits gas hydrate formation. More than 99% of the hydrocarbon gases present in the natural hydrates are methane. Carbon isotopic compositions of methane from natural gas hydrate samples have



Gas Hydrates, Fig. 1 Three common clathrate hydrate structures, including the constituent cavities (Adapted from Strobel et al. 2009)

conclusively proved that source of methane in the subsea environment is microbial degradation of organic matters as methane is the only hydrocarbon generated in significant amounts. It is estimated that about 98–99% of the world's gas hydrates are concentrated within marine sediments and the rest beneath permafrost. Figure 2 shows the distribution of gas hydrate confirmed occurrences (marked with star) where hydrates were directly identified by taking out hydrate samples from the sea bed or it was inferred based on indirect measurement techniques discussed in the next section.

Moridis and Collett (2004) proposed a classification system for potential reservoirs. It does not distinguish between permafrost and marine gas hydrates, focusing instead on the association with mobile gas/fluids and concentration of the deposits. Classes 1–3 assume that the gas hydrate is contained with host sediment of high reservoir quality (sand-rich). Class 4 generally equates to gas hydrate within marine muds.

Class 1: Highly saturated deposits at the base of gas hydrate stability and underlain by free gas
Class 2: Deposits overlying a zone of mobile fluids
Class 3: Gas hydrate bearing layer with no mobile fluid above or below
Class 4: Generally marine deposits that are poorly saturated and for which there are no apparent lateral or vertical seals

Boswell and Collett (2006) suggested a distribution of natural gas hydrates based on the lithology of the host sediment. The pyramid shaped representation serves a dual purpose; it not only gives the quantity of such resource it also estimates the quality of these resources in terms of its ease of exploitation and commercialization. Boswell and Collett (2011) suggests that 10^5 TCF as an order of magnitude estimate of potential resources within resource grade deposits in marine settings. In comparison, the gross estimate for proven free natural gas is roughly 7×10^3 TCF (Fig. 3).

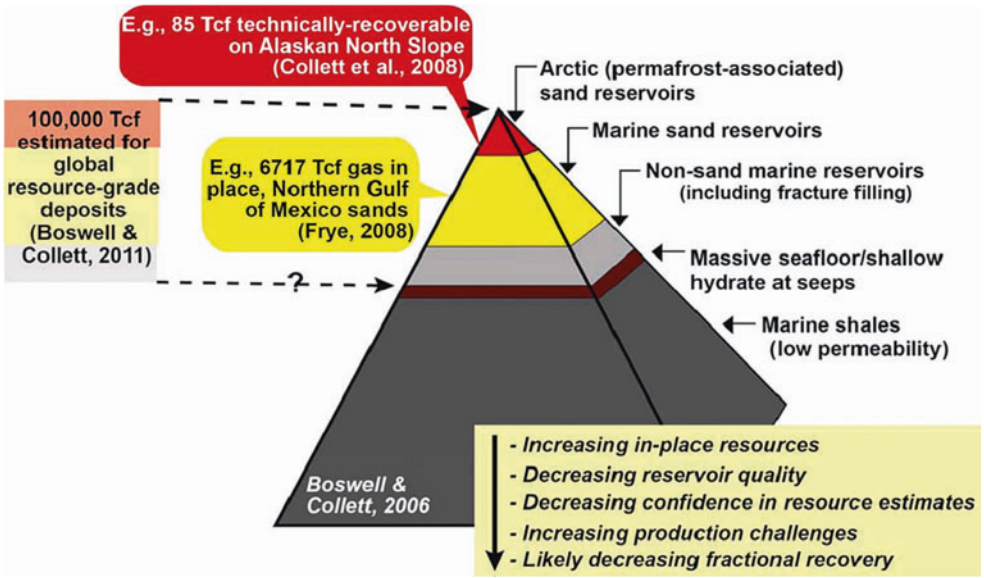
Locating Gas Hydrate Zones

Locating gas hydrate deposits has always been a major challenge; Bottom Simulating Reflector (BSR) was initially the primary tool in locating the presence of gas hydrates. BSRs are indicators of the base of the stability zone for a GHD (Gas Hydrate Deposit). However, gas hydrates have been sampled in many places even without the presence of a BSR. Inferences can also be made regarding the distribution and concentration of gas hydrates by systematic analysis of seismic data. Exploration approaches that integrates geological and geophysical methods and that focus on direct indicators of concentrated gas hydrate occurrence such as strong amplitude anomalies and intervals of increased velocity have shown great promise worldwide (Saeki et al. 2008; Boswell et al. 2016). 3D seismic data along with data from borehole logs have been used to outline the extent of GHDs in various places such as the Japanese and the Indian margins (Collett et al. 2009).

Production of Methane from Gas Hydrates

Exploitation of natural gas (or methane) from marine gas hydrate is quite different from the conventional gas production. Gas production from hydrate deposits goes through a

Gas Hydrates, Fig. 2 Global Map of Gas Hydrate occurrence as inferred from direct sampling or geophysical surveys (Map is a copyright of Encyclopedia Britannica, Inc.)



Gas Hydrates, Fig. 3 Gas hydrate resource pyramid (Adapted from Boswell and Collett 2006)

phase change from solid hydrate to liquid water and gaseous methane. Furthermore, hydrates being a crystalline solid releases a significant amount of energy during its formation and requires a sustained supply of energy during dissociation. Coupled with the mass transfer limitations, this becomes a multiphase heat and mass transfer controlled process which requires significant understanding at lab scale and pilot scale from the process engineering point of view. Existing technology employed in conventional oil and gas fields along with recent understanding from fracking of shale oil is a good starting point to identify the right tools and processes required for energy production from gas hydrate deposits. Production of natural gas from marine hydrate deposits are even more complicated compared to permafrost deposits.

Figure 4 explains the possible production scenario through simplified schematic. In essence, the three methods shown are thermal stimulation (supply of heat to dissociate hydrates), depressurization (reduction of pressure to dissociate the hydrates), and the injection of chemicals (shift the thermodynamic stability to dissociate hydrates). There is a body of work that summarizes the production strategies, challenges, production models, economics, and feasibility of production of energy from hydrates (Moridis et al. 2009, 2011; Chong et al. 2016; Yin et al. 2016).

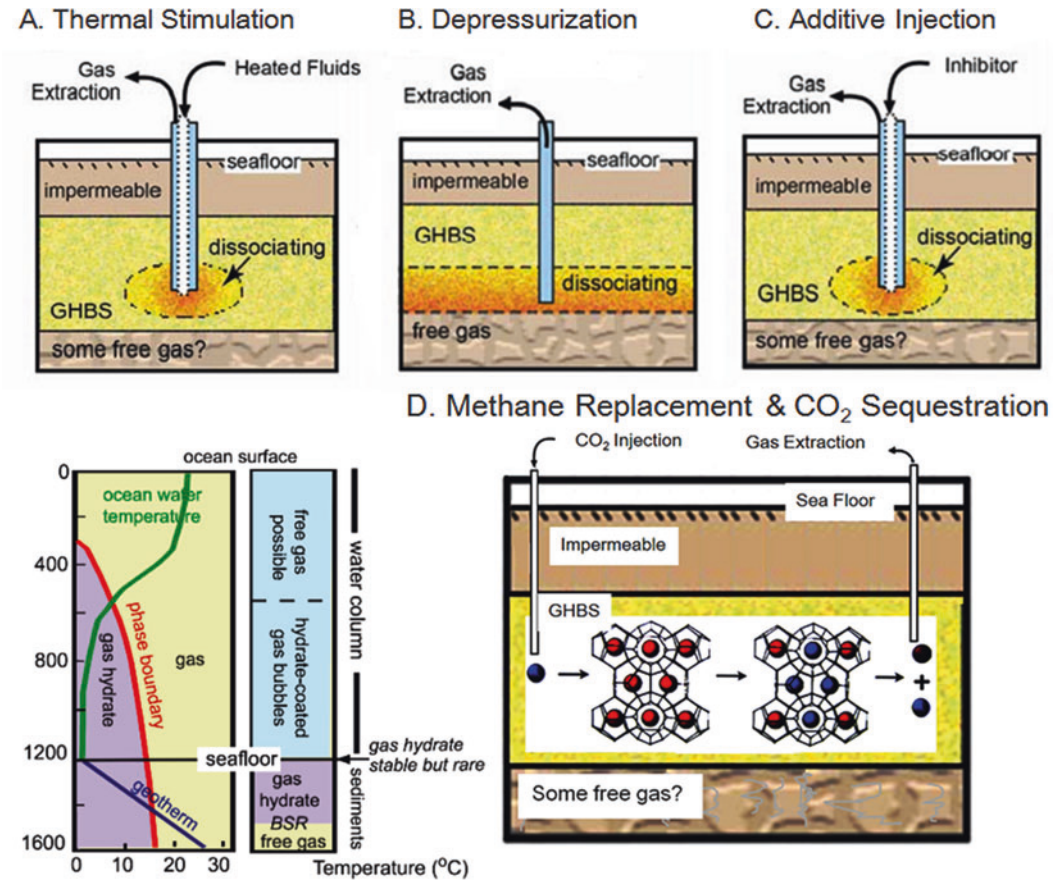
An alternative approach similar to chemical injection is to inject a greenhouse gas like CO_2 into hydrate sediments; with this approach CH_4 gas could be extracted without coproduction of water. An added advantage of one such approach is that CO_2 would be sequestered as gas hydrate. It is a well-known fact that the thermodynamic condition for stable CO_2 hydrate is milder than that of methane hydrate. Methane recovery from hydrates through this approach has been studied at lab scale, bench scale, and pilot scale. A field trial has also been done by ConocoPhillips; however from the geochemist view point following questions still remains

1. Can CO_2 alone replace methane form large as well as small cages?
2. Can 100% methane be recovered from one such approach, if not? How to maximize methane recovery at the shortest possible time?
3. How do we ensure diffusion of CO_2 in the solid hydrate and enhance the kinetics of replacement?
4. Will the left-over hydrate would be as stable as pure methane hydrate? In other words, can CO_2 be sequestrated in an environmentally sustainable manner? This aspect is essential to safeguard the future emission of these greenhouse gases.

Challenges Faced During Extraction of Methane (Field Trials)

There is still a long way to go before commercial production from gas hydrates becomes a reality. Recovery factor and technoeconomic deliberations will be the key to successfully commercializing gas production from gas hydrates. A number of field trials have already been carried out across the world in order to validate the proof of concept of production of gas from gas hydrates. There are several challenges that have arisen from these field studies and these issues need to be addressed before we can move on from "methane hydrate resources" to "methane reserves."

In Mallik Production Research Program, a 6-day production test successfully demonstrated the proof of concept of producing gas from gas hydrates using the depressurization



Gas Hydrates, Fig. 4 Different methods for producing gas from gas hydrates (Adapted from Ruppel 2007, 2011)

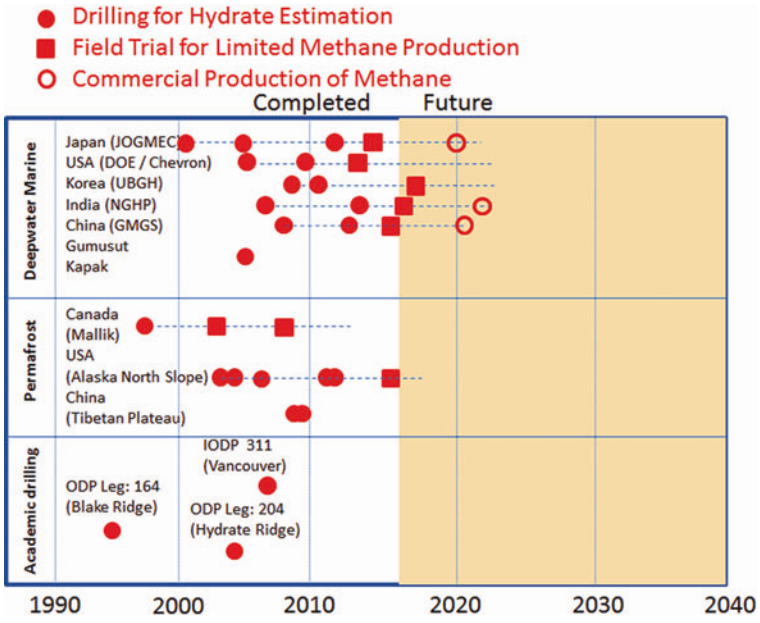
method. One of the achievements was to successfully maintain a sustained gas flow rates (2000–4000 m^3/day) throughout the course of the program. However, handling of sand during gas production was the biggest bottleneck which culminated in an abrupt halt in gas production. Thus, long production test could not be achieved. During the Nankai trough field trial by Japan, some of these problems were handled with better mechanical designs.

The contribution of gas hydrates to global warming and the greenhouse effect has become a major societal concern. However, natural destabilization (not due to human intervention) of gas hydrate is not a great concern as these hydrates have existed for millions of years. Moreover, there can't be a runaway effect as hydrate dissociation is an endothermic process. So-called global warming induced by either human interference or otherwise may gradually allow these hydrates to dissociate, released methane may further contribute to global warming. Zander et al. (2017) give a detailed discussion on the hazards of gas hydrate exploitation. There is a need to look at techniques for the production of gas from gas hydrates which avoid reservoir subsidence. One such technique which is being widely looked at the moment is the methane release via substitution of CO_2. This process, if found suitable, may also alleviate the excess production of sand and water as encountered during the field trial runs via depressurization. This process of methane replacement by CO_2 injection was pilot tested in the Iġnik Sikumi Field by Conoco Phillips in the Prudhoe Bay area of Alaska in 2012 (Boswell et al. 2017).

Current Status of Natural Gas Hydrate Exploitation

There have been some major developments in the area of gas hydrates research in the last few years with some countries successfully managing to extract a steady stream of gas from natural gas hydrate deposits. In 2012, the DOE in partnership with Conoco Phillips conducted an expedition in the Prudhoe Bay region of Alaska. They used the CO_2 injection method to ensure a steady stream of gas output. However, if the recovered methane was actually due to CO_2 replacement or due to thermal stimulation is still a big question.

In order to prove the feasibility of the depressurization method to extract methane from gas water hydrates at the subsea level, Japan Oil, Gas, and Metals National Corporation



Gas Hydrates, Fig. 5 Natural gas hydrates research, development, and exploitation; past, present, and future (Based on the data available from the US Geological Survey)

(JOGMEC) conducted its first offshore methane hydrate production test off the coast of Honshu Island in March, 2013. JOGMEC succeeded in producing methane gas from the hydrate bearing sediments on March 12, 2013, after lowering the bottom hole pressure in the production well from 13.5 MPa to 4.5 MPa. Approximately, 120,000 cubic meters of gas was produced when production was stopped due to an increase in sand production. More recently China from a production site southeast of Hong Kong have extracted 230,000 cubic meters of methane in a month long trial.

Figure 5 shows the road map of proper exploitation of gas hydrate resource. The targets for next 5 years and beyond that can be identified as

- Drilling and identification of deep-water gas hydrate deposits for methane recovery by countries currently not active.
- More deep-water and permafrost field trials. One field trial each from China and Japan has just been concluded in the year 2017. India, China, and Japan are poised to do multiple field trials in next 5 years.
- Large-scale experimentation in the CO_2 injection method for extracting methane from gas hydrates.
- Small-scale production of methane from gas hydrates in order to meet local demands in remote areas such as the Alaskan North Slope (Ruppel 2011).

Summary and Conclusions

Natural gas hydrates are potentially one of the largest sources of unconventional natural gas,Gas hydrates which is the cleanest burning fossil fuel on earth. Given the widespread geographical distribution, production of methane from natural gas hydrates is going to be on potential options for curtailing the anthropogenic source of CO_2 in the atmosphere. Apart from the extraction of methane from the vast hydrate resource, potentially huge amount of CO_2 can be sequestered in an environmentally sustainable manner. However, there is a need for further laboratory and field tests, which employ better technologies to overcome some of the known problems and maintain continuous production over a sustained longer duration of time.

Electron bombardment mass spectrometry; Electron impact mass spectrometry

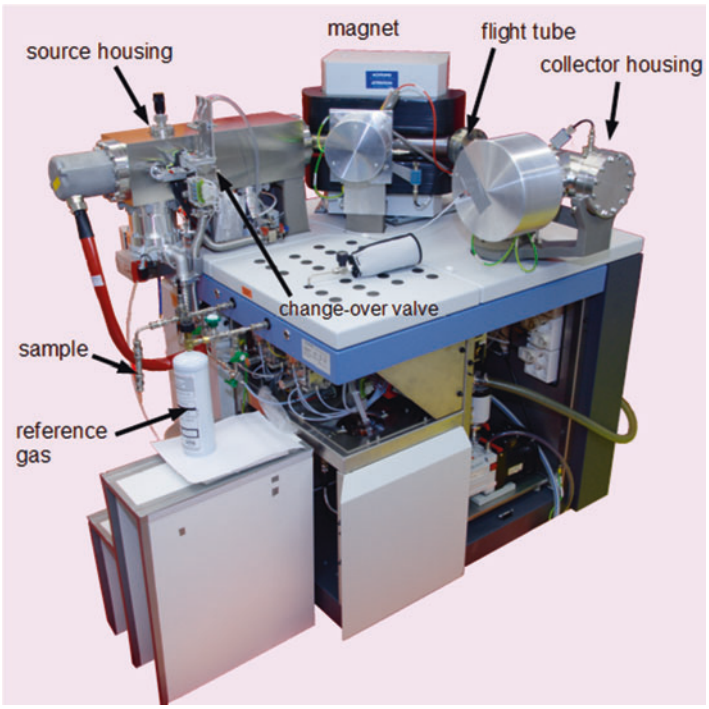
Definition

Gas source mass spectrometry (GS–MS) is the technique and instrumentation used to measure elemental and isotopic compositions of particular elements; these principally include light-element stable isotopes (H, C, N, O, and S) and noble gases (or rare gases) (He, Ne, Ar, Kr, and Xe). GS-MS instrumentation is composed of (1) an ion source for ionizing these gases, (2) an analyzer for separating ions on the basis of the ratio of ionized mass (m) to charge (z), and (3) a detector for counting ions. Figure 1 presents a typical mass spectrometer dedicated for the analyses of stable isotopes.

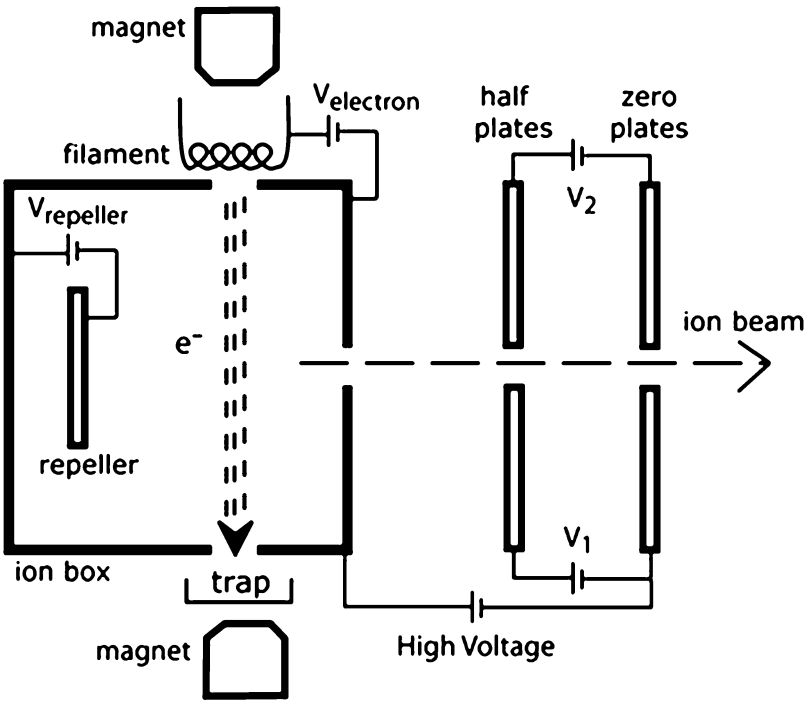
Introduction

To ionize these elements or gaseous compounds containing elements of interest for isotope analyses, Nier (1947) designed an electron bombardment-type ionization source. A similar type of ion source is still used in modern instruments. As shown in Fig. 2, gases are positively ionized in an ion box (or chamber; the ion source) by thermal electrons, with typical electron energies of 70–100 eV emitted from a hot tungsten (in some cases rhenium) filament, under vacuum ($<10^{-5}$ Pa). To improve ionization efficiencies, source magnets with a few hundred gauss are applied. A repeller plate is used to control the gradient of electrons/ions within the ion box to maximize ionization processes. A range of several kilovolts, relative to a zero plate, is applied to an ion box to accelerate ions produced inside the ion box. Half plates are used as a lens to converge and to extract ions.

For GS-MS, a magnetic sector mass analyzer is commonly utilized. In some cases a quadrupole mass analyzer and/or a time of flight (TOF) mass analyzer are used. For a magnetic sector mass analyzer, ions produced inside the ion box with



Gas Source Mass Spectrometry (GS-MS), Fig. 1 A stable isotope mass spectrometer (Thermo Scientific MAT 253) at the University of Wollongong. This instrument is configured with a dual inlet (note the position of the sample gas and a reference gas). Some features are not evident in the photograph. For example, the collector housing contains six Faraday collectors set to m/z of 44, 45, 46, 47, 48, and 49 to perform clumped-isotope analyses of prepared CO_2. The capillaries above the change-over valve are electropolished nickel. For scale, the benchtop is 0.87 × 1.04 m



Gas Source Mass Spectrometry (GS-MS), Fig. 2 Nier-type electron ionization source for stable isotopes and noble gases (from Mabry et al. 2012). As an approximate scale, the length of the ion box, in various instruments, is commonly about 3 cm

certain kinetic energy, determined by acceleration voltage, travel along a flight tube and enter into a uniform magnetic field (normally a few thousand gauss) where ions (m/z) are deflected by the magnetic field (named as Lorentz force), which is balanced with the centrifugal force. As a function of magnetic field strength and accelerating voltage, the ions with a certain m/z will have a unique trajectory, and ions having different m/z are separated from each other, and arrive at respective focal points. When the ion beam is high ($>10^{-13}$amp), a Faraday cup is used to directly detect ion current using the Faraday amplifier with feedback resistors of $10^{11,\ 12,\ \text{or}\ 13}$ Ω. With a 10^{13} Ω Faraday amplifier a background of 10^{-18} amp can be obtained. When the ion beam is expected to be even lower, a secondary electron multiplier is used. Combining with an ion-pulse counting method, ion beams as low as 10^{-20} amp can be detected.

Stable Isotope Mass Spectrometry

In stable isotope geochemistry (q.v.), GS-MS is appropriate to the isotopic analysis of hydrogen (using H_2 as the analyte or working gas), carbon and oxygen (as CO_2), nitrogen (as N_2), sulfur (as SO_2 or SF_6), and less commonly to Cl (as CH_3Cl), silicon (as SiF_4), Se (as SeF_6), and Br (as CH_3Br). The isotopic ratios of the latter three elements may also be measured by other techniques, such as multicollector inductively coupled plasma mass spectrometry (MC-ICP-MS). A good reference to all aspects of the field of stable isotope geochemistry is the monograph by Hoefs (2015), and Brand (2004) describes the principles and practice of mass spectrometry.

Accordingly, much of the effort in conventional stable isotope analysis is concerned with producing appropriate pure and isotopically unfractionated working gases from geological materials. Modern systems include online preparation accessories attached directly to the mass spectrometer inlet, so that gas production, extraction, and purification and mass spectrometry are integrated and fully automated. There are many individually different gas-extraction protocols, for samples of water, air, organic matter, carbonates, silicates, phosphates, sulfates, sulfides; some procedures remain difficult to automate and involve extensive wet chemical preparation offline, that is, well away from the mass spectrometer.

Among the simplest and, probably most widespread procedure, remains the (now commonly automated) production of CO_2 from carbonate minerals using as little as 5–100 μg $CaCO_3$, by reaction with phosphoric acid (McCrea 1950), enabling the mass spectrometric analysis of both oxygen and carbon isotopes. Particularly small samples of gas may be liberated from spatially selected volumes within minerals by laser ablation heating and/or reaction within an evacuated cell.

The most commonly used inlet system to the mass spectrometer is a dual inlet (DI), where rapid cycling (alternating introduction) of a sample gas and a reference gas allows their comparison and provides highly precise analyses (to about 0.01 per mil of the normalized ratio between two or more isotopes of a given element). The sample and reference gas are introduced in individual geometrically matched stainless-steel capillaries of about a meter length and internal diameter of about 0.1 mm that cause each gas to enter the mass spectrometer under a viscous flow regime that precludes isotopic fractionation. The two capillaries are crimped so that these flows are balanced for both gases. The gases are usually pressure-balanced and then alternated through a change-over valve so that a uniform dynamic flow is maintained; at any time, one gas is entering the mass spectrometer source while the other is flowing to waste. The commonly determined ratios are $^{2}H/^{1}H$, $^{13}C/^{12}C$, $^{15}N/^{14}N$, $^{18}O/^{16}O$, $^{34}S/^{32}S$, $^{37}Cl/^{35}Cl$, and $^{30}Si/^{28}Si$. Some elements have more than two stable isotopes, and specialized applications, such as the search for non-mass-dependent isotopic fractionation, require measurement of additional isotopes. Thus, for example, $^{17}O/^{16}O$ as well as $^{18}O/^{16}O$ (using O_2 as the working gas) and $^{33}S/^{32}S$ and $^{36}S/^{32}S$ may be measured (using SF_6), the latter requiring quantification of all four stable isotopes of sulfur, ^{32}S, ^{33}S, ^{34}S, and ^{36}S.

A further inlet type is also common, namely the continuous flow (CF) inlet. This allows smaller gas samples (nanomoles to picomoles) to be measured, swept into the mass spectrometer source in a stream of helium, after gas chromatographic purification. There is no internal standardization as can be achieved with dual-inlet comparison, although reference materials are introduced at suitable intervals, as if samples, within each analytical session. The precision of CF analyses is less, commonly 0.2–0.5 per mil, than for the DI mode. However, the addition of automated preparation systems permits rapid analysis of bulk organic matter and the separation of individual organic compounds (i.e., compound-specific analysis) by gas or liquid chromatography, prior to their combustion or pyrolysis and analysis of their H, C, N, O, and S isotopes.

The precision of stable isotopic ratios is also enhanced by the universal use of multicollector Faraday cups applied in both DI and CF modes, as this allows simultaneous collection of all the isotopes of a given species. For example, the molecular ions of CO_2 have masses (m/z) of 44, 45, 46, 47, 48, and 49, given that oxygen has m/z of 16, 17, or 18 and carbon 12 or 13. Measurement of masses 44, 45, and 46 provides sufficient information to calculate the ratios $^{13}C/^{12}C$ and $^{18}O/^{16}O$ for most terrestrial samples. Accordingly, mass spectrometers equipped with three appropriately spaced collectors for these masses are the norm. The new field of clumped-isotope geochemistry (Eiler 2007) calculates the paleotemperature of carbonates by measurement of the relative abundance of $^{13}C^{18}O^{16}O$ (i.e., m/z of 47), so that specialized mass spectrometers with up to six collectors are required, as all masses of CO_2 are monitored, with masses 48 and 49, used as indicators of contamination.

The stable isotopic analyses of all materials are normalized to a set of internationally agreed values for reference materials that are available for distribution through the International Atomic Energy Agency (IAEA) in Vienna. Each laboratory is asked to use these sparingly and to establish and calibrate its own working standards for routine analyses (see the section on ▶ "Stable Isotope Geochemistry").

Noble Gas Mass Spectrometry

In contrast to the relatively abundant stable isotopes, noble gasNoble gases abundances in natural samples are minute and analyses of noble gas abundance of $10^{-22} \sim 10^{-12}$ mol are required. To fulfill this requirement, Reynolds (1956) deployed a glass noble gas mass spectrometer operated in

static mode (retaining all sample gases by isolating the system from the vacuum pumps). In addition, in order to reduce the background of noble gases and their interferences in a mass spectrometer, ultra-high ($<10^{-7}$ Pa) and clean vacuum is required, which can be achieved by baking the system in excess of 350 °C. Now that specialty steels and a variety of more exotic metals are more common, all-metal noble gas mass spectrometers are commercially available. In some cases, the nitrogen isotopes from minute amounts of gas from geological samples (for example, mantle-derived samples) are analyzed by a noble gas mass spectrometer in static mode.

In order to measure noble gas elemental and isotope abundances in geological (solid or fluid) samples, it is necessary to equip a dedicated sample handling system online to a noble gas mass spectrometer. Because helium permeates through normal glass, an all-metal sample handling system is usually used. The system consists of (1) gas extraction, (2) gas purification, (3) noble gas separation, and (4) standard pipettes.

In order to extract noble gases from solid samples, samples are heated by a high temperature furnace, as high as 2,000 °C as required in the case of graphitization of diamonds to extract noble gases, for bulk analyses or laser light for localized analyses. Vacuum crushing techniques to release inclusion-hosted noble gas components are also commonly used. Fluid samples collected in the field and stored in copper tubes (with both ends clamped) or lead glass containers are connected to the sample handling system for further processing. The gas purification section to remove active gas species, such as water and carbon dioxide, includes a bulk getter containing titanium-zirconium foils held at temperature higher than 600 °C, a low temperature (<400 °C) getter comprising titanium-aluminum alloys, and a titanium sublimation pump. After the gas purification, noble gases are physically adsorbed on an activated charcoal trap held at below 10 K. It is ideal to analyze each noble gas species separately to overcome the problem of isotope fractionation caused by the existence of other abundant noble gas species (for example, He in a Ne fraction, Ar in a Kr fraction). Noble gases are sequentially desorbed, starting with He, for isotopic analysis with a mass spectrometer. Effective separation of He from Ne, Ne from Ar, Ar from Kr, and Kr from Xe are attained at approximately 50 K, 125 K, 200 K, and 250 K, respectively. To calibrate instrumental sensitivity and mass discrimination (instrument-induced isotope fractionation that occurs mainly during the ionization processes in the ion box), it is necessary to install standard gas pipette tanks, which deliver aliquots of known amounts and isotopic compositions of noble gases and atmospheric noble gases are commonly used for this purpose. Data sets, performed by peak-jumping or multicollection, comprise the data acquisition time and peak intensity after subtraction of noise level. In order to compensate for the pumping action of noble gases by ionization in a mass spectrometer, the initial intensity when the gas was first introduced into the mass spectrometer is calculated by extrapolating the intensity back to the initial gas inlet time (T zero). In contrast to abundant stable isotope analyses with 0.01 per mil level precision, for noble gases analyses at per mil level precision is at best achievable.

In the 2010s, some commercial manufacturers launched multicollector noble gas mass spectrometers, which revolutionized applications in the cosmo-geo-sciences. Analyses of noble gas isotopes by multicollector systems have substantially improved precision and accuracy of measurements. For example, using a high-sensitivity, multicollector noble gas mass spectrometer, high precision measurements of atmospheric Ar isotopic ratios were undertaken, and atmospheric Ar isotope compositions were reevaluated. Similarly, $^{40}Ar/^{39}Ar$ geochronology analyses conducted on a multicollector mass spectrometer have produced significantly enhanced (by a factor of 10) precision levels. This capability is particularly well suited to high precision $^{40}Ar/^{39}Ar$ dating of young (<100 ka) basalts. In addition, a high mass resolution (~1,800), multicollector noble gas mass spectrometer is commercially available and this enables separation of the majority of isobaric interferences (e.g., hydrocarbons, hydrides, chlorides) relating to noble gas isotopes. For example, partial separation of $^{20}Ne^{1}H$ from ^{21}Ne makes it possible to precisely determine ^{21}Ne abundances in the atmosphere. Precise analyses (better than 0.5%) of Kr and Xe isotopes achieved by high mass resolution, multicollector noble gas mass spectrometers have demonstrated the existence of nonatmospheric isotope compositions in some terrestrial reservoirs which may directly link to early differentiation processes of the Earth.

Summary

Gas source mass spectrometry had its origins 70 years ago. Modern machines utilize the same principles although there have been significant advances in precision owing to multiple ion-beam collection, ion detection and amplification, and electronic stability. Substantial automation of both measurement and, in some cases, extraction of useable gases from geological, biological, atmospheric, and hydrological materials has led to higher productivity and analysis of smaller samples. The technique continues to be the principal analytical tool applied to both light-element stable isotope and noble gas geochemistry. It is anticipated that, utilizing multicollector noble gas mass spectrometers, the area of noble gas cosmo-geochemistry will continue to advance significantly in the next decade.

Definition

Geochemists classify elements in various ways based on their abundance, behavior, and distribution in the Earth.

Introduction

Elements can be qualitatively classified into **major** (>0.4 wt%), **minor** (0.1–0.4 wt%), and **trace** elements (<0.1 wt%). Major elements are those that define the primary structure of a given phase, which can be a mineral, liquid, or vapor. Major elements are abundant enough that they dictate a system's physical properties, including the assemblage of phases. Trace elements are not essential to the structure of a phase and do not directly influence the properties of a phase or system. Instead, trace elements occur passively as dissolved constituents or in the form of minor amounts of accessory phases. The distribution of elements on Earth is heterogeneous, ranging from the scale of hundreds to thousands of kilometers in the form of the Earth's layered structure (core, mantle, crust, ocean, and atmosphere) down to the scale of millimeters or less in the form of mineral grains or living organisms. Thus, although >99% of the bulk Earth, which includes the crust, mantle, and metallic core, is composed of Fe, O, Mg, Si, S, Ni, Ca, and Al, in order of decreasing abundance by weight, much of the Fe and almost all the Ni are sequestered in the core, whereas most of the Earth's O is locked up in the mantle and crust in the form of oxides (O makes up nearly 50% by weight of the mantle). The same element can be a major element in one geologic environment and a trace element in another. For example, during certain petrogenetic processes, an element initially occurring at trace levels can become concentrated enough to be a major or minor element. Cu ore deposits or Li-rich pegmatites are examples where elements normally in trace abundances can locally become quite enriched. Other examples are H, N, and C, which are trace elements in the mantle but major constituents of the oceans, atmosphere, and life. Redistribution of elements throughout the Earth, a process called differentiation, is dominantly controlled by the formation and physical segregation of silicate liquids, aqueous fluids, and gases, which serve as potential carriers of all elements of the periodic table.

Exactly how elements are spatially redistributed in a planetary body depends on their chemical behaviors and how they partition into different phases during geologic and biochemical processes. Chemical behavior of elements is dictated by the "stability" of the outer electrons. Elements whose outermost electron shells are nearly filled tend to readily attract electrons (high electronegativity), forming anions in chemical bonds. Elements with only partially filled outer shells tend to donate electrons (low electronegativity) and become cations in chemical bonds. Elements with very different electronegativities (opposite ends of the periodic table) tend to transfer electrons between atoms, resulting in ionic bonds. In contrast, elements with similar electronegativities tend to share electron clouds in chemical bonds (covalent bonds), making such bonds very strong. Most of the rocks on Earth are silicates, which are composed of complexes of silica tetrahedra (SiO_4^{4-}), where the similar electronegativities of Si and O result in significant degree of covalent character. Cations on the left side of the periodic table (alkali and alkali Earth metals), such as Mg^{2+}, Ca^{2+}, Na^{+}, and K^{+}, generate ionic bonds with the O^{2-} anions

making up the apices of the silica tetrahedra to form, for example, the silicate minerals that make up most of the Earth's mantle (olivine, Mg_2SiO_4) and crust (feldspar, e.g., $CaAl_2Si_2O_8$ and $NaAlSi_3O_8$). Elements with filled energy shells, such as the noble gases, tend to be chemically inert.

Partitioning Classifications

The efficiency to which an element partitions into a particular phase is controlled to first order by charge and ionic radius (cations are smaller and anions are larger than their respective atomic radii). During melting, elements can be classified into **compatible** or **incompatible** relative to the solid phase, that is, an incompatible element preferentially partitions into the melt phase, whereas a compatible element partitions into the solid phase. A cation becomes incompatible in a particular crystallographic site when excess electrostatic and strain energy is generated due to charge imbalance or when an ion is too big or too small for a particular crystallographic site (Wood and Blundy 2003). These effects are manifested as general trends in partitioning behavior as a function of ionic radii for a given charge. For any given mineral/melt pair, there is an optimum ionic radii for maximum compatibility (Wood and Blundy 2003). In the case of the rare earth elements in most mantle minerals, the heavy rare earths typically exhibit maximum compatibility because the lighter rare earths are too large. This variation in ionic radius, known as the "lanthanide contraction" of the f-orbital shell, thus manifests itself as a distinct decrease in compatibility toward the left-hand side of the periodic table for the rare earth elements.

Most of the high mass trace metals, such as Sr, Rb, and Ba, and the rare earth elements tend to be incompatible during mantle melting because of their large cationic radii. First-row transition metals, with ionic radii more similar to the cation crystallographic sites in mantle minerals, tend to be compatible (Ni and Co) or moderately incompatible (Sc, V, Mn) during melting (Canil 2004). Some highly charged transition metals, such as high field strength elements Ti, Zr, and Nb, are highly incompatible in common silicates due to charge imbalance. Some elements, however, can be highly compatible in a given phase, but exhibit overall incompatible behavior during melting if that phase represents a minor constituent in the rock. For example, Cu is highly compatible in sulfide, but because sulfides are low in abundance in typical mantle rocks, Cu behaves effectively as an incompatible element during mantle melting (Lee et al. 2012).

Partitioning behavior for a given element is rarely ever a constant due to many factors: (1) effective oxidation, which is controlled by the oxygen fugacity of the environment, (2) temperature, (3) pressure, (4) mineral composition, and (5) melt or fluid composition, which changes complexation behavior. An example of redox effects is seen in the difference in partitioning behaviors between Eu^{2+} and Eu^{3+} and between V^{2+} and V^{3+} (Canil 1997). An example of the influence of mineral composition is the effect of coupled substitutions. The presence of Al^{3+} as a major element in a pyroxene can enhance the compatibility of rare earth elements (+3) by providing a means of charge balance. Bridgmanite, a lower-mantle mineral with perovskite structure, can enhance the compatibility of Fe^{3+} if Al^{3+} is contained in its structure (Frost et al. 2004). The subsolidus transformation of wadsleyite or ringwoodite, which contains minimal Al^{3+}, to bridgmanite has been suggested to lead to disproportionation of Fe^{2+} into Fe^0 and Fe^{3+}, the latter dissolving into bridgmanite.

Another important quantity is the charge to ionic radius ratio, known as the **ionic potential**. Elements with high ionic potential are referred to as **high field strength elements** (HFSEs) and include Ti^{4+}, Zr^{4+}, Nb^{5+}, Ta^{5+}, and Hf^{4+}. Elements with low ionic potential are often referred to as **large ion lithophile elements** (LILEs) in the geochemical community. LILEs include Na^+, K^+, Rb^+, Cs^+, Sr^{2+}, and Ba^{2+}. Low ionic potential elements readily form inner sphere aquo-complexes in aqueous solutions because they are large enough to be surrounded and coordinated to water molecules (Langmuir 1997). This makes LILEs soluble in aqueous solutions. The high charge of HFSE and rare earth element cations reduces electron shielding within their outermost electron shell, resulting in significant reduction in ionic radii. Because of their small cationic radii and high charge, H is expelled from the solvation shell, preventing such elements from forming aquo-complexes and rendering them relatively insoluble in water (Langmuir 1997). Only by complexing with other anions, such as halides and oxyanions, can such elements become more soluble in water. These are the reasons why geochemists generally consider LILEs **fluid mobile** and HFSEs **fluid immobile**, but even fluid immobile elements can become mobile under certain conditions.

Geochemical Classifications

Elements are often categorized based on their general geochemical behaviors even though an element's chemical behavior depends strongly on variables such as temperature, pressure, and chemical environment; the latter of which can dictate an element's valence state and ability to form complexes. These classifications broadly follow Goldschmidt's original classifications (Goldschmidt 1937) with the addition of organophile and fluid-mobile elements.

Lithophile elements ("rock loving") are preferentially partitioned into silicate minerals. These include cations that commonly form oxides, such as Ca, Mg, Mn, Ti, Na, K, the rare earth elements, U, Th, Si, and Fe in its oxidized states.

Siderophile elements ("iron loving") are those that are preferentially partitioned into the metallic core, typically in the form of alloys with Fe. Elements exhibiting metallic behavior include the noble metals (Pt, Pd, Ir, Ru, Rh, and Os) as well as W, Ni, and Co. Some elements in their reduced states or at high enough pressures to impart metallic behavior can alloy with Fe metal; these include Si, C, and some high field strength elements like Nb. Sulfur may dissolve in the core as a sulfide complex and, under these conditions, is also considered siderophile.

Chalcophile elements are those that commonly form sulfide-type minerals. These include Cu, Pb, Zn, Cd, Mo, Hg, Sb, Sn, Tl, Te, As, as well as noble metals.

Atmophile elements are those that readily form volatile compounds at relatively low temperatures (<300 K), many of which are preferentially concentrated in planetary atmospheres. Atmophile elements include C, O, H, N, S, and the noble gases.

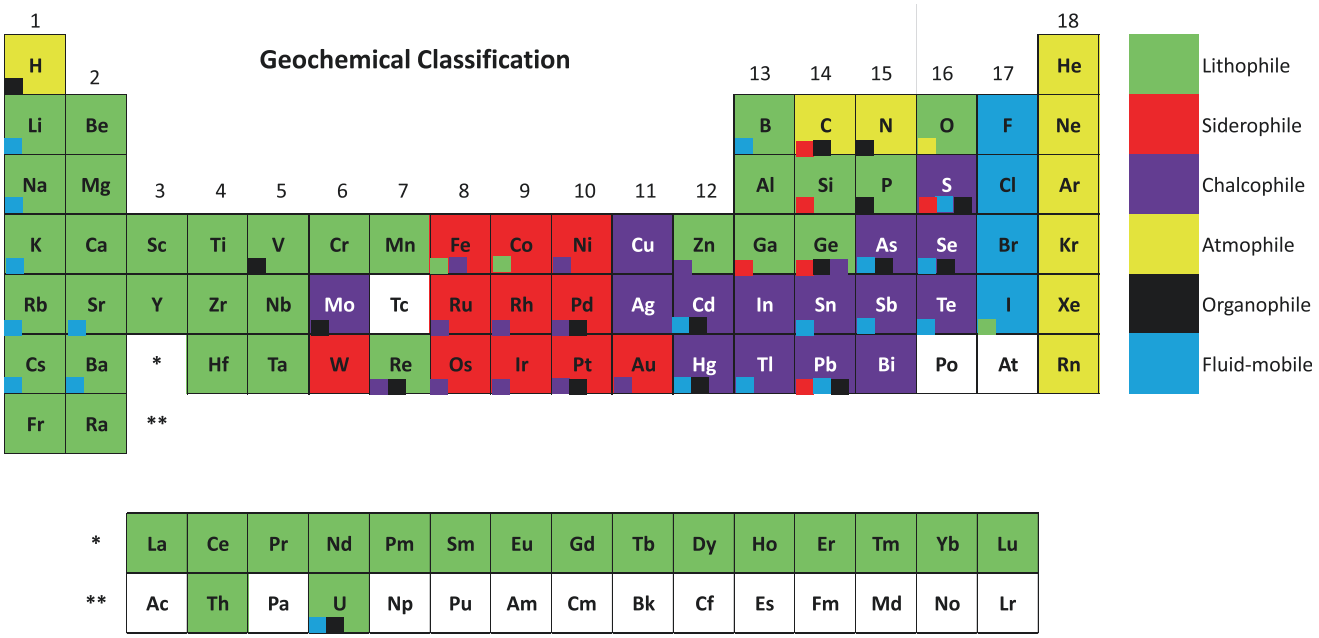
Organophile elements are those that form or associate with organic compounds (hydrocarbon molecules) in biochemical and biogeochemical processes. These include C, H, N, S, and P, but also include various metal-organic complexes. Many metals, such as U, V, Ge, Pb, and Mo, can complex with organic molecules, generating organic-rich sediments with high metal contents.

Fluid-mobile elements are those that readily dissolve in fluids, typically water-rich fluids. Elements with high solubility in water tend to be low field strength elements, such as the alkali and alkali Earth group elements, which readily form inner sphere aquo-complexes or highly electronegative elements, such as the halogens. High field strength elements, in the absence of complexation, tend to be insoluble. Transition metals tend to have lower solubilities, but the presence of anions in the water can greatly enhance their solubilities through complexation. For example, noble metals and high field strength elements can become more soluble if complexed with certain halogens or oxyanions. Introduction of carbonate ions into fluids or silicate melts can also enhance solubilities of certain elements.

It is important to recognize that elements can behave in different ways. Obviously, oxygen in its molecular form can be atmophile, but it also forms oxides and dominantly behaves as a lithophile element in the presence of metals. Elements like Ge can be lithophile, organophile, chalcophile, and siderophile, depending on oxidation state and chemical environment (Fig. 1).

Cosmochemical Classifications

There is a cosmochemical classification of elements that is primarily used to describe the temperature interval over which elements condense from a gaseous state to a solid or liquid state during nebular condensation and planetary accretion. These classifications are based on theoretical condensation temperatures calculated from a nebula with a solar composition and a pressure of 10^{-4} bar (at the 50% condensation



Geochemical Classification of Elements, Fig. 1 Cosmochemical classification of elements: Cosmochemical classification of elements based on 50% condensation temperatures at 10^{-4} bar using data from Lodders and Fegley (1998)

level) and are most applicable in the study of meteorites, impact processes, and planetary accretion (Lodders and Fegley 1998):

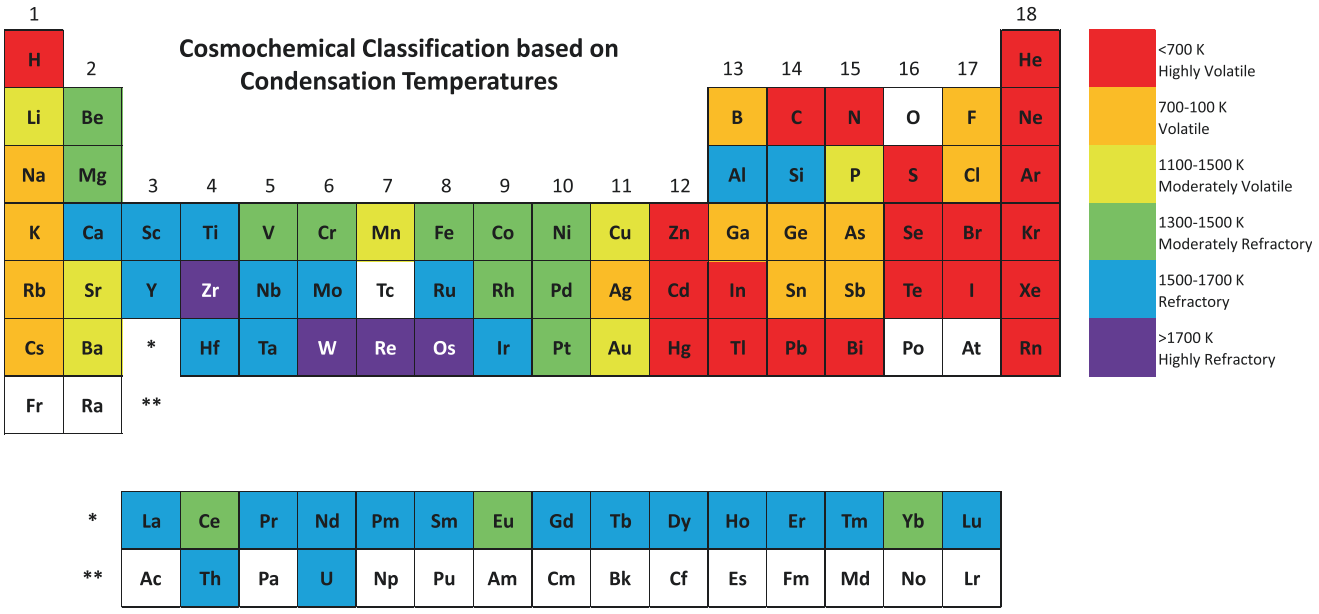
Highly refractory (>1700 K) – Re, Os, W, Zr, and Hf
Refractory (1500–1700 K) – Al, Sc, Ca, Ti, most rare earth elements, Th, and U
Moderately refractory (1300–1500 K) – Be, Mg, Si, Cr, Fe, Co, Ni, Nb, Ce, Yb, Pt, and Pd
Moderately volatile (1100–1500 K) – Cu, Ba, Mn, Sr, P, and Au
Volatile (700–1100 K) – Na, K, B, S, Rb, Cs, Ga, Sn, and Se
Highly volatile (<700 K) – Pb, Zn, Tl, In, Bi, O, C, N, H, and noble gases

The use of these classifications should generally be restricted to cosmochemical processes or during the high temperatures of planetary accretion instead of for differentiation within an already condensed planetary body. For example, refractory elements, in a cosmochemical sense, can be siderophile, lithophile, or even chalcophile during planetary differentiation. Care must also be taken when using the terms atmophile and volatile. For example, Pb and Zn are considered highly volatile from a cosmochemical perspective, but would not be considered atmophile. Nevertheless, under unusual situations, such as during a meteorite impact or volcanic processes, Pb and Zn can be volatilized briefly into the atmosphere before recondensing out of the atmosphere upon cooling. Ge can be volatile in a cosmochemical sense, but can be lithophile or siderophile in a geochemical sense (Fig. 2).

Using Elements in Geochemistry and Cosmochemistry

Major elements are best used for determining how phase assemblages evolve during petrogenesis of rocks. Compatible and moderately compatible trace elements can also be used to evaluate phase assemblages. Together, major elements and moderately incompatible to compatible trace elements can be powerful tools for unraveling the mineralogy of the source regions of magmas. Incompatible trace elements are less diagnostic of mineralogy because effects of fractionation strongly accentuate changes in incompatible trace element abundances. For example, continental crust is highly enriched in incompatible elements owing to extreme magmatic differentiation. Contamination of mantle-derived magmas with small amounts of continental crust or fluids can lead to significant changes in trace element signatures with only minor change in major element systematics. Because some trace element systems are associated with radioactive isotopic systems, a full understanding of the geochemical behavior of parent and daughter elements is critical for interpreting isotopic evolution of the Earth.

Because many factors influence element partitioning, some elements can be used to track various intensive variables, such as temperature, pressure, and oxygen fugacity, when used judiciously. For example, rare earth element partitioning between solid and melt and at subsolidus conditions can be used indirectly as a qualitative barometer by signaling the presence of high-pressure minerals (garnet) or as a quantitative thermobarometer with proper calibration (Liang et al. 2013). Variations in the oxidation state of Fe,



Geochemical Classification of Elements, Fig. 2 Geochemical classification of elements

Eu, and Ce influence their geochemical behaviors, allowing them to be used for tracking oxygen fugacity in the mantle, crust, oceans, and atmosphere through time.

Finally, elemental abundances provide first-order constraints on how different reservoirs interact and how elements are cycled through these reservoirs. For example, the abundance of an element in the ocean may shed light on the element's residence time, that is, elements in high abundance tend to be soluble and have long residence times (Na and Cl), whereas elements in low abundance tend to be insoluble and have short residence times (e.g., rare earth elements). Temporal variations in seawater composition have been used to reconstruct past variations in climate, ocean circulation, and weathering (Holland 1984). Similar approaches can be applied to better understand magma chamber dynamics.

Summary

The elements of the periodic table provide many different ways of investigating how the Earth system operates. In many cases, however, the study of major and trace elements is often treated separately. Many of the most interesting advances in geochemistry have come from a holistic understanding of the periodic table.

Geochemical Exploration

John F. H. Thompson
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Definition

Geochemical exploration, or exploration geochemistry, is a Geochemical explorationspatial sampling and analysis methodology used extensively in the search for mineral resources and routinely for petroleum. The approach is based on the natural dispersion of elements, minerals, and compounds from exposed or concealed mineral or petroleum deposits, whether by physical, chemical, or biological processes. Dispersion generates geochemical footprints significantly larger than the source deposit. Detection of concentrations of elements or minerals above what is expected or defined as background, and definition of the dispersion pattern, can lead to the discovery of new resources of economic interest. A similar methodology can be used to document contamination or pollution from anthropogenic sources, this approach usually being considered part of environmental geochemistry.

Background

Chemical sampling of soils and plants began in Russia and Scandinavia in the 1930s but was developed as exploration geochemistry to support mineral exploration when analytical techniques became routinely available, especially for trace element analysis, in the postwar period (Hawkes 1957; Ginzburg 1960; Kyser et al. 2015). Extensive use of exploration geochemistry in the 1960s and 1970s, particularly in

northern countries, led to a series of important publications (e.g., Levinson 1980; Govett 1981–1984). Throughout this period, and subsequently in the 1980s and 1990s, the use of geochemical surveys expanded in the search for different types of mineral deposit in a wide range of geological, surficial, and environmental settings. Over time, the focus expanded from trying to detect partially exposed deposits to include terrains where potential mineral deposits may exist beneath cover sequences at considerable depth (Cameron et al. 2005; Kelley et al. 2006). Geochemical exploration continues to advance with new approaches and improved analytical methods (Coker 2010).

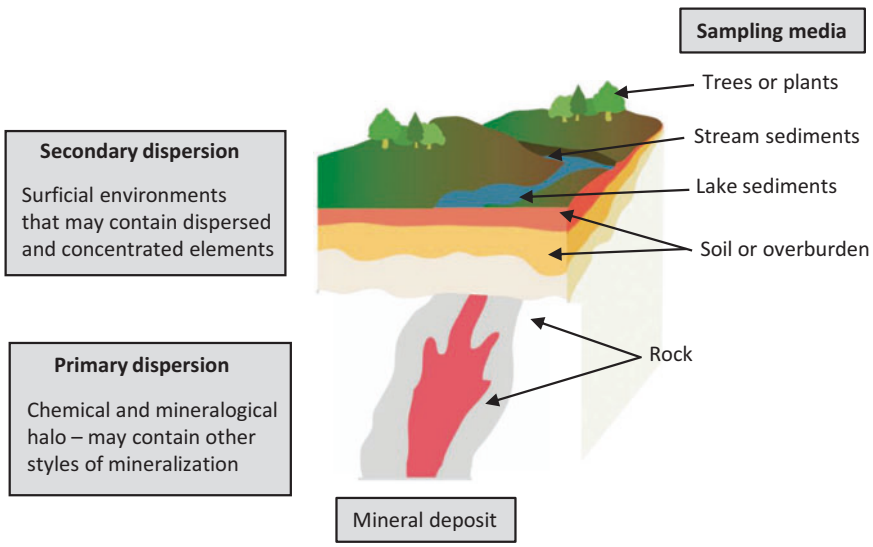
Dispersion Processes

Mineral deposits represent natural concentrations of elements or minerals, which if proven to be economic may be termed an ore deposit (Arndt et al. 2017; Fig. 1). In some cases, formation of mineral deposits is concurrent with a significant chemical and mineralogical halo extending up to several kilometers from the deposit. The resulting geochemical pattern may contain specific trace elements related to the mineral deposit and complementary changes in secondary mineralogy. In some cases, the broad halo hosts distinct zones that change in character with increasing distance away from the principal mineral deposit. The processes that generated these geochemical haloes during formation of mineral deposits are termed primary dispersion by Kyser et al. (2015).

In contrast to primary dispersion, secondary dispersion typically occurs due to movement of elements in the near-surface environment relatively recently (1000s of years to a few million years ago), in most cases long after formation of the mineral deposit (Kyser et al. 2015). Secondary dispersion results from the presence of mineral deposits within a few hundred meters of the surface and therefore is an important discovery tool.

A variety of surface and near-surface processes may result in the dispersion of elements or minerals including:

1. Physical erosion and transport of minerals away from the mineral deposit in streams, glaciers, or during mass wasting. Minerals that are resistant under surface conditions may be transported tens of kilometers from their source. Other minerals may breakdown resulting in chemical transport of elements and precipitation or entrapment in secondary minerals or organic sites. Stream flow and other geomorphic processes may concentrate elements and minerals locally enhancing the dispersion pattern.
2. Physical and chemical movement of elements and minerals in soils that form above exposed or buried mineral deposits. The character and nature of the dispersion pattern in soils and regolith profiles are strongly influenced by climate, soil type, and topography. Dispersion can be on the hundreds of meters to kilometers in scale.
3. Chemical mobility in the subsurface may result from electrochemical reactions between conductive, sulfide-rich mineral deposits, wall rocks, and groundwater. The resulting subtle dispersion pattern may be detected at surface even where the mineral deposit is located tens or hundreds of meters below surface and in some cases when covered by overburden that is completely unrelated to the mineral deposit. In some environments, the sediments in lakes may accumulate elements that reflect regional dispersion from mineral deposits in the area.
4. Biological activity can release elements, e.g., through bacterially enhanced oxidation of sulfides, with subsequent transport of elements through plant root systems and



Geochemical Exploration, Fig. 1 Different types of media that can be sampled to detect a mineral deposit (in *red*) including those related to primary and secondary dispersion processes (Adapted from Kyser et al. 2015)

concentration in the various parts of trees and plants. The understanding and use of these dispersion processes is termed biogeochemistry (Dunn 2007).

Sampling Media and Methods

Based on the understanding of dispersion processes and their likely activity in different geologic, climatic, and topographic settings, geochemical exploration programs are designed to sample specific media that are most likely to display the distal geochemical signature of a desired mineral deposit, if present (Fig. 1). Media in widespread use include:

- Rocks sampled at surface or from drill core that are analyzed to detect variations in bulk chemistry (lithogeochemistry) resulting from mineralizing processes (Lawie 2009). Elevated levels of pathfinder elements in the rock or within specific minerals and the presence of characteristic mineral assemblages may be indicative of the outer zones of mineral deposits (e.g., Cooke et al. 2014).
- Stream sediments selected from hydromorphic sites that are most likely to collect heavy minerals and related elements. In some cases, large bulk samples are collected for bulk leaching (BLEG), while other techniques focus on specific size fractions or locations in stream beds.
- Soils form from the underlying bedrock and surface plant organic material with their character largely dependent on climate. If the bedrock is mineralized, soils will likely contain elements indicative of this mineralization. The geochemical signature may be significantly larger than the underlying mineralization due to chemical mobility at the water table or mass movement of soils. Soils form distinct horizons reflecting different climatic and topographic conditions, and the concentration of critical elements commonly varies among these horizons. Soil sampling therefore targets specific horizons during geochemical exploration using pits, augers, or overburden drills to reach the desired level. Particle size fractions and organic material have also been targeted for partial or selective leach extraction based on evidence to suggest that specific elements may reflect deeply buried mineralization (e.g., Cameron et al. 2005).
- Talus or scree may be sampled in mountainous or arid regions where soils are poorly developed. The fine fraction (<100 μm) sieved from talus material may contain elevated elements reflecting the presence of a mineral deposit beneath the talus.
- In glaciated terrains, overburden consisting of extensive glacial till masks local geology and hinders most conventional geochemical exploration approaches. In some regions with subdued topography, major esker systems can be preserved over hundreds of kilometers. Individual eskers may contain distinct suites of minerals that are characteristic of kimberlites, the host for diamonds, a considerable distance down-ice from the sample site. Sampling of specific size fractions and careful sample preparation are required. This approach was significant in the discovery of diamonds in the Northwest Territory, Canada.
- Organic-rich sediments in lakes that are abundant in glaciated terrains may contain enriched levels of elements indicative of mineralization in the region. Rapid sampling over large areas is possible using helicopters with floats. While useful as a first pass, the data can be ambiguous and other approaches are required to verify and define the presence of elements that may reflect mineralization.
- Trees and plants, particularly those with deep root systems, may concentrate elements indicative of buried mineralization. Selective sampling (e.g., bark, new growth, treetops, tree cores) of specific species has been found to generate the best signature, i.e., elevated concentrations of specific elements relative to background.
- In some regions, ants and termites build large mounds above extensive deep networks of small passageways. These mounds may include material from unexposed bedrock and therefore provide a medium for mineralogical and geochemical sampling.
- The importance of microbes in soils is well recognized. The recent development of genomic techniques allows the identification of specific species, that is, some cases may reflect geochemical conditions related to buried mineralization. The efficacy of this approach is still under investigation and development.
- Water wells for individual properties and communities provide access to local groundwater, and more extensive surveys of groundwaters and aquifers have been completed in some areas. Where documented, the chemistry of groundwaters varies considerably as result of interaction with rocks at local and potentially regional scales. The use of these data for mineral exploration has been considered, but there are few examples of direct relationships between water chemistry and mineralization and related successful application to mineral exploration.

Selection of an appropriate sampling medium and sampling technique is usually aided and tested by an orientation survey in the area of interest. This may be carried out over known mineralization, if available, but may be based on the relative response from different media, for example, different soil horizons.

Analytical Techniques

Over the last 20–30 years, there have been major advances in the available analytical techniques for analyzing samples of

bulk and selected mineralogical samples from geochemical exploration programs (Kyser et al. 2015). The detection limits have decreased markedly from ppm to ppb and, in some cases, ppt levels. At these levels, subtle and distal anomalous signatures may be detected with careful data analysis required to define background values (see below). Furthermore, many techniques now routinely provide multi-element data (30–45 elements) at relatively low costs. Commercial analytical laboratories commonly offer different packages each designed for different types of program (reconnaissance to detailed project scales), media, and geological environment or mineral deposit type. Isotopic analyses are also becoming more routinely available and are being used for geochemical exploration in selected settings.

Field work has also benefited from the development of handheld analytical tools that enable real-time analysis of soils and rocks at concentration levels that may be meaningful for exploration even with higher detection limits and lower precision than laboratory techniques. The most used tool for geochemical Short-wave infrared (SWIR) toolsX-ray fluorescence spectroscopy (XRF)analysis is portable X-ray fluorescence spectroscopy (XRF) (e.g., Hall and McClenaghan 2013), while portable short-wave infrared (SWIR) tools provide important mineralogical data.

Data Analysis and Interpretation

Interpretation of geochemical data (Grunsky 2010) requires careful data analysis, first and foremost to verify the quality of the data using quality control – quality assurance (QA/QC) procedures with blanks, duplicates, and standards. Assuming the data meets analytical standards, subsequent procedures may be used to level data from different programs and examine the influence of regional bedrock, topography, catchment basins, overburden types, and sampling media. The goal is to establish geochemical background levels for critical elements of interest for carefully defined regions with uniform characteristics and hence identify specific areas with geochemical values above background. These anomalous results may require follow-up sampling and application of other exploration techniques to define targets for detailed work and drill testing. Given the volume of multi-element data now routinely available, a variety of spatial and multivariate statistical techniques may be used to aid interpretation and seek anomalous results that are not immediately obvious from individual pathfinder elements. Lithogeochemical analysis of whole-rock geochemical data may directly identify distal metal signatures or can be used to define rock units and alteration of these units that may be indicative of mineralizing processes even in the absence of metal signatures.

Summary

Exploration geochemistry has been a critical component of mineral exploration for well over 50 years. Many discoveries of economic mineralization were made using geochemical exploration methods, although usually in conjunction with other methods. Approximately 40% of discoveries in the 1970–2000 period can be attributed at least partially to geochemical exploration (Schodde 2014), but the contribution appears to have declined somewhat in recent years due to the increased emphasis on exploration around existing mines and at depth (Arndt et al. 2017). New techniques and different media, decreasing detection limits, increasing multi-element and isotopic techniques at lower cost, and new portable technologies continue to offer improved ways to discover mineral deposits, particularly when integrated with other geological, geophysical, and remote-sensing exploration techniques.

Geochemical Reference Materials

Thomas C. Meisel
General and Analytical Chemistry, Montanuniversität Leoben, Leoben, Austria

Definition

The ISO/REMCO Committee on reference materials defines reference materials (RMs) as "material, sufficiently homogeneous and stable with respect to one or more specified properties, which has been established to be fit for its intended use in a measurement process." This definition is accompanied by several notes. Note 2 states that properties can be quantitative or qualitative. Other notes relate to the use of RMs, which may include the calibration of a measurement system, assessment of a measurement procedure, assigning values to other materials, and quality control. Note 4 highlights the importance of using an RM independently of other processes: "An RM can only be used for a single purpose in a given measurement. For example, it cannot be used for both calibration and method validation in the same measurement process" (ISO Guide 30, 2015).

History and Production of Geochemical Reference Materials

In the field of geosciences, compared with other scientific fields, analytical (geo)chemists realized the need for matrix-matched geochemical reference materials in the first half of the twentieth century. The first large-scale interlaboratory study (Fairbairn et al. 1951) in the 1950s resulted in the production of a whole series of geochemical reference materials that have been used for calibration, method development, and validation and for quality control purposes in analytical geochemical laboratories ever since.

In the early days of the production and characterization of reference materials, compilations of data from large-scale interlaboratory studies were used to characterize the major, minor, and trace element and compound mass fractions. Emphasis for characterization studies was put on homogenous, easy to digest geological materials to reduce additional uncertainty components of the consensus value. The top ten most accessed geochemical reference materials on the GeoReM database (http://georem.mpch-mainz.gwdg.de), which is about 40% of all searches, are seven basalts (five as powder and two as glass), one andesite, and two synthetic glasses (NIST SRM 610 and 612). Unfortunately, this distribution does not reflect the current diversity of geochemical studies.

The nonconformity of the previous RM characterizations with modern metrological standards and the limited diversity of available reference materials have led the International Association of Geoanalysts (IAG) to produce certified reference materials (CRMs) according to ISO/REMCO ISO Guides 34 and 35 (ISO Guide 34 2009; ISO Guide 35 2006). The guides, based on internationally accepted metrological concepts valid for all types of CRMs, have been specifically adapted for the certification of geochemical reference materials (IAG protocol, Kane et al. 2003; Kane et al. 2007). The selection of competent laboratories providing data, a diversity of independent measurement principles, measurement uncertainties, and traceability statements are all integral parts of metrologically correct certificates.

Although for the latest geochemical reference materials, certified data for all rare earth elements are provided, and other scientifically and economically important elements such as Tl, Bi, In, Te, Se, Re, Au, and platinum group elements (Ru, Rh, Pd, Os, Ir, and Pt) as well as all halogens are not yet certified. Reasons for this unsatisfactory situation are the low natural abundance of these elements in the ng/kg and µg/kg range and the limited number of specialized laboratories capable of providing reliable data.

The development and certification of microanalytical reference materials for their trace element content as well as isotope amount ratio measurement and age determinations with SIMS and LA-ICP-MS is the most recent and challenging development in geochemical reference material production.

Definition

The transfer of energy between useful work and heat.

Introduction

Thermodynamics concerns the conversion of energy in the Earth. Length scales and times scales for Earth processes are so vast, and the mineral assemblages and fluids in nature are so complicated, that equilibrium thermodynamics is usually the starting point for any geochemical investigation. This point was established in the earliest days of modern science by the renowned physical chemist Jacobus Van't Hoff (1852–1911), who used the then newly established Gibbs Phase Rule to reconstruct the composition of ancient seawater from the mineral assemblages found in evaporite deposits (see Eugster 1971).

Peter A. Rock is deceased.

Laws of Thermodynamics

The laws of thermodynamics differ from most other scientific laws in that they are usually stated in terms of the *impossibility* of achieving certain types of energy transfers. The laws can be stated in terms of the operation of machines or in terms of the primary thermodynamic variables of temperature, energy, heat, work, and entropy. Here we do both:

First law: It is impossible to construct a device that operates in a cyclical manner and performs work without putting energy into the device.

Second law: Entropy increases in the universe. Or, stated differently, it is impossible to construct a device that can transfer energy as heat from a low-temperature reservoir to a higher-temperature reservoir without adding energy as work. It is impossible to construct a device that operates in a cyclical manner and takes in energy as heat from a high-temperature reservoir and performs work without, in some part of the cycle, discharging energy as heat to a low-temperature reservoir.

Third law: It is impossible to construct a device capable of decreasing the temperature of any macroscopic system to the absolute zero of temperature (0 K).

Stated in terms of the primary thermodynamic functions of temperature, energy, and entropy, the laws of thermodynamics can be stated succinctly as follows:

First law: The total energy is conserved (i.e., remains unchanged).

Second law: The total entropy increases.

Third law: The absolute (Kelvin) temperature remains above 0°.

These laws provide geochemists with (i) the conditions for the establishment of equilibrium in a system that includes chemical reactions, heat transfer, and mechanical strain; (ii) criteria to eliminate impossible processes; (iii) equations to convert thermodynamic data, such as the energy and entropy changes, into an equilibrium constant; and (iv) equations to predict the effects of changes in temperature, pressure, or composition on this reaction equilibrium.

The starting point in exploring thermodynamic laws is with knowledge of the experimental and thermodynamic properties of temperature, heat, work, energy, and entropy. Understanding work and heat is not difficult, but an understanding of temperature, energy, and entropy requires more effort.

Temperature

A device designed to measure temperature is called a thermometer, of which there are many types. Familiar examples are the liquid-in-glass capillary, thermocouples, and

resistance thermometers such as platinum wires and thermistors. All of these devices have a property that varies monotonically with temperature. The most fundamental thermometer, for example, is the constant-volume, ideal-gas thermometer, which is based on the fact that nonassociating gases obey the ideal-gas equation:

$$PV = nRT \tag{1}$$

in the limit as $P \rightarrow 0$ where P is the pressure of the gas, V is the volume, n is the number of moles of the gas, and R is the gas constant. With a constant-volume gas thermometer, we measure the temperature of a fixed reference point, such as the melting point of tin metal, as follows:

$$\begin{aligned} T &= (273.16\,\mathrm{K}) \lim_{P_{273.16\mathrm{K}} \rightarrow 0} \left[\frac{P_T}{P_{273.16\mathrm{K}}} \right] \\ &= (273.16\,\mathrm{K}) \left(\frac{nRT/V}{nR273.16/V} \right) \end{aligned} \tag{2}$$

We measure P_T, the pressure of n moles of the gas at temperature T for progressively smaller values of n. The resulting calculated values of temperature are extrapolated to zero pressure to obtain the thermodynamic temperature. The value of $P_{273.16\,K}$ is the corresponding measured pressure of the gas when the thermometer bulb is in contact with water at its triple point. The triple point of water is the single most important accessible reference point in thermometry and is assigned a temperature of exactly 273.16 K to preserve close numerical agreement with older temperature scales, such as the Celsius scale.

The temperature scale defined by Eq. 2 is an absolute scale where zero is the lowest possible temperature and all temperatures are positive. This scale is called the absolute Kelvin temperature scale, and temperatures are expressed as kelvins. Celsius temperatures are related to Kelvin temperatures via the equation

$$t/^{\circ}\mathrm{C} = T/K - 273.16 \tag{3}$$

The temperatures of fixed reference points obtained in the manner outlined above are, in turn, used to calibrate other more convenient thermometers.

Energy, Work, and Heat

Energy is an abstract mathematical concept that is quantified in terms of an energy function, U. Some other thermodynamic functions also are called energy functions (Gibbs energy, Helmholtz energy) and are chosen specifically as state functions that yield exact differentials in terms of experimentally convenient variables such at T and P.

Energy is not a thing. There are no meters capable of directly measuring energy, yet there are electric-current meters, gas-flow meters, volume meters, mass meters, pressure meters, length meters, time meters, and thermometers. These measureable properties are used to calculate energy changes. Determination of the amount of energy transferred from one system to another always involves measurements of the appropriate physical parameters followed by calculations involving the appropriate energy formulae.

The most significant mathematical property of the energy function is that of conservation. The principle of energy conservation amounts to the statement that, for any real process, the total amount of energy remains exactly the same at the end of the process as it was at the beginning. Energy can be transferred and transformed, but it cannot be created or destroyed. This conservation relates to the definition of a state function, which is also independent of path.

Work and heat are the only modes of energy transfer between systems. The transfer of energy as work requires the existence of an unbalanced force between a system and its surroundings. The transfer of energy as *heat* requires the existence of a temperature difference between the system and its surroundings. When a force F acts on a system and displaces the system by a differential amount dx, then the work done on the system is given by classical mechanics as

$$\delta w = -F dx \tag{4}$$

In general, the *work* done on a system depends on the path along which the process is carried out and must be specified (here from states $1 \rightarrow 2$):

$$w = -\int_1^2 \mathrm{F dx} \tag{5}$$

in order to calculate work: w. The minus sign in Eq. 5 is chosen to make work done on the system ($dx < 0$) a positive quantity. When the path must be specified before the integral in Eq. 5 can be evaluated, then the integral is called a line integral. If the work done is independent of the path, e.g., the work done in lifting a weight in a constant gravitational field

$$\begin{aligned} w &= -\int_1^2 F dx = \int_1^2 mg\, dh \\ &= mg(h_2 - h_1) \end{aligned} \tag{6}$$

then the force F is said to be conservative; in this case the formula $w = mg\Delta h$ is used to calculate the amount of energy.

A conservative force always can be expressed as the negative derivative of a potential energy, φ, with respect to the displacement:

$$F = -\frac{d\varphi}{dx} \tag{7}$$

and thus for a conservative force:

$$w = -\int F dx = \int_1^2 \frac{d\phi}{dx} \qquad dx = \int_1^2 d\phi = \phi_2 - \phi_1 \tag{8}$$

Note that if the force is conservative, then the work done depends only on the end states (initial and final) for the process and is thus path independent; this point is very important. These path-independent (state) functions and their manipulation lie at the core of thermodynamics.

If at any stage in the process energy is transferred as heat, then the force is not conservative, the value of w depends on the path, and we move from classical mechanics to thermodynamics. Energy added as heat to a system is taken as positive; and the SI unit of energy is the joule, J:

$$\begin{aligned} \text{energy} &= \text{force} \cdot \text{displacement} \\ &= \text{mass} \cdot \text{displacement} \cdot \text{acceleration} \end{aligned}$$

$$1\ \text{J} = (1\ \text{kg}) \cdot (1\ \text{m} \cdot \text{s}^{-2}) \cdot (1\ \text{m}) = 1\ \text{kg} \cdot \text{m}^2\text{s}^{-2} \tag{9}$$

For a general process involving both work and heat transfers, the first law of thermodynamics takes the form

$$dU = \delta q + \delta w \tag{10}$$

The energy function, U, is also called the internal energy and is a thermodynamic state function. The differential of a state function is said to be exact, because the value of $\Delta U = U_2 - U_1$ for the process is path independent, even if energy is transferred as heat in the process:

$$\int_1^2 dU = U_2 - U_1 = \Delta U = \int_1^2 dq + \int_1^2 dw = q + w \tag{11}$$

A key point to recognize is that for a given change (i.e., $1 \rightarrow 2$), the value of $U_2 - U_1$ is independent of path, whereas the values of q and w depend on the path. It is only the sum $q + w$ that is independent of path. This statement constitutes the *essence* of the first law of thermodynamics. If the process is adiabatic (i.e., $\delta q = 0$), then δw is exact, because $w = \Delta U$. If no work is done (i.e., $\delta w = 0$), then δq is exact (pure heat transfer), because $q = \Delta U$.

In summary, heat and work are modes of energy transfer, and energy cannot be created or destroyed; the energy of a system is characterized by its internal energy U. A system cannot *possess* heat or work; one can only perform work, that is, add energy by force gradients, and transfer heat.

Enthalpy and Heat Capacity

Much of the mineralogy that we observe at the Earth surface was formed by reactions at much higher temperatures, and these are slowly converted to minerals that are stable at low temperatures and in the presence of water. It is therefore desirable to have a thermodynamic function that describes the energy transferred as heat at a constant pressure but which does not depend on the path. Consider a process involving only pressure-volume work for which

$$w = -F\,dx = -\left(\frac{F}{A}\right)A\,dx = -P_{ext}\,dV \tag{12}$$

where P_{ext} denotes the externally applied pressure and we employ the definition of pressure $P =$ force/area $P = \frac{F}{A}$ and note that the volume element $dV =$ (area of the base)$\cdot$ (vertical displacement) $= A\,dx$. Combining Eqs. 11 and 12 yields

$$dU = \delta q - P_{ext}\,dV \tag{13}$$

We now define the enthalpy, H, a thermodynamic state function, as

$$H \equiv U + PV \tag{14}$$

From Eq. 14 we obtain by differentiation

$$dH = dU + PdV + VdP \tag{15}$$

Combining Eqs. 13 and 15 yields

$$dH = \delta q + VdP \tag{16}$$

or at constant pressure ($dP = 0$):

$$dH = \delta q_p \tag{17}$$

From Eq. 17 we see that the addition or removal of energy as heat from a system at constant P is equal to the change in enthalpy of the system.

The *heat capacity* of a system is a quantitative measure of the capacity of a system to take in energy as heat. The greater the heat capacity of a system, the smaller the change in temperature produced by the input of energy as heat. The heat capacity is necessarily positive and for a two-phase system (e.g., ice + liquid water) is infinite as long as both phases exist in equilibrium. The heat capacity, C_x, of a system

at constant x (where x is a thermodynamic state function, such as pressure) is defined as follows:

$$C_x = \lim_{\Delta T \to 0} \left(\frac{q_x}{\Delta T} \right) = C_x(x, T) \tag{18}$$

where $C_x(x,T)$ denotes that C_x is a function of both x and T. For a constant-pressure process we have from Eqs. 18 and 17:

$$C_p = \lim_{\Delta T \to 0} \left(\frac{q_p}{\Delta T} \right) = \lim_{\Delta T \to 0} \left(\frac{\Delta H}{\Delta T} \right)_P = \left(\frac{\partial H}{\partial T} \right)_P \tag{19}$$

Note also from Eq. 19 that

$$q_P = \int_1^2 C_P dT \tag{20}$$

A large heat capacity indicates that the system can take up substantial amounts of energy as heat owing to storage of the energy in the internal modes (translation, rotation, vibration, molecular dissociation) of the constituent particles. For example, the molar heat capacities of solid, liquid, and gaseous water over the temperature range 250–500 K are

$$\mathrm{H_2O(s)}: C_p = 37.66\ \mathrm{J \cdot K^{-1} \cdot mol^{-1}}$$
$$\mathrm{H_2O(l)}: C_p = 75.32\ \mathrm{J \cdot K^{-1} \cdot mol^{-1}}$$
$$\mathrm{H_2O(g)}: C_p = 30.54\ \mathrm{J \cdot K^{-1} \cdot mol^{-1}} + \left(1.03 \cdot 10^{-2} T\right)\ \mathrm{J \cdot K^{-2} \cdot mol^{-1}}$$

The roughly twofold greater heat capacity of liquid water relative to solid or gaseous water arises from the fact that a substantial (roughly half) of the heat energy input to liquid water is absorbed in breaking the hydrogen bonds in liquid water (≈20 kJ/mol). Ice absorbs energy as heat below its melting point without breaking any hydrogen bonds; ice is a completely hydrogen-bonded solid, whereas there are no hydrogen bonds in gaseous water.

Entropy

The concept of entropy and the science of thermodynamics have their origin in the fact that most naturally occurring processes involve the transfer of energy as heat. The first law of thermodynamics places no restrictions on energy transfers other than conservation and is completely silent about the direction of transfer. It is well known, however, that there are other restrictions on energy transfers. Some restrictions are:

(a) Heat always flows spontaneously from higher- to lower-temperature systems.
(b) Heat can be induced to flow from a lower- to a higher-temperature system only through the addition of energy as work.
(c) When a system undergoes a change in thermodynamic state, then the system and its surrounding (i.e., everything but the system) cannot both be restored exactly to their original states. All naturally occurring processes are in this sense irreversible.

A thermodynamically *reversible* process is defined as one for which the force and temperature differences between the system and the surroundings are never more than infinitesimal. A reversible process constitutes an ideal limiting case where the system can be restored to their original state and is thus of theoretical importance.

The second law of thermodynamics is fundamentally different from the first law in that it concerns the direction in which processes occur in nature. Rudolf Clausius, in 1865, chose the word *entropy* because it translates from the Greek as τρεπειυ (to a give direction), and the implicit connection of the second law with the passage of time has led to its characterization as "times arrow." The total entropy of the universe can only increase with time as the universe evolves to more probable distributions of mass and energy.

A mathematical statement of the second law of thermodynamics is as follows: for any change in defined thermodynamic states of a system, the change in entropy of the system, dS_{sys}, is

$$dS_{sys} \geq \frac{\delta q_{sys}}{T} \tag{21}$$

where T is the absolute thermodynamic temperature (K). The equality sign holds if the process is reversible, and the inequality sign holds if the process is irreversible. The function, S, the entropy, is a thermodynamic state function and has the units $\mathrm{J \cdot K^{-1}}$.

Suppose we have a system and its surroundings between which energy can be transferred. If the system undergoes a change in state, then the total entropy change is

$$dS_{tot} = dS_{sys} + dS_{sur} \tag{22}$$

If the process is adiabatic, then $\delta q_{sys} + \delta q_{sur} = 0$ and from Eq. 21 $dS_{sur} \geq 0$ and $dS_{sys} \geq 0$. Thus $dS_{tot} \geq 0$. The maximization of entropy provides the stability criterion for Gibbs energy and ultimately for our definition of equilibrium.

Suppose now that the system undergoes an isothermal process, $T = T_{\mathrm{sys}} = T_{\mathrm{sur}}$. From the second law, we have

$$\mathrm{dS_{sys}} \geq \frac{\delta q_{\mathrm{sys}}}{T} \text{ and } \mathrm{dS_{sur}} \geq \frac{\delta q_{\mathrm{sur}}}{T} \tag{23}$$

but $q_{\mathrm{sys}} = -q_{\mathrm{sur}}$ and thus $\Delta S_{\mathrm{tot}} \geq 0$. Note that in both cases there is net entropy production if the process is

irreversible, whereas the total entropy remains unchanged if the process is reversible.

All real processes involve some degree of irreversibility and thus lead to an increase in the total entropy of the universe. Unlike energy, entropy is not conserved, except in the hypothetical limiting case of a reversible process.

A thermodynamic system is said to be in an equilibrium state when it can no longer undergo any spontaneous, entropy-producing processes. The increase in total entropy that occurs in an irreversible process is a consequence of the failure to fully exploit the potential for doing work. When less than the maximum possible work is done in a process, net entropy is produced. The total entropy can never decrease, and, for a given energy and volume, a maximum in entropy indicates the most stable configuration, that is, equilibrium (see Dill and Bromberg 2011).

Entropy, like energy, is in essence an abstract mathematical concept. Because entropy is a state function:

$$\int_1^2 dS = S_2 - S_1 = \Delta S \tag{24}$$

For a given change in state (e.g., 1 → 2), the change in entropy of the system (but not the total entropy change, $\Delta S_{tot} = \Delta S_{sys} + \Delta S_{sur}$) is independent of the path that the system takes from state 1 to state 2.

Entropy is not a thing, and there are no entropy meters. Rather, entropy changes are calculated from measurable quantities, such as temperature, pressure, volume, and heat capacity. Entropy was described by the great thermodynamicist J. Willard Gibbs as a measure of the "mixed-up-ness" of a system, that is, the more disordered or random a system is, the higher is its entropy. Modern statistical mechanics relates this concept to the probability of accessible energy states (see Dill and Bromberg 2011).

Compared to the same pressure and temperature, liquids are more disordered than solids, and gases are more disordered than liquids. This result follows from the fact that the molecules of a gas have more freedom to move around than the molecules of a liquid. The same holds true for the molecules or ions of a liquid as compared to those of a solid. The melting of a solid involves an entropy increase of 8–40 J K^{-1} mol^{-1}. The temperature dependence of the entropy is found from Eqs. 21 and 18. From Eq. 21 we have for an isothermal pure heat transfer (i.e., $\delta w = 0$) at constant pressure $q_p = T\Delta S$. Substitution of this result into Eq. 19 yields

$$C_p = \lim_{\Delta T \to 0}\left(\frac{q_p}{\Delta T}\right) = T \lim_{\Delta T \to 0}\left(\frac{\Delta S}{\Delta T}\right)_p = T\left(\frac{\partial S}{\partial T}\right)_p \tag{25}$$

$$\text{Thus}: \left(\frac{\partial S}{\partial T}\right)_p = \frac{C_p}{T} \tag{26}$$

or

$$\Delta S = \int_1^2 \frac{C_p}{T} \mathrm{dT}\ (\text{at constant } P) \tag{27}$$

Because $C_p > 0$, the entropy of a substance always increases with increasing temperature at constant pressure. The increase in the entropy of a substance that undergoes an increase in temperature at fixed pressure is a consequence of the increased thermal randomness of the molecules at the higher temperature. A greater amount of energy is distributed over the same number of particles.

Entropies of solids can be determined using Eq. 27 and cryogenic calorimetry where the temperature of state 1 is near (but of course not at) absolute zero. These *third-law entropies* have been determined for a range of minerals, leading to important thermodynamic equations of state for describing the minerals in rocks (see Robie et al. 1978; Chase et al. 1986). They are referred to as "third-law entropies" because they employ the property that the entropy of a pure substance is zero at 0 K (the third law of thermodynamics).

Applications of the First and Second Laws of Thermodynamics

Combination of the first law with the second law yields

$$dU \leq TdS + \delta w \tag{28}$$

In applying Eq. 28 it is essential to include all of the relative work terms, of which there may be several. That is,

$$\delta w = \sum_i \delta w_i \tag{29}$$

as required by energy conservation. Some commonly encountered types of work are pressure-volume (expansion/compression) work, electrical work, surface area increases and decreases, and magnetic work.

Suppose we only have to deal with pressure-volume work and that the process occurs reversibly. In this special case Eq. 28 becomes

$$dU = TdS - PdV \tag{30}$$

Because U and S are state functions, we can compute the values of ΔU and ΔS along a reversible path between the given initial and final states of the actual process and equate the results for ΔU and ΔS for the system to those for the actual irreversible process. The values of q and w differ for the two paths, but not ΔU_{sys} or ΔS_{sys}.

Equation 28 is the differential equation used to calculate ΔU, which can be converted into more convenient stability criteria by choice of fixed variables. It expresses the change in the dependent variable in terms of changes in the independent variables S and V, that is, $U = U(S,V)$. The variables S and V are not convenient variables in geochemistry because they are difficult to control in the laboratory. More convenient variables for experimental work are pressure and temperature, which lead directly to a definition of the Gibbs energy via a Legendre transform of the combined first and second laws of thermodynamics. We can transform Eq. 30 into a differential equation with P and T as independent variables as follows:

$$\begin{aligned} &dU - TdS + PdV = 0 \\ &dU - TdS + PdV - SdT + VdP = -SdT + VdP \\ &d(U - TS + PV) = -SdT + VdP \end{aligned} \tag{31}$$

For compactness, we now define the thermodynamic energy state function, G, that can be used as stability criterion for system equilibrium in terms of the more convenient variables, T and P:

$$\begin{aligned} &G = U + \mathrm{PV} - \mathrm{TS} = H - \mathrm{TS} \\ &\text{where}: H = U + \mathrm{PV} \end{aligned} \tag{32}$$

The function G is called the Gibbs energy, or Gibbs free energy, after its creator, J. W. Gibbs, and plays a familiar role in geochemistry. From Eqs. 28 and 29 we have a combination of the first and second laws of thermodynamics:

$$dG = -SdT + VdP \tag{33}$$

which gives the differential equation for dG, where $G = G(T,P)$. Because dG is an exact differential, G is a state function, and from mathematics we can write

$$dG = \left(\frac{\partial G}{\partial T}\right)_p dT + \left(\frac{\partial G}{\partial P}\right)_T dP \tag{34}$$

Comparison of Eqs. 34 and 33 leads to

$$\left(\frac{\partial G}{\partial T}\right)_p = -S \tag{35}$$

$$\left(\frac{\partial G}{\partial P}\right)_T = V \tag{36}$$

Equation 35 is a restatement that the temperature dependence of the Gibbs energy is determined by the entropy, and Eq. 36 shows that the pressure dependence of the Gibbs energy is controlled by the volume. One could have employed a similar approach to achieve the Helmholtz free energy from the combined first and second laws of thermodynamics. The Helmholtz energy has as its natural variables temperature and volume rather than the natural variables of temperature and pressure of the Gibbs energy. Helmholtz free energies are used in cases where the volume is easily controlled, such as in computer simulations.

Because dG is an *exact* differential, it follows directly that the second cross partial derivatives are equal. This property is characteristic of an exact differential:

$$\left[\frac{\partial}{\partial P}\left(\frac{\partial G}{\partial T}\right)_P\right]_T = \left[\frac{\partial}{\partial T}\left(\frac{\partial G}{\partial P}\right)_T\right]_P \tag{37}$$

Substitution of Eqs. 35 and 36 into 37 yields

$$\left(\frac{\partial V}{\partial T}\right)_P = -\left(\frac{\partial S}{\partial P}\right)_T \tag{38}$$

Equation 38 is called a Maxwell relation after the early thermodynamicist James Clerk Maxwell (1831–1879) and is especially useful for computing changes in entropy with pressure when the equation of state (e.g., $V = V(T,P)$) for the system is known.

It is simple to illustrate the connection between the abstract thermodynamic functions and measurable properties of a mineral or solution if these measured properties are expressible as equations. For example, consider $S = S(T,P)$ from which we can write

$$dS = \left(\frac{\partial S}{\partial T}\right)_P dT + \left(\frac{\partial S}{\partial P}\right)_T dP \tag{39}$$

Substitution of Eqs. 26 and 38 into 39 yields

$$dS = \frac{C_p}{T} dT - \left(\frac{\partial V}{\partial T}\right)_P dP \tag{40}$$

One job of experimental petrologists is to evaluate equations of state that describe minerals and fluids as a function of temperature and pressure. Suppose we have a solid for which data on these properties had been accumulated and shown to be fit by equations of the form

$$C_p = n(a + bT) \qquad \text{and} \qquad V = nV_o(1 + \alpha T - \beta P) \tag{41}$$

where n is the number of moles and a, b, α, β, and v_o are constants characteristic of the particular solid. Substituting these two expressions into Eq. 40 yields

$$dS = n\left(\frac{a}{T} + b\right)dT - (nV_o\alpha)dP \tag{42}$$

which, on integration from P_1, T_1 to P_2 and T_2, yields for the entropy change of the substance:

$$\Delta S = n\left(a \ln \frac{T_2}{T_1}\right) + nb(T_2 - T_1) - nV_o\alpha(P_2 - P_1) \tag{43}$$

Partial Molar Thermodynamic Functions: Chemical Potential

A conspicuous feature of most rock-forming minerals is their capacity to change composition and to form solid solutions. Furthermore, aqueous solutions evolve considerably in composition along a flow path. Yet up to this point we restricted our treatment to a particular mass of substance of fixed composition. Mother Nature is not so kind.

If we allow the composition and/or the amount of the various chemical components to vary, then we must take this fact into account in our thermodynamic equations. In such case, the Gibbs energy of the system depends not only on T and P but also on the number of moles of the various components of the system (n_1, n_2, n_3,. . . . . .,n_c) where c is the total number of components. Thus:

$$G = G(T, P, n_1, n_2, n_3 \ldots n_c) \tag{44}$$

Because dG is an *exact* differential, we have from mathematics and the chain rule:

$$dG = \left(\frac{\partial G}{\partial T}\right)_{P, n_j} dT + \left(\frac{\partial G}{\partial P}\right)_{T, n_j} dP + \sum_{i=1}^{c} \left(\frac{\partial G}{\partial n_i}\right)_{T, P, n_{j \neq i}} dn_i \tag{45}$$

The notation $n_{j \neq i}$ denotes the set of all mole number except i itself. We now define the chemical potential of the i^{th} component, μ_i, of the system as

$$\mu_i \equiv \left(\frac{\partial G}{\partial n_i}\right)_{T, P, n_{j \neq i}} \tag{46}$$

The chemical potential of component i is thus its partial molar Gibbs energy.

Combination of Eqs. 45, 46, and 33 yields

$$\mathrm{dG} = -\mathrm{SdT} + \mathrm{VdP} + \sum_{i=1}^{c} \mu_i \mathrm{dn}_i \tag{47}$$

Equation 47 is the key equation for the analysis of thermodynamics of solutions and is an expression of the combined first and second laws of thermodynamics. Rearranged, it leads to a familiar form of the Gibbs-Duhem expression.

Another useful equation for solutions is obtained from Eq. 33:

$$\frac{\delta}{\delta n_i}(dG = -SdT + VdP)_{T, P, n_{j \neq i}}$$

or :

$$d\mu_i = -\overline{S}_i dT + \overline{V}_i dP_i \tag{48}$$

where :

$$\overline{S}_i = \left(\frac{\delta S}{\delta n_i}\right)_{T, P, n_{j \neq i}} \quad \text{and} \quad \overline{V}_i = \left(\frac{\delta V}{\delta n_i}\right)_{T, P, n_{j \neq i}}$$

where $\overline{S}_i = \left(\frac{\delta S}{\delta n_i}\right)_{T, P, n_{j \neq i}}$ and $\overline{V}_i = \left(\frac{\delta V}{\delta n_i}\right)_{T, P, n_{j \neq i}}$ are the partial molar entropy and the partial molar volume, respectively, of the ith component in the solution.

A Geochemical Example

A simple geochemical example would be making diamond from graphite at 298 K. Can we circumvent the very exploitive mining of kimberlite pipes by a clean industrial process at equilibrium? Experimental data reported in Robie et al. (1978) yield a change in the volume of the reaction:

$$\mathrm{C(diamond)} = \mathrm{C(graphite)} \tag{49}$$

of $\Delta V^o_{rxn} = +\ 0.1882$ J/mol and a value of ΔG^o_{rxn} (1 bar, 298 K) $= -2.9$ kJ/mol. At equilibrium the chemical potentials of carbon in each phase are equal. Because the activities of these solids are on the mole-fraction scale, and because they are pure, integration of this equation at constant temperature yields

$$\Delta G^o_{\mathrm{rxn}}(\mathrm{P}, 298\mathrm{K}) = 0 = \Delta G^o_{\mathrm{rxn}}(1\,\mathrm{bar}, 298\mathrm{K}) + \int_{1\,\mathrm{bar}}^{P} \Delta V_{\mathrm{rnx}} \mathrm{dP} \tag{50}$$

We use the approximation that ΔV^o_{rxn} is independent of pressure to rearrange the equation:

$$\frac{-\Delta G^{o}_{\mathrm{rxn}}(1\,\mathrm{bar}, 298\mathrm{K})}{\Delta V^{o}_{\mathrm{rxn}}(1\,\mathrm{bar}, 298\mathrm{K})} + 1 = P(\mathrm{bar}, 298K) \qquad (51)$$

The equilibrium pressure to make diamond from graphite is predicted to be 15.4 kbar, which is easily within the reach of commercial equipment or explosive shock-loading methods of synthesis. This example calculation does not tell one whether the reaction can be made to proceed; only that equilibration is possible at the stated conditions.

In summary, equilibrium thermodynamics allows geochemists to describe possible reactions that form and modify the mineral assemblages that make up rocks and soils. The tools are absolutely general and can be applied equally well to solutes in groundwater or the phase changes that account for seismic discontinuities in the deep crust and mantle. Thermodynamic truths are inescapable. The "no" of thermodynamics is absolute. The "yes" of thermodynamics is actually a "maybe" to be decided by the rates of the processes.

Conclusions

An understanding of geochemical thermodynamics allows scientists to make meaningful predictions about the chemical state of mineral and fluid assemblages in the Earth. It is the underpinning of all geochemistry.

Geochemistry

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Definition

As the term implies, geochemistry is a marriage between chemistry and geology, or more broadly geosciences or earth science, and it is arguably a subdiscipline of both. A better explanation of geochemistry is that it is applies chemistry and chemical principles to understanding the Earth and its cosmic environment and to using that understanding to better the human condition. The latter includes not only exploitation of resources but also safeguarding humans and the environment from the consequences of that exploitation.

Impact

Geochemistry has grown over the last 50 or 60 years to touch virtually every aspect of earth science. The contributions of geochemistry to this advance have been simply enormous. Much of this progress has come from innovation in analytical techniques and the ability to assess the nature of natural materials with evermore precision and on evermore finer scales. Geochemists have quantified the geologic time scale through analysis of radioactive and radiogenic isotopes. Through analysis of trace elements such as Ir and stable isotope ratios of C, O, and other elements, geochemists have been able to infer the causes of the crises and events that define that time scale (e.g., Alvarez et al. 1980). Geothermometers and geobarometers based on chemical thermodynamics are used to quantify the depths and temperatures at which magmas crystallize and at which the various metamorphic facies form. These can be combined with radiogenic isotope geochemistry to determine rates of geologic processes, such as magma crystallization, uplift, and erosion. Chemical and isotopic analysis of the components of meteorites provides some of the few hard constraints on how and when the solar system formed and with it the Earth. It is principally through isotope geochemistry that the timing and temperature swings of Louis Agassiz's ice ages have been determined and consequently their cause deduced. The evidence, albeit still controversial, that life was present on Earth by at least 3.8 billion years ago is not physical fossils, but carbon isotope ratios (Rosing et al. 1996). We have learned the atmosphere was barren of oxygen prior to 2.3 billion years ago, the so-called Great Oxidation Event (Holland 2006), and

that its present oxygen-rich nature is due to photosynthesis. Geochemistry is used to trace ocean circulation and biologic productivity, both now and in the past. Indeed, geochemistry is also used to unravel mantle convection patterns. Not surprisingly, instruments for chemical analysis have been key part of probes sent to other heavenly bodies, including Mercury, Venus, Mars, Vesta, Ceres, Jupiter, Saturn, and Pluto and their moons.

Problems such as water and soil pollution, acid rain, the ozone hole, and global warming and climate change are geochemical problems. Addressing these problems requires knowledge of geochemistry. Similarly, most of our nonrenewable resources, such as metal ores and petroleum, form through geochemical processes. Locating new sources of these resources requires geochemical approaches. This will be no less true in the carbon-free energy economy of the future as demand increases for scarce metals such as lithium, neodymium, dysprosium, and tellurium used in batteries, electric generators and motors, and photovoltaics.

Geochemistry has also contributed to archeology and understanding human history, particularly the period preceding written history. Techniques such as ^{14}C and U-Th decay series have been used to date everything from bones and artifacts to cave painting (Pike et al. 2012). Carbon and oxygen isotopes tell us about our ancestor's diet and environment, and the trace element and isotopic compositions of stone and metal tools and coins tell us about trade patterns.

Physicochemical Basis

In the nineteenth century, geochemistry, like geology, was more descriptive than quantitative. As chemists of the late nineteenth and earlier twentieth centuries such as Maxwell, Van't Hoff, Gibbs, Arrhenius, Lewis, and Randall laid the foundations of chemical thermodynamics and kinetics, geochemists such as F.W. Clarke and Victor Goldschmidt (Goldschmidt 1923, 1933) began to apply these approaches that eventually allowed deeper insights into geochemical processes.

Thermodynamics enables prediction of the equilibrium state of a system through analysis of energy and its transformations between chemical energy, heat, and work. In principle then, thermodynamics can predict which minerals will break down as a rock undergoes chemical weathering, which new minerals will replace them, and which elements will be carried away in solution. Thermodynamic magmatic process modeling can predict the sequence of minerals precipitating as magma of a given composition cools and how magma composition will consequently evolve. Thermodynamics can predict the metamorphic reactions and processes that will occur as igneous or sedimentary rocks experience elevated temperature and pressure. Perhaps more valuably, given the composition of a metamorphic rock, the temperature and pressure of metamorphism can be deduced from its constituent minerals and their compositions: something known as thermobarometry.

Before thermodynamics can be applied to geochemical problems, basic thermodynamic properties such as molar volume, entropy, enthalpy, heat capacity, compressibility, and the coefficient of thermal expansion must be determined for a vast array of natural substances. It was not until the second half of the twentieth century that the necessary data was available to allow geochemists such as Hal Helgeson (e.g., Helgeson 1968) and Ian Carmichael (Carmichael and Eugster 1987; Ghiorso et al. 1983) and their students to develop quantitative models to augment experimental approaches. Although this data set remains incomplete, much progress has been made and thermodynamics has become a routine tool across the breadth of geochemistry.

Geochemical systems are often not at equilibrium, particularly at surface temperatures, which limits the applicability of thermodynamics. Perhaps nothing better illustrates this than metamorphic assemblages equilibrated at lower crustal pressures and temperatures that persist in that state at the Earth's surface, or even more spectacularly the persistence on the surface of diamond, which is thermodynamically stable only at depths of 100 km or more (Kennedy and Kennedy 1976). Consequently, kinetics, which is the study of reaction rates and mechanisms, has an importance in geochemistry nearly equal to that of thermodynamics, and its importance and application in geochemistry has grown in tandem with thermodynamics. As opposed to the chemistry laboratory when reactions often occur in the gas or liquid phase in the restricted space of a beaker, geochemical scales are vast, and many solid-state geochemical reactions rates are limited by the rates at which reactants can be brought together by diffusion. Kinetics allows geochemists to understand under what circumstances equilibrium will or will not be achieved and how rapidly it is approached. As in thermodynamics, application of kinetics requires knowledge of fundamental properties such as activation energies and volumes and diffusion coefficients, and progress continues to be made on this front. Geochemical kinetics is applied on broader scales as well since, although it appears static, the Earth is a dynamic system. The oceans perhaps illustrate this best. Although their composition is nearly static over millions and tens of millions of years, this composition is maintained through constant fluxes from sources into the oceans and fluxes out of them. The carbon cycle is another illustration of this point. CO_2, which has been a key control on climate, has a residence time in the atmosphere of only about 4 years, as carbon cycles continually between the oceans, the atmosphere, the biosphere, and the soil. Shifts in carbon between these reservoirs have been responsible for climate change throughout Earth's

history (Berner 2006), just has it been doing since the industrial revolution.

Thermodynamics can be approached macroscopically – that is, one often need not know what occurs on the molecular or atomic level. Kinetics generally requires a more microscopic approach and some knowledge of the atomic/molecular nature of reactants to understand reaction fundamentals. In the last few decades, geochemistry has begun to approach problems from an even finer level, namely, the *ab initio* approach, which begins with calculations of atomic electronic and molecular orbitals. This requires enormous computational power but has already proved useful in a number of applications.

Breadth and Subdisciplines

Geochemistry can be divided into a variety of overlapping subfields. One such division is between applied geochemistry, on the one hand, and what could be called "pure" or "theoretical" geochemistry. The focus of the latter is understanding how the Earth works, how it has evolved, and how it operates as a chemical system. The focus of the former is to apply that understanding to finding and developing resources and avoiding or mitigating the environmental impacts of human activity. Occasionally, this flow of information reverses, and discoveries and techniques made by applied geochemists turn out to be useful in "pure" geochemistry.

Another division is between "low-temperature" and "high-temperature" geochemistry. The temperature of this divergence is not firmly established: certainly processes occurring at temperatures up to 100 °C or so would fall within the range of low-temperature geochemistry, while those at and above the temperatures of hydrothermal systems, 350–400 °C, would fall within the realm of high-temperature geochemistry. The latter is closely related to the fields of metamorphic and igneous petrology. Biogeochemistry and organic geochemistry are part of low-temperature geochemistry but are nevertheless distinct specialties. Isotope geochemistry is another distinct subfield and has applications in both low- and high-temperature geochemistry. The Earth is best understood, particularly its origins, in context of the solar system of which it is part and more broadly the universe in which its continuant elements have been created. These are the realms of cosmochemistry.

Low-Temperature Geochemistry

"Low-temperature geochemistry" is nearly synonymous with "environmental geochemistry," with the latter term having a more applied connotation. These fields focus on processes occurring in the oceans, in the atmosphere, and in the "critical zone," defined as Earth's permeable surface, from the top of the trees to the bottom of the groundwater zone, most of which involve reaction with, in, or mediated by water. The concept of the critical zone endeavors to acknowledge and integrate the complexity of the Earth's surface environment with the biological processes that strongly shape it: Vladimir Vernadsky's (1926) biosphere. They encompasses topics such as aquatic and groundwater chemistry, chemical oceanography, chemical weathering, mineral dissolution and precipitation, sedimentary chemistry and diagenesis, soil chemistry, atmospheric chemistry, and contaminant transport.

Current research on the critical zone involves learning about the kinetics of weathering reactions, including deducing exact reaction pathways and their dependence on factors such as temperature, rainfall, biota, rates of gas exchange, and anthropogenic disturbance (Brantley et al. 2006). Chemical components are also cycled within the critical zone, between solution, soils, colloids, and the biota, so that the residence time of weathering products within it can be considerable. This includes a continual cycling of nitrogen between N_2 and "fixed" nitrogen, which includes both oxidized and reduced forms such as NO_3^- and NH_4^-. This too is critical for life because, with the exception of some bacterial classes, autotrophs can only utilize fixed nitrogen.

Rivers carry the products of chemical weathering to the ocean; as Antoine Lavoisier noted, "The water of the sea results from a washing of the entire surface of the globe." Despite this continuous supply of salts, the saltiness, or salinity, of the oceans does not change substantially over time as salts are also continuously removed from the oceans and the concentrations of specific salts depend on the rate at which they are removed as well as the rate at which it is added. The major ions in seawater, Na, Ca, Mg, K, Cl, and SO_4, are always present in constant proportions to one and other and to total salinity, as was postulated by Forchhammer's Rule, and they all have very long residence times in seawater, hundreds of millions of years in some cases. Although the major element composition of seawater has been known since the nineteenth century, chemical oceanographers continue to improve understanding of the controls on it. For example, it was only with the discovery of deep-sea hydrothermal vents that it became clear that hydrothermal processes at mid-ocean ridges were the principal mechanism by which Mg is removed from seawater (Corliss et al. 1979). Although the general outlines of these processes have been known for sometime, the oceans are so vast and sampling is so limited; much of the detail is missing. Analytical advances and large-scale international sampling programs such as GEOTRACES in the last decade or two are greatly advancing knowledge of ocean chemistry, including the chemical speciation of key nutrients, such as Fe, and the distribution of anthropogenic contaminants such as Pb and Hg and radioisotopes (e.g., Boyle et al. 2015).

Sediments are the history book of the planet, and that history is recorded not only in sedimentary structures and

minerals but also in their chemistry. Studies of that chemistry have vastly expanded sedimentary petrology to reveal, for example, that while Earth's atmosphere first became oxidizing 2.3 billion years ago, it was only much later, perhaps 600 million years ago (Lyons et al. 2014), when that oxygen finally became abundant enough to support multicellular life and penetrated to the ocean's deep water (Xiao 2014).

Low-temperature processes are also responsible for many useful materials, such as evaporites, which are a primary source of halite, gypsum, Li, Mg, K, and other elements. Weathering and sorting produce deposits of high purity quartz sands, the raw material for silicon, and heavy mineral placers, a source of Zr, Cr, Ti, platinum group elements, Au, diamonds, etc. Sediments comprised of carbonate minerals such as limestone and its metamorphic equivalent, marble, are not only useful building materials in themselves but the source of lime, the key ingredient in cements and concrete, without which our cities would be very different. Contrasting oxidation states of the atmosphere and surface waters on the one hand and deep ocean water on the other in the Neoarchean and Paleoproterozoic resulted in oxidation–reduction reactions that produced banded iron formations, the major source of iron ore. A variety of U and other ore deposits also formed through oxidation–reduction reactions. Extreme weathering also produces useful deposits, including bauxite, the principal Al ore, lateritic Ni deposits, etc. Diagenetic brines are also capable of dissolving and subsequently precipitating metals as in Mississippi Valley-type ores or the Kupferschiefer of Germany and Poland.

While mining and refining metals has been key to the development of civilization, it also has and continues to impose a burden on society. The amount of mine waste generated annually is comparable to the amount of solids moved by natural geologic processes (Fyfe 1981). While this in itself can blight the landscape, the bigger problem is that this material is often toxic. The problem is particularly acute when the ores consist partly or wholly of sulfide minerals, which is often the case, particularly for so-called base metal ores such as Cu, Pb, and Zn. When exposed to oxygenated water, sulfide minerals quickly undergo oxic weathering, producing sulfuric acid.

The consequence of this is what is known as *acid mine drainage*, a classic example of which is the Rio Tinto in Andalusia, Spain, and ironically also the mine from which the huge multinational mining conglomerate Rio Tinto takes its name. Some 5000 years of mining of copper, silver, gold, and other metals as well as natural weathering have given the river a reddish hue due to the presence of dissolved iron. pH values of 2 and less extend 60 km downstream from the mine nearly to the estuary and tidal flat. Toxic levels of Cu, Zn, As, and Pb are found in sediments along the entire length of the river (Davis et al. 2000). Preventing future environmental problems and mitigating past ones requires a geochemical understanding of how metals and other elements in mine waste behave in the near-surface environment.

Biogeochemistry

Biogeochemistry is a subfield of low-temperature geochemistry that focuses on the interaction between life and its environment. The focus can range from the interaction of individual organisms with the soil and solutions surrounding them to the global scale of biogeochemical cycles, which considers the fluxes of elements and compounds between reservoirs such as the atmosphere, the ocean, the biosphere, etc.

The carbon cycle is an example of such a cycle and one of key importance given the control that atmospheric CO_2 exerts on climate. The residence time of CO_2 in the atmosphere is short, about 4 years, as it quickly cycles between the oceans, the biosphere, and soils. Of these reservoirs, the atmosphere is the smallest and the oceans the largest. Changes in the ocean–atmosphere carbon balance during Pleistocene ice ages reduced atmospheric CO_2 concentrations from 280 parts per million by volume (ppmv) to 180 ppmv, greatly amplifying the climate change induced by variations in Earth's orbit and rotation known as the Milankovitch cycles.

The above could be described as the exogenic or short-term carbon cycle. A deeper cycle also operates, but at a much slower rate. Weathering reactions such as

$$2H_2O + CO_2 + 2NaAlSi_3O_8 \rightharpoonup Al_2Si_2O_5(OH)_4 + 4SiO_2 + 2Na^+ + CO_3^{2-} \quad (1)$$

effectively convert atmospheric CO_2 to carbonate or bicarbonate ions, which are carried to the oceans by rivers and precipitated as calcium carbonate by marine organisms and ultimately buried in marine sediments. Variations in the rate of weathering have acted as one of the controls on atmospheric CO_2 and climate throughout the Phanerozoic (Berner 2006). In addition, some of the organic matter produced by marine phytoplankton is not respired but is buried along with marine sediment. Vastly more carbon is stored in sedimentary carbonate and organic carbon reservoirs than in all the exogenic reservoirs combined (e.g., Broecker 2012). These are slowly returned to the exogenic cycle when sediments are exhumed and weathered and organic carbon oxidized to CO_2. In addition, some carbonate in the oceanic crust and sediment is carried into the mantle in subduction zones where some of it undergoes decarbonation reactions with the CO_2 released through subduction zone volcanism. Some of it is carried into the deep mantle, but this too is ultimately returned to the atmosphere by volcanism, thus completing the cycle.

Fluxes into and out of these long-term reservoirs are not always in balance, leading to changes in atmospheric

composition. Fossil fuel burning since the industrial revolution has greatly accelerated loss from the sedimentary organic matter reservoir, and CO_2 has consequently increased from a preindustrial level of about 280 ppmv to a present (2016) level of $\gtrsim$400 ppmv. This increase, thus far at least, is small compared to variations in atmospheric CO_2 over Earth's history; those naturally driven changes, however, occurred far more slowly; the present rate of increase appears to be unprecedented.

The carbon cycle, because it involves photosynthesis and respiration, is closely linked to the oxygen and sulfur cycles, as well as to the behavior of redox-sensitive metals such as Fe, Mn, Mo, U, etc. and this has led to profound changes in the Earth's chemistry. There is considerable evidence that Earth's early atmosphere was quite different than the present one and was mostly likely dominated by CO_2 and N_2, similar to that of its sister planets. Photosynthesis, together with geologic burial of some fraction of the organic matter produced by that process, was responsible for the transition to the present N_2–O_2 composition (Holland 2006). A variety of geochemical and geological approaches have now established that molecular oxygen became a significant atmospheric component only in the Paleoproterozoic about 2.3–2.4 billion years ago, a time known as the Great Oxidation Event, although some free oxygen may have been present earlier in ocean surface waters (Farquhar et al. 2000; Kasting and Catling 2003).

Organic Geochemistry

Organic matter is an important part of the carbon cycle as the amount of carbon in soil and sediment organic matter vastly exceeds the amounts in the atmosphere and biosphere. Organic geochemistry is the study of nonliving organic matter in soil, water, air, and sediments and the reactions of those organic molecules under a broad range of Earth's surface and subsurface conditions. Oxidation by bacteria and other decomposers gives rise to the formation of oxygen-containing functional groups such as the hydroxyl and carboxyl group, which are polar, so that in the early stages of decomposition, the solubility of organic matter increases. Recent experimental work has also shown that simple organic molecules can be oxidized and reduced abiotically under hydrothermal conditions (300°C and 100 MPa) to produce similarly oxygenated functional groups (e.g., Shipp et al. 2013). Much of polar dissolved organic matter (DOC) consists of humic and fulvic acids that are rich in functional groups, notably amino and carboxylic acids, and that readily complex transition metals; consequently a substantial fraction of dissolved trace metals in natural waters may be complexed by these acids, enhancing their abundance as the solubility of these metals in natural aqueous solution is otherwise often quite limited.

Organic matter is also an important component of soils, where it plays an important role in soil fertility by releasing nutrients as it decomposes, stabilizing soil structure, increasing ion exchange capacity, and modulating porosity and water content. Recent advances in the past two decades have resulted in a paradigm shift as to the nature of soil organic matter and why it persists despite its thermodynamic instability (Kleber and Johnson 2010; Schmidt et al. 2011). Rather than recalcitrant condensates of biomolecules as previously thought, much of soil organic matter appears to consist of molecular aggregates of partially decomposed plant polymers loosely held together by entropic interactions and/or noncovalent bonds and that such aggregates are not inherently stable against decomposition (Kleber and Johnson 2010). Instead of molecular structure, environmental and biological factors, which remain poorly understood, appear to control the stability of soil organic matter (Schmidt et al. 2011).

Understanding how this organic matter is preserved in sediments and how it is transformed is an important part of organic geochemistry, not the least because the small fraction ultimately transformed to petroleum, gas, and coal is such an important energy resource. Even in aerobic environments, some organic matter survives, including some biomolecules or fragments of them that should be quite labile. Recent work suggests coprecipitation or chelation reactions result in macromolecular complexes between organic carbon and iron oxyhydroxide minerals that stabilize organic components and explain their survival (Lalonde et al. 2012).

The organic matter that does survive in sediments is transformed by bacterial and chemical processes that are part of the diagenetic process. The ultimate product of these processes is *kerogen*, the name given to the recalcitrant mixture of complex organic compounds that dominates the organic fraction in sediments. As sediments are buried, they experience progressively increasing temperature and pressure, and a number of new reactions, collectively called *catagenesis*, occur. During this process, kerogen disproportionates into comparatively simple hydrogen-rich molecules (hydrocarbons) and a hydrogen-depleted carbon-rich residue. As temperatures in the range of 100–150°C are reached, the so-called oil window, petroleum, a complex mixture of hydrocarbons, is produced. The petroleum is mobile and will migrate out of the source rock if a migration pathway exists. As temperatures approach and exceed 150°C, natural gas, a mixture of methane with some short-chain hydrocarbons such as ethane and propane, is produced in the *metagenesis* stage.

Despite changes occurring during diagenesis and catagenesis, some organic compounds in petroleum retain some of their original chemical structure and can be associated with specific classes of organisms; these are known as *biomarkers*. Biomarkers can be used to associate petroleum with the specific sedimentary source rocks and determine migration pathways (Peters et al. 2007), used to forensically

associate hydrocarbon pollution to specific sources (Briggs and Summons 2014), and in understanding the evolution of life (Eglinton and Eglinton 2008; Lalonde et al. 2012). Other organic compounds have proved useful for other paleoclimatology studies, including paleotemperature.

High-Temperature Geochemistry

High-temperature geochemistry focuses on magmatic, metamorphic, and hydrothermal processes occurring at temperatures well above those at the Earth's surface. In its broadest definition, high-temperature geochemistry includes igneous and metamorphic petrology and mineralogy. Among other ways, geochemistry expands these traditional topics by including study of trace elements, i.e., ones that are not stoichiometric components of the main igneous and metamorphic minerals. Studies of such elements, despite their inconsequential abundances, have proved invaluable to these fields in part because of their vast variation in abundances, orders of magnitude, in similar rock types, and because many elements are sensitive to factors to which major elements are insensitive, such as the extent of partial melting. Geochemistry also expands petrology's focus beyond the formation and evolution of rocks to the Earth's formation and the subsequent evolution of the continental crust and mantle.

Particularly when combined with geochronology and isotope geochemistry, described below, the geochemistry of igneous rocks has elucidated this evolution. Magmas produced from different tectonic environments usually have a distinctive chemical signature. For example, mid-ocean ridge basalts carry the signature of a mantle reservoir long ago depleted in "incompatible elements" – those elements that readily partition into a melt phase and hence transferred to the crust. In contrast, magmas produced in subduction zones carry a signature of having been produced from water- and oxygen-rich sources modified by fluids released by subducting oceanic crust and sediment (Plank 2016). Many intraplate magmas, including oceanic island basalts, carry yet a different signature – one of ancient re-enrichment in those incompatible elements concentrated in the Earth's crust (Jackson 2016). These magmas are often associated with mantle plumes, which can be traced to the deep mantle, which suggests the deep and shallow Earth are connected.

Geochemistry reveals that the continental crust has grown through time, apparently mainly, although not exclusively, through subduction-related volcanism (Rudnick, this volume). This growth has been uneven and pulsed (e.g., Condie and Aster 2010), but many details about the rate of continental growth remain obscure and debated, particularly during Earth's earliest history (e.g., Hawkesworth et al. 2010). Similarly, while plate tectonics has dominated crust–mantle evolution over the last three billion years, its importance before that remains debated (e.g., Condie and Pease 2008).

Many mineral deposits, which have enabled the development of human civilization since copper and bronze tools began to replace stone ones, are the consequence of high-temperature processes. These include magmatogenic ore deposits, including Cu–Ni sulfide deposits, platinum group element deposits, and chromite deposits, that formed as minerals or sulfide-rich immiscible melt droplets segregated within large magmatic intrusions as well as deposits of Li, Zr, rare earth elements, U, Th, Ta, Nb, Sn, Sb, and other metals that formed through extreme fractional crystallization of alkaline or silicic magmas or pegmatite veins related to them. Other important ore deposits, including those of base metals such as Cu, Zn, and Pb as well as precious ones such as Ag and Au, form through syngenetic hydrothermal processes usually associated with metamorphism, magmatism, or volcanism. These form when temperature, pressure, fluid composition, and oxidation state enable dissolution of metals from large volumes of rock, and subsequent change in these parameters results in their precipitation in much smaller volumes. Understanding the behavior these elements in magmatic and hydrothermal systems has significantly advanced our ability to identify future deposits and consequently insure the availability of these essential resources to future generations.

Isotope Geochemistry

Isotope geochemistry has two branches: radiogenic and stable. Radiogenic isotope geochemistry derives from the radioactive decay of isotopes of nine elements whose half-lives are long enough that they survive in measurable abundance on the Earth, yet short enough that they produce measurable isotopic variations in their radiogenic daughter elements. These half-lives range from 7×10^8 years to 4.5×10^{11} years. Variations in the relative abundances of radiogenic isotopes of a few shorter-lived nuclides that are now "extinct," such as ^{129}Xe, the product of ^{129}I (e.g., Mukhopadhyay 2012; Staudacher and Allègre 1982), and ^{142}Nd, the decay product of ^{146}Sm (Harper and Jacobsen 1992), and ^{182}W, the decay product of ^{182}Hf, have been studied in meteorites and Archean terrestrial rocks (Rizo et al. 2016). In addition, "cosmogenic" isotopes are produced by cosmic ray-induced nuclear reactions. Because the rate of radioactive decay is insensitive to external influences, this forms the basis of geochronology, determining the age of geologic events and thus the quantification of the geologic time scale, and, with the inclusion of the extinct radiogenic nuclides mentioned above, in early solar system chronology. Geochronology requires the rocks and minerals investigated to have been closed systems; even where this is not the case, variations in parent/daughter ratios produce variations in radiogenic isotope ratios that can be exploited as tracers.

Radiogenic isotope ratios are particularly valuable in understanding the composition and evolution of the Earth's mantle, which represents over half the Earth's mass and most of its volume. Basalts are the most common mantle sample but are a highly biased sample as a consequence of chemical fractionations occurring during partial melting and fractional crystallization. However, as Gast (1960) explained, radiogenic isotope ratios are not chemically fractionated, hence are identical to those ratios in the basalt source (or sources, including material assimilated during ascent).

Gast pointed out that differing behavior of parent and daughter elements in radioactive decay systems results, in time, in differences in the isotope ratios of terrestrial reservoirs, such as the crust and mantle. Thus radiogenic isotope ratios can be used to trace the evolution of these reservoirs. For example, Rb, Nd, and Hf partition preferentially into mantle melts and ultimately into the crust relative to Sr, Sm, and Lu. Consequently initial $^{87}Sr/^{86}Sr$ ratios will be lower and $^{143}Nd/^{144}Nd$ and $^{176}Hf/^{177}Hf$ higher in magmas that are new additions to the crust than in ones produced by remelting of crust, which allows the growth of continental crust to be traced through time (e.g., Allègre 1987; Hawkesworth et al. 2010).

Radiogenic isotope studies have demonstrated the existence of distinct reservoirs in the mantle (White 2015): a region, most likely the uppermost asthenospheric mantle, that is highly depleted in incompatible elements that gives rise to mid-ocean ridge basalts, the subcontinental lithospheric mantle, which is generally highly incompatible element-depleted but variably re-enriched in these elements by melts percolating into it from below, the mantle beneath island arc volcanoes which has been metasomatized by hydrous fluids and silicate melts from the subducting oceanic crust and sediment, and the deep mantle source of mantle plumes, which appears to consist of a mixture of relatively primitive material (most clearly evidenced in noble gas isotope ratios) and material recycled from the Earth's surface.

Elemental fractionation also occurs when the raw materials of glass or metal alloys are melted and smelted, which limits somewhat the use of elemental analysis in establishing provenance of archeological artifacts. Again, this is not the case for isotope ratios; hence, radiogenic isotope ratios including those of Pb, Nd, Os, and Sr as well as stable isotope ratios such as Sb, Sn, and B have been used to determine provenance in archeological geochemistry. Radiogenic isotope ratios are also useful tracers of groundwater (Jacobson and Wasserburg 2005) and ocean circulation, both past and present (e.g., Albarède et al. 1997; Godfrey et al. 2009).

Stable isotope geochemistry exploits isotopic fractionations that result from the effect of neutron mass on chemical bonding, diffusion, reaction rates, and the ability of molecules to transition between energy states. These effects are quite small and typically lead to a percent or less variation in the isotope ratios. Hydrogen is an exception with variations in the $^{2}H/^{1}H$ ratio often being tens of percent. Most of the focus of this field is on a handful of light elements: H, C, N, O, and S. Furthermore, since isotope fractionation decreases with the inverse square of temperature, the focus of stable isotope geochemistry is primarily on low-temperature processes at or near the Earth's surface. As a consequence of this temperature dependence, oxygen isotope fractionation between water and calcium carbonate shells of marine organisms provides useful paleothermometers (Urey et al. 1951) to, among other things, reveal the climatic swings of the Pleistocene (Imbrie 1985) which is certainly among stable isotope geochemistry's greatest contributions. In recent years this has been augmented through studies of hydrogen isotopes in Antarctic and Greenland ice sheets (Jouzel et al. 2007). Sulfur isotope geothermometry has been applied to the genesis of sulfide ore deposits; the end of mass-independent fractionation of sulfur isotopes 3.3 billion years ago records the initial oxidation of the atmosphere (Farquhar et al. 2000). Photosynthesis is the principal cause of variations in carbon isotope ratios, and all biogenic organic compounds are depleted in ^{13}C, typically in the range of 15–25 or more per mil. That petroleum carries this isotopic signature removes any doubt of its ultimate biological origin. That same signature is found in a subset of diamonds carrying deep mantle mineral inclusions, leading to the much more surprising inference that the carbon in them was derived from organic matter carried into the deep mantle (Walter et al. 2011). While photosynthetically produced compounds are depleted in ^{13}C, the remaining inorganic carbon in the system, such as the ocean, is necessarily enriched in this isotope. This has been exploited to trace both paleo-ocean circulation (Curry and Oppo 2005) and the biologic productivity and diversity through time, demonstrating the coupling of those to biogeochemical cycling and tectonics (Hannisdal and Peters 2011).

Stable isotope geochemistry has proved useful in archeology and paleontology as well. Carbon and nitrogen isotopes in bone collagen and apatite are widely used to determine food sources of ancient peoples and animals and, with caveats, can distinguish between marine diets and terrestrial ones and the extent of reliance on C_4 plants such as maize and sugarcane and C_3 plants, such as wheat, barley, etc. (e.g., Lee-Thorp 2008). Isotopic analysis of cooking residues on pottery has evolved from bulk isotopic analysis to analysis of specific compounds, such as lipids, providing insight not only into the diet of ancient peoples but their social interactions (Craig et al. 2015).

Several new exciting developments have occurred in stable isotope geochemistry over the past several decades (Eiler et al. 2014). One of these is, as in other fields of geochemistry, the development of new analytical techniques that allow more precise measurements and in situ measurements on very small samples. Another development is compound-specific isotopic analysis such as that mentioned in the preceding paragraph.

Another development is the extension of stable isotope geochemistry from a few light elements to nearly every polyisotopic element in the periodic table, including most of the transition metals as well as quite heavy ones such as U and Tl. Another advance is the development clumped isotopic analysis: the analysis of isotopes of pairs of elements, such as C and O, in individual isotopic species or isotopologues.

The noble gas isotopes are of particular interest because many are produced either by radioactive decay, secondary nuclear reactions triggered by radioactive decay, cosmic rays, or have experienced mass-dependent fractionation. Noble gas isotope geochemistry been applied to studies as diverse as fluids in the crust, ocean circulation, and erosion rates. Xenon isotopes produced by decay of the extinct radionuclides ^{129}I and ^{244}Pu provide clues to Earth's earliest history and the origin of its atmosphere.

Cosmochemistry

The Earth's formation is intimately linked to the formation of the Sun, its sister planets, and other objects in the solar system. Yet among these objects, the Earth is uniquely habitable. That habitability is in large measure a consequence of events occurring as the solar system formed – producing a rocky inner solar system planet with enough water and carbon to eventually sustain life and sufficient mass to hold on to volatile components over the eons. Earth's sister planets, Venus and Mars, formed from similar ingredients but evolved along different pathways. Much of what we know of how the solar system formed and planets developed comes from geochemical studies of meteorites – pieces of asteroids whose composition and mineralogy has been preserved over four and a half billion years. These studies, in conjunction with astronomical observations of young stars, have confirmed the nebular theory of Immanuel Kant.

Chondritic meteorites are composed of collections of the dust of the nebula from which the solar system, including the Earth, formed. They consist of high-temperature condensates such as calcium–aluminum inclusions or CAIs that formed as early as 4568.67 ± 0.17 Ma ago (Bouvier and Wadhwa 2010) and amoeboid olivine aggregates, chondrules, aggregations of dust melted during transient heating events, and fine-grained matrix which condensed at far lower temperatures, likely at a great distance from the Sun. Isotopic compositions of chondritic meteorites vary, most dramatically for oxygen (Clayton et al. 1976), likely reflecting a self-shielding of UV photodissociation of gas molecules in the nebula (Clayton 2002) and, subtlety in other elements, betraying incomplete mixing between nuclides synthesized by slow neutron capture in red giant stars and ones synthesized in rapid neutron and proton capture processes in supernova explosions (e.g., Burkhardt 2016), and the short-lived radionuclides must have been synthesized only shortly before solar system formation. And some chondrites preserve solids, such as SiC, graphite, diamond, and olivine (Mg_2SiO_4), which condensed from the outflow of those stars and supernovae, are preserved in the fine-grained matrix.

In contrast to chondrites, rocky achondrites and iron meteorites are remains of disrupted asteroid-sized planetesimals that melted and differentiated into iron cores and silicate mantles. NASA's DAWN spacecraft confirmed that some of these are from the asteroid Vesta, which apparently formed within the first few million years of solar system history.

In contrast to Vesta, formation of the Earth appears to have taken much longer, perhaps as long as 100 million years (Rudge et al. 2010). This process is generally thought to have culminated in a giant impact (Hartmann and Davis 1975), which formed the Moon. The great advantage of the impact model is that it explains the angular momentum constraints of the Earth–Moon system, and it is consistent with computer simulations that show that planets grow by collisions between progressively larger bodies. It is also consistent with the small size of the lunar core – the impact would have happened after the Earth's core had largely formed – and the general chemical similarity between the Earth and the Moon. But that same similarity is now seen as a problem – the two bodies are almost too similar, particularly in the isotopic compositions that vary between various solar system bodies, such as H, O, Fe, Si, Mg, K, Ti, Cr, and W. This requires very efficient mixing between material of the proto-Earth and the impactor (Elkins-Tanton 2013; Young et al. 2016), Theia, which in turn requires rather specific impact scenarios (e.g., Ćuk et al. 2016).

Summary

Study of the chemistry of natural materials and application of chemical principles to understanding natural processes has greatly advanced our understanding of the Earth and its neighbors. The range of topics to which geochemistry is applied is enormous ranging over, among others, formation of the solar system, geochronology, the evolution of life, plate tectonics, anthropogenic climate change, soil fertility, and ocean circulation. Advances in analytical techniques and our ability to model geochemical processes continue to push the frontiers of knowledge forward and reveal surprising details of how the Earth works.

Geochronology and Radiogenic Isotopes

Jeff Vervoort
Geological Sciences, School of the Environment, Washington State University, Pullman, WA, USA

Definition

Geochronology is the science of determining absolute ages of geological events and Earth materials. It utilizes radioactive isotopes and the production and accumulation of radiogenic daughter isotopes naturally present on Earth. It can be applied to a wide range of samples including rocks, minerals, and some biological materials.

Introduction

Geochronology plays a critically important role in most fields of the Earth Sciences. Not only has geochronology provided an absolute time framework for the Earth and Solar System, but it has also provided important constraints on the rates and timing of diverse processes that have helped form and shape our planet. *Long-lived decay systems* (e.g., U-Pb, Sm-Nd, Lu-Hf, Rb-Sr, K-Ar, Re-Os; Table 1), with half-lives typically in the billions of years, have provided remarkably tight constraints on the absolute age of the solar system (e.g., Amelin and Ireland 2003), the age of Earth's oldest minerals (e.g., Wilde et al. 2001) and rocks (e.g., Bowring and Williams 1999), and the formation and modification ages of a wide variety of rocks throughout Earth's history. *Short-lived (extinct) radionuclides* (e.g., Al-Mg, Mn-Cr, I-Xe, Sm-Nd, Hf-W; Table 2) have half-lives ranging from less than a million years to tens of millions of years and have long since vanished from the solar system. Their daughter products have remained, however, and provide details on the timing of various processes during the early history of the solar system (e.g., Amelin and Ireland 2013), on core separation and moon formation (e.g., Kleine et al. 2002; Yin et al. 2002; Touboul et al. 2007), and on the differentiation of the silicate Earth and formation of Earth's early crust (e.g., ^{146}Sm-^{142}Nd, Boyet and Carlson 2005; O'Neil et al. 2008). *Intermediate short-lived radioactive daughters*, produced from the U-series decay chain (e.g., ^{234}U, ^{230}Th, ^{210}Pb; Table 3), have provided important constraints on a range of magmatic processes (e.g., Reid et al. 1997) and on refining climate records (e.g., Edwards et al. 1987). *Unstable cosmogenic nuclides* (e.g., ^{14}C, ^{36}Cl; Table 4), produced by interaction of cosmic rays with the atmosphere and solid Earth, have likewise provided important age constraints on the human timescale (e.g., ^{14}C, Beck et al. 2001) as well as on the timing of surficial processes on Earth (e.g., ^{36}Cl, Phillips et al. 1986).

In sum, geochronology has provided a detailed timeline for our solar system and planet from its very beginning through to processes operating today on a human timescale. This entry will discuss the long-lived decay systems. The short-lived decay systems are discussed elsewhere: extinct radionuclides are covered in chapters on Mg and Nd isotopes; U-series isotopes are discussed in uranium decay series; and cosmogenic isotopes are covered in the chapter on cosmogenic nuclides.

The long-lived decays are used in geochronology in two fundamentally different ways. For some of the decay systems – and with some mineral phases – there is little if any daughter isotope present when the rock or mineral forms allowing for an accurate calculation of radiogenic daughter accumulation over time. Two prominent examples of this are the U-Pb and K-Ar systems in zircon and hornblende (among many other phases), respectively. The second type is where

there are abundant daughter isotopes present in the rock or mineral that cannot be unambiguously corrected for (e.g., Rb-Sr and Sm-Nd) and which require a different approach. These will be discussed separately below.

Fundamentals

Geochronology is based on the fundamental principle that an unstable (radioactive) nuclide will decay at a constant rate that is defined by the decay constant of that radionuclide and which depends only on the state of the nucleus and is independent of external factors such as temperature, pressure, or the past history of the nuclide. This fundamental principle can be applied in a number of different ways to determine "dates," or "ages," of various physical events and processes. [Note: Some geochronologists prefer to use "date" for what is measured and calculated for an individual rock or phase and "age" for the time that is assigned from all dates to a geological event. In reality (and probably much to the consternation of strict geochronology practitioners), however, "age" is widely used in both senses.]

Basic Equation of Radioactive Decay

All geochronology is based on the fundamental equation of radioactive decay,

$$\frac{dN}{dt} = -\lambda N \tag{1}$$

which states that the change in the number of radioactive atoms (dN) with time (dt) is proportional to the number of atoms present (N) and the decay constant (λ). The negative sign on λ indicates the numbers of radioactive atoms are decreasing with time.

Using this expression, the radiogenic decay equation can be derived.

$$N = N_0\, e^{-\lambda t} \tag{2}$$

This states that the number of radioactive parent isotopes present at a given time, N, is a function of the number present initially (N_0), the decay constant for that radionuclide, and time.

From this, an expression of the half-life of a particular radioactive isotope can be derived. By definition, this is the time when half of the radioactive nuclides have decayed to a daughter nuclide and is simply expressed as $N_0/N = 1/2$. Combining this with Eq. 2 gives the expression for the half-life of a radioactive isotope:

$$t_{1/2} = \frac{\ln 2}{\lambda} \tag{3}$$

It should be noted from this expression that the half-life can be calculated, provided the decay constant is known (and vice versa).

The radioactive decay of a parent isotope also produces a radiogenic daughter isotope (D^*), which is equal to the number of parent decays: $D^* = N_0 - N$. Substituting this into

Eq. 2 gives the expression for the production of radiogenic daughters from a radioactive parent:

$$D^* = N\left(e^{\lambda t} - 1\right) \tag{4}$$

Geochronology Applications with No (or Correctible) Preexisting Daughter Nuclides

A simple application of this expression can be applied in the case where no daughter isotopes existed when the rock or mineral formed. We can call this "time 0" – the time when the material is effectively "closed" to movement of the elements of interest in or out of the system (i.e., becomes a closed system). In reality for most radioisotope decay systems, however, there are appreciable daughter nuclides present in the system at time 0, either from nucleosynthesis or from some prior decay. In this case, we need to subtract their presence from the total number of daughter isotopes,

$$D^* = D - D_0 = N\left(e^{\lambda t} - 1\right) \tag{5}$$

where D is the total number of daughter nuclides in the system of interest and D_0 is the number present at time 0.

Rearranging this equation to solve for t gives the expression:

$$t = \frac{\ln\left(\frac{D^*}{N} + 1\right)}{\lambda} \tag{6}$$

Thus, an age can be calculated using this expression by measuring N, the number of radioactive nuclides present today, and D*, the number of radiogenic daughter nuclides present. This assumes that neither N nor D has been lost or gained over the time of interest, and there are either no initial daughter nuclides present or that their abundance can be accurately calculated.

An example of this approach is the U/Pb system in zircon ($ZrSiO_4$) where – in the ideal case – no Pb isotopes were present when the zircon crystallized (referred to as "common" Pb) *or* that this common Pb can be accurately measured and corrected. In this case, the following expression can be used to determine an age using the ^{238}U to ^{206}Pb decay series (Table 1):

$$t_{^{206}Pb^*/^{238}U} = \frac{\ln\left(^{206}Pb^*/^{238}U + 1\right)}{\lambda^{238}U} \tag{6}$$

This is commonly called a U-Pb (or $^{206}Pb/^{238}U$) age and is widely used in U-Pb zircon geochronology. A similar approach can be used to calculate a U-Pb age using the ^{235}U to ^{207}Pb decay (Table 1). This is discussed further in the zircon geochronology section below.

The Isochron Method

For radiogenic isotope systems in most rocks and minerals, however, the amount of pre-existing daughter isotopes is large and cannot be accounted for unambiguously. In these cases, the so-called "isochron method" can be used to calculate an age. In practice, this method involves measuring both parent and daughter nuclides relative to a stable isotope of the daughter isotope.

Thus, the expression

$$D = D_0 + N\left(e^{\lambda t} - 1\right)$$

becomes:

$$\left(\frac{D}{D_r}\right)_p = \left(\frac{D}{D_r}\right)_i + \left(\frac{N}{D_r}\right)_p \left(e^{\lambda t} - 1\right) \tag{8}$$

where D_r is the reference isotope of the daughter element.

For the Rb-Sr isotope system (based on the ^{87}Rb to ^{87}Sr decay), this would be expressed in the following way, with ^{86}Sr as the commonly used reference isotope for Sr:

$$\left(\frac{^{87}Sr}{^{86}Sr}\right)_p = \left(\frac{^{87}Sr}{^{86}Sr}\right)_i + \left(\frac{^{87}Rb}{^{86}Sr}\right)_p \left(e^{\lambda t} - 1\right) \tag{9}$$

As written here, i denotes the initial isotope composition (e.g., at the crystallization or formation age) and p signifies the present time. A general expression for this is:

$$R_{(p)} = R_{(i)} + R_{p/d(p)}\left(e^{\lambda t} - 1\right) \tag{10}$$

For determining an age, however, this poses a problem in that there are now two unknowns: time (t) and the initial ratio, $R_{(i)}$. In these cases, the isochron method can be used to determine an age (t). This approach uses the isotope composition of a suite of rocks or minerals that are assumed to have had the same isotope composition at the time of formation.

This can then be expressed in two parallel equations for phases A and B:

$$R_{A(p)} = R_{A(i)} + R_{A\ p/d(p)}\left(e^{\lambda t} - 1\right) \tag{11}$$

$$R_{B(p)} = R_{B(i)} + R_{B\ p/d(p)}\left(e^{\lambda t} - 1\right) \tag{12}$$

The isochron approach assumes that all phases are in isotopic equilibrium at the time of their formation. If this is true, $R_{A(i)} = R_{B(i)}$ and, therefore, when taking the difference between these two equations, the initial isotope composition of both phases drops out of the equation. This leaves the expression:

$$R_{A(p)} - R_{B(p)} = \left[R_{A\ p/d(p)} - R_{B\ p/d(p)}\right]\left(e^{\lambda t} - 1\right) \tag{13}$$

For the Rb-Sr isotope system, this is expressed as

$$\left(\frac{^{87}Sr}{^{86}Sr}\right)_{A(p)} - \left(\frac{^{87}Sr}{^{86}Sr}\right)_{B(p)} = \left[\left(\frac{^{87}Rb}{^{86}Sr}\right)_{A(p)} - \left(\frac{^{87}Rb}{^{86}Sr}\right)_{B(p)}\right]\left(e^{\lambda t} - 1\right) \tag{14}$$

Defining the difference in isotopic composition between the two phases as Δ, and rearranging terms gives

$$\frac{\Delta\left(\frac{^{87}Sr}{^{86}Sr}\right)}{\Delta\left(\frac{^{87}Rb}{^{86}Sr}\right)} = \left(e^{\lambda t} - 1\right) \tag{15}$$

The expression on the left hand of the equation defines a slope on a $^{87}Sr/^{86}Sr$ vs. $^{87}Rb/^{86}Sr$ diagram as shown in Fig. 1.

Figure 1 shows the principle of the isochron method for the Rb/Sr isotope system. Starting with a simple case of a homogeneous magma cooling and solidifying, different phases forming in that rock at t = 0 will have the same Sr isotope composition (A in Fig. 1) but, because of varying partitioning of elements into these different phases, will have different Rb/Sr ratios (B). Over time, ^{87}Sr accumulates at the expense of ^{87}Rb due to its radioactive decay, thus resulting in an increase in $^{87}Sr/^{86}Sr$ ratios with time (C). A phase with more ^{87}Rb relative to ^{86}Sr will evolve to a higher $^{87}Sr/^{86}Sr$. At some later time (t) – if the system has been closed – these different mineral phases will define a line (D) whose slope is proportional to the age. In practice, multiple points are used to define the line and slope, which help to identify inherited components that were not in isotopic equilibrium with the rest of the rock and also to identify open-system behavior.

If a slope can be determined for a set of phases with the same starting isotope composition (and assuming a closed system), an isochron age can be calculated using the expression:

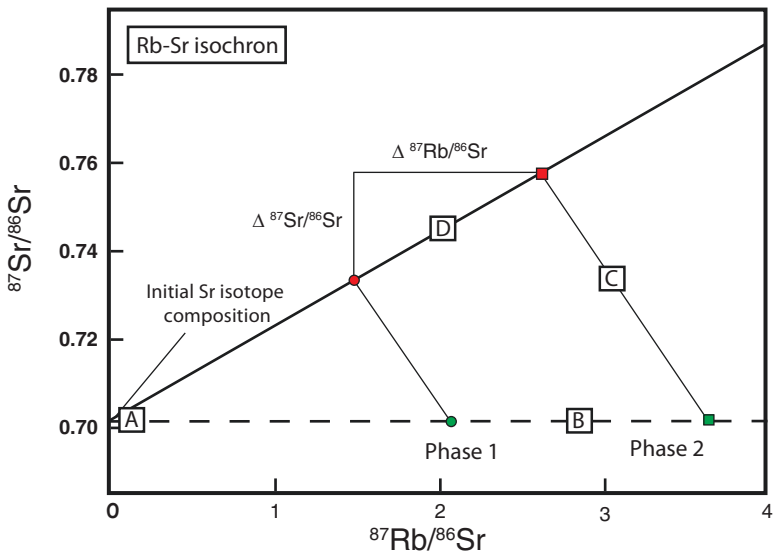
$$\text{slope} = \left(e^{\lambda t} - 1\right) \tag{16}$$

Rearranging this gives:

$$t = \ln(\text{slope} + 1)/\lambda \tag{17}$$

From this method, it is not only possible to determine an age, but also an initial isotope composition by determining the intercept of this regression line. This is the point where the parent/daughter ratio = 0 and, therefore, the isotope composition is time invariant (A in Fig. 1).

The isochron method was widely used to determine Rb-Sr ages from whole rocks (e.g., Moorbath et al. 1977) and, to a



Geochronology and Radiogenic Isotopes, Fig. 1 Generalized Rb-Sr isochron diagram showing two phases with the same $^{87}Sr/^{86}Sr$ ratios at time = 0, but with different $^{87}Rb/^{86}Sr$ ratios. These phases will evolve at different rates as a function of their Rb/Sr ratios and, if the system has been closed over its history, will define a line, the slope of which corresponds to the time since the phases formed (t = 0). The significance of labels A-D is explained in the text

lesser extent, Sm-Nd (Hamilton et al. 1977), but is now recognized to suffer from some significant limitations: (1) in most cases, it is difficult (if not impossible) to assume that a suite of rocks (a sequence of lava flows, for example) indeed had identical isotope compositions at the time of their formation; (2) there is a likelihood of open-system behavior in many rocks for isotope systems with mobile elements such as in the Rb-Sr and K-Ar systems; and (3) there is generally a limited spread in parent/daughter ratios (especially for the Sm-Nd isotope system) for rocks that are truly cogenetic. In total, these problems violate the premise for determining an age using the isochron approach and, as a result, this method is now only rarely used to determine ages using bulk rock samples. The isochron method, however, has been used with somewhat better success for determining ages in internal (mineral) isochrons where there has been closed-system behavior such as in meteorites (e.g., Lugmair and Galer 1992) and with great success where there is a sufficiently large spread in parent/daughter ratios to overcome slight violations of the homogeneous initial isotope composition assumption (e.g., garnet Lu-Hf and Sm-Nd geochronology). These are discussed in greater detail below (section "Garnet Lu-Hf and Sm-Nd Geochronology"). The isochron method has also had important utility in K-Ar and $^{40}Ar/^{39}Ar$ dating (section "K-Ar and Ar-Ar Geochronology") as well as in Re-Os geochronology (e.g., Kendall et al. 2006).

Pb-Pb Isochrons

A variant on the isochron method is afforded by the dual decays of ^{238}U-^{206}Pb and ^{235}U-^{207}Pb. Both the ^{238}U and ^{235}U decays can be written in the standard radiogenic growth equation:

$$\left(\frac{^{206}Pb}{^{204}Pb}\right)_p = \left(\frac{^{206}Pb}{^{204}Pb}\right)_i + \left(\frac{^{238}U}{^{204}Pb}\right)_p \left(e^{\lambda_{238U}t} - 1\right) \quad (18)$$

$$\left(\frac{^{207}Pb}{^{204}Pb}\right)_p = \left(\frac{^{207}Pb}{^{204}Pb}\right)_i + \left(\frac{^{235}U}{^{204}Pb}\right)_p \left(e^{\lambda_{235U}t} - 1\right) \quad (19)$$

These equations are rarely, if ever, used in an isochron application for whole-rock compositions because of the mobility of U in Earth surface environments, but can be combined to determine whole-rock Pb-Pb ages. Rewriting these equations in terms of the radiogenic Pb added over an interval of time (e.g., $\Delta^{207}Pb/^{204}Pb = {}^{207}Pb/^{204}Pb_{(p)} - {}^{207}Pb/^{204}Pb_{(i)}$), substituting μ for the $^{238}U/^{204}Pb$ ratio, and incorporating the natural $^{238}U/^{235}U$ ratio, gives the following expressions.

$$\Delta\frac{^{206}Pb}{^{204}Pb}\Big)_p = \mu\left(e^{\lambda_{238U}t} - 1\right) \quad (20)$$

$$\Delta\frac{^{207}Pb}{^{204}Pb}\Big)_p = \frac{\mu}{137.88}\left(e^{\lambda_{235U}t} - 1\right) \quad (21)$$

These equations can then be combined to yield the following:

$$\Delta\frac{^{207}Pb}{^{206}Pb}\Big)_p = \frac{1}{137.88}\,\frac{\left(e^{\lambda_{235U}t} - 1\right)}{\left(e^{\lambda_{238U}t} - 1\right)} \quad (22)$$

[Note: The historic consensus $^{238}U/^{235}U$ value of 137.88 has been shown by recent determinations to be not invariant, sensu stricto, and these new determinations are lower than the value of 137.88. See Condon et al. (2010), Richter et al. (2010), Heiss et al. (2012) and Goldmann et al. (2015)].

It can be noted that combining these two equations eliminates the present-day U/Pb ratios and, therefore, what remains are only two variables, $\Delta^{207}Pb/^{206}Pb$ and time. This means that the age (or the $^{207}Pb/^{206}Pb$ ratio) is not affected by any change in the present day U/Pb ratio because it has been removed from the equation. Although $\Delta^{206}Pb/^{204}Pb$ and $\Delta^{207}Pb/^{204}Pb$ cannot be calculated unambiguously in whole rocks due to uncertainty in determining the initial Pb ratio (because of U mobility), $\Delta^{207}Pb/^{206}Pb$ can be calculated from the slope of a regression line drawn through a series of cogenetic samples on a $^{206}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ diagram (Fig. 2) in a way analogous to determining a Rb-Sr isochron date. Another important difference between this and a conventional isochron calculated with the parent isotope in the equation (e.g., Rb-Sr) is that initial Pb isotopic compositions cannot be determined from the intercept method (e.g., as can be done for isochron diagrams such as Rb-Sr) when the U/Pb ratio equals zero.

It should also be noted that Eq. 22 is a transcendental equation – time in this equation cannot be solved for directly. Rather, "t" is determined iteratively by estimating values for t, calculating a $\Delta^{207}Pb/^{206}Pb$ ratio, and comparing this to the calculated slope (Pb-Pb isochron application) or measured/calculated $^{207}Pb^*/^{206}Pb^*$ ratio, where the asterisk denotes just the radiogenic fraction (zircon application), until a solution has been made. This is easily now done in many software programs such as with solver in Excel.

The Pb-Pb whole-rock isochron approach is what was used by Claire Patterson (1956) to determine the first accurate estimate for the age of the Earth using a suite of meteorites (Fig. 2). $^{207}Pb/^{206}Pb$ ages are also widely used in zircon geochronology because of the very small amounts of ^{206}Pb and ^{207}Pb (i.e., "common Pb") present in zircon when it forms, requiring only small corrections. This means that the $^{207}Pb/^{206}Pb$ isotope ratios of the zircons can be used to determine ages. This is discussed further in the zircon U-Pb geochronology section below.

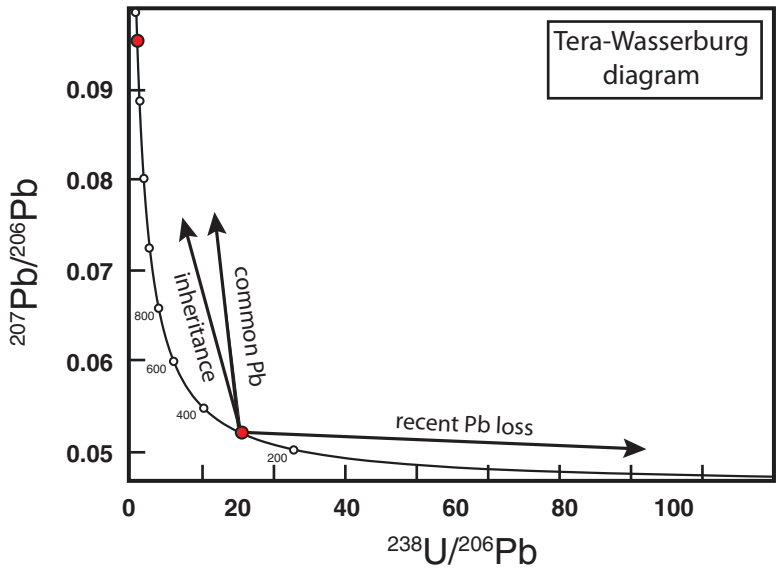
Examples and Presentation

Zircon U-Pb Geochronology

Zircon U-Pb data are typically presented in two different ways that differ in how they represent the companion decays of ^{238}U-^{206}Pb and ^{235}U-^{207}Pb. The first of these to be used – and the more traditional presentation – is called the Wetherill concordia diagram (Fig. 3) named for its developer George Wetherill (Wetherill 1956). It plots the ratios of radiogenic daughter Pb to the parent U, for each system (e.g., $^{206}Pb^*/^{238}U$ and $^{207}Pb^*/^{235}U$, where the asterisk denotes radiogenic Pb). When zircon forms, it has no radiogenic Pb and, therefore, plots at the origin of the diagram (i.e., when $Pb^*/U = 0$). With time, radiogenic Pb accumulates corresponding to the U decays, resulting in increasing $^{206}Pb^*/^{238}U$ and $^{207}Pb^*/^{235}U$. Because of the differences in half-lives between ^{238}U and ^{235}U, radiogenic ^{206}Pb and ^{207}Pb accumulate at different rates throughout Earth's history. Early in Earth's history, when ^{235}U was still abundant, ^{207}Pb kept approximate pace with ^{206}Pb. Progressively over time, however, ^{235}U decreased dramatically in abundance, due to its short half-life (~ 0.7 Ga), resulting in progressively less ^{207}Pb production to the point today where ^{235}U is nearly extinct (^{235}U abundance ~0.7%) and radiogenic ^{207}Pb production is very small. The difference between the ^{238}U and ^{235}U decays, and their corresponding radiogenic Pb production rates, results in the characteristic curvature of the Pb growth curve. Equivalent $^{206}Pb^*/^{238}U$ and $^{207}Pb^*/^{235}U$ ages in this diagram define this curved Pb evolution line, referred to as Concordia; zircons that have been closed systems since formation will plot on this curve. These are referred to as concordant and are generally considered to yield reliable ages.



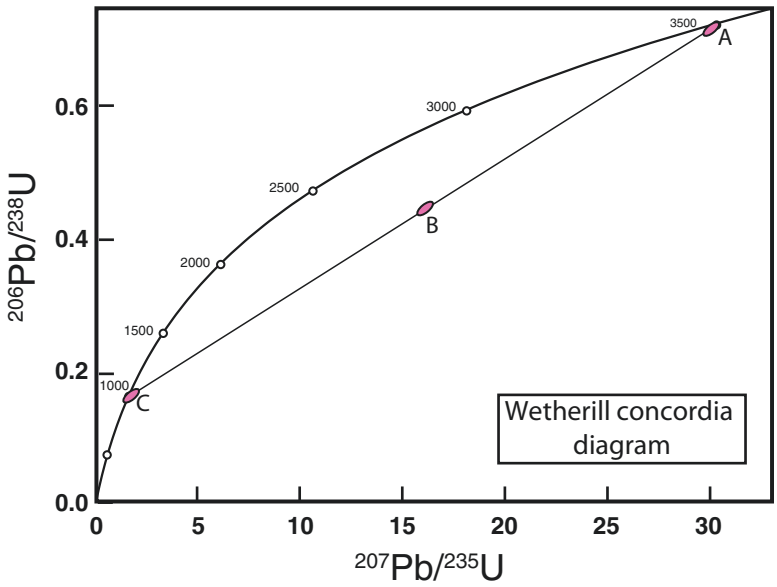
Geochronology and Radiogenic Isotopes, Fig. 4 The Tera-Wasserburg Concordia diagram. Arrows show the effects of inheritance of a ~ 1550 Ma zircon, common Pb, and recent Pb loss on a zircon with a crystallization age of 300 Ma

Disturbances and complexities in the U-Pb system, however, are common and can often be effectively illustrated by the Concordia diagram. These complexities generally take two forms: Pb loss (or, more rarely, gain) and multiple zircon growth components. In the case of the former, Pb loss will have lower Pb/U ratios and plot below Concordia. The loss of Pb from the zircon, if occurring in a discrete event, will plot along a straight line with an upper intercept on the concordia curve, representing no Pb loss, and a lower intercept, representing loss of all Pb from the zircon. This line is referred to as a "discordia" line. In this scenario, the upper intercept is taken to represent the crystallization age and the lower intercept is taken to represent the timing of Pb loss. Zircons plotting below Concordia are called normally discordant. In the more uncommon situation of zircons plotting above Concordia – due to Pb gain or U loss – these are called reversely discordant.

A second U-Pb diagram (called the Tera-Wasserburg concordia diagram; Fig. 4) plots $^{207}Pb/^{206}Pb$ vs. $^{238}U/^{206}Pb$ (Tera and Wasserburg 1972). There are some advantages of using this diagram. First, this diagram is less dependent on common Pb corrected Pb*/U ratios as is the case with the Wetherill Concordia diagram. Arrays of data points in this diagram, with variable uncorrected common Pb, can plot along linear arrays, whose upper intercept is taken to be the common Pb component and whose lower intercept is taken to be the crystallization age. This is useful for ^{204}Pb poor analyses and – especially – for microbeam methods (e.g., ion microprobe and LA-ICPMS) where quantitatively determining and removing a common Pb component is difficult. Finally, errors are only weakly correlated in this diagram allowing for a more rigorous assessment of any linearity in the data. A disadvantage of this diagram is that for old samples – whose analyses are close to concordia – it is difficult to identify a common Pb component, should it exist. In addition, it may be difficult to differentiate an inherited component from a common Pb component. Again this is particularly so for old samples.

The traditional way of presenting data – especially for data generated by ID-TIMS – is to use the Wetherill Concordia, which, for many users, may be more intuitive because it plots, on each axis, the ratio of the radiogenic daughter to the radioactive parent (i.e., $^{206}Pb^*/^{238}U$). U-Pb data generated by ion microprobe (e.g., SHRIMP) or by laser ablation ICPMS, however, typically measure $^{238}U/^{206}Pb$ and $^{207}Pb/^{206}Pb$ and calculate $^{235}U/^{207}Pb$ (which is not directly measured) from these two ratios and the natural $^{238}U/^{235}U$ ratio. As a result, many authors generating data with these methods plot their U-Pb data using the Tera-Wasserburg diagram as this plots the ratios actually being measured.

Despite the fact that the U-Pb system is widely considered to be the "gold standard" for geochronology – particularly for zircon and some other accessory phases – there are a number of potential factors that can complicate interpretations. For example, the U-Pb data shown in Fig. 5 can be produced in different ways. One way would be for zircon crystallizing from a rock at 3.8 Ga (A) and with subsequent variable Pb loss at 1.0 Ga (B,C). The discordia trend, however, could also be produced by mixing of two discrete age components. Using the example shown in Fig. 5, this could be produced by a rock crystallizing zircon at 3.8 Ga (A) and with magmatic or metamorphic overgrowths at 1.0 Ga (C, mixture at B). Alternatively, it could also be produced by the rock crystallizing at 1.0 Ga (C) but with some inheritance of 3.8 Ga zircons (A, mixture at B). In these two cases, the magmatic event (generally what we are most interested in dating) is very different and resolving between these two scenarios is not always straightforward. Fortunately, with modern in situ



Geochronology and Radiogenic Isotopes, Fig. 5 A Wetherill Concordia diagram showing three hypothetical data points that can be explained by (1) Pb loss of 0%, 50% and 100% at 1.0 Ga from a zircon formed at 3.5 Ga or (2) mixing of components with ages of 3.5 and 1.0 Ga. See text for further explanation

analytical methods, integrated with cathodoluminescence imaging and informed by allied geochemical data such as Hf isotope compositions of the zircon zones, these different types of zircon growth can be resolved.

Both of these graphical methods have the ability to calculate upper and lower intercepts on discordia lines (when appropriate) as well as calculating concordia ages, which are weighted average ages of concordant analyses. In addition, weighted average $^{238}U/^{206}Pb$ and $^{207}Pb/^{206}Pb$ dates are commonly used for uniform populations of ages – typically $^{238}U/^{206}Pb$ for ages <1 Ga and $^{207}Pb/^{206}Pb$ for ages >1 Ga. The caveats with using these ages are that they can be affected by both Pb loss and inheritance, which can lead to spurious ages. The appropriate use of weighted ages can be generally informed by data plotted on the Concordia diagrams because these can help identify both Pb loss and inherited components in the populations by examination of the coupled U-Pb systematics.

For stand-alone ages, such as for detrital zircons, practitioners again typically use $^{238}U/^{206}Pb$ for dates < ~ 1 Ga and $^{207}Pb/^{206}Pb$ for dates > ~1 Ga. Data are commonly screened for potential complications on the basis of concordance; if a grain is >90% concordant (< 10% discordant based on the difference between the $^{238}U/^{206}Pb$ and $^{207}Pb/^{206}Pb$ dates), it is generally considered reliable. It is important to keep in mind that for detrital zircons the host rock is no longer present, making it difficult to determine the effect of ancient Pb loss or inheritance on the ages. Because this Pb loss trajectory can be parallel to Concordia, grains can have significant Pb loss or inheritance and still appear largely concordant based on the criteria described above.

The discussion above has focused on zircon because it is, by far, the most common phase used with the U-Pb system to determine dates. It is important to note, however, that the U-Pb system has been applied to other accessory phases with success and which have yielded complementary information to that obtained from zircon. Monazite U-Pb geochronology is chief among these other phases and has been used increasingly to determine ages of monazite growth during metamorphic events. Other phases include titanite, apatite, xenotime, and allanite (e.g., Ireland and Williams 2003; Woodhead et al. 2016). The challenge in many of these phases is the presence of higher amounts of common Pb, which can compromise the quantification of radiogenic Pb.

Monazite also has very high amounts of Th, which permits calculation of dates, based on the ^{232}Th-^{208}Pb decay scheme, to complement the U/Pb dates. In practice, however, the utility of the coupled U-Pb decays (e.g., in determining concordance, lead loss) generally outweighs the advantage of adding the Th-Pb chronometer and, therefore, the U-Pb systems are most widely used in monazite geochronology.

There are three primary analytical techniques that are routinely used in U-Pb geochronology of zircon and other accessory phases: ID-TIMS (isotope dilution-thermal ionization mass spectrometry), SIMS (secondary ionization mass spectrometry), and LA-ICPMS (laser ablation-inductively coupled plasma mass spectrometry). Each of these techniques has strengths and weaknesses – all have applications they are especially well suited for and others for which they are not. Description of these techniques has been discussed in detail elsewhere (e.g., Parish and Noble 2003; Ireland and Williams 2003; Kosler and Sylvester 2003). In general, however, it is useful here to briefly highlight their important features, strengths, and weaknesses as well as the applications to which they are most commonly applied.

Isotope dilution-thermal ionization mass spectrometry (ID-TIMS) involves complete dissolution of all of a zircon or zircon fragment, spiking the resulting solution with a

mixed U-Pb isotope tracer, separating Pb and U using ion chromatography, and analyzing these purified elements using thermal ionization mass spectrometry. In recent years, the technique of "chemical abrasion" (Mattinson 2005) has been added to this method (commonly called CA-ID-TIMS) which uses a combination of thermal annealing and partial dissolution of zircon with HF acid to remove radiation damaged domains, which are more subject to higher Pb loss, to greatly improve the concordance of the analysis. ID-TIMS offers, unquestionably, the highest precision measurements of the three techniques but has the poorest spatial resolution. This technique is best applied to simple zircons that have not been complicated by older inherited domains or younger overgrowths. It has been especially powerful in providing tight age constraints on the geological timescale by dating volcanic ash layers interbedded with sedimentary strata (e.g., Bowring and Schmitz 2003).

Secondary ionization mass spectrometry (SIMS) uses a primary beam of high-energy ions (typically O_2^- or $^{16}O^-$) that is focused onto a polished surface to produce a small volume of secondary ions that are then accelerated, focused, and analyzed by the mass spectrometer (e.g., Ireland and Williams 2003). The most common SIMS instrument for use in geochronology is the ion microprobe. The first of these instruments to be used for U-Pb geochronology was the SHRIMP (for Super High Resolution Ion Microprobe), later followed by the Cameca 1270 ion microprobe. These instruments use a large radius magnet and high resolution to separate and analyze the Pb and U (and Th) masses of interest. Typically a small (~30 μm; range 10–50 μm) primary ion beam ablates the surface of the target and consumes a pit (or spot) a few microns deep. Invariably these analyses are used in conjunction with cathodoluminescence (CL) and/or back scattered electron (BSE) images of the zircon grains, which provide essential information on the internal structure and growth domains of the zircon. In conjunction with the essentially nondestructive nature of the analysis, this technique affords unquestionably the highest spatial resolution and is particularly powerful in targeting specific domains of zircon crystals. These analyses, however, are not nearly as precise as the ID-TIMS measurements (Schmitz and Kuiper 2013).

Laser ablation-inductively coupled plasma mass spectrometry (LA-ICPMS) has seen an explosion of use in the last decade because it has brought the capability of U-Pb geochronology to many more laboratories through the acquisition of considerably lower cost instrumentation and with a technique that does not require low-blank clean chemical laboratories. This method uses a laser (typically a 193 or 213 nm) in conjunction with an inductively coupled plasma mass spectrometer. The laser is used to ablate the sample creating an aerosol, which is swept with carrier gases into the mass spectrometer's plasma where it is ionized, accelerated, and analyzed. Typical laser spot sizes are comparable to SIMS analyses (~30 μm), but the depth of the ablation pit – and, therefore, the ablated volume – is about an order of magnitude greater. Therefore, although this technique provides some spatial resolution, it is not as fine as it is for SIMS. The precision of individual spot analyses are comparable to SIMS, but this technique has had challenges with the normalization of U/Pb elemental fractionation during analysis and so it is currently limited to ~1–2% accuracy (the "so-called" 2% problem; Kosler et al. 2013).

The power of this technique is in its ability to produce a large throughput of relatively low-cost data with good spatial resolution and reasonable quality. This has been especially useful for applications requiring a large number of dates, such as detrital zircon U-Pb geochronology (e.g., Fedo et al. 2003), but also has allowed – owing to its greater access and lower cost – for the dating of many more rocks and minerals than would ever have been possible with ID-TIMS and SIMS alone. Although LA-ICPMS primarily began as a U-Pb zircon technique, it has also been successfully used for dating of monazite and other accessory phases (e.g., summary in Woodhead et al. 2016). In the last several years, the so-called "LASS" (laser ablation split stream) technique has been developed, which has been used to augment the U-Pb age data with other geochemical information. In this technique, the aerosol from the laser ablation is split into two mass spectrometers: one to analyze U-Pb to determine an age and the other to measure either isotopes (e.g., Hf isotopes in zircon, Yuan et al. 2008; Xie et al. 2008; Fisher et al. 2014a; Nd isotopes in monazite, Fisher et al. 2014b) or trace elements (Kylander-Clark et al. 2013). This has allowed for the integration of ages with isotopic or chemical data and has proved exceptionally useful in determining the source (e.g., Bauer et al. 2017) or petrogenesis (e.g., Kylander-Clark et al. 2013) of rocks as recorded by accessory phases. In sum, these three analytical techniques provide important complementary information and, for most applications, are much more powerful when used in concert rather than in isolation. In total, these techniques–and their integration–have solidified U-Pb as the pre-eminent geochronological tool.

K-Ar and Ar-Ar Geochronology

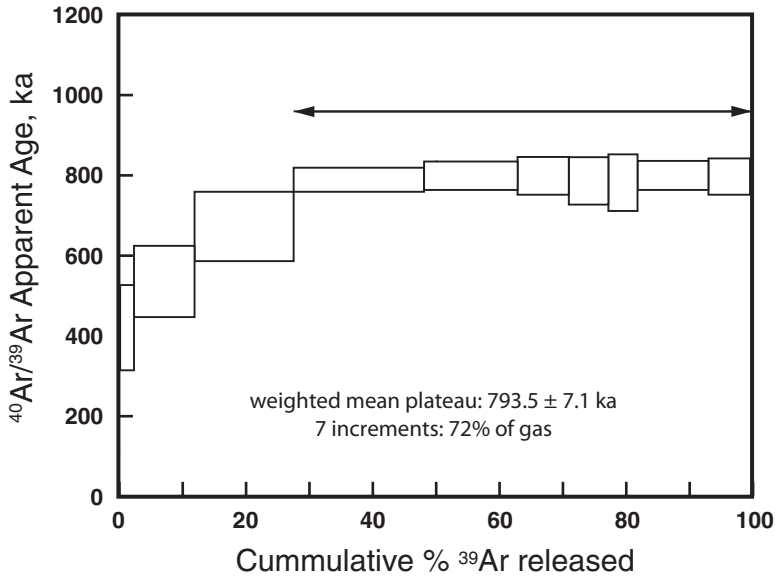
The K-Ar isotope system is based on the decay of ^{40}K to ^{40}Ar. This system has some advantages that make it particularly useful for geochronology. First, ^{40}K has one of the shortest half-lives (1.28×10^9 yr) of all the long-lived radioactive nuclides (Table 1). Second, K is a major element and is abundant in a wide variety of minerals. These factors make K-Ar (and $^{40}Ar/^{39}Ar$, described below) often the systems of choice for dating young geological events. But the K-Ar system is different from the others discussed here in a number of fundamental ways. First, ^{40}K has a branched decay with part of ^{40}K (~81%) decaying to ^{40}Ca by β^- decay and the rest (~19%) decaying to ^{40}Ar by electron capture. This branched

decay must be taken into account when calculating ages. Secondly, and more significantly for the ^{40}K-^{40}Ar decay, the parent nuclide is a lithophile element and is in a solid phase, whereas the daughter is a gas and is trapped in mineral phases and rocks rather than bound within crystallographic sites. This characteristic results in some significant challenges, but also confers some distinct advantages.

In an ideal case, we could imagine a mineral crystallizing from a magma and trapping neither atmospheric Ar nor radiogenic Ar from source or surrounding rocks. In this case, there would be no ^{40}Ar in the system at $t = 0$ and we could calculate an age directly from the measured $^{40}Ar/^{40}K$, in an analogous manner to calculating an age from $^{206}Pb/^{238}U$ ratio in zircon with no common Pb. In practice, however, trapped ^{40}Ar can exist in many cases (e.g., trapped atmospheric Ar by a sub-aerial lava flow, or ^{40}Ar present in source rocks from decay from K-rich minerals) and its presence needs to be corrected. Conversely, because Ar is a gas and not bound into crystal lattices, it can, and does, escape. This is an obvious disadvantage in the sense that loss of the radiogenic ^{40}Ar would result in anomalously young ages, but can also be used as a tool by utilizing the fact that Ar loss happens as a function of mineralogy, grain geometry, as well as the thermal history of the rock and mineral. This Ar loss is diffusion limited and is, therefore, quantifiable.

In practice, the K-Ar system is no longer widely used because, with K in a solid phase and Ar in the gas phase, it is difficult to determine the $^{40}K/^{40}Ar$ ratio precisely for calculating ages. To overcome this analytical hurdle, the $^{40}Ar/^{39}Ar$ approach was developed. In this technique, K-rich samples are irradiated in a nuclear reactor and ^{39}Ar is produced from ^{39}K present in the sample by neutron capture. The amount of ^{39}Ar produced is a function of the amount of K present in the target, the natural $^{40}K/^{39}K$ ratio, and the production factor of ^{39}Ar from ^{39}K in the reactor. In this way, ^{39}Ar can be used as a proxy for ^{40}K (and $^{40}Ar/^{39}Ar$ a proxy for $^{40}Ar/^{40}K$). The advantage of this technique is not only that $^{40}Ar/^{39}Ar$ can be measured more accurately but also that this ratio can be measured simultaneously in discrete gas fractions. In this technique, Ar is collected from samples as they are heated under vacuum. The $^{40}Ar/^{39}Ar$ ratio is then measured in these individual gas fractions (Fig. 6). In the case of a mineral grain, one would expect Ar to have been lost from the edges of the crystal, while the interior of the grain will have retained more of its Ar. Thus, as a grain is heated under vacuum, the first parts of the Ar released will likely come from the Ar pool that has already lost some Ar (and thus display lower $^{40}Ar/^{39}Ar$ ratios and younger apparent ages) and later fractions from Ar more tightly held by the mineral grain (and thus yielding higher $^{40}Ar/^{39}Ar$ ratios and older apparent ages closer to the true age). This technique, called step heating, has become a powerful technique in revealing the thermal history of rocks and minerals and for determining accurate ages for K-bearing minerals. In addition, the Ar isotope data can be plotted on an isochron diagram using $^{40}Ar/^{36}Ar$ on the ordinate and $^{39}Ar/^{36}Ar$ on the abscissa (again, where ^{39}Ar is a proxy for ^{40}K) or on an inverse isochron diagram where $^{36}Ar/^{40}Ar$ is on the ordinate and $^{39}Ar/^{40}Ar$ is on the abscissa. These diagrams are useful in identifying extraneous sources of Ar such as atmospheric or trapped Ar. All aspects of the $^{40}Ar/^{39}Ar$ method of dating are discussed in detail in McDougall and Harrison (1999).

In summary, several characteristics of the $^{40}Ar/^{39}Ar$ chronometer have contributed to its utility: the introduction and refinement of the $^{40}Ar/^{39}Ar$ method has improved determination of ages using the ^{40}K-^{40}Ar decay; the fact that this system is based on a major element present as a stoichiometric constituent in several rock-forming minerals makes it applicable to a wide variety of rock types; the relatively short half-



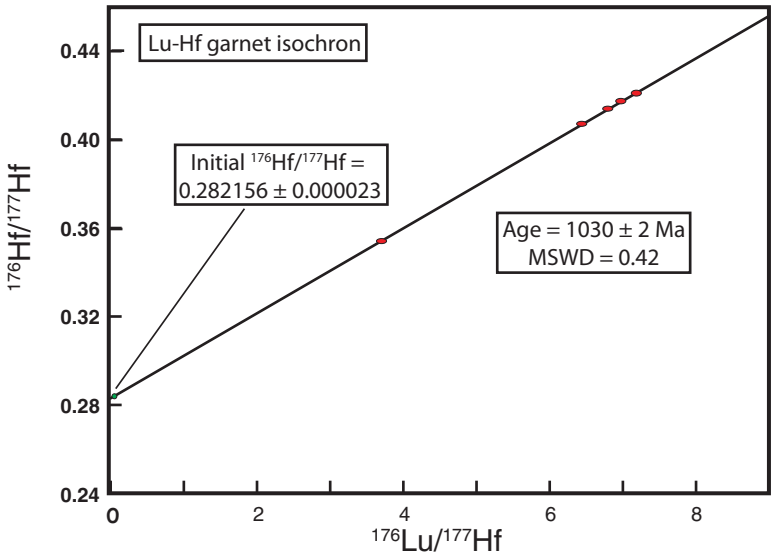
Geochronology and Radiogenic Isotopes, Fig. 6 An example of a $^{40}Ar/^{39}Ar$ age spectrum of a sample from a basaltic lava flow. Ten gas steps were released by successively raising the temperature in 50 °C increments. The plateau age in this example is calculated from seven contiguous steps comprising 72% of the gas released. The younger ages from gas released at lower temperatures are interpreted as Ar loss during weathering. Figure is from Singer 2007

life of ^{40}K allows this system to date young geological events; and Ar diffusion from the mineral lattice can be used to model the thermal history of a rock. These characteristics have contributed to making $^{40}Ar/^{39}Ar$ dating an exceptionally useful and diverse geochronological and thermochronological tool used widely throughout the geosciences.

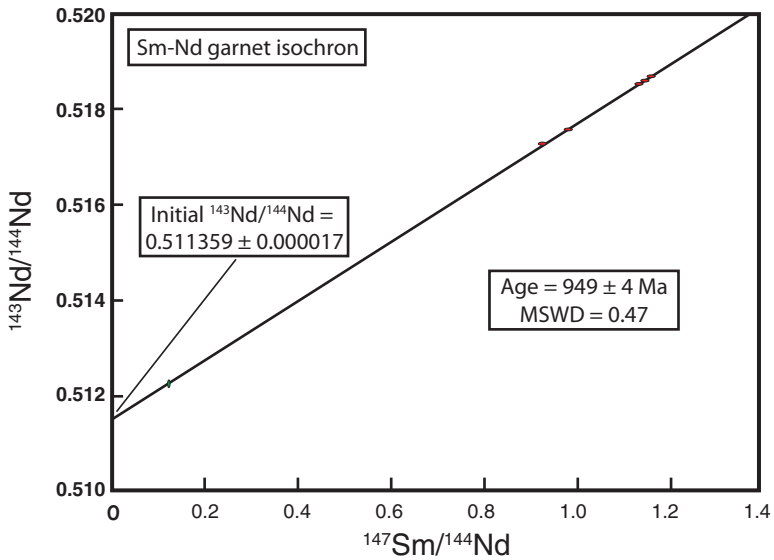
Garnet Lu-Hf and Sm-Nd Geochronology

Garnet geochronology is an example of an effective use of the isochron method for determining reliable ages (Figs. 7, 8). This application utilizes both the Lu-Hf and Sm-Nd isotope systems (^{176}Lu to ^{176}Hf, $t_{1/2} = 36$ billion years; ^{147}Sm to ^{143}Nd, $t_{1/2} = 106$ billion years; Table 1) and provides constraints on the timing of garnet growth in the rock and, therefore, has been used to provide constraints on the timing of metamorphism by directly dating a major index mineral that is produced during metamorphism.

This chronometer utilizes garnet's ability to incorporate the parent elements Lu and Sm preferentially over their respective daughter elements (Hf, Nd) during growth, which results in highly elevated Lu/Hf and, to a lesser extent, Sm/Nd ratios in the garnet relative to the bulk rock. Whereas the bulk Earth has low $^{176}Lu/^{177}Hf$ and $^{147}Sm/^{144}Nd$ ratios (0.0336 and 0.1960, respectively; Bouvier et al. 2008), garnets often have parent/daughter ratios 2 to 3 orders of magnitude (or more) higher. Over time, these elevated parent/daughter ratios result in the growth of highly radiogenic Hf and Nd (i.e., elevated $^{176}Hf/^{177}Hf$ and $^{143}Nd/^{144}Nd$). Such high parent/daughter ratios and highly radiogenic Hf and Nd isotope compositions provide large leverage in regression of a line



Geochronology and Radiogenic Isotopes, Fig. 7 Lu-Hf garnet isochron from a garnet granulite gneiss from the Virginia Grenville massif. The high Lu/Hf ratios (e.g., $^{176}Lu/^{177}Hf > 6$) in the garnet result in highly radiogenic Hf isotopic compositions ($^{176}Hf/^{177}Hf > 0.40$). This large range of parent/daughter ratios and Hf isotope compositions provide tight constraints for the regression line and result in a precise age



Geochronology and Radiogenic Isotopes, Fig. 8 Sm-Nd garnet isochron from the same garnet granulite gneiss as in Fig. 7. Note that this age, although tightly constrained as the Lu-Hf garnet age, is over 80 Ma younger. Johnson et al., (2017) have suggested this represents differences in the closure temperatures for the Lu-Hf and Sm-Nd isotope systems

through the data and, therefore, in a tightly constrained isochron age.

One of the major requirements for an accurate isochron age is that the system must be in isotopic equilibrium at time = 0. That is certainly not the case in the strict sense because the garnets are often riddled with inclusions, including zircon and other phases, which often do not have the same Hf isotopic composition as the garnet at the time the latter grew. The large radiogenic in-growth occurring during garnet growth, however, helps to compensate for initial isotopic heterogeneities that may have existed at the time of garnet growth and lessens the stringency of this isochron requirement. Initial Hf isotopic heterogeneity – particularly in robust, refractory, and Hf-rich inclusions like zircon – however, is still something to be vigilant about, especially for young rocks or rocks with a small range in Lu-Hf or Sm-Nd (e.g., Scherer et al. 2000). Fortunately, these inclusions can be effectively avoided, in many cases, using different dissolution and leaching strategies (e.g., Ankiewicz and Thirlwall 2003; Baxter and Scherer 2013; Cheng et al. 2008).

The coupled use of the Lu-Hf and Sm-Nd garnet chronometers can provide important information on the thermal conditions during metamorphic events. For example, the Lu-Hf and Sm-Nd isochrons shown in Figs. 7 and 8 are determined from the same mineral fractions and, despite both having tightly constrained ages, differ by over 80 Ma. This has been interpreted to represent different rates of diffusion of elements in these granulite-grade gneisses during prolonged heating during the Grenville orogeny (Johnson et al. 2017). Similar differences in Lu-Hf and Sm-Nd garnet dates from granulite terranes have been noted by Smit et al. (2013).

In summary, Lu-Hf and Sm-Nd garnet chronology is widely used for providing age constraints on garnet growth. When used in concert with other chronometers, such as monazite U-Pb geochronology, and also interpreted within the context of the petrography and mineral chemistry of the rock assemblage, it can be a very powerful tool in helping understand metamorphic histories and processes.

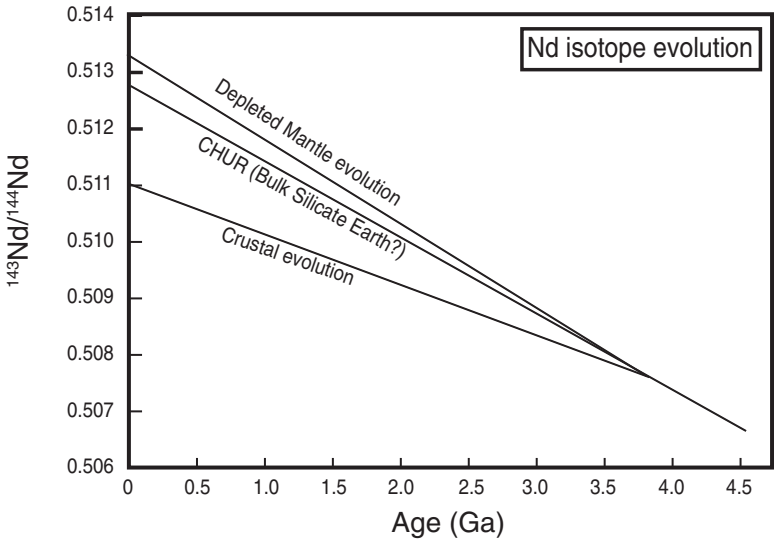
Tracer Isotopes and Model "Ages"

Radiogenic tracer isotope applications, by their very nature, include the element of time as recorded by the accumulation of the daughter isotope. In order to take full advantage of their utility, radiogenic tracer isotopes need to be placed in the proper temporal framework. In most cases, what is of most interest is the isotope composition of the rock or mineral at the time of formation rather than what it is at present. If there are independent constraints on the age of the rock or mineral, its isotopic composition at any time in the past can be calculated by subtracting the amount of radiogenic daughter atoms that had accumulated over the time interval of interest. For the Sm-Nd isotope system, this would be:

$$\left(\frac{^{143}Nd}{^{144}Nd}\right)_t = \left(\frac{^{143}Nd}{^{144}Nd}\right)_p - \left(\frac{^{147}Sm}{^{144}Nd}\right)_p \left(e^{\lambda t} - 1\right) \qquad (23)$$

where the subscript t is the time of interest and p signifies the present. What this equation shows is that the Nd isotope composition ($^{143}Nd/^{144}Nd$) at some time, t, can be calculated from the present-day $^{143}Nd/^{144}Nd$ and subtracting the amount of radiogenic ingrowth that has occurred over a given interval of time, which can be calculated from the $^{147}Sm/^{144}Nd$ ratio measured at present and the amount of time, t, that has elapsed.

If the *t* of interest is calculated at the time of formation (e.g., crystallization) of the rock, this is often denoted with the subscript "i" signifying the "initial" isotope ratio (e.g., $^{143}Nd/^{144}Nd_{(i)}$). Figure 9 shows the generalized evolutionary paths for chondritic (bulk silicate Earth), depleted mantle, and crustal reservoirs for the Sm-Nd isotope system, with a



Geochronology and Radiogenic Isotopes, Fig. 9 Diagram showing model evolutionary paths for chondritic (bulk silicate Earth), depleted mantle, and crustal reservoirs for the Sm-Nd isotope system, with a hypothetical separation of the depleted mantle and a crustal reservoir from the bulk silicate Earth at ~3.8 Ga

hypothetical separation of the depleted mantle and a crustal reservoir from the bulk silicate Earth at ~3.8 Ga.

Radiogenic isotopes have also been used to calculate what has been called a "model age," which uses the trajectory of the radiogenic growth back into time to estimate the time of separation from a particular reservoir such as the depleted mantle (DM) or a chondritic Earth composition (e.g., CHUR or chondritic uniform reservoir). These are calculated in two basic ways. One is when there are no age constraints on the rock or mineral. In this case, the present-day parent/daughter ratio is used to calculate the trajectory back to the intersection with the estimated reservoir evolution. For a depleted mantle Nd model age, for example, this would be calculated with the following expression:

$$t_{CHUR} = \frac{1}{\lambda}\left[\frac{\frac{^{143}Nd}{^{144}Nd\ (\text{sample})} - \frac{^{143}Nd}{^{144}Nd\ (DM)}}{\frac{^{147}Sm}{^{144}Nd\ (\text{sample})} - \frac{^{147}Sm}{^{144}Nd\ (DM)}} + 1\right] \quad (24)$$

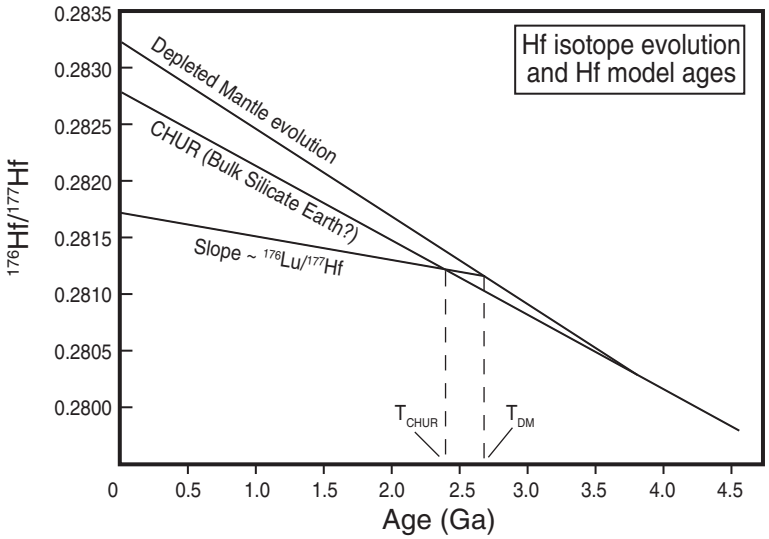
This method has been frequently used on sediments to calculate what has been called a "crustal residence" age, which is intended to estimate the *average* time the sources of the sediment have resided in the crustal reservoir (or the time since the precursor materials have been extracted from the mantle). A parallel expression can be written for the Lu-Hf isotope system. A graphical representation of chondritic (T_{CHUR}) and depleted mantle (T_{DM}) ages is shown in Fig. 10. Model ages have also been used effectively in the Re-Os system (see Shirey and Walker 1998, for a full discussion).

In many cases, however, there are independent constraints on the age of the rock or mineral. In such cases, the age and parent/daughter ratio are used to calculate the isotopic evolution back to the age of crystallization. From this point, a different trajectory often has to be assumed because the precursor evolution will be different from the rock or mineral that formed at that time. A clear example of this is for zircon Hf model ages, which have become increasingly common in detrital zircon studies because of the ability to measure both U-Pb and Hf isotopes on single zircon grains or spots of grains. In this case, the age and Lu/Hf ratio are used to calculate back to the age of the zircon. In the case of detrital zircons, however, there no longer is information on the rock from which that zircon was derived and a Lu/Hf ratio has to be assumed for its precursor rock. This assumed Lu/Hf ratio is then used to estimate the evolution path back to the reservoir of interest. This is shown diagrammatically in Fig. 11.

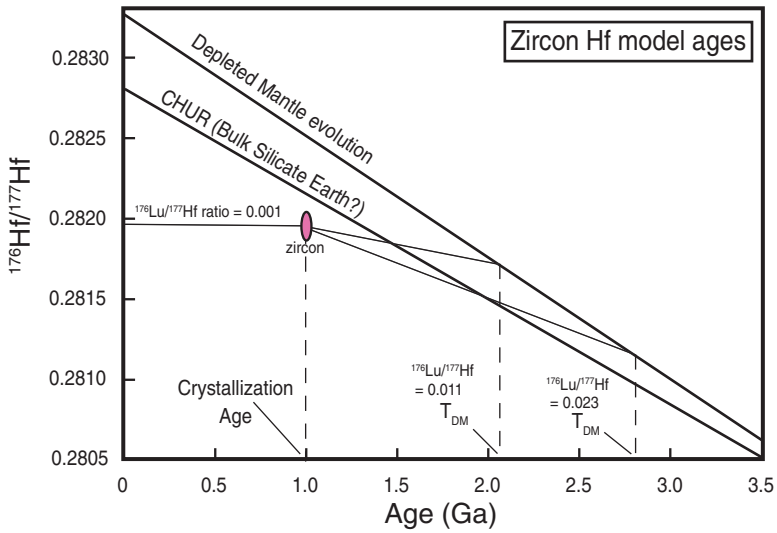
It is important to keep in mind, however, that there are many assumptions built into these calculations and even though these are commonly called model "ages," they are not ages at all in the quantitative sense. Rather, they are highly qualitative models to estimate a time of separation from a particular reservoir. The inherent uncertainty in these many assumptions should clearly be kept in mind in the interpretation of zircon Hf model ages. The limitations of model ages have been discussed in considerable depth in Vervoort and Kemp (2016).

Summary

In summary, geochronology is an essential part of Earth Sciences and has made profound contributions throughout virtually every aspect of this discipline for the simple reason that it provides information on timing and rates that is an integral part of Earth Sciences. Early applications of geochronology mostly involved employing one chronometer to answer a problem (e.g., using the Rb-Sr isotope system to



Geochronology and Radiogenic Isotopes, Fig. 10 Diagram showing model evolutionary paths for chondritic (bulk silicate Earth) and depleted mantle, and crustal reservoirs for the Lu-Hf isotope system, with a hypothetical separation of the depleted mantle from the bulk silicate Earth at ~3.8 Ga and separation of a crustal rock from the depleted mantle at 2.7 Ga. Also shown is a graphical representation of chondritic (T_{CHUR}) and depleted mantle (T_{DM}) Hf model ages



Geochronology and Radiogenic Isotopes, Fig. 11 Diagram showing the calculation of Hf model ages for a zircon with a crystallization age of 1.0 Ga. The Hf isotope composition of the zircon is calculated back to 1.0 Ga using the low Lu/Hf ratio of the zircon. Past that point, however, a precursor Lu/Hf needs to be assumed because the rock from which the zircon was derived no longer exists. A low Lu/Hf ratio, typical of an evolved precursor rock, would yield a model zircon Hf age of ~2.1 Ga, whereas a higher Lu/Hf ratio, typical of a more primitive precursor, would yield an older model age of ~2.8 Ga. This illustrates some of the uncertainty inherent in determining zircon Hf model ages (see Vervoort and Kemp 2016)

date a rock). It is becoming increasingly apparent, however, that each chronometer gives us a different set of information and, therefore, geochronology is much more powerful – and provides a more complete picture of past history – when used in concert with other chronometers. In addition, the information that these isotope systems provide is more meaningful when integrated with other isotope data (e.g., tracer isotopes) and also interpreted in the context of other geologic data from allied fields such as petrology, petrography, structural geology, tectonics, and geophysics.

Geologic Time Scale

Mark D. Schmitz
Department of Geosciences, Boise State University, Boise, ID, USA

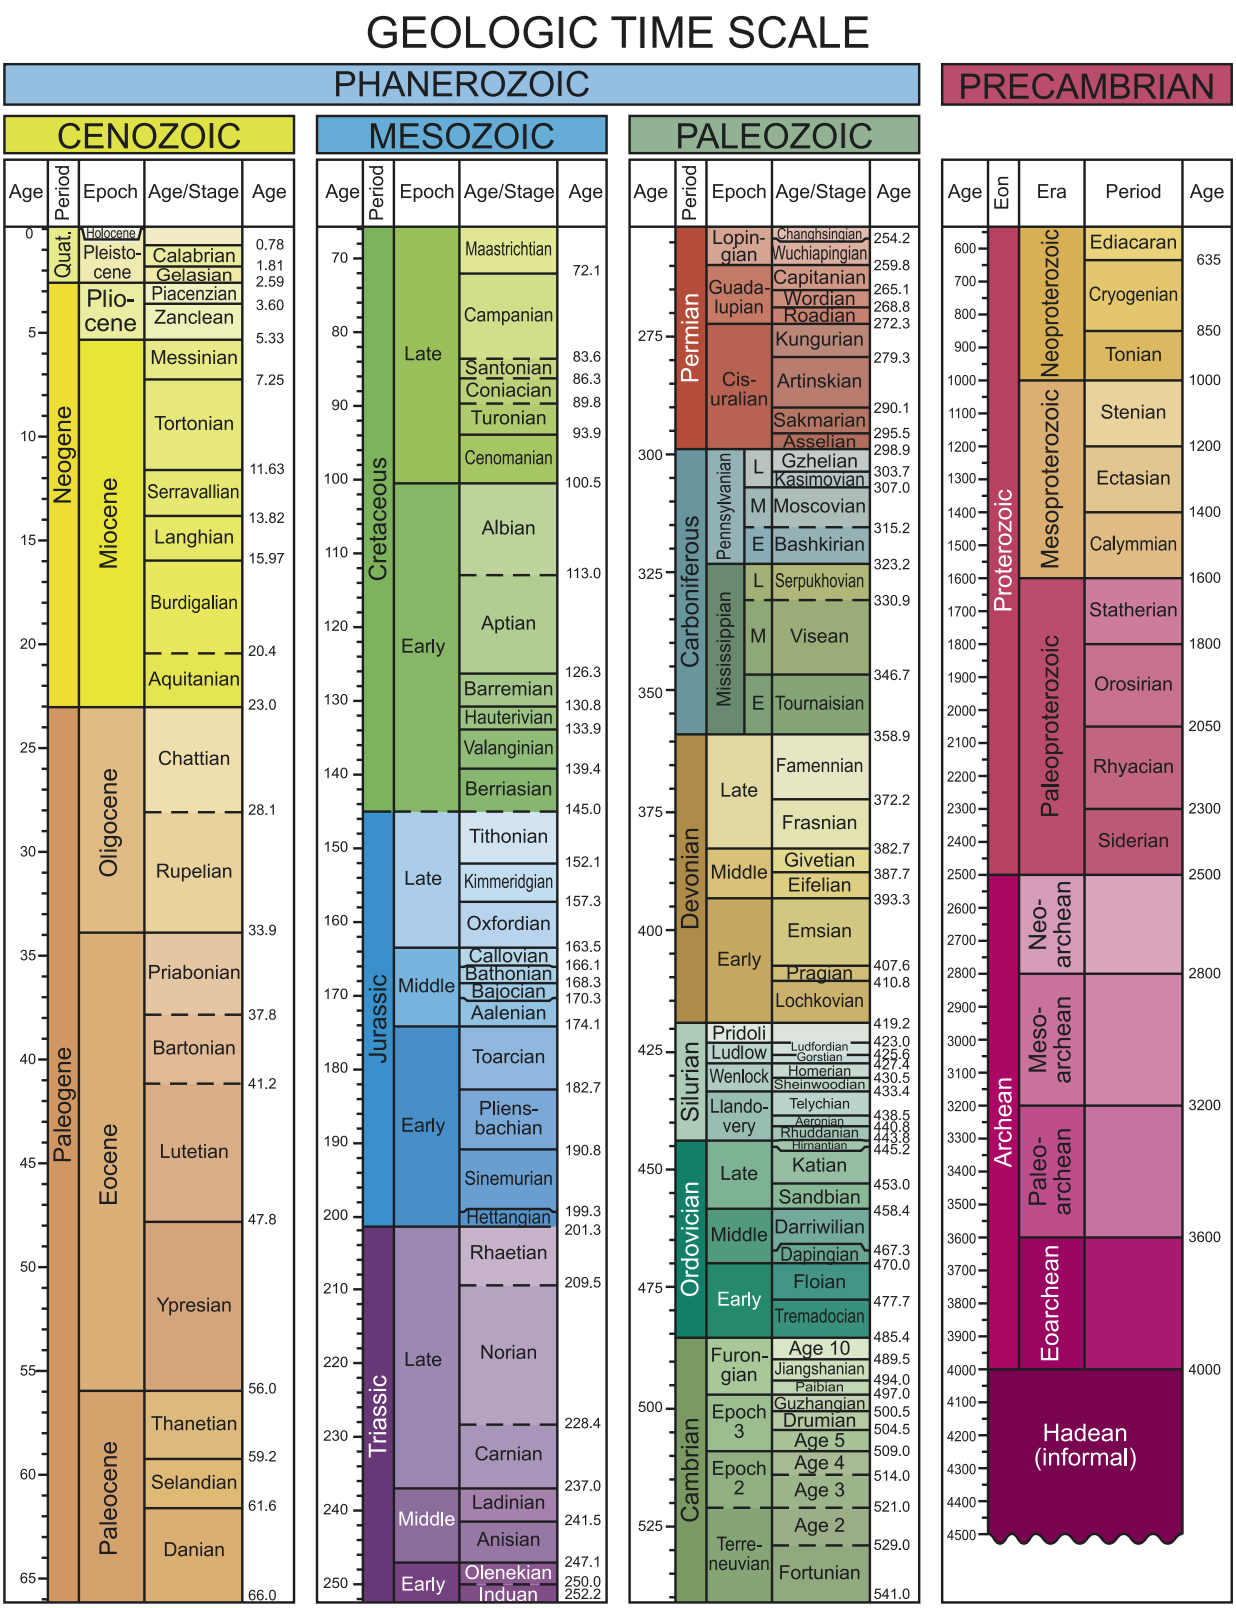
Definition

The geologic time scale is the scientific reconstruction and representation of Earth's history from its rock record. The geologic time scale has its origins in the nineteenth-century recognition that through the application of the laws of superposition and fossil succession, a reproducible relative age order of rock strata could be assembled. The geologic time scale consists of two conceptual frameworks, one linked to the observable rock record of superposed sedimentary strata and their embedded physical, chemical, and fossil assemblage characters and the other tied to the theoretical construct of absolute time (Gradstein 2012). This rock versus time duality of the geologic time scale is manifested in the two distinct nomenclatures for *chronostratigraphic* and *geochronologic* age.

Time Scale Construction

In the Phanerozoic and the latest Precambrian, chronostratigraphic units are constructed from fossiliferous strata. The appearance, absence, acme, or coexistence of fossil organisms is variously used to construct a hierarchy of units, in the following order of increasing stratigraphic resolution: eonothem, erathem, system, series, and stage. The parallel geochronologic units are the eon, era, period, epoch, and age. Global chronostratigraphic units are developed and ratified through the efforts of the International Union of Geological Sciences (IUGS) International Commission on Stratigraphy (ICS) and its subcommissions. These units of the time scale are defined through boundary stratotypes, which preserve in a rock sequence the transition between two stages. The precise reference point for each stage boundary is established as a Global Stratotype Section and Point (GSSP), which comprises a set of primary and secondary correlation markers expressed within a stratigraphically complete interval of rock accumulation (Remane et al. 1996). The geologic time scale is thus defined by a series of GSSPs (Fig. 1).

Subsequent efforts to place this relative rock scale within an absolute time scale, notably first by Holmes (1913), have used a variety of radioisotopic dating methods based mainly upon K-Ar and U-Pb decay (Harland et al. 1982). Key criteria for precise and accurate age estimates are closed system behavior through geologic time, minimization or mitigation of initial daughter products in the dated minerals, precise and representative isotope ratio measurements, and accurately measured rate constants for the radioactive decay processes. The current standard methods for precise and accurate radioisotopic time scale calibration are the ^{238}U-^{206}Pb decay scheme measured by isotope dilution thermal ionization mass spectrometry in accessory minerals like zircon and the ^{40}Ar/^{39}Ar variant of ^{40}K decay as measured by multi-collector gas source mass spectrometry in sanidine feldspar (Schmitz 2012). Both methods provide numerical ages for geologically instantaneous event beds like volcanic tuffs or bolide ejecta with a relative precision and accuracy of *ca* 0.1% of the absolute age. Geologic time scale calibration involves the careful radioisotopic dating of these event beds within fossiliferous strata that also may record geochemical and geomagnetic correlation signals. In the Cenozoic and much of the Mesozoic, radioisotopic dating has been used to calibrate seafloor spreading models upon which the global magnetic polarity time scale has been constructed (Cande and Kent 1992; Ogg 2012). In the fossil-poor Precambrian, the geologic time scale is almost wholly dependent upon radioisotopic dates for establishing correlative strata and geochronologic intervals.



Geologic Time Scale, Fig. 1 Current global geologic time scale compiled by the 69 authors and contributors to *The Geologic Time Scale 2012* (Gradstein et al. 2012)

G

Chemostratigraphy

The use of geochemical signals in the stratigraphic record – chemostratigraphy – plays an important role in geologic time scale development, in tracking both endogenous (volcanism, weathering, biological productivity) and exogenous (cosmogenic ray flux, bolide impact) drivers for change in biogeochemical cycles and their associated geochemical excursions preserved in the rock record. Carbon isotope excursions are often found associated with major climatic and biological crises that accompany or even drive macroscopic lithological changes in the rock record. Where these excursions have been shown to be global and synchronous, they now provide important correlation markers (Halverson et al. 2010) and even define the GSSPs for some units of the geologic time scale (Aubry et al. 2007).

Cyclostratigraphy and Astrochronology

Geochemistry often elucidates rhythmic elemental or isotopic fluctuations within rock sequences that underlie the discipline of cyclostratigraphy. The causes of sedimentary cycles are varied, as are their megaannum to sub-annual periods. Most important to the geologic time scale are ca 20–400 kiloyear cycles corresponding to variations in the Earth's orbital and rotational parameters. Early attempts to identify within the rock record the rhythm of Earth's orbital variations and associated changes in incoming solar radiation began with Gilbert (1895), were placed on a quantitative astronomical footing by Milankovitch (1941), and reached fruition with the oxygen isotope records of Hays et al. (1976). When these cyclostratigraphic records are tuned to forward modeling of Earth's orbital motion (Berger et al. 1992; Laskar et al. 2011), the resulting astrochronology has provided a continuously calibrated time scale for the Neogene tied to the present day (Hinnov and Ogg 2007; Hilgen et al. 2012). Other cyclic records in deeper time provide floating astrochronologies that can be linked to the geologic time scale through both stratigraphic markers and radioisotopic dates (Pälike et al. 2006; Meyers et al. 2012). Extending astrochronology across the Paleogene and into the Mesozoic remains a primary goal for future refinement of the geologic time scale (Westerhold et al. 2008; Hilgen et al. 2010; Kuiper et al. 2008).

Summary

The geologic time scale provides a foundation for investigations of the correlation, causality, and rates of Earth processes in deep time. By pacing the tempo of biological and geological evolution, it reveals the interactions and feedbacks between Earth's complex systems. In bringing together stratigraphic and geochronologic records, it bridges the sedimentary, igneous, and metamorphic realms and allows paleogeographic and plate tectonic integration. Revision and refinement of the geologic time scale is an active endeavor facilitated by an interdisciplinary geoscientific community.

Geoneutrinos

William F. McDonough
Department of Geology, University of Maryland, College Park, MD, USA

Definition

Geoneutrinos are electron antineutrinos ($\overline{\nu}_e$) produced during beta-minus (β^-) decay and electron neutrinos (ν_e) produced during beta-plus (β^+) decay and electron capture of naturally occurring radionuclides. The generic versions of these decay schemes are

$$\text{beta} - \text{minus } (\beta^-) \text{ decay} \qquad {}^{A}_{Z}X \rightarrow {}^{A}_{Z+1}X' + e^- + \overline{\nu}_e$$

$$\text{beta} - \text{plus } (\beta^+) \text{ decay} \qquad {}^{A}_{Z}X \rightarrow {}^{A}_{Z-1}X' + e^+ + \nu_e$$

$$\text{electron capture} \qquad {}^{A}_{Z}X + e^- \rightarrow {}^{A}_{Z-1}X' + \nu_e$$

with mass number (A) being conserved, atomic number (Z) increasing or decreasing by one from the parent (X) to daughter (X′) element in the decaying nucleus and the production of a nuclear electron and electron antineutrino during β^- decay, nuclear positron and electron neutrino during β^+ decay, or only an electron neutrino during electron capture. Table 1 defines the elements in the Earth that undergo beta-minus (β^-) decay.

Geoneutrino Detection

Only four isotopes, two in the ^{232}Th decay chain (^{228}Ac and ^{212}Bi) and two in the ^{238}U chain (^{234}Pa and ^{214}Bi), emit electron antineutrinos with sufficient energies to be detected by present-day methods, which involves scintillation detection via the inverse beta decay mechanism (IBD). This process involves an electron antineutrino transiting a large volume (e.g., typically kiloton in scale), underground liquid scintillation detector and interacting with a free proton (hydrogen atom in the hydrocarbon scintillator) to produce a positron and a neutron $p + \overline{\nu}_e \rightarrow e^+ + n$. This reaction requires that the $\overline{\nu}_e$ possesses at least 1.806 MeV of energy to initiate the reaction. Consequently, inside the liquid scintillation detector, there are two flashes of light, the prompt flash associated with positron–electron annihilation, which occurs some several hundred picoseconds after the initial interaction, and the delayed flash from the neutron capture by a proton producing deuterium, with this latter flash generating 2.2 MeV of light and occurring approximately 30 cm and about 200 μm seconds further away. This highly synchronized event chain, which is only accessible to electron antineutrinos, eliminates most background and permits kiloton detectors to record at the feeble rate of about one event per month due to the incredibly weak interaction force and negligible interaction cross section (10^{-43} cm^2) of these neutrinos. The first detection of geoneutrino was reported in *Nature* in Araki et al. (2005), and to date only two detectors, KamLAND (1 kton) in Japan and Borexino (0.3 kton) in Italy, have reported on the Earth's flux (Gando et al. 2013; Agostini et al. 2015). The Earth is estimated to be radiating $\sim 3 \times 10^{25}$ antineutrinos per second to space, with an average surface flux of about ~6 million $\overline{\nu}_e$ cm^{-2} s^{-1} (Usman et al. 2015), although the surface flux varies considerably depending on if it is from the oceanic crust (low flux) or the continental crust (high flux). The dominant flux comes from potassium geoneutrinos and lesser amounts from U, Th, and Rb (Fig. 1); the remaining β^- decay schemes (including ^{235}U) contribute much less than 1% of the total flux. The Earth's flux of electron neutrinos from beta-plus (β^+) decay and electron capture has yet to be detected because of their low energies and weak signal as compared to the solar flux of electron neutrinos

Constraining Earth's Composition and Terrestrial Heat Production

Geoneutrino studies will provide a quantitative measure of the amount of uranium and thorium inside the Earth. Based on these measurements and assuming negligible Th and U in the core and a K/U value for the silicate Earth (Arevalo et al. 2009), we can establish the planet's budget of the heat-producing elements (K, Th, and U provide more than 99% of its radiogenic power) and the absolute abundances of the refractory elements (e.g., Ca, Al, Th, and U) in the Earth. These data in turn provide critical constraints on the power driving plate tectonics, mantle convection, and the geodynamo. Estimates of the content of heat-producing elements in the continental crust, the most accessible part of the Earth, are 7 ± 1 TW (10^{12} W) (Huang et al. 2013), whereas estimates of the planetary production of radiogenic heat differ by a factor of 3 (~10 to 33 TW for the bulk silicate Earth (BSE)). Consequently, estimates of the production of radiogenic heat in the mantle vary by a factor of ~30 (subtracting 7 ± 1 (crustal estimate) from 10 ± 2 or 33 ± 3 low and high estimate of the BSE, respectively; see Šrámek et al. (2013) for details. Knowing the amount of radiogenic power in the mantle will in turn exclude end-member compositional models for the Earth and place significant limits on models defining the mode of mantle convection (Šrámek et al. 2016).

Future Studies

Geoneutrino research is an emerging field in the geosciences that has only recently completed its first decade of data taking. The detectors in Japan and Italy will soon be joined by the SNO+ detector (1 kton, expected to be counting in 2017) in Sudbury, Canada; the JUNO detector (20 kton, expected to be counting in 2020) in Jiangmen, China; and the Jinping detector (3 kton, expected to be counting in 2022) in Mianning County, Sichuan Province, China. The annual geoneutrino count rate at these detectors is low (measured at KamLAND at 14 events/year and Borexino at 4.2 and predicted at SNO+, 20; JUNO, 400; and Jinping, 100, with approximately 20% of the signal from Th and 80% from U), and so the total exposure time is significant for these experiments, as measurement uncertainties follow Poisson's statistics (Šrámek et al. 2016). Differences in count rates vary according to detector size, detector efficiency, and geologic setting. The convention is to report signal intensity in TNU (terrestrial neutrino units: given as one event per 10^{32} target nuclei (free protons) per year at 100% detection efficiency; Mantovani et al. (2004)), with the scaling between flux and TNU given as $C = \phi/R$ [$C_U = 7.6 \times 10^4$ cm^{-2} s^{-1} TNU^{-1} and $C_{Th} = 2.5 \times 10^4$ cm^{-2} s^{-1} TNU^{-1}] (Dye 2012). A recent projection for the year 2025, which was based on a reference BSE model and integrated counts from these detectors, yields a mantle flux of 8.2 ± 2.9 TNU (or 12 ± 4 TW) (Šrámek et al. 2016).

A proposal for an ocean-based detector (Hanohano: Hawaiian Anti-neutrino Observatory; said twice for added emphasis) has been put forth (Learned et al. 2007) for deployment at depth in the ocean, remote from nuclear reactors, and continental crust. Deploying such a detector in the Pacific Ocean, equidistant from Australia, South America, and the core–mantle boundary would offer the best mantle-only flux measurement. Šrámek et al. (2013) proposed that such a neutrino geoscope could be used to critically evaluate mantle structures such as the seismologically imaged LLSVPs (large low-shear-velocity provinces), which would generate tomographic images of the deep Earth based on north to south Pacific Ocean surveys. In addition, the promise of detector directionality is on the horizon (Tanaka and Watanabe 2014), where such imaging could potentially examine differences in mantle and core versus mantle-only signals (Dye 2010).

Finally, another form of neutrinos, called atmospheric electron neutrinos and electron antineutrinos, is produced from cosmic ray interactions with the atmosphere. These neutrinos can traverse the planet and ultimately be detected before leaving the Earth. Recently, Rott et al. (2015) showed that these neutrinos can probe the composition and density of the Earth as these neutrinos are sensitive to the Earth's electron density. These studies promise to bring insights into the Z/A state of the Earth's core and would be most sensitive to the amount of hydrogen in the core. Moreover, with greater sensitivity in future instrumentation, these measurements will place constraints on the nature of the light element mixture in the outer and inner core.

Definition

Geothermal systems form a continuum having a wide range of geologic and thermal conditions depending on: (1) their depth and temperature (geothermal gradient); (2) the amount of natural steam and/or water they contain; and (3) the permeability and porosity of the geologic formation in which fluids flow. At one extreme are convective geothermal systems where nature provides sufficiently high temperatures, fluid content, and permeability to support convective fluid transport. At the other extreme are conduction dominated systems where fluid content and permeabilities are very low and reservoirs are at greater depth due to lower geothermal gradients. Although it is challenging to specify geologic conditions for each system, high-grade hydrothermal reservoirs are often contained in highly fractured volcanic rocks at or near tectonic plate boundaries. In contrast, conduction dominated systems are frequently associated with deeper sedimentary basins or basement rock formations that contain well-sealed fractures with very low permeability and porosity (Mock et al. 1997; Glassley 2010; IPCC 2011; Tester et al. 2012).

In this article, we focus on a class of geothermal systems dominated by convective circulation of subsurface fluids between cold, near-surface reservoirs and hot reservoirs.

Introduction

Heat sources in Earth's crust at depths ranging from roughly 2–5 km drive convective fluid circulation between cold shallow reservoirs and deeper hot reservoirs (Cathles 1977; Norton and Knight 1977; Hayba and Ingebritsen 1997). As dense, cold water in shallow reservoirs descends by gravity to reach a deeper heat source, fluid temperatures increase and densities decrease causing the fluid to rise buoyantly towards surface. In natural settings, fluid is then either discharged in surface features such as hot springs, geysers, and fumaroles or recirculated as it cools near ground surface. The circulation is further maintained by relatively continuous meteoric and/or oceanic recharge.

Geographic occurrences of geothermal systems are controlled by the distribution of heat sources in Earth's crust. Volcanic regions, such as subduction zones, spreading centers, and hot spots (i.e., an anomalous upwelling of mantle material to Earth's surface), frequently produce geothermal systems when sufficient fluid recharge and rock permeability are present. Additional geologic regions that produce geothermal systems are extensional and/or transtensional regions and regions with high radiogenic activity (such as radiating intrusive igneous rocks).

Geothermal systems have been utilized for thousands of years as a thermal heat source and for over a century for generating electricity and for district heating (see Stober and Bucher 2013 for a review of the history of geothermal utilization). Beginning in 1904 in Italy, steam from the hydrothermal Lardarello field in Tuscany was used to produce electric power. By 2015, total installed nameplate capacity worldwide reached over 12.5 GW_e (Bertani 2015; Matek 2015).

Direct thermal use of heating has been used for centuries. Today there are extensive geothermal district heating systems in Iceland, Paris, China, and other countries supplying several million homes and total installed capacity of direct geothermal utilization reached 70.3 GW_{th} in 2015 (Lund and Boyd 2015). In addition, the use of energy stored in shallow aquifers or conductive environments at low temperatures has been extensively utilized via geothermal heat pumps (IPCC 2011; Lund and Boyd 2015).

Additional interest in geothermal fluids arose due to the demand for concentrated chemical constituents frequently found within geothermal fluids. As far back as the early nineteenth century, boron was separated from geothermal fluids at the Larderello geothermal field in Italy (Armstead 1983; Burgassi 1999). Other potential coproduced commodities in geothermal fluids include lithium, zinc, silica, manganese, lead, gold, silver, and rare earth elements (Blake 1974; Harper and Thain 1992; Gallup 1998; Bourcier et al. 2005).

The chemical composition of geothermal fluids is highly variable and dependent largely upon fluid sources, water interactions with minerals comprising the reservoir, fluid phase separation, and fluid mixing. In general, geothermal fluids are frequently classified by the relative abundance of important components such as chloride, sulfate, and bicarbonate (Nicholson 1993). The relative abundance of certain constituents, including reactive components, are used to infer important characteristics of the geothermal system, such as heat source temperature, fluid sources, and the spatial distribution of fluid flow paths. "See the sections titled 'Primary Geothermal Fluids' and 'Secondary Geothermal Fluids' for a more detailed description of common chemical compositions."

Heat Sources

Shallow heat sources in Earth's crust develop as a result of magmatic emplacements, tectonic activity, and radiogenic

heat. Volcanic sources, such as subduction zones, spreading centers, and hot spots (i.e., an anomalous upwelling of mantle material to Earth's surface), produce high temperatures generally in the range of 150–300 °C at depths less than a few kilometers. Examples of geothermal energy exploitation in volcanic regions include Japan (subduction zone), The Great Rift Valley in Kenya (intra-continental rift), and Iceland (volcanic hot spot and divergent tectonic plate boundary).

Tectonic heat sources, such as those found in the Geysers region of California and throughout the Basin and Range of Nevada, typically result from extensional and/or transtenional regimes. Extension results in crustal thinning and, as a consequence, increases the geothermal gradient. Fluid flow paths are generated in regions of faulting which produce "damage zones" of high fluid permeability.

Isotopic decay of radiogenic elements in certain rocks can produce substantial heat fluxes. In Western Australia, for example, radiogenic heat is produced from isotopic decay of uranium, thorium, and potassium, which are found in igneous rock bodies at depth.

Fluid Sources

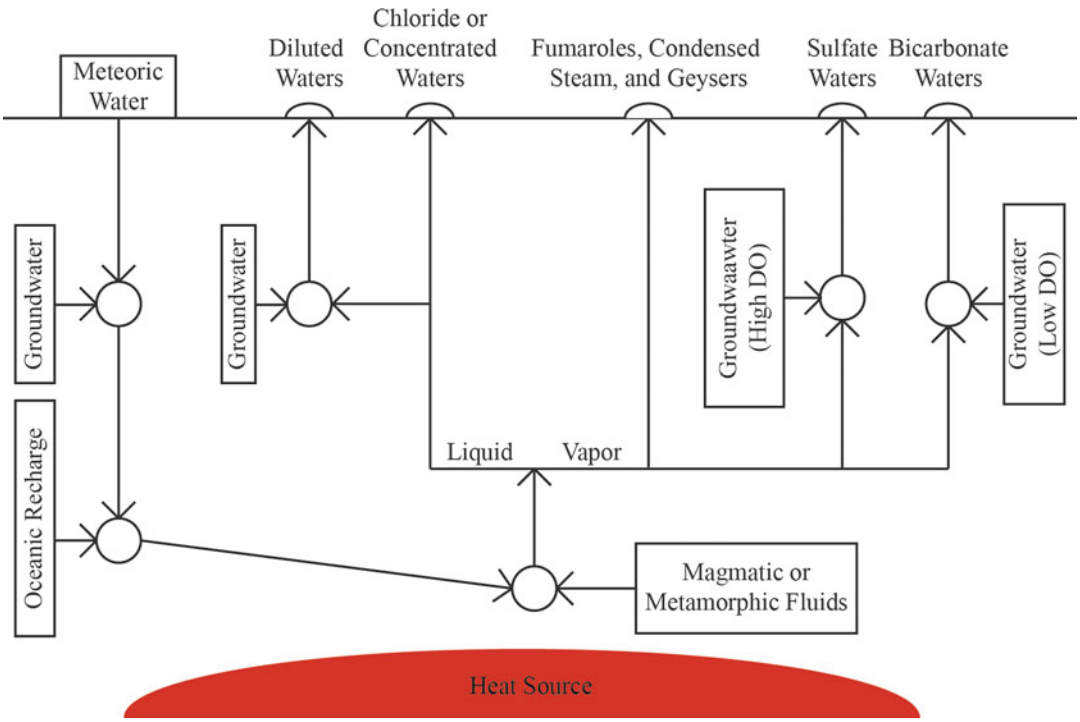
Geothermal fluids originate from several sources, including meteoric, oceanic, magmatic, metamorphic, and connate (see ▶ "Geothermal Systems," Fig. 1). In general, meteoric and oceanic recharge are considered the dominant source of geothermal fluids. As these source fluids migrate towards geothermal heat sources, several reactions alter their chemical state. Dissolution and precipitation can occur as source waters come into equilibrium with geothermal minerals. In addition, cation exchange reactions result in changes in the chemical composition of the descending and heated fluids.

Primary Geothermal Fluids

Geothermal fluids are considered "primary" fluids when they are at, or near, their heat source. These fluids are broadly grouped into three categories: Chloride waters, acid-sulfate waters, and high salinity waters.

The most common primary fluids found in deep high-temperature geothermal systems have near-neutral pH (at the temperature of measurement) with chloride as the dominant anion and is referred to as "chloride waters," but may also be referred to as "alkali-chloride" or "neutral-chloride" waters. Concentrations of chloride in chloride waters typically range from 1000 to 10,000 ppm. Other main constituents include sodium and potassium as the dominant cations with significant concentrations of silica and boron (Nicholson 1993).

Chlorides found in chloride waters are produced from magmatic fluids or through reactions with magmatic HCl



Geothermal Systems, Fig. 1 Schematic of fluid circulation through a geothermal system. Several potential sources, including meteoric, groundwater, oceanic, and magmatic/metamorphic form primary fluids near a heat source. As primary fluids rise buoyantly towards Earth's surface they form secondary fluids as they interact with rock minerals, undergo phase changes, and mix with near-surface waters

and rock-forming minerals. Chlorides in geothermal fluids from other sources, such as oceanic or dissolution of rock by meteoric water, are often classified separately as "high salinity waters" and are discussed later in this section. Concentrations of chloride in primary fluids depend on the lithology of their host rocks. For example, primary fluids in basalts and gabbros, in general, are relatively less rich in chloride whereas fluids in rhyolite and diorite are more concentrated. The variation results from deviations in each lithology's chlorine content. In basalts and gabbros, chlorine averages roughly 130 and 190 ppm, respectively, whereas rhyolites and diorites average roughly 330 and 335 ppm, respectively (Johns and Huang 1967).

Primary geothermal fluids with total dissolved solids (TDS) levels ranging from about 10,000–300,000 ppm are referred to as "high salinity waters." These fluids are produced mostly from oceanic recharge and evaporite dissolution in meteoric water, but might also form from connate water. Concentrations of TDS in these fluids can reach as high as 20–30 wt% as in Salton Sea, California, USA (Williams and McKibben 1989). These fluids can be heavily enriched in mineral commodities. In Salton Sea, California, USA, for example, high concentrations of several valuable commodities have been produced from geothermal wells, such as manganese (~500–700 ppm), lithium (~130–140 ppm), silicon (~180–200 ppm), and zinc (~200–350 ppm) as well as precious metals such as silver (~0.5–0.7 ppm), gold (~0.1 ppm), and platinum (~0.06 ppm) (Maimoni 1982).

Deep acid-sulfate waters form when HCl and SO_2 are transferred from a magmatic heat source to a circulating fluid. HCl and/or HSO_4 produce acidic conditions and such conditions have been found in many volcanic geothermal systems, particularly in andesitic rocks.

Secondary Geothermal Fluids

As primary fluids migrate towards Earth's surface they experience changes in their thermodynamic properties and chemical composition. In addition, they can be altered by mixing with shallow groundwater. As a result of these alterations the modified fluids are referred to as "secondary" geothermal fluids.

At depth, primary fluids may exist as a single phase liquid or gas, or a mixture of liquid and gas phases. When a liquid geothermal system encounters declining pressures, a vapor phase may appear. In addition, two phase flow may be encountered in the production well as fluid rises to ground surface Under hydrostatic conditions, geothermal liquid phase fluids between 200 and 250 °C boil at depths of roughly 200–500 m. Above 250 °C, the depth of boiling increases dramatically from roughly 500 m at 250 °C to roughly 1.5 km at 320 °C (Arnórsson et al. 2007). Under natural hydrostatic conditions, two-phases can exist within the reservoir. As a result of this phase separation, the residual liquid may be concentrated in TDS and the steam may contain high concentrations of hydrogen sulfide and carbon dioxide. The residual liquid component would be classified as a "concentrated" secondary geothermal fluid as the nonvolatile components of the primary geothermal fluid are concentrated due to liquid mass loss during vaporization.

If the steam phase is mixed into shallow groundwater, two different secondary geothermal fluids may be broadly classified. "Sulfate waters" will form if the shallow groundwater is rich in dissolved oxygen due to oxidation of sulfur by the reaction:

$$H_2S(g) + 2O_2(aq) = 2H^+(aq) + SO_4^{2-}(aq)$$

This reaction produces sulfate concentrations typically in the range 300–1300 ppm.

Sulfur oxidation also results in a reduction in pH which will reduce bicarbonate concentration as CO_2 is released from solution resulting in bicarbonate concentrations typically under ~1 ppm. At low pH, sulfate waters frequently contain high concentrations of dissolved metals such as aluminum (up to 7000 ppm), iron (up to 4500 ppm), manganese (up to 2500 ppm), chromium (up to 8.5 ppm), and arsenic (up to 15 ppm) (Hartley 1978). These high concentrations occur because lower pH (<~3–4) favors aqueous forms of these metals either through desorption or dissolution reactions.

In contrast, condensation of geothermal vapors in shallow groundwater that is depleted in dissolved oxygen will produce "bicarbonate waters" that are rich in bicarbonate (~300–2500 ppm) relative to sulfate waters (Nicholson 1993) by the reactions:

$$CO_2(g) + H_2O(l) = H_2CO_3(aq)$$

$$H_2CO_3(aq) = H^+(aq) + HCO_3^-(aq)$$

$$HCO_3^-(aq) = H^+(aq) + CO_3^{2-}(aq)$$

Because of the low redox potential of oxygen depleted groundwater, sulfur cannot be oxidized and the fluid remains high in total alkalinity. In these mixed fluids, bicarbonate, rather than CO_2, is the dominant species because it is the dominant species at near-neutral or mildly acidic pH.

"Dilute waters" can form when any primary geothermal fluid is diluted in near-surface groundwater. The term "dilute" is used to indicate the fact that primary geothermal fluids are typically concentrated in TDS relative to shallow groundwater and, as a consequence, dilute waters are typically lower in TDS relative to their primary fluid source. Identification of dilute waters can be an important task in the process of

geothermometry. For example, temperature estimates derived from the use of silica as a geothermometer assumes that the concentration of dissolved silica in sampled fluid is in equilibrium with precipitated silica (either as quartz or another polymorph) at the temperature of the reservoir at depth. In dilute waters, this assumption would lead to an underprediction of subsurface temperatures because shallow groundwater contains much lower concentrations of silica. Hot springs discharging dilute fluids can be identified by a negative correlation between surface fluid temperature and flow rate (Arnosson et al. 2007).

When primary or secondary geothermal fluids approach Earth's surface, they are either recirculated into the deep geothermal reservoir or they are discharge at ground surface either as hot springs (if liquid) or fumaroles (if gas). Fumaroles are direct releases of geothermal vapor and gasses at Earth's surface. Hot springs can consist of either primary geothermal fluids or secondary fluids, such as acid-sulfate waters, bicarbonate waters, dilute waters, and concentrated waters.

Geysers form when high confining pressures lead to pressure build up below ground surface. Once the confining pressure is overcome, a mix of liquid and gas is rapidly released and can cause streams of two-phase fluid to eject from Earth's surface as high as several tens of meters (Rinehart 1974).

Fluid-Rock Interactions

Dissolved constituents within geothermal fluids can be described as either conservative or reactive. Species that are highly soluble that tend to remain in solution, such as Cl, B, Br, As, and Cs, are considered conservative species because their fluid concentration is not heavily influenced by temperature dependent mineral-fluid equilibria nor do they readily participate in ion exchange processes. A notable exception would occur if the solution encountered another constituent that led to the precipitation of one or more of the soluble species. An example would be As precipitation in the presence of H_2S. In reality, chloride is the only truly conservative species as some other conservative species in geothermal fluids may participate in near-surface ion exchange reactions, particularly with clay minerals and iron oxides.

Reactive species, such as SiO_2, Na, K, Ca, and Mg, are subject to mineral-fluid equilibria that are dependent on the thermodynamic and mineralogical properties of the reservoir. The two most relevant types of fluid-rock reactions in geothermal systems are dissolution/precipitation reactions (e.g., SiO_2 and $CaCO_3$) and ion exchange reactions (e.g., Na and K). For many minerals of interest, solubility increases with increasing temperatures. For example, the concentration of a reactive species such as silica can be used to infer reservoir temperature based on the measured temperature dependence of silica solubility (Fournier and Potter 1982).

Retrograde solubility occurs when there is an inverse relationship between solubility and temperature. Calcite and gypsum, for instance, both have retrograde solubility and therefore will precipitate at higher temperatures. Solubility of calcite is also affected by the partial pressure of CO_2 and, as a consequence, calcite may precipitate as deep geothermal fluids migrate upwards and release CO_2 from solution. Calcium is not considered a reliable geothermometer, however, because calcite precipitation/dissolution reactions occur too rapidly. In contrast, silica precipitation/dissolution kinetics are very slow at low temperatures. Therefore, measured silica concentrations in nondiluted geothermal hot springs or in water samples taken from geothermal wells have been reliably used as a geothermometer.

Ion-exchange reactions, such as between Na in albite and K in potassium feldspar, are also temperature dependent and may therefore be used as an additional or alternative geothermometer. At high temperature, K is depleted in solution as potassium feldspar dominates over albite. The ratio of Na/K, therefore, is an indicator of reservoir temperature. Because this indicator is a ratio, it is sometimes a more reliable geothermometer than silica, particularly when geothermal fluids are mixed with shallow groundwater that is relatively low in Na and K concentration.

Several other geothermometers are utilized in geothermal systems such as additional liquid water ionic species (e.g., Na/Li, Li/Mg, K/Mg, Na-K-Ca, Na-K-Mg), isotopic tracers (e.g., ^{16}O vs. ^{18}O and ^{12}C vs. ^{13}C), and gas geothermometers (e.g., CO_2/H_2 and H_2/H_2). Which geothermometer is used depends largely upon the extent of fluid mixing, the temperature range, phase (gas or liquid), pH, and reaction kinetics. Examples of liquid water ionic geothermometers can be found in Fournier and Potter (1982), Fouillac and Michard (1981), Kharaka and Marina (1989), Giggenbach (1988), Fournier (1979), and Fournier and Truesdell (1973). Examples of isotopic geothermometers can be found in Arnórsson et al. (2000), Nuti et al. (1981), and Yokoyama et al. (1999). Examples of gas phase geothermometers can be found in D'Amore and Panichi (1980) and Arnórsson and Gunnlaugsson (1985).

A final group of chemical species useful in geothermal reservoir characterization are "applied tracers." In practice, a specific chemical tracer is introduced into a geothermal reservoir in an injection or monitoring well. A monitoring well or production well nearby can then be used to monitor these tracers as they appear at the surface. An important characteristic is the ability to measure extremely low concentrations (ideally less than 10 ppb). Commonly used tracers for geothermal reservoirs include salts, such as bromide and iodide; organic dyes, such xanthene, rhodamine, and fluorescein; radioactive tracers, such as Iodide-125; and polyaromatic sulfonates, such as naphthalene sulfonates (Adams and Davis (1991) and Rose et al. (2001)). The residence time

distribution (RTD) of fluid flowing through a geothermal reservoir can be determined by measuring the tracer concentration in production wells in response to a pulse or step change of tracer concentration in the injection well. The RTD is used to estimate attributes of the reservoir such as the reservoir volume and interwell connectivity.

Applied reactive tracers have long been proposed to infer geothermal reservoir properties such as temperature distribution (e.g., Robinson et al. 1988) and the fluid/rock surface area in-between two wells (e.g., Vetter and Crinchlow 1979). In recent field trials, reactive tracers have been shown to successfully characterize fluid permeability in a model geothermal reservoir (Hawkins et al. 2016, submitted).

Summary

Hydrothermal systems are produced when shallow heat sources drive convective circulation between cold shallow fluids and hot fluids at depth. The geochemistry of these systems is controlled by their fluid sources, fluid-rock interactions, phase separation, and dilution/concentration effects. Understanding these systems is important in quantifying the relative contribution from different fluid sources, estimating subsurface temperatures, controlling scaling, and evaluating the geothermal resource potential.

Geothermometry and Geobarometry

Keith Putirka
Department of Earth and Environmental Sciences, California State University – Fresno, Fresno, CA, USA

Origins and Definitions

In its 1875 edition, *Encyclopaedia Britannica* described "natural philosophy" as "the science of energy"; by implication, thermometers and barometers, which measure the transfer of energy, are among the most fundamental of scientific instruments. Their development is traceable to the birth of science in the seventeenth century when, driven by curiosity about heat transfer, Santorre, Galileo, Sagredo, and Torricelli each constructed instruments to measure temperature (T) and pressure (P). These early instruments are in a liberal sense "geothermometers" and "geobarometers" as they were used to measure Earth's atmosphere, and mineral-bearing chemical reactions, in an age when mineralogy and chemistry were not distinct sciences. In geology, though, we invariably use these terms to refer to mathematical models that are used to estimate P and T of the solid Earth. And since P and T are usually interdependent, we often speak of "thermobarometers." Such "models" are invariably based on thermodynamic theory; they are usually analytic, i.e., involving equations that can be solved without recourse to differentiation, integration, or limits. An appropriate admonition from the statistician, George Box, is that "all models are wrong; some are useful." Models are simplifications of nature; none, however well known or successful, represent nature in some perfect, errorless sort of way. Many models, though, e.g., gravity, the ideal gas law, the covalent bond, etc., are nonetheless useful, allowing progress, in spite of inherent and unavoidable assumptions and flaws. But all models have limits, and to apprehend their regions of usefulness, error analysis during calibration and application is imperative.

The history of thermometry and barometry is indelibly tied to experiments of Boyle, Gay-Lussac, Charles, and others, whose work led to the ideal gas law ($PV = RT$). As we shall see, this law is central to most equations in physical chemistry, including geothermobarometers, and may be the single most influential equation ever devised. But while P-T estimates are now vital to discussions ranging from climate change to mantle convection, progress in the earth sciences was initially slow. Howard (1771) obtained a temperature estimate of a lava flow at Vesuvius (of 240 degrees, apparently on the Fahrenheit scale), by inserting a thermometer into crevices of a recent flow. Hall (1790, 1798) and Spallanzani (1789) would later measure the temperatures at which rocks melt, and their experimental studies would be advanced in the late 19th century (e.g., Joly 1891; Cusack 1896; Barus 1893; Doelter 1901; Day and Sossman 1911; see Young 2003). But the firm roots of geothermometry begin in the 20th century. Goldschmidt (1912) perhaps first introduced the term "geological thermometer," using thermodynamic data to chart the reaction: wollastonite = calcite + quartz (Q). But it would take several decades before thermobarometry would catch on, apparently beginning with Barth's (1934, 1951) calibration of feldspar thermometers and Bowen's (1940) development of the petrogenetic grid. Evans (2007) suggests that the delay may stem from a lack of thermodynamic data and this may be true for metamorphic systems (see Powell et al. 1998). But in igneous systems, experimental phase equilibria have proven to be the foundation on which thermobarometers have been based. We shall review how thermobarometers are developed and evaluated and how the resulting models can best be applied to understand natural systems.

Sources for Commonly Used Thermobarometers

There are far too many important and well-calibrated thermobarometers to summarize in anything but a massive tome. Several comprehensive reviews by Bohlen and Lindsley (1987), Spear (1993), Anderson (1996b), Anderson et al. (2008), Putirka (2008), and Putirka (2016a, b) provide context and access to important methods and models for metamorphic and igneous systems. To supplement these, and bring others up to date, we have: the Fe-Ti oxides (Ghiorso and Evans 2008; Buddington and Lindsley 1964; Anderson and Lindsley 1988), garnet-mica thermobarometers (Holdaway 2001; Wu et al. 2002; Wu and Zhao 2007; Caddick and Thompson 2008; Wu 2015), garnet + pyroxene thermobarometers (Powell 1985; Beyer et al. 2015), amphibole + plagioclase thermometers (Blundy and Holland 1990;

Holland and Blundy 1994), and recent calibrations of Ti-in-quartz (TitaniQ) and related accessory phase thermobarometers (Watson et al. 2006; Wark and Watson 2006; Ferry and Watson 2007; Hayden and Watson 2007; Thomas et al. 2010; Huang and Audetat 2012). In addition to these, mostly solid solution-based models, P estimates can be obtained from equations of state and fluid inclusion densities (Roedder 1965; Hansteen et al. 1998; Hansteen and Klugel 2008), which carry some fascinating potential to obtain P-T time (t) paths (Kohn 2014, 2016). And analytic expressions from all these works are complemented by computer-aided models, such as QUILF (Anderson et al. 1993), VOLATILECALC (Newman and Lowenstern 2002), THEMOCALC (Powell et al. 1998), and MELTS (Ghiorso and Sack 1995). The latter two can be used to estimate P-T positions of phase boundaries and so serve as an invaluable direct test of P-T estimates. In many of these models, though, whether analytic or computer enhanced, errors are not always well constrained and sometimes not identified at all. Without estimates of error, P-T estimates may not only be meaningless but misleading. Kohn and Spear (1991a, b) provide an outstanding summary of error sources and analysis, which are applicable to any thermobarometer or system.

An Illustration of Common Pitfalls: Controversy at the Bishop Tuff (BT)

Before reviewing equations and methods, the Ti-in-quartz (TitaniQ) thermobarometers (Wark and Watson 2006; Thomas et al. 2010), and their application to the Bishop Tuff (Wark et al. 2007; Wilson et al. 2012), illustrate some common pitfalls. The issues of calibration and application of Ti-in-qtz thermobarometers are general and can be carried over to other models and systems.

Wark and Watson (2006) present a thermometer, calibrated as: $\log C^{Q}_{\mathrm{Ti}} = 5.69 - 3765/T(K)$, where C^{Q}_{Ti} is the concentration of Ti-in-quartz in ppm. Using this model, Wark et al. (2007) obtain $T = 720$–810 °C for BT quartz grains, a range that closely matches that obtained by Fe-Ti oxides (714–818 °C; Hildreth and Wilson 2007). In Wark and Watson's (2006) experiments, quartz is co-saturated with rutile and glass and/or a fluid phase. Wark et al. (2007) reasonably posit that C^{Q}_{Ti} should be replaced by C^{Q}_{Ti}/a^{liq}_{Ti}, where a^{liq}_{Ti} is the activity of Ti in a liquid (or fluid), since Ti-in-quartz should be sensitive not just to T but to Ti contents of equilibrated phases. They define $a^{liq}_{Ti} = 1$ at rutile saturation (see Hayden and Watson 2007), and for the Bishop Tuff (not rutile saturated), they use $a^{liq}_{Ti} = 0.6$. Wark and Watson's (2006) experiments are also performed at 10 kbar and are applied to the BT assuming, based on molar volume arguments, that the P effect on the thermometer is small.

But Thomas et al. (2010) show that TitaniQ is indeed P sensitive and they derive a new Ti-in-quartz thermobarometer. The fun starts when Wilson et al. (2012) insert the apparently reliable Fe-Ti oxide temperatures into the new model to obtain $P = 9$ kbar, a value of which they reasonably reject, given the unlikelihood that BT quartz grains grew within the lower crust or upper mantle. Thomas and Watson (2012) counter that Fe-Ti oxide temperatures are too high and that a^{liq}_{Ti} might be closer to 0.3 rather than 0.6. Meanwhile, (a) Huang and Audetat (2012) are unable to reproduce the results of Wark and Watson (2006), and (b) Evans et al. (2016), using Roozeboom (1891)-type arguments, suggest that the Fe-Ti oxide T estimates at the BT are valid. Evans et al.'s (2016) tests are of interest. Roozeboom diagrams are tests of equilibrium. The most common geologic example is the Fe-Mg exchange coefficient ($K_{\mathrm{D}}^{\mathrm{Fe-Mg}}$) between olivine and liquid (Roeder and Emslie 1970). The general idea is that if two phases dissolve a similar component, then the concentrations of that component should vary monotonically in such phases, as P, T, and bulk composition varies (so that chemical potentials are equalized in each phase). Evans et al. (2016) show that Fe, Ti, Mg, and Mn in BT ilmenites, magnetites, and glasses co-vary in a way suggestive of equilibrium. So the Fe-Ti oxide temperatures, first invoked as a validity test for TitaniQ and then rejected due to conflict with the reformulated thermometer, are resurrected.

Lessons from the Bishop Tuff

There are difficulties related to the BT controversy that apply to any thermobarometer:

1. *Proper model calibration*. One problem is that none of the published C^{Q}_{Ti} thermobarometers are properly calibrated. Each are based on linear least squares regression methods that predict $\log_{10} C^{Q}_{Ti}$ when T is provided. But regression is not symmetric (see Putirka 2008 for an illustration); new regressions are needed to predict T when C^{Q}_{Ti} is given. In Wark and Watson's (2006) data, the $\log_{10} C^{Q}_{Ti}$ versus $1/T$ correlation is strong enough that this regression error is trivial (±2 °C), but on larger data sets, the problem is significant. Data from Wark and Watson (2006), Ostapenko et al. (2007; excluding their 500–750 °C data), Thomas et al. (2010), and Huang and Audetat (2012) yield

$$\frac{10^4}{T(^{\circ}C)} = 21.56 - 0.217P(\mathrm{kbar}) - 3.32\log_{10}\left[\frac{C^{Q}_{Ti}(\mathrm{ppm})}{a^{liq}_{TiO_2}}\right] \quad \text{(A)}$$

which reproduces T ±35 °C (a realistic error, typical of polybaric thermometers). Equation A yields T estimates for the Bishop Tuff that are 55 °C greater than those obtained

by rearranging a regression of $\log_{10} C_{\mathrm{Ti}}^{Q}$ using the same data. For a barometer, a proper regression of the data of Huang and Audetat (2012) yields

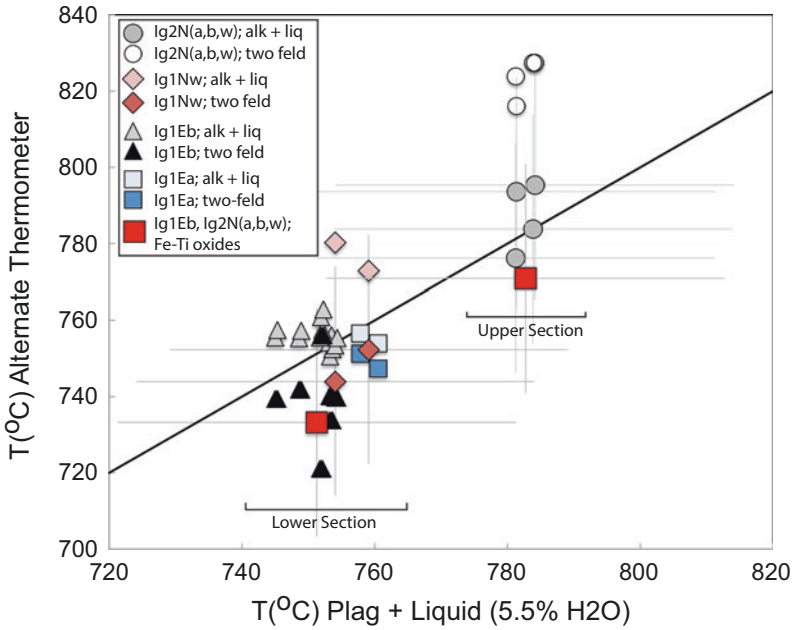
$$P(\mathrm{kbar}) = -29.53 - 0.0153T(^{\circ}C)\log_{10}\left[\frac{C_{Ti}^{Q}(\mathrm{ppm})}{a_{TiO_2}^{liq}}\right] + 0.0766T(^{\circ}C) \quad \text{(B)}$$

which reproduces P for all data (again excluding the Ostapenko et al. 500–750 °C data) to ±1.8 kbar. Equation B also yields reasonable P estimates (see Anderson et al. 2000) for the Bishop Tuff of 1.5 kbar, when $a_{TiO_2}^{liq} = 0.31, T(^{\circ}C) = 720$ and $C_{Ti}^{Q} = 48$ ppm. When other experimental data are used in the regression, the resulting barometers yield >4 kbar for the same conditions, regardless of regression method. Such comparisons, though, probably tell us less about experimental equilibrium or data quality and instead indicate that $a_{TiO_2}^{liq}$ may vary with P, T, and bulk composition. Ironically, $a_{TiO_2}^{liq}$ was introduced to apply TitaniQ to non-rutile saturated systems; but by being forced to estimate $a_{TiO_2}^{liq}$, we have drawn a useless circle.

2. *Single-phase thermobarometers have large errors*. Anderson and Smith (1995) show that Al-in-hornblende barometers are sensitive to T and composition and so are valid only under highly restrictive compositional and thermal limits (see Putirka 2016b for updated tests and Nimis and Taylor (2000) for an example based on clinopyroxene). Ti-in-quartz thermometry is no different. A useful Ti-in-quartz thermometer will await new experiments where Ti is measured in coexisting quartz and glass/fluid phases.
3. *Like validates like*. The only reliable tests for a thermometer or barometer are other thermometers and barometers; all other tests are inferential. The BT contains not just quartz and Fe-Ti oxides but two feldspars and a glass; four different thermometers from the latter agree within typical thermometer error (±30 °C), assuming $P = 2$ kbar and 5.5 wt. % H_2O in silicate liquids (Anderson et al. 2000). Temperature estimates need not agree, but such convergence is compelling evidence that we are approaching accurate magmatic temperatures for the BT. Lacking independent thermobarometers, Roozeboom (1891) diagrams are the next best tools, however indirect.
4. *Error must be expressly indicated*. The MELTS model yields quartz + two feldspar equilibrium for a BT liquid at 720–730 °C (Gardner et al. 2014), apparently validating the results of Fig. 1. But Scaillet and Evans (1999) show quartz saturation at 800–850 °C, at 5.5% H_2O and 2.2 kbar, for rhyolitic glasses that are not too different from those from BT. For any model, we must compare $T^{\mathrm{calculated}}$ versus T^{measured} to estimate error and accuracy; otherwise, model discrepancies, or agreements, cannot be judged.
5. *You cannot test an atomic clock with a wristwatch*. Huang and Audetat's (2012) results show that the Ti-in-quartz thermometer is a work in progress (Thomas et al. 2015 do not rectify the issues noted here). In contrast, Fe-Ti thermometers are well tested, both experimentally and in their application to natural systems. Interlaboratory tests are vital for any model, and it is too early to use TitaniQ as a test of Fe-Ti oxide thermometry.
6. *Errors on P-T estimates could be lower when averaged*. This precept assumes that error is random. To be sure, systematic error can affect experiments and our approach to natural samples (e.g., thermocouples may not measure the hot zone of a sample capsule; we may analyze un-equilibrated crystal compositions, instead of rims). But phases may approach equilibrium from different, random directions, and this sort of randomness may be quite important, as averaging appears to lead to more accurate P and T estimates (Powell and Holland 1994; Putirka et al. 1996; see Putirka 2016a). Moreover, if this were not the case, we would have no justification for using Fe-Mg exchange coefficients (e.g., Roeder and Emslie 1970) as we currently do, to test equilibrium. The issue is illustrated in Fig. 1: T estimates from the upper and lower stratigraphic sections of the BT cluster near 780 °C and 750 °C, respectively. That clustering, and t tests, indicate that the thermal contrasts are real. Thermal contrasts are also evident in Ti-in-quartz, which range from 722 °C for cores (48 ppm Ti) to 780 °C for rims (100 ppm Ti) using Eq. A. We might still be learning more about a_{Ti}^{liq} rather than absolute T, but TitaniQ may be immensely useful for translating quartz zoning patterns into *relative* T *estimates*, when other models delimit P, T, and a_{Ti}^{liq}. Used in this way, the intra-laboratory error of ±8 °C error (the standard error of estimate derived from Wark and Watson's (2006) data) might also be applicable, providing a powerful method to decipher geologic processes when using thermobarometers in concert. In the following sections, we will revisit some of these issues, first through theoretical foundations, and then some additional examples of model calibration and application.

Univariant and Multivariant Equilibria

Nearly all geothermobarometers involve heterogeneous equilibria – reactions that involve more than one phase (ice transforming to water), as opposed to homogenous equilibria where all chemical constituents of a "reaction" occur in a single phase (H_2O disassociating into OH^- and H^+). Bohlen and Lindsley (1987) provide a useful fivefold division of heterogeneous equilibria, which we will reduce to two: (a) multivariant equilibria – reactions that involve multiple phases, some of which exhibit solid solution. In the cases that interest us, the



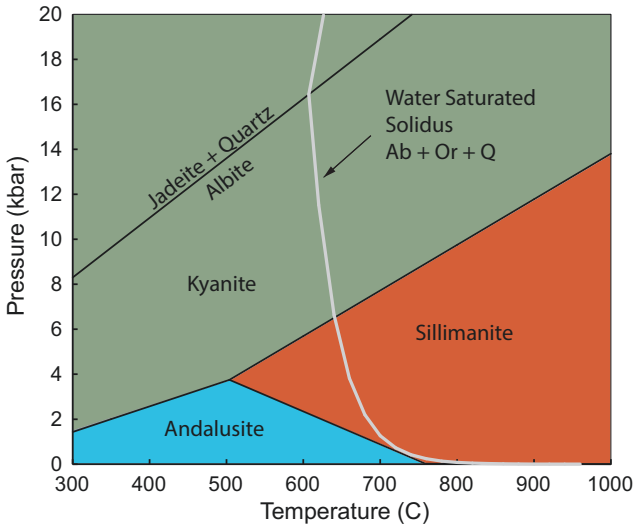
Geothermometry and Geobarometry, Fig. 1 A comparison of T estimates from plagioclase + liquid (Putirka 2008; Eq. 24a), alkali feldspar + liquid (Putirka 2008; Eq. 24b), two-feldspar (Putirka 2008; Eq. 27b), and Fe-Ti oxide thermometers (mean T of Fe-Ti estimates reported in Hildreth and Wilson (2007)). Feldspar compositions are from Chamberlain et al. (2014); silicate liquids are from Hildreth and Wilson (2007). We assume $P = 2$ kbar and that silicate liquids contain 5.5% H_2O (Anderson et al. 2000). The results are consistent with Gardner et al. (2014). It is not clear whether quartz (Q) should saturate at higher or lower T compared to plagioclase (Pl) or alkali feldspar (Af). Gardner et al. (2014) would place saturation as $T^{Af} > T^{Q} > T^{Pl}$, but the Pinatubo compositions of Scaillet and Evans (1999) are not very different, and their rhyolitic glasses have $T^{Pl,} > T^{Q} > T^{Af}$; in either case, quartz saturation temperatures should be similar to T estimates shown here

reactions do not go to completion. (b) Univariant equilibria: reactions that nominally involve pure phases, and usually go to completion – unless we are very lucky.

A classic example of case (b) is the system Al_2SiO_5. The polymorphs kyanite, sillimanite, and andalusite occupy different regions of P-T space (Fig. 2), separated by univariant curves. The term "univariant" herein means that if two or more pure phases are in equilibrium, then P and T cannot vary independently, so if one is specified, the other is determined. Geologists recognized the usefulness of such reactions very quickly. Iddings (1888) applied the quartz-tridymite transition to the origin of lithophysae at Obsidian Cliff, Yellowstone, while Barrow (1893) used the sillimanite-kyanite ["cyanite" in Barrow (1893)] transition in his classic study of contact metamorphism. Only one mathematical relationship is needed to evaluate univariant reactions, Clapeyron's (1834) equation:

$$\frac{dP}{dT} = \frac{\Delta H_r}{T\Delta V_r} = \frac{\Delta S_r}{\Delta V_r} \quad (1)$$

where ΔV_r, ΔH_r and ΔS_r are the volume, enthalpy, and entropy of reaction, respectively (e.g., $\Delta H_r = H^{products} - H^{reactants}$). Since only pure phases are involved, only P-T space is relevant. For an unalloyed barometer or thermometer, dP/dT (Fig. 2) should, respectively, approach either zero ($\Delta S_r \rightarrow 0$) or infinity ($\Delta V_r \rightarrow 0$). Few equilibria have such characteristics, but interdependency is not always disadvantageous. Sillimanite-bearing pelites and interbedded meta-sandstones containing albite (Ab), orthoclase (Or), and quartz (Q)



Geothermometry and Geobarometry, Fig. 2 P-T diagram showing aluminosilicate phase boundaries (Holdaway and Mukhopadhyay 1993), the albite + quartz = jadeite boundary (Holland 1980) and the water-saturated granite solidus (Johannes and Holtz 1996). Below the Ab + Q = Jd boundary, the granite solidus is P(kbar) = exp[(19.556–0.0276(T °C)]

that show no evidence of partial melting, must have *P-T* conditions that fall to the low-T side of the granite solidus (Ab + Or + Q = Liq), but within the sillimanite stability field, limiting the possible range of *P-T* conditions (Fig. 2). Similarly, equilibrated kyanite + albite defines, however, broadly a *P-T* window of stability (Fig. 2). A grand prize is awarded when phases that define a univariant curve or, better yet, an invariant point coexist; rocks containing both kyanite and andalusite must fall on the univariant curve that separates the two stability fields (Fig. 2). If all three aluminosilicates are at equilibrium, the system must have passed through the triple point: 3.75 kbar and 504 °C (Fig. 2). Lest any reader believe that the method was facile, the placement of the Al_2SiO_5 univariant boundaries consumed decades of work: from Althaus (1967), to Richardson et al. (1969), to Bohlen et al. (1991), to Holdaway and Mukhopadhyay (1993), the triple point fell from 6.5 to 3.75 kbar and 595 °C to 504 °C (~0.07 kbar/year and 3.7 °C/year). But as the number of phases in a lithologic system increases, so do the opportunities for improved *P-T* precision. It is thus possible to derive a rather dense fishing net of *P-T* curves (e.g., Caddick and Thompson 2008). As powerful as this method is, however, it is rare to obtain definite values of *P* and *T*, with specified errors. Multivariant equilibria offer such a prospect and will be the focus of the remainder of this review.

Thermodynamic Basis of Multivariant Equilibria

The theoretical basis of thermobarometry is what Anderson (1996a) calls the "most useful equation in thermodynamics":

$$-RTlnK_{\mathrm{eq}} = \Delta G_r^{o,T,P} \tag{2}$$

In Eq. 2, R is the gas constant, K_{eq} is the equilibrium constant (to be discussed forthwith), and $\Delta G_r^{o,\,T,\,P}$ is the Gibbs free energy difference between products and reactants (so $\Delta G_r^{o,T,P} = G^{o,T,P}_{\mathrm{products}} - G^{o,T,P}_{\mathrm{reactants}}$), as pure substances, at the P and T of interest. Some texts imply a 1 bar standard state, using $\Delta G_r^{o,T,\,1\,\mathrm{bar}}$. However, we follow what Castellan (1971, p. 358) refers to as the "rational system," which is convenient for understanding Eq. 2 and commonly used in geology. The superscript T in $\Delta G_r^{o,\,T,\,P}$ is the very same T as occurs in the $-RT\ln K_{\mathrm{eq}}$ term. To find a new value of K_{eq}, at some new T or P, it is necessary not only to insert a new value for T on the left-hand side of Eq. 2 but often (unless $\Delta G_r^{o,\,T,\,P}$ does not greatly change with P or T) to calculate a new $\Delta G_r^{o,\,T,\,P}$ at the P and T of interest as well. Textbooks have long presented Eq. 2 as if it were a Platonic form, falling ethereally out of some perfect realm. We will turn our heads to see how the shadows have been cast.

In the development of Eq. 2, revolutions and brilliant masterstrokes are rare. It has roots in Dalton's atomic hypothesis (ca. 1804), but the equilibrium constant had its birth much later, with Guldberg and Waage's (1864, 1879) work on a "law of mass action." Inspired by Berthelot, they posit that chemical reactions are driven by "chemical forces" that are proportional to mass, analogous to forces in Newtonian mechanics. Early experimenters knew that some reactions do not go to completion but rather stop partway, leaving an apparent stable assemblage of products and reactants. For chemical species A and B, reacting to form C and D, we can have:

$$\alpha\mathrm{A} + \beta\mathrm{B} = \gamma\mathrm{C} + \delta\mathrm{D} \tag{3}$$

where α, β, γ, and δ are stoichiometric coefficients, which give the numbers of chemical species involved in the balanced, chemical equilibrium. For Guldberg and Waage (1864), the idea was that a large mass of A and/or B creates a rightward-directed force to yield greater masses of C and D. Equilibrium is established when the two opposing forces are equal. The ideas of a chemical or an "affinity force" are now obsolete; today, we use molar concentrations instead of masses and speak of reaction rates instead of chemical forces. But the broad ideas are the same. Guldberg and Waage also hypothesized that to obtain the chemical forces, the masses of the species must be raised to some exponent; so for the forward reaction, the force would be $k_1A^xB^y$, where x, y, and k_1 are arbitrary constants, determined by experiment, and the reverse "force" would be $k_2C^wD^z$. The coefficients k_1 and k_2 are now called rate constants (so the reaction rate is $r_1 = k_1[A^xB^y]$). Guldberg and Waage (1864) did not yet recognize that the stoichiometric coefficients of Eq. 2 could serve as exponents. Lund (1965) credits August Horstman (1877) with this insight, and the idea would be demonstrated by Van't Hoff (1887) using the ideal gas law and Avogadro's idea that equal volumes of gases contain equal numbers of atoms. Guldberg and Waage (1879) applied this new idea, and so by 1879–1888, we approach a modern equilibrium constant – inspired from a theory of "chemical forces" that we no longer use and a theory of atoms that would not be widely accepted for another quarter century:

$$K_{eq}^{ideal} = \frac{(X_C)^{\gamma}(X_D)^{\delta}}{(X_A)^{\alpha}(X_B)^{\beta}} \tag{4a}$$

In Eq. 4a, terms such as $(X_C)^{\gamma}$ or $(X_A)^{\alpha}$ are, respectively, the mole fractions of C and A, X_C and X_A raised to an exponent equal to their stoichiometric coefficients γ and α. The molar concentrations, however, are only applicable when the chemical species do not interact (we say in this case that the system is "ideal"); more generally, we use activities:

$$K_{eq} = \frac{(a_C)^{\gamma}(a_D)^{\delta}}{(a_A)^{\alpha}(a_B)^{\beta}} \quad (4b)$$

where a_c is the activity of component C. For a geologic example:

$$2SiO_2{}^{liq} + 0.5Na_2O^{liq} + 0.5Al_2O_3{}^{liq} = NaAlSi_2O_6{}^{pyx} \quad (5)$$

where $NaAlSi_2O_6{}^{pyx}$ is jadeite (Jd) in pyroxene (pyx) and chemical species such as Na_2O^{liq} are oxides in a coexisting liquid. The equilibrium constant for Eq. 5, using Eq. 4b, is:

$$K_{\text{eq}} = \frac{a_{Jd}^{pyx}}{\left(a_{SiO_2}^{liq}\right)^2 \left(a_{Na_2O}^{liq}\right)^{0.5} \left(a_{Al_2O_3}^{liq}\right)^{0.5}} \quad (6)$$

and a_i^j is the activity of species i in phase j (so a_{Jd}^{pyx} is the activity of jadeite in pyroxene, and $a_{Na_2O}^{liq}$ is the activity of Na_2O in a coexisting silicate liquid). The idea of activity is another innovation from the late nineteenth century, formalized by Gilbert Lewis (1907). It is an effective concentration. For example, let us say that in the silicate liquid in Eq. 6, that Na_2O partially interacts with Fe_2O_3 or Cr_2O_3, in the liquid, perhaps forming $NaFe^{3+}O_2$ or $NaCrO_2$ molecular clusters. These Na-bearing clusters might not be equally available to participate in Eq. 6, thus reducing the amount of Na available to make jadeite. The effective concentration of Na_2O might thus be less than its molar concentration, $X_{Na_2O}^{liq}$. To count only that fraction of Na_2O available for Eq. 6, we use $a_{Na_2O}^{liq}$. The quantities $a_{Na_2O}^{liq}$ and $X_{Na_2O}^{liq}$ are related to one another by the activity coefficient λ_{Na_2O}, so that $a_{Na_2O}^{liq} = \lambda_{Na_2O} X_{Na_2O}^{liq}$ or, more generally,

$$a_i^j = \lambda_i X_i^j \quad (7)$$

where i is some chemical component in a solution of phase j. The limiting values of a_i^j are 0, when i is absent from solution, or 1 when the solution consists of pure i. The activity coefficient λ_i can range from 0 to any positive value. For $\lambda_i < 1$, component i is tied up as it interacts with other components in solution, as in the above example. For repulsive forces acting on component i in solution j, the effective concentration may be greater than X_i^{liq}, in which case $\lambda_i > 1$.

The concept of activity can also be related to Lewis' idea of fugacity, f_i, which measures the "tendency" of a chemical species i to "escape" from one phase and enter another (Lewis 1901). So activity can be defined as $a_i = \frac{f_i}{f_i^o}$ where f_i is measured in units of pressure and f_i^o is fugacity of i at a standard state. Because f_i^o can be defined at any P or T, a_i is not uniquely defined – even when P and T are fixed. For aqueous solutions, defining f_i^o is necessary since f_i is never equal to one; so $a_{\text{i}} = 1$ (a necessary condition for pure substances, as we shall see) only when $f_i = f_i^o$. For liquids and minerals, we can express concentrations as mole fractions, similar to pure substances, making the fugacity relationship unnecessary.

Activities are tied to "solution models," and some important examples are Raoult's (1884) law, where $a_i^j = X_i$, and Henry's law (dilute solutions, i.e., when X_{i} is small), where $a_i^j = \lambda_i X_i$ and λ_i does not depend upon composition. At high X_{i}, activity coefficients can be modeled as a function of composition, using Margules parameters (Nordstrom and Munoz 1986). For solid solutions, entropy of mixing is used to create a "mixing on sites" (MOS) model (see Nordstrom and Munoz 1986). But while the MOS model is accepted for minerals, nothing comparable has been developed for liquids. The activity model of Bottinga and Weill (1972), Nielsen and Drake (1979), and Nielsen and Dungan (1983) seems to describe mineral-liquid equilibria quite well but has not gained a stout following. The model is based on viscosity and spectroscopic observations (see Mysen 1991) where silicate melts are divided into network-forming (NF) cations, which are tetrahedrally coordinated units charge-balanced by K and Na, and network modifiers, which comprise all other cations. The MELTS model (Ghiorso et al. 2002) is currently the most utilized of igneous liquid activities. It employs a "regular solution" model, which means that volumes of mixing are zero and entropies of mixing are entirely configurational. MELTS is not only useful for interpolating experimental phase equilibria, but Stebbins (2016) shows that it successfully predicts compositional dependencies of Si activity, first noted by Ryerson (1985).

Equations 2, 4a, b and 7 are the basis of all multivariate geothermobarometers. P-T information comes from the fact that K_{eq} is not truly a constant, but varies with P and T, as is implicit in Eq. 2. To better understand Eq. 2, we can use:

$$\Delta G_r^{T,P} = \Delta G_r^{0,T,P} + RT\ln Q \quad (8)$$

In Eq. 8, $\Delta G_r^{T,P}$ is the Gibbs free energy difference between products and reactants as they actually exist in nature, at some P and T; with luck, nature approaches equilibrium where $\Delta G_r^{T,P} = 0$. In Eq. 8, we use Q (the "reaction quotient") instead of K_{eq}, because while it can be calculated in the same way, it is only equal to K_{eq} when $\Delta G_r^{T,P} = 0$. If $\Delta G_r^{T,P} \neq 0$, the concentrations of A, B, C, and D (Eq. 3) should spontaneously change until Q reaches the value of K_{eq} (but like diamond converting to graphite at 1 atm, energy barriers may prevent equilibrium from being achieved) and when this happens $\Delta G_r^{T,P} = 0$, we have Eq. 2.

The Meaning of K_{eq}

Equations 2 and 8 show that K_{eq} serves a unitary purpose: to account for all disturbances to equilibrium that result from

impurities; the term $RT\ln K_{eq}$ describes the free energy effect of *impure systems*. When all phases are pure, all activities are unity; Eq. 4b is equal to 1, and $-RTlnK_{eq} = 0$. For the case $\Delta G_r^{o,T,P} = 0$ (Eq. 8), then $\Delta G_r^{0,T,P} = 0$, which is why activities must be unified for standard states. In any case, if a system is not ideal, we can divide K_{eq} into ideal and nonideal parts:

$$K_{eq} = \frac{a_C^{\gamma} a_D^{\delta}}{a_A^{\alpha} a_B^{\beta}} = \frac{(\lambda_C X_C)^{\gamma}(\lambda_D X_D)^{\delta}}{(\lambda_A X_A)^{\alpha}(\lambda_B X_B)^{\beta}} = \left(\frac{X_C^{\gamma} X_D^{\delta}}{X_A^{\alpha} X_B^{\beta}}\right)\left(\frac{\lambda_C^{\gamma}\lambda_D^{\delta}}{\lambda_A^{\alpha}\lambda_B^{\beta}}\right) \quad (9)$$

where $K_{eq}^{ideal} = \left(\frac{X_C^{\gamma} X_D^{\delta}}{X_A^{\alpha} X_B^{\beta}}\right)$ and the nonideal part is $K_{\lambda} = \left(\frac{\lambda_C^{\gamma}\lambda_D^{\delta}}{\lambda_A^{\alpha}\lambda_B^{\beta}}\right)$; K_{λ} is the "excess" Gibbs free energy. With rearrangement, Eq. 2 thus becomes:

$$lnK_{eq} = \ln\left(\frac{X_C^{\gamma} X_D^{\delta}}{X_A^{\alpha} X_B^{\beta}}\right) + \ln\left(\frac{\lambda_C^{\gamma}\lambda_D^{\delta}}{\lambda_A^{\alpha}\lambda_B^{\beta}}\right) = -\frac{\Delta G_r^{0,T,P}}{RT} \quad (10)$$

To Construct a Thermobarometer

One avenue to develop a thermobarometer is to quantify how $\Delta G_r^{0,T,P} = 0$ varies with P and T. In 1883 Van't Hoff (1896) used the ideal gas law and concepts of heats of reaction to show that Guldberg and Waage's "law of mass action" should vary with temperature, creating his eponymous equation:

$$\frac{dlnK_{eq}}{dT} = \frac{-\Delta H_r^o}{RT^2} \quad \text{or} \quad \frac{dlnK_{eq}}{d\left(\frac{1}{T}\right)} = \frac{-\Delta H_r^o}{R} \quad (11)$$

where ΔH_r^o is the heat of reaction between pure substances at a reference P and T.

Josiah Willard Gibbs had already presented his ideas of chemical potential energy (Gibbs 1874–1878) – a work that was not immediately appreciated. But Van der Waals (1891) and Van Laar (1892) would later use Gibbs' ideas to derive Van't Hoff's equation (Eq. 11), and Van Laar (1892) would derive a P dependency for K_{eq}:

$$\frac{\mathrm{d}\ln K_{eq}}{\mathrm{dP}} = \frac{\Delta V_r^o}{RT} \quad (12)$$

where ΔV_r^o is the volume of reaction between pure substances at a reference P and T (see also Lewis 1899).

The key issue for us is that K_{eq} is a constant only when P and T are fixed. In igneous systems, we can use:

$$\Delta G_r^{o,T_{\mathrm{fus}},1bar} = \Delta H_r^{o,T_{\mathrm{fus}},1bar} - T\Delta S_r^{o,T_{\mathrm{fus}},1bar} \quad (13)$$

where T is the temperature of interest and T_{fus} can really be any reference T, but here it is the T of fusion of pure substances at 1 bar. A term such as $\Delta H_r^{o,T_{\mathrm{fus}},1\mathrm{bar}}$ is the heat of fusion of a pure substance at 1 bar. Values for $\Delta H_r^{o,T_{\mathrm{fus}},1\mathrm{bar}}$ and $\Delta S_r^{o,T_{\mathrm{fus}},1\mathrm{bar}}$ are nearly constant when heat capacities between products and reactants, ΔC_p, are close to zero. If ΔC_p is far from 0, then additional corrections are needed:

$$\Delta G_r^{o,T,1\ \mathrm{bar}} = \Delta H_r^{o,T_{\mathrm{fus}},1\mathrm{bar}} + \int_{T_{\mathrm{fus}}}^{T} \Delta C_p \mathrm{dT} - T\left[\Delta S_r^{o,T_{\mathrm{fus}},1\mathrm{bar}} + \int_{T_{\mathrm{fus}}}^{T} \frac{\Delta C_p}{T} dT\right] \quad (14)$$

For barometry, we need to define the P effects on $\Delta G_r^{0,T,P}$, which is

$$\Delta G_r^{o,T,P} = \Delta G_r^{o,T,1\ bar} + \int_{1\ bar}^{P} \Delta V_r^o dP \quad (15)$$

where ΔV_r^o is the molar volume difference between pure products and reactants at T. Adding Eqs. 14 and 15, we have

$$\Delta G_r^{o,T,P} = \Delta H_r^{o,T_{\mathrm{fus}},1\mathrm{bar}} + \int_{T_{fus}}^{T} \Delta C_p dT - T\left[\Delta S_r^{o,T_{fus},1bar} + \int_{T_{fus}}^{T} \frac{\Delta C_p}{T} dT\right] + \int_{P_o}^{P} \Delta V_r^o dP \quad (16)$$

The last integral in Eq. 15 is challenging because ΔV_r^o depends upon both P and T. Assuming ΔC_p = constant and constant values for differences in compressibility ($\Delta\beta = \beta^{\mathrm{products}} - \beta^{\mathrm{reactants}}$) and thermal expansion ($\Delta\alpha = \alpha^{\mathrm{products}} - \alpha^{\mathrm{reactants}}$) (see Putirka 1998), we obtain:

$$lnK_{eq} = \frac{A}{T} + B + Cln\left[\frac{T}{T_o}\right] + D\frac{P}{T} + E\frac{P^2}{T} + FP + GP^2 \quad (17)$$

where T_o is a reference temperature and $A = -\Delta H_r^{T_o}/R$, $B = \Delta S_r^{T_o}/R, C = \Delta C_p/R, D = -\Delta V_r^o/R$, $E = \Delta\beta\Delta V_r^o/2R$, $F = \Delta\alpha\Delta V_r^o/R$, and $G = \Delta\alpha\Delta\beta\Delta V_r^o/2R$. Experimental error on phase equilibria experiments, though, is such that $\Delta C_p \approx 0$ and $\Delta V_r^o \approx$ constant, so Eq. 17 can be simplified to:

$$lnK_{eq} = \frac{\Delta H_r^{o,T}}{RT} - \frac{\Delta S_r^{o,T}}{R} + \frac{P\Delta V_r^o}{RT} \quad (18)$$

G

Combining Eqs. 9 and 10 with Eq. 18, we have:

$$lnK_{eq} = lnK_{eq}^{ideal} + lnK_{\lambda} = ln\left(\frac{X_C^{\gamma}X_D^{\delta}}{X_A^{\alpha}X_B^{\beta}}\right) + ln\left(\frac{\lambda_C^{\gamma}\lambda_D^{\delta}}{\lambda_A^{\alpha}\lambda_B^{\beta}}\right) = \frac{A}{T} + B + D\frac{P}{T} \quad (19)$$

which we rearrange to obtain:

$$ln\left(\frac{X_C^{\gamma}X_D^{\delta}}{X_A^{\alpha}X_B^{\beta}}\right) = \frac{A}{T} + B + D\frac{P}{T} + ln\lambda_C^{\gamma} + ln\lambda_D^{\delta} - ln\lambda_A^{\alpha} - ln\lambda_B^{\beta} \quad (20)$$

In theory, we could use Eq. 20 as a thermometer or barometer if only we knew the values of $\Delta H_r^{T_o}$, $\Delta S_r^{T_o}$, and ΔV_r^o (which we will simply write as ΔH_r^o , ΔS_r^o , and ΔV_r^o) and could somehow derive values for the activity coefficients. We now have a rich database of thermodynamic data (Richet and Bottinga 1986; Berman 1988; Lange and Carmichael 1987; Berman 1988; Lange and Navrotsky 1992; Navrtosky 1995; Holland and Powell 1998). But compositional complexities are hidden within Eq. 9, and they are not trivial. So instead, we rearrange Eq. 20 to obtain a regression equation for barometry:

$$P = \in_1 + \in_2 T + \in_3 T ln\left(\frac{X_C^{\gamma}X_D^{\delta}}{X_A^{\alpha}X_B^{\beta}}\right) + \in_4 ln\lambda_C^{\gamma} + \in_5 ln\lambda_D^{\delta} - \in_6 ln\lambda_A^{\alpha} - \in_7 ln\lambda_B^{\beta} \quad (21)$$

And using T as the dependent variable, a useful regression equation for a thermometer is:

$$T = \frac{v_1 + v_2 P}{v_3 + v_4 ln\left(\frac{X_C^{\gamma}X_D^{\delta}}{X_A^{\alpha}X_B^{\beta}}\right) + v_5 ln\lambda_C^{\gamma} + v_6 ln\lambda_D^{\delta} - v_7 ln\lambda_A^{\alpha} - v_8 ln\lambda_B^{\beta}} \quad (22)$$

The coefficients $\in_i$ and v_i can be related to thermodynamic parameters as in Eqs. 18, 19, and 20. The use of Eq. 22, though, requires problematic nonlinear regression techniques, so it can be rearranged to:

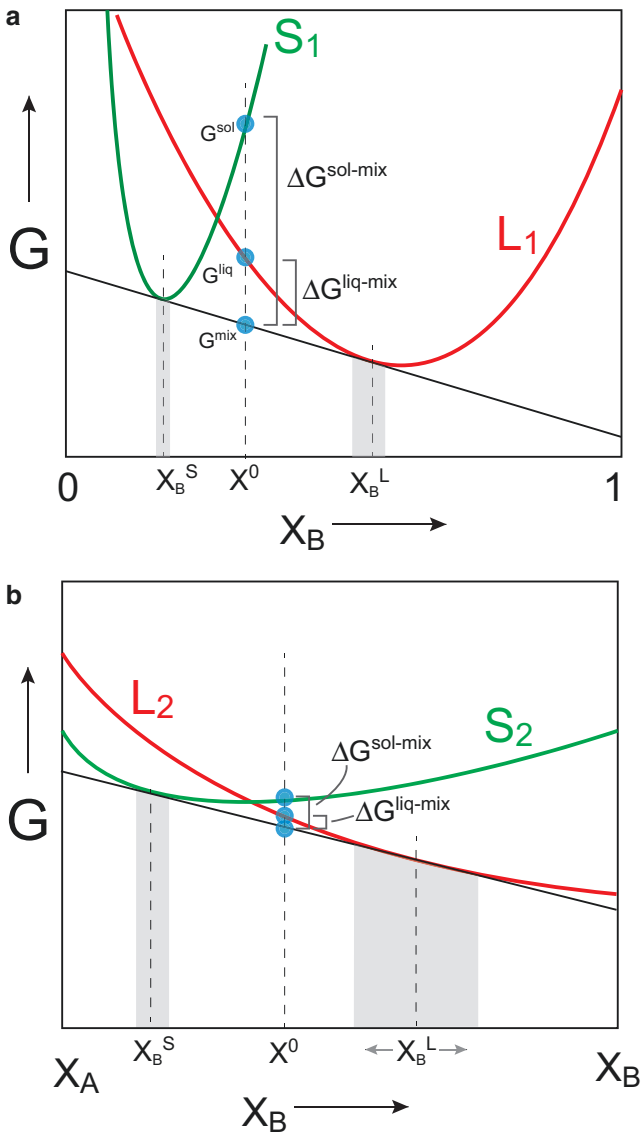
$$\frac{10^4}{T} = aln\left(\frac{X_C^{\gamma}X_D^{\delta}}{X_A^{\alpha}X_B^{\beta}}\right) + b + cln\lambda_C^{\gamma} + dln\lambda_D^{\delta} + eln\lambda_A^{\alpha} + fln\lambda_B^{\beta} + gP \quad (23)$$

where coefficients a through g are empirical constants that may or may not approximate thermodynamic quantities (we usually regress on $10^4/T$ rather than $1/T$ to avoid obtaining values of a through g that are exceedingly small). Although empirical, Eq. 23 retains the natural mathematical relationships between T and its various dependent quantities.

Putting Theory into Practice (And the Problems Therein)

Clearly, a large ΔV_r^o provides a good barometer, while a large ΔS_r^o(or ΔH_r^o) provides a good thermometer. Essene (1982) suggests minimum values of $\Delta V_r^o \geq 0.2$J/bar and $\Delta S_r^o \geq 4$ kJ/mole for sub-solidus systems. But a good thermobarometer also requires phases that have very definite compositions. There may be no better illustration of this issue than the Al-in-hornblende barometer of Hammerstrom and Zen (1986) and attempts to expand this model to volcanic systems by Ridolfi and Renzulli (2011). The original data of Hammerstrom and Zen (1986) reveal very wide variations in Al-in-amphibole at low pressures. Such variation nearly encompasses the entire range of Al-in-hornblende observed at higher pressures (Putirka 2016b). Such wide compositional ranges may reflect amphibole solid solution traits, hypothetically illustrated in Fig. 3.

Figure 3 shows two components, A and B, in a solid and liquid solution; for each diagram, P and T are fixed (say, 1,050 °C and 2 kbar, although the specific values do not matter). In Fig. 3a, solid phase S_1 has limited solid solution and so has a very narrow G-x surface, compared to a coexisting liquid phase L_1. These G-x surfaces can move up or down as P and T change or even side to side if another component, say C (not shown), affects the mutual solubility of A and B in either S_1 or L_1. For the bulk composition X^o, its lowest Gibbs free energy is that of a mixture of S_1 and L_1 (G^{mix}), compared to the Gibbs free energy if it were completely solid (G^{solid}) or liquid (G^{liquid}) at the given P and T. In this hypothetical system, raising T would have the effect of lowering the G-x surface of L_1 relative to S_1, until that surface was everywhere lower than S_1; at this point, the system would be completely liquid. At temperatures where both solid and liquid are stable, the compositions of the coexisting phases are given by the common tangent to the curves S_1 and L_1 : X_B^S for the solid and X_B^L for the liquid. Although the tangent curve is mathematically a point, one can see that even small disturbances to equilibrium, due to very small changes in P, T, or X_B, can, in practice, lead to different compositions, X_B^S and X_B^L, as shown by the gray regions in Fig. 3a. Now compare these gray regions to Fig. 3b, where the two phases S_2 and L_2 exhibit much greater extents of solid solution. Aluminum contents of amphiboles may be analogous to Fig. 3b, and indeed, our uncertainty or lack of reproducibility in any experimental system may be limited by this effect. If this is the case for Al-based components in amphibole, then the very nature of solid solution may hamper



Geothermometry and Geobarometry, Fig. 3 Two diagrams illustrating hypothetical two-component (**a** and **b**) Gibbs free energy composition (or G-x) relationships, both at a fixed P and T. (**a**) illustrates hypothetical solid and liquid phases S_1 and L_1, which have narrower G-x surfaces compared to phases S_2 and L_2 in (**b**). The G-x surfaces can move up or down with changes in P and T and can also move side to side or change shape, depending upon how the compositions of other phases affect the mutual solubility of components A and B in the phases S and L. In both panels, an arbitrary bulk composition, X^o, has a lower Gibbs free energy (G^{mix}) if it decomposes into a mixture of S + L, compared to the Gibbs free energy it would have if it were completely liquid (G^{liq}) or solid (G^{sol}). The composition of the equilibrium solid and liquid phases, (X_B^S) and (X_B^L), is given by the common tangent in both panels. But in panel (b), due to the wider, flatter G-x surfaces, the equilibrium composition of the two phases is less sharply defined, as shown by the *gray* areas that surround the precise equilibrium compositions (given by *vertical dashed lines*). For solid solution behavior such as in panel (**b**), a variety of liquids may precipitate very similar solid phases, and because the Gibbs free energies, G^{mix}, G^{liq}, and G^{sol}, are closer together, crystals may move in or out of saturation, even without large changes in T or P. Calibrating a thermobarometer from phases that exhibit such solid solution behavior may be intrinsically challenging

attempts to find a unique equilibrium composition at a given P and T, and the nearness of G^{solid}, G^{liquid}, and G^{mix} may cause a crystalline phase to move in or out of equilibrium with just small changes in P, T, or X_B.

Using Calorimetric Data and Activity Models

In this section, we will take a critical look at the role of calorimetric data and activity models in the development of thermobarometry. One of the more precise thermometers for igneous systems is based on anorthite (An = $CaAl_2Si_2O_8$; Ab = $NaAlSi_3O_8$) crystallization, and the reaction can be written as (liq = liquid; pl = plagioclase; pyx = pyroxene):

$$CaO^{liq} + 2SiO_2{}^{pyx} + 2AlO_{1.5}{}^{liq} = CaAl_2Si_2O_8{}^{pl} \quad (24)$$

Eq. 24 can also be written as:

$$CaAl_2Si_2O_8{}^{liq} = CaAl_2Si_2O_8{}^{pl} \quad (25a)$$

or

$$0.5Ca_2Si_2O_6{}^{liq} + 0.25Si_4O_8{}^{pyx} + 0.5Al_4O_6{}^{liq} = CaAl_2Si_2O_8{}^{pl} \quad (25b)$$

Equation 25a is useful for describing the simple binary system investigated by Bowen (1913) and Eq. 25b uses the liquid components of MELTS (Ghiorso et al. 2002) (Tables 1, 2, and 3 show how to transform a set of conventional oxides, as in Eq. 24 into any set of equally numbered molecular components, as in Thompson 1982). The phase boundaries of the plagioclase crystallization loop (Fig. 4) can be computed using the following equations:

$$X_{Ab}^{liq} = \frac{exp\left[\frac{\Delta H_f^{An}}{R}\left(\frac{1}{T_f^{An}} - \frac{1}{T}\right)\right] - 1}{\frac{exp\left[\frac{\Delta H_f^{An}}{R}\left(\frac{1}{T_f^{An}} - \frac{1}{T}\right)\right]}{exp\left[\frac{\Delta H_f^{Ab}}{R}\left(\frac{1}{T_f^{Ab}} - \frac{1}{T}\right)\right]} - 1} \quad (26a)$$

$$X_{Ab}^{pl} = \frac{\exp\left[\frac{\Delta H_f^{An}}{R}\left(\frac{1}{T_f^{An}} - \frac{1}{T}\right)\right] - 1}{exp\left[\frac{\Delta H_f^{An}}{R}\left(\frac{1}{T_f^{An}} - \frac{1}{T}\right)\right] - exp\left[\frac{\Delta H_f^{Ab}}{R}\left(\frac{1}{T_f^{Ab}} - \frac{1}{T}\right)\right]} \quad (26b)$$

where terms such as X_{Ab}^{liq} and X_{Ab}^{pl} are the mole fractions of Ab in a binary Ab-An mixture of liquid or plagioclase, terms such as

Geothermometry and Geobarometry, Table 1 Express molecular components as a function of oxides

	SiO_2	TiO_2	$AlO_{1.5}$	FeO	MnO	MgO	CaO	$NaO_{0.5}$	$KO_{0.5}$	$PO_{2.5}$

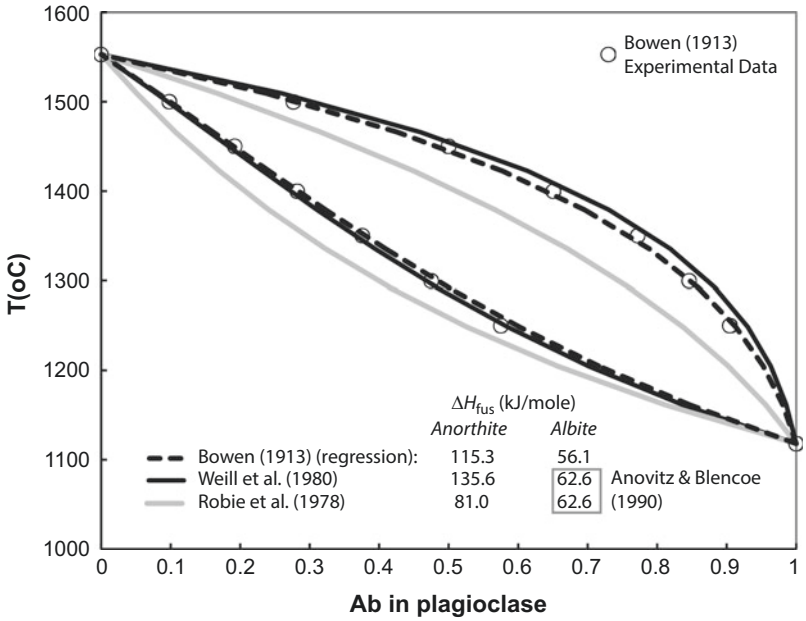
5. MELT components	0.464	0.036	0.137	0.093	0.003	0.066	0.085	0.089	0.020	0.005

Row 1 is a liquid composition expressed in weight % of oxides. Row 2 provides oxides as cation proportions (only one cation per oxide unit), so the weight % of Al_2O_3, for example, is divided by the molecular weight of $AlO_{1.5}$. Row 3 is a renormalization of row 2 to provide a cation fraction (sum = 1). Row 4 gives the MELT components expressed as proportions; it is the product row matrix obtained by multiplying the row matrix Row 3 by the square matrix, Table 2, which converts the oxides to the molecular components shown in Tables 1 and 2. MELTS also calculates Si and Al as Si_4O_8 and Al_4O_6; to obtain these, use 4 atoms each of Si and Al in rows 1 and 3 of Table 1a. Row 5 is a renormalization of Row 4.

T_f^{An} are the fusion temperatures of pure An, and T is the T of the mixture in question. Equations 26a and 26b can be obtained from Bowen (1913) and Van Laar (1906); they are general and can be applied to any two-component system. In these equations, ΔH_f^{An} and ΔH_f^{Ab} are the heats of fusion of pure anorthite and pure albite at 1 atm. We can obtain these by regressing Bowen's (1913) experiments, using Eqn. 18 (where $\Delta V_r = 0$, since the experiments are performed at 1 atm) and (25a) and using $K_{eq}^{An-liq} = X_{An}^{pl}/X_{An}^{liq}$. This yields $\Delta H_f^{An} = 115$ kJ/mole and $\Delta H_f^{Ab} = 56$ kJ/mole, which, if inserted into Eqs. 26a and 26b, unsurprisingly fit Bowen's (1913) experiments quite well (Fig. 4b) – slightly better than Bowen's reported values of $\Delta H_f^{Ab} = 53$ and $\Delta H_f^{An} = 121$ kJ/mole.

Can we then use $\Delta H_f^{An} = 115$ kJ/mole (and $\Delta S_f^{An} = 63$ J/mole, from the same regression) in Eq. 18 to obtain a plagioclase thermometer? Despite Bowen's (1913) excellent



Geothermometry and Geobarometry, Fig. 4 The anorthite-albite (An-Ab) binary phase diagram. Experimental data (*circles*) are from Bowen (1913); the *dashed* phase loop is derived by regression of Eq. 18 using the Bowen (1913) data, to obtain heats of fusion for Ab and An (rather than Bowen's reported values, which are slightly different). For comparison, the phase loops using the Ab enthalpy of fusion of Anovitz and Blencoe (1999) and An enthalpies of fusion from Weill et al. (1980; *black curves*) and Robie et al. (1978; *gray curves*) are shown

experiments, calorimetric work yields different values for ΔH_f^{An} : Weill et al. (1980) and Richet and Bottinga (1986) obtain $\Delta H_f^{An} = 135.6$ and 134.0kJ/mole , respectively (identical within a ± 10 kJ/mole error); and Anovitz and Blencoe (1999) obtain $\Delta H_f^{Ab} = 62.6$kJ/mole . These estimates do not fit Bowen's (1913) data nearly as well (Fig. 4).

However, the misfit obtained using $\Delta H_f^{\mathrm{An}} = 135$kJ/mole may mean that we are using the wrong activity model $\left(K_{eq}^{An-liq} = X_{An}^{pl}/X_{An}^{liq}\right)$. We let $a_{An}^{pl} = X_{An}^{pl} = X_{CaO}^{pl}/\left[X_{CaO}^{pl} + X_{NaO_{0.5}}^{pl} + X_{KO_{0.5}}^{pl}\right]$. Instead, let us use Eq. 24, $K_{eq}^{An-liq} = a_{An}^{pl}/\left(X_{CaO}^{\mathrm{liq}}\left(X_{AlO_{1.5}}^{liq}\right)^2\left(X_{SiO_2}^{liq}\right)^2\right)$, and the Holland and Powell (1992) activity model, $a_{An}^{pl} = 16X_{Ca}^{pl}\left(X_{Al(T)}^{pl}\right)^2\left(X_{Si(T)}^{pl}\right)^2$, where X_{Ca}^{pl} is the fraction of Ca on the A site in plagioclase (effectively $\mathrm{Ca} = X_{CaO}^{pl}/\left[X_{CaO}^{pl} + X_{NaO_{0.5}}^{pl} + X_{KO_{0.5}}^{pl}\right]$) and $X_{Al(T)}^{pl}$ and $X^{pl}{}_{Si(T)}$ are the fractions of Al and Si on the tetrahedral sites (so $X_{Si(T)}^{pl} = X_{SiO_2}^{pl}/\left(X_{SiO_2}^{pl} + X_{AlO_{1.5}}^{pl}\right)$). This yields $\Delta H_f^{\mathrm{An}} = 139$kJ/mole for Bowen's (1913) data, which is within error of the Weill et al. (1980) and Richet et al. (1982) results.

Is this a victory for Holland and Powell? Not really. If our K_{eq} term and the activity models contained therein account for the free energy of mixing, then we should always recover the calorimetric value of ΔH_f^{An} – it should not change if we regress a different set of compositions. Table 4 shows regression results at 1 atm for anhydrous partial melting experiments performed on natural bulk compositions; each activity model yields a different value for ΔH_f^{An}, and for the natural data, the Holland and Powell (1992) model yields 19.6 kJ/mole.

Geothermometry and Geobarometry, Table 4 $\Delta H_{\mathrm{fus}}^{\mathrm{An}}$ (as $CaAl_2Si_2O_8$) in kJ/mole from regression (Eq. 18) using different activity models and experimental data (from Bowen 1913, and 1 bar anhydrous experiments on natural compositions)

[i]Calorimetric value for An heat of fusion, from Weill et al. (1980)

In contrast, Nielsen and Drake's (1979) activity model for liquid (liq) components (we revert back to $a_{An}^{pl} = X_{An}^{pl}$) yields 139 kJ/mole. Nielsen and Drake (1979), building on the work of Bottinga and Weill (1972), argue that silicate liquid cations fall into either network-forming (NF) sites, which consist of interconnected SiO_2, $NaAlO_2$, and $KAlO_2$ units, or "network-

modifying" (NM) sites, where NM = CaO + $AlO_{1.5}$ + FeO + MgO + MnO + $CrO_{1.5}$, and where NM cations disrupt the network. In Nielsen and Drake's (1979) model, $K_{eq}^{An-liq} = a_{An}^{pl} / \left(a_{CaO}^{liq}\left(a_{AlO_{1.5}}^{liq}\right)^2\left(a_{SiO_2}^{liq}\right)^2\right)$ where $a_{An}^{pl} = X_{An}^{pl} = X_{CaO}^{pl} / \left(X_{NaO_{0.5}}^{pl} + X_{KO_{0.5}}^{pl} + X_{CaO}^{pl}\right)$ and the activities of the liquid components are calculated as in Nielsen and Drake (1979): $a_{CaO}^{liq} = X_{CaO}^{liq}/\mathrm{NM}, a_{(AlO_{1.5})}^{liq} = \left(X_{(AlO_{1.5})}^{liq} - X_{(NaO_{0.5})}^{liq} - X_{(KO_{0.5})}^{liq}\right)/\mathrm{NM}$ and $a_{SiO_2}^{liq} = X_{SiO_2}^{liq} / \left(X_{SiO_2}^{liq} + X_{NaO_{0.5}}^{liq} + \mathrm{KO}_{0.5}^{liq}\right)$. And $a_{\mathrm{NaAlO_2}}^{\mathrm{liq}} = X_{\mathrm{NaO_{0.5}}}^{\mathrm{liq}} / \left(X_{NaO_{0.5}}^{liq} + X_{KO_{0.5}}^{liq} + X_{SiO_2}^{liq}\right)$.

What if we apply both Nielsen and Drake's (1979) and Holland and Powell's (1992) models? Then the 1 bar experiments using natural compositions yield $\Delta H_f^{\mathrm{An}} = 124\mathrm{kJ/mole}$, quite close to Bowen's (1913) original estimate but still short of the calorimetric value. But it is not clear that this represents a success, nor that the other activity models fail. MELTS successfully predicts plagioclase saturation temperatures for anhydrous liquids over a wide range of pressures (Putirka 2005). And while the very low ΔH_f^{An} values for some models would imply that they would make poor thermometers, this is not the case. In fact, the activity models have no impact upon thermometer calibration at all. Each of the models of Table 4, including one using simple cation fractions:

$$\frac{10^4}{T(K)} = 3.66 + 0.158\left[ln\left(\frac{X_{\mathrm{An}}^{\mathrm{pl}}}{X_{CaO}^{liq}\left(X_{AlO_{1.5}}^{liq}\right)^2\left(X_{SiO_2}^{liq}\right)^2}\right)\right] + 7.60\left[X_{KO_{0.5}}^{liq}\right] - 1.04\left[ln\left(X_{AlO_{1.5}}^{liq}\right)\right] - 0.013\left[ln\left(X_{NaO_{0.5}}^{liq}\right)\right] - 0.44\left[ln\left(X_{An}^{pl}\right)\right], \quad (27a)$$

yield thermometers that reproduce T for the anhydrous, 1 atm experimental data to within ±10–12 °C. The larger, often unappreciated issue is twofold: we do not understand activities well enough to fix the coefficients in Eq. 17 to theoretical values, and regression coefficients are sensitive to the kinds of parameters used in a model, the data used for regression, and the choice of independent variable. Regression analysis is a terrible way to determine thermodynamic parameters.

Worse still for activity modeling efforts, the two following equations show how some activity models, however justified by theory, actually impair our ability to predict T (or P). These two thermometers are calibrated using both anhydrous and hydrous data, at pressures of <3 kbar (low enough that we may ignore ΔV_r^o):

$$\frac{10^4}{T(K)} = 4.0 + 0.42\left[ln\left(\frac{X_{An}^{pl}}{X_{\mathrm{CaO}}^{liq}\left(X_{AlO_{1.5}}^{liq}\right)^2\left(X_{SiO_2}^{liq}\right)^2}\right)\right] - 2.92\left[X_{MgO}^{liq}\right] - 0.71\left[ln\left(X_{An}^{pl}\right)\right] + 0.2\left[C_{H_2O}^{liq}\right] \quad (27b)$$

$$\frac{10^4}{T(K)} = 6.13 + 0.19\left[ln\left(\frac{a_{An}^{pl}}{a_{CaO}^{liq}\left(a_{AlO_{1.5}}^{liq}\right)^2\left(a_{SiO_2}^{liq}\right)^2}\right)\right] - 6.24\left[a_{NaAlO_2}^{liq}\right] + 2.01\left[X_{Ab}^{pl}\right] + 0.26\left[C_{H_2O}^{liq}\right] \quad (27c)$$

As in Eq. 27a, all liquid components in Eqn. 27b, except for H_2O are cation fractions (X_i), (row 3 of Table 3), and $X_{An}^{pl} = X_{CaO}^{liq} / \left(X_{NaO_{0.5}}^{liq} + X_{KO_{0.5}}^{liq} + X_{CaO}^{liq}\right)$. In both equations, $C_{H_2O}^{liq}$ is the concentration of H_2O in a liquid, expressed in weight %. In Eq. 27c, all liquid components, except for H_2O, are as in Nielsen and Drake (1979), and a_{An}^{plag} is from Holland and Powell; X_{Ab}^{pl} is the cation fraction $X_{NaO_{0.5}}^{pl} / \left(X_{NaO_{0.5}}^{pl} + X_{KO_{0.5}}^{pl} + X_{CaO}^{pl}\right)$. The coefficients 0.42 and 0.19 in Eqs. 27b and 27c, respectively, translate to $\Delta H_f^{An} = 198$ and 438kJ/mole. No longer do the Holland and Powell (1992) and Nielsen and Drake (1979) activity models yield even remotely close approximations of calorimetric ΔH_f^{An}. Moreover, Holland and Powell's (1992) model does not save us from requiring a correction to the activity of An-in-plagioclase (the $\ln\left(X_{An}^{pl}\right)$ term), which is needed by both models to obtain the most precise T estimates possible. But finally, and most importantly, Eq. 27b actually *extrapolates better* than Eq. 27c, *providing better predictions of T for data not used in regression*. Both equations recover T for calibration data (n = 337; 850–1,244 °C, 1 atm to 3 kbar, and 0–8% H_2O) with comparable errors (±19 °C for Eq. 27a; ±21 °C for Eq. 27b). But Eq. 27b predicts T to ±55 °C for the test data, (n = 912) compared to ±67 °C for Eq. 27c (test data range from 1 atm to 27 kbar, 700–1,430 °C, and 0–19% H_2O). And Eq. 27b exhibits less systematic error: for a

regression of test data of $T^{predicted}$v . $T^{measured}$, Eq. 27b yields a slope and intercept of 0.99 and 25 °C, compared to a slope and intercept of 0.88 and 144 °C when $T^{predicted}$ is from Eq. 27c.

Summary

Part I: Guidelines for Calibration of a Thermobarometer

The above examples, of Ti-in-quartz, Al-in-hornblende, and plagioclase thermometry, reveal that thermodynamic theory provides the correct form of the equations needed for thermobarometry, but parameter coefficients are not easily defined. With this in mind, we end this section with guidelines for the calibration and application of geothermobarometers:

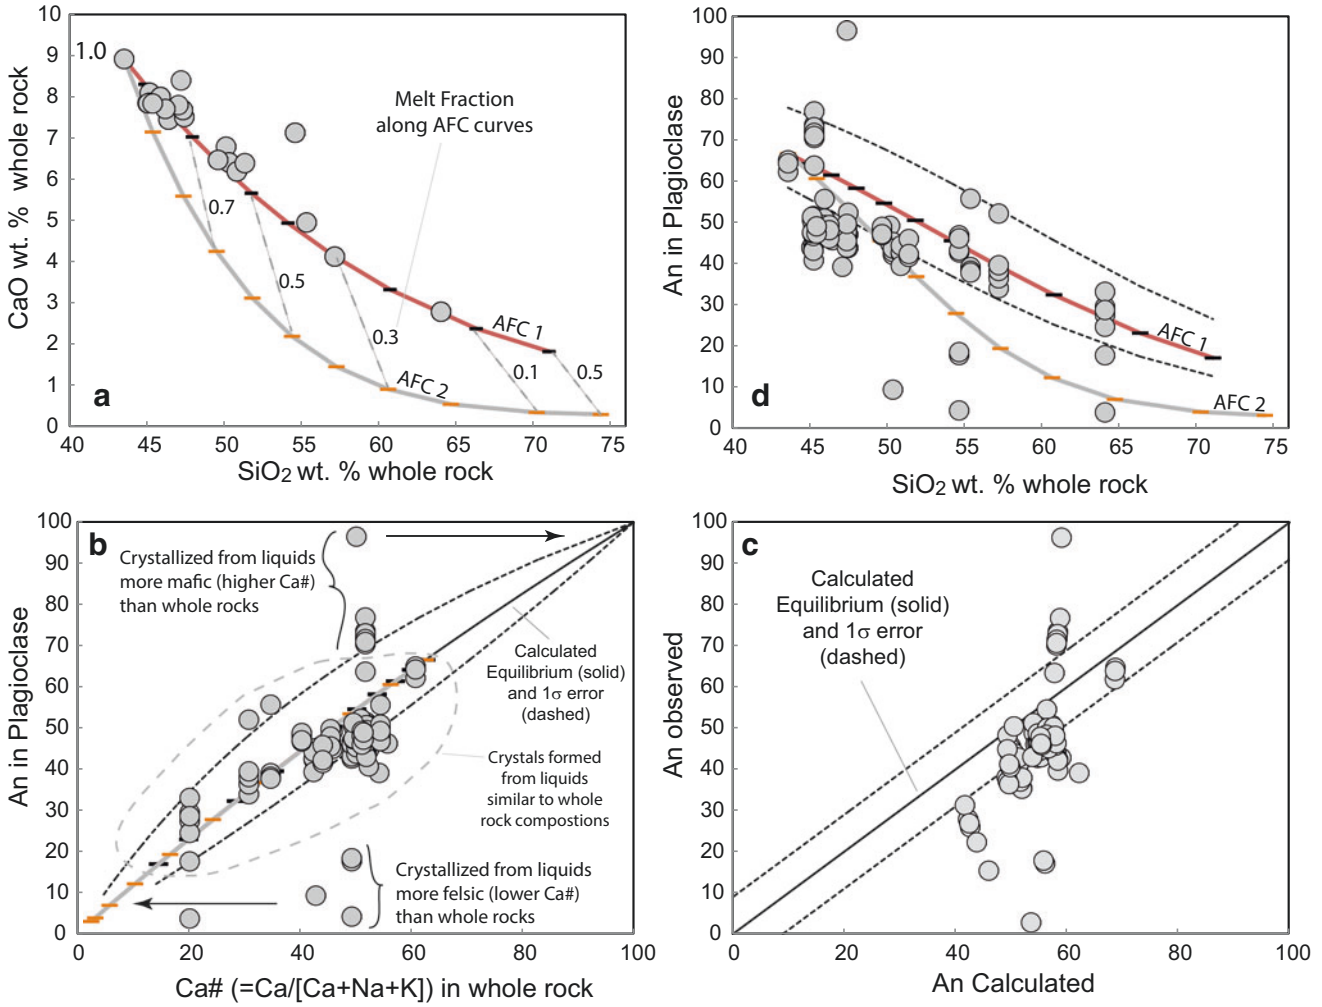
1. ***Select calibration data with care***. Bad data in a calibration will yield a bad model; the hallmarks of good data are those that are reproducible by other laboratories. There are no other simple or easy tests that allows one to say that one set of data are good and another are bad. A useful strategy is to look for data that are coherent (e.g., $\ln K_{eq}$ is highly correlated to $1/T$, as in Wark and Watson 2006) among multiple laboratories.
2. ***Use test data***. These are data that are not used for calibration. They are invaluable to calibrations, activity models, etc., as shown above for a plagioclase-liquid thermometer.
3. ***Use linear least squares when possible***. This approach allows error analysis on individual terms, and the regression-derived coefficients are certain to minimize error on the dependent variable. Nonlinear methods lack these qualities.
4. ***Isolate the quantity of interest (P or T) as the dependent variable***. As emphasized in Putirka (2008), and noted above, regression is not a symmetric method: errors reduced on y, in $y = mx + b$, will not minimize error on predictions of x, when rearranged. A new equation, using x as the dependent variable, is needed if x is to be calculated.
5. ***Use as few parameters as possible (and leverage tests)***. This is Occam's Razor, which has a statistical basis (Jefferys and Berger 1992), and is required by limits on experimental precision. For example, we know that ΔC_p is not zero, but terms such as $\ln\left[\frac{T}{T_o}\right]$ (Eqn. 17) rarely reduce error. Leverage plots from linear least squares are also useful, by allowing one to delete parameters that are controlled by just one or a few, possibly errant, data. Adding poorly supported terms can affect all other model coefficients, rendering a model less precise when used to predict P or T.

Part II: Guidelines for Applying Thermobarometers to Nature

Mineral compositions are important and powerful because of their often slow rates of diffusion at near-surface temperatures. A resistance to re-equilibration means that the samples we collect at the surface today preserve a P-T record of geologic processes of the past. But thermobarometers are based on ideas of equilibrium, and we sometimes need to infer or reconstruct an equilibrium state to infer P and T. In igneous systems, this is especially problematic because magma mixing, a ubiquitous process, mingles crystals with magmas from which they did not crystallize. The following guidelines may minimize the probability that our inferences of P and T go astray:

1. *Compare independent estimates of P and/or T*. Direct tests trump inferential ones, as shown above for the BT, keeping in mind that T (and P) estimates need not match, if minerals saturate at different temperatures (and pressures, e.g., Putirka and Condit 2003). This approach is no better illustrated than in Klügel and Klein (2005), who show that fluid inclusions and mineral-melt barometers yield convergent estimates for P of partial crystallization for the Madeira volcanic system. And Anderson (1996b) obtains P-T estimates of granitic rocks using both metamorphic and igneous equilibria. Putirka (2016b) also shows a convergence of amphibole and clinopyroxene barometers at some arcs. But also important are correlated estimates. In Hawaii, olivines yield higher temperatures than clinopyroxene, but the T contrast matches that predicted from phase equilibria (Putirka 1997), and the T ranges are remarkably similar (so we are apparently truly differentiating high and low T samples).
2. *Error should be well defined; averaged estimates are better*. Reported model errors, when quantified, are a *minimum estimate of actual error when predicting P or T in a natural system*, at least on individual estimates. Averaged P and T estimates are likely to be more accurate (Powell and Holland 1994). For example, Putirka et al. (1996) show that a clinopyroxene-liquid barometer has a precision of ±1.5–2.0 kbar for individual estimates but, when averaged, might be as low as ±0.7 kbar. This is evident in low P experiments where the models can yield negative pressures; but small negative estimates are not necessarily wrong. A series of clinopyroxenes, yielding pressures of, say −2 kbar to +3 kbar, can converge to a correct answer (1 kbar) in both experiments and in nature.
3. *Roozeboom diagrams and tests for equilibrium*. Lacking independent thermobarometers, tests for equilibrium are vital. Perhaps the single most successful example is the Fe-Mg exchange coefficient, developed by Roeder and Emslie (1970) for olivine + liquid equilibrium and

G



Geothermometry and Geobarometry, Fig. 5 An illustration of how to reconstruct equilibrium liquid compositions that would be paired with mineral compositions so as to predict *P* and *T* for igneous systems. (**a**) A variation diagram for whole-rock compositions from the Craters of the Moon Lava Field, ID (Putirka et al. 2009). The *gray* and *red curves* show AFC curves that use a primitive COM magma as a parent magma and an Idaho Batholith granite (AFC1) and a COM rhyolite xenolith (AFC2) as possible felsic end-members; hachures indicate melt fraction. (**b**) A Roozeboom-type diagram comparing Ca# for both Plagioclase and liquid. Ca# is the molar ratio $CaO/(CaO+NaO_{0.5}+KO_{0.5})$ in either a liquid or solid phase, and is equal to the An content in plagioclase. The solid *black line* is the inferred equilibrium ratio for Ca# determined from plagioclase-saturated experiments (LEPR); *dashed lines* show 1σ error. Some crystals are allowably in equilibrium with liquids that are similar to observed whole-rock compositions. (**c**) Shows a test of observed versus calculated An contents assuming that whole rocks act as liquids; *T* is calculated from model A of Putirka (2005), assuming *P* estimates in Putirka et al. (2009) and $H_2O = 0\%$. With these conditions, plagioclase An fractions (which are multiplied by 100 in the charts) are predicted using: $An = \exp(-2.13+3.74[X^{liq}_{AlO_{1.5}}]+13.97[X^{liq}_{CaO}]-25.44[KO^{liq}_{0.5}] - 31.6[P(kbar)]/T(K)+0.108[Mg\#^{liq}] + 829.9/T(K) + 157.96[KO^{liq}_{0.5}][X^{liq}_{AlO_{1.5}}] - 18.42[SiO^{liq}_2][X^{liq}_{CaO}])$. Clearly, plagioclase with very high and low An (**b** and **c**) must be derived from liquids with higher- and lower- than- observed $Ca\#^{liq}$ compared to whole rocks. Magma mixing homogenizes magma compositions, but mineral compositions at least partially preserve felsic and mafic end-member magma compositions. (**d**) Comparison of an contents with whole rock SiO_2; here, we use the bulk compositions generated along AFC1 in (**a**) to predict equilibrium An contents for such liquids using the equation just noted, with error bounds noted by dashed lines. The gray circles are the measured An contents compared to their host whole rock SiO_2. The *curve* AFC1 better describes the whole rock trend, but AFC2 can explain low An crystals. For example, plagioclase of <10% An content can equilibrate from liquids (along AFC2) that have 70–75% SiO_2. Whole rocks with such SiO_2 contents are not erupted at the COM, but low An crystals provide evidence that such high SiO_2 liquids existed prior to mixing with mafic magmas

employed in the Rhodes Diagram that compares the Mg# of Ol and liq (Putirka 2008). Through experiments and thermodynamic arguments, Roeder and Emslie showed that ΔH^o_r and ΔV^o_r are sufficiently small for the reaction between forsterite ($MgSi_{0.5}O_2$) and fayalite ($FeSi_{0.5}O_2$):

$$MgSi_{0.5}O_2 + FeO^{liq} = FeSi_{0.5}O_2 + MgO^{liq} \qquad (28a)$$

such that P and T do not affect K_{eq}:

$$K_{eq}^{ol-liq} = \frac{\left(a_{Fa}^{ol}\right)\left(a_{MgO}^{liq}\right)}{\left(a_{Fo}^{ol}\right)\left(a_{FeO}^{liq}\right)} \quad (28b)$$

To ease calculation, instead of using K_{eq} (Eq. 28b), Roeder and Emslie (1970) defined an exchange coefficient:

$$K_{D}^{ol-liq} = \frac{\left(X_{FeO}^{ol}\right)\left(X_{MgO}^{liq}\right)}{\left(X_{MgO}^{ol}\right)\left(X_{FeO}^{liq}\right)} \quad (28c)$$

Equation 28c is an approximation of Eq. 28b, where X_{Feo}^{ol} is a proxy for a_{Fa}^{ol}. Roeder and Emslie (1970) use only Fe^{2+} in liquid (FeO) in Eq. 28c, which removes the effect of oxygen fugacity (fO_2). Subsequent studies have shown that K_D^{ol-liq} is not greatly affected by composition or P (Putirka 2016b). This type of coefficient is something of a holy grail in petrology and is used for other igneous phases. If we let $X_{FeO}^{ol} = X_{FeOt}^{ol}$ (where FeO is total Fe, which introduces fO_2 sensitivity), then coefficients of the type $K_D^{\phi 1-\phi 2}$ (where ϕ_1 and ϕ_2 are coexisting, potentially equilibrated, phases) have similar values for a number of mineral-melt pairs, such as olivine (0.30; Roeder and Emslie 1970; Putirka 2016a), clinopyroxene (0.27; Putirka 2008), orthopyroxene (0.28; Beattie 1993), and amphibole (0.28; Putirka 2016b); the approach can even be applied to feldspars (0.55; Longhi et al. 1976).

The problem with this approach is that different equilibria can equilibrate at different rates. Due to higher expected rates of diffusion for Fe^{2+} and Mg^{2+}, compared to Al^{3+} (Brady and Cherniak 2010), for example, a clinopyroxene + liquid system may exhibit Fe-Mg exchange equilibrium, but not reflect equilibration with respect to the jadeite + liquid components that are used to estimate P. This approach is thus not a substitute for independent estimates of T and P although some experiments indicate that cooling rates might be obtained from systematic departures from equilibrium (Mollo et al. 2013a, b).

4. *Correcting igneous compositions and additional tests.* Igneous systems pose unique challenges to the application of thermobarometers since equilibrated crystals and liquids are easily separated from one another. Equilibrium tests can be applied to reconstruct possible equilibrium systems. Whole rock and plagioclase compositions from the Craters of the Moon (COM) Lava field (Putirka et al. 2009) provide an example. As a test of plagioclase + liquid equilibrium, we can use a Na-Ca exchange coefficient:

$$K_{D}^{pl-liq} = \frac{\left(X_{NaO_{0.5}}^{pl}\right)\left(X_{CaO}^{liq}\right)}{\left(X_{CaO}^{pl}\right)\left(X_{NaO_{0.5}}^{liq}\right)} \quad (29)$$

This coefficient ranges widely, but not systematically with P, or T, and except for H_2O, it is not affected by liquid or mineral compositions. Silicate liquids containing <0.5 wt. % H_2O yield a mean value of 0.84 ± 0.36, while hydrous systems (or systems at T<1,050 °C) yield a mean value somewhere between 0.38 ± 0.17 (n = 362) and 0.30 ± 0.09 (n = 313), depending upon which data are used.

The error on the coefficients (e.g., ±0.36) may seem broad, but the model is still effective. Figure 5a compares weight % values of CaO and SiO_2 for COM whole-rock compositions, with an assimilation-fractional crystallization (AFC 1) curve that explains their compositional variation (see Putirka et al. 2009). But Fig. 5b, making use of Eq. 29, reveals that not all plagioclase crystals formed from liquids that approximate observed whole-rock compositions. Figure 5c illustrates an independent test of the same idea: here we compare the observed An contents of plagioclase to those predicted to precipitate if the whole-rock compositions are liquids. Of course, magma mixing is a likely explanation for the discrepancy. But nonequilibrated plagioclase grains can tell us about pre-magma mixing conditions.

Figure 5d perhaps shows the issue more intuitively, where we again use Eq. 29 to compare plagioclase grains and whole rocks. Clearly, a given whole-rock composition can contain a wide range of plagioclase compositions – but it cannot be in equilibrium with all of them. Curve AFC2 shows how it might explain at least some of the dis-equilibrium plagioclase compositions (Fig. 5a). This curve does not reproduce whole-rock compositions, but the high SiO_2 liquids (70–75% SiO_2) produced along AFC2 have Ca# values that can produce the observed crystals with the lowest An content, which cannot be produced by liquids that look like the whole rocks themselves. A plausible explanation is that high SiO_2 liquids were indeed produced by a process like AFC2, but either were not erupted or were homogenized with mafic liquids to yield whole rocks with <64% SiO_2.

The key approach here is to explore a range of possible liquid compositions that are obtained by AFC, liquid lines of descent or mixing lines. These calculated liquids should simultaneously reproduce observed whole-rock compositions and yield mineral compositions that satisfy experimentally constrained conditions of equilibrium. A final test if possible, would be to compare multiple P and T estimates using such hypothetical liquids. When the convergences are numerous, such liquids and their calculated P-T conditions are likely to describe natural processes, rather than numerical accidents and so tell us something about Nature.

Germanium

Louis A. Derry
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Element Data
Atomic Symbol: Ge
Atomic Number: 32
Atomic Weight: 72.63
Isotopes and Abundances: ^{70}Ge 20.57%, ^{72}Ge 27.45%, ^{73}Ge 7.75%, ^{74}Ge 36.50%, Ge ^{76} 7.73%
1 Atm Melting Point: 983.3 °C
1 Atm Boiling Point: 2820 °C
Common Valences: 2+, 4+
Ionic Radii: Ge^{4+} IV: 39 pm, Ge^{4+} VI: 53 pm, Ge^{2+} VI: 73 pm
Pauling Electronegativity: 2.01
First Ionization Potential: 762 kJ mol^{-1}
Chondritic (CI) Abundance: 33.2 ppm
Silicate Earth Abundance: 1.1 ppm
Crustal Abundance: 1.3 ppm
Seawater Abundance: 5–160 pmol kg^{-1}
Core Abundance: 28–41 ppm

Properties

Germanium has an atomic number of 32 and atomic weight of 72.63. It is both siderophile and volatile, with an electronic structure $[Ar]3d^{10}4s^24p^2$. Under the older CAS or IUPAC nomenclature Ge was classified as either group IVA or IVB, an unfortunately confusing situation. The modern IUPAC classification for Ge is in Group number 14. It is normally found in two oxidation states, Ge^{II} and Ge^{IV}, with Ge^{IV} the most common under Earth surface conditions. Germanium has five stable isotopes, as well as radioactive ^{68}Ge and ^{71}Ge with half lives of 271 and 11 days, respectively. Ge forms stable halides, including hydrides, fluoride and chlorides. Generation of GeH_4 in the laboratory is a useful analytical technique.

History and Use

The existence of an element with properties between those of silicon and tin and an atomic mass of 73 was first predicted by Newlands in 1864, while Mendeleev made specific and generally accurate predictions of the properties of "eka-silicon" in 1872. Winkler (1886) isolated this element from a silver sulfide and named it in honor of his country.

The largest industrial uses of germanium are in catalyst production, optics, and semiconductor manufacturing (Höll et al. 2007). Ge is obtained commercially as a by-product of zinc production, typically by volatilization of GeF_4 or $GeCl_4$ from Zn and Ge-enriched flue dusts. Ge is also produced from coal fly ash.

Geochemical Behavior

The condensation temperature for Ge from the solar nebula into Fe alloy is estimated to be 885 K, making it one of the more volatile elements (Lodder 2003). As a consequence, the bulk Ge terrestrial abundance is approximately a factor of 2–3 below the chondritic value, i.e., ≈11–16 ppm. Experimental data on metal-silicate partitioning implies that Ge is strongly partitioned into the core (Righter et al. 2011), which retains 92–95% of terrestrial Ge. The mantle has [Ge] ≈ 1 ppm, and the continental crust is slightly enriched at ≈1.3 ppm. The geochemical behavior of germanium has long been recognized to be similar to that of silicon, where it embodies the "principle of camouflage" and readily substitutes into lattice positions occupied by Si (Goldschmidt 1937; Goldsmith 1950).

Germanium dioxide has close affinities to SiO_2. Hexagonal GeO_2 has a 4-coordinated β-quartz structure, while tetragonal GeO_2 forms a 6-coordinated stishovite structure. A number of germanate analogs of alumino-silicate minerals have been synthesized. Ge can readily substitute for Si in common mineral structures, where it appears to form mostly ideal solid solutions. It is useful to characterize Ge abundances by the Ge/Si ratio, typically near 1×10^{-6} mol mol^{-1} (μmol mol^{-1}) in most silicates. Ge/Si appears to vary with crystal structure, with lower values in quartz (<1 μmol mol^{-1}), intermediate values in feldspars and olivine (1.5–3 μmol mol^{-1}), and higher values in sheet silicates (micas and clays, 4–7 μmol mol^{-1}) (Kurtz et al. 2002). Partition coefficients for Ge with common mantle minerals are mostly within a factor of two of unity, and so Ge/Si ratios in melts should closely reflect their source regions (Le Roux et al. 2015).

Although GeS_2 is rare as a mineral phase, Ge is commonly enriched in sulfide minerals, notably in sphalerite and enargite (Bernstein 1985). Oxidized portion of sulfide ore bodies can contain high [Ge] in iron oxides. Ge also has an active organic chemistry. The majority of Ge in seawater is methylated (Lewis et al. 1985), while Ge is variably but often strongly enriched in coals.

In the oceans Ge/Si ratios are near a constant 0.7 μmol mol^{-1}, and thus exhibits nutrient-like depth profiles as does

silica. This ratio reflects a mixture between river inputs of dissolved Ge (present as germanic acid, Ge(OH)4) with Ge/Si $\approx$ 0.6 μmol mol^{-1}, and mid-ocean ridge hydrothermal systems with Ge/Si ≈10–20 μmol mol^{-1} (Froelich et al. 1985). The low Ge/Si of river waters relative to crustal sources implies the existence of an enriched reservoir, and soils with secondary clays commonly have high Ge/Si (Murnane and Stallard 1990; Kurtz et al. 2002). Silicate weathering reactions fractionate Ge/Si in a predictable way that can be used to quantify reaction pathways and yields (Lugolobi et al. 2010). Geothermal fluids can be extremely enriched in Ge, with Ge/Si up to ≈1000 μmol mol^{-1}. This enrichment results from both temperature effects on Ge solubility and Rayleigh fractionation related to quartz precipitation (Evans and Derry 2002).

The stable isotopic composition of germanium is commonly expressed as:

$$\delta^{74}Ge = \left[\frac{\left({}^{74}Ge/{}^{70}Ge\right)_{\text{sample}}}{\left({}^{74}Ge/{}^{70}Ge\right)_{\text{standard}}} - 1\right] \times 1000$$

Isotopic variations up to ≈7 ‰ have been reported to date, with the lowest values from hydrothermal minerals and the highest from marine biogenic silica (Rouxel et al. 2006; Belissont et al. 2014). A widely accepted Ge isotopic standard has not yet been established, with two solutions currently in use (JMC and Aldrich) that differ by 1.70 ± 0.22 ‰ (Luais 2007). Relative to the heavier JMC standard, magmatic iron meteorites thought to be representative of undifferentiated parent bodies have $\delta^{74}Ge = 1.77 \pm 0.22$‰, which is the current best estimate of the early solar system value (Luais 2007). Relative to the JMC standard the bulk silicate Earth (BSE) is estimated to have $\delta^{74}Ge = -0.4 \pm 0.2$‰, or 1.3 ± 0.2 relative the lighter Aldrich standard (Rouxel et al. 2006). This low value for the BSE may reflect the substantial loss of volatile Ge during planetary formation. Seawater has not been directly determined but based on data from marine sponges Rouxel et al. proposed that $\delta^{74}Ge_{sw} \geq 3.0$‰ relative to the Aldrich standard. Ab initio calculations support a moderately positive isotope fractionation factor ($\Delta_{min—Ge(OH)4}$) between aqueous $Ge(OH)_4$ and quartz, and strong negative fractionation between $Ge(OH)_4$ and sphalerite (Li et al. 2009), results that appear consistent with published data on hydrothermal minerals. Both Ge/Si and $\delta^{74}Ge$ ratios therefor appear promising as tracers of geothermal transport and mineralization processes.

Biological Utilization and Toxicity

Germanium is not toxic at typical environmental levels, and is taken up by siliceous marine organisms as well as terrestrial plants (Azam and Volcani 1981). Ge is not known to have a biological function. Inhibition of diatom growth has been noted at Ge/Si ≥ 0.01 mol/mol, but this ratio is four orders of magnitude higher than in natural waters. Renal function was negatively impacted in humans with high chronic exposure to GeO_2 via use as dietary supplements (Tao and Bolger 1997), but Ge does not appear to have carcinogenic or mutagenic activity, and appears to be "an element of rather low risk to man" (Gerber and Léonard 1997). Siliceous diatom frustrules have the same Ge/Si as the ambient seawater, and Ge is evidently not fractionated from Si by this major consumer of marine dissolve silica (Froelich et al. 1985). Consequently the residence time of inorganic Ge should be near that of silica, i.e., ≈15 kyr. In contrast, vascular plants fractionate germanium from silicon fairly strongly. While silica uptake varies significantly among plant groups, opal phytoliths from vascular plants generally have low Ge/Si (Delvigne et al. 2009). Biocycling of silica can be of considerable importance in terrestrial ecosystems, imparting a characteristic low Ge/Si signature to stream waters (Derry et al. 2005).

Environmental Significance

While germanium is not in itself normally a direct environmental concern, strong enrichment of Ge in sulfide ore bodies, in geothermal systems, and in coal ashes make it a potentially sensitive and unique tracer for inputs from these sources. Geothermal fluids have both high [Si] and high Ge/Si, and this signal can mix with ambient river waters. Simple mixing models of geothermal and "background" stream water can be used to quantify geothermal fluid fluxes in some systems (Evans et al. 2004). Coal fly and bottom ash are also strongly enriched in Ge, with Ge most enriched in the fine fraction of coal ash (Querol et al. 1995). Rivers in regions with a history of coal combustion commonly have Ge/Si ratios significantly elevated above background (Froelich et al. 1985). As a metalloid Ge has similar behavior to elements of concern such as arsenic (As) and antimony (Sb), and so Ge/Si anomalies have potential to be effective tracers of input of PM10 particulates and As and Sb arising from coal combustion.

Summary

Germanium is a siderophile, volatile element during planetary formation and is a trace element in both mantle and crustal rocks. It substitutes readily into lattice sites normally occupied by Si (tetrahedral coordination). Both Ge/Si and $\delta^{74}Ge$ ratios are useful tracers for weathering and geothermal processes, and also for inputs from sulfide mineralization and coal combustion.

Giant Impact Hypothesis

Hidenori Genda
Earth-Life Science Institute (ELSI), Tokyo Institute of Technology, Tokyo, Japan

Definition

The giant impact hypothesis is one of the theories for the origin of the Moon. In this theory, a Mars-sized object hit Earth obliquely about 4.5 billion years ago, which ejected a lot of materials to form a disk around Earth. From this disk, a single huge moon was formed. Unlike the other hypotheses (the fission, capture, and binary accretion hypotheses), the giant impact hypothesis satisfies almost all physical and chemical constraints of the Moon (Stevenson 1987). Thus, the giant impact hypothesis is regarded as the leading theory for the origin of the Moon (e.g., Canup 2004).

Rise of Giant Impact Hypothesis

Before the 1970s, the fission, capture, and binary accretion hypotheses had been considered for the origin of the Moon. It is now known that these hypotheses have one or more crucial

difficulties in physically making the Moon and explaining the lunar chemical compositions (see review articles Boss 1986; Wood 1986). However, before the 1970s, the constraints on the origin of the Moon were not enough to verify these hypotheses. Thanks to Apollo missions, lunar samples returned to Earth revealed that the Moon had been covered entirely by a deep magma ocean. The lunar highlands crust was found to be made of anorthosites containing 75–95% plagioclase (Warren 1985). Anorthosite forms and floats as it crystallizes from denser magma ocean. The evidence of the lunar magma ocean is also supported by the positive europium (Eu) anomaly in lunar highlands crust and the negative Eu anomaly in lunar mare basalts (Warren 1985). Additionally, seismometers put on the Moon confirmed that it has no metallic iron core (or a tiny core even if it was). With these new constraints, scientists started to think of an alternative theory for the origin of the Moon.

Soon after the detailed analysis of the returned lunar samples, the idea that the Moon originated from oblique impacts ejecting material into Earth's orbit was independently proposed by both Hartmann and Davis (1975), and Cameron and Word (1976). Initially, these ideas were not taken seriously because of the claim that such a catastrophic event and extreme results seemed unlikely. However, 10 years later, the giant impact hypothesis emerged as the leading hypothesis after "The Origin of the Moon Conference" held in Kona, Hawaii, in 1984. A collection of papers from this meeting was published in the 1986 book titled *Origin of the Moon* (Hartmann et al. 1986).

After several series of hydrodynamic simulations of the lunar-forming giant impact (Canup 2004), it has been found that an oblique impact of a Mars-sized protoplanet (about 10% of the Earth's mass) onto the proto-Earth (almost fully-grown Earth) can eject a lot of materials to form a disk around Earth called "the proto-lunar disk," whose typical mass is about 2–3 lunar masses. It has also been confirmed that a single lunar-sized moon can be created from the proto-lunar disk (Ida et al. 1997). Since the energy released by the giant impact is enormous, the giant impact hypothesis naturally explains the formation of the lunar magma ocean, and volatile depletion (e.g., K, Na, and Zn) in the Moon. Since the impactor's mantle is selectively ejected, a metallic iron-depleted proto-lunar disk is formed, which leads to metallic iron depletion in the Moon. Impact angular momentum gives the current huge angular momentum of the Earth-Moon system. Therefore, nowadays, the giant impact hypothesis is the leading theory for the origin of the Moon.

Special or Common Event?

For a while after the giant impact hypothesis was first considered scientifically as the origin of the Moon, the event of the lunar-forming giant impact was thought to be a special event that Earth experienced only once. However, in the 1980s, planet formation theory based mainly on the analytical methods (Wetherill 1985) came to predict that occurrence of giant impacts during the growth of the terrestrial planets is not rare. This prediction was proven to be robust after direct *N*-body simulations in planet formation in the 1980s and 1990s, thanks to enormous development in computational performance (Kokubo and Ida 1998; Chambers and Wetherill 1998). The detailed processes in planet formation were revealed one after the other, and giant impacts are regarded as a natural consequence for terrestrial planet formations.

According to recent planet formation theory, planets are formed in a protoplanetary disk. In the disk, the building blocks of planets with kilometer-sized objects called planetesimals are formed through the accumulation of dust (Safronov 1969; Hayashi et al. 1985). Before the 1980s, it was thought that the Earth was formed through accretion of km-sized planetesimals from the beginning to the end, but the concept has completely changed. In the terrestrial planet region in our solar system, several tens of Mars-sized protoplanets form through accretion of planetesimals (e.g., Lissauer 1987; Kokubo and Ida 1998) and these protoplanets collide with each other to form Earth-sized planets such as the Earth and Venus (e.g., Chambers and Wetherill 1998; Agnor et al. 1999). Therefore, Earth and Venus should experience several giant impacts during their formation, especially the last giant impact onto Earth, as it created the Moon.

Hafnium-tungsten (Hf-W) dating suggests that the last giant impact on Earth happened more than 50 Myrs after the oldest age in our solar system, which was estimated from CAICa–Al-rich inclusion (CAI) (Ca–Al-rich inclusion) in meteorites (Touboul et al. 2007; Kleine et al. 2009). This timing is consistent with the duration time (~100 Myrs) of the giant impact stage deduced from numerical calculations (Kokubo and Genda 2010; O'Brien et al. 2014). Planet formation theory also predicts that Mars and Mercury experienced no giant impact or few giant impacts at most, and thus they are survivors of the protoplanets. This is also consistent with the early resetting time (~ several Myrs) of Hf-W chronometer in SNC meteorites that are thought to have come from Mars.

Recently, it has been thought that giant impacts happened not only on Earth, but also on other planets. Owing to its strangely high bulk density, Mercury has a huge metallic core (60–80 wt% in total mass) compared to the other terrestrial planets' cores (~ 30 wt%). A high-velocity giant impact onto proto-Mercury has the potential to extensively erode its mantle, resulting in a huge core (Benz et al. 2007). A giant impact would also be responsible for the formation of two small satellites orbiting Mars (Citron et al. 2015;

Rosenblatt et al. 2016), and the formation of huge satellite Charon orbiting Pluto (Canup 2005; Sekine et al. 2017). A giant impact of an Earth-sized object onto Uranus would tilt its obliquity up to 98 °. Thus, giant impacts were common during planet formation in our solar system. Even in extrasolar systems, configurations of observed super-Earths likely indicate giant impacts during their formation (Ogihara and Ida 2009).

Approaching Shadow

Since the giant impact hypothesis was proposed, the oxygen (O) isotopic composition of lunar materials has been revealed to be identical to that of the Earth's mantle within the analytical uncertainties (< 0.005‰) (Wiechert et al. 2001; Young et al. 2016). Chromium (Cr) and titanium (Ti) isotopic compositions were also recently revealed to be identical between the Earth and the Moon (Lugmair and Shukolyukov 1998; Zhang et al. 2012). However, there is clearly heterogeneity of isotopic compositions in our solar system because most types of meteorites, including SNC meteorites, have different isotopic compositions from those of the Earth-Moon system (Clayton 1993). This isotopic similarity casts a shadow over the giant impact hypothesis.

The simplest explanation for the isotopic similarity between the Earth and the Moon is that the Moon was formed mainly from Earth's mantle. However, in the canonical lunar-forming giant impact (i.e., collision of a Mars-sized impactor onto Earth), the proto-lunar disk is predominantly (> 60 wt%) composed of material originating from the impactor (Canup 2004), which is expected to have a different isotopic composition than Earth. Another explanation is that the impactor had an identical isotopic composition to Earth. It had been suggested that the impactor came from an orbit similar to that of Earth (Wood 1986), but it turned out that this was improbable given the degree of radial mixing expected during the giant impact stage (Pahlevan and Stevenson 2007). Therefore, if the isotopic similarity were the only constraint for the origin of the Moon, the fission or binary accretion hypothesis would be the most promising one. However, these hypotheses are physically unlikely and inconsistent with the other constraints (Stevenson 1987).

Postimpact isotopic equilibration by vigorous mixing between the proto-lunar disk and Earth's magma ocean via vapor materials was suggested as an explanation for the isotopic similarity (Pahlevan and Stevenson 2007). However, some weak points of this isotopic equilibration have been pointed out; angular momentum transfer in the proto-lunar disk involved in material mixing inhibits the isotopic equilibration (Melosh 2014), and Cr and Ti isotopic equilibration via the vapor phase is not achieved because of their refractory nature (Zhang et al. 2012).

In order to overcome this isotopic crisis, another type of giant impacts was proposed; the collision between a small impactor and a fast-spinning proto-Earth (Ćuk and Stewart 2012), and the collision between equal-sized planets half the mass of Earth (Canup 2012). These types of collisions naturally produce the proto-lunar disk whose isotopic composition is similar to the Earth. However, these collisions should have an excess of angular momentum, which is twice as much as that of the current Earth-Moon system. Ćuk and Stewart (2012) also argued that the excess of angular momentum could have been drained away through a resonance with the Sun, known as the evection resonance (Touma and Wisdom 1998), after the Moon formation. However, this resonance only seems to work in a narrow range of tidal parameters (Wisdom and Tian 2015). Thus, at this moment, the isotopic similarity between the Earth and the Moon has not yet been completely solved. A breakthrough in the giant impact hypothesis is needed, otherwise it seems another completely new idea for the origin of the Moon is needed.

Recent successive discoveries of water in lunar samples are also casting a shadow over the giant impact hypothesis. The discovery of water in lunar anorthosites (Hui et al. 2013) means that the Moon should have formed in a wetter environment than previously thought. The energy released by the giant impact is so huge that scientists have simply thought that volatiles should be enormously depleted. However, the detailed behavior of volatiles during the giant impact and in the proto-lunar disk has not been well investigated. More works with detailed chemical processes are clearly needed.

Summary

There are a lot of physical and chemical constraints for the origin of the Moon, including the comparatively huge mass ratio of the Moon to Earth (= 1/83), the current angular momentum of the Earth-Moon system, the lack of metallic iron core in the Moon, the similarity of chemical and isotopic compositions between the Moon and Earth's mantle, lunar volatile depletion (e.g., K, Na, and Zn), and formation of the lunar magma ocean. Although the giant impact hypothesis is not a perfect theory at this moment, it is a promising theory.

Gibbs-Duhem Equation

William H. Casey[1] and Peter A. Rock[2]

[1]Department of Chemistry and Department of Earth and Planetary Sciences, University of California, Davis, CA, USA

[2]College of Math and Physical Sciences, Department of Chemistry, University of California, Davis, CA, USA

Definition

The Gibbs-Duhem equation describes the relationship between simultaneous changes in temperature, pressure, and composition in a solution: $SdT - VdP + \sum_{i=1}^{c} n_i d\mu_i = 0$.

Introduction

Equilibrium thermodynamics plays a central role in geochemistry, much more than other physical disciplines, because of the immense time and length scales of geological processes, and the enormous range of temperatures and pressures. The

Peter A. Rock is deceased.

Gibbs-Duhem equation (GDE) considerably simplifies thermodynamic analysis of multicomponent solutions and is essential to derivation of the Gibbs phase rule.

Elaboration

The GDE places a restriction on the simultaneous variations in the intensive thermodynamic variables of a phase. For a phase with c components, for which the temperature T, the pressure P, and composition can be varied, the GDE has the form

$$SdT - VdP + \sum_{i=1}^{c} n_i d\mu_i = 0 \quad (1)$$

where n_i and μ_i are the numbers of moles and the chemical potential of the *ith* component and S and V are the total entropy and volume of the phase. Geochemists are familiar with a manifestation of the GDE as the phase rule. The GDE shows that, for the total of $c + 2$ intensive variables, namely, the c chemical potentials [μ_1, μ_2 ... μ_c] plus temperature and the pressure, only $c + 1$ of the variables can be independently varied. For a system involving p phases in equilibrium, such as an ensemble of minerals, there is a total of p GDEs of the form of Eq. 1, with one GDE for each phase. Thus, in an equilibrium, multiphase system of c components and p phases, there is a total $of f = c + 2 - p$ independent, intensive variables (or degrees of freedom, f).

The most common application of the GDE is for a solution phase at fixed T and P for which, from the general form of the GDE, we obtain

$$\sum_{i=1}^{c} n_i d\mu_i = 0 \quad (2)$$

Equation 2 is an expression of a partial-molar property of a solution where an extensive thermodynamic property is the sum of contributions from each component, so that the sum of derivatives equals zero.

The simplest case, for $c = 2$, we have

$$n_1 d\mu_1 + n_2 d\mu_2 = 0 \quad (3)$$

The chemical potential of a component is related to the thermodynamic *activity* of that component by: $d\mu_i = RT$ d ln (a_i). Thus Eq. 3 becomes

$$n_1 d\ln(a_1) + n_2 d\ln(a_2) = 0 \quad (4)$$

or, by dividing through by the total number of moles, n_1+n_2, an expression is reached on the mole-fraction concentration scale:

$$x_1 d\ln(a_1) + x_2 d\ln(a_2) = 0 \quad (5)$$

The form of the GDE represented by Eqs. 4 and 5 shows us that if we know (or can measure) the activity of one component in a solution over a composition range (say $0 \leq x_1 \leq 1$), then we can use Eq. 5 to calculate the activity of the other component over that range. Such an approach is a central application of the GDE to determine the activity of a component in a mixture that cannot be probed directly.

Thus the GDE is particularly useful for solutions composed of a nonvolatile solute in a volatile solvent, for example, a salt dissolved in water. If we measure the equilibrium vapor pressure of the water over the solution (which gives the activity of water) as a function of the concentration of dissolved salt, then we can calculate the activity of the dissolved salt by integration. Integration of Eq. 6 yields activities (or activity coefficients) as a function of composition. Such integrations require careful consideration of the limits of integration (Rock 1983). Using $a_i = x_i\gamma_i$, we have for the activity coefficient of the second component (γ_2):

$$\ln\gamma_2 = -\int_1^{\gamma_1} \frac{x_1}{x_2}\, d\ln(\gamma_1) \quad (6)$$

Summary and Conclusions

The GDE is essential to thermodynamic analysis, and a typical geochemical application would be to interpret the composition of coexisting phases in a rock, such as ion exchange among coexisting feldspars. It can also be employed for low-temperature studies where the activity of one component in a solid solution can be measured. For example, electrochemical cells can be constructed (Rock et al. 1994) where the activity of $CaCO_3$ in a solid can be sensed from the voltage. Two nearly identical electrochemical cells can then be constructed and wired together in series opposition so that one cell contains pure calcite, while the other contains a solid in which the activity of $CaCO_3$ is less than unity, such as a $Ca_xCd_{1-x}CO_3$ material. The resulting voltage of the tandem cells is related to the activity of $CaCO_3$ in the solid solution relative to pure calcite. The activity of $CdCO_3$ in the $Ca_xCd_{1-x}CO_3$ solid is then directly calculable via Eq. 6 using the values of x and the measured activities of $CaCO_3$, even though the $CdCO_3$ activity cannot be sensed directly.

Properties

Gold (Emsley 1991, 2001; Anthoni 2006; Anders and Grevesse 1989; McDonough 2005) is a soft metal with a shiny yellow color in bulk. Micro and nanoparticles including colloidal gold can be black, red/ruby, or purple. Gold is a soft metal that is the most malleable and ductile metal and is mostly alloyed to give it more strength. Gold is unaffected by air, water, alkaline solutions, and acids except aqua regia (a mixture of nitric and hydrochloric acids) and selenic acid. Supercritical water (water heated under pressure to a temperature of about 374 °C) will dissolve gold as well. The most common gold compounds are auric chloride ($AuCl_3$) and chlorauric acid ($HAuCl_4$).

Although gold is considered to be a noble metal, it has a broad chemistry. For example, gold is a pseudohalogen as it has a large electron affinity leading to the formation of auric (Au^{-1}) compounds (Pyykkö 2002). The chemistry of gold is dominated by relativistic effects, and gold has been shown to be the most relativistic element with $Z < 100$ (Pyykkö 2004). In addition, gold compounds exhibit a bond length contraction due to relativity. The dominant relativistic effects in the atom are the contraction and stabilization of the 6 s orbital coupled with an expansion and destabilization of the 5d orbital.

History and Use

The name gold is the Anglo-Saxon word for the metal, and the symbol comes from the Latin “aurum” for gold. Gold has been known since prehistoric times, at least 3000 BC. Gold was probably one of the first metals to be worked because it was found as grains/particles or even nuggets in stream beds from which it was easily recovered. By 2000 BC, the Egyptians were already beginning to mine gold by following the veins of the metal in underground rocks. The death mask of Tutankhamen (died 1323 BC) was 100 kg of gold. The royal graves of ancient Ur (Iraq today), one of the earliest civilizations which flourished about 5000 years ago, contained skillfully worked gold objects.

Gold was easily separated from alloys and refined. The first pure gold coins were minted in Lydia (Turkey today) under King Croesus (ruled from about 561–547 BC).

For centuries, the lure of gold drove people to find ways of making gold, and alchemists spent much time searching for the “Philosopher’s Stone,” a key material that they hoped would transform basis metals like lead into gold.

Gold is used as bullion and in jewelry, glass, and electronics. The purity of gold has been measured in carats with pure gold being 24 carats, but it is very soft. Most gold is alloyed with silver or copper and 0.2% zinc to harden it. Jewelry consumes around 75% of all gold produced. Gold is also used for coinage, and it has been used as the standard for monetary systems in some countries.

Gold can be beaten into very thin sheets called “gold leaf” to be used in art, for decoration, and as an architectural ornament. Electroplating can be used to cover another metal with a very thin layer of gold. This is used in gears for watches, artificial limb joints, cheaper forms of jewelry, and electrical connectors. It is very useful for the protection of electrical copper components because gold is a good conductor of electricity but at the same time does not corrode. Thin gold wires are also used inside computer chips to produce circuits.

Colloidal gold is added to glass to color it red or purple, and metallic gold is applied as a thin film on windows of large buildings to reflect the heat of the Sun's rays, as gold has high infrared reflective properties. For the same reason, gold is used in space exploration systems.

Gold nanoparticles are being used as industrial catalysts. Vinyl acetate, used to make PVA (for glue, paint, and resin), is produced using a gold catalyst, for example.

Geochemical Behavior

Gold is one of the few elements to occur in its natural state. It is found in veins and alluvial deposits. Every year, about 1500 tons of gold are mined with two-thirds coming from South Africa and most of the rest from Russia. Gold is often extracted using a cyanide-based process which can lead to environmental issues due to the toxicity of the cyanide. Historically, gold was extracted using mercury which also had environmental and health effects.

Seawater contains 4 g of gold/10^6 tons of water. The concentration is so low that attempts to separate gold from seawater have failed.

Gold occurs mainly as a metal, sometimes as crystals, but more generally as grains, sheets, and flakes in other rocks. There are some gold ores as sylvanite, a combination of gold, silver, and tellurium. Mount Erebus, in Antarctica, the continuously erupting volcano, is unique among volcanoes because it emits gold dust.

There are some plants (Douglas fir, honeysuckle, and the mustard plant) that absorb gold from the soil in which they grow.

Biological Utilization and Toxicity

Inhalation of gold may cause irritation if exposure is prolonged or excessive. Gold may cause skin irritation and allergic reactions as well as eye irritation. Dentists sometimes use gold alloys in fillings, and a gold compound (Chrysotherapy) is used to treat some cases of arthritis.

Gouy-Chapman Theory

Garrison Sposito
Environmental Science, Policy and Management, University of California, Berkeley, CA, USA

G

Definition

Gouy-Chapman theory (Gouy 1910; Chapman 1913) is an electrostatic model of the spatial distribution of ions adsorbed, but not immobilized, by a charged particle surface reacting with an aqueous electrolyte solution. These ions are relatively free to move about while reacting with surface charge either by accumulation (positive adsorption) or depletion (negative adsorption) in the interfacial region. The fundamental question answered by Gouy-Chapman theory is how this "diffuse swarm" of adsorbed ions with given valence and radius will distribute itself near a particle of given charge and radius solely under the influence of coulomb forces between the ions and between them and the particle surface.

Introduction

The objective of Gouy-Chapman theory (Verwey and Overbeek 1999; Hunter 2001; Sposito 2004) is to calculate the spatial distribution of ions in the vicinity of a uniformly charged, molecularly smooth solid surface. This is accomplished by solving a nonlinear, second-order differential equation known as the Poisson-Boltzmann equation:

$$\frac{d^2\psi}{dx^2} + \frac{(1-2\nu)}{x}\frac{d\psi}{dx} = -\frac{1}{\varepsilon_0 D}\sum\nolimits_i Z_i F c_{i0} \exp\left(\frac{-Z_i F\psi}{RT}\right) \quad (1)$$

where $\psi(x)$ is the average electrostatic potential at a point x in a diffuse swarm of ions with differing valence Z_i ($i = 1, 2$, etc.); D is the dielectric constant of water; ε_0 is the permittivity of vacuum; F is the Faraday constant; c_{i0} is the concentration of ions of type i at a reference point far from the surface (bulk solution concentration of ion i), where $\psi \equiv 0$; R is the gas constant; and T is the absolute temperature. The coordinate x in Eq. 1 is measured along an axis perpendicular to the charged particle surface and extending into the aqueous

solution contacting it, with origin at the center of the particle. The particle surface may be planar ($\nu = ½$), cylindrical ($\nu = 0$), or spherical ($\nu = -½$) (Moon and Spencer 1988).

Equation 1 is subject to a charge-potential relationship, equivalent to Gauss's law in electrostatics, which acts as a boundary condition at the particle surface ($x = a$) (Hunter 2001):

$$\left(\frac{d\psi}{dx}\right)_{x=a} = -\frac{\sigma_p}{\varepsilon_0 D} \tag{2}$$

where σ_p is the net total particle charge, equal to the algebraic sum of the intrinsic surface charge, due to isomorphic substitutions in the particle structure and proton adsorption/desorption reactions, and the Stern layer charge, due to ions adsorbed in surface complexes (Sposito 2008). The distance a in Eq. 2, ranging typically from tens of nanometers to tens of micrometers, is equal to the distance from the center of the charged particle to its geometric surface plus the "distance of closest approach" of an ion to the geometric particle surface, $d_0/2$, equal to the sum of the crystallographic radius of the ion and the diameter of a water molecule (0.280 nm).

The derivation of Eq. 1 is based on three fundamental physical postulates (Carnie and Torrie 1984):

1. The charged particle surface is uniform and smooth, characterized by a charge density σ and by high symmetry, such that the electrostatic potential varies spatially only along a coordinate axis perpendicular to the particle surface, which is planar, cylindrical, or spherical.
2. Liquid water is modeled as a uniform continuum characterized solely by its dielectric constant.
3. The potential of mean force, which is the average energy required to move an ion from the reference point ($\psi \equiv 0$) to a point somewhere in the diffuse swarm near the particle surface, is proportional to $\psi(x)$.

The first two postulates imply that the molecular structure of both the solid particle surface and liquid water is neglected. The third postulate implies that short-range correlations among the ions in the swarm are neglected, with only long-range correlations arising from the coulomb force accounted for. However, regardless of its valence, an ion experiences non-coulombic, short-range repulsive interactions with other ions as it is moved along a path from the reference point to its place in the swarm, these interactions and the spatial correlations they produce coming as an effect of finite ion size. In addition, the accumulation of ions (counterions) near a particle surface of opposite charge sign allows the ions having the same charge sign as the surface (coions) to approach the surface more closely than they would otherwise because the repulsive effect of like charge is screened by the positively adsorbed counterions. These kinds of short-range spatial correlations are not reflected in the average electrostatic potential, which derives only from the Coulomb force.

The third postulate leads to a mathematical relationship between $c_i(x)$, the concentration of ions of type i at a point x, and the average electrostatic potential (Carnie and Torrie 1984):

$$RT\frac{d\ln c_i}{dx} = -Z_i F\frac{d\psi}{dx} \tag{3}$$

Eq. 2 states that ion concentration gradients in the diffuse swarm are produced by an average electrostatic force proportional to minus the gradient of the average electrostatic potential. [More generally, Eq. 2 is a relationship between the gradient of $\ln c_i(x)$ in the diffuse swarm and the average force acting on an ion of type i which produces the gradient, which by definition is proportional to minus the gradient of the potential of mean force (Carnie and Torrie 1984). In Gouy-Chapman theory, the potential of mean force is approximated by $Z_i F\psi$.] It follows that $c_i(x)$ has an explicit mathematical form obtained by integrating Eq. 2:

$$c_i(x) = c_{i0}\exp[-Z_i F\psi(x)/RT] \tag{4}$$

where the boundary condition on $c_i(x)$ at the reference point $\psi = 0$ is imposed. This expression appears on the right side of Eq. 1 as a term in a summation which is proportional to the net charge density in the ion swarm at a point x.

Gouy-Chapman Scaling

Equation 1 is not invariant in mathematical form under multiplication of either ψ or x by an arbitrary scale factor, which means that Gouy-Chapman theory must exhibit intrinsic scales of both the electrostatic potential and length (Sposito 2004). The intrinsic scale of electrostatic potential is RT/F (=25.7 mV at 298 K), which appears in the exponent on the right side of Eq. 1. After dividing both sides of Eq. 1 by this factor to define the dimensionless electrostatic potential, $y \equiv F\psi/RT$, the parameter:

$$\beta \equiv 2F^2/\varepsilon_0 DRT \tag{5}$$

emerges as the coefficient of c_{i0} in the summation on the right side. The product βc_{i0} has dimensions of inverse-length squared, leading to the definition of an intrinsic length scale as the inverse square root of the parameter:

$$\kappa_i^2 \equiv \beta c_{i0} \tag{6}$$

The value of κ_i^{-1} ranges from 1 to 30 nm at 298 K as the bulk solution concentration c_{i0} ranges from 0.1 to 100 mol m^{-3}, common in freshwaters, whereas $\kappa^{-1} \approx 0.36$ nm for standard seawater. Thus, nanometer length scales characterize the spatial variability of $\psi(x)$ as governed by Eq. 1, while millivolt potential scales characterize the magnitude of $\psi(x)$.

A second intrinsic length scale is associated with the boundary condition on $\psi(x)$ in Eq. 2. It involves the net total particle charge, σ_p (Sposito 2004):

$$\ell \equiv \varepsilon_0 DRT/F|\sigma_p| = 2F/\beta|\sigma_p| \tag{7}$$

Setting σ_p equal to the typical range of intrinsic surface charge for clay minerals and oxides (Sposito 2008), one finds that the minimal range of ℓ is between 0.05 and 0.25 nm, which is well below typical values for κ_i^{-1}. However, if intrinsic surface charge neutralization by ions adsorbed in the Stern layer reduces σ_p (in absolute value), the length scale ℓ can be larger than the upper limit of this minimal range. The physical significance of ℓ can be seen after dividing the boundary condition in Eq. 2 by the intrinsic electrostatic potential scale, RT/F, to derive the scaled boundary condition:

$$\left(\frac{dy}{dx}\right)_{x=a} = -\frac{\text{sgn}(\sigma_p)}{\ell} \tag{8}$$

where

$$\text{sgn}(\sigma) = \begin{cases} +1 & \sigma_p > 0 \\ -1 & \sigma_p < 0 \end{cases} \tag{9}$$

Equation 8 shows that ℓ defines an intrinsic length scale for the spatial variation of $\psi(x)$ at the particle surface: small values of ℓ imply sharp gradients of $\psi(x)$ at the particle surface.

Counterion Condensation and Coion Exclusion

Gouy-Chapman theory predicts a very high concentration of counterions near a planar charged surface, even at a relatively low net particle surface charge or bulk solution concentration (Verwey and Overbeek 1999; Sposito 2004). In quantitative terms, let $\varphi(x)$ be the fraction of the surface charge density σ_p at the point x that is screened by counterions occupying the region $x > a$. This fraction will depend on the surface charge density and the bulk solution concentration. Counterion condensation is said to exist if $\varphi(x)$ does not vanish as the bulk solution ion concentration goes to zero; that is, a fraction of the counterions remains very close to the charged surface even if the electrolyte solution which contacts it becomes infinitely dilute (Zimm and Le Bret 1983). Evidently, their electrostatic attraction to the charged surface is strong enough to prevent the counterions from drifting out into the bulk solution even as it decreases to zero concentration. Note that, in the context of Gouy-Chapman theory, even though compressed against the particle surface, the counterions remain mobile and do not form surface complexes.

For a diffuse swarm containing monovalent, positively charged counterions and monovalent, negatively charged coions, a quantitative description of condensation is given by the definition (Zimm and Le Bret 1983):

$$\begin{aligned} \varphi(x) &\equiv \left(F/|\sigma_p|\right)\int_a^x [c(s) - c_0]\, ds \\ &= \left(Fc_0/|\sigma_p|\right)\int_a^x \{\exp|y(s)| - 1\}\, ds \\ &= \frac{1}{2}\left(\kappa^2/\ell\right)\int_{|y_0(a)|}^{|y_0(x)|} \frac{[\exp|y| - 1]}{dy/dx}\, dy \end{aligned} \tag{10}$$

where y(x) is the scaled electrostatic potential and Eqs. 4, 5, 6, 7, and 8 have been applied to derive the final result. The limiting value of the right side of Eq. 10 as $k \downarrow 0$ can be shown to be (Zimm and Le Bret 1983)

$$\lim_{\kappa \downarrow 0} \varphi(x) = 1 - \{1 + [(1/2\ell)\ (x - a)]\}^{-1} \tag{11}$$

At 298 K, the numerator in Eq. 7, 2 F/β, has the value 1.781×10^{-11} C m^{-1}, leading to an estimate of $\ell = 0.178$ nm for $|\sigma_p| = 0.1$ C m^{-2}, which is typical of the intrinsic surface charge density for the planar surfaces of 2:1 clay minerals. With this value of ℓ, it follows from Eq. 11 that counterions within 1 nm of the particle surface screen about 75% of its charge. More generally, half the net particle surface charge is balanced by diffuse swarm counterions within the rather small distance 2ℓ ($0.10 < 2\ell < 0.50$ nm) from the particle surface, another reflection of the fact that small values of this intrinsic length scale signal sharp-negative gradients in the electrostatic potential (Eq. 8). However, this conclusion applies strictly to planar charged surfaces. The limit of $\varphi(x)$ as $k \downarrow 0$ is dependent on $|\sigma_p|$ for cylindrical particle surfaces, becoming equal to 0 below a certain absolute value of the net total particle charge (O'Shaughnessy and Yang 2005), and it is equal to 0 at any net total particle charge for spherical particle surfaces (Zimm and Le Bret 1983).

Coion exclusion refers to the pronounced depletion of ions by repulsion from a region near a particle surface having the same charge sign as the ions (Verwey and Overbeek 1999; Hunter 2001). Gouy-Chapman theory provides a mathematical model of coion exclusion through the parameter d_{ex}, the coion exclusion distance. For monovalent ions in a diffuse swarm (Pashley and Quirk 1997),

$$d_{ex} \equiv \int_a^{\infty} \left[1 - \frac{c(x)}{c_0}\right] dx + \frac{1}{2} d_0$$
$$= \int_{y(a)}^{0} \frac{\{1 - \exp[-|y|]\} dy}{dy/dx} + \frac{1}{2} d_0$$
$$= \frac{2}{\kappa} \{1 - \exp[-|y(a)|/2]\} + \frac{1}{2} d_0 \quad (12)$$

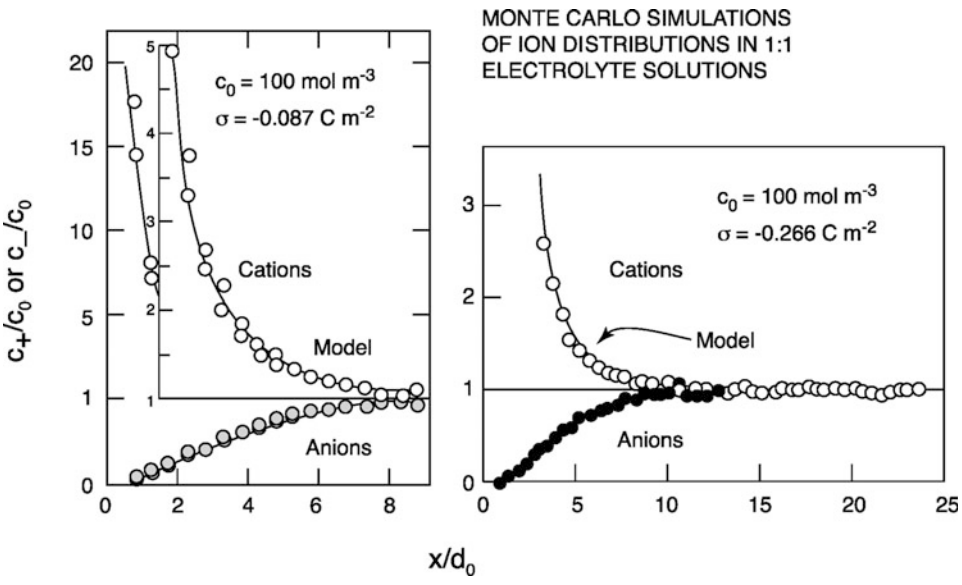
where y(x) is the scaled electrostatic potential, and a procedure like that used in developing Eq. 10 has been followed. By the definition of an integral, d_{ex} is a weighted sum of distance intervals within the diffuse swarm, the weighting factor being the fraction of coions not in the open interval (x, x + dx). In this sense, d_{ex} may be interpreted as an average distance from the surface of a charged particle over which coions are excluded. For calculated values of y(a) that are typical of planar 2:1 clay mineral surfaces and for typical values of the distance of closest approach, the exponential term in Eq. 12 is negligible (Sposito 2004) and d_{ex} closely equals twice the length scale, k^{-1}. If $0.1 < c_0 < 100$ mol m^{-3}, then, by Eq. 6, $0.033 < k < 1$ nm^{-1} at 298 K and, therefore, $2 < d_{ex} < 60$ nm (Sposito 1992).

These applications further illustrate the physical significance of the two intrinsic length scales of that arise in Gouy-Chapman theory. The scale factor k^{-1} is seen to provide a measure of coion exclusion, in that $2\,k^{-1}$ is approximately the average distance from a charged particle surface over which coions are effectively excluded from the interfacial region. The scale factor ℓ provides a measure of counterion accumulation, in that 2ℓ is the distance from a charged particle surface over which half the surface charge is screened by counterions in the limit of infinite dilution. This latter scale factor, intimately related to the magnitude of the net particle surface charge, gives a measure of the spatial extent or "thickness" of the diffuse swarm (Sposito 2004).

Validating Gouy-Chapman Theory

Equation 1 can be solved analytically for planar charged surfaces interacting with symmetric, 2:1, and 1:2 electrolyte solutions or their mixtures (Liu et al. 2013). Only approximate solutions of Eq. 1 are available for cylindrical and spherical charged surfaces, except under the condition that the electrostatic potential is small enough in absolute value to justify replacing each exponential term on the right side of Eq. 1 by the first two terms of its Maclaurin expansion, thereby linearizing the Poisson-Boltzmann equation (Sposito 2004). This is known as the Debye-Hückel approximation (Verwey and Overbeek 1999), equivalent in the present context to imposing the condition $\kappa\ell > 2$ on the two intrinsic length scales (Sposito 2004). This condition requires high bulk solution concentrations of the ions and/or low absolute values of the net particle surface charge.

The accuracy of Eq. 1 as a description of a diffuse swarm interacting in a dielectric continuum has been assessed by comparing its predictions of ion concentrations according to Eq. 4 with the results of Monte Carlo simulations of a swarm of monovalent hard-sphere ions immersed in a continuum dielectric fluid contacting a planar charged surface like that encountered for 2:1 clay minerals (Torrie and Valleau 1982). Figure 1 shows the concentration of cations (c_+) or anions (c_-), scaled by c_0, as calculated with Eq. 4, compared with those predicted by Monte Carlo simulation, both plotted against distance from the geometric particle surface scaled by $d_0 = 0.425$ nm. (In this application, the origin of the coordinate x was placed at the



Gouy-Chapman Theory, Fig. 1 Comparison between Monte Carlo simulations (*circles*) of spatial ion distributions near a planar charged surface with the predictions of Gouy-Chapman theory (curves labeled "Model") (Reprinted with permission from Sposito, G. (2004) The surface chemistry of natural particles. Oxford, New York)

geometric particle surface instead of at the particle center, and $d_0/2$ was set equal to the ionic radius alone instead of the sum of the ionic radius and the diameter of a water molecule, thus allowing counterions to touch the geometric particle surface.) The bulk solution concentration is set at the upper end of the typical range for freshwaters, corresponding to $k \approx 1\ nm^{-1}$ at 298 K, while σ_p, here set equal to σ_0, the intrinsic surface charge density, takes on two values that bracket the normal range for smectites, corresponding to $\ell = 0.21$ and 0.085 nm, respectively, at 298 K. (Note that ℓ is far too small for $\kappa\ell$ to satisfy the condition required by the Debye-Hückel approximation.) Counterion condensation is apparent from the high concentration of cations (about 20 times larger than c_0) found at the distance of closest approach ($x = d_0/2$), even for $|\sigma|$ as low as $0.087\ C\ m^{-2}$. Similarly, coion exclusion is apparent in Fig. 1 by the anion concentration within about five ionic diameters of the particle surface lying well below the bulk solution concentration.

Thus Eq. 1 is thus validated for monovalent ions in a diffuse swarm for bulk solution concentrations up to 100 mol m^{-3}. Above this concentration, however, Gouy-Chapman theory is found to be inaccurate because of ion-ion correlation effects (Torrie and Valleau 1982; Carnie and Torrie 1984). Also because of these correlations, Eq. 1 proves to be inaccurate for bivalent ions at bulk solution concentrations as low as 5 mol m^{-3}. Gouy-Chapman theory overpredicts bivalent counterion concentrations (counterion condensation is overpredicted) while underpredicting monovalent coion concentrations in the presence of bivalent counterions (coion exclusion is also overpredicted); the latter counterion-coion correlations as described above can actually lead to a small positive coion adsorption (Torrie and Valleau 1982). Diffuse swarm models that go beyond Gouy-Chapman theory to include these correlations provide a much more accurate description of planar charged surfaces bearing adsorbed bivalent cations (Carnie and Torrie 1984; Blum and Henderson 1992; Attard 1996).

Summary

A net particle surface charge different from zero implies the existence of adsorbed ions in a diffuse swarm. Diffuse swarm species respond to surface charge by distributing themselves in order to screen it through counterion accumulation and coion exclusion. Screened particle charge, in turn, mediates the interparticle interactions in colloidal suspensions that determine their stability (Verwey and Overbeek 1999; Hunter 2001; Sposito 2008). Thus particle charge screening is the most important resultant chemical property of the diffuse swarm. Gouy-Chapman theory offers perhaps the simplest quantitative description of the spatial distribution of ions in a diffuse swarm through the Poisson-Boltzmann equation (Eq. 1), a nonlinear differential equation whose solution gives the spatial dependence of the average electrostatic potential in an adsorbed electrolyte solution modeled as a swarm of mobile hard-sphere ions immersed in a continuum dielectric medium contacting a charged particle surface that can be planar, cylindrical, or spherical.

Because they are not invariant under arbitrary scaling of the position coordinate, the Poisson-Boltzmann equation and its boundary value at the particle surface admit two intrinsic length scales (Eqs. 6 and 7):

k^{-1} Intrinsic length scale for spatial variability of $\psi(x)$ within the diffuse swarm

ℓ Intrinsic length scale for spatial variability of $\psi(x)$ at the particle surface

The intrinsic length scale ℓ provides a robust measure of the "thickness" of the electrical double layer comprising a diffuse swarm. Over the range of bulk solution concentrations that typify freshwaters, the dimensionless length ratios, $\kappa\ell$ and ka, where a locates the particle surface along a surface normal emanating from the center of the particle, give relative measures of electrostatic potential magnitude and colloidal particle size, respectively. Electrostatic potentials can be considered to be relatively small if the bulk solution concentration is sufficiently high and the net particle surface charge is very low (large $\kappa\ell$), whereas charged particles can be considered to be relatively small if the bulk solution concentration is sufficiently low (small ka).

Element Data
Atomic Symbol: Hf
Atomic Number: 72
Atomic Weight: 178.49 g/mol
Isotopes and Abundances: ^{174}Hf 0.16%, ^{176}Hf 5.26%, ^{177}Hf 18.60%, ^{178}Hf 27.28%, ^{179}Hf 13.62%, ^{180}Hf 35.08%
1 Atm Melting Point: 2233 °C
1 Atm Boiling Point: 4603 °C
Common Valences: 4+
Ionic Radii: 6-fold: 78 pm (Hf^{4+})
Pauling Electronegativity: 1.3
First Ionization Energy: 658.5 kJ/mol
Chondritic (CI) Abundance: ~0.1 ppm
Silicate Earth Abundance: ~0.3 ppm
Crustal Abundance: 3.7 ppm
Seawater Abundance: ~0.5 pmol/kg
Core Abundance: 0

Properties

Hafnium's atomic number is 72, its standard atomic weight 178.49(2) g/mol, its density 13.31 g/cm^3, and its ionic radius between 0.58 and 0.83 Å depending on coordination state, with 0.78 Å for Hf^{4+} in sixfold coordination with oxygen, which is most common. Natural Hf has five stable isotopes (^{176}Hf, ^{177}Hf, ^{178}Hf, ^{179}Hf, and ^{180}Hf) and one very long-lived isotope (^{174}Hf with a half-life of 2×10^{15} years) with relative abundances of: ^{174}Hf = 0.16(1)%, ^{176}Hf = 5.26(7)%, ^{177}Hf = 18.60(9)%, ^{178}Hf = 27.28(7)%, ^{179}Hf = 13.62(2)%, and ^{180}Hf = 35.08(16)% (http://www.nist.gov/pml/data/comp.cfm). One of the stable isotopes (^{176}Hf) is radiogenic, produced, in part, by the beta decay of radioactive ^{176}Lu with a half-life of 37.12×10^9 years (Ga) and a decay constant λ^{176}Lu of $1.867 \pm 0.008 \times 10^{-11}$ year^{-1} (Scherer et al. 2001; Söderlund et al. 2004). Together, ^{176}Lu and ^{176}Hf provide the basis for the Lu-Hf chronometer. Over the age of the Earth and the Solar System (~4.5 Ga), ~3% of ^{176}Lu has decayed to ^{176}Hf and ~1% of ^{176}Hf is radiogenic with the rest being "common" Hf produced during nucleosynthesis. Hafnium also has a large number of unstable (radioactive or short-lived) isotopes with ^{182}Hf, now extinct for all practical intents and purposes, being the most pertinent to the field of earth and planetary sciences as its half-life of 8.9×10^6 years (Ma) and its beta decay product ^{182}W make it a powerful chronometer for dating silicate-metal segregation in the early Earth and other terrestrial bodies of the Solar System. Variations in ^{182}W have been observed in both meteorites and terrestrial materials and are described in the entry on ▶ Tungsten Isotopes, which covers the ^{182}Hf-^{182}W system.

In pure form, Hf is a silvery or steel gray, shiny, ductile, corrosion-resistant, transition metal of Group 4 (IVb) of the periodic table and has hexagonal crystal structure. It has oxidation states of 0 (the pure metal), 2+, 3+, and 4+, but in nature Hf is essentially exclusively tetravalent. Due to the lanthanide contraction of the rare earth elements in the sixth period of the periodic table, Zr and Hf have nearly identical ionic radii (Zr^{4+} being 0.79 Å compared with Hf^{4+} at 0.78 Å) resulting in the canonical terrestrial Zr/Hf ratio of ~34.3. Hafnium, therefore, substitutes readily for Zr in Zr minerals, first and foremost zircon ($ZrSiO_4$, where ~1–4% is Hf) and baddeleyite (ZrO_2, with ~0.1–2% Hf). It also substitutes in the Ti minerals rutile (TiO_2) and ilmenite ($FeTiO_3$) due to Ti and Hf having the same charge, and, like Zr, being in the same

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

group in the periodic table. Owing to the similar properties of Zr and Hf (and Ti and Hf) and the much higher abundance of Zr (and Ti) in nature, Hf does not form any minerals of its own.

History and Use

Although the existence of Hf was predicted from the systematics of the periodic table of elements by Dmitri Mendeleev already back in 1869, the so-called missing element 72 was not discovered until 1922 by Dirk Coster, a Dutch physicist, and Georg Charles von Hevesy (also known as George Charles de Hevesy), a Hungarian Swedish chemist, at the Niels Bohr Institute in Copenhagen. Coster and de Hevesy used X-ray spectroscopy to study the arrangement of the outer electrons of atoms in samples of Zr ore. The electron structure of Hf had previously been predicted by Niels Bohr, and Coster and de Hevesy found a matching X-ray pattern. Their discovery, which at long last confirmed the existence of Hf, was published in *Nature* early the following year (Coster and de Hevesy 1923). The Latin name for Copenhagen is *Hafnia*, hence the name "hafnium" for the place where "the missing element 72" was finally discovered. Hafnium was the next-to-last stable element to be discovered, with Re, identified 2 years later in 1925, being the last. The reason it took over half a century to discover Hf after its existence had first been predicted, and why the analytical approach chosen was that of X-ray spectroscopy and not wet chemistry, is that Hf so closely resembles Zr chemically (because of having the same number of valence electrons, nearly the same ionic radius, and belonging to the same group in the periodic table) that it is extremely difficult to separate the two in the chemistry laboratory (although this was eventually accomplished the year after Hf's initial discovery by X-ray spectroscopy). The strong similarity of Hf and Zr, probably the two chemically most similar of all the elements in the periodic table, poses a major analytical challenge to Hf isotope geochemistry, but geochemists also take advantage of this property in Hf isotope studies coupled to zircon geochronology (see entry on ▶ Hafnium Isotopes).

Hafnium is extracted from the same sources as Zr, which are, primarily: (i) heavy mineral sand ore deposits of zircon, ilmenite, and rutile; (ii) pegmatites; and (iii) carbonatites. The production of Hf-free Zr is the main source of Hf. Hafnium-free Zr is needed for nuclear fuel rods because Zr, contrary to Hf, has a very small neutron capture cross-section, which makes it ideal as cladding material. Hafnium, with the exact opposite property, if present as impurities in the Zr, would offset the small neutron capture cross-section of Zr.

Hafnium mostly forms inorganic compounds in the oxidation state of 4+. Due to its refractory nature, Hf is responsible for the existence of several extreme compounds. Hafnium carbide (HfC) is the most refractory binary compound known, with a melting point of 3890 °C, while the mixed TaHf carbide Ta_4HfC_5 has the highest melting point (4215 °C) of any currently known compound. Hafnium nitride (HfN) is the most refractory of all known metal nitrides with a melting point of 3310 °C. Other Hf compounds include Hf chloride ($HfCl_4$), Hf fluoride (HfF_4), and Hf oxide (HfO_2).

The large thermal neutron capture cross-section of Hf makes it useful for neutron absorption in control rods in nuclear reactors and most of the Hf produced today is used for this purpose in nuclear power plants. Hafnium also is used in filaments and electrodes, while HfO_2 has found application in integrated circuits in semiconductors. Finally, together with other metals like Fe, Ti, Nb, Ta, and W, Hf is part of some superalloys used for special applications such as liquid propellants, and as a means of increasing corrosion resistance.

Another important use of Hf is in isotope geochemistry due to the decay of ^{176}Lu to ^{176}Hf. Owing to Hf's high first ionization potential, its isotopic composition is measured most practically by multicollector inductively coupled plasma mass spectrometry (MC-ICP-MS), the plasma source of which reaches temperatures of up to 6000–8000 °C. Since MC-ICP-MS was not developed until the mid 1990s, the routine exploitation of the Lu-Hf isotope system, as well as that of ^{182}Hf-^{182}W, as a chronometer and a tracer for dating and understanding the formation, evolution, and differentiation of the Earth, Moon, Mars, and other terrestrial materials of the Solar System, has only been possible for the last two decades. For details about the Lu-Hf isotope system, see entry on ▶ Hafnium Isotopes.

Geochemical Behavior

Hafnium is lithophile, strongly refractory, and incompatible. Due to its charge of 4+ in nature and its relatively small ionic radius, Hf is geochemically classified as a high field strength element together with Ti, Zr, Nb, Ta, and W. As a consequence of its high valence state it is highly insoluble in most aqueous solutions, although it does form a soluble fluoride complex. Hafnium is chemically similar to Zr and has similar incompatibility to Sm. Typical abundances of Hf in various rock types and meteorite groups can be found at http://earthref.org/GERMRD/e:72/. Here it suffices to mention just a few key illustrative examples such as CI chondrites (taken as representative of the Solar System and the bulk silicate Earth), which contain ~0.1 ppm Hf, Earth's core, which holds no Hf, komatiites with ~0.1–0.5 ppm Hf (though some range up to ~1.5 ppm), basalts with ~2–4 ppm Hf, tonalites-trondhjemites-granodiorites with ~4–5.5 ppm Hf, continental crust, including upper and lower crust, for which most average bulk crustal abundance estimates vary from ~3 to ~5 ppm

Hf, sediments, including Fe-Mn crusts and nodules, spanning a wide range of concentrations from a few ppm to tens of ppm of Hf, carbonates with ~0.5 ppm Hf, and seawater with ~0.5 pmol Hf/kg.

The similar incompatibility of Hf and Sm is demonstrated by the constant and chondritic Hf/Sm ratio of oceanic basalts of 0.75 ± 0.12 (Blichert-Toft et al. 1999, 2002), which is identical within error to the chondritic Hf/Sm ratio of 0.74 ± 0.03 that can be calculated from the data of Bouvier et al. (2008). While the Hf/Sm ratio is largely unaffected by magmatic processes such as melting, it is sensitive to fractionation by sedimentary processes and in particular zircon segregation. Zircon-rich clastic sediments have higher-than-chondritic Hf/REE ratios, whereas zircon-free pelagic, or hydrogenous, sediments have low Hf/REE ratios (Patchett et al. 1984; Plank and Langmuir 1998). Variable Hf/Sm in basalts, as well as in komatiites (Blichert-Toft et al. 2015), therefore betrays the presence of sedimentary material in their mantle source (White and Duncan 1996). The Hf/Sm ratio also attests to the role of ilmenite in planetary magmatic fractionation processes, such as recorded by some lunar rocks and Martian meteorites (Blichert-Toft et al. 1999; Bouvier et al. 2009).

Biological Utilization and Toxicity

Hafnium has no known biological utility and is not toxic.

Summary

In the context of the present *Encyclopedia of Geochemistry*, Hf, as part of both the long-lived, refractory, lithophile, incompatible, high-temperature Lu-Hf isotope system and the Hf/Sm ratio, the latter of which is remarkably constant in magmatic rocks but undergoes fractionation in the sedimentary cycle, has most interest as a tracer and a chronometer in geochemistry and cosmochemistry.

Introduction

Hafnium consists of the five stable isotopes ^{176}Hf, ^{177}Hf, ^{178}Hf, ^{179}Hf, and ^{180}Hf. Of these, ~1% of ^{176}Hf is radiogenic (the rest being "common" Hf created during nucleosynthesis), produced by the beta decay of radioactive ^{176}Lu with a half-life of ~37 Ga. In addition, radioactive ^{182}Hf, with a half-life of 8.9 Ma, was present in the early Solar System, leading to variable abundances of its daughter ^{182}W in the Earth and in Solar System materials. Together, ^{176}Lu and ^{176}Hf constitute the long-lived Lu-Hf chronometer in which variations in

^{176}Hf resulting from the decay of ^{176}Lu, combined with variations in the Lu/Hf ratio of rocks and minerals, are used to date these rocks and minerals, track the chemical evolution and differentiation of the Earth, Moon, and other planetary bodies and materials of the Solar System, and constrain the nature of magma sources and the provenance of sediments.

History

The Lu-Hf isotope system with applications to tracer isotope geochemistry, cosmochemistry, and geochronology was pioneered in the early 1980s by Jon Patchett and co-workers (Patchett and Tatsumoto 1980a; Patchett and Tatsumoto 1980b; Patchett and Tatsumoto 1980c; Patchett et al. 1981; Patchett 1983a; White and Patchett 1984) using thermal ionization mass spectrometry (TIMS). They were inspired by Boudin and Deutsch (1970) whose first measurement of the ^{176}Lu decay constant held great promise for the Lu-Hf isotope system as a chronometer. However, as it turned out, because of its very low thermal ionization efficiency, the sheer quantity of Hf necessary for isotopic measurement by TIMS (several micrograms) posed a severe analytical challenge greatly limiting the type and number of samples that could be analyzed. Most crucially, extremely Hf-poor meteorites such as chondrites (~0.1 ppm Hf), used as a benchmark for the undifferentiated state of the Solar System and as a plausible composition for the bulk silicate Earth (BSE) (approximations justified by the refractory and lithophile nature of Lu and Hf), could not be analyzed, hence leaving the Lu-Hf isotope system without a baseline relative to which Earth and planetary evolution could be gauged. The Lu-Hf isotope system did not become a fully exploitable, routine geochemical tool until the advent in the mid-1990s of multi-collector inductively coupled plasma mass spectrometry (MC-ICP-MS), which combined the efficient ionization of Hf provided by the high-temperature (~6000–8000 °C) ICP source with the high precision of multi-collection (Walder and Freedman 1992; Blichert-Toft et al. 1997; Albarède et al. 2004). The Hf and Lu separation chemistry protocols needed for compatibility with this new technique, while still laborious, became significantly simpler and less time-consuming than those demanded by TIMS (Blichert-Toft et al. 1997; Blichert-Toft 2001; Münker et al. 2001; Connelly et al. 2006), and the amount of Hf required for high-precision isotopic analysis decreased by an order of magnitude from several micrograms to about a hundred nanograms. This led to a rapid increase in sample throughput and broadened the variety of rocks, meteorites, and minerals that could hereafter be targeted for Lu-Hf isotope analysis. The Hf sample size has since decreased even further to about ten nanograms in sync with MC-ICP-MS transmission increasing as new instrumental developments continue to render plasma source mass spectrometers ever more sensitive.

As a result of MC-ICP-MS, the Lu-Hf isotope system is today on a par with other routinely used long-lived radiogenic isotope systems, such as the Sm-Nd, Rb-Sr, and U-Th-Pb chronometers. Over the last two decades, (i) the Lu-Hf chondritic reference parameters, presumed representative of the bulk silicate Earth, have been established (Blichert-Toft and Albarède 1997; Bouvier et al. 2008; Iizuka et al. 2015); (ii) the ^{176}Lu decay constant, which was poorly defined prior to MC-ICP-MS, has been accurately and precisely determined (Scherer et al. 2001; Söderlund et al. 2004); (iii) Hf-poor samples, such as komatiites, have been analyzed in large numbers (see compilation in Blichert-Toft et al. 2015) shedding new light on early Earth evolution; and (iv) similarly Hf-poor but Lu-rich minerals, most notably garnet, have been put to use in the new powerful dating technique known as Lu-Hf garnet geochronology, which geologists use to unravel tectonic processes such as subduction, burial, and exhumation and the rates at which these mechanisms take place within the lithosphere (e.g., Duchêne et al. 1997; Blichert-Toft et al. 1999a; de Sigoyer et al. 2000; Scherer et al. 2000, to mention just the first few such successful garnet geochronology studies by MC-ICP-MS, which have since been followed by a whole field of diverse garnet dating applications). Moreover, (v) tiny but Hf-rich and highly refractory zircons can now be analyzed one at a time, whether by solution chemistry or laser ablation (e.g., Griffin et al. 2000; Harrison et al. 2005; Nebel-Jacobsen et al. 2005; Blichert-Toft 2008). Because zircon contains percent levels of Hf, incorporated directly into the crystal lattice by substitution with Zr, but only traces of Lu, leading to a very low Lu/Hf ratio (<0.005) and hence negligible radiogenic ingrowth, even over billions of years, the Hf isotopic composition of zircon is essentially frozen at the time of crystallization. Since zircons can be precisely dated by U-Pb geochronology, they provide a first-order record of the Hf isotopic evolution of the Earth's mantle and crust and in this way monitor crustal growth. Finally, (vi) Hf isotope systematics of magmas and sediments track their origins in the mantle or the crust, thereby portraying the timing and processes of planetary mantle-crust differentiation and, again, informing on crustal growth.

Geochemical Properties

Both Lu and Hf are lithophile and refractory elements. Because Lu is a heavy rare earth element (REE) with +3 valency and Hf is a high field strength element (HFSE) with +4 valency and properties very similar to those of Zr, the Lu/Hf ratio is readily fractionated by magmatic processes such as partial melting and fractional crystallization. This contrasts with the Sm-Nd isotope system, in which both the

parent and daughter elements are neighboring +3 charged light REE and therefore very difficult to fractionate from one another. Thus, owing to the different geochemical behavior between the REE and HFSE, there is generally stronger fractionation of the Lu/Hf than the Sm/Nd ratio, an important feature particularly manifested in minerals with affinities for REE, such as garnet and apatite. Another critical difference between these two otherwise very similar chronometers is that ^{176}Lu decays about three times faster than ^{147}Sm, rendering the Lu-Hf isotope system overall more time sensitive than the Sm-Nd isotope system by growing in larger and hence more easily resolvable, radiogenic isotopic differences in less time. The higher rate of ingrowth of ^{176}Hf compared to ^{143}Nd is particularly useful for identifying processes that lead to incongruence between the Lu-Hf and Sm-Nd isotope systems. Because the two systems usually are well correlated in the crust and the mantle, when they are not, their decoupling is telltale evidence of specific processes being at work.

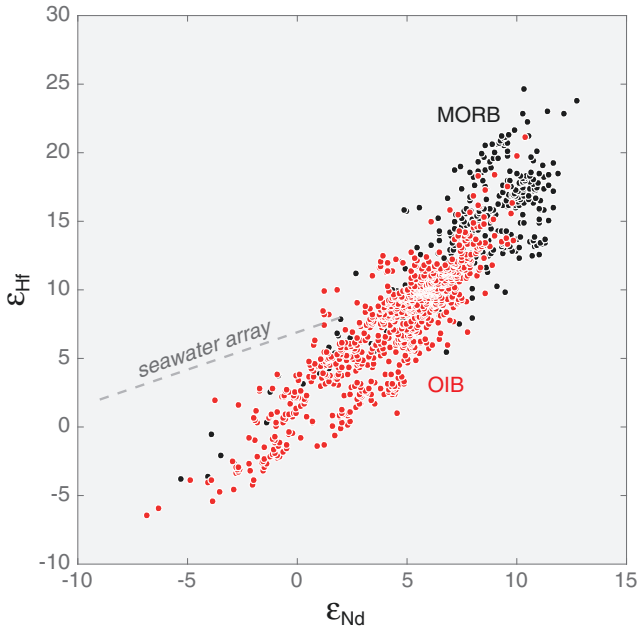
The Lu-Hf and Sm-Nd isotope systems are often used in conjunction because of their broad geochemical similarities, including incompatible behavior during melting leading to their joint buildup in the melt over the residual solid. In addition, both the Lu-Hf and Sm-Nd isotope systems are, for the most part, resistant to perturbations and tend to preserve their isotopic records despite exposure to weathering, hydrothermal alteration, and metamorphic processes. The daughter elements of both systems, Hf and Nd, are relatively more incompatible than their respective parents, Lu and Sm, resulting in lower Lu/Hf and Sm/Nd in the melt than the residual solid. Over time, the melts and residual solids grow in isotopic signatures that are, respectively, less and more radiogenic than their source, and these differences in reservoir isotopic composition can be used to trace the nature of geological processes and the course of planetary differentiation and evolution. Because of the similar behavior during melting of the Lu-Hf and Sm-Nd isotope systems, the Hf and Nd isotope compositions of magmatic rocks are highly (positively) correlated, forming the so-called mantle, or terrestrial (mantle-crust), array (Fig. 1) (e.g., Patchett 1983b; Salters and Hart 1991; Johnson and Beard 1993; Blichert-Toft and Albarède 1997; Vervoort and Blichert-Toft 1999; Vervoort et al. 1999; Chauvel and Blichert-Toft 2001; Chauvel et al. 2008). Exceptions to this general correlation arise when zircon (with high affinity for Hf) and garnet (with high affinity for Lu) are involved, whether directly or indirectly.

^{176}Lu-^{176}Hf System Fundamentals

^{176}Lu disintegrates to ^{176}Hf by beta decay with a decay constant λ^{176}Lu of 1.867 ± 0.008 × 10^{-11} year^{-1} (Scherer et al. 2001; Söderlund et al. 2004) corresponding to a half-life of 37.12 Ga. For a review of the long path to finally arriving at an accurate determination of the ^{176}Lu decay constant, see Begemann et al. (2001) and Vervoort (2015). By convention, the reference stable isotope for the Lu-Hf isotope system is ^{177}Hf. When measuring the radiogenic ^{176}Hf/^{177}Hf ratio, as well as the stable ^{178}Hf/^{177}Hf and ^{180}Hf/^{177}Hf ratios, they are, likewise by convention, corrected for instrumental mass-dependent fractionation relative to the stable ^{179}Hf/^{177}Hf ratio, which is arbitrarily fixed at a value of 0.7325 (Patchett and Tatsumoto 1980b). Hafnium isotopic compositions are conveniently expressed in terms of the so-called epsilon (ε) notation, which is the deviation in parts per ten thousand of the Hf isotopic composition of a given sample from that of chondrites (i.e., the Solar System and bulk silicate Earth reference):

$$\varepsilon_{Hf} = \left[\frac{\left(^{176}Hf/^{177}Hf\right)_{\text{sample}} - \left(^{176}Hf/^{177}Hf\right)_{\text{chondrites}}}{\left(^{176}Hf/^{177}Hf\right)_{\text{chondrites}}}\right] \times 10,000$$

The original Hf solution standard used for Hf isotope analysis since the pioneering work of Jon Patchett and collaborators, which is still in use today, 35 years on, is the JMC-475 Hf standard, a Hf metal obtained from the Johnson Matthey Corporation and dissolved in hydrofluoric acid to produce the JMC-475 Hf standard solution (Patchett and Tatsumoto 1980b). This standard can still be obtained upon request from Dr Jeffrey Vervoort at Washington State University in Pullman (vervoort@wsu.edu) as long as stock remains.



Hafnium Isotopes, Fig. 1 The mantle and seawater arrays in ε_{Hf}-ε_{Nd} space. *Black* symbols are mid-ocean ridge basalts (*MORB*) and *red* symbols are ocean island basalts (*OIB*). The respective slopes of the mantle and seawater arrays are 1.4 and 0.5

A true (accurate) $^{176}Hf/^{177}Hf$ value of the original JMC-475 Hf standard solution was determined by MC-ICP-MS to be 0.282163 ± 0.000009 (Blichert-Toft et al. 1997).

Isotopic Composition of CHUR and BSE

Usable Hf isotope compositions and Lu/Hf ratios of chondritic meteorites were first measured by Blichert-Toft and Albarède (1997). Their present-day $^{176}Hf/^{177}Hf$ and $^{176}Lu/^{177}Hf$ data accurately established the chondritic uniform reservoir (CHUR) reference parameters, which, due to the refractory, lithophile character of both Lu and Hf, are also taken as tenable values for the bulk silicate Earth (BSE). A decade later, with greatly improved analytical capabilities, Bouvier et al. (2008) redetermined the Lu-Hf CHUR/BSE parameters on unequilibrated chondrites, which exhibit less scatter. Most recently, Iizuka et al. (2015) measured the Lu-Hf CHUR/BSE parameters on refractory, low-Lu/Hf meteorite zircon. All three sets of reference parameters are listed in Table 1 and are all currently in use as they are indistinguishable within the associated analytical uncertainties and have calculated Solar System initial Hf isotopic compositions consistent within 1.2 ε units.

Blichert-Toft and Albarède (1997), based on mass balance constraints dictated by terrestrial and chondritic Hf and Nd elemental and isotopic compositions, postulated the existence of an enriched "hidden" reservoir, possibly early mafic crust either recycled into the deep mantle (Chase and Patchett 1988; Galer and Goldstein 1991) or lost to space by collisional erosion (e.g., Caro et al. 2008). Although a missing enriched reservoir is consistent with ^{146}Sm-^{142}Nd systematics between chondrites and the Earth (Boyet and Carlson 2005), it is now well understood that the isotopic compositions of a number of elements, such as ^{16}O and the neutron-rich ^{54}Cr and ^{50}Ti (e.g., Trinquier et al. 2009), vary among chondrite classes as well as between the Earth, Mars, and the Sun. It must further be kept in mind that CHUR is only a hypothetical reference and does not imply that the Earth is genetically related to any particular type of chondrite. Hence, if the underlying fundamental assumption that the Earth is chondritic does not hold up, the requirement of a missing reservoir is lifted. Consequently, the composition of the BSE and the degree to which it is chondritic is still an outstanding question (Caro et al. 2008).

The Seawater Array

The correlation between Hf and Nd isotopes in Fe-Mn crusts and nodules deviates from the terrestrial array toward highly radiogenic Hf for a given Nd isotopic composition forming what has become known as the "seawater array" (Fig. 1) and indicates that, in the ocean, Hf and Nd fractionate independently of the processes taking place in the mantle and the crust and, hence, provide a powerful tracer of the recycling of oceanic sediments into the mantle (White et al. 1986; Albarède et al. 1998). The Lu-Hf and Sm-Nd isotope systems are decoupled in the sedimentary system because zircon, which contains most of the Hf budget, is a heavy, refractory mineral that is deposited predominantly in fluvial or coastal settings, while most of the Lu budget (and that of the other REE) is contained in clays deposited in deeper water as pelagic sediment (Patchett et al. 1984). Furthermore, Hf in zircon is particularly unradiogenic and zircon is highly resistant to chemical weathering; thus, the dissolved load of rivers is more radiogenic than continents as a whole. Over time, the high-Lu/Hf fine-grained sediment resulting from this incongruent weathering develops unusually radiogenic Hf for a given Nd isotopic composition. This decoupling from the otherwise well-correlated Hf-Nd isotope array of terrestrial rocks arising from the "zircon effect" (Patchett et al. 1984; White et al. 1986; Blichert-Toft et al. 1999b) and defining a distinct separate array with a comparatively shallower slope (0.5 vs. 1.4 for the mantle array) is giveaway testimony to the presence in the source of high-$^{176}Hf/^{177}Hf$, low-$^{143}Nd/^{144}Nd$ rocks of Hf-depleted fine-grained sediment.

Lu-Hf Garnet Geochronology

The Lu-Hf isochron method is described in detail in Vervoort (2015) and will not be repeated here.

The proof of concept of the Lu-Hf garnet dating technique by MC-ICP-MS, which has upheld its early promise of great potential for accurate and precise chronology, was first demonstrated by Duchêne et al. (1997) and has since found multiple applications (Vervoort 2015 and references therein). Because Lu, but not Hf, partitions into garnet leading to high Lu/Hf ratios (inclusion-free garnet typically has Hf contents of 0.03–0.3 ppm, while Lu contents are of the order of 1–2 ppm), garnet is an ideal phase for high-precision

[a]Calculated using $\lambda^{176}Lu = 1.867 \times 10^{-11}$ year^{-1} (Söderlund et al. 2004)

chronometry. Garnet is usually combined with clinopyroxene, which contains relatively more Hf (about a factor of ten more than Lu) and less Lu than garnet and hence plots nearer the origin in an isochron diagram widely separated from garnet, thereby producing high-precision ages. The Lu-Hf garnet chronometer is used by geoscientists for dating petrological processes and duration of metamorphism, particularly in the context of subduction, burial, and exhumation and the rates at which these processes operate within the crust and the lithosphere. The so-called "garnet effect" further allows tracking the recycling of, especially, ancient garnet-bearing material into the mantle, such as delaminated lower crust or subcontinental lithospheric mantle foundering into the underlying mantle during continental breakup and with time giving rise to highly depleted Hf isotopic compositions accompanied by "normally" depleted Nd isotopic signatures (e.g., Hanan et al. 2004; Blichert-Toft et al. 2005). The Hf-Nd isotopic signature arising from the garnet effect is readily told apart from that due the zircon effect, despite both of them being characterized by unusually radiogenic Hf for a given Nd isotopic composition, by the former being far more radiogenic for both Hf and Nd than the latter.

Another reason why Lu-Hf garnet geochronology is powerful at keeping time is because of the high closure temperature of the Lu-Hf isotope system in garnet, which, although not well constrained, appears to be ~800 °C, making it particularly well suited for dating deep-seated rocks such as eclogites, peridotites, pyroxenites, granulites, and amphibolite-facies rocks. Since Lu-Hf garnet ages almost always are older than the corresponding Sm-Nd ages measured on the same mineral (e.g., Scherer et al. 2000; Bedini et al. 2004; Chin et al. 2015 and references therein), it can rather safely be deduced that the Lu-Hf system closes at a higher temperature than the Sm-Nd system.

Summary

MC-ICP-MS technology has made it possible over the last two decades to put the refractory Lu-Hf isotope system to full use on a routine basis as a tracer and a chronometer in geochemistry and cosmochemistry on a par with other isotope systems, to which it is largely complementary, such as the Sm-Nd, Rb-Sr, and U-Th-Pb systems. The ^{176}Lu decay constant has been determined, as have chondritic and bulk silicate Earth parameters with the caveat that Earth may not actually be chondritic; the Hf-Nd seawater array has been discovered, which allows the recycling of sediments into the mantle to be tracked closely over time; the development of a powerful dating technique based on garnet has shed new light on small- and large-scale petrological, metamorphic, and tectonics processes; Hf-poor samples, such as komatiites, can now be measured and have brought crucial insights into early Earth evolution; and single rather than batches of zircons are being analyzed, whether by solution or laser ablation protocols, monitoring crustal growth from the Hadean until today.

Halide Minerals

John Warren
Petroleum Geoscience Prog., Chulalongkorn University, Bangkok, Thailand

Definition

Halide minerals are a group of naturally occurring inorganic compounds that are salts of the halogen acids and encompass minerals with a dominant halide anion (F^-, Cl^-, Br^-, and I^-).

Complex halide minerals can also have polyatomic anions addition to, or that include, halides. With the notable exceptions of halite (rock salt), sylvite, carnallite, which are the result of the solar evaporation of a brine, and fluorite a widespread hydrothermal precipitate, halide minerals are typically rare and of very local occurrence. Most are fumarolic sublimates or alteration/weathering products tied to exposure to, or brine interaction with, various metalliferous ore deposits (Table 1).

Introduction

In the classification scheme pioneered by James Dana in the early 1800s, minerals are classified into eight major groups, based on the main type of cation present in the mineral structure, namely, (1) native elements; (2) sulfides; (3) oxides and hydroxides; (4) halides; (5) carbonates, nitrates, borates, and iodates; (6) sulfates, chromates, molybdates, and tungstates; (7) phosphates, arsenates, and vanadates; and (8) silicates.

Naturally occurring halide minerals are characterized by combinations with large, highly electronegative, monovalent anions, namely, fluorine (F^-), chlorine (Cl^-), bromine (Br^-), and iodine (I^-). These elements, collectively called the halogens, occur in row 17 (class VIIA) of the periodic table and are essential constituents of halide minerals in which they are ionically bonded with electropositive, metallic cations such as sodium (Na^+), potassium (K^+), calcium (Ca^{2+}) and various base and precious metals. The halides' ionic bonding and small ionic charge mean many of the resulting precipitates are brittle, translucent, and soluble in water. They also tend to possess low to moderate hardness, moderate to high melting temperatures, and to be poor conductors of heat and electricity. More than 80 halide minerals exist, and a selection covering most natural halide salts is listed in Table 1.

However, only three halide minerals – halite (NaCl), fluorite (CaF_2), and sylvite (KCl) – are common worldwide, two of them are evaporite salts (halite and sylvite) and are discussed in detail in that section of the encyclopedia, along with additional halides, sulfates, and carbonates, typical of evaporite deposits. The third, fluorite, is a relatively common hydrothermal precipitate. A fourth natural and locally common halide, cryolite (Na_3AlF_6), was formerly essential to the refining of aluminum ore, such as bauxite, and has a type occurrence at the former Ivigtut Mine, Greenland.

Compositionally and structurally, three broad categories of halide minerals are recognized. These three categories, which are also distinguishable in their modes of occurrence, encompass (1) simple halides, (2) halide complexes, and (3) oxyhydroxy-halides (Table 1).

Simple Halides

The simple halides are salts of the alkali, alkaline earth, and transition metals. Most are soluble in water, with the transition metal halides unstable upon exposure to air. Halite, sodium chloride (NaCl), is the most familiar example of a halide mineral; it often occurs with other evaporite minerals in enormous beds resulting from solar concentration of large accumulation of brines and trapped oceanic water in large shallow subsea-level isolated basins (see evaporites). Economically significant amounts of sylvite and other more complex chloride and sulfate salts are present in some such evaporite beds. Sylvite is the main source mineral for potash fertilizer, while halite is an essential feedstock to the world's chemical industries, is essential to human nutrition as table salt, and is widely used as a road deicer.

Fluorite, or calcium fluoride (CaF_2), another simple halide, is widespread in limestones that have been permeated by hydrothermal solutions containing the fluoride anion (Richardson and Holland 1979). Hence, it is a commonplace precipitate in Mississippi Valley-type (MVT) deposits and igneous skarns (Kendrick and Burnard 2013). Noteworthy deposits of fluorite occur in Mexico; Cumberland, England; and Illinois, Missouri, Kentucky, and Colorado in the United States. Other simple halide minerals such as sal ammoniac, ammonium chloride (NH_4Cl); lawrencite and ferrous chloride ($FeCl_2$); and molysite and ferric chloride ($FeCl_3$) occur in fumarolic vents and are highly unstable in air (Table 1). A few hydrothermal vein minerals in silver deposits, such as chlorargyrite and calomel, serve as minor and occasional ores of silver and mercury, respectively. A few double salts (e.g., carnallite and tachyhydrite) included among the simple halides have formed under evaporitic conditions similar to, but significantly more saline, than the brines that precipitate halite.

Halide Complexes

In the halide complexes, halide anions are tightly bound to a cation, usually aluminum; the resulting unit behaves as a single negative ion. The most common examples are the fluoroaluminates; cryolite, cryolithionite, thomsenolite, and weberite. Significant quantities of cryolite formerly were mined at Ivigtut, Greenland, and once used as flux in the recovery of aluminum from bauxite.

Oxyhydroxide Halides

Most oxyhydroxy-halides are rare and usually highly insoluble. Many have formed by the action of halide-bearing groundwater and thermal waters upon the oxidation products of previously existing sulfides: atacamite, matlockite,

Halide Minerals, Table 1 Natural halide minerals

Mineral Name	Mineral Properties: Formula, Mohs hardness, S.G., lustre, colour	Comments	References
Anarakite (see also herbertsmithite)	$ZnCu_3(OH)_6Cl_2$ (oxyhalide) 3–3.5, 3.8, vitreous to adamantine, light-green to blue-green	Alteration product of Cu mineralization in Triassic dolomites, near Anarak Iran, and syenitic porphyries and granites in Chile. Synthetic form of this salt exhibits properties of a quantum spin liquid and so shows constantly fluctuating scattered magnetic orientations	Adib and Ottemann 1972; Braithwaite et al. 2004
Antarcticite (see also sinjarite)	$CaCl_2.6H_2O$ (simple halide – hydrated) 2–3, 1.7, vitreous, deliquescent, colourless	Hydroscopic, cryogenic, precipitate in the hyperarid Don Juan pool, Wright Valley, Antarctica (type area). Also noted within fluid inclusions within quartz in pegmatite bodies in the Bushveld complex of South Africa and in association with halite, gypsum and celestine in brine pans in Bristol Dry lake, California	Torii and Ossaka 1965; Warren 2016
Atacamite	$Cu_2(OH)_3Cl$ ((oxyhalide) 3–3.5, 3.8, adamantine, various bright green shades, dark emerald green to black	Atacamite (minor ore product) forms in arid climates where copper minerals are exposed to oxidation or long-term arid-zone hydrothermal flushing, e. g. Chuquicamata, Mantos Blancos Cu-Ag deposit, Antofagasta, Atacama Desert. Atacamite is polymorphous with botallackite, clinoatacamite and paratacamite, and can be produced in in small amounts during biomineralisation	Cameron et al. 2007
Avogadrite	$(K,Cs)BF_4$ (Complex halide) n.d, 2.5-3.3, vitreous, colourless to white	Typically occurs as a sublimation product around volcanic fumaroles, as on Mt Vesuvius, Italy. Isostructural with baryte	Gaines et al. 1997
Bischofite	$MgCl_2.6H_20$ (simple halide – hydrated) 1.5-2, 1.6, vitreous, colourless, white, astringent bitter taste	Bittern precipitate from highly concentrated seawater brines. Significant amounts have precipitated in association with carnallite and sylvite in shallow subsurface salt beds in the Dallol depression, Ethiopia. (See evaporites)	Warren 2016
Bismoclite	(BiO)Cl (oxyhalide) 2–2.5, 7.8, vitreous to greasy, white, pale grey, yellowish brown	Bismuth salt, typically hosted in pegmatites in granites and greisen (is a member of matlockite mineral group). First described in 1937 from alluvium near bismuth-bearing pegmatites at Jackals Water, SW of Prieska, South Africa, also found at Bygoo, Australia and Tintic District Utah	Mountain 1937
Boleite	$KPb_{26}Ag_9Cu_{24}(OH)_{48}Cl_{62}$ (hydroxyhalide) 3–3.5, 5.1, vitreous to pearly, deep Prussian blue to indigo	Very minor ore product first described in 1973 from El Boleo Mine, Mexico. Worldwide, it occurs in association with numerous other secondary oxidation minerals in oxide zones, such as pseudoboleite, cumengite and diaboleite, all with similar crystal structures	Winchell and Rouse 1973
Botallackite	$Cu_2(OH)_3Cl$ (oxyhalide) Soft, 3.6, transparent to translucent, mountain green, bluish	Forms as alteration product in copper deposits exposed to weathering and salt water, type locality is Botallack mine, Cornwall, also Lubin Mine, Poland. Also reported from deep seafloor black smoker deposits, due to reaction of primary sulfide minerals with seawater and also found on copper bearing slag exposed to seawater. Botallackite is polymorphous with atacamite, clinoatacamite, and paratacamite	Hawthorne 1985
Bromargyrite	AgBr (Simple halide) 2.5, 6.5, adamantine, resinous, yellowish, greenish brown, bright green	Oxidation product of primary silver ore minerals, first described in 1859 for an occurrence in Plateros, Zacatecas, Mexico. Occurs in arid weathering environments along with native silver. Dimorphous with chlorargyite	Gaines et al. 1997

(*continued*)

Halide Minerals, Table 1 (continued)

Mineral Name	Mineral Properties: Formula, Mohs hardness, S.G., lustre, colour	Comments	References
Calomel	Hg_2Cl_2 (Simple halide) 1.5, 6.5, adamantine, colourless, dense white, greyish, yellowish white, brown. Insoluble in water	Secondary mercury salt that was result of alteration of Hg minerals in the oxidized zone of Hg deposits. For example, natural calomel is found together with native mercury, cinnabar, calcite, limonite, and clay at Moschellandsberg, Germany; Zimapán, Mexico; Avala, Serbia; and Brewster county, Texas, U.S.A. Mercuric chloride can be toxic but until the early 20th century, calomel was taken internally as a purgative or a laxative, and once used as disinfectant, as well as in the treatment of syphilis its previous internal usage once caused widespread mercury poisoning in the form of "pink Disease", with a mortality ratio of 1:10. Until 1954 it was also a common ingredient in teething powders in Britain	Korbel and Novik 2001
Carnallite	$KMgCl_3.6H_2O$ (simple halide – hydrated) 2.5, 1.6, resinous, dull to shining, milk-white to colourless, sometimes reddish from included Fe, Distinct highly bitter taste, soluble	Bittern precipitate from seawater brine. Ore for potassium and magnesium. Widespread precipitate in modern salt pans at the southern end of the Dead Sea. It is the dominant primary potassic bittern salt from the evaporation of modern seawater, which tends to be enriched in $MgSO_4$ compared to Palaeozoic seawater (see evaporites)	Warren 2016
Challacolloite	KPb_2Cl_5 (Simple halide) 2.3, 4.8, adamantine to greasy on exposure to air, colourless to white	Occurs as white fumarolic encrustations on lava, often intergrown with cotunnite. For example, at the Challacollo silver mine, Atacama Desert, northern Chile, at Vesuvius, Naples, Campania and in the La Fossa crater, Vulcano, Aeolian Archipelago, Sicily, Italy. Synthetic analogs, dosed with REE cations, are promising new laser host crystals	Schlüter et al. 2005
Chiolite	$Na_5Al_3F_{14}$ (complex halide) 3.5-4.0, 3.0, vitreous, colourless to snow-white	Pegmatite (cryolitic) veins in granites. For example, at Miass, Ilmen Mountains, Southern Ural Mountains, Russia. and the the Ivigtut cryolite deposit, southwestern Greenland. In the USA, occurs in the Morefield pegmatite mine, Amelia, Amelia Co., Virginia	Jacobini et al. 1981
Chlorargyrite	AgCl (simple halide) 2.5, 5.5, resinous, colourless, grey to violet	Secondary ore mineral, typically in oxidised zones of silver deposits, as in outcrops of Bonanza Ag-vein, Nevada, USA and Yinchangpo Pb-Zn-(Ag) deposit, Yunnan, China. Also known as cerargyrite and, when weathered in desert air, as "horn silver"	Gaines et al. 1997
Chlorocalcite	$KCaCl_3$ (simple halide) 2.5-3, 2.2, white, tinged violet, deliquescent	Typically found in active volcanic fumaroles as on Vesuvius, Campania, Italy, also in Mengye potash beds China and co-association with antarcticite in Bristol Dry Lake, California and at Stassfurt, 34 km south of Magdeburg, Saxony-Anhalt, Germany	Gaines et al. 1997
Chlormanganokalite	K_4MnCl_6 (complex halide) 2.5, 2.3, vitreous, champagne, lemon- to canary-yellow	Fumarolic precipitate in fissures and cavities in scoria blocks in Mt Vesuvius	Gaines et al. 1997
Chloroxiphite	$Pb_3CuO_2Cl_2(OH)_2$ (oxyhalide) 2.5, 6.8, adamantine, olive green to pistachio green	Typically formed as alteration product of Pb ore (as does the associated mendipite). Found in association with mendipite in the Mendip Hills, Somerset, England, and other areas where chloride-rich groundwaters flush Pb-ore	Finney et al. 1977; Siidra et al. 2008

(*continued*)

H

Halide Minerals, Table 1 (continued)

Mineral Name	Mineral Properties: Formula, Mohs hardness, S.G., lustre, colour	Comments	References
Coccinite	HgI_2 (simple halide) 2, 3.2, translucent, orange-red, volatile at room temperature, slightly soluble in water	Reported as secondary mineral from Broken Hill, New South Wales, and from a uranium mine in Thuringia and old mercury workings in the Rhineland-Palatinate in Germany. At the Thuringia deposit it is a sublimation product resulting from fires associated with pyrite-bearing, graptolitic slate	Witzke 1997
Cotunnite	$PbCl_2$ (simple halide) 2.5, 5.8, adamantine, colourless to white	Volcanic sublimate or as an alteration of galena in saline environments, also as an alteration product on leaden archeological objects or slag immersed in seawater. For example, on Vesuvius, Campania; in the Niccioleta mine, 40 km southwest of Siena; and along Baratti Beach, Tuscany, in slag. Also occurs in association with galena, cerussite, anglesite and matlockite in Caracoles, Chile and the Tolbachik volcano on the Kamchatka Peninsula, Russia	Gaines et al. 1997
Cryolite	Na_3AlF_6 (complex halide)2.5, 3.0, vitreous to greasy, colourless, white, pale brown, pink, smoky to black	Late stage precipitate in granitic (cryolitic) pegmatites, also occurs in tin-bearing alkalic granites; as vapor-phase mineral along fractures and in the groundmass of some fluorine-rich, topaz-bearing rhyolites; in pods in a carbonatite veins cutting fenitized biotite gneiss. Is also as a rare authigenic component of the marlstones and shales of the Green River Formation. Appears to disappear when immersed in water due to similar refractive indices. Was once an important ore feed for aluminum production (mined commercially at Ivigtut, Greenland)	Gaines et al. 1997
Cryolithionite	$Na_3Li_3Al_2F_{12}$ (complex halide) 2.5-3.0, 2.8, vitreous, colourless to white	Late stage precipitate in granitic (cryolitic) pegmatites as at Ivigtut and Arlsukfiord, West Greenland	Geller 1971
Cryptohalite	$(NH_4)_2SiF_6$ (complex halide) 2.5, 2.0, vitreous, colourless, grey, white	Formed as a sublimation product in fumaroles (Mt Vesuvius) and coal fires (Kateřina colliery, Radvanice, Eastern Bohemia, Czech Republic). It is a toxic salt, like all salts of fluorosilicic acid. Historically is was also called bararite, which is now considered a co-associated mineral, as is sal ammoniac	Klein and Dutrow 2008
Cumengeite	$Pb_{21}Cu_{20}Cl_{42}(OH)_{40}$ (oxyhalide) 2.5, 4.7, weakly vitreous, Indigo blue, can form distinctive "star-shaped" crystals	Secondary mineral formed through reaction of chloride ions with primary sulphides in the oxidized zone of some Pb-Cu deposits (Boleo Mine, Mexico) and exposed smelter slags (Larium, Greece)	Hawthorne and Groat 1986
Diaboleite	$Pb_2CuCl_2(OH)_4$ (oxyhalide) 2.5, 5.5, adamantine, deep blue	Occurs in association with manganese oxide ore, as a secondary mineral in lead and copper oxide ores and seawater exposed smelter slag (name means "distinct from boleite"). It is a low-temperature phase, that is stable under hydrothermal conditions at temperatures less than 100 to 170 °C. At higher temperatures, the first stable mineral to form is cumengeite	Hawthorne and Groat 1986; Winchell and Wenden 1968
Douglasite	$K_2Fe^{2+}Cl_4.2H_2O$ (hydrated complex halide) n.d., 2.1, vitreous, pale green, yellow-green, brownish red on exposure	Typically occurs as minor salt in a halite–potash deposit, Douglashall mine, Germany	Klein and Dutrow 2008
Embolite	Ag(Br, Cl) (simple halide) 1.5-2, 5.7, adamantine, resinous, yellowish green to greyish yellow	One of three natural minerals that contain bromine, others are idiobromite (Ag(Cl,Br,I) and bromyrite AgBr). Occurs as a weathering product of silver ore in the arid Broken Hill region, Australia and Chanarcillo region, Chile	Barclay and Jones 1971

(*continued*)

Halide Minerals, Table 1 (continued)

Mineral Name	Mineral Properties: Formula, Mohs hardness, S.G., lustre, colour	Comments	References
Erythrosiderite	$K_2Fe^{3+}Cl_5.H_2O$ (hydroxyhalide) N.d., 2.4, vitreous, translucent, ruby-red to red, soluble in water, deliquescent	Occurs as active fumarolic sublimates (highly hygroscopic) and associated with rinneite rims in some bedded salt deposits	Stewart 1963
Ferruccite	$NaBF_4$ (complex halide) 3.0, 2.5, translucent, colourless to white, soluble in water, bitter acid taste	Occurs as active fumarolic sublimate at Vesuvius, Campania, Vucano, Aeolian Islands, Italy and on volcanoes on the Kamchatka Peninsula, Russia	Brunton 1968
Fiedlerite	$Pb_3ClF(OH).H_2O$ (hydroxyhalide) 3.5, 5.9, transparent, colourless to white	Reaction of halide-bearing brines with Pb ore (Argent Pb-Zn Mine, Transvaal) or ancient smelter slag (Larium, Greece)	Merlino et al. 1994
Fluocerite	$(Ce,La)F_3$ (halide) 4–5, 5.9, vitreous, pale greenish yellow	Pegmatite REE association, hydrothermal veins in granite, as in the Zhanuzak area, Kent massif, Karaganda region, central Kazakhstan	Chistyakova and Kazakova 1969; Dill 2015
Fluorite (aka fluorspar)	CaF_2 (halide) 4, 3.2, vitreous, allochromatic: Purple, lilac, golden-yellow, green, colourless, blue, pink, champagne, brown	Widespread, typically a hydrothermal (vein) gangue associated with galena, sphalerite and barite ores in China, South Africa and Mexico also as cavity fill precipitates in MVT associations. Meta-evaporite igneous association at Dalnegors'k, Russia. Can be produced in small amounts during biomineralisation	Richardson and Holland 1979
Frankdicksonite	BaF_2 (halide) 2.5, 4.9, vitreous, colourless white	Extremely rare, occurs naturally as a hydrothermal precipitate in the Carlin gold deposit of Eureka County, Nevada as cubic crystals (0.1 - 4 mm) encased in quartz	Radkte and Brown 1974
Halite	NaCl, (halide) 2, 2.5, vitreous, colourless to white, als blue to red with impurities, salty taste	Worldwide it is the main evaporite salt produced by evaporation of seawater (See evaporite). Typically associated salts include sylvite, polyhalite, kieserite, carnallite, gypsum, anhydrite, dolomite. Can be produced in biomineralisation	Warren 2016
Hieratite	K_2SiF_6 (complex halide) 2.5, 2.7, vitreous, colourless, white to grey	Forming in active fumarolic sublimates, as in Italy, on Vulcano, Lipari Islands, and from Vesuvius, Campania. Can be produced in biomineralisation and was noted in the volcanic ash of the Eyjafjallajökull eruption, Iceland	Klein and Dutrow 2008; Gislason et al. 2011
Hydrohalite	$NaCl.2H_2O$ (hydrated halide) n.d. 1.6, vitreous, colourless, melts under own vapour pressure at $-0.1°C$ and converts to halite	Cryogenic precipitate in a saturated halite brines at cold temperatures ($\approx -5°C$), e.g. occurs naturally in Lake Bonney, Taylor Valley, Antarctica	Warren 2016; Starinsky and Katz 2003
Iodargyrite (aka Iodyrite)	AgI (halide) 1.5-2, 5.7, adamantine, resinous, colourless, pale yellow, greenish yellow	Silver ore. Naturally occurring mineral form of silver iodide formed in oxidized zoned of silver deposits, e.g. Broken Hill region Australia and Schöne Aussicht Mine in Wied Iron Spar district, Germany	Gaines et al. 1997; Gillard et al. 1997
Jarlite	$Na(Sr,Na)_7MgAl_6F_{32}(OH,H_2O)_2$ (hydrated complex halide) 4–4.5, 3.8, vitreous, colourless, grey to white	In vugs in cryolitic pegmatite veins along with with other fluorides as at Ivigtut, Greenland	Pauly et al. 1997
Kempite	$Mn_2(OH)_3Cl$ (oxyhalide) 3.5, 3, semi-transparent, emerald-green	Associated with platinum-group minerals in the Noril'sk Complex, and with the Korshunovskoye iron ores of the southern Siberian platform and in the Deep Copper Zone of the Sudbury Complex and in Alum Rock Canyon. California	Gaines et al. 1997; Saini-Eidukat et al. 1998
Laurionite	(Ag,Cu)I (halide) 3–3.5, 6.2, adamantine, Colourless to white	First documented at Larium, Greece, now known to be a natural mineral in the oxidized zone of some Pb–Zn–Cu–Ag deposits, especially in arid regions, e.g. Broken Hill region, Australia. Dimorphous with paralaurionite	Gaines et al. 1997

(*continued*)

H

Halide Minerals, Table 1 (continued)

Mineral Name	Mineral Properties: Formula, Mohs hardness, S.G., lustre, colour	Comments	References
Lawrencite	$(Fe,Ni)Cl_2$ (halide) soft, 3.2, translucent, green to brown, deliquescent	Forms in volcanic sublimates as at Mt Vesuvius, Italy and via terrestrial alteration of iron meteorites as in the Tazewell, Ovifak and Canyon Diablo meteorites	Buchwald and Clarke 1989
Lorettoite (chubutite)	$Pb_7O_6Cl_2$ (oxyhalide) 3, 7.7, adamantine, honey-yellow to reddish-yellow	Forms in oxidized lead ore zones, typically associated with ancient lead slags as at Larium, Greece, also at Loretto, Oklahoma. Probably discredited name as is manmade equivalent to chubutite	Gaines et al. 1997
Malladrite	Na_2SiF_6 (halide) n.d., 2.7, semi-transparent, pale rose, slightly soluble in water	Forms in volcanic sublimates, e.g. Vesuvius and the explosive ash cloud of the Eyjafjallajökull volcano when the meltwaters of the Eyjafjallajökull glacier mixed with hot magma. It Is a mineral with silica in the lattice but it is not a silicate	Zalkin et al. 1964; Gislason et al. 2011
Marshite	CuI (halide) 2.5, 5.6, transparent, colourless pale honey yellow to salmon red (on exposure)	Occurs as a rare mineral in the oxidized zone of Cu ores, as in the Broken Hill and Moonta mine regions, Australia and Chuquicamata porphyry Cu deposit, Atacama Desert, Chile	Barclay and Jones 1971; Garrett 1985
Matlockite	PbFCl (double halide) 2.5-3.0, 7.1, adamantine, colourless, pale yellow to yellow-orange	Forms in the oxide zone of some lead-bearing mineral deposits. Matlockite group consists of a number of minerals which share a similar crystal structure. The group includes bismuth, lead or calcium halides: bismoclite (BiO)Cl, daubréeite (BiO)(OH,Cl), laurionite PbCl(OH), paralaurionite PbCl(OH), rorisite CaFCl, zavaritskite (BiO)F and the eponymous matlockite	Pasero and Perchiazzi 1996
Mendipite	$Pb_3Cl_2O_{2.5}$ (oxyhalide) 2.5, 7.2, adamantine to pearly, colourless to white to brownish	Typically formed as alteration product (like chloroxiphite). Occurs in nodules Mendip Hills, Somerset, England, and other areas where chloride-rich groundwaters flush Pb-ore, as in the Broken Hill region, Australia	Symes and Embrey 1977; Gillard et al. 1997
Miersite	(Ag,Cu)I (Halide) 2.5, 5.6, adamantine, canary yellow	Rare mineral in the oxidized zone of some Pb–Zn–Cu–Ag deposits, especially in arid regions, e,g. Broken Hill region, Australia	Barclay and Jones 1971
Molysite	$FeCl_3$ (halide) Soft, 2.9, semitransparent, brownish red to yellow, very deliquescent	Rare, found as fumarolic sublimate as at Vesuvius and Vulcano, Lipari Islands, Italy. Toxic, highly corrosive and acidic. Co-associated minerals include; tridymite, hematite, anhydrite, halite	Gaines et al. 1997
Nantokite	CuCl (halide) 2.5, 4.1, adamantine, white, greyish to greenish on exposure	Forms a secondary mineral in hydrothermal copper-bearing deposits; rarely as volcanic sublimates, as in Carmen Bajo mine, Atacama, Dzhezkazgan, Kazakhstan. Also found in the Broken Hill and Cloncurry districts, Australia and the nitrate soils of the Atacama Desert	Gaines et al. 1997; Gillard et al. 1997
Pachnolite	$NaCaAlF_6.H_2O$ (hydrated complex halide) 3, 2.97, vitreous, colourless to white	Alteration product in cryolitic pegmatite veins along with other alkali aluminum fluorides, as at Ivigtut, Greenland and rare earth pegmatites in the Olary Block, Australia	Hawthorne and Ferguson 1983; Lottermoser and Lu 1997
Paralaurionite (rafaellite)	PbCl(OH) (oxyhalide) Soft, 6.1, sub-adamantine, colourless, white, pale greenish	Forms in lead-bearing slags exposed to seawater, as at Laurium, Greece, also occurs in alteration zones in some polymetallic ore deposits as at Higher Pitts mine, Mendip Hills and Argent Pb-Ab mine, South Africa	Merlino et al. 1993
Paratacamite	$Cu_2(OH)_3Cl$ (oxyhalide) 3, 3.7, vitreous, green to dark green	An oxidation product of other copper minerals, especially under arid, saline conditions as in Generosa Mine, Chile; also in fumarolic deposits and as a weathering product of sulphides in subsea black smoker deposits	Frondel 1950; Fleet 1975; Cameron et al. 2007

(*continued*)

Halide Minerals, Table 1 (continued)

Mineral Name	Mineral Properties: Formula, Mohs hardness, S.G., lustre, colour	Comments	References
Penfieldite	$Pb_2Cl_3(OH)$ (Oxyhalide) n.d, 5.8, adamantine to greasy, colourless to white, soluble in water	In oxidized hydrothermal lead deposits (Sierra Gordo District, Chile) and as an alteration product of lead-bearing slag immersed in seawater as at Laurium, Greece	Merlino et al. 1995
Prosopite	$CaAl_2(F,OH)_8$ (Complex halide) 4.5, 2.9, vitreous, weak, colourless, greyish white to blue	Disseminated precipitate in fluorine-rich granites, greisens, and granite pegmatites; more rarely in base-metal deposits, e.g., Ivigtut, Greenland; St. Peter's Dome near Pike's Peak, Colorado, USA; Mt Bischoff, Tasmania	Petersen 1986
Pseudoboleite	$Pb_5Cu_4Cl_{10}(OH)_8.2H_2O$ (hydroxyhalide) 2.5, 4.9, translucent, indigo blue	Secondary mineral precipitate formed through reaction of chloride with primary sulfides in the oxidized zone of Pb–Cu deposits as in the Amelia Mine, Boleo, Mexico and Larium Greece	Winchell and Rouse 1974
Ralstonite	$Na_xMg_xAl_{2-x}(F,OH)_6.H_2O$ (Hydroxyhalide) 4.5, 2.6, vitreous, colourless to milky white	Precipitates in some granite pegmatites and greisenized zones rich in fluorine; also in hydrothermal antimony deposit in silicified limestones, as in Ivigtut, Greenland and Mt Cleveland Tin mine, Tasmania and in volcanic caves	Pauly 1965; Forti 2005
Rinneite	$K_3NaFeCl_6$ (complex halide) 3, 2.3, adamantine silky, colourless, rose red to violet	Secondary mineral in marine saline evaporite deposits (see evaporites); in some salt diapirs, as in Sar Pohl diapir, southern Iran, or as a volcanic sublimate as at Mt. Vesuvius, Italy	Beattie and Moore 1982; Talbot et al. 2009
Sal Ammoniac	NH_4Cl (halide) 1.5-2, 1.5, vitreous, white to off-white, water soluble	Typically forms as encrustations formed by sublimation around volcanic vents as at Mt Vesuvius, also forms by alteration of guano and burning coals. Minor component of Alum stalactites in the Alum Cve, Italy. Named after fumarole occurrences at the Ancient Roman "Temple of Jupiter (Amun or Ammon)	Gaines et al. 1997; Forti 2005
Scacchite	$MnCl_2$ (halide) Soft, 3.0, transparent, colourless to rose red. deliquescent	Product of fumarolic activity as a Vesuvius Italy, also formed in the explosive ash cloud of the Eyjafjallajökull volcano when the meltwaters of the Eyjafjallajökull glacier mixed with hot magma	Gaines et al. 1997; Gislason et al. 2011
Sellaite	MgF_2 (halide) 5, 3.1, vitreous, colourless to white, slightly soluble in water	At its type locality, sellaite occurred within a bitumen-bearing dolomite-anhydrite rock within the moraine deposits of the Gebroulaz Glacier, France and Stassfurt salts, Germany. Also occurs in the Carrara Marble, granite pegmatites in Norway, fumarolic sublimates at Mt Vesuvius, and natrocarbonatites of the Oldoinyo Lengai volcano, Tanzania	Koritnig 1951; Raade and Haug 1981; Mangler et al. 2014
Sinjarite	$CaCl_2.2H_2O$ (hydrated halide) 1.8, 1.5, vitreous-resinous, light pink	Found in detritus in a wadi cutting across the Sinjar anticline, Iraq. Highly deliquescent. See also Antarcticite. Also present in hypersaline fluid inclusion in quartz in the meta-evaporites of the western Zambian copper Belt, Africa	Aljubouri and Alddabbagh 1980; Eglinger et al. 2014
Sylvite	KCl (halide) 2, 2, vitreous, colourless to white to red with iron oxides, soluble in water, salty taste with bitter overtones	Worldwide it is the main potash ore mineral in evaporite salt beds produced by evaporation of seawater (See evaporite) Can be produced in small amounts during bio-mineralisation and also occurs in sublimate in volcanic fumaroles as at Mt Vesuvius, Italy	Warren 2016
Tachyhydrite	$CaMg_2Cl_6.12H_2O$ (hydrated halide) 2, 1.7, vitreous, colourless, wax yellow to pale yellow, highly deliquescent, very sharp, bitter taste	Can be a minor component of marine evaporite deposits, especially in Aptian-age evaporites, where its relatively widespread occurrence is tied to $MgSO_4$-depleted world ocean chemistry (see evaporite)	Clark et al. 1980; Warren 2016

(*continued*)

Halide Minerals, Table 1 (continued)

Mineral Name	Mineral Properties: Formula, Mohs hardness, S.G., lustre, colour	Comments	References
Thomsenolite	$NaCaAlF_6.H_2O$ (complex halide) 2, 3, vitreous, colourless to white, reddish with iron oxides	Alteration product in cryolitic pegmatite veins along with other alkali aluminum fluorides, such as acuminite, as at Ivigtut, Greenland and in rare earth pegmatites as in the Olary Block, South Australia	Adhikesavalu et al. 1985; Lottermoser and Lu 1997
Villiaumite	NaF (halide) 2–2.5, 2.8, vitreous, carmine-pink to lavender-red, soluble in water	Occurs in nepheline syenite intrusives and pegmatites and in natrocarbonatites and nearby trona crusts in Lake Magadi. Toxic salt that can cause dental fluorosis in residents of African Rift valley	Stormer and Carmichael 1970; Mangler et al. 2014

nadorite, and diaboleite are examples. A few halide compounds such as fiedlerite, laurionite, and penfieldite have been documented as forming through the action of seawater upon ancient lead slags from the historic deposits at Laurium (Lavrion), Greece, although other natural occurrences are now known, since the initial documentation at Laurium. There are more than 300 and 70 minerals known from this locality, and many of them are halides (Kohlberger 1976).

Laurium was a mine for centuries, first for its silver ores starting with the Greeks under Peisistratus in the sixth century BC and then the Romans for the lead content of its ores (ending around 100 AD) (Jones 1982). Gangue rock, judged too poor in metals to be processed by the ancient miners, was dumped into the nearby ocean. Beginning in the nineteenth century, and periodically, the slag has been economically reprocessed (Skarpelis and Argyraki 2009). Related to this interest in reprocessing from this site, analysis of the slag rocks has yielded a wide variety of halide minerals, some unique, and many of which were created by exposure and interaction with halides in the seawater over the millennia since being dumped. Daily exposure to seawater, either by immersion or sea spray, altered exposed surfaces of low-grade lead ores and produced an unusual assortment of rare halide minerals. Purists do not consider many of these neo-formed minerals at Laurium to be true "natural" minerals as their creation was indirectly aided by anthropogenic activities, as are other halide minerals created by exposure to waters and brines in mined areas worldwide (Table 1).

Conclusions

Although halides are rare, they are nevertheless of great economic importance as fertilizer, in nutrition and chemical feedstock, and as ore of some metals.

Definition

The halogen group of elements includes the four stable elements, fluorine (F), chlorine (Cl), bromine (Br), and iodine (I), and the short-lived radioactive element astatine

(At) which exists only fleetingly in the Earth's crust (Chang 2016). The halogens occupy group 17 of the periodic table and are characterized by an S^2P^5 outer electron shell configuration enabling their characteristic ability to form halide anions in ionically bonded salts. The heavy halogens can exist in several valence states, however, the atomic radii of halogens and the ionic radii of the common halide ions, which have valences of −1, increase down the group (Table 1).

Properties

At room temperature, fluorine ($F_{2(g)}$) and chlorine ($Cl_{2(g)}$) are respectively toxic yellow and green-yellow diatomic gases. Exposure to concentrations of more than 25 ppm of either gas will cause significant irritation to eyes and respiratory system, and exposure to more than 1000 ppm is fatal within minutes. Bromine ($Br_{2(l)}$) is a toxic and corrosive red-brown liquid that can burn the skin. Iodine ($I_{2(s)}$) is a lustrous metallic gray solid that is a skin irritant and toxic if taken orally. The toxicity of the halogens derives from their highly reactive and oxidizing nature which enables them to generate acids and denature proteins. However, the halogens rarely occur in their molecular forms, and certain halogen compounds are essential for life. The hydrogen halides ($HF_{(g)}$, $HCl_{(g)}$, $HBr_{(g)}$, and $HI_{(g)}$) are diatomic gases at room temperature. They do not ionize in the gaseous phase, but disassociate to H^+ and a halide ion producing strong acids once dissolved in water.

Fluorine and iodine each have a single stable isotope (^{19}F and ^{127}I), whereas Cl and Br have two stable isotopes each: ^{35}Cl and ^{37}Cl have isotopic abundances of 75.76% and 24.24%, and ^{79}Br and ^{81}Br have isotopic abundances of 49.31% and 50.69%, respectively (Chang 2016). There are two geologically important radioactive halogen isotopes, ^{36}Cl with a half-life of 301.3 ka and ^{129}I with a half-life of 15.7 Myr (Chang 2016). Both isotopes are produced by cosmic rays at the Earth's surface and by nuclear processes in the Earth's crust; ^{36}Cl is produced by thermal neutron reactions with K, Ca, and ^{35}Cl, and ^{129}I is produced by fission of ^{238}U. There are several additional short-lived radioactive I isotopes produced by U fission including ^{131}I ($t_{1/2} = 8.0$ d; Chang 2016). The high mobility of I coupled with its role in the human thyroid means it constitutes a significant short-term hazard associated with radioactive waste. Radioactive ^{36}Cl decays to ^{36}Ar, whereas radioactive ^{129}I and ^{131}I decay to ^{129}Xe and ^{131}Xe, respectively (Chang 2016).

Contrasting Geochemical Behaviors

Fluorine is the most strongly electronegative element in the periodic table. The fluoride ion is smaller than the hydroxide (OH^-) and oxygen (O^{2-}) ions which have ionic radii of ~1.4 Å (cf. Table 1). Fluoride can substitute for O^{2-} in nominally anhydrous mafic minerals and behaves more compatibly in the Earth's mantle than the larger halogens (Dalou et al. 2012). Fluoride readily replaces the OH-group in many hydrous minerals and two F^- ions can substitute for carbonate (CO_3^{2-}) (Kendrick 2017). The high compatibility of F in a range of minerals means it has a low solubility in aqueous fluids (at surface conditions) and a concentration of only 1.3 ppm in seawater (Table 2). In comparison, the heavier halogens (Cl, Br, and I) all have similarly strong incompatibilities in the mantle (similar to K or Nb; Kendrick et al. 2013) and high solubilities in aqueous fluids. The heavy halogens are however fractionated from each other by the evaporation of seawater beyond the point of halite saturation, because Br and I are incompatible in halite, and Cl substitutes for the OH-group in many hydrous minerals more easily than the larger Br and I ions (Kendrick 2017).

Iodine is uniquely redox sensitive among the halogens: iodate (IO_3^-) is the dominant form of iodine in seawater, but there can be up to ~5 ppb dissolved organic iodine, and iodide (I^-) is important in surface waters and anoxic basins.

Halogens, Table 1 Physical properties of halogens

	Atomic mass	Phase	Melting point K	Boiling point K	Condensation T 10^{-4} bar K	Electronegativity	Ionization energy kJ mol^{-1}	Atomic radius Å	Ionic radius Å	Common valence states
F	18.998	Gas	53.5	85.0	739	3.98	1681.1	0.7	1.3	**−1**
Cl	35.453	Gas	171.7	239.1	954	3.16	1256.2	1.0	1.8	**−1**, 1, 3, 5, 7
Br	79.904	Liquid	266	332	546?	2.96	1139.9	1.1	2.0	**−1**, 1, 3, 5, 7
I	126.904	Solid	386.9	457.6	535?	2.66	1008.4	1.3	2.2	**−1, 1**, 3, 5, 7

Halogens, Table 2 Halogen abundance data

	Solar	CI chondrite	Primitive mantle	Depleted mantle	Cont. crust	Seawater	Evaporites	Marine sediments
F ppm	0.4	60	15–30	5–15	520–620	1.3		100–1000
Cl ppm	4.8	680	15–30	1–5	140–470	19,300	<600,000	<1000
Br ppb	23	3600	40–80	10–20	1000–2000	66,000	50,000–200,000	500–100,000
I ppb	3	460	5–10	<1	500–1000	58		500–50,000

Seawater iodate is sequestered by algae, and its concentration correlates with other nutrients in seawater, whereas all the other halogens are present as halides and have constant concentrations in seawater (Table 2; Kendrick 2017).

Halogens are beneficial for life: fluoride aids in forming strong teeth and bones in vertebrates; chloride is the dominant anion that enables cellular level electrochemistry; and bromine and iodine are involved in a range of biochemical pathways that probably evolved in fairly primitive prokaryotes. Iodine is essential in the production of thyroid hormones in unicellular and multicellular organisms, and iodine deficiency causes goiter in humans (Kirk 1991; Crockford 2009).

Discovery and Utilization

Chlorine gas was first isolated by Carl Wilhelm Scheele in 1774 and was recognized as an element by Sir Humphry Davy in 1810 (Davy 1811). Iodine was separated from seaweed ash by the French chemist Bernard Courtois in 1811 and independently identified as an element at the end of 1813, by Gay-Lussac and Humphry Davy (Kirk 1991). Bromine was discovered independently in 1825 by Carl Jacob Löwig and in 1826 by Antoine Balard who separated it from seaweed ash. Initial studies on fluorine were dangerous and resulted in the deaths of several nineteenth-century experimenters who were subsequently dubbed the fluorine martyrs. Henri Moissan finally isolated F which was regarded as "a savage beast among the elements" in 1886 and received a nobel prize for this achievement in 1906 (Kirk 1991).

Halogen salts have been in use since ancient times. The name fluorine is derived from the Latin verb fluo meaning flow, because fluorite (CaF_2 or fluorspar) is used as a flux to purge iron of impurities and render slag more liquid at smelting temperatures. Common salt (NaCl – halite) has been used in cooking and food preservation since prehistoric times. Halite is produced commercially by the evaporation of seawater and halogen-salts are mined. Fluorine and chlorine gas are produced by electrolysis of CaF_2 or NaCl, respectively. Today, bromine and iodine are produced by treating naturally occurring Br- and I-rich brines with Cl_2 gas which oxidizes the dissolved halides to produce Br_2 and I_2 gas, and iodine is also produced by mining I-rich caliche.

The halogens have numerous industrial applications that result from their high reactivity, oxidizing properties, and their abilities to bond with C in organic molecules and form strong acids. The largest application of F gas is to make UF_6 which is used for ^{235}U enrichment in the nuclear fuel cycle. Hydrofluoric acid [$HF_{(aq)}$] is used in a variety of laboratory procedures including the digestion of silicate rocks and ArF is used in 193 nm excimer lasers. Prior to being phased out, chlorofluorocarbons (CFCs) which deplete stratospheric ozone, were widely used as refrigerants and aerosol propellants. Chlorine is used as a disinfectant for killing bacteria in drinking water and swimming pools and in the manufacture of paper, paint, textiles, and plastics including PVC (polyvinyl chloride) which is used extensively in the building and automotive industries. Cl compounds are also used in the manufacture of many pharmaceuticals and some insecticides. The largest current use of Br is in flame retardants; however, Br has a variety of uses including in the manufacture of plastics and some insecticides, and AgBr is used in photographic film. Iodide is present in dietary supplements used to ensure the health of livestock and humans (e.g., iodized table salt), and iodine is used in various forms as a disinfectant or antiseptic.

Distribution on Earth and in the Cosmos

The solar system contains 0.4 ppm F, 4.8 ppm Cl, 23 ppb Br, and 3 ppb I, making the halogens the 25th (F), 18th (Cl), 34th (Br), and 50th (I) most abundant elements in the solar system (Table 2; Lodders 2003). The halogens are all moderately volatile and have similar relative abundances in the solar photosphere and CI chondrites (Table 2; Lodders 2003). In contrast, Cl, Br, and I are more depleted in the terrestrial primitive mantle than F (Table 2). This could indicate that the highly incompatible heavy halogens were either partitioned into the Earth's core, or more likely that they were lost during Earth's accretion either with the early oceans and atmosphere or with other incompatible elements and crustal material lost by collisional erosion (Sharp and Draper 2013).

On Earth, the moderately compatible F is concentrated in the mantle and crust and has a low concentration in seawater (Table 2; Kendrick 2017). In comparison, the heavy halogens are concentrated in the surface reservoirs of seawater and sediments (Table 2). A bit less than half the Cl in the surface reservoir is in the oceans which have a salinity of ~3.5 wt% salt (1.9 wt% Cl), and about a quarter is in evaporites which contain up to 60 wt% Cl. Iodine is overwhelmingly concentrated in organic-rich marine sediments which contain 1–50 ppm I. Bromine which has properties intermediate of Cl and I is split between the oceans and organic-rich marine sediments (Table 2). Kelp is a type of seaweed (multicellular macroalgae) that contains an average of 1.0 wt% I and thousands of ppm of Br (Kendrick 2017).

Mid-ocean ridge and oceanic island basalt glasses (MORB and OIB) have typical concentrations of 60–1500 ppm F, 30–1000 ppm Cl, 30–4000 ppb Br, and 1–70 ppb I, with the highest concentrations in enriched OIB and the lowest in depleted MORB. The subduction flux of halogens into the deep mantle is not well known. However, hydrothermal alteration of the oceanic slab is likely to cause greater enrichment of Cl than the other halogens, because F has a low

concentration in seawater and Br and I have low compatibilities in many hydrous minerals (Kendrick 2017). Iodine and bromine can however attain ppm-level concentrations in serpentinized mantle lithosphere (Kendrick 2017).

Significance in Geochemistry and Geochronology

Chloride is the dominant anion in most geofluids, and it acts as an important ligand for the transport of metals in hydrothermal solution (Yardley 2005). As a result, Cl chemistry underpins a wide range of geological processes including chemical mass transfer by hydrothermal fluids in the oceanic crust and in subduction zones and the formation of economically important hydrothermal ore deposits. In addition, the movement of saline formation waters (oil field brines) is sometimes linked to the migration of hydrocarbons. In sedimentary environments with a high water-rock ratio, the concentration of Cl in a geofluid is considered to be "conservative" (i.e., unchanging), and together with halogen abundance ratios (Br/Cl and I/Cl), it is often used to infer a fluid source or migration pathway (Hanor 1994). In higher temperature metamorphic environments with lower fluid-rock ratios, the concentrations of Cl and other halogens are not conservative. Fluid salinity provides important evidence for phase separation of seafloor hydrothermal fluids, and the Cl content of metamorphic minerals are used to track the involvement of saline fluids in metamorphic processes (Kendrick 2017).

Chlorine and F are often described as "volatiles" in the Earth's mantle (along with H_2O, CO_2, and S). However, halogens are generally undersaturated in submarine lavas and behave as lithophile rather than volatile elements in the mantle. Halogens are degassed from subaerial volcanoes as $HF_{(g)}$, $HCl_{(g)}$, $HBr_{(g)}$, and $HI_{(g)}$ and have a significant influence on climate and ozone depletion (Kutterolf et al. 2013).

Bromine and iodine are trace constituents on the Earth but play a critical role in marine biochemistry. In addition, the analysis of halogen abundance ratios provides a critical means for tracing fluid origins and geodynamic processes (Hanor 1994; Kendrick 2017).

The stable isotope compositions of Cl and Br are reported using the delta notation relative to standard mean ocean chloride (SMOC) or bromide (SMOB) where

$$\delta^{37}\mathrm{Cl}\,‰ = \frac{\left(\frac{^{37}\mathrm{Cl}}{^{35}\mathrm{Cl}}\right)_{\mathrm{sample}} - \left(\frac{^{37}\mathrm{Cl}}{^{35}Cl}\right)_{\mathrm{SMOC}}}{\left(\frac{^{37}\mathrm{Cl}}{^{35}\mathrm{Cl}}\right)_{\mathrm{SMOC}}} \times 1000 \quad \text{and}$$

$$\delta^{81}\mathrm{Br}\,‰ = \frac{\left(\frac{^{81}\mathrm{Br}}{^{79}\mathrm{Br}}\right)_{\mathrm{sample}} - \left(\frac{^{81}\mathrm{Br}}{^{79}\mathrm{Br}}\right)_{\mathrm{SMOB}}}{\left(\frac{^{81}\mathrm{Br}}{^{79}\mathrm{Br}}\right)_{\mathrm{SMOB}}} \times 1000$$

(Eggenkamp et al. 2016). Terrestrial δ^{37}Cl varies by about 10 ‰ and has been applied more widely than δ^{81}Br which varies by about 5 ‰ and has been limited to studies of groundwater and atmospheric organo-halogen cycling (Eggenkamp et al. 2016). Recent analyses show the δ^{37}Cl of chondrites and samples from the terrestrial mantle cluster slightly below 0 ‰ suggesting Cl was isotopically uniform in the inner solar nebular (Sharp et al. 2013). However minor variations have been reported for the δ^{37}Cl of Earth's mantle, with δ^{37}Cl values of up to +3 ‰, which are among the highest on Earth, attributed to the subduction of sediments (John et al. 2010). The mechanisms of Cl isotope fractionation on Earth are however not well understood, and the majority of materials from Earth's surface including sediments have δ^{37}Cl of less than zero, with the lowest values of −8 reported for sedimentary pore waters (Barnes and Straub 2010). In contrast to chondrites and the Earth, the Moon exhibits much greater variation in δ^{37}Cl: the minimum value of ~0 ‰ is consistent with a uniform nebular, and maximum values of +25 ‰ have been attributed to fractionation during metal-halide degassing from anhydrous melts at lunar atmospheric pressure (Sharp et al. 2010).

The short-lived ^{36}Cl isotope ($t_{1/2} = 301.3$ ka) can be used to date groundwaters and is one of the most widely used tools for cosmogenic exposure dating. It has been applied to dating a wide variety of processes linked to landforms including young lava flows and glacial retreat aged from thousands of years to about 1 Ma (Ivy-Ochs and Kober 2008). The ^{129}I isotope ($t_{1/2} = 15.7$ Ma) is used in dating much older groundwaters and iodine source rocks from which CH_4 and gas hydrates are derived (Fehn et al. 2000). In addition, the I-Xe system was the first extinct nuclide system to be exploited for dating the early solar system (Hohenberg and Pravdivtseva 2008).

Summary

The halogen group of elements is defined by the ability of each halogen to form a halide ion, but their chemical properties and abundances combine to give each element a unique geochemical cycle. Fluorine is the most reactive halogen and its compatibility in a range of minerals result in a low solubility in aqueous fluids. The heavy halogens are strongly incompatible in the mantle and highly soluble in aqueous fluids. Chlorine is the dominant ligand enabling metal transport in geofluids. Bromine and iodine are trace constituents on Earth, iodine is redox sensitive, and both elements are involved in a number of biochemical pathways. As a result, organic-rich marine sediments are the dominant reservoir of iodine on Earth. Halogen stable and short-lived radiogenic isotopes have been widely applied in groundwater studies, and Cl isotopes, together with halogen abundance ratios, are being employed to investigate geochemical cycling of halogens.

Heat Capacity

Brian F. Woodfield
Department of Chemistry and Biochemistry, Brigham Young University, Provo, UT, USA

Definition

Heat capacity, or sometimes called the specific heat in a physics context, can be defined as

$$C \equiv Q/\Delta T$$

where C is the heat capacity of the material, Q is a known amount of heat put into a system, and ΔT is the resulting temperature rise.

Alternatively, you can think of the heat capacity as the amount of energy, or heat, required to raise the temperature of the material one degree Celsius. From this perspective, heat capacities may appear to be a rather uninteresting physical quantity; however, high-quality heat capacity measurements as a function of temperature play a key role in chemical thermodynamics and provide important insights to the intrinsic physical properties of a wide range of materials. Below we give a brief overview of the role heat capacities can play in chemical thermodynamics, the low temperature physics of materials, and outline how heat capacity measurements are performed.

Chemical Thermodynamics

In order to understand the central role heat capacities play in chemical thermodynamics, a brief review of chemical thermodynamics is necessary. The three foundational laws of thermodynamics can be written mathematically as ("Enthalpy," "Gibbs Energy," and "Entropy")

1. $\Delta U_{universe}=0$
2. $\Delta S_{Universe} \geq 0$
3. $S_{T=o} = 0$ for a perfectly ordered substance.

These laws can be described in words for a chemical or geologic process as (1) the energy content of the universe is constant; (2) for a chemical or geologic reaction to occur, the entropy of the universe must increase; and (3) at absolute zero, the entropy of a perfectly ordered substance is zero. The details and implications of these laws are described elsewhere, but they form the foundation of chemical thermodynamics. A more practical usage of these laws is to introduce the thermodynamic variable ΔG, which can be defined as ("Gibbs Energy" entry)

$$\Delta G = \Delta H - T\Delta S$$

where, for a process to occur, $\Delta G \leq 0$. The important principle to note here is that we can predict stability and the direction of chemical and geological processes by calculating ΔG, which is governed by the balance between enthalpic ("Enthalpy" entry) and entropic ("Entropy" entry) considerations. That is, the driving force for a chemical or geologic process can be described as the interplay between the change in enthalpy and change in entropy for the process. Details on measuring and using enthalpies are described elsewhere ("Enthalpy" entry), but heat capacities play a key role in calculating the entropy changes for reactions.

We show here how to calculate the entropy change for a reaction from the heat capacity. From the second law for a system at equilibrium, the change in entropy can be calculated using

$$\Delta S = \int_{T_1}^{T_2} \frac{q_{rev}}{T}$$

Since the vast majority of processes occur at constant pressure, we can apply the condition that $dH = q_p$ or the enthalpy is equal to the heat of the reaction. Substituting yields,

$$\Delta S = \int_{T_1}^{T_2} \frac{dH}{T}$$

We also note under the same conditions that the definition of the heat capacity can be written in differential form as

$$C_p \equiv q_p/dT = dH/dT$$

which can be rearranged to produce

$$dH = C_p dT$$

Substituting this into our equation for the change in entropy shows us how entropy changes can be calculated from the heat capacity,

$$\Delta S = \int_{T_1}^{T_2} \frac{C_p dT}{T}$$

Thus, the integral of C_P/T as a function of T provides a measure of the change in entropy of a material. However, we can apply the third law of thermodynamics to provide a much more useful relationship. If we change the lower limit of the integration to $T = 0$, we note that

$$\Delta S = \int_{0}^{T_2} \frac{C_p dT}{T} = S(T) - S(0)$$

From the third law, $S(0) = 0$; thus, we are able to calculate an absolute entropy from the heat capacity using

$$S(T) = \int_{0}^{T_2} \frac{C_p dT}{T}$$

This relationship implies that heat capacity measurements must extend from low temperatures near absolute zero up to the temperature of interest, usually 298.15 K or higher. From a practical standpoint, measurements should extend down to 10 K, and preferably even lower in temperature, where the heat capacity can be extrapolated to 0 K using theoretical functions. Thus, measuring the heat capacity of a material from low temperatures and over a wide temperature region allows us to calculate the absolute entropy for that material. These are often called third-law entropies and the measurements are often referred to as third-law calorimetry. Third-law entropies have been tabulated for a wide range of chemically and geologically relevant materials and can be found in various chemically and geologically focused databases.

Having absolute entropies, however, still does not provide us with a measure of the change in entropy for chemical reactions. A generic reaction can be represented by the following

$$a\mathrm{A} + b\mathrm{B} \rightarrow c\mathrm{C} + d\mathrm{D}$$

where A, B, C, and D represent reactants and products for the reaction and a, b, c, and d represent the stoichiometric coefficients. If the absolute entropies for A, B, C, and D have been measured, then the entropy change for the reaction, ΔS_{rxn}, can be calculated using this equation,

$$\Delta S_{rxn} = cS_C + dS_D - aS_A - bS_B$$

Thus, to know the free energy of a process, both the enthalpy and entropy of reaction must be known. In the vast majority of cases, the only route to obtaining the absolute entropies from which the change in entropy of a reaction can be calculated is through the accurate measurement of heat capacities from near absolute zero to above room temperature. While conceptually straightforward, accurate heat capacity measurements over such a wide temperature range are not trivial but play a vital role in understanding the thermodynamic driving forces in chemical geologic reactions. Later, we will give a basic overview of how these measurements are performed. More details on the role of heat capacities in chemical thermodynamics can be found in the excellent reference text, *Chemical Thermodynamics: Principles and Applications* by Ott and Boerio-Goates (2000).

Low Temperature Physics

In addition to chemical thermodynamics, heat capacity data can also play a key role in understanding the intrinsic properties of materials. The total heat capacity is a measure of all the energetic states of a material. Modeling the heat capacity data with theoretical functions provides a means with which to extract valuable information about the magnetic, electronic, and vibrational properties of a sample. Heat capacity data can cover a wide range in temperatures from milliKelvin to thousands of Kelvin, and the temperature dependence of the heat capacity depends on the energy states being thermally accessed. Thus, we often divide the heat capacity data into temperature regions and use different models or fitting expressions to fit the data. Analyzing heat capacity data to extract intrinsic properties comes down to fitting the data to the right function.

In the low temperature regime ($T < 15$ K), lattice vibrations are modeled by a function containing odd powers in temperature, which represents the harmonic oscillators:

$$C_{Lat} = \sum_{n=3,5,7,\ldots} B_n T^n$$

A linear dependence on T (denoted as γT) is traditionally associated with electronic contributions to the heat capacity, but for insulating materials this linear dependence is also due to oxygen vacancies and defects. Magnetic contributions can take on various forms depending on the nature of the magnetism, and for a system of noninteracting energy levels, a Schottky anomaly can occur. A simple two-level system has the form:

$$C_{Sch} = R\left(\frac{\theta}{T}\right)^2 \frac{g_0}{g_1} \frac{e^{\frac{\theta}{T}}}{\left(1 + \frac{g_0}{g_1} e^{\frac{\theta}{T}}\right)^2}$$

where R is the gas constant, θ is the energy separation of the two energy levels in Kelvin, and g_0 and g_1 are the degeneracies for the ground and first excited states, respectively. For interacting magnetic systems such as ferromagnets or antiferromagnets, the magnetic heat capacity has the form:

$$C_{mag} = M_n T^n$$

where M_n is the coefficient and the power n is typically 3/2 for ferromagnets and 3 for antiferromagnets, although more complicated magnetic systems can have different powers of n and there can be gaps in the magnon spectrum.

Data from 10 to 75 K is an intermediate temperature region where there are few theoretical functions that can adequately represent the heat capacity data. Traditionally in this temperature region, the data are fit to a polynomial function to provide sufficient overlap with the low temperature and high temperature fits and to smoothly fit the inflection point around 50 K. Fits are usually of the form:

$$C_{mid\ T} = \sum_{n=0,1,2\ldots6} A_n T^n$$

The high temperature data (T > 35 K) are fit to a sum of Debye and Einstein functions that provide information on the lattice-specific heat

$$C_{high\ T} = m \cdot D(\Theta_D/T) + n_1 \cdot E\left(\Theta_{E,1}/T\right) + n_2 \cdot E\left(\Theta_{E,2}/T\right)$$

where $D(\Theta_D/T)$, $E(\Theta_{E,1}/T)$, and $E(\Theta_{E,2}/T)$ are Debye and Einstein functions; m, n_1, n_2, Θ_D, $\Theta_{E,1}$, and $\Theta_{E,2}$ are all adjustable parameters; and $(m + n_1 + n_2)$ should be approximately equal to the number of atoms in the formula unit. Generally, one Debye and one Einstein function are sufficient to fit high temperature data, but occasionally an extra Einstein function is needed and a $aT + bT^2$ term is often added to account for the differences in C_V, the constant volume heat capacity, and C_p, the constant pressure heat capacity.

Fitting heat capacity data to combinations of these functions in these different temperature regions allows us to extract the intrinsic properties of the materials. Low temperature, where the lattice contribution becomes small, is a particularly useful region to extract the various contributions to the overall behavior of a material. The use of low temperature heat capacity data to understand a wide range of materials is still a useful and important experimental method to understand new and modern materials. An old but still useful reference to learn more about analyzing heat capacity data is

by Gopal (1966), and a few modern examples can be found in these references (Snow et al. 2010; Boerio-Goates et al. 2013; Schliesser et al. 2015; Schliesser and Woodfield 2015a, b).

Heat Capacity Measurements

For decades, high quality heat capacity data, meaning data with accuracies and precisions on the order of 0.1%, were performed using adiabatic or semi-adiabatic techniques. In these methods, large samples were required (10 g to 100 g) and the samples were loaded in calorimeters where an adiabatic environment was created around the samples and known amounts of heat were added followed by measurement of the resulting temperature changes. These methods were highly accurate but also very slow, requiring often one or two months to cover the temperature range from 5 K to 350 K. Few in the world are still using this technique, but details can be found in Gopal (1966).

For the most part, these adiabatic calorimeters have been replaced by commercial relaxation calorimeters such as the Quantum Design Physical Property Measurement System (PPMS) that use a thermal relaxation technique. While these instruments are not as accurate, they are much easier to use and a full set of data can be collected automatically in a matter of days or a week. These instruments are convenient, but a sound knowledge of heat flow and how to properly mount samples is still needed in addition to learning how to properly analyze the data.

The relaxation method is based on adding a pulse of heat to the sample/sample platform and then measuring the temperature relaxation curve as the sample temperature relaxes back to the bath temperature. An analysis of the relaxation curve reveals the time constant, τ_1, from which the heat capacity can be calculated using the following equation:

$$C = \kappa \cdot \tau_1$$

where κ is a measure of the thermal conductivity between the sample and the bath. The standard PPMS instrument, as of this writing, can easily cover 1.9 K to 300 K and various options can extend the range to milliKelvin and to 400 K. Measurements in magnetic fields are also possible. More details on proper measurement techniques for a range of sample types can be found in these references (Shi et al. 2010, 2011).

Conclusion

Heat capacity data provide a fundamental gateway to understanding solid materials. Heat capacity measurements down to near absolute zero can be integrated to provide absolute entropies, and high quality heat capacity measurements over a wide temperature interval can be represented with theoretical models to reveal intrinsic properties.

Heat-Producing Elements (HPEs)

Hugh StC O'Neill
Research School of Earth Sciences, Australian National University, Acton, Australia

Definition

The heat-producing elements are thorium, uranium, and potassium, which are those elements having radioactive isotopes with abundances and activities that are sufficient to produce geologically significant amounts of radiogenic heat.

Radiogenic Heat Production

In the early solar system, the decay of ^{26}Al, with a half-life of 0.74 Ma, supplied the heat to metamorphose the small planetesimals that accreted from the solar nebula and partially melt larger planetesimals and planetary embryos formed during the initial stages of assembling rocky planets. Another long-extinct radionuclide, ^{60}Fe, with a half-life of 1.5 Ma, was once suggested as an additional heat source, but recent measurements on primitive meteorites indicate that its concentration in the early solar system was too low to matter (e.g., Tang and Dauphas 2012). Today, only four radionuclides (^{40}K, ^{232}Th, ^{235}U, and ^{238}U) have high enough abundances in the solar system combined with sufficient rates of decay to produce significant heat. The radiogenic heat production of a rock or a geochemical reservoir is the sum of the contributions from each of these four isotopes. At time Δt from the present, the radiogenic power (rate of heat production) per unit mass is:

$$Q_R = \Sigma H_{A_M} f_{A_M} [M] \exp\left(\frac{0.693\,\Delta t}{t_{1/2}^{A_M}}\right) \quad (1)$$

where ^{A}M is the isotope A of element M, H_{A_M} is the net energy per unit mass of ^{A}M retained in the Earth (i.e., excluding the energy of beta decays carried off as antineutrinos and neutrinos), f_{A_M} is the isotopic fraction, [M] is the concentration of the element by mass, and $t_{1/2}^{A_M}$ is the half-life of ^{A}M (Table 1).

Serendipitously for geochemists, the three elements involved, namely K, Th, and U, share rather similar chemical properties in the context of global differentiation processes. This is not surprising for Th and U, which are next-nearest neighbors in the actinide series of the periodic table, but the similarity of K with Th and U is more of a felicitous happenstance. As a result of this geochemical coherence, Th/U and K/U in the major geochemical reservoirs of the Earth are thought to be close to their Bulk Silicate Earth (BSE) values. Moreover, to a first approximation, these ratios are also typical of the averages found in many of the common rock types, such as peridotites, basalts, granitoids, and many sediments. Hence, knowing the concentration in a reservoir or even a rock of one of the HPEs is often a good clue to the concentrations of the other two. A more nuanced insight into the distribution of the HPEs in geochemical reservoirs is afforded by the geochemical study of the daughter products of their decay. The stable daughter products of the decay of ^{232}Th, ^{235}U, and ^{238}U are isotopes of Pb plus ^{4}He, while ^{40}K decays in part to another noble gas, ^{40}Ar (Table 2). Other noble-gas isotopes are also produced by nuclear reactions involving U and Th, with particularly ^{21}Ne and the heavy Xe isotopes produced in amounts that are significant to noble-gas geochemistry, although not to heat production. Thus, much may be inferred about the concentrations and distributions of the HPEs in the Earth from Pb isotope geochemistry (e.g., Galer and O'Nions 1985), supplemented by insights from noble gas geochemistry.

Concentrations of Th, U, and K in the Bulk Silicate Earth

The BSE concentrations of Th, U, and K determine the Earth's radiogenic heat production. For Th and U, estimating their BSE concentrations has relied on a cosmochemical argument. Both Th and U are "refractory lithophile elements" (RLEs), a cosmochemically defined group comprising 28 elements, including the major elements Ca and Al, which occur in the same ratios relative to each other in all bulk analyses of chondritic (undifferentiated) meteorites. These ratios are thought to be those of the solar system as a whole, because they appear to be the same within experimental uncertainty as in the solar composition, as derived from modeling spectroscopic measurements of the solar photosphere; but the uncertainty in the solar composition is large for many elements, and for Th and U, spectroscopic measurements are not available. One small group of chondrites, the CI carbonaceous chondrites, appear to match the solar composition in their abundances of nearly all elements except the most volatile and have become the traditional proxy for the solar composition. Chemically, the RLEs are defined by two properties: they are refractory, in that they condense from a gas of solar composition at temperatures higher than the main constituents of rocky planets, the magnesium silicates and iron metal; and they are lithophile, because they do not enter metal or sulfide phases in most chondrites (enstatite chondrites excepted), nor

[a]Ocean floor basalt (*OFB*) is a general term for all the types of basalt making up the oceanic crust, predominantly mid-ocean ridge basalt but also basalt from back-arc basins, seamounts, etc.
[b]From the parental ocean floor basalt, assuming the latter is produced by 20% partial melting
[c]The "convecting mantle" is taken as the bulk silicate earth, less the continental crust and subcontinental lithospheric mantle

partition into the metallic cores formed during planetary differentiation. Iron meteorites are likely samples of some such cores from small planetary bodies. Until recently it has been almost universally assumed that the chondritic (that is, by inference, solar) ratios among the RLEs were preserved during accretion of the Earth. With this assumption, estimating the BSE concentrations of Ca and/or Al relative to Mg, Si, and Fe is all that is required to deduce Th and U abundances in the BSE. An estimate of the ratio of the RLEs to Mg, normalized to the CI-chondrite abundances, denoted $(RLE/Mg)_{CI}$, is 1.21 ± 0.10, implying 85 ng g^{-1} Th and 22 ng g^{-1} U (Palme and O'Neill 2014). Evaluations of Pb isotope systematics in the Earth as a whole (e.g., Galer and Goldstein 1996) are broadly consistent with the BSE having the chondritic Th/U ratio of 3.9 (Blichert-Toft et al. 2010), but the Th/U ratio in the sub-oceanic upper mantle, as sampled by mid-ocean ridge and related basalts, is lower, at ~2.5, compensated for by elevated Th/U in the continental crust (Huang et al. 2013). The differentiation of Th and U between crust and mantle is thought to be related to the oxidation of U^{4+} to water-soluble U^{6+} in the surface environment of the Earth, causing U to be recycled preferentially over Th back into the mantle, a process only possible after the rise in atmospheric oxygen at ~2.4 Ga (Andersen et al. 2015).

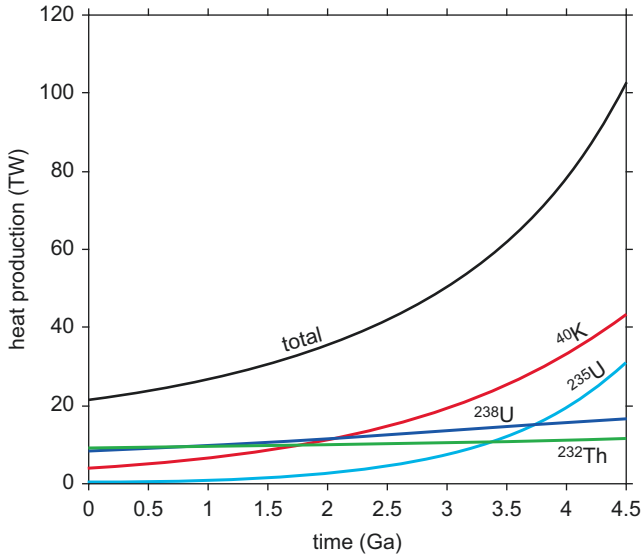
Potassium is not a RLE: it is calculated to condense from a gas of solar nebula composition at lower temperatures than the main elements that form rocky planets (Mg, Si, and Fe), defining it as a moderately volatile element. Therefore, its BSE concentration has to be estimated empirically, traditionally by invoking the geochemical similarity with U and averaging observed K/U ratios in oceanic basalts and representative crustal rocks. A more detailed appraisal of element ratios reveals that K is intermediate in its behavior between U and La, another RLE, such that K/(U + 0.03La) makes a better estimator than either K/U or K/La alone. In terrestrial basalts, K/(U + 0.03La) averages about 6000, implying K = 260 μg g^{-1}, and a depletion factor relative to the CI-chondrites and Mg, denoted $(K/Mg)_{CI}$, of 0.20. This depletion factor is similar to those of other elements of comparable cosmochemical volatility, whether these have similar chemical properties like other alkali metals (Na, Rb) or very different properties like boron or fluorine. This argues against there being much K in the Earth's core, a possibility that is sometimes suggested in order to account for the energy powering the core's geodynamo. Likewise, Th-U-Pb isotope systematics may not preclude a small fraction of U in the core (e.g., Wohlers and Wood 2015), but they do suggest it would be almost insignificant. Most elements can be metallized under sufficiently extreme conditions (low oxygen potentials and/or high sulfur potentials and/or high pressures). Finding conditions where K or U partition into Fe-rich metal is necessary to show that they could partition into a planet's core, but it is not sufficient to show that they did partition into the Earth's core. That requires comparing the siderophile tendencies of K or U with those of other elements at equivalent conditions and balancing these tendencies against estimates of their depletion factors in the BSE.

Due to their different accretion histories, other rocky bodies in the solar system may be expected to have different concentrations of the HPEs. The enrichment of RLEs (hence Th and U) relative to Mg and Si is difficult to evaluate, because of the lack of samples from the mantles of any

differentiated planet other than the Earth. By contrast, the depletion of K may be estimated, as on Earth, from basalts. For example, the bulk Moon K/U evaluated from the returned samples from the Moon is approximately five times lower than the average terrestrial ratio (O'Neill 1991), whereas values of K/U in basaltic meteorites from Mars (shergottites) are broadly similar to terrestrial values. K/Th and/or K/U in surface materials are mappable on the planetary scale by orbital gamma-ray spectrometry, but deducing bulk planetary values from such measurements is fraught with difficulty, particularly where surfaces are affected by weathering. Overall, the surfaces of Mars and Mercury have K/Th that are Earth-like rather than Moon-like (Peplowski et al. 2012) and likewise for Venus, from the limited data obtained by the landing missions (Surkov et al. 1987).

The Earth's Heat Budget

The heat production in the BSE from its estimated abundances of K, Th, and U is shown in Fig. 1, for time from the present back to 4.5 Ga, the approximate age of the Earth. Currently, radiogenic heat production from the abundances of Th and U of the "chondritic RLE" model with estimated K as discussed in the previous section is 21.5 ± 3 TW, which is less than half of the global heat flux of 47 TW (Davies and Davies 2010), whose uncertainty is estimated as ± 1 TW, one standard deviation. The difference of 25.5 ± 3 TW principally comes from secular cooling of the mantle and the heat flux out of the core, which, assuming that the concentration of HPEs in the core is negligible, is mediated by the crystallization of the inner core. Because the uncertainties in the values of the various components of the thermal budget of the Earth are highly model-dependent, and have a large covariance, they cannot be quoted satisfactorily as single values; hence, this discussion will omit uncertainties, and focus on average values, given to the nearest 0.5 TW.



Heat-Producing Elements (HPEs), Fig. 1 Radiogenic heat production in the bulk silicate Earth (*BSE*) with time, with concentrations of the heat-producing elements estimated from the chondritic refractory lithophile element model (260 μg g^{-1} K, 85 ng g^{-1} Th, and 22 ng g^{-1} U)

The heat flux out of the core is not well known; one appraisal suggests anything from 5 to 15 TW may be reasonable (Lay et al. 2008). Recent modeling has tended to favor the higher estimate (Olson et al. 2015), which represents a fundamental change in the understanding of the Earth's heat budget. Previously, the heat flux from the core was thought to be only ~3 to 5 TW, inferred from the global buoyancy flux associated with large mantle plumes at Earth's surface (e.g., Davies 1999). However, it is now argued that the buoyancy flux of plumes is ~3 times larger in the lower mantle (e.g., Bunge 2005), while additional input from the core, as postulated by the more recent models, could be transferred into the mantle by warming of subducted lithosphere that has descended to the base of the mantle or by smaller scale plumes that do not make it to the Earth's surface.

A large fraction of the HPEs in the BSE is in the continental crust, especially the uppermost part of it. In many areas, surface heat flow measurements vary linearly with the local radiogenic heat production in the surface rocks, which is consistent with a broadly exponential decrease of the concentrations of HPEs with depth (Schubert et al. 2001). A detailed inventory of K, Th, and U in crustal rocks has been made by Huang et al. (2013), using an observational approach that is independent of what BSE model is assumed. The average concentrations of crustal reservoirs are summarized in Table 2. Given the chondritic-RLE-ratio model of the BSE, the BSE fractions of the HPEs in the continental crust would be about 30%, with another ~3% in the subcontinental lithospheric mantle (Huang et al. 2013), together producing 7.5 TW of radiogenic heat. Subtracting this value from the total BSE production of 21.5 TW implies 14 TW of radiogenic heat from the rest of the mantle - that is, the convecting mantle plus any isolated mantle reservoirs, should these exist. A dense, negatively buoyant layer above the core-mantle boundary corresponding to the D″ layer of seismology might be an example of the latter. As the total heat flux out of the continental crust is 15 TW (Davies and Davies 2010), the flux from the convecting mantle into the continental lithosphere is 8 TW.

Subtracting the radiogenic heat production of the continental crust (7 TW) from the global heat flux (47 TW) gives the heat flux out of the mantle as 40 TW, while the radiogenic heat production of the total mantle less the subcontinental lithosphere is 14 TW. The ratio of these latter numbers, known as the mantle Urey ratio, is therefore 0.35. While the Urey ratio is often stated to be a key constraint for thermal evolution models, it does not take into account the heat flux

into the mantle from the core. If the input from the core is 15 TW, subtracting this and the internal radiogenic heating of 14 TW from the output of 40 TW gives a deficit of 11 TW, to be supplied by secular cooling. The average specific heat capacity of mantle material, estimated from the heat capacities of mantle minerals (Holland and Powell 2011), is 1300 J K^{-1} kg^{-1}, giving a total heat capacity of the mantle of 5×10^{27} J K^{-1}. As other contributions to the heat budget, like the energy from thermal contraction, are more-or-less irrelevant (Jaupart et al. 2007), present-day secular cooling is therefore 0.07 K per Ma. In the unlikely but conceptually useful scenario in which all factors apart from the increase in the radiogenic heat production (Eq. 1) have not changed over geological time, heat loss would have balanced radiogenic heat production at 2.3 Ga, when the mantle would have been 100 K hotter (calculated by integration of Eq. 1). In actuality, the mantle in the past may have had higher concentrations of the HPEs if the continental crust were smaller or less enriched in its composition, or both, while fluid-dynamic scaling laws suggest that a hotter mantle would have lost heat faster through more vigorous convection.

This discussion of the Earth's thermal budget has rested on the assumption that the BSE has chondritic relative abundances of the RLEs. This assumption has recently come under reexamination (e.g., Campbell and O'Neill 2012), prompted by advances in modeling how the terrestrial planets may have accreted (O'Neill and Palme 2008). Chondritic meteorites may not be a faithful guide to the composition of the Earth. They come from undifferentiated parent bodies, which were too small to have been melted by ^{26}Al heating or other means. Such small bodies are the left-overs from the earliest stages of accretion; by definition, they escaped the subsequent processing by collisions and mergers undergone by the material that formed the terrestrial planets. If, at any stage of the accretion process, crust from previous melting and differentiation events was preferentially eroded from the ensemble of planet-forming bodies and lost, the final composition of the planet would be depleted in the incompatible elements, like the HPEs, that are concentrated into crusts. For the Earth, the Moon-forming impact may have been the last significant collisional erosion event. The upper limit to the extent by which the Earth could have been depleted in K by this process is given by the amount of radiogenic ^{40}Ar in the Earth's atmosphere, which corresponds to 120 ppm K in the BSE; allowing for some undegassed ^{40}Ar in crustal reservoirs, this means that the BSE could be depleted in K by ~ 50%. Given the geochemical coherence of Th and U with K during crust formation, the upper limit to Th and U depletions relative to Ca and Al should be similar. This kind of nonchondritic BSE composition would resolve several paradoxes raised by the chondritic-RLE model (O'Neill and Palme 2008; Campbell and O'Neill 2012). For example, the lower Th and U concentrations might explain why the flux of radiogenic ^{4}He from the mantle is much less than the heat flow expected of the chondritic-RLE model (O'Nions and Oxburgh 1983; Bianchi et al. 2010). The extreme nonchondritic composition (corresponding to a 50% depletion in K, Th, and U over the chondritic-RLE model) requires a mass balance in which the convecting mantle would constitute $>$ 90% of the whole mantle. The proportion of the BSE inventory of the HPEs extracted into the continental crust would be ~60%, and the radiogenic heat production in the mantle would be only 3 TW (Table 2). Such low radiogenic heat production might seem to pose a challenge to thermal evolution models, but one that can be addressed (e.g., Jellinek and Jackson 2015).

Eventually, the concentrations and distributions of the HPEs in the Earth may be constrained observationally from the study of "geoneutrinos" (e.g., Dye 2012; Gando et al. 2013; Huang et al. 2013), which are the detectable antineutrinos produced by the beta decays in the decay chains of ^{232}Th and ^{238}U.

Summary and Conclusions

Ragiogenic heat in the Earth is produced by three elements, K, Th, and U, which share somewhat similar geochemical properties in the context of global differentiation processes. Estimates of the abundances of K, Th, and U in the continental crust imply radiogenic heat production that almost matches heat loss, but models of the composition of the Bulk Silicate Earth based on solar-system abundances and analogies with chondritic meteorites give abundances of K, Th, and U that account for just less than half of the heat currently being lost from the solid Earth. Alternative nonchondritic models suggest lower abundances and even less radiogenic heat. The difference is made up by cooling of the mantle and heat from the Earth's core, evaluating the details of which are central to the understanding of Earth's global geodynamics, both present and past.

Element Data

Atomic Symbol: He
Atomic Number: 2
Atomic Weight: 4.002602
Isotopes and Abundances: ^{3}He, ^{4}He, ^{5}He, ^{6}He, ^{7}He, ^{8}He, ^{9}He, ^{10}He
^{3}He $1 \times 10^{-9} \sim 1 \times 10^{-5}$
^{4}He 0.999999999 ~ 0.99999
^{5}He, ^{6}He, ^{7}He, ^{8}He, ^{9}He, ^{10}He not stable
1 Atm Melting Point: 1.15 K
1 Atm Boiling Point: 4.22 K
Common Valences: 0
Ionic Radii: 140 pm
Pauling Electronegativity: 0
First Ionization Energy: 2370 KJ/mol
Chondritic (CI) Abundance: $2.72 \times 10^{9}/10^{6}$ silicon
Silicate Earth Abundance: $6–7 \times 10^{16}$ mol
Crustal Abundance: 3.4×10^{16} mol
Seawater Abundance: 2.3×10^{12} mol
Core Abundance: not available

Properties

Helium belongs to Group 18 of the periodic table of chemical elements: "noble gas" or "rare gas" element. Its electron shell configuration is $1s^2$, meaning that the s sub-shell is

occupied by two electrons, which produces a chemically closed shell. The first ionization potential is the highest of all elements, with the value of 24.587 eV. Consequently, helium does not combine easily with other elements. No known chemical compound contains helium at standard temperature and pressure. Helium is a considerably mobile element. It even permeates a normal Pyrex glass wall quickly because it is extremely small (1.86×10^{-10} m). Therefore, care should be taken when a natural helium sample is stored in a glass bottle for a long time (Sano and Fischer 2013). Helium has eight isotopes: ^{3}He, ^{4}He, ^{5}He, ^{6}He, ^{7}He, ^{8}He, ^{9}He, and ^{10}He. Among them, the six heavier isotopes (^{5}He, ^{6}He, ^{7}He, ^{8}He, ^{9}He, and ^{10}He) are radioactive, with short half-lives from 7.6×10^{-22} s to 801 ms (Audi et al. 2012). They are not naturally occurring. The two lighter isotopes, ^{3}He and ^{4}He are physically stable, with atomic masses of 3.0160293 and 4.00260325, respectively (Audi et al. 2012). In terrestrial helium samples, the abundance of ^{4}He dominates that of ^{3}He: the isotopic ratio (^{3}He/^{4}He) is 10^{-9}–10^{-5} (Mamyrin and Tolstkhin 1984). Rock and fluid samples from volcanic regions such as hot spot and mid-ocean ridge show higher ^{3}He/^{4}He ratios than air value of 1.38×10^{-6}, while those from continental and oceanic crust indicate lower ratios. There is a clear relationship between geotectonic setting and helium isotopes, because ^{3}He is the only unambiguous mantled derived component (Mamyrin and Tolstkhin 1984). Details of isotopic ratios are given in the section of helium isotopes. The properties of elemental helium mostly derive from ^{4}He. For example, the atomic weight is 4.002602±2, equivalent to the ^{4}He mass. The liquid density and boiling point of helium are, respectively, 120 kg/m^3 and 4.22 K. The gas density is 0.176 kg/m^3 at 101,325 Pa and 273.15 K, the lightest value after molecular hydrogen.

History and Use

Helium is an element of gas at room temperature, colorless, odorless, and non-toxic, and is completely unreactive. Its name derives from "helios" the Greek god of the sun because the element was first detected in solar spectral lines of the suns corona during an eclipse in 1868 by Janssen. On Earth, helium was discovered by Ramsay in 1895 in spectral lines of gases extracted from the mineral cleveite (impure uraninite). Contemporaneously, Cleve and Langer found helium similarly in Sweden and attempted to measure its atomic weight. The existence of terrestrial helium was subsequently confirmed using a spectroscopic method (Crookes 1895). Commercial production of helium gas has been conducted at natural gas wells in Texas, Oklahoma, Kansas, New Mexico, and Montana in the USA. It is used in industry for cryogenic purposes, welding, and space missions in addition to heat transfer in nuclear reactors and as a carrier gas of instruments such as gas chromatographs. Its total production rate was 7.6×10^{9} mol/year in 2006 (US Geological Survey 2009). This value is 10 times greater than the natural crustal degassing rate of 6.1×10^{8} mol/year (Ozima and Podosek 2002), suggesting that there are likely to be anthropogenic sources of helium in the atmosphere.

Geochemical Behavior

Helium is the most abundant element in the universe (approximately 24.0% in weight fraction) after hydrogen (73.9%). Hydrogen and helium are believed to have been produced by nucleosynthesis shortly after the Big Bang. Other elements might be generated by stellar processes and are called "metals" in astronomy. Helium abundance in the solar system is 2.72×10^{9} relative to 10^{6} silicon atoms. Again, it is second largest to hydrogen, 2.79×10^{10} (Anders and Grevesse 1989). Helium is scarce in the terrestrial atmosphere, with abundance of 5.24 ppm (Gluckauf 1946), although it is a member of "atmophile" elements by the Goldschmidt definition because helium is released from the upper atmosphere to interplanetary space by thermal and/or nonthermal escape at the rate of 8.3×10^{8} mol/year (Ozima and Podosek 2002). That figure contrasts markedly to the argon abundance in air, 0.924%. Argon is not rare; it is trapped by Earth's gravity while both helium and argon have radiogenic nuclides as dominant isotopes in the crust and mantle. An approximate balance might prevail between the degassing flux of helium from solid Earth to the air and escape from the atmosphere to space. The typical concentration of helium in surface seawater is 1.7 nmol/kg, which is governed by the solubility equilibrium between air and seawater at 14.4 °C (Sano and Takahata 2006). The total inventory of helium is 2.3×10^{12} mol in oceans, which is two orders of magnitude smaller than that of atmosphere, 9.3×10^{14} mol. The total inventory of helium in the crust is 3.4×10^{16} mol based on the hypothetical contents of 1.3×10^{-6} mol/kg in typical rock (Mamyrin and Tolstikhin 1984). Although the whole mantle inventory is not well documented, it is probably similar to the crust because the average contents of U and Th are two orders of magnitude smaller and its mass is two orders larger. Therefore, the silicate Earth inventory of helium is much greater than that in the atmosphere or oceans.

Biological Utilization and Toxicity

There is no biological utilization of helium. It is totally nontoxic.

Summary

Helium is a member of atmophile elements, enriched in gas phase such as atmosphere, natural gas, and volcanic gas. It is chemically inert, colorless, and odorless. It is rare in the Earth but has become an important geochemical tracer since it is widely considered to be the only unambiguous mantled derived component with high $^3He/^4He$ ratio.

Definition

Stable isotopic ratio of helium ($^3He/^4He$).

Variations in He Isotope Ratios

Helium has two stable isotopes: ^3He and ^4He. Both isotopes were produced by nucleo-synthesis in the very early universe about 100 s after the Big Bang, possibly because of the fusion of deuterium (D) as shown below.

$$D + D \rightarrow {}^3He + n.$$
$$D + D \rightarrow {}^4He + \gamma.$$
$$T + D \rightarrow {}^4He + n.$$
$${}^3He + n \rightarrow {}^4He + \gamma.$$
$${}^3He + D \rightarrow {}^4He + p.$$

In those expressions, n, γ, T, and p, respectively, denote neutron, γ ray, tritium (^3H), and proton. The helium isotopic ratio ($^3He/^4He$) has been calculated approximately 8×10^{-5} (Burles et al. 1999) because the ^4He nucleus is much more stable than that of ^3He. The ratio has evolved through stellar processes. Both ^3He and ^4He are produced by a proton–proton chain reaction occurring deep in stars like the Sun with high pressure and temperature as follows.

$$p + p \rightarrow D + \beta^+ + \nu.$$
$$D + p \rightarrow {}^3He + \gamma.$$
$${}^3He + {}^3He \rightarrow {}^4He + 2\,p.$$

Therein, β^+ and ν, respectively, denote positron and neutrino. The best estimate of the $^3He/^4He$ ratio for the present-day outer convective zone of the Sun is 3.8×10^{-4} based on Apollo experiments and spacecraft observations (Geiss and Gloeckler 1988). However, planetary helium identified in Q phase (acid-resistant residues) of primitive carbonaceous

chondrite showed the $^3He/^4He$ ratio of 1.6×10^{-4} (Wieler et al. 1992), which is markedly lower than the solar value, but appreciably larger than the early universe, even though the origin has not been well understood. Probably planetary helium is more primitive than solar helium because the latter has evolved by a proton–proton chain reaction since the early solar system time: 4.6 Ga. Helium isotopes of different reservoirs are presented in Fig. 1.

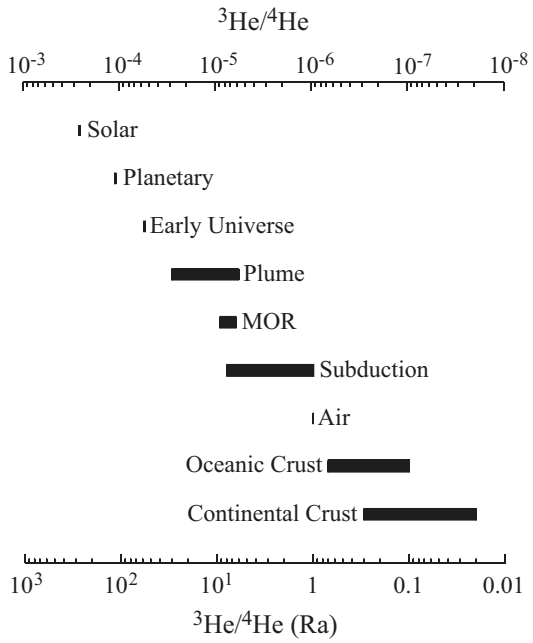
Within solid Earth as well as meteorites, ^4He is produced by radioactive decay of U and Th in the samples. The relevant decays are summarized as follows.

$$^{232}Th \rightarrow {}^{208}Pb + 6\,{}^4He + 4\,\beta^-.$$
$$^{238}U \rightarrow {}^{206}Pb + 8\,{}^4He + 6\,\beta^-.$$
$$^{235}U \rightarrow {}^{207}Pb + 7\,{}^4He + 4\,\beta^-.$$

In those expressions, β^- is an electron. Subject to the decay chains of ^{232}Th, ^{238}U, and ^{235}U series isotopes, the growth rate of ^4He in silicate rock is approximated by concentrations of U and Th as shown below.

$$J = 0.2355 \times 10^{-12}\,(U) \times [1 + 0.123(Th/U - 4)].$$

Therein, J, (U), and Th/U denote the ^4He growth rate in units of cm^3/g per year, the concentration of U in parts per million, and the concentration ratio of Th to U in weight. Typical crustal rock of 1 kg mass with U = 3 ppm and Th = 12 ppm produces 3×10^{-14} mol of ^4He per year.



Helium Isotopes, Fig. 1 Helium isotopes of different reservoir in geochemistry and cosmochemistry. There are two ways to express the $^3He/^4He$ ratio, absolute one (*top*) and relative to air value of 1.382×10^{-6} (*bottom*)

Considering the blank level of helium analytical system, it might be possible to date the rock and minerals at several hundred ka by U, Th-^4He dating method if the closed system has been maintained, the initial magmatic and air helium is negligible, and the U and Th contents are measured precisely.

On Earth, helium-3 was first found in natural gas helium by Alvarez and Cornog (1939) using a 60-in cyclotron as a mass spectrograph. Aldrich and Nier (1948) measured the $^3He/^4He$ ratios of the atmosphere, natural gas wells, and several minerals using a helium gas extraction and purification system and a single focusing gas mass spectrometer. They reported that the $^3He/^4He$ ratio of air is about 10 times larger than that of natural gas because of radiogenic helium. Clarke et al. (1969) measured the $^3He/^4He$ ratios of deep Pacific water and found elevated ratios relative to the air. They attributed the excess helium-3 to the terrestrial primordial (planetary) helium derived from the mantle by submarine volcanism. Mamyrin et al. (1969) measured the $^3He/^4He$ ratios of volcanic gases using a magnetic resonance mass spectrometer. They claimed that the high $^3He/^4He$ ratios were derived from the deep Earth, a discovery that was made independently from that by Clarke et al. (1969).

Terrestrial Helium Reservoir

Since the first findings of primordial helium in 1969, many helium isotope data have been reported (Mamyrin and Tolstikhin 1984; Ozima and Podosek 2002). This wealth of data is attributable to the wider use of commercial gas mass spectrometers available since 1980. Based on the helium isotope data, three major reservoirs of terrestrial helium have been inferred: those of the atmosphere, mantle, and crust. Each is described below:

Atmospheric helium: mean residence time of helium in the air is approximately 10^6 years, as estimated from the degassing rate from the solid Earth and the total inventory (Ozima and Podosek 2002). Atmospheric $^3He/^4He$ ratio had been believed to be a constant because the residence time is much longer than the mixing time of air, which is a few years. This idea was inspired by Mamyrin et al. (1970) who measured various air $^3He/^4He$ ratios and reported that the ratio did not vary with latitude, longitude, and altitude (up to 10 km) within error of 2–3%. On this basis, most laboratories engaged in helium isotope measurements have used atmospheric helium as a natural isotopic standard. Sano et al. (1989) measured the $^3He/^4He$ ratios of 20 air samples at several different sampling sites and dates. A change of the atmospheric helium isotope ratio possibly occurred with time: a decrease in $^3He/^4He$ of about 0.74%/year. Although this change might be attributed to the local effects or experimental artifacts, the observations were also consistent with a significant anthropogenic release of crustal He with a low $^3He/^4He$ ratio. Since then, contradictory results have been published in the literature, indicating either a decrease in the $^3He/^4He$ ratio

of the order of 0.1–0.3‰/year during the last few decades or no detectable change since 1973. Very recently, Mabry et al. (2015) reported no significant temporal decrease of the $^3He/^4He$ ratio (0.010 ± 0.033‰/year) during 1978–2011 using a selection of air samples archived in Tasmania. Then atmospheric helium is expected to be homogeneous and a reliable natural standard such as nitrogen. There are four absolute $^3He/^4He$ measurements of atmospheric helium. The average of these measurements, when considering their weighted errors, becomes $(1.382 \pm 0.005) \times 10^{-6}$ (1σ), which is likely to be the best estimate of the atmospheric helium isotopic composition (this value is defined as Ra).

Mantle helium: at first, it was well documented that the $^3He/^4He$ ratio of hundreds mid-ocean ridge basalt (MORB) glass is constant with a value of 6.5–9.5 Ra (where Ra is atmospheric ratio as described above), irrespective of the three different divergent plate boundary systems of the Mid-Atlantic Ridge, East Pacific Rise, and Central Indian Ridge (Graham 2002). The $^3He/^4He$ ratios of submarine hydrothermal fluids do not vary significantly from 7.2 to 9.2 Ra with an average of 8.1 ± 0.5 Ra (1σ) in MOR-volcanism, which is identical to that of the worldwide average of MORB glass (Sano and Fischer 2013). Therefore, the upper mantle above 670 km depth is characterized by a globally constant $^3He/^4He$ ratio of 8.0 ± 1.5 Ra, which suggests that either the $^3He/(U + Th)$ ratio is constant within the upper mantle during the most recent 1 Gyr or the mixing of helium is sufficiently rapid to reduce local heterogeneity (helium isotope anomaly) in the convective mantle. This most important reservoir of primordial helium is defined as MOR-type helium. Another distinctive reservoir results from a large deep component with $^3He/^4He$ ratios significantly higher than 9.5 Ra, probably related to the mantle under 670 km depth. These high ratios were found in active volcanism, occurring within the plate interiors such as Hawaii (ca. 16.6 Ra in Loihi seamount) and Yellowstone (ca. 15.8 Ra in Mud Volcano) in the USA. They are commonly called hot spots, although it is fed anomalously by hot mantle compared with the ambient asthenosphere and possibly originated in the lower mantle. In this context, Iceland is also regarded as a hot spot because of its huge volcanic output, even though it is located on the Mid-Atlantic Ridge. The terrestrial highest $^3He/^4He$ ratio of the fluid sample reached 29 Ra in northwestern Iceland. Seismic tomograms of these three hot spot regions suggest that a continuous low-velocity anomaly has been imaged from the surface to the lower mantle or the core-mantle boundary. The other hot spot regions such as Afar, Azores, Canary Islands, Cape Verde, Galapagos, and Reunion showed the $^3He/^4He$ ratios higher than MOR-type helium. These values higher than 9.5 Ra are defined as plume-type helium (Sano and Fischer 2013). In contrast, some other hot spot regions such as Socorro Island and Cameroon showed values equal to or lower than MOR-type helium. These $^3He/^4He$ ratios might be affected by crustal or radiogenic helium with low $^3He/^4He$ ratios in the source magma or subsurface regions. A third group of helium isotopes higher than the atmosphere was found in hundreds of volcanic rock and fluid samples in subduction zones such as Alaska, the Aleutians, Kamchatka, northeastern Japan, Mariana, the Philippines, Banda, Java, the Solomons, Chile, Ecuador, Colombia, Mexico, and the Cascades in the USA (Hilton et al. 2002). They vary significantly from less than 1Ra to 8Ra, where the lower ratios are probably affected by crustal or radiogenic helium. These geographical variations are related to the tectonic setting of the sampling site, whereas the temporal variations might be attributable to volcanic and seismic activity of the regions (Sano and Fischer 2013). The highest $^3He/^4He$ ratio in a subduction zone is consistent with MOR-type helium, suggesting their origin from the upper mantle. The average of the maximum $^3He/^4He$ ratio of 7.4 ± 1.3 Ra (1σ) is defined as subduction-type helium.

Crustal helium: The $^3He/^4He$ ratio of natural gases in the USA showed approximately 0.1 Ra by early measurements of terrestrial helium isotopes (Aldrich and Nier 1948). To explain the 0.1 Ra value, Morrison and Pine (1955) reported that the crustal production of ^3He in the continental crust is accounted for by successive nuclear reactions: $^6Li\ (n, \alpha)\ ^3H\ (\beta^-)\ ^3He$ where the source of n is reactions between α-particles derived from U and Th decay and light elements such as oxygen and silicon in crustal silicate rocks by $^{18}O(\alpha, n)^{21}Ne$ and $^{29}Si(\alpha, n)^{32}S$. Therefore, the in situ radiogenic $^3He/^4He$ ratio depends on the contents of U, Th, Li, and other light elements such as O, Si, Al, and K. The theoretical $^3He/^4He$ ratio was calculated as shown below

$$\frac{^3He}{^4He} = (n_f + n_a) \times P_t \times \frac{\sigma_{Li} N_{Li}}{\sum_i \sigma_i N_i}$$

In that equation, n_f is the ratio of neutrons produced by the spontaneous fission of ^{238}U and other heavy nuclides to α particles produced by U and Th decay, which is approximately 8×10^{-8}. Also, n_a is the ratio of neutrons to a particles produced by (α, n) reactions with light elements. P_t is the probability that a neutron will reach thermal energy. N_i is the number of atoms of the element (i) in a 1 g sample, and σ_i is the thermal neutron capture cross section of element (i). In fact, n_a is expressed as the following

$$n_a = \frac{\sum_k q_k S_k N_k}{\sum_i S_i N_i}$$

Therein, q_k is the neutron yield produced by a particle in a thick target composed of the element (k); S_k is the relative stopping power of the element (k). The $^3He/^4He$ ratio calculated for typical sedimentary material was approximately 0.015 Ra based on the equations above, which is significantly

lower than the observed natural gases. This extremely low value is defined as radiogenic helium. Crustal rock and fluid samples are principally admixtures of the radiogenic and primordial helium derived from the upper or the lower mantle (Mamyrin and Tolstikhin 1984). A weak positive correlation exists between the $^3He/^4He$ ratios of fluid samples in continental crust and the formation age of the region. This correlation is explained by the *in grow* production of radiogenic helium in addition to initial magmatic helium (mantle derived one either MOR-type or plume-type) in a crustal rock, i.e., the initial $^3He/(U + Th)$ ratios do not vary markedly on a continental scale.

Helium isotopes account for a few minor components of terrestrial samples. They are all related to the nuclear reactions induced by high-energy cosmic rays. First, cosmogenic helium was found in young basaltic lava flows, glacially polished rocks, and moraines. It is produced by the spallation reaction of light elements in silicates by cosmic rays (Kurz 1986). These ^3He abundances are useful to ascertain the erosion rate of uprifting area. Second, tritium (^3H) is generated by spallation of nitrogen and oxygen in the upper atmosphere in addition to past nuclear tests in the 1960s. It is easily assimilated in rainwater and is incorporated in groundwater at recharge areas. Dating of groundwater has been well documented using the ^3H-^3He method (Schlosser et al. 1988). Third, ^3He was produced in cosmic dust by spallation in interplanetary space. The dust is expected to precipitate on the Earth. This component was well identified in deep sea sediments, where the sedimentation rate was extremely low (Amari and Ozima 1985).

Summary

Element "Helium" has two stable isotopes (^3He and ^4He) and six radioactive ones (^5He, ^6He, ^7He, ^8He, ^9He, and ^{10}He). Half lives of the latter ones are significantly short, up to only 0.8 sec. They are not naturally occurring and do not contribute geochemistry and cosmochemistry. There are three helium end members, "solar," "planetary," and "early universe" in cosmochemistry with individual isotopic compositions. Both solar and planetary helium were evolved from hypothetical early universe component with the $^3He/^4He$ ratio increasing. Within the solid Earth, ^4He is produced by radioactive decay of U and Th. On the other hand, major part of ^3He is attributable to planetary (primordial) helium trapped deep in the Earth at the time of accretion. The $^3He/^4He$ ratios of rock and fluid samples from quaternary volcanic regions such as hot spot, mid- ocean ridge, and island arc generally show higher ratios than atmospheric ratio of 1.382×10^{-6}. On the other hand, those collected in nonvolcanic and tectonically stable areas of continental and oceanic crust indicate lower ratios.

Henry's Law

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Synonyms

Gas solubility

Definition

Henry's Law states that the mole fraction of a component in a solution is linearly proportional to its vapor pressure in a gas phase in equilibrium with that solution. Henry's Law also expresses a special case of nonideal behavior where the activity coefficent of a component in a solution is independent of the concentration of that component.

Henry's Law and Gas Solubility

Henry's Law derives its name from nineteenth-century English chemist William Henry (1774–1836) who observed that the concentration of atmospheric gases dissolved in water increased in direct proportion to an increase in pressure. In its modern formulation, Henry's Law expresses the equilibrium solubility of gases in solution, stating:

Henry's Law, Table 1 Henry's Law constants for gases in water at standard temperature and pressure

	mol/m^3 Pa	mol/L atm
O_2	1.30×10^{-05}	1.32×10^{-03}
H_2	2.60×10^{-06}	2.63×10^{-04}
CO_2	3.40×10^{-04}	3.45×10^{-02}
N_2	6.40×10^{-06}	6.48×10^{-04}
He	3.90×10^{-06}	3.95×10^{-04}
Ne	4.50×10^{-06}	4.56×10^{-04}
Ar	1.40×10^{-05}	1.42×10^{-03}
CH_4	1.40×10^{-05}	1.42×10^{-03}

$$X_i = h_i P_i \tag{1}$$

where X_i is the mole fraction of species i in the solution, P_i is the vapor pressure of i in equilibrium with the solution, and h_i is the constant of proportionality known as the Henry's Law Constant, which is unique to each solution and solute and is a function of temperature and total pressure.

Henry's Law may also be written with the concentration of the dissolved species expressed in molality, molarity, parts per million, etc., and the value of Henry's Law constant will depend on the concentration units used. Values for the Henry's Law constants for several atmospheric gases in aqueous solution at standard temperature (298.15 K) and pressure (0.101 MPa) are listed in Table 1 with the dissolved concentration that is expressed in S.I. units, moles/m^3-Pa, and as moles/liter with the vapor pressure expressed in atmospheres. Thus, for example, the concentration of oxygen in pure water in equilibrium with the atmospheric oxygen whose partial pressure is 0.209 atms would be 0.275 mM. A fuller compilation of Henry's Law constants is given in Sander (2015).

Broader Application of Henry's Law

Henry's Law differs from Raoult's Law, which states:

$$X_i = \frac{P_i}{P_i^o} \tag{2}$$

where P_i^o is the pressure of the pure gas phase of i. Raoult's Law expresses the behavior of ideal solutions (or ideal behavior). Such behavior is rare, even in the approximate, and occurs only where interactions between different molecules are the same as between like molecules. In nature, nonideality is the rule. In the general nonideal case, the solubility of a substance will be a function of the concentration of that substance in solution as well as that of other components, temperature, and pressure. Henry's Law predicts that the

solubility of a substance is independent of its concentration in the solution and is thus a special case of nonideal behavior.

In highly dilute solutions, all substances approach Henry's Law behavior. This occurs as interactions between molecules of the solute become so rare compared to solute-solvent interactions that they have a negligible effect on the properties of the solution.

Because all substances in principle exert finite vapor pressures, Henry's Law can be applied to solutions other than gases in liquids, including solid solutions. Henry's Law thus provides a useful definition of a trace component, namely one sufficiently scarce that it does not affect the properties of the substance in which it is dissolved.

High Field Strength Elements

Vincent J. M. Salters
National High Magnetic Field Laboratory and Department of Earth, Ocean and Atmospheric Sciences, Florida State University, Tallahassee, FL, USA

Definition

This term refers to metals forming cations with a small radius and high charge (valence state), therefore high associated electric field – high field strength. The definition of field strength as charge over ionic radius (Z/r) and importance of field strength in the geochemical behavior of elements was first pointed out by Ahrens (1953). Metal ions with $Z/r > 20$ (with r measured in nanometer) are generally thought to be high field strength elements (Rollinson 1993). Although the high field strength elements (HFSE) consists of all elements whose valence state is three or higher including the rare earth elements, for the platinum group elements, uranium and thorium, in geochemistry the term is mostly reserved for tetravalent Hf, Ti, Zr, pentavalent Nb, Ta, and hexavalent W and Mo.

Geochemical Behavior

The HFSE can be used to geochemically discriminate between tectonic settings of igneous rocks as rocks with HFSE depletion only occur at convergent plate boundaries (Gill 1981). This depletion in calc-alkaline rocks was first noted for Ti (Chayes 1965). The depletion of HFSE is most easily recognized on incompatible element diagrams (Sun et al. 1979) where element concentrations are reported normalized to their chondritic or silicate earth abundance and arranged according to increasing compatibility in a four-phase lherzolite-melt system. On these incompatibility diagrams, igneous rocks from convergent boundaries show a deficiency in Nb, Ta, Ti, Hf, and Zr compared to their neighboring elements. However, not all volcanic rocks in convergent settings have HFSE depletions. Basalts without HFSE depletions are found in the Cascades as well as in the Central Mexico Volcanic Belt.

The deficiencies in the HFSE are attributed to their low solubility in aqueous fluids or their partitioning into accessory phases like rutile (Zack et al. 2002) During subduction, the down-going slab dehydrates and fluxes the overlying mantle. Compared to other elements, the HFSE are less mobile in the slab-derived fluid (Kogiso et al. 1997; Ayers 1998; Johnson and Plank 1999) and mostly remain in the slab. Therefore, the overlying mantle wedge will be enriched in fluid mobile elements resulting in a relative depletion of the HFSE. Subsequent melting of the fluxed mantle wedge transfers the HFSE depletions to the crust. W is potentially the exception and is enriched in arc volcanics compared to elements with similar behavior during melting (U, Th, Ta). With increasing pressure and temperature as the fluid transitions towards a supercritical fluid the solubility of the HFSE into the fluid increases (Kessel et al. 2005a). This transition takes place at pressures in excess of 4 GPa (Kessel et al. 2005b).

HFSE Fractionation

Because of their similar charge and ionic radius, Zr and Hf as well as Nb and Ta are often considered geochemical twins and up till recently their ratios were thought to be chondritic throughout the crust and upper mantle. High precision analyses (Münker et al. 2001) of the Nb/Ta and Zr/Hf ratios have shown this is not the case. Partition studies have shown that both rutile, amphibole, and sphene can significantly fractionate both Nb/Ta and Zr/Hf (Foley et al. 2002; Klemme et al. 2005). A detailed comparison between fluid-dominated and melt-dominated island arc regimes, however, have not shown significant fractionation of Zr/Hf or Nb/Ta, in most cases.

Zr/Hf ratios are relatively similar in arc rocks and MORB (Münker et al. 2004; Kirchenbaur and Münker 2015) although partition studies have shown that Hf is consistently more compatible than Zr in clinopyroxene (Salters and Longhi 1999; Pertermann and Hirschmann 2002; Salters et al. 2002) and melting of four-phase lherzolite can fractionate the Hf/Zr ratio and lead to lower Zr/Hf in the residue. Similarly, Nb partition coefficients are consistently lower than Ta (van Westrenen et al. 2001; McDade et al. 2003) and positive correlations between Nb/Ta and Zr/Hf are expected.

With the high precision HFSE concentration determination it is now known that relative to Ta the accessible silicate earth is depleted in Nb requiring that some of the Earth's Nb reside in a high Nb/Ta reservoir (McDonough 1991; Green 1995; Rudnick et al. 2000; Kamber et al. 2003; Münker et al. 2003). The Nb/Ta ratio is lower than chondritic (Jochum et al. 2000; Münker et al. 2003) in the continental crust (Rudnick and Fountain 1995; Barth et al. 2000), the depleted mantle (Salters and Stracke 2004), and ocean island basalts (Pfänder et al. 2007). Some have argued that the missing Nb may be in the Earth's core (Wade and Wood 2001; Münker et al. 2003) others argue for a hidden reservoir from ancient subducted slabs (Rudnick et al. 2000). The subducted slab is implied as eclogites can have very high Nb/Ta ratios (Barth et al. 2001 2002), although a separate study on slab-derived eclogites do not show Nb enrichment over Ta (Schmidt et al. 2009).

Summary

The difference in behavior of the HFSE in fluid-saturated and fluid absent systems and their affinity for very specific mineral (rutile, amphibole, sphene) makes them very useful fingerprinting magmatic processes.

High-Resolution Mass Spectrometry

Elizabeth B. Kujawinski
Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Definition

The use of mass spectrometers with high resolving power (>50,000 at *m/z* 400) and mass accuracy (≤2 ppm).

Overview

All mass spectrometry instruments measure the mass to charge ratio of ions (*m/z*). However, the precision of this measurement depends on the type of mass spectrometer utilized. Quadrupole mass spectrometers generally measure the *m/z* value to the nearest integer, or nominal mass. High-resolution mass spectrometers provide information on the fractional mass, or the digits after the decimal point. Two terms are used to compare these mass spectrometers: mass accuracy and resolving power. Mass accuracy is defined as ((observed mass – true mass)/true mass) and is expressed in parts per million (ppm). Resolving power (R) is defined as the value of the full width at half of the peak's maximum value (FWHM) at a specific *m/z* (often *m/z* 400). The two most common high-resolution mass spectrometers are the time-of-flight (TOF) mass spectrometers (R ~ 1000–10,000) and the Fourier transform (FT)-based mass spectrometers (R ~ 100,000 to 1,000,000). TOF MS is often used for mass analysis of components within fairly simple mixtures and will not be discussed further. The FT-MS, in contrast, is widely used to analyze very complex mixtures, including petroleum and natural organic matter from a variety of environments. For further information on mass analyzers, I refer the reader to a mass spectrometry textbook such as Watson and Sparkman (2007) or Gross (2011).

FT-ICR MS

The focus of this section is the ultrahigh resolution mass spectrometers, or those based on Fourier transform technology. These instruments are comprised of an ionization source, optics to focus and transfer the ion beam, and a magnetic or electric field-based mass analyzer where ion motion is measured in order to determine mass to charge ratio (*m/z*). There are two primary instrument types, the Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer, which uses a magnetic field to induce ion motion, and the Orbitrap mass spectrometer, which uses electric fields. The two instruments differ in important ways in their ion optics and trapping technologies. Nevertheless, they both rely on the principle that a charged particle will alter its path under the influence of a magnetic or electric field and they both force ions into a circular motion within the magnetic or electric field. Ion packets rotate around a central axis in both instruments, and the frequency of ion motion is inversely related to the ion's mass to charge ratio. To facilitate detection in the FT-ICR MS, ions' orbits are expanded by the application of a radio-frequency (RF) pulse. The movement of each ion group past detection sensors or plates is monitored over time and can be approximated as a decaying sine wave, where the frequency is related to its mass to charge ratio and the amplitude is related to its relative abundance. The detected signal is a superposition of sine waves from ions with unique mass to charge ratios, collectively termed the transient. In each transient, the frequencies and amplitudes of the overlapping sine waves from ions with unique *m/z* are deconvoluted through

Fourier transformation. These frequencies can be converted to *m/z* values through external calibration using standards. In complex mixtures, many hundreds (or thousands) of ions are present in each sample. Because high mass ions have lower frequencies, transients with longer duration are critical to establishing sufficient detection of these ions. In addition, repeat transients can be added together to remove random signals from background noise and to enhance detection of low-abundance ions. Overviews of the design and physics of FT-ICR MS and Orbitrap are available in Marshall et al. (1998) and Zubarev and Makarov (2013), respectively.

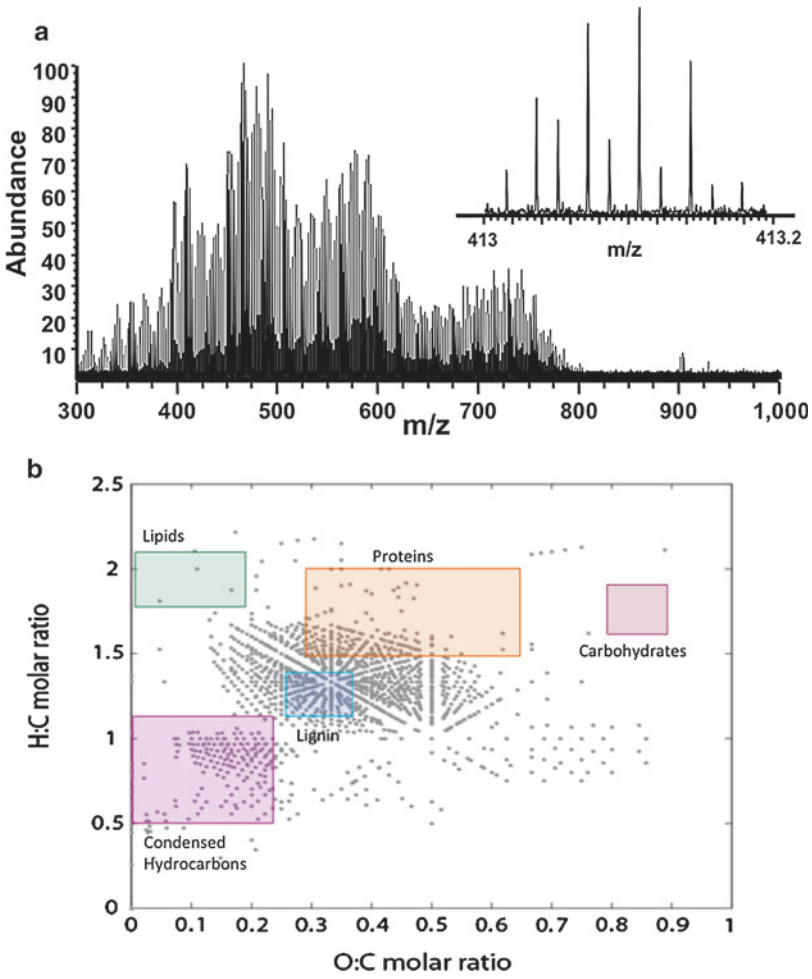
The strength of the electric or magnetic field affects the mass accuracy and the dynamic range of ions detected. In Orbitrap technology, the electric field does not have the same resolution as the newest FT-ICR instruments, although this parameter is superior to all non-FT instruments. Recent improvements in the Orbitrap hardware, as well as advances in raw data transformations, have led to Orbitrap mass resolving powers of 500,000 or more at 200 *m/z* (as of May 2017). In FT-ICR MS, the dynamic range and mass accuracy is related to magnetic field strength, because the ICR cell can accommodate more ions and the signal attenuation (or transient) can be measured for a longer period in larger magnets. Thus, more ions are detected, and their *m/z* value is determined with higher resolution. Instruments in common use (as of May 2017) utilize magnetic field strengths of 7-tesla (T), 9.4-T, 15-T, and 21-T, yielding resolving power of 200,000 to >1,000,000 at 400 *m/z*, respectively. These instruments detect thousands of individual ions within each spectrum, often resolved to the baseline (Fig. 1a).

Both the FT-ICR and the Orbitrap mass spectrometer can be interfaced with numerous ionization sources. The most common is electrospray ionization (ESI) which transfers ions in a solution into the MS. For most applications, the ions are dissolved in a solution that contains water and so positive ion mode preferentially ionizes basic functional groups such as amines. Sodiated complexes (i.e., $[M + Na]^+$, where M is the original molecule) are very common for natural mixtures. Indeed, both the protonated and sodiated adducts are often observed in positive ion mode spectra of natural organic matter. By contrast, negative ion mode preferentially ionizes acidic functional groups such as carboxylic acids or phenols. Complexes are also possible but occur less frequently (e.g., chlorine adducts such as $[M + Cl]^-$). Other ionization sources include atmospheric pressure photoionization (APPI), atmospheric pressure chemical ionization (APCI), and matrix-assisted laser desorption ionization (MALDI). These sources use energy to make ions and so some degree of fragmentation is likely. However, the relative benefits and caveats of each source can be effectively managed to address specific science questions. For example, ESI is used for analysis of polar molecules that are dissolved in aqueous solution such as dissolved organic matter. This excludes nonpolar molecules such as hydrocarbons, but these compounds are more appropriately ionized and detected using APCI or APPI. APPI can be used to explore the composition of photoactive molecules, thus allowing the analysis of this specific fraction relative to nonreactive components.

Data

Mass accuracy is high with these instruments because so many periods of ion motion are detected; thus, the frequency and by extension the *m/z* value are known to high precision. With current FT-ICR MS instruments, it is common to achieve mass accuracy below 1 ppm or smaller than the mass of an electron. This enables the determination of an elemental formula based on the mass measurement alone. An elemental formula is the unique combination of elements such as carbon (C), hydrogen (H), oxygen (O), and nitrogen (N) that match the measured *m/z* value within a specified error. Many methods exist to assign elemental formulas to ultrahigh resolution mass spectrometry data (e.g., Koch et al. 2007; Green and Perdue 2015), but they all incorporate the premise that elemental formula assignments for natural mixtures can generally be constrained to C, H, O, and N with minor contributions of sulfur (S) and phosphorus (P). The atoms within an elemental formula can often be arranged in multiple ways yielding structural isomers. The number and complexity of structural isomers increases with mass as the number and variety of atoms increases. Thus, elemental formulas cannot be used for compound identification at the structural level, except for very simple molecules such as carbon dioxide (CO_2) or methane (CH_4) where only one structure is possible. Nevertheless, elemental formulas provide an indication of a compound's class and thus are useful for assessing general mixture composition. For example, lipids are characterized by high hydrogen content relative to carbon (H:C ratio), while aromatic hydrocarbons have many fewer hydrogen atoms for the same carbon number. These differences are often visualized on van Krevelen plots (Fig. 1b), which guide interpretations regarding shifts in composition with experimental parameters.

Although the Fourier transform of ion motion yields an amplitude, the relative abundance of ions should be viewed with caution in FT-MS data. The ionization efficiencies of molecules in ESI are affected dramatically by the sample matrix. Molecules with poor ionization efficiency can be suppressed by less abundant molecules with higher ionization efficiencies. This has been shown nicely in studies where samples are compared before and after chromatographic pre-separation. For natural organic matter, pre-separation significantly enhances the number of ions detected. Ionization efficiency can affect the relative spectral abundances of ions, such that changes in peak height are not necessarily related



High-Resolution Mass Spectrometry, Fig. 1 (**a**) Representative FT-ICR mass spectrum of Suwannee River dissolved organic matter, collected on a 9.4 T instrument in negative ion mode. The spectrum represents the co-addition of 200 scans (Reprinted from Kujawinski et al. 2004. Copyright (2004), with permission from Elsevier). (**b**) Visualization of FT-MS data using a van Krevelen plot. The data comes from negative ion mode analysis of seawater samples (Reprinted from Kujawinski et al. 2009. Copyright (2009), with permission from Elsevier). Each gray dot corresponds to a unique elemental formula, plotted according to its hydrogen/carbon (H:C) molar ratio and its oxygen/carbon (O:C) molar ratio. Colored boxes indicate regions associated with different compound classes, as compiled in Kujawinski and Behn (2006)

linearly to changes in abundance in the sample. Investigators can mitigate these caveats by injecting samples multiple times to assess peak reproducibility, by focusing their interpretation on molecules with relatively elevated peak heights and by comparing their interpretations based on relative peak height and on presence-absence normalizations (e.g., Kido Soule et al. 2010; Riedel and Dittmar 2014). Many recent studies incorporate one or more of these mitigation strategies and are using multivariate statistics and meta-data to interpret shifts in composition observed in FT-MS data.

Applications

The use of FT-ICR MS in organic geochemistry has exploded since the first papers in the early 2000s. It has been applied to many of the most complex mixtures on Earth, including petroleum (Hughey et al. 2001; Rodgers et al. 2000), soil humic and fulvic acids (Brown and Rice 2000; Kujawinski et al. 2002), and aquatic dissolved organic matter (Koch et al. 2005; Stenson et al. 2003). Over the past decade, studies have moved from descriptive analysis of a few samples (<10) to multivariate statistical analysis of many samples. FT-ICR MS is used effectively to compare compositional changes as a function of different environmental or experimental parameters, yielding molecular-level insights into the fundamental reactions in organic geochemistry (reviewed in Minor et al. 2014). In most cases, these insights are not possible with lower-resolution analyses, thus establishing FT-ICR MS as a uniquely capable mass spectrometer for these efforts. For example, polar components within petroleum are largely invisible to gas chromatography-based instruments due to low volatility. Instead, FT-ICR MS not only detects these molecules but provides a basis for comparing sulfur remediation strategies or for identifying the products of environmental weathering (e.g., Ruddy et al. 2014). Likewise, with its unparalleled ability to resolve thousands of components in complex mixtures, ESI FT-ICR MS has now been used to characterize and compare the polar molecules in dissolved organic matter in all aquatic environments, including (but not limited to) soils (Ohno et al. 2010), rivers (Sleighter and Hatcher 2008), lakes (Minor et al. 2012), seawater (Dittmar

and Koch 2006), glaciers (Bhatia et al. 2010), and hydrothermal vents (Rossel et al. 2015). The Orbitrap has not been applied as extensively as the FT-ICR MS instruments and, in general, does not yield data with similar mass resolving power. However, the faster speed of data acquisition coupled with lower maintenance costs (i.e., the Orbitrap does not require cryogens to cool a superconducting magnet) has made these instruments attractive to organic geochemists studying dissolved organic matter (e.g., Remucal et al. 2012).

Summary

Limitations still exist in the application of FT-MS to organic geochemistry because (1) molecular structure cannot be assigned based on elemental formulas alone and (2) some molecules are not detected due to sample matrix effects. In the first case, structural clues can be gleaned from complementary nuclear magnetic resonance (NMR) spectroscopy measurements (Hertkorn et al. 2008) or from fragmentation (MS/MS) of individual ions (Stenson et al. 2002). These tools are appropriate for the dominant molecules in a mixture but are not practical for low-abundance molecules. Liquid chromatography (LC) can be used to reduce sample complexity by generating subsamples based on physical or chemical properties. Subsamples are then analyzed by ESI FT-ICR MS, and the data is concatenated to yield a more comprehensive view of the original sample (Capley et al. 2010). This approach enhances the detection of lower-abundance ions, particularly those that elute at different times from higher-abundance ions. Alternatively, an LC is coupled directly to the FT-ICR MS to measure full mass spectra along the full chemical gradient. Some hybrid instruments (e.g., the linear ion trap FT-ICR MS) use the low-resolution ion trap MS to collect fragmentation spectra of selected ions, thus enabling structural characterization in tandem with compositional analysis (Kido Soule et al. 2015). Mass spectral databases currently have limited coverage of natural organic molecules, but as they mature, fragmentation spectra will be increasingly useful for identifying compounds within environmental organic mixtures.

History of Geochemistry

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Definition

Geochemistry grew out of the Renaissance arts of alchemy and metallurgy. Over much of that long past, geochemistry was intimately intertwined with chemistry itself, evolving into a distinct subfield of both chemistry and earth sciences only with the dawn of the twentieth century. It now holds a central role in understanding the Earth, its neighboring planets, and their evolution.

Early Roots in Alchemy and Chemistry

The term "geochemistry" was coined in 1838 by the German-Swiss chemist Christian Friedrich Schönbein, a professor of chemistry and physics at the University of Basel and better known as the discoverer of ozone, who wrote, "*In a word, a comparative geochemistry ought to be launched. . . before the mystery of the genesis of our planets and their inorganic matter may be revealed*" (Krough 2001). Revealing the "mystery of the genesis of our planets and their inorganic matter" remains a remarkably accurate description of what geochemistry has become, with qualification that geochemistry also includes the study of nonliving organic matter.

The roots of geochemistry are, however, much older and intimately intertwined with the roots of chemistry, both nurtured in the fertile soil of alchemy and the practical arts of metallurgists. A principal goal of alchemy was to transform one substance derived from the Earth into another, such as gold. Even as chemists came to recognize that there were certain fundamental substances, elements, that could not be so transformed and sought to identify them, it was in natural substances that they sought them. This continued into the twentieth century when the last two stable elements were identified: hafnium in zirconium ores by Coster and von Hevesy in 1923 and rhenium in platinum ores in 1925 by Noddack, Tacke, and Berg based on the 1869 predictions of Mendeleev.

Georg Agricola's 1556 treatise on mining and metallurgy, *De re metallica*, might be considered the first text on geochemistry, but Gustav Bischof's 4-volume *Lehrbuch der chemischen und physikalischen Geologie* (Bischof 1847) is probably more deserving of that distinction. Among other things, Bischof emphasized the importance of water in what we would call today geochemical cycles and understood that water chemistry reflected weathering reactions with the rocks through which it flowed. At about the same time, Jacques Joseph Ebelman (1845) pointed out the importance of plants in silicate weathering and of marine fauna in precipitating weathering products in the ocean, effectively laying out the carbon cycle as we understand it today (Galvez and Gaillardet 2012). The three-volume *Allgemeine und chemische Geologie* by Justin Roth (1879) replaced Bischof's as the standard text on geochemistry and remained widely cited well into the twentieth century.

Fathers of Geochemistry: Clarke, Goldschmidt, and Vernadsky

Frank W. Clarke (1847–1931) received his B.S. in chemistry from Harvard University in 1868. He went on to serve as an assistant in chemistry at the new Cornell University in 1869, but his interest in geology led him to explore the gorges and

waterfalls bordering the campus and write a guide book on them (Clarke 1869). He went on to subsequent appointments as a chemistry professor in the Boston Dental College, Howard University, and University of Cincinnati. It was during this period that Clarke wrote a remarkable prescient article in the new magazine *Popular Science* entitled *Evolution and the Spectrograph* in which he speculated that the chemistry of the universe had evolved over time (Clarke 1873b), with light elements having been formed earlier than heavier ones. This was based on observations of stellar composition from the newly developed astrospectrograph. His elaboration on that idea years later foreshadows modern nucleosynthetic theory (Clarke 1918, 1925). Other important contributions in those years included a compilation of specific gravities, boiling points, and melting points of chemical compounds for the Smithsonian Institution series *The Constants of Nature* (Clarke 1873a) and a chemistry textbook (Clarke 1884). Clarke served as president of the American Chemical Society in 1901 (Fig. 1).

Clarke became chief chemist of the US Geological Survey in 1883, a position he held until his retirement in 1924. His publication record over this period is remarkable for its abundance (some 136 papers listed by Google Scholar), diversity, and importance. A broad summary of the chemistry of rocks and natural waters, *The Data of Geochemistry* (Clarke 1908), is his most cited work. Clarke nicely summarizes the objective of geochemistry in the fifth edition of this work:

> *To determine what changes are possible, how and when they occur, to observe the phenomena which attend them, and to note their final result are the function of the geochemist.*

Others works include papers on the heat of formation of water from hydrogen and hydroxyl ions, chemical denudation, systematic studies of the chemistry of mineral classes such as micas, silicates, a review of atomic theory and papers on the composition of US rivers and lakes, and, with Henry Washington, works on the composition of igneous rocks (Clarke and Washington 1922) and the Earth's crust (Clarke and Washington 1924), which was based on an average of 5197 analyses selected from a total of over 8000. Many of his papers in his last decade at the Geological Survey are on the inorganic composition of marine invertebrates, summarized in Clarke and Wheeler (1922).

Victor M. Goldschmidt was born to Jewish parents in Zurich in 1888 and moved to Oslo in 1901, received his PhD at the University of Christiania (later Oslo) in 1911, and immediately thereafter became professor and director of the Mineralogical Institute. His work on the metamorphic and magmatic rocks of southern Norway at the time is notable for the first application of the Gibbs Phase Rule to petrology. Using the newly invented x-ray spectrograph, Goldschmidt discovered that the even atomic-numbered rare earth elements (REE) have higher abundances than the odd-numbered ones, a key to nuclear structure. Analyzing mineral structures with the newly invented x-ray diffractometer, he discovered that the REE atomic radii decreased with atomic number, which he called the lanthanide contraction. He and his colleagues went on to determine the ionic radii of 67 elements by 1925 and deduced now well-known relationships between ionic radius, ionic charge, atomic number, and periodic group. This led to his Goldschmidt Rules of substitution (Fig. 2).

His papers on the differentiation of the Earth foreshadowed modern thinking on Earth's formation and evolution (Goldschmidt 1922). By considering their properties and in which phases they occurred in meteorites, Goldschmidt divided the elements into atmophile, lithophile, siderophile, and chalcophile (the Goldschmidt Classification) and argued that the first three groups were concentrated in the atmosphere-hydrosphere, the crust and mantle, and the core, respectively (Goldschmidt 1923), a classification still used today. He recognized that the cosmic abundances of the elements could best be deduced from meteorites and the value of glacial clays as samples of Earth's crust, an approach still used today (see ▶ "Earth's Continental Crust" in this volume), and his own estimate of crustal composition based on analysis of 81 samples compared well with that of Clarke and Washington (1924).

In 1929, Goldschmidt accepted a professorship in 1929 at the Mineralogisches Institüt at the University of Göttingen and subsequently published papers on the carbon cycle emphasizing the importance of biochemical reactions. He also pointed out that the amount of CO_2 released through burning of fossil fuels greatly exceeded the volcanic flux and was increasing the CO_2 content of the atmosphere.

In 1935, Goldschmidt resigned his professorship in protest of the Nazi anti-Jewish agitation. Returning to Oslo, he published the ninth volume of his *Geochemische Verteilungsgesetze der Elemente* (the distribution laws of the elements) (Goldschmidt 1937) with data on the abundance of elements in the solar atmosphere, meteorites and terrestrial rocks, and plotted the logarithms of the ratios of atomic species in the solar system relative to the abundance of Si – an approach still used today. His work led directly to the concept of "magic numbers" of nuclei and the shell theory of nuclear structure.

Goldschmidt continued his interest in nuclear physics and was working with Fritz Houtermans on plutonium and the actinide elements (Goldschmidt 1941–1942) at the time of the German invasion in 1940. He was arrested by the Nazis in 1942 and sent to the Berg concentration camp but was released soon afterward, probably because of his work related to phosphate fertilizer. He escaped to Sweden shortly thereafter and then went on to England in 1943, where he worked with officials involved with the war effort. He returned to Norway and his position at Oslo in 1946, but the war had taken a toll on his health and he died in 1947.

Vladimir Vernadsky (1863–1945) was born in St. Petersburg to Ukrainian parents (Fig. 3). He received his PhD in mineralogy from Moscow University in 1897 and was appointed professor there in 1898. Much of his early work was on mineral paragenesis and alumino-silicate minerals. Vernadsky was caught up in the excitement of the newly discovered phenomenon of radioactive decay and was one the first to recognize its significance as a terrestrial energy source, establishing a Radium Commission in 1909. Vernadsky was active in prerevolution Russian politics and served as a member of the Constitutional Democratic Party in parliament. In 1911, he resigned his professorship in Moscow, along with a quarter of the faculty, in protest to a government crackdown on student protests and returned to St. Petersburg where established a geochemical laboratory. After the February Revolution of 1917, Vernadsky was appointed to various government committees and as head of the Dept. of Mineralogy and Geology at Moscow University by the provisional government of Alexander Kerensky, while continuing to hold positions in St. Petersburg (Bailes 1990). However, when the Bolshevik took over in October, he moved to the Ukraine, eventually settling in Kiev. He set about establishing a

Ukrainian Academy of Sciences and, despite the political turmoil and violence of the Russian Civil War, it was during this time that began the work for which he is best known: biogeochemistry, a term he coined, and the elaboration of concept of the biosphere, a term coined earlier by the Austrian geologist Edwin Suess, whom Vernadsky had met in 1912. Vernadsky argued that life was not independent of its surroundings but was itself a geologic force, both affecting and being affected by the inert world, an idea later popularized by J. E. Lovelock (1972) as the Gaia hypothesis.

Vernadsky returned to St. Petersburg in 1921, but in 1922, he accepted an invitation to teach in the Sorbonne in Paris where, among other things, he worked on radioactivity with Marie Curie. He published *La géochimie* (Vernadsky 1924) there in 1924. He returned to Russia in 1926 where another seminal book, *The Biosphere* (Vernadsky 1926), was published. He organized the Biogeochemical Laboratory in St. Petersburg (by then renamed Leningrad), which moved to Moscow in 1934. There he led studies of permafrost, mineral resources, and determining the composition of living organisms and the relationship between health, including human health, and oversupply or deficits of elements such as iodine, calcium, and barium in the local environment. He continued his strong interest in radioactivity and isotopes, leading a program for concentration of heavy water and initiating construction of the first cyclotron in the Soviet Union. Having learned of work on nuclear fusion in Germany and the USA in 1938, Vernadsky began strongly urging the government to initiate a program on the development nuclear energy and to identify uranium deposits within the USSR. His efforts led directly to the establishment of a Uranium Commission and indirectly to the Soviet atomic bomb project, which began in 1943. Although strongly patriotic, Vernadsky was often directly critical of the Stalinist government; these criticisms were tolerated because of his renown and stature. Although he published papers in French, German, and English, Venadsky's work was largely overlooked in the West until the 1980s. His rediscovery has greatly influenced not only geochemistry, but also fields such as ecology and microbiology.

Birth and Development of Isotope Geochemistry

Geochronology

Within the lifetimes of these three scientists, Henri Bacquerel's 1896 discovery of radioactivity revolutionized physics, chemistry, and geochemistry. Rapid progress followed, particularly by Marie Curie in Paris and Ernst Rutherford in Montreal. By 1905, it was understood that uranium and thorium decayed through a chain including radium and polonium; decay constants were approximately known but the ultimate product was not. Yale chemist Bertram Boltwood proposed that is was Pb and recognized the potential to measure geologic time from the buildup of Pb in U-rich minerals, reporting ages up to 2.2 billion years (Boltwood 1907), implying the Earth was vastly older than Lord Kelvin had estimated. Thus was born radiometric geochronology, but not yet isotope geochemistry as isotopes were not known until Fredrick Soddy, a student of Rutherford, proposed them in 1913 and F. W. Aston confirmed them in 1919. By then, it was understood that U decayed to ^{206}Pb and Th to ^{208}Pb. F. W. Clarke (1918), however, questioned Boltwood's U-Pb dating technique because Clarke had found that uranogenic Pb had a variable atomic weight, up to 206.8, seemingly inconsistent with the radiogenic production of ^{206}Pb.

The problem was that no one knew then of ^{235}U, which was discovered in only 1935, or that it decayed to ^{207}Pb. Once Alfred Nier (1939), then at Harvard, had measured the ^{238}U/^{235}U ratio and the decay constants with reasonable accuracy, he was able to produce the first accurate ages and confirm that the age of the Earth was greater than 2.2 billion years. Nier returned to his native Minnesota setting up a laboratory at the University of Minnesota where he continued his work in geochronology, determining the isotopic composition of the elements and natural variations in them, and designing a variety mass spectrometers in the process. In 1940, Nier was able to separate sufficient ^{235}U that its fission properties could be determined. From 1942 to 1945, Nier was part of the Manhattan Project, designing mass spectrometers used to assess U isotope separation. He returned to the University of Minnesota where he continued to work on geochronology, determining the isotopic composition of the elements and their masses, and designing mass spectrometers, including ones for NASA spacecraft, up to his death at age 82 in 1994.

Ultimately, the age of the Earth turned out to be much greater. Russian physicist E. R. Gerling estimated an age of 3.1 billion years in 1942, Authur Holmes estimated it to be 3.3 billion years, and Fritz Houtermans (1953), who had the unenviable distinction of having been a political prisoner of both the Nazis and the Soviets, estimated an age of 4.5 ± 0.3 billion years based on the isotopic composition of Pb ores and the initial solar system Pb isotopic composition measured in iron meteorites.

Rapid progress in geochronology and isotope geochemistry followed directly from the Manhattan Project, not only in Alfred Nier's University of Minnesota lab, but also at the Institute of Nuclear Studies, which Enrico Fermi founded at the University of Chicago in 1945 (and now known as the Enrico Fermi Institute). There, Harrison Brown and some of his fellow Manhattan Project veterans including Harold Urey and Willard Libby decided to establish a new scientific field of "nuclear geochemistry" (Revelle 1994). Brown's former student Claire Patterson (1956), by then at Cal Tech, declared

the issue of the age of the Earth settled when he wrote, "*It seems we should now admit that the age of the Earth is known as accurately and with as much confidence as the concentration of aluminum is known in the Westerly, Rhode Island granite*" (the Westerly granite is the source of the USGS chemical standard W1), concluding from meteorite and terrestrial standards that the Earth was 4.55 ± 0.07 billion years old. Having discovered in the course of his analytical work that Pb contamination was ubiquitous, Patterson spent much of his later career warning of the dangers of anthropogenic Pb in the environment (e.g., Patterson 1965; Settle and Patterson 1982) and is perhaps the scientist most responsible for the removal of Pb from gasoline and paint. Interestingly, while we know from U-Pb dating that solar system formation began 4568.22 ± 0.17 million years ago (Bouvier and Wadhwa 2010), the age of the Earth itself is known no better than Patterson's value.

As the first half of the twentieth century came to a close, W. F. Libby (Libby et al. 1949) had already developed the ^{14}C dating method (for which he won the Nobel Prize in Chemistry in 1960), and a number of other cosmogenic nuclide dating schemes followed in subsequent decades. In 1956, Thomas Aldrich, a former student of Nier, and others (Aldrich et al. 1956) at Carnegie Institution of Washington determined the half-life of ^{87}Rb and showed the Rb-Sr decay system could be used as a geochronometer. About the same time, workers in a number of laboratories, including the same Carnegie group (Wetherill 1957), Jerry Wasserburg, another product of the Institute of Nuclear Studies and student of Harold Urey, and R.D. Russell in Toronto, developed the K-Ar dating method. This method later saw a big advance with the advent of $^{40}Ar/^{29}Ar$ dating, a variation on K-Ar dating technique in which ^{39}Ar is produced from ^{39}K by neutron bombardment (Merrihue and Turner 1966). W. F. Libby had discovered that samarium was radioactive in his doctoral dissertation (Libby 1934), but only 40 years later was Lugmair (1974) able to report the first Sm-Nd ages. The Lu-Hf (Patchett and Tatsumoto 1980) and Re-Os (Allègre and Luck 1980) systems were introduced shortly thereafter, although some previous work had been done on both. The Apollo lunar program also had a big impact on geochronology, not so much with the development of new systems as with a giant step forward in mass spectrometry and analytical precision. Jerry Wasserburg, whom Harrison Brown had recruited after he moved to Cal Tech, was at the forefront of these developments. Across the Atlantic, Claude Allègre at the Institut de Physique du Globe at the University of Paris was also pioneering new approaches and techniques. Wasserburg and Allègre shared the Crawfoord Prize in 1986 for their advancements in isotope geochemistry.

The discovery that primordial ^{3}He was leaking into the oceans through the oceanic crust opened the field of rare gas isotope geochemistry (Clarke et al. 1969), and identification of isotopic variations in other noble gases followed (e.g., Sarda et al. 1988; Staudacher and Allègre 1982) and ultimately revealed primordial heterogeneity in the deep Earth (e.g., Mukhopadhyay 2012). This completed the radiogenic isotope geochemist's toolkit, although developments in analytical techniques have continued to improve them in subsequent decades.

Radiogenic Isotope Geochemistry

Radiogenic isotope ratios proved to have a value beyond measuring geologic time, particularly in understanding crust-mantle evolution. Paul Gast (1960), a former student of Nier, measured Sr isotope ratios in crustal granites and mantle-derived basalts, demonstrating a dramatic difference between them but also concluding that the Earth "*did not contain K, Rb, Cs, U, Ba, and Sr in the proportions found in chondrites.*" Subsequent studies by Gast et al. (1964) demonstrated Pb and Sr isotopic heterogeneity in the mantle, and it soon became clear that "*Oceanic island basalts are derived from a different type of mantle than submarine ridge basalts*" (Hart 1971). The latter, mid-ocean ridge basalts (MORB), as they became known, had compositions consistent with the being partial melts of mantle depleted in incompatible elements, i.e., elements not well accommodated in mantle minerals, by a previous episode of melting. Oceanic island basalts (OIB) lacked that depleted signature. Based in part on this difference, Jason Morgan (1971) proposed that oceanic island volcanoes were produced by convection plumes from the lower mantle, but what were mantle plumes composed of?

The roots of the answer lie in the work of Dick Armstrong (1971), who had been analyzing radiogenic isotope ratios in lavas from island arcs overlying subduction zones. He concluded that sediment was being subducted into the mantle along with oceanic crust and was contributing to the source of these oceanic volcanoes. The greater significance of this was that continental crust could be destroyed and recycled into the mantle as he pointed out. Sediment subduction remained controversial until the remarkable discovery by Tera et al. (1986) of ^{10}Be in arc lavas. Because ^{10}Be is produced only in the atmosphere by cosmic ray spallation and has a half-life of 1.6 million years, this was decisive evidence of sediment being subducted into the mantle.

A couple of years after Lugmair reported the first Sm-Nd age, Don DePaolo and Wasserburg (1976) reported Nd isotopic compositions in a variety of crust and mantle rocks, including MORB and OIB; Claude Allègre's lab in Paris quickly followed with additional data. The Sm-Nd system is particularly useful because the Earth's Sm/Nd ratio is the same, or nearly so, as chondrites, which is not the case for Rb-Sr or U-Th-Pb, as Gast had pointed out. DePaolo and Wasserburg proposed, as Schilling (1973) had earlier, that mantle plumes were derived from primitive mantle, but Pb isotope ratios were not consistent with this idea. And as more

data accumulated, a different explanation seemed required. Hofmann and White (1982) argued that mantle plumes were composed, in part, of subducted oceanic crust and sediment. Subsequent evidence, particularly from stable isotope ratios, has supported that interpretation, which is now widely accepted.

Radiogenic isotope geochemistry has found application far beyond mantle studies. For example, the Sr isotopic composition of ocean water is uniform, but varies with time, reflecting the balance of inputs from ridge crest hydrothermal systems and weathering. Carbonate sediments record this variation providing a geochronological tool for dating marine sediments (Sr isotope chronostratigraphy). Beyond that, this variation in marine Sr isotopic composition provides constraints rates of sea floor spreading and continental weathering through time. In contrast, Nd isotope ratios vary geographically in seawater. Consequently, they can be used as water mass tracers and, through their incorporation in sediments such as Mn nodules, used to deduce past ocean circulation (Albarède et al. 1997). Isotope ratios, particularly Nd and Hf, have also been of enormous value in tracing crustal evolution (e.g., Hawkesworth et al. 2010). Radiogenic isotope ratios have also proved useful in archeology (Bentley 2006); among other notable uses, Müller et al. (2003) used Sr and Pb isotope ratios along with those of oxygen and carbon to determine that Ötsi, the Copper Age alpine mummy discovered in the Alps by German hikers in 1991, was from Italy rather than Austria.

Stable Isotope Geochemistry

In 1947, Harold Urey (Urey 1947) and his University of Chicago colleagues Jacob Bigeleisen and Maria Mayer (1947) demonstrated theoretically that nuclear mass has a temperature-dependent effect on chemical bonding. Urey, who had won the 1934 Noble Prize in chemistry for the discovery of deuterium and had led the U separation efforts for the Manhattan Project, quickly realized that this temperature dependence provided the potential for determining paleotemperatures (Urey et al. 1951). Curiously, his motivation was to test his suspicion that cooling was responsible for the extinction of the dinosaurs (Epstein 1997), which, of course, turned out not to be the case. His students and postdocs demonstrated experimentally that actual fractionations matched the predicted ones (e.g., Epstein et al. 1951). Casare Emiliani was given the task of determining O isotope ratios in the calcite shells of planktonic foraminifera from deep-sea cores. Emiliani (1955) concluded that the climate swings of the Pleistocene were a consequence of small variations in the Earth's orbit and rotation, as Milutin Milanković had theorized half a century earlier. Although not all of Emiliani's conclusions have held up, the idea that Milankovich cycles were the primary driver of climate cycles has become a central paradigm in paleoclimatology (Shackleton and Pisias 1985) and stable isotope ratios have become the premier paleotemperature proxy. Through pioneering work of Danish geochemistry Willi Dansgaard, these studies were augmented by studies of oxygen and later hydrogen isotopes in Greenland and Antarctic ice sheets, providing an extraordinarily detailed history of Pleistocene climate oscillations (e.g., Dansgaard et al. 1969; Jouzel et al. 2007). Dansgaard, along with oceanographer Nickolas Shackleton won the 1995 Crawfoord Prize for their paleoclimate work.

Urey and his academic descendants were responsible for much of the early development of stable isotope geochemistry. Harmon Craig (1953) documented the variation in $\delta^{13}C$ in terrestrial materials demonstrating the systematic depletion of organic carbon in ^{13}C, with the details of the fractionation during photosynthesis worked out by Rodrick Park and Samuel Epstein (Park and Epstein 1960). Craig (1961) also documented the correlation between oxygen and hydrogen isotopes and climate in meteoric water, the so-called meteoritic water line and from that resolved a long-standing question of the origin of hydrothermal water. Other examples include establishing the oxygen and hydrogen fractionation between minerals in water-rock reaction (Taylor and Epstein 1963) and carbon and nitrogen fractionation in the food chain (e.g., DeNiro and Epstein 1978), the latter having value in ecology, archeology, etc., as well as geochemistry.

The carbon cycle has intimately linked the evolution of climate and life on Earth and it is in turn is linked to the oxygen and sulfur cycles through photosynthesis and respiration. When life began is still unclear but the discovery of very negative $\delta^{13}C$ ratios in metasediments from Isua, Greenland (Rosing 1999) and hydrothermal vent deposits in Nuvvuagittuq, Labrador (Dodd et al. 2017) tenuously suggests that life began as early as 3.8 billion years ago. Changes in rates of photosynthesis and burial of organic carbon change the levels of both oxygen and CO_2 in the atmosphere, in turn affecting climate. The work of Robert Berner et al. (Berner et al. 1983), and subsequent papers over the following two decades, using carbon isotopes to deduce the evolution of atmospheric CO_2 was another landmark in stable isotope geochemistry. A more detailed record of atmospheric CO_2 through the Cenozoic was achieved through two other quite different isotopic approaches: compound specific carbon isotopic analysis (e.g., Jasper and Hayes 1994; Pagani et al. 1999) and boron isotopes (e.g., Pearson and Palmer 2000).

Theoretical calculations predicted the fractionation between pairs of isotopes should depend on their mass difference. When Robert Clayton et al. (Clayton et al. 1973) measured both $^{17}O/^{16}O$ and $^{18}O/^{16}O$ ratios in meteorites, they found that this was not the case. Initially thought to be a nucleosynthetic effect, this was subsequently recognized as mass independent fractionation (MIF) resulting from photodissociation and self-shielding (Clayton 2002). Subsequently, MIF has been identified in a variety of terrestrial materials,

particularly stratospheric gases. The most significant such discovery was perhaps that of sulfur isotopes in Archean and early Proterozoic sediments (Farquhar et al. 2000) and their absence in all subsequently deposited sediments. Farquhar and Wing (2003) identified ultraviolet photolysis of SO_2 in the atmosphere as the cause. This discovery provided confirmation that atmosphere first became oxidizing around 2.3 billion years ago, the so-called Great Oxidation Event" (Holland 1984). Remarkably, MIF sulfur has also been found in diamonds and in sulfide inclusions in oceanic island basalts from Mangaia (Cabral et al. 2013) and Pitcairn (Delavault et al. 2016) Islands, both in the central Pacific Ocean, demonstrating that terrestrial geochemical cycles extend from the atmosphere to the base of the mantle.

An important recent advance has been so-called clumped isotope analysis, which involves analysis of the distribution of the isotopes of pairs of elements, for example carbon and oxygen. Wang et al. (2004) demonstrated theoretically that the relative abundance of a specific isotopic species, or isotopologues, $^{18}O^{13}C^{16}O$ in CO_2 gas for example, depends on temperature and Ghosh et al. (2006) demonstrated this experimentally. Consequently, clumped isotopic geothermometry offers an advantage over conventional isotope geothermometry in that equilibration temperature can be determined from an analysis of a single phase as well as the isotopic composition of phase with which it equilibrated (Eiler 2013).

The Evolution of Igneous and Metamorphic Rocks

As F. W. Clarke and his colleagues were analyzing the diverse compositions of igneous rocks in the USGS Laboratory in downtown Washington DC, uptown at Carnegie Institution's new Geophysical Laboratory Norman L. Bowen was experimenting with the melting and crystallization of them to explain this diversity. Bowen (1922), along with Norwegian J.H.L. Vogt, thought of "magmas in the light of the laws of solutions, or, better, of phase equilibrium." Bowen's work demonstrated the importance of fractional crystallization in producing compositional diversity and his book, *The Evolution of Igneous Rocks* (Bowen 1928), laid the groundwork for modern experimental and theoretical petrology. Bowen's colleagues and successors at Carnegie, including O. F. Tuttle, H. S. Yoder, and C. E. Tilley continued this work. Meanwhile in Finland, Pentti Eskola (1920) had developed the facies concept of metamorphic rocks. The development of "hydrothermal bombs" enabled experiments exploring the temperature-pressure-composition relationships of metamorphic rocks and ore-forming fluids by many experimenters, including Helmut Winkler (1957) in Germany. With these data, J. B. Thompson (1955) was able to put Eskola's facies concept into a thermodynamic framework.

These experiments were limited to low pressures, so most of the Earth was out of experimental reach and its seismic structure unexplained. On the other side of the world at the Australian National University (ANU), A. E. (Ted) Ringwood, who made many important contributes to mantle geochemistry, realized that the structure of germinates should mimic those of silicates under high pressure. Based on his experiments with germinate analogs, Ringwood (Ringwood 1966) proposed that the seismic discontinuity at 660 km depth was due to the transformation from tetrahedrally to octahedrally coordinated silicon. With the development of multi-anvil presses (Kawai and Endo 1970) and the diamond anvil cell (Merrill and Bassett 1974), experiments were eventually able to reach pressures corresponding to the Earth's core. This apparatus combined with laser heating enabled Ringwood's ANU colleague Lin-Gun (1976) to confirm the transformation of olivine into octahedrally coordinated $MgSiO_3$, recently named bridgmanite, plus MgO. Subsequently, a post-bridgmanite phase was synthesized at pressures corresponding to the lowermost mantle also using the diamond anvil cell (Murakami et al. 2004).

Experiments of this type led to a more quantitative, and ultimately to a thermodynamic, approach to petrology and to the development of thermobarometry: determination of the temperature and pressure at which a rock equilibrated. One of the first such geothermometers was developed by Buddington and Lindlsey (1964) based on exchange reactions between iron-titanium oxides.

Data acquired in experiments over the decades eventually enabled the development of thermodynamic models, such as THERMOCALC (Powell and Holland 2008), MELTS (Ghiorso et al. 2002), and Perple_X (Connolly 2005), to predict the phase assemblages of igneous and metamorphic rocks as a function of temperature, pressure, and composition. Increasingly, ab initio calculations are used as well (e.g., Lin et al. 2016).

Chemistry of the Earth's Surface

Weathering and the Critical Zone

At the surface of the Earth, in the oceans, and the so-called *Critical Zone*, the region most critical life and human society and defined as Earth's permeable surface from the top of the trees to the bottom of the groundwater zone, water plays predominate role in the rock cycle as Gustav Bischof (1847) had realized. Correns and Von Engelhardt (1939) demonstrated the importance of hydrogen and hydroxyl ions, i.e., pH, in weathering. Krumbein and Garrels (1952) added oxidation state to this, introducing E_H-pH diagrams to geochemistry. If one can identify a single founder of modern low-temperature geochemistry, it is Robert M. Garrels (1916–1988). Over his career, he and his colleagues,

including Hal Helgeson, Fred Mackenzie, and Robert Berner established the thermodynamic approach to water-rock interactions including weathering and chemical sedimentation. His books, including *Solutions, Minerals, and Equilibria* (Garrels and Christ 1965) and *Evolution of Sedimentary Rocks* (Garrels and Mackenzie 1971), are still cited. Helgeson (1968) took this to a new level using a computer program to model the evolution of aqueous solutions reacting with rock. At the low temperatures of the Earth's surface, thermodynamic equilibrium is often not achieved, thus the kinetics of geochemical reactions must also be considered. This same group was among the first to quantitatively investigate the kinetic controls on reaction rates (e.g., Garrels et al. 1949; Helgeson 1971). Much additional progress has been made over the last few decades in understanding the kinetics and thermodynamics of weathering within the critical zone (e.g., Brantley and Lebedeva 2011).

Chemical Oceanography

Robert Boyle made the first systematic determination of the saltiness, i.e., salinity, of seawater in 1674, concluding that it was approximately uniform throughout the oceans. A century later, Antoine Lavoisier (1772) reported the first analysis of seawater, albeit in terms of precipitated salts such as *sel gypseux* ($CaSO_4 \cdot H_2O$), *terre calciane* ($CaCO_3$), *sel d'epsom* ($MgSO_4$), etc., rather than elements. Yet another century later, the 77 samples taken on the HMS Challenger Expedition allowed William Dittmar (1884) to confirm that the major ions are always present in constant proportions to one and other and to total salinity as Georg Forschammer (Forchhammer 1862) had postulated. Svante Arrhenius won the 1903 Noble Prize in chemistry for recognizing that such salts existed in solution as dissociated ions and by the mid-twentieth century, equilibrium constants were well enough known for Garrels and Thompson (1962) to calculate the speciation of these ions.

Antoine Lavoisier realized that seawater was part of a larger geochemical cycle, writing, "*The water of the sea results from a washing of the entire surface of the globe; these are in some ways the rinsing of the grand laboratory of nature*" (Lavoisier 1772). The view that oceans did not merely accumulate salt but were in some sort of steady state with outputs balancing inputs began to emerge in the mid-twentieth century (Conway 1942; Holland 1962; Rubey 1951), culminating with T.F.W. Barth's (1952) introduction of the residence time concept. As data on deep sea sediments accumulated, their importance in the geochemical balance became apparent (Goldberg and Arrhenius 1958). The steady-state concept reached maturity with the work of Mackenzie and Garrels (1966), although it was not until 1979 that ridge crest hydrothermal activity was discovered as the major sink for magnesium and sulfate (Edmond et al. 1979) and research on sources and sinks of elements in the oceans continues. Because the oceans are so vast, much of the effort over the last half century has been large-scale international sampling programs such as GEOSECS and GEOTRACES (e.g., Boyle et al. 2015).

Organic Geochemistry

Much of the research into organic geochemistry has been motivated by the search for hydrocarbon energy reserves. By the late nineteenth and early twentieth century, Canadian T. S. Hunt and American D. White had recognized that the formation of petroleum, natural gas and coal resulted from the progressive transformation of organic matter in the sediments during burial (Durand 2003). Along the same lines, Trask and Wu (1930) concluded that petroleum was derived from *kerogen*, a word introduced by Scottish chemist Alexander Crum Brown. A full understanding of the process of transformation of sedimentary organic matter into petroleum did not come until the second half of the twentieth century, much of that through the work of Louis Tissot and colleagues in France (e.g., Tissot and Welte 1984; Tissot 1967).

Alfred Treib's realization that alkyl metalloporphyrins in petroleum were derived from chlorophyll (Treibs 1934) was an important breakthrough and chemical confirmation of the biological origin of petroleum. Organic compounds such as these whose chemical structure can be related to specific biomolecules are known as *biomarkers.* Biomarkers are used to associate petroleum with the specific sedimentary source rocks, determine migration pathways and in assessing the size, extent, thermal maturity, and potential of deposits and forensically to associate hydrocarbon pollution to specific sources. Biomarkers have also proved useful in unraveling the evolution of life (Briggs and Summons 2014). As noted earlier, carbon isotopic analysis of C_{37} alkadienone, produced by marine algae, has been used to determine atmospheric CO_2 through time (e.g., Pagani et al. 1999). Other organic compounds have proved useful for other paleoclimatology studies, including paleotemperature (Eglinton and Eglinton 2008).

August Pütter (1907) found that the amount dissolved organic carbon (DOC) in seawater exceeded the amount of particulate organic carbon, both living and dead. Indeed, the amount of carbon as DOC is comparable to that of the total living biomass and atmospheric CO_2 (Hedges 1992). Williams and Druffel (1987) showed that deep ocean DOC is surprisingly old, with a radiocarbon age of ~6000 years; most of it appears to be of marine rather than terrestrial origin (Hedges and Mann 1979). Research over the past several decades has shown that organic acids complex a substantial fraction of trace metals dissolved in natural waters (e.g., >99% of Fe^{3+}, ~98% of Zn, ~80% of Cd) (Bruland et al. 2014).

The high molecular weight fraction of DOC was long thought to consist of "geomolecules," i.e., abiologic

condensates of biomolecular fragments (e.g., Burges 1960). New extraction and characterization techniques, such as Fourier transform ion cyclotron resonance mass spectrometry and nuclear magnetic resonance, indicate much of this high molecular weight fraction actually consists of biocondensates and is remarkably uniform in composition throughout the ocean (e.g., Aluwihare et al. 1997).

Organic matter is also an important component of soils. Waksman (1936) wrote that "the chemical composition of humus . . .consists of numerous organic complexes" including lignins, proteins, carbohydrates, fats, organic acids, and alcohols. Here too a paradigm emerged that soil humic substances consist of "geomolecules" formed by condensation of biomolecular fragments and its resistance to microbial attack accounted for its persistence (e.g., Parton et al. 1987). This paradigm is shifting as recent advances suggest that humin consists of molecular aggregates of partially decomposed plant polymers loosely held together by entropic interactions and/or noncovalent bonds and that such aggregates are not inherently stable against decomposition and that environmental and biological factors control the stability of soil organic matter (e.g., Kleber and Johnson 2010).

Biogeochemistry

Organic matter is, of course, an important part of the biogeochemical cycle of carbon. A basic understanding of photosynthesis, respiration, and plant nutrition was achieved by the beginning of the nineteenth century through the work of, among others, Lavoisier, Joseph Priestley, and Nicolas-Théodore de Saussure. By the beginning of the twentieth century, Sergei Winogradsky and Martinus Beijerinck had demonstrated bacterial anaerobic and aerobic nitrogen fixation and bacterial sulfur oxidization and reduction. The role of CO_2 and organic acids in rock weathering was also understood by the mid-nineteenth century; indeed, J. J. Ebelman (Ebelman 1845) had pointed out that CO_2 consumed in weathering reactions was subsequently precipitated in the ocean as Ca- and Mg-carbonates. Jean Baptiste Dumas outlined the biochemical oxygen cycle in the mid-nineteenth century. Nevertheless, it was Vernadsky who integrated biological cycles with geological ones, i.e., biogeochemical cycles.

Alfred Redfield discovered that the dissolved nitrate/phosphate ratio in seawater is nearly the same as that in plankton and furthermore nitrate, phosphate, and carbonate increased in concentration with depth in a ratio of 106C:16N:1P (Redfield 1934): the Redfield Ratio. Since carbon and other key nutrients such as potassium are present in seawater in much great abundance, he concluded that N and P limited biological productivity and essentially laid out the present view of the marine biochemical cycle of these elements (Redfield et al. 1963). In the same period, Aleksandr Vinogradov (1953), a student and successor of Vernadsky, published a more extensive compilation of the elemental composition of marine organisms. By 1983, Bolin et al. (1983) wrote "The main features of the natural cycles of carbon, nitrogen, phosphorus and sulphur (C, N, P, S) have been described," although certainly much more has been learned since then, as described by Wally Broecker, the 2006 Crafoord Prize winner, in his memoir (Broecker 2012).

Much work on biogeochemical cycles has focused on how they have evolved over Earth's history and their interaction with climate. Holland (1962) and Cloud (1968), among others, had argued that the Earth's early atmosphere first became oxidizing around two billion years ago as a result of photosynthesis. Discoveries over the last two decades, including the MIF sulfur isotope work mentioned earlier, now establishes the time of the "Great Oxidation Event" at around 2.3 Ga, although there is evidence of "whiffs" of oxygen in the late Archean (Anbar et al. 2007). Recent studies have also revealed that oxygen levels remained low through most of the Proterozoic only began to rise to levels necessary to support metazoans in the late Proterozoic (e.g., Lyons et al. 2014). It is probably no coincidence that the first metazoan fossils date to this time.

Jean-Baptiste Joseph Fourier (1827) realized that the atmosphere worked like a greenhouse, warming Earth's surface. By the late nineteenth century, the work of Irish physicist John Tyndall and American physicist Samuel Langley, among others, had established the mechanism as adsorption of infrared radiation by CO_2 so that Savante Arrhenius (1896) could predict that burning of fossil fuels would ultimately lead to warming. Urey (1952b) recognized the importance of weathering reactions between CO_2 and silicate rocks in moderating atmospheric CO_2 levels. Subsequent landmarks include the hypothesis of Walker et al. (1981) that silicate weathering and subsequent carbonate precipitation has buffered atmospheric CO_2 over Earth's history in pace with increasing solar luminosity so as to maintain habitable surface temperatures and the previously recited work of Berner et al. (1983) and Berner's subsequent revisions of the "BLAG" model of the carbon, oxygen, and sulfur cycles and climate.

Cosmochemistry

The term "cosmochemistry," coined by Rupert Wildt (1940), can be a bit misleading as its principal focus is the Solar System and its origins. Much of the evidence for that origin comes from meteorites. Like geochemistry itself, its roots predate the term. In 1800, French chemist Charles Barthold made the first chemical analysis of a meteorite, the LL6 chondrite that had famously fallen in Ensisheim, Alsace in 1492. Edward Howard (for whom the howardite achondrites are named), John Williams, and Jacques-Louis Count de Bournon (Howard et al. 1802) analyzed four stones and four irons, and their components, including separated metal and

"small globules" (chondrules, as Gustav Rose would name then 60 years later), and emphasized the similarity of all four stones (all ordinary chondrites). These results moved scientific consensus toward acceptance of an extraterrestrial origin of meteorites advocated by German physicist Ernst Chaladni in his 1794 book, but did not settle the debate. The distinguished Swedish chemist and mineralogist Jöns Jacob Berzelius made the first analysis of a carbonaceous chondrite, *Alais* (CI1), which had fallen in 1806. He reported 12% carbon and noted the similarity of the carbonaceous component to humus, which confused the relatively simple picture of meteorites presented by Howard et al. Things were further confused by the fall of the igneous-textured achondrite *Stannern* in Moravia in 1808, and by *Chassigny*, an SNC achondrite, in France in 1815.

By the mid-nineteenth century, the extraterrestrial origin of meteorites was widely accepted and Robert Greg, Auguste Dabrée, and Adolph Boisse had independently proposed that they were the pieces of a disrupted asteroid or planet. In 1884, Henry Sorby began examining meteorites with the petrographic microscope he had invented, describing chondrules as congealed droplets of fiery rain and proposing that they formed within the solar nebula. Viennese mineralogist Gustav Tschermak's (1883) subsequent microscopic studies became the standard work of this era, and, along with Gustav Rose and Aristides Brezina, were responsible for an early system of meteorite classification.

Both Clarke and Goldschmidt were, as described earlier, interested in the relationship between the compositions of meteorites, the Sun, and the Earth. Oliver Farrington (1901), of Chicago's Field Museum, suggested the bulk Earth has the same composition as meteorites, and indeed chondrites remain the basis of estimating Earth's composition, albeit with some modification. Farrington made a number of other key observations about meteorites, including that iron meteorites had crystallized from liquid slowly and that chondrules had crystallized from liquid rapidly. Subsequent important papers on meteorites and their composition were published over the next few decades by, among others, Harrison Brown and Claire Patterson (1948), at the time both of the University of Chicago, and Harvey Nininger.

Cosmochemistry accelerated in the middle of the twentieth century. Harold Urey wrote a number of influential papers on the origin of the Earth, the cosmic abundances of the elements (e.g., Urey 1951, 1952a), and classification of ordinary chondrites (Urey and Craig 1953). Around this time, radiometric dating had matured enough to establish the age of the meteorites at 4.5 Ga (e.g., Patterson 1956) and more high-quality data was accumulating. Van Schmus and Wood (1967) established the present twofold method of classifying chondrites based on composition/mineralogy and parent body alteration/metamorphism; oxygen isotopes subsequently became an additional criterion of classification. Perhaps the most significant addition to this classification was the recognition that a subset of achondrites, the Shergottites, Nakhlites, and Chassignites (SNC), were from Mars (Smith et al. 1984), confirmed by analyses made by the various NASA and ESA spacecraft, landers, and rovers. Subsequently, NASA's DAWN mission confirmed that another subset of achondrites, the HED meteorites, including *Stannern*, are derived from Vesta.

Harry Lord (1965) calculated the condensation sequence of the solar nebula, an effort subsequently improved upon by many others such as John Larimer and Larry Grossman. These calculations predicted Ca-, Al-, and Ti-rich oxides and silicates should be among the first phases to condense. The discovery of calcium-aluminum inclusions (CAI's) in the newly fallen *Allende* meteorite (Marvin et al. 1970) verified those predictions.

In 1957, Margaret Burbidge along with her husband Geoffrey, William Fowler and Fred Hoyle (Burbidge et al. 1957) laid out the modern polygenetic theory of nucleosynthesis. Shortly thereafter, John Reynolds (1960) discovered isotopic anomalies in xenon from meteorites, some of which were clearly due to the decay of ^{129}I ($t_{1/2}$ = 15.7 Ma), but others that were apparently nucleosynthetic. Isotopic anomalies were subsequently found in other rare gases, the source of which turned out to be presolar grains: star dust from red giants and supernovae (e.g., Ming and Anders 1988), and many other elements.

The discovery of the decay products of very short-lived radionuclides, most notably ^{26}Al (Lee et al. 1976) and ^{53}Mn (Birck and Allègre 1985) in the *Allende* meteorite, demonstrated that newly synthesized nuclides had been added to the solar nebula only shortly before and would eventually result in a detailed quantitative time scale of early solar evolution, surprisingly revealing that the evolved parent bodies of achondrites and irons were older, not younger, that those of more primitive meteorites. It now appears that the inner part of the solar nebula, including the materials from which the Earth formed, was slightly enriched in nuclides produced in red giants and the outer solar system slightly more enriched in nuclides produced in supernovae (e.g., Bouvier and Boyet 2016).

Summary

Geochemistry evolved from same roots in metallurgy and alchemy as chemistry and began to immerge as a distinct subfield of both chemistry and geology in the nineteenth century. The works of F. W. Clarke, V. Goldschmidt, and V. Vernadsky laid the groundwork for the subsequent development and progress of the field in the twentieth and twenty-first centuries. Much of that progress can come from technological developments, as described by Johnson et al. (2013).

Over that period, geochemistry has become an integral part of all aspects of earth and planetary sciences, greatly enriching our knowledge of the nature and evolution of our planet and ourselves and our cosmic neighborhood.

Holmium

Scott M. McLennan
Department of Geosciences, Stony Brook University, Stony Brook, NY, USA

Element Data
Atomic Symbol: Ho
Atomic Number: 67
Atomic Weight: 164.93033(2)
Isotopes and Abundances: ^{165}Ho, 100%
1 Atm Melting Point: 1474 °C
1 Atm Boiling Point: 2700 °C
Common Valences: +3
Ionic Radii: 90.1 pm (CN6), 101.5 pm (CN8), and 122.1 pm (CN12)
Pauling Electronegativity: 1.23
First Ionization Energy: 580.99 kJ mol^{-1}
Chondritic (CI) Abundance: 0.0567 ppm
Silicate Earth Abundance: 0.126 ppm
Crustal Abundance: 0.78 ppm
Seawater Abundance: 0.33 ppt
Core Abundance: ~0

Properties

Holmium (Ho), named after *Holmia*, the Latin name for Stockholm, is a soft, malleable, dense (8.795 g cm^{-3}), bright silvery-white metal. Its electronic configuration is [Xe] $4f^{11}6s^2$. It is relatively stable at room temperature, readily oxidizes in the presence of water, and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE). In geochemical terminology, it is grouped with heavy rare earth elements (HREE; Gd-Lu). Holmium has one stable isotope.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Ho as a significant component are restricted to Y and HREE varieties, such as xenotime [$Y(PO_4)$], gadolinite-Y [$Y_2FeBe_2(Si_2O_{10})$], bastnäsite [REE(CO_3)F], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+},Fe^{3+})_3(SiO_4)_3(OH)$], and britholite [$(REE,Ca)_5(SiO_4,PO_4)_3(OH,F)$].

Details of properties, mineralogy, history, and uses of Ho were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner (2016), Hammond (2016), and Meija et al. (2016a b).

History and Use

Holmium was first recognized in 1878 by Marc Delafontaine and Jacques-Louis Soret, who termed it "element X," and independently discovered in 1879 by Per Teodor Cleve, who separated the oxide and named it *holmia*; the pure metal was separated in 1911. Holmium has the highest magnetic moment of any natural element and accordingly is used in pole pieces of high-strength magnets. It is also used in a variety of solid-state lasers used for medical, outer space, and military applications. Ho_2O_3 produces red/yellow colorant for glass, cubic zirconia, and jewelry, and the sharp Ho optical absorption peaks make it a good spectrophotometer calibration standard.

Geochemical Behavior

The fundamental importance of Ho in geochemistry is that it is one of the small trivalent rare earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction."

Holmium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element, with a 50% $T_{condensation}$ of 1659 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Ho is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Ho normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Ho contents of clastic sediments typically reflect their average provenance.

In seawater, Ho has very low concentrations (sub-ppt) and residence times (~1820 year) with speciation dominated by Ho^{3+}, $HoCO_3^+$, and $Ho(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Ho can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Ho. REE (including Ho^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Ho) in human tissues and fluids are very low (~ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Hydrocarbons

John K. Volkman
Oceans and Atmosphere Flagship, CSIRO, Hobart, TAS, Australia

Definition

Hydrocarbons are a class of organic compounds formed solely from carbon and hydrogen. They are broadly classified into two groups: aliphatic and aromatic.

Introduction

The term aliphatic hydrocarbon refers to compounds which may be normal (i.e., straight-chained, designated *n*-), branched, or alicyclic (i.e., containing ring systems, also called naphthenes). Aliphatics may be saturated (i.e., alkanes or "paraffins" having no double or triple bonds with formula C_nH_{2n+2}), or unsaturated (alkenes having one or more double bonds with formulae C_nH_{2n}, C_nH_{2n-2}, etc. or alkynes having one or more triple bonds with formulae C_nH_{2n-2}, C_nH_{2n-4}, etc.). The term olefin is sometimes used to include alkenes, cycloalkenes, and other hydrocarbons containing more than one double bond.

Aliphatic hydrocarbons occur in a wide variety of structural forms each of which can have dramatically different physical properties and chemical reactivities. The simplest naturally occurring hydrocarbon is the gas methane (CH_4; bp −164 °C), which is a saturated alkane and the main constituent of natural gas. The simplest alkene is ethylene ($H_2C{=}CH_2$).

Aromatic hydrocarbons contain ring systems having resonance-stabilized "alternating" double bonds. Aliphatic groups may be attached to the ring (called substituents) or, alternatively, the aromatic ring may be fused to other aromatic or alicyclic rings. Hydrocarbons containing more than two aromatic rings fused together are called polycyclic aromatic hydrocarbons (PAHs). The simplest aromatic hydrocarbon is liquid benzene (C_6H_6; bp 80.1 °C); others include toluene ($CH_3{-}C_6H_5$), naphthalene ($C_{10}H_8$), phenanthrene ($C_{14}H_{10}$), and its structural isomer anthracene ($C_{14}H_{10}$).

Analysis and Identification

Hydrocarbons are extracted from geological materials using organic solvents, such as hexane, chloroform, or dichloromethane, which provide a crude extract containing a variety of organic compounds. The hydrocarbon fraction can be purified using open column chromatography by eluting the hydrocarbons from activated silica and alumina using a nonpolar solvent such as hexane. Elemental sulfur can be removed by treating the extract with activated copper. By judicious choice of solvents and sample:adsorbent ratios, it is usually possible to obtain a clean separation of aliphatic and aromatic hydrocarbons, although some overlap is possible due to the wide range of molecular weights found in the two fractions. The unsaturated hydrocarbon fraction can be further separated according to the number of double bonds present by argentation thin layer chromatography (TLC) or high-performance liquid chromatography (HPLC), where the adsorbent contains adsorbed silver ions which form weak complexes with the double bonds. In these systems, alkanes migrate further than compounds with double bonds. Straight-chain components can be separated from branched-chain ones by adducting straight-chain compounds into urea, thiourea, or molecular sieves, or by using a synthetic zeolite such as silicalite. By judicious choice of the adducting agent, it is also possible to separate simple branched compounds. Gel permeation provides another means of separating hydrocarbons based on molecular size, but this technique is less frequently used.

The amount of aliphatic and aromatic hydrocarbons in an extract can be determined gravimetrically by weighing the fractions after separation, by analysis using Iatroscan thin layer chromatography with flame ionization detection (TLC-FID), or by HPLC with a mass detector. In both cases, considerable care must be exercised to avoid the loss of volatile constituents. An approximate measure of the amount of aromatic hydrocarbons in a sample can be determined using ultraviolet–visible spectroscopy or fluorescence, although this technique typically uses a single calibration to represent a complex mixture.

Each purified fraction is usually analyzed by capillary gas chromatography with flame ionization detection (GC–FID) and by capillary gas chromatography–mass spectrometry (GC–MS) to identify and quantify individual components. The great complexity of hydrocarbon mixtures found in geological samples requires the use of high-resolution capillary columns (often 50 or 60 m in length), but even so the chromatogram of a crude oil often shows a "hump" or baseline rise due to unresolved compounds. This is termed a UCM ("unresolved complex mixture"); for a history of this term, see Farrington and Quinn (2015). Improved resolution of these complex mixtures can be obtained using two-dimensional GC×GC–MS techniques (e.g., Ventura et al. 2008).

The carbon or hydrogen isotope signature of individual hydrocarbons separated by the gas chromatograph can be

determined using GC–irm–MS systems (the so-called CSIA, which is an abbreviation for compound-specific isotope analysis) by passing the effluent from the GC through a combustion furnace and then measuring using an isotope mass spectrometer the isotope composition of the CO_2 or H_2O produced (e.g., Freeman et al. 1990). This ability to ascertain the isotope signature of particular compounds has dramatically improved the ability of organic geochemists to attribute likely sources to different compounds. A further development is the ability to measure the ^{14}C signature of hydrocarbons isolated from geological materials and hence determine their approximate age (e.g., Eglinton et al. 1997).

Occurrence in the Biosphere

Hydrocarbons are ubiquitous in nature where they may occur as solids, liquids, and gases. Hydrocarbons are produced in small quantities by most organisms, and thus small amounts in the range of a few parts per million can be found in all sediments. The distributions in modern sediments can be quite complex due to this variety of natural sources (e.g., Volkman et al. 1986). Some hydrocarbons found in contemporary sediments that have not been contaminated by petroleum products include the C_{30} isoprenoid hydrocarbon squalene, which (as oxidosqualene) is a precursor to the sterols, pristane which is common in zooplankton, phytenes and phytadienes from degradation of phytol, fernenes from certain bacteria, sterenes from sterol degradation, hopenes from bacteria and from degradation of bacterial hopanoids, and C_{25} and C_{30} highly branched isoprenoid (HBI) alkenes from diatoms. Short-chain alkanes, such as *n*-C_{15} and *n*-C_{17}, can be derived from species of microalgae and macroalgae.

Hydrocarbons in Bacteria

The main lipids of bacteria are polar lipids containing straight-chain and methyl-branched (e.g., *iso*- and *anteiso*-odd-chain) fatty acids and polyhydroxylated versions of bacteriohopanepolyols (BHP). Branched alkanes are termed *iso* where the penultimate carbon atom in the chain contains an additional methyl group, or *anteiso* where the carbon atom third from the terminal end contains a methyl substituent. On diagenesis, these lipids can give rise to aliphatic hydrocarbons and hopanoid hydrocarbons respectively. However, a few bacteria and cyanobacteria make significant amounts of a C_{30} hopene called diploptene (hop-22(29)-ene; Bird et al. 1971). Freeman et al. (1994) were able to show using $\delta^{13}C$ values that diploptene in the Cariaco Trench and the Black Sea was likely derived from the lipids of chemoautotrophs living above the oxic/anoxic boundary. Aliphatic hydrocarbons with no odd-even predominance were reported in early studies of the lipids of sulfate-reducing bacteria (Davis 1968), but it is possible that these were contaminants.

Modern sediments deposited under stratified water columns with anoxic bottom waters often contain carotenoid hydrocarbons, such as chlorobactene and isorenieratene derived from the green-colored and brown-colored strains of the green sulfur bacteria (Chlorobiaceae). These lipids are often ^{13}C-enriched (Schouten et al. 2001). On diagenesis, isorenieratene produces a number of compounds including the fully saturated isorenieratane and likely degradation products C_{15}–C_{31} 2,3,6-aryl isoprenoids, which provide biomarkers for photic zone euxinia in ancient seas (Sinninghe Damsté et al. 2001; Slowakiewicz et al. 2015). Chlorobactane can also be used in this way, but it appears to be less common in ancient sediments.

Hydrocarbons in Archaea

In contrast to bacteria, archaea make a diversity of lipids based on isoprenoid chains ether-linked within polar lipids and so are a major source of isoprenoid hydrocarbons in sediments and oils. An example is the C_{20} irregular isoprenoid crocetane (2,6,11,15-tetramethylhexadecane), which is a biomarker for the anaerobic oxidation of methane by archaea (Summons and Lincoln 2012), and a possible marker for photic zone euxinia (Maslen et al. 2009). Methanogens synthesize a variety of isoprenoid hydrocarbons including the C_{25} isoprenoid 2,6,10,15,19-pentamethylicosane (PMI), which can be found in sediments and petroleum (Brassell et al. 1981). Squalane is another methanogen marker, but it can also be formed by reduction of squalene which is widely occurring in aquatic organisms. The C_{40} isoprenoid alkane lycopane is found in a number of organic-rich sediments, but its origins are uncertain and some have attributed it to a phototrophic source rather than from archaea (Wakeham et al. 1993). In the Black Sea and Cariaco Trench, this suggestion is supported by $\delta^{13}C$ evidence (Freeman et al. 1994).

Hydrocarbons in Cyanobacteria

Simple distributions of midchain branched alkanes have been found in some species of cyanobacteria (called blue-green algae in the older literature). These include 7- and 8-methylheptadecane (and traces of the 6-methyl) found in early studies of cyanobacterial lipids by Han and Calvin (1970). Much more complex distributions occur in a few species. For example, Köster et al. (1999) found 21 C_{17}–C_{20} branched alkanes presenting mono-, di-, and trimethyl-branched isomers in cultures of the filamentous cyanobacterium *Calothrix scopulorum*. The major compounds were 4,13-, 5,13-, and 4,5-dimethyl-, and 4,5,13- and 4,5,14-trimethylheptadecane indicating a predominance of substituents at C-4 and C-5 from the end of the chain. Short-chain branched alkanes from cyanobacteria are often found in ancient sediments predating the occurrence of eukaryotes.

Coates et al. (2014) have shown that cyanobacteria produced hydrocarbons from fatty acids by one of two pathways. One involves a two-step conversion of fatty acids first to fatty aldehydes and then alkanes. The second involves a polyketide synthase (PKS) pathway that first elongates the acyl chain followed by decarboxylation to produce a terminal alkene. Their work also revealed new double bond positions (2- and 3-heptadecene) and methyl group positions (3-, 4-, and 5-methylheptadecane).

In addition to diploptene, cyanobacteria synthesize a variety of oxygenated hopanoid derivatives, which on diagenesis can give rise to hopanoid hydrocarbons. 2-Methylbacteriohopanepolyols occur in high proportions in cultured cyanobacteria and in cyanobacterial mats, and thus are a likely source of 2α-methylhopanes and derivatives in organic-rich sediments as old as 2,500 Ma (Summons et al. 1999). In contrast, 3β-methylhopanes are thought to be derived from oxygen-respiring methanotrophs (Eigenbrode et al. 2008).

Hydrocarbons in Microalgae

Hydrocarbons are not usually abundant in microalgae (e.g., Volkman et al. 1986), although many contain the *n*-$C_{21:6}$ alkene (synthesized by decarboxylation of the 22:6 fatty acid) and the pigment β-carotene. An unusual class of highly branched unsaturated C_{25} and C_{30} isoprenoid (HBI) alkenes are abundant in many marine sediments and are now known to be constituents of some diatoms in the genera *Navicula*, *Rhizosolenia*, *Pseudosolenia*, and *Pleurosigma* (e.g., Volkman et al. 1994; Brown and Belt 2016; Kaiser et al. 2016; Belt et al. 2017). HBI alkanes have not been found in oils or sediments older than 92 Ma (Sinninghe Damsté et al. 2004), which implies that this biosynthetic pathway evolved around that time. Certain C_{25} HBIs occur in sea-ice diatoms and the presence of these HBIs in polar sediments has been used as an index of sea-ice extent (Belt et al. 2017).

The green alga *Botryococcus braunii* (from the algal class Trebouxiophyceae) has interested geochemists for many years as it is often associated with organic-rich ancient sediments and today it is being examined as a possible source of biofuels (Largeau et al. 1984; Volkman 2014). Unlike most algae, it contains abundant hydrocarbons and their distribution can be used to define at least four biochemically distinct races A, B, or L (Metzger and Largeau 2005), plus a new race termed S each of which has a distinctive hydrocarbon composition. Race A contains large amounts of long-chain C_{25}–C_{31} alkadienes and alkatrienes derived from the C_{18} monounsaturated fatty acid oleic acid as well as complex mixtures of C_{52}–C_{64} *n*-aldehydes (botryals) formed by aldol condensation of fatty aldehydes and epoxides and complex lipids derived from these lipids. Race B contains C_{30}–C_{37} unusually branched isoprenoid hydrocarbons referred to as botryococcenes as well as squalene and mono- di-, tri-, and tetramethylsqualenes. Race L contains the C_{40} isoprenoid hydrocarbon lycopadiene (2,6R,10R,14,19,23R,27R,31-octamethyldotriaconta-14(E),18(E)-diene). The newly defined S race produces C_{18} and C_{20} *n*-alkanes and epoxy alkanes but lacks botryococcenes and lycopadiene and is thus similar to race A. A related green alga *Choricystis* contains alkanes (*n*-C_{17}, *n*-C_{21} and *n*-C_{23}) and alkenes (*n*-$C_{17:1}$, *n*-$C_{19:1}$, *n*-$C_{21:1}$, *n*-$C_{23:1}$, and *n*-$C_{25:1}$) in different proportions according to the particular strain analyzed.

Hydrocarbons in Vascular Plants

Vascular plants are a major source of organic matter in terrestrial sediments, peats, and coals, and significant inputs can even be recognized in sediments deposited in marine environments far from land. The presence of long-chain (C_{25}–C_{35}) *n*-alkanes showing a strong predominance of odd chain lengths is usually ascribed to plant inputs since such distributions are common in higher plant leaf waxes. Some plant waxes also contain long-chain *iso* and *anteiso*-branched alkanes – tobacco is a good example – but amounts of these hydrocarbons in sediments are usually very minor. Note that long-chain *anteiso*-branched alkanes and the corresponding fatty acids have been found in Antarctic soils containing cryptoendolithic bacteria (Matsumoto et al. 1992).

Various proxies have been proposed based on different carbon-number ranges of *n*-alkanes that purport to distinguish between aquatic submerged vegetation and terrestrial plants. For example, Aichner et al. (2010) showed that emergent aquatic macrophytes contain mainly *n*-C_{27} and *n*-C_{29} alkanes, while C_{21}–C_{23} *n*-alkanes are particularly abundant in floating and submerged aquatic plants (Wang and Liu 2012). Ficken et al. (2000) reported that *n*-alkane distributions from submerged and floating plants ranged from *n*-C_{19} to *n*-C_{33}, maximizing at *n*-C_{25}, with a very low content of C_{29}–C_{31} *n*-alkanes. These authors noted that high relative concentrations of C_{23} and C_{25} *n*-alkanes in cores from Kenyan lakes corresponded to high counts of aquatic pollen taxa, notably Nymphaea (Ficken et al. 2000).

Some plants such as eucalypts also contain abundant volatile sesquiterpene hydrocarbons which can be a major source of atmospheric haze, as typically seen in Australia during summer. However, it is unusual to find significant concentrations of such hydrocarbons in sediments.

Occurrence of Biogenic Hydrocarbons in the Geosphere

The concentration of hydrocarbons in sediments depends on the abundance of the source organism and transfer of its organic matter to sediments, possible formation from other lipids in the sediment and destruction either by biological or abiological processes. Hydrocarbons can be degraded by many

bacteria and such hydrocarbonoclastic bacteria can be found in all modern environments. If this were not so, the globe would be awash with oil from natural seepages alone. Hydrocarbons can be oxidized in air, seawater, and oxic sediments to non-hydrocarbon products or alternatively may be converted to organic sulfur compounds (OSCs) under anoxic conditions by reaction with H_2S, elemental sulfur, or polysulfides.

Many hydrocarbons are also produced by chemical or biological degradation of functionalised lipids, and thus the concentrations of hydrocarbons in sediments generally increase with depth in a core. The complexity of the mixtures can also increase dramatically as the number of structural types and isomeric forms multiplies rapidly. Common examples include the formation of sterenes from dehydration of sterols, phytadienes from phytol, and hopenes from C_{31}–C_{35} polyhydroxyhopanes (bacteriohopanepolyols; BHPs). Alkanes may also be produced by decarboxylation of fatty acids although this is not thought to be significant in recently deposited sediments.

Polycyclic aromatic hydrocarbons (PAHs) are common in many resin-producing plants such as conifers. Retene (1-methyl-7-isopropylphenanthrene) is a major constituent in pine tar and co-occurs with a variety of related compounds. It is not surprising therefore that this general family of compounds is often found in sediments and has been used as a biomarker for conifer contributions to the paleovegetation (e.g., Buggle and Zech 2015). A complicating factor is that retene, dehydroabietin, and 1,2,3,4-tetrahydroretene have been identified in pyrolysates of the green alga *Chlorella protothecoides* and the cyanobacterium *Synechocystis* sp. (Zhou et al. 2000). Wakeham et al. (1980b) recognized five classes of PAH in sediments that have biogenic sources from early stage diagenesis. These were: (1) perylene, the origins of which are still debated but may be from terrestrial fungi (e.g., Zhang et al. 2014); (2) an extended series of phenanthrene homologs; (3) retene and pimanthrene derived from diterpenes; (4) a series of tetra- and pentacyclic PAH derived from pentacyclic triterpenes of the amyrin-type; and (5) tetra- and pentacyclic PAH formed from pentacyclic triterpenes with five-membered E-rings.

Ancient Sediments

Hydrocarbon biomarkers, along with other lipids, have provided considerable information about the depositional environments of ancient sediments and the history of life on Earth (Walters et al. 2010). This information has been instrumental in understanding the factors leading to the deposition of oil shales and petroleum source rocks as well as understanding how the Earth's environment has changed over time. A key proxy has been *n*-alkane distributions which can be ascribed to C-3 or C-4 plants depending on their chain-length distributions and $\delta^{13}C$ values (Garcin et al. 2014). It is becoming common to see a multiproxy approach adopted. For example, Zech et al. (2009) used: (i) the $\delta^{13}C$ of the grass-derived alkanes n-C_{31} and n-C_{33}, (ii) the alkane ratio n-C_{31}/n-C_{27}, and (iii) lacustrine-derived short- and mid-chain alkanes to reconstruct paleoenvironmental changes in the Late Quaternary of NE Argentina.

A great advance has been the ability to measure the δD (δ^2H) content of *n*-alkanes (e.g., Sachse et al. 2012; Guenther et al. 2013), since this can be related to the isotopic composition of the water in which the organism grows and hence its paleoenvironment. δD and $\delta^{13}C$ values of sedimentary biomarkers, such as plant wax alkanes, are being used extensively as paleohydrological proxies, which are able to estimate contributions from C-3, C-4, and CAM plants and changes in climate over a range of geological timescales (e.g., Rose et al. 2016). This has even been exploited in studies of ancient hominids' diet (Uno et al. 2016). However, the isotopic fractionation observed between hydrogen in environmental water and hydrogen in lipids is sensitive to vegetation type and biochemical, physiological, and environmental influences, such as evapotranspiration which are being actively studied (e.g., Guenther et al. 2013).

Other hydrocarbons have been used in paleoenvironmental studies, particularly those associated with vascular plants. In an interesting application, Alexander et al. (1989) were able to use distinctive diterpane and aromatic hydrocarbons produced by trees of the kauri pine group which first became prominent in the Early Jurassic to distinguish Jurassic oils from earlier Permo-Triassic oil in the Eromanga Basin of Australia.

Another category of organic-rich immature ancient sediments that have attracted considerable interest from geochemists is torbanites (also called boghead coals), which contain the fossilized remains of the green alga *Botryococcus braunii* as well as organic matter from bacteria and plants. A variety of hydrocarbons have been described including botryococcenes (markers of the B race of *B. braunii*), *n*-alkanes, isoprenoids, drimanes, macrocyclic alkanes, and various aromatics including alkylnaphthalenes, alkylphenanthrenes, and retene (e.g., Grice et al. 2001).

Hydrocarbons in Coal

Coals contain abundant hydrocarbons ranging from *n*-alkane distributions typical of plant waxes to complex mixtures of PAHs (e.g., Izart et al. 2015). For an overview of the aromatic molecules found in coal, see Radke et al. (1990). Diterpanes are often abundant and have been used in paleoclimate reconstructions. For example, Schulze and Michaelis (1990) studied the hydrocarbons in German coals from the Late Carboniferous Ruhr and Saar Basins. Differences in facies,

maturity, and age were reflected in the distribution of the alkylcyclohexanes. Cyclic diterpenoid hydrocarbons of the phyllocladane type were found in some samples of Carboniferous age. Retene and cadalene have been used as a measure of the relative coniferous input (van Aarssen et al. 2000). PAHs such as benzo[a and e]pyrenes provide markers of combustion of wood during forest fires and peat fires.

While most hydrocarbons in coal are plant-derived, a significant imprint from microbial sources is also common. For example, there is typically a dominance of the C_{30} hopane in the *m*/*z* 191 mass fragmentograms and a high hopanes/steranes ratio (7–46 in Sydney Basin coals; Izart et al. 2015) indicative of the extensive biodegradation of organic matter caused by microbial communities during coal deposition.

Occurrence of Hydrocarbons in Petroleum

With increasing sediment burial, thermal cracking reactions eventually become more important. The high abundance of hydrocarbons in crude oils and thermally mature ancient sediments results from the thermal cracking of macromolecular organic matter (kerogen; Durand 1980) preserved in sediments as well as the release of carbon skeletons that were bound through heteroatoms such as S, N, and O. Kerogen contains diagenetically formed polymeric organic matter plus selectively preserved resistant biopolymers produced by microalgae (algaenans) and higher plants (cutans and suberans; Derenne and Largeau 2001), which survive early diagenesis in sediments. Pyrolysis of these materials yields *n*-alkanes and *n*-alkenes with little odd or even predominance extending in carbon chain length to C_{35} and beyond. Closed-vessel hydrous pyrolysis in which water is added before heating can yield distributions of alkanes remarkably similar to those found in crude oils. Hydropyrolysis (Hy–Py or Hypy; Berwick et al. 2010) at high hydrogen pressures (10 MP) in the presence of a dispersed sulfided molybdenum catalyst also produces mainly hydrocarbon products. Thus, contrary to earlier views that kerogen was formed solely by condensation of lipids, sugars, amino acids, and other biochemicals during early diagenesis, it is now recognized that the kerogen in some sediments can be dominated by resistant biopolymers such as preserved algaenan.

Hydrocarbons are the major constituent of crude oils and natural gas together with smaller amounts of polar compounds and more complex materials such as asphaltenes. As a consequence, hydrocarbons have been the focus of a great number of geochemical studies. Many of these hydrocarbons are termed biomarkers because they retain many of the structural features of their precursor biologically produced lipids. Early studies such as that of Bray and Evans (1961) attempted to use simple *n*-alkanes to identify the source rocks of crude oils, whereas now the great complexity of petroleum hydrocarbon compositions can be exploited. The chain lengths of *n*-alkanes range from C_1 to about C_{40}, although a few oils are known where the *n*-alkanes extend to about C_{100}.

Another common class of branched alkane biomarkers is the isoprenoids which are formed by linking C_5 isoprene (methylbutadiene) units together. Often the most abundant branched alkanes in crude oils are the isoprenoids pristane ($C_{19}H_{40}$) and phytane ($C_{20}H_{42}$). The pristane/phytane ratio in an oil is often used to infer the degree of oxicity of the source rock depositional environment, where values <0.8 in oils are thought to reflect an anoxic depositional environment. A few oils also contain the C_{30} isoprenoid squalane, botryococcanes from green microalgae, and a range of C_{31}–C_{40} isoprenoids from archaea including methanogens (Volkman and Maxwell 1986).

Many polycyclic hydrocarbon biomarkers are used for oil-oil and oil-source rock correlation, as well as to study diagenesis, maturation, and biodegradation of organic matter in sediments and to assess the paleoenvironment prevailing when ancient sediments were deposited (e.g., Peters and Moldowan 1991). Polycyclic hydrocarbons fall into a number of classes depending on the number of carbon atoms in the ring (typically five or six), number of rings, degree of unsaturation, and pattern of alkyl substitution. Cyclic alkanes include the steranes (which have three six-membered rings fused to a five-membered ring plus additional alkyl substituents) which are end-products of sterol diagenesis. The ratio of C_{27}:C_{28}:C_{29} steranes can give an indication of the importance of algal (C_{28}) or plant (C_{29}) contributions to the organic matter. The C_{30} sterane 24-*n*-propylcholestane has been used to infer the presence of algal organic matter (Moldowan et al. 1990), but the related sterane 24-isopropylcholestane is thought to be derived from the sterols of sponges (McCaffrey et al. 1994) and hence can be used to date the first appearance of these organisms. Diasterenes are formed by rearrangement reactions and high levels of diasterenes or diasteranes are often associated with source rocks containing high levels of clay minerals (e.g., Rubinstein et al. 1975), and thus smaller amounts are typically found in coals and carbonate rocks.

Hopanes (which have four six-membered rings fused to a five-membered ring plus various alkyl substituents) are derived from the hopenes and bacteriohopanepolyols (BHPs) synthesized by bacteria and hence are good indicators of bacterial contributions to the organic matter (e.g., Albrecht and Ourisson 1971). Hopane distributions in oils typically range in carbon number from C_{27} to C_{35} with those from C_{31}–C_{35} (sometimes generically termed homohopanes although this strictly refers to the C_{31} components) clearly derived from the corresponding BHPs. A variety of related hopanoids also occur in some oils. These include

25-norhopanes (demethylated hopanes) in which the C-25 methyl group has been removed from its point of attachment at C-10; these demethylated compounds are thought to be produced during late-stage biodegradation of petroleum (e.g., Volkman et al. 1983). If two or three atoms are missing, then the prefix dinor- or trinor-, respectively, is used. Thus, 28,30-dinorhopane (in the older literature 28,30-bisnorhopane) lacks the C-28 and C-30 methyl groups found in hopanes. This unusual hopanoid is found in a variety of settings and it is abundant in some Californian oils (e.g., Schoell et al. 1992). It commonly appears as the free hydrocarbon, rather than in oxygenated forms such as other hopanoids, and its origin is still uncertain. Schoell et al. (1992) suggested an origin from chemoautotrophic bacteria, while Sinninghe Damsté et al. (2014) have suggested an origin from bacteria living at the oxic-anoxic boundary. The 8,14-secohopanes consist of hopanes where the bond between C-8 and C-14 carbon atoms in the C-ring has been broken. Hopane distributions and ratios are used in a number of ways to determine the source, maturity, and extent of biodegradation of an oil (Peters et al. 2005).

Other cyclic hydrocarbons found in crude oils include bicyclic alkanes (sesquiterpanes) which can be derived either from higher plants (e.g., van Aarssen et al. 1990, 2000) or from degradation of hopanes and related compounds (e.g., drimane and homodrimane). Tricyclic terpanes (such as extended cheilanthanes) are found in many oils and are particularly abundant in tasmanite oil shales. Their origins are still the subject of much debate (Dutta et al. 2006). Pentacyclic triterpanes having oleanane, lupane, and ursane skeletons are excellent biomarkers for contributions from vascular plants. Other source markers include cadinanes and bicadinanes common in crude oils from South East Asia, which are derived from a cadinene biopolymer found in fossil and extant dammar resins (van Aarssen et al. 1990). The presence of gammacerane typically indicates a high salinity, stratified depositional environment. A full discussion of these biomarkers can be found in Peters et al. (2005).

Ratios of saturated hydrocarbons, principally various steranes and hopanes, are commonly used as maturity ratios in petroleum studies (e.g., Mackenzie et al. 1988; Peters and Moldowan 1991; Peters et al. 2005). Other proxies have been developed including bicadinanes and related compounds which can be useful maturity indicators for some tertiary oils (Sosrowidjojo et al. 1996). Diamondoids, such as adamantane, are cage-like hydrocarbons with structures resembling those of diamonds, hence their name. They are found in most crude oils, and because of their resistance to thermal and biological destruction, they have proven to be useful biomarkers in petroleum studies. Unlike the biomarkers, they are not produced directly from natural lipids but arise from thermal maturation. They have been used to assess the thermal maturity of highly mature source rocks and crude oils, to assess the extent of oil cracking and as biomarkers for correlating highly biodegraded crude oils (e.g., Fang et al. 2013).

Aromatic hydrocarbons are typically less abundant than aliphatic hydrocarbons in oils have been shown to vary in a systematic way with thermal maturity (e.g., Requejo et al. 1996). This has led to several maturity parameters being proposed. An example is the methyl-phenanthrene index (MPI-1) devised by Radke and Welte (1983), and the trimethylnaphthalene ratio (TNR-2) which proved useful for distinguishing oils from the Java Sea (Radke et al. 1994). Smaller aromatic hydrocarbons can be lost from an oil due to water washing and biodegradation, but PAH and triaromatic steroids are much less affected (e.g., Volkman et al. 1984).

Pollutant Sources of Hydrocarbons

Petroleum-derived hydrocarbons are common in aquatic environments, particularly those near urban centers or where crude oil has been spilled. The techniques of organic geochemistry, such as analysis of biomarkers by GC–MS, are widely used to fingerprint the source of the contamination (e.g., Wakeham et al. 1980a; Volkman et al. 1992; Eganhouse 1997). More advanced analytical methods with a greater resolution, such as two-dimensional GC×GC–MS and ultrahigh resolution Fourier transform ion cyclotron resonance (FT-ICR), are increasingly being used (McKenna et al. 2013). Such techniques were applied to the massive oil spill that followed the explosion on 20 April 2010 of the *Deepwater Horizon* drilling unit, which initiated an uncontrolled release of oil and gas for 87 days from the Macondo seafloor well into the Gulf of Mexico. The Macondo well discharged at least 5 million barrels of oil (~210 million US gallons) and at least 250,000 metric tons of natural gas, largely methane (Joye 2015).

Municipal and sewage outlets are major contributors of hydrocarbons to aquatic environments. Some are petroleum-derived hydrocarbons from industrial sources or road run-off but detergents are also important. Indeed, linear alkyl benzenes (LABs), which are unreacted residues of linear alkylbenzenesulfonate surfactants, have proven to be excellent tracers of urban inputs (Eganhouse 1986).

Complex assemblages of polycyclic aromatic hydrocarbons (PAH) and their alkylated homologs are found in soils and aquatic sediments (Wakeham et al. 1980a). In most cases, these have anthropogenic origins due to increased combustion of fossil fuels (primarily coal) over the last 200 years. In view of the known carcinogenic properties of several PAH, a suite of 16 US EPA priority PAHs are routinely included in analyzes of contaminated sites.

Extraterrestrial Hydrocarbons

Simple organic molecules are continually being delivered to Earth from outer space from meteors and other extraterrestrial bodies. Although most interest has been in compounds such as amino acids that might have been important for questions regarding the origin of life (Pohorille 2002), there has been recent attention to the occurrence of hydrocarbons in space. In 2003 and 2004, telescopes and spacecraft appeared to detect large methane clouds in Mars' atmosphere, but they vanished after a few months. Most recently, NASA's Curiosity rover detected a brief burst of methane in 2013. Methane has now been detected in meteorites from Mars (Blamey et al. 2015). Perhaps more impressive is the occurrence of lakes of liquid methane, ethane, and propane on Saturn's largest moon Titan. These were initially indicated by Data from Voyagers 1 and 2 and later corroborated by the Hubble telescope and the Cassini-Huygens mission Titan.

Summary

Hydrocarbons are ubiquitous in geochemical systems. They can be produced de novo by a variety of organisms, and particular structures, or distributions, can be related to specific sources such as higher plants, microalgae, bacteria, or archaea. They can also be formed in sediments by diagenetic transformations from functionalized lipids by removal of the heteroatom (O, N, P, S, etc.), often accompanied by double bond formation. Hydrocarbons are the major constituents of crude oils due to thermal cracking of the kerogen and algaenans preserved in ancient rocks. The presence of specific biomarkers can be used to indicate the type of depositional environment, and ratios of different isomers can be used as an index of thermal maturity.

Hydrogen

James G. Brophy and Arndt Schimmelmann
Department of Earth and Atmospheric Sciences, Indiana University, Bloomington, IN, USA

Element Data
Atomic Symbol: H
Atomic Number: 1
Atomic Weight: 1.0079 g/mol
Isotopes and Abundances: $^{1}H \sim 99.97\%$, $^{2}H \sim 0.028\%$. ^{3}H trace
1 Atm Melting Point: −259.14°C
1 Atm Boiling Point: −252.87°C
Common Valences: 1+, −1, 0
Covalent Radius: 37 pm
Pauling Electronegativity: 2.2
First Ionization Energy: 1312 kJ/mol
Chondritic (CI) Abundance: 1.97%
Silicate Earth Abundance: 0.012%
Crustal Abundance: 0.014%
Seawater Abundance: 10.8%
Core Abundance: uncertain

Properties

Hydrogen (H) is the lightest chemical element with only a single proton in the nucleus surrounded by a 1 s electron, therefore placing hydrogen in position 1 of the periodic table.

Natural hydrogen is a mixture of two stable isotopes ^{1}H and ^{2}H (see also ▶ "Hydrogen Isotopes"). Protium, ^{1}H, has no neutrons in its nucleus and is the most common form of hydrogen, with an atomic mass of ~1.0078 Da (dalton) and an isotopic abundance of ~99.972% of all hydrogen on Earth. Deuterium, ^{2}H, contains one proton and one neutron in the nucleus giving it an atomic mass of ~2.014 Da, with an abundance on Earth of ~0.028% complementing that of ^{1}H to yield ~100%. Deuterium has been traditionally abbreviated as D, although ^{2}H is recommended officially. In addition to the two stable isotopes of hydrogen, trace amounts of radioactive tritium, ^{3}H, with a half-life of 12.32 years occurs in the atmosphere and hydrosphere. ^{3}H derives from (1) cosmogenic nucleosynthesis via cosmic ray spallation in the atmosphere, (2) nuclear reactions in the Earth's crust, (3) nuclear testing in the atmosphere during the 1950s and 1960s and nuclear accidents like Chernobyl and Fukushima (Povinec et al. 2013), (4) continuous release of tritium from nuclear power plants, and (5) tritium production facilities in nuclear reactors via neutron activation of mainly lithium. The presence of one proton and two neutrons in the nucleus of tritium yields an atomic mass of ~3.016 Da. ^{3}H has been traditionally abbreviated as T, although ^{3}H is recommended officially. Extremely short-lived, artificial hydrogen nuclides with more than two neutrons in nuclei have been observed. Based on hydrogen's atomic number of 1 and the average abundances of its isotopes on Earth, an average atomic weight of ~1.0079 Da has been assigned by IUPAC (http://ciaaw.org/hydrogen.htm). The relative abundance of deuterium is typically larger in abiotic extraterrestrial organic matter (Martins 2011); hence, the ratio of ^{2}H atoms and ^{1}H atoms in the cosmos is not identical to that on Earth. Common valence states are +1 (e.g., hydrogen chloride, $H^{+}Cl^{-}$), 0 (elemental H_2), and −1 (e.g., in metal hydrides). Elemental hydrogen's boiling point of −252.87° C and its melting point of −259.14°C at 101,325 Pa (i.e., 1 atm) make it difficult to transport and store H_2 in condensed form. The bond length in $^{1}H_2$ is 74.13 pm. Hydrogen's empirical covalent atomic radius is ~37 pm, and its empirical atomic radius is ~25 pm. The relative ~100% mass difference between ^{1}H and ^{2}H is the largest in any stable isotope system, strongly affecting the strength of chemical bonds and promoting large isotope effects. Accordingly, the variation in the ratio of ^{2}H and ^{1}H atoms in natural terrestrial materials is larger than that of any other element (see ▶ "Hydrogen Isotopes").

History and Use

Elemental hydrogen H_2 had been first prepared as a gas in the seventeenth century and was finally recognized to represent an elemental substance in 1766 by English scientist Henry Cavendish who called it "inflammable air." The modern name "hydrogen," i.e., "water former," was coined in 1783 by French scientist Antoine Lavoisier.

Elemental hydrogen is mainly generated industrially via electrolysis of water and by high-temperature chemical reaction of coal or other fossil fuels with water steam. Novel techniques for H_2 generation include biochemical and photoelectrical methods. Elemental hydrogen finds many industrial uses, for example, for the production of clean fuels (e.g., catalytic hydrotreating of diesel for removal of sulfur) and the saturation of carbon-carbon chemical double and triple bonds in oils to make margarine. The vision of a "hydrogen economy" where energy will be stored and distributed in the form of elemental hydrogen faces challenges by the difficulty to store H_2 gas in sufficiently compact form (e.g., compressed or adsorbed H_2 gas for use as vehicular fuel). Iceland's availability of inexpensive geothermal energy enabled it to plan for a hydrogen economy, followed in 2014 by similar ambitions in Japan. Safety concerns focus of the explosive nature of hydrogen/air mixtures. Of all combustible gases, hydrogen gas expresses the widest mixing range with air or oxygen supporting combustion and explosion. Although H_2 is far cheaper and more readily available than helium for use in balloons, the Hindenburg airship disaster of 1937 in Lakehurst, New Jersey, has curbed the acceptance of H_2 in lighter-than-air aviation. Liquid hydrogen is the fuel of choice for large rockets lifting payloads into orbit. Proton nuclear magnetic resonance ^{1}H–NMR spectroscopy and imaging (also termed MRI for medical diagnostic applications) uses the nuclear magnetic spin characteristics of ^{1}H nuclei to investigate chemical environments of hydrogen and the distribution of ^{1}H–containing compound classes. Deuterated "heavy water" $^{2}H_2O$ is used in nuclear reactors to moderate neutrons and as a coolant. Industrially generated tritium $^{3}H_2$ high-pressured gas is employed in nuclear triggers.

Occurrence

Hydrogen is the most abundant form of matter in the universe. As remnants of the Big Bang, hydrogen and helium combined constitute about 99.9% of the mass of the solar system (Lauretta 2011). Hydrogen contributes most to the mass of main sequence stars, where nuclear fusion of hydrogen generates energy. "Nuclear burning" of ^{1}H via proton-proton additive chain reactions occurs in solar-mass stars, whereas larger stars with higher core temperatures "burn" hydrogen with the assistance of carbon, nitrogen, and oxygen nuclei until hydrogen is consumed in the core. After a star has aged to become a white dwarf star, explosive hydrogen "burning" on the star's surface can form a nova (Lauretta 2011) giving rise to nucleosynthesis of heavier elements.

Hydrogen is an atmophile element and is the most abundant element in the solar system making up approximately

74 wt. % by mass. It constitutes approximately 0.0055 wt. % of the atmosphere, 0.014 wt. % of the crust, and 0.012 wt. % of the mantle. On the Earth's surface, hydrogen occurs predominantly as water (H_2O), as methane (CH_4), as various ammonia compounds (NH_4^+), and as organically bound hydrogen. In the uppermost crust, hydrogen is present as OH^- in numerous minerals including clay minerals (e.g., kaolinite), zeolites (e.g., natrolite), hydroxides (e.g., brucite), various sulfates (e.g., gypsum), carbonates (e.g., malachite), phosphates (e.g., apatite), as well as many other minerals (Table 1). Within the deeper parts of the crust, it is primarily present as OH^- in high-temperature silicate minerals such as micas, amphiboles, and serpentine. Within the mantle, a small amount of hydrogen is present as OH^- in hydrous silicates (e.g., phlogopite), but most of it is dissolved as OH^- in nominally anhydrous minerals such as olivine and its high-pressure polymorphs wadsleyite and ringwoodite. Though present in such minerals in extremely small concentrations, the large volume of the mantle translates into volumes of OH^- that rival that found in the Earth's oceans today (Pearson et al. 2014; Schmandt et al. 2014). Water partially dissociates into H^+ and OH^- ($K_W = 10^{-14}$). H^+ plays a critical role in the chemical weathering of silicate minerals wherein H^+ substitutes for structurally bound cations which in turn are released as dissolved ions in solution.

Small fluxes of elemental hydrogen naturally emanate from underground reservoirs to Earth's surface, for example, from ultramafic rocks undergoing serpentinization, from some metal mines, and from some young sediments where microbes generate hydrogen from buried organic matter (Smith et al. 2005). Deep H_2 from serpentinization may react with carbon dioxide to form abiotic (or abiogenic) methane that is not a fossil fuel in terms of being generated from organic sedimentary matter (Etiope and Sherwood-Lollar 2013). Radiation from the decay of radioactive nuclides in the lithosphere results in the radiolytic generation of elemental hydrogen from water (Lefticariu et al. 2010). Elemental hydrogen from radiolysis may power a deep microbial biosphere that is operating independently from sunlight and photosynthesis (Colwell and D'Hondt 2013; Colman et al. 2017).

The vast majority of atoms in the hydrocarbon molecules of natural gas (and to a lesser degree in petroleum) are hydrogen atoms that do not contribute carbon dioxide upon combustion. The use of natural gas therefore exerts a smaller carbon footprint than the combustion of energetically equivalent amounts of coal. The O-H and C-H bonds in atmospheric water and methane absorb infrared wavelengths and thus contribute to greenhouse warming. Much organic hydrogen is stored in methane that is physically trapped in water-bearing clathrates (i.e., methane hydrates) at low temperatures and/or high pressure, for example, on the seafloor and in high-latitude permafrost. Incremental warming may destabilize clathrates at high latitudes resulting in methane emissions into the atmosphere, thereby providing of a positive feedback toward enhanced greenhouse warming.

Hydrogen, Table 1 Some common hydrogen-bearing minerals

Mineral	Mineral group	Formula
Kaolinite	Clay	$Al_2Si_2O_5(OH)_4$
Natrolite	Zeolite	$Na_2Al_2Si_3O_{10}.\ 2H_2O$
Brucite	Hydroxide	$Mg(OH)_2$
Gypsum	Sulfate	$CaSO_4.\ 2H_2O$
Malachite	Carbonate	$Cu_2CO_3(OH)_2$
Apatite	Phosphate	$Ca_5(PO_4)_3(F,cl,OH)$
Muscovite	Mica	$KAl_3Si_3O_{10}(OH)_2$
Hornblende	Amphibole	$(ca,Na)_{2-3}(mg,Fe,al)_5Si_6(Si,al)_2O_{22}(OH)_2$
Serpentine	Serpentine	$Mg_3Si_2O_5(OH)_4$
Phlogopite	Mica	$KMg_3AlSi_3O_{10}(OH)_2$
Olivine	Olivine	Mg_2SiO_4

Biological Utilization and Toxicity

Hydrogen is essential for all life and does not express toxicity. Although life on Earth is typically characterized as being carbon-based, there are about twice as many hydrogen atoms in biomass compared to carbon atoms. For example, carbohydrates and lipids have the approximate stoichiometries of $C(H_2O)_n$ and $(CH_2)_n$, respectively. The hydrogen bonding between biochemicals and surrounding cell water is of paramount importance for tertiary chemical structures of biochemicals (e.g., DNA, enzymes) and their associated biochemical reactivity. Subterranean hydrogen trace gas can energetically support microbial consortia.

Summary and Conclusions

Hydrogen is the lightest and most abundant chemical element in the universe. Life on Earth depends on hydrogen in the form of liquid water and organic hydrogen. It is hard to imagine life on other planets in the universe without the essential participation of hydrogen. The solid surface and much of the outer crust of planet Earth have been chemically altered and physically shaped by the influence of liquid water and ice via weathering and sedimentary transport. A world without substantial quantities of hydrogen in water at and near its surface would look vastly different from Earth (e.g., moon, mars), although hydrogen in lakes of liquid methane occurs on planets like Titan. Hydrogen on Earth further plays important roles as a chemical constituent in fossil fuels, especially in natural gas and oil. Elemental hydrogen may become an important clean fuel for transportation if challenges of fuel

cell development and hydrogen gas storage can be met technologically.

Hydrogen Isotopes

Arndt Schimmelmann and Peter E. Sauer
Department of Earth and Atmospheric Sciences, Indiana University, Bloomington, IN, USA

Definition

Natural hydrogen is a mixture of two stable isotopes ^{1}H and ^{2}H and one radioactive isotope ^{3}H. Protium, ^{1}H, has no neutrons in its nucleus and is the most common form of hydrogen, with an atomic mass of ~1.0078 Da (dalton) and an isotopic abundance of ~99.972% of all hydrogen on Earth. Deuterium, ^{2}H, contains one proton and one neutron in the nucleus giving it an atomic mass of ~2.014 Da, with an abundance on Earth of ~0.028% complementing that of ^{1}H to yield ~100%. Tritium, ^{3}H, bears one proton and two neutrons in its nucleus yielding an atomic mass of ~3.016 Da. Tritium is radioactive with a half-life of 12.32 years. Extremely short-lived, artificial hydrogen nuclides with more than two neutrons in nuclei have been observed.

Introduction and Occurrence

Based on hydrogen's atomic number of 1 and the average abundances of its isotopes on Earth, an average atomic weight of ~1.0079 Da has been assigned by IUPAC (http://ciaaw.org/hydrogen.htm). The relative ~100% mass difference between ^{1}H and ^{2}H is the largest in any stable isotope system, strongly affecting the strength of chemical bonds and promoting large isotope effects. Accordingly, the variation in the ratio of ^{2}H and ^{1}H atoms in nature is larger than that of any other element. The relative abundance of deuterium is typically larger in abiotic extraterrestrial organic matter (Martins 2011); hence, the ratio of ^{2}H atoms and ^{1}H atoms in the cosmos is not identical to that on Earth. Deuterium has been traditionally abbreviated as D, although ^{2}H is recommended officially. Only trace amounts of tritium occur in the atmosphere and hydrosphere. ^{3}H derives from:

1. Cosmogenic nucleosynthesis via cosmic ray spallation in the atmosphere
2. Nuclear reactions in the Earth's crust
3. Nuclear testing in the atmosphere during the 1950s and 1960s and nuclear accidents like Chernobyl and Fukushima (Povinec et al. 2013).
4. Continuous release of tritium from nuclear power plants
5. Tritium production facilities in nuclear reactors via neutron activation of mainly lithium

^{3}H has been traditionally abbreviated as T, although ^{3}H is recommended officially.

Nomenclature of Hydrogen Stable Isotope Ratios and Standardization of δ-Values

The stable isotope ratio of hydrogen $^{2}H/^{1}H$ [correctly: R ($^{2}H/^{1}H$), i.e., $N(^{2}H)/N(^{1}H)$, where N is number of entities; Coplen 2011] is traditionally expressed in terms of $\delta^{2}H$ values (formerly δD) in permil, per mil, or ‰. In compliance with IUPAC guidelines for the International System of Units (SI), Brand and Coplen (2012) introduced the unit mUr (i.e., milliurey) as a replacement of ‰ for expressing $\delta^{2}H$ values. Recommendations by IUPAC give an updated definition of $\delta^{2}H$ values without the previous factor 1000, mandate the use of δ in italics, and deprecate the acronym D for ^{2}H (Coplen 2011):

$$\delta^{2}H = \left[R\left(^{2}H/^{1}H\right)_{sample} - R\left(^{2}H/^{1}H\right)_{standard}\right] \times / R\left(^{2}H/^{1}H\right)_{standard}$$

As of fall 2015, $\delta^{2}H$ values are quantified along an isotope scale that is anchored at its origin (≡ 0 mUr) by Vienna Standard Mean Ocean Water (VSMOW) and additionally constrained by Standard Light Antarctic Precipitation (SLAP) with a defined value ≡ –428 mUr (Brand et al. 2014). Accurate determination of $\delta^{2}H$ values mandates the use of multiple-point calibrations with at least two different hydrogen stable isotope standards to account for instrumental scale compression. A listing of international hydrogen stable isotope standards is available in Brand et al. (2014).

Analytical Methods

The measurement of stable hydrogen isotope ratios has undergone major improvements over the past two decades (Beauchemin and Matthews 2010; Jochmann and Schmidt 2012). Traditional mass spectrometry had required preparation of elemental hydrogen from water and other analytical substrates on vacuum lines prior to admission of gaseous hydrogen samples into the mass spectrometer via manual dual-inlet mode. Many "off-line" chemical methods existed to convert hydrogen from various substrates first to water and subsequently to elemental hydrogen (Schimmelmann and Sauer 2010). The analytical efficiency improved by more than an order of magnitude with the introduction of "on-line" high-temperature conversion methods whereby an analyte is introduced into a peripheral instrument in a stream of helium (e.g., a gas chromatograph or an elemental analyzer), through a reducing high-temperature interface, and into the ion source of a mass spectrometer (Wang and Sessions 2008; Elsner et al. 2012). The introduction of chromium into the high-temperature interface served to scavenge interfering heteroelements like nitrogen and sulfur, optimized the hydrogen yield, and minimized isotopic fractionation (Renpenning et al. 2015). The mass spectrometer determines the hydrogen isotope ratio from the relative ion current intensities of mass-to-charge-3 (i.e., $^{2}H^{1}H^{+}$) and mass-to-charge-2 ($^{1}H_{2}^{+}$) ions. A correction for small amounts of $^{1}H_{3}^{+}$ with mass-to-charge-3 ions is instrument-dependent and is called H_3 factor.

An alternative approach for measuring H isotopes based on differences in the vibrational frequencies of ^{2}H and ^{1}H bonds, cavity ring-down spectroscopy (CRDS), has made major advances toward precise compound-specific measurements of $\delta^{2}H$ values of water and methane (e.g., Affolter et al. 2014). CRDS-based on-line systems are inexpensive, can be field-portable, don't require high vacuum or helium carrier gas, and allow fast sample throughput and now rival traditional mass spectrometry for some applications. However, CRDS is still plagued by matrix effects in complex samples and has larger sample size requirements than traditional isotope ratio mass spectrometer (IRMS) instruments.

Some hydrogen in organic matter is linked to oxygen, nitrogen, and sulfur via relatively weak O—H, N—H, and S—H bonds and can readily exchange with water hydrogen, even at room temperature in the laboratory during sample preparation. Bulk $\delta^{2}H$ values of such organic samples are therefore a composite of C-bound H (typically with a primary isotopic signature) and exchangeable H dependent on the seasonally variable isotopic character of local water and atmospheric moisture. Mitigation of the influence of isotopically exchangeable organic hydrogen is possible (1) via derivatization, where problematic functional groups are replaced by moieties that do not contain exchangeable hydrogen, and (2) via controlled equilibration of exchangeable hydrogen with water vapor or steam with known $\delta^{2}H$ values at standardized conditions (e.g., Sauer et al. 2009).

Radioactive tritium's low environmental concentrations are quantified in terms of radiation intensity in ion chambers, gas-flow-proportional-counter-based tritium monitors, and liquid scintillation spectrometry. The measurement unit is becquerel (Bq), i.e., the number of radioactive decay events per second. The most sensitive approach to quantify ^{3}H is mass spectrometry of the daughter decay product ^{3}He (Wood et al. 1993).

Applications of Hydrogen Stable Isotopes

As the most ubiquitous element, hydrogen is involved in a wide range of geologic, biologic, and astronomical systems, and its isotopes are important for archaeology, biochemistry, (bio)geochemistry, cosmochemistry (Martins 2011), diagnostic medicine, ecology, environmental sciences (Elsner et al.

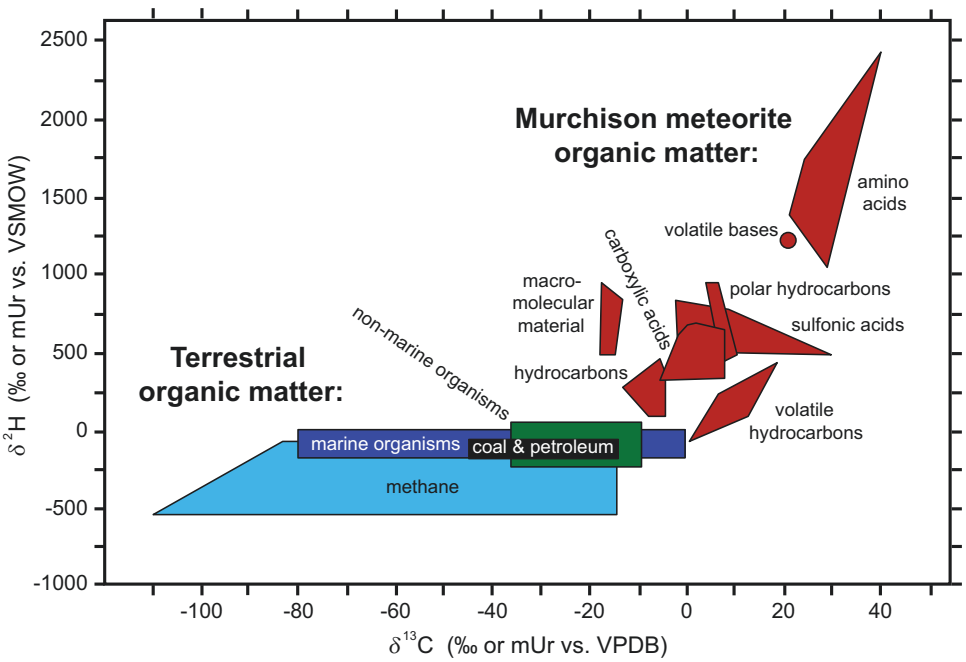
2012), food authentication and forensics (Ehleringer et al. 2015), fossil fuel exploration (Schimmelmann et al. 2006), glaciology, hydro(geo)logy (Bowen et al. 2011), and paleoclimatology.

Hydrogen Stable Isotope Distribution in Nature

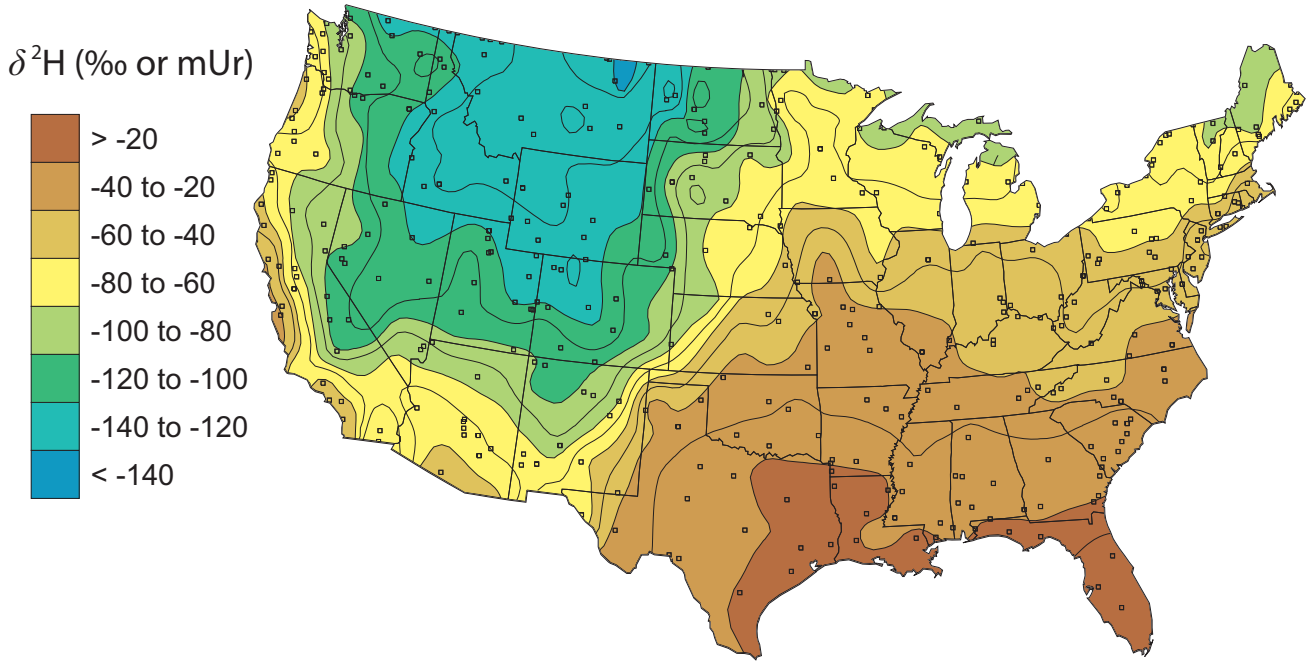
Relative to extraterrestrial materials (McKeegan and Leshin 2001), hydrogen on Earth occupies a relatively narrow isotopic range because almost all organic matter and the hydrogen-rich minerals resulting from weathering of silicates are genetically related to, and isotopically buffered by, the highly active global water cycle and the overwhelmingly large and well-mixed hydrogen pool of the global ocean. The pools of inorganic and organic hydrogen on Earth cover similar, limited δ^2H ranges from about +180 to −530 mUr (Lis and Sauer 2010). In comparison, the δ^2H range of extraterrestrial organic hydrogen from the Murchison meteorite is about four times larger and strongly shifted to ^{2}H-enrichment (Fig. 1), in spite of the fact that mineral hydrogen in meteorites is isotopically comparable to that of terrestrial mineral hydrogen (Yang and Epstein 1983). Based on measurements of Jupiter's atmosphere, the protosolar nebula is thought to have a δ^2H value on the order of −800 mUr (Altwegg et al. 2015). ^{2}H-enrichment increases in the order from interstellar hydrogen to organic molecules in meteorites, to interstellar organic molecules, and has been reported to reach 10,000 mUr (reviewed by Martins 2011). Such a high δ^2H contrast is likely related to isotopic fractionation during the condensation of H-bearing gases in the early stages of solar system evolution and subsequently to the difference in ionic bonding of hydrogen in minerals (primarily as OH^- ions that can equilibrate with H_2O) versus covalent bonding of organic hydrogen to a carbon-based molecular structure (note: the meaning of "organic" is limited to chemical characterization of molecules with a carbon skeleton and does not insinuate any biotic or biogenic origin). Radiation-induced ionization, low temperatures, and high vacuum in space favor very large hydrogen isotopic fractionation during abiogenic syntheses of organics from structurally simple molecules (Yang and Epstein 1983).

Hydrogen Isotopes in the Global Water Cycle

Water vapor evaporating from liquid water is depleted in ^{2}H and leaves behind ^{2}H-enriched water (the same principle applies to oxygen stable isotopes). The isotopic fractionation can be modeled after a Rayleigh distillation. Moist air masses lose ^{2}H-enriched H_2O as rain or snow. The last precipitation from relatively dry air masses in colder climates and at higher elevation is strongly ^{2}H-depleted. As a result, the isotopic pattern of annually averaged precipitation shows ^{2}H-enriched rain in coastal areas near warm oceans and a poleward trend toward ^{2}H-depletion that is enhanced at higher altitude (Fig. 2). The short mixing time of the modern global ocean of ~1500 years results in a narrow range of δ^2H in global ocean water centering around zero mUr or ‰, with a slight ^{2}H-enrichment in areas of enhanced evaporation (e.g., Red Sea) and ^{2}H-depletion where large rivers introduce ^{2}H-depleted freshwater (e.g., Arctic Ocean, Bay of Bengal).



Hydrogen Isotopes, Fig. 1 Hydrogen-carbon stable isotope cross-plot of organic materials and compound classes from the Murchison meteorite (*red fields*) and from terrestrial sources (*blue*, *green*, and *black fields*) expressing a stark difference between extraterrestrial abiogenic and terrestrial biogenic organics (adapted from Sephton and Botta 2005). The stable hydrogen and carbon stable isotope ratios are expressed in traditional δ-units relative to Vienna Standard Mean Ocean Water (VSMOW) and Vienna Pee Dee Belemnite (VPDB) in ‰ or mUr. (Note the much larger isotopic range of more than 2500 mUr for δ^2H values compared to ~150 mUr for δ^{13}C values testifying to much larger isotope fractionation for hydrogen)



Hydrogen Isotopes, Fig. 2 Mean annual hydrogen isotope distribution in discharge-weighted river waters of the contiguous United States (adapted from Kendall and Coplen 2001). The $^{2}H/^{1}H$ stable isotope ratio is expressed in traditional δ-units along the VSMOW-SLAP isotopic scale in ‰ or mUr

The δ^2H values of brackish waters roughly fall on a mixing line between seawater and freshwater. The storage of large amounts of ^{2}H-depleted ice on polar ice caps and glaciers during ice ages intermittently increased the δ^2H value of the global ocean. Groundwaters on continents are typically "fossil precipitation" that reflects the isotopic character of regional precipitation at the time of groundwater recharge. In most temperate zones where precipitation is sufficient to support perennial rivers, δ^2H values of river water reflect those in local groundwater (Fig. 2).

Hydrogen in Biota

All autotrophic organisms (i.e., mostly photoautotrophic plants utilizing sunlight, but also lithoautotrophic organisms using geochemical energy) receive hydrogen for organic biosynthesis from water, albeit with significant isotopic fractionation depending on the biosynthesized chemical and the biosynthetic pathway (Hayes 2001). Compound-specific δ^2H values of biochemicals from autotrophs are therefore related to, and can serve as proxies for, the isotopic composition of environmental water that had supported biosynthesis. Such an approach requires that isotope variations associated with metabolic effects on the target biomarker are minimal. Paleoenvironmental use of δ^2H values of fossil organic matter needs to avoid the influence of isotopically exchangeable organic hydrogen that is mainly linked to oxygen, nitrogen, and sulfur in the form of O─H, N─H, and S─H because such hydrogen continually exchanges with environmental water and does not reliably carry paleoenvironmental information. Ideal compounds to serve as proxies for the reconstruction of δ^2H values of paleoenvironmental waters only contain carbon-bound hydrogen that does not readily exchange with other hydrogen, for example, *n*-alkanes, long fatty acids that can be esterified, and tree-ring cellulose where O─H is derivatized to form nitric acid esters. Heterotrophic organisms (e.g., animals, fungi) metabolize biomass to form their own biomass, which adds the complication of additional isotopic fractionation and the influence of body water that is isotopically different from water available to autotrophs. Nevertheless, empirical scrutiny of δ^2H values of biochemical biomarkers, compound classes, or tissues of algae, plants, animals, and humans resulted in fruitful applications in archaeology, paleoclimatology, ecology, and forensics (Sachse et al. 2012; Ehleringer et al. 2015). For example, δ^2H values in sedimentary lipids have been used to reconstruct source water variations, and δ^2H values in feather and hair keratin, as well as bone collagen, have been used for tracking migrations and for paleodietary reconstruction. The analytical noise from exchangeable hydrogen in solid analytes can be reduced via controlled equilibration with isotopically characterized water vapor or steam at standardized conditions (Sauer et al. 2009).

Hydrogen in Fossil Fuels, Minerals, and Rocks

A small fraction of the organic matter that is co-deposited with detrital mineral grains in sediments escapes early biodegradation and becomes buried. Microbial methanogenesis liberates ^{2}H-depleted methane as long as the temperature remains low. Compaction, increasing pressure, and slow heating along the geothermal gradient transform biochemicals into geochemicals via chemical reactions that eliminate many of the hydrogen-containing functional groups. With increasing thermal maturity, the hydrogen isotopic character of residual organic matter changes in a predictable pattern (Schimmelmann et al. 2006). At elevated temperatures, carbon-carbon bond cracking within larger organic molecules liberates smaller molecules forming thermogenic gas and oil. Cracking generates short-lived radicals that have an opportunity to engage in limited hydrogen isotopic exchange between relatively ^{2}H-enriched pore water and ^{2}H-depleted organic hydrogen, whereby the resulting organic matter becomes more enriched in ^{2}H. The loss of hydrocarbons from maturing sedimentary organic matter leads to a long-term decrease in the elemental H/C ratio of residual insoluble organic matter called kerogen. Regardless of the complex chemical reactions during maturation, paleoenvironmentally relevant information has been gleaned from δ^{2}H values of chemically complex biogeochemicals, such as kerogen, humic acids, and bulk coal (Schimmelmann et al. 2006). Hydrogen stable isotope ratios of components of natural gas and oil have value for the identification of source rocks and discrimination among genetically different types of natural gas (see entry "Natural Gas"). An exception to the origin of hydrocarbons from fossil sedimentary organic matter is methane derived from purely abiotic sources at depth. At least nine abiotic (or abiogenic) methane production mechanisms have been identified that pertain to either magmatic processes or to gas-water-rock reactions, for example, reactions of carbon dioxide and elemental hydrogen resulting in methane. Abiotic methane tends to be slightly enriched in ^{2}H relative to biogenic methane (Etiope and Sherwood-Lollar 2013).

Weathering of silicates in rocks takes up environmental water to generate hydrogen-rich phyllosilicates. Some hydrogen in phyllosilicates is bonded strongly enough to preserve its hydrogen isotopic character after weathering. Hydrogen isotope fractionation factors have been determined for a variety of clay minerals at different weathering temperatures. The δ^{2}H values of non-exchangeable hydrogen in clay minerals serve as proxy for weathering conditions and the isotopic composition of paleoenvironmental water (Clauer and Chaudhuri 1995). Hydrogen stable isotope ratios have been useful for studying water-rock interaction and the formation of minerals in hydrothermal systems (Shanks 2001).

Summary and Conclusions

The scientific, medical, industrial, and forensic importance of hydrogen isotopes, especially of the stable isotopes protium ^{1}H and deuterium ^{2}H, has increased dramatically since the turn of the millennium, which is in part due to a revolutionary simplification and automation of analytical methods. As the lightest of all elements, hydrogen expresses the largest natural isotope fractionation effects. Hydrogen's enormous natural isotopic range is being exploited by an increasing number of scientific and technical fields. From cosmochemical considerations of life on other planets to ice age paleoenvironmental reconstructions based on hair from extinct mastodons and to medical diagnosis of metabolic disorders, to name a few, hydrogen isotopes express astounding versatility and utility with ever-more exciting applications.

H

Hydrologic Cycle

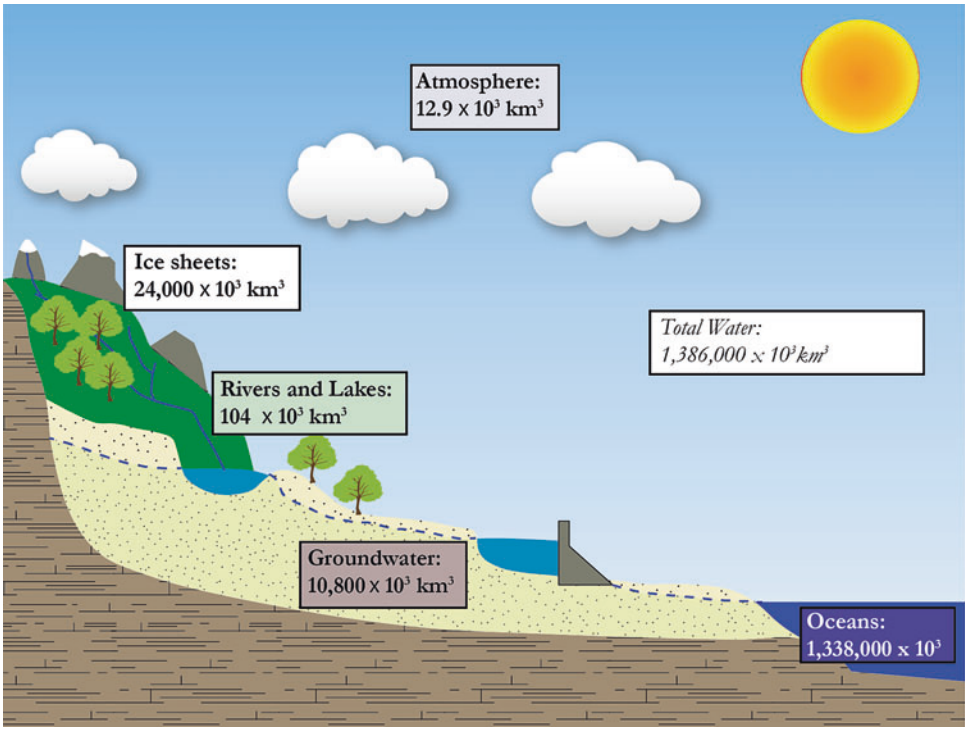
Giuseppe Mascaro
School of Sustainable Engineering and the Built Environment, Arizona State University, Tempe, AZ, USA

Definition

The *hydrologic cycle* refers to the distribution and circulation of water on Earth's surface and subsurface, oceans, and atmosphere. The cycle is a system of *fluxes* of water among different *reservoirs*, where water is stored according to diverse proportions and phases (liquid and solid in the terrestrial and oceanic components; vapor in the atmosphere). Solar energy, required for evaporation and mixing of water in the atmosphere, and gravity are the drivers of the hydrologic cycle. Given the central role of water in all physical, biological, and chemical processes occurring on Earth, studying and quantifying fluxes and reservoirs of the hydrologic cycle is crucial for understating and managing the environment and our relation to it.

Reservoirs and Fluxes of the Hydrologic Cycle

Figure 1 reports estimates of the global water reserves in the major reservoirs. The total reserves sum up to 1,38 6,000 $\times$ 10^3 km^3, with the oceans making up 96.5% (1,338,000 $\times$ 10^3 km^3) and fresh water 2.5%



Hydrologic Cycle, Fig. 1 Estimates of the global water reserves in the major reservoirs of the Earth in km^3 (from http://scied.ucar.edu/longcontent/water-cycle)

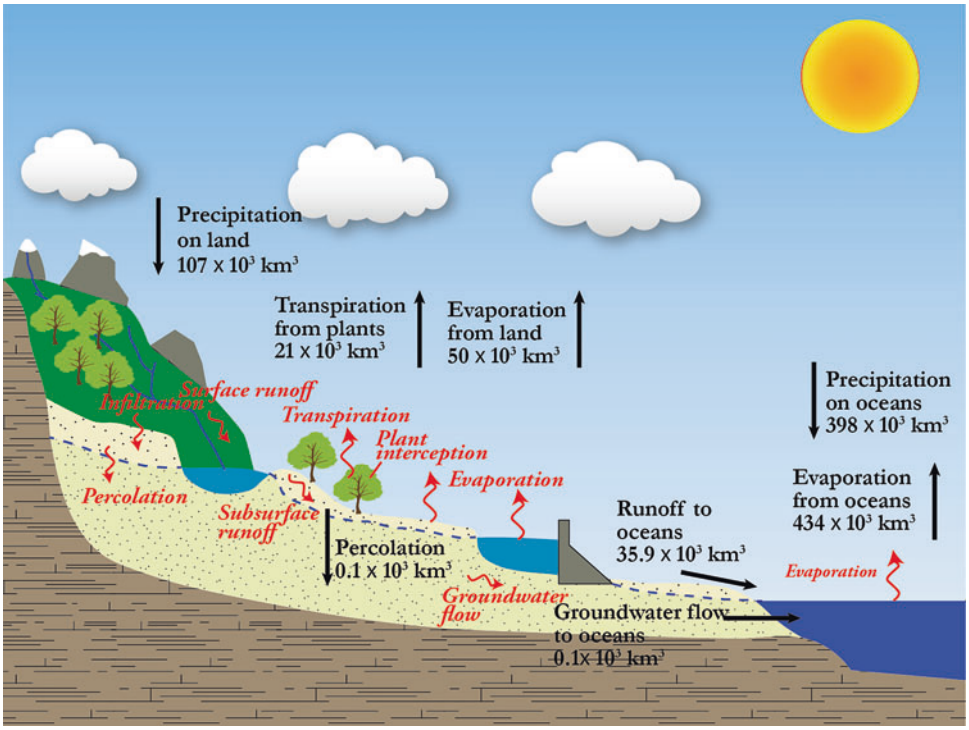
(35,030 × 10^3 km^3) of the total. The remaining portion is saline water in diverse reservoirs. Ice sheets are the largest storages of fresh water (68.7%), followed by groundwater (30.1%), while surface water (rivers, lakes, and swamps) is a minor portion (about 1%). While the total volume of water remains the same globally, water is in continuous motion among the different reservoirs. Figure 2 shows the main fluxes of the hydrologic cycle. Each major reservoir has input and output fluxes that sum up to zero, based on the principle of mass conservation. For example, the flux of water leaving the oceans through evaporation is 434 × 10^3 km^3/year, which is equal to the water entering this reservoir as precipitation (398 × 10^3 km^3/year), river discharge (35.9 × 10^3 km^3/year), and groundwater flow (0.1 × 10^3 km^3/year). The *residence time* of water in each reservoir can be calculated as the ratio between the volume stored and the total input or output fluxes. The residence times range from more than 3000 years in the oceans to only 9 days in the atmosphere.

Main Processes of the Hydrologic Cycle

The main processes of the hydrologic cycle are depicted in Fig. 2 (red italic font). Water moves from the Earth to the atmosphere via *evaporation* from open water bodies (oceans, lakes, rivers, etc.), soil and vegetation surfaces, and *transpiration* from plants whose roots are capable of extracting water from the soil. A change of phase from liquid to vapor is involved in these processes, which are mainly driven by solar energy, wind, and vapor concentration in the air immediately above the evaporating surface or the canopy. Evaporation and transpiration are often lumped together into the term *evapotranspiration*. Water vapor in the atmosphere is transported over long distances due to pressure and temperature gradients and, if conditions permit, it condensates or freezes leading to *precipitation* occurrence on land and oceans in the forms of rainfall, snow, or hail. Precipitation on land may either be *intercepted* by vegetation and then evaporate, *infiltrate* into the soil, or become *surface runoff*. Water infiltrated in the soil can evapotranspire, flow laterally as *subsurface runoff*, or *percolate* through the vadose zone and recharge the aquifers, thus becoming *groundwater*. Surface runoff converges to rivers and lakes and eventually discharges into the oceans as streamflow. Water in the aquifers flows laterally with velocities that are order of magnitudes lower than streamflow velocities. Depending on the geological, topographic, and climatic settings, groundwater can return to the rivers as baseflow or discharge directly into the oceans (Mays 2012).

Measurements of the Hydrologic Cycle Components

Fluxes and stocks of the hydrologic cycle are measured by ground instruments and remote sensors at various spatial and temporal scales and with different level of accuracy. Ground



Hydrologic Cycle, Fig. 2 Estimates of the main fluxes of the hydrologic cycle in km^3/year, showed with *black* arrows (from http://scied.ucar.edu/longcontent/water-cycle). The main processes of the hydrologic cycle are indicated with *red* arrows and italic font. They include evaporation from ocean and land (bare soil, lake, reservoirs, and rivers) to the atmosphere; transpiration from plants to the atmosphere; plant interception; infiltration of precipitated water into the vadose zone; percolation of infiltrated water from the vadose zone to the aquifer (delimited by the *dashed blue* line on the top and by the bedrock on the bottom); groundwater flow; and surface runoff, including overland and channel flow

instruments usually provide measurements at a point with relatively high temporal resolution (subdaily). Examples are rain and snow gages, lysimeters for estimation of evapotranspiration, and soil moisture probes. Remote sensors can be ground-based and air- or satellite-borne and are able to provide spatially distributed measurements with various coverage and spatial and temporal resolution. For example, ground weather radars measure rainfall rates at a resolution of few kilometers in space and tens of minutes in time over a circular area with a radius of about 200 km (http://radar.weather.gov/); satellite sensors provide global estimates at relatively coarse spatial (tens of kilometers) and temporal (from one to several days) resolution of several variables, including precipitation (e.g., Global Precipitation Measurement (the website is reported in the References)), soil water content (e.g., Soil Moisture Ocean Salinity Mission (the website is reported in the References) and the Soil Moisture Active and Passive (the website is reported in the References) mission), evapotranspiration (e.g., Moderate Resolution Imaging Spectroradiometer (the website is reported in the References.)), and groundwater variation (Gravity and Recovery Climate Experiment (the website is reported in the References)).

Spatial and Temporal Variability of the Hydrologic Cycle

Due to the complex interaction of dominant weather patterns, latitude, and surface and subsurface characteristics (topography, soil, geology, vegetation, and land cover), the fluxes and stocks of water vary with location, time of the year, and from year to year. Precipitation is characterized by annual totals that mostly depend on latitude (up to 2000 mm/year within the tropics and less than 100 mm/year close to the poles) and elevation, and by marked seasonality in certain regions such as those affected by the monsoons. Evapotranspiration is strongly controlled by latitude (maximum near the equator and almost zero at the poles) and displays diurnal and seasonal cycles, as an effect of the spatial and temporal variability of the solar radiation balance. The spatial distribution of runoff is mostly correlated with that of precipitation, while its time variability is affected by the seasonality of precipitation and evapotranspiration, as well as by the timing of snowmelt (Dingman 2002).

Link Between Hydrologic Cycle, Energy Balance, and Climate Change

The hydrologic cycle is directly linked to the energy balance of the Earth: the evapotranspiration component multiplied by the latent heat of vaporization (~2.45 MJ/Kg at ordinary temperatures and pressures) is the latent heat flux, which is the largest component of the atmospheric energy balance. The term "latent" refers to the fact that, in the phase transition from liquid to vapor, water absorbs energy without changing temperature. This energy is subsequently released during condensation.

The concentration of greenhouse gases in the atmosphere affects the energy balance of the Earth. As a result, an increase in concentration of these gases is expected to impact the hydrologic cycle, possibly causing modifications of spatial patterns and temporal distribution of the main water fluxes and changes in the reservoir storages. For example, recent observations have shown evidence of ongoing changes of parts of the climate system at unprecedented rates that can be associated to higher concentration of greenhouse gases. These include an increase in mean global temperature; melt of mountain glaciers and ice sheets in Antarctic, Greenland, and Arctic regions; and sea level rise. Understanding how global change of climate affects the hydrologic cycle at regional and local scales is crucial for the sustainable management of water resources, as well as for predicting, forecasting, and mitigating water-related hazards. As a result, this represents an active interdisciplinary research area involving hydrologic, climate, social, and political sciences.

Summary

The hydrologic cycle accounts for the movement and storage of water (in its three phases) on Earth. This process is driven by solar energy and is characterized by spatial and temporal variability of both fluxes and storages. The great majority of the Earth's water is contained in the oceans, while only a very small portion is fresh and, thus, useful for human activities. In the land, water moves and is stored in the surface, subsurfaces and biotic components, according to complex processes that are measured with ground and remotely sensed instruments. The hydrologic cycle is intimately tied to the energy balance via the evopotranspiration term. As a consequence, the emission of greenhouse gases in the atmosphere, which is known to impact the energy balance of the Earth, may modify intensity and variability of the hydrologic cycle. Quantifying and predicting the hydrologic cycle at multiple scales through observations and numerical models is crucial for the sustainable management of water resources, mitigation of hydrologic extremes, and preservation of ecosystems.

Hydrothermal Alteration

Andri Stefánsson and Barbara I. Kleine
Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland

Definition

Hydrothermal alteration involves the replacement of primary glass and minerals with alteration minerals stable at the conditions of alteration, generally in the temperature range of 50–400 °C. Hydrothermal alteration is sometimes referred to as low-grade metamorphism or metasomatism. The physical and chemical changes leading to the formation of hydrothermal alteration are temperature, pressure, and chemical changes of the system or any combination of these. Hydrothermal alteration is a common feature of geothermal systems. Alteration textures range from weak alteration of only some of the minerals or matrix in the host rocks to complete replacement of the primary minerals by the alteration minerals. Hydrothermal alteration may occur within the crust associated with hot rock or magmatic activity as well as at the Earth's surface.

Alteration Processes

The process of alteration involves the dissolution of primary glasses and minerals by thermal fluids and precipitation of alteration minerals. The primary minerals and glasses are formed at high temperatures and upon cooling become thermodynamically unstable. In contact with thermal fluids, they dissolve forming aqueous and gases species in the fluid. Progressive dissolution results in increased concentrations of the rock-forming elements in the thermal fluids. Eventually, they become saturated with respect to minerals that subsequently may form.

The Source and Chemistry of the Thermal Fluid

The sources of thermal fluids resulting in hydrothermal alteration are mainly three: (1) near surface and groundwater generally meteoric or seawater, (2) magma volatiles exsolved from melt termed juvenile water, and (3) fluids originated from dehydration upon metamorphic reactions. The hydrothermal fluids range in chemical composition from dilute (<100 ppm NaCl) to concentrated brine (up to ~50% NaCl) and have very variable volatile concentrations with the main volatiles often being C-, S-, Cl-, and F-containing compounds (e.g., Arnórsson et al. 2007; Heinrich 2007; Webster and Mandeville 2007).

Formation of Hydrothermal Minerals

Hydrothermal alteration minerals are sometimes referred to as secondary minerals. Many are common, for example, in low-grade metamorphic rocks and hydrothermal ore deposits, whereas others are rare. Common hydrothermal minerals are: quartz and other forms of silica (chalcedony, opal, amorphous silica), illite, sericite, smectites, zeolites, chlorite, serpentine, albite, K-feldspar, epidote, prehnite, actinolite, garnet, sulfides, carbonates, talc, kaolinite, pyrophyllite, sulfates, oxides, and hydroxides (Browne 1978).

The formation of hydrothermal minerals depends on several factors including: (1) temperature, (2) pressure, (3) rock type, (4) permeability, (5) hydrothermal fluid composition, and (6) duration of alteration or extent of reaction.

Hydrothermal mineral stabilities depend on temperature. This is related to changes in the mineral solubilities with temperature. As a result, hydrothermal minerals commonly show temperature-related zonation with typically low-temperature minerals like smectites and zeolites formed at <150 °C and high-temperature geothermal minerals like quartz, albite, chlorite, and epidote formed at 200–300 °C and amphibole, hornblende, and garnet at >300 °C (Kristmannsdóttir 1979).

Fluid pressures in geothermal systems are generally low, rarely exceed ~200 bar, and are not considered to affect the type of hydrothermal alteration. However, changes in pressure can lead to boiling and changes in gas pressure and mineralization. An example is calcite formation associated with depressurization boiling (Simmons and Christenson 1994).

The rock type affects hydrothermal alteration mainly through changes in permeability. In fact, the initial primary mineralogy has limited effects on hydrothermal alteration, particularly at temperatures >200 °C. For example, quartz, albite, K-feldspar, chlorite, epidote, calcite, and pyrite are the dominate alteration minerals associated with rhyolite, andesite, and basalt (Browne 1978).

Permeability is a major factor affecting hydrothermal alteration. The process of hydrothermal alteration involves interaction of fluids with minerals. The availability of fluids and contact between minerals and fluids is therefore of central importance. At low permeability and associated with limited availability and flow of hydrothermal fluids, primary minerals and rocks can withstand alteration to high temperatures. In contrast, along fluid flow paths, e.g., along fractures, the mineralogy is commonly dominated by hydrothermal minerals.

Thermal fluid composition can have a major factor on the nature of hydrothermal alteration. An example of this is the low-temperature alteration of basalts. In fluids of meteoric origin with low CO_2 concentrations and at temperatures of 100–150 °C, fluid-basalt interaction leads to alkaline fluid pH, and formation of smectites, zeolites, chlorite, and quartz (Neuhoff et al. 1999), whereas under similar conditions in CO_2-rich fluids, Ca-Mg-Fe carbonates and quartz predominate the alteration mineralogy (Rogers et al. 2006). At higher temperatures (200–300 °C), the alteration mineralogy can be effected by acidity of the fluids. Strong acids, such as HCl and H_2SO_4, commonly originated from magma gases, can cause the pH of the thermal fluid to be low. This results in formation of argillic alteration consisting of sulfates like alunite and gypsum, kaolinite, illite, smectite, quartz, and oxides, whereas the hydrothermal alteration associated with fluids with low magma gas input is dominated by zeolites, chlorite, epidote, prehnite, quartz, sulfides, and carbonates (e.g., Browne 1978; Lonker et al. 1990, 1993). Argillic alteration can also form at the surface of geothermal systems as a result of magma gases, e.g., when associated with volcanic lakes (e.g., Delmelle and Bernard 1994; Africano and Bernard 2000), and due to oxidations of H_2S to sulfuric acid and formation of low-pH surface fluids (e.g., Markússon and Stefánsson 2011).

The duration of hydrothermal alteration can also play a significant role in both extend of alteration and alteration mineralogy. Increased alteration time can be expected to increase the mass of alteration minerals until all the primary minerals have been replaced. Additionally, progressive fluid-rock interaction may lead to changes in the alteration mineralogy. Such an effect has been demonstrated for low-temperature alterations of basalts, where under closed system conditions alteration mineral assemblages reflect time zonation from clays, to chlorites to zeolites as a function of extent of reaction or reaction time (Neuhoff et al. 1999).

Hydrothermal Alteration and Metal Deposits

Hydrothermal alteration often forms hydrothermal metal deposits. The simplest is a vein that forms where a hydrothermal fluid flows through an open fissure and precipitates minerals along the flow path. At great depth many veins occur close to bodies of intrusive igneous rocks because the igneous rocks serve as heat sources that create convectively driven flows in hydrothermal solutions. Hydrothermal deposits formed at shallower depths are commonly referred to as epithermal. Many of the famous silver and gold deposits are epithermal. Among the most distinctive hydrothermal deposits are porphyry copper deposits, which are invariably associated with igneous intrusions, with some deposits containing many billions of tons of ore. Skarn deposits are formed upon high-temperature alteration of limestone or marble. Most skarns are formed adjacent to igneous intrusions and result in formation of minerals like pyroxene, amphibole, and garnet. Volcanic massive sulfide deposits form alteration of volcanic rocks with seawater beneath the sea. These constitute some of the richest deposits of copper, lead, and zinc known.

Summary

Hydrothermal alteration occurs in geothermal systems and involves the replacement of the primary mineral assemblage by alteration minerals. Changes in temperature, pressure, and chemistry of the system usually induce extensive alteration of the host rock. Hydrothermal alteration processes are of great economic interest as they have an important role in the formation of epithermal mineral deposits such as porphyry copper deposits.

Hydrothermal Solutions

Jean-François Boily
Department of Chemistry, Umeå University, Umeå, SE, Sweden

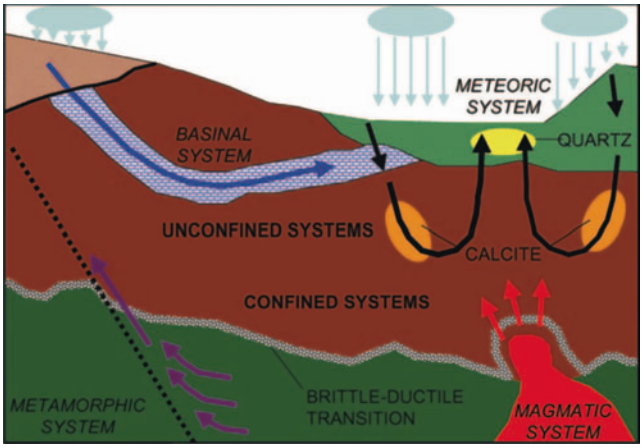
Definition

An aqueous solution with temperatures exceeding Earth's surface temperature (*hydro* = water, thermal = hot). Hydrothermal solutions originate in Earth's subsurface and carry dissolved minerals, salts, and gases.

Introduction

In Earth Sciences, hydrothermal solutions are predominantly hot briny aqueous solutions present in Earth's subsurface and surface. They exist in meteoric, seawater, (sedimentary) basinal, metaphormic as well as magmatic systems, and are solvents for mineral-building and carbon-bearing species, as well as gases, and often carry high concentrations of sodium chloride. These solutions are key actors to both mass and heat transport in the subsurface, and have formed vast numbers of hydrothermal mineral deposits throughout geological times. The study of hydrothermal solutions is needed to resolve the conditions under which metals ions migrate in hot briny fluids in Earth's crust to form economically valuable mineral deposits, known as hydrothermal ore deposits (Barnes 1997). Another strong motivation for the study of these solutions lies in the possibility that life may have originated in hydrothermal vents (Wächtershäuser 1990).

Hydrothermal solutions can be produced by a variety processes (Fig. 1) in what (Kesler 2005) describes in unconfined and confined systems. Those in unconfined systems are largely contacted with cool brittle rocks at hydrostatic pressures and are in contact with Earth's surface. Examples of solutions include those of meteoric origin or seawater that have seeped to greater depths via fractions or porous media. Hydrothermal vents represent another source of unconfined hydrothermal solutions, and notably include submarine systems along mid-ocean ridges as well as terrestrial systems (e.g., hot springs, fumaroles, geysers). Those in confined systems are not in contact with the surface. These include connate (or formation) waters trapped in sediments, which are involved in diagenetic processes, as well as those associated with hot and ductile rocks in metamorphic and magmatic settings where water can also be produced as a result of mineral (re)crystallization reactions. Hydrothermal



Hydrothermal Solutions, Fig. 1 Schematic representation of hydrothermal systems (Taken from Kessler (2005)

solutions can be directly or indirectly heated by magmas, but also by radioactive decay of host rocks or even frictional heating by faulting of Earth's crust (Stein 2013). Flow of the resulting hot briny aqueous solutions in the subsurface can be driven by gravity, as well as thermal or concentration gradients. As such, hydrothermal solutions can migrate from one geological setting to another, and thus aquire (isotopic) compositions reflecting the rocks and/or external bodies of water with which they have been contacted.

Mineral deposits formed by hydrothermal solutions can be spatially confined in pre-existing pores and fractures or by openings produced by replacement of surrounding rocks. Ore deposition reactions can be triggered by phenomena including, mixing with other fluids, cooling, boiling, loss of pressure, changes in oxygen fugacity, or reactions with host minerals. Deposits can be concentrated as veins in fractured rocks, in pores, disseminated deposits through large volumes of rocks, stratabound deposits in unconsolidated sediments, or even as sorbed on host rock (e.g., invisible gold on sulphide minerals). Deposits of these types as well as fluid inclusions (Roedder 1984) offer a window into the composition of ancient hydrothermal solutions. Modern-day hydrothermal solutions can be studied in hot springs, sedimentary basins, oil fields, and submarine volcanoes. The latter produce chimneys (e.g., black smokers, white smokers) composed of minerals that precipitated as dissolved ions from incoming hydrothermal solutions react with cold seawater.

Comprehensive and historical review-type publications dedicated to hydrothermal solutions in Earth Sciences include those of Palmer et al. (2004), Yardley and Bodnar (2014), and Barnes (2015). In this article, salient physicochemical properties of hydrothermal solutions are presented. This level of knowledge provides the basis upon which geochemical reactions taking place in these fluids can be understood.

Physicochemical Properties of Hydrothermal Solutions

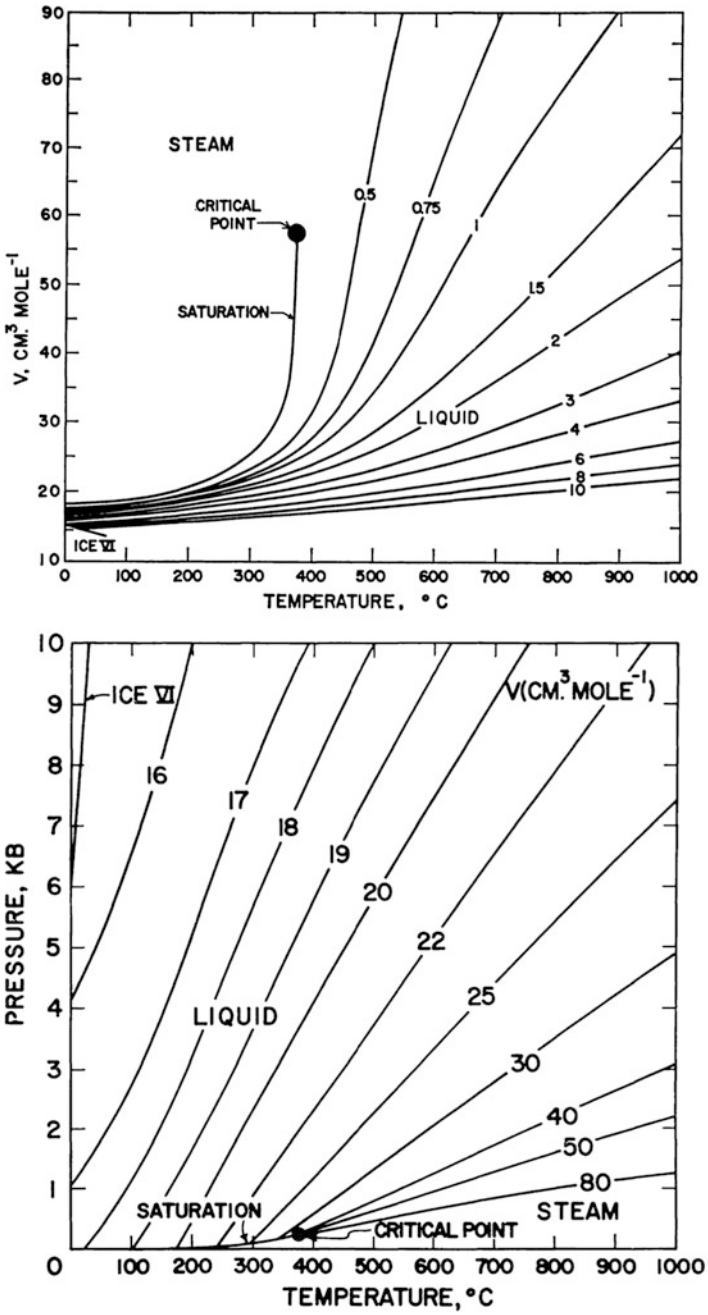
Knowledge of the thermodynamic stability and stoichiometries of aqueous complexes formed in hydrothermal solutions is key to the prediction of the pressure and temperature dependent solubilities of minerals in Earth's subsurface. Most notably, changes in molar volume, polarity, and acidity affect the ability of water at solvating ions and hosting aqueous reactions at various temperatures and pressures. Salient examples of such effects can for example be found in (Palmer et al. 2004) for water (Harvey and Friend 2004; Seward and Driesner 2004), gases (Fernández-Prini et al. 2004), and acids and bases (Tremaine et al. 2004).

The International Association for the Properties of Water and Steam (www.iapws.org) provides, in this regard, pertinent tools for predicting their properties (Wagner and Pruss 2002). The SUPCRT92 code of (Johnson et al. 1992) is a well-known tool in Earth Sciences providing means to estimate the free energies of aqueous species to 1000 °C and 5 kbars using the HKF equations of state (cf. Helgeson and Kirkham 1972, 1974, 1976; Helgeson et al. 1981). At the same time, new experimental and theoretical studies of aqueous speciation and mineral solubility in hydrothermal solutions continuous to advance the field.

The pressure-temperature phase diagram of pure water is characterized by the liquid-vapour curve. This curve denotes the pressure/temperatures pairs at which both liquid and vapour coexist. It ranges from a triple point, where all three phases of water coexist at 273.16 and 611.657 Pa (Bielska et al. 2013; Guildner et al. 1976), to a critical point at 647.096 K and 22.064 MPa. Liquid water is present at pressures above while gaseous water is present at pressures below this curve. Isochores (lines of constant volume) are steeper above the liquid-vapour curve are nearly-vertical because the fluids are nearly imcompressible (Fig. 2). Lines below the curve are, on the other hand, largely horizontal because water vapour is considerably more compressible. Above 373.95 °C solutions become supercritical, such that both liquid and gaseous phases coexist as hydrogen-bonded clusters within a gas-like phase (Wagner and Pruss 1995). These values are however shifted by dissolved salts, such as sodium chloride (Bischoff and Rosenbauer 1988).

Volumetric properties are instrumental to the the study of hydrothermal solutions (Fig. 2). At a thermodynamic level, the total differential of Gibbs free energy (dG)

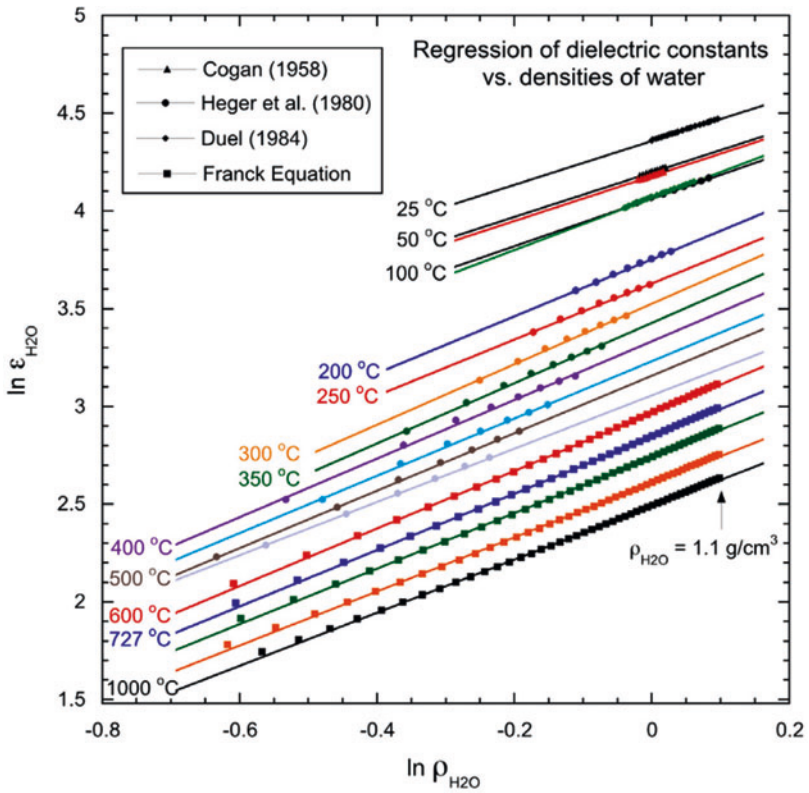
$$dG = VdP - SdT + \mu dX \quad (1)$$



Hydrothermal Solutions, Fig. 2 (**a**) Molal volumes of water as a function of temperature (From Helgeson and Kirkham 1974) (**b**) Molal volumes plotted as isochores. (From Helgeson and Kirkham 1974)

is expressed in terms of the volume (V), entropy (S) and chemical potential of a (μ) system, respectively for gradients in pressure (P), temperature (T) and composition (X). Thus changes in Gibbs free energy as a function of pressure and constant temperature and composition can be derived from volumetric measurements. Yardly and Bodnar (Yardley and Bodnar 2014) provide further details on how enthalpy and entropy have been derived further from such values. Equations are also available for the reliable prediction of density, enthalpy and entropy of water for saturated liquid and vapor (Wagner and Pruss 1993).

The temperature dependence on the dielectric constant (static permittivity) of water (Fig. 3) provides means to understand changes in chemical speciation. For instance, the HKF equation of state expresses solvation contributions to the free energy of the system through Born solvation (ΔG_B):



Hydrothermal Solutions, Fig. 3 Relationship between ε and water density (Taken from Sverjensky et al. 2014)

$$\Delta G_B = \omega \frac{1}{\varepsilon} \quad (2)$$

where ω is a species-related parameter. Dielectric constant relates to the dipole moment of the water molecule, and thus to its chemical polarity. The aqueous solutions of high ε consist of polar water molecules with greater abilities to solvate highly charges ions than those of low ε. Because ε is lowered by high temperatures, hydrothermal solutions have the tendency to stabilize species of lower charge than those of at low temperature. This also translates to the stabilization of low-charged aqueous complexes in solutions of low ε (Fig. 3). Recent development in the estimation of ε now allow predictions of speciation to 1200°C and 60 kbars (Pan et al. 2013; Sverjensky et al. 2014). See, for instance, predictions of quartz solubility in *Solubility.*

Finally, temperature- and pressure-induced changes in the self-dissociation of water ($K_w = a_{H^+} \cdot a_{OH^+}$) represent a property of central interest to the study of hydrothermal solutions (Fig. 4), and that is key to the concept of pH. Increasing temperatures facilitate water dissociation, with maximal H^+ and OH^- concentrations achieved at ~249 °C. Above this temperature higher partial molal volumes (lower water densities) work against water self-dissociation by limiting proton transfer reactions via, for instance, Zundel-type clusters ($H_5O_2^+$) (Han et al. 2006). pH neutrality, defined as $-^1/_2 \log K_{w,}$ then becomes strongly temperature- and pressure-dependent.

Summary

Hydrothermal solutions are predominantly hot briny solutions in Earth's subsurface. They can migrate from one geological setting to another as they acquire isotopic and chemical compositions characteristic of the rocks and fluids with which they have been contacted. They are the principle sources of hydrothermal ore deposits that have formed as a result of the precipication of metal ions from hydrothermal solutions, an event that can be triggered by mixing with external bodies of water and/or temperature or pressure changes.

The aqueous speciation of hydrothermal solutions relies upon an understanding of the temperature- and pressure-induced changes in water chemistry. Variations in water partial molal volume, dielectric constant, and ionization constant impact the ability through which water molecules interact with ions and host a range of geochemical reactions.

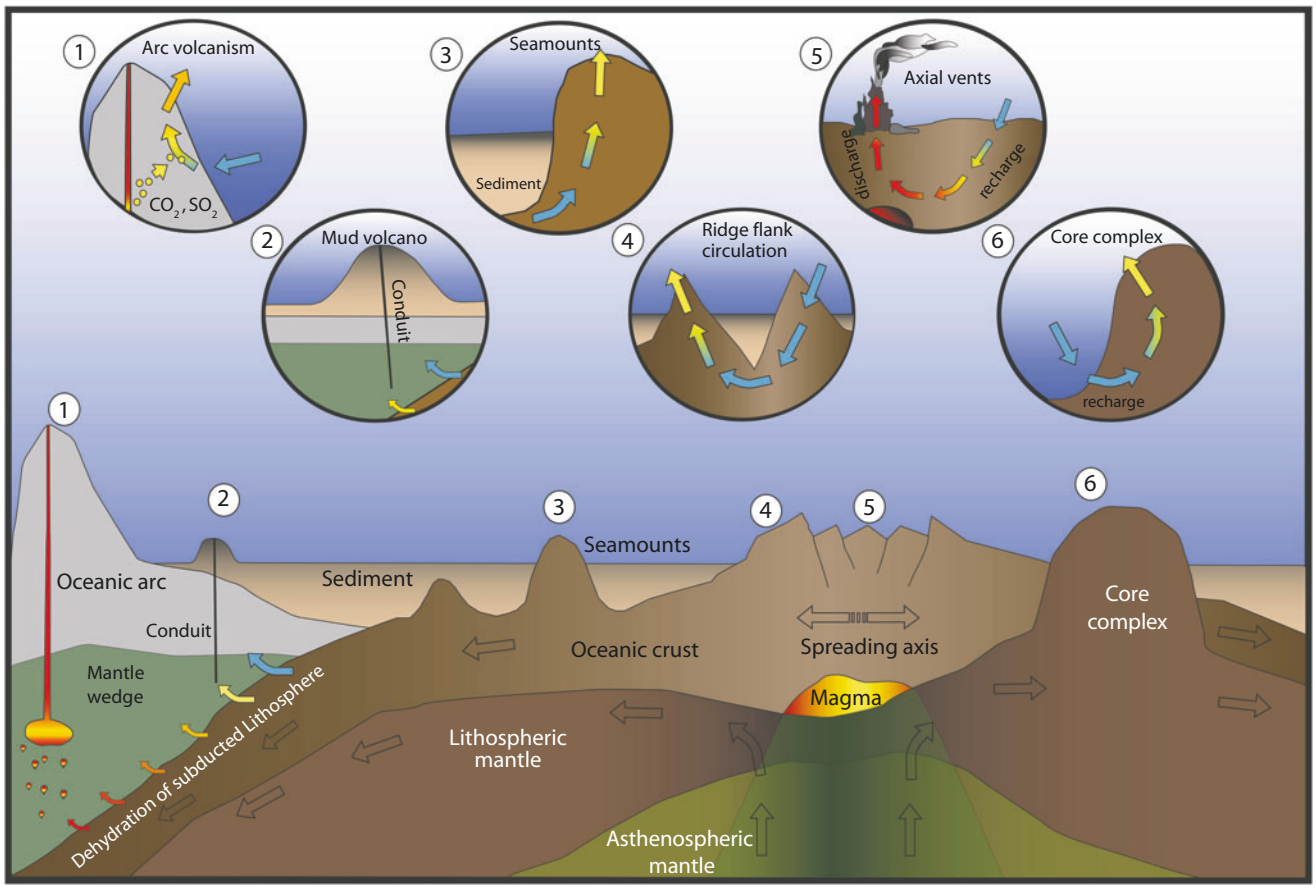
Definition

Hydrothermal vents are seafloor expressions of seawater circulation within the oceanic crust. Seafloor venting is driven by buoyancy of warm seawater-derived fluids that have mined heat and solutes from the basement rock. Temperatures and compositions of these fluids vary drastically, depending on the proximity of the heat source, basement composition, and local hydrological constraints. The venting of hydrothermal fluids is commonly associated with the deposition of hydrothermal precipitates, including sulfides, sulfates, carbonates, oxides, and hydroxides. In seafloor massive sulfide mounds, accumulation of these precipitates reaches extents that make them potentially economical for mining activities. Hydrothermal vent sites are also oases for life in a deep ocean otherwise mostly barren of macrofauna. Diverse and rich ecosystems can develop around areas of venting, and chemosynthetic microorganisms accomplish the primary production of biomass by converting geochemical energy and hydrothermal inorganic precursor compounds into biomolecules.

Introduction

Submarine venting of fluids occurs abundantly in different seafloor settings (Fig. 1). Along a global system of submarine spreading centers, new oceanic lithosphere continuously forms and exchanges heat and matter with the overlying oceans. Hydrothermal fluids – typified by mineral-rich "black smoker" venting – emanating from the axes of the spreading centers are spectacular manifestations of this interaction. These vent fields are typically tens to hundreds of meters in diameter, often containing multi-spire mounds. They have power outputs between 0.1 and 3.8 GW, and they occur at a frequency of 1–4 fields per 100 km length of spreading ridge (e.g., Baker 2007). Along 55,000 km of mid-ocean ridges (MORs) and 11,000 km of backarc spreading centers – of which only about one third have been explored (many cursorily) for hydrothermal activity – at least 1,300 ± 600 vent fields are predicted to occur



Hydrothermal Vents, Fig. 1 Overview of the different types of hydrothermal venting in the oceans

(Beaulieu et al. 2015). Additional hydrothermal venting can be found along 7,000 km of intraoceanic volcanic arcs (e.g., de Ronde and Stucker 2015). On the order of 1 TW of heat are mined from the oceanic crust by high-temperature (200–400 °C) hydrothermal venting. The size of vent fields, the structure and composition of the vent deposits, and the chemistries of the vent fluids are all highly variable. The type of basement rocks, the distribution of permeability, and the size and longevity of the heat source are just some of the key factors controlling this variability. Slow-spreading MORs (<40 mm/year full rate) tend to host vent fields with higher heat fluxes and larger mineral deposits than their faster-spreading counterparts due to long-lived large-scale tectonic faults (allowing persistent fluid flow) (Wilcock and Delaney 1996; Baker 2007). Fast-spreading MORs (80–160 mm/year full rate) typically tend to host smaller sulfide deposits due to more frequent diking-eruptive events and continuous off-axis migration of deposits.

Seawater descends into the oceanic crust in *recharge zones*, which are spatially not well constrained but can be away from or immediately surrounding the spreading axis. Circulating seawater separates into two fluids with contrasting contents of dissolved gases and ions when it is heated to high temperatures several kilometers beneath the seafloor and encounters the two-phase boundary (critical curve). This leads to a general observation that high-temperature hydrothermal vents show strongly variable salinities. Reaching peak temperatures near ~450 °C or higher in some cases, the seawater-derived fluids leach metals and sulfide from the basement rock in the *root zones* of the hydrothermal vents. They become buoyant and rise up to the seafloor in narrow, pipe-like structures called hydrothermal *upflow zones*. The development of these upflow zones is variably controlled by magmatic diking and tectonic faulting. Cold seawater is typically entrained and heated in the periphery of these zones. Ca-sulfate (anhydrite) precipitates from this heated seawater, however, and can partially isolate the high-temperature upwelling hydrothermal fluids from dilution with this entrained seawater. Entrainment of seawater would cool and oxidize the hydrothermal fluids upon mixing, which would result in metal precipitation in the form of sulfides and oxides. This fluid mixing invariably occurs to some extent, leading to cooler, diffuse fluid seepage at the seafloor on the periphery of the high-temperature vent structures or mounds, which funnel the focused discharge of

hydrothermal fluids. These structures form forests of "chimney" complexes that consist of sulfide, sulfate, and oxide minerals. More than 160 occurrences of seafloor massive sulfide accumulations associated with active hydrothermal vent fields are known, and the abundance of related metal ore has been estimated at 600 million tonnes (Hannington et al. 2011). A sizeable fraction of the metals dissolved in vent fluids are conveyed to hydrothermal plumes in the water column, with important ramifications for the oceanic budget of biogeochemically critical trace metals, such as the nutrient Fe (e.g., Resing et al. 2015).

While the majority of hydrothermal vents are acidic, venting of highly alkaline waters has been documented in the Lost City Hydrothermal Field, 30 km west of the Mid-Atlantic Ridge spreading axis at 30 °N (Kelley et al. 2001). These systems are related to exhumation of mantle rocks in oceanic core complexes. Up to 60-m tall carbonate-hydroxide chimneys vent 40–90 °C solutions that are poor in transition metals and dissolved sulfide and consequently do not precipitate sulfide minerals. Even farther off-axis, in the flanks of MORs, abundant hydrothermal circulation of seawater is evident from heat flow constraints. Few occurrences of low-temperature venting off-axis have been discovered to date (e.g., Wheat and Fisher 2008), however, in part due to their chemical and temperature signals in the water column being much more difficult to detect. These vent fluids likely have compositions similar to seawater but play an important role in global ocean-crust exchange, as the heat and solute flux is much greater than in axial hydrothermal systems.

Water-Rock Interactions

Interactions between rocks that make up the oceanic basement and seawater that circulates within the basement are important in setting the chemical and isotopic composition of the oceans. Along its flow path, the circulating seawater experiences major compositional modifications and isotopic exchange with the crust. These changes include a loss of Mg^{2+} and Na^{+} from the seawater-derived fluid, which then acquires Ca^{2+} and $SiO_{2(aq)}$ from the crust. The release of Ca and silica to the oceans is an important source of these elements, which are used by marine algae (coccolithophores and diatoms) to build calcium carbonate and opal tests. Because these algae fix a large amount of atmospheric CO_2, water-rock interactions within the oceanic crust therefore play a key role in the global carbon cycle. The full details of these interactions are quite complex, but simplified reactions, such as that which occurs when the main mineral constituents of basalt react with seawater to form the secondary minerals chlorite and quartz, exemplify some of the basics of these exchange processes:

$$\underset{\text{Plagioclase}}{CaAl_2Si_2O_8} + \underset{\text{Clinopyroxene}}{CaMgSi_2O_6} + 4Mg^{2+} + 6H_2O \rightarrow \underset{\text{Chlorite}}{Mg_5Al_2Si_3O_{10}(OH)_8} + \underset{\text{Quartz}}{SiO_2} + 2Ca^{2+} + 4H^{+}$$

Many of these reactions, especially those responsible for Mg^{2+} loss and acidity production, are common to many different basement compositions, from ultramafic to felsic rock. Since these reactions create acidity at elevated temperatures, hydrothermal fluids can dissolve large quantities of metals into solution. The composition of the fluids at the deepest part of the hydrothermal circulation cells is controlled (buffered) by secondary minerals that form in the course of fluid-rock interactions in these root zones (e.g., Seyfried et al. 1991). This takes place because silicate, oxide, and sulfide phases in the hydrothermally altered rocks have specific solubilities with respect to metals like Cu, Zn, Fe, and Mn, as well as other components. Specific assemblages of secondary minerals form depending on the pressure-temperature conditions in the root zone, the composition of rocks in that zone, and the mass flux of seawater through the system. It has been shown that ultramafic rock, common at slow-spreading MORs, forms mineral assemblages that are notably distinct from those that form in basaltic rock. Hydrothermal vents hosted in ultramafic rocks hence discharge fluids with systematically higher dissolved H_2 and CH_4, while H_2S and SiO_2 are lower in concentration. In addition, ultramafic rock-hosted systems may be strongly alkaline, if temperatures in the root zone do not exceed about 250 °C. Alkaline fluid venting in the oceans is known from ultramafic settings in MORs and from serpentine mud volcanoes in fore-arc settings. Arc and backarc hydrothermal vents, in contrast, are often more acidic and much less reducing (i.e., have low contents of dissolved H_2). These vents are often affected by very different styles of magma degassing (see below) in addition to common water-rock reactions such as the reaction above. The compositional spectrum of vent fluids in these different settings continues to grow as exploration of deep-sea vents continues. Recent discoveries include vents with liquid sulfur and carbon dioxide, some of which are extremely acidic (summarized in de Ronde and Stucker 2015). Arc and backarc rocks are enriched in elements that are removed from the dewatering subducting oceanic crust. These elements include B, Ba, As, Sb, Ag, Au, etc., which are strongly enriched in arc/backarc hydrothermal vents relative to vents at MORs (e.g., German and Seyfried 2014).

Magma Degassing

Many hydrothermal vent systems on ocean ridges are hosted in mid-ocean ridge basalt (MORB). The mafic magma responsible for MORB typically releases volatile mantle components such as CO_2 and primordial ^3He, plus trace amounts

of N_2 and water, during crustal formation. These species are degassed and entrained in circulating hydrothermal fluids to be vented at the seafloor. They tend to be relatively inert, however, since the only reactive components (CO_2 and N_2) are mostly stable at the acidic pH values and conditions encountered by many hydrothermal fluids. Volatile species are continuously degassed to varying degrees during steady-state hydrothermal circulation around magmatic intrusions, but their abundances in hydrothermal fluids increase drastically during diking-eruptive events. Rapid increases in dissolved CO_2 as well as hydrothermal fluid temperatures, for example, can often indicate some magmatic activity has taken place recently or is currently ongoing.

In contrast to MOR settings, chemical compositions of hydrothermal vents hosted in convergent margin settings (submarine arc/backarc volcanoes) can be profoundly influenced by the different magmatic volatiles degassed there. The presence of extensive slab-derived water (released during partial melting of subducting crust) dramatically changes the melting dynamics in the arc/backarc mantle wedge, leading to more oxidizing, H_2O- and silica-rich melts that degas water- and CO_2-rich fluids containing abundant acidity-generating volatiles (primarily sulfur dioxide (SO_2), HF, and HCl acids). SO_2 reacts with water to create abundant sulfuric acid (H_2SO_4) and often elemental sulfur. These "acid-sulfate" magmatic fluids either vent directly on the seafloor (resembling terrestrial "solfatara" fumaroles) or are entrained into circulating hydrothermal fluids (e.g., Seewald et al. 2015). The strong acidity of these fluids leads to dramatically different styles of crustal alteration than in MOR settings, and has implications for greatly increased metal leaching and transport, and potentially richer ore deposit formation.

Carbon Cycling

Inorganic CO_2 derived from magma degassing is typically the dominant form of carbon in hydrothermal fluids. Although organic carbon is a less abundant dissolved constituent, organic carbon cycling in these settings is complex and an active area of research. As early as the discovery of deep-sea hydrothermal vents in 1977, links were drawn between the physico-chemical conditions of these fluids and their suitability for the formation of organic molecules necessary for early microbial life to emerge (Corliss et al. 1981). Strongly reducing (H_2-rich) fluids, in theory, energetically favor the reduction of CO_2 to organic molecules such as hydrocarbons and other classes of compounds, aided kinetically by mineral catalysts in reactions that mirror the industrial Fischer-Tropsch synthesis. Research in the last decade, however, has discovered only limited evidence for complex organic molecules formed from CO_2 during fluid circulation. Major problems with identifying truly abiotic organic compounds (formed without any biological involvement) include their often trace abundance and the widespread and diverse plethora of organic molecules derived from numerous biological organic materials (McCollom and Seewald 2007). The latter include microbial biomass, vent organisms, or background deep ocean organic carbon sources such as particulate or dissolved organic carbon. The effectiveness of hydrothermal vent fluids in decomposing complex organic matter to a range of organic compounds is best illustrated in the sedimented Guaymas Basin hydrothermal system. There, the ridge axis has been continuously buried with organic-rich pelagic sediment. Magmatic dike and sill intrusions directly into the sediment overburden lead to hydrothermal petroleum formation (both oil and dissolved natural gas) on timescales as short as a few thousand years (Peter et al. 1991), in contrast to the Myr timescales of formation in slowly subsiding sedimentary basins.

The abundance of reduced components (H_2, CH_4, H_2S, Fe^{2+}, Mn^{2+}) in hydrothermal fluids allows diverse chemosynthesis-based ecosystems to develop around hydrothermal vent structures and sites of fluid release, as well as in the hydrothermally heated aquifer within oceanic layer 2A. The base of the food web in this environment is CO_2 fixation by chemosynthetic microorganisms that enzymatically catalyze the oxidation of the reduced solutes (H_2S commonly) in vent fluid and use the energy yields from these redox reactions to produce cellular matter. Microbial carbon fixation is an important component of carbon cycling within hydrothermal vent systems and differs between active and inactive sulfide chimney structures (Reeves et al. 2014). There also appear to be drastic differences in the quantities of available geochemical energy for various metabolic reactions between vents in different ridge and backarc settings, a direct consequence of the diverse types of fluid chemical compositions possible in these environments (Amend et al. 2011).

Summary and Conclusions

Submarine hydrothermal vents occur abundantly along oceanic spreading centers and intraoceanic arcs. They are sites of great geochemical diversity due to varying substrate composition, magma degassing, permeability structure, and subseafloor entrainment of seawater. Metal accumulations in related massive sulfide deposits, as well as rich and diverse chemosynthesis-based ecosystems, continue to make these systems targets for multi- and cross-disciplinary research. Hydrothermal vents directly and vividly illuminate the linkages between plate tectonics and life, and with roughly two thirds of global hydrothermal vents yet to be explored, many exciting discoveries remain to be made.

Hypogene

Barbara I. Kleine and Andri Stefánsson
Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland

Definition

The term *hypogene* is mainly used in the field of ore geology. It describes mineralization within and below the Earth's crust that is caused by ascending thermal fluids which derive from a magmatic source. Hypogene also often refers to primary, unaltered ore that formed directly from thermal aqueous solutions that derived from great depths (e.g., Ague and Brimhall 1989; Webb and Rowston 1995; Rakovan 2003). On the contrary the term *supergene* describes mineralization caused by descending fluids close to the Earth's surface and is usually associated with weathering and alteration of the primary mineral assemblage (e.g., Ague and Brimhall 1989; Webb and Rowston 1995; Robb 2013). A variety of the ore-forming minerals formed by hypogene processes are of great economic interest. These are usually associated with porphyry ore and volcanogenic massive sulfide (VMS) deposits (e.g., Galley and Koski 1999; Seedorff et al. 2005).

Origin of the Thermal Fluid

The thermal fluids that lead to the formation of hypogene mineral deposits originate from within a body of magma. For the formation of significant amount of fluids, extensive magmatic volatile exsolution needs to occur within the magma chamber. For the formation of large ore deposits, sufficient amounts of metals need to be washed out from the magmatic sulfides and liquid by the fluids and gathered under the roof of the magma chamber prior the fluid ascends (Candela and

Piccoli 2005). Thereby, the bulk composition and the water content of the magma play an important role on which chemical components will be contained in the resulting thermal fluid. For large mineral deposits of economic value, depth, geometry of magma chamber roof, and homogeneity of the magma chamber, i.e., appearance of convection, are additional crucial criteria for the enrichment of certain metals and other rare elements in the fluid (e.g., Dilles 1987; Cline 1995; Shinohara and Hedenquist 1997). Thermal fluids that derive from a magmatic source commonly carry significant amounts of volatiles such as CO_2. Other chemical components include sulfur and a variety of other major chemical components such as chlorine, sodium, calcium, magnesium, and potassium as well as iron, manganese, copper, zinc, and lead (e.g., Robb 2013). These components may derive from the magmatic source and/or were leached from the surrounding rocks while the fluid was ascending through Earth's crust.

The driving force behind the ascend of the fluids is provided by the heat of the magma at great depth and fluid density. Due to their low density, the fluids can easily transport upward in the crust. Large hypogene mineral deposits commonly form where fluid flow becomes additionally structurally focused, e.g., along shear and fault zones (e.g., Ague 2003).

Formation of Hypogene Mineral Deposits

Minerals that precipitate directly out of the ascending thermal fluid are called primary or hypogene minerals. In contrast to secondary, or supergene minerals, the hypogene minerals have not undergone any alteration caused by descending fluids. The formation of hypogene mineral deposits out of a thermal fluid is dependent on numerous factors such as temperature, pressure, phase separation, fluid-rock reactions, and adsorption (e.g., Robb 2013). Already small changes in one or more of these parameters may lead to mineral precipitation out of the fluid phase. In particular, a decrease in temperature would lead to precipitation of metals from the solution as the solubility of metal-ligand complexes is highly dependent on temperature (Seward and Barnes 1997). The infiltration of magmatic-thermal fluids usually causes significant hydrothermal alteration of the surrounding rock. A characteristic alteration feature of, e.g., hypogene ore deposits within large porphyry ore deposits is distinct potassium alteration of the host rock caused by the infiltration of magmatic-thermal fluids (e.g., Seedorff et al. 2005). The deposition of hypogene minerals usually occurs at several stages throughout the thermal history of the magmatic-thermal fluid. At moderate temperature in the early beginning of magma emplacement and fluid ascending minerals such as quartz and pyrite may precipitate out of the fluid. As the magma chamber grows, eventually more thermal fluids will be released. The temperature above the magma body will increase, and other minerals such as pyrrhotite and chalcopyrite will start to precipitate out of the fluid phase and replace the already existing ones. Further, with the cooling of the magmatic body, minerals will precipitate out of the fluids that are more stable at lower temperatures. Therefore, it is likely that hypogene minerals may be overprinted by several fluid and thermal events throughout the formation of the mineral deposit. The parageneses of hypogene mineral deposits are usually further complicated by recrystallization and replacement during post-hydrothermal metamorphism.

Occurrence of Hypogene Mineral Deposits

Hypogene processes play an important role in the formation of porphyry, orogenic Au deposits and volcanogenic massive sulfide (VMS) deposits. These hypogene minerals (e.g., pyrite, ore-hosting quartz, chalcopyrite, sphalerite, galena) that precipitated out of the ascending thermal fluid commonly occur at the base of the large mineral deposits. Porphyry deposits are nonferrous metallic mineral resources and are characterized by sulfides and oxides within veinlets enveloped by hydrothermally altered rocks. Non-altered, hypogene minerals that can host significant amounts of copper, molybdenum, gold and tungsten occur in the deepest parts of the porphyry deposits just above a commonly intermediate to silicic magma chamber (e.g., Seedorff et al. 2005). The thermal fluids originate directly from the magma, and deposition of hypogene ore is usually associated with potassic alteration of the host rock (e.g. Ulrich et al. 2001). Biotite bearing and sugary quartz veinlets and quartz veins containing molybdenite are the most common vein types that form from the cooling thermal fluid (e.g., Grant et al. 1980; Carten et al. 1988; Proffett 2003). Orogenic Au deposits usually form by the ascending of metamorphic fluids that there released during prograde devolatilization reactions of subducted material (e.g., Goldfarb et al. 2005). However, the source of fluids and metals as part of gold-forming processes in orogenic Au deposits located proximal to magmatic intrusions has been highly debated in the past years (e.g., Goldfarb et al. 1997; Cassidy et al. 1998; Bouchot et al. 2000). There is evidence that many of these gold deposits in metamorphic rocks are products of magmatic exsolution (e.g., Goldfarb et al. 1997; Haeberlin et al. 2004) and ascending magmatic-thermal fluids and the process of mineral precipitation could be classified as hypogene. The ancient VMS deposit at Bald Mountain (Slack et al. 2003) illustrates a complex hypogene mineral deposit pattern. During an initial stage at moderate temperatures, the minerals pyrite, marcasite, sphalerite, and quartz precipitated out of an ascending magmatic-thermal fluid. These hypogene minerals were subsequently replaced by pyrrhotite and

chalcopyrite as temperatures increased. This stage was followed by a phase of mineral precipitation in veins that crosscut the pyrrhotite and chalcopyrite deposit (Slack et al. 2003).

Summary

Hypogene processes are crucial for the formation of large mineral deposits therefore achieve high attention in the research fields of economic ore geology. However, hypogene minerals are usually overprinted by post-hydrothermal metamorphic or fluid events which makes it often difficult to determine the primary mineral assemblage and to unravel the complex fluid history of these mineral deposits.

Incompatible Elements

Catherine Chauvel
ISTerre, University Grenoble Alpes, CNRS, Grenoble, France

Definition

The term "incompatible elements" has been introduced in igneous geochemistry to define trace elements that cannot easily substitute into the major element sites in igneous minerals either because of their large ionic radius or because of their high ionic charge. In contrast, compatible elements are those that enter easily the major element sites.

Use of Incompatible Elements in Geochemistry

When a magma crystallizes, the incompatible elements preferentially remain in the liquid, and when a solid such as mantle peridotite melts, they enter the liquid phase as soon as possible. While this definition is quite broad, the extent to which elements are enriched or depleted into the liquid magmatic phase is easily quantified using the concepts and equations of Gast (1968) and Shaw (1970). The partitioning of elements between a solid and a liquid phase is defined as:

$$K_{elt}^{min/liq} = \frac{C_{elt}^{min}}{C_{elt}^{liq}}$$

where *min* corresponds to mineral, *liq* to liquid, *elt* to element, and *C* to concentration (Fig. 1).

Of course, during partial melting or fractional crystallization, several mineral phases are usually involved, and the overall behavior of the element is governed by the distribution coefficient D that is defined as:

$$D_{elt}^{sol/liq} = \sum_{min} m_{min} K_{elt}^{min/liq}$$

with *sol* the total solid and *m* the mass fraction of the various minerals.

In principle, a trace element can both be incompatible when it does not fit into the mineral assemblage that crystallizes and compatible when the crystallizing assemblage has a different composition. In practice, the term is now used in a looser way, and it only refers to the behavior of a given element during mantle melting.

The enrichment of incompatible elements in the liquid phase is primarily controlled by two parameters, the distribution coefficient *D* and the degree of partial melting *F*. The maximum enrichment is found when both *D* and *F* are small, and it decreases when either *D* or *F* increases following the general relationship that describes the simplest melting equation, the equilibrium batch melting equation:

$$C_{elt}^{liq} = \frac{C_{elt}^{source}}{D^{sol/liq}(1-F)+F}$$

with *C* the concentration of the element of interest. The batch melting equation given above is a simple and easy-to-use model, but it does not necessarily describe the geological reality of melting processes. For further detail, I refer the reader to the original publications of Gast (1968) and Shaw (1970) or to the book written by Bill White (2013).

The first attempt to create an order of incompatibility among trace elements was probably that of Sun and Hanson in 1975 when they compared the behavior of several incompatible elements during mantle melting to produce alkali basalts. In 1988, Hofmann extended the approach and focused on the behavior of a large range of trace elements in both oceanic and continental crust. He suggested an order of incompatibility that is now used by the entire geochemical community and that corresponds to the relative incompatibility of trace elements during formation of oceanic crust. The

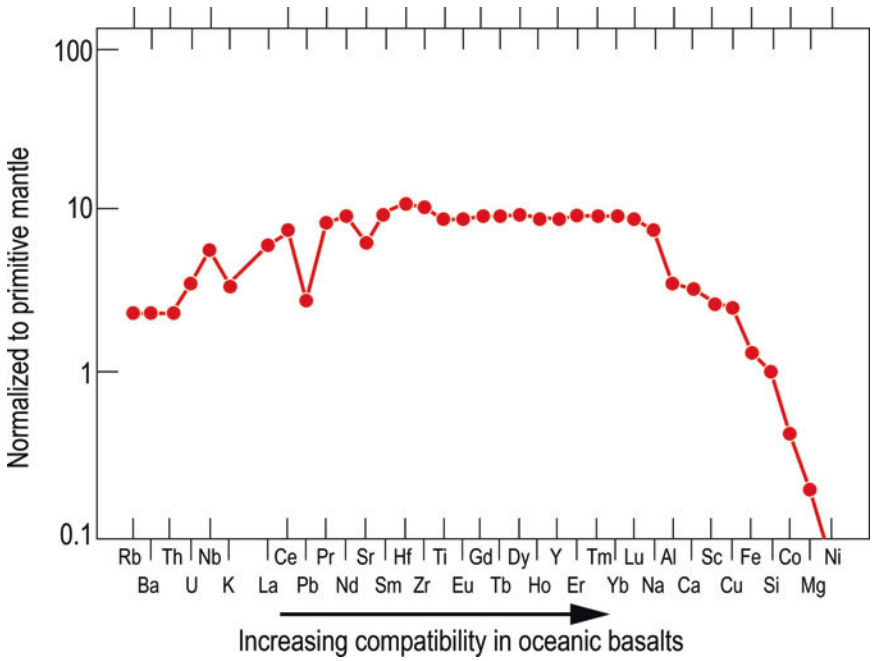
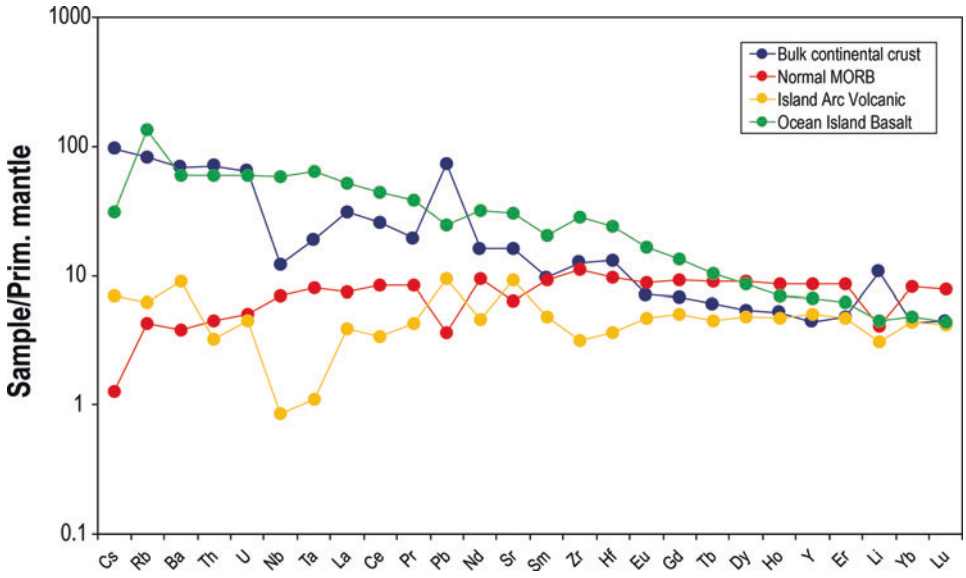
Incompatible Elements, Fig. 1 Ionic radius versus ionic charge for a range of trace elements showing how trace elements can substitute to major elements following Goldschmidt's rules. The *red dots* show the major elements in clinopyroxene and the *blue dots* various trace elements. The *dark blue curves* contour the clinopyroxene/liquid partition coefficients



Incompatible Elements, Fig. 2 Major and trace element pattern for average mid-ocean ridge basalt. The concentrations are normalized to primitive mantle concentrations, and the elements are arranged along the X axis as a function of increasing compatibility in oceanic basalts. Adapted from Hofmann (1988). Lead (Pb) shows a very large negative anomaly that is not due to the melting process but comes from the mantle source (see Hofmann et al. 1986 for further details)

most incompatible elements are located on the left side of the figure, and the most compatible elements are on the right end of the list (see Fig. 2).

Typical trace element patterns (also called "spidergrams") are shown in Fig. 3. The continental crust (dark blue symbols) is generally enriched in incompatible elements that have been transferred through magmatic processes from mantle to crust. The mantle has consequently become depleted in these elements, and magmas produced along mid-ocean ridges (MORB, red symbols) show a typical depletion in the most incompatible elements. Ocean island basalts (OIB, green symbols) produced by low degree melting are enriched in the most incompatible elements relative to the more compatible elements. Finally, island arc volcanics (IAV, yellow symbols) have complex patterns due to the combined influence of dehydration/melting of the subducted slab and unusual residual mineralogy during melting in the mantle wedge.



Incompatible Elements, Fig. 3 Trace element patterns normalized to primitive mantle (Sources: bulk continental crust from Rudnick and Gao (2003), normal MORB from Gale et al. (2013), island arc volcanic from Labanieh et al. (2012), ocean island basalt (from Bora Bora, Society Islands) from Chauvel et al. (2011), and primitive mantle from McDonough and Sun (1995))

Conclusion

Incompatible elements are the most useful trace elements to quantify magma formation processes because their enrichment or depletion can be extreme. Applications are numerous and include the modeling of continental crust formation, mantle depletion, and more complex processes such as those occurring in subduction zones.

Indium

Monica Vasiliu and David A. Dixon
Department of Chemistry, University of Alabama, Tuscaloosa, Al, USA

Element Data

Atomic Symbol: In
Atomic Number: 49
Atomic Weight: 114.82
Isotopes and Abundances: ^{111}In 4.3%, ^{115}In 95.7%
1 Atm Melting Point: 429.32 K
1 Atm Boiling Point: 2353 K
Common Valences: 1, 3

(*continued*)

Ionic Radii: (+I) 92, (+III) 132 ppm
Pauling Electronegativity: 1.78
First Ionization Potential: 5.79 eV
Chondritic (CI) Abundance: 0.08 ppm
Silicate Earth Abundance: 0.01 ppm
Crustal Abundance: 0.049 ppm
Seawater Abundance: 10^{-7} ppm
Core Abundance: 0

Properties

Indium is a group 13 element, which is a soft, ductile, and malleable lustrous metallic metal (Emsley 1991, 2001; Anthoni 2006; Anders and Grevesse 1989; McDonough 2005). Indium has a silvery white color, and it is liquid over a wide range of temperatures. It is stable in air and water but dissolves in acids. Similar to gallium, it can wet glass. When heated above its melting point, it ignites and burns with a violet flame.

Out of the two naturally occurring isotopes, the most abundant, ^{115}In, is very weakly radioactive as a β-emitter with a half-life of 6×10^{14} years.

History and Use

Indium was discovered in 1863 by Ferdinand Reich and Hieronymus Theodor Richter at the Freiberg School of Mines in Germany. Reich and Richter were searching for traces of ▶ thallium in samples of ▶ zinc ores and a brilliant violet line in the sample's spectrum revealed the existence of indium. Indium is about as abundant as ▶ silver but is much easier to recover since it typically occurs along with zinc, iron, lead, and copper ores. Indium-rich zinc blends were discovered in 1876 in Colorado and in Bergamo, Italy. Indium was detected in the pumice ejected from in the 1883 eruption of Krakatoa. Some zinc minerals have sufficient indium to give the characteristic strong indigo atomic spectra line without the need of chemical concentration.

Its name comes from the Latin "indium" meaning violet or indigo, which refers to the brightest line in its atomic spectrum.

Indium is used to make indium tin oxide which is an important part of touch screens, flat screen TVs, and solar panels because it conducts electricity, bonds strongly to glass, and is transparent. Indium is used to coat ball bearings of F1 racing cars because, due to its low coefficient friction, additional lubricants are not needed. Indium is used to dope ▶ germanium to make transistors. It is also used in the manufacture of other electrical components such as rectifiers, thermistors, microchips, and photoconductors. When evaporated and allowed to deposit on glass, indium produces a mirror of as good a quality as that of silver. Thus, indium metal is used to form corrosion-resistant mirror surfaces on windows of tall buildings and as a protective film on welder's goggles. Indium foils are used to assess what is going on inside nuclear reactors. Indium is used as a light filter in low pressure sodium vapor lamps. Indium is also used to make low melting alloys (liquid at room temperature), and one of these alloys is used in fire-sprinkler systems in shops and warehouses.

Geochemical Behavior

Indium is one of the least abundant minerals on Earth, and it is very rare to find it uncombined in nature. In Siberia, an indium mineral called indite ($FeIn_2S_4$) has been found. Typically, indium is found associated with zinc minerals and iron, lead, and copper ores. Cultivated soils are reported to be richer in indium (up to 4 ppm) than noncultivated sites. Indium produced by industry comes as the by-product of smelting zinc and lead sulfide ores, some of which can contain 1% indium. World production comes mainly from Canada and is around 75 tons per year; reserves of the metal are estimated to exceed 1500 tons.

Biological Utilization and Toxicity

Indium is not known to have a biological role, although in small doses, its salts may stimulate metabolism. Indium compounds are highly toxic, even though people rarely come in contact with them. If more than a few mg are ingested, they will cause a toxic reaction and affect the liver, heart, and kidneys; indium compounds may be teratogenic.

Environmental effects from indium and indium compounds have not been investigated as indium is not widely dispersed in the environment, but probably it poses no threat to land or marine life at low dose.

Summary

Indium, named after the violet flame observed when it burns and led to its discovery, is not very abundant and is rarely found uncombined in Nature. Indium, which is silvery white in color and a soft, ductile, and malleable lustrous metallic metal, is stable in air and water. Indium, mostly combined with other metals, has a broad range of uses from touch screens, flat screen TVs, and solar panels to the indium foils used in detectors for nuclear radiation. Indium is not known to have a biological role.

Inductively Coupled Plasma Mass Spectrometry (ICP-MS)

Maria Schönbächler
Institute of Geochemistry and Petrology, ETH, Zurich, Switzerland

Definition

Inductively coupled plasma mass spectrometry (ICP-MS) represents a major geochemical tool for both elemental and isotope ratio analysis. It allows analyses of elements at concentrations as low as 1 part per trillion (ppt) or even lower depending on instrument and application. This is accomplished by ionizing the sample in an inductively coupled plasma (ICP), followed by ion extraction into a mass spectrometer for separation and quantification of those ions. Different types of mass spectrometers are combined with an ICP source such as quadrupole, sector field mass spectrometry (ICP-SFMS), and multi-collector (MC) ICP-MS instruments. The latter are sector field instruments that feature multiple detectors (normally Faraday cups) for simultaneous detection of ions with different masses. The MC-ICP-MS analyses yield unprecedented precisions for isotope ratio measurements in the parts per million (ppm) range, which are only matched by thermal ionization mass spectrometry (TIMS).

Introduction

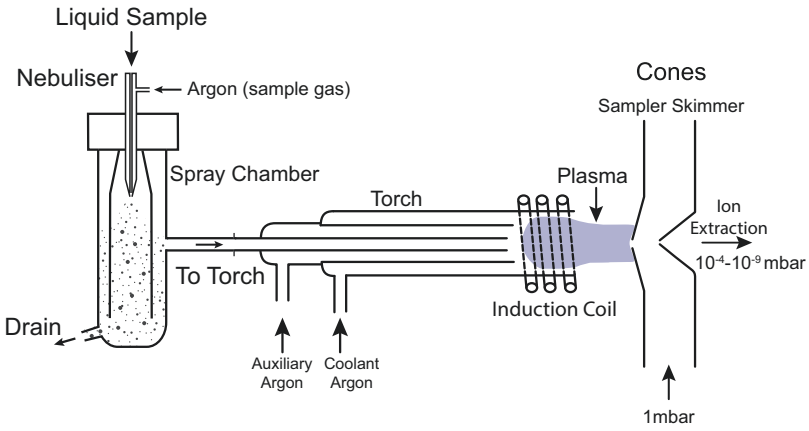
Inductively coupled plasma mass spectrometry (ICP-MS) is a versatile technique capable of elemental abundance and isotope ratio analyses. It is widely applied in geochemistry for trace and ultratrace element analysis because of its high sensitivity, the straightforwardness of multielement measurements, and its ability to determine accurate and precise isotope ratios. A broad variety of samples can be analyzed. These range from natural waters to solids, such as rocks, sediments, dust, soil, plants, and other organic matter. Solids must be dissolved prior to introduction into the ICP-MS. Alternatively, a laser ablation system can be used to make in situ isotope and concentration analyses. Gas chromatography-ICP-MS and liquid chromatography-ICP-MS combine chromatographic column systems with ICP-MS. They have important applications in environmental research, e.g., for speciation analyses of organometallic compounds (Bouyssiere et al. 2002).

For ICP-MS analyses, the sample is injected into a plasma in the form of an aerosol and ionized in an inductively coupled plasma (ICP) at temperatures of ~6000–8000 K. After ionization, the ions are extracted into a high-vacuum region (at 10^{-4}–10^{-9} mbar) and further analyzed using specific mass spectrometers. These include (i) quadrupole mass spectrometers that can rapidly measure selected masses over the entire periodic table in sequence and are widespread in geochemical research; (ii) single-collector sector field mass spectrometers (ICP-SFMS, also referred to as high-resolution (HR) ICP-MS), which provide higher sensitivity and/or higher mass resolution than quadrupole ICP-MS; and (iii) multi-collector ICP-MS (MC-ICP-MS) instruments, which are magnetic sector field mass spectrometers fitted with multiple detectors to simultaneously measure different isotopes with the goal to determine isotope ratios at extremely high precision. For solution ICP-MS, where liquid or dissolved solid samples are analyzed, the instrument sensitivity (signal per unit concentration) often reaches the level where the detection limits for many elements are constrained by contamination rather than the instrument sensitivity. These analyses, therefore, need to be carried out in a clean environment.

Basic Principles

The Inductively Coupled Plasma as an Ion Source

The plasma in ICP-MS mass spectrometry consists of a hot, partially ionized gas (typically argon), which contains neutral atoms and molecules, but also ions and electrons (Vanhaecke 2012). The plasma is generated at the end of a quartz torch (Fig. 1), which consists of three concentric tubes. These tubes are used to feed (i) the sample gas (Ar, occasionally combined with N, typically ~1 l/min), (ii) the auxiliary gas (Ar, typically ~1 l/min), and (iii) the coolant gas (Ar, typically at 15–20 l/min) to the plasma. A radiofrequency (RF) induction coil is placed around the tip of the torch (Fig. 1). By sending a RF current through this coil, an oscillating magnetic field is generated. The ions and electrons of the plasma are accelerated and decelerated by the oscillating field, thereby heating the plasma inductively. This leads to high temperatures causing thermal ionization in the hot gas at the center of the plasma



Inductively Coupled Plasma Mass Spectrometry (ICP-MS), Fig. 1 Example of a sample introduction system for ICP-MS adapted for liquid samples. The figure shows nebulizer, spray chamber, torch, plasma, cones, and high-vacuum region. The pressure after the skimmer cone is typically 10^{-3}–10^{-4} mbar with increasingly better vacuum with greater distance from the plasma. A desolvating sample injection system can replace the spray chamber

(Niu and Houk 1996). The plasma is sustained as long as the Ar flow and the RF current through the coil for energy transfer are maintained. For plasma ignition, a high-voltage spark is applied to the Ar flow that strips electrons off the Ar atoms, thereby providing seed electrons for the plasma. At the temperatures of the Ar plasma (~6000–8000 K), elements with first ionization potentials of <10 eV are ionized up to 75% or more and are thus accessible for isotopic analysis with a plasma source (Rehkämper et al. 2001). This includes most elements of the periodic table except, e.g., noble gases.

Sample Introduction into the Plasma

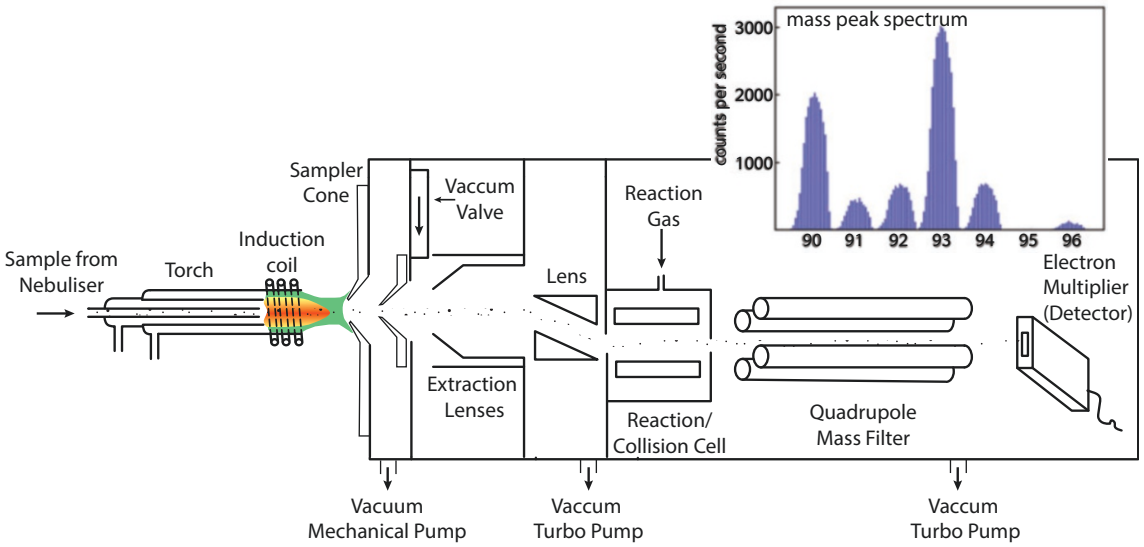
A variety of sample introduction systems have been developed for ICP-MS. The most widely used involves liquid samples, which are converted to an aerosol (fine liquid droplets) using a nebulizer (Fig. 1). This primary aerosol is subsequently introduced into a spray chamber that filters out droplets with diameter >10 µm (Vanhaecke 2012; Olesik 2014). This reduces the sample introduction efficiency 10 to 100-fold depending on the type of nebulizer and spray chamber, but it is required to maintain stable plasma conditions and ascertain efficient atomization and ionization in the ICP. In the plasma, the aerosol droplets evaporate, and individual molecules are released and atomized before ionization takes place (Niu and Houk 1996). Desolvating nebulizer systems are used to reduce the solvent content of the sample aerosol prior to injection into the plasma. They contain a long heated capillary, coated with a semipermeable fluoropolymer membrane to extract the sample solvent (e.g., H_2O). This can enhance the sensitivity of the ICP-MS by a factor 3–10 or more depending on the application, because the balance of the various ionization reactions competing in the plasma is changed. However, desolvating systems are also more prone to retain traces of previously analyzed samples (memory effects), in particular when analyzing solutions at high concentrations, which can require long washout times for cleaning after sample analyses.

Sampler/Skimmer Interface

The extraction of ions from the plasma into the mass spectrometer requires bridging the pressure difference between the ICP source at atmospheric pressure and the mass spectrometer with a mass analyzer region at 10^{-5}–10^{-9} mbar. Such vacuum is necessary, because collisions between sample ions and residual atoms/molecules present in the mass spectrometer severely affect the ability to separate ions of different masses. The ICP region is interfaced to the mass spectrometer via two coaxially placed cones (sampler and skimmer) each with a small, central orifice (~0.6–1.2 mm) through which ions and gas can supersonically expand into the vacuum region (Vanhaecke 2012) (Fig. 1). Most of the extracted plasma gas is removed by the vacuum system. Starting behind the skimmer cone, positive ions are accelerated using static electric fields. A system of ion lenses focus and direct the positive ions to the entrance slit of the analyzer for mass separation and ion detection.

Quadrupole ICP-MS

This type of ICP-MS utilizes a quadrupole filter for mass separation. The filter consists of four parallel rods containing conducting material (Fig. 2). Superimposed DC and AC voltages are applied pairwise to diametrically opposed rods (Vanhaecke 2012) such that the induced fields electrostatically steer ions with *a specific mass-to-charge ratio* (m/z) down the middle of the four rods, where they emerge from the quadruple filter and reach the detector. In ICP-MS, most ions carry a single charge ($z = 1$), such that m/z is reduced to the atomic mass. The quadrupole voltage settings can be selectively changed in quick succession, such that ions with predefined masses pass through the quadrupole filter in a sequence and can be analyzed. Continuous scanning over the whole mass spectrum of the periodic table is possible with a few exceptions (e.g., mass 40 amu is forbidden because $^{40}Ar^{+}$ is abundantly produced in the Ar plasma and would saturate the detector). Continuous scanning yields a mass peak spectrum with peaks (Fig. 2), whose heights are



Inductively Coupled Plasma Mass Spectrometry (ICP-MS), Fig. 2 Schematic setup of a quadrupole ICP-MS. Some instruments feature a reaction/collision cell, which allows the user to minimize polyatomic interferences through interaction with a reaction gas. In the *upper right*, a continuous scan over the mass range of Zr and Nb (90–96 amu) is shown

proportional to the number of positive ions transmitted for each specific mass. Rapid jumping from peak to peak (within a few milliseconds) instead of continuous scanning offers the advantage of shorter measurement time. For concentration analyses, it is important that the detector has a large linear dynamic range, i.e., that it is able to detect small to large ion beam intensities and reacts linearly to varying input signals. Present-day detectors can provide a linear dynamic range of nine to ten orders of magnitude. This is typically achieved by employing two detection types (ion counting and analogue mode). In ion counting, each transmitted ion is detected individually (e.g., (Rehkämper et al. 2001; Thomas 2001)). This detection method can be applied up to particle currents of ~10^6 cps (counts per second). At higher count rates, the ion-counting detector is used in analogue mode, operating as a current amplifier. This mode extends the dynamic range of an ion counter by about another three orders of magnitude. Most present-day detectors offer dual mode and automatically switch between ion counting (digital) and analogue mode on the basis of the encountered signal intensities. The integration time of the signal for the ions of a specific mass is normally only milliseconds, which allows for very fast data acquisition of many isotopes.

Important Characteristics of a Mass Spectrometer

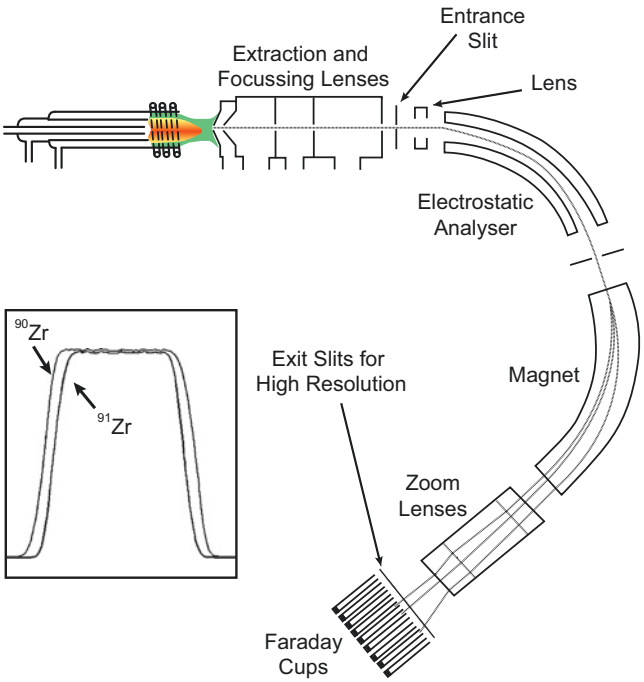
Two important characteristics of a mass spectrometer are defined in the following: the abundance sensitivity and the mass resolution. Both provide quantitative information on the instruments' capability to distinguish between ions with small relative mass differences and therefore to resolve neighboring peaks.

The *abundance sensitivity* is a measure for the contribution of a peak to the adjacent peaks because of peak tailing (IUPAC "Gold Book" 1997). It is usually determined as the intensity of the ^{238}U peak tail at mass 237 (Rehkämper et al. 2001). This effect is particularly important when dealing with adjacent isotopes that exhibit a large difference in the isotopic abundance.

The *mass resolution* describes the extent to which an instrument can separate ions with different masses. It is often expressed as the mass difference that the centers of two adjacent peaks of equal height have, such that a valley that corresponds to 10% of the peak height separates them. Or more precisely, the mass resolution is given as M/ΔM, where M is the mass of a peak and ΔM is the mass difference at which a 10% valley between the overlapping peak tails is generated (IUPAC "Gold Book" 1997; Rehkämper et al. 2001). The mass resolution can be determined based on a single peak because ΔM is also equal to the width of a peak at 5% of the peak height, because for two overlapping equal sized peaks, each peak contributes 5% to the observed valley height at 10%.

HR-ICP-MS: Improved Mass Resolution

The mass resolution achievable with quadrupole ICP-MS is ~300. More powerful systems are required for applications, e.g., that suffer from molecular interferences (see below). The double-focusing ICP-SFMS achieves adjustable mass resolutions up to ~10,000. Operated at low mass resolution, it also provides higher sensitivity than quadrupole ICP-MS. The basic principles of ICP-SFMS are as follows. After ionization in the plasma, a set of extraction and focusing lenses (Fig. 3)



Inductively Coupled Plasma Mass Spectrometry (ICP-MS), Fig. 3 Schematic setup of MC-ICP-MS based on the Nu Plasma II. These instruments are double-focusing magnetic sector ICP-MS with multiple collectors. The term HR-ICP-MS is normally used for single-collector instruments. Commercial MC-ICP-MS are available from Nu Instruments Ltd. (Nu Plasma and Nu Plasma 1700, both with fixed detectors and zoom lenses) and Thermo Fisher Scientific (Neptune *Plus*, with movable detectors). A combination of a narrow entrance slit and individual exit slits in front of the collector(s) is used to achieve high mass resolution, e.g., on the Nu Plasma 1700 or single-collector HR-ICP-MS instruments. Flat-topped overlapping peaks are achieved (see inset for ^{90}Zr and ^{91}Zr peaks scaled to the same signal height)

accelerate the ions and shape the ion beam to fit the entrance slit that is placed before the mass analyzer. The mass analyzer consists of an electrostatic spherical analyzer (ESA) followed by a laminated electromagnet (magnetic sector field) (or the reverse (Vanhaecke 2012; Wieser et al. 2012; Olesik 2014)). The magnet separates ions by both mass (i.e., m/z) and velocity. The plasma, however, produces ions with kinetic energy spreads such that ion separation by a magnet alone would result in broad, fuzzy peaks. The ESA is added to mitigate this effect and filter ions depending on their kinetic energy. In a double-focusing instrument, magnet and ESA are optimally attuned to each other such that ions with identical m/z, but slightly diverging kinetic energies, are focused to one point at the exit slit in front of the detectors, where they can be detected without substantial losses of the ion transmission.

For high mass resolution analyses, the entrance and exit slits are narrowed (Fig. 3). This prevents unwanted ions with marginally different m/z from reaching the detector. Mass resolutions of ~10,000 (M/ΔM) can be realized with present-day instrumentation. However, ion transmission will also be reduced, and the instrument becomes less sensitive.

Normally, HR-ICP-MS instruments are equipped with a *triple-mode detector system* (Vanhaecke 2012). A Faraday cup is installed in addition to the ion-counting detector operated in dual mode. When the signal intensity exceeds the analogue mode capacity of the detector (corresponding to 10^9–10^{12} cps), the ion beam is automatically deflected to the Faraday collector, where the electrical current – carried by the ions – can be measured directly. When ions hit the Faraday collector, they are neutralized by electrons that move from ground to the collector via a high resistance (typically 10^{11} Ω). The potential difference, i.e., voltage created over the resistance, is a measure of the ion signal intensity.

MC-ICP-MS: Achieving High-Precision Isotope Ratio Measurements

The precision of isotope ratio measurements performed with quadrupole ICP-MS instruments is limited to about 2 ‰ mainly by peak shape and the single-collector system (Turner et al. 1998). In MC-ICP-MS, these shortcomings are mitigated by combining an ICP-SFMS with a detector array able to simultaneously detect multiple isotopes. The instrument also offers flat-topped peaks (Fig. 3), which are important to ensure that small fluctuations in the position of the ion beam do not cause spurious results. For example, if the peak maximum is very narrow, tiny variations in the ion beam position will lead to analyses on the peak shoulder, where the signal is lower and thus introduces an error. Additionally, in MC-ICP-MS, several detectors (or more accurately, the exit slits in front of the detectors) are arranged along the focal plane of the mass analyzer to collect the ion currents of different isotopes simultaneously. This way, ion current instabilities are canceled out for isotopic ratio analyses and precise data are achieved.

Since the physical distance between the ion beams of two adjacent isotopes in the focal plane (mass dispersion) depends on their relative mass difference (the heavier the isotopes, the smaller the distance), careful alignment of the detectors to the individual isotope beams needs to be carried out when analyzing different elements. This can be achieved in two ways: (i) the detectors are moved along the focal plane of the mass analyzer and are positioned to collect each isotope beam optimally, or (ii) a zoom lens system is applied to change the mass dispersion, achieving peak alignment even when all detectors are mounted in fixed positions (Fig. 3).

Multi-collector ICP-MS can provide isotope ratio data with precisions of a few ppm. However, such ultrahigh precision can only be obtained after careful purification of the target isotopes from the sample matrix to avoid interferences and matrix effects (see below). The purification procedure generally includes ion exchange chromatography (see "Cross-References").

Additionally, key for high-precision analyses is to control and correct for the instrumental mass fractionation (so-called mass bias). The bias is generally expressed as the deviation of a measured isotope ratio from a reference value, normalized to a mass difference of 1 amu. The mass bias can range from 15% to 40% per amu for B (Boron) to less than 0.5% for Pb and U (Rehkämper et al. 2001). The mass bias originates from heavier ions being transmitted more efficiently through the mass spectrometer, but the cause is not entirely clear (Meija et al. 2012). It could result from the supersonic expansion of ions passing through the sampler cone into the expansion chamber, and space-charge effects in the skimmer cone region, which are generated by mutual repulsion of positively charged ions in the ion beam.

Interferences and Matrix Effects

Interferences and matrix effects are common in ICP-MS and need careful evaluation to obtain accurate and precise data.

Interferences can be (i) isobaric or (ii) polyatomic. (i) Isobaric interferences refer to different elements whose isotopes share a common mass. For example, Ti, V, and Cr possess isotopes at mass 50. Therefore, the signal measured at mass 50 can have contributions from all three elements. Moreover, doubly charged $^{100}Mo^{++}$ or $^{100}Ru^{++}$ can also interfere at mass 50 because the ions are separated by m/z. (ii) Polyatomic interferences arise from ionized molecules that consist of two or more isotopes from different elements present in the plasma adding up to the mass of the isotope of interest. The elements can originate from the sample, the sample solvent, the sample introduction gas, or the Ar of the plasma. The more abundant an element, the more likely it forms molecular interferences. An example for a polyatomic interference is $^{40}Ar^{16}O^{+}$ on $^{56}Fe^{+}$, occurring at mass 56. The ArO^{+} forms from a combination of the plasma Ar and O from the air or the sample solvent. Polyatomic interferences are particularly abundant for isotopes below mass 100.

There are various strategies to deal with interferences. For concentration analyses, interference-free isotopes can be selectively chosen. MC-ICP-MS and HR-ICP-MS often provide sufficient mass resolution (4000–10,000) to resolve overlaps due to molecular ions, because molecules often display slightly different masses than the monoatomic isotopes. In addition, collision/reaction cells are also available to reduce polyatomic molecules through interaction with a reaction gas (Fig. 2) (Olesik 2014).

Matrix effects provoke changes in sensitivity or isotope ratios due to sample components (matrix) other than the target element. They lead to signal suppression or enhancement and affect the instrumental mass bias. If standard and samples are analyzed that are matched with the same matrix and signal intensity, matrix effects can be accounted for. However, very high element concentrations (>2000 ppm) of matrix or target elements can lead to clogging of sample introduction system (e.g., nebulizer) or the cone orifice and should be avoided.

Conclusions

Applications of ICP-MS include the determination of major and trace element concentrations, the measurement of radiogenic and stable isotope ratios, and the possibly of in situ isotope and concentration analyses using a laser ablation system. This versatility underlines the great importance of ICP-MS for present and future geochemical research.

Iodine

Hélène Bureau
Institut de Minéralogie, de Physique desMatériaux et de Cosmochimie (IMPMC), Sorbonne Universités – UPMCUniv, Paris, France

Element Data
Atomic Symbol: I
Atomic Number: 53
Atomic Weight[a]: 126.90447
Stable Isotope: ^{127}I
Long-Lived Radioisotope: ^{129}I
1 Atm Melting Point: 113.7
1 Atm Boiling Point: 184.3
1 Atm of Nebular Condensation[b]: 535 K
Common Valences: −I, 0, +I, +III, +V, +VII
Ionic Radius: 206 pm
Pauling Electronegativity: 2.66
First Ionization Potential: 1008.7 kj/mol
Upper Crust Abundance: 1.5 ppm[c]
Bulk Crust Abundance: 0.7 ppm[c]–0.295 ppm[d]
Oceanic Crust Abundance: 777 ppb[d]
Volcanic Rocks: 4–9 ppb[d]
Metamorphic Rocks: 24 ppbI[d]
Sedimentary Rocks: 1.49 ppm[d]
Whole Earth: 40.5 ppb[e]
Silicate Earth Abundance: 10 ppb[fgh]
Chondritic (CI) Abundance: 0.433 ppm[i]
Core Abundance: from 3.3 to 130 ppb[j]
Seawater Abundance: 450.10^{-9} mol/kg[k] (1.8 ppm)
Troposphere: 0.001–0.002 ppbv[l]
From: [a]Meija et al. 2016; [b]Lodders 2003; [c]Rudnick and Gao 2003; [d]Muramatsu and Wedepohl 1998; [e]Allègre et al. 2001; [f]Déruelle et al. 1992; [g]McDonough and Sun 1995; [h]Kargel and Lewis 1993; [i]Palme and Jones 2003; [j]Armytage et al. 2013; [k]Bruland and Lohan 2003; [l]Warneck 2000.

Properties

Iodine is the fourth halogen element located in the group XVII of the periodic table. It has 53 protons and has one stable isotope ^{127}I. Iodine is a minor component on Earth (about 10 ppb for the bulk silicate Earth); it is mostly concentrated in the oceans and crust, where it is strongly associated with life. Iodine is the second heaviest element to be essential in living organisms, the first is tungsten. Iodine has an extinct radiogenic isotope (^{129}I) that is commonly used for geochronology and planetology. Iodine is highly volatile during volcanic eruptions. It contributes to the destruction of the stratospheric ozone.

History and Use

Iodine was discovered in 1811 by Bernard Courtois, a french chemist and saltpeter manufacturer. The name "iode" was given by Joseph Louis Gay-Lussac from the greek "ioeides" meaning violet because of the color of iodine vapor.

It is highly soluble in water; free iodine occurs as I_2. At standard conditions it is a black orthorhombic crystal that can sublimate into a violet gas.

Iodine is commonly used in medicine and pharmaceutical industry. Elemental iodine is used as a disinfectant having a quick antimicrobial action even at low concentrations. It is present in pharmaceuticals and antimicrobial agents. Iodine radioisotopes are used in medical applications. Iodine readily absorbs X-rays and is used as a contrasting agent in medical X-ray imaging. It is a catalyst or reagent in the synthesis of active pharmaceutical ingredients (antibiotics). Calcium iodate, potassium iodate, and potassium iodide are compounds added to animal feeds and to salt for human consumption to prevent medical disorders (e.g., thyroid malfunctioning, mental retardation, abnormal growth in developing fetuses) through lack of iodine in the body. Iodine-based biocides are used in industrial applications such as paints, adhesives, wood treatment, and metalworking fluids. Iodine is also a key ingredient for polarizing films for optics.

Isotopes

Iodine exhibits 37 known isotopes, but only one is stable: ^{127}I. The most common radioisotopes are: ^{129}I (half-life 15.7 million years); ^{125}I (59 days); ^{123}I (13 h); and ^{131}I (8 days). This last is produced by nuclear fission and during nuclear accidents such as Fukushima as illustrated from estimations of release amounts of ^{131}I (Chino et al. 2011).

Today ^{127}I is still produced from cosmic rays, but the original ^{127}I has been transformed in ^{127}Xe. Iodine is an important tracer of the evolution of the solar system's volatile reservoirs, and its presence is inferred from the observation of an excess of its daughter ^{129}Xe:

$$^{129}_{53}\mathrm{I} \rightarrow {}^{129}_{54}\mathrm{Xe} + \beta^-$$

In geochemistry and planetology the pair ^{129}I-^{129}Xe is used to date early stages of the Earth history such as degassing events (Pepin and Porcelli 2006). The isotopic ratios

$^{129}Xe/^{132}Xe$ are used to propose models about the origin and history of volatiles for the Earth and Mars (e.g., Musselwhite et al. 1991; Marty 2012) or to date and characterize chondrites (e.g., Gilmour et al. 2006).

Mineralogy and Geochemistry

All halogen elements are characterized by the s^2p^5 outer shell configuration, with one missing electron in the last electron shell.

Iodine is found in nature in several valence states and in a range of inorganic and organic forms including iodide (I^-), iodate (IO_3^-), elemental iodine (I_2), and organic iodine. Its form depends partly on pH and the redox status of the surrounding environment. The iodide ion is very large making it difficult to fit into the lattice sites of common rock-forming minerals. It is observed in accessory minerals such as amphiboles, apatites, and serpentines. There are rare mineral iodine species, such as iodargyrite (AgI).

Because iodine is highly soluble it is mostly concentrated in seawater, rainfalls, surface waters, pore waters, and fluid inclusions trapped in minerals. Soils contain much more iodine than the rocks from which they are derived. The high affinity of iodine for aqueous fluids makes it a very mobile element.

Geochemistry of Iodine in Terrestrial Reservoirs

Whereas it is classified as a lithophile element (see McDonough and Sun 1995) iodine has also been described by Goldschmidt (1954) as a biophile element.

If the chondritic model applies for the Earth, a strong depletion in iodine in the bulk silicate Earth is observed (McDonough and Sun 1995). This would mean that iodine either has been lost from the Earth or that it is stored and hidden at depth. Because iodine is also chalcophile (Fuge and Johnson 1984), its affinity for sulfur may imply a fractionation of iodine into the core during the Earth's differentiation. The iodine bulk Earth silicate content would range from 7 ppb (O'Neill and Palme 1998) to 10 ppb (Déruelle et al. 1992; Kargel and Lewis 1993; McDonough and Sun 1995). The origin of iodine is still debated. It is proposed that iodine originates either from a solar, or a chondritic or a cometary origin, or from a combination of the latter (see Marty 2012; Palme and O'Neill 2014).

Iodine in Upper Crust, Oceans, and Atmosphere

Iodine is mostly concentrated in the sediments and oceans (about 1.8 ppm). It is present in seawater as water-soluble iodide ion I^-. It is significantly assimilated in organisms such as algae (up to 0.4 wt% I, Lyday 2005). About 70% of the iodine present in the crust is provided by sea water sediments of organic origin and organic matter; it is also present in evaporitic deposits, shales, pelagic clays, limestones, sandstones, and greywackes at levels ranging from 50 to 20,000 ppb, up to 30 ppm in deep-sea carbonates (Muramatsu and Wedepohl 1998).

Rocks contain little iodine and most soil iodine is derived from volatilization of methylated forms from seawater which then enters the soil–plant system via rainfall and dry deposition (Shetaya et al. 2012). It is also shown that iodine is atmophilic, and the areal migration of iodine is an important part of its cycle as it determines the levels of iodine in soils and natural waters.

The atmospheric chemistry of iodine is important (Saiz-Lopez et al. 2012): (1) It helps to understand the iodine cycle. (2) It influences the capacity of the atmosphere to oxidize and remove organic and inorganic species emitted from both natural and anthropogenic sources. This occurs through the catalytic destruction of ozone (e.g., Solomon et al. 1994) and changes to the important radical species such as OH, controlling the oxidizing chemistry. The injection of iodine into the stratosphere may exert a stratospheric ozone depletion equivalent to 30% of the ozone loss through catalytic cycles. Most of iodine injection is marine, but a part is volcanic. (3) Iodine oxides play a role in the formation of ultrafine aerosol particles possibly impacting the climate. (4) In the polar atmosphere, iodine may enhance depletion of gaseous elemental mercury by oxidation to reactive gaseous mercuric compounds that may enter in the food chain after deposition.

Iodine in Igneous Processes and Mantle

Subduction, volcanic activity, and associated processes play a key role in chemical exchanges of iodine between terrestrial repositories. While the external cycle of iodine is starting to be understood, the fluxes and storage of iodine in the planetary interior are still poorly constrained. Iodine is expected to be incompatible during partial melting and differentiation; Br, Cl, and I are not strongly fractionated during partial melting or fractional crystallization, and they are expected to behave similarly in magmas (e.g., Pyle and Mather 2009). The halogen ratios (Br/I, Cl/I) provide information about halogen mantle sources (Kendrick et al. 2012a; Kendrick et al. 2012b), crystallization, and degassing processes in volcanic systems (see Aiuppa et al. 2009).

Magmatic abundances (from a few to a few hundred of ppb I, Déruelle et al. 1992) are determined from the analysis of volcanic glasses. Bulk analysis of whole rocks have also been performed (Shinonaga et al. 1994) showing very low amounts of I. Recent measurements of iodine in volcanic plumes and volcanic fluids (e.g., Snyder and Fehn 2002; Aiuppa et al. 2005; Frische et al. 2006; Witt et al. 2008) show that iodine is degassed from subduction zones volcanism. This is linked to the affinity of iodine for hydrous fluids as confirmed by experiments (Bureau et al. 2000, 2016) showing that iodine is the most hydrophilic halogen element

that totally degas from silicic melts with water. The iodine volcanic contribution to the atmosphere is probably underestimated.

Iodine is very mobile at depth during subduction during dehydration of subducted materials such as serpentinites (e.g., John et al. 2011; Kendrick et al. 2013). Sediments, altered oceanic crust, and serpentinites introduce iodine in the mantle. Fluids fertilize the mantle sources in iodine for arc-related magmatism. Evidences of the shallow recycling of iodine are found in brines and fluids and through their isotopic signatures in ^{129}I (e.g., Snyder and Fehn 2002; Fehn 2012). Iodine is recycled at least in the lithospheric mantle, as evidenced from the study of altered oceanic crust (Chavrit et al. 2016), exhumed mantle wedge peridotites (Sumino et al. 2010), and xenoliths (Broadley et al. 2016). It is difficult today to know if iodine is only recycled at a shallow level or thorough the whole mantle. The deep recycling of I is supported by the presence of iodine in fluid inclusions trapped in upper mantle diamonds (Johnson et al. 2000; Burgess et al. 2002). Experiments show that I storage in the core is possible (Armytage et al. 2013); a deep iodine storage in silicate minerals or in high-pressure melts in the mantle must be experimentally confirmed.

Biological Utilization and Toxicity

Iodine is used by life in biological functions. Organoiodine compounds are produced by marine life forms, such as algae. Iodine is required by animals and humans for the synthesis of hormones in the thyroid gland, and it is essential for growth and development. Because iodine radioisotopes are rapidly taken up by people and organisms, large doses of iodine are given as tablets so as to flood the body with iodine and minimize uptake of iodine radionuclides released in nuclear accidents.

Summary and Conclusions

Iodine is very little abundant in the Earth, and it exhibits different properties: biophilic, hydrophilic, moderately lithophile to volatile during igneous processes, chalcophile, and possibly siderophile at high pressure and temperature. For these reasons, the iodine mass balance calculation and cycles are difficult to assess. Today, there is an apparent depletion with respect to iodine compared to chondrites. However, the overall iodine budget may be subject of examination because the Bulk Silicate Earth iodine content is calculated from MORB values and does not consider the enrichment of ultramafic rocks through hydrothermal alteration and a possible storage in the deep mantle. A part of the iodine may be stored in the core.

Ion Exchange Chromatography

Maria Schönbächler
Institute of Geochemistry and Petrology, ETH, Zurich, Switzerland

Definition

Ion exchange chromatography represents a versatile analytical technique that separates ions and polar molecules in a solution (mobile phase) based on their affinities for an ion exchanger (stationary phase). It is widely used as a preparative technique for Atomic Absorption Spectroscopy (AAS), Multiple Collector Inductively Coupled Plasma Mass Spectrometry (MC-ICP-MS), and Thermal Ionization Mass Spectrometry (TIMS) or techniques using electrical conductivity or UV detectors.

Introduction

Ion exchange chromatography allows for the separation and enrichment of many organic and inorganic compounds and elements from a sample. This widely applied analytical technique is utilized in organic and inorganic geochemistry and also in numerous other fields, such as environmental sciences, economic geology, biochemistry, pharmaceutics, nuclear and food industries, and in water processing/purification processes (Zagorodni 2007). The theory and applications of ion exchange chromatography are described in various books and articles (Harland 1994; Korkisch 1989; Paterson 1970; Peters et al. 1974; Schönbächler and Fehr 2014; Shaw and Haddad 2004; Weston and Brown 1997; Zagorodni 2007). These publications are either of a general nature or focus on specific applications such as high performance liquid chromatography

(HPLC) (Weston and Brown 1997). The latter is often used in low-temperature geochemistry to determine anions and cations in aqueous samples. Schönbächler and Fehr (2014) covered aspects that are important for element separation and enrichment prior to MC-ICP-MS and TIMS. A high degree of element purification is required for these measurements because matrix elements (other elements present than those of interest) can interfere with the analyses of the targeted isotopes. This is particularly important for applications that require accurate high-precision isotope data (precisions < 0.1 permil, Fehr et al. 2004; Rehkämper et al. 2011; Schönbächler et al. 2004). These applications include nontraditional stable isotope studies in geo- and cosmochemistry (Rehkämper et al. 2011; Weiss et al. 2008) and age determinations using radioactive decay systems.

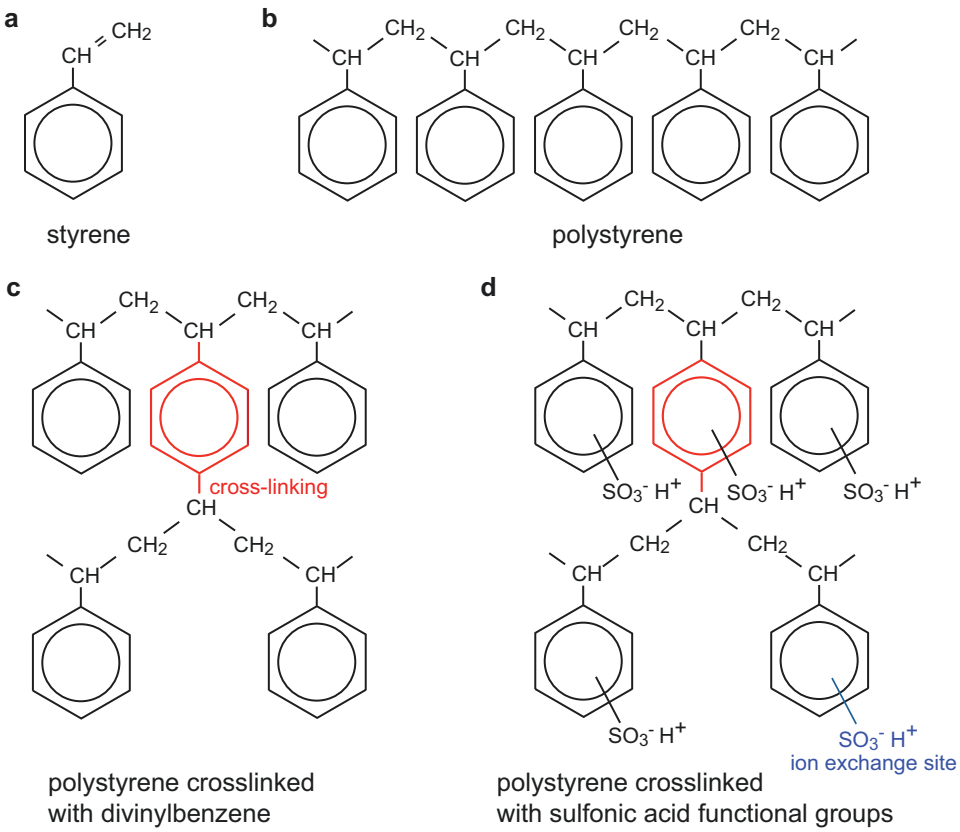
In the following, a brief overview of the basic principles relevant for ion exchange chromatography is given. The focus is on column techniques that employ commercially available ion exchange resins for the separation of inorganic anions and cations prior to MC-ICP-MS and TIMS measurements (Schönbächler and Fehr 2014). The principles, however, are also relevant for other applications, where the eluates are analyzed using other techniques, such as electrical conductivity or UV detectors.

Principles of Ion Chromatography

Ion chromatography generally involves two phases: *a mobile phase*, which moves relative to *a stationary phase*. The sample is initially dissolved in the mobile phase (e.g., a mineral acid), which is then added to the stationary phase, i.e., the ion exchange resin. The dissolved sample components (*the solutes*) in the mobile phase interact with the ion exchange resin (stationary phase) and distribute themselves between mobile and stationary phases according to their relative affinities to each phase. These affinities are specific to each component. Therefore, ion exchange resins retain distinct components to different degrees. This is exploited to separate these components (molecules or elements) from each other.

Structure of Ion Exchange Resins

Stationary phases commonly used are commercially available anion and cation exchange resins. These resins are crossed-linked copolymers composed of styrene and divinylbenzene (DVB) to which functional groups are attached as ion exchange sites (Fig. 1). Based on the functional group, different types of resins can be distinguished:



Ion Exchange Chromatography, Fig. 1 The backbone of commercial ion exchange resins is based on (**a**) styrene that forms (**b**) polystyrene chains. The polystyrene chains are cross-linked with divinylbenzene (**c**). To this polymer, functional groups are added. Panel (**d**) illustrates the resin structure of a strong cation exchange resin with sulfonic acid functional groups (After Schönbächler and Fehr 2014)

(i) Strong *cation exchange resins* exchange cations and feature sulfonic ($-SO_3H$) acid functional groups (Korkisch 1989; Smith and Chang 1983). Weak cation exchange resins possess carboxylic acid (–COOH) or phosphonic acid ($–PO_3^{2-}$) functional groups and are chemically less resistant (Smith and Chang 1983). When purchased, the ion exchange sites are occupied by counter ions, such as H^+, Na^+, or NH_3^+. These are replaced during ion chromatography.

(ii) *Anion exchange resins* possess basic functional groups such as quaternary ammonium or ammine groups that facilitate anion exchange. The counter ions of commercial anion resins are often Cl^- but also acetate, formate, or hydroxide anions.

(iii) *Amphoteric exchangers* include both acid and basic ionogenic groups and can thus exchange cations and anions.

(iv) The functional groups of *chelating resins* selectively respond to a specific, small group of ions (Korkisch 1989).

Anion and cation exchange resins are commercially available in the form of small beads. They display a narrow particle size distribution (e.g., 200–400 mesh) and generally contain low levels of contamination from metal ions and organic compounds. The chains produced during the polymerization of styrene are cross-linked to each other through DVB groups (Fig. 1). A higher fraction of DVB increases the degree of cross-linkage between the chains. This improves the mechanical strength and reduces swelling in aqueous solution. Swelling in water is common for these ion exchangers. However, the porosity of the resin also decreases, and the solute less easily reaches the functional groups to exchange ions. Moreover, less functional groups can be attached to higher cross-linked resins. This leads to a less efficient ion exchange process for highly cross-linked resins (Korkisch 1989). Most commercially available resins feature cross-linkages of 4–8% to equalize the different effects.

The Ion Exchange Process

The ion exchange reaction is an equilibrium process. After adding a mobile phase with solute (A) to the stationary phase, the solute will be distributed between the mobile phase and the resin until equilibrium is reached. An ion exchange reaction that involves two ions A and B can be expressed as:

$$a\overline{R}B + bA^a \Leftrightarrow b\overline{R}A + aB^b \quad (1)$$

$\overline{R}$ denotes the ion exchange resin including its functional group that serves as ion exchange site, whereas a and b are the charges of the ions A and B. The ion B is originally attached to the resin. During ion exchange, the counter ions A and B are partially or completely exchanged until equilibrium is established. The reaction is reversible; an increase of solute A in the mobile phase will augment the amount of A sorbed onto the resin. The equilibrium for a distinct solute (also referred to as component or analyte) can be expressed with the *equilibrium distribution coefficient* (K_d):

$$K_d = \frac{\text{amount of solute per gram dry exchanger}}{\text{amount of solute per milliliter of mobile phase}} = \frac{C_{solid}}{C_{liquid}} \quad (2)$$

where C_{solid} is the concentration of the solute in the ion exchange resin (dry form) and C_{liquid} is the concentration of the solute in the liquid that is in equilibrium with the ion exchanger. The distribution coefficient governs the chromatographic separation. Solutes with a high K_d are strongly retained by the resin, whereas a $K_d < 1$ indicates limited interaction with the resin and the solute mainly remains in the mobile phase (Higson 2004).

The Kd values for a specific resin are influenced by various parameters such as the composition of the mobile phase (e.g., acid and solvent media and their concentrations) and resin properties such as functional groups, particle size distributions, and cross-linkage (Korkisch 1989; Schönbächler and Fehr 2014). Distribution coefficients that are experimentally determined for the different ion exchange resins in various types of aqueous media are readily available in literature (Korkisch 1989; Schönbächler and Fehr 2014 and references therein). Overall, the K_d value determined for a solute (in combination with a specific ion exchanger and solvent) remains constant over a wide range of solute concentrations (Korkisch 1989; Letho and Harjula 1995; Schönbächler and Fehr 2014; Zagorodni 2007).

Batch and Column Methods

Two types of ion exchange methods can be considered: (i) the batch and (ii) the column method (Korkisch 1989; Schönbächler and Fehr 2014; Zagorodni 2007).

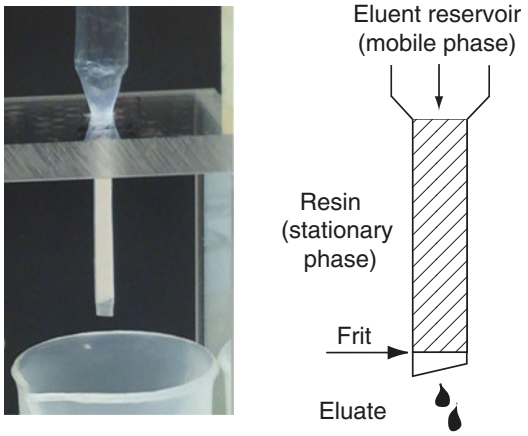
Batch Method

The sample solution is added to the ion exchange resin in a suitable vessel and equilibrates while stirring or shaking. Subsequently, the ion exchanger is separated from the liquid phase, e.g., by filtration or centrifugation.

Column Method

The resin is filled into a column (Fig. 2) and the sample (mobile phase) passes through the ion exchange resin either driven by gravity (Fig. 2) or pumped at a certain flow rate

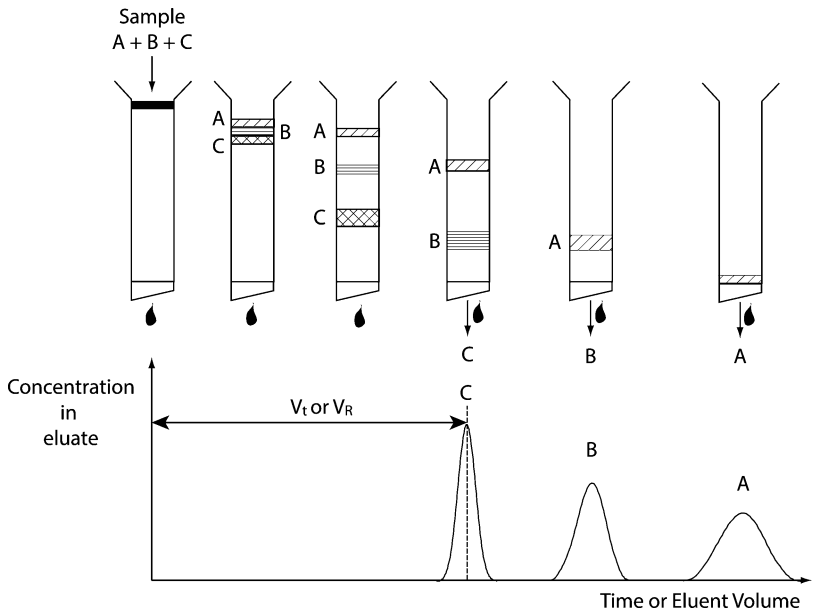
(e.g., HPLC). Components of the sample solution that do not interact with the functional groups of the resin ($K_d \ll 1$) pass directly through the column at the speed of the mobile phase. In contrast, components interacting with the resin are delayed. The different sample components therefore move through the column at different speeds and will elute at different times (Fig. 3). The column method can be thought of as a large number of successive batch operations (Letho and Harjula 1995) and can be described using the following model:



Ion Exchange Chromatography, Fig. 2 Image and schematic of an ion exchange column used in combination with gravitational flow. The frit can be a perforated glass disk, porous Teflon, or other suitable materials that retain the resin but let the mobile phase pass

(1) *Sample loading*: For the purpose of illustration, let us divide the resin reservoir (Figs. 2 and 3) into arbitrary small equal-sized sections. The solute (e.g., A) is loaded onto the resin and equilibrates with the top section of the resin reservoir according to its K_d such that a constant C_{solid}/C_{liquid} ratio is achieved. Subsequently, the sample solution travels to the adjacent section below, with its concentration of solute A reduced by the amount of A sorbed onto the column in the first section. The depleted solution equilibrates with the new resin section and less of solute A will be sorbed onto the column compared to the section above. The same process is repeated when the solution travels to the next section below and so forth. This results in a sorption front, where the concentration of A decreases downward until virtually all the solute A is sorbed onto the column.

(2) *Elution*: After the sample solution, more mobile phase (devoid of solute A) is added onto the column and desorption is initiated. The solution devoid of A equilibrates with the top section of the resin, which contains the solute A. This leads to the removal of A from the resin into the



Ion Exchange Chromatography, Fig. 3 Interaction of solutes A, B, and C with the ion exchange resin using the column method. The diagram also shows the elution curve (concentration in the eluate versus time and eluent volume) for the column. Components A, B, and C in a sample solution display distinct K_d (K_d A > K_d B > K_d C) and therefore, move at different speeds. This leads to well-separated elution peaks. Comparison of subsequent elution peaks illustrates that the peak broadens and the peak maximum decreases with increasing time and volume of solution passed through the column (eluent volume). Overall, the longer (and the faster) a solute band travels through the resin, the broader the elution peak becomes (Schönbächler and Fehr 2014 and references therein). The *black arrow* illustrates the retention time or volume for solute C. V_t: retention time – time passed until the peak maximum is reached. V_R: retention volume – volume passed through the column until peak maximum elutes

mobile phase to keep C_{solid}/C_{liquid} constant. The mobile phase, still low in A, moves further down and equilibrates with the section below and so forth. Provided that sufficient new mobile phase is added to the column, a sorption band of solute A moves down the column until it reaches the end of the resin reservoir and elutes (Fig. 3).

Based on Eq. 1, it can be demonstrated that the concentration of the solute recovered in the solution emerging from the column (eluate) approaches a Gaussian curve (Fig. 3). Experimentally obtained elution peaks confirm the theory, although the elution peaks can become asymmetric or show peak tailing, depending on experimental conditions (Schönbächler and Fehr 2014).

The Retention Volume: Mobile Phase Required for Solute Elution

By definition, the *retention volume* (V_R) is the volume of the mobile phase required to pass through the column to reach the maximum of the elution peak for a specific solute (Fig. 3). The following equation applies for V_R (Korkisch 1989):

$$V_R = K_d \times m \tag{3}$$

where m is the mass of the resin (dry) in the column. This equation shows that V_R is a function of K_d. This relationship can be used to estimate the amount of mobile phase required to elute a solute from a specific resin mass. For this estimate, the K_d for the experimental conditions (resin type in combination with the utilized mobile phase) must be available. For example, an experiment with 1 g of dry resin and a solute with a K_d of 1 requires 1 ml mobile phase to elute half of the solute from the column ($=V_R$) and between 1 and 2 ml to elute the entire solute depending on the peak width. The predictions need to be verified by experiments because small changes in the experiment (e.g., resins with different particle size distributions or cross-linkage) affect the K_d values.

The Efficiency of an Ion Exchange Column to Separate Elution Peaks

The goal of ion exchange chromatography is to efficiently separate different sample components. The *selectivity* of a chromatographic system (Weston and Brown 1997; Zagorodni 2007) is a measure of how efficiently two components can be separated from each other (Fig. 3). It is governed by the preference of the ion exchanger for one specific ion over another. The *separation factor* α_A^B for two solutes A and B describes the experimentally determined selectivity of an ion exchanger (Harland 1994):

$$\alpha_A^B = \frac{(C_B)_r \times (C_A)_s}{(C_A)_r \times (C_B)_s} = \frac{(K_d)_B}{(K_d)_A} \tag{4}$$

where C_B and C_A are the concentrations of A and B in the solution (s) and the resin (r), respectively. Large differences between the K_d values of solute A and B yield a separation factor α_A^B significantly different from 1 and indicate a good separation of the elution peaks. Similar K_d values for A and B ($\alpha_A^B < 1$) lead to overlapping elution peaks and full separation of the two components is not possible.

General Considerations

Chromatographic ion exchange procedures can follow different strategies. Many procedures represent mixtures of these strategies:

Strategy (i)

The sample is loaded onto the column in a medium, in which the element(s) of interest are strongly retained by the resin (high K_d), while the majority of the matrix moves almost directly through the column (low K_d). The various matrix elements are then further eluted using one or several types of chemical media, which may vary in concentrations, before the analyte is stripped from the column. An example for this strategy is the cation exchange column used for Ag separation from matrix elements (e.g., Pd and Mo) that interfere during MC-ICP-MS analyses (Schönbächler et al. 2007). In this procedure, the sample is loaded in 0.5 M HNO_3, in which Pd and Mo elute directly, while the Ag sorption band move down the column and elutes after further 16 ml of 0.5 M HNO_3.

Strategy (ii)

The sample is loaded in a medium, where the element of interest directly elutes with the mobile phase, while matrix elements are strongly retained. This procedure requires that enough ion exchange sites are available to accommodate all matrix ions and this limits the sample amount that can be processed in a single column. An example of this strategy is the separation of Li for geological applications (James and Palmer 2000). The sample is loaded onto cation exchange resin in 0.2 M HCl, in which Li only weakly interacts with the resin, while most matrix elements are moderately to strongly retained.

Strategy (iii)

This strategy is referred to as "stick and strip" and represents an end-member of both (i) and (ii). The sample is loaded in a medium, in which the analyte is strongly retained by the resin (extremely high K_d). It remains with the top layer, while matrix elements elute. Thereafter, the analyte is stripped from the resin with a different medium in which the analyte has little or no affinity for the resin (very low K_d). Strategy (iii) does not

depend on analyte bands that move at different speeds through the column (Fig. 3). The analyte is sorbed onto the top layer of the column and then directly stripped. The method can also be inverted, i.e., the matrix elements stick to the top layer of the resin, while the target element directly elutes.

For successful performance of ion exchange chromatography, sufficient ion exchange sites must be available to accommodate and exchange the solute ions. The number of required ion exchanges sites for a given sample amount can be calculated based on the composition of the loaded sample. The result can be compared to the exchange sites available in a certain resin volume estimated from the resin capacity (generally provided by the manufacturer). For strategy (iii), the sample ions can occupy up to 50% of the total ion exchange capacity of the resin (Korkisch 1989), whereas for a true chromatographic separation (strategies i and ii), the sorbed ions should not occupy more than ~3–5% to ensure good separation and narrow elution peaks (Korkisch 1989).

Conclusion

Ion exchange chromatography is key for the separation of many organic and inorganic compounds and elements from a sample matrix and is widely used in geological research. In addition to the ion exchange resins discussed here, more recently designed resins for extraction chromatography (e.g., TRU, Ln, or TODGA resin) are also widely utilized (Pin and Rodriguez 2014). Fast and efficient techniques that yield excellent separation already exist; however, they can be further improved using novel ion exchange materials (Zagorodni 2007) or alternative approaches, such as tandem columns or pressurized column systems with increased flow rates.

Ion Microprobe

Kazuhide Nagashima
Hawai'i Institute of Geophysics and Planetology, University of Hawai'i at Mānoa, Honolulu, HI, USA

Definition

An ion microprobe is a mass spectrometer that uses the principle of secondary ion mass spectrometry (SIMS) and enables in situ elemental and isotopic analysis of a solid sample.

Operation Principle

Ions accelerated at ~10 kV under high vacuum (i.e., primary ions) are focused onto sample surface. The primary ion bombardment leads to collision cascades in a solid sample. Recoil particles that reach sample surface with an energy exceeding the surface binding energy are ejected from sample surface (i.e., sputtering). The sputtered particles are mostly neutral, while small fraction of them (typically much less than 10%) is ionized (i.e., secondary ions). The secondary ions are extracted into a mass spectrometer and analyzed to determine the elemental and isotopic compositions of sample. While various ions can be used in the primary ion beam, Cs^+, O^-, O_2^-, and O_2^+ are the most common as these ions enhance secondary ionization efficiency. The secondary ions can be positive and negative. The mass spectrometer is usually set to have a polarity opposite to that of the primary ion. Among the mass spectrometers that have been adopted for ion microprobes (magnetic sector, time-of-flight (TOF), quadrupole mass analyzer), the magnetic sector is most common in geochemical applications as it in general has the best quantitative performance. In the magnetic-sector mass spectrometer, secondary ions are spatially separated by the magnet as a function of mass-to-charge ratio. Ions of interest are detected either sequentially by changing strength of magnetic field (i.e., peak jumping) or simultaneously with multiple detectors (i.e., multi-collection).

Advantages of Ion Microprobe Technique

The ion microprobes have several advantages over other analytical techniques used in geochemistry. In situ elemental and isotopic analysis with a high spatial resolution ranging from several tens of microns to submicron is possible. This contrasts with other conventional techniques that require processing of a sample, thereby destroying the textual context. Higher sensitivity is achieved compared to other surface analytical techniques such as electron beam techniques (e.g., EPMA) and laser ablation ICP-MS; quantification of $<$ppb level is possible with ~10 μm spot. All elements from hydrogen to uranium and above can be measured. Since the sputtering process removes materials continuously from surface, analysis as a function of depth can be made (i.e., depth profiling). Two-dimensional analysis (i.e., imaging) is possible either by scanning or direct ion imaging techniques. The scanning ion image is obtained by scanning the primary beam over sample surface and recording secondary ion signals as a function of the primary beam position. Some instruments have stigmatic ion optics and can transmit a mass-filtered, two-dimensional ion image of a sample to an imaging detector. By combining depth-profiling and two-dimensional imaging techniques, three-dimensional analysis is also possible.

There are technical difficulties in geochemical applications using ion microprobes. The ion probe fractionates the elemental and isotopic abundances of a sample during a measurement. This is because the secondary ionization efficiencies depend on not only the properties of the particular element but also chemical composition of the sample (i.e., matrix effect). Physical models to describe the formation of sputtered ions in chemically complex solids are too immature to be accurately correct for the elemental and isotopic fractionation of secondary ions. In addition, the mass spectrometer can also fractionate secondary ions. As a result, quantitative analyses for elemental and isotopic abundances require empirical corrections of the instrumental fractionation using standard materials having similar matrix and well-determined elemental and isotope compositions. The sputtering process produces not only single atom ions but many different molecular ions and multiply charged ions, some of which may overlap to the ion of interest (e.g., $^{16}OH^-$ onto $^{17}O^-$, and $^{178}Hf^{28}Si^+$ onto $^{206}Pb^+$). Because of this, the mass spectrometer in an ion probe is constructed to resolve ion species with small difference in mass-to-charge ratio. Mass resolution is a measure of the instrument ability to resolve peaks with small differences in their mass-to-charge ratios. The large magnetic sector ion probes, such as SHRIMP series (developed at Australian National University) and IMS 1270/1280 series (Cameca, France), have a high mass resolution while keeping relatively high transmission, sufficient for a variety of isotopic analyses in geochemistry. Even with those instruments, atomic isobars are often impossible to be resolved (e.g., ^{87}Rb and ^{87}Sr). It is also possible to suppress molecular interferences using the energy filtering technique, which utilizes a difference in energy distributions of secondary ions between single ions and molecular ions. However, the energy filtering is not sufficient in many applications, especially in isotopic analyses. For more details of ion probes in geochemistry, see a review paper by Ireland (1995).

Successful Applications to Geo-/Cosmo-Chemistry and Recent Advancements

The ion probes have been successfully used in a wide range of geochemical applications, and have led to the important discoveries and contributions. Just a few examples among these include: the Earth's oldest zircons dated with U-Pb isotope systems (e.g., Froude et al. 1983), the carbon isotope signature of the earliest life on Earth (e.g., Mojzis et al. 1996), the

discoveries of silicates formed prior to the solar system formation (e.g., Messenger et al. 2003; Nagashima et al. 2004), the discovery of water in rocks from the mantle of the supposedly bone-dry Moon from OH analyses in lunar glasses and minerals (e.g., Saal et al. 2008).

Since the mid-1990s, many instrumental advances on ion probes have been made. The IMS 1270/1280 instrument is equipped with the multi-collection system that significantly improves analytical precision, and achieves several tenths of a per mil in some isotope systems such as oxygen, magnesium, and sulfur (e.g., Kita et al. 2009). The NanoSIMS instrument (Cameca, France) brought a significant advance in spatial resolution for elemental and isotope analysis. It is capable of focusing the primary ion beam to <100 nm and quantitative analysis with a large sector magnet and multi-collections. In addition to the scanning isotope imaging with NanoSIMS, there has been an advance in isotope imaging using the direct ion imaging; the isotope microscope system has been developed using IMS 1270/1280 and the solid-state two-dimensional detector SCAPS (Nagashima et al. 2004). There have been instrumental advances also in SIMS-related techniques. The MegaSIMS that combines the stigmatic ion microprobe and accelerator mass spectrometer was used for measuring oxygen isotopic composition of the solar wind returned by the Genesis mission (McKeegan et al. 2011). The nanometer resolution isotope analyses are being achieved by instruments built around SIMS and laser photoionization techniques (e.g., Ebata et al. 2012).

Summary

An ion microprobe (SIMS) uses high-energy ion beam to sputter surface materials of a solid sample. Because of this sampling method, the ion microprobe allows in situ elemental and isotopic analysis of a solid sample with μm-scale spatial resolution. Since the sputtering process removes materials continuously from surface, depth profiling is a commonly used technique, and also three-dimensional analysis is possible by combining with two-dimensional imaging analysis. Ion microprobes have been successfully applied to large variety of Geo-/Cosmo-chemical studies and have led to important discoveries.

Ionic Radii

Hugh Rollinson and Jacob Adetunji
Geoscience, University of Derby, Derby, UK

Definition and Assumptions

An ion is an atom with an electrical charge, achieved either by gaining or losing one or more electrons. *The ionic radius of the ion (r_{ion}) of an atom (either a cation or anion) is a measure of the size of a spherical ion.* The ionic radius is similar to but different from the atomic radius for the ionic size is dependent on the distribution of its outermost electrons and is inversely proportional to the effective nuclear charge experienced by ions. It is calculated from the internuclear distance between a cation and a neighboring anion in a lattice. Ionic radii are typically reported in picometers (pm, 1×10^{-12} m) or in the older literature as Angstroms (Å), where 1 Å = 100 pm.

A typical range of ionic radii is 25–170 pm for four to eightfold coordination (see Table 1).

Methods of Measurement

The wave nature of the electron means that it is difficult to define precisely the size of an atom or of an ion, for the electron cloud density does not stop at some distance from the atomic nucleus, rather it fades away. This means that a somewhat arbitrary decision has to be made about where the boundary of an atom or ion lies. Nevertheless atoms and ions do behave as though they have characteristic sizes. The ionic radius is generally smaller than the atomic radius.

Ionic radii are measured using the methods of X-ray diffraction on solid crystalline materials. This means, of course, that the radii determined are applicable to crystalline solids. X-rays are scattered by electrons and areas of high electron density close to the nucleus can be identified. In detail the internuclear distance can be measured and equates to the sum of the radii of the cation and adjacent anion. Estimating where the boundary between the two lies can be done through the measurement of electron density contour maps and the identification of a minimum in electron density between the cation and anion (Fig. 1). More normally, however, the results are obtained from a large number of measurements which are analyzed in order to produce a self-consistent data set, for it can be assumed that if an ion is in a similar coordination in different crystal structures it will have the same radius each time. In silicate mineralogy ionic radii are most commonly calculated for ions bonded with oxygen.

The Determination of Ionic Radii

Early attempts to measure ionic radii include that of Landé (1920) who measured the ionic radius of iodine in LiI by assuming that the lithium ions are so much smaller than the iodide ions that the lithium fits into holes within the crystal lattice, allowing the iodide ions to touch. On this basis the iodide ion was deduced to be 214 pm. This value was then used to determine the radii of eight other ions. Wasastjerna (1923) estimated ionic radii by considering the relative volumes of ions as determined from electrical polarizability and measurements of refractive index. These results were extended by Goldschmidt (1926). Both Wasastjerna and Goldschmidt used a value of 132 pm for the O^{2-} ion. Pauling (1960) used a semi-empirical method, a combination of theoretical and experimental, to determine the ionic radii based on the concept of electronegativity and effective nuclear charge.

The Shannon (1976) Dataset: "Effective Ionic Radii"

The principal source of ionic radii now used in mineralogy and geochemistry is that of Shannon (1976). This study was built on the earlier work of Shannon and Prewitt (1969) who determined cation radii in oxides and fluorides. The current dataset is based upon the large number of crystal structure refinements that were available by the mid-1970s and is based upon refined oxide and fluoride data from Shannon and Prewitt (1969) augmented with data from "halides, chalcogenides and molecular inorganic compounds." The usefulness of these data was because ionic radii were reported for the different oxidation states of an element taking account of differences of coordination number (the number of anions in contact with a single cation), electronic spin state (d-orbital electron pairing in transition metals) and were calculated to take account of covalency, repulsive forces, and polyhedral distortion. The ionic radii were determined to a first approximation from their internuclear distances and then refined using plots of radii versus unit cell volume (r^3 vs V), whose regular curvilinear form allowed the prediction of radii. Further refinement was made using plots of radii versus coordination number and radii versus oxidation state.

Ionic radii are reported by Shannon (1976) in two forms – *crystal radii* based upon the radius of the oxygen anion (O^{2-}) in sixfold coordination = 126 pm (and F^- in sixfold coordination = 119 pm) and their *effective ionic radii* based upon the oxygen anion (O^{2-}) in sixfold coordination = 140 pm (and F^- in sixfold coordination = 133 pm). The effective ionic radii are the values which have been adopted in mineralogy and geochemistry. They have been calculated from internuclear distances by the subtraction of the relevant cation value and differ from crystal radii by the constant value of 14 pm. The term effective ionic radii is intended to indicate that while these values are useful they are not necessarily "real" and are applicable to bonds which have a significant degree of ionic character. A summary of mineralogically and petrologically useful ionic radii is given in Table 1.

Whittaker and Muntus (1970) proposed a set of values intermediate between the crystal radii and the ionic radii of Shannon and Prewitt (1969) based upon O^{2-} = 126 pm in order to conform with the "radius ratio principles of crystal chemistry." These values have not been widely adopted. Ghosh and Biswas (2003) have provided a more recent theoretical/quantum mechanical approach in the calculation of ionic radii but in their study ignore the importance of the coordination state in governing differences in ionic size. Hence these values have not been adopted in geochemistry.

The ionic radii of Shannon (1976) are most useful for oxides (including silicates). A separate set of values has been determined for sulfides (Shannon 1981) where the

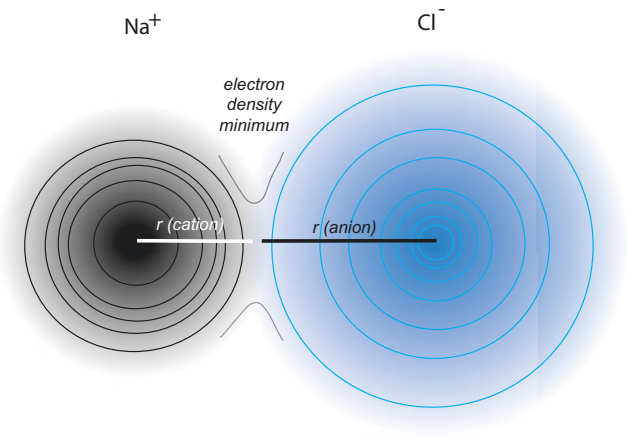
effects of metal-metal and anion-anion bonding also need to be accounted for. Bartelmehs et al. (1989) show that calculated ionic radii for sulfides are 12 pm larger than those for equivalent oxides.



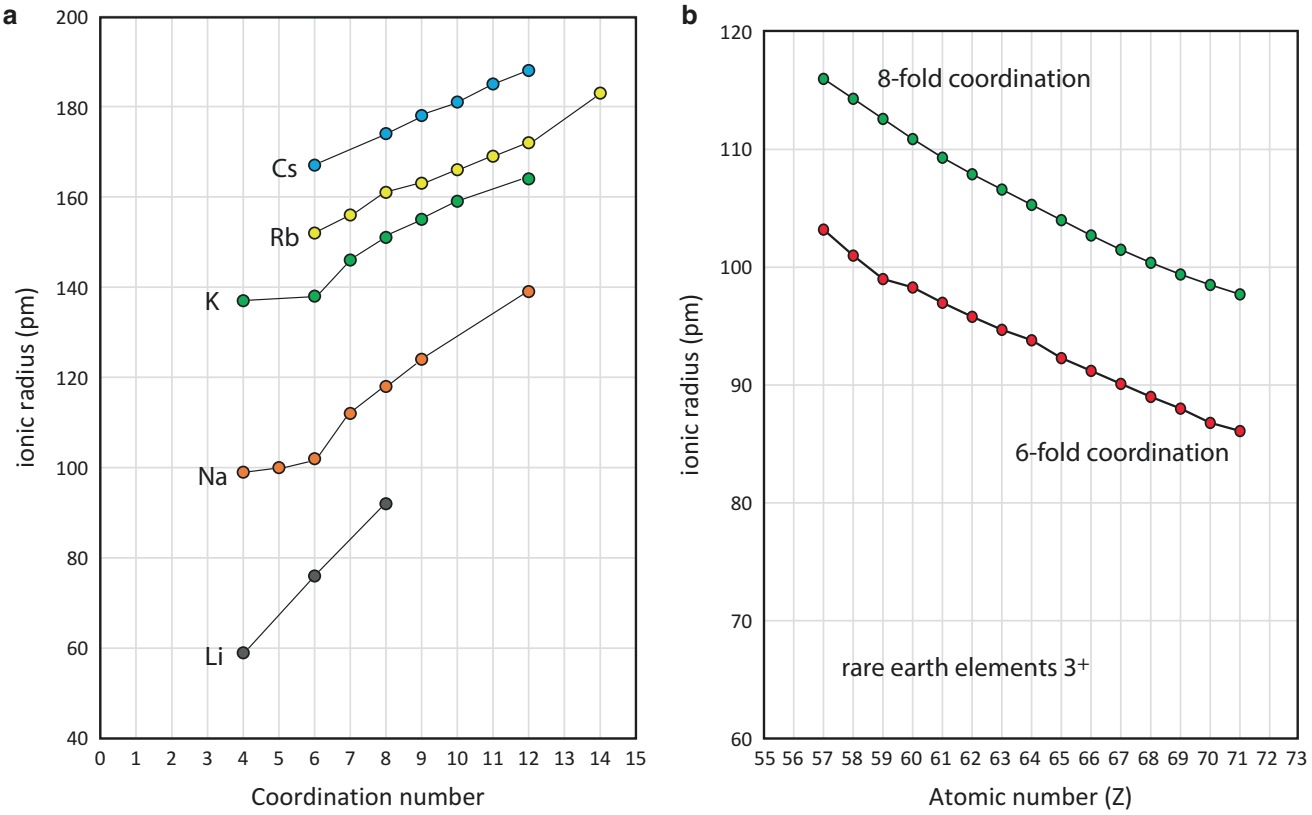
Ionic Radii, Fig. 1 Schematic electron density map for the ionic solid NaCl showing the electron density contours, the electron density minimum between the two ions, and the ionic radii

Patterns in Ionic Radii

As noted above, the ionic radius varies with coordination number, spin state, and other parameters; nevertheless, periodic trends can still be recognized (Fig. 2). It can be seen that ionic radii increase when descending a periodic group (Fig. 2a) and ionic size (for the same ion) increases with increasing coordination number (Fig. 2a, b). Ions in a high-spin state will be larger than the same ion in a low-spin state (see Table 1). Most commonly the ionic radius decreases with increasing positive charge but in anions increases with increasing negative charge.

The Use of Ionic Radii in Mineralogy and Petrology

Classically an accurate knowledge of ionic radii have been used to solve crystal structure types and problems of coordination in mineralogy. With the advent of precise methods of mineral analysis ionic radii have also become useful in solving complex ionic substitutions in minerals. This was formalized by Goldschmidt (1926) who formulated a series of "rules of substitution." These are summarized by White (2013) as follows:



Ionic Radii, Fig. 2 (**a**) Ionic radii for the Group 1 alkali metals showing the increase in ionic radius with increase in atomic number through the group and the increase in ionic radius with coordination number; (**b**) ionic radii for the ions of the rare earth elements with a 3+ charge showing the decrease in ionic radius with increasing atomic number for ions in sixfold and eightfold coordination

1. If two ions have the same radius and the same charge they will enter a given lattice site with equal facility.
2. If two ions have similar radii and the same charge the smaller ion will enter a given site more readily.
3. If two ions have similar radii the ion with the higher charge will enter a given site more readily.
4. Whenever a substitution is possible between two elements with significantly different electronegativities the one with lower electronegativity will be preferentially incorporated.

More recently, however, an accurate knowledge of ionic radii has become important in understanding mineral-melt partition coefficients and in diffusion studies in minerals and melts. For trace elements, Blundy and Wood (2003) show how the lattice strain model of element partitioning predicts a relationship between the log of the mineral-melt partition coefficient and ionic radius, such that for an isovalent series of ions in a particular mineral phase with a specific coordination they define a near-parabolic relationship. These plots are known as Onuma diagrams. Interestingly Tiepolo et al. (Tiepolo et al. 2000) show how subtle differences in partition coefficient as a result of small mineral-chemical differences within amphiboles result in the differential portioning of Nb and Ta requiring a small difference in their ionic radii, differences beyond the limits of resolution of the Shannon (1976) radii.

There is also a relationship between ionic radius and the rate of diffusion in minerals. This is illustrated in the study of Van Orman et al. (2001) who show that in clinopyroxene the diffusion rates of the rare earth elements decrease significantly with increasing ionic radius. They show that the diffusion rate of La is ca 35 times slower than that for the smaller ion of Yb and argue that the relationship between diffusivity and ionic radius is consistent with an elastic strain model for the motion of an ion through a crystal. These results have huge relevance for disequilibrium melting and isotopic equilibrium in the Earth's mantle.

Summary

The ionic radius of the ion of an atom is a measure of the size of a spherical ion. The principal source of ionic radii now used in mineralogy and geochemistry is that of Shannon (1976) and is based upon crystal structure refinements of oxide and fluoride structures. The data set was adopted in geochemistry and mineralogy because ionic radii were reported for the different oxidation states of an element taking account of differences in coordination number, electronic spin state and were calculated to take account of covalency, repulsive forces, and polyhedral distortion. Initially ionic radii were used to solve crystal structure types but increasingly they are used in the understanding of mineral-melt partition coefficients and diffusion studies.

Iridium

Thomas C. Meisel
General and Analytical Chemistry, Montanuniversität Leoben, Leoben, Austria

Element Data

Atomic Symbol: Ir
Atomic Number: 77
Atomic Weight: 192.217(3)
Isotopes and Abundances: ^{191}Ir 37.3 ± 2% and ^{193}Ir 62.7 ± 2%
Atm Melting Point: 2447 °C
1 Atm Boiling Point: 4428 °C
Common Valences: +3 and +4

(*continued*)

Ionic Radii: 3+: 68 pm, 4+: 63 pm
Pauling Electronegativity: 2.20
First Ionization Energy: 880 kJ/mol
Chondritic (CI) Abundance: 462 μg/kg (Fischer-Gödde et al. 2010)
Silicate Earth Abundance: 3.5 μg/kg (Becker et al. 2006)
Crustal Abundance: 0.022 μg/kg (Park et al. 2012)
Seawater Abundance: 0.5 to 1 fmol/kg
Core Abundance: ~2.6 mg/kg (McDonough 2014)

Properties

Iridium ($_{77}$Ir) with the electron configuration [Xe] $4f^{14}\ 5d^7\ 6s^2$ is a d-block transition element in the cobalt group (cobalt, rhodium, iridium, and meitnerium) and is one of the six platinum group elements (PGE). The atomic radii of the Os, Ir, Pt subgroup, caused by the lanthanide contraction of the 4*f* group elements, are similar compared to the Ru, Rh, Pd subgroup of the PGE. The almost doubling of the number of nucleons with the same atomic radii leads to elements with the high density and chemical inertness. Iridium possesses a density 22.56 g/cm^3, which is only slightly smaller than that for Os with 22.58 g/cm^3. The valence shell configuration and the high effective nuclear charge are expressed in the high tendency toward complex formation (similar to the horizontal neighbors Os and Pt). Small differences between the valence shells (6*s* and 5*d*) allow iridium to occur in several oxidation states. Possible oxidation states are −1, 0, +1, +2, +3, +4, +5, and +6 with +3 and +4 being the most stable forms. The behavior toward acids on the other hand is similar to its vertical neighbor Rh. Iridium has two stable isotopes ^{191}Ir and ^{193}Ir with mole fractions of 0.373(2) and 0.627(2), respectively. The most stable radioisotope is ^{192}Ir, a strong gamma ray emitter used as a source in industrial radiography.

History and Use

In 1804 iridium ($_{77}$Ir) was discovered by Smithson Tennant in the black residues after aqua regia digestion of crude alluvial platinum ore (Hunt 1987). Iridium forms colorful salts giving this metal the name after an ancient Greek word literally meaning "of rainbows" (ἰριοειδής *irio-eides*).

Specialized applications of Ir are found where high melting point, corrosion resistances, and hardness are of importance. The corrosion and heat resistance, in combination with hardness, allow special applications. Iridium or Pt–Ir alloys have low wear and are used as crucibles, spinnerets, etc. Space and aircraft engine parts are made of iridium alloys to increase the lifetime. Iridium can also be found in corrosion-resistant spark plugs. Iridium is also used in industrial catalysis and also catalytic converters. Enrichments of Ir can be found in the environment of higher traffic density (Fritsche and Meisel 2004).

Geochemical Properties

Iridium is one of the most sensitive and selective elements for neutron activation analysis (NAA). Using this method, a large body of Ir data has been acquired on terrestrial and extraterrestrial samples during the last 50 years. The presence of two stable isotopes (^{191}Ir and ^{193}Ir) also allows the application of isotope dilution mass spectrometry, after preconcentration chemistry, as an accurate measurement procedure, which is now state of the art for Ru, Pd, Re, Os, Ir, and Pt analysis (Meisel and Horan 2016).

Iridium and Mass Extinctions

The marked difference between the meteoritic and crustal Ir abundances and the availability of NAA in the 1970s for the analysis of low abundance sediments lead to the common hypothesis that meteorite impacts are the source for the Ir anomalies observed at Cretaceous–Paleogene (K–Pg also known as Cretaceous–Tertiary or K/T) boundaries observed worldwide (Alvarez et al. 1980). These few mm-thin layers are also associated with shocked quartz, which is clear evidence for high velocity impacts. Iridium anomalies have also been observed in sediment layers associated with other mass extinction events (e.g., Devonian–Carboniferous or Permian–Triassic boundary (Holser et al. 1989; Wang et al. 1993)).

Natural Occurrence

Iridium occurs as native metal mostly associated with common impurities of Pt, Au, Pd, Cu, and Fe or as alloys mostly with Os, Ru, Pt, and Fe. Several Ir sulfides (e.g., cuproiridsite $CuIr_2S_4$) and sulfarsenides (e.g., iridarsenite $[(Ir,Ru)As_2]$) exist in nature (O'Driscoll and González-Jiménez 2016).

The CI concentration for Ir of 462 μg/kg (Fischer-Gödde et al. 2010) is thus well established. Iridium is highly enriched in iron meteorites relative to silicate phases in chondrites. As the results of highly siderophile–chalcophile geochemical behavior, iridium is highly depleted in the Earth's mantle and crust (Day et al. 2016). For upper mantle rocks 3.5 μg/kg (Becker et al. 2006) and for the upper continental crust 0.022 μg/kg (Park et al. 2012) are the estimated abundances, making Ir, along with Rh, Ru, Re, and Os, to be one of the least abundant nonradioactive elements in the Earth's crust.

Biological Utilization and Toxicity

Iridium and iridium compounds have no biological function. Very little is known about the aqueous behavior, the mobility, and toxicity of iridium compounds because of its rareness and very limited industrial use. A possible $Ir(OH)_3^0$ species in the concentration range of 0.5 to 1 fmol/kg has been described for seawater (Bruland and Lohan 2003).

Summary

Iridium is one of the rarest elements in the Earth's crust and is characterized by geochemical behavior similar to that of Os and Ru. As a marker for influx of extraterrestrial material, there has been a significant amount of data collected over the decades. Combined thermal, corrosion, and chemical resistance allows special industrial applications.

Element Data

Atomic Symbol: Fe
Atomic Number: 26
Atomic Weight: 55.847 g/mol
Isotopes and Abundances: ^{54}Fe 5.845%, ^{56}Fe 91.754%, ^{57}Fe 2.119%, ^{58}Fe 0.282%
1 bar Melting Point: 1,538 °C
1 bar Boiling Point: 2,862 °C
Common Valences: 0, +2, +3
Ionic Radii: Fe^{+2} 78 pm (6-fold, high-spin); Fe^{+3} 64.5 pm (6-fold, high-spin)
Pauling Electronegativity: 1.83
First Ionization Potential: 762.5 kJ/mol
Chondritic (CI) Abundance: 18.28 wt. %
Silicate Earth Abundance: 6.26 wt. %
Crustal Abundance: 5.04 wt. %
Seawater Abundance: 30 pg/g
Core Abundance: 78–88 wt. %

Properties

Iron is one of a small group of metals that has been known to humans since antiquity. An entire period of human history, the Iron Age, followed the Bronze Age, as iron alloys replaced Cu alloys for tools and weapons. Since the Industrial Revolution, the production of steel makes iron one of the 2–3 most highly used elements.

Iron is one of the most abundant elements in the terrestrial planets, constituting ~30 wt. % of the Earth, Venus, and Mars. The electronic configuration for neutral Fe is Ar, $3d^6$, $4s^2$; for ferrous ion, Fe^{+2}, is Ar, $3d^6$; and for ferric ion, Fe^{+3}, is: Ar, $3d^5$. As a transition metal, Fe ions have a high-spin state and a low-spin state. The high-spin state of ferrous iron has one orbital (t_{2g}) with paired electrons and 4 orbitals with unpaired electrons contributing its paramagnetic property, while its low-spin state has 3 orbitals (t_{2g}) with fully paired electrons and is diamagnetic. The high-spin state of ferric iron has 5 orbitals each filled with one unpaired electron contributing its paramagnetic property, while its low-spin state has 2 (t_{2g}) orbitals filled with paired electrons and one orbital (t_{2g}) with an unpaired electron and is also paramagnetic. Ferrous and ferric iron both exhibit high-spin states in minerals at low pressure. The unpaired electrons in Fe cause the phenomenon of ferromagnetism. Iron has four stable isotopes. It has one radioactive isotope of interest in cosmochronology and as a planetary heat source: ^{60}Fe (half-life 2.6 Ma).

History and Use

Meteoritic iron has been used in tool making since before civilization (Comelli et al. 2016). The oldest known artifacts include beads found at Gerzeh dating to 3,500 BC and a dagger from Ur, dating to 3,000 BC, both of which contain high nickel contents (7–10 wt. %) indicative of meteoritic iron (Tylecote 1992). The earliest smelting of iron may have been in Anatolia before 2,000 BC. By the start of the Iron Age in 1,200 BC, techniques for smelting iron were widely developed in Africa, Eurasia, and the Indian subcontinent, and steel replaced bronze for weapons and tools.

Smelting of iron ores using coke (carbon) in blast furnaces made iron alloys, especially steels, the most important metals of the Industrial Revolution. Iron alloys are widely used to produce the infrastructure of modern civilization including transportation (e.g., trains, ships, automobiles, aircraft, and spacecraft) and construction (e.g., skyscrapers).

Isotope Cosmochemistry

Iron is the ninth most-abundant element in the cosmos, comparable in abundance to Si and Mg. Given that Fe (A = 56) is approximately twice as heavy as Si (A = 28), the exceptional abundance of Fe stands out from the abundances of other heavy elements that form the iron peak, a group that includes Cr, Mn, Fe, Co, and Ni. The Fe peak nuclei have the highest nuclear binding energy/nucleon, and ^{56}Ni, the progenitor of ^{56}Fe, is a double magic number ($Z = 28$, $N = 28$) nucleus. The synthesis of the isotopes of Fe occurs mainly during nuclear statistical equilibrium burning in the cores of large stars ($M > 15\ M_{solar}$), in the final fusion step preceding a supernova explosion. The most abundant isotope, ^{56}Fe, is produced as ^{56}Ni (half-life 5.9 days), the subsequent decay of which yields ^{56}Co (half-life 77 days) and then ^{56}Fe. Core-collapse (Type II) supernovae produce a massive amount of Fe in their cores, but much of this iron ends up in the subsequent neutron star, so that Type I supernovae (accreting white dwarfs) contribute about half of the Fe in the galaxy (Clayton 2003). The Fe peak nuclei, particularly ^{56}Fe, are the seed nuclei for both the slow neutron capture (s-process) and the rapid neutron capture (r-process) heavy nuclei. Neutron capture modifies the isotope abundances of Fe nuclei, particularly for the neutron-rich ^{58}Fe (s-process). The short-lived ^{60}Fe nuclide (half-life 2.6 Ma; decays to stable ^{60}Ni) is of interest in cosmochemistry both for chronology in the early solar system and as a possible radiogenic heat source in planetary cores (Sahijpal et al. 2007). This isotope has been found to occur globally in deep-sea sediments about 3 Ma old, implying a supernova event close enough to increase the terrestrial ^{60}Fe inventory (Wallner et al. 2016).

Geochemical Behavior

Iron Mineralogy

Telluric iron is metallic iron formed naturally on Earth. It is known from only a handful of locations where the iron contained in basaltic magmas became reduced by carbonaceous sedimentary rocks. The largest telluric iron crystal (22 tons) is found at Uivfaq Disko Island, Greenland, in Tertiary basalts (Bird et al. 1981). Other occurrences have been documented in intrusions in the Permian Siberian Traps (Ryabov and Lapkovsky 2010). Several extraterrestrial minerals, including taenite (γ-Fe, fcc) and kamacite (α-Fe, bcc), consist of native iron alloyed with >5 wt. % Ni. These minerals are the main constituents of iron meteorites, with some of the largest irons weighing as much as 60 tons (Buchwald 1975). In meteorites, Fe also occurs in carbides, oxides, phosphides, and sulfides, e.g., cohenite (Fe_3C), magnetite (Fe_3O_4), schreibersite (Fe-Ni_3P), and troilite (FeS) (Mittlefehldt et al. 1998). The ordinary chondrites, enstatite chondrites, and carbonaceous chondrites of the CB and CR groups contain abundant metallic Fe-Ni alloy. Aqueous alteration in the other carbonaceous chondrites (e.g., CI, CM, CK) resulted in the production of magnetite and Fe-sulfides as the principal Fe hosts.

Ferrous iron is an abundant component of meteoritic and terrestrial minerals and is found in olivines, pyroxenes, spinels, etc., and even as nearly pure fayalite (Brearley and Jones 1998). The fayalite content of olivine is a means of classifying chondrites of low metamorphic grade. Overall, the Fe^{+2} content of olivines and pyroxenes decreases as a function of parent asteroidal redox state with enstatite chondrites having the lowest Fe^{+2} contents (<1 mol. %) in silicate minerals, terrestrial mantle minerals at about 10 mol. %, and lunar and martian minerals at about 20 mol. % (Righter et al. 2006). All terrestrial planets and meteorites (representing the asteroid belt) contain Fe-Mg silicates that are too ferroan to have formed in equilibrium with hot hydrogen gas. The ferrous iron contents of chondritic silicates imply that chondrule formation must have occurred in gases that were enriched in oxygen (by the addition of vaporized ices) implicating asteroidal collisions in their formation (Grossman et al. 2008).

Core Geochemistry

Iron is the dominant constituent of the Earth's core, but it has long been known that pure metallic iron is too dense to explain the observed density of the core. Both the outer and inner core must contain a significant amount of lighter elements (about 10%) in the form of FeO, Fe-Si, or Fe-S, alloyed with liquid or solid metallic iron (Poirier 1994).

The Earth's inner core is solid (ε-Fe, hcp) due to the high confining pressure (330 GPa) at the inner core-outer core boundary. The melting relations of Fe alloys at megabar pressures place a constraint on the temperature of the inner core-outer core boundary (≤6,000 K; Ma et al. 2004) lowered by the addition of Si, O, and S in that relative order (e.g., Fischer et al. 2013).

The high entropy of melting of iron (118 $J.kg^{-1}.K^{-1}$) makes crystallization of the inner core an important heat source for the Earth, powering the magnetic field. If the core has no other source of heat, then the rapid rate of crystallization of the inner core required to supply the inferred heat flux implies a young (<2.5 Ga) inner core (Labrosse et al. 2001).

Mantle Geochemistry

Iron, in the form of ferrous iron (Fe^{+2}), is the most abundant transition metal in the mantle where it is distributed in all the major phases constituting the upper mantle: olivine, orthopyroxene, clinopyroxene, spinel, and garnet. The mole fraction of Fe in mantle olivine is 11 ± 2% (McDonough and Sun 1995). In the lower mantle, iron is partitioned principally into ferropericlase, (Mg, Fe)O, and less in bridgmanite, (Mg, Fe)SiO_3 (Lin et al. 2013).

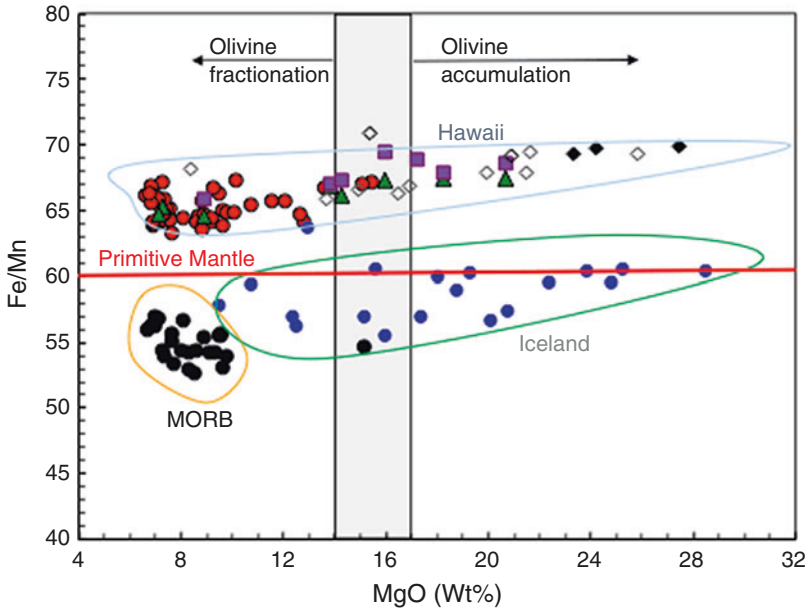
The low-spin forms of ferrous (62 pm vs. 78 pm) and ferric (55 pm vs. 64.5 pm) iron have smaller ionic radii favored by denser mineral structures at higher pressures. Evidence from mineral physics and geophysics indicates that iron undergoes a high-pressure spin transformation in the Earth's lower mantle from the high-spin to the low-spin state at depths below 1,700 km (Badro et al. 2003; Lin et al. 2013).

The distribution of iron in the upper mantle is considered to be relatively uniform, at 6.26 wt. % (McDonough and Sun 1995). The distribution of Fe (Fe/Mg) plays a principal role in controlling the density of the mantle, with competing influences from Si and temperature. Tomographic evidence indicates that iron is heterogeneously distributed in the mantle, with higher iron contents in the lower mantle beneath the African and Pacific superswells (Trampert et al. 2004). Chemical evidence that there are higher iron contents in the mantle beneath plumes comes from measurements of the Fe/Mn ratio in volcanic lavas erupted at mid-oceanic ridges versus those erupted in plume settings (Fig. 1), particularly Hawaiian lavas (Humayun et al. 2004; Huang et al. 2007). The Fe/Mg ratio is strongly affected by crystal fractionation processes, but the Fe/Mn ratio remains nearly constant during mantle melting (Davis et al. 2013) and subsequent fractionation processes (Fig. 1), unless chemical interactions occur between the core and the mantle. As the largest repository of iron on Earth, the core exerts a subtle influence on the mantle's Fe/Mg ratio by exchanging FeO (say) between solid ferropericlase in the lowermost mantle and the liquid outer core.

The ratio of ferric to ferrous iron in the mantle is controlled by the mantle's mineralogy and oxygen fugacity (Frost and McCammon 2008). The $Fe^{+3}/\Sigma Fe$ of the Earth's mantle has been a subject of much debate since it is several log units higher than expected from iron-wüstite equilibrium. One compelling explanation of the higher $Fe^{+3}/\Sigma Fe$ of the upper mantle involves the coupled substitution, $Fe^{+3}Al^{+3} = Mg^{+2}Si^{+4}$, into bridgmanite in the lower mantle that is thermodynamically favored where the Fe^{+3} is formed by the high-pressure disproportionation of FeO, as $3FeO = Fe_2O_3 + Fe$ (Frost and McCammon 2008). Removal of some of the metal formed in this reaction into the core would have left the lower mantle higher in $Fe^{+3}/\Sigma Fe$. Whole mantle convection then supplied oxidized material to the upper mantle, resulting in an excess $Fe^{+3}/\Sigma Fe$ relative to other planetary mantles (e.g., Mars) that do not reach the stability field of bridgmanite.

Comparative Planetology of Iron

The $Fe^{+3}/\Sigma Fe$ of the Earth's mantle is set near the Quartz-Fayalite-Magnetite (QFM) buffer (Bryndzia and Wood 1990; Bezos and Humler 2005; Cottrell and Kelley 2011), making the Earth's mantle arguably the most oxidized planetary mantle. The mantles of other planets and the Moon have lower redox states (Righter et al. 2006). New techniques, like synchrotron micro-X-ray Absorption Near Edge Structure (micro-XANES), are rapidly advancing our understanding of iron oxidation states in the mantle (Cottrell and Kelley 2011, 2013).



Iron, Fig. 1 Precise Fe/Mn ratios of basaltic rocks determined by solution ICP-MS for mid-oceanic ridge basalts (*MORB*), picrites from Iceland, and picrites and basalts from Hawaiian volcanoes (Humayun et al. 2004; Huang et al. 2007). The Primitive Mantle estimated from peridotites is from McDonough and Sun (1995). The primary melt compositions of Hawaiian lavas are shown as the *gray band*, with the compositional range controlled by olivine accumulation or loss. The Hawaiian volcanoes are individually depicted, Loihi: *filled diamonds*; Kilauea: *green triangles*; Mauna Loa: *open diamonds*; Mauna Kea: *purple squares*; Ko'olau: *red circles*

The surface rocks of Mercury contain the lowest known FeO abundances (~2–4%) of a planetary surface (Weider et al. 2012), while the Moon and Mars have ~15% FeO in their crustal rocks. Terrestrial MORBs have ~6–8% FeO, which may represent high-pressure dissolution of FeO into the Earth's core rather than primary differences in redox state between the Earth, Moon, and Mars (Rubie et al. 2004).

Iron in Earth's Crust

Iron is supplied to the crust mainly as ferrous iron from the mantle ($Fe^{+3}/\Sigma Fe$ ~0.15), but is subsequently oxidized by atmospheric oxygen at the weathering interface between the crust and the atmosphere. Ferrous iron is the most abundant of three natural reducing agents, the others being sulfide (S^{-2}) and organic carbon, $(CH_2O)_n$, in crustal sediments that act as sinks for atmospheric oxygen. Much of the oxidation may be microbially mediated. Modern soils are dominated by ferric iron (e.g., goethite, limonite, maghemite), which act to isolate the atmosphere from reduced crustal rocks.

In the oceanic crust, hydrothermal alteration converts olivine to serpentine, ±brucite, and magnetite, a process that releases significant amounts of H_2, CH_4, H_2S, and other reduced compounds, driving the oxidation of the oceanic crust. The partitioning of iron between serpentine, brucite, and fluid plays a very important role in this hydrothermal chemistry. At $T < 300$ °C, serpentine and brucite take up very little Fe compared to the initial olivine. Since wüstite and ferrous hydroxide are thermodynamically less stable relative to magnetite at these temperatures, the ferrous iron released from the alteration of olivine oxidizes with water to form magnetite and H_2 (McCollom et al. 2016). This is a process of fundamental importance in planetary science requiring olivine, water, CO_2/carbonate, and/or sulfate to create oxidized crust while upward migration of hydrogen (H_2), methane (CH_4), and hydrogen sulfide (H_2S) gases creates local highly reducing environments around serpentinization sites. Serpentinization occurs ubiquitously on Mars, icy asteroids, the Jovian moon Europa, the Saturnian moon Enceladus, Pluto, Kuiper Belt Objects, and extrasolar planets, where it might create important locales for organic synthesis.

Iron on the Martian Surface

The surface of Mars is covered with basaltic rocks exposed to an oxidizing but thin atmosphere. The modern Martian surface is extremely dry, with water frozen as permafrost in the regolith or at the poles or present as traces of water vapor in the atmosphere. In the absence of liquid water or a biosphere, the origin of the oxidized iron that creates the visually striking red hue of the fabled Red planet might be understood in terms of ancient weathering processes on Mars. The ancient Martian meteoritic breccia, NWA 7034/NWA 7533, contains 15% Fe-oxides as magnetite and maghemite, and superparamagnetic goethite, as its principal magnetic minerals of possible Noachian (3.7–4.0 Ga) origin and near IR spectra compatible with much of the Martian highlands (Gattacceca et al. 2014; Beck et al. 2015). In situ investigation by the Mars Exploration Rover (MER) *Opportunity* rover at Meridiani Planum revealed abundant hematite concretions ("blueberries") and ubiquitous jarosite, (K, Na, H_3O, X^+) $Fe_3(SO_4)_2(OH)_6$, a hydrated Fe^{+3}-sulfate, in outcrops around Eagle Crater, evidence for acidic aqueous alteration conditions on early (3.6–3.8 Ga) Mars (Squyres et al. 2004). Detailed in situ studies of iron oxidation state and mineralogy by the MER rover *Spirit* at the Columbia Hills revealed the presence of Fe^{+3}-sulfate soils (Paso Robles) of hydrothermal or fumarolic origin, hematite-rich outcrops, and goethite-

bearing outcrops formed at low water/rock ratios, together with olivine and pyroxene-bearing igneous rocks (Morris et al. 2008). Thus, the Martian iron cycle involved oxidation of basalts during weathering and aqueous alteration creating abundant secondary Fe^{+3} oxides, oxyhydroxides, and sulfates, on the early (3.6–4.0 Ga) Martian surface that have been globally distributed by subsequent aeolian activity as the modern soil (Beck et al. 2015).

Iron in Natural Waters

The solubility product of ferric hydroxide, $Fe(OH)_3$, is $\sim 10^{-36}$ M in contrast to that of ferrous hydroxide, $Fe(OH)_2$, $\sim 10^{-14}$ M (Greenwood and Earnshaw 1984), making ferric iron extremely insoluble in water. Iron is typically found in oxidized surface waters mainly in particles ranging in size from nanoparticles and colloids to larger particles, complexed with organic ligands (Wozniak et al. 2015), bound to dissolved or particulate organic matter or attached to mineral surfaces with only a small fraction as free ions (Dupré et al. 1999; Raiswell and Canfield 2012). In reducing groundwaters or sediment porewaters, microbial respiration converts Fe-oxyhydroxides to ferrous iron which can accumulate significantly until the build-up of hydrogen sulfide (H_2S) regulates the dissolved Fe^{+2} abundance by forming Fe-sulfides, marcasite, and eventually pyrite (Raiswell and Canfield 2012). The presence of pyrite or magnetite framboids in sediments indicates a microbial role for iron deposition from natural waters.

Aqueous iron is extremely low in seawater far from land. Iron exhibits a nutrient-like profile, i.e., low concentrations in surface waters (<500 m depths) increasing to a steady value of 0.4–0.8 nM concentrations in deeper water (Johnson et al. 1997). Its principal supply includes atmospheric aerosol deposition (Wozniak et al. 2015) and hydrothermal plumes in ocean bottom waters (Raiswell and Canfield 2012). The extremely low iron in surface waters results in iron being the limiting nutrient for primary marine biological productivity. This gave rise to the iron fertilization hypothesis that algal blooms stimulated by deliberately adding bioavailable iron (e.g., ferrous acetate) to surface waters of the open oceans could increase burial of organic carbon in the oceans (Raiswell and Canfield 2012). Field tests of iron fertilization have not been promising due to rapid oxidation of the iron and by remineralization of organic carbon in deeper waters (rather than burial in sediment).

Prior to the rise of oxygen in the atmosphere, the Archean ocean may have been green from high levels of dissolved ferrous iron. Annual springtime pulses of oxygen from cyanobacterial photosynthesis resulted in precipitation of insoluble ferric oxyhydroxides or magnetite. The subsequent die-off of marine microbes produced biogenic silica layers. Alternating silica-magnetite sediments were abundant in the Archean and Proterozoic periods and are termed "banded iron formations" (e.g., Hammersley formation, Western Australia). Such rocks are the principal source of iron ore for modern industry. The last episode of banded iron formation occurred during the Neoproterozoic snowball Earth (~700 Ma) due to isolation of the oceans from the atmosphere (Canfield et al. 2008). Hydrothermal sources supply the oceans with abundant iron that, in the absence of oxygen, would result in unusually high water column abundances of dissolved ferrous iron during the Neoproterozoic.

Biological Utilization and Toxicity

Iron plays an important role in biological processes due to the redox chemistry of ferrous and ferric ions, e.g., photosynthesis (iron-sulfur ferredoxins), oxygen transport (heme), metabolism (cytochromes), and nitrogen fixation (MoFe-nitrogenase). Iron is utilized as an essential nutrient by all organisms from archaea and bacteria to plants and animals. In the absence of ligands, ferric iron is extremely insoluble in biological fluids, where Fe^{+3} occurs bound to chelating molecules, like heme, ferritin, and transferrin. In humans, iron deficiency is the most common nutritional deficiency (anemia). Less commonly, iron excess can result in free Fe ions in cells, leading to iron toxicity.

Due to the low solubility of ferric iron, most organisms live in environments where iron availability is limited even when abundant Fe-minerals are present and competition for the biologically available Fe is intense. Microbes and plants secrete siderophores, molecules that complex iron from solution, to help increase biological iron availability. Proteins tightly regulate iron availability in the human body, which poses a challenge for pathogens. Stable isotope tracing of proteins and gene knockouts have helped identify the iron sources for *Staphylococcus* infections (Skaar et al. 2004), providing potential new treatment pathways involving the iron limitation of methicillin-resistant *Staphylococcus aureus* (MRSA).

The chemical cycle of iron near the Earth's surface is likely to be strongly controlled by biological processes. Microbial life plays a vital part in the weathering and dissolution of ferroan minerals by oxidizing ferrous iron to ferric iron resulting in the precipitation of new Fe-minerals. Species like *Acidithiobacillus ferrooxidans* metabolize Fe-sulfides (e.g., pyrite) at low pH releasing ferric iron-bearing sulfuric acid contributing to acid mine waste. Ferric iron-reducing organisms like *Geobacter metallireducens* and *Shewanella putrefaciens* utilize ferric iron as an electron acceptor in anaerobic respiration releasing ferrous iron. Magnetotactic bacteria precipitate magnetite in their magnetosomes. Astrobiologists employ biomineralized magnetites as fossil biomarkers. The difficulties in interpreting the biological origin of magnetite are illustrated by the debate over the origin of

magnetite in carbonate globules of the Martian meteorite, ALH 84001 (Weiss et al. 2004).

Summary

Iron (atomic number 26) is one of the most abundant elements in terrestrial planets, as the dominant constituent of the core and an important constituent of the mantle and crust. Iron naturally occurs in three valence states, as the metal (Fe^0), and as ferrous (Fe^{+2}) and ferric (Fe^{+3}) ions. As the most abundant transition metal in the Earth, it plays a dominant role in controlling oxygen fugacity in the mantle. Since antiquity (the Iron age, 1,200 BC), iron is one of the most widely used industrial raw materials, particularly in the manufacture of steel. In aqueous fluids, iron is extremely insoluble as ferric iron, and the rise of atmospheric oxygen resulted in the formation of thick sedimentary iron ore deposits (banded iron formations) that are the principal source of the metal for modern industry. Iron is an essential nutrient for all organisms, particularly in heme-proteins. Iron-deficiency is a common disease, but in rare instances iron toxicity is known.

Iron Formations

Clark M. Johnson
Department of Geoscience, University of Wisconsin, Madison, WI, USA

Definition

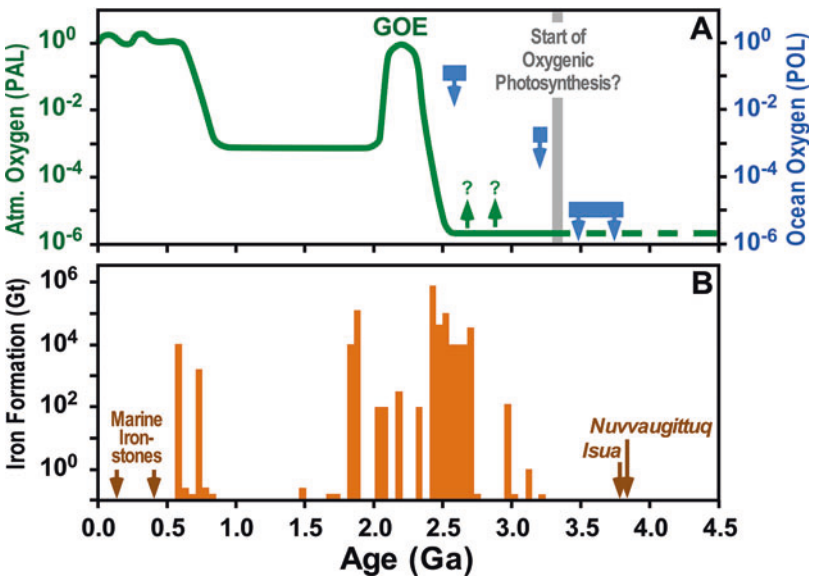
Iron formations (IFs) are marine chemical precipitates that contain >15 wt.% Fe (James 1954) that were deposited in the Precambrian. Gross (1965) classified IFs into four types, two of which continue in use today: *Algoma,* which are relatively small in total volume and are associated with significant volcanic input including volcanogenic massive sulfide associations, and *Superior,* which are large and laterally extensive, and thought to have formed in passive continental margin settings. IFs have drawn interest from geologists because they represent Fe deposition on a scale not seen in the Phanerozoic and hence record an extensive Fe biogeochemical cycle on the early Earth that does not occur today. The largest IFs supply the vast majority of the world's Fe needs, where the largest mines produce over 200×10^6 tons of Fe per year. Many IFs are characterized by banding at mm to m scales, often defined by alternating silica-rich and silica-poor layers mixed with abundant Fe minerals (Trendall and Blockley 1970), and such IFs are termed "Banded Iron Formations (BIFs)." The laterally extensive layering in BIFs is generally thought to record deposition in relatively deep water, below wave base. Other IFs contain granular or oolitic textures, termed "Granular Iron Formations (GIFs)," and are generally considered to have been deposited in shallow water (Beukes and Klein 1990). Other Fe-rich chemical sediments include jaspers and ironstones, which tend to have more restricted distributions as compared to BIFs. The distribution, origin, and genesis of IFs have been extensively studied over several decades, and a recent comprehensive discussion can be found in Bekker et al. (2014).

Geologic Occurrences

The temporal occurrence of IFs is punctuated, and models for IF genesis have been closely linked to evolution of O_2 levels

(Fig. 1). The oldest occurrences are small, undoubtedly reflecting fragmental preservation of the earliest IF record, and include the 3.7–3.8 Ga Isua and Nuvvaugittuq IFs, the latter of which could be as old as ~4.3 Ga, depending upon interpretation of ^{146}Nd-^{142}Nd ages (O'Neil et al. 2008). The largest IFs are the laterally extensive *Superior*-type IFs that formed in the Neoarchan to Paleoproterozoic, including the famed Hamersley IFs of the Pilbara craton in Western Australia and the Transvaal IFs of the Kaapvaal craton in South Africa that likely reflect deposition in what was once the same continental margin basin (Beukes and Gutzmer 2008). Relative to current models for the evolution of atmospheric O_2 (Lyons et al. 2014), the majority of IFs were deposited prior to the first major rise in atmospheric O_2 ("Great Oxidation Event," or GOE; Fig. 1), although there is evidence for transient increases in atmospheric O_2 prior to the GOE, and increasing evidence that the photic zone of the oceans attained significant free O_2 contents after ~3.2 Ga (Fig. 1). IFs are relatively scarce through the GOE but reappear in the geologic record between ~2.0 and 1.8 Ga. Few IFs have been found in the Mesoproterozoic (Fig. 1), despite excellent preservation of marine basins in the geologic record. This was once thought to record a shift to euxinic ocean conditions, where high sulfide contents would suppress Fe(II) transport (Canfield 1998), but it is now generally accepted that pervasive oceanic anoxia characterized the Mesoproterozoic, but with restricted euxinic environments (Reinhard et al. 2013), and so it is not clear why IF deposition was limited. The last period of major IF deposition is the late Neoproterozoic, broadly correlative with major glaciations and the second major rise in atmospheric O_2 (Fig. 1). The Phanerozoic records scattered occurrences of marine iron stones, interpreted as deposition in shallow, restricted basin conditions on a local scale.

The mineralogy of IFs may include Fe oxides, Fe carbonates, Fe silicates, and quartz but only trace aluminosilicate minerals, reflecting low clastic input (Klein 2005). Pyrite is rare in IFs, except in interbedded siliciclastic units. Simonson (2003) stressed that, contrary to common conception, hematite or goethite are *not* the major Fe-bearing phases in many large IFs that are free from significant weathering, supergene alteration, mineralization, or metamorphism. Klein and Beukes (1992) noted that the average oxidation stage of Fe in IFs is $Fe^{2.4+}$, indicating that, on average, 60% of the Fe in IFs is in ferrous form, equivalent to an assemblage of magnetite (60%) and siderite (40%). The mineralogy of IFs has been used to define various lithofacies, including *oxide* and *carbonate* lithofacies (Beukes et al. 1990), where the *oxide* facies is generally considered to reflect deposition in the most distal environments. The major "primary" Fe oxide in IFs, particularly the large Neoarchean to Paleoproterozoic *Superior*-type IFs, is magnetite. "Primary" hematite is



Iron Formations, Fig. 1 Temporal variations in atmospheric O_2 (*green curve* in **a**), shallow ocean O_2 (*blue boxes* in **a**), and iron formation (IF) abundance (**b**). Atmospheric O_2 *curve* relative to Present Atmosphere Level (PAL) (Adapted from Lyons et al. (2014)). GOE marks the "Great Oxidation Event" that may record an "over-shoot" in the first major rise in atmospheric O_2, followed by low periods in most of the Proterozoic. Evidence also exists for transient increases in atmospheric O_2 before the GOE, shown with green arrows. Estimates for maximum O_2 contents in the shallow oceans (photic zone) in *blue boxes* relative to Present Ocean Level (POL) are based on modeling stable Fe isotopes (Czaja et al. 2012, 2013; Li et al. 2013b; Satkoski et al. 2015) and show that the shallow oceans likely had significant free O_2 levels by 3.2 Ga, prior to rise in atmospheric O_2, which is taken to record the latest start of oxygenic photosynthesis. Iron formation abundance (in gigatons) from Bekker et al. (2010). Small volume early IFs also shown, including Isua and Nuvvaugittuq (the latter of which might be as old as ~4.3 Ga). Periods of Phanerozoic marine ironstone deposition also shown

subordinate to magnetite in Paleoproterozoic and older IFs but is much more abundant in Neoproterozoic IFs and Phanerozoic marine ironstones. Iron-bearing carbonates include siderite-magnesite solid solutions (average $Mg_{0.2}Fe_{0.8}CO_3$), ankerite ($Ca_{0.5}Fe_{0.5}CO_3$), and ferroan dolomite. Iron silicates include greenalite, stilpnomelane, and minnesotaite in the *oxide* facies of BIFs (Klein 2005), an order that generally reflects increasing metamorphism. Quartz is almost always present as a major mineral, generally most abundant in *oxide*-facies IFs.

Iron Sources and Relations to Seawater Chemistry

The ultimate source of Fe in IFs has been the subject of extensive debate. Early work suggested a continental source through anoxic weathering and transport of Fe(II) in river systems under anoxic conditions (Cloud 1973). Rare Earth Element (REE) studies documented positive Eu anomalies in IFs, which, based on similar anomalies in modern mid-ocean ridge (MOR) hydrothermal fluids, and the high distribution coefficient for REES on Fe oxides, was taken to indicate a hydrothermal source, where Fe was transported as Fe(II) in relatively anoxic seawater, followed by oxidation to Fe(III) minerals (Klein and Beukes 1989; Derry and Jacobsen 1990; Bau and Möller 1993). This interpretation has largely remained as the accepted origin for Fe in IFs since it was proposed. Broad temporal correlations between IF abundance and seafloor basaltic volcanism have supported the interpretation that Fe in IFs is sourced to MOR hydrothermal fluids (Isley and Abbott 1999). In contrast, Nd isotope data have shown variable contributions from continental Nd, raising the possibility that Fe from continental sources also contributed to IFs (Alexander et al. 2009; Viehmann et al. 2013), potentially bringing us back, at least in part, to Cloud's (1973) original hypothesis.

The high sorption coefficients for a variety of trace elements onto Fe(III) oxides and hydroxides has led to the use of IFs as a repository for long-term records of seawater chemistry. This includes the REEs, as discussed above, as well as redox-sensitive elements and elements cycled by biology. Temporal changes in the abundance of U in IFs, for example, is interpreted to reflect changes in the oxidized (soluble) form of U in seawater, where major peaks in U abundances are seen during the GOE and the late Neoproterozoic rise in atmospheric O_2 (Partin et al. 2013; Fig. 1). Recently, U-Th-Pb geochronology has been used to constrain primary U contents in early Archean jaspers and IFs, and document the oldest known marine redox gradient at 3.2 Ga (Satkoski et al. 2015), which has been interpreted to mark the latest evolution of oxygenic photosynthesis (Fig. 1). Frei et al. (2009) showed small increases in $\delta^{53}Cr$ values in IFs immediately before the GOE, taken to record mobilization of soluble Cr(VI) related to small increases in atmospheric O_2, as well as a very large increase in $\delta^{53}Cr$ values for late Neoproterozoic IFs that coincided with the second rise in atmospheric O_2. Phosphorus is a bio-limiting nutrient, and P abundances in IFs have been used to infer phosphate concentrations in seawater. Bjerrum and Canfield (2002) argued that phosphate drawdown during IF deposition would cause phosphate levels to remain low during peaks in IF deposition, and hence limiting primary productivity, but Konhauser et al. (2007a) argued that competitive sorption of silica would limit phosphate drawdown. Planavsky et al. (2010) documented a large peak in P contents of IF in the late Neoproterozoic immediately after "snowball Earth" events and suggested this recorded a peak in primary productivity and organic carbon burial related to the second rise in atmospheric O_2 (Fig. 1). Some trace elements may be tied to specific microbial processes, such as the key role that Ni plays as a cofactor in enzymes used by methanogens. Konhauser et al. (2009) noted a large decrease in Ni contents in IFs prior to the GOE (Fig. 1), which they interpreted to reflect a "nickel famine" that led to collapse of methane production, which in turn allowed atmospheric O_2 contents to rise.

A key issue in using IFs as a proxy for ancient seawater is the effects of early diagenesis. Although it seems safe to use the overall abundance of IFs to infer an Fe(II)-rich ocean in the Archean and Paleoproterozoic (Holland 1984), more problematic is the use of minerals that may record diagenetic processes, which, if not formed in equilibrium with the oceans, would weaken their use to infer surface environmental conditions. For example, siderite in IFs has $\delta^{13}C$ and $\delta^{18}O$ values that are too low and $^{87}Sr/^{86}Sr$ ratios that are too high to be in equilibrium with the oceans (Becker and Clayton 1972; Beukes et al. 1990; Heimann et al. 2010; Johnson et al. 2013), and therefore inferences of high ambient CO_2 contents based on siderite stability (Ohmoto et al. 2004) may not be correct. In situ analysis of O and Fe isotope compositions of coexisting hematite and magnetite in IFs show that they do not reflect equilibrium with each other or with the oceans (Li et al. 2013a), and such a conclusion extends to magnetite-siderite pairs in IFs (Frierdich et al. 2014). Although there seems little doubt that IFs record biogeochemical processes in marine environments, it is now recognized by many workers that these involve a variety of components, including the source(s) of initial Fe(II), processes of oxidation (commonly envisioned in the shallow oceans), and early diagenetic processes on the seafloor.

The Role of Biology in IF Genesis

Possible relations between IF genesis and biology have been discussed for a century (Harder 1919), despite the fact that

microfossil and organic carbon abundances are very sparse in IFs. Direct morphological evidence for the presence of microbes in the environments of IF deposition includes the first recognized Precambrian microfossils, found in the Gunflint IF (Barghoorn and Tyler 1965), although such associations do not constrain specific biogeochemical roles for microbes. Recent discussions on the potential role for biology in IF genesis have focused on direct and indirect biological pathways for oxidation of hydrothermal Fe(II) to Fe(III)-bearing oxides and hydroxides (Konhauser et al. 2002). Production of Fe(III)-bearing minerals in IFs, relative to the reduced sources of Fe inferred for IFs, requires oxidative pathways, in part under conditions of a reducing atmosphere for the large IFs of the Neoarchean (Fig. 1). Moreover, the large proportion of Fe(II) in IFs (e.g., magnetite and siderite) requires a reductive component (Konhauser et al. 2005). Although the low measured organic carbon contents in IFs has been used to argue against a role for biology in IF genesis (Klein 2005; Planavsky et al. 2012), the low $\delta^{13}C$ values of siderite and high abundance of magnetite in IFs, if converted to the equivalent abundance of organic C, suggests initial organic C contents approaching 5 wt.%, which is two to three orders-of-magnitudes higher than measured values (Li et al. 2013a). The evidence for potential biological roles in IF genesis, therefore, most likely lies in the chemical and isotopic compositions of IFs.

Three pathways have been proposed for oxidation of hydrothermally (or continentally) sourced Fe(II): reaction with free O_2, photoferrotrophy, and UV-photo oxidation. Cloud (1968, 1973) was an early proponent for the first reaction, where free O_2 was supplied by oxygenic photosynthesis:

$$H_2O + CO_2 \rightarrow CH_2O + O_2 \quad (1)$$

followed by oxidation of aqueous Fe(II) to form amorphous ferric hydroxides:

$$4Fe^{2+} + O_2 + 8OH^- + 2H_2O \rightarrow 4Fe(OH)_3 \quad (2)$$

which in turn would convert to hematite via dewatering upon lithification:

$$2Fe(OH)_3 \rightarrow Fe_2O_3 + 3H_2O \quad (3)$$

In this model, the role of biology is indirect in the sense that free O_2 is produced by oxygenic photosynthesis, which then oxidizes Fe(II). Support for this model comes from the recognition that the photic zone of the oceans became oxygenated before the atmosphere (Fig. 1). The second pathway was highlighted by Widdel et al. (1993), where Fe(II) serves as an electron donor and Fe(II) oxidation is coupled to reduction of CO_2 to organic carbon via the reaction:

$$4Fe^{2+} + CO_2 + 4H^+ \rightarrow CH_2O + 4Fe^{3+} + H_2O \quad (4)$$

Kappler et al. (2005) showed that this pathway, using reasonable rates of phototrophic oxidation, could explain the Fe(III) inventories found in IFs. Moreover, it seems reasonable such a pathway was involved in producing Fe(III) contents in early Archean IFs and jaspers when free O_2 contents in the shallow oceans were very low (Fig. 1). The third pathway is an entirely abiological one, where oxidation occurs in the shallow oceans through UV-photo catalyzed reactions (Cairns-Smith 1978):

$$2Fe^{2+} + 2H^+ + h\nu \rightarrow 2Fe^{3+} + H_2 \quad (5)$$

Limitations on this process have been highlighted by Konhauser et al. (2007b), who showed that this process was inhibited in natural seawater compositions as compared to earlier studies that used simple experimental conditions. Constraints on the extent of Fe(II) oxidation, although not the specific pathway, have been supplied by Fe isotope studies, which generally show that partial oxidation occurred at periods of time when atmospheric O_2 contents were relatively low before and after the GOE, but relatively high during the major period of IF deposition in the Neoarchean when photic zone O_2 contents were relatively high (Fig. 1; Dauphas et al. 2004; Planavsky et al. 2012: Czaja et al. 2012; Li et al. 2013a, b).

A biological reduction pathway as the source for Fe(II) in IFs has been proposed based on experimental studies that produce abundant magnetite and siderite from microbial reduction of Fe(III) oxides/hydroxides, and recognition that primary productivity in the photic zone during IF deposition likely produced a "rain" of ferric hydroxides and organic carbon to the seafloor that could support microbial Fe(III) reduction in unlithified, water-rich IF gels (Konhauser et al. 2005). The products of Eqs. 1, 2, and 4 would supply reactants for microbial Fe(III) reduction, and siderite may be produced via:

$$4Fe(OH)_3 + CH_2O + 3HCO_3^- \rightarrow 4FeCO_3 + 3OH^- + 7H_2O \quad (6)$$

This requires additional carbonate beyond that supplied by oxidation of organic carbon, but this fits well with the $\delta^{13}C$ and $\delta^{18}O$ values measured for IF siderite relative to that expected to reflect equilibrium with the oceans (Heimann et al. 2010). Production of magnetite by microbial Fe(III) reduction would occur via:

$$12Fe(OH)_3 + CH_2O \rightarrow 4Fe_3O_4 + CO_2 + 19H_2O \quad (7)$$

A test of this pathway is supplied by O and Fe isotope studies that show "inheritance" of O and Fe isotope compositions in low-temperature magnetite from a common Fe (III) precursor, rather than inter-mineral isotopic equilibrium between magnetite and hematite (Li et al. 2013a). On a basin-wide scale, it has been proposed that microbial Fe(III) reduction may release aqueous Fe(II) from continental margin sediments that is exported to the deep basin (Anderson and Raiswell 2004; Severmann et al. 2008), sometimes referred to as a "benthic iron shuttle", and this has now been recognized in the large Neoarchean IFs based on Fe-Nd isotope relations (Li et al. 2015). The close association of Fe and Si in the Precambrian oceans and Fe precipitates has led to the suggestion that microbial Fe(III) reduction could have also transported, on a basin-wide scale, silica that was released during microbial Fe(III) reduction (Fischer and Knoll 2009), and recent Si isotope studies have shown than such a model can explain the unusually low δ^{28}Si values of quartz in IFs (Reddy et al. 2016; Zheng et al. 2016).

Summary

As chemical precipitates, IFs provide a view of biogeochemical cycling in the Precambrian oceans and demonstrate an "iron world" that was distinct from that of the Phanerozoic. Juxtaposition of redox contrasts is central to all models of IF genesis, reflecting the mixed redox state of Fe in IFs, as well as the large contrast in solubility of dissolved Fe(II) and Fe(III) species at neutral pH. Debate continues as to whether or not the signals recorded in IFs largely reflect seawater compositions or the influence of biology, or, probably most likely, a combination of both. Research on IFs is likely to continue to be strong because the biogeochemical signals recorded in IFs inform us about changes over Earth's history in environmental conditions, including redox, as well as evolution of the biosphere.

Definition

Iron has four naturally occurring isotopes, with ^{56}Fe (91.754%) and ^{54}Fe (5.845%) being the most abundant and ^{57}Fe (2.119%) and ^{58}Fe (0.282%) being relatively rare. Iron isotope variations are reported, using the delta notation (e.g.,

δ^{56}Fe), relative to IRMM-014, a metallic iron standard from the Institute for Reference Materials and Measurements. Iron isotopes have been actively measured since 1999 and have been used to track a wide range of both high- and low-temperature geochemical, as well as cosmochemical processes. Iron isotope work is premised on a strong experimental foundation that is the basis for interpreting both modern environmental and geological iron isotope signals and the system has, arguably, been used most extensively to track the evolution of redox-sensitive iron biogeochemical cycling through Earth's early history and oxygenation.

Introduction

Iron isotopes were originally developed to provide a novel tool for the detection of biosignatures and a means to track environmental iron cycling (e.g., Beard et al. 1999). This work in large part grew from theoretical calculations on the magnitude of equilibrium stable Fe isotope fractionation (e.g., Polyakov 1997; Polyakov and Mineev 2000). Over the past couple decades, there has been a surge of work on the iron isotope system and a large increase in the number of labs actively measuring iron isotopes. There are well over a thousand papers on iron isotopes to date, with bodies of work on modern as well as ancient high- and low-temperature systems. This surge of work has been fueled in large part by the relative ease with which iron isotope measurements can be made using a multicollector inductively coupled plasma mass spectrometer (MC-ICP-MS), although iron isotopes can also be accurately measured by other means (see review in Dauphas and Rouxel 2006). Given the vast scope of iron isotope work we will, below, only scratch the surface of the range of questions and uses to which iron isotopes can and have been applied. We have tried to highlight areas in which iron isotope research has been especially active, and touch upon some of the recent successes of this system.

Methods

Iron isotopes were initially measured with thermal ionization mass spectrometer, TIMS (Völkening and Papanastassiou 1989), while all labs today in which iron isotopes are measured do so via MC-ICP-MS. However, although MC-ICP-MS measurements of iron isotopes are becoming increasingly common, this process remains, by some metrics, challenging. First, iron needs to be separated from all matrix elements by means of column chromatography. Separation of iron is achieved with an anion exchange resin, most typically the AG1-X8 resin (e.g., Beard et al. 1999; Dauphas et al. 2004), although other methods have been presented. The most difficult aspect of MC-ICP-MS measurement is, moreover, overcoming oxygen and nitrogen argide interferences. Several approaches have been used to deal with isobaric interferences, including using a collision cell or a cold plasma to minimize interferences. However, most measurements are now made by resolving the interferences, which entails measurement on the shoulder of interference rather than a flat-topped peak as is typically done with for other isotope systems (Weyer and Schwieters 2003). Lastly, instrument mass bias needs to be corrected by using either sample-standard-bracketing (SSB; Schoenberg and von Blanckenburg 2005), Cu/Ni doping, or a spike on isotopes ^{57}Fe and/or ^{58}Fe (Millet et al. 2012). The ^{56}Fe/^{54}Fe and ^{57}Fe/^{54}Fe ratios are expressed in the usual δ notation in per mil (‰) as:

$$\delta^{5X}\mathrm{Fe}_{\mathrm{sample}} = \left[\left({}^{5X}\mathrm{Fe}/{}^{54}\mathrm{Fe} \right)_{\mathrm{sample}} / \left({}^{5X}\mathrm{Fe}/{}^{54}\mathrm{Fe} \right)_{\mathrm{standard}} - 1 \right] \times 1000$$

where ^{5X}Fe represents either ^{56}Fe or ^{57}Fe, and the standard is generally IRMM-014. However, it should be noted that a few laboratories report Fe isotope composition relative to average igneous rocks, which is shifted by ~0.08‰ relative to IRMM-014 (Beard et al. 2003a). δ^{56}Fe is the most widely used notation in the literature although few labs still use ^{57}Fe because of high precision obtained on the ^{57}Fe measurement.

Biogeochemical Iron Cycling

Iron isotopes have been used extensively to track local and global biogeochemical iron cycling. Microbial processes play an important role in iron redox cycling. Foremost, dissimilatory microbial iron reduction (DIR) leads to extensive iron recycling by readily converting ferric to ferrous iron. Iron isotopes have therefore been proposed to directly track DIR (e.g., Johnson et al. 2008). Dissolved Fe(II) produced by dissimilatory Fe-reducing bacteria can be markedly depleted relative to parent ferric oxides (e.g., Beard et al. 1999). Additionally, Fe(II) from DIR can be nearly 3‰ lower than oxide-associated ferric iron, where fractionations occurring during DIR seem to be linked to isotope exchange between dissolved ferrous iron, sorbed ferrous iron, and reactive ferric iron at the surface of oxide undergoing reduction (Crosby et al. 2005; Crosby et al. 2007). In this light, the bacteria are catalyzing exchange and moving the system toward equilibrium Fe isotope partitioning. This is consistent with the direction of the isotope fractionation, in that ferric iron tends to have a higher coordination number and stronger, stiffer bonds. The equilibrium fractionation between aqueous Fe(II) and Fe(III) is ~3‰ at room temperature, with Fe(III) being enriched in heavy isotope (Welch et al. 2003). Iron oxidation and precipitation thus result in the formation of a light (more negative

δ^{56}Fe value) residual dissolved Fe(II) reservoir and there is not a clear difference between the fractionation that occurs during abiogenic and what occurs during biogenic iron oxidation (Croal et al. 2004; Wu et al. 2011).

Nonredox-dependent processes are typically associated with smaller fractionations than iron oxidation and reduction. For example, precipitation of iron carbonates from Fe(II) results in a fractionation near 0.5‰, enriching the solid in the light isotope (Wiesli et al. 2004). A notable exception to this trend, however, is the potential for large isotope fractionations to occur during pyrite formation in which there is not quantitative Fe scavenging (Guilbaud et al. 2011). As with all isotope systems, iron isotope fractionations will scale with temperature and the temperature dependence of key processes (e.g., iron oxidation) is analytically resolvable (>0.1‰) within the range of Earth's surface temperatures.

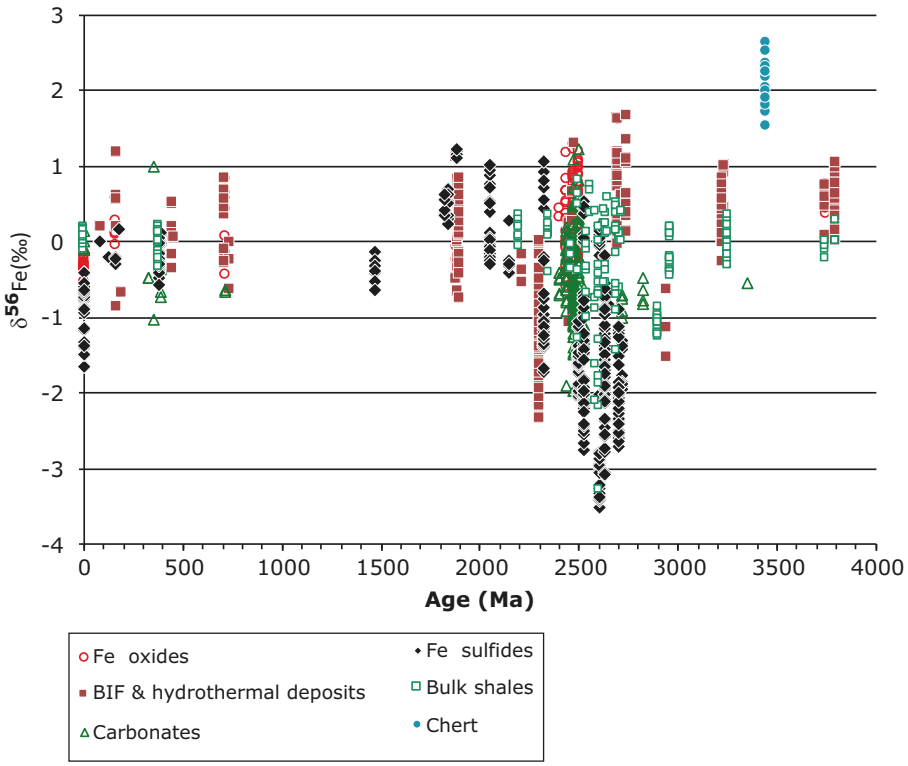
A basic understanding of isotope fractionation factors and of the isotope composition of different iron reservoirs paves the way for using iron isotopes to track modern iron cycling. The most intense interest in this application of iron isotopes has been tracking Fe sources into the marine realm. Much of this interest is linked to iron being a key colimiting nutrient in the oceans and to the large uncertainties in the magnitude of different iron input fluxes. Different iron sources to the oceans have in cases isotopically distinct compositions. There are three main seawater Fe sources, dust, hydrothermal fluids, and a sediment flux. Dust has a near uniform δ^{56}Fe values close to 0‰; however, there may be a slight negative fractionation factor associated with leaching Fe from dust particles (Beard et al. 2003a; Revels et al. 2015). Hydrothermal fluids have slightly negative δ^{56}Fe values, between −0.5 and 0‰ (e.g., Sharma et al. 2001; Beard et al. 2003b), but there can be isotope fractionations within the hydrothermal plume – with the direction of the fractionation likely depending on the ratio of iron oxidation to sulfide formation (Bennett et al. 2009). Reducing marine sediments are the most likely to have a distinct iron isotopic composition. Where there is a discrete ferruginous (anoxic and iron rich) zone in the porewaters, there can be large benthic iron flux. Further, this iron flux is strongly isotopically depleted because of DIR or partial oxidation of reduced iron reservoir that has undergone quantitative iron reduction. Sulfidic and oxic sediments will have lower iron fluxes than reducing marine sediments that have less distinct isotopic compositions. Specifically, oxic sediments are likely to have an iron flux near 0‰ (Homoky et al. 2009), while sulfidic sediments have slightly positive δ^{56}Fe values (Severmann et al. 2008). There can be iron isotope fractionation during ligand binding, which will complicate using δ^{56}Fe values as source tracers. In sum, although there is some overlap in isotope values of different iron fluxes, iron isotope can be a useful tool to probe.

Finally, Fe isotopes can also provide valuable insight into the physicochemical processes affecting Fe during soil-water interactions, particles and dissolved load in river systems, and then help to better constrain the fluxes of Fe to the ocean. Riverine particles generally have δ^{56}Fe values in a small range from −0.1 to 0.1‰, similar to igneous rocks and mean continental crust (Beard et al. 2003a; Fantle and DePaolo 2004; Chen et al. 2014). In contrast, dissolved load show a large range of δ^{56}Fe values reflecting various colloidal fractions, mostly Fe-oxyhydroxides and/or Fe bound to organic carbon (Ingri et al. 2006; Ilina et al. 2013). Studies on soil formation and continental weathering demonstrate that the fraction of exchangeable Fe is typically enriched in light isotopes relative to Fe-substrate in rocks (e.g., Brantley et al. 2004). This light isotope signature of the exchangeable Fe in soils is likely the result of complex interplay between ferric iron reduction by microorganisms, adsorption of isotopically heavy ferrous iron on soil minerals, and formation of Fe-rich organic ligands (Brantley et al. 2004; Ingri et al. 2006). An understanding of iron isotopes in these geological systems is still being developed, and has great potential for tracing interactions between the different Fe pools in soil and river systems.

The Sedimentary Iron Isotope Record

There is a >4‰ range in sedimentary iron isotope data from shales, iron oxide-rich rocks, sulfides, and carbonates (Fig. 1). Extreme isotope variability also occurs between mineralogical phases on a micron scale (e.g., as detected by SIMS and laser ablation work), but there is also a several per mil range of Fe isotope variability within bulk samples of sedimentary rocks. This large amount of micron-scale variability is likely linked to a combination of factors, but it is certainly driven in part by fractionations that occur during mineral formation. Significant iron isotope variability in bulk marine sediments is likely a signal for the presence of multiple isotopically distinct dissolved iron reservoirs within aqueous systems although, in specific instances, isotope fractionation during mineral formation may also play a role.

The most obvious temporal trend in the sedimentary iron isotope record is the shift starting during the Archean (ca. ~2.9 to 2.7 Ga) from variable and often highly depleted δ^{56}Fe values to less variable, near-crustal δ^{56}Fe values (Rouxel et al. 2005; Yamaguchi et al. 2005; Johnson et al. 2008) (Fig. 1). This trend is most pronounced in strata from typical continental margin sediments – as hydrothermal systems can be isotopically variable well after the Archean. Although it is clear that this interval of time marks a significant shift in iron cycling, the processes driving this trend in the iron isotope record have been extensively debated. This change in sedimentary iron isotope variability was originally linked to a shift in marine redox conditions and the development and expansion of marine environments where quantitative iron oxidation prevailed (Rouxel et al. 2005). In this case,



Iron Isotopes, Fig. 1 Iron isotope composition of sedimentary rocks through time (updated from Busigny et al. 2014; Kurzweil et al. 2015; Stevenson et al. (2017); Wawryk and Foden et al. 2015; Delte Raye et al. 2015). There is almost 6‰ variability in the sedimentary record, with the most pronounced variability in the Archean (see text for further information)

negative and positive iron isotope excursions in the early rock record can be linked to partial iron oxidation in a water column without a distinct oxygen chemocline. Partial oxidation would have created isotopically heavy ferric Fe(III) iron and left behind an isotopically depleted dissolved ferrous Fe (II) reservoir, which could be captured and transferred to the sedimentary record (Rouxel et al. 2005; Planavsky et al. 2012; Busigny et al. 2014). In this model, the decline in iron isotope variability observed at ca. 2.4 Ga would be linked to the transition of the upper ocean to a well-oxygenated state.

Alternatively, this iron isotope trend has been interpreted to reflect changes in the extent of DIR (e.g., Yamaguchi et al. 2005; Johnson et al. 2008), where the Fe isotopic shift is attributed to the rise of DIR respiration by bacteria since at least 2.9 Ga (Yamaguchi et al. 2005). As highlighted above, DIR facilitates release of isotopically light ferrous iron. In a low-oxygen and low-sulfate anoxic ocean (i.e., the Archean ocean), extensive light iron from DIR would be released into the water column, where it could be transported to other portions of an ocean basin. Therefore, DIR in the Archean may have led to the development of a very pronounced benthic iron shuttle (Li et al. 2015). Lastly, the very negative Fe isotope values observed in the Archean record may also be linked to the large kinetic fractionation involved in pyrite precipitation in iron-rich oceans (Guilbaud et al. 2011). The disappearance, beginning in the Proterozoic, of markedly negative iron isotope values would then be due to more complete Fe(II) utilization in pyrite precipitation (Guilbaud et al. 2011). However, markedly negative Fe isotope values are also found in euxinic shales, where iron is by definition limiting, and in nonsulfide iron mineral phases (Rouxel et al. 2005; Busigny et al. 2014), indicating that kinetic fractionations associated with pyrite precipitation cannot be the sole explanation for the observed trends in the sedimentary iron isotope record. Indeed, the pyrite precipitation model omits several processes – including biological fractionations and Fe redox – that may contribute to Fe isotope compositions (Czaja et al. 2012).

Although iron isotope variability outside of the Archean has received relatively less attention, several studies have highlighted the utility of iron isotopes as tracers of iron cycling in Proterozoic and Phanerozoic sedimentary successions. Foremost, iron isotopes have been used to track the source of sedimentary iron enrichments. This builds from the principles outlined above – hydrothermal iron is likely to have a near-crustal iron isotope value, relative to iron from a benthic shuttle, which will be strongly isotopically depleted (e.g., Severmann et al. 2006). Further, iron isotopes can be used to detect partial iron oxidation and can thus be used as a local redox proxy.

High Temperature Processes: Terrestrial Mantle and Crustal Rocks

Pioneering work on the iron isotope composition of igneous rocks initially described relative homogeneity and proposed

to use these rocks as geostandard for international normalization (Beard et al. 2003a). Later studies revealed that there are significant variabilities inherited from partial melting and subsequent crystallization processes. During partial melting of mantle peridotite, Fe(III) is more incompatible than Fe(II), thus producing an enrichment in heavy Fe isotope in the melt relative to the source (Williams et al. 2004; Weyer and Ionov 2007; Dauphas et al. 2009, 2014). This process is illustrated by the slightly elevated δ^{56}Fe values of mid-ocean ridge and ocean island basalts, typically around 0.10‰, relative to fertile mantle peridotite, with δ^{56}Fe values of ~0‰ (Beard et al. 2003a; Dauphas et al. 2009). Igneous rocks with the largest range in δ^{56}Fe values are reported from carbonatites, with values from −1.0 to +0.8‰ (Johnson et al. 2010). Mantle metasomatism, as well as subducted Fe, may also generate isotope variability in the mantle (Beard and Johnson 2004; Zhao et al. 2010; Poitrasson et al. 2013). Magma differentiation in crustal level induces Fe isotope fractionation, enriching the residual melt in the heavy Fe isotope relative to crystals, with a $\Delta^{56}Fe_{melt\text{-}crytals}$ value between 0.1 and 0.2‰ (Teng et al. 2008; Schuessler et al. 2009). Granites show relatively large range of δ^{56}Fe variation from 0.1 to 0.4‰, with Si-rich rocks corresponding to the heaviest Fe isotope compositions (Beard et al. 2003a; Poitrasson and Freydier 2005). The δ^{56}Fe-SiO_2 positive correlation may reflect fluid exsolution from siliceous hydrous magmas (e.g., Heimann et al. 2008) or iron structural changes in silicic magma (Dauphas et al. 2014). Despite δ^{56}Fe heterogeneity in granites, the average Fe isotope composition of bulk continental crust is ~0.1‰, and is thus not significantly different from that of oceanic crust (Poitrasson 2006).

Cosmochemistry

Primitive meteorites, including carbonaceous, ordinary, and enstatite chondrites all have δ^{56}Fe values ~0‰, similar to the fertile mantle (Schoenberg and von Blanckenburg 2006; Craddock and Dauphas 2011). Considering that the Earth was made from chondritic material, this similarity suggests that terrestrial core-mantle differentiation did not significantly fractionate Fe isotopes, although ~87% of the total Fe in bulk Earth was included into the core. A limited metal-silicate Fe isotope fractionation is also supported by laboratory experiments (Hin et al. 2012) and negligible $\delta^{56}Fe_{metal\text{-}olivine}$ values (< 0.017‰) predicted by reduced partition function calculation at the temperature of core formation, i.e., T ~ 2000–3000 °C (Polyakov and Mineev 2000). The Fe isotope composition of the Moon has generally been considered as slightly enriched in heavy isotopes (by 0.1‰) relative to bulk silicate Earth, interpreted tentatively as reflecting evaporative Fe loss during the Giant Impact having formed the Moon (e.g., Poitrasson et al. 2004; Weyer et al. 2005; Moynier et al. 2006). However, a recent study determined that lunar dunite samples are enriched in light isotopes and proposed, from a mass-balance approach, that bulk silicate Moon and Earth are in fact identical (Wang et al. 2015). Iron isotope analyses of Shergotty-Nakhla-Chassigny (SNC) meteorites assumed to originate from Mars, and eucrites and diogenites from asteroid Vesta show δ^{56}Fe values ~0‰ (Poitrasson et al. 2004; Schoenberg and von Blanckenburg 2006), similar to fertile mantle iron isotope composition. Taken together, all these data suggest that bulk Fe isotope compositions of rocky planets in the solar system are identical.

Summary and Conclusion

Iron isotopes are now a routinely measured well-established geochemical system with wide range of applications, including tracing modern iron cycling, igneous processes, and the redox evolution of the oceans.

Iron Meteorites

Henning Haack
Maine Mineral and Gem Museum, Bethel, ME, USA

Definition

Iron meteorites are fragments of the metallic cores of asteroids.

Introduction

Iron meteorites are possibly the most foreign geological samples to be found on Earth. Their chemistry, structure, shape, and massive weight make them unlike anything else to be found on the surface of our planet. Due to their unusual properties, iron meteorites are more easily recognized as meteorites than stony meteorites. According to the Meteoritical Bulletin, 1129 out of 62,827 meteorites (as of March, 2016) are iron meteorites. 49 of the known iron meteorites are observed falls (out of a total of 1288 observed meteorite falls); the rest are either prehistoric or have fallen unnoticed. Since iron meteorites will rust when exposed to the humid surface of the Earth, they rarely survive more than a few thousand years. The iron meteorites we find are therefore only those that have fallen in the most recent past.

Origin of Iron Meteorites

Iron meteorites are prime examples of asteroids that underwent an igneous evolution in the early Solar System – i.e., asteroids that melted and subsequently differentiated into a metallic core and a silicate mantle and crust, resulting in a structure broadly similar to the Earth interior. Since iron meteorites are samples of the cores of differentiated asteroids, their presence here on Earth tells us that the parent asteroids must have been destroyed. Estimates of the number of asteroids sampled by our iron meteorites vary, but the number is probably somewhere between 60 and 100. This is a surprising high number. Despite their relative low abundance (4.3%) among observed meteorite falls, iron meteorite sample ~90% of the asteroids were represented in our meteorite collections worldwide.

Studies of iron meteorites can be used to reconstruct their entire evolutionary history: (1) accretion of the parent body from the early protoplanetary disk, (2) heating of the parent body by mainly ^{26}Al inherited from massive stars, (3) melting and differentiation of the parent body, (4) core crystallization, (5) cooling of the core, (6) catastrophic destructing of the asteroid and the core, (7) orbital transfer of the core fragments to Earth-crossing orbit, (8) fall on Earth, and (9) use of iron meteorites by humans.

Accretion of Iron Meteorite Parent Bodies

The iron meteorite parent bodies accreted from dust and particles in the protoplanetary disk. Since the original material subsequently melted, we cannot date phases in the accretion process directly. However, since we know that the parent bodies must have included sufficient amounts of the short-lived radioactive heat source, ^{26}Al, to melt, we can infer that accretion was largely complete within a few hundred thousand years of the birth of the Solar System (Ruzicka et al. 2016; Benedix et al. 2014).

Although the iron meteorites only sample the siderophile (metallic) elements of the original parent body, differences in composition between different types of iron meteorites show that original bulk chemical composition of the parent bodies was variable. In particular, the volatile (low boiling point) siderophiles Ga and Ge show large variations among different groups of iron meteorites. A low concentration of Ga and Ge implies that the parent body accreted at a temperature, which was close to or above the boiling point of these elements, or that volatile elements were able to escape from the parent body after it accreted. The variations in abundance of Ga and Ge between groups of iron meteorites are orders of magnitude larger than the corresponding variation between different types of chondrites. The other major difference between the iron meteorite groups is the oxidation level. Some iron meteorite parent bodies apparently accreted from highly reduced bodies whereas other iron meteorites formed in oxidized bodies. The variation in oxidation state between groups of

iron meteorites is similar to the variation observed among groups of chondrites.

Heating of the Parent Bodies

Heating of differentiated asteroids was due to a short-lived radioactive isotope of Aluminum – ^{26}Al (Ruzicka et al. 2016; Benedix et al. 2014). ^{26}Al has a half-life of 730,000 years and is primarily synthesized in supernova explosions. Decay of ^{26}Al can potentially heat the parent body several thousand degrees centigrade, but due to the short half-life, only early formed bodies were heated. Therefore, although chondrites contain inclusions that formed before the iron meteorites, the iron meteorite parent bodies must have formed earlier than the chondrite parent bodies. In order to melt, the achondrite parent bodies must have accreted within one million years of the birth of the Solar System.

Melting and Differentiation of Iron Meteorite Parent Bodies

Decay of ^{26}Al heated the iron meteorite parent bodies to the point where the metallic elements melted together with a significant fraction of the silicates. When the degree of melting is sufficiently high, the more dense metallic elements will gravitationally separate from the lighter silicates. Whether or not an element goes into the core or stays in the mantle depends on its geochemical properties – not its density. Elements with a preference for the metal phase are called siderophiles, whereas elements with a preference for the silicates are called lithophiles. For example, the heaviest naturally occurring element, uranium, is concentrated in the crust of differentiated asteroids, because it is lithophile. Other elements, like iron, are only moderately siderophile and are therefore fractionated between the metallic core and the silicate mantle and crust. Highly siderophile elements like nickel, iridium, and gold differentiate almost completely into the core. These elements are therefore relatively abundant in iron meteorites but very rare on the surfaces of differentiated bodies like the Earth.

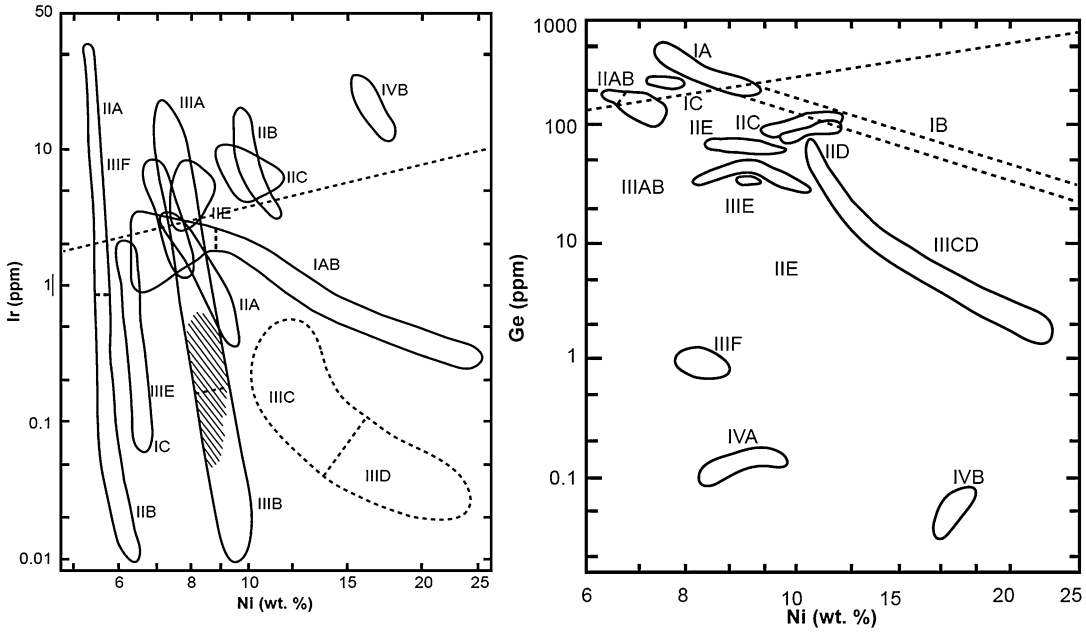
It is possible to date the formation of the core using the decay of the short-lived radioactive isotope ^{182}Hf. ^{182}Hf is lithophile but the decay product, ^{182}W, is siderophile. If a ^{182}Hf atom decays to ^{182}W before core formation, the resulting ^{182}W will differentiate with the rest of the siderophile (metallic) elements and end up in the core. However, if a ^{182}Hf atom decays to ^{182}W after core formation, the resulting ^{182}W will be left behind in the silicate (stony) part of the asteroid. The amount of ^{182}W in the silicate metallic parts of an asteroid are therefore measures of the time where the core formed (Fig. 1).

Core Crystallization

After the heat source, ^{26}Al, had decayed away, cooling of the iron meteorite parent bodies commenced. When the temperature at the base of the mantle had reached the liquidus of the metallic liquid in the core, the first metal began to solidify. This is a very different situation compared to the Earth core, which due to the high pressure at the center crystallizes from the center outward. In the asteroids, the pressure at the center did not exceed a few hundred bar and therefore had an insignificant effect on core crystallization.

During the crystallization process, elements were fractionated between the growing solid and the remaining metallic melt. Some elements, like iridium, are highly compatible with the growing solid phase and were therefore concentrated in the first solid to crystallize. As crystallization proceeded, the remaining liquid was progressively depleted in iridium and

Iron Meteorites, Fig. 1 The 20.1 t iron meteorite Agpalilik and its finder, Vagn Buchwald, in front of the Natural History Museum of Denmark. Vagn Buchwald found Agpalilik in NW Greenland on July 31, 1967. In 1975, Vagn Buchwald published a book with detailed descriptions of all iron meteorites known at that time (Buchwald 1975) (Photo credit: Anne Haastrup Hansen, Natural History Museum of Denmark)



Iron Meteorites, Fig. 2 Iron meteorites can be classified based on their chemical composition. Germanium is a particular useful element to use since different types of iron meteorites in most cases plot in distinct clusters on Ge versus Ni diagrams (**a**). Ge shows minor variation within each group but large variation between groups. Ni versus Ir diagrams show a very different pattern. Iridium is highly variable within each group (**b**). The Iridium variation within each group is smaller than the variation between the groups (Redrawn from Scott and Wasson (1975))

the last metal to solidify was therefore highly depleted in Ir (Fig. 2). Other elements, like S, are highly incompatible with the solid phase and therefore remain in the melt as crystallization proceeds. Since S is a light element, the resulting S-enriched metallic liquid will be buoyant and therefore concentrate below the growing metallic solid, below the base of the mantle. Since S is incompatible, it also lowers the melting point of the metal, and the boyant S-enriched liquid at the top of the core will therefore slow down the crystallization at the uppermost part of the core, in favor of the deeper parts, where the S abundance is lower. The result was probably that the core crystallized in the form of km-sized dendritic structures which grew from the mantle downward (Haack and Scott 1992).

Sulfur also controlled the growth of the solid metal in a different way. As stated above, most siderophile elements are either compatible or incompatible with the crystallizing solid metal. The behavior of each element is a function of the composition of the metallic melt – in particular of the sulfur abundance. Since sulfur itself is highly incompatible, the sulfur concentration of the metallic liquid increases significantly during the crystallization of the core. As a consequence, most elements change their behavior during crystallization. Some elements, like Ga and Ge, even change their behavior from being incompatible to compatible. This can be seen in Fig. 2 where the Ge concentrations in some groups initially increase with Ni concentrations and later revert to a decreasing trend. Ni itself is slightly incompatible and the Ni concentration in the solid therefore increases as the core crystallizes.

Cooling of the Core and Formation of the Widmanstätten Structure

When the core temperature reached ~800 °C, an important phase transition occurred in most of the iron meteorites (exceptions are those relatively rare iron meteorites with Ni concentrations above ~25 wt%). What happened was that a new phase, kamacite, nucleated and grew at the expense of the initial taenite phase. Since kamacite has a lower Ni concentration than the original metal, the growth of kamacite was controlled by the diffusion of Ni through the solid metal. Diffusion of Ni through the original taenite phase is extremely slow, and the resulting intergrowth of kamacite and taenite are therefore never completely equilibrated. The degree of equilibration may therefore be used to measure the cooling rate of the core at the time where kamacite grew. These cooling rates are usually referred to as metallographic cooling rates. Typical metallographic cooling rates are of the order of 1–100°/million years. Since small asteroids cool faster than large asteroids, the cooling rates may be used to constrain the size of the original parent body.

The resulting Widmanstätten structure is the hallmark of iron meteorites. Since the low-Ni kamacite phase is less resistant to etching with nitric acid than the high-Ni taenite phase, the structure may be revealed by etching a polished

Iron Meteorites, Fig. 3 Three different iron meteorites are shown to the same scale, to illustrate the large variation in structure. Gibeon, an IVA iron meteorite with a fine Widmanstätten structure, is shown at the *top*. Carbo, a medium octahedrite, is shown in the *middle*, and Old Woman, a coarsest octahedrite, with low Ni (5.7 wt%) concentration, is shown at the *bottom*. The *white bar* at the *top* is 5 cm long (Photo credit: Jens Astrup, Natural History Museum of Denmark)

surface with weak nitric acid (Fig. 3). The width of the kamacite lamellae in the Widmanstätten structure is mainly controlled by the original Ni concentration. Typical dimensions are in the range between 0.1 and 100 mm, and different types of iron meteorites may therefore often be distinguished on the basis of the appearance of the Widmanstätten structure.

Catastrophic Destruction of the Asteroid and the Core

The fact that iron meteorites from up to ~100 different differentiated asteroids are now present in our meteorite collections shows us that their parent bodies must have been destroyed. Three types of processes appear to have been significant:

Hit and Run Collisions

In the early solar system where planets grew at the expense of smaller bodies, collision rates were many orders of magnitude higher than now. A small number of the impacts were grazing impacts where the projectile was destroyed but escaped accretion with the growing planets. Such so-called hit and run events can potentially strip most of the mantle off a differentiated body and/or remix mantle, core, and crust (Haack and Scott 1992).

Collisional Erosion

Small bodies are much more abundant in the main asteroid belt than large bodies. For any given diameter, D, there are approximately 100 times more bodies with a diameter of 0.1 D. Most impacts experienced by an asteroid are therefore relatively minor cratering events. Over time these may, however, gradually erode the asteroid and eventually expose the core.

Catastrophic Collisions

Larger catastrophic collisions involving "projectiles" that are large enough to destroy and disrupt the asteroid are less common, but several groups of meteorites appear to originate from catastrophically destroyed asteroids (Keil et al. 1994). Although we do not have stony meteorites from the mantle and crust of the iron meteorite parent bodies, some of the cores of iron meteorite parent bodies appear to have been destroyed in single events.

Orbital Transfer of the Core Fragments to Earth Crossing Orbit

Fragments from asteroid collision typically orbit the Sun for millions of years before they collide with a planet or the Sun or become ejected from the Solar System. The travel time can be estimated because meter-sized fragments are exposed to cosmic radiation. It is possible to measure the radiation dose these fragments have received and use that to calculate the cosmic exposure age, which we infer is usually equal to the travel time. Stony meteorites typically have cosmic-ray expose ages up to a few tens of millions of years, whereas iron meteorites have cosmic-ray exposure ages up to two billion years.

Transfer to Earth-crossing orbit is mainly carried out in two steps. After ejection from the parent bodies, the fragments usually end up in semi-stable orbits around the Sun. The so-called Yarkovsky effect causes slow orbital drift in- or outward in the Solar System (depending on whether the object

rotates clockwise or counterclockwise). After millions of years of slow drift, the object will at some point encounter one of the orbital resonances with Jupiter. Gravitational interaction with Jupiter will subsequently rapidly change the orbit (on a time scale less than one million years).

There are probably several reasons that iron meteorites have longer cosmic-ray expose ages. One reason is that they are stronger than stony meteorites and therefore can survive longer in space. Another reason is that the orbits evolve more slowly for iron meteorites. Meter-sized fragments drift in- or outward because of the so-called Yarkovsky effect. The drift is caused by the difference in thermal radiation between the warm dayside and the cold nightside. If the object is rotating, there will be a net force which either accelerates the object or slows it down. However, metallic objects with a high thermal conductivity have a smaller temperature difference between night- and dayside and therefore drift much more slowly.

Since iron meteorites have much longer travel times to Earth-crossing orbit, they also sample the collisional evolution of the asteroid belt on a much longer time scale. This is probably the main reason that iron meteorites appear to sample a much larger number of parent bodies than stony meteorites.

Fall on Earth

Meteorites survive the impact with the Earth because the Earth atmosphere slows them down to subsonic speed, before they hit solid ground. When the object enters the atmosphere at 15–30 km/s, the drag forces are so powerful that even solid metal objects are often torn apart. After each fragmentation event in the atmosphere, the smallest fragments are slowed down more quickly than the large fragments. Since most objects enter the atmosphere at an angle, the resulting fall area is elongated with the biggest fragments concentrated furthest downrange.

Since iron meteorites are heavier and much harder to break apart than stony meteorites, they are also more difficult to slow down. Whereas stony meteorites rarely exceed a few hundred kilograms, iron meteorites commonly have masses of several tons. The most massive iron meteorite known is the 60 ton Hoba from Namibia. Some of the larger fragments of iron meteorites impact the Earth at supersonic speeds. Upon impact, a supersonic iron meteoroid penetrates the surface and vaporizes and creates an explosion crater. Smaller fragments from the same fall usually survive the fall because they are slowed down sufficiently in the atmosphere. These fragments may be found scattered around the explosion crater. Because iron meteorites tend to hit the surface at higher velocities, many of the known explosion craters are caused by iron meteorites. Although only ~4% of meteorite falls are iron meteorites, more than 90% of the smallest and youngest impact craters are caused by iron meteorites.

Use of Iron Meteorites by Humans

Subsequent to their fall on Earth, many iron meteorites have been used to forge tools and weapons, and in some cases, they appear to have had a religious significance (1 – Appendix 6). In North Greenland, the Cape York iron meteorites were the local Inuits' only source of metal (Buchwald 1975). The Inuits have knocked off pieces of some of the Cape York irons since ~700 AD. Tools with Cape York irons can be used to follow trade routes along the west coast of Greenland and more than 1000 km into Canada.

Chemical Classification of Iron Meteorites

The bulk chemical composition of iron meteorites can be used to define clusters of iron meteorites with similar chemistry. Clusters with at least five members are designated iron meteorite groups. Currently 13 such groups of iron meteorites have been defined, where each group is assumed to represent a single parent body. The largest group is IIIAB with almost 300 members. Fifteen percent of the iron meteorites are not included in the main groups (Krot et al. 2014) and are believed to represent another 50–100 parent asteroids.

Historically, iron meteorites were divided into four groups based on their concentration of the highly volatile siderophiles (metallic) elements Ga and Ge (Fig. 2) (Buchwald 1975; Ruzicka et al. 2016; Benedix et al. 2014; Krot et al. 2014; Chabot and Haack 2006). Ga and Ge are very useful for classification purposes, because most iron meteorites fall in tight clusters on Ga and Ge diagrams (Fig. 3). Members of the original group I have the highest abundances of Ga and Ge. Groups II, III, and IV had still lower volatile inventories, with group IV having Ga and Ge abundances 3–4 orders of magnitude below those of group I. Improved analytical techniques allowed the original four groups to be subdivided into smaller groups. The smaller groups had a letter added to the original roman numerals – i.e., IA, IIIA, IIIB, etc. Although the smaller groups were separated in the early studies, later studies added more iron meteorites which closed the gaps between some of the earlier groups. IIIA and IIIB thus became IIIAB, which is the term used today. Also, two silicate-bearing groups IAB and IIICD are now believed to come from the same body and have therefore been merged to a single group (Krot et al. 2014).

Figure 3 shows germanium and iridium plotted nickel for the main groups of iron meteorites. The large differences in Ga abundance between the different groups are probably due to differences in bulk chemical composition between the groups (see section "Accretion of Iron Meteorite Parent Bodies" above). Differences in Ni composition are mainly due to differences in oxidation state of the parent body. In oxidized parent bodies, a larger fraction of the element iron remains in

the mantle. The relative abundance of Ni is therefore larger in oxidized parent bodies. The chemical variation within each group is mainly due to core crystallization (see section "Melting and Differentiation of Iron Meteorite Parent Bodies" above). In groups IIAB and IIIAB, the Ir abundances span more than three orders of magnitude between the early crystallized high-Ir members to the late crystallized low-Ir members.

Structural Types of Iron Meteorites

Etched and polished surfaces of iron meteorite display the characteristic Widmanstätten structure. The structure is composed of alternating lamellae of the low-Ni kamacite phase and the high-Ni taenite phase. Because the Ni content is different in the two phases, iron meteorites with different bulk Ni concentrations also have different ratios of kamacite and taenite. Iron meteorites with very low Ni concentration (~5.5 wt%) have normally transformed to single crystals of kamacite and are referred to as hexahedrites. Likewise, Ni-rich iron meteorites (above ~25 wt% Ni) are usually pure taenite crystals. These irons are called ataxites. Most iron meteorites have intermediate Ni concentrations and can be easily distinguished because of the large variation in width of the kamacite lamellae (Fig. 3). Iron meteorites with Ni concentrations around 5.9 wt% have kamacite bandwidths up to 10 cm, whereas irons with Ni concentration around 14 wt% typically have kamacite bandwidths down to 0.1 mm. Although kamacite bandwidth is mainly controlled by the Ni concentration, the cooling rate of the core, during growth of the kamacite phase, also plays a role.

Connection to Asteroids

Since iron meteorites are believed to originate from the exposed or possible destroyed metallic cores of differentiated asteroids, it follows that there must be asteroids with surfaces that are entirely or partially metallic. Spectral studies of the sunlight reflected from the surfaces of meteorites can be used to constrain the surface mineralogy of asteroids even though their surface features cannot be resolved with even the biggest telescopes. Several silicates, such as pyroxene and olivine, absorb the sunlight at specific wavelength and may therefore be positively identified. Although metal absorbs more of the shorter wavelength than it absorbs long wavelength, it does not have any absorption lines that could have been used to make a positive identification of metal. Several asteroids, like the 150 km diameter, 16 Psyche, do however have spectral characteristics consistent with metal and could therefore be examples of large exposed cores.

Summary

Iron meteorites are core samples of asteroids that melted 4.5 Gy ago and differentiated into a layered structure with a central metallic core, a stony mantle, and a volcanic crust. The more than 1000 known iron meteorites probably represent 50–100 different asteroids. Studies of iron meteorites provide information on the early history of our Solar System and of planetary evolution. The iron meteorites are the best available analogues to the metallic core at the center of the Earth.

Isotope Dilution

Jon Woodhead
School of Earth Sciences, The University of Melbourne, Melbourne, VIC, Australia

Definition

In its original, and most widely used form, isotope dilution is a method for determining elemental concentrations in samples of minerals, rocks, and fluids. It involves adding a known quantity of an enriched isotope "spike" to the (usually dissolved) sample, followed by isotopic analysis of the resulting spike-sample mixture in an isotope ratio mass spectrometer. One of the main applications of the technique is in radiometric age determinations (geochronology) where the concentrations of parent and daughter isotopes must be measured in order to calculate the geological age of a sample. The

concept has evolved further, with the development of double- and triple-spikes composed of multiple enriched isotopes. These more complex variants are designed to allow the monitoring and correction of instrumental mass bias effects encountered during mass spectrometric isotope ratio measurements of many different elements, allowing the acquisition of isotope ratio data with very high levels of precision and accuracy.

Elemental Concentration Determinations

With the exception of accelerator-based designs, most modern mass spectrometers are not sufficiently sensitive to record the arrival of single atoms in their detectors. Instead, they typically measure only the ratios between different isotopes of an element, based upon ion currents representing many individual atoms. There are, however, situations where it is essential to determine the absolute concentrations of elements – and to a high level of accuracy – here the isotope dilution method is employed. The approach requires the isotopic compositions of both the sample and an isotopically enriched tracer (termed a "spike") to be known. Then, by adding a known quantity of the spike to a known weight of the sample, equilibrating the mixture, and then measuring the resulting isotopic composition, the elemental concentration in the original sample can be readily determined. The term "isotope dilution" stems from the dilution of the isotopic constituents of the sample in the spike-sample mixture.

The method can be applied to all elements for which two or more isotopes are present and also to mono-isotopic elements provided an appropriate long-lived artificially produced isotope exists. Ideally the choice of spike corresponds to an isotope that is present in relatively small abundance in natural samples. Thus, for example, in geochemistry, spikes such as ^{84}Sr, ^{149}Sm, ^{150}Nd, and ^{180}Hf are commonly employed. When available, it can be even more advantageous to use artificially produced isotopes that do not occur in nature such as ^{233}U, ^{229}Th, and ^{205}Pb.

As an example, in Rb-Sr geochronology where we need to know the concentration of the daughter element, Sr, as part of the process of determining an age, an ^{84}Sr-enriched spike is often used. The measured ^{84}Sr/^{86}Sr ratio in a sample-spike mixture is then given by Eq. 1:

$$\left[\frac{84Sr}{86Sr}\right]_{measured} = (Sa84 + Sp84)/(Sa86 + Sp86) \qquad (1)$$

where "Sa86" and "Sa84" are the contributions of ^{86}Sr and ^{84}Sr from the sample and "Sp86" and "Sp84" are the contributions of ^{86}Sr and ^{84}Sr in the ^{84}Sr-enriched spike.

From this simple relationship (Eq. 1) an equation can be derived to allow determination of the element concentration in the sample, expressed in terms of measurable isotope ratios and known quantities (i.e.,weights and isotopic compositions of spike and sample), shown in a generic form below (from Stracke et al. 2014, where the full deviation can be found), Eq. 2:

$$conc_{Sa} = \frac{\frac{A}{B_{mix}} - \frac{A}{B_{Sp}}}{\frac{A}{B_{Sa}} - \frac{A}{B_{mix}}} x \frac{weight_{Sp} conc_{Sp} abundance(B_{Sp}) atwt(element_{Sa})}{weight_{sa} abundance(B_{Sa}) atwt(element_{Sp})} \qquad (2)$$

where subscripts "*Sa*" and "*Sp*" refer to sample and spike, respectively, "*A*" is the enriched isotope (present in both spike and sample, i.e., ^{84}Sr in the case of Sr) and "*B*" is a reference isotope (also present in both; ^{86}Sr in the example shown above), "*atwt*(*element*)" is the atomic weight of the element of interest, and "*abundance*(*B*)" refers to the abundance of the reference isotope. A number of variants of this "isotope dilution equation" can be found in the literature depending on the form of the input parameters and nature of the reference isotopes (natural or artificial) but all essentially perform the same function. In real-world applications the isotope dilution equation is often solved iteratively in concert with a correction for instrumental mass bias effects.

The isotope dilution method was developed in the early twentieth century and is attributed to Hevesy and Hofer (1934) although it did not find mainstream acceptance until the work of Rittenburg and Foster (1940). Since that time, due to the extremely high levels of precision and accuracy obtainable, it quickly became the "gold standard" for trace element determination – a method against which all other analytical techniques may be evaluated.

The optimum mixture ratio of spike to sample is provided by the following, Eq. 3:

$$R^{optimal}_{measured} = \sqrt{(R_{sample} x\, R_{spike})} \qquad (3)$$

When the spike:sample ratio departs from this optimum, notably in strongly over- or under-spiked situations where the isotopic composition of the mixture approaches that of the spike or unknown, respectively, the uncertainty in $R_{measured}$ becomes magnified due to unfavorable error propagation systematics (e.g., Webster 1960). Ideally, therefore, it is useful to have first-order estimate of the likely sample concentration in order to perform optimum spiking and thus obtain the highest quality data.

As a method of concentration determination the technique has many significant advantages. Primarily, as a result of the mass spectrometric measurement, the technique is

characterized by very high analytical precision and accuracy together with high sensitivity and concomitant low limits of detection. In addition, once the spike and sample are equilibrated, any partial loss of the analyte during the chemical separation of the element of interest is inconsequential. Unfortunately, the method can be expensive and time consuming and enriched isotope spikes are often difficult to procure (e.g., ^{229}Th), and in some cases, unavailable (e.g., ^{205}Pb which is no longer manufactured). Recent detailed reviews of the isotope dilution method have been provided by Alonso and Rodriguez-Gonzalez (2013) and Stracke et al. (2014).

Mass Bias Control

The isotope dilution method employing enriched isotope spikes can be used in other ways. For example, in most types of mass spectrometer, the isotope ratios measured at the detectors are not the same as those present in the analyte – they have been modified during their transit through the instrument, primarily through instrument-specific physical processes in the ion source region. In the case of thermal ionization mass spectrometers (TIMS), it is common for lighter isotopes to be measured preferentially since they are mobilized from the metal filament carrying the analyte more readily than heavier isotopes of the same element. In contrast, in Inductively Coupled Plasma Mass Spectrometers (ICPMS), that have an ion source operating at atmospheric pressure, heavier ions tend to be detected preferentially since they more easily navigate space-charge effects occurring in the region of the skimmer cone adjacent to the argon plasma ion source.

A number of methods can be employed to correct for these so-called mass bias effects. If the element in question is characterized by one or more isotopes that are stable (hence invariant) in nature then the ratio of the two can be compared with the measured ratio to estimate the degree of bias, and an appropriate correction then applied to the other isotope ratios. However, for some elements, no stable isotope pair is available to make such a correction, e.g., Pb-isotope analysis. Here the most elegant and effective solution for high precision isotope ratio determination involves simulating the presence of a stable isotope pair by mixing a so-called double spike, comprising two enriched isotopes of known composition, with the sample and measuring the resultant mixture (e.g., Dodson 1963). Double spiking of this type requires two mass spectrometer runs, one with the natural sample and the other with the spike-sample mixture. From these measurements a highly accurate bias-corrected isotope ratio can be determined (e.g., Hamelin et al. 1985). Additional variants involving triple spikes or two double spike runs have been proposed (e.g., see Taylor et al. 2015 for a summary of these techniques for Pb-isotope analysis).

The method is widely applicable and has been used to facilitate high quality isotope ratio determinations in many isotope systems such as Ca, Cr, Fe, Mo, and Cd. Software is also now available to allow the optimum design of double spikes for mass bias correction (Rudge et al. 2009) and to assist in subsequent data deconvolution (Creech and Paul 2014).

Summary

Isotope dilution is an essential technique employed in a wide array of geochemical studies, providing both highly accurate and precise elemental concentration determinations and also a methodology to correct for mass bias effects encountered during isotope ratio mass spectrometry. In both of these applications it allows the acquisition of extremely accurate and precise data that are generally unrivalled by any other technique.

Kerogen

Steven Petsch
Department of Geosciences, University of Massachusetts Amherst, Amherst, MA, USA

Synonyms

Fossil organic matter; Geogenic carbon; Petrogenic carbon; Sedimentary organic matter

Definition

Kerogen is solid-phase, macromolecular organic matter that occurs in sedimentary rocks and is insoluble in common organic solvents.

Occurrence of Kerogen in the Geosphere

As the definition of kerogen is operational, the term "kerogen" does not imply a particular structure, appearance, origin, or composition, beyond being based on chemically reduced organic carbon and not comprising readily identified low-molecular-weight compounds. As such, kerogen encompasses a broad suite of geologic materials that vary in their sources, their chemical and physical properties, and their ultimate fates under geological processes. In typical sedimentary rocks, most organic matter is in the form of kerogen, with 80% or more of the total mass of organic carbon in a given rock coming from Kerogen (Tissot and Welte 1984; Hunt 1996; Hedges and Oades 1997). The remainder of rock organic matter, termed bitumen, comprises solvent-soluble materials that are nominally lower in molecular weight and includes identifiable compounds such as biomarkers. Coarse-grained clastic sedimentary rocks (e.g., sandstones) are typically poor in kerogen, as are biochemical sedimentary rocks (cherts, limestones) and evaporites, but there are exceptions. In contrast, finer-grained clastic sedimentary rocks (mudrocks such as shales and siltstones) commonly contain at least some kerogen, though typically $<1\%$. The "world average shale" contains 1.2% organic carbon (Turekian and Wedepohl 1961), while kerogen-rich mudrocks termed black shales typically contain closer to 5–10% organic carbon. Some particularly kerogen-rich black shales may be upwards of 30% carbon by weight (e.g., the Green River Shale of Wyoming, Utah and Colorado), and coal, which can be considered a special case of kerogen, can be nearly 100% organic matter.

Origin of Kerogen

Much like coal, kerogen represents the remains of biological materials that became incorporated into sediments and ultimately sedimentary rocks. Unlike coal, which mainly derives from the remains of terrestrial plants and occurs as nearly pure organic matter, kerogen in rocks is substantially diluted by inorganic minerals (primarily silicates, carbonates, and sulfides) and derives from a wide array of biological sources. These include materials derived from leaves, wood, spores, and pollen of terrestrial plants, degraded soil organic matter, and for most kerogens, substantial contributions from freshwater and marine algae as well as zooplankton and bacteria. Kerogen also differs from coal in its environments of deposition. While coal formed in low-lying, flooded but essentially terrestrial environments with little to no transport occurring between biological source and sediment deposition, kerogen reflects the transport of organic materials and sediments through soil, fluvial, lacustrine, and/or marine systems. This can result in substantial modification in kerogen composition compared to its original biological sources.

Much effort has been focused on understanding the processes and controls on organic matter preservation in sedimentary rocks, and thus on the formation of kerogen. Early

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

descriptions of kerogen formation via geopolymerization in which biomolecules underwent random condensation reactions in soils and sediments either abiotically or through the mediation of microorganisms (Tissot and Welte 1984), have been largely replaced, although cross-linking of peptides, sulfurization of carbohydrates, and formation of nitrogen-bearing heterocyclic components may all be important in some settings. Instead, the majority of kerogen formation (which in turn, represents the majority of organic matter burial in sediments and occurrence in sedimentary rocks) results from a combination of (i) the selective preservation of certain biopolymers and other materials (combustion residues, recycled kerogen) that are most resistant to degradation (Hatcher et al. 1983; Tegelaar et al. 1989); (ii) physical protection mechanisms such as association with mineral surfaces (Mayer 1994; Keil et al. 1994) or encapsulation within degradation-resistant biopolymers (Knicker and Hatcher 1997) that prevent or slow the degradation of biological materials; and (iii) limitations on the supply of degradation reactants such as dissolved O_2 (Hartnett et al. 1998; Hedges et al. 1999). Thus, kerogen can be understood as a mixture of components that are selectively preserved, components that have been protected from degradation, and components that experienced only limited time exposed to oxic degradation conditions.

Analysis, Composition, and Kerogen Types

A variety of tools are used in the analysis of kerogen. Organic petrography is the examination of morphological and optical properties of kerogen and coal using transmitted and reflected light microscopy. Morphologically distinct remnants of primarily plant and algal remains are termed macerals and categorized into three maceral groups: liptinite – translucent, yellow-orange materials derived from the lipid-rich remains of ancient leaves, pollen, spores and algae; vitrinite – lustrous, black-brown maceral group derived from woody plant materials; and inertinite – opaque, black-brown brittle materials that represent charred or otherwise heavily degraded woody tissue. Within these groups, various specific macerals are recognized and tied to specifically biological origins. Vitrinite reflectance, in which the percent of incident light reflected off a polished surface containing vitrinite is measured, is an important petrographic technique in evaluating the thermal maturity of coals and vitrinite-bearing kerogens. This, together with subtle changes in the appearance of certain macerals, provides useful information on the burial and thermal history of kerogen- and coal-bearing rocks and their past oil and gas generation.

Kerogen can be classified as Type I, Type II, or Type III on the basis of elemental composition (Tissot and Welte 1984). The three most abundant elements in kerogen are carbon, hydrogen, and oxygen. When expressed as atomic H/C and O/C ratios, kerogen compositions can be displayed on a van Krevelen diagram. Type I kerogens have high H/C ratios (>1) and low O/C ratios (<0.1). Type I is the least common of the three kerogen types. Petrographic analysis reveals that this kerogen comprises mainly liptinite. Type III kerogens are common and most similar to coals in composition with low H/C ratios (<1) and high O/C ratios (>0.1). These kerogens are rich in vitrinite. Type II kerogens are intermediate between Types I and III in H/C and O/C ratios. Type II kerogens are abundant and derived from the degraded remains of marine algae and other plankton, together with degraded remains of terrestrial plants. Kerogens of any type can have anomalously high concentrations of organic sulfur (up to 0.05 atomic S/C ratio) and are termed Type I-S, II-S, or III-S. Many other elements can be found in kerogens, notably redox-sensitive trace metals such as Fe, V, Ni, Mo, U, Cr, Co, Re, and Os.

Rock-Eval pyrolysis is a technique in which programmed heating of kerogen in the absence of O_2 releases CO_2 and hydrocarbon gases (Espitalié et al. 1977). The masses of these gases are measured at different stages of the pyrolysis, as is the residual carbon content following pyrolysis. A variant of a van Krevelen diagram can be constructed from Rock-Eval data, using a hydrogen index (HI) and an oxygen index (OI). A plot of kerogen HI vs. OI values can be used for kerogen typing much like H/C and O/C ratios. Together with T_{max} data (the temperature of maximum hydrocarbon gas generation during Rock-Eval pyrolysis), HI-OI plots can also reveal information about the thermal history of kerogen and its potential for oil and gas generation.

Kerogen's macromolecular nature and varied biological origins have confounded a direct determination of its chemical structure. In addition, many of the analytical techniques applied to kerogen either require demineralization which may alter kerogen composition or are compromised by the presence of minerals (e.g., paramagnetic materials). Spectroscopic techniques such as solid-state ^{13}C nuclear magnetic resonance, Raman, and infrared spectroscopy reveal information about the abundance of different types of chemical bonds and chemical environments in a kerogen (i.e., organic functional groups), but do not specify a three-dimensional structure. The solid-phase nature of kerogen precludes chromatographic analysis, but pyrolysis coupled with gas chromatography and/or mass spectrometry can be used to identify and quantify kerogen fragments and components liberated by pyrolysis and amenable to GC analysis. When pyrolyzed with H_2, H_2O, or methylating agents, further structural information can be obtained. However, only a fraction of the total kerogen, pyrolysis products together with NMR and IR interpretations provide a picture of kerogen structure and composition that is consistent with elemental analysis and organic petrography (Behar and Vandenbroucke 1987). While not defined as a particular structure, kerogen is thus

understood to comprise long polymethylenic moieties (i.e., straight-chain aliphatic groups), polycyclic and partially aromatized components derived from steranes, hopanes and porphyrins, residues from lignin monomers, together with residues and cross-linkages from carbonyl, acid, amine, and thiols, among others.

Fate, Maturation, and Petroleum Generation

Kerogen has long held academic and economic interest as the source from which petroleum reserves derive. As kerogen-bearing sedimentary rocks become deeply buried in sedimentary basins and are exposed to higher temperatures and pressures, kerogen undergoes chemical and physical changes that affect its composition and result in generation of low-molecular-weight hydrocarbons (i.e., crude oil and natural gas). This process is known as thermal maturation. The thermal maturity of a kerogen is a gauge of the time-temperature history of the source rock and can be assessed using vitrinite reflectance and Rock-Eval techniques as well as with spectroscopic techniques and certain lipid biomarkers. Most generally, thermal maturation results in cleavage of low molecular weight fragments from kerogen, namely CH_4, CO_2, H_2O, and *n*-alkanes of various lengths. As such, the pathways of kerogen composition during thermal maturation on a van Krevelen diagram can be understood as the progressive cleavage and loss of these components.

The stages of thermal maturation are separated into diagenesis, catagenesis, and metagenesis (see Killops and Killops 2005). During diagenesis, sediments are still undergoing lithification and are considered thermally immature. The only hydrocarbon generation that occurs is methane produced through biological methanogenesis. As temperatures increase and the rock is now lithified, it enters the stage of catagenesis. Thermal decarboxylation results in loss of CO_2 from organic acids, while *n*-alkyl fragments break off from aliphatic components of kerogen. Initially these result in long *n*-alkanes ($>C_{30}$) but as source rocks progress through the oil window (100–150 °C), low- and medium-length alkanes and other hydrocarbons are produced. With higher temperatures, increasingly shorter alkyl fragments are produced: "wet gas" comprising C_1–C_4 alkanes (methane, ethane, propane, and butane) through the end of catagenesis (approximately 200 °C) followed by "dry gas" made of mainly methane during metagenesis up to temperatures of approximately 250 °C. As hydrocarbons, H_2O and CO_2 are broken off during oil and gas generation, the residual kerogen evolves towards a more condensed structure rich in aromatic and polyaromatic groups. Ultimately, once no further hydrocarbons can be cleaved, kerogen approaches a composition resembling amorphous graphite and with further metamorphism becomes graphite.

The amounts and distribution of petroleum products generated during thermal maturation depends in part on the time-temperature-pressure pathway experienced by the source rock. Geologically slow increases in temperature result in long durations of time spent in the oil window, with commensurate high production of oil. Rapid increases in temperature, in which the source rock rapidly passes the oil window into higher temperatures, results in mainly gas and graphitized kerogen residues. In addition, kerogen composition and type play a role. Type I kerogens and liptinitic components of other kerogens are most capable of yielding oil, while Type III kerogens and vitrinitic components and other kerogens generate limited amounts of oil and instead mostly form natural gas. Severely degraded and precombusted kerogens (i.e., inertinites) generate very little oil or gas upon maturation.

Role of Kerogen in Carbon Cycling

Earth's crust contains some 75 million Gt of carbon, of which approximately 20% is organic carbon. This is orders of magnitude more carbon than the combined mass other surficial carbon reservoirs such as soils, terrestrial and marine biomass, atmospheric gases, and dissolved carbon in the oceans and other aquatic systems. As the majority of crustal organic carbon is kerogen, kerogen thus represents a substantial carbon reservoir in the global carbon cycle. However, the cycling of carbon between geologic carbon reservoirs (namely, kerogen and carbonate minerals) and surficial reservoirs is very slow compared to the cycling among those surficial reservoirs, and residence times for carbon as kerogen or carbonate minerals are hundreds of millions of years.

The global rate of addition of carbon to the kerogen reservoir is not precisely known, but can be constrained. Estimates of global organic carbon delivery to sediments range over an order of magnitude (0.16–2.5 Gt C y^{-1}; Burdige 2007), while the flux of organic carbon that escapes degradation and remineralization during early diagenesis and is thus incorporated into sedimentary rocks as kerogen must necessarily substantially smaller. Mass balance constraints from global carbon cycle models suggest that 0.04–0.1 Gt C y^{-1} is added to the global kerogen reservoir (Petsch 2014a), which sets a rough scale for the magnitude of the flux but does not imply that this rate has been entirely constant through geologic time. Because kerogen derives from biological precursors, kerogen formation ultimately derives from the process of photosynthesis. As such, relatively small changes in the global-scale rate at which kerogen is formed can have substantial impacts on atmospheric reservoirs of CO_2 and O_2 (Holland 1973; Garrels and Lerman 1981, 1984; Berner 1987; Petsch and Berner 1998).

Kerogen also plays a role in the global carbon cycle during rock weathering and erosion. Oxidative weathering of

kerogen during erosion and soil formation consumes O_2 and forms inorganic carbon species such as CO_2. The global rate of oxidative kerogen weathering is approximately equal to the rate of kerogen burial: 0.04–0.1 Gt y^{-1} (Petsch 2014a). Sustained large imbalances between kerogen formation and oxidative kerogen weathering would have caused significant changes in the CO_2 and O_2 concentrations of Earth's atmosphere over geologic timescales, which are not inferred from the rock record. However, small imbalances favoring slightly more weathering or slightly more burial have occurred, driving in part the CO_2 and O_2 concentrations in Earth's atmosphere over geologic time (Kump and Garrels 1986; Berner and Canfield 1989; Petsch and Berner 1998; Berner 2006). One notable example of this is the inferred high atmospheric O_2 content during the Carboniferous, when coal and kerogen burial rates far outpaced oxidative kerogen weathering (Berner 2003; Petsch 2014b).

The role of kerogen in the global carbon cycle remains an active area of research. Kerogen is not necessarily oxidized during weathering. Instead, there is growing recognition that some kerogen may be physically weathered, eroded, transported by fluvial system and ultimately re-buried in sediments without oxidation (Longworth et al. 2007; Galy et al. 2007 2008, 2015; Blair and Aller 2012; Hilton et al. 2008, 2011). Furthermore, some kerogen may be metabolized and incorporated into living biomass during weathering (Petsch et al. 2001; Shillawski and Petsch 2008; Matlakowska et al. 2010, Matlakowska and Sklodowska 2011) and fluvial transport (Caraco et al. 2010).

Summary and Conclusions

Kerogen is a complex, naturally occurring macromolecular form of organic matter found in sedimentary rocks. It derives from biological precursors through selective preservation of materials resistant to chemical and biological degradation, through physical protection mechanisms that impede degradation, and/or in environments where exposure to degradation is limited. While detailed chemical structural information on kerogen cannot be defined due to its structural complexity, randomness, and insolubility, there is broad classification of kerogen into Types I, II, and III based on both chemical and morphological properties. Kerogen is the source material for nearly all petroleum reserves, and understanding of thermal maturation of kerogen and the generation of oil and natural gas holds both academic and economic interest. The global mass of kerogen is estimated at approximately 15 million Gt, orders of magnitude greater than all surficial carbon reservoirs combined. Thus, cycling of carbon into and out of the kerogen reservoir plays a key role in the global carbon cycle and provides a control on the composition of Earth's atmosphere over geologic time.

Kinetics of Geochemical Processes

Don Sparks
Department of Plant and Soil Sciences, University of Delaware, Newark, DE, USA

Definition

Chemical kinetics. Chemical kinetics is the investigation of rates of chemical reactions and of the molecular processes by which reactions occur where transport is not limiting. **Kinetics** is a generic term referring to time-dependent processes.

Time Scales of Geochemical Processes

An array of reaction time scales occur in geochemical systems and often in combination with one another. They can range from milliseconds for many ion association and some ion exchange, sorption, and redox reactions to years for many mineral solution and mineral crystallization phenomena and for some sorption/release reactions. Ion association reactions include ion pairing, inner and outer-sphere complexation, and chelation in solution. Gas-water reactions involve gaseous exchange across the air-liquid interface. Ion exchange reactions occur when cations and anions are adsorbed (outer-sphere complexation) and desorbed from soil surfaces by electrostatic attractive forces. Ion exchange reactions are reversible and stoichiometric. Sorption reactions can involve adsorption processes including partitioning, outer-sphere and inner-sphere complexation, and multinuclear complexation (e.g., surface precipitation). Mineral-solution reactions include precipitation/dissolution of minerals, and coprecipitation reactions in which small constituents become a part of mineral structures (Amacher 1991; Sparks 1989, 2011).

The type of geosorbent can significantly affect the reaction rate. For example, sorption reactions are often more rapid on clay minerals such as kaolinite and smectites than on vermiculitic and micaceous minerals. This is primarily due to the availability of sites for sorption. Kaolinite has readily available planar external sites, and smectites have primarily internal sites that are also quite available for retention of sorbates. Thus, sorption reactions on these phyllosilciates are often quite rapid, even occurring on time scales of seconds and milliseconds (Sparks 1989, 2005, 2011).

Other phyllosilicates such as vermiculite and micas have multiple sites for retention of sorbates including planar, edge, and interlayer sites, with some of the latter sites partially to totally collapsed. Thus, sorption and desorption reactions on these sites can be slow, tortuous, and mass transfer controlled. Often, an apparent equilibrium may not be reached even after several days or weeks (Sparks 1989, 2011).

Sorption reactions on oxides, hydroxides, and humic substances depend on the type of surface and sorptive being studied but are often very rapid. For example, chemical reaction rates of metals and oxyanions on goethite occurred on millisecond time scales (Grossl et al. 1994, 1997; Zhang and Sparks 1989; Zhang and Sparks 1990a; Zhang and Sparks 1990b). Reaction rates of redox processes can also be very rapid. For example, Parikh et al. (2008) found that 50% of the initial reaction process for As(III) oxidation on Mn-oxides occurred in one minute. Half-times for divalent Pb, Cu, and Zn sorption on peat ranged from 5 to 15 s (Bunzl et al. 1976). A number of studies have shown that heavy metal sorption on oxides (Ainsworth et al. 1994; Bruemmer et al. 1988; Scheidegger et al. 1996a, 1998; Scheidegger and Sparks 1996) and clay minerals (Lövgren et al. 1990) increase with longer residence times. The mechanism for these lower reaction rates is not well understood but has been ascribed to diffusion phenomena, sites of lower reactivity, and surface nucleation/precipitation (Scheidegger et al. 1996b; Sparks 1998, 1999, 2011).

Sorption/desorption of metals and organic chemicals on heterogeneous soils is often very slow which has been attributed to diffusion into micropores of inorganic minerals and into humic substances, retention on sites of varying reactivity, and surface nucleation/precipitation (Borda and Sparks 2008; Matocha et al. 2005; Scheidegger et al. 1996b; Sparks 1989, 1997, 1999, 2002, 2005, 2011).

Application of Chemical Kinetics to Heterogeneous Geomedia

Chemical kinetics can be defined as the investigation of rates of chemical reactions and of the molecular processes by which reactions occur where transport is not limiting (Gardiner 1969). It is extremely difficult, due to mass transfer and diffusion processes to determine the chemical kinetics of geochemical systems that contain multiple components, particle sizes, and porosities. In most cases, both chemical kinetics and multiple transport processes are occurring simultaneously. Transport processes include (Aharoni and Sparks 1991): (1) transport in the solution phase; (2) transport across a liquid film at the particle/liquid interface (film diffusion [FD]); (3) transport in liquid filled macropores (>2 nm), all of which are nonactivated diffusion processes and occur in mobile regions; (4) particle diffusion (PD) processes which include diffusion of sorbate occluded in micropores (<2 nm) (pore diffusion) and along pore wall surfaces (surface diffusion); and (5) diffusion processes in the bulk of the solid, all of which are activated diffusion processes. Pore and surface diffusion within the immediate region can be referred to as interaggregate (interparticle) diffusion while that in the solid is intraaggregate diffusion. In systems where transport is the rate-limiting process, one is studying kinetics, which is a generic term referring to time dependent or nonequilibrium processes.

The actual chemical reaction (CR) at the surface, for example, adsorption, is usually almost instantaneous. The slowest of the CR and transport processes is rate limiting (Sparks 2011).

Rate Laws

There are two important reasons for investigating the rates of soil chemical processes (Sparks 1989, 1995, 1998, 1999, 2002, 2011): (1) to determine how rapidly reactions attain equilibrium and (2) to infer information on reaction mechanisms. One of the most important aspects of chemical kinetics is the establishment of a rate equation or law. By definition, a rate law is a differential equation. For the following reaction (Bunnett 1986; Sparks 1989, 1995, 1998, 1999, 2002, 2011):

$$aA + bB \rightarrow yY + zZ \tag{1}$$

the rate is proportional to some power of the concentrations of reactants A and B and/or other species (C, D, etc.) in the system and a, b, y, and z are stoichiometric coefficients and are assumed to be equal to one in the discussion that follows on rate laws. The power to which the concentration is raised may equal zero (i.e., the rate is independent of that concentration), even for reactant A or B. Rates are expressed as a decrease in reactant concentration or an increase in product concentration per unit time. Thus, the rate of conversion of reactant A above, which has a concentration $[A]$ at any time t, is $(-d[A]/(dt))$ while the rate with regard to product Y having a concentration $[Y]$ at time t is $(d[Y]/(dt))$.

The rate expression for Eq. 1 is therefore,

$$|d[Y]/dt| = |-d[A]/dt| = k[A]^{\alpha}[B]^{\beta} \tag{2}$$

where k is the rate constant and α and β are the orders of the reaction with respect to reactants A and B, respectively, and can be referred to as partial orders for the total reaction. These orders are experimentally determined and not necessarily integral numbers. The sum of all the partial orders (α, β) is the overall order (n) of the total reaction and may be expressed as:

$$n = \alpha + \beta + \ldots \tag{3}$$

Once the values of α, β, etc., are determined experimentally, the rate law is defined. Reaction order provides only information about the manner in which rate depends on concentration. Order does not mean the same as molecularity which concerns the number of reactant particles (atoms, molecules, free radicals, or ions) entering into an elementary reaction. One can define an elementary reaction as one in which no reaction intermediates have been detected or need to be postulated to describe the chemical reaction on a molecular scale. An elementary reaction is assumed to occur in a

single step and to pass through a single transition state (Bunnett 1986).

To demonstrate that a reaction is elementary, one can use experimental conditions that are different from those employed in determining the reaction rate law. For example, if one conducted kinetic studies using a flow technique with set steady-state flow rates, one could see if reaction rate and rate constants changed with flow rate. If they did, one would not be determining mechanistic rate laws (see definition below).

Rate laws serve three purposes: (1) they assist one in predicting the reaction rate; (2) mechanisms can be proposed; and (3) reaction orders can be ascertained. There are four types of rate laws that can be determined for geochemical processes (Skopp 1986): mechanistic, apparent, transport with apparent, and transport with mechanistic. Mechanistic rate laws assume that only chemical kinetics are operational and transport phenomena are not occurring. As mentioned earlier, it is difficult to determine mechanistic rate laws for most geochemical systems. However, as will be discussed later, if initial rates of reactions can be measured and back reactions minimized, one can approximate chemical kinetic measurements with certain geosorbents. Apparent rate laws include both chemical kinetics and transport-controlled processes. Thus, porosity, stirring, mixing, and flow rate all would affect the kinetics. Transport with apparent rate laws emphasize transport limited phenomena. One often assumes first-order or zero-order reactions (see discussion below on reaction order). In determining transport with mechanistic rate laws, one attempts to describe simultaneously transport-controlled and chemical kinetics phenomena. One is thus trying to explain accurately both the chemistry and physics of the system (Skopp 1986; Sparks 2011).

Determination of Reaction Order and Rate Constants/Coefficients

There are three basic ways to determine rate laws and rate constants/coefficients (Bunnett 1986; Skopp 1986; Sparks 1989, 1995, 1998, 1999, 2002, 2011): (1) initial rates, (2) directly using integrated equations and graphing the data, and (3) using nonlinear least square analysis.

Let us assume the following elementary reaction between species A, B, and Y,

$$A + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Y \tag{4}$$

A forward reaction rate law can be written as

$$d[A]/dt = -k_1[A][B] \tag{5}$$

where k_1 is the forward rate constant and α and β (see Eq. 2) are each assumed to be 1.

The reverse reaction rate law for Eq. 4 is

$$d[A]/dt = +k_{-1}[Y] \tag{6}$$

where k_{-1} is the reverse rate constant.

Equations 5 and 6 are only applicable far from equilibrium where back or reverse reactions are insignificant. If both forward and reverse reactions are occurring, Eqs. 5 and 6 must be combined such that:

$$d[A]/dt = -k_1[A][B] + k_{-1}[Y] \tag{7}$$

Equation 7 applies the principle that the net reaction rate is the difference between the sum of all reverse reaction rates and the sum of all forward reaction rates.

One way to ensure that back reactions are not important is to measure initial rates. The initial rate is the limit of the reaction rate as time reaches zero. With an initial rate method, one plots the concentration of a reactant or product over a short reaction time period during which the concentrations of the reactants change so little that the instantaneous rate is hardly affected. Thus, by measuring initial rates, one could assume that only the forward reaction in Eq. 4 predominates. This would simplify the rate law to that given in Eq. 5 which as written would be a second-order reaction, first order in reactant A and first order in reactant B. Equation 5, under these conditions, would represent a second-order irreversible elementary reaction. Integrated rate equations can also be used to determine rate constants/coefficients. If one assumes that reactant B in Eq. 5 is in large excess of reactant A, which is an example of the method of isolation to analyze kinetic data, and $Y_o = 0$, where Y_o is the initial concentration of product Y, Eq. 5 can be simplified to:

$$d[A]/dt = -k_1'[A] \tag{8}$$

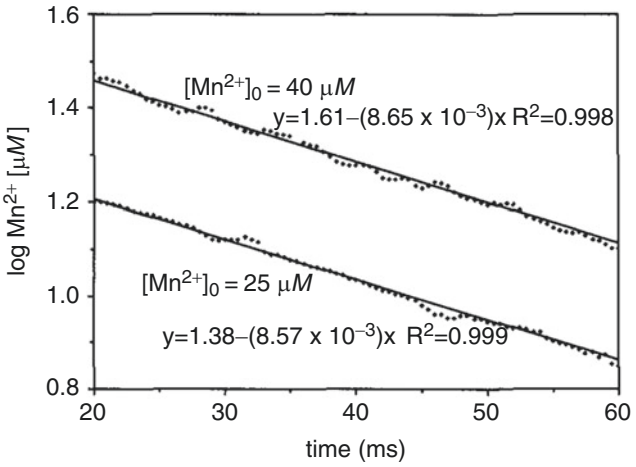
where $k_1' = k_1[B]$

The first-order dependence of $[A]$ can be evaluated using the integrated form of Eq. 8 using the initial conditions at $t = 0$, $A = A_o$,

$$\log[A]_t = \log[A]_o = -\frac{k_1' t}{2.303} \tag{9}$$

The half-time ($t_{1/2}$) for the above reaction is equal to $0.693/k_1'$ and is the time required for half of reactant A to be consumed.

If a reaction is first order a plot of log $[A]_t$ versus t should result in a straight line with a slope $= k_1'/2.303$ and an intercept of log $[A]_o$. An example of first-order plots for Mn^{2+} sorption on δ-MnO_2 at two initial Mn^{2+} concentrations, $[Mn^{2+}]_o$ (25 and 40 μM), is shown in Fig. 1 where a electron paramagnetic resonance-stopped flow (EPR-SF) spectroscopic method,



Kinetics of Geochemical Processes, Fig. 1 Initial reaction rates depicting the first-order dependence of Mn^{2+} sorption as a function of time for initial Mn^{2+} concentrations of 25 and 40 μM. (Reprinted by Permission, ASA, CSSA, SSSA.)

which is a form of a chemical relaxation technique, was employed (Fendorf et al. 1993). One sees that the plots are linear at both concentrations which would indicate that the sorption process is first order. The $[Mn^{2+}]_o$ values, obtained from the intercepts in Fig. 1 were 24 and 41 μM, which are in good agreement with the two $[Mn^{2+}]_o$ values and the rate constants were 3.73×10^{-3} and 3.75×10^{-3} s^{-1}, respectively. The fact that the rate constants do not significantly change with concentration is a good indication that the reaction in Eq. 8 is first order under the imposed experimental conditions, that transport/mass transfer are minimized, and that chemical kinetic phenomena are being measured.

It is dangerous to conclude that a particular reaction order is correct, based simply on the conformity of data to an integrated equation. As illustrated above, multiple initial concentrations that vary considerably should be employed to see if the rate is independent of concentration. One should also test multiple integrated equations. It may also be useful to show that reaction rate is not affected by a species whose concentration does not change considerably during an experiment, such as substances not consumed or present in large excess (Bunnett 1986; Sparks 1989, 1991, 1995, 1998, 1999, 2011).

Least squares analysis can also be used to determine rate constants/coefficients. With this method, one fits the best straight line to a set of points that are linearly related as $y = mx + b$ where y is the ordinate and x is the abscissa datum point, respectively. The slope (m) and the intercept (b) can be calculated by least squares analysis.

When kinetic data are plotted, curvature may be observed due to an incorrect assumption of reaction order. If first-order kinetics is assumed and the reaction is really second-order, downward curvature results. If second-order kinetics is assumed but the reaction is first order, upward curvature is observed. Curvature can also be due to fractional, third, higher, or mixed reaction order. Nonattainment of equilibrium often results in downward curvature. Temperature changes during the study can also cause curvature; thus, it is important that temperature be accurately controlled during a kinetic experiment (Sparks 2011).

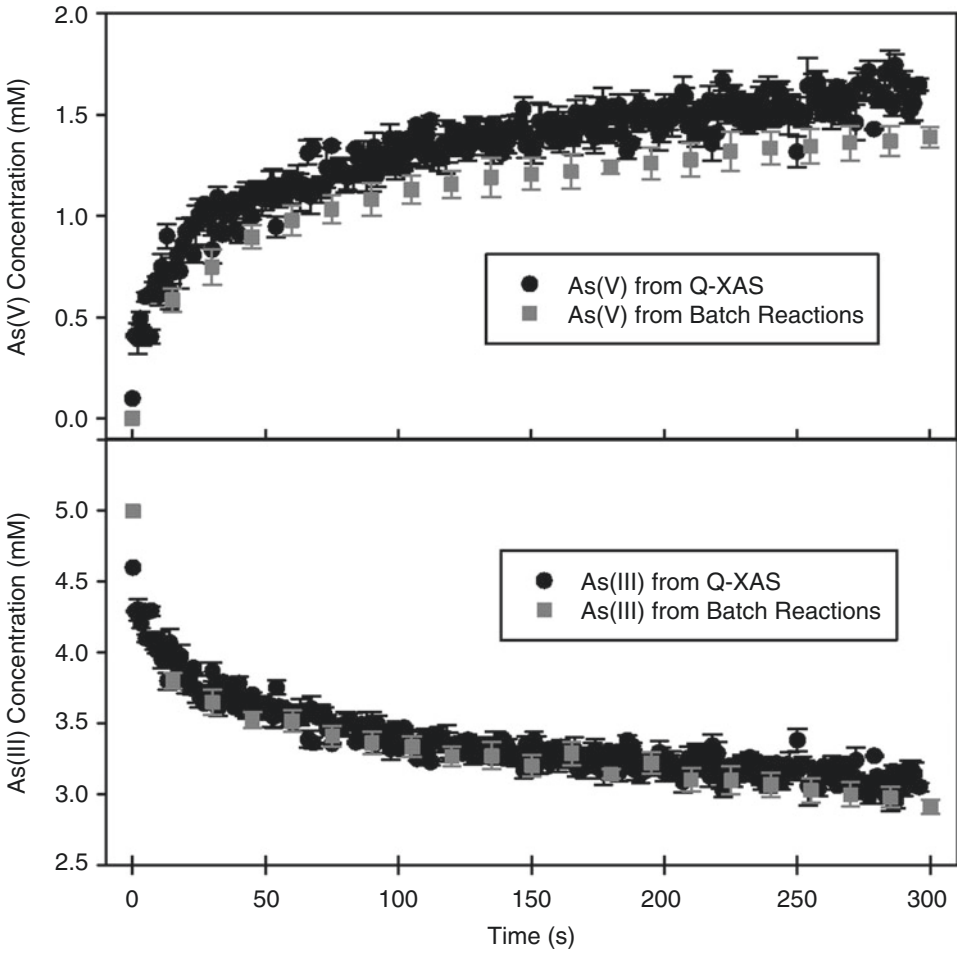
Methods to Determine Chemical Kinetics in Geochemical Systems

Chemical relaxation techniques such as pressure jump (p-jump) and concentration jump (c-jump e.g., stopped-flow) allow rapid initial rate data collection on time scales of milliseconds where back reactions should be minimized. However, with chemical relaxation techniques, rate "constants" are calculated from linearized rate equations that often include parameters that were determined from equilibrium and modeling studies. Consequently, the rate "constants" are not directly determined (Ginder-Vogel et al. 2009; Ginder-Vogel and Sparks 2010; Sparks 2013, 2014).

Over the past decade or so there have been major advances in the employment of real-time molecular scale kinetic techniques where initial reaction rates can be measured on time scales of milliseconds. This minimizes back reactions and transport, enabling the measurement of chemical kinetics and the determination of reaction mechanisms.

Real-time molecular scale ATR-FTIR and Q-XAS techniques have been employed to elucidate the rapid redox kinetics and mechanisms of As(III) oxidation (Ginder-Vogel et al. 2009; Parikh et al. 2008) and Cr(III) oxidation (Landrot et al. 2010) on Mn-oxides and Ni-Al layered double hydroxide phase precipitate formation on pyrophyllite (Siebecker et al. 2014).

Figure 2 shows Q-XAS and traditional batch data for As (III) oxidation on hydrous Mn-oxide (HMO). An initial concentration of 5 mM of As(III) was used. After one second of reaction the As(V) concentration, indicating oxidation of As(III), reached 0.37 mM and continued to increase rapidly for 45 s to reach a concentration of 1 mM. The As(V) concentration continued to increase for the remainder of the reaction, reaching the initial 1.5 mM concentration after 300 s of reaction time (Ginder-Vogel et al. 2009). A complete XANES spectrum was collected in 980 ms (Fig. 3). In the study of Ginder-Vogel et al. (2009), the oxidation states in both the solution and at the mineral/water interface were probed using Q-XAS. The average oxidation state was then determined by fitting each individual XANES spectra with a linear combination of As(III) and As(V) standard solutions (in this experiment, 5 mM standards were used). The fits provide the molar ratio

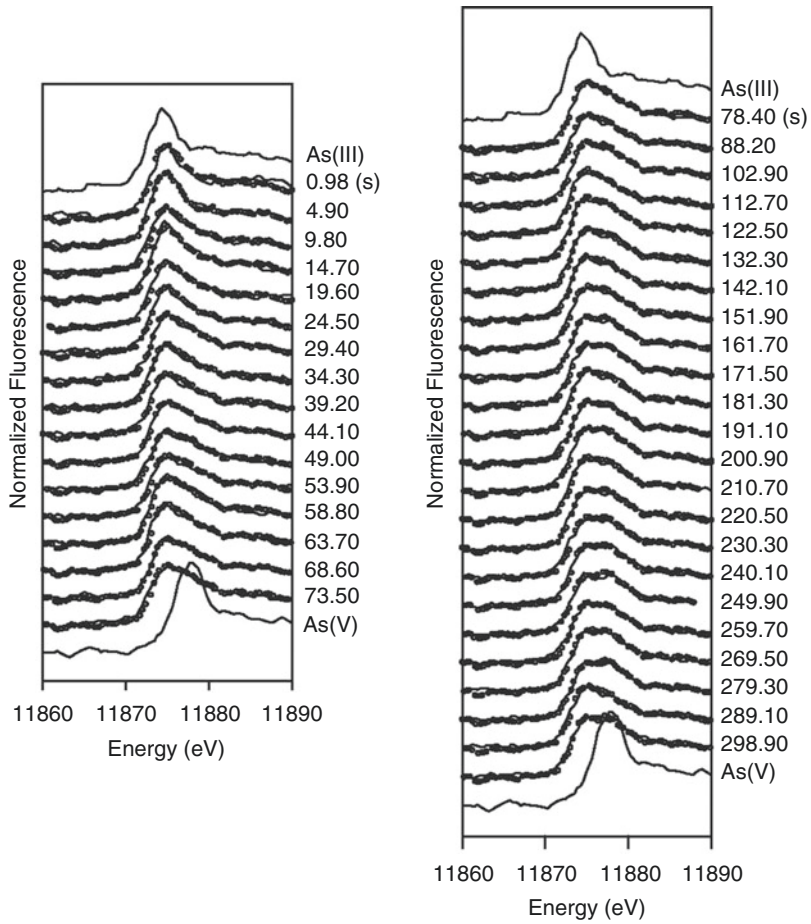


Kinetics of Geochemical Processes, Fig. 2 As(V) and As(III) concentrations determined from traditional batch and Q-XAS reactions. Error bars represent the SD of three measurements made at each time point. XANES spectra and fits used to calculate Q-XAS As concentrations are shown in Fig. 3. (Reprinted from PNAS, Ginder-Vogel M, Landrot G, Fischel JS, Sparks DL, Quantification of rapid environmental redox processes using quick-scanning X-ray absorption spectroscopy (Q-XAS), 106;16124–16128 (2009), with permission from National Academy of Sciences.)

of As in solution, from which the concentrations of As(III) and As(V) in the system can be calculated, using the initial As concentration. In Fig. 3 one sees the XANES spectra for the reaction of As(III) with HMO over time scales ranging from 0.98 to 298.9 s. One sees the rapid transformation of As(III) to As(V) on the HMO surface. Rate constants were determined from first-order plots for both the Q-XAS and batch experiments, based on biphasic kinetics (Table 1) and show, independent of method, that rate constants for As(III) depletion are about an order of magnitude larger during the initial portion of the reaction that in the later segment (Table 1). But, the initial rate constant of As(III) depletion based on Q-XAS was nearly twice as large (4.7×10^{-3}/s) as the rate constant measured with the batch method (2.5×10^{-3}/s, Table 1).

Landrot et al. (2010) employed the same technique as Ginder-Vogel et al. (2009) to measure the rapid, initial kinetics of Cr(III) oxidation on HMO. A complete XANES spectrum was determined in 0.75 s. Data were collected at pHs of 2.5, 3.0, and 3.5 at Cr(III) concentrations of 40–100 mM. Chromium (VI), resulting from the oxidation of Cr(III) on the HMO surface, displays the prominent pre-edge feature in the XAS spectrum, which is related to the proportion of Cr(VI) in the system. Therefore, one only needs to measure the height of the pre-edge feature and compare it to a set of Cr(III)/Cr(VI) mixtures to determine the amount of Cr(VI) present in the system (Landrot et al. 2010; Peterson et al. 1997). One sees in Fig. 4 that the pre-edge feature increases in intensity with time, indicating the oxidation of Cr(III) to Cr(VI). Chromium (III) oxidation is quite rapid during the first 120 s of the reaction, when about 35 mM of chromate was produced. Initial reaction rates were determined by quantifying the Cr(VI) from the pre-edge feature height for each experiment during a time range of 0–1 min of the reaction using the kinetic model below.

With this approach, one of the reactants is fixed at a constant value (but not necessarily in excess) in a set of experiments, while the concentration of the other reactant is successively varied. Therefore, both of the reactants must be considered in the overall rate equation. During the early stage of the reaction, a linear relationship relates [Cr(VI)] and time. The slope of this linear trend is the initial rate i, which is defined as:



Kinetics of Geochemical Processes, Fig. 3 Data (*solid*) and linear combination fits (*dots*) of individual As K-edge XANES spectra used to determine As(III) and As(V) concentrations during the batch reactions. Each spectrum was collected in approximately 980 ms, with the time (in s) next to each spectrum indicating the time the last data point of each spectrum was collected

Kinetics of Geochemical Processes, Table 1 Apparent, first-order rate constants determined from batch and Q-XAS experiments

Experiment type	Time period (s)	No. of data points	k (s − 1)	$r2$
As (III)–Batch	1–60	4	2.5 (3) × 10 − 3	0.96
As (III)–Batch	135–300	14	6.1 (4) × 10 − 4	0.82
As(III)–Q-XAS	1–30	30	4.7 (4) × 10 − 3	0.91
As(III)–Q-XAS	135–300	168	4.9 (4) × 10 − 4	0.74

The rate constants of As(III) depletion were determined by linear regression analysis of first-order As(III) depletion rate plots
Reprinted from PNAS, Ginder-Vogel M, Landrot G, Fischel JS, Sparks DL, Quantification of rapid environmental redox processes using quick-scanning X-ray absorption spectroscopy (Q-XAS), 106;16124–16128 (2009), with permission from National Academy of Sciences

$$\frac{d[\mathrm{Cr(VI)}]}{dt} = -k[\mathrm{Cr(III)}]_0^{\alpha}[\mathrm{MnO_2}]_0^{\beta} = i \qquad (10)$$

where k, α, and β were defined earlier, 0 represents the initial concentrations, and i is the initial rate of the reaction. To measure the partial rate coefficient of chromium α at a given pH value for the experiments where $[MnO_2]$ was fixed and [Cr(III)] was varied, Eq. 13 was used, which is a simplified expression of Eq. 11 :

$$\frac{i_{\mathrm{exp1}} = -k\left[\mathrm{Cr(III)}_{\mathrm{exp1}}\right]^{\alpha}[\mathrm{MnO_{2fixed}}]^{\beta}}{i_{\mathrm{exp2}} = -k\left[\mathrm{Cr(III)}_{\mathrm{exp2}}\right]^{\alpha}[\mathrm{MnO_{2fixed}}]^{\beta}} \qquad (11)$$

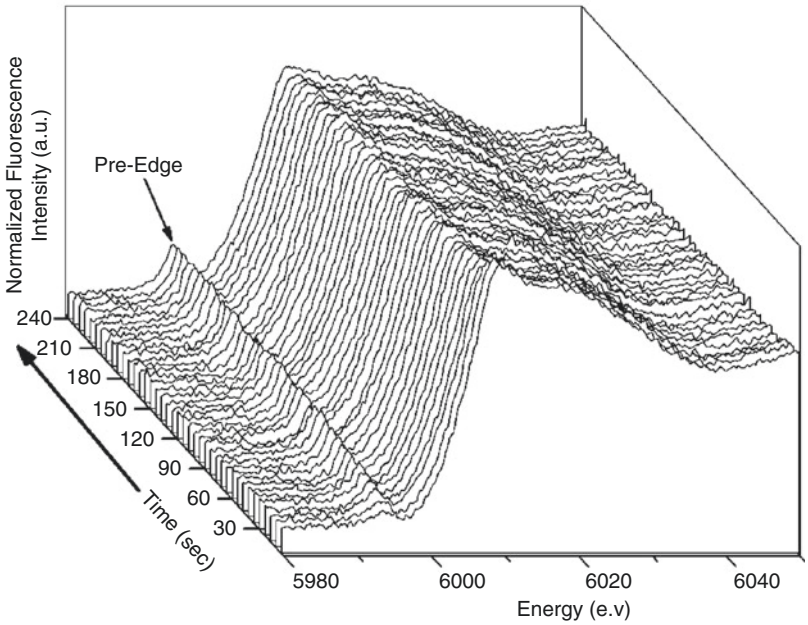
where exp = experiment

Hence:

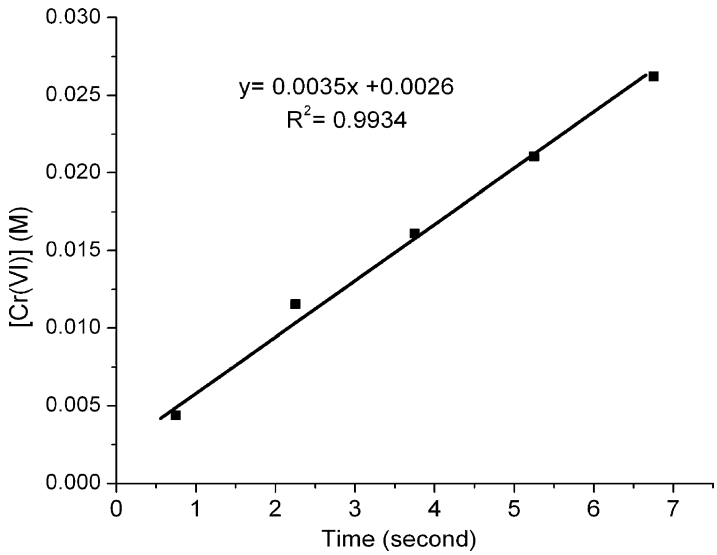
$$\frac{i_{\mathrm{exp1}}}{i_{\mathrm{exp2}}} = \left(\frac{\left[\mathrm{Cr(III)}_{\mathrm{exp1}}\right]}{\left[\mathrm{Cr(III)}_{\mathrm{exp2}}\right]}\right)^{\alpha} \qquad (12)$$

Therefore:

$$\alpha = \frac{\mathrm{Log}\left(\frac{i_{\mathrm{exp1}}}{i_{\mathrm{exp2}}}\right)}{Log\left(\frac{\left[\mathrm{Cr(III)}_{\mathrm{exp1}}\right]}{\left[\mathrm{Cr(III)}_{\mathrm{exp2}}\right]}\right)} \qquad (13)$$



Kinetics of Geochemical Processes, Fig. 4 Cr(III) oxidation kinetics using a Q-XAFS technique, at pH 2.5, [Cr (III)] = 100 mM, [HMO] = 20 g/ L, and 0–240 s. Each XANES spectrum shown represents 3 s of the reaction (average of four 0.75 s spectra). (Reprinted with permission from Landrot G, Ginder-Vogel M, Sparks DL (2010) Kinetics of chromium(III) oxidation by manganese (IV) oxides using quick scanning X-ray absorption fine structure spectroscopy (Q-XAFS) Environ Sci Technol 44:143–149. Copyright (2010) American Chemical Society.)



Kinetics of Geochemical Processes, Fig. 5 Initial rate measurement for an experiment at pH 2.5, where [Cr(III)] = 80 mM and [HMO] = 20 g/L. (Reprinted with permission from Landrot G, Ginder-Vogel M, Sparks DL (2010) Kinetics of chromium(III) oxidation by manganese (IV) oxides using quick scanning X-ray absorption fine structure spectroscopy (Q-XAFS) Environ Sci Technol 44:143–149. Copyright (2010) American Chemical Society.)

To measure the partial rate coefficient of manganese β at a given pH value for the experiments where [Cr(III)] was fixed and [MnO_2] was varied, Eq. 16 was used, which is a simplification of Eq. 14:

$$\frac{i_{\text{exp3}} = -k\left[\text{Cr(III)}_{\text{fixed}}\right]^{\alpha}\left[\text{MnO}_{2\ \text{exp3}}\right]^{\beta}}{i_{\text{exp4}} = -k\left[\text{Cr(III)}_{\text{fixed}}\right]^{\alpha}\left[\text{MnO}_{2\ \text{exp}_4}\right]^{\beta}} \tag{14}$$

Thus:

$$\frac{i_{\text{exp3}}}{i_{\text{exp4}}} = \left(\frac{\left[\text{MnO}_{2\ \text{exp3}}\right]}{\left[\text{MnO}_{2\ \text{exp4}}\right]}\right)^{\beta} \tag{15}$$

Therefore:

$$\beta = \frac{\text{Log}\left(\frac{i_{\text{exp3}}}{i_{\text{exp4}}}\right)}{\text{Log}\left(\frac{\left[\text{MnO}_{2\ \text{exp3}}\right]}{\left[\text{MnO}_{2\ \text{exp4}}\right]}\right)} \tag{16}$$

The rate constant k was calculated for each experiment using the i values experimentally measured, and the β and α calculated for each pH values using Eq. 17, which is a rearrangement of Eq. 10:

[a]The partial rate coefficients α, β at pH 2.5, pH 3, and pH 3.5 shown in this table are averaged values from α and β calculated using Eqs. 13 and 16 and by combining the initial rates measured at different experimental conditions. The rate constant for each experiment was measured with Eq. 17. Since all experiments were duplicated, the initial rates and rate parameters are reported with two values separated with "/". The standard error (95% confidence interval) for each initial rate is *italicized*. Averages of duplicate values are highlighted in *bold*

$$k = \frac{i}{[\mathrm{Cr(III)}]^{\alpha}[\mathrm{MnO_2}]^{\beta}} \tag{17}$$

A plot of one initial rate experiment is shown in Fig. 5.

Landrot et al. (2010) found at a given pH and for varying Cr(III) and HMO concentrations that the rate constants were similar (Table 2). This strongly suggests that the k values are chemical rate constants since only temperature should impact the magnitude of the k values. Therefore, the use of a method

like Q-XAS not only provides valuable information on rapid, initial reaction processes but an additional benefit is that one can determine chemical kinetics rate constants.

Together, these provide important insights on reaction mechanisms. Using most other techniques, one cannot significantly reduce or eliminate transport processes. Consequently, the rate parameters that are measured are apparent rate coefficients and not rate constants (Sparks 1989, 2002).

Siebecker et al. (2014) employed a Q-XAS flow technique, for the first time, to measure the rapid (6–15 min) formation of Ni layered double hydroxide (LDH) precipitate phases on pyrophyllite. These results suggest that adsorption and precipitation could occur on similar time scales and perhaps concurrently. Thus, there can be a continuum in sorption processes, which dictates that more robust sorption models need development that capture multiple sorption processes over reaction time.

Summary

This chapter covers the kinetics of geochemical processes and reactions. Time scales of geochemical reactions, rate laws and reaction order, and rate constants/coefficients are discussed. Novel molecular scale real-time methods, with an emphasis on synchrotron-based quick X-ray absorption spectroscopy (Q-XAS), are presented. This method is applied to the investigation of oxidation kinetics of arsenic and chromium on manganese oxides and to rates of layered double hydroxide formation on clay minerals.

Krypton

Greg Holland
School of Earth and Environmental Sciences,
University of Manchester, Manchester, UK

Element Data
Atomic Symbol: Kr
Atomic Number: 36
Atomic Weight: 83.798 ± 0.002
(*continued*)

Isotopes and Abundances: Percent molar abundances of stable isotopes in the atmosphere are $^{78}Kr = 0.355 \pm 0.003$, $^{80}Kr = 2.286 \pm 0.010$, $^{82}Kr = 11.593 \pm 0.031$, $^{83}Kr = 11.500 \pm 0.019$, $^{84}Kr = 56.987 \pm 0.015$, $^{86}Kr = 17.279 \pm 0.041$
1 Atm Melting Point: 115.78 K
1 Atm Boiling Point: 119.93 K
Common Valences: 0 (rarely 1,2)
Ionic Radii: n/a
Pauling Electronegativity: 3.00
First Ionization Potential: 1350.7 kJ/mol
Chondritic (CI) Abundance: 2.2 ± 0.2 ppb (parts per billion)
Silicate Earth Abundance: 0.1–0.2 ppt (parts per trillion)
Crustal Abundance: ~100 ppt
Seawater Abundance: 0.1–0.2 ppb
Core Abundance: unknown

History and Use

Krypton is one of the three noble gases discovered in 1898 by Sir William Ramsay and Morris William Travers. It is purified by cryogenic cooling with liquid nitrogen followed by passing it over hot titanium metal. Due to the inert nature of noble gases, there are no minerals or ores containing krypton. Solid krypton is white in color and has a cubic crystalline structure. However, unlike the lighter noble gases, it can occasionally form chemical compounds: krypton fluoride (principally KrF_2) is used in some excimer lasers. General uses are limited to the gaseous phase of the element: energy-saving fluorescent lights, flash lamps used for high-speed photography, gas discharge automobile headlights, and fluorescent signage. Monoisotopic ^{83}Kr has found use in MRI imaging (Pavlovskaya et al. 2005).

General Geochemical Behaviour

Krypton is one of the six noble gas elements that are also termed inert or rare gas elements. The term "noble" or "inert" correctly implies that the noble gases, including krypton, hardly ever engage in chemical reactions like most other elements. "Rare gas element" refers to their scarcity within the Earth system. Krypton has six naturally occurring isotopes with additional isotopes from cosmic ray interactions and products from nuclear reactions bringing the total known to 25. Notable unstable Kr isotopes are ^{81}Kr (half-life 229,000 years), produced by spallation reactions in the atmosphere, and ^{85}Kr (half-life = 10.76 years) from ^{238}U decay.

Krypton is colorless, odorless, and nontoxic, and is not used in biological systems. It is a highly volatile element and is extremely atmophile, accounting for 1.14 ± 0.01 ppm (parts per million) of dry tropospheric air. Krypton partitions strongly into the gas phase. Krypton solubility in silicate melt increases with increasing pressure (Paonita 2005) but is independent of temperature (Carroll et al. 1993), whereas solubility decreases with increasing temperature in water (Weiss and Kyser 1978). It is preferentially adsorbed onto organic matter compared to lighter noble gases (Marrocchi et al. 2005).

Uses in Geochemical Studies in Concert with Other Noble Gases

There are many scientific research areas in which Kr plays a critical role in combination with other noble gases. One such example is palaeoclimate studies. Bubbles trapped within polar ice contain gases from the atmosphere that have been trapped undisturbed for up to 10^6 yrs. These trapped gases faithfully reproduce the isotopic and elemental concentrations in the atmosphere. Solubility in water of the heavy noble gases (Kr and Xe), in particular, is strongly temperature dependent; therefore, trapped Kr/Xe ratios are controlled by mean ocean temperature and can be used as a record of ocean temperature variation (Headly and Severinghaus 2007). In addition, thermal diffusion can alter the elemental and isotopic ratio of these trapped noble gases, allowing scientists to reconstruct abrupt warming and cooling periods over the past few hundred thousand years (Severinghaus and Brook 1999). Similarly, basal ice sheet melting and glacial ice melting can be quantified by heavy noble gas/He ratios (Huber et al. 2006). Because the heavier noble gases (Kr and Xe) have solubilities in water that are most sensitive to temperature, reconstruction of palaeotemperatures in both groundwater systems (Aeschbach-Hertig and Solomon 2013) and water trapped within stalagmites/stalactites in caves (Schiedegger et al. 2011) is also possible.

Specific Applications of Krypton Isotope Geochemistry

Groundwater Dating

^{81}Kr is the product of spallation reactions in the atmosphere (proton addition to ^{82}Kr) and has a half-life of 229 kyrs. This potential dating tool for old groundwaters is little used due to very low concentrations of ^{81}Kr (~1000 atoms/liter with ^{81}Kr/Kr 5×10^{-13}). However, groundwaters have been dated using ^{81}Kr measured by AMS (accelerator mass spectrometry) (Collon et al. 2000). With the advent of the high sensitivity ATTA (atom trap trace analysis) mass spectrometer (Aeschbach-Hertig 2014), this environmental tracer and dating tool may be revisited. ^{85}Kr is produced by fission of uranium and plutonium and has a half-life of 10.76 years, making it a relevant tool for understanding shallow groundwater and transport of chemical pollutants. Sources include nuclear-bomb testing and nuclear reactors. ^{85}Kr is more abundant than ^{81}Kr: ~50,000 atoms/liter and ^{85}Kr/Kr 2×10^{-11}. It has a similar half-life to ^{3}H from nuclear bomb testing in 1960s, but, unlike ^{3}H, it is increasing in concentration in the atmosphere. Concentrations of ^{85}Kr in the atmosphere show spatial variability, reflecting primary source locations (Solomon et al. 1998), with concentrations at the North Pole approximately 30% higher than the South Pole (Jacob et al. 1987; Zimmerman et al. 1989).

Cosmic Ray Exposure Dating of Meteorites

Cosmic ray-induced spallation reactions in minerals containing Y, Rb, Sr, and Zr also produce ^{81}Kr. This is the basis of ^{81}Kr exposure dating in rocks that has been utilized for nearly half a century (e.g., Eugster et al. 1967; Marty 1967). The production rate of krypton depends on cosmic ray flux and the concentration of target element. Eventually, ^{81}Kr equilibrium concentration between production and radioactive decay is achieved. ^{81}Kr production rate can be inferred from the well-characterized decay rate, allowing the duration of exposure to cosmic rays to be calculated. Again low concentrations of ^{81}Kr are a challenge, but progress is being made with ultrasensitive RIMS (resonance ionization mass spectrometry) techniques (Strashnov et al. 2011).

Mantle Geochemistry: Source of Earth's Volatiles

Kr measured in igneous rocks, both ocean island basalts (OIBs, e.g., Hawaii) and mid-ocean ridge basalts (MORBs) show isotopic compositions identical to modern atmosphere. For this reason, Kr is often overlooked in noble gas geochemistry of the mantle. However, the subcontinental lithosphere seems to possess Kr isotopic anomalies with interesting implications for origin of volatiles on Earth (Holland et al. 2009). Two principle schools of thought exist for the origin of Earth's volatiles: one is gravitational capture of volatiles directly from the solar nebula (Porcelli et al. 2001); the other is acquisition of volatiles implanted into the accreting dust and planetesimals which subsequently accreted to form the Earth. These two models are not mutually compatible: the gravitational capture theory requires that the solar nebula is still present when the Earth has reached a significant proportion of its present mass, whereas the volatile planetesimal model requires dissipation of the solar nebula to allow implantation of solar wind into dust and fine particles before substantial accretion of material had occurred. The Kr isotopic composition of the subcontinental lithosphere suggests primitive Kr in

the Earth is like that found in carbonaceous chondrites and unlike solar Kr, implying volatiles were accreted into dust and planetesimals.

Mantle Geochemistry: Origin of the Atmosphere

Identification of the starting composition of primordial Kr in the Earth also applies tight constraints on the processes by which the atmosphere is related to the Earth's interior. Kr in the atmosphere is enriched in heavy isotopes relative to solar compositions. These isotopic enrichments are the natural consequence of the loss of noble gas from the atmosphere by processes that caused mass-dependent fractionation. Heavy noble gases, particularly Kr and Xe, are not presently lost from the atmosphere but have been modified by an extant process of atmospheric process of gas loss and mass fractionation (Hunten et al. 1987; Pepin 1991). The model is one of the initial overfractionation followed by buffering back to present-day atmosphere by outgassing of solar Kr from the mantle. Results from the subcontinental lithosphere show that the Earth does not presently contain solar Kr required in the mantle outgassing models (Holland et al. 2009). Therefore, one can therefore conclude that neither early outgassing nor impact-driven degassing of the early mantle is responsible for generating the noble gases in the present-day atmosphere. The relationship between Kr isotopes within the solid Earth and the atmosphere requires, from a noble gas perspective, an external source for the atmosphere. This has been postulated by various workers as a later volatile-rich reservoir which could include comets, asteroids, or Kuiper Belt objects (e.g., Marty and Meibom 2007).

Solar System Studies

Noble gases trapped in meteorites are categorized into solar, planetary, and exotic components and Kr is no exception. The solar Kr component (SW-Kr) is taken to be the average solar system composition as defined by solar wind. The most significant component to planetary noble gases in terms of abundance is Kr-Q. Kr-Q is the component found by etching primitive meteorites (Busemann et al. 2000) and is broadly explained by mass fractionation with respect to SW-Kr. This ubiquitous Q component is best explained by further contributions from exotic components Kr-s (s-process nucleosynthesis) and HL-Kr (another nucleosynthetic component enriched in light and heavy isotopes) (Gilmour 2010). Minor differences between Kr-Q and other planetary components Kr-P1 and Kr-P3 within meteorites suggests minor variation in the proportions the exotic components added to the mixture (Gilmour 2010). In combination with Xe isotopes, which can be used to date early solar system processes, the timing of incorporation of the nucleosynthetic components to the variable planetary components is beginning to yield a consistent story of the variety of supernovae sources that have contributed nucleosynthetic material to our solar system and the timing of processes that have occurred in the first few million years of the solar system to generate the relative abundances of elements and isotopic compositions that we observe in the solar system today.

Summary

In the past, krypton has often been the overlooked member of the noble gas family. In mantle and crustal geochemistry, its isotopic similarity to air has led to a focus on the lighter noble gases, He, Ne, and Ar. In groundwater hydrology, the low concentrations of radioactive krypton isotopes have meant that the focus of research in this area is on other tracers. In solar system science, "xenology" has been taken up by the community to a greater extent than "kryptology." However, with the advent of new ultrasensitive analytical techniques such as ATTA, together with the realization that perhaps krypton has an important future role to play in both terrestrial and solar system geochemistry, future research of krypton looks set to be exciting and fruitful.

Laboratory Simulations of Organic Geochemical Processes at Elevated Temperatures

Jeffrey S. Seewald
Marine Chemistry and Geochemistry Department, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Definition

Organic matter undergoes a series of chemical transformations when heated in natural environments. The chemical and physical evolution of this material as a function of time and temperature, commonly referred to as thermal maturation, involves numerous organic and inorganic reactions that can be simulated in the laboratory using artificial maturation experiments. A variety of techniques have been developed to provide information regarding the rates of reactions as a function of time and temperature, the amounts of products generated, reaction pathways and mechanisms, and the role of water and other inorganic species.

Introduction

Organic compounds are pervasive in a broad range of geologic environments where they are involved in numerous geochemical processes at elevated temperatures and pressures. The generation and accumulation of petroleum (oil and natural gas) in sedimentary basins is an obvious and economically important example. Others include the transport and deposition of ore-forming metals in hydrothermal systems, sediment diagenesis, and the formation of methane gas-hydrates. Organic compounds formed in many of these environments also represent a source of nutrients and energy that can support microbial communities. Therefore, a major goal for the organic geochemist is to understand geochemical processes that regulate the production and degradation of organic matter. Owing to the complexity and, in many cases, difficulties associated with accessing geologic environments, factors that regulate organic transformations are difficult to determine from field studies alone. Consequently, a variety of approaches involving laboratory experiments have been developed to provide information regarding geochemical processes that regulate the abundance of naturally occurring organic compounds. Many of these efforts are focused on understanding the origin of oil and natural gas in relation to the thermal maturation of organic-rich sediments, while others have examined the generation and stability of organic compounds dissolved in water.

Oil and Natural Gas Formation

The thermal degradation of kerogen to produce liquid oil and natural gas is generally believed to occur at temperatures from 50 °C to 120 °C (Hunt 1996; Tissot and Welte 1984). Continued heating of oil at higher temperatures may result in its subsequent degradation and conversion to natural gas. Because natural maturation processes typically occur on million year time scales, it is common practice to conduct laboratory simulations at temperatures higher than in natural systems to enhance reaction rates and allow observation of organic transformations on laboratory time scales. Results of experiments generating petroleum as a function of time and/or temperature can be used to determine the rate of oil and natural gas formation in sedimentary basins (Behar et al. 1992; Burnham et al. 1987; Espitalié et al. 1977; Lewan 1985; Schenk and Dieckmann 2004). Indeed, such experiments have played an important role in guiding much of the petroleum exploration that has occurred to date in conventional sedimentary systems. A key premise underpinning this practice is the assumption that petroleum generation is primarily a kinetically controlled process in which the effects of time and temperature are interchangeable.

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

Extrapolation of reaction rates observed at high temperatures in the laboratory to lower temperatures that characterize petroleum producing sedimentary basins is achieved through use of the Arrhenius equation:

$$k = A_0 e^{-(Ea/RT)}$$

where k is the rate constant, A_0 is the pre-exponential constant, E_a is the activation energy, R is the ideal gas constant, and T is temperature. There are important limitations associated with this approach. In particular, because the thermal maturation of sedimentary organic matter to produce oil and natural gas is an inherently complex process involving millions of sequential and parallel reactions, often in complex reaction networks, even the most complex kinetic models based on the Arrhenius equation represent gross simplifications of the natural process (Dominé et al. 1998). Moreover, the substitution of time for temperature during laboratory experiments may introduce significant uncertainty in extrapolated reaction rates since at lower temperatures substantial changes may occur in the relative rates of the reactions involved, the relationship between the rates of molecular diffusion and reaction, thermodynamic drives, and reaction mechanisms. Despite these limitations, laboratory experiments provide one of the few means by which processes associated with natural thermal alteration of sedimentary organic matter can be studied and represent effective tools for predicting the geochemical evolution of sedimentary basins.

Laboratory experiments designed to simulate the maturation of sedimentary organic matter vary widely with respect to complexity, the type of information they provide, and the extent to which they replicate natural systems. Collectively, they involve pyrolysis reactions induced by heating sedimentary organic matter in the absence of molecular oxygen. Major differences are related to whether the experimental system is open or closed, the temperature of the simulation, and the presence or absence of added water. In closed-system experiments, bulk sediments, petroleum source rocks, or isolated kerogen (the fraction of sedimentary organic matter insoluble in common organic solvents) are heated in a confined reaction chamber. A variety of reaction chamber designs and materials have been employed for this purpose, including relatively large volume (~500 ml) stainless steel pressure vessels (Lewan 1997) and smaller volume gold (Behar et al. 1992; Gao et al. 2014; Landais et al. 1989) or quartz tubes (Horsfield and Duppenbecker 1991) that are sealed at both ends. Artificial maturation within sealed gold tubes is typically referred to as confined pyrolysis since confining pressure is applied to the flexible tubes by water within an external pressure vessel to eliminate a vapor headspace above the reactants. During closed-system experiments, reaction products remain in the reaction chamber in intimate contact with the starting materials for prolonged periods of time, thereby promoting secondary reactions. In contrast, during open-system experiments (e.g., see programmed temperature pyrolysis), sediment or kerogen is maintained at or near ambient pressure conditions and is continuously swept by an inert carrier gas (usually helium) to remove volatile products to a detection device for quantitation (Burnham et al. 1987; Espitalié et al. 1977). Rapid removal of reaction products from the reaction chamber minimizes secondary reactions. As a result, there are significant compositional differences between organic products generated during open- and closed-system pyrolysis. In particular, alkenes are a major product during open-system pyrolysis, but are only produced during early heating stages in closed-systems and subsequently disappear during prolonged heating (Tannenbaum and Kaplan 1985). Since alkenes are present at relatively low concentrations in naturally occurring crude petroleum, these observations suggest that closed-system experiments more accurately replicate organic transformations responsible for the generation of oil and natural gas under quasi-closed conditions that prevail in natural sedimentary environments. Temperature conditions and the duration of heating also vary widely during laboratory simulations. Closed-system experiments are typically conducted isothermally at temperatures as high as high 550 °C for periods of time ranging from a few hours to several years (Saxby and Riley 1984). In contrast, open-system pyrolysis experiments typically involve relatively rapid non-isothermal heating (several degrees/min) of samples from ambient conditions to temperatures as high as 1000 °C (Burnham et al. 1987; Espitalié et al. 1977).

Role of Water and Other Inorganic Species

Laboratory experiments have been used extensively to examine the role of water and other inorganic materials such as minerals and sulfur species during organic geochemical processes. During the generation of oil and natural gas, water has been identified as an important variable that influences the composition and amounts of individual organic constituents (Lewan 1997; Price and Wenger 1992). Closed-system laboratory experiments reacting sedimentary organic matter or kerogen with added water (referred to as hydrous or aqueous pyrolysis) can also provide information regarding physical expulsion processes since this approach may produce a free-flowing liquid oil that floats on liquid water within the reaction chamber, allowing expelled products to be distinguished from those retained within the rock matrix (Lewan 1997). Hydrous pyrolysis experiments have demonstrated that in addition to acting as a confining medium, liquid water also participates in many organic reactions and acts as a source of hydrogen and oxygen for the generation of hydrocarbons and oxygen-bearing alteration products such as organic acids and

carbon dioxide (Hoering 1984; Lewan 1997; Seewald 2001; Stalker et al. 1994).

Several experimental studies have focused on investigating chemical reactions involving organic compounds dissolved in water at elevated temperatures and pressures (Reeves et al. 2012; Seewald 2001; Shipp et al. 2014; Siskin and Katritzky 2001). Although relevant to organic-rich petroleum producing sedimentary basins, results of these experiments have widespread application to hydrothermal systems located on land and in the marine environment, where, in most instances, the absence of organic-bearing sediments results in substantially lower organic matter abundance. Hydrothermal systems are characterized by higher temperatures than environments responsible for the generation of petroleum in sedimentary basins, allowing experiments focused on hydrothermal organic geochemistry to be conducted at temperatures comparable to natural systems. Recognizing that organic reactions are influenced by both the organic and inorganic chemical environment in which they occur, and that a significant fraction of organic reactions are redox dependent, many of these experiments have utilized approaches that allow key chemical variables such as the activities of H_2, various sulfur species, and H^+ to be carefully regulated or monitored during an experiment. Experiments containing naturally occurring Fe-bearing mineral assemblages that buffer the activity of aqueous H_2 and H_2S have been used to study the stability of individual aqueous hydrocarbons (McCollom et al. 2001; Seewald 2001). Unlike experiments examining the maturation of sedimentary organic matter or kerogen, these experiments typically contain a single or limited number of model compounds, thereby reducing the number of possible reactions and facilitating the identification of specific reaction pathways that may result in the production or degradation of an individual compound or class of compounds. A major finding of these experiments is that kinetic barriers to the attainment of total thermodynamic equilibrium allow the metastable persistence of many organic compounds such as hydrocarbons, alcohols, and ketones that may react reversibly to attain a partial thermodynamic equilibrium state with respect to other organic compounds, water, and redox-dependent minerals (Seewald 2001; Shipp et al. 2013; Yang et al. 2012). Moreover, these experiments have demonstrated that the presence of liquid water promotes aqueous reactions that utilize reaction pathways and mechanisms not available in dry systems.

Other experiments have been instrumental in demonstrating that minerals and aqueous species may be catalytically active during organic reactions. A variety of sulfur species have been shown to play a catalytic role in both the formation and degradation of diverse reduced carbon compounds. For example, organic sulfur radicals released by the decomposition of sulfur-bearing organic compounds accelerate the cleavage of C–C bonds in kerogen, resulting in the generation of oil at lower temperatures from sulfur-rich source rocks (Lewan 1998), while aqueous organic sulfur compounds such as thiols may play a catalytic role in the high temperature decomposition of oils by a process known as thermochemical sulfate reduction (Amrani et al. 2008). Aqueous inorganic sulfur species have also been implicated as being catalytically active during redox reactions that result in the oxidation of aqueous hydrocarbons (Goldhaber and Orr 1995; Seewald 2001; Toland 1960). The sulfide mineral sphalerite (ZnS) has been shown to act as a heterogeneous catalyst for the making and breaking of C–C bonds during isomerization of dimethylcyclohexanes (Shipp et al. 2014). Other heterogeneous catalysts include clay minerals and transition metals that have been shown to accelerate the degradation of petroleum to natural gas (Mango and Hightower 1997; Tannenbaum and Kaplan 1985).

Summary and Conclusions

Laboratory experiments represent a powerful means to identify and quantify geochemical processes associated with the thermal maturation of organic matter in natural environments. The ability to control physical and chemical conditions and remove many of the complexities associated with natural systems allows an assessment of key variables that regulate organic transformations under geologically relevant conditions. Experiments have demonstrated that organic reactions are strongly influenced by the presence or absence of inorganic chemical species. Liquid water is particularly important in facilitating reaction pathways not available in dry systems, and may facilitate the attainment of metastable thermodynamic equilibrium involving organic compounds, water, and minerals. Water also represents an abundant source of hydrogen and oxygen that can be incorporated into organic alteration products in addition to the limited amounts available in organic matter. Many inorganic and organic species have been shown to catalyze organic reactions in both aqueous and dry systems and participate in redox-dependent organic reactions. Information of this type represents an important foundation for the development of predictive models used to constrain geochemical process that regulate the composition and abundance of organic matter in natural systems.

Lanthanide Rare Earths

Scott M. McLennan
Department of Geosciences, Stony Brook University, Stony Brook, NY, USA

Definition

Rare earth elements (REE) consist of Group 3 (or Group IIIB) transition elements $_{21}$Sc, $_{39}$Y, $_{57}$La, and f-block (inner transition) elements $_{58}$Ce, $_{59}$Pr, $_{60}$Nd, $_{61}$Pm, $_{62}$Sm, $_{63}$Eu, $_{64}$Gd, $_{65}$Tb, $_{66}$Dy, $_{67}$Ho, $_{68}$Er, $_{69}$Tm, $_{70}$Yb, and $_{71}$Lu. In geochemical usage, the term *rare earth elements* refers only to the lanthanides (La–Lu), and commonly Y due to geochemical behavior similar to Ho. However, Sc typically is excluded in discussions of REE because it is a smaller cation with geochemical behavior closer to the first row (ferromagnesian) transition elements Fe, V, Cr, Co, and Ni, with which it is typically grouped. This well-entrenched geochemical

nomenclature differs from formal chemical nomenclature, thus providing a source of confusion. Geochemists also subdivide REE into light rare earths (LREE: La–Sm) and heavy rare earths (HREE: Gd–Lu) with some further recognizing a group of middle rare earths (MREE; Nd (or Sm)–Tb). The REE promethium (Pm) lacks any stable nuclides or long-lived radionuclides and is not normally considered in geochemical discussions. Although only very rarely used in geochemical literature, the International Union of Pure and Applied Chemistry recommends the term "*lanthanoid*" rather than "*lanthanide*," since in chemistry the word-ending "ide" generally refers to anionic species.

General Geochemistry

The mostly trivalent rare earth elements (REE) are arguably the most significant group of trace elements in geochemistry. The lanthanide series develops by filling 4f orbitals, which do not effectively shield each other from increasing nuclear charge, leading to highly coherent geochemical behavior as a group. Among other things, the trivalent state is especially stable in geological settings (Eu^{2+} and Ce^{4+} being the two notable exceptions) and trivalent ionic radii decrease in a particularly systematic fashion: the "*lanthanide contraction*" (e.g., Douglas 1954; Table 1; Fig. 1). The dominant

Lanthanide Rare Earths, Fig. 1 Plot of ionic radius versus atomic number for the trivalent lanthanide elements. Also shown for reference are the ionic radii for the other trivalent rare earth elements Y and Sc, for Eu^{2+} and Ce^{4+}, and for other selected cations. The extremely regular decrease in the ionic radii of the trivalent lanthanides is termed the "lanthanide contraction." Note that Sc^{3+} is much smaller than other rare earth elements, more similar in size to Fe^{2+} and Mg^{2+}, which is the reason why it is generally not included with the REE in geochemical literature

controls on the geochemical and cosmochemical behavior of REE are their valence (including redox behavior), size (ionic/crystal radius), volatility (e.g., 50% condensation temperature), and complexing behavior (speciation). Useful reviews of REE geochemistry may be found in Henderson (1984), Taylor and McLennan (1988), Lipin and McKay (1989), Nozaki (2001), Hoatson et al. (2011), Chakhmouradian and Wall (2012), and McLennan and Taylor (2012). Some basic REE properties, of geochemical and cosmochemical interest, are summarized in Table 1.

REE are lithophile and, apart from Sc, in most igneous systems are incompatible (i.e., bulk partition coefficients, $D < 1$) with the degree of incompatibility typically increasing with increasing size (i.e., decreasing atomic number). Accordingly, the trivalent lanthanides (and Y) tend to be concentrated in magmatic liquids and late crystallizing phases. Of the major elements in the crust and mantle, only Na and Ca come close in size (apart from Sc), however substitution for these elements (especially Na) may lead to serious charge imbalances, requiring a coupled substitution (Fig. 1). Traditionally, trivalent lanthanides have also been considered large-ion lithophile elements (LILE) but since their level of incompatibility is more a function of charge than of size, this terminology is now discouraged (Chauvel and Rudnick 2016).

In general, the REE have very low fluid/rock bulk partition coefficients ($D \ll 1$) and thus during most diagenetic, hydrothermal and metamorphic conditions are only significantly redistributed beyond the mineralogical scale at very high fluid/rock ratios. Under aqueous conditions, REE exist mostly as a variety of complexes, with seawater speciation being dominated by metal (REE^{3+}), carbonate ($REECO_3^+$), and bicarbonate ($REE(CO_3)_2^-$), with carbonate complexes being the most abundant. Scandium, on the other hand, is strongly hydrolyzed in seawater (i.e., $Sc(OH)_2^+$, $Sc(OH)_3^0$, $Sc(OH)_4^-$ speciation) (Byrne 2002).

A more controversial influence on REE behavior, notably in aqueous and late-stage magmatic fluids, is the so-called "*tetrad*" or "*double-double*" effect, resulting from 1/4, 1/2, 3/4, and fully filled 4f shells (Masuda et al. 1987). Distinctive M- and W-shaped chondrite-normalized REE patterns have been observed with inflections corresponding to the four tetrads (La-Nd; (Pm)Sm-Gd; Tb-Ho; Er-Lu). McLennan (1994) suggested that many apparent tetrad effects could be artifacts of incomplete analyses, analytical error, inappropriate normalization, or complex mixing processes.

However, claims of tetrad effects continue to appear (e.g., Bau and Koschinsky 2009) and final resolution of the controversy requires systematic interlaboratory comparisons of the same samples by a variety of laboratories and analytical methods.

Eu and Ce Redox Geochemistry

Of great importance to geochemistry is the fact that Eu and Ce commonly exist in other than trivalent states in geological environments ($Eu^{2+/3+}$; $Ce^{3+/4+}$). Reduced Eu^{2+} occurs by reducing, typically magmatic, conditions. The ionic radius of Eu^{2+} is about 17% larger than Eu^{3+} and almost identical to Sr^{2+} (Fig. 1). Accordingly, Eu^{2+} behavior differs considerably, resulting in REE distributions with anomalous Eu abundances (Eu-anomalies; see below). One important example is that Eu becomes highly concentrated in plagioclase feldspar (substituting into the Ca site). Plagioclase is only stable to about 40 km depth on Earth and so anomalous Eu behavior in terrestrial magmatic rocks is commonly taken as a sign of relatively shallow igneous processes (e.g., Taylor and McLennan 1985). Under surficial aqueous conditions, Eu is present in its oxidized form, although under highly reducing and alkaline conditions, Eu reduction could potentially take place (Sverjensky 1984). Evidence for mixed Eu^{2+}/Eu^{3+} under certain hydrothermal conditions has also been documented (e.g., Takahashi et al. 2005).

In contrast, Ce is found in the Ce^{3+} state under magmatic conditions but is readily oxidized under many surficial aqueous conditions, notably in early marine diagenesis to form manganese nodules and under oxidizing weathering conditions. Ce^{4+} is ~15% smaller than Ce^{3+} and tends to form highly insoluble Ce-hydroxide complexes that can thus readily separate from more soluble REE^{3+} complexes, resulting in anomalous REE distribution patterns (Ce-anomalies; see below). The substantial depletion of Ce in seawater (i.e., negative Ce anomalies), resulting ultimately from manganese oxide formation, is a direct manifestation of such redox controls (e.g., Nozaki 2001).

Normalization of Rare Earth Element Abundances

Absolute concentrations of lanthanides are highly variable in rocks, minerals, and natural waters (Table 2), as are relative abundances of adjacent lanthanides in any given sample, due to the Oddo-Harkins (odd-even) effect. Accordingly, it is customary to display lanthanide data as plots of normalized values (on a logarithmic scale) versus atomic number or ionic radius (on a linear scale), termed Coryell-Masuda plots. Yttrium in some cases is also plotted at about the position of the lanthanide Ho, because it typically behaves similarly to this HREE in most geological processes. The two most commonly used datasets for normalization are average chondritic meteorites, reflecting solar and bulk silicate Earth abundances, and average shale, reflecting upper continental crust abundances. Commonly used values are given in Table 2 but for both chondrites and shales, different workers use values that differ by up to ~15% in absolute abundances (but with

Sources: [a]Lodders (2003; note that these abundances also equate to assuming $Si=10^{7.51}$); [b]from compilations in Taylor and McLennan (2009); [c]McLennan (1989); [d]Nozaki (2001), Parker et al. (2016)

relative abundances differing by no more than a few percent). In addition to chondrites and shales, other normalization values may be used for specific problems; for example, it is common to normalize data from a related suite of samples to a single sample within the suite to evaluate processes giving rise to variable REE distributions.

Due to variable redox states described above, it is also common that Eu and Ce display anomalous depletion or enrichment on normalized REE plots. These are termed Eu- and Ce-anomalies with negative anomalies denoting relative depletions and positive anomalies denoting relative enrichments. Such anomalies are quantified as follows:

$$Eu/Eu^* = Eu_N/(Sm_N \bullet Gd_N)^{0.5} \text{ and}$$
$$Ce/Ce^* = Ce_N/(La_N \bullet Pr_N)^{0.5}$$

where Eu* and Ce* are the expected values for smooth normalized REE patterns and the subscript "N" denotes the normalized value. Eu/Eu* and Ce/Ce* values of >1 denote positive anomalies whereas values <1 denote negative anomalies and for all but the most precise analyses, anomalies should be greater than ~5% (i.e., $\leq$0.95; $\geq$1.05) to be considered significant.

Isotope Geochemistry Involving Lanthanides

Because the lanthanides have such coherent interelement relationships and are not readily disturbed by later chemical alteration, radiogenic isotope systems involving these elements are especially useful as geochronometers and isotope tracers. The most useful of these is the $^{147}Sm/^{143}Nd$ alpha decay system (^{147}Sm decay constant, $\lambda = 6.54 \bullet 10^{-12}$ year^{-1}) which, for example, is useful for evaluating the timing of extraction of the continental crust from the mantle (DePaolo 1988). The $^{176}Lu/^{176}Hf$ beta decay system ($\lambda = 1.867 \bullet 10^{-11}$ year^{-1}) is well established and useful for examining the fractionation between the least incompatible REE and another refractory element with different geochemical behavior (i.e., high field strength) (Patchett 1983). A final, less used long-lived system involves the branched beta decay of ^{138}La to ^{138}Ce and ^{138}Ba ($T_{1/2} = 3.08 \bullet 10^{11}$ year). In addition to long-lived radiogenic isotope systems, there is one important short-lived system, the alpha decay $^{146}Sm/^{142}Nd$ system. ^{146}Sm has a short half-life ($T_{1/2} = 1.012 \bullet 10^8$ year), considerably less than the age of the Earth, and thus has been "extinct" since early in the history of the solar system. Accordingly, this system can be used to evaluate the fractionation of Sm from Nd very early in planetary histories, prior to the age of the oldest rocks (e.g., early planetary crust formation). A review of isotope geochemistry, including systems involving the lanthanides, can be found in Allègre (2008).

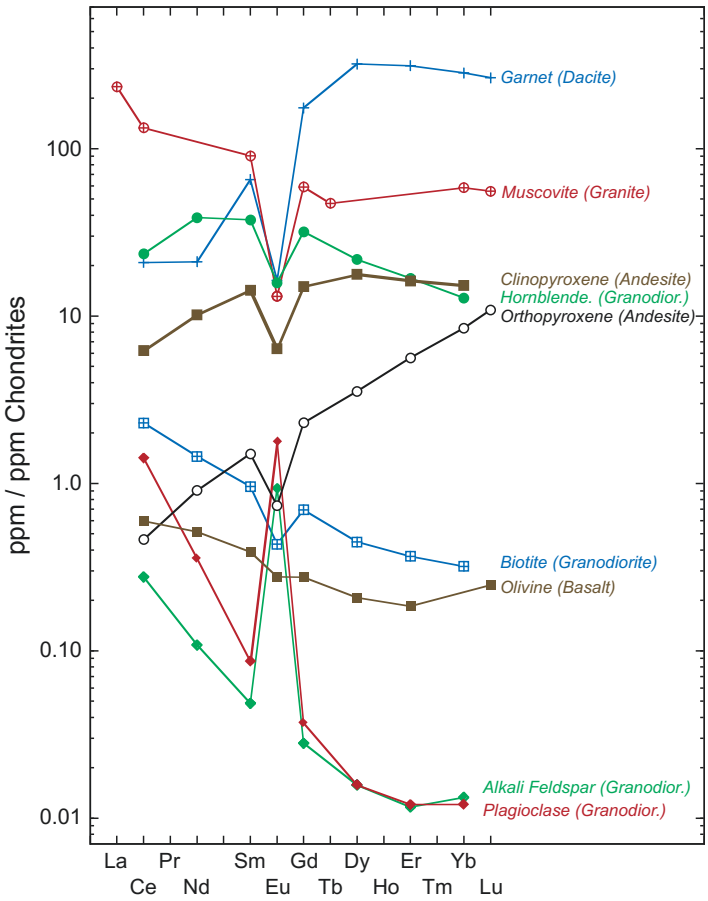
Mineralogy

Most common rock-forming minerals (e.g., olivine, pyroxene, feldspar, micas) do not have cation site conditions (size, charge) that are favorable to substitution of lanthanide REE, which is why they are typically incompatible trace elements for rock-forming minerals under magmatic conditions (i.e., mineral-melt partition coefficients, $K_d < 1$). Nevertheless, both relative and absolute abundances of REE in common rock-forming minerals are highly variable, by orders of magnitude in concentration (Fig. 2). It is this variability, in both abundances and REE pattern shapes (e.g., Eu-anomalies, HREE enrichment), that makes the REE such useful trace elements for evaluating igneous processes because bulk rock REE patterns are sensitive to the mineralogical, and thus the pressure-temperature-compositional, history of the magmatic system (e.g., partial melting, crystal fractionation).

Lanthanides are highly electropositive (i.e., electronegativities in range 1.0–1.3; Table 1) and thus tend to form ionic compounds. REE serve as essential structural constituents in more than 270 different silicate, carbonate, oxide, phosphate, halide, sulfate, arsenate, and vanadate minerals. Among the most abundant REE minerals are bastnäsite [$REE(CO_3)F$], monazite [$(Ce,La,Nd,Th)(PO_4)$], britholite [$(REE,Ca)_5(SiO_4, PO_4)_3(OH,F)$], and xenotime [$YPO_4$]. Some additional REE minerals that are of interest in geochemistry are lanthanite [$(La,Ce,Nd)_2(CO_3)_3 \cdot 8H_2O$], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+}, Fe^{3+})_3(SiO_4)_3(OH)$], the phosphates florencite [$(Ce,La)Al_3(PO_4)_2(OH)_6$], and rhabdophane [$(La,Ce)(PO_4) \cdot H_2O$]. A review of REE mineralogy may be found in Jones et al. (1996).

Sources and Uses of Lanthanides

Based on 2015 United States Geological Survey estimates (Gambogi 2016), China dominates mine production of rare earth elements accounting for 85% of the global production of $1.24 \bullet 10^5$ metric tons of total rare earth oxides, with Australia (8.1%), U.S.A. (3.3%), Russia (2.0%), and Thailand (1.6%) accounting for most of the remaining production. China also possesses the largest fraction (42%) of the global ~$1.3 \bullet 10^8$ metric tons of rare earth oxide reserves. Brazil (17%), Australia (2.5%), India (2.4%), and U.S.A (1.4%) also account for significant reserves, with the remaining ~35% being divided among many countries, including Canada, Greenland, Kyrgyzstan, Malawi, Malaysia, Russia, Sweden, Thailand, Vietnam, Zambia, and others. The past decade has witnessed a considerable increase in REE ore deposit exploration activities due both to a dramatic price increase between 2008 and 2011 (prices subsequently dropped greatly between 2012 and 2016) and growing applications for military and



Lanthanide Rare Earths, Fig. 2 Chondrite-normalized REE patterns for selected common igneous rock-forming minerals (with host rocks also shown beside mineral name), illustrating both the overall variation in absolute REE abundances (>10^4) and in the shapes of the REE distributions, including highly variable LREE/HREE ratios and variable Eu-anomalies (Data from the compilation in Taylor and McLennan 1988)

other strategic purposes (e.g., night vision and precision guidance systems, stealth technology).

The major geological settings of REE ore deposits include hydrothermally altered (carbonatite fluid source) Proterozoic dolomitic marbles (Bayan Obo deposit of China, the largest in the world), lateritic ion-adsorption clays (southern China, notable for relative enrichment of scarce HREE), carbonatites (e.g., Mountain Pass, CA, the largest REE deposit in North America), and heavy mineral placer sands. Other REE ores are associated with Precambrian quartz-pebble conglomerate paleoplacers and alkaline magmatism (Castor and Hedrick 2006; Hoatson et al. 2011; Kynicky et al. 2012; Mariano and Mariano 2012).

The industrial applications of rare earth metals and compounds have greatly expanded over the past several decades (Castor and Hedrick 2006; Goonan 2011; Hoatson et al. 2011; Zaimes et al. 2015). Early applications were restricted to polishing agents, incandescent gaslight mantles, and coloring agents in glasses and ceramics. Currently, rare earths have a wide diversity of industrial uses, including (in approximate order of importance by volume) in permanent magnets (e.g., $Nd_2Fe_{14}B$ and $SmCo_5$ magnets); as catalysts in petroleum refining, automobiles, and various other industrial and chemical processes; in various metallurgical applications (e.g., steel and battery alloys); as polishing agents; as coloring agents in glasses and ceramics; and as phosphors in lighting and display screens (e.g., computers, television). Other minor but important uses include as components in lasers (e.g., Nd-YAG and Er-YAG lasers), microwaves (e.g., Y-Fe-garnets or YIG), satellites, chemicals and military systems. In terms of monetary value, applications in magnets, phosphors, and metals account for more than 80% of rare earth oxide markets.

Summary

The lanthanides (La-Lu), along with Y and Sc, comprise the rare earth elements (REE), that are among the most important trace elements for evaluating a wide array of geological processes. In geological settings, they are trivalent (except $Eu^{2+/3+}$ and $Ce^{3+,4+}$), electropositive, and refractory lithophile elements that, apart from Sc, are incompatible in most magmatic settings. In aqueous settings, they have low fluid/rock partition coefficients such that their concentrations in natural waters, along with their oceanic residence times, are very low. Dominant controls on geochemical and cosmochemical distributions are valence (including redox behavior), size and systematic variations in ionic radii (i.e., lanthanide

contraction), volatility, and complexing behavior. Radiogenic isotopes of REE (^{147}Sm-^{143}Nd, ^{176}Lu-^{176}Hf, ^{138}La-^{138}Ce, ^{146}Sm-^{142}Nd) are important geochronometers and isotope tracers. Rare earths are major constituents of >270 (mostly rare) minerals representing most mineral groups (silicates, phosphates, carbonates, etc.) and are mined mainly from hydrothermally altered carbonates, ion-adsorption clays, and carbonatites. Rare earths are strategic metals with wide industrial applications, including many in high technology.

Seawater Abundance: ≈30 picomole/kg
Core Abundance: unknown

Properties

Lanthanum is a soft and ductile metallic element with a silver-white color that rapidly tarnishes in air. It generally occurs as oxide and hydroxide and in substitution to major elements in minerals.

History and Use

Lanthanum was discovered in Stockholm (Sweden) in 1839 by C.G. Mosander who gave it the name of "latane" [Greek, lanthanein = to lie hidden] because it was "hidden" in cerium carbonate fluoride from the Bastnäs mine (Berzelius 1839). It was isolated only in 1923, almost 100 years later. Lanthanum gave its name to the lanthanide series (also called rare earth elements), a group of 15 similar elements between lanthanum and lutetium in the periodic table.

In the past, lanthanum was not widely used in industry, but the demand increased drastically with the onset of rechargeable batteries for hybrid automobiles.

Geochemical Behavior

Lanthanum, as other rare earth elements, is usually not a constituent of mineral phases on Earth. It is refractory and under most conditions is lithophile and found in the trivalent state. During partial melting and fractional crystallization of magmas, it behaves as an incompatible element and is concentrated in melts. It is therefore enriched in basalts relative to their mantle source and enriched in continental crust relative to Earth mantle. Together with the other rare earth elements, it is widely used in geochemistry to trace geological processes.

Geochronology

Lanthanum has two isotopes, ^{138}La (0.09017%) and ^{139}La (99.9098%). ^{139}La is stable; ^{138}La is radioactive and decays into ^{138}Ce with a half-life of ≈ 292.5 Ga, one of the longest of radioactive decay systems used in isotope geochemistry.

Biological Utilization and Toxicity

Lanthanum has no known biological role and has low to moderate toxicity.

Large-Ion Lithophile Elements

Catherine Chauvel[1] and Roberta L. Rudnick[2]
[1]ISTerre, University Grenoble Alpes, CNRS, Grenoble, France
[2]Department of Earth Science, University of California, Santa Barbara, CA, USA

Definition

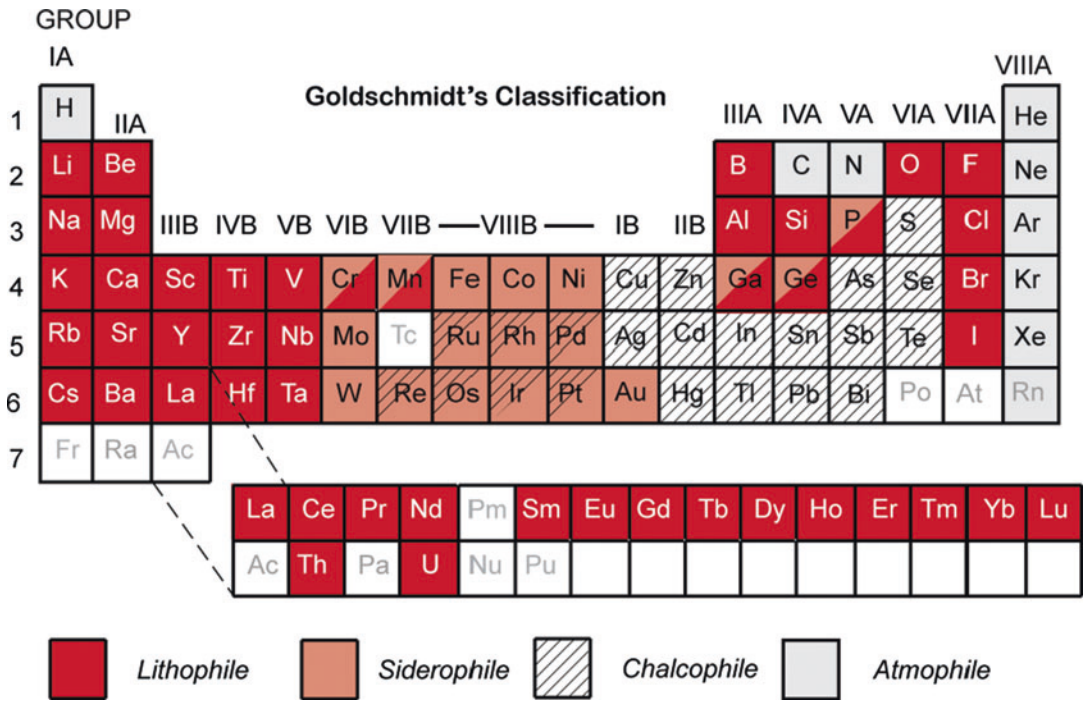
The term large-ion lithophile element (or LILE) is frequently used but poorly defined in the geochemical literature. The word "*lithophile*" comes from the classification of elements suggested by Goldschmidt over a hundred years ago. It describes elements that have an affinity for silicate phases in the Earth. As shown in Fig. 1 from White (2013), the lithophile elements are numerous and generally correspond to elements located at both ends of the periodic table.

The *large-ion* lithophile elements represent only a subset of these lithophile elements and refer to the trace elements characterized by large radius to charge ratio (or low field strength elements; see Fig. 2 below).

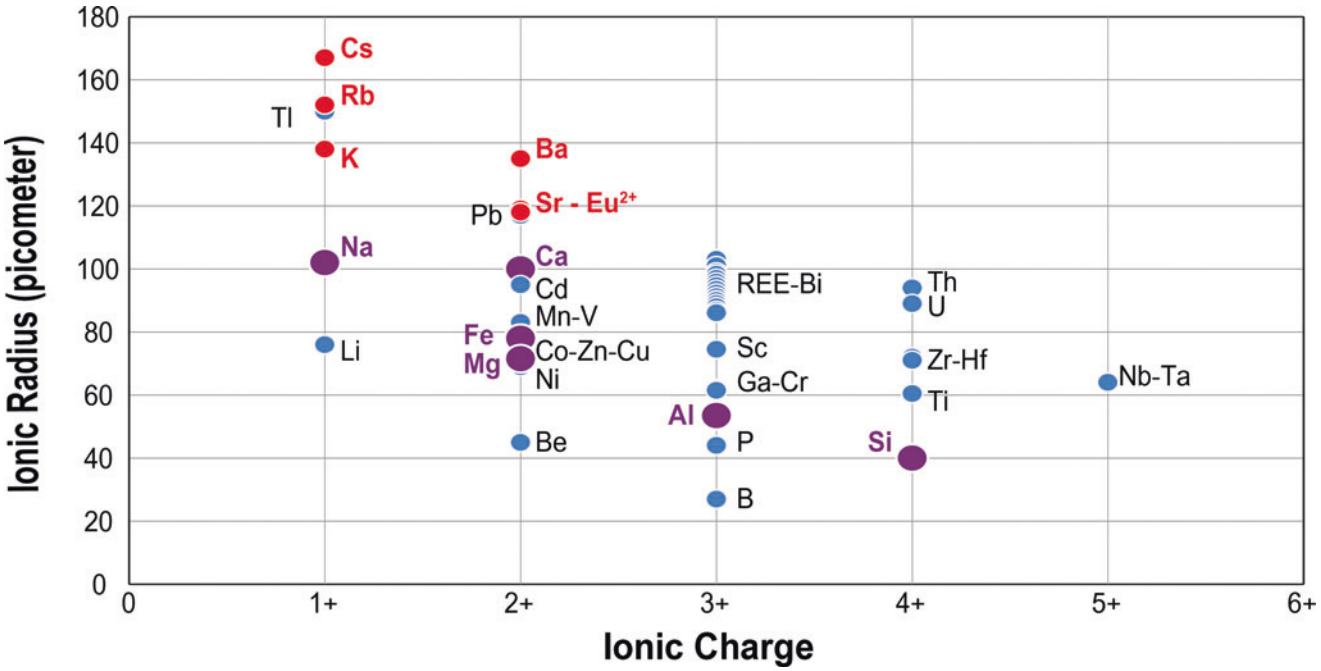
Origin of the Term and LILE Geochemistry

The term was first used by Gast (1972) to encompass the cations K, Rb, Sr, Cs, Ba, REE, Th, and U. Gast also included Li as a LILE, since it has a large radius to charge ratio, even though it is small. Because of the confusion in the literature regarding usage of LILE, it is recommended that the term be restricted to lithophile trace elements having large radius to charge ratios and which also have ionic radii greater than those of Ca^{2+} and Na^{1+} (100 and 102 picometers), the largest cations common to rock forming minerals. By this definition, the list of LILE is restricted to K, Rb, Sr, Cs, Ba, and Eu^{2+}.

Because of their large radii, LILE behave incompatibly (see entry ► "Incompatible Elements") during mantle melting and so are highly enriched in mantle melts relative to their source. They are enriched in intraplate basalts (Hofmann 1997) and island arc basalts (Kelemen et al. 2014) relative to more compatible trace elements, but they are depleted in mid-ocean ridge basalts, demonstrating that these lavas derive from a mantle source that experienced prior melt extraction (see entry ► "Mantle Geochemistry"). The LILE are strongly enriched in the upper continental crust (Rudnick and Gao 2014) but occur in lower concentrations in the deep continental crust due to its overall more mafic character and selective loss of some LILE during high-grade metamorphism (see



Large-Ion Lithophile Elements, Fig. 1 Goldschmidt's classification of the elements (From White 2013)



Large-Ion Lithophile Elements, Fig. 2 Ionic radius versus ionic charge diagram showing the LILE in *red*. Major cations are shown in large *purple* symbols and other trace elements are shown as small *blue* symbols

entry ▶ "Earth's Continental Crust"). Between 15–55% of the Earth's LILE budget is found in the continental crust (Rudnick and Fountain 1995).

Summary

The recommended list of large-ion lithophile elements is K, Rb, Sr, Cs, Ba, and Eu^{2+}.

Laser Ablation – Inductively Coupled Plasma Mass Spectrometry

Takafumi Hirata
Geochemical Research Center, The University of Tokyo, Tokyo, Japan

Definition

Mass spectrometers utilizing atmospheric pressure Ar-ICP as an ion source (ICP-MS) have been widely used for both element and isotopic analyses for geochemical samples such as rocks, minerals, aquatic solutions, as well as gaseous samples. Since the ICP is operating under atmospheric pressure, various sample introduction techniques can be applied for analysis. Among these, the laser ablation sampling technique is likely to become

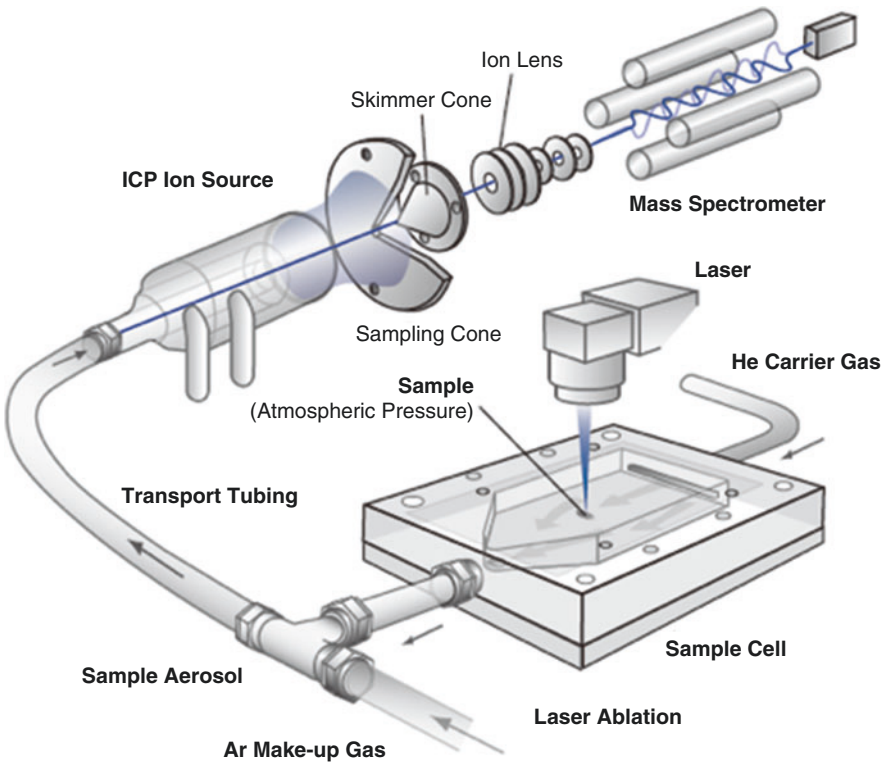
a method of choice for many geochemists because it is a highly sensitive and versatile method of elemental and isotopic analyses. Laser ablation is the process of removing materials from the surface of solid materials by the irradiation of a laser beam. Laser-induced sample aerosols and vapors will be introduced to the ICP, and the ionized elements are extracted into a high-vacuum and separated by mass. With the LA-ICPMS technique, direct elemental and isotopic analyses can be made without chemical decomposition or dissolution procedures. Moreover, analytical capability for in situ elemental and isotopic analyses can be made in various spatial resolution, ranging from 1 to 1000 μm. The LA-ICPMS technique has opened up new applications for geochemistry, such as in situ stable isotope studies, in situ isotope dating, and simultaneous mappings for major to trace elements (imaging mass spectrometry).

Introduction

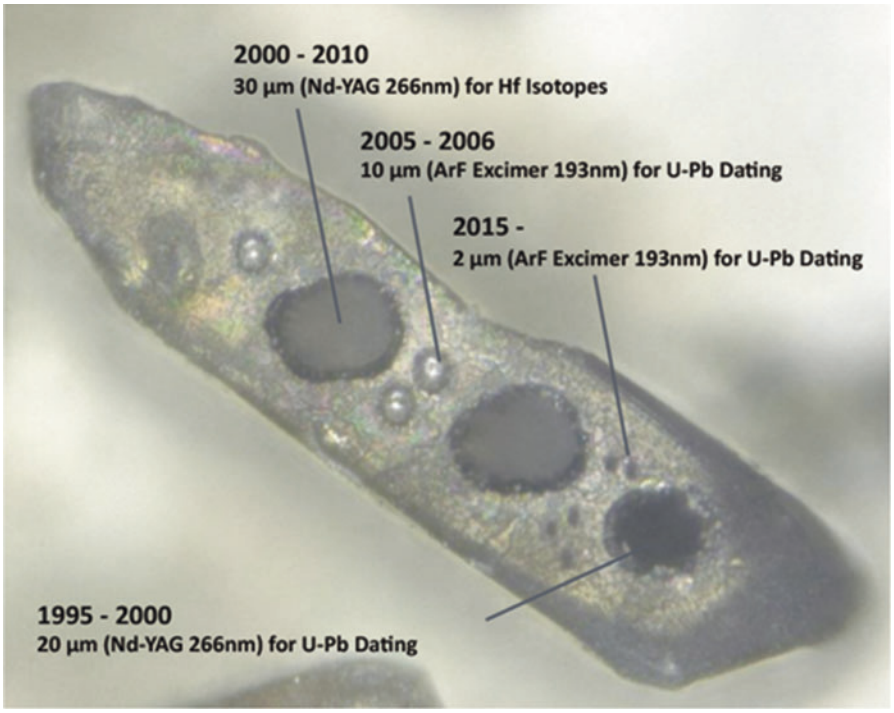
The mass spectrometric technique utilizing inductively coupled plasma as an ion source (ICP-MS) has been widely used for both abundance and isotope ratio measurements (e.g., Niu and Houk 1996; Hattendorf et al. 2003; Becker 2007). The basic advantage of the ICP-MS lies in the ion source, which achieves nearly complete ionization efficiency for almost all elements compared to other mass spectrometry techniques, such as thermal ionization mass spectrometry (TIMS) or secondary ion mass spectrometry (SIMS). The ICP high ionization efficiency can be achieved through both the charge-exchange reaction ($Ar^+ + M \rightarrow Ar + M^+$) and electron impact reaction ($M + e^-_{(fast)} \rightarrow M^+ + e^-_{(slow)}$). Moreover, long residence time of the sample in the ICP (i.e., >10 msec) results in smaller contribution of nonmass spectrometric interferences (e.g., matrix effect), providing high quantitative capability for elemental analysis.

The ICP ion source has further analytical advantages as it is possible to analyze dry sample aerosols produced by the laser ablation technique. The laser ablation technique is one of the most versatile solid sampling techniques for the ICP-MS (Durrant 1999; Günther and Hattendolf 2005). The interaction of laser beam with solid materials induce various effects including surface heating and melting to ejection of sample material. The material is released from solid materials as vapor, molten droplets, solid particulates, and its agglomerates. The laser-induced sample particles or vapors are introduced into the ICP, operating at atmospheric pressure, and the produced ions are extracted into the vacuum region through a vacuum interface (Fig. 1). Analytes are separated from major constituents through mass spectrometers, including a magnetic sector (MS), quadrupole (Q), or time-of-flight (TOF)-type mass spectrometers (e.g., Duckworth et al. 1986; Wieser and Schwieters 2005).

Signal intensity for analyses is dependent upon both the concentration and the total amount of sample released. Numerous laser parameters can affect the signal response, and the data quality is influenced by laser types, experimental



Laser Ablation – Inductively Coupled Plasma Mass Spectrometry,
Fig. 1 Schematic diagram of laser ablation-ICP-mass spectrometer. When focused laser beam with sufficient energy is directed onto the sample, material or constituent elements from surface will be explosively sputtered and evaporated. The laser-induced sample particles or vapors will be transported in mixture of He and Ar gas to the ICP for atomization ionization



Laser Ablation – Inductively Coupled Plasma Mass Spectrometry,
Fig. 2 Comparison of the ablation pit size for in situ isotope chronology. Progresses in the LA-ICPMS technique can be well demonstrated by the size of ablation pits. With increasing of both the elemental sensitivity of the ICPMS system and better understanding of the mechanism for the laser ablation, smaller ablation pit size can be adopted for in situ elemental and isotopic analyses for geochemical samples (Sample: PMA7, courtesy of Dr. Jean Jacques Peucat, Univ. Rennes, France)

settings, or calibration strategy. Continuous improvements in enhancing the elemental sensitivity of ICP-MS instruments, together with a better understanding of the mechanism of the laser ablation process, have led to successive enhancements in both data quality and spatial resolution for in situ analysis (Fig. 2).

Multi-Element Determinations

The LA-ICPMS technique has been widely used for rapid multielement determinations for major to trace elements in rocks or minerals (e.g., Hattendorf et al. 2003; Jochum et al. 2007; Fricker et al. 2011; YongSheng et al. 2013). Typical size of the laser ablation pit, adopted for the elemental analysis, ranges from approximately 20–60 µm. Despite the slightly poor spatial resolution, the LA-ICPMS technique has major advantages on the elemental sensitivity, compared to the conventional probe techniques, including electron probe microprobe analyzer (EPMA) or micro-X-ray fluorescence (µXRF) techniques (e.g., Weiss et al. 2008).

Limits of detection and the resulting precision of the measurements are significantly influenced by three major parameters: (a) matrix effect, (b) particle size distribution of laser-induced same particles, and (c) mass spectrometric inferences by isobaric ions or polyatomic ions (Longerich et al. 1996; Günther et al. 1997; Kozlov et al. 2003; Koch et al. 2006). Among these, size distribution of the laser-induced sample particles is one of the most important parameters to achieve better precision and accuracy of the measurements (Koch et al. 2004; Kuhn et al. 2004). For geochemical samples, UV wavelength lasers, such as ArF Excimer laser (193 nm) or Nd:YAG 5HG (213 nm), can produce smaller size distribution of the sample particles, which result in higher atomization and ionization efficiency in the ICP. Moreover, with the smaller sample particles, a smoothed signal intensity profile can be obtained, resulting in higher precision in the elemental analysis. With UV laser and with ablation pit of 30–40 µm, typical detection limits of better than 10 ng/g can be achieved by the LA-ICPMS system.

The limits of detection for trace elements in silicates or ceramic materials are generally superior to those for the elements in metallic materials. The lower signal response from metallic materials is mainly due to reduced ablation yield, which is caused by the energy loss through high-thermal conductivity of the metallic materials. Moreover, incomplete heating results in the release of molten particles from solid samples or preferential release of the volatile elements from the samples (i.e., large elemental fractionation during the laser ablation), which can be a major source of analytical error. To minimize the elemental fractionation during the laser ablation, the use of shorter pulse duration could be the best solution as the rate of thermal diffusion for metallic materials (e.g., >10 ps) is significantly longer than the typical pulse duration achieved by femtosecond lasers (10–500 fs) (Koch et al. 2004, 2006; Hirata and Miyazaki 2007). Smaller contribution of the laser-induced heating onto the sample materials can result in minimal size-related elemental fractionation during the laser ablation. With femtosecond lasers, signal responses obtained from metallic Cu improve by a

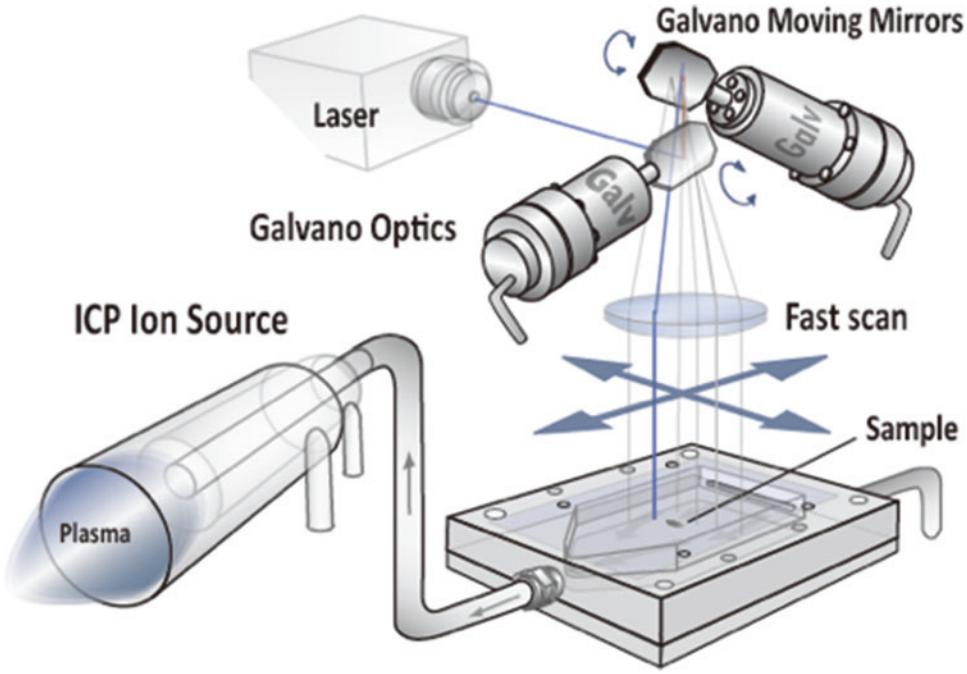
factor of 20, compared with that obtained with conventional nanosecond lasers (Zeng et al. 2004; Horn and Blanckenburg 2007; Hirata and Kon 2008).

Quantification Protocol

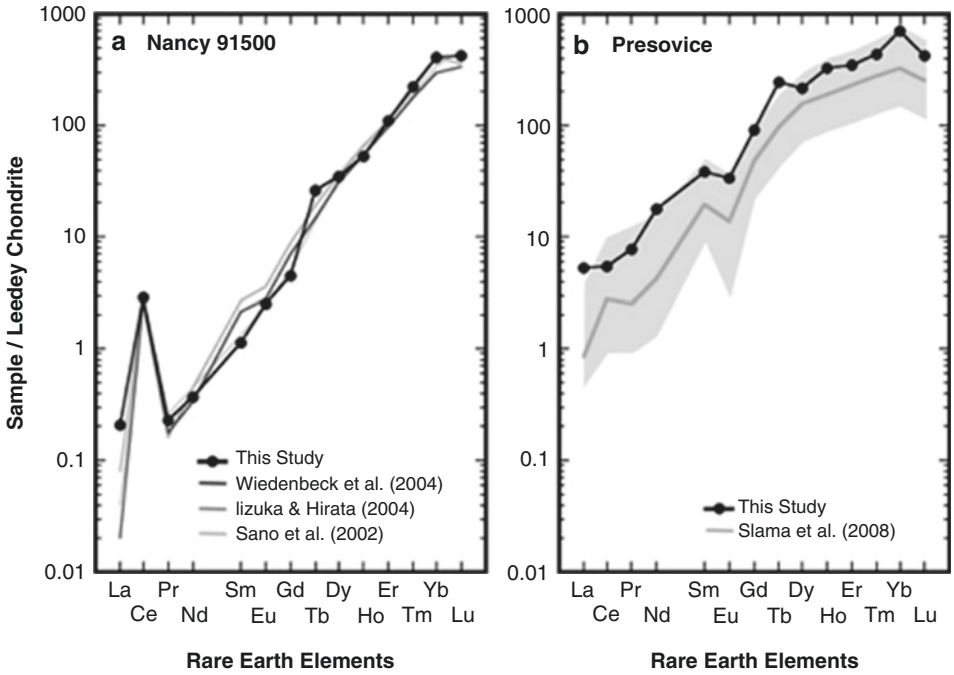
The LA-ICPMS technique has further analytical advantages as it is less sensitive to the matrix effect (non-mass spectrometric interferences) for the analytes. The smaller contribution of the matrix effect is mainly related to two factors. (1) A long-residence time for the ionization process within the ICP with typical time duration for the sample particles exceeding 10 ms, which is significantly longer compared to most other ion sources adopted for the mass spectrometer. (2) Post-ionization system setup in the LA-ICPMS technique as the sampling (laser ablation) and ionization processes are separate steps. This implies that laser operational settings and ionization conditions can be optimized independently. In fact, qualitative or semiquantitative analysis can be made with a nonmatrix matched calibration standard. Nevertheless, it should be noted that the matrix-matched calibration standard is highly desired for elemental and isotopic analysis of solid geochemical materials.

Availability of a calibration standard is a key issue to obtain reliable elemental and isotopic data. For the LA-ICPMS technique, matrix-matched standards have been widely used for the calibration. However, data traceability cannot be maintained based on an inhouse standard, in which the evaluation of heterogeneity would be difficult. To overcome this, calibration using the synthetic glass standards (e.g., USGS BCR-2G, BHVO-2G, BIR-1G etc.), NIST SRM glasses (e.g., NIST SRM610, 612, or 613 etc.) or MPI-DING (MPI-DING glasses KL2-G, ML3B-G, StHs6/80-G, GOR128-G etc.), combined with internal standardization using major-minor elements (e.g., Ca, Si, P, or Sr) is a widely adopted analytical approach (e.g., Myers et al. 1995; Pearce et al. 1997; Jochum et al. 2005; Jochum et al. 2006). Typical precision or accuracy of the abundance measurements ranges from 1% to 20% with a spatial resolution of 30 μm. One of the major sources of the analytical error is the counting statistics, and therefore, great care must be given to control the number of analytes. Although longer ablation can reduce the contribution of counting statistics for the analytes, laser ablation with high aspect-ratio craters (i.e., deep ablation pit) can induce elemental fractionation during analysis (e.g., down-hole fractionation) (Hirata and Nesbitt 1995; Horn et al. 2000). To obtain reliable abundance data, data acquisition must be made with a minimal number of analytes and short-time duration for the laser ablation.

Several additional techniques can be applied for quantitative analysis. Isotope dilution represents an important choice for elemental determinations. For the LA-ICPMS technique, mixing of analytes and enriched-isotopes can be achieved by mixing of laser-induced aerosols released from a sample and standard, which contains the selected enriched isotopes. This can be achieved by applying galvanometric optics (Fig. 3), which is utilizing a pair of two moving mirrors. The position of the laser ablation can be moved by changing the angle of the mirrors. With galvanometric optics, ablation points can be jumped with a time interval of 10 ms or shorter, and therefore, the simultaneous laser ablation for two or more solid materials



Laser Ablation – Inductively Coupled Plasma Mass Spectrometry,
Fig. 3 Schematic diagram of galvanometric optics for LA-ICPMS. Galvanometric optics consists of two moving mirrors. Ablation points can be moved by adjusting the angle of two mirrors. With the LA system equipped with the galvanometric optics, two or more sample can be ablated nearly at the same time. This suggests that analytes in the different solid materials can be mixed



Laser Ablation – Inductively Coupled Plasma Mass Spectrometry,
Fig. 4 Determination of rare earth elements (REE) in zircon samples by means of the standard addition technique. With the galvanometric optics, standard addition technique can be applied for the elemental determinations. The particles released from sample was mixed with the particles released from standard materials, and mixed particles were then introduced into the ICP ion source (Yokoyama et al. 2011)

can be obtained. The sample aerosols released from two or three samples are well mixed in the laser ablation cell, and the mixed aerosols are introduced into the ICP. Based on the signal intensity data for isotopes, the element concentrations can be defined (Fernandez et al. 2008; Heilmann et al. 2009).

With the galvanometric optics, a standard addition method can also be applied by mixing of aerosols released from sample and standard references. The mixing ratio (sample: standard) can be controlled by changing the number of laser shots for each component. Abundances of rare earth elements (REE) in natural zircon samples can be determined by the standard addition technique by mixing of REEs from glass standard material (Fig. 4) (Yokoyama et al. 2011). The galvanometric optics can provide flexible calibration protocols for elemental analysis, where no proper (matrix-matched) calibration standard is available (Fig. 4).

In Situ Isotope Ratio Measurements

Precision and accuracy in isotope ratio measurements can be dramatically improved by the multiple collector system setup adopted in the magnetic sector based ICP-mass spectrometry (MC-ICPMS) (e.g., Albarède et al. 2004; Walczyk 2004). Combination of LA and MC-ICPMS techniques (LA-MC-ICPMS) enables to detect small variations in the isotope ratios of elements in small minerals or inclusions (Iizuka and Hirata 2005; Horn and Blanckenburg 2007; Nishizawa et al. 2010). For in situ isotope ratio measurements, several key parameters, such as size distribution of the aerosols, aspect ratios, aerosol transport efficiencies, ionization efficiencies in the plasma and/or laser-induced isotope fractionation, must be considered to obtain reliable isotope ratio data (Jackson and Günther 2003; Hirata 2012).

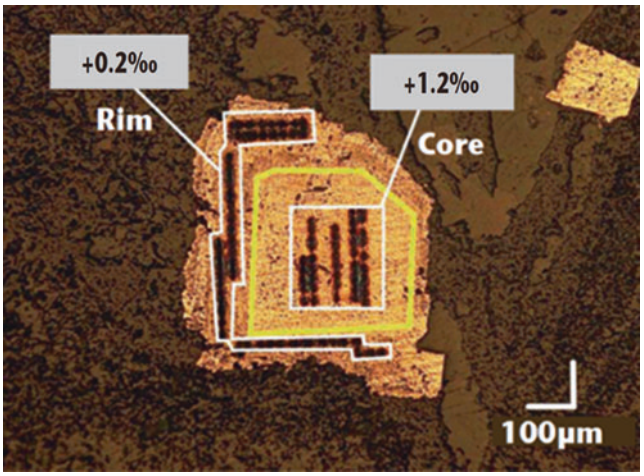
Similar to the elemental analysis, advances in laser ablation utilizing shorter wavelength and shorter pulse duration lasers (i.e., femtosecond lasers) provide better analytical results (Guillong et al. 2003; Koch et al. 2006; Russo et al. 2013). With the UV wavelength laser ablation, particle size distribution can be modified toward smaller, and therefore, stable signal intensity profiles. Smoother signal intensity profile is essential for isotope ratio measurements using Faraday collectors caused by slow response of the Faraday amplifier. With unstable or transient signals, the measured isotope ratios can deviate from the accurate ratios (Hirata 2012). To overcome this, analysis of smaller size distribution of the sample particle is important (Guillong and Günther 2002). Introduction of smaller particles results in smaller changes in the plasma conditions, such as kinetic temperature, electron density, or plasma potential. Moreover, with a femtosecond laser ablation, the efficiency of energy transfer from laser photons to electrons in solid samples can be dramatically improved (Hirata and Kon 2008; Poitrasson et al. 2003; Russo et al. 2002). This leads the release of smaller particles from samples. This results in both a stable signal intensity profile and smaller changes in elemental sensitivity and/or mass bias factors for the isotope ratio measurements. With the combination of fs-laser ablation and MC-ICP-MS, a precision of better than 0.1‰ can be achieved for most Fe and Cu-rich materials (e.g., metal, oxide, or sulfide). The resulting precision of the isotope ratio measurements is significantly better than the natural variations in the $^{56}Fe/^{54}Fe$, $^{65}Cu/^{63}Cu$

or $^{98}Mo/^{95}Mo$ ratios (e.g., Horn et al. 2000; Ikehata et al. 2008). The major advantage to use the LA-MC-ICPMS is the reliable and inherent isotopic signature that can be derived from a specific small sample area, avoiding the risk of analysis from secondary growth regions or contaminated areas (e.g., Nishizawa et al. 2010; Yoshiya et al. 2015a, 2015b) (Fig. 5).

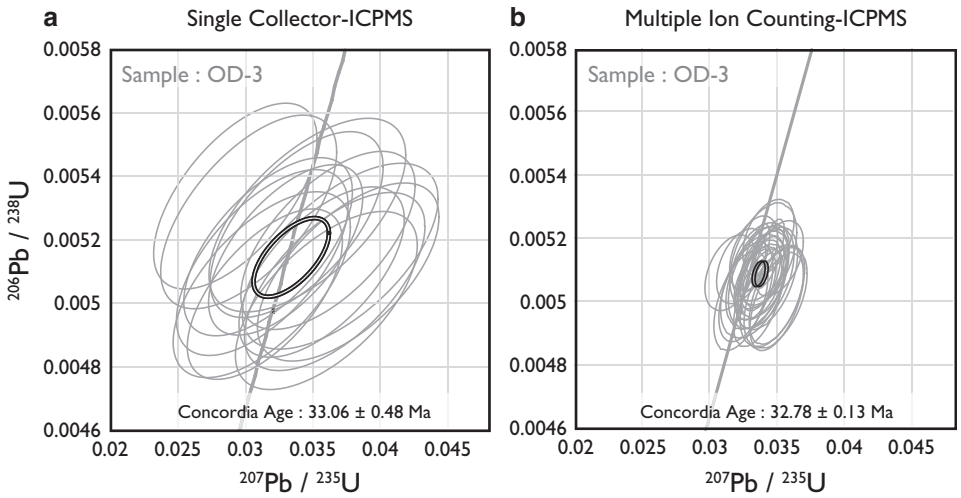
In Situ Dating

Applications of several isotope chronometers have been developed by the MC-ICPMS technique comprising the Lu-Hf, Hf-W, and U-Pb isotope chronometers. High ionization efficiency can be achieved by the ICP ion source, and precise and accurate isotopic analyses from small sample size can be obtained by the MC-ICPMS (Thirlwall and Walder 1995; Tiepolo 2003; Iizuka and Hirata 2004, 2005; Snow and Friedrich 2005). Even for more conventional isotope chronometers, such as Rb-Sr, Sm-Nd, and U-Pb dating by TIMS analysis, the MC-ICPMS technique has become a major tool for the measurements as the MC-ICPMS enables a higher sample throughput and simpler chemical separation procedures. In fact, MC-ICPMS has been widely applied for the fast and precise Nd and Hf isotope ratio measurements (e.g., Woodhead 2002; Sims et al. 2008; Be'eri-Shlevin et al. 2010). The ICP-MS technique is now one of the principal methods for isotope analysis for geochronological studies.

For the U-Pb dating method, the isotopic composition of Pb can vary widely due to contribution of radioactive decay of ^{232}Th, ^{235}U, and ^{238}U, by reflecting both the Pb/U and Pb/Th ratios and the age of the samples. Because of small contribution of mass spectrometric interferences onto the Pb, Th, and U isotopes, single collector-based ICP-MS instrument were widely used for the U-Th-Pb age determinations (Hirata and Nesbitt 1995; Crowley et al. 2005; Tiepolo 2003; Simonetti et al. 2005; Cottle et al. 2009; Woodhead et al. 2009; Schaltegger et al. 2015). The resulting precision and accuracy of the U-Th-Pb age determinations can be further improved by a multiple-collector system setup (Jackson et al. 2004). The MC-ICPMS instruments, equipped with a multiple ion counting system setup, can improve the precision of the age determination (Fig. 6), and the data quality achieved by the LA-ICPMS technique is comparable or enhanced compared to those obtained by secondary ion mass spectrometry (SIMS), including SHRIMP-type instruments (Ireland and Williams 2003; Rasmussen et al. 2004; Holden et al. 2009). Moreover, the analysis time for U-Th-Pb age determinations can be significantly reduced by a multiple ion counting system setup to 1–10 sec/spot with shorter analysis time enabling to obtain an age distribution of the zircons collected from a sample (Hattori et al. 2017; O-bayashi et al.



Laser Ablation – Inductively Coupled Plasma Mass Spectrometry, Fig. 5 In situ $^{56}Fe/^{54}Fe$ isotope ratio data obtained from core and rim of the single pyrite grain. Pyrite grain shown here consists of two domains: core and rim. With the LA-MC-ICPMS technique, Fe isotope signature from distinguished can be derived (Nishizawa et al. 2010)



Laser Ablation – Inductively Coupled Plasma Mass Spectrometry, Fig. 6 Comparison in the resulting precision of the Pb/U ratio measurements between single collector-ICPMS and multiple ion counting-ICPMS. With the LA-ICPMS technique combined with multiple ion counting technique, the resulting precision of the U-Pb ages can be dramatically improved. Moreover, total analysis time can be shortened, obviating the laser sampling with high aspect ratio (i.e., deep drilling). Sample is OD-3 standard zircon (Iwano et al. 2013)

2017). This analytical approach allows to decipher the contribution of multiple geological events or multiple sources of the zircons. The "age distribution" is a useful and conventional approach to understand the geological sequence underlying the sample formation. Advantage of the age distribution analysis can be well demonstrated by the growth rate of the continental crust based on the U-Pb ages and Lu-Hf isotope systematics derived from >500 to 20,000 zircon grains (Rino et al. 2004; Iizuka et al. 2006).

With shorter duration time for the laser ablation, the resulting depth of the ablation pit can be smaller than 1 μm, and therefore, age determinations from thin-layer rim of zircon crystal can be made. Schmitt (2011) reported that the U-Th-Pb age derived from the outer rim (<5 μm) of the zircon crystals can reflect the timing of overgrowth through eruption processes (Schmitt 2011). This means that multiple chronological information can be derived from a single zircon grain. With the shorter ablation time achieved by the MC-ICPMS system setup, precise U-Th-Pb ages can be derived from the depth of shallower than 1 μm. This technique can be applied for geochemical evolution processes within magma chambers by determining the difference between crystallization of the zircons and timing of eruption, and thus the U-Th-Pb ages obtained from the rim of zircon crystals can reflect low-temperature geological events (e.g., Rasmussen et al. 2004; Schmitt 2011; Sakata et al. 2017).

Imaging

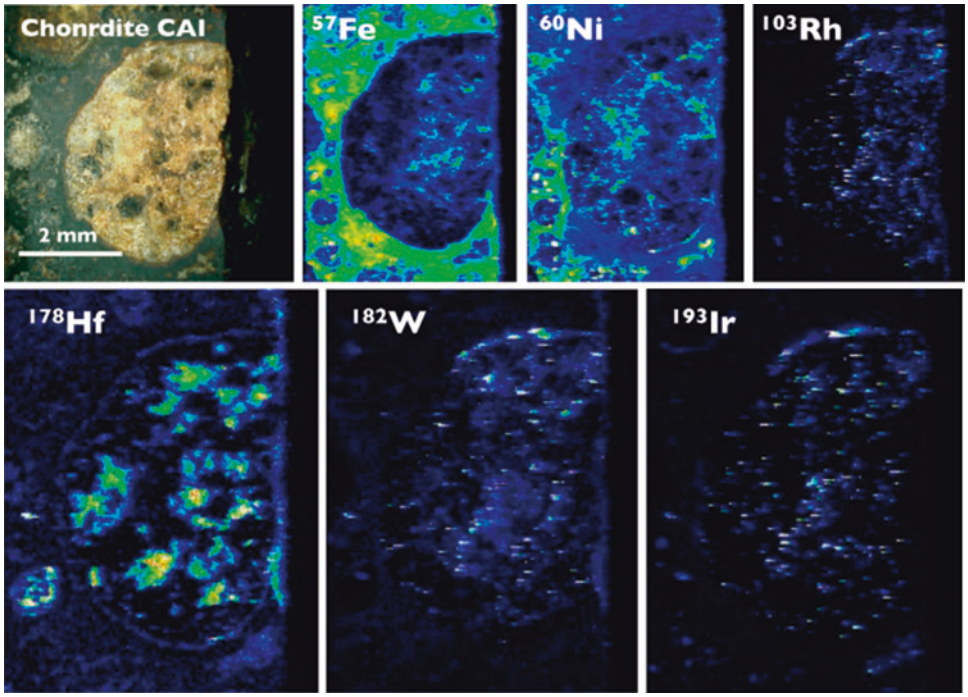
Images of trace elements or isotopes can provide key information to evaluate the contribution of metamorphic events or movements of elements through secondary heating events. The LA-ICPMS technique is a useful tool to obtain image data of major to trace elements from samples. Elemental and isotope images can be obtained by repeated analysis of line-scanning measurements using the LA-ICPMS technique. Time resolved-signal intensity profile obtained by laser rastering can be converted to a position based-signal intensity profile via the relationship between the rastering rate and the elapsed time. The resulting spatial resolution and the elemental sensitivity is dependent upon several key operational parameters such as size of laser beam, raster rate, and time slice of the data acquisitions (i.e., dwell time for each analytes). Typically laser beam size of 1–100 μm is used for imaging analysis. The LA-ICPMS technique is highly sensitive to determine the abundance of the trace elements (e.g., Ghazi et al. 2002; Durrant 1999; Russo et al. 2013). One of the main advantages to use the LA-ICPMS technique for imaging analysis is that the sample is located under atmospheric pressure, and neither evacuation of the sample housing nor coating with conductive materials is required. Moreover, because of both the minimum sample preparation and the postionization system configurations, the LA-ICPMS technique represents a fast and accurate method for quantitative imaging technique for trace elements from biochemical or geochemical samples (e.g., Jackson et al. 2006; Lobinski et al. 2006; Zoriy et al. 2007; Becker 2007; Becker et al. 2010; Hare et al. 2011; Gordalíza et al. 2011; Konz et al. 2011).

Another important feature of the elemental imaging using the LA-ICPMS technique is the analytical capability for large-sized samples (>10 mm). This is of crucial importance to secure a bridge between the microscopic and macroscopic realm in geochemical studies. The elemental imaging for trace elements is an essential tool to derive inherent information from samples. Figure 7 illustrates an example of the mapping image for ^{57}Fe, ^{60}Ni, ^{103}Rh, ^{178}Hf, ^{182}W, and ^{193}Ir isotopes obtained from calcium and aluminum-rich inclusion (CAIs) in chondrite material, demonstrating a clear difference of the distribution pattern for these isotopes. Difference in the distribution pattern of the isotopes can reflect the cosmochemical features of the elements. Moreover, the images suggest possible contribution of a re-distribution or secondary movement of these elements through heating or weathering. In addition, difference or similarity in the distribution pattern of the elements may provide key information concerning the status of system closure for chronologies.

Several alternative analytical techniques, such as EPMA, SIMS, or μXRF, can be applied for in situ imaging analysis. The SIMS technique allows both high sensitivity and high-spatial resolution (e.g., Chandra and Morrison 1995; McDonnell and Heeren 2007; Becker et al. 2010), whereas the μXRF technique has been recognized as one of the most reliable imaging techniques for the trace elements (Matsuyama et al. 2006; Fukuda et al. 2008; Donner et al. 2011). Despite the unique features of these techniques, they are time-consuming and therefore less suitable for the routine high throughput analysis. More importantly, these techniques are not suitable for imaging analysis for large-sized samples (> 1 mm). The LA-ICPMS technique is likely to become a significant, quantitative, and cost-effective tool for elemental and isotopic imaging, as it is highly user friendly and an efficient method for supplementary in situ imaging.

Summary and Conclusions

The laser ablation-inductively coupled plasma mass spectrometry (LA-ICPMS) technique is widely accepted as one of the most advanced, sensitive, and rapid analytical tools for elemental and isotopic analysis of solid materials. The continuous development of the LA-ICPMS techniques has provided precise elemental and isotopic data. With a better understanding of the mechanism of the laser ablation process, and with a higher elemental sensitivity of the LA-ICPMS technique, the precision of the isotopic ratio



Laser Ablation – Inductively Coupled Plasma Mass Spectrometry, Fig. 7 Isotope imaging for trace elements in CAI. With the LA-ICPMS technique, the elemental and isotopic mapping analyses can be made on various geochemical materials of various sizes (μm scale to mm scale). This is very important to evaluate the contamination, secondary movement of the elements, and/or system closure of the minerals

measurement has successively improved, and new applications were developed in various research fields such as bioscience, material science, and archeological science. Despite its success, it should be noted that there still remain several possible cause for the analytical error such as elemental fractionation occurring during laser ablation, or the limited spatial resolution and elemental sensitivity for the analytes achieved by the LA-ICPMS technique. The complexity in the physical and chemical processes related to the laser ablation of solid samples has prevented a detailed understanding of the elemental and isotopic fractionation induced by laser ablation, and therefore, both the instrumental developments and understanding of further detailed mechanism for the laser ablation would be still a key issue to improve the data quality. Continuous technological developments will enable new analytical methodologies to derive geochemical information from the samples. Based on the rapid growth in analytical capabilities demonstrated in last decade, a realistic prospect is that the LA-ICPMS technique has immediate potential as a reconnaissance method for both the in situ stable isotope geochemistry or isotope chronology. Now the LA-ICPMS technique has evolved into a unique analytical approach, not the alternative choice.

Element Data
Atomic Symbol: Pb
Atomic Number: 82
Atomic Weight: 207.2 g/mol
Isotopes and Abundances: ^{204}Pb 1.4%, ^{206}Pb 24.1%, ^{207}Pb 22.1%, ^{208}Pb 52.10%
^{210}Pb traces, radioactive ($t_{1/2} > 22.3$ yr)
^{205}Pb synthetic
1 Atm Melting Point: 327.5 °C
1 Atm Boiling Point: 1749 °C
Common Valences: 2+, 4+
Ionic Radii: 116 pm and 129, in 6-fold and 8-fold coordination respectively
Pauling Electronegativity: 2.33
First Ionization Potential: 715.6 kj/mol
Chondritic (CI) Abundance: 1–2.4 ppm
Silicate Earth Abundance: ~0.1–0.2 ppm
Crustal Abundance: 14 ppm
Seawater Abundance: 0.03 ppb
Core Abundance: ~0.5 ppm

Properties

Because it has a "magic number" of protons (82), the lead nucleus is particularly stable and is the end product of three separate radioactive decays. The most common valence state of lead is +2, with the +4 valence state being less stable.

Lead belongs to group 14 in the periodic table that together with C, Si, Ge, and Sn shows different chemical properties.

Lead can be sometimes found free in nature, but is mostly mined from the ores galena (PbS), anglesite ($PbSO_4$), cerussite ($PbCO_3$), and minum (Pb_3O_4). Lead is easily mined and refined, and is not considered to be a rare element, even with an abundance of only about 0.0014% in the Earth's crust. Most lead has been obtained by roasting galena in hot air, although more recently, nearly one third of the lead used in the United States is derived through recycling efforts.

History and Use

Together with tin (also a member of group 14), lead has been known since the antiquity. The two letters for the symbol for lead come from the Latin name: plumbum (i.e., waterworks). It is a soft, malleable, and corrosion-resistant material, easily worked into sheets. There is evidence for its use going back almost 6000 years. Hippocrates and Pliny already documented evidence of lead poisoning (Hernberg 2000). The ancient Romans used lead to make water pipes, some of which are still in use today. Because lead is a cumulative poison, the decline of the Roman Empire has been blamed, in part, on lead in the water supply (Nriagu 1983; Delile et al. 2014).

Even if the lead abundance in the Earth's crust is relatively low, lead has been mined for centuries and disseminated throughout the environment; living organisms gradually have incorporated it in their tissues, where it accumulates.

Lead is used to line tanks that store corrosive liquids, such as sulfuric acid (H_2SO_4). Lead's high density makes it useful as a shield against X-ray and gamma-ray radiation, and it is used in X-ray machines and nuclear reactors. Lead is also used as a covering on some wires and cables to protect them from corrosion, as a material to absorb vibrations and sounds and in the manufacture of ammunition. Most of the lead used today is used in the production of lead-acid storage batteries as lead dioxide (PbO_2), such as the batteries found in automobiles.

Lead also forms alloys, several of which are widely used. Conventional solder is an alloy consisting of nearly 50% lead and 50% tin that has a relatively low melting point and is used to join electrical components, pipes, and other metallic items. Type metal is an alloy made of lead, tin, and antimony used to make the type used in printing presses and plates. Babbitt metal, another lead alloy, is used to reduce friction in bearings.

Lead forms many useful compounds that have been used extensively through the years. Litharge is lead monoxide (PbO) and a yellow solid used to make some types of glass, such as lead crystal and flint glass, in the vulcanizing of rubber and as a paint pigment. Lead compounds have been used in various types of paints. The use of lead carbonate in paints has largely been stopped in favor of titanium oxide (TiO_2).

Lead arsenate ($Pb_3(AsO_4)_2$) has been used as an insecticide although other, less harmful, substances have now largely replaced it. Lead nitrate ($Pb(NO_3)_2$) is used to make fireworks and other pyrotechnics. Lead silicate ($PbSiO_3$) is used to make some types of glass and in the production of rubber and paints.

To improve combustion, lead has been used in petrol as an antiknock additive in the form of tetraethyl lead (TEL) and tetramethyl lead (TML). This has represented one of the most

dispersive sources of lead into the environment and into humans because the tiny particle size ensures efficient pulmonary penetration and adsorption. Increased levels of petrol lead can be traced all the way into the Arctic and Antarctica. This source of lead into the environment has been drastically reduced over the years, since the introduction of catalytic converters (1975 in the United States, 1990 in France, 1993 in the United Kingdom) that could not operate with leaded gasoline.

Clair C. Patterson, while working on Pb isotope systematics to establish the absolute age of the Earth in the mid-1960s, discovered the extent of Pb pollution related to its use as an antiknock additive in gasoline (Patterson 1965). He went on a campaign, both in the United States and internationally to quantify the issue, including by coring ice sheets in Greenland and Antarctica and documenting that recent human bones had lead levels much higher (by 1000 times) than the *Homo sapiens sapiens* (Patterson et al. 1991).

Geochemical Behavior

Lead is a relatively volatile element, so it is anticipated that its concentration in the Earth is lower than in chondrites. Lead is a chalcophile element, and it is possible that if the core contains S, it might also contain some Pb. Due to lead's relatively large ionic size, it is an incompatible element, in the range of the incompatibility of the rare Earth elements and not as much as Th or U. Galena is the most common Pb mineral, whereas in silicates, Pb can substitute for K, especially in alkali feldspar.

The element concentration of Pb has been used to constrain the composition and evolution of the Earth's mantle. Most mantle-derived rocks (OIB and MORB) have uniform Ce/Pb ratios ~ 25 that are different from bulk Earth values and also significantly higher than in the continental crust. This indicates that the mantle source of OIB (and MORB) cannot be primitive (Hofmann et al. 1986).

The distribution of Pb in the oceans, together with Al, is distinctive as these two elements are depleted in deep waters relative to surface waters. Studies of the fate of Pb in the open-ocean environments can be used to model ocean metal transport and reactivity (Pb has a high particle reactivity and is scavenged onto particles). In addition, because of Pb high volatility, especially at high temperatures, anthropogenic uses have distributed Pb everywhere on the planet and also in the world oceans (Boyle et al. 2014). With Pb isotope distinctive fingerprinting capability, it is possible to trace the source of contamination and build circulation models and pollutant pathways.

Lead isotopes are extremely useful in geochronology and geochemistry. Three decay systems (^{232}Th,^{238}U, and^{235}U) end in three different Pb isotopes, respectively,^{208}Pb,^{206}Pb, and^{207}Pb. This makes the dating of zircon, a very resistant mineral on Earth, one of the powerful geochronometer available to date geological events in a distant past. With the combination of three isotopic ratios and the recent improvements in analytical techniques allowing to measure isotopic compositions with a better precision, Pb isotopes constitute a powerful tracer in mantle geochemistry, in crustal and planetary evolution.

Biological Utilization and Toxicity

Lead is the only metal, among the six principal pollutants for which the EPA has established NAAQS (National Ambient Air Quality Standards): the limit not to be exceeded is 0.15 μg/m^3. Lead has no known biological role; however, as it can accumulate in the body, it can cause serious health problems.

High lead levels in the human body have been shown to generate many negative health outcomes: (1) effects on the nervous system (decline in cognitive functions, symptoms of depressive disorder, general anxiety disorder), especially for children (low IQ, loss of memory, decrease in academic performance, hyperactivity, inattention); (2) cardiovascular effects such as hypertension and increased blood pressure and subclinical artherosclerosis; (3) effects on the hematologic system with alteration of various blood parameters including heme synthesis; (4) and developmental and reproductive effects, with early birth and associated low birth weight and delayed onset of puberty in males and females.

The major sources of lead in urban environment are: (a) Homes built before 1978 (date when lead-based paints were banned) probably contain lead-based paint. Children are especially susceptible to this source of pollution, as when the paint dries and peels, it cracks and makes lead dust that can be swallowed or inhaled by children. (b) Certain water pipes may contain lead, or are made of lead, especially in houses built before the 1970s. The main risk for contamination here depends on the hardness of the water, as it will form a layer of protective lime deposits in the pipes that will isolate the lead from the water. (c) Lead can be found in some products, such as toys and toy jewelry; recent exposures have occurred with toys produced in countries with less control. (d) Lead has been found in some traditional home remedies or makeup. (e) Certain jobs involve working with lead-based products like smelting, stain glass work, and other activities where lead cannot be replaced by another metal.

The recent crisis of Pb contamination in Flint, Michigan, was related to a change in water supply. Depending on the type of water, Pb can be remobilized from previously contaminated sites or simply from piping if the water stagnates

too long. This also leads to an investigation at the national level by *USA Today* that documented a large number of water systems with significantly too high lead contamination. The EPA stresses that there is no safe level of lead exposure.

Summary

Humans have mined, smelted, and used Pb since ancient times, but its high toxicity very much compromises its value and it is being phased out in many applications. Particularly because of its radiogenic nature and one of the end product of three decay systems, it remains among the most useful of elements in geochemistry.

Introduction

Isotopic ratios of Pb are key geochemical tracers for unraveling the compositional evolution of the solar system, the Earth, and the continental crust, and are an important geochronometer with many different applications.

Lead has of four naturally occurring stable isotopes, ^{204}Pb (1.4%), ^{206}Pb (24.1%), ^{207}Pb (22.1%), and ^{208}Pb (52.10%). ^{204}Pb is non-radiogenic; the latter three are the final decay products of the three decay chains from uranium (^{238}U and ^{235}U) and thorium (^{232}Th), where all the intermediate members of each series have relatively short half-lives and can be ignored on long geological timescales (tens millions of years). Some of the U decay series and ^{230}Th decay present applications for shorter time periods (i.e., volcanic eruption, sedimentation at the bottom of the oceans, coral dating).

^{238}U has a half-life comparable to the age of the Earth, i.e., 4.47 Ga, whereas ^{235}U half-life is much shorter, 0.704 Ga, and as a result, almost all the original ^{235}U present in the Earth at its formation has now decayed into ^{207}Pb. This means that there are minimal relative variations in ^{207}Pb over the last 1.5–2 Ga. ^{232}Th has a half-life (14.01 Ga) comparable to the age of the universe. In addition, ^{210}Pb is a member of the ^{238}U decay chain and has a half-life of 22.2 years.

Lead isotopes were used very early in the development of isotopic analyses to determine the age of the meteorites and the Earth (Patterson 1956). It is also while measuring lead isotopic compositions of various Earth materials that Patterson discovered the extent of Pb contamination the Pb tetraethyl added to gasoline as an antiknock agent (e.g. Patterson 1965). From the human health perspective, this was a very important discovery as Pb accumulates in organisms and has many negative health outcomes, especially on the neurological system. His work eventually led to the removal of Pb from gasoline, paints, and other products.

Pb Isotope Ratio Determinations

Lead is chemically isolated from other elements by cation exchange chromatography, except when it is extracted from galena where it represents 82% of the mineral. Lead isotope ratios have been measured by thermal ionization mass

spectrometry (TIMS) or by multi-collector inductively coupled mass spectrometry (MC-ICPMS). During ionization and transmission through the mass spectrometer, as observed for other isotopic systems, the lead isotope ratios fractionate differentially from the true value as a function of the relative isotope masses. In contrast to other radiogenic systems, such as Sr, Nd, and Hf isotopes, where a stable isotope ratio is available to measure the extent of fractionation, only one isotope is not radiogenic in the case of the Pb system. Lead isotopic compositions have been measured on TIMS instruments for about half a century, and fractionation is monitored by repeated analysis of a Pb standard, such as SRM-981 or SRM-982 (Catazanro et al. 1969) under conditions comparable to those of the samples (especially temperature). This led to precision of about 1.2–1.5 permil for $^{208}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, and $^{206}Pb/^{204}Pb$. With time, the addition of double or triple spike allowed for better precision to be achieved (e.g., Galer 1999), but it is only with the development of MC-ICP-MS that precision could be improved by a factor of 10, with doping with a Tl standard allowing for fractionation correction on the basis of $^{205}Tl/^{203}Tl$ (White et al. 2000). Depending on the matrix of the samples, typically two separations through columns are necessary (Nobre Silva et al. 2009). When data from different laboratories are compared, care should be taken that measurements are normalized to the same standard value to avoid interlaboratory bias, and when MC-ICP-MS instruments are used, it is also important to analyze reference materials with comparable matrix (Weis et al. 2006; Fourny et al. 2016).

Geochronology

When discussing Pb isotopic compositions, one usually distinguishes two systems: (a) radiogenic-rich system where the mineral (zircon, titanite, monazite, apatite) has high U and/or Th concentrations and where (b) decay through time generates very radiogenic Pb isotopic compositions (i.e., very high $^{208}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, $^{206}Pb/^{204}Pb$) and "common lead" when the Pb isotopic compositions are representative of the source of the rock or mineral, with minimal growth by radioactive decay. These two systems represent two very different applications of Pb isotopic compositions: the radiogenic systems represent a powerful dating tool, providing in many cases the most accurate and precise ages, while common lead has proved extremely useful in tracer geochemistry to model the evolution of Earth's reservoirs.

The ^{238}U-^{206}Pb, ^{235}U-^{207}Pb, and ^{232}Th-^{208}Pb decay systems

For a closed system where the parent and daughter isotopes remain undisturbed from any process other than radioactive decay, the Pb ratios will increase over time due to the decay of ^{238}U, ^{235}U, and ^{232}Th to ^{206}Pb, ^{207}Pb, and ^{208}Pb, respectively, according to the decay equation:

$$\frac{^{206}Pb}{^{204}Pb} = \left(\frac{^{206}Pb}{^{204}Pb}\right)_i + \frac{^{238}U}{^{204}Pb}\left(e^{\lambda_{238U}t} - 1\right), \quad (1)$$

where $^{206}Pb/^{204}Pb$ is the measured isotope ratio of the sample (so-called present-day), $^{238}U/^{204}Pb$ is the measured parent-daughter ratio, $(^{206}Pb/^{204}Pb)_i$ is the initial ratio of the sample at the time where the U-Th-Pb system became closed to elemental and mass exchange, t is the time since system closure, and $\lambda^{238}U$ is the decay constant of ^{238}U.

Comparable equations can be written for both the ^{235}U-^{207}Pb (Eq. 2) and ^{232}Th-^{208}Pb (Eq. 3) decay systems and three isotopic ratios can then be combined.

Uranium- and Thorium-rich ystems

In this case, the initial "common" Pb, if not negligible, is much less abundant than the radiogenic Pb and can be subtracted from the radiogenic Pb. One can then write

$$\frac{^{206}Pb*}{^{238}U} = e^{\lambda_{238U}t} - 1 \quad (4)$$

$$\text{where } \frac{^{206}Pb*}{^{238}U} = \frac{^{206}Pb/^{204}Pb - \left(^{206}Pb/^{204}Pb\right)_0}{^{238}U/^{204}Pb} \quad (5)$$

and the asterisk denotes only the radiogenic Pb produced since time t.

A comparable equation can be written for ^{235}U and ^{207}Pb (Eq. 5).

In the case of U-bearing mineral that behaved as a closed system (for U and all its intermediate decay products) since its crystallization, it will provide a "concordant" age in the two U-Pb systems, which is to say that the ^{238}U-^{206}Pb age equals the ^{235}U-^{207}Pb age. In addition, one can also calculate a 207-206 age by combining the two systems (Eqs. 4 and 5):

$$\frac{^{207}Pb/^{204}Pb - \left(^{207}Pb/^{204}Pb\right)_0}{^{206}Pb/^{204}Pb - \left(^{206}Pb/^{204}Pb\right)_0} = \frac{^{207}Pb*}{^{206}Pb*} = \left(\frac{^{235}U}{^{238}U}\right)\frac{e^{\lambda_{235U}t} - 1}{e^{\lambda_{238U}t} - 1}, \quad (6)$$

The age obtained from this equation will be concordant with those of Eqs. (4 and 5) in the case of a closed system and in a diagram of $^{206}Pb^*/^{238}U$ vs $^{207}Pb^*/^{235}U$, where all concordant ages plot along a curve that Wetherill (1956) called "concordia."

Recently, the potential of in situ U-Pb dating by laser ablation, coupled to either an ICP-MS (HR-ICP-MS or quadrupole) or an MC-ICP-MS, has opened new avenues of research and allowed for a expansion of applications of this robust dating technique, especially on the mineral zircon.

Uranium-poor Systems

When the natural system lacks U and Th, as does the mineral galena (PbS), the Pb isotopic composition of the mineral does not change after crystallization of the mineral and corresponds to the initial composition. In such systems, one can apply the "common lead" method, based on the evolution of Pb in a given system since the origin of the Earth (age T) until the time (t) where Pb is extracted and separated from its radiogenic parents U and Th.

The method was developed by Nier (1938, 1939) who reported systematic variations of Pb isotopic compositions in galena from different geological settings, and Gerling (1942), Holmes (1946), and Houtermans (1946) developed independently models for the evolution of Pb at the scale of the Earth.

$$\begin{aligned}\left(\frac{^{206}Pb}{^{204}Pb}\right)_t &= \left(\frac{^{206}Pb}{^{204}Pb}\right)_0 + \frac{^{238}U}{^{204}Pb}\left(e^{\lambda_{238U}T} - 1\right) \\ &\quad - \frac{^{238}U}{^{204}Pb}\left(e^{\lambda_{238U}t} - 1\right) \\ &= \left(\frac{^{206}Pb}{^{204}Pb}\right)_0 + \frac{^{238}U}{^{204}Pb}\left(e^{\lambda_{238U}T} - e^{\lambda_{238U}t}\right), \qquad (7)\end{aligned}$$

The same equations can be developed for ^{207}Pb and ^{208}Pb. In these equations, T is the age of the Earth, and t corresponds to the time elapsed since removal of a common Pb sample from its source.

Combining these equations leads to very interesting applications, including the first absolute value for the age of the Earth (Patterson 1956) or the common lead dating method: modern single-stage leads in Earth and meteorites (with $t = 0$) define a line, called the geochron, that originates from the Canyon Diablo troilite composition, the primordial Pb isotopic composition of the Earth. Patterson had the brilliant idea to analyze a series of meteorites (three stony meteorites, two iron meteorites with the Canyon Diablo troilite being the least radiogenic compositions measured) and a sample of recent oceanic sediment (representative of the bulk Earth Pb isotopic composition); they all plotted on one Pb-Pb line, giving an age of 4.55 Ga.

All single-stage leads that were removed from their sources at the same time t will lie on a straight line (isochron) in the Pb-Pb diagram.

In nature, there are also intermediary systems, where both U and Th decay into their relative Pb isotopes through time, however in case of a closed system, in a Pb-Pb plot, the equation of the slope will always be proportional to t.

In such a diagram, and because such a diagram and because we are dealing with only one chemical element, mixing between two end-members with different and homogeneous isotopic compositions will also generate a straight line.

Dating of Ancient Rocks

Pb-Pb whole rock dating methods depend only on isotopic compositions and are therefore less sensitive to element mobility compared to other dating methods. Extensive use of Pb-Pb dating was therefore applied to Archean rocks, especially in the North Atlantic Province (Taylor et al. 1980).

Dating of Meteorites

Lead isotope dating systematics have also been applied to extraterrestrial material, such as meteorites (pioneer work of Patterson 1956), and more recently to other planetary bodies such as Mars and the Moon (e.g., Bouvier et al. 2009).

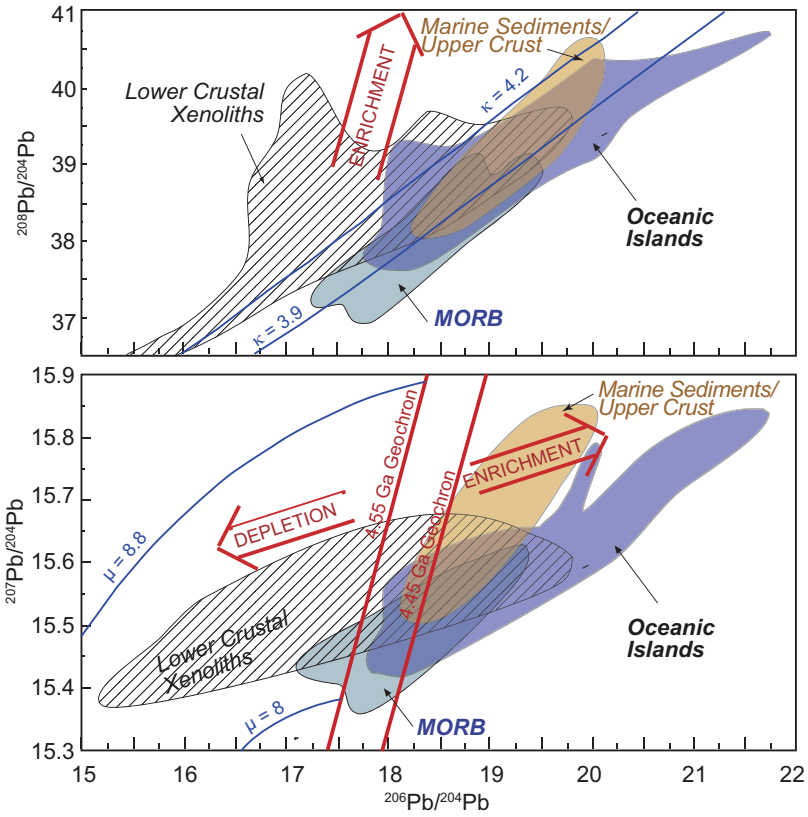
Crust-Mantle Evolution

Typical lower continental crust and upper continental crust are represented by lower crustal xenoliths and modern marine sediments, respectively (these somewhat underestimate the total variance in these reservoirs). MORB and oceanic islands represent the isotopic composition of upper mantle and deep mantle, respectively (Fig. 1).

Lead Isotope Applications

Oceanic Basalts, Implications for Mantle Evolution

In 1964, the analyses of basalts from Gough and Ascension islands provided the first evidence of heterogeneity of the oceanic mantle (Gast et al. 1964). This represented an important milestone in geochemistry as, conventional wisdom was that the mantle was homogeneous. Further work (e.g., Tastumoto 1978), on other oceanic islands, also provided another fundamental observation; most of their Pb isotopic compositions were more radiogenic than the geochron (i.e., had future ages in single-stage history) (Fig. 1). This led to the so-called "Pb paradox" (e.g., Hofmann 2003). Recent volcanic rocks from various areas, including those from subduction zones, define linear trends in Pb isotopic diagrams; these trends have been interpreted as mixing trends between two end-members (among different reservoirs in the Earth's mantle, the mantle and oceanic crust, the mantle and the continental crust), as the age corresponding to the slope of these trends does not have direct age significance. Pb isotopic systematics in mantle-derived rocks also formed the basis, together with Sr and Nd, for the model by Hofmann and



Lead Isotopes, Fig. 1 Pb isotope ratios in major terrestrial reservoirs (Modified from W.M. White 2013). The evolution *blue* curves correspond to the values of κ ($^{232}Th/^{238}U$) and μ ($^{238}U/^{204}Pb$), respectively. All points having evolved in a closed system since the origin of the Earth lie on the geochron

White (1980) suggesting that recycled subducted oceanic crust plays a role in mantle evolution. Recent work on oceanic islands with much improved precision (e.g., Abouchami et al. 2005; Weis et al. 2011) or with in situ techniques (Saal et al. 2005) document much finer scale variations in Pb isotopic compositions that are tentatively attributed to the presence of different reservoirs deep in the Earth mantle, at the core-mantle boundary, with material brought to the surface via a mantle plume.

Continental Crust Growth, Episodic or Recycling

One of the first applications of Pb isotopes was through the analyses of galena, a Pb sulfide where there is no U, and as a result, the Pb isotopic composition is frozen at the time of crystallization of the mineral. This is where Eq. 7 comes into play.

Initially, single-stage models were developed (e.g., Holmes-Houtermans model), however scientists quickly realized that in light of the complexity of the Earth's evolution, it was physically impossible for the host rocks of galena to have been a closed system since the formation of the Earth. More complex systems were developed, with either evolving U/Pb ratios different between the crust and the mantle, or with continental crust evolution in two stages with a major event at 3.7 Ga (Stacey and Kramers 1975). The 1970s and 1980s showed the development of numerous models of crust evolution, with the involvement of various reservoirs with a given U/Pb ratio. There were also strong debates about the role of recycling of Pb between the crust and the mantle (see Armstrong 1968). Doe and Zartman (1979) developed a computer model for the Pb evolution of the Earth with three reservoirs: the upper crust with the highest U/Pb ratio, the lower crust with the lowest U/Pb ratio, and the upper mantle (with an intermediate U/Pb ratio). They argued that crustal accretion began earlier in the Earth evolution and that orogenies mixed mantle and crustal sources, with a U/Pb ratio in between the upper crust and the mantle.

The mineral galena is very common in various rock types. Galena Pb isotopic compositions have been used over the past four or five decades, in models of continental growth, in the sourcing of metals in mineral deposits, and as a geochemical "fingerprint" for distinguishing between different styles of mineralization in a district.

Environmental Applications

Tracing Pb Pollution

Tetraethyl Pb has been used since the early part of the twentieth century as an antiknock additive in gasoline. The amount of Pb that has been released into the atmosphere and then deposited into the environment reached astronomical levels (by 1965, up to 2.6 M tons). Patterson (1980) is the scientist who alerted the world to the widespread distribution of Pb into the environment as well as to the dangers of long-term exposure to Pb. Patterson and colleagues worked for decades

to document the source of anthropogenic Pb via isotopic analyses of soils, seawater, and snow/ice. The fingerprinting was relatively straightforward as the source of the Pb added to gasoline had very distinctive isotopic compositions. In the USA, Pb was extracted from galena-sphalerite depositions of the Mississippi Valley (Heyl et al. 1974); in Europe and Australia, Pb was extracted from the Broken Hill ore deposit characterized by very unradiogenic isotopic compositions.

Anthropogenic contributions of Pb also came from paint, lead smelters, metal manufacturing plants, waste incinerators, and batteries. See element Pb entry.

Seawater

When it became possible to isolate natural Pb from anthropogenic Pb (see review in Boyle et al. 2014), some fundamental applications were developed for Pb isotopes in seawater (i.e., Paul et al. 2015) and other reservoirs where Pb concentrations are very low.

Summary

Lead is present in detectable (i.e., measurable) quantities in many common rocks and minerals. Lead has four isotopes, three of these are radiogenic derived by radioactive decay of uranium and thorium. The isotopic composition of Pb evolves with time in most environments and has been used extensively for dating applications and fingerprinting sources of minerals, lavas, and also pollutants in the environment.

Lipids (Bacteria and Archaea)

Ann Pearson
Department of Earth and Planetary Sciences, Harvard University, Cambridge, MA, USA

Definition

Lipids are fundamental biochemical constituents of all cells. Membrane lipids form bilayer or monolayer structures and provide physical and energetic barriers between intracellular processes and the external environment. Accessory lipids such as pigments and small-molecule metabolites also are important for cell function. In geosciences, the study of these lipids – known as "biomarkers" – takes advantage of two critical properties: (i) lipids are more resistant to degradation than other molecular classes (e.g., proteins, nucleic acids), allowing long-term preservation in the geologic record; and (ii) lipids have a large variety of chemical structures that can be taxonomically and physiologically diagnostic. Applications of lipid biomarker analysis range widely and tackle questions of recent and ancient Earth history and environmental processes.

Introduction

Geochemical approaches to reconstructing the history of the Earth and its ecosystems rely on a variety of proxies. Lipid biomarkers preserved in sedimentary rocks are an important part of this toolbox, providing records of community composition and the operation of specific metabolic pathways (Brocks and Pearson 2005; Grice and Eiserbeck 2014; Peters et al. 2005). The most valuable biomarkers are taxonomically specific and can be traced to organisms that perform specific functions, e.g., sulfide-oxidizing photosynthesis or anaerobic oxidation of ammonia (Anammox). The biomarker record can reveal information about the redox state of ancient oceans (e.g., Brocks et al. 2005), sources of sediments to continental margins (e.g., Prahl et al. 1992), past thermal histories of the surface ocean (e.g., Sluijs et al. 2006), dynamics of mass extinctions (e.g., Sepúlveda et al. 2009), and the operation of specific biogeochemical cycles (e.g., Rush et al. 2012).

Key to the utility of lipid studies is the fact that these molecules are inherently resistant to degradation. Although most biologically synthesized lipids contain one or more oxygen-, nitrogen-, and/or sulfur-containing groups, diagenesis often removes only these groups, leaving the parent structure largely intact (although with stereochemical and/or other minor structural rearrangements). The resulting molecules are the hydrocarbon skeletons of the original products, and they can persist in low-maturity sedimentary rocks for millions of years (Peters et al. 2005).

Siliciclastic sedimentary rocks (e.g., shales, mudstones) are the major reservoirs of biomarker molecules, although organic-rich marls and carbonate and silicic sediments (oozes) also contain extractible lipids. Records of biomarker lipids date back to at least the Mesoproterozoic ($\geq$1.6 Ga); but lipids previously identified in samples from 2.7 Ga (Brocks et al. 1999) now are known to be contaminants; i.e., at present, there is no confirmed biomarker record of life in the Archean (French et al. 2015a).

Biomarker analyses in recent time or in modern analogue environments often investigate lipids in their original, biological form, called "intact polar lipids" (IPLs; e.g., Schubotz et al. 2009). Ancient sediments typically contain only the hydrocarbon diagenetic products, albeit with some exceptions (Melendez et al. 2013). Analysis of hydrocarbons usually is done by gas chromatography-mass spectrometry (GC/MS), while analysis of biomarkers in IPL form usually is done by liquid chromatography-mass spectrometry (LC/MS). Many advanced technologies exist for both types of analyses (Grice 2014). In all cases, the fundamental goal is to identify diagnostic structures and relate them to their source organisms and environmental processes.

Lipid Structural Classes

The two major structural families of lipids are called ***acetogenic*** and ***isoprenoid*** based on their biosynthetic origins as polymers of acetate (two carbons, C_2) and isoprene (five carbons, C_5), respectively. Bacteria synthesize their major membrane structures from acetogenic lipids, while archaeal membranes are composed of isoprenoid lipids. Most other geochemically useful lipids of both bacterial and archaeal cells (e.g., carotenoid pigments, quinones) are isoprenoids.

Common bacterial and archaeal lipid classes used in geochemical studies are (Fig. 1; parent compound/geologic hydrocarbon):

Fatty acids/n-alkyl lipids – hydrophobic component of bacterial and eukaryotic membrane lipids

Sterols/steranes – polycyclic isoprenoid lipids, generally diagnostic for eukaryotes

Bacteriohopanepolyols (*BHPs*)/*hopanes* – polycyclic isoprenoid lipids, analogues of eukaryotic sterols

Phytol/phytane (*and pristane*) – isoprenoid sidechain of chlorophyll pigments

Carotenoids – isoprenoid accessory pigments for photosynthesis and energy metabolism

Archaeal diethers/phytanes – glycerol dialkyl diether lipids of archaeal bilayer membranes (also called archaeols)

Archaeal tetraethers/biphytanes – glycerol dialkyl glycerol tetraether (GDGT) lipids of archaeal monolayer membranes (also called caldarchaeols)

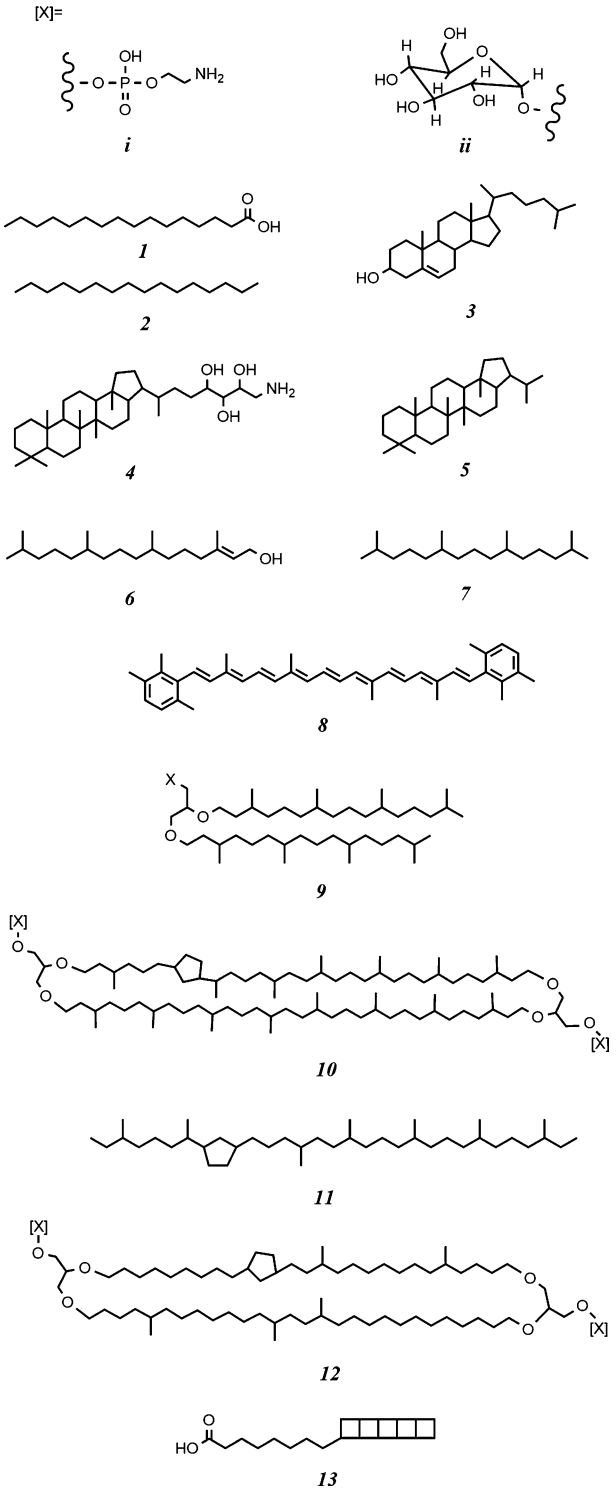
Bacterial tetraethers – branched, but not isoprenoid, glycerol dialkyl glycerol tetraether (brGDGT) lipids of bacterial monolayer membranes

Ladderanes – cyclobutane chain lipids of Anammox bacteria

Membrane bilayers of bacteria are composed of acetogenic lipids, typically containing a polar (often phospho- or glyco- (***i, ii***)) head group, glycerol backbone, and two esterified alkyl tails (***1***). Hydrolysis of these lipids yields biomarker fatty acids, and subsequent diagenesis ultimately yields alkanes (***2***). Numerous structural variations, including terminal branching (*iso-* or *anteiso-*; Kaneda 1991), unsaturation (always with *cis-* configuration), and mid-chain cyclopropyl versions, all are common and in some cases can provide taxonomic or metabolic information (Bodelier et al. 2009).

Polycyclic isoprenoid lipids such as the eukaryotic compound cholesterol (***3***) are membrane-rigidifying structures. The bacteriohopanepolyols (BHPs) (***4***) are analogous to sterols and share a common biochemical ancestry. Their corresponding hydrocarbons are called hopanes (***5***) and are among the most widely studied lipid biomarkers in geologic investigations (Newman et al. 2016; Ourisson et al. 1987; Summons et al. 1999).

Pigment molecules provide records of photosynthetic life. Lysis of the esterified C_{20} isoprenoid side chains of bacteriochlorophylls and chlorophyll *a* yields phytol (***6***), which during oxic and anoxic diagenesis degrades to pristane (***7***, C_{19}) and phytane (C_{20}), respectively (Didyk et al. 1978). Accessory C_{40} carotenoid pigments, often with terminal aromatic groups (aryl-, e.g., okenone; or diaryl-, e.g., isorenieratene (***8***)), are sufficiently taxonomically specific to reveal different types of photosynthesis in past environments (Brocks et al. 2005; French et al. 2015b; Sinninghe Damsté et al. 1993).



Lipids (Bacteria and Archaea), Fig. 1 Examples of lipid structures commonly used for geochemical studies: (***i, ii***), phospho- and glyco- head groups (many other structures are possible; e.g., Schubotz et al. 2009); (***1***), $C_{16:0}$ fatty acid; (***2***), *n*-C_{16} alkane; (***3***), cholesterol; (***4***), aminobacteriohopanetriol; (***5***), hopane; (***6***), phytol; (***7***), pristane; (***8***), isorenieratene; (***9***), archaeol; (***10***), GDGT-1, containing one cyclopentane ring; (***11***), $C_{40:1}$ biphytane; (***12***), brGDGT IIIb, containing one cyclopentane ring and 5 methyl groups; (***13***), C_{20} [5]-ladderane fatty acid

Lipids of archaea are invariably isoprenoid (Kates 1992). Archaeal membranes are composed of bilayers of diether lipids (***9***) or monolayers of tetraether lipids (***10***; GDGT), also with polar head groups (e.g., ***i, ii***). Due to the ether bonds linking the hydrocarbon side chains to the glycerol moieties, archaeal lipids are highly resistant to degradation. Diagenesis of GDGTs yields biphytanes (***11***), although intact (known as "core," i.e., without polar head groups) tetraether lipids are preserved at least as far back as the Jurassic; Jenkyns et al. 2012). Biphytanes can contain up to four or more internal cyclopentane rings and/or a single cyclohexane ring (Sinninghe Damsté et al. 2002a).

Tetraether lipids also are found in bacteria, although their taxonomic sources remain poorly understood (Weijers et al. 2006, 2009). These lipids resemble archaeal GDGTs, but their hydrocarbon centers are acetogenic (***12***) and contain up to six methyl branches and/or cyclopentane rings in a variety of structural positions (De Jonge et al. 2014). Collectively, they are regarded as "branched" (brGDGTs), even when containing cyclopentane rings; they persist in the geologic record at least since the Eocene (Inglis et al. 2017).

Ladderanes are a class of unusual lipids having concatenated chains of cyclobutane rings (***13***) (Sinninghe Damsté et al. 2002b). They are produced exclusively by the divisions of *Planctomycetes* bacteria that mediate the anaerobic oxidation of ammonia (Strous et al. 1999), where they are thought to provide an impermeable barrier to the toxic intermediate hydrazine. Their resulting diagenetic hydrocarbons are not yet known, although intact ladderanes in ocean waters and sediments provide records of Anammox in the recent past (e.g., Rush et al. 2012).

Selected Applications in Geosciences

Sources of bacteriohopanepolyols (*BHPs*) – Hopanoids are synthesized by a minority of bacteria and are not found in any archaea (Pearson 2014). The high resistance of hopane skeletons (***5***) to biotic and abiotic degradation makes hopanoids excellent tracers for ancient bacterial communities, resulting in several important applications. The ratio of total hopanes to total steranes has been used to interpret changes in the fraction of bacterial versus algal input (Moldowan et al. 1985). Hopane chain length proxies such as the C_{35} homohopane index, defined as $[C_{35}/(\Sigma C_{31}\text{-}C_{35})]$, record the extent of degradation of hopanoids. A higher index, denoting less degradation, is believed to indicate anoxia (Peters et al. 2005).

Some intact BHPs are believed to correspond to specific metabolisms. For example, aminobacteriohopanetriol (***4***) is found in methanotrophs and is observed in environments mediating aerobic methane oxidation (Talbot et al. 2003). The 2-methylhopanoids, previously regarded as markers for Cyanobacteria (Summons et al. 1999), now are regarded also as products of Alphaproteobacteria and perhaps other taxa (Welander et al. 2010). In general, the relatively greater occurrence of hopanoids in terrestrial ecosystems and the physiological association of hopanoids with microbial stress responses indicate they may be important biomarkers for terrestrial and/or benthic microbial activity (Newman et al. 2016).

Carotenoid distributions over time – Carotenoids provide a record of bacterial and algal photosynthesis. The detection of isorenieratane, an early diagenetic product of isorenieratene (***8***), in mid-Holocene sediments of the Black Sea (Sinninghe Damsté et al. 1993), provided evidence that photic-zone euxinia (anoxic, sulfide-containing surface water) predates human influence on the region; isorenieratene is only produced by photosynthetic green sulfur bacteria.

Recent improvements in the detection of a wide variety of carotenoids (French et al. 2015b) allowed their reassessment in geologic sediments dating back to the Proterozoic. This work confirms the extinction of the pigment paleorenieratane at the Permo-Triassic boundary, perhaps associated with the loss of unknown photosynthetic taxa. Conversely, the pigment okenone – found in purple sulfur bacteria (Brocks and Schaeffer 2008) – was shown to be more common than previously believed.

Paleotemperatures from GDGTs and brGDGTs – Accurate reconstruction of past sea surface temperatures (SSTs) and continental mean annual air temperatures (MAATs) is fundamental to a better understanding of paleoclimate. GDGTs of archaea (***10***) are used in the SST proxy known as the TEX_{86} index (Schouten et al. 2002). These compounds are believed to be produced primarily by ammonia-oxidizing, planktonic archaea that are critical and ubiquitous players in the global nitrogen cycle (c.f., Schouten et al. 2013). The distribution of GDGTs in marine surface sediments is calibrated to modern overlying waters (e.g., Tierney and Tingley 2014), and this calibration is subsequently applied to generate paleorecords from sediments. Such records have been fundamental tools for understanding SSTs over Cenozoic and Mesozoic timescales.

The analogous bacterial compounds, brGDGTs, have found utility as MAAT proxies (Weijers et al. 2007). Some of these compounds may be produced by the phylum *Acidobacteria*, although their sources remain generally unknown (Sinninghe Damsté et al. 2014). Calibrations show that brGDGTs are influenced by both temperature and pH and that soils and lakes require separate (region-specific) calibrations (Loomis et al. 2014; Peterse et al. 2012; Tierney et al. 2010). Records generated from brGDGTs have been important for studies of changes in Pleistocene/Quaternary climate patterns, especially over Africa, Asia, and the Caribbean.

Summary

Lipid biomarkers have broad utility in studies of historical geobiology, paleoclimate, and ecosystem reconstruction. Their structural diversity and high potential for preservation make them a critical tool in geochemical investigations of modern and ancient systems.
