ENCYCLOPEDIA OF GEOCHEMISTRY

Volume Editor

After receiving his B.A. in geology from the University of California, Berkeley, William White earned a Ph.D. in oceanography from the University of Rhode Island in 1977. White did postdoctoral work at the Carnegie Institution of Washington and at the US Geological Survey in Denver between 1977 and 1980. From 1980 to 1985 he was a staff scientist at the Max Planck Institut für Chemie in Mainz, Germany, and then spent a year as associate professor in the College of Oceanography at Oregon State University. White joined the Cornell faculty in 1986 where he currently serves as professor of earth and atmospheric sciences. He spent 7 months of 1995 as a visiting professor at the École Normale Supérieure de Lyon and the Université de Rennes, served as a visiting professor at the Université de Brest in 2001–2002, and was a Merle Tuve Senior Fellow at Carnegie Institution of Washington in 2002. White is a fellow of the Geochemical Society and the American Geophysical Union. He served as founding editor of the electronic journal *Geochemistry, Geophysics, Geosystems* (G-cubed) from 1999 to 2005.

Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.
These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the back of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to http://www.springerlink.com/reference-works/ to visit the "Earth Sciences Series" online.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the *Encyclopedia of Earth Sciences Series*. He has been the Executive Director of the Coastal Education and Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research* for the past 35 years. He is also the Series Editor of the Coastal Research Library (Springer). In addition to these duties, he is Distinguished University Professor Emeritus at Florida Atlantic University (FAU) (Boca Raton, Florida). He is a graduate of Oregon State University (Corvallis) and the University of Western Australia (Perth). Work experience includes the International Nickel Company of Australia (Perth), Coastal Planning & Engineering (Boca Raton, Florida), and Technos Geophysical Consulting (Miami, Florida). He has published numerous peer-reviewed technical research papers and edited or co-edited and contributed to many books. Dr. Finkl is a Certified Professional Geological Scientist (Arvada, Colorado), a Certified Professional Soil Scientist (Madison, Wisconsin), a Certified Wetland Scientist (Lawrence, Kansas), and a Chartered Marine Scientist (London). Academically, he served as a Demonstrator at the University of Western Australia, Courtesy Professor at Florida International University (Miami), Program Professor and Director of the Institute of Coastal and Marine Studies at Nova Southeastern University (Port Everglades, Florida), and Full Professor at FAU. During his career, he acquired field experience in Australia; the Bahamas; Puerto Rico, Jamaica; Brazil; Papua New Guinea and other SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA. Dr. Finkl is a member of several professional societies including the Geological Society of America; Soil Science Society of America; Institute of Marine Engineering, Science and Technology; and the Society of Wetland Specialists. He is a recipient of the International Beach Advocacy Award (Florida Shore & Beach Preservation Association), Certificate of George V. Chilingar Medal of Honor (Russian Academy of Natural Sciences), and Lifetime Commitment to Coastal Science Award (International Coastal Symposium).

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WWII intelligence officer in the SW Pacific, and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil, and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Print and electronic bundle under ISBN 978-3-319-39313-1

Cover illustration: The poly-extreme hydrothermal terraces of Dallol, Afar Triangle, Ethiopia. Hydrothermal chimneys and miniature geysers discharge high temperature (105–108 °C), oxygen-free, hyper-acidic (pH ~ 0), and Fe-rich (26 g/L of Fe) brines, creating a series of colorful terraces and pools. Unlike other hydrothermal sites where the colors are related to the presence of microorganisms, the color palette of Dallol results from the slow oxidation of aqueous ferrous species and precipitation of Fe(III)-chlorides/-oxyhydroxides/-sulfates. Photograph was taken during the fieldtrip of 2017 in the framework of the ERC grant Prometheus. Electra Kotopoulou, Spanish National Research Council (IACT-CSIC-UGR), Spain.

Printed on acid-free paper

Preface

Few fields within the earth sciences have grown as rapidly or had as great an impact as geochemistry. The impact of geochemistry has been vast and greatly influenced our understanding of virtually every aspect of this planet, its neighbors, and the life that makes it so unique.

As an example, consider what Darwin wrote in 1859 in *Origin of Species*: "*If the theory* [evolution] *be true*, *it is indisputable that before the lowest Cambrian stratum was deposited, long periods elapsed. . .and that during these vast periods, the world swarmed with living creatures. But to the question why we do not find rich fossiliferous deposits belonging to these assumed earliest periods before the Cambrian system, I can give no satisfactory answer*." Darwin understood that the Precambrian comprised "long periods" but had no idea how long. Geochemistry, in particular analysis of radioactive elements and their daughter products, provided the answer: four billion years. While the answer to " how long" could have been given more than half a century ago, the answer to his question "why" has only become apparent within the last decade, and that answer also comes from geochemistry. Recent studies of redox-sensitive metals such as uranium and molybdenum in ancient marine sediments have revealed that although the Earth's atmosphere first became oxidizing about 2.3 billion years ago, oxygen levels remained too low to support animal life for nearly another 2 billion years. Animals appear in the fossil record shortly, geologically speaking, after that rise.

Why oxygen levels began to rise in the Neoproterozoic remains unclear, but biomarkers in sediments of the time hint at possible answers. Biomarkers are fragments of original biomolecules that survive in sediment and contain clues to ancient environments and operation of the carbon cycle. The carbon cycle is intimately connected to both the oxygen cycle through photosynthesis, respiration, and burial of organic carbon and climate through the greenhouse gases CO_2 and CH_4.

In another example, Louis Agassiz first recognized that the Earth had experienced extensive recent glaciation in the first half of the nineteenth century. Only in the last half of the twentieth century has geochemistry, particularly the analysis of oxygen and hydrogen isotope ratios, provided answers to the when and why of the Agassiz's "Ice Ages." Geochemistry continues to provide all the main tools for paleoclimate analysis. Understanding what controlled climate in the past is key to predicting how it will change in the future. This is, of course, critical, because humans have shifted the balance in the carbon cycle by burning anciently buried organic carbon, and climate is changing as a consequence.

Geochemistry is also revealing the workings of the Earth's interior. Thermobarometers based on the distribution of elements between different minerals reveal the temperatures of metamorphism and crystallization in magma chambers. Combined with geochronometers, they can reveal the rates of these processes and the rates at which mountains rise and erode. The 1960s James Bond film proclaimed that "Diamonds are Forever," but it is zircon that holds the record for longevity. Because zircons concentrate uranium, they are natural clocks. Chemical and isotopic analysis of zircons reveals that creation of the continents began 4.4 billion years ago and proceeded subsequently in pulses that appear to correspond to times of supercontinent formation.

We have learned that geochemical cycles extend to the base of the mantle. Water, carbon, nitrogen, and sulfur are carried into the mantle at subduction zones. Isotopic analyses, among other approaches, reveal that these are then carried upward in mantle plumes, which seismic imaging show rise from the base of the mantle, and are released back to the surface by "hot spot" volcanoes such as Hawaii, Réunion, etc. These deep cycles operate much more slowly than surficial ones, as the discovery of the mass independently fractionated isotopic signature of Archean atmospheric sulfur in lavas from volcanoes of French Polynesia demonstrates.

Geochemistry has its roots in the ancient arts of metallurgy, refining elements from the Earth, and alchemy, transforming those elements into new ones. The latter proved fruitless, of course, but transforming elements

into new ones happens continually in stellar interiors, supernovae, and neutron star mergers. The disparate isotopic signatures of these various nucleosynthetic processes are found in meteorites – the "left-overs" from solar system formation 4.5 billion years ago. The impact of geochemistry thus extends to understanding how planetary systems form and how the cosmos has evolved.

The beginnings of metallurgy mark the transition of humanity out of the Stone Age and the founding of modern civilization. Many of the metals that the ancients mined and refined, such as copper, tin, lead, and iron, are still essential to us, but modern society depends increasingly on a vast array of less common elements: as many as 70 different elements are components of smart phones, including lithium, yttrium, rare earths, indium, tantalum, gallium, and antimony. Many of these and others such as cadmium, tellurium, and thallium are increasingly needed as we transition to carbon-free, energy efficient societies. Finding sufficient sources of them requires understanding their behavior in nature and the processes that concentrate them. At the same time, many of these elements are toxic or form environmentally destructive compounds. Geochemistry is essential both in supplying society's resources and dealing with its wastes.

Many ore deposits are formed as a result of hydrothermal activity. The cover photo of the colorful salt deposits of the Dallol dome in the Danakil depression of Ethiopia is an example of such activity, and it also illustrates how all aspects of geochemistry are ultimately interconnected. There, a mantle plume causes rifting and volcanism. The magmatic heat drives a mixture of magmatic volatiles, formation brines, and groundwater upward through layers of basalt and evaporites, dissolving a variety of elements from both. Once this hot, acidic solution reaches the surface, cooling and reaction with atmospheric oxygen result in precipitation. Thus, the resulting salts are ultimate products of all of the Earth: its interior, the oceans, and the atmosphere.

The point is that the scope of geochemistry is so vast that it is impossible for any one person to know the entire field. This is *raison d'etre* for this encyclopedia. The 331 entries include brief summaries of the behavior of the naturally occurring chemical elements, and their isotopes in many cases, brief definitions of important terms such as quantum numbers, overviews of important topics such as evaporites, and extensive reviews of broad topics such as the formation and evolution of the Earth. All of these entries are written by experts on the subject. None of them are exhaustive, rather they are meant to acquaint the reader with the topic and, with the references at the end of each entry, provide a point of departure for further understanding. The encyclopedia is aimed at students, teachers, professionals working in other aspects of earth science, and anyone wanting to understand more about the chemistry of nature. Given, again, the vast scope of geochemistry, we expect it should also be useful to geochemists needing to understand topics outside their own area of specialty.

Aknowledgments

The editors wish above all to thank the hundreds of scientists from academia, industry, and government organizations who have graciously contributed their time and effort in writing the entries that comprise this encyclopedia. It is primarily their efforts which have produced this volume. We would also like to thank the many other hundreds of scientists who have provided peer reviews for these entries and improved them with their constructive comments. Finally, we would like to thank the Springer team, Petra van Steenbergen, Sylvia Blago, and Johanna Klute for their work and assistance in assembling this volume.

Definition

Molecular orbital theory is an approach to solving the Schrödinger equation for the motion of electrons in molecules (as well as atoms). Such calculations are known as *ab initio* (from first principles) electronic structure calculations. The molecular orbitals are usually expressed as sums of atomic orbitals, and the rules of quantum mechanics including the Pauli exclusion principle are followed. The use of molecular orbital theory ranges from qualitative where it is used to provide a description of the electron occupancy in a molecule to explain experimental results from photoelectron spectroscopy and electronic spectroscopy to extremely quantitative with a focus on precise predictions of molecular energetics and spectroscopic parameters.

Overview

Molecules contain electrons which have a low enough mass that the laws of quantum mechanics must be used to describe them if the electronic structure of an atom or molecule needs to be studied. In order to predict the energy of the electrons in a molecule by solving the Schrödinger equation for the electronic motion, we make the Born-Oppenheimer approximation based on the fact that the electrons are 1836 times lighter than the smallest nuclear mass (the proton or the H atom nucleus) so that we can separate the electronic and nuclear motion. The Born-Oppenheimer approximation underlies all of how we interpret molecular structure and spectroscopy as it effectively states that the electrons readjust immediately as the nuclei move in a molecule (Hehre et al. 1986; Hirst 1990; Grant and Richards 1995; Lowe and Peterson 2006; Levine 2014; Foresman and Frisch 2015).

Current electronic structure methods are based on the solution of the time-independent Schrödinger wave equation

$$H\Psi = E\Psi \tag{1}$$

for the motion of electrons in atoms and molecules including complexes and charged systems, where H is the Hamiltonian operator which is Hermitian, Ψ is the wave function, and E is the energy. Equation 1 is an eigenvalue equation and can only be solved analytically for very simple systems usually involving a single electron. Initially, the Hamiltonian did not include relativistic effects, but recently, it has become possible to solve the relativistic Schrödinger equation for electronic motion as such solutions are needed to describe molecules containing heavy elements which play an important role in many environmental geochemical issues (Pykkö and Descleaux 1979; Wilson 1988; Reiher 2012).

For a molecular system, the exact nonrelativistic Hamiltonian in atomic units (the electron mass and charge, Planck's constant divided by 2π, and the Coulomb constant are all set to unity) is given by

$$-\sum_{i=1}^{n}\frac{1}{2}\nabla_i^2-\sum_{i=1}^{n}\sum_{A=1}^{M}\frac{Z_A}{r_{iA}}+\sum_{i=1}^{n}\sum_{j>i}^{n}\frac{1}{r_{ij}}-\sum_{A=1}^{M}\frac{1}{2M_A}\nabla_A^2+\sum_{A=1}^{M}\sum_{B>A}^{M}\frac{Z_AZ_B}{R_{AB}} \tag{2}$$

In Eq. 2, the capital letters correspond to the M nuclei, and the lower case letters correspond to the n electrons. In atomic units, the mass of a nucleus is in terms of the mass of an electron. The first term represents the kinetic energy of the electrons and includes the quantum operator for the

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

momentum squared (K.E. = $p^2/2$ m). The second term is the kinetic energy of the nuclei, and in the Born-Oppenheimer approximation, does not depend on the electronic wave function so it can be calculated classically. The third term is the potential energy due to the Coulombic attraction of the i^{th} electron to the A^{th} nucleus, is the term in the Hamiltonian representing the force that holds electrons to the nucleus, and is responsible for the stability of the system. This term is relatively cheap to compute. The fourth term is the inter-electron repulsion energy and this is the difficult term to calculate. The reason for this is that the electrons are not points but are probability distributions based on their wave-like properties, their deBroglie wavelengths. In addition, due to the Pauli exclusion principle, a nonclassical component, the exchange integral is introduced. The final term is the internuclear repulsion energy, and again the Born-Oppenheimer approximation makes this term classical and independent of the electronic wave function. The atomic unity of energy is the hartree which is twice the ionization potential of the H atom and equals 4.359744×10^{-18} J. The atomic unit of distance is the bohr, the most probable distance of the electron from the proton in the 1 s orbital of the H atom, and equals $5.2917721 \times 10^{-11}$ m.

Quantum chemical molecular orbital (MO) theory methods can usually be classified either as *ab initio* or semi-empirical. The first label, *ab initio*, means "from the beginning" = first principles and uses no empirical parameters. This category includes the starting level Hartree-Fock (HF) approach and methods that include a treatment of the electron correlation including configuration interaction (CI), many-body perturbation theory (MBPT), coupled-cluster (CC) theory, and other approaches. The second category, semiempirical (SEMO), includes methods which make significant approximations to substantially reduce the number of integrals and then use empirical parameters to evaluate the integrals that are kept in a minimal basis set. These methods include the modified neglect of differential overlap (MNDO) (Dewar and Thiel 1977), Austin Model 1 (AM1) (Dewar et al. 1985), and Stewart's PMn ($n = 3, 6, 7$) (Stewart 2013). The goal of SEMO methods is to reproduce experiment or equivalently very accurate correlated molecular orbital theory calculations.

An advantage of computational molecular orbital theory methods is that many properties can be calculated to varying degrees of accuracy depending on the amount of computation. Examples of these properties are given in Table 1.

There is always a compromise between computational speed and accuracy. We define "chemical accuracy" for thermochemistry as 1 kcal/mol or about 4 kJ/mol (1 kcal/mol = 4.184 kJ/mol), for structures as ±0.005 Å, and for spectroscopy as ±5 cm^{-1} for vibrational frequencies. As an example of the need for accurate calculations, if one has a 50:50 starting mixture of two components, a change in the free energy ΔG of 5.86 kJ/mol leads to a change in the equilibrium constant of a factor of 10 leading to a 10:1 mixture at 25 °C. A factor of 2–4 in a rate constant can have an impact on whether a compound will degrade quickly in the environment so that there will be little if any impact, for example, on atmospheric infrared absorption. A factor of 10 in a rate constant at room temperature (25 °C) corresponds to a change in the activation energy of 5.86 kJ/mol.

Ab Initio Calculations, Table 1 Properties obtainable from quantum mechanical methods

Molecular structures (rotational spectra)
Vibrational energy levels (infrared and Raman spectra)
Nuclear magnetic resonance (NMR) chemical shifts
Electronic energy levels (UV and visible spectra)
Accurate thermochemistry (gas phase)
Potential energy surfaces (barrier heights, transition states)
Ionization potentials (photoelectron and X-ray spectra)
Electron affinities
Dipole moments
Polarizabilities
Electron density maps and population analysis

Hartree-Fock (HF) Theory

The simplest first principles solution in the molecular orbital theory approach is Hartree-Fock theory, a self-consistent method, which describes the energy of an electron in the average field of the other n–1 electrons. This approximation makes Hartree-Fock theory much simpler than the full N-body problem. The HF method is based on using a Slater determinant for the molecular orbitals, and each molecular orbital is expanded as a linear combination of atomic orbitals (LCAO). The Hartree-Fock method iteratively solves for the linear expansion coefficients (the quantities which determine which atomic orbitals make up the molecular orbitals) until they do not change within a prescribed limit within successive iterations. The Hartree-Fock molecular orbitals represent an approximation to the solution of the electronic Schrödinger equation. In many cases where the properties are not good to first order, this approximation can give poor results, for example, covalent bond energies. The HF method can provide a set of starting orbitals that can be used to substantially improve the results with more accurate methods. A key correction to deal with is the Coulomb hole, which arises because the motions of electrons in an orbit are correlated. The HF approach does not properly treat the interaction of an electron with the other electron in a doubly occupied orbital as it allows the electrons to overlap which is not possible due to Coulomb's law so the motion of the electrons

is correlated (they repel each other). This is known as dynamic correlation.

One of the great triumphs of modern quantum chemistry has been the development of analytical derivative methods which allow one to find minimum energy structures and then to characterize these structures as minima, transition states, saddle points, etc. The first derivatives of the energy E with respect to the nuclear coordinates x can be used in efficient search algorithms to find minimum energy structures. Remember that $dE/dx = 0$ defines a minimum or a maximum. Given the second derivatives of the energy with respect to the nuclear coordinates, one can characterize the minima and obtain the force constants and thus the vibrational spectra. Remember that d^2E/dx^2 defines the curvature at the place where $dE/dx = 0$. If $d^2E/dx^2 > 0$, then the structure is a minimum, and if $d^2E/dx^2 < 0$, it is a maximum. If there is only one negative d^2E/dx^2, the structure is a transition state.

Basis Sets

Ab initio electronic structure computations are almost always carried out numerically using a basis set of atomic orbitals as matrix/vector operations can be fast on computers, and such an approach connects to simple chemical descriptions of how the electrons in atoms form bonds in molecules. It is important to choose a basis set that is large enough to give a good description of the molecular wave function. The basis set is often described as the one-particle problem. Typically, the basis functions are centered on the atoms and so are called atomic orbitals. These atom-centered basis functions are usually chosen to be Gaussian-type orbitals (GTOs), which have the form

$$\mathrm{GTO}(x, y, z) = x^a y^b z^c \exp\left(-\xi r^2\right) \tag{3}$$

where x, y, z are the local (atom-centered) Cartesian coordinates, *a, b, c* are positive integers which describe the angular momentum of the orbital, r is the radial distance to the atomic center, and ξ is an exponent optimized in some way to provide the best values for a set of properties. Unlike hydrogen atom orbitals, GTOs do not have radial nodes, but radial nodes can be obtained by combining different GTOs. An atomic basis function is usually given as a fixed linear combination of GTOs, a contracted Gaussian basis function, where the coefficients are obtained from an electronic structure calculation usually on an atom. The smallest basis set to give practically useful results is a polarized double-ζ set which has two sets of orbitals for each orbital in the minimal set needed to describe an atom plus a set of functions with a value of the angular momentum quantum number one higher than needed for a minimal basis set. As an example, for C, there are two 1 s orbitals, two 2 s orbitals, 2 sets of 3 2p orbitals and one set of 5 d orbitals. As the core electrons do not usually participate in the chemistry of the valence electrons, the core is often treated by a single set of orbitals to reduce the computational expense giving a split valence basis set. The most commonly used split valence double-zeta plus polarization basis set is Pople's 6–31G* or 6–31G(d) basis.

Much larger basis sets are needed for treating the correlation energy, and a number of such sets have been developed including atomic natural orbitals (Almlöf and Taylor 1991; Neese and Valeev 2011) and correlation consistent basis sets (Dunning 1989). By exploiting the systematic convergence properties of the correlation consistent basis sets including additional diffuse functions (Kendall et al. 1992), it is possible to obtain accurate estimates of the complete basis set (CBS) limit (Feller et al. 2011) without having to resort to such extremely large basis sets that would unavoidably limit calculations to small diatomic molecules (Peterson 2007). Such basis sets are being developed for the entire periodic table and are currently available for elements up to Z = 86, excluding the lanthanides which are under development and for some of the actinides with the remainder under development. An advantage of a consistent set of basis sets that converges to the CBS limit is the elimination of the 1-particle truncation problem arising from basis set incompleteness. This provides a measure of the intrinsic error associated with a given n-particle method. In addition, issues with basis set superposition error (BSSE) are minimized.

The high atomic numbers (Z) of the heavier elements beyond the second row imply that relativistic effects must be properly included to attain even semiquantitative accuracy (Wilson 1988; Hess and Dolg 2002; Reiher 2012; Dolg 2015). For many of the properties of interest, the core electrons are chemically inert. It is possible to eliminate the core contributions from direct consideration by using small-core pseudopotentials or relativistic effective core potentials (RECPs) (Küchle et al. 1998; Reiher 2012). This is equivalent conceptually to ignoring the correlation effects of the 1 s electrons for second row atoms like S and Cl. Recently, Peterson and coworkers have developed correlation consistent basis sets in combination with effective core potentials from the Stuttgart/Köln group for all of the main group atoms and transition metals enabling reliable predictions for compounds containing most of the elements in the periodic table (Peterson 2015). Good sources for the basis sets are the EMSL Basis Set Exchange website (Feller 1996; Schuchardt et al. 2007; EMSL) and the K. Peterson website at Washington State University (Peterson). Many computer programs have basis sets embedded in them, but

one should take care to make sure that the basis sets are implemented the same in different programs and even in different versions of the same program when calculating various quantities.

Electron Correlation Methods

Many methods have been developed to treat the n-particle or correlation energy problem. The simplest method is second-order Møller-Plesset (MP2) (Møller and Plesset 1934; Pople et al. 1976) which is based on a perturbation theory expansion and can be extended to higher orders. The most common reliable methods that one can use to treat the correlation problem adequately are coupled-cluster-based approaches (Bartlett and Musial 2007). Until the last 20 years, it was believed that most of the problems in the accurate treatment of molecular systems were due to the difficulties in treating the n-particle problem. In fact, based on full configuration interaction benchmark studies, it has been found that many of the problems previously attributed to the solution of the n-particle problem were actually due to deficiencies in the solution of the 1-particle problem, the choice of the atomic orbital basis sets (Dunning 1989). There is a good understanding today of the means to solve many problems to chemical accuracy, and there is a growing consensus that for systems based predominantly on a single configuration, the coupled cluster with all single and double excitations plus a correction for the connected triples (CCSD(T)) method can provide such results. However, the computational cost can be very high as one must use very large extended basis sets and the CCSD (T) scales as N^7 where N is the number of basis set functions. Recently developed F12 methods utilize a Slater-type correlation factor, $F_{12} = e^{-\gamma r_{12}}$, and exhibit significantly faster convergence toward the CBS limit, especially for geometries and frequencies (Kutzelnigg 1985; Adler et al. 2007; Helgaker et al. 2008; Knizia et al. 2009; Peterson et al. 2012b; Feller 2015).

For cases with multireference (MR) character or when more accurate results (<1 kcal/mol) are needed, extension of the correlation treatment beyond CCSD(T) is required. This can be done by performing calculations with higher order coupled-cluster methods (CCSDT, CCSDT(Q), CCSDTQ, etc.) to estimate the remaining contributions between full CI (FCI) and CCSD(T). Another approach is to use multireference methods with some additional treatment for electron correlation such as configuration interaction (MRCI) or perturbation theory methods (CASPT2). The idea of configuration interaction is to take a set of Slater determinants generated by promoting electrons from the HF occupied orbitals to the unoccupied orbitals. We represent the wave function as a sum of these Slater determinants with a set of optimized coefficients which describe how much a Slater determinant contributes to the overall wave function. As the coefficients of each determinant are optimized, CI is a variational approach. An issue with any truncated configuration interaction calculation is that they are not size consistent (proportional to the number of electrons as the distance between them gets large). An MR wave function is one where a single configuration wave function is not a good representation of the molecule, e.g., N_2 dissociating to large R or NO_3 an open shell molecule with 3 equivalent Lewis dot structures or O_3 with 2 equivalent Lewis dot structures. This type of correlation is known as static correlation. In the MR approach, one writes the molecular wave function as a sum of configuration state functions (CSF) and varies both the expansion coefficients of the CSFs and those of the molecular orbitals in each CSF. MRCI uses the MR wave function as the starting point for additional CI calculations to get an estimate of the dynamic correlation. This is a computationally very expensive process. One issue with MRCI methods is the choice of the active electrons and orbitals which are to be optimized. This is relatively straightforward for smaller systems such as N_2 where the active space consists of the $\sigma(2\,s)^2$ and $\sigma^*(2\,s)^2$ and $\sigma(2p)^2$ and $\pi(2p)^4$ electrons and orbitals and the unoccupied (virtual) $\sigma^*(2p)$ and $\pi^*(2p)$ orbitals to give what is known as a complete active space or CASSCF. The choice of the CASSCF can get quite complicated for larger molecules with more electrons, and there is currently a rough limit of about 16 electrons in 16 active orbitals due to computational cost.

An example of how to use high accuracy calculations to get the heat of formation from the calculated total atomization energy in combination with accurate experimental heats of formation of the atoms at 0 K is now given, the Feller-Peterson-Dixon (FPD) method (Dixon et al. 2012; Feller et al. 2012; Peterson et al. 2012a). The expression for the zero point inclusive, total atomization energy (TAE = ΣD_0), is given by the following expression:

$$\begin{aligned} TAE &= \Sigma D_0 \\ &= \Delta E_{elec}(CBS) + \Delta E_{CV} + \Delta E_{SR} + \Delta E_{SO} \\ &\quad + \Delta E_{HO} + \Delta E_{ZPE} \end{aligned} \tag{4}$$

The various energy terms in the calculation are treated as accurately as possible, exploiting the fact that each piece can be handled with different levels of approximation. The best available appropriate geometry for each computational level should be used. The first term in the energy expression is the electronic energy contribution of the "valence electrons," which we will take to be the complete basis set (CBS) limit of the CCSD(T) energy. For molecular systems with wave

functions dominated by a single Slater determinant, this is an appropriate approach. The second term is the correlation of the outer-core electrons with themselves and with the valence electrons, the core-valence term. If possible, this contribution is also estimated at the CBS limit. The third and fourth terms deal with the effects of relativity with the third term accounting for scalar relativistic effects and the fourth term dealing with the spin orbit interaction for atoms and molecules. The fifth term deals with corrections to the TAE beyond the CCSD (T) level. The final value is the zero point energy, which will be negative and decrease the TAE. The TAE, i.e., the enthalpy for reaction (2), can then be used to calculate the heat of formation of the molecule $A_aB_bC_c$ at 0 K from reaction (5) with expression (6).

$$A_aB_bC_c \rightarrow aA + bB + cC \tag{5}$$

$$\Delta H_f{}^{0K}(A_aB_bC_c) = a\Delta H_f{}^{0K}(A) + b\Delta H_f{}^{0K}(B) + c\Delta H_f{}^{0K}(C) - \Sigma D_0 \tag{6}$$

Solvation Effects

Geochemical applications often require the treatment of aqueous systems. In order to include the effects of solvation, one has to use either explicit solvent molecules in the calculation which is computationally very expensive due to the large number of atoms and electrons involved and the many solvent molecule conformations or self-consistent reaction field (SCRF) approaches (Tomasi et al. 2005) or some combination (Gutowski and Dixon 2006). One SCRF approach is the Conductor-like Screening Model (COSMO) originally developed by Klamt (Klamt and Schümann 1993; Klamt 2005). This approach starts by determining the interaction of a dipole in the center of a conducting sphere field given by Eq. (7)

$$\Delta E = -\frac{1}{2}\sum_{ij}\frac{q_i q_j R}{\sqrt{R^4 - 2R^2 \boldsymbol{r_i r_j} + r_i^2 r_j^2}} \tag{7}$$

where R is the radius of the surrounding conducting sphere, q is the charge, $\boldsymbol{r}$ is the position vector of the charge with respect to the spherical center, and r is the distances of the charge from the center. When combined with the dielectric scaling function for dipoles derived by Kirkwood, this basic model gave good results. Although this exact solution works well for many systems, a more realistic cavity shape is needed. The resulting Green's function takes the form of:

$$G_S^X = -\frac{1}{2}f(\varepsilon)Q^X B^t A^{-1} \equiv \frac{1}{2}Q^X D Q^X \tag{8}$$

where G_S^X is the total free-energy gain, $f(\varepsilon)$ is the dielectric scaling factor, Q^X is charge density, A is the Coulomb interaction matrix of the surface segments, B is an operator that generates a potential from the charge density, t is the matrix transposition, and matrix D is the Green's function of the continuum. This is essentially an additional charge-charge interaction to the charge density, Q^X, of the Coulomb interaction energy. Note that SCRF approaches give a free energy of solvation. The reaction free energies in solution at 298 K can be predicted by combining $\Delta G_{solvation}$ with ΔG_{gas} to get $\Delta G_{solution}$. ΔG_{gas} is obtained by taking ΔH_{gas}(298 K) value and combining it with ΔS_{gas}(298 K) using calculated frequencies and geometries with the usual statistical mechanical approaches and the equation $\Delta G = \Delta H - T\Delta S$. There are many additional solvation approaches, and another common one is the SMD approach developed by Cramer and Truhlar (Marenich et al. 2009).

Conclusions

Ab initio molecular orbital theory is currently the best current way to get "the right answer for the right reason" (Borden et al. 2002) for a broad range of molecular properties and energetics. Reliable heats of formation for gas phase molecules containing most atoms in the periodic table can be obtained to chemical accuracy of ± 1 kcal/mol by using composite methods such as FPD, although these methods are computationally expensive. Such methods also provide reliable predictions of nonbonded interactions, which are important in geochemical applications but difficult to predict with most density functional theory exchange-correlation functionals. Similar high-level predictions can be made for structures and spectroscopic properties. For example, reliable calculated vibrational frequencies can be used to determine the correct isotope fractionation factors (Rustad et al. 2010) as was done for the fractionation of ^{11}B and ^{10}B between $B(OH)_3$(aq) and $B(OH)_4^-$(aq), which has been used in paleoclimate studies to estimate the pH of the oceans on timescales of 20 my (Hemming and Hanson 1992). Improvements in methods are still being made especially for molecules with multireference character, solvent effects, and the solid state (Yang et al. 2014).

Definition

Achondrites are meteorites that formed by varying degrees of melting and differentiation on their parent bodies. They are divided into asteroidal and planetary achondrites. Asteroidal achondrites are remnants of differentiated planetesimals and protoplanets that existed shortly after the formation of the Solar System. They are partially to totally melted rocks. Planetary achondrites represent material derived from large planetary bodies (the Moon and Mars) and formed by complex igneous processing.

Introduction

This section covers achondrites and achondritic clasts in stony-iron meteorites (Table 1). Achondrites comprise ~6% of the global collection. Achondrites were derived either from asteroids (asteroidal achondrites) or larger planetary bodies (planetary achondrites). Asteroidal achondrites are broadly classified into primitive and differentiated types. Primitive achondrites experienced partial melting and preserve isotopic and some chemical signatures of their precursor chondritic materials (Fig. 1). They include the acapulcoite-lodranite clan, the winonaites and silicate inclusions in IAB-IIICD irons, achondritic inclusions in IIE irons, brachinites, and ureilites. Differentiated achondrites are igneous rocks with highly fractionated compositions. They include the HED meteorites (acronym of Howardites, Eucrites, and Diogenites), angrites, aubrites, and mesosiderite silicate clasts. The petrologic characteristics and oxygen isotopic homogeneity of these groups (Fig. 1) indicates that their parent bodies experienced global-scale melting. Asteroidal achondrites originated from planetesimals and protoplanets that accreted shortly after the formation of the Solar System. Planetary achondrites, include lunar and Martian meteorites and formed in large part from a wide variety of magmas produced as a result of complex igneous processing. They generally have much younger ages than those of asteroidal achondrites. Modern classification schemes for achondrites are presented by Hutchison (2004), Weisberg et al. (2006), Krot et al. (2014), and Mittlefehldt (2014). Detailed information for individual achondrite groups is provided in the review papers of Benedix et al. (2014), Goodrich et al. (2004), Greenwood et al. (2012), Keil (2010, 2012, 2014), Korotev (2005, 2016), McSween and McLennan (2014), Mittlefehldt et al. (1998), Mittlefehldt (2014, 2015), Warren and Taylor (2014), and the Meteoritical Bulletin Database (2016). The descriptions of individual achondrite groups below are given in approximate order of differentiation, from least melted to most extensively melted.

Acapulcoites and Lodranites

Isotopic and petrological evidence indicates that the acapulcoites and lodranites were derived from a single parent body (e.g., McCoy et al. 1997). Acapulcoites and lodranites are equigranular, recrystallized rocks composed of orthopyroxene, olivine, diopside, plagioclase, Fe,Ni metal, schreibersite, troilite, whitlockite, Cl-apatite, chromite, and graphite. The constituent minerals are similar to those in ordinary chondrites. Acapulcoites are finer-grained (150–230 μm) with chondritic abundance of major minerals and lodranites are coarser-grained (340–700 μm) and depleted in troilite and plagioclase. Mg# (= 100× molar Mg/(Mg + Fe)) of mafic minerals (olivine $Fa_{3–13}$) are higher than those of ordinary chondrites. Acapulcoites and lodranites are considered to be residues after ~10–20% partial melting. The degree of partial melting is significantly higher in the lodranites than in the acapulcoites.

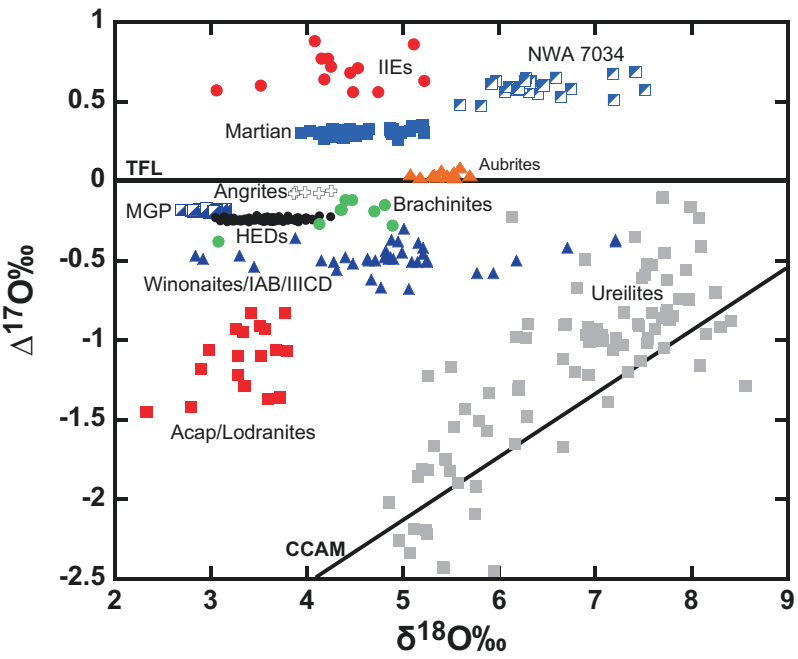
Winonaites and Silicate Clasts in IAB and IIICD Irons

Winonaites and silicate clasts in IAB and IIICD irons may have originated from the same source based on their similar oxygen isotopic and mineralogical compositions (e.g., Benedix et al. 1998). Winonaites are fine- to medium-grained (55–230 μm) equigranular rocks mainly composed of olivine and pyroxene and are petrologically similar to acapulcoites and lodranites. Minor minerals include schreibersite, daubréelite, and alabandite. The Mg# values of mafic minerals (olivine $Fa_{1–8}$) are between H and E chondrites and are higher than those of the acapulcoite-lodranite clan. Most are unbrecciated rocks. Some contain relict chondrules. Winonaites and IAB inclusions experienced partial melting of both Fe, Ni-FeS, and silicate materials.

Achondrites, Table 1 Characteristics of major groups of achondrites and achondritic clasts in stony-iron meteorites

Group	Textures	Major minerals	Fa in olivine	$\Delta^{17}O$	Statistics[a]	Petrogenesis
Asteroidal achondrites						
Primitive achondrites						
Acapulcoites-lodranites	Equigranular	ol, px, feld, FeNi-FeS	3–13	−1.39 to −0.81	0.26%	Partial melting
Winonaites	Equigranular	ol, px, feld, FeNi-FeS	1–8	−0.60 to −0.24	0.05%	
Brachinites	Granular	ol, px	30–35	−0.39 to −0.11	0.07%	
Ureilites	Granular	px, ol	3–26 (cores)	−2.45 to −0.35	0.79%	
IIE silicates (achondritic)	Equigranular	px, ol, FeNi-FeS	15–20	0.63–0.78		
Differentiated achondrites						
Angrites	Igneous	Ca-Al-Ti px, ol	Vary widely	−0.003 to −0.042	0.04%	Global-scale melting (magma ocean?)
Aubrites	Coarse-grained	px, ol	0	−0.02 to 0.08	0.14%	
HED meteorites					3.17%	
Howardites	Brecciated		Vary widely			
Eucrites	Brecciated, basaltic/gabbroic	px, feld, sil		−0.246 to −0.230		
Diogenites	Brecciated, coarse-grained	px, ol	27–35	−0.247 to −0.231		
Mesosiderites	Brecciated	px, pl, ol, FeNi-FeS	8–42	−0.265 to −0.231	0.42%	
Main-group pallasites	Coarse-grained	ol, px, FeNi-FeS	11–18	−0.194 to −0.165	0.10%	
Planetary achondrites						
Lunar meteorites				−0.012 to 0.018	0.45%	Complex igneous processing (wide variety of magmas)
Feldspathic	Brecciated	pl, px, ol	Vary widely			
Mingled	Brecciated		Vary widely			
Mare	Brecciated, basaltic	px, pl	Vary widely			
Martian meteorites				0.300–0.327	0.31%	
Basaltic shergottites	Basaltic	px, pl				
Iherzolitic shergottite	Coarse, poikilitic		34–40			
Nakhlites	Coarse-grained	px	70–83			
Chassignites	Coarse-grained	ol	21–47			
ALH 84001	Coarse-grained	px				
NWA 7533, 7034 etc.	Brecciated					

[a]Statistics of approved meteorite fall and finds. Total number of meteorites is 52,782 (as of Jan 4, 2016)



Achondrites, Fig. 1 Oxygen isotopic compositions of achondrites. *TFL* terrestrial fractionation line, *CCAM* carbonaceous chondrite anhydrous minerals

Brachinites

Brachinites are olivine-rich rocks (dunitic or wehrlites) (olivine: 73–93 vol%, $Fa_{27–36}$), with minor to trace amounts of augite, plagioclase, orthopyroxene, chromite, Fe-sulfide, phosphates, and Fe,Ni metal. The brachinite group is poorly defined, such that there are many petrologically similar, "brachinite-like" achondrites, such as *Divnoe*, whose relationship with the brachinite group is presently unknown. Brachinites have lithophile and siderophile element abundances that display variable depletions compared to chondrites. The presence of a lineation and foliation defined by alignment of olivine in some brachinites and *Divnoe* suggests that they may have formed as igneous cumulates. Feldspar-rich meteorites, GRA 06128 and 06129 could be genetically related to brachinites (Day et al. 2012).

Ureilites

Ureilites are the second largest group of achondrites after the HED meteorites. Ureilites are ultramafic rocks mainly composed of olivine and pyroxene with interstitial carbon-bearing phases (<5 vol%). The proportion of olivine and pyroxene varies widely. Minor minerals include carbon polymorphs (graphite, diamond, lonsdaleite, and chaoite), Fe,Ni metal (kamacite), and exceptionally chromite and plagioclase. Most ureilites are unbrecciated. Except for rims and veins in olivine, silicates (i.e., olivine cores and pyroxenes) are quite uniform in Fe/Mg ratios within any given ureilite. However, compositions from one sample to another exhibit considerable variation, as shown by the olivine-cores, which range from Fa_3 to Fa_{26}. Mineralogical evidence indicates that ureilites equilibrated at high temperatures (1200–1300 °C) and subsequently experienced rapid cooling, consistent with impact-excavation or disruption of their parent body (Takeda 1987). A few ureilites are fragmental breccias composed of typical monomict ureilite clasts, plus a variety of other lithic clasts and mineral fragments.

Compared to chondrites, bulk ureilites are depleted in Al and have fractionated rare earth element (REE) patterns. Refractory siderophile elements are roughly chondritic (~0.1–2× CI). Ureilites retain high concentrations of fractionated planetary type noble gases. Oxygen isotopic compositions plot close to the carbonaceous chondrite anhydrous mineral (CCAM) line.

Ureilites are residues after >15% partial melting. Feldspathic clasts found in some polymict ureilites, including the Almahata Sitta fall, are remnants of lavas extracted from ureilites.

IIE Silicate Clasts

IIE iron meteorites contain a wide variety of silicate inclusions from primitive, chondritic to highly differentiated (basaltic partial melts) types (Mittlefehldt et al. 1998). Oxygen isotopic compositions indicate a genetic relationship between IIE silicate clasts and the H chondrites. The silicate clasts give a range of radiometric dates, from ~3.7–4.5 Ga, which may represent impact ages. There are two principal end member models for the origin of the IIE silicate clasts, endogenous igneous processes, or impact melting of an H chondritic parent body (McDermott et al. 2016).

Angrites

Angrites are a small group of achondrites with an unusual mineralogy and bulk composition. Their oxygen isotopic compositions fall on a well-constrained mass fractionation line consistent with a high degree of partial melting (Greenwood et al. 2005). They are medium to coarse-grained igneous, unbrecciated rocks mainly composed of Ca-Al-Ti rich pyroxene, Ca-rich olivine, anorthositic plagioclase and a range of minor minerals including: spinel, troilite, kirschteinite, whitlockite, titanomagnetite, and Fe, Ni metal. They are subdivided into plutonic and volcanic varieties. Angrites are highly depleted in alkali elements but are not very depleted in the highly volatile elements (e.g., Br, Se, Zn, In, and Cd). Although they are unbrecciated, angrites contain moderate abundances of siderophile elements. Angrites are believed to have formed by partial melting of primitive sources under oxidizing conditions. However, an impact melt origin has been proposed to account for their relatively high abundance of siderophile elements (Riches et al. 2012). Angrites are known to be amongst the most ancient basalts in the Solar System (Schiller et al. 2015).

Aubrites

Aubrites (or enstatite achondrites) are the most reduced achondrites. They comprise unbrecciated rocks, as well as regolith and fragmental breccias. They mainly consist of nearly FeO-free enstatite (75–98 vol%) with variable amounts of plagioclase, high-Ca pyroxene, and forsterite. Other constituent phases include Si-bearing Fe,Ni metal, oldhamite, daubréelite, ferroan alabandite, caswellsilverite, djerfisherite, niningerite, and schreibersite. Aubrites are igneous rocks formed by melting and differentiation of enstatite chondrite-like precursors. However, their relationship with known enstatite chondrites has not yet been established.

HED Meteorites

HED meteorites represent the largest group of achondrites. Monomict or unbrecciated eucrites and diogenites have essentially the same oxygen isotopic compositions ($\Delta^{17}O$), indicating that they are derived from a single source (Greenwood et al. 2015), probably asteroid 4 Vesta. Eucrites are divided into basaltic (noncumulate) and cumulate eucrites. They are mainly composed of pyroxene and plagioclase; minor phases include silica minerals, ilmenite, chromite, troilite, Fe,Ni metal, and Ca-phosphates (apatite and merrillite). Trace minerals include baddeleyite and zircon. Basaltic eucrites, which experienced varying degrees of shock and thermal metamorphism, are subdivided into four chemical groups (trends): main group, Nuevo Laredo trend, Stannern-trend, and residual eucrites (e.g., Yamaguchi et al. 2009). Diogenites are orthopyroxenites or harzburgites (olivine abundances up to 80 vol%). Most of them are brecciated, coarse-grained rocks and recrystallized breccias. They are composed of orthopyroxene and olivine, with minor chromite, silica minerals, and Fe,Ni metals.

HED polymict breccias are divided into polymict eucrites, howardites, and polymict diogenites (Delaney et al. 1983). The boundaries between these various types are not clear and form a continuum with respect to different types of lithic clasts and mineral fragments. Polymict eucrites contain >90 vol% eucritic clasts and polymict diogenites contain >90 vol% diogenitic clasts. The polymict breccias may contain minor exotic materials, such as chondritic clasts and Fe, Ni metals.

Geochemical evidence suggests that basaltic eucrites are residual melts after extensive fractional crystallization in a magma ocean (e.g., Righter and Drake 1997). The origin of diogenites seems to be more complex. They may have formed as cumulates after magma ocean crystallization, or alternatively crystallized in intrusions within the early-formed eucritic crust (Barrat et al. 2008). It is likely that eucrites and diogenites crystallized shortly after the formation of the Solar System. In a similar manner to lunar crustal rocks, their parent body experienced a heavy meteorite bombardment from ~4.4–3.0 Ga that resulted in the formation of most HED polymict breccias (Bogard 2011).

Mesosiderites

Mesosiderites are polymict breccias (stony-irons) consisting of silicates and Fe,Ni metal (>20 vol%). The silicate clasts are very similar to HED meteorites. Mesosiderites are classified into three petrologic classes on the basis of increasing orthopyroxene abundances, from A (basaltic) to B (more ultramafic) to C (orthopyroxenites). They are also subdivided into four metamorphic grades based on silicate textures, from grade 1 (lowest) to 4 (highest). The silicate fraction consists of mineral and lithic clasts in a fine-grained (recrystallized) or igneous matrix. The most common types are basalts, gabbros, and orthopyroxenites. Basaltic and gabbroic clasts are petrologically similar to eucrites. However, some basaltic clasts have low FeO/MnO in mafic silicates and show extreme REE depletions with very large positive Eu anomalies. The composition of Fe,Ni metal is roughly similar to that of the IIIAB irons. HED meteorites and mesosiderite silicates have identical oxygen isotopic compositions, consistent with a common source (e.g., Greenwood et al. 2015). Petrologic and geochemical features of mesosiderite silicate clasts can be explained by complex igneous processes or by metamorphism and partial melting resulting from metal-silicate mixing on a parent body similar to Vesta (Table 1).

Pallasites

Pallasites consist of subequal amounts of silicate (mostly, olivine) and Fe,Ni metal. Minor minerals include troilite, chromite, schreibersite, pyroxene, phosphates, and phosphoran olivine (Bosenberg et al. 2012). Sizes of individual olivine grains are up to a few centimeter. They are divided into main group pallasites, the Eagle Station group, the pyroxene pallasite grouplet, and ungrouped pallasites (e.g., *Milton*). They have distinct oxygen isotopic, mineral, and metal compositions. Pyroxene pallasites contain pyroxene (<3 vol%). It is widely thought that pallasites formed by mixing of molten Fe,Ni metal from the core of one asteroid with mantle from another differentiated asteroids. Based on oxygen isotopic compositions, the pallasites are derived from at least five parent bodies.

Lunar Meteorites

Lunar meteorites are crustal rocks from the Moon. They are divided into feldspathic breccias, mixed breccias of basalts and anorthosites, KREEP-rich (K, Rare Earth Elements, and P) breccias, and mare basalts. Feldspathic breccias are mostly composed of plagioclase with minor olivine and pyroxene and have high Al_2O_3 (26–31%), low FeO (3–6%), and low incompatible elements. Mare basalts have high FeO (18–22%) and moderately low Al_2O_3 (8–10%) (Korotev 2005). KREEP-rich breccias have very high concentrations of incompatible elements.

Lunar meteorites provide a more representative sampling of the lunar crust than the samples obtained by Apollo and Russian Luna missions that collected rocks and regoliths almost exclusively from the equatorial regions of the Procellarum KREEP Terrane. Feldspathic breccias represent ancient lunar crust that formed ~4.4–4.5 Ga. The precursors to the feldspathic breccias may originally have been cumulate

rocks that floated on the top of a global magma ocean. KREEP-rich rocks are contaminated with the final dregs of the magma ocean. Alternative models for crust formation, such as serial volcanisms, have also been suggested. Almost all highland rocks were brecciated during the cataclysmic bombardment ~3.9 Ga. Mare basalts formed during later volcanism and continued to ~1.2 Ga on the basis of remote-sensing data (Hiesinger et al. 2003).

Martian Meteorites

Martian meteorites are crustal rocks from Mars. They are shergottites, nakhlites, chassignites, orthopyroxenite (*ALH 84001*), and polymict breccias (e.g., *NWA 7034* and paired rocks) (Agee et al. 2013; Humayun et al. 2013). The former three were collectively called "SNC meteorites." Shergottites are divided into basaltic, lherzolitic, and olivine-phyric types and mainly consist of pyroxene, maskelynite (transformed from plagioclase), and minor minerals. Nakhlites are clinopyroxenites. Chassignites are dunites. Basaltic and olivine-phyric shergottites, and nakhlites are volcanic rocks formed in lava flows. Other SNC meteorites are plutonic rocks. The polymict breccias are compositionally similar to Martian regolith and have an oxygen isotopic composition distinct from other Martian meteorites. Some Martian meteorites experienced aqueous alteration after crystallization. The ages are generally younger than those of asteroidal achondrites varying from 4.4–0.2 Ga (Nyquist et al. 2001; Humayun et al. 2013).

Ungrouped Achondrites

There are ~70 ungrouped achondrites consisting of ~30 "groups." The largest group is similar to brachinites ("brachinite-like"). There are 17 basaltic achondrites that are petrologically similar to basaltic eucrites but have distinct O-isotopic compositions (e.g., *NWA 011*). These meteorites could have been derived from the crust of differentiated bodies similar to Vesta. *NWA 6704* and paired rocks are orthopyroxenites. *NWA 7325* and paired rocks are olivine gabbros and have a reduced mineralogy. These rocks formed from an unusual melt characterized by very low REE abundances and a very large positive Eu anomaly, generated by the remelting of an ancient gabbroic lithology (Barrat et al. 2015).

Summary

Achondrites represent samples from several tens of differentiated asteroids. Asteroidal achondrites record early differentiation of planetesimals that took place a few million years after the formation of the solar system. Planetary achondrites provide important information about the differentiation processes that took place on larger bodies. The number of achondrite samples is currently expanding rapidly, due in large part to ongoing collection activities in hot and cold desert regions. These new samples provide a wealth of evidence concerning the magmatic and metamorphic processes that took place on their parent bodies.

Acid Deposition

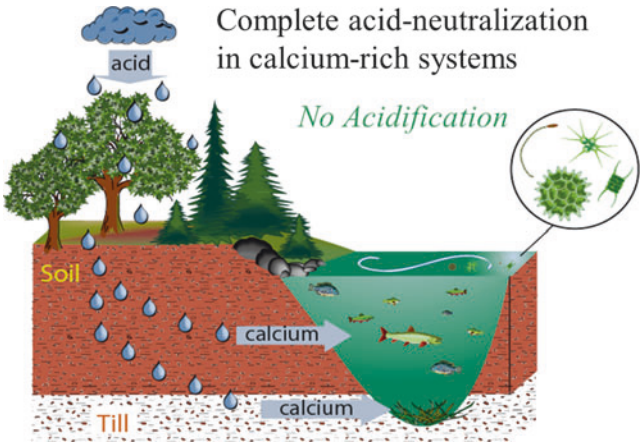
Gregory B. Lawrence
New York Water Science Center, U.S. Geological Survey, Troy, NY, USA

Definition

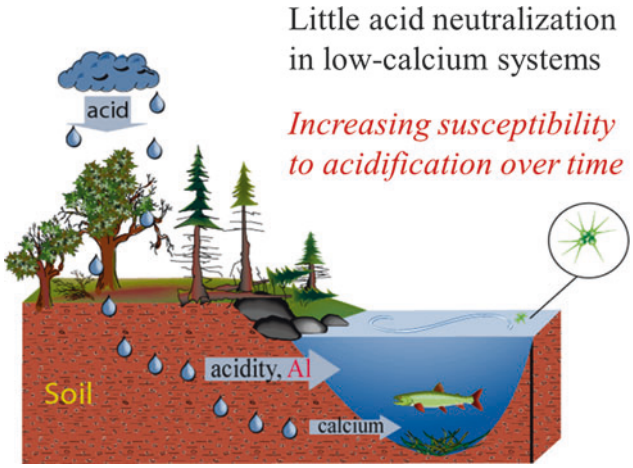
Acid deposition, often referred to as acid rain, is a term used to describe the deposition of pollutant-derived chemical compounds from the atmosphere to the Earth's surface. These compounds result from emissions produced by fossil fuel combustion for energy production and vehicular use and from agricultural practices that create air pollution. Some of the pollutants can be deposited relatively close to the emission source, but others can be transported hundreds of miles from the source before being deposited. Much of the acid deposition occurs in a strongly acidic form as sulfuric or nitric acid (H_2SO_4 or HNO_3), but some compounds are deposited in nonacidic forms that can be transformed into acids through complex ecosystem processes. In particular, nitrogen deposited as NH_3 or nitrogen oxides (NO_x) can be converted to HNO_3 through a series of biochemical transformations involving both plants and microbes.

Landscape Sensitivity to Acid Deposition

Deposition occurs in the form of rain, snow, and sleet (termed wet deposition) when precipitation is occurring, as well as particles and gases (termed dry deposition) and fog (termed cloud deposition). Some acid deposition falls directly onto water surfaces, but because the surface area of freshwater lakes and streams is small relative to the surface area of land (less than 7% in the United States), the vast majority of acid deposition interacts with terrestrial ecosystems before reaching surface waters. This is a key factor, because the geochemical makeup of soil and underlying till and bedrock determines the impact that acid deposition will have on both terrestrial and aquatic ecosystems.



Acid Deposition, Fig. 1 Landscapes with abundant Ca in the soil and subsoil (till in glaciated regions, weathered bedrock or saprolite in unglaciated regions) effectively neutralize acid deposition, preventing harmful effects to terrestrial and aquatic ecosystems



Acid Deposition, Fig. 2 Landscapes developed from slowly weathering rocks with low Ca content have limited acid-neutralizing ability. Acid deposition depletes the naturally low levels of Ca causing acidification of soils and surface waters

As deposited acids move in solution through soil and deeper pathways en route to surface waters, they can be neutralized through (1) the consumption of H^+ by dissolution of minerals; (2) electrostatic exchange between H^+ and base cations that are adsorbed to particle surfaces such as calcium (Ca), magnesium (Mg), sodium (Na), and potassium (K); (3) adsorption of SO_4^{2-} to soil particles (particularly in non-glaciated soils); (4) uptake of nitrate by vegetation; and (5) conversion of deposited nitrogen into gaseous N_2 (termed denitrification). If the soil and subsoil are rich in base cations, such as those derived from carbonates, acid deposition will be fully neutralized with little or no effects on aquatic and terrestrial ecosystems (Fig. 1). However, some landscapes are derived from bedrock types such granite or gneiss, which weather slowly and are comprised of minerals poor in base cations. In these landscapes, the limited buffering of acid inputs is not sufficient to prevent surface water acidification (Fig. 2). For this reason, the impact of acid deposition can vary from little or no effect on soils and surface waters to severe acidification depending upon the mineralogical composition of the predominant rock types of the landscape. Upland areas that are typically forested most often have bedrock types with limited ability to neutralize acids. This characteristic plus high levels of precipitation make these areas the most susceptible to acid deposition. The rate of acid deposition plays an important role in determining the severity of effects. Proximity to emission sources and location relative to prevailing winds are important factors in determining the levels of acidic deposition to which an area is exposed.

History of Acid Deposition Effects

Negative environmental effects of air pollution from fossil fuel combustion were documented for areas of central and northern Europe, and for eastern North America by the mid-1900s, and for eastern Europe and Southeast Asia by the late 1900s. However, acidification of surface waters first became apparent in Scandinavia in the 1960s and in North America in the 1970s from observations of fish kills. It's estimated that acid deposition levels peaked throughout eastern North America (Driscoll et al. 2001) and much of Northern Europe during the 1970s (Wright et al. 2005). The data collected by the National Atmospheric Deposition Program, established in the late 1970s to monitor acid deposition throughout the United States, showed that sulfur deposition decreased by as much as 70% from 1980 to 2010 (http://nadp.sws.uiuc.edu/; accessed March 5, 2017) with similar or larger decreases achieved in Europe, largely as a result of various forms of government legislation that reduced air pollution, such as the 1970 Clean Air Act Amendments in the United States.

Effects of acid deposition on aquatic ecosystems caused widespread concern that led to a rapid development of monitoring and research programs. Fish as well as many other forms of aquatic life were found to be sensitive to the decreased pH, but the primary toxicant was identified as inorganic monomeric aluminum (Al), a group of aluminum compounds released from the soil by the acid deposition. Although Al occurs naturally in the soil, it is not converted into harmful forms without the addition of acidic deposition. In the early stages of acid deposition research, the importance of acidity derived from atmospheric pollution was questioned relative to natural acidity produced by decomposition of plant material (Krug and Frink 1983). This natural organic acidity was found to be a significant factor in lowering the pH of some surface waters, and organic acids moving through soil were known to mobilize Al (Fakhraei and Driscoll 2015). However, through the process of organic acid mobilization,

Al becomes complexed with organic anions, rendering it innocuous to aquatic ecosystems. In sharp contrast, the strong mineral acids (H_2SO_4 and HNO_3) that comprise acid deposition release Al in several inorganic forms that negatively impact all levels of the aquatic food chain. As a result, surface waters in many poorly buffered regions became episodically or chronically toxic to aquatic biota, thereby degrading aquatic ecosystems and rendering some lakes and streams incapable of supporting fish populations.

Terrestrial effects of acid deposition were first suggested by mass die-offs of red spruce (*Picea rubens* Sarg.) trees in the mountains of the Northeastern US and Norway spruce (*Picea abies* H. Karst.) in countries such as Germany and the Czech Republic the early 1980s. Some forests lost up to 50% of the trees without any apparent natural cause. By the 1990s elevated mortality of red spruce was also being seen at relatively low elevations in the United States, such as the Western Adirondack Region of New York (Lawrence et al. 1997). Research through the 1980s and 1990s focused on direct effects of acid deposition on foliage. Extensive periods of acidic fog at high-elevation sites were found to damage spruce needles, which eventually led to mortality. However, a widely cited paper published in 1988 (Shortle and Smith 1988) drew the first link between red spruce decline and acid deposition effects on soils. At that time, effects of acid deposition on soils were unclear, but this study spurred increased research on possible soil effects of acid deposition. Eventually, the primary cause of widespread red spruce decline was determined to be depletion of soil calcium from enhanced leaching by acid deposition (Schaberg et al. 2001).

The Key Role of Soils

Possible effects on soils had been suspected soon after the discovery of acid deposition, but without soil data that predated the onset of the problem, knowledge of soil effects was limited largely to theory. In the early 1980s, a renowned German soil scientist developed the conceptual model of how acid deposition affected soils through a three-stage process (Ulrich 1983). In the first stage, release of base cations through weathering of primary and secondary minerals is sufficient to fully buffer the elevated inputs of acids. However, in soils with small amounts of rapidly weatherable minerals, due to long-term natural weathering, or in soils developed from slowly weathering silicate minerals, the rate of acid buffering from weathering could be exceeded by the rate of acid inputs from acid deposition. This condition leads to phase 2 in which buffering of acid deposition would be dependent on exchange between base cations adsorbed to soil particle surfaces and protons (H^+) in soil solution. Replenishment of adsorbed base cations is ultimately dependent on weathering, so if acid deposition levels exceed weathering rates, the buffering of acidity through cation exchange will lead to depletion of exchangeable base cations. This condition leads to phase 3 in which buffering of acidity shifts to release of inorganic Al to soil solution. Once in solution, various chemical species of inorganic Al become mobile in association with SO_4^{2-} and NO_3^-, enabling movement from soils to surface waters.

Ulrich's theory explained the acidification of surface waters, and by the early 2000s, data from soil resampling studies showed that depletion of exchangeable Ca concentrations was common in regions where surface water acidification occurred (Warby et al. 2009). The link between soil Ca depletion and Al mobilization was fully confirmed with archived soils from northwestern Russia that showed depletion of exchangeable Ca between 1926 and 1964, followed by little further Ca depletion, but a pronounced mobilization of Al from 1964 to 2001 (Lawrence et al. 2005). Quantification of these soil changes resulting from acidification was an important step to aid in the assessment of ecosystem recovery responses from declining acid deposition levels.

Once it had been established that acid deposition had depleted soils of Ca, research on ecosystem effects of acid deposition expanded beyond acidification to evaluate the direct effects of decreased Ca availability. Because Ca is an essential nutrient for plants and animals, depletion of soil Ca can have negative effects on both terrestrial and aquatic species. In addition to red spruce mortality, loss of soil Ca has also been linked to decreased growth and increased mortality of sugar maple trees, decreases in abundance of some songbird species, decreased abundance and diversity of terrestrial snails, and negative effects on zooplankton in lakes and benthic algae in streams (Lawrence et al. 2016).

The Status of Recovery from Acid Deposition in 2017

The large decrease in acid deposition levels in North America dating back to the early 1980s led to partial recovery of surface waters in the late 1990s. The most pronounced change has been the decrease in inorganic Al concentrations, although recovery has also been seen with increases in pH and acid-neutralizing capacity (Driscoll et al. 2001). Nevertheless, in 2017, surface waters that experience toxic levels of inorganic Al during periods of high stream flow remained common in the most acid-sensitive landscapes. Furthermore, increases in the organic acidity of surface waters that have occurred during the period of recovery have slowed the increase of pH and ANC, although this response is likely to represent a return to pre-acid deposition conditions and therefore is likely to be tied to recovery (Monteith et al. 2007).

Evidence of soil recovery from acidification effects was first shown in a study covering a large region of the Northeastern United States and eastern Canada (Lawrence et al. 2015). Sites

showing the greatest decrease in acid deposition also showed the strongest recovery response. Decreases in Al in surface or near-surface organic soils indicated that Al mobilization had decreased markedly and decreases in Ca were no longer seen. However, the soil recovery identified in 2015 must be considered to be in its early phase. In the upper mineral soil, Al continues to show increases. Although this increase could indicate further acidification, it may also indicate a recovery phase as Al moves downward from the organic horizons to be immobilized in the upper mineral soil (Lawrence et al. 2015). The widespread decreases in surface water Al concentrations support the interpretation that Al has become less mobile within the soil profile. Overall, monitoring of soils and waters indicates continued progress toward full recovery, but uncertainties remain regarding the rate at which soils will recover, and these uncertainties carry over into the chemical recovery surface waters. Biological recovery of terrestrial and aquatic ecosystems remains dependent on chemical recovery and therefore has also shown limited recovery. The legacy of acid deposition effects on terrestrial and aquatic ecosystems seen in 2017 is likely to persist over future decades.

Acid–Base Reactions

Carl O. Moses
Provost and Vice President for Academic Affairs, Grand View University, Des Moines, IA, USA

Acid–base concepts provide one of the most important and enduring foundations for correlating chemical reactivity. A *general theory* of acid–base reactivity has yet to be developed but, in fact, there may be little need in view of the utility of the various concepts that provide a framework for understanding and, in many cases, quantitatively accounting for or predicting chemical reactivity. Several such frameworks are available, but this entry focuses on two concepts that have contributed significantly to geochemistry: Brønsted-Lowry acidity and Lewis acidity. In addition to reactions in aqueous solution (the focus of this entry), both Brønsted-Lowry and Lewis acid–base reactions occur at the interface between mineral surfaces and aqueous solutions. Surface acidity and the consequent formation of surface complexes constitute a very active area of current research (see ▶ "Surface Geochemistry"), owing to the fundamental importance of acid–base reactivity in explaining and correlating processes (e.g., dissolution and precipitation, ion exchange, catalysis) in heterogeneous systems (Huang 1981; Schindler 1981; Davis and Kent 1990; Stumm 1992).

Originally published in : Marshall CP, Fairbridge RW (eds) Encyclopedia of Geochemistry, Springer Netherlands, 1999

The Braønsted-Lowry Concept

The most familiar acid–base concept is the Brønsted-Lowry definition: an acid donates a proton (i.e., hydrogen ion, H^+), and a base accepts a proton (Eq. 1).

$$\text{acid} = \text{base} + H^+ \tag{1}$$

The Brønsted-Lowry concept broadened the antecedent Arrhenius concept, with which it is often confused. According to Arrhenius, acids donate H^+ and bases donate OH^- (hydroxide ion); furthermore, water was the requisite solvent system. As it was recognized that electrolyte dissociation takes place in other solvents, it was also recognized that basicity can be treated as the inverse of acidity and not restricted to OH^-. The Brønsted-Lowry concept thus broadens the notion of base as any species capable of combining with H^+. The hydrogen ion acquired a special status in early studies of electrolyte dissociation owing to its small size, very high charge density, high mobility, and complete lack of electrons. It is natural that while the Brønsted-Lowry concept broadened the concept of a base, the definition of an acid remains restrictive.

A general acid dissociation reaction and its equilibrium constant $K_{\text{acid, HA}}$ are written, respectively, as

$$HA = H^+ + A^- \text{ and } K_{\text{acid,HA}} = \frac{a_A - a_{H^+}}{a_{HA}}, \tag{2}$$

where a_i represents the activity of species i (activity is a thermodynamic concept related to concentration: $a_i = \gamma_i m_i$, where m is molality (mol kg^{-1}) and γ is the solution composition-dependent activity coefficient; see ▶ "Equilibrium Constant" and Activity and activity coefficients). For a general base, B, we write:

$$B + H^+ = BH^+ \text{ and } K_{\text{base,B}} = \frac{a_{BH^+}}{a_B a_{H^+}}. \tag{3}$$

Base association is thus the reciprocal of acid dissociation, in accord with the definition in Eq. 1. We could write:

$$K_{\text{base},A^-} = \frac{a_{HA}}{a_A - a_{H^+}} = K^{-1}_{\text{acid,HA}}$$

or:

$$K_{\text{acid},BH^+} = \frac{a_B a_{H^+}}{a_{BH^+}} = K^{-1}_{\text{base, B}},$$

and we observe that:

$$\left(K_{\text{base},A^-}\right)\left(K_{\text{acid,HA}}\right) = 1 \quad \text{and}$$
$$\left(K_{\text{acid},BH^+}\right)\left(K_{\text{base, B}}\right) = 1.$$

The magnitudes of K_{acid} and K_{base} indicate the relative strengths of acids or bases. Smaller values of K_{acid} reflect a smaller tendency for an acid to dissociate (a weaker acid), while smaller values of K_{base} reflect a smaller tendency for a base to acquire a proton (a weaker base). Equations 2 and 3 are hypothetical representations, however, because protons are too reactive to exist independently. A Bronsted-Lowry acid–base reaction is a proton *transfer,* so a proton-donation reaction such as Eq. 2 must be coupled with a proton-acceptance reaction such as Eq. 3. In general,

$$\begin{aligned} HA = A^- + H^+ \quad & K_{\text{acid}} = \frac{a_A - a_{H^+}}{a_{HA}} \\ B + H^+ = BH^+ \quad & K_{\text{base}} = \frac{a_{BH^+}}{a_H + a_B} \\ \hline HA + B = BH^+ + A^- \quad & K_{AB} = \frac{a_A - a_{BH^+}}{a_{HA} a_B} = K_{\text{acid}} K_{\text{base}} \end{aligned} \tag{4}$$

Neither K_{acid} nor K_{base} can be measured independently of one another, owing to the need to couple proton donations and acceptances.

H_2O is an *amphoteric* solvent (i.e., it can behave both as an acid and as a base). The autoprotolysis reaction (Eq. 5) involves one H_2O that behaves as an acid and donates H^+ and another H_2O that acts as a base and accepts H^+.

$$H_2O + H_2O = H_3O^+ + OH^- \tag{5}$$

Equation 5 represents the coupling of $H_3O^+ = H_2O + H^+$ (K_{acid}, H_3O^+) and $OH^- + H^+ = H_2O$ ($K_{\text{base, OH}^-}$). The autoprotolysis equilibrium constant is $K_w = a_{H3}{}^{o+} a_H{}^-$ in which the mass-action expression for K_w is written without a denominator because we assume that the solution is sufficiently dilute that $a_{H2}{}^o \rightarrow 1$. Following the coupling scheme in Eq. 4, K_{AB}, $H_2O = K_{\text{acid,H}_3\text{O}^+} K_{\text{base,OH}^-}$, so $K_W = K^{-1}_{AB,\text{H}_2\text{O}}$ (at 25°C, $K_W = 10^{-14}$). The formalism of using H_3O^+ for the acid species of water is often relaxed, and K_w is called the hydrolysis constant for $H_2O = H^+ + OH^-$. Similarly, Eq. 2 is used as a prototypical acid dissociation. Using H^+ as a shorthand notation for H_3O^+ is harmless as long as we remember that protons have no independent existence and are transferred in coupled reactions.

In aqueous solutions, Braønsted-Lowry acid dissociation reactions are coupled to the inverse of H_3O^+ dissociation by the scheme in Eq. 4, i.e., H_2O is the proton-accepting base, so $HA + H_2O = H_3O^+ + A^-$, and $K_{AB} = K_{\text{acid,HA}} K^{-1}_{\text{acid}}$, H_3O^-. The K_a values reported in the literature for aqueous Bronsted-Lowry acids (e.g., $H_2CO_3 = HCO^-{}_3 + H^+$, $K_a = 10^{-6.35}$) are understood to be the same as K_{AB} and implicitly include the inverse dissociation of H_3O^+ (e.g., $H_2CO_3 + H_2O = HCO^-{}_3 + H_3O^+$, $K_{AB} = 10^{-6.35}$). Similarly, aqueous Bronsted-Lowry base-association reactions are

coupled to the inverse of OH^- association, giving $B + H_2O - BH^+ + OH^-$, for which the reported K_b values are $K_{AB} - K_{BK} = K_{base,B}$, K^{-1}_{base,OH^-} (e.g., $NH_3 + H_2O = NH^+_4 + OH^-$, $K_b = 10^{-4.75}$). Generally, for an aqueous acid and its conjugate base, $K_a K_b = K_W$ (e.g., $NH^+_4 = NH_3 + H^+$, $K_a = 10^{-9.25}$).

Braønsted-Lowry acid–base reactivity plays a fundamental role in geochemistry because so many geochemical processes involve proton transfers. The hydration of oxide gases generally yields acids that may dissociate to yield protons in aqueous solution (e.g., $CO_2 \rightarrow H_2CO_3$, $SO_3 \rightarrow H_2SO_4$; see Acid deposition). Furthermore, many mineral dissolution reactions involve the consumption or production of protons in solution and are, in fact, promoted by the amphoteric character of H_2O.

pH

The Braønsted-Lowry proton-transfer concept of acidity also leads to the familiar concept of pH, which provides a reference scale for the relative H^+ concentration of different solutions in a given protonic solvent. The definition of pH is based on using the prefix "p" to mean the "negative base-10 log of" the indicated quantity, and the "H" indicates the quantity a_{H^+} Eq. 6 for aqueous solutions).

$$\mathrm{pH} \equiv -\log a_{H_3O^+} \tag{6}$$

With the p-notation, we can also write $pK_w = \mathrm{pH} + \mathrm{pOH} =$ 14 (at 25 °C). A neutral pH is the pH where $a_{H_3O^+} = a_{OH^-}$ ($\mathrm{pH_{neutral}} = \mathrm{pOH_{neutral}}$), so $PK_W = 2\mathrm{pH_{neutral}}$; at 25 °C therefore, $\mathrm{pH_{neutral}} = 7$. The conventional limits of the aqueous pH scale are 0 ($a_{H_3O^+} = 1$, $a_{OH^-} = 10^{-14}$) and 14 $a_{OH^-} = 1$), but concentrated solutions of strong acids can have pH < 0 and concentrated solutions of strong bases can have pH > 14. Measurements of pH in such concentrated solutions are quite difficult, owing to the need for significant activity coefficient corrections and the often nonlinear character of device or indicator calibrations. In natural waters, pH values outside the range 3–11 are uncommon, and most living organisms are best suited to a significantly narrower range of near-neutral values. Butler (1964) elaborates on the calculation of pH and other parameters of Brønsted-Lowry acid–base reactivity in solution.

The Lewis Acid Concept

The Lewis concept is based on the donation and acceptance of bonding electrons. Lewis acids and bases are not to be confused with reducing and oxidizing agents whose oxidation states change by virtue of electron transfers without bonding. A Lewis acid has a vacant orbital that can accept a pair of electrons, and a Lewis base has at least one pair of valence electrons that are not being used for a bond (Jensen 1980). Lewis acidity is a broader concept than Braønsted-Lowry acidity, but all Brønsted-Lowry bases are also Lewis bases because the portion is a Lewis acid. Lewis acid–base reactivity involves the formation of *coordination complexes* (also called *adducts*; Eq. 7).

$$\mathrm{A} + : \mathrm{B} = \mathrm{A} : \mathrm{B} \tag{7}$$

The use of the: emphasizes the electron donation and acceptance. In the specific case where A is a metal ion, :B is often termed a *ligand.* A Lewis acid may also be called an *electrophile*, and its acidity is *electrophilic* in nature, owing to its tendency to react with an electron-rich species. The corresponding terms for a Lewis base are *nucleophile* and *nucleophilic.*

Depending on the reactants, Lewis acid reactions like Eq. 7 are usually coupled with Lewis base reactions (the inverse of Eq. 7). A coupled complexation reaction thus involves the exchange of acids and bases: $A_1B_1 + A_2B_2 = A_1B_2 + A_2B_1$.

Lewis acidity is an especially useful concept for understanding the formation of complexes in aqueous solution and for rationalizing or correlating the relative stability of complexes. Under the Lewis concept, cations are acids, anions are bases, and salts are complexes. For example, solid Na·$\ddot{\mathrm{C}}$l is a complex of acidic Na^+ and basic $\cdot\ddot{\mathrm{C}}\mathrm{l}^-$. In solution, cations (generally metal ions, Me^{x+}) are coordinated with basic ligands (L^{y-}), $MeL_n^{(x+)-(n(y-))}$, where n is the ligand number. Neutral species can also behave as acids or bases, depending on their ability to accept or donate electron pairs. H_2O can bond as a base via the oxide anion (e.g., with Fe^{3+}, $Fe(H_2O)^{3+}_6$); in these hydration complexes, the ligand number is the hydration number. Owing to its polar nature, H_2O can also be a Lewis acid via hydrogen bonding and, thereby, hydrate base anions (e.g., with Cl^-, $(OH_2)_n Cl^-$). For example, in aqueous solution,

$$Fe(H_2O)^{3+}_6 + (OH_2)_n Cl^- = FeCl(H_2O)^{2+}_5 + (n+1)H_2O.$$

Although such reactions are coupled, we usually write $Fe^{3+} + Cl^- = FeCl^{2+}$, and the formation (association) constant, $K_{FeCl^{2+}}$, implicitly includes the acid–base exchange of H_2O molecules.

In the absence of other ligands, an aqueous cation is surrounded by a hydration "sphere" in which the H_2O molecules are positioned according to the coordination geometry of the cation and oriented with their protons away from the cation; for example, Fe^{3+} tends toward octahedral coordination, so its primary hydration sphere contains 6 H_2O molecules. Outside the primary hydration sphere, there is a more diffuse zone of H_2O molecules whose movement and position

are influenced somewhat by the charge on the cation; this secondary hydration sphere is not constrained to the cation's coordination geometry, and the number of H_2O molecules in the secondary sphere is less determinate. In a hydrated Lewis acid, the repulsive force between the cation and a proton on a coordinated H_2O is approximately proportional to z, the charge of the cation, and r^{-1}, the distance between the cation and the proton. In the literature, various ionic potential functions $I_P = z^p/r^q$ are used; usually, $p = 1$ or 2, and $q = 1$. In any case, increased I_P gives increased hydration (i.e., larger n) and increased tendency to eject H^+ from the complex and form a metal-hydroxide complex (e.g., $FeOH(H_2O)^{2+}_5$). Owing to their large size, anions have small I_P and are generally only weakly hydrated; n is often indeterminate for an anion.

There are two types of Lewis complexes of metals and non-H_2O ligands in aqueous solution. In an *inner-sphere complex,* the ligand displaces an H_2O molecule from the primary hydration sphere and resides in one of the cation's coordination sites. In an *outer-sphere complex* (sometimes called an ion pair), the ligand resides outside the primary hydration sphere; the ligand is shielded from direct interactions with the cation by the H_2O molecules of the primary hydration sphere. A given complex is generally not purely inner-sphere or outer-sphere, but the character of the complex can be dominated by one type or the other in the same sense that bonds are dominated by covalent bonding (inner-sphere; short-range forces with lots of electron sharing between cation and ligand) or electrostatic bonding (outer-sphere; long-range forces with little electron sharing). Inner-sphere complexes are characterized by greater stability and larger association constants than outer-sphere complexes.

There is no widely used method of or scale for quantitatively comparing Lewis acid–base strengths that compares with the pK_a–pH relationships of Brønsted-Lowry acids. Any Lewis acid–base reaction does, of course, have an equilibrium constant, but the problem lies in establishing a reference acid against which the strength of other acids can be compared in the necessary coupling reaction and, similarly, establishing a reference base for measuring basicity. In aqueous solutions, the Brønsted-Lowry definition points clearly toward H_3O^+ as the reference acid and OH^- as the reference base, but the benefits of the broader Lewis definition come at the expense of less clarity with respect to references. The magnitude of ΔH (enthalpy change) for a reaction represents the strength of the bonds made or broken, and efforts have been made to use multiple parameters relating to electrophilicity and nucleophilicity of reactants to predict ΔH for complexation reactions (e.g., Drago and Wayland 1965) or to predict K (Edwards 1954). In either case, the computed values provide a basis for predicting the relative stability of complexes.

On the other hand, the proton is a rational choice for a reference Lewis acid in aqueous solution. The proton is small and unpolarizable, and it has a very high I_P. If the proton thus defines one end of a scale of Lewis acidity, the opposite end would be represented by a large, polarizable cation with low I_P (e.g., Ag^+ and Hg^{2+}). Bases could then be classified according to their reactivity with acids. It is observed that bases in which the donor atoms are relatively small and unpolarizable tend to bond with acids at the proton end of the Lewis acidity scale in preference to acids at the opposite end and vice versa.

Although it is not quantitative, the principle of hard and soft acids and bases (HSAB, also known as Pearson's Rule) has proved to be very useful in correlating the relative stability of complexes along the lines of such a qualitative scale (Pearson 1973). HSAB holds that hard acids tend to combine with hard bases, while soft acids tend to combine with soft bases. If B_2 is softer than B_1 and A_2 is softer than A_1, the exchange reaction $A_1B_2 + A_2B_1 = A_1B_1 + A_2B_2$ tends to proceed to the right ($K > 1$). Acids and bases are thus each classified into three categories: (a) hard species that are smaller, more charge-dense, and less polarizable, (b) soft species that are larger, less charge-dense, and more polarizable, and (c) borderline species. The borderline category allows for the qualitative and relative nature of the correlation and for the fact that molecular environment (e.g., the presence of different ligands) can influence the relative hardness of a species.

The geochemical significance of Lewis acid–base reactivity lies in two areas. In the first, the specificity or sequence of reactivity of one species (a cation, an anion, a mineral surface site) with others can often be explained according to Pearson's rule. The second area of significance is the formation or relative stability of aqueous complexes, which generally promotes the mobility of elements in the hydrosphere by enhancing their solubility.

Acidic and Basic Rocks

Although it is not common to see these designations in current literature, the older literature often refers to "acidic rocks" and "basic rocks." Those designations have much more to do with a classification of rocks on the basis of their composition than on the basis of their reactivity, which is the principal use of acid–base concepts in other contexts. The origin of the term "acid rock" is the tendency of non-metal oxides to form acids when they dissolve in water (e.g., $SiO_2 + 2H_2O = H_4SiO_{4(aq)}$; silicic acid is a weak acid). Hence rocks rich in silica (those containing large proportions of quartz or feldspar) have been called acidic. "Basic rock" originates in the tendency of metal oxides to form bases upon

dissolution (e.g., $MgO + H_2O = Mg^{2+} + 2OH^-$), and rocks rich in iron oxide or alkali earth oxides have been called basic. The more common recent trend is to reserve acidic and basic for descriptions of reactivity and to use terms like silicic, felsic, or mafic to describe the composition of rocks. "Alkaline" is a synonym for "basic,," but it has also been used to describe rocks rich in the alkali metals sodium or potassium. It is still common for such rocks to be referred to as alkaline, although "sodic" and "potassic" are clearer alternatives. It is also true that terms like "base metal" and "acid alteration" occur frequently in the literature, where they often lead to some confusion if they are used without a clear explanation of their meaning in context.

Activation Parameters: Energy, Enthalpy, Entropy, and Volume

William H. Casey[1] and C. André Ohlin[2]
[1]Department of Chemistry and Department of Earth and Planetary Sciences, University of California, Davis, CA, USA

Definition

Activation parameters are used in chemical kinetics to describe the equilibrium between reactants of a chemical reaction and a single, unstable molecule called a transition state.

Transition State Theory and Elementary Versus Overall Reactions

Transition-state theory is the central underpinning of all chemical kinetics. It postulates that for elementary reactions, there is equilibrium between reactants and an unstable form called the transition state, which is a single molecule. The equilibrium is conventional in all ways except that the transition state has a loose vibrational mode that dissociates and leads to products (Glasstone et al. 1941). The thermodynamic terms that describe this activated equilibrium between the reactants and the transition state are called activation parameters and have exact analogues with the standard thermodynamic parameters that describe a conventional equilibrium between the reactants and the products in a reaction. However, the transition state determines the rate of reaction is unstable.

For geochemists, it is essential to understand the definition and scope of an elementary reaction – these are reactions that have a single energy barrier between reactants and products. Thus, the rotation of a methyl group from staggered to eclipsed orientation could be an elementary reaction. Transfer of a proton from a metal-bound water molecule to a bulk water one could be an elementary reaction. Transfer of a solvation water molecule to the bulk could be an elementary reaction. The key is that one can follow the movement of each atom over the single-step barrier.

Reactions that do not consist of a single molecular step and concerted motions are overall reactions. Inversion of the structure of cyclohexane from *chair* to *boat* conformation is *not* an elementary reaction because intermediate states can be identified, even though the molecule doesn't dissociate. Thus, geochemical reactions such as:

$$SiO_2(s) + 2H_2O(l) = H_4SiO_4(aq) \quad (1)$$

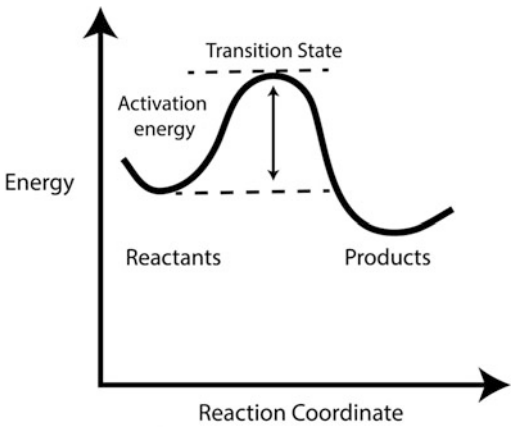
are *not* elementary reactions because one cannot enumerate the actual concerted motions of each atom in the reacting structure as the reaction proceeds at the molecular scale. There must be hundreds or thousands of elementary reactions, each of which has an energy barrier. The energy landscapes for geochemical reactions are complicated, not simple.

Transition state theory can be adapted to treat overall reactions but with enormous loss of information (Boudart 1976; Boudart and Djega-Mariadasson 1984; Lichtner 2016) so that these become effectively empirical relations. Even simple isotope-exchange reactions, involving molecules where the structures can be known with complete confidence and which can be studied in excruciating experimental detail, usually proceed via metastable states and many steps (Casey and Rustad 2016; Rustad 2010; Rustad and Casey 2012).

Activation Parameters

For true single-step reactions, the activation energy is defined as the energy that must be surmounted for reactants to reach the transition state (Fig. 1). Note that there is a single barrier and no intermediates. Practically the activation energy, E_a, is estimated from the temperature dependence of a reaction rate coefficient or, in rare but increasingly frequent cases, from electronic-structure calculations.

Because transition state theory postulates an equilibrium between reactants and the transition state, the conventional derivative properties of an equilibrium constant have exact analogues in chemical kinetics. The temperature variation of the rate coefficient yields the familiar Arrhenius rate law:



Activation Parameters: Energy, Enthalpy, Entropy, and Volume, Fig. 1 The activated equilibrium for an elementary reaction has a single energy barrier

$$k = A_o e^{\frac{-E_a}{RT}} \tag{2}$$

where A_o is an empirical pre-exponential term that can be interpreted to include activation entropies and activity coefficients. The similarity of this expression to the conventional Van't Hoff expression for the temperature variation of an equilibrium constant is not accidental:

$$\left(\frac{\delta \ln k^{\neq}}{\delta\left(\frac{1}{T}\right)}\right)_P = \frac{-\Delta H^{\neq}}{R} \tag{3}$$

Similarly the pressure variation of the activated equilibrium yields activation volumes:

$$\left(\frac{\delta \ln k^{\neq}}{\delta P}\right)_T = \frac{-\Delta V^{\neq}}{RT} \tag{4}$$

and the activation enthalpy relates to the activation energy via:

$$E_a = H^{\neq} + RT \tag{5}$$

where E_a is the activation energy derived from the Arrhenius equation (analogous to the Van't Hoff equation of equilibrium thermodynamics), The parameter $H^{\neq}$ is the enthalpy of activation, R is the gas constant, and T is the temperature in Kelvins.

The activation barriers for common reactions in aqueous solutions vary from about 20 kJ/mol for the cost of solute diffusion to the exchange of a water bound in $[Ir(OH_2)_6]^{3+}$ with a bulk water, which has an activation enthalpy of over 130 kJ/mol (Helm and Merbach 2005). For aqueous reactions, there is usually a strong correlation between the logarithm of the rate coefficient and the activation energy or enthalpy. For homoleptic ligand-exchange reactions, such as exchange of a bulk water for a water bound in an inner solvation sphere of a metal, the activation volume, $\Delta V^{\neq}$, is used to infer the form of the transition state. Because a bulk water is much more loosely packed than a solvation-shell water, a positive $\Delta V^{\neq}$ value is used to infer a reaction pathway that has considerable dissociative character, meaning that the reaction involves a decrease in coordination number in the transition state. Conversely a negative $\Delta V^{\neq}$ value is used to infer gain in coordination number of the metal during the ligand-exchange reaction. In reality most reactions fall intermediate between these extremes.

Conclusion

Activation parameters are experimental parameters that shed light into the relationship between the rate of an elementary reaction, the motions of the atoms, and the changes in bonding

as the reaction proceeds. In most geochemical systems, activation parameters correspond to overall reactions and are composites from many steps. Thus they can vary with solution composition and experimental conditions as the relative importance of different steps varies (e.g., Casey and Sposito 1992).

Activity and Activity Coefficients

Barry R. Bickmore and Matthew C. F. Wander
Department of Geological Sciences, Brigham Young University, Provo, UT, USA

Definition

The *activity* of a chemical entity is a dimensionless quantity derived by multiplying a correction factor (called an *activity coefficient*) by some measure of its molar abundance, such as molar concentration (molarity), molality, partial pressure, or mole fraction. See Eq. 1, where (a_i) is the activity of a species or component i, γ_i is the activity coefficient, and x_i is a measure of molar abundance.

$$a_i = \gamma_i x_i \tag{1}$$

Activities are thus used as "effective concentrations" and are necessary to the extent that chemical behavior is not *ideal* – i.e., strictly proportional to molar abundance – and so $\gamma_i \neq 1$. Formally, a_i is defined by Eq. 2, where it described as a function of the difference between the chemical potential of i (μ_i) and its chemical potential in some standard state $\left(\mu_i^{\ominus}\right)$, temperature ($T$), and the gas constant (R).

$$a_i = e^{\left(\mu_i - \mu_i^{\ominus}\right)/RT} \tag{2}$$

Molar Abundance and Ideal Behavior

Many foundational advances in chemistry were based on the recognition that various behaviors of atoms and molecules are roughly proportional to their local abundance (Levere 2001). The pressure of a gas at constant volume and temperature is proportional to the number of molecules present (Avogadro's law and the Ideal Gas law). The concentration of a dissolved gas is proportional to its partial pressure in the gas phase (Henry's law). The vapor pressure of each liquid in a mixture is proportional to both the vapor pressure of each pure component and its mole fraction in the mixture (Raoult's law).

That such behaviors *should* be proportional to molar abundance is intuitively obvious and can be illustrated by a simple example. Consider a chemical reaction, A + B → AB. The rate at which molecules A and B react necessarily depends on how often they encounter one another. If the number of A molecules in the available space is doubled, then the B molecules will be twice as likely to encounter them.

Therefore, many standard equations describing chemical behavior, especially rate laws and mass action (equilibrium constant) expressions, are intentionally formulated to reflect the expected proportional behavior. Chemists consider systems that act strictly in this manner to be behaving *ideally*.

The activity and the corresponding standard state chemical potential is always tied to a particular scale of molar abundance, generally mole fraction for all condensed phase solutions, except that activities for solutes in aqueous solutions are linked to the molal concentration scale (Robinson and Stokes 1965). The *fugacity* of gases, which is closely related to activity, is based on partial pressures (Atkins and Jones 2008). Therefore, although activity is dimensionless, one must take care to use the appropriate scale with a particular tabulation or model of activity coefficients.

At the standard state, the activity coefficient is equal to 1, denoting ideal behavior, but the choice of what that standard state should be is arbitrary. For chemical entities measured on the mole fraction scale in condensed phases, this corresponds to a pure substance, where the mole fraction is equal to 1. For dissolved species in aqueous solutions, the standard state is a hypothetical state of infinite dilution, extrapolated from experimental data.

Nonideal Chemical Behavior and Activity

Real chemical systems always diverge from ideal behavior to some degree because of interactions (attraction or repulsion) between the chemical entities involved and their surroundings. One classic example is Johannes van der Waals's analysis of deviations of real gas behavior from the Ideal Gas Law (Levere 2001). He noted that real gases tend to deviate most from ideal behavior at low temperatures and high pressures – i.e., when one would expect the gas molecules to be closer to one another – and showed that the observed behavior could be explained by assuming short-range attraction between them. This also explained how condensation of gases into liquid form is possible.

Any interaction other than simple chemical reaction or elastic collision (a collision in which kinetic energy is conserved) will contribute to nonideal behavior, and the closer the chemical entities involved approach one another, the more pronounced such effects will be. Therefore, the simplest models to predict activity coefficients tend to focus on longer-range forces and are only accurate under a limited range of conditions. More accurate models extend that range by, at least implicitly, taking into account increasingly complex interactions between the chemical entities involved.

In dilute aqueous solutions (Wolery 1990), for instance, activity coefficients depend mostly on long-range electrical forces, so the simplest models for estimating activity coefficients are solely based on the formal charge (Z_i) of individual ions and the total ionic strength (I) of the solution. For example, Eq. 3 shows one form of the Debye-Hückel equation, where A_γ is a constant for a given temperature. Equation 4 shows the Davies equation, in which 0.2 is sometimes replaced by 0.3.

$$\ln \gamma_i = \frac{-A_\gamma Z_i^2 \sqrt{I}}{1 + 1.5\sqrt{I}} \tag{3}$$

$$\ln \gamma_i = -A_\gamma Z_i^2 \left(\frac{\sqrt{I}}{1 + \sqrt{I}} - 0.2I \right) \tag{4}$$

The Debye-Hückel equation is reasonably accurate in solutions up to 0.1–0.3 molal ionic strength, while the Davies equation is useful up to ~0.5 molal ionic strength. In more concentrated solutions, however, both models fail badly because other factors become more important when dissolved species are forced closer together. Both equations predict $\gamma_i = 1$ for uncharged species, for instance, but this could only be accurate over short distances if the distribution of charge around neutral species like silicic acid (H_4SiO_4) could be approximated by a point or spherical charge. Therefore, molecular shapes, electronegativity differences among atoms, the tendency to pair with neighboring ions, and the disruption of surrounding water structure, all of which could be very different among individual species with the same formal charge, begin to dominate the behavior of aqueous species (Pitzer 1991).

Both the Debye-Hückel and Davies equations imply a monotonic decrease in γ_i with increasing ionic strength, but in high ionic strength solutions, γ_i values often actually start to climb, and may even rise to values greater than 1. Improved activity coefficient models must, therefore, incorporate increasing levels of detail regarding how the solute species interact with one another. This is often done by introducing interaction terms for every pair of dissolved species. For example, to estimate the activity coefficient for Na^+ in a high ionic strength solution containing dissolved Na^+, Cl^-, H^+, and OH^-, one would have to account for interactions between Na^+ and every other species present. One common method for implementing this is the Specific Ion Interaction Theory (SIT) of Brønsted (1922), Guggenheim (Guggenheim and Turgeon 1955), and Scratchard (1936), shown in Eq. 5. Here, a Debye-Hückel term dominates at low ionic strengths, but a summation of pair-wise interaction terms, which depend on interaction coefficients specific to the species i and all other species $j(\varepsilon_{i,j})$ and the molal concentrations of all other species (m_j).

$$\log_{10} \gamma_i = \frac{-A_\gamma Z_i^2 \sqrt{I}}{1 + 1.5\sqrt{I}} + \sum\nolimits_j \varepsilon_{i,j} m_j \tag{5}$$

To estimate activity coefficients in the most concentrated brines, however, one needs to take into account interactions between triplets, in addition to pairs, of species. Pitzer's equations (Pitzer 1991) include such interaction terms, but also make pair-wise interaction terms functions of ionic strength. The most famous Pitzer-based model among geochemists is the Harvie-Møller-Weare (Harvie et al. 1984) model for the sea-salt system at 25 °C, which can accurately reproduce the solubilities of salts in highly concentrated brines up to 14 molal ionic strength.

As interaction terms for pairs and triplets of species are added, activity coefficient models can be made more and more accurate over a wider range of conditions, but the information required to calibrate the models increases exponentially as more species are added to the solution, to the

point that it can be prohibitive to use Pitzer, or even SIT, models for very complex solutions.

There is an extensive literature dealing with activity coefficients in nonaqueous phases such as solid solutions, gases, and silicate melts. For an introduction to this, see Nordstrom and Munoz (1985) and references cited therein.

Summary and Conclusions

Attractive or repulsive interactions between chemical components or species cause them to behave in a "nonideal" manner. That is, their reactivity is not strictly proportional to their molar abundance (molar concentration, molality, partial pressure, mole fraction). When using equations to describe chemical kinetics and equilibrium, therefore, chemists account for nonideality by replacing measures of molar abundance with activity, which is a dimensionless "corrected" concentration obtained by multiplying a correction factor (activity coefficient) by the molar abundance. Standard models to estimate activity coefficients vary widely in their complexity and accuracy.

Alkali and Alkaline Earth Metals

Ricardo Arevalo Jr.
Planetary Environments Lab, NASA Goddard Space Flight Center, Greenbelt, MD, USA

A

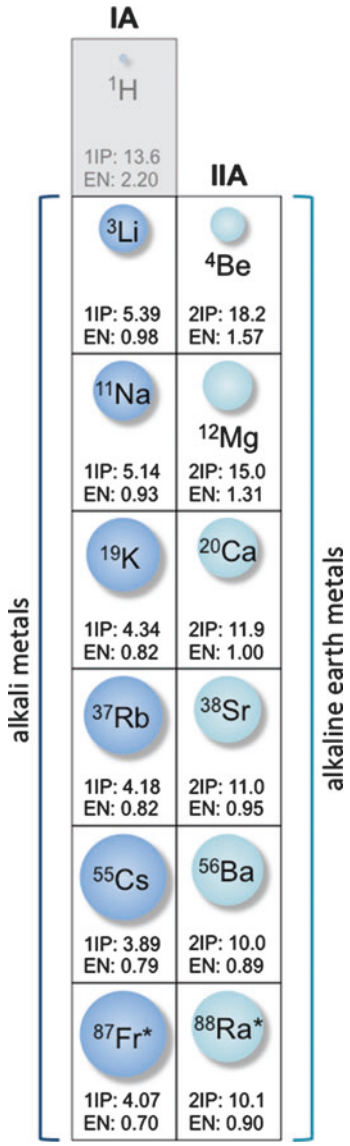
Introduction

The alkali and alkaline earth metals comprise the first two columns of the periodic table, traditionally referred to as Groups IA and IIA, respectively (Fig. 1). Although H is technically considered a member of Group IA, it is not an alkali metal like the rest of the elements in this column; rather, H is a highly volatile non-metal and the smallest and lightest atom of them all. From lithium (Li) through francium (Fr) in Group IA, and beryllium (Be) through radium (Ra) in Group IIA, the rest of the alkali and alkaline earth metals share a number of physical characteristics, such as: malleability, ductility, electrical/thermal conductivity, and reactivity at standard temperature and pressure. Although often associated with biological systems and dietary supplements, alkali and alkaline earth metals represent an extraordinarily important and versatile suite of elements that can be applied as geochemical tracers for a multitude of planetary processes. Moreover, many of these elements are extraordinarily common in geological materials; for example, calcium (Ca), magnesium (Mg) and sodium (Na) represent the 5th, 6th and 7th (respectively) most abundant elements in the Earth's continental crust (Rudnick and Gao 2003).

Chemistry and Geochemical Behavior

The exploitation of alkali and alkaline earth metals as serviceable geo- and/or cosmochemical proxies is enabled by the systematic and predictable behavior of these elements in planetary environments, which is controlled ultimately by their distinctive electronic configurations. All of the Group IA and IIA elements, including H, belong to the s-block of the periodic table. Although He is also technically an s-block element, it is not described here as it falls into Group VIIIA. The alkali metals representing Group IA are characterized by a single outer shell electron held in an *s* (spherical) orbital; *s* orbitals may only be occupied by a maximum of two electrons with opposite spin directions, following the Pauli Exclusion Principle. The alkaline earth metals, on the other hand, are characterized by "full" outer *s* orbitals.

Because *s* orbital electrons are only loosely bound (relative to electrons occupying *p*, *d* and/or *f* orbitals), Group IA and



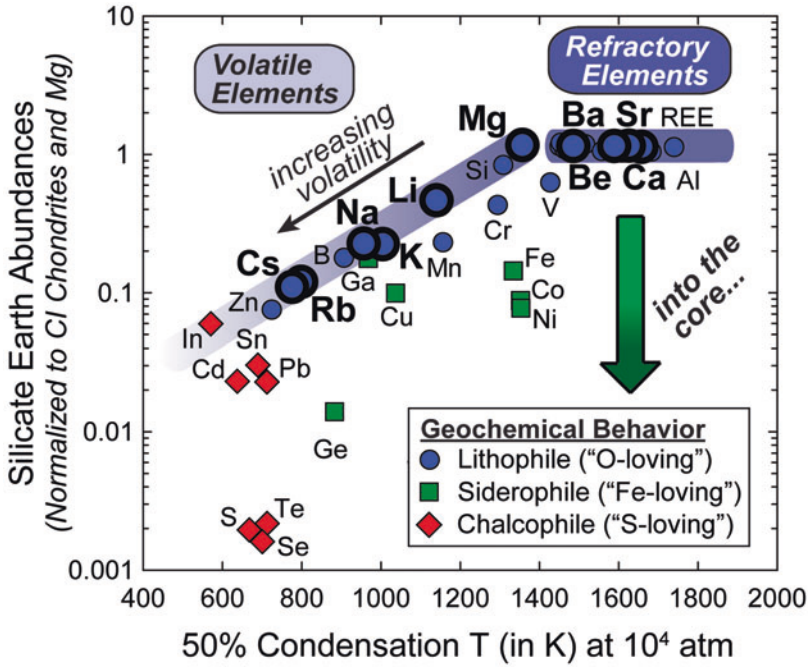
Alkali and Alkaline Earth Metals, Fig. 1 Isolation of the alkali and alkaline earth metals (Groups IA and IIA, respectively) from the rest of the periodic table. Relative atomic radii (depicted as spheres), and absolute values for first and second ionization potentials (labeled as 1IP and 2IP, respectively, in eV) and electronegativities (EN, following the Pauling scale) are taken from (CRC 2001). Francium (Fr) and radium (Ra) are highly unstable, and thus labeled with an asterisk

IIA elements are characterized by large atomic radii, low electronegativities and high reactivities. The alkali metals are defined by the lowest first ionization potentials (1st IP, the energy required to remove a single electron from the neutral atom) of all the elements, with cesium (Cs) defining the lowest 1st IP (3.89 eV; (CRC 2001)) of the group. In comparison, the alkaline earth metals are defined by some of the lowest second ionization potentials (2nd IP), with barium (Ba) defining the lowest 2nd IP (10.00 eV; (CRC 2001)) of all the stable elements.

The homologous behavior of the elements in each Group enables substitution for one another in mineral lattices. For example, because ions of potassium (K^+) and rubidium (Rb^+) share identical valence states and similar ionic radii as members of Group IA, Rb^+ is easily substituted into the cation site designated for K^+ in micas and potassic feldspars. Minimal work is required to substitute Rb^+ for K^+, as no charge balancing is required, nor significant strain imposed on the mineral lattice (Wood and Blundy 2003); in contrast, fitting ions of scandium (Sc^{3+}) or uranium (U^{6+}) into the same site would require a coupled substitution to achieve electroneutrality, plus significantly more strain energy.

Despite their common electronic structures, the alkali and alkaline earth metals vary widely in their relative volatilities, as measured by their respective 50% condensation temperatures at a total pressure of 10^{-4} bar (Fig. 2). The condensation temperature of an element is controlled primarily by its geochemical affinity as well as the presence of a suitable host phase during condensation of the solar nebula. All of the elements within Group IA are considered moderately to highly volatile, with condensation temperatures ranging from 1140 K down to 800 K (Lodders 2003). In general, the elements in this group become progressively more volatile with size/mass; Li is the least volatile in the group, whereas Cs is the most (note Fr is unstable). In contrast, the elements of Group IIA are substantially more refractory with condensation temperatures extending from 1300 to 1500 K; no obvious trend in volatility is exhibited as a function of size/mass in this group. All of the alkali and alkaline earth metals are characterized as lithophile (or oxygen-loving) elements as they are hosted primarily in the silicate portion of the earth, with only negligible to trace amounts estimated in the planet's core (McDonough 2003; Murthy et al. 2003; Corgne et al. 2007).

Due to their large atomic (and ionic) radii and their abundances in silicate rocks and minerals, alkali and alkaline earth metals are often referred to as Large Ion Lithophile Elements (LILE) in the geological community. In general, all of these elements are fluid mobile (Taylor and McLennan 1985) and thus commonly associated with metasomatism, hydrothermal alteration and slab dehydration processes, to name a few examples. Other than Ca, Mg and Na, the rest of the alkali and alkaline earth metals behave largely as incompatible trace elements during differentiation of the Earth's silicate shell; that is to say, they prefer to migrate into the melt rather than remain behind (during melting) or be forced into a crystal lattice (during crystallization). Consequently, most of the alkali and alkaline earth metals are concentrated in the continental crust relative to the modern mantle (Hofmann 1988).



Alkali and Alkaline Earth Metals, Fig. 2 Elemental abundances in the silicate portion of the Earth plotted relative to 50% condensation temperatures at 10^{-4} bar total pressure, a measure of elemental volatility. Siderophile (iron-loving) and chalcophile (sulfur-loving) elements that plot below the volatility trend line, as defined by lithophile (oxygen-loving) elements, are likely depleted due to sequestration into the core. In general, alkali metals become increasingly more volatile with size/mass, whereas all of the alkaline earth metals are considered refractory in nature. All members of Groups IA and IIA behave as lithophile elements. Figure modified from (McDonough and Sun 1995). Condensation temperatures from (Lodders 2003)

Geological Applications

The characteristic attributes of the alkali and alkaline earth metals (some of which are described above), and the homologous behavior of the respective constituents of each Group in geological materials, make these elements particularly useful as geochemical proxies for a number of terrestrial processes. For example, Li abundances and isotopic exchange between aqueous and silicate systems provides important information on chemical weathering processes, including erosion rates, provenances, local temperatures, and pH conditions (Chan et al. 1992; Pistiner and Henderson 2003; Teng et al. 2004; Kısakűrek et al. 2005; Misra and Froelich 2012). Anthropogenic ^{137}Cs, with a half-life on the order of 30 years, has found employment as a tracer of: (i) soil erosion (Walling et al. 1999); (ii) sedimentation rates (Pennington et al. 1973); and, (iii) runoff (Rogowski and Tamura 1965) in environments that have been exposed to nuclear fission byproducts. Ratios of strontium (Sr), Mg and Ba to Ca captured by reef-building corals (Gagan et al. 1998), the carbonate shells of benthic foraminifera (Lea et al. 1999) and aragonitic ear stones of marine fish (Bath et al. 2000) have been used to map fluctuations in sea surface paleotemperatures and reconstruct global ocean nutrient content, circulation dynamics and fluxes.

Alkali and alkaline earth metals also serve as witnesses of the accretion and internal differentiation of other planetary bodies. Due to the lower condensation temperature of K relative to Th and U (Lodders 2003), K/Th and K/U ratios measured via orbiting spacecraft have been invoked as gauges of the volatile element depletion of Mercury, Venus, Mars, the moon, and the asteroid Vesta (Vinogradov et al. 1973; Prettyman et al. 2006; Taylor et al. 2006; Peplowski et al. 2011; Prettyman et al. 2015). Uniform Be and Mg initial isotopic compositions measured in terrestrial materials, calcium-aluminum inclusions (CAIs) and hibonite grains derived from chondritic meteorites indicate that the solar nebula was relatively well mixed during accretion of the inner solar system (McKeegan et al. 2000; Marhas et al. 2002; Teng et al. 2010). Short-lived ^{41}Ca ($t_{1/2}$ = 0.10 Myr) and ^{26}Al ($t_{1/2}$ = 0.72 Myr), which together track with stable ^{40}Ca, implicate a nucleosynthetic origin (likely an asymptotic giant branch or more massive star) for of these valuable geochronometers and early sources of radiogenic heat (Srinivasan et al. 1996; Sahijpal et al. 1998; Huss et al. 2009).

More applications of the alkali and alkaline metals as geo- and/or comoschemical proxies of planetary processes can be found in the chapters dedicated to each element. Unfortunately, the highly unstable natures of Fr and Ra complicate the use of their abundances and/or isotopes as mainstream geological tools.

Summary

Alkali (Group IA) and alkaline earth metals (Group IIA) share a host of common physicochemical attributes. The homologous behavior of each Group allows for substitution of major elements (e.g., Na) with less abundant elements (e.g., K, Rb

and Cs) in designated structural sites within mineral lattices. Together, the alkali and alkaline earth metals define the LILE, are highly soluble in aqueous solutions (and thus fluid-mobile), and generally incompatible during mantle melting and subsequent crystallization of magmas (with the notable exceptions of Ca, Mg and Na). However, the alkali metals are significantly more volatile than the alkaline earth metals. Because both Groups of elements are often found in appreciable quantities in many geological materials, including those derived from the Earth as well as other planetary bodies, they have been exploited as tracers for a litany of geological processes, fractionation mechanisms and source contributions/provenances.

Element Data
Atomic Symbol: **Al**
Atomic Number: **13**
Atomic Weight: 26.98 g/mol
Isotopes and Abundances: ^{27}Al 100%, ^{26}Al (short-lived)
1 Atm Melting Point: 660.3 °C
1 Atm Boiling Point: 2519 °C
Common Valences: 3+
Ionic Radii: 53 pm (4-fold); 67.5 pm (6-fold)
Pauling Electronegativity: 1.61
First Ionization Energy: 577.5 kJ/mol
Chondritic (CI) Abundance: 0.84%[1]
Silicate Earth Abundance: ~2.3%
Crustal Abundance: 8.45%[2]
Seawater Abundance: 1–2 × 10^{-9} kg/L
Core Abundance: ~0

[2]Rudnick and Gao (2014)

Properties

A metallic element that is silver-white in color, weighs less, does not readily oxidize, i.e., resistant to corrosion, ductile, malleable, and is a good electrical conductor. The metal occurs as oxides, hydroxides, and aluminosilicate minerals in the Earth's crust.

History and Use

In 1825, Danish physicist Hans Christian Oersted obtained aluminum by heating aluminum chloride with potassium. However the aluminum was impure. In 1827, German chemist Friedrich Wöhler used similar method to obtain pure aluminum by heating aluminum chloride with sodium instead of potassium. The name for aluminum is derived from the Latin name for alum – "alumen" meaning bitter salt.

In the present day, aluminum is mined from bauxite deposits and reduced to metallic state. Metallic aluminum is widely used in our daily life. Use of metallic aluminum ranges from kitchen appliances, packaging, construction materials, transport industry, to electricity cables. Owing to its lighter weight and high strength-to-weight ratio, aluminum alloys are extensively used in manufacturing aircraft, spacecraft, and freight cars, and also in high-speed trains. Aluminum alloys are also extensively used in modern ships owing to their resistance to corrosion in both fresh-water and sea-water. Modern energy efficient skycrapers, pavilions, and sports facility, all use aluminum alloys. Around 25% of all aluminum produced world-wide is used for modern construction.

Isotopes and Cosmochemistry

The only stable isotope of aluminum is ^{27}Al. Aluminum also has several other isotopes, among them ^{26}Al is a short-lived cosmogenic radionuclide with half-life ($\tau_{1/2}$) of 7×10^5 year. ^{26}Al is likely to have played an important role in producing heat during the initial accretion stages of terrestrial planets (Hostetler and Drake 1979). Together with ^{10}Be, ^{26}Al in quartz provides valuable constraints on rates of surface processes including uplift, erosion (Balco et al. 2008), denudation, sedimentation (Hippe et al. 2012, von Blanckenburg and Willenbring 2014) and de-/glaciation (Ivy-Ochs and Briner 2014). Evidence of the existence of ^{27}Al is found mainly in calcium-aluminum rich inclusions (CAI), which are light colored inclusions in carbonaceous chondrite meteorites. CAIs are submillimeter to centimeter sized inclusions and are likely have formed by condensation at high temperature in the protoplanetary disks. Recent studies indicate that CAIs are one of the oldest (4568.2 million years) known materials in the solar system (Bouvier and Wadhwa 2010).

Mineralogy and Geochemistry

Based on Goldschmidt's classification, aluminum is primarily a lithophile element. In the Earth, together with silicon and oxygen, it forms a wide variety of aluminosilicate minerals that dominate all rock types including igneous, metamorphic, and sedimentary rocks. Igneous rocks such as basalts are composed of aluminosilicate framework minerals such as feldspar [$(K,Na)AlSi_3O_8$-$Ca_2Al_2Si_2O_8$]. Aluminosilicate polymorphs such as kyanite, andalusite, and silimanite [Al_2SiO_5] are often found in metamorphic rocks and provide valuable clues to the pressure-temperature conditions prevailing during the formation of the rock. Aluminum is also an important constituent of clay minerals such as kaolinite [$Al_2Si_2O_5(OH)_4$], which forms due to weathering and often associated with sedimentary rocks. In most aluminosilicate minerals, the [Al-O-Al] bonds are energetically unstable

with respect to [Al-O-Si] arrangement. The [Al-O-Si] arrangement better conforms to Pauling's electrostatic valence principle and is often referred to as "aluminum avoidance principle" (Loewenstein 1954). Calorimetric results on aluminosilicate minerals and glasses also indicate that reactions such as [Si-O-Si] + [Al-O-Al] = 2 [Si-O-Al] are energetically favorable by 40–100 kJ/mol (Navrotsky et al. 1982). Aluminum is a minor element in many of the major minerals in mantle rocks such as peridotites. Through coupled substitution [$Si^{4+} = Al^{3+}+H^{+}$], aluminum plays important role in sequestering water in mantle mineral phases including enstatite pyroxene [$MgSiO_3$] (Mierdel et al. 2007) and stishovite [SiO_2] (Pawley et al. 1993). In addition, incorporation of aluminum in hydrous phases enhances the thermodynamic stability (Ohtani et al. 2001; Bromiley and Pawley 2003) thus providing viable mechanism for transporting water into the deep Earth. Based on high-pressure studies it is also known that aluminum also stabilizes a suit of minor mineral phases in the deeply subducted oceanic and continental crust, such as hollandite [$(K,Na)AlSi_3O_8$], new aluminous phase (NAL) [$CaMg_2Al_6O_{12}$], and calcium ferrite [$(Ca,Mg)Al_2O_4$] (Irifune and Ringwood 1993, 1994; Mookherjee and Steinle-Neumann 2009; Mookherjee 2011). These aluminous phases have a wide range of chemistry and could host large alkali cations such as sodium and potassium in their crystal structure [$(Na,K)AlSiO_4$] (Miyajima et al. 2001; Mookherjee et al. 2012).

At deep crustal conditions where fluids and aluminosilicate minerals interact, the solubility silicon and aluminum in aqueous fluids are quite distinct. Silicon solubility is significantly greater than aluminum. Silica [SiO_2] initially dissolves in aqueous fluid as [$Si(OH)_4$] monomer and eventually forms dimer [$(OH)_3$-Si-O-Si-$(OH)_3$] and higher order polymers (Zotov and Keppler 2002). Unlike silicon, solubility of aluminum in neutral aqueous fluid is low (Walther 1997; Tropper and Manning 2007). At elevated pH the dominant aluminum species in aqueous fluid is [$Al(OH)_4^{1-}$] (White 2013). Unlike silicon, aluminum does not readily polymerize in aqueous fluids (Mookherjee et al. 2014) at neutral chemistry. Elevated pH or complexation with silica might enhance aluminum solubility by affecting speciation.

Biological Utilization and Toxicity

Some studies have hinted that adults who are exposed to high levels of aluminum may develop Alzheimer's disease. However, other results do not agree with these findings. So at present, the exposure to high levels of aluminum and Alzheimer's disease is highly contentious.

Children exposed to high levels of aluminum may develop bone disease since aluminum in the stomach may prevent adsorption of phosphate, which is required for growth of healthy bones.

Plants, however, are affected by aluminum toxicity. Most of the aluminum in the soil is often bound by ligands or aluminosilicates. However, lowering of the pH caused by irrigation practices or acid rain often releases Al^{3+} in the soil, which affects the growth and productivity of plants (Delhaize and Ryan 1995). Active research is being pursued to enhance understanding and also to engineer plants with higher tolerance towards aluminum toxicity.

Summary

Aluminum is the third most abundant element in the Earth's crust. Together with silicon and oxygen, it forms the framework of wide variety of oxides, hydroxides, and aluminosilicate minerals that are stable in the Earth's crust and mantle. Aluminum plays an important role in the water transport in the deep Earth. Aluminum metal is used in materials of daily use and almost 100% of aluminum is recyclable. Aluminum is typically not toxic but children should be protected from high levels of exposure.

Analytical Techniques

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Definition

Geochemical analytical techniques are used to determine the elemental, molecular, and isotopic compositions of natural materials including rocks, fluids, gases, and their components. They are also used to characterize molecular or crystal structure of these materials and the valance states of their constituent atoms, the nature of chemical bonds between them, and the nature and rates of reactions. This entry only summarizes the broad principles and applications of various analytical techniques; details of these techniques are reviewed in individual entries.

Compositional and Isotopic Analysis

The objective of elemental analysis is to quantify the relative proportions of the chemical elements in a sample. In principle, all chemical elements are present in most natural materials, although not necessarily at detectable levels. Generally, just a few elements make up more than 95% of these materials; these are generally referred to as the *major* elements, components, salts, etc. Some techniques have the sensitivity to analyze only major elements; other techniques have been developed to determine trace element abundances. The technique employed will depend on the abundance of the elements of interest. In some cases, the most abundant components are not determined by analysis. For example, oxygen is the most abundant element in most rocks, but its abundance is often inferred rather than determined. Similarly, the amount of water, and by extension the amount of O and H in aqueous solutions, is rarely directly determined.

Modern elemental analysis is almost always instrumental, having replaced earlier gravimetric and colorimetric methods over the course of the twentieth century. There are several broad classes of these techniques. The first are "spectroscopic" techniques in which abundance of elements or compounds is determined by measuring the amount of characteristic electromagnetic radiation either adsorbed or emitted by them. The second is mass spectrometric techniques in which a sample or a part of it is ionized, the ions separated by mass, and counted. A third class of techniques measures other particles, such as emitted beta or alpha particles, neutrons, geoneutrinos, or back-scattered electrons, but

these techniques have limited application. In most techniques, calibration against a geochemical reference material is necessary.

Spectroscopic Techniques

These techniques vary by the nature of the radiation employed, whether it is natural or induced, the materials analyzed, and whether emission or absorption is measured. The radiation varies from infrared to gamma. Infrared radiation is associated with molecular vibrations and rotations. For example, infrared absorption is used to routinely determine the abundances of CO_2, CH_4, and other trace gases in the atmosphere, either in flasks using artificial illumination or directly in the atmosphere using solar illumination (e.g., Vanderkluysen et al. 2014; Wunch et al. 2011) and to determine the abundance of CO_2 and H_2O in volcanic glasses (Dixon et al. 1988).

Techniques of atomic adsorption and atomic emission spectroscopy are based on the adsorption or emission of photons in or near the optical spectrum as electrons surrounding atoms transition between quantized energy levels. In atomic adsorption spectrometry (AAS), a sample solution is atomized in a flame or a graphite furnace and illuminated with the emission spectrum of the element of interest. The intensity of this light absorbed by the sample is proportional to the concentration of the element in it. In atomic emission spectroscopy, electrons in a sample are excited into higher energy states, either thermally (flame emission spectroscopy or flame photometry), through electrical discharge (spark and arc atomic emission spectroscopy), or in a radio-frequency-induced inductively coupled argon plasma (variously known as inductively coupled plasma optical emission spectroscopy (ICP-OES) or inductively coupled plasma atomic emission spectroscopy (ICP-AES)). Regardless of the excitation method, the principle is same: electrons decay to lower states by emitting photons with energy/wavelength characteristic of the element. Consequently, the intensity of light at that wavelength is proportional to the element's abundance in the sample. Of these techniques, ICP-OES is rapidly replacing older techniques such as AAS and flame photometry as it allows for simultaneous measurement of most naturally occurring elements because the higher temperatures in the plasma result in greater intensities and more complete breakdown of compounds, leading to greater sensitivity and accuracy (Hou et al. 2006).

For the most part, these optical techniques are most readily used to analyze aqueous solutions (although electrothermal vaporization is possible). This is ideal for water samples, but a disadvantage for rock and soil samples. In contrast, x-ray fluorescence (XRF) is ideally suited for analysis of solids. This technique has a long history, having been first used by Victor Goldschmidt in the early twentieth century. The principle involved is similar to optical techniques in that it is based on detecting photons emitted by electrons as they decay from excited states. The difference is that in XRF electrons in inner shells are excited by illuminating the sample with x-rays; the energy difference between states of inner electrons is greater than those of outer electrons excited in optical techniques, and consequently they emit photons in the x-ray rather than optical part of the spectrum. This technique has the advances of relatively little sample preparation and an ability to quantify many trace elements as well as the major constituents of materials. Most XRF analysis is done with x-rays generated with a cathode-ray tube; synchrotrons are capable of producing a much more intense photon beam. Thus, synchrotron-XRF allows greater sensitivity and analysis at micron-scale resolution (e.g., Dyl et al. 2014).

X-ray emission can also be induced by bombardment with energetic particles. This allows for some variations on the XRF technique such as electron probe microanalysis (EPMA), in which x-ray emission is induced by bombardment with an energetic electron beam, and particle-induced x-ray emission (PIXE), in which it is induced by bombardment with a proton or alpha particle beam. These techniques are particularly appropriate for in situ microanalysis. With a beam diameter of 10 μm and less, the electron microprobe has become the standard method for quantitative analysis of major and minor elements in solid phases or parts of phases (such as inclusions or crystal zones) as well as qualitative mapping of those phases. Synchrotron-based micro-PIXE has sufficient sensitivity that trace element concentrations can also be measured and mapped. A PIXE instruments utilizing ^{210}Po-sourced alpha particles aboard the NASA's *Curiosity* rover has provided in situ analysis of Martian materials.

Gamma rays are produced by quantized nuclear energy state transitions associated with radioactive decay and hence can be also used to quantify the amount of an element. There are two approaches to gamma-ray spectroscopy: the first measures gamma-ray emissions of naturally occurring radionuclides, and the second measures gamma rays emitted by radionuclides produced by neutron bombardment. In gamma-ray logging, a gamma spectrometer is lowered down a borehole to determine the concentrations of K, Th, and U in the adjacent rock as a function of depth (e.g., Hampson et al. 2005). Gamma-ray spectrometers can also be flown in aircraft to survey the distribution of natural and man-made (e.g., Fukushima accident) radioactive elements. Finally, gamma-ray spectrometers have frequently been flown on spacecraft for elemental analysis of surfaces of other solar system bodies. In addition to gamma rays emitted by K, U, and Th, cosmic rays impacting on the surfaces of bodies with little or no atmosphere initiate nuclear reactions producing

unstable nuclides, which then decay emitting characteristic gamma rays. Used in conjunction with neutron detectors, the abundances of a number of elements, including O, Mg, Al, Si, Cl, Ca, Ti, and Fe (Prettyman 2007) can be determined. In the second approach, known as *neutron activation analysis*, a sample is irradiated with neutrons in a reactor. Some of those neutrons are captured by sample nuclei to produce radioactive isotopes, which then decay with the emission of a characteristic gamma-ray spectrum. The technique can be applied directly to solids and has the advantage of requiring relatively little preparation and being extremely sensitive for elements with high neutron capture cross sections, such as many of the rare earths and noble metals. The disadvantage is that abundances of elements with low neutron capture cross sections, such as Nb, cannot be determined.

Mass Spectrometric Techniques

Two broad classes of mass spectrometers are employed by geochemists. The first is so-called isotope ratio mass spectrometry (IRMS), which are primarily designed to determine isotopic compositions but can also be used to determine elemental abundances. The second is designed to analyze organic molecules. In both classes, ions are formed in the mass spectrometer's source, accelerated by an electric field, separated by mass-to-charge ratio in the analyzer section, and the ion current measured or individual ions counted by a detector. Isotope ratio mass spectrometers are, of course, the primary tool of stable and radiogenic isotope geochemists and geochronologists. High-precision isotope ratio determination generally requires a Nier-type magnetic sector instrument (Nier 1940) and pre-purification of the element of interest, for example, by ion exchange chromatography, cryogenic separation of gases, or in-line gas chromatography. From a perspective of elemental analysis, they have the ability to accurately and precisely analyze elements in geologic materials at concentration levels well below the effective detection limit of spectroscopic techniques. One approach to elemental analysis is isotope dilution, in which a known amount of "spike," a purified isotope of the element of interest, is added to the sample. The isotope ratio of the sample-spike mixture is then measured and the abundance of that element calculated from it. Isotope dilution can be used with a variety of ion source designs, including gas source (GCMS), spark source, inductively coupled plasma (ICP-MS), and thermal ionization (TIMS). Although highly accurate, it is time-consuming. The other approach is to measure the ion beam intensity of specific isotopes and comparing that to the ion beam intensity in a standard. This is the basis of spark source mass spectrometry as well as inductively coupled plasma mass spectrometry (ICP-MS), which has now almost entirely supplanted the former. As in optical techniques, samples are usually introduced into an ICP-MS in solution, although other introduction methods such as hydride generation can be used. In laser ablation-ICP-MS (LA-ICP-MS), material is ablated from a small pit of a solid sample with a laser and the ablated material carried into the plasma by a gas stream. This allows for direct analysis of elemental abundances or isotope ratios in minerals and other geologic solids on spots with a radius as small as 5 μm.

Ion microprobes, or secondary ionization mass spectrometry (SIMS), are instruments designed for isotopic and chemical microanalysis. A primary ion beam, often O or Cs, sputters secondary ions from a small (nm to μm scale) region of the polished surface of a sample, and the secondary ions are extracted by an electric field into a mass spectrometer. Such instruments require higher mass resolution than conventional isotope ratio mass spectrometers to avoid interferences. Among other things, these instruments have been particularly useful in dating complex zircons, including Earth's oldest surviving mineral grains (Wilde et al. 2001) and evaluating intracellular and metabolic processes (e.g., Orphan et al. 2009).

Because of their extreme rarity, cosmogenic nuclides such as ^{14}C, ^{10}Be, and ^{26}Al are measured by accelerator mass spectrometers. In accelerator mass spectrometers, ions are initially separated in a sector mass spectrometer, then stripped of electrons, and accelerated to very high energies (200 kV–2 MV compared to $\leq$10 kV in conventional mass spectrometers) before entering a second-stage mass spectrometer and a detector. This is highly effective in eliminating isobaric interferences allowing quantification of isotope ratios as low as 10^{-12}–10^{-18}.

Mass spectrometers used for analysis of organic compound analysis are generally combined with liquid (LC) or gas chromatographs (GC) and a variety of hard (electron impact) or soft (electrospray or chemical) ionization techniques. Different compounds move through the chromatographic column at different speeds depending on their properties and the nature of the stationary phase. Thus, in liquid and gas chromatography-mass spectrometry (GC-MS), compounds will enter the mass spectrometer sequentially. In the case of hard impact ionization, compounds typically partially breakdown into fragments, producing a characteristic distribution of mass/charge ratios. From that, the elemental formula can be reconstructed. In contrast, the softer ionization techniques fragment less and thus can retain a suite of molecular ion peaks from a complex mixture. GC-MS and LC-MS instruments typically utilize a quadrupole or time-of-flight mass spectrometer rather than the sector design of IRMS due to their ability to very quickly scan the mass spectrum. Compound-specific isotope analysis (CSIA) operates in a similar manner employing a liquid

or gas chromatograph to separate organic compounds, but employs a sector-design IRMS rather than a quadrupole. High-resolution mass spectrometry (time-of-flight or ion-cyclotron resonance) is necessary in studying large macromolecules common in nature that contain a distribution of isotopes resulting in different components having nearly identical m/z ratios. For example, ^{14}N differs from $^{12}C^{1}H_2$ by 0.0126 u. Resolving these as individual ions requires a mass resolution of only 0.1%, but resolving them as constituents of a molecule of mass 500 u would require a resolution of 2 ppm.

Crystalline, Molecular, Oxidation State, and Chemical Bonding Characterization

Determination of mineral structure is generally done by x-ray diffraction (XRD). Samples are irradiated by monochromatic x-rays, which are diffracted by the crystal lattice. The angle of diffraction is a function of the interatomic spacing, which is in turn characteristic of the crystal structure. Because the crystal structure and x-ray diffraction patterns of nearly all minerals are known, XRD can be used to determine the minerals present and their relative abundances in a rock or soil sample. This kind of analysis is generally done with a powdered sample. XRD can, of course, be used to determine crystalline structure when it is not already known. This type of research is often conducted on single crystals.

The absorption techniques described above measure the absorption photons with energies corresponding to quantized molecular or atomic transitions. However, when a sample is irradiated, some photons are inelastically scattered, i.e., they lose or gain some fraction of their original energy. This results in a shift in wavelength. Raman spectroscopy exploits this inelastic photon scattering. Samples are irradiated with intense monochromatic radiation, which can range from x-ray to infrared, and the intensity of the inelastically scattered photons measured as a function of wavelength shift. This shift depends on the nature of atoms and molecules, their chemical bonds, and their rotational and vibrational motions. From analysis of the distribution of these energies, inferences about the presence of certain functional groups, conformations and symmetry of the molecules, anisotropy, chirality, and polymer and crystal orientations can be drawn. Since the scattering depends in part on the atoms present, Raman spectroscopy also provides semiquantitative analysis and information on crystal structure that compliments other techniques ranging from infrared spectroscopy to XRD. It can also be used to measure temperature and pressure in experiments. Raman spectroscopy is nondestructive, requires minimal sample preparation, and can be used at high spatial resolution, 10 μ and less for Raman microspectroscopy.

X-ray near-edge absorption spectroscopy (XANES) is used to interrogate the chemical state, such as valence, coordination number, bonding distances, etc., of atoms in soil minerals, volcanic glasses, etc. XANES exploits the absorption of x-rays by atoms as a function of the energy (or equivalently, wavelength) of an x-ray beam generated by a synchrotron. Whereas XRF utilized a photon source of fixed energy, XANES uses an x-ray beam of tunable energy. Absorption increases sharply when the energy of the incident photon matches the energy of an electron in a specific inner atomic orbital – this is the absorption edge. The energy of the edge is a function of the oxidation state of the atom (a higher oxidation state requires more energetic x-ray to excite inner electrons because the nucleus is less shielded). The edge also has structure (i.e., variation in absorption efficiency as a function of energy) that results from scattering resonances of the electrons ejected at low kinetic energy. This in turn depends on the position of neighboring atoms including interatomic distances and bond angles. XANES has been used, among other things, to determine Fe^{3+}/Fe^{2+} ratios in volcanic glasses (e.g., Kelley and Cottrell 2009).

Mössbauer spectroscopy exploits small changes in the energy of gamma-ray absorption by a nucleus due to factors such as transition of electrons within its orbital, the surrounding electric field gradient, and interaction between the nucleus and a surrounding magnetic field. In this technique, the sample is illuminated by gamma rays emitted by a nucleus identical to the one in the sample being studied, most commonly ^{57}Fe (the daughter of radioactive ^{57}Co). The gamma-ray source is moved toward and away from the sample during analysis, resulting in Doppler shifts in gamma-ray energy and absorbance measured as a function of energy. Oxidation state and information on the local crystallographic and chemical environment of Fe nuclei can then be determined from the absorption spectrum. The application of this technique is broad including study of redox reactions in sediments and soils, oxidation state of mantle rocks and melts, and iron isotope fractionation (e.g., Polyakov and Mineev 2000). Mössbauer spectrometers have been included in the instrumentation package of NASA's Martian rovers.

Nuclear magnetic resonance (NMR) spectroscopy exploits the intrinsic "spin" of protons and neutrons. Because the spins of paired nucleons cancel, only nuclei with an odd number of protons or neutrons have a net spin. The spin of such nuclei will align with that of an applied magnetic field. Application of radio-frequency (RF) radiation of the appropriate frequency (the resonant frequency) can then excite

these nuclei into higher spin states. The precise energy difference between spin states and hence the precise RF frequency that must be absorbed for the transition to occur will depend on the atomic environment of the nucleus as a consequence of electrons in the vicinity of the nucleus. As a result of this so-called chemical shift, NMR spectroscopy can be used to explore the structure, dynamics, and chemical environment of atoms. It has been used, among other things, to explore the structure of aluminosilicate glasses (analogies of silicate liquids) (e.g., Gambuzzi et al. 2014), the structure of kerogen and humic substances (e.g., Mann et al. 1991), and reaction rates in aqueous solutions (e.g., Harley et al. 2011).

Summary

Geochemists have a wide variety of analytical instruments at their disposal to characterize the nature and composition of the atmosphere, aqueous solutions, rocks, minerals, and soil. Much of the progress in geochemistry has come from the enormous innovation in analytical techniques over the last century.

Anthropogenic CO_2

Klaus S. Lackner
School of Sustainable Engineering and the Built Environment, Arizona State University, Tempe, AZ, USA

Synonyms

Anthropogenic carbon dioxide; Human-generated carbon dioxide

Definition

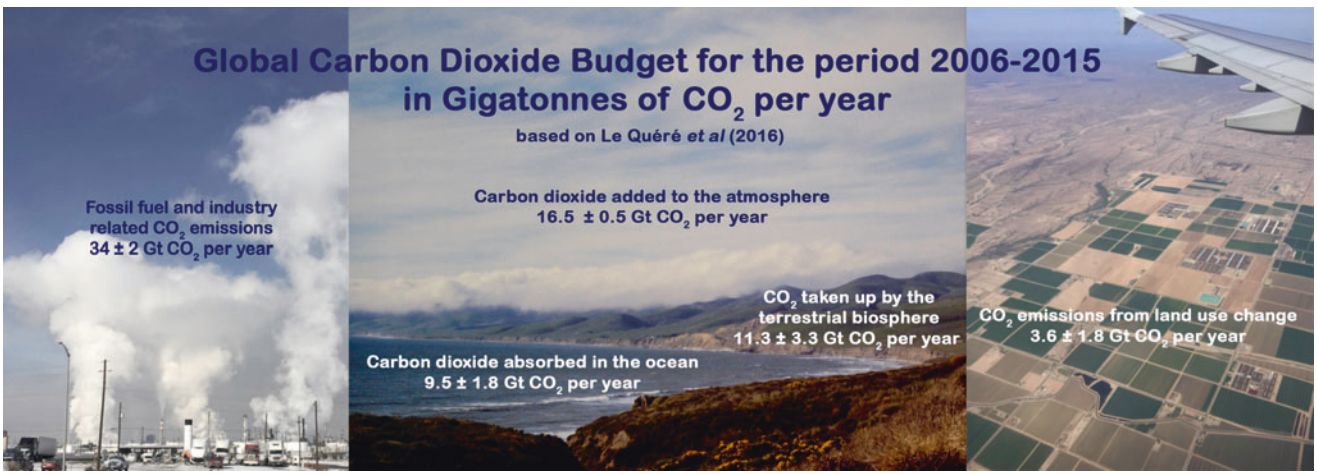
Carbon dioxide, generated by human activities, that enters the natural carbon cycle (usually through the atmosphere).

Anthropogenic carbon dioxide, chemical formula CO_2, is produced in the chemical conversion of various carbon bearing compounds or by releasing CO_2 from geological reservoirs that without human interference would have remained isolated from the more mobile carbon pools in the atmosphere, the ocean, and the biosphere.

Sources of Anthropogenic CO_2

Generation of anthropogenic CO_2 began with the introduction of fire and the combustion of biomass, which mainly produces CO_2 and H_2O. Until the industrial revolution, anthropogenic CO_2 production remained small compared to the natural carbon cycle and was essentially balanced by the uptake of CO_2 by plants. For biomass to be burned, it first has to grow. The carbon balance was more seriously upset with the introduction of coal as an important heating fuel in Britain in the late eighteenth century at the dawn of the industrial revolution (Christianson 2000). Coal consumption grew rapidly during the nineteenth century. Prior to the industrial revolution, the occasional use of coal and oil that spontaneously comes to the surface was insignificant. By contrast, the industrialization of Britain was based on large-scale consumption of coal, and coal energy became a major foundation of modern societies. Initially, coal simply replaced wood for heating, but then took a role in powering the steam engines (Newcomb's first steam engine) (Christianson 2000) driving the pumps that kept coalmines dry. As steam engines improved, their uses spread to many different applications revolutionizing modern societies. Add to this the invention of modern steel making with coke produced from coal, and the combustion of coal released so much CO_2 to the atmosphere that it became an important and additive player in the overall carbon cycle. The rate of anthropogenic CO_2 generation accelerated even more at the end of the nineteenth century with the introduction of petroleum, which is easily refined into convenient liquid fuels like gasoline, kerosene, diesel, and jet fuel. Finally, natural gas was added to the mix, and today's CO_2 emissions from fossil fuel combustion exceed 30 billion metric tons per year. Coal, oil, and gas each contributes comparable amounts (Fig. 1).

Other anthropogenic releases of CO_2 result from the calcination of carbonates, usually lime stone, mainly in the production of cement. About half of the CO_2 in cement making results from fuel combustion, the remainder is the CO_2 freed as limestone (calcium carbonate) is converted to



Anthropogenic CO_2, Fig. 1 The global carbon dioxide budget for the decade from 2006 to 2015. The budget numbers are given in Gigatonnes of carbon dioxide per year and reflect a 10 year average. The anthropogenic fuel cycle liberates carbon from fossil fuel resources and land use. The carbon, mainly in the form of carbon dioxide enters the atmosphere, and redistributes itself between the atmosphere, the ocean and the terrestrial biosphere. Most of the CO_2 in the ocean is dissolved inorganic carbon. Most of the carbon stored in biomass is organic matter. Here the numbers are given in terms of CO_2 masses, but often they are given in terms of carbon. One ton of carbon equals 3.67 tons of CO_2. The carbon dioxide flows have been adapted from Le Quéré C et al. (2016), Global carbon budget 2016. Earth Syst Sci Data 8(2):605.)

lime (calcium oxide). The cement industry produces about 7% of all anthropogenic CO_2 emissions (calculated from data provided by van Oost 2016 and Fischedick et al. 2014).

Not all of the carbon present in oil, coal, or gas that is extracted from the ground is directly oxidized to CO_2, some is incorporated into other chemical compounds, for example, plastics, asphalt, or carbon for carbon black in tires or in carbon electrodes. Some of these carbon-based materials will persist in the environment for long times, but many will degrade over time producing CO_2 in the process; others will be combusted in waste incineration plants that again release anthropogenic CO_2.

Finally, anthropogenic sources include CO_2 from underground gas reservoirs that are either tapped for their CO_2 content or produce CO_2 as an unintended byproduct. For example, many natural gas wells contain significant amounts of CO_2 that is co-produced with methane. In most cases, the CO_2 will have to be removed from the gas before it can be distributed to customers. For example, the Sleipner Field in the North Sea operated by Statoil produces a gas that contains about 10% carbon dioxide, too much to leave it in the gas (IPCC 2005).

Adding up the total carbon mobilized by human activities (Ciais et al. 2013), including the sources mentioned above and carbon released from deforestation and land use changes, minus the uptake induced by human activities for example in reforestation, still leaves a net release of CO_2 of 33 billion tons per year, or nine billion tons of mobilized carbon. Even though this is much smaller than the natural annual flow of carbon from the atmosphere into biological reservoirs (on the order 170 billion metric tons of carbon per year), it matters because it is not matched by an opposing flow. Photosynthesis with its large uptake and release rates causes an annual fluctuation of about 6 parts per million by volume (ppm) in the atmosphere, but does not lead to a significant change in the annual average concentration. By contrast, human emissions currently raise CO_2 concentration by about 2.2 ppm per year. Since the beginning of the industrial revolution, the CO_2 concentration in the atmosphere rose from 280 to 410 ppm in May of 2017.

Environmental Concerns Over Anthropogenic CO_2 Emissions

Anthropogenic CO_2 emissions have become a large environmental concern as they represent by far the largest contribution to human-induced climate change. Excess CO_2 redistributes itself between the atmosphere, the ocean, and the biosphere. The surface ocean is in equilibrium with the atmosphere, but the deep ocean will take many centuries to adjust to changes in the atmosphere. In equilibrium, about 80% of the excess CO_2 will end up in the ocean. Roughly half the CO_2 emitted to the atmosphere will stay there for centuries. Over tens of thousands of years, natural removal of CO_2 from the combined atmosphere/ocean/biosphere system proceeds by geochemical processes that produce mineral carbonates (Archer et al. 2009).

As a greenhouse gas in the atmosphere, CO_2 causes global warming. Dissolved as carbonic acid in the ocean, it changes the ocean pH, and with it the carbonate chemistry of the ocean, which is important to many calcifying organisms like corals. Lastly, CO_2 leads to worldwide eutrophication of bioecosystems with concomitant imbalances.

Computational models corroborate and even strengthen the simple and physical story that CO_2 emissions are cumulative and tend to pile up in the atmosphere. Models all agree (MacDougall 2015) that the warming caused by CO_2 emissions is driven by total cumulative emission and does not depend on the shape of the emission profile. Models suggest that the reduction of the greenhouse effect due to uptake of CO_2 into the ocean is compensated for by the gradual warming of the ocean. The temperature increase will stop when emissions stop, but excess temperatures will persist for about a millennium (Solomon et al. 2009). Moreover, models agree that the expected warming is simply linear in the cumulative emissions, which hints at complex feedback mechanisms because the underlying greenhouse effect is logarithmic in the CO_2 concentration.

Policy makers and climate change scientist agree that climate change needs to be kept to a manageable level. Most countries of the world including the United States, China, and European Union signed and ratified the 1992 United Nations Framework Convention on Climate Change in Rio de Janeiro that obligates all parties to prevent dangerous levels of climate change. Today, the Intergovernmental Panel on Climate Change (IPCC) discusses a 2°C rise over preindustrial global temperatures as a threshold beyond which warming poses severe risks to humans and the environment (IPCC 2014). This corresponds to about 450 ppm of CO_2 in the atmosphere, or 45 ppm above the current level. The 21st United Nations Conference of the Parties on Climate Change in Paris in 2015 resulted in an agreement that reaffirms the 2°C limit and adds that the world should be aiming for a temperature increase of no more than 1.5°C leaving very little room for additional CO_2 emissions.

Balancing the Carbon Budget

Stabilizing the CO_2 concentration in the atmosphere at any reasonable level requires balancing the anthropogenic carbon budget. This in turn means that fossil fuel combustion must either be eliminated completely by moving to nonfossil energy sources or the remaining fossil fuel consumption has to be balanced by the safe and permanent disposal of an

equivalent amount of CO_2. Renewable energy including solar and biomass or nuclear energy could replace oil, coal, and gas, which today comprise more than 80% of the world's primary energy consumption. To the extent that fossil fuels will still be used, e.g., as jet fuels in the aviation industry, disposal of an equivalent amount of CO_2 will become necessary. Disposal processes are referred to as carbon sequestration or carbon capture and storage (IPCC 2005). Carbon dioxide storage could involve the injection of CO_2 into deep underground reservoirs, where it would occupy the pore space in a manner similar to how oil and gas are naturally stable in geological reservoirs. A second option is to bind CO_2 to natural minerals that react with carbon dioxide and water to form carbonate salts or bicarbonate salts. This process is referred to as mineral sequestration (Lackner et al. 1995). Bicarbonates tend to be water-soluble and would end up in the ocean, and carbonates are often insoluble and form minerals like limestone or calcium carbonate. Such mineralization processes occur naturally and are known as geological weathering. In their natural form, they are far too slow to keep up with anthropogenic CO_2 production, but over tens or hundreds of thousands of years, they will reinstate the natural carbon balance of the system. For practical carbon dioxide storage, mineralization would need to be accelerated by many orders of magnitude. A third option, which actually was the first to be proposed (Marchetti 1977), is to put the CO_2 into the ocean, either by dissolving it in the water column or forming lakes of CO_2 at the ocean floor. However, ocean storage of CO_2, which in water turns to carbonic acid, has been criticized on environmental grounds. The capacity of the ocean to hold sufficient CO_2 for a sufficient time may not be available. At the present rate of three trillion tons per century, CO_2 production in the coming century could easily be several trillion tons. For comparison, Lake Michigan contains 5 trillion tons of water. Ocean circulation turns over the ocean in roughly 1000 years. Considering that it will take natural processes many thousands of years to eliminate the excess CO_2, a residence time in the ocean of less than a thousand years would be too short. Similar concerns over capacity and storage time have been raised about storing anthropogenic CO_2 in the standing biomass.

Before CO_2 can be stored, it must be collected or captured. In the case of biomass growth, capture is part of the natural process of photosynthesis. For other approaches to carbon sequestration, there need to be active processes to collect CO_2. The most suitable locations for capture are the big point sources of CO_2, like power plants, refineries, steel plants, and cement plants (IPCC 2005). Among these point sources, power plants tend to be bigger and in aggregate produce much more CO_2 than other point sources. Natural gas wells frequently co-produce CO_2 that needs to be sequestered. One of the largest CO_2 disposal effort is at the above-mentioned Sleipner Gas Field in the North Sea, where the Norwegian oil company Statoil separates the CO_2 from the natural gas at the well site and injects about one million tons of CO_2 per year into a deep saline aquifer 800 m below the seafloor (Arts et al. 2008).

Point source capture could involve retrofitting existing power plants, building new power plants with more efficient and more integrated CO_2 capture. In order to truly close the anthropogenic carbon cycle, it is not sufficient to reduce emissions or capture a large fraction of the CO_2 that is produced in the combustion process, but it will be necessary to collect all of the CO_2, even that which escapes into the atmosphere. Moreover, it may become necessary to create negative emissions where CO_2 that has already been emitted is removed from the environment. Unless emissions are reduced much more rapidly than today an overshoot scenario becomes unavoidable, and some climate scientists consider it already necessary (Hansen et al. 2013).

Collection from the environment, for example directly from the atmosphere, also makes it possible to balance out emissions from sectors of the economy that do not lend themselves to point source capture, because emissions are distributed and mobile and individually small (Lackner 2014). Vehicles, ships, and airplanes may carry fuel that is converted at the point of consumption into CO_2 and H_2O. While point source capture, for example, from flue gas can go back to well-established scrubbing technologies using, for example, amine solutions to bind CO_2 that is regenerated during a heating step, capture from ambient air requires innovative approaches, which are being developed, or combust biomass, which during its growth collected CO_2 from the atmosphere, in power plants that capture their own CO_2 and permanently dispose of it.

Conclusion

In summary, human activities have profoundly altered the natural carbon cycle on Earth by converting stable carbon from deep underground into CO_2 that flows through the mobile carbon pool. This pool includes the atmosphere, the ocean, and biomass. Since natural processes for balancing the carbon cycle are too slow to prevent the accumulation of excess CO_2 in the atmosphere, options for managing anthropogenic CO_2 and balancing the world's carbon budget are being developed.

Antimony

Jacqueline R. Houston
CSUS – California State University, Sacramento, CA, USA

Element Data
Antimony (Sb: atomic weight 121.76) is a silvery metalloid with common oxidation states of (−3), (+3) and (+5). Antimony has two stable isotopes: ^{121}Sb (natural abundance of 57.36%) and ^{123}Sb (natural abundance of 42.64%).

Properties

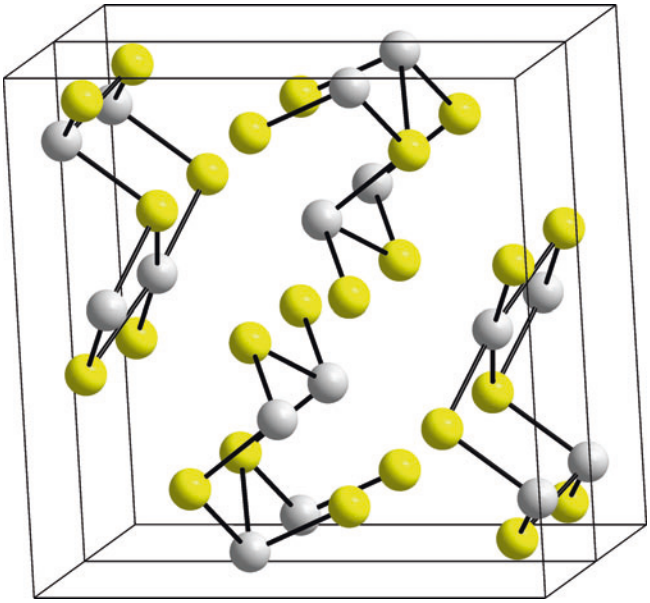
Antimony has four allotropes, which include the blue-white metalloid, the most common allotrope of antimony, and three meta-stable allotropes, yellow, black and explosive. Antimony forms a variety of chemical compounds such as chlorides ($SbCl_3$), fluorides (SbF_3), oxides (Sb_2O_3 and Sb_4O_{10}) and sulfides (Sb_2S_3) (Greenwood and Earnshaw 1997; Wiberg et al. 2001).

History and Use

Antimony has found many commercial applications. Antimony trioxides (Sb_2O_3) are most often used as fire retardants in foam filled furniture, accounting for roughly 60% of its commercial production. Antimony is also used as an alloying material for lead-acid batteries, bullets, and solder (roughly 20% of commercial use). Other applications include the use of antimony sulfides and oxides in pigments, as catalysts for the production of polyethyleneterphthalate and in the production of glasses and pyrotechnics (Butterman and Carlin Jr 2003).

Antimony Minerals

Although the abundance of antimony in the Earth's crust is less than 0.5 parts per million, it forms over a hundred mineral species, many of which are sulfide minerals. In reducing environments with high sulfide concentrations, such as those found in hydrothermal ore deposits, sulfide containing minerals such as stibnite form readily (Sb_2S_3, Fig. 1). The metal ore stibnite often occurs as iridescent needles and is mined in only a few countries, with China



Antimony, Fig. 1 Structure of stibnite (Source: American-Mineralogist-Crystal-Structure-Database: Stibnite. Permission granted to copy under GNU Free Documentation License)

being the largest producer (Carlin Jr 2011). The metal ore has a specific gravity of 4.63 and belongs to the orthorhombic crystal class system. Other antimony minerals include kermesite (Sb_2S_2O), ullmannite (NiSbS), valentinite (Sb_2O_3), and tetrahedrite (Cu_3SbS_3). Additionally, minerals such as cervantite[Sb(III)Sb(V)O_4] demonstrate that antimony can exist in more than one oxidation state within one mineral phase.

Aqueous Geochemistry

Weathering of rocks, soil runoff, and anthropogenic activities contribute to the occurrence of antimony in natural waters. Because aqueous antimony has two common oxidation states in natural systems (+3 and +5), its speciation primarily depends on the oxidative conditions. Under oxic conditions, dissolved antimony is primarily present as $[Sb(OH)_6]^-$ (pH values > 2.5) in which Sb is present in the (+5) oxidation state (Krupka and Serne 2002). Contrary to thermodynamic data (Baes and Mesmer 1976; Krupka and Serne 2002), several studies have suggested that metastable Sb(+3) has also been found under oxic conditions, which may have resulted from biotic processes and when antimony oxidation rates are slow (Krupka and Serne 2002). Under moderately reducing conditions, the speciation is dominated by the $Sb(OH)_3$ species (pH 2–12) in which the antimony is in the (+3) oxidation state. As one would expect, the adsorption of antimony to mineral surfaces in aqueous environments is determined by the speciation of antimony. The hydrolytic anion, $[Sb(OH)_6]^-$ is the dominant species under oxic conditions and over a relatively wide pH range. Under acidic conditions, where the mineral surface is positively charged, adsorption of $[Sb(OH)_6]^-$ is greatest. At near neutral pH to basic pH conditions, electrostatic repulsion between the negatively charged mineral surface and the anionic $[Sb(OH)_6]^-$ complex reduces the likelihood of adsorbed antimony. As a result, under oxic and somewhat basic conditions, antimony is thought to be highly mobile in the natural environment (Krupka and Serne 2002).

Summary

Compared to other elements, little is known regarding the geochemical behavior of antimony. In natural waters, the common oxidation states of antimony are (+3 and +5) in which the hydrolytic anion $[Sb(OH)_6]^-$ is thought to be the dominant species under oxic conditions and pH range of 2–12. Even though the abundance of antimony is low in the Earth's crust, antimony is known to form over a hundred mineral species including the metal ore stibnite.

Aqueous Solutions

Barry R. Bickmore and Matthew C. F. Wander
Department of Geological Sciences, Brigham Young University, Provo, UT, USA

Definition

An *aqueous* solution is one in which the *solvent* is liquid water. That is, *solute* (dissolved) ions and molecules are surrounded by water molecules and incorporated into the network of bonds within the water. The dissolved species then spread throughout the water.

Aqueous Solutions in Geochemistry

In geochemistry, by far the most important solvent is water. In general, geochemists divide natural waters into three types: freshwaters (including rain, rivers, lakes, and shallow groundwaters), seawater, and brines (including evaporative basins, many hydrothermal waters, and deep groundwaters). Natural waters also may be intermediates between these types, formed by mixing (e.g., estuarine waters from seawater and river water) or by evaporation (e.g., a brine from partial evaporation of seawater). The typical chemical characteristics of natural waters are shown in Table 1.

Aqueous solutions are the reservoirs or the means of transport for elements in biochemical and geochemical cycles and, thus, are the primary media through which matter and energy are exchanged at the Earth's surface. The chemical reactions effecting this exchange may be of five types: acid/base, complexation, oxidation/reduction, dissolution/precipitation, and adsorption/partitioning reactions. Many of these reactions also may be biologically mediated. The compositions of aqueous solutions reflect the extent of reaction with sediments, rocks, or gases. All the properties of aqueous solutions are strongly linked to their molecular-scale structure.

Structure

Water structure is dominated by two factors: (1) lone-pair effects causing the bent structure of the water molecule, resulting in an electrical dipole, and (2) the preference of H atoms for asymmetrical bonding between O atoms, resulting in weaker attractions between H_2O molecules than within them.

The H-O bonds within and between water molecules generally exhibit bond orders greater than ~0.65 and less than ~0.35, respectively, with the most common values about 0.83 and 0.17 (Brown 2002; Bickmore et al. 2009) (see ▶ "Chemical Bonds"). In pure water, nearly all H atoms are bound strongly to one O atom within the molecule, and to one or (less commonly) more O atoms on other molecules. This results, on average, in a distorted tetrahedral distribution of H atoms around each O atom, with molecules associated in various cluster and ring formations on a larger scale (Bunker and Casey 2016).

When other species are dissolved, the water molecules reorient themselves around the ions and molecules, to some extent altering the original structure of the solution and the ability of the water molecules to reorient themselves in response to changes in local conditions. The H atoms in water are oriented to bond with any negatively charged atoms, and the O atoms orient themselves to bond with positively charged atoms.

The local bonding environments generated by this reorganization are remarkably similar to those found in oxide solids. Al^{3+} ions, for instance, would typically be found surrounded by four to six O^{2-} ions, just as in the structures of common minerals. Larger, low-charge ions like K^+ would typically be connected to the surrounding O^{2-} via a larger number (8–12) of weaker bonds. The bonding environments of the O^{2-} atoms would be determined by bond order considerations and lone-pair effects. In other words, these local bonding environments can largely be rationalized in terms of Pauling's Rules for crystal structures (Bunker and Casey 2016).

Thermodynamic Description

Thermodynamic description of an aqueous solution requires that two properties be defined for the solvent water and each dissolved species: concentration and activity. Concentration is usually expressed in units of molarity (mol/L) or molality (mol/kg of solvent). The latter is the most broadly useful because the mass of water, as opposed to its volume, is invariant with temperature, pressure, and solute content. Activity (see ▶ "Activity and Activity Coefficients") is a unitless quantity that is the concentration of a species multiplied by a correction factor (activity coefficient) necessary to account for changes in chemical behavior related to interactions between species and changes in local water structure. By convention, activity coefficients of dissolved species in aqueous solutions are 1 at infinite dilution and vary from that value at higher solute concentrations. Typically, values are <1 at low to moderate concentrations, but then can rise to >1 in very concentrated brines. The activity of pure water is 1, and

Aqueous Solutions, Table 1 Chemical characteristics of natural waters. Data from several sources (Baas Becking et al. 1960; Collins 1975; Millero and Schreiber 1982; Berner and Berner 1987; Boggs 1992)

Environment	pH	Eh range (V)	Major ions in order of abundance	Dissolved organic carbon (mg/L)
Rainwater				
Continental	4–6	Oxic	SO_4^{2-}, Ca^{2+}, Cl^-, NO_3^-, Na^+, K^+, NH_4^+, Mg^{2+}	?
Marine and coastal	5–6	Oxic	Cl^-, Na^+, SO_4^{2-}, Mg^{2+}, Ca^{2+}, K^+, NO_3^-, NH_4^+	?
Rivers	5–9	0.3–0.5	HCO_3^-, Ca^{2+}, $H_4SiO_4°$, SO_4^{2-}, Cl^-, Na^+, Mg^{2+}, K^+	<1 to >30
Lakes				
Fresh	5.9	−0.1–0.5	HCO_3^-, Ca^{2+}, $H_4SiO_4°$, SO_4^{2-}, Cl^-, Na^+, Mg^{2+}, K^+	<1 to >100
Saline	5–10	−0.1–0.5	Cl^-, Na^+, SO_4^{2-}, HCO_3^-, Mg^{2+}, K^+, Ca^{2+}, $H_4SiO_4°$	<1 to >100
Shallow groundwater	6–8.5	−0.1–0.45	HCO_3^-, SO_4^{2-}, Ca^{2+}, Na^+, Cl^-, Mg^{2+}, $H_4SiO_4°$, K^+	<1 to 20
Marine	7.5–8.4	0.2–0.4	Cl^-, Na^+, SO_4^{2-}, Mg^{2+}, Ca^{2+}, K^+	<0.1 to 3
Evaporative marine	7.5–9.0	Oxic or anoxic	As for marine then inc. Mg^{2+} with mineral precipitation	?
Brackish marine	7.5–8.4	Oxic or anoxic	As for marine	?
Deep connate groundwater	6.0–8.0	−0.25–0.4	Cl^-, Na^+, K^+, SO_4^2, Ca^{2+}, Mg^{2+}	<10 to 4500

decreases with increasing solute concentrations. For most natural solutions, however, the activity of water remains close to one. Even for seawater, the activity of water is >0.98, and so it is usually treated as a constant except in association with the most concentrated brines (Stumm and Morgan 1995). Activity coefficients are estimated via a wide variety of models, the simplest of which take into account only the formal charges of the ions in solution and the overall ionic strength. For solutions with ionic strengths greater than ~0.5 molal, however, it is necessary to use more complex formulations, such as Pitzer or Specific Ion Interaction Theory models (Langmuir 1997). For hydrothermal solutions, geochemists often use the model of Helgeson and coworkers (Helgeson et al. 1981).

Acid-Base Reactions

An acid, in the Brønsted-Lowry definition, is a species that can dissociate and donate H^+ to an adjacent water molecule to create H_3O^+. The adjacent water molecule is usually ignored and H_3O^+ abbreviated as H^+, so that an acid dissociation reaction is written as $HB \leftrightarrow H^+ + B^-$, where HB is the acid and B^- is the conjugate base. A base is a species that can accept H^+ in the reverse reaction. A given aqueous solution is designated as "acidic" or "basic" based on the relative concentrations of H^+ and OH^- ions, acidic solutions being those with more H^+.

The acidity/basicity of a solution is commonly characterized according to the pH scale, where pH is the negative of the base-10 logarithm of the H^+ activity (equal to the H^+ concentration in dilute solutions). Most natural waters have pH values between 5 and 9.

The most fundamental acid-base reaction is water dissociation, written $H_2O \leftrightarrow H^+ + OH^-$. The equilibrium constant for this reaction (K_w) is 10^{-14} at 25 °C, which implies that a "neutral" solution (i.e., one in which there are equal activities of H^+ and OH^-) has ~10^{-7} molal of both ions, assuming activity coefficients of ~1. In a neutral solution at 25 °C, therefore, pH = 7. The value of K_w changes with temperature, however, so that at 100 °C, for instance, $K_w = 10^{-12.25}$, and under neutral conditions the H^+ and OH^- concentrations would be ~$10^{-6.125}$ molal. In other words, the neutral solution pH is 6.125 at 100 °C.

In addition to H^+ (or H_3O^+) and OH^-, the most common ions in natural waters participating in acid-base reactions are HCO_3^- and CO_3^{2-}-, which act as bases, and dissolved CO_2 ($H_2CO_3°$) and silica ($H_4SiO_4°$), which act as acids. (Some species, like HCO_3^- or water itself, can act as either an acid or a base.) Any metals in solution, via hydrolysis, also can act as acids. (In hydrolysis, water molecules surrounding a metal cation dissociate.) In acid rain, nitrogen and sulfur species may be important acids.

The equilibrium constants for acid dissociation reactions are usually abbreviated as K_a or pK_a (the negative of the base-10 logarithm of K_a). Mathematically, it works out that the pK_a value for a given acid dissociation reaction equals the pH at which the acid and its conjugate base have equal concentrations. For example, pK_a = 9.84 for the dissociation of silicic acid ($H_4Si0_4°$), so at pH = 9.84, there would be equal concentrations of $H_4Si0_4°$ and $H_3Si0_4^-$.

Acid-base reactions play critical roles in rock weathering. Rainwater is a low ionic strength, dilute aqueous solution with a pH value of about 5.7 resulting from the equilibration of water with atmospheric CO_2 (Langmuir 1997). In percolating through soil, the solution becomes much more acidic

from re-equilibration with soil gas $C0_2$, which is typically about 10 times higher than the atmospheric value. In the underlying rock, this solution is highly corrosive with respect to basic minerals, such as carbonates and feldspars. As these minerals dissolve, the solution pH rises and the solution becomes more concentrated in ions such as Ca^{2+}, Na^{+}, Mg^{2+}, K^{+}. These ions may subsequently participate in precipitation reactions to form authigenic carbonates, clays, or metal hydroxides. At the other end of the natural solution spectrum from unreacted rainwater is seawater. Reflective of the aggregate effects of innumerable water-rock interactions, seawater is a high ionic strength solution, with a basic pH of about 8.2.

Complexation

In aqueous solutions, complexation can occur between solute species and water molecules, hydrogen ions, hydroxide ions, or other solute species, resulting in charged or uncharged complexes. The tendency to form complexes is related to the relative attraction between the solute species versus that between those species and water molecules.

Metals form some of the most important complexes in natural waters. These consist of a central metal ion and electron-donating ligand, forming a complex with negative, positive, or neutral charge. The complexed metal may have a different oxidation state to the free metal ion and, thus, have a different reactivity. In particular, complexation often results in increased metal solubility and leaching. In many waters, natural organic molecules, such as amino acids and humic substances, and anthropogenic pollutants, such as EDTA, are important complexing agents. Many biological processes rely on metal complexes to maintain metals in solution during cell transport processes.

Oxidation-Reduction Reactions

In oxidation-reduction (redox) reactions, water plays a critical role acting as an electron donor or acceptor. The stability limits for Eh-pH diagrams are defined by the stability limits for water according to the reactions:

$$O_{2(g)} + 4\,H^{+} + 4e^{-} = 2\,H_2O$$
$$2\,H^{+} + 2e^{-} = H_2(g)$$

The upper and lower limits usually are set by convention using partial pressures of O_2 at 1 and $10^{-83.1}$ atm (Drever 1982).

The predominant elements involved in redox reactions are carbon, nitrogen, oxygen, sulfur, iron, and manganese. With water in equilibrium with atmospheric oxygen (PO_2 = 0.21 atm), carbon should be present only as dissolved CO_2, HCO_3^{-}, CO_3^{2-}, nitrogen as NO_3^{-}), sulfur as SO_4^{2-}, iron as FeOOH or Fe_2O_3, and manganese as MnO_2. More reduced species, such as H_2S, CH_4, and free Fe^{2+} and Mn^{2+} (as hydrated forms), are common in surface environments, however, and their presence reflects the importance of biological processes in creating reducing microenvironments and regulating natural aqueous solution chemistry.

Dissolution/Precipitation Reactions

Whether a mineral will dissolve or precipitate from a solution of a given composition can be estimated using thermodynamic criteria. Computer models, such as WATEQ (Truesdell and Jones 1974), SOLMINEQ (Kharaka and Barnes 1973), REDEQL (Morel and Morgan 1972), PATI-II (Helgeson et al. 1970), and the various more recent computer codes derived from these models, use input solution ion concentrations to calculate ion speciation and the saturation states of the water with respect to the possible minerals which could form from or might have dissolved to produce a water of such composition. Once again, the tendency for compounds to precipitate or dissolve depends on the relative attraction between the species combined in the solid versus that between those species and water molecules (Brown 2002).

The kinetics of reactions in aqueous solutions also must be considered, however. Although the thermodynamic driving force for a given reaction may be significant, there may be species in solution which inhibit reaction progress. A well-known example is the oversaturation of surface seawater with respect to calcite, which is maintained because dissolved sulfate and magnesium inhibit the progress of the precipitation reaction.

Adsorption/Partitioning Reactions

Solute and colloidal transport in aqueous solutions are strongly dependent on the properties of solid-solution interfacial regions. The surfaces of natural minerals in contact with aqueous solution are often electrically charged due to local charge imbalances. This induces concentration gradients between the ions around these surfaces, and when in contact with water there is an offsetting imbalance of electrical charge in solution at and near the solid surface, because solute ions of opposite charge are attracted to the charged surface, and ions of the same charge are repelled. Therefore, chemical models involving functional groups on solid surfaces must employ electrostatic corrections to bulk ionic concentrations/activities. This "electric double layer" (i.e., the layer of altered ionic concentrations at the interface) decreases in thickness with increasing ionic strength. This allows suspended solid particles to approach each other more closely, promoting aggregation (Stumm 1992).

The polar nature of water molecules also influences the transport and partitioning of molecules that are not necessarily

ionic. That is, molecules with more polar bonds tend to strongly attract polar water molecules, and so are "hydrophilic," whereas those with less polar or fully covalent bonds tend to be "hydrophobic." Therefore, hydrophobic compounds like waxes tend to partition at solid-solution interfaces.

Summary and Conclusion

Aqueous solutions provide one of the major means of chemical transformation and transport near the surface of the Earth. They provide a liquid-phase oxide network similar to the solid-phase oxide networks of most minerals, so that ions may be dissolved, transported, and recombined in various ways. The characteristics of the chemical bonds involving water molecules, including their spatial distribution as influenced by lone-pair effects, are at the heart of water's unique properties.

Definition

Archaeological geochemistry is the discipline which integrates geochemical analysis techniques and methods into the study of the human past, to answer questions on subsistence, migration, environment, and the transport and use of natural raw materials.

Introduction

Archaeology is an interdisciplinary science par excellence. In its quest to reconstruct human behavior in the natural and cultural environment in the past, it uses knowledge and techniques from many different academic disciplines. As the exact sciences are increasingly integrated into archaeological

research throughout the world, a range of geochemical tools are applied to archaeological questions dating from early hominins of the Plio-Pleistocene to Paleolithic hunter-gatherers, early Neolithic farmers, and great early state civilizations. Archaeological geochemistry began with the investigation of ancient materials, particularly stone and pottery. More recently, archaeological chemistry has seen a growth of biogeochemical tools applied to human and plant remains as part of an integrated science of the Anthropocene, as human societies first began to substantially transform their environment (Smith and Zeder 2013).

With the spectacular growth of this field in the last decades, certain topics are not covered in this entry. One of those subjects is geochronology, even though isotopic systems such as K-Ar, Rb-Sr, U-Th-Pb, and U-decay series are used both to refine and extend archaeological dating beyond the limits of radiocarbon dating (e.g., Deino et al. 1998). U-series dates on calcite flowstone growths on the surfaces of paintings, for example, have shown the world's earliest cave art is both surprisingly old (~40 kyr ago) and geographically extensive (Aubert et al. 2014; Pike et al. 2012).

As much as we would like to cover these and related topics, we focus mainly on two primary lineages of archaeological geochemistry. The first is the elemental and isotopic characterization of inorganic materials to infer provenance and production. The second is the biogeochemical characterization of organic materials to infer diet, migration, and subsistence practices.

Geochemical Study of Inorganic Materials

In archaeology, ancient artifacts are not simply materials intended for classification, but they are direct proof of how ancient production and technology evolved. The better we understand the different contexts in which people used and produced artifacts, the more likely we are to understand their everyday life, crafts, or trade. By characterizing material exchange, aspects of social stratigraphy and standard of living can be documented as well.

While archaeological chemistry dates to eighteenth- and nineteenth-century studies of Greco-Roman coins and Roman pigments and pottery (Pollard and Heron 2008), the use of exact scientific tools mainly developed after World War II (Peacock 1970). Since the 1970s, exact scientific techniques for provenancing, especially optical microscopy and an array of chemical analysis, have been used more and more frequently and on more and more material categories.

Provenance Studies

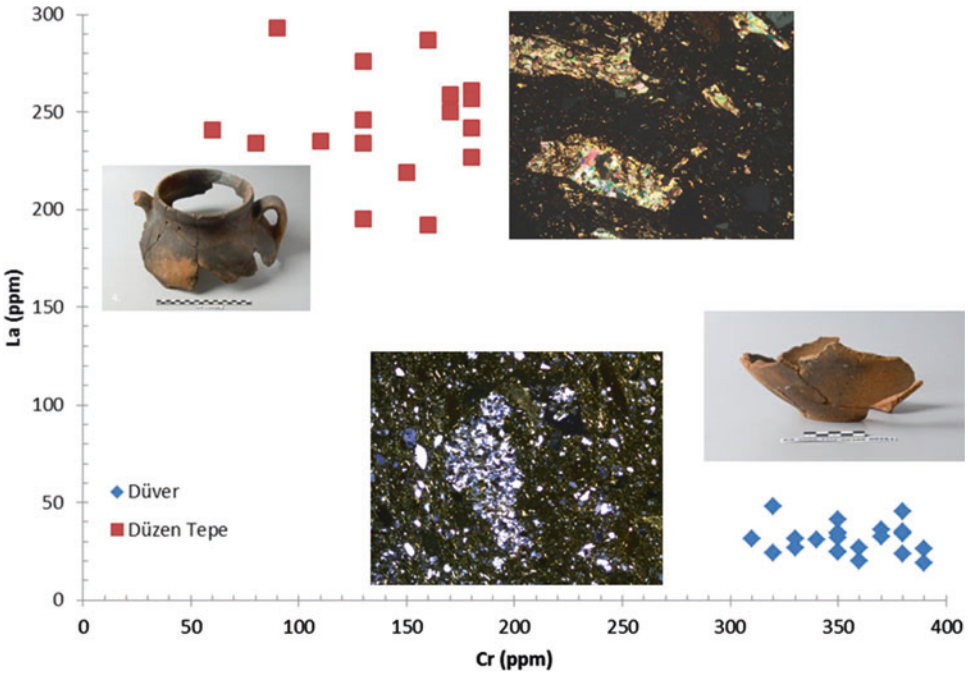
An essential assumption in provenance studies – measuring some property to trace an artifact to its particular source or production site – is that the between-source differences must exceed within-source variation (Weigand et al. 1977). In general, many techniques from the geosciences are applied to study the source of raw materials for ancient craft production in different chronological-geographical contexts and on different artifact types (pottery, vitreous materials, metals), in which trace element profiles and isotopic analysis have proven essential (Henderson 2000; Pollard and Heron 2008).

Just about every element of the periodic table has been used at some time to compare the typical composition of resource materials to that of archaeological artifacts. Depending on the nature of the materials analyzed (e.g., clay compared to ceramic, sand to glass, ore to metal), elements are chosen for their occurrence as major or trace element and the nature of the geological-mineralogical information they provide. Multimethod provenance studies will often combine petrography and chemical techniques such as (but not exclusive to) element and isotope ratio analysis.

Provenance of Pottery and Glass

The provenance determination of stone and ceramics is often accomplished through chemical and mineralogical-petrographic analysis (e.g., Degryse and Braekmans 2014; Kempe and Harvey 1983). In such studies, the analytical data from stone objects or ceramics are compared to the geological characteristics of the potential raw material sources, such as stone quarries, mines, soil surveys, and clay pits. For example, aluminum, magnesium, and potassium are typical major elements, which provide information on the type of clay minerals used for ceramic manufacturing. However, since most clays have similar, if not overlapping, major element compositions, there is little resolution in such analysis to distinguish different ceramic origins. The variation in trace elements, such as the transition metals or the rare earth elements (REEs), may then be much more useful to distinguish different raw materials used. Overall, trace element analysis has been successful in answering archaeological questions on ceramic raw material provenance, recipes, and manufacturing processes and technological (r)evolutions (Fig. 1). In provenance studies of ceramics, since the introduction of petrography and geochemistry in the 1950s and 1960s (e.g., Peacock 1970), these techniques have been used routinely over the years.

As for glass, some diagnostic chemical compositions of ancient glass provide a characterization which suggest a specific source. The first regular production of glass uses four basic components (Degryse and Braekmans 2014): silica as a network former, a network modifier or flux (alkali and/or lead), stabilizers (usually lime), and colorants (in the form of many different possible metals). Specific compositions of glass production may indicate certain sources, technical processes, and ages (Brill 1999; Sayre and Smith 1961). The elements magnesium, potassium, and phosphorous separate the earliest plant ash-based glasses, in which quartz pebbles



Archeological Geochemistry, Fig. 1 Comparison of the La-Cr trace element content and a micrograph of Iron Age ceramics from the sites of Tepe Düzen (*squares*) and Düver (*diamonds*) (SW Turkey – 20 km apart), indicating the use of two different clay raw material sources (Data from Braekmans et al. 2011)

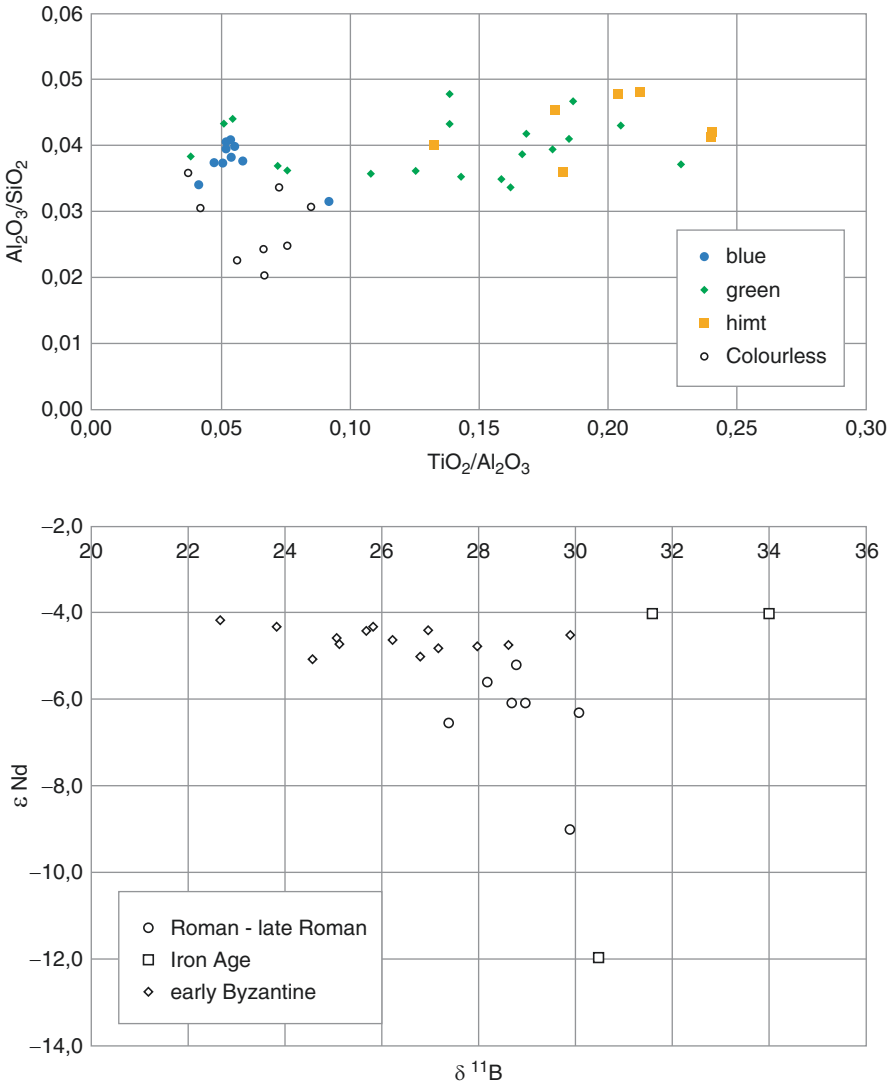
and plant ashes were used as flux, from natron-based glasses of the Mediterranean and Europe, which contained soda-rich minerals, crushed lime, and quartz sand. Usually, contents higher than 1.5% in both magnesia and potash are thought to prove the use of plants as a flux. Elements like iron, titanium, and aluminum are usually related to the concentrations of specific minerals (feldspars, clays, etc.) in the silica source of the glass (Freestone 2006).

Some minor elements in ancient glass were added to color or decolor the material, such as cobalt in dark-blue glass or copper in lighter blue or greenish glass, or opacity imparted through addition of antimony, tin, or lead. Since these coloring elements were often added in the form of ores (e.g., stibnite), minerals (e.g., alum), or metals (e.g., bronze), these elements do not source the raw material of the glass itself but indicate the source of the colorant/opacifier. Trace elements in glass can also help to separate compositional groups and assign individual objects to them (Brill 1999; Shortland et al. 2007). Egyptian and Mesopotamian glasses, for example, are distinguishable particularly by their concentrations of titanium, zirconium, chromium, and lanthanum, which may reflect different geological sources, plant ash compositions, silica sources, and/or contamination of the melt by clay or grinding debris (Rehren and Pusch 2005; Shortland et al. 2007). In Roman natron glass, for another example, the REE content has been shown to be dependent on the clay fraction of the sand and is identical for most possible provenance areas in the Mediterranean. Elements such as zirconium, hafnium, titanium, etc. are controlled by heavy mineral concentrations in sand and offer potential as indicators of glass provenance (Degryse and Shortland 2009). For instance, Schibille et al. (2016) proposed a new classification scheme for the composition of first millennium natron glass, in which the ratios TiO_2/Al_2O_3 versus Al_2O_3/SiO_2 distinguish an Egyptian versus a Syro-Palestinian primary origin (Fig. 2a). Glazes applied to clay bodies have similar compositional features to contemporary glass (Tite and Shortland 2008).

Strontium and neodymium isotopes, discussed more below, have been used to trace the provenance of vitreous materials including ceramics and glass (Degryse 2012). As shown in Fig. 2b, neodymium isotopic analysis of ancient glass identifies the sources of non-quartz minerals in the silica raw material used to make this glass (Degryse 2014). The element boron is inherited in glass through the flux, and the boron isotopic composition of evaporites has been used to distinguish different sources of natron raw material (Devulder et al. 2014, 2015).

Metals and their Geologic Sources

The analysis of metal alloys involves the identification of the presence/absence of a sufficient concentration of a particular element to conclude that it has a significant effect on the properties of the alloy and is not just an impurity. Nevertheless, care has to be taken as to the intent of the early metallurgists in mixing metals to obtain certain properties. Copper alloys are often assigned to categories such as bronze (Cu + Sn), leaded bronze (Cu + Sn + Pb), antimonal copper (Cu + Sb), arsenical copper (Cu + As), brass (Cu + Zn with or without Pb), or gunmetal (Cu + Zn + Sn with or without Pb).



Archeological Geochemistry, Fig. 2 (**a**) Plot of the TiO_2/Al_2O_3 versus Al_2O_3/SiO_2 ratio in sixteenth- to seventeenth-century AD glass from Sagalassos (Turkey), distinguishing the Egyptian primary origin of the local "*yellow-brown*" HIMT glass from the Syro-Palestinian primary origin of the local *blue* and *colorless glass* and the locally recycled nature of the *green glass* (Degryse et al. 2006). (**b**) Plot of the ε_{Nd} versus $\delta^{11}B$ isotopic composition of Iron Age to early Byzantine natron glass from around the Mediterranean. The range in ε_{Nd} indicates the use of silica raw materials from the Eastern Mediterranean ($-6 < \varepsilon_{Nd} < -4$) as well as (rarely) from the Western Mediterranean ($\varepsilon_{Nd} < -6$), while the $\delta^{11}B$ is typical for North African natron sources from evaporitic lakes in Tunisia, Libya, and Egypt (Data from Devulder et al. (2014) and Degryse (2014))

An element is then considered significant if it is present at a concentration of more than about 1% for tin, antimony, and arsenic and 2% for lead (Pike 2002). Trace elements are commonly used to assign metal (alloys) to ore sources. Typically, for example, the contents of bismuth, cobalt, silver, gold, zinc, nickel, and iron are used fin tracing copper alloys. However, this needs to be treated with care as recycling and reuse of metal may significantly influence their composition. Also, (s)melting may have had a dramatic effect on the concentrations of many minor and trace elements (Wilson and Pollard 2001; Rehren 2008). As the chemical relationship between raw materials and metal artifacts made from them may have been altered, provenance of and trade in metal artifacts have been addressed using heavy radiogenic isotopes of strontium, neodymium, and lead (Degryse 2012). The isotopic composition of a raw material is dependent on the geological age and origin of that material. Heavy isotopes are not fractionated during technical processing due to their relatively high masses and low internal relative mass differences. As melting will hence have had little effect on isotope ratios, these may be used in tracing raw materials in craft production. The isotopic composition of the artifact will be identical, within analytical errors, to the raw material (mixture) from which it was derived, while the signatures of different raw materials used, and hence the resulting artifacts, may differ (Brill and Wampler 1965).

Lead isotopes were one of the first used to investigate ancient materials, in particular to trace the provenance of lead, silver, and bronze metal (mainly from the Mediterranean Bronze Age period) since the 1960s. These efforts, but also the disadvantages and controversy around the use of Pb isotopes, have been extensively reviewed (Pollard 2009). Lead isotopic analysis has also been used to study a range of archaeological vitreous materials and to provenance ancient iron (Degryse 2012) and copper alloys using lead isotope mixing models (Pollard and Bray 2015). Elsewhere in the world, lead isotope analyses have been used to source

copper, tin, and bronze objects from late prehistoric Myanmar to known prehistoric copper mines elsewhere in Southeast Asia (Pryce et al. 2016).

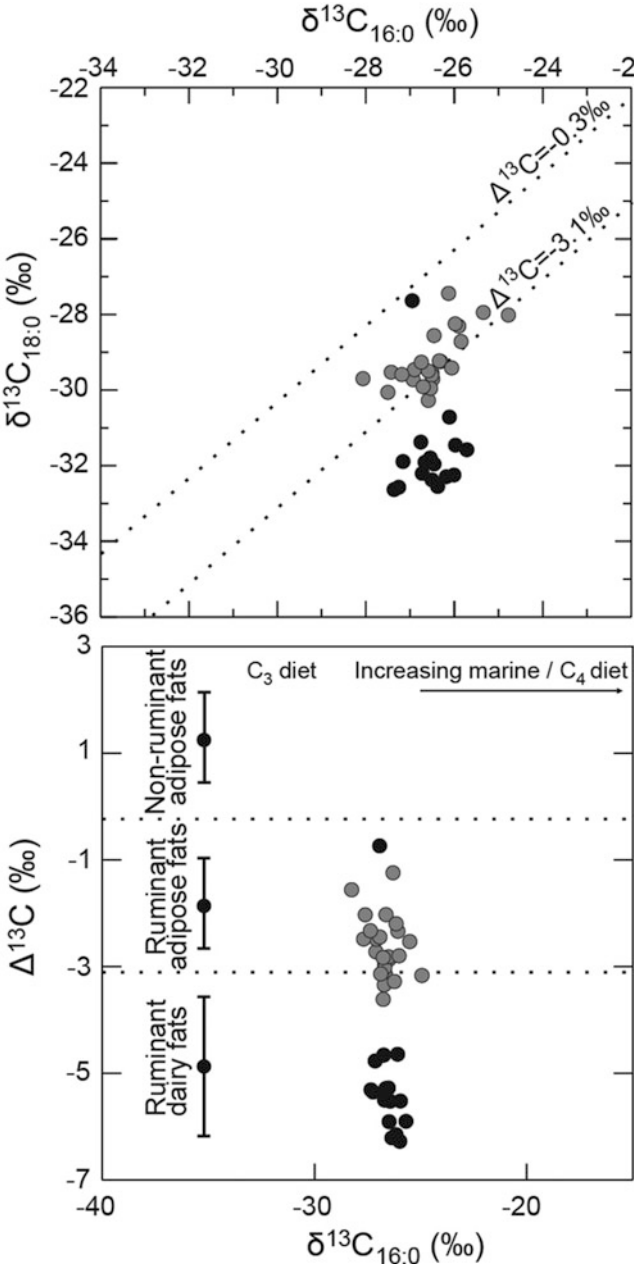
Tin was another vital commodity in ancient times, but the provenance of prehistoric tin, used for the production of bronze from the third millennium BC onward, is still unsolved. Since lead in ancient bronze comes mostly from the copper ore, lead isotopic analysis cannot be applied for determining the provenance of tin (Begemann et al. 1999). Analysis of tin isotope ratios (Gale 1997) with large sample sizes has shown homogeneous isotopic compositions within ore deposits and significantly different between deposits (Haustein et al. 2010). Isotopic analysis also provides a means to investigate the provenance of antimony in glass and ores (e.g., Lobo et al. 2014), which may reveal that the origin of antimony in early glass coincides with its use in metallurgy in the Caucasus in the Bronze Age (Degryse et al. 2015).

For inorganic materials, new analysis technologies include laser ablation multi-collector ICP-MS (Devulder et al. 2015) and portable X-ray fluorescence spectrometers (Tykot 2016). Because these methods are fast and fairly nondestructive to the artifacts, they will likely become more widespread in the near future.

Geochemical Study of Organic Materials

Organic Residues

Answering questions on diet is approached through the analysis of preserved biomolecular components of residues in and on archaeological materials, usually ceramics. This biomarker approach looks at compound-specific isotope compositions of a range of major biochemical components of animals and plants (Cramp and Evershed 2014). A wide range of biochemicals including lipids and proteins can be derived from human and animal remains and particularly in pottery, which preserves the biochemical remains of animal fats, waxes, or dairy products (Cramp and Evershed 2014). Molecular and stable isotopic techniques now exist for identifying the fats of the major classes of domesticated animals, i.e., ruminants versus nonruminants, and of some hunted terrestrial species (e.g., Copley et al. 2003; Outram et al. 2009). This led to a series of discoveries in identifying the world's oldest dairy residues on pottery remains (Copley et al. 2003; Dunne et al. 2012; Salque et al. 2013; Smyth and Evershed 2015) – in each case centuries or millennia earlier than had hitherto been assumed. The organic residue work can involve painstaking preparation and analysis of hundreds of potsherds over a wide geographical range (Salque et al. 2013). Compound-specific stable isotope measurements in fatty acids are made using a gas chromatograph (GC) linked to an isotope ratio mass spectrometer (IRMS). The typical means of identifying dairy fats is by a plot of the $\delta^{13}C$ values in the $C_{16:0}$ fatty acid versus $\delta^{13}C$ in the heavier $C_{18:0}$ fatty acid (Fig. 3). Ruminant dairy fats typically plot with $\delta^{13}C$ in the $C_{18:0}$ about 3–5 per mil lower than in adipose fats from meat.



Archeological Geochemistry, Fig. 3 Isotopic distributions in animal fat residues extracted from Neolithic sieves and cooking pots from the sixth millennium BC in Northern Europe (Salque et al. 2013). The *top* shows $\delta^{13}C$ in the $C_{16:0}$ and $C_{18:0}$ fatty acids, with one data point for each vessel, the sieves shown in *black* and the cooking pots in *gray*. The *bottom* shows $\Delta^{13}C$ values = ($\delta^{13}C_{18:0} - \delta^{13}C_{16:0}$) of the extracts plotted against their $\delta^{13}C_{16:0}$. Ranges on the *left* show expected $\Delta^{13}C$ values for a global database. Note how the cheese sieves contained residues of dairy fats (Modified after Salque et al. (2013), with kind permission from Mélanie Roffet-Salque)

Diet and Environment

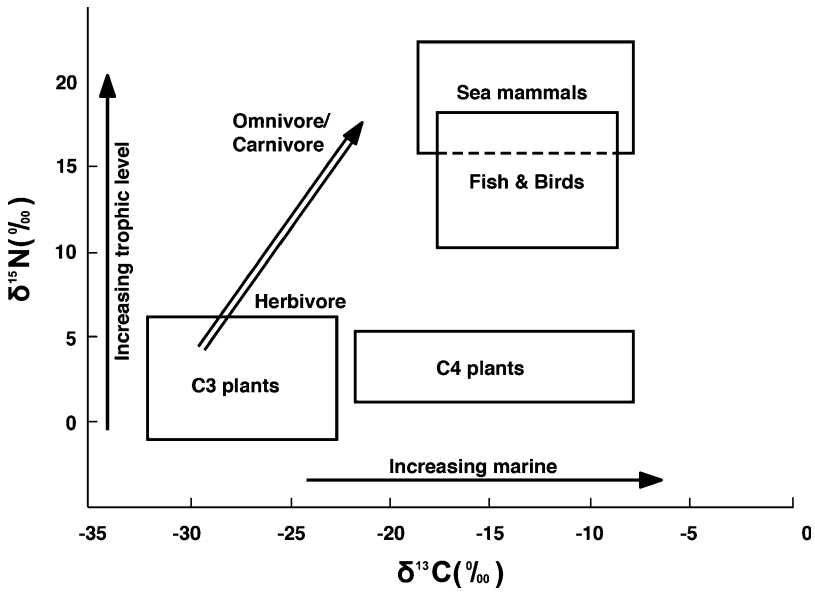
Inferences concerning migration, diet, climate, and subsistence can be made through the identification and quantification of animal and plant remains found at archaeological sites. Hydrogen isotope values in animal fats, for example, bioaverage local water sources and thus can act as proxies for the climate (temperature/precipitation) of the region in which the animals were raised (Outram et al. 2009).

Contamination due to the uptake and diffusion of chemical elements or other alteration processes, like dissolution or erosion, can change the composition and distort the results of environmental and dietary studies. Compositional studies on fossilized bone have provided information on various aspects of the paleoenvironment because of diagenetic changes during the fossilization process of buried bone (Denys et al. 1996). The nature and degree of diagenesis have been evaluated through the study of changes in the fossil bones' chemical composition (Hedges 2002).

Stable isotope analysis of animal and human remains is mainly used for diet reconstruction. Traditional carbon and nitrogen isotope analysis of bulk collagen in bone, and recently in individual amino acids, is used to estimate dietary patterns. The isotopic signal in bone collagen reflects dietary inputs averaged over at least the last decade of life but often with a particular emphasis on the period of adolescence (Hedges et al. 2007; Stenhouse and Baxter 1979). As the stable isotope signals in aquatic food products (freshwater and marine species) are different from those in terrestrial organisms, and as they are variable according to the organism's place in the food chain (which are shorter in terrestrial environments), the contribution of various food stuff to the former human diet can be evaluated through the analysis of stable isotopes (Fig. 4).

Carbon isotopes ^{12}C and ^{13}C fractionate during primary production of organic matter during photosynthesis, such that C_3 plants (e.g., most plants including rice, wheat, etc.) have $\delta^{13}C_{PDB}$ values between −23 and −34‰ (Heaton 1999). The C_4 plants, adapted to hot and dry climates, fix CO_2 more efficiently than C_3 plants, via a 4-carbon acid (hence C4), and exhibit less isotopic fractionation of carbon than C_3 plants. C_4 plants include tropical grasses and importantly teosinte and maize in the new world and sorghum and millet in the old world. The $\delta^{13}C_{PDB}$ value in C_4 plants ranges from about −10 to −18‰ (O'Leary 1988). There are a number secondary effects on $\delta^{13}C$ in plants, including temperature, humidity, forest density, altitude, and insolation (Heaton 1999). In animals and humans, the major causes of $\delta^{13}C$ variations include consumption of marine resources, generally enriched in ^{13}C by several per mil compared to terrestrial C_3 plant foods and meat consumption, whereby $\delta^{13}C$ increases by about one per mil per trophic level (Schoeninger and DeNiro 1984).

Applications of bulk $\delta^{13}C$ and $\delta^{15}N$ in archaeological bone collagen over the past 40 years (Lee-Thorp 2008) have mainly focused on differentiating between diets based on marine and terrestrial protein sources and diets that emphasizing C_3 versus C_4 plants and estimating dietary trophic level. By analyzing different tissues (dentine, rib, and femur) from the same individual, a dietary history can be established from childhood to the last few years of their life. Carbon isotopes have most frequently been measured in bone collagen, in which ^{13}C is enriched by about +5‰ relative to diet, but measurement of $\delta^{13}C$ can also be done in the carbonate fraction of tooth enamel, enriched by about 9.4‰ relative to the whole diet (Ambrose et al. 1997; Koch et al. 1995). Since these materials represent different



Archeological Geochemistry, Fig. 4 Conceptual plot of the use of carbon and nitrogen isotope ratios, measured on bone collagen, in diet reconstructions

biomolecular pathways – collagen representing protein in the diet, tooth enamel apatite reflecting the whole diet – additional value is gained by observing the differences in $\delta^{13}C$ measured in more than one of these tissues (Schoeninger 2009).

Using these end-members for a linear mixing model, $\delta^{13}C$ has been used to estimate percentages of marine foods in the diet, despite the uncertainties regarding $\delta^{13}C$ in coastal food webs and in apatite itself (e.g., Prowse et al. 2004; Schoeninger and DeNiro 1984). A pure C_3 plant diet might yield $\delta^{13}C$ of −16‰ in enamel carbonate, for example, versus a pure marine diet at − 4.6‰, such that each 1‰ of $\delta^{13}C$ change is modeled as reflecting 9% dietary change along the continuum (Ambrose et al. 1997). This can be complemented by sulfur isotope analysis where there is a question of freshwater versus marine food uptake (Bocherens et al. 2015; Richards et al. 2003).

Nitrogen is derived from dietary protein and used by the body to synthesize amino acids. Averaged in bone collagen as signature of the whole diet, the bulk $\delta^{15}N$ in collagen has long been assumed to reflect trophic level, with about 3–4‰ increase in $\delta^{15}N$ per trophic level, from plants to herbivores to carnivores, as this trophic effect continues up the food chain (Schoeninger and DeNiro 1984). Diets based on legumes tend to exhibit lower $\delta^{15}N$ values, because legumes have nitrogen fixed for them by bacteria and have $\delta^{15}N$ close to 0‰. $\delta^{15}N$ is usually measured in concert with bulk $\delta^{13}C$ in collagen, and innovative new case studies include a comparison of palaeogenetic data versus $\delta^{13}C$, $\delta^{15}N$, and $\delta^{34}S$ in Neolithic human skeletons, which identified two distinct human groups coexisting across a frontier for millennia (Bollongino et al. 2013).

Because bulk $\delta^{13}C$ and $\delta^{15}N$ analyses of collagen, however, only reflect an average across the constituent amino acids, a notable advance lies in measuring $\delta^{13}C$ and $\delta^{15}N$ in specific compounds separated by gas chromatography, including amino acids and cholesterol extracted from skeletal materials (e.g., Naito et al. 2013; Styring et al. 2015). Compared to bulk C and N isotopes from bone collagen, $\delta^{13}C$ in different amino acids, such as glycine versus phenylalanine, carries additional information due to different biochemical pathways from the diet (e.g., Choy et al. 2010; Styring et al. 2015). Measuring $\delta^{15}N$ in amino acids helps resolve the ambiguities of bulk $\delta^{15}N$ signal (e.g., from nutrient recycling) and has been used, for example, to identify early agricultural manuring (Bogaard et al. 2013). Also, since amino acids can be prepared by acid hydrolysis of a subsample of collagen used for the bulk analyses, bulk $\delta^{13}C$ and $\delta^{15}N$ analyses are increasingly used as a screening method to select well-preserved and "interesting" (e.g., exceptional bulk values) samples for compound-specific isotopic analysis.

Mobility

By substituting as a + 2 cation for calcium, elements similar to Ca, including Sr, Ba, and Pb, are permanently preserved in the mineral phase (hydroxyapatite) of archaeological tooth enamel, which is more resistant to post-burial contamination with respect to these elements than bone (Kamenov and Gulson 2014; Trickett et al. 2003; Willmes et al. 2016). As they have large atomic mass and therefore relatively small mass differences between their respective isotopes, isotopes of Sr, Ba, or Pb enter the food chain without fractionation relative to their weathered geologic sources (Bentley 2006; Ericson 1985; Evans et al. 2015; Kamenov and Gulson 2014). In tooth enamel, the isotope signature therefore reflects the concentration-weighted average of those sources while the enamel was forming (Beard and Johnson 2000). For settled communities, a parsimonious interpretation of a "nonlocal" isotope signature in tooth enamel is that the person was an immigrant, but often another possibility is that the person spent substantial childhood time elsewhere (e.g., a childhood hunter-gatherer who later joined a settled community).

The most widely used of these systems is the strontium isotope signature ($^{87}Sr/^{86}Sr$) in tooth enamel (Ericson 1985). High-profile applications include an exceptionally well-preserved bog body from the Bronze Age of Denmark, ca. 3400 BP, whose bones, teeth, and even woolen clothing were traced using strontium isotopes (Frei et al. 2015). Geology provides a general basis for what we expect the biologically available $^{87}Sr/^{86}Sr$ to be in different areas, and maps of bioavailable strontium or Sr maps are becoming more common (Evans et al. 2010; Frei and Price 2012; Hodell et al. 2004; Montgomery et al. 2006). One challenge to mapping $^{87}Sr/^{86}Sr$ is its environmental variability in soils and plants (Sillen et al. 1998). The $^{87}Sr/^{86}Sr$ in tooth enamel reflects a concentrated-weighted average of all inputs during enamel formation, with much lower coefficient of variation than within their environmental sources (Burton and Price 2003; Bentley 2006; Montgomery et al. 2010). Due to this bioaveraging effect, while stream or groundwater can be good proxies for bioavailable $^{87}Sr/^{86}Sr$ (Montgomery et al. 2006), archaeological tooth enamel in animals is often good for mapping $^{87}Sr/^{86}Sr$ (Bentley and Knipper 2005). For coastal settings, however, seaspray or precipitation can supply significant Sr of marine derivation ($^{87}Sr/^{86}Sr = 0.7092$), presenting a challenge to untangling the various contributions of coral reefs, seaspray, and seafood in the diet. Measuring Ba/Sr in tooth enamel can help triangulate the food sources from enamel samples because seawater has orders of magnitude lower Ba/Sr ratios than typical terrestrial environments (Bentley et al. 2007; Burton and Price 2003).

Micro-sampling across a human or animal tooth, either by laser ablation or by micro-milling, provides $^{87}Sr/^{86}Sr$

measurements within a single tooth. Measurements along the growth of a cow's tooth, for example, track its mobility over about 2 years of its life (Gron et al. 2016; Montgomery et al. 2010). A challenge in measuring $^{87}Sr/^{86}Sr$ by the laser ablation method, LA-ICP-MS, however is the isobaric interferences at atomic masses from 84 to 88, including inert gasses used by the mass spectrometer and from the source material itself (Nowell and Horstwood 2009). Instrumental correction methods are improving, however (Müller and Anczkiewicz 2016; Willmes et al. 2016), and the noise in the LA-ICP-MS data can also be smoothed through a moving average of the raw signal (Lewis et al. 2014). Nevertheless, the best accuracy is still achieved through TIMS analysis on micro-drilled samples in which the strontium is purified through traditional column chemistry (Müller and Anczkiewicz 2016; Nowell and Horstwood 2009).

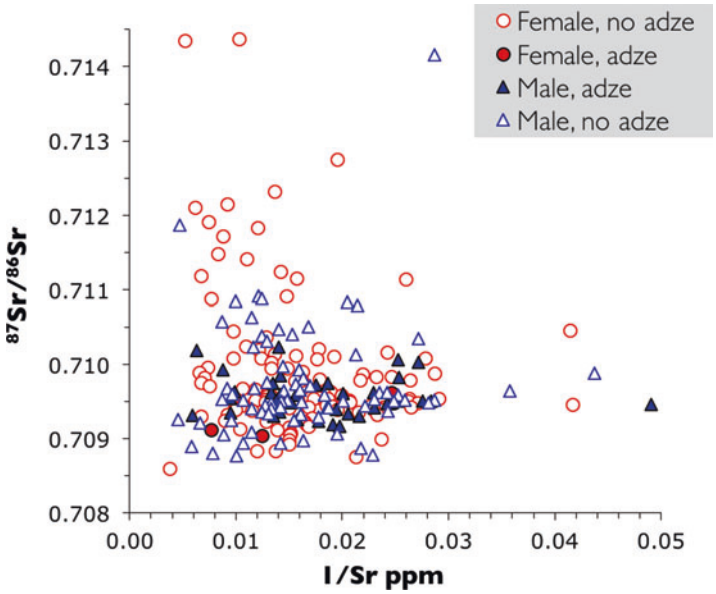
For over 40 years, studies of Pb isotopes – radiogenic isotopes ^{206}Pb, ^{207}Pb, and ^{208}Pb versus the non-radiogenic isotope ^{204}Pb – have been used to identify anthropogenic sources of lead in humans, whose blood, teeth, and bones incorporate trace amounts of Pb from the local environment through dust and soil particulates (Evans et al. 2015; Kamenov and Gulson 2014). Homogeneous anthropogenic sources have dominated atmospheric Pb for centuries – from silver and lead mining 3000 by the ancient Greeks and Romans to the leaded gasoline in the twentieth century – as visible in the $^{207}Pb/^{206}Pb$ signatures in peat core records and in modern human teeth (Kamenov and Gulson 2014; Shotyk et al. 1998). In pre-metal prehistoric times, however, Pb concentrations in the environment and the human body were several orders of magnitude lower, i.e., less than 1 ppm in human teeth (Chiaradia et al. 2003; Kamenov and Gulson 2014). Lead isotopes in the biosphere have been mapped in the United States at coarse resolution (Keller et al. 2015). In the Mayan region of the Yucatan Peninsula, regional differences Pb isotopes between limestone-rich lowlands and metamorphic or volcanic highlands make this a promising region for lead isotope studies of Mayan human and animal remains (Sharpe et al. 2016).

Geographic origins are reflected in enamel $\delta^{18}O$ values measured in animals that take in much of their oxygen through ingested water (Kohn 1996). Oxygen isotopes can be measured in either the phosphate or structural carbonate fraction of tooth enamel, with a fixed offset in $\delta^{18}O$ between the two materials (Bryant et al. 1996). In precipitation, $\delta^{18}O$ depends on the source water, temperature, distance from the coast, altitude, rain shadow effects, and other aspects of the hydrologic cycle (Bowen and Wilkinson 2002). The altitude effect is about 1–2‰ reduction in $\delta^{18}O$ per 1000 m (Poage and Chamberlain 2001). In mammals, the oxygen isotopic composition of skeletal matter is controlled by drinking water, food, and atmospheric oxygen, but as moderated by complex physiological fractionations (Kohn 1996; Kohn and Cerling 2002). Due to the time-averaging effect of enamel formation, however, measurements of $\delta^{18}O$ in sequential samples of livestock teeth can reveal seasonal herd movements (Balasse et al. 2012) or serve as a proxy for paleoclimate (Sarkar et al. 2016). In humans, drinking water can include different geographic sources such as precipitation, stream, and groundwater. Humans with a consistent water supply, such as groundwater from wells in prehistoric Britain, may yield tooth enamel with $\delta^{18}O$ variation of 1‰ or less within a sedentary community (Budd et al. 2004). This is not always the case, however. In tropical regions, $\delta^{18}O$ in enamel may vary more within populations than between them, whereas in alpine regions, like the Andes or Alps, both seasonal differences and altitudinal effects in meteoric water $\delta^{18}O$ may be larger than differences between groups.

Overall, by combining isotope signatures with all the archaeological details and genetic (DNA) analyses, such elusive phenomena such as prehistoric kinship and the origin of social inequality can be identified. For example, Sr, O, and C isotope measurements in tooth enamel, compared with heritable dental traits, revealed group structure among the victims of a Neolithic massacre buried in a mass grave at Talheim, Germany (Bentley et al. 2008). Given evidence for differential land access in the Neolithic, from carbon and nitrogen isotopes in plant and animal remains (Bogaard et al. 2011; Fraser et al. 2013) as well as strontium isotopic signatures in humans such as the example shown in Fig. 5, others have looked for and found different animal husbandry patterns in prehistoric domestic animal teeth (Balasse et al. 2012, 2016; Gron et al. 2016; Madgwick et al. 2012; Montgomery et al. 2010). These inferences about land use are combined with evidence from plant remains to reconstruct the food webs (Fraser et al. 2013), climate change (Riehl et al. 2008), or land management practices (Wallace et al. 2015; Bogaard et al. 2013).

Conclusion

Chemical and isotopic analyses are a means to characterize the origin and/or nature of raw materials used in artifact production and therefore contribute to models of trade, manufacture, and ancient economy. The combination of isotopic results with the macroscopic analysis of the human, animal, and plant remains from archaeological sites can create a clearer picture of the dietary patterns and natural environment of a society. New instrumentation continually makes new analysis possible first for specialists and then later for archaeologists more widely. Ideally, a full archaeological interpretation should combine chemical results with evidence from archaeological excavations,



Archeological Geochemistry, Fig. 5 $^{87}Sr/^{86}Sr$ in archaeological human enamel samples from early Neolithic sites across Central Europe, where early Neolithic farmers preferred the rich loess soil ($^{87}Sr/^{86}Sr$ between 0.709 and 0.710). Most males buried with distinctive Neolithic stone adzes (*filled triangles*) yielded $^{87}Sr/^{86}Sr$ within the *loess* range, with lower variance than the rest of the sample ($p < 0.01$). Most individuals outside this range were females or males without adzes ($p < 0.01$). As males with adzes yielded strontium isotope signatures consistent with their preferred loess soils, the implication is that males without adzes were not cultivating their food in local soils; perhaps they were pastoralists or they had to farm less optimal uplands (Modified after Bentley et al. (2012))

historical sources, and typo-chronological study. The use of techniques adapted from the geosciences and developments in microanalysis and in (semi-) nondestructive analysis of archaeological materials (Neff 2012; Resano et al. 2010) have allowed to look at archaeological research questions in an entirely new way.

Argon

Mark A. Kendrick
Research School of Earth Sciences, Australian National University, Canberra, ACT, Australia

Element Data
Atomic Symbol: Ar
Atomic Number: 18
Atomic Weight: 39.984
Isotopes and Abundances: ^{40}Ar (99.6%), ^{38}Ar (0.06%), and ^{36}Ar (0.34%)
1 Atm Melting Point: 83.95 K
1 Atm Boiling Point: 87.29 K
(*continued*)

Common Valences: 0
First Ionization Potential: 1520.6 kJ mol^{-1}
Chondritic (CI) Abundance: ~10^{-6} mol g^{-1} (~93 ppm by mass)
Silicate Earth Abundance: ~10^{-12} mol ^{36}Ar g^{-1} (parts per trillion range)
Crustal Abundance: $<10^{-11}$ mol ^{36}Ar g^{-1}
Seawater Abundance: ~1–2 × 10^{-8} mol ^{36}Ar g^{-1}

Properties

Argon is the most abundant noble gas and accounts for 0.934 volume % of dry air. Argon has a calculated atomic radius of 0.71 Å and a van der Waals radius of 1.88 Å. Argon is a colorless, odorless, tasteless, nontoxic gas at room temperature, and like the other noble gases in group 18 of the periodic table, Ar usually has a full valence shell of electrons and does not form chemical bonds. Chemical inertness and volatility are defining features of group 18 gases which exist in monatomic states and are commonly known as the noble, inert, or rare gases. This behavior is further emphasized by the name argon which is derived from the Greek *argos* meaning lazy, idle, or inactive.

Argon has three stable isotopes: ^{40}Ar now dominates on all rocky planets and meteorites because it is produced by radioactive decay of ^{40}K, which has a half-life of 1.25 Ga. The scarce ^{38}Ar and ^{36}Ar isotopes are not significantly produced by any radiogenic or nucleogenic pathway and are therefore regarded as primordial isotopes on Earth. The ^{37}Ar and ^{39}Ar isotopes are short-lived radionuclides with half-lives of 35 days and 269 years, respectively, that are exploited by ^{40}Ar-^{39}Ar dating (below) but are only produced at very low levels in the Earth's crust (Chang 2015; McDougall and Harrison 1999).

Discovery and Utility

Argon was the first noble gas to be isolated (Rayleigh and Ramsay 1894). The first hint of its existence came in 1766 when Henry Cavendish noted that 1% of the gas in air could not be chemically combined. However, argon was only isolated from air and identified as a new element in 1894 (Rayleigh and Ramsay 1894). Its isolation followed some months after Lord Rayleigh and Sir Ramsey first noted that nitrogen purified from decomposing ammonium nitrite appeared to be 0.5% lighter than nitrogen purified from air. The discrepancy that indicated the presence of an unknown heavier gas contaminating atmospheric nitrogen and argon was later isolated from this mixture by reaction with heated

magnesium. The residual gas had a volume of ~1% the original volume of air and was shown to have distinct spectral lines.

Argon has a number of industrial and scientific applications, and it is produced for these purposes by fractional distillation of liquefied air, together with liquid nitrogen and liquid oxygen. Due to its abundance, argon is the cheapest noble gas used for industrial processes. Argon is used to sparge dissolved gas impurities from molten metals including steel; it is used in some types of arc welding/cutting of reactive metals and in the production of reactive elements and growing crystals. Argon is used as a preservative to displace moisture and air from some food and medicine packages. The low thermal conductivity of argon means it can be used to fill the gap in sealed double glazing units. The inert chemical and characteristic electrical properties of Ar are used in lighting: argon prevents oxidation of the filament in incandescent light bulbs and produces a characteristic violet/lilac light in gas-discharge lamps. Argon is used in science to provide inert atmospheres within glove boxes and can be used as a carrier gas for gas chromatography or laser ablation inductively coupled plasma mass spectrometry. The breakdown of ArF is used to produce 193 nm light in Excimer lasers.

Distribution in the Cosmos and on Earth

Argon is the tenth most abundant element in the solar system accounting for ~3 atoms per million (~93 ppm by mass or ~10^{-6} mol g^{-1}) of the solar photosphere, where it is dominated by the non-radiogenic ^{36}Ar and ^{38}Ar isotopes and is similarly abundant as calcium (Ca) and aluminum (Al) (Lodders 2003). The high volatility of Ar, which has a 50% condensation temperature of 48 K at 10^{-4} bar (Lodders 2003), means that it is strongly depleted in chondritic meteorites that condensed from the solar nebula. Argon and other noble gases are further depleted in differentiated terrestrial planets like Earth, where they are strongly partitioned into the atmosphere and regarded as atmophile elements. The Earth's atmosphere is estimated to have a total Ar inventory of 1.7×10^{18} mols equivalent to ~70 trillion tons (Ozima and Podosek 2002). The absolute abundance of argon within the Earth is subject to substantial uncertainty; however, the atmosphere probably contains 95–99% of all $^{36\text{-}38}$Ar on Earth and 50–95% of all ^{40}Ar. Given the crust and mantle contain K, they have uniformly higher ^{40}Ar/^{36}Ar than the atmosphere. However, the proportion of ^{40}Ar outgassed from the Earth hinges on how the K content of the Earth is estimated. Argon has a total abundance on Earth on the order of 10–20 ppb with primordial $^{36\text{-}38}$Ar in the parts per trillion range (e.g., ~10^{-12} mol g^{-1}). Primordial Ar is therefore approximately a million times less abundant on Earth than in the Sun, which explains why noble gases like Ar are also known as rare gases.

Seawater represents Earth's second largest Ar reservoir, after the atmosphere, and has a typical Ar concentration of ~$1–2 \times 10^{-8}$ mol g^{-1}, with the absolute concentration varying as a result of solubility fluctuations related to temperature and salinity (Ozima and Podosek 2002). Argon does not usually form chemical bonds, but it can be adsorbed onto mineral surfaces via van der Waals forces. If present, argon is trapped in fluid inclusions in minerals, and it is also incorporated in lattice defect structures and vacant ring sites in hydrous minerals (Jackson et al. 2015). Maximum ^{36}Ar concentrations of 10^{-11} mol g^{-1} have been reported for hydrous minerals and sediments (Kendrick et al. 2013), whereas the mantle has an estimated ^{36}Ar concentration of only ~$2–3 \times 10^{-15}$ mol g^{-1}. Some ionic molecules containing Ar have been formed under laboratory conditions including the hydrate ion ArH^+ which forms readily under vacuum conditions and short-lived molecules such as ArF and HArF. Argon is also trapped in the lattice structure of gas hydrate.

Significance in Geochemistry, Geochronology, and the Composition of Air

The radioactive decay of ^{40}K to ^{40}Ar forms the basis of one of the most widely used geochronometers in Earth science today (McDougall and Harrison 1999). The radioactive decay of ^{40}K is branched: it decays to produce 11.2% ^{40}Ar via electron capture and 88.8% ^{40}Ca via beta decay. However, the strong depletion of argon on Earth means that radiogenic ^{40}Ar is much easier to measure than radiogenic ^{40}Ca and ^{40}Ar is therefore the most important decay product for geochronology. The 1.25 Ga half-life of ^{40}K decay has enabled the K-Ar dating technique to be applied to primitive meteorites that represent some of the oldest objects in the solar system, down to events occurring at sub-million year timescales. Most modern "K-Ar" ages are obtained via the ^{40}Ar-^{39}Ar technique. In this technique the geological sample is irradiated in a nuclear reactor to convert a small portion of the samples ^{39}K into ^{39}Ar via a neutron reaction. K is then measured via the irradiation-produced ^{39}Ar proxy isotope by mass spectrometry together with ^{40}Ar. This technique has the advantages that K and Ar are measured simultaneously and possible ^{40}Ar-loss can be assessed via age spectra diagrams. It also provides very high precision and its high sensitivity enables application to materials with young ages in the tens of thousands of years age range (McDougall and Harrison 1999).

The importance of Ar in geochronology means that there has been great interest in precisely determining its isotopic composition in air (Table 1). The IUGS subcommission on geochronology recommended an atmospheric ^{40}Ar/^{36}Ar ratio of 295.5 ± 0.5 (Steiger and Jager 1977), which has been widely used, but includes a rounding error compared to the value of 296 originally recommended by Nier (1950)

Argon, Table 1 Isotopic composition of Ar in air

	$^{40}Ar/^{36}Ar$	$^{38}Ar/^{36}Ar$
Nier (1950)	296.0 ± 0.5	0.1880 ± 0.0004
IUGS	295.5 ± 0.5	
Lee et al. (2006)	298.6 ± 0.3	0.1885 ± 0.0003
Valkiers et al. (2010)	298.7 ± 0.1	0.1898 ± 0.0002

(Table 1). More recent determinations suggest a $^{40}Ar/^{36}Ar$ ratio about 1% higher than Nier's value (Lee et al. 2006; Valkiers et al. 2010). It has not yet been possible to reproduce the abundance of all three argon isotopes at the quoted levels of uncertainty (Table 1); however, Mark et al. (2011) suggests that the combined $^{40}Ar/^{36}Ar$ and $^{38}Ar/^{36}Ar$ values of Lee et al. (2006) show the greatest internal consistency. Until consensus is reached regarding the best $^{40}Ar/^{36}Ar$ ratio for air, the value adopted for measurement calibration should ideally be stated.

The second major use of Ar is as a geochemical tracer. The $^{40}Ar/^{36}Ar$ composition of fluid inclusions in crustal minerals is sensitive to the introduction of atmospheric components with low $^{40}Ar/^{36}Ar$, whereas mantle (or ancient crustal) fluids have elevated $^{40}Ar/^{36}Ar$. As a result of degassing ^{40}Ar from the mantle and crust, the atmospheric $^{40}Ar/^{36}Ar$ ratio has increased over Earth history (Cadogan 1977; Pujol et al. 2013). The argon isotope signature of the mantle provides information about mantle degassing and re-gassing through subduction recycling. The maximum $^{40}Ar/^{36}Ar$ of the mantle sampled by mid-ocean ridge basalt is ~40,000 (Moreira et al. 1998), whereas the mantle sampled by ocean island basalts (e.g., Hawaii, Iceland) has a substantially lower $^{40}Ar/^{36}Ar$ of $<$15,000 because it is less degassed and contains more primordial ^{36}Ar (Mukhopadhyay 2012). The $^{38}Ar/^{36}Ar$ of the mantle is of considerable interest for identifying the primordial origin of noble gas in the mantle. Most recent analyses suggest the mantle and atmosphere have indistinguishable $^{38}Ar/^{36}Ar$ that is slightly higher than the solar value (Holland and Ballentine 2006; Raquin and Moreira 2009). This is consistent with the possibility that atmospheric noble gases have been extensively cycled into the mantle by subduction (Holland and Ballentine 2006); however, the ultimate origin of noble gases in the mantle and atmosphere remain an area of active debate.

Summary

Argon is the most abundant noble gas accounting for 0.934% of dry air. As a result of its abundance, argon was the first noble gas to be chemically isolated and is the cheapest noble gas used in industrial processes. Argon has three stable isotopes; ^{40}Ar is produced by radioactive decay of ^{40}K, whereas ^{38}Ar and ^{36}Ar are primordial isotopes on Earth. Argon is strongly depleted on Earth and concentrated in the atmosphere. The ^{40}Ar-^{39}Ar method is a powerful and widely used geochronometer. The variable distribution of Ar isotopes between Earth's mantle, crust, and atmosphere provides important constraints on mantle outgassing, fluid flow in the crust and subduction-recycling.

Argon Isotopes

Philippe Sarda
GEOPS, Univ. Paris-Sud, CNRS, Université Paris-Saclay, Rue du Belvédère, Orsay, France

Introduction

Argon (Ar) has three natural isotopes with masses 36, 38, and 40. ^{36}Ar and ^{38}Ar are stable, that is, they are not radioactive, and they are also not produced by radioactivity processes. In detail, these isotopes can be produced in tiny amounts by rare reactions such as the β^-radioactive decay of ^{36}Cl *yielding* ^{36}Ar. Besides such minor productions, the isotopes ^{36}Ar and ^{38}Ar have been essentially produced in stars before solar system formation. They are therefore mostly primordial in origin and they bear a message about the processes that occurred at and before planetary formation.

Argon-40 is not radioactive but is produced by the decay of ^{40}K, a rare isotope of potassium. Models of nucleosynthesis indicate that ^{40}Ar is produced in stars in tiny amount compared to ^{36}Ar and ^{38}Ar (e.g., $^{40}Ar/^{36}Ar \sim 10^{-4}$). Thus, practically all ^{40}Ar present in Earth is radiogenic. The terrestrial atmosphere presents a concentration of argon of 0.934 mol.% (dry air), mainly made of ^{40}Ar ($^{40}Ar/^{36}Ar = 298.6$ in air), as a result of the production of ^{40}Ar in the crust and mantle through time and its accumulation in the atmosphere. Potassium-40 decays to ^{40}Ar with a half-life of 1.25 Ga. Potassium has three isotopes with masses 39, 40, and 41, and only ^{40}K is radioactive, with the particularity that it can decay following two schemes, one being a β^-radioactivity producing ^{40}Ca, and the other one being an electronic capture producing ^{40}Ar. The fact that ^{40}Ar is essentially radiogenic is fully confirmed by isotopic measurements of meteorites, which show extremely low $^{40}Ar/^{36}Ar$ isotopic ratios. Indeed, in outer space and extraterrestrial objects, i.e., in environments other than telluric planets, ^{36}Ar and ^{38}Ar are much more abundant that ^{40}Ar.

Atmospheric Argon Isotopes

From a historical point of view, the high abundance of ^{40}Ar in air, an anomaly compared to ^{36}Ar and ^{38}Ar (and other noble gases), led German physicist Carl Friedrich von Weizsäcker, in the middle of the twentieth century, to suspect that (i) ^{40}Ar was radiogenic, (ii) a new, radioactive, isotope of potassium existed that had to be ^{40}K (only ^{39}K and ^{41}K were known at that time), and (iii) ^{40}K could decay by a new scheme, unknown at that time, that had to be electronic capture (von Weizsäcker 1937). A beautiful reasoning based on a geochemical observation.

The terrestrial atmosphere is the main noble gas reservoir with a fast mixing timescale of the order of a few years. It therefore constitutes a convenient international isotope standard for noble gases. The isotopic composition of atmospheric argon, given as $^{38}Ar/^{36}Ar$ and $^{40}Ar/^{36}Ar$, is thus the interlaboratory reference. The normalization to ^{36}Ar is based on the fact that ^{36}Ar is the most abundant of the nonradiogenic isotopes, hence the easiest to measure with the smallest uncertainty. Measurements of argon isotopes in air have long shown that ^{36}Ar is about five times more abundant than ^{38}Ar, and that ^{40}Ar is roughly 300 times more abundant than ^{36}Ar (and thus, 1500 more abundant than ^{38}Ar).

Until recently, the recommended values were those obtained by Alfred O. Nier (1950, who proposed. $(^{38}Ar/^{36}Ar)_{\mathrm{AIR}} = 0.1880 \pm 0.0003$ (1σ) and $(^{40}Ar/^{36}Ar)_{\mathrm{AIR}} = 295.5 \pm 0.5$ (1σ). These values were adopted and recommended by the International Union of Geological Sciences in 1977 (Steiger and Jäger 1977). Since then, the $(^{40}Ar/^{36}Ar)_{\mathrm{AIR}}$ ratio was found slightly different by Lee et al. (2006), with a value of 298.6 ± 0.1 (1σ). Lee et al. (2006) also confirmed the value of Nier for the $(^{38}Ar/^{36}Ar)_{\mathrm{AIR}}$ ratio, with a measured value of 0.1885 ± 0.0001 (1σ).

In addition to ^{36}Ar, ^{38}Ar and ^{40}Ar, two radioactive Ar isotopes are used in geochronology in the so-called ^{39}Ar-^{40}Ar dating method. Neutron activation of potassium-40 produces ^{39}Ar, which β^- decays to ^{39}K with a half-life of 268 years. ^{37}Ar is also produced by neutron activation of ^{40}Ca and decays by electronic capture to ^{37}Cl, with a half-life of 35 days. The rocks or minerals to be dated are therefore radioactive and demand caution when manipulated. Some advanced mass-spectrometers can measure the five argon isotopes simultaneously, i.e., masses 36, 37, 38, 39, and 40, by using the so-called multicollection technique, where the five isotopes are received in five collectors (Faraday cups or electron multipliers).

Geochemists use the argon isotopes for two main applications, geochronology and isotope tracing of geological phenomena.

Radiochronometric Dating with Argon Isotopes

The method consists in measuring the concentrations of ^{40}Ar, and of ^{40}K, which permit to calculate, from the equation of radioactivity, an age based on the assumption that the object to be dated did not lose or gain any argon or potassium isotopes ("closed-system hypothesis"). In practice, the $^{40}Ar/^{36}Ar$ ratio is also measured, which permits to correct the amount of ^{40}Ar from the contribution of atmospheric argon. Under the assumption that ^{36}Ar is from air, the contribution of atmospheric ^{40}Ar is estimated by multiplying

^{36}Ar by the $(^{40}Ar/^{36}Ar)_{AIR}$ ratio of 298.6. Removing this contribution from total ^{40}Ar permits to estimate the amount of radiogenic ^{40}Ar produced in the sample by the decay of ^{40}K.

The basic method, called *K-Ar* dating, or ^{40}K-^{40}Ar, requires splitting the sample to be dated into two aliquots. *Ar* isotopes are extracted from one aliquot by heating under high vacuum and analyzed by static mass spectrometry. The *K* concentration is measured on the other aliquot after acid dissolution and usually with an optical method such as atomic absorption. The *K-Ar* dating method is suitable for samples that have been emplaced at the surface of the Earth and thus may have incorporated present atmospheric argon. This is often the case of volcanic samples, which cool rapidly at the surface of the Earth. However, if argon incorporated during rock/mineral cooling (often called "initial argon") is not atmospheric, then the *K-Ar* method is problematic because it is then difficult to correct for initial argon. Such a problem arose when attempting to date volcanic samples from Mid-Ocean Ridges in the 1960s. It was found that the initial Ar isotope composition was non-atmospheric, with a $^{40}Ar/^{36}Ar$ ratio much higher than the atmospheric value. This eventually led to the identification of strongly radiogenic argon in the mantle of the Earth, a trace of the massive and very ancient degassing of our planet (see below).

The difficulty of evaluating the isotopic composition of initial argon led to the development of a more sophisticated K-Ar dating method, the so-called *Ar-Ar* method, or ^{39}Ar-^{40}Ar method, where ^{40}K is transformed into ^{39}Ar by neutron activation. Combined with stepwise heating extraction of both natural and neutron-produced Ar isotopes, this method permits to identify radiogenic ^{40}Ar produced in-situ by the decay of ^{40}K from inherited ^{40}Ar. Another advantage of this method is that only one aliquot of the sample is used to determine both the parent (^{40}K) and the daughter (^{40}Ar) isotope amounts by static mass spectrometry. The sample is usually heated in several temperature steps, and the five Ar isotopes are measured for each step (see above). An age is calculated for each step and the results are represented in a diagram showing age versus fraction of Ar released. When several successive steps give the same age within analytical uncertainty, this is called a "plateau" and this age is considered reliable (previous steps being perturbed by Ar loss or mixing with air). This elegant method was developed in the 1960s by Merrihue and Turner (1966).

Tracing Geological Processes with Argon Isotopes

Argon isotopes can also be used to trace geological phenomena. We take the example of the generation of the atmosphere by degassing of the Earth's interior. When, in the 1960s, several scientists attempted to date fresh basaltic samples from Mid-Oceanic Ridge axes using the *K-Ar* method, they found ages of tens to hundreds of million years, at odds with the very young character of ridge axes (Ozima and Kudo 1972). The problem was that the initial $^{40}Ar/^{36}Ar$ ratio was much higher than the atmospheric value. As these basalts came directly from the mantle beneath the ridge, and because isotopes with such high masses as argon are certainly very little isotopically fractionated, the meaning of these measurements was that mantle argon was different from atmospheric argon. This discovery prompted efforts from the noble gas community to identify the isotopic composition of Ar trapped in such samples of Mid-Ocean Ridge basalts (MORBs), by extracting gases either by progressive heating of the samples or by vacuum crushing. These samples contained very little Ar, but, upon progressive heating, they degassed Ar with $^{40}Ar/^{36}Ar$ ratios that were increasingly higher with increasing temperature. Such "exotic" $^{40}Ar/^{36}Ar$ ratios could reach extremely high values, up to 20,000 (Sarda et al. 1985). Values close to 30,000 are not rare (Moreira et al. 1998), and the highest values reach ~40,000. Because Mid-Ocean Ridge basalts are sampling magmas from the underlying mantle, such extreme ratios were likely to represent the mantle Ar isotope composition. Why was mantle argon so radiogenic compared to atmospheric argon? The answer to this question is that this radiogenic character is the geochemical record of both very strong and very early degassing of the Earth. A $^{40}Ar/^{36}Ar$ isotopic ratio of 30,000 is about 100 times the value of air argon, and this means that ^{36}Ar in the present mantle is just 100 times lower than it was initially. Simple calculations using the ^{40}K decay constant show that, for the present $^{40}Ar/^{36}Ar$ ratio in the mantle to be so high, degassing of ^{36}Ar from the mantle into the atmosphere must have occurred within the first 100 million years of the Earth's existence (Sarda et al. 1985).

Among the rare gases, xenon also bears the same message, when using the extinct β^- radioactivity of iodine-129 (^{129}I) that yields ^{129}Xe with a half-life of 16 Ma. Using both xenon and argon systematics, degassing can be modeled using simple first-order kinetics, combined with the decay constants appropriate for *K-Ar* and *I-Xe*. This gives a picture of the degassing kinetics during the 4.5 billion years: clearly two stages are present (Allègre et al. 1983). A very strong degassing stage, with degassing rate decreasing very fast, occurred during the first 100 million years or so, and this stage was followed by about four billion years of more gentle degassing, with a degassing rate analogous to the present one. The first stage could represent degassing that occurred during planet growth or during the magma ocean stage of the young Earth, while the second stage could represent the times when the mantle became solid and animated by solid-state convection.

Concurrently, ^{40}Ar produced by the decay of ^{40}K accumulated in the atmosphere, with the $(^{40}Ar/^{36}Ar)_{AIR}$ increasing with time. The accumulation rate depends of the degassing rate of the mantle and of the continental crust, the latter being a major reservoir of potassium. Thus, the $(^{40}Ar/^{36}Ar)_{AIR}$ ratio of ancient air might have the potential to trace the geodynamics of the mantle and crust. In agreement with this possibility, a $(^{40}Ar/^{36}Ar)_{AIR}$ ratio of 143 ± 24 (1σ) was measured in 3.5 Ga-old fluid inclusions, presumably representing the Ar isotope composition of air at this time (Pujol et al. 2013). This result allowed these authors to propose a major crustal growth event ~3 Ga ago.

Conclusion

The isotopic composition of argon is widely used in Earth sciences, mainly for two purposes. The decay of potassium-40 to argon-40 led to the development of the so-called "K-Ar" geochronology, probably the most widely used method for dating rocks and minerals. For example, this method permitted to date oceanic rocks which, combined with paleomagnetism, provided the definite proof of plate tectonics. Combined with the volatile character of argon, this decay scheme has the potential to trace geological processes involving transfer of volatile species between geochemical reservoirs. This approach showed that the terrestrial atmosphere is an ancient reservoir which formed within the first tens to hundreds of Ma of the Earth's history.

Arsenic

Monica Vasiliu and David A. Dixon
Department of Chemistry, University of Alabama, Tuscaloosa, AL, USA

Element Data
Atomic Symbol: As
Atomic Number: 33
Atomic Weight: 74.9216
Isotopes and Abundances: ^{75}As 100%
1 Atm Melting Point: 1090 K
1 Atm Boiling Point: 887 K (sublimes)
Common Valences: +5, +3, and −3
Ionic Radii: (+V) 46, (+III) 69, and (−III) 222 ppm
Pauling Electronegativity: 2.18
First Ionization Energy: 947.0 kJ/mol
Chondritic (CI) Abundance: 1.86 ppm
Silicate Earth Abundance: 0.05 ppm
Crustal Abundance: 2.1 ppm
Seawater Abundance: 0.0026 ppm
Core Abundance: 5 ppm

Properties

Arsenic (Emsley 1991, 2001; Anthoni 2006; Anders and Grevesse 1989; McDonough 2005), a metalloid, has three allotropic forms: yellow, black, and gray. The most common form is a shiny, gray, brittle, metallic-looking crystalline solid. The less common yellow form is a crystalline solid which is produced when vapors of arsenic are cooled suddenly. It tarnishes rapidly in air and when heated does not melt, but sublimes although it can be forced to melt as well. When arsenic is heated in air, it reacts with oxygen to form arsenic oxide forming a blue flame with a garlic-like odor.

History and Use

Arsenic was certainly known to the ancient civilizations under different forms, but the credit for its discovery goes to alchemist Albert the Great (Albertus Magnus, 1193–1280).

Arsenic is a well-known poison, being used in insecticides or in rat poisons. Arsenic can be used in making special types of glass and as a wood preservative. When combined with gallium, it is a III–V direct bandgap semiconductor with a zinc blende crystal structure with uses in integrated circuits, light-emitting diodes, as well as optical windows. It is also used in bronzing and pyrotechnics and for hardening shot. Arsine (AsH_3) gas, which is extremely toxic, is used as a dopant gas in the microchip industry. Surprisingly, arsenic compounds can have medicinal applications.

Geochemical Behavior

A small amount of arsenic is found in its native state as microcrystalline masses. Arsenic is usually found as ores, and the most common ones are arsenopyrite (FeAsS), orpiment (As_2S_3), and realgar (As_4S_4) which are obtained as a by-product of the mining purification of a metal. The world production is 50,000 t/year in the form of oxides which is far more than industry needs.

Volcanoes release about 3,000 t/year of arsenic into the atmosphere, and microorganisms release up to 20,000 t/year of volatile methylarsines as well. The largest atmospheric emissions are the 80,000 t/year of arsenic released from burning fossil fuels.

Biological Utilization and Toxicity

Arsenic is one of the most toxic elements found, but at the same time, some scientists believe that it might be essential to human diet in very low doses. In very small doses, arsenic stimulates metabolism and boosts the formation of red blood cells. Prolonged exposure to inorganic arsenic can cause various health effects from irritation of the stomach and intestines, decrease in the production of white and red blood cells, lung irritation, and skin changes due to DNA damage leading to improved chances of developing cancer (skin, lung, liver, and lymphatic). Organic arsenic is not as harmful as inorganic arsenic compounds. Humans can be exposed to arsenic through food, water, and air or even through skin contact with soil or water that contains high levels of arsenic. High levels of arsenic are found in fish because they can absorb arsenic from water. A lethal dose of arsenic oxide is about 100 mg. An example of the use of arsenic as a poison is the play and movie, "Arsenic and Old Lace" from the late 1930s and early 1940s. Arsenic poisoning, whether accidental or explicit, has been attributed to the deaths of many important historical figures.

Crustal Abundance: trace amount in some minerals
Seawater Abundance: –
Core Abundance:

Properties

Astatine (Emsley 1991, 2001) is a reactive, radioactive nonmetal element which resembles iodine. The properties of astatine are not well established. It has been not extensively studied because all its isotopes have short half-lives. Much of what is known about astatine has been estimated from its

position in the periodic table, below iodine, and by studying its chemistry in extremely dilute solutions.

History and Use

In 1931 a group of chemists led by Fred Allison reported that they had detected the previously unknown element below iodine in the periodic table. They decided to call it alabamine, after Alabama, but their claim was a mistake. In 1940, three chemists (Dale R. Corson, Kenneth R. Mackenzie, and Emilio Segre) working at the University of California at Berkeley found evidence of element 85 at the end of an experiment they were conducting in a cyclotron. They reported this discovery but were unable to continue research on the element due to World War II and the Manhattan Project. In 1947, they named the new element astatine because there are no stable isotopes for the element and in Greek the word for unstable is "astatos."

Geochemical Behavior

Astatine actually appears in the Earth's crust for a short time from decay of radioactive isotopes of uranium and thorium. Astatine is usually synthesized in very small amounts in nuclear reactions, for example, neutron bombardment of ^{209}Bi produces ^{211}At. No more than 10^{-6} g of astatine has ever been synthesized in the laboratory.

Biological Utilization and Toxicity

Astatine is a highly radioactive element.

Atmophile Elements

Daniele L. Pinti
GEOTOP, Research Center on the Dynamics of Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

Volatile elements

Definition

In the Goldschmidt geochemical classification, *atmophile* (literally "gas-loving") are those elements that are extremely volatile, i.e., they form gases or liquids at the surface of the Earth, and they are usually concentrated in the terrestrial atmosphere and hydrosphere. The atmophile elements are Hydrogen (H), Carbon (C), Nitrogen (N), and noble gases, namely Helium (He), Neon (Ne), Argon (Ar), Krypton (Kr), Xenon (Xe), and Radon (Rn).

Overview

Victor Moritz Goldschmidt, Swiss mineralogist and geologist is considered the father of geochemistry. His major achievement is the so-called Goldschmidt geochemical classification of the elements. The Goldschmidt geochemical classification of elements groups the chemical elements according to their preferred host phases within the Earth into lithophile (rock-loving), siderophile (iron-loving), chalcophile (sulfur-loving), and atmophile (gas-loving). For this reason, elements from each group are concentrated in specific terrestrial reservoirs. Strictly speaking, the atmophile elements are H, C, N, He, Ne, Ar, Kr, Xe, and Rn. These elements are those able to form gases or liquids. They are concentrated mainly in the Earth's atmosphere and hydrosphere. Atmophile elements are also called "volatile elements." However, this last term might bring to confusion with the planetary science classification of the chemical elements. In this classification, "volatile" is any chemical element and chemical compound with low boiling points (< 1100 K) that is associated with a planet's or moon's crust (i.e., K, Rb, S, etc.) and/or a planetary atmosphere (i.e., C, N, ammonia, noble gases, halogens). For this reason, it is often believed that halogens are atmophile elements, being concentrated in the atmospheres of the giant planets. However, for the Goldschmidt geochemical classification of elements, halogens are nonmetallic lithophile elements, forming on Earth salty minerals found in seawater and in pegmatites.

Atmophiles in Earth's Atmosphere

Atmophile elements are stable except for Radon (^{222}Rn) which is radioactive and decays rapidly with a half-life of 3.82 days.

Oxygen is a major component of the present-day atmosphere (20.9435 vol% in air; Gatley et al. 2008), but it is not considered an atmophile element in the Goldschmidt geochemical classification of elements. Oxygen is mainly present in the Earth's crust as oxide and silicate minerals and thus it is commonly considered a lithophile element. Its accumulation

in the Earth's atmosphere at the end of the Archean era is likely the result of a complex interplay between oxygen sources (production from photosynthesis) and sinks (burial of organics, volcanic gas oxidation, etc.) (e.g., Catling 2015).

The recent discover of molecular O_2 in the coma of the comet 67P/Churyumov–Gerasimenko by the Rosetta instrumentation (Bieler et al. 2015; Mousis et al. 2016) might call for a redefinition of oxygen as an atmophile element in celestial bodies.

Carbon has a double geochemical behavior. It behaves as an atmophile element when forms compounds with oxygen as carbon dioxide (CO_2), the fourth more abundant gas in the present-day Earth's atmosphere (406 ppm), or carbon monoxide (CO) emitted in the atmosphere by volcanoes with a short residence time of a few months. Carbon behaves also as a siderophile element and is one of the candidate light elements proposed to account for the density deficit of the Earth's core (Zhang and Yin 2012). Hydrogen occurs mainly as water (H_2O) in the hydrosphere and in the present atmosphere as water vapor.

Nitrogen forms molecular N_2 with a strong triple covalent bond that makes it mostly unreactive, as noble gases, and thus it is mainly partitioned into the atmosphere. Nitrogen can occur in silicate rocks, mainly as ammonium (NH_4^+), replacing K^+ ions in mica and feldspars (Pinti and Hashizume 2011). Although atmospheric nitrogen is cycled in the modern ocean by microorganisms through three dominant metabolic processes, namely fixation ($N_2 \rightarrow NH_3$), nitrification ($NH_3 \rightarrow NO_3^-$), and denitrification ($NO_3^- \rightarrow N_2$) (Sigman et al. 2009), the resulting concentration in the atmosphere is assumed constant (78.048 volume % in air). Kasting (1993) suggested that nitrogen partial pressure in the atmosphere was close to 1 atm since the formation of the secondary atmosphere of the Earth. More recently, Marty et al. (2013) suggested that the partial pressure of N_2 of the Archean atmosphere was lower than 1.1 bar, possibly as low as 0.5 bar from the analysis of nitrogen and argon isotopes in fluid inclusions trapped in 3.0- to 3.5-billion-year-old hydrothermal quartz.

Finally, noble gases have their outer electron shell filled, making them chemically inert as well as volatile elements per excellence. They are typically present at very low concentrations in the Earth's atmosphere with argon being the most abundant (0.9340 volume % in air). Although rare, the elemental and isotopic abundance of noble gases has been pivotal for the understanding of the origin and evolution of the hydrosphere-atmosphere system on Earth (e.g., Marty 2012) and Mars (e.g., Atreya et al. 2013). Helium has two stable isotopes of masses 3 and 4, respectively. The ^{3}He which is abundant in the Earth's mantle is a primordial noble gas of solar origin. Together with mantle neon ^{3}He could be the only remnant of the Presolar Nebula or PSN-derived primitive atmosphere of the Earth. The primitive atmosphere of the Earth, as those of Venus and Mars, have been stripped almost totally by strong solar winds during the first phases of the Sun formation, the so-called *T-Tauri stage*. This is the name of a class of young stars very bright and emanating powerful stellar winds.

^{4}He is radiogenic and mainly derived from the decays of ^{238,235}U and ^{232}Th in the Earth's crust, as for ^{40}Ar which has been accumulated since the Earth's formation by the decay of ^{40}K contained in the crust. It was believed that argon, krypton, and xenon were mainly of secondary origin, brought on Earth by chondritic bodies. Indeed, when the terrestrial abundance of these gases (and C, N) is compared with the solar abundance and that of carbonaceous chondrites, the Earth's atmosphere and mantle Ar, Kr, and Xe abundance match closely that of chondrites, except for Xe which is depleted by a factor of ~20 relative to Kr (Marty 2012). This Xe depletion known under the synonym of "*Missing Xenon*" has been generally interpreted as indicative of a small contribution of cometary volatiles having low Xe/Ar ratios (Dauphas 2003), although alternative views have been recently proposed (see ▶ "Earth's Atmosphere" entry for details).

Based on recent measurements of volatiles in the coma of the comet 67P/Churyumov–Gerasimenko by the Rosetta onboard instrumentation, it has been suggested that cometary C, N, and water makes less than 1% of their total respective inventories on Earth (Marty et al. 2016), most of them having been contributed by wet asteroids. However, ^{36}Ar could be up to 90% of cometary origin and it suggests that the terrestrial atmosphere could contain a significant, possibly dominant, fraction of cometary heavier noble gases (Ar, Kr, and Xe), which might have been delivered during the Terrestrial Late Heavy Bombardment around 4 Ga ago (Marty et al. 2016).

Summary

Atmophile elements *sensu stricto* are those which have an affinity for gaseous/fluid phases, enriched in the atmosphere and hydrosphere of the Earth. Volatile elements include the atmophiles but extend to all elements having a low boiling point and which, at certain conditions, can occur in planetary atmospheres such as the halogens in the outer layers of the giant planets.

Although occurring in notable amounts in the Earth's atmosphere, oxygen is not considered an atmophile element. Oxygen forms silicate minerals and thus it occurs mainly in crusts and mantles of telluric planets. Its occurrence in the commonness molecular form O_2 in primitive bodies such as comets might change our vision on this element. N, C, H, and noble gases are believed to have been brought on Earth by wet planetesimals such as asteroids and comets. This event took place after the Earth's core formation with possible additional contributions of volatile to Earth during the Terrestrial Late Heavy Bombardment, 4 Ga ago.

Atmospheric Evolution

Colin Goldblatt
School of Earth and Ocean Sciences,
University of Victoria, Victoria, BC, Canada

Definition

Earth's atmosphere has evolved as volatile species cycle between the atmosphere, ocean, biomass, and the solid Earth. The geochemical, biological, and astrophysical processes that control atmospheric evolution are reviewed from an "Earth Systems" perspective, with a view not only to understanding the history of Earth but also to generalizing to other solar system planets and exoplanets.

Introduction

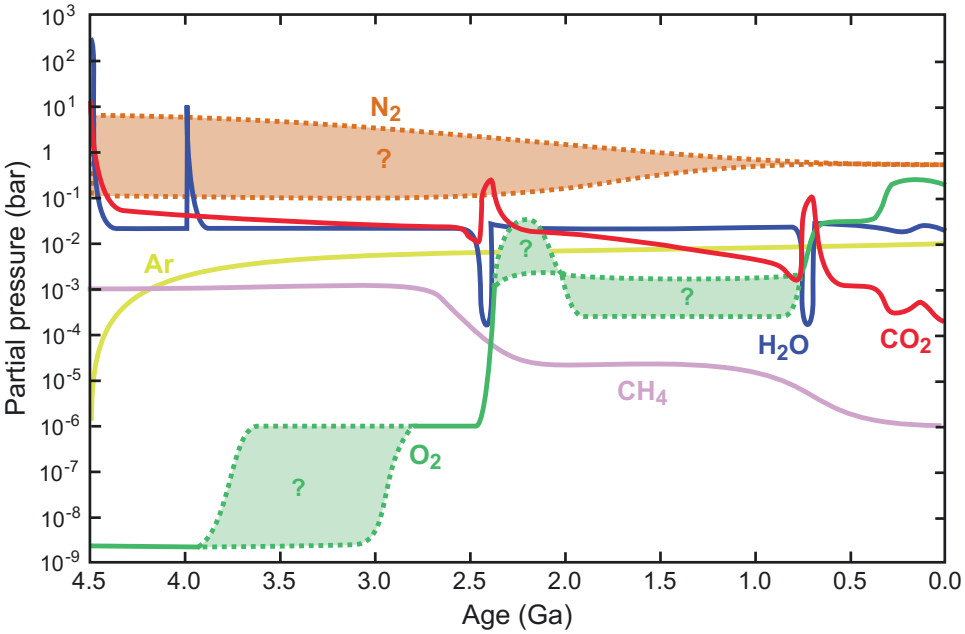
The evolution of Earth's atmosphere has been a function of the cycling of volatile species between the atmosphere, ocean, biomass, and the solid Earth. The composition of the atmosphere largely determines the climate, thus whether life can thrive, and the rate of many geochemical processes. Atmospheric evolution is an inherently interdisciplinary problem, requiring an "Earth system" approach; it is replete with feedback processes and neither a single branch of science nor study of any single part of the Earth is sufficient to make progress.

In the preface to *The Biosphere*, a visionary work of what would now be Earth system science, Vernadsky (1926) wrote

> Historically, geology has been viewed as a collection of events derived from insignificant causes, a string of accidents. This of course ignores the scientific idea that geological events are planetary phenomena and that the laws governing these events are not peculiar to Earth alone.

This review proceeds from that paradigm, with a focus on process and mechanism applicable to the evolution of Earth's atmosphere that are generalizable to other atmospheres, either comparison planets in our solar system or other inhabited planets.

Indeed, as we enter the age of exoplanets, understanding the evolution of Earth's atmosphere gains greater meaning. The practical method of remotely determining the geochemistry of a planet, and potentially detecting life, is a spectroscopic analysis of the planetary atmosphere (Lovelock 1965; Hitchcock and Lovelock 1967). Interpreting whether a remotely detected atmospheric composition implies life requires an understanding the range of compositions that an inhabited planet atmosphere could have, and Earth history is the biggest sampling of this parameter space available.



Atmospheric Evolution, Fig. 1 The evolution of Earth's atmosphere (an artist's conception). Uncertainties of a factor of a few are implied; smooth lines mostly correspond to lack of theory and constraints. Snowball Earth periods likely involve two or three glacials and interglacials but are shown as one for simplicity

The structure of this review is to first introduce the role of the atmosphere in maintaining climate, then treat atmospheric gasses beginning with the most abundant: nitrogen, oxygen, carbon dioxide, and then water. Trace species are treated with the more abundant gas that they are most closely linked to. Figure 1 gives a schematic summary of atmospheric evolution.

The Atmosphere and Climate

A Climate Primer

On timescales relevant to atmospheric evolution, Earth's atmosphere is in energy balance: energy in equals energy out. Solar energy incident on Earth (F_{solar}) dominates over the transfer of accretional and radiogenic heat to the surface by four orders of magnitude (342 Wm^{-2} versus 82 mWm^{-2}), so the Sun is the driver of climate. A fraction of the incident sunlight is reflected back to space by clouds, molecules, or the surface, referred to as the planetary albedo (α_p), around 0.3 for Earth today. Some sunlight is absorbed by water vapor in the lower atmosphere, but the bulk is absorbed at the surface. The result is that the atmosphere is heated from the base. Convection, therefore, dominates the lowest layer of the atmosphere, the troposphere, with temperature decreasing with height as rising air expands and cools. Above the top of this layer (the tropopause), vertical motions are minimal and the temperature structure is set by the balance of radiative absorption and emission. This layer is the stratosphere. Today, temperature increases in the stratosphere (a "temperature inversion") due to strong absorption of UV light by ozone.

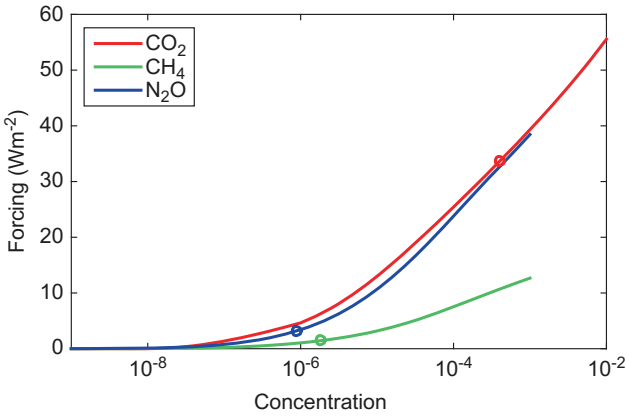
Were Earth airless, radiative emission to space would equal surface emission and planetary temperature would be trivial to calculate. Surface emission approximates a black-body and would balance absorbed solar radiation averaged over the surface: $(1-\alpha_p)F_{\text{solar}} = \sigma T_{\text{surf}}^4$, where σ is the Stefan-Boltzmann constant and T_{surf} is the surface temperature, giving $T_{\text{surf}} = 255$ K.

Earth, of course, has an atmosphere which imparts a greenhouse effect, meaning that thermal emission to space for a given surface temperature is less than the black-body flux. This greenhouse effect occurs as infrared radiation is absorbed in the atmosphere by gases ("greenhouse gases") or particles (e.g., clouds), which then emit radiation both upward and downward. Given that the atmosphere is colder than the surface, the total thermal radiation to space is less in the presence of greenhouse absorption than it would be without.

For greenhouse gases at climatically relevant levels, it is fundamental to note that the strength of the greenhouse effect is proportional to the logarithm of gas abundance (Fig. 2). This relates to the absorption spectra of real gasses; see an excellent review of the greenhouse effect by Pierrehumbert (2011) for an explanation. Arising from this is the common misunderstanding that methane is an inherently strong greenhouse gas. It is actually a rather weak infrared absorber; however, its low abundance *in the present-day atmosphere,* 300 times lower than carbon dioxide, means that adding a fixed number of moles of carbon as CH_4 rather than CO_2 will give a larger forcing.

The Faint Young Sun Paradox

The amount of solar energy incident on Earth has increased by 30% through Earth history due to stellar evolution, yet it does not appear that Earth was substantially colder in the past



Atmospheric Evolution, Fig. 2 Greenhouse gas forcing (change in net flux at the tropopause) relative to zero concentration of that gas (Byrne and Goldblatt 2014b)

(Sagan and Mullen 1972). This is the so-called Faint Young Sun Paradox (FYSP), which substantially motivates the study of atmospheric evolution from a paleoclimate perspective: the past atmospheric composition must have been very different in order to keep Earth warm.

Primary evidence for temperate early Earth climate comes from the ubiquity of fluvial successions and subaqueously deposited strata in the Archean, compared to a dearth of glacial features (Nisbet 1987). Whereas regional glaciation recurs every ~100 Myr during the Phanerozoic, Precambrian glaciation is rare: low-latitude "Snowball Earth" glaciation in the Cryogenian (Neoproterozoic) and Siderian (Palaeoproterozoic) and regional glaciations in the Ediacaran (Neoproterozoic) and Mesoarchean (Evans 2003, Paul Hoffman, private communication).

Given lower insolation, temperate climate requires either a much stronger greenhouse effect or a lower planetary albedo, or both. Most attention has focused on greenhouse gases, with likely contributions from carbon dioxide (Owen et al. 1979) and methane (Haqq-Misra et al. 2008) and many other possible contributors (Byrne and Goldblatt 2014a). Clouds could contribute to a stronger greenhouse effect if there were more high clouds, or reduce the albedo if there were less low clouds (Goldblatt and Zahnle 2011).

See Feulner (2012) for a recent review of the FYSP.

Nitrogen

Nitrogen is present in the atmosphere as dinitrogen (N_2), the dominant background gas, and as more reactive and radiatively active species, primarily nitrous oxide (N_2O) and ammonia (NH_3). Nitrogen is a major element in life and thus has a fast biological cycle. There is also a slow geological cycle which determines atmospheric N_2 levels, which has only recently begun to be elucidated.

An understanding of the biological N cycle (Entry ▶ Nitrogen Cycle) underpins all theory of N evolution. In summary: for nitrogen to be bioavailable, it must be chemically reduced (fixed) from N_2 to ammonium (NH_4^+). Fixation is dominated by organisms; there is a metabolic cost to N-fixation, but this is selected for when N is a limiting nutrient. In oxic conditions (in confined oxygen oases in the Neoarchean, then widespread from the Paleoproterozoic onward), NH_4^+ may be returned to N_2 via nitrification and denitrification. If denitrification is incomplete, nitrous oxide (N_2O) is produced, then returned to N_2 by atmospheric photolysis. Under widespread anoxia (Meoarchean and earlier, and often in the Neoarchean), the major destruction pathway for (NH_4^+) would be outgassing of ammonia from the ocean followed by atmospheric photolysis (Entry ▶ Earth's Atmosphere). Evolution of the N cycle is reviewed by Stüeken et al. (2016).

Dinitrogen

Dinitrogen dominates Earth's atmosphere ($pN_2 = 0.78$ bar at present) and is subject to slow geologic cycling, making variations in the N_2 inventory likely. Until recently, atmospheric N_2 had generally been thought of as constant, with the implicit assumption that the biological cycle was entirely closed. However, a small leakage of fixed N from the ocean to the geosphere drives a whole Earth N cycle, just as organic carbon burial drives a large part of the coupled carbon-oxygen cycle. Recent whole-Earth nitrogen budgets have shown that there is more nitrogen in the silicate-Earth than in the atmosphere and that this nitrogen is necessarily of atmospheric origin and fixed biologically. This calls for a cycle of nitrogen between the atmosphere and the crust and mantle, operating over billions of years. Variations in the size of the atmospheric N_2 inventory by a factor of two or three are expected but are very poorly constrained at present (Goldblatt et al. 2009; Johnson and Goldblatt 2015).

Table 1 shows Earth's nitrogen reservoirs. The total nitrogen inventory is consistent with a chondritic source with ~10% retention. Nitrogen in the core is assumed to be inaccessible to the rest of the Earth system, leaving dominant exchangeable reservoirs to be the mantle (a few times the present atmospheric inventory), continental crust (around half the present atmospheric inventory), and the atmosphere itself. Understanding of the evolution of the atmospheric reservoir must, therefore, emerge from understanding the history of exchange with the crust and mantle.

The most important way that nitrogen enters rocks is as NH_4^+, which substitutes well for potassium ions (K^+) in silicate rocks, as they have the same change and a similar ionic radii. Organic nitrogen in sedimentary rock is an additional source, and this may be transferred to silicate-bound NH_4^+ during hydrothermal alteration, diagenesis, or

Atmospheric Evolution, Table 1 Earth system nitrogen reservoirs, after Johnson and Goldblatt (2015). The "high N" mantle reservoir is quite uncertain. The core is likely a large N reservoir, but is excluded as it is not thought to exchange with the atmosphere after core-mantle segregation

Reservoir	Size (10^{18} kg N)
Biomass (live and dead)	**9.3×10^{-4}**
Land	1.3×10^{-4}
Ocean	8.0×10^{-4}
Ocean	**2.4×10^{-2}**
Atmosphere	**4.0**
Ocean crust	0.47± 0.20
Sedimentary	0.41 ± 0.20

MORB source	7.2 ± 5.9
High N	17 ± 15
TOTAL	**30.2 ± 16**

metamorphosis. The geological N cycle and budget were recently reviewed by Johnson and Goldblatt (2015).

Nitrogen concentrations in continental crust rocks have increased with time. Upper crust concentrations from tills are 66 ± 100 ppm for the Neoarchean and Palaeoproterozoic and 290 ± 165 ppm for the Neoproterozoic to present day (Johnson and Goldblatt 2017). This change implies net drawdown from the atmosphere.

Mantle nitrogen is of subducted origin (Marty 1995), with a return flux via mantle outgassing. This is evident from noble-gas systematics, specifically the relationship between N and Ar (which has a similar solubility to N). Nitrogen abundance does not correlate with the primordial Ar isotope, ^{36}Ar, indicating that most primordial nitrogen has been outgassed. Rather, it correlates well with ^{40}Ar, the radiogenic daughter product of ^{40}K. This correlation suggests a mantle inventory a few times the size of the atmospheric reservoir (Marty 1995; Marty and Dauphas 2003). Given that K is lithophile (incompatible with mantle rock, preferentially entering melt and thus residing in the crust), the association of N with K requires that the mantle N is of subduction origin (Marty 1995, Marty and Dauphas 2003). Given the source species is NH_4^+, biological fixation of atmospheric N_2 is necessarily invoked (Goldblatt et al. 2009).

While the size and source of the mantle reservoir are evident, there are presently neither constraints on its age, nor on the balance of N subduction and outgassing through time. Present day rates suggest a slow net transfer of N to the mantle (Li and Bebout 2005; Li et al. 2007; Goldblatt et al. 2009), with a mantle N lifetime of billions of years (Goldblatt et al. 2009). Nitrogen transfer into the subduction zone depends on how much NH_4^+ can substitute into ocean crust and on how much nitrogen is retained in sediments; both of these may have been higher in the past when the deep ocean was anoxic. Some proportion of the subducted nitrogen returns to the atmosphere through arc volcanoes, depending on the temperature gradient of the subduction zone (Bebout et al. 1999). Assessing the nitrogen transfer across subduction zones is challenging because of the need to fully account for geological nitrogen entering the system, and atmospheric contamination makes estimating the gas flux outward hard. Nonetheless, modern studies do call for net subduction (Li and Bebout 2005, Li et al. 2007, Goldblatt et al. 2009).

In developing a theory of atmospheric N_2 evolution, primary uncertainties remain. At the end of accretion and differentiation of Earth, was the N in the mantle or atmosphere? How has the rate of N subduction changed through time, and how has it been balanced by mantle outgassing? A first-order understanding of the N_2 evolution, and thus the evolution of atmospheric mass, is only presently being developed: histories of increasing or decreasing atmospheric di-nitrogen, or of local maxima and minima, are all permissible.

Reactive N Species

Ammonia and nitrous oxide are both potent greenhouse gases and may have played a role in keeping early Earth warm. Indeed, ammonia is one of the best greenhouse gases, absorbing strongly in the 10 μm water vapor window (Sagan and Mullen 1972; Byrne and Goldblatt 2014a), and nitrous oxide is of similar strength to CO_2 (Roberson et al. 2011; Byrne and Goldblatt 2014a). They would require concentrations of 0.8 and 5 ppmv, respectively, in a 1 bar atmosphere to give a 10 Wm^{-2} radiative forcing and counter 20% of the 50Wm^{-2} radiative deficit from the faint young Sun (Byrne and Goldblatt 2014a).

Ammonia was the original proposal to resolve the Faint Young Sun Paradox (Sagan and Mullen 1972). However, this was predicated on a highly reducing Archean atmosphere, which is no longer supported. Ammonia is very soluble in seawater and photochemically unstable (Kuhn and Atreya 1979) so long-term, high concentrations would have been difficult to support, though the presence of an organic haze could enhance the photochemical lifetime of ammonia (Sagan and Chyba 1997). A trace amount could be sustained by a balance of nitrogen fixation followed by ocean outgassing and photochemical destruction.

Nitrous oxide is the product of partial denitrification. This could be favored in anoxic and sulfidic oceans, which may have been the norm in the Proterozoic, as copper limitation may have prevented the formation of the nitric oxide synthase (NOS) enzyme which transitions N_2O to N_2, possibly giving

N_2O fluxes 20 times the modern rate (Buick 2007). However, reduced atmospheric oxygen leads to faster photolysis of N_2O, making concentrations above 1 ppmv difficult to support (Roberson et al. 2011).

Oxygen and Ozone

Di-oxygen (O_2) is the second most abundant gas in the modern atmosphere (21%), and ozone (O_3) is a photochemical product of this. The atmospheric evolution of these are interwoven; producing ozone requires a sufficient oxygen inventory, whereas the formation of the stratospheric ozone layer provided photochemical shielding to the troposphere, allowing oxygen concentrations to rise towards modern levels. The evolution of these two gases must, therefore, be discussed together.

The di-oxygen in Earth's atmosphere is a biological product, formed during oxygen producing (oxygenic) photosynthesis, and it is able to accumulate in the atmosphere only in the absence of consumption of organic matter by aerobic respiration. The oxygen and organic carbon cycles are thus intrinsically linked. Oxygen is highly reactive (it will oxidize volcanic gases, crustal rocks, organic carbon, and so on), so the oxygen evolution must further be considered in the context of the global redox budget.

After introducing the record of redox evolution of Earth, the processes determining oxygen levels are described, so as to place oxygen evolution in the context of the development of these Earth system processes.

The History of O

Oxygen evolution has occurred in a number of steps. There is ample evidence, described below, for a "Great Oxidation" of the Earth, a geologically rapid transition from a reducing to an oxidizing atmosphere, early in the Paleoproterozoic. Oxygen levels are inferred to be parts per million or less prior to this and up to a percent afterward. Proterozoic oxygen levels were likely a fraction of a percent. The next major transition was in the Neopro-terozoic, when oxygen reached several percent, and near modern levels were achieved in the Devonian. The Great Oxidation represents by far the most profound change in geochemistry in Earth history and is the focus here.

Oxygen oxidizes; thus there is an excellent record from which this history has been elucidated. Traditional indicators of oxygen levels use the redox state of minerals in the sedimentary record (Holland 1984). Iron is one of the most important redox-sensitive elements, with two oxidation states: a reduced species Fe^{2+} (ferrous), which is water soluble, and an oxidized species Fe^{2+} (ferric), which is insoluble. Two classical oxygen indicators derive from this and serve as tutorial examples. Redbeds are detrital sedimentary rocks (commonly sandstones), which contain a red ferric oxide cement formed through subaerial alteration in an oxidizing atmosphere; they are found since 2.3 Ga. Banded iron formations are ocean sediments containing alternating layers of chert and either magnetite or haematite. These are formed distant from any iron source, so require long-range transport of iron in the ocean. This, in turn, requires a reduced ocean such that iron is soluble. Banded iron formations occur mostly before 2.4 Ga (Holland 1984; Isley and Abbott 1999). Other classical redox indicators include detrital grains of reduced minerals common in Archean sediments (requiring a reduced atmosphere) and changes in the mineralogy of paleosols (see Holland 1984, for a wide-ranging discussion). The ensemble of these is sufficient that it has long been possible to identify a change from a reducing to an oxidizing atmosphere around the Archean-Proterozoic boundary.

Twenty-first-century work has constrained oxygen evolution via numerous isotope systems. The defining modern indicator of the Great Oxidation comes from sulfur isotopes (Farquhar et al. 2000). The sulfur isotope record prior to 2.4 Ga is characterized by anomalies from the expected mass dependent trend in triple-isotope measurements, the so-called "mass-independent fractionation" of sulfur isotopes (MIF-S), whereas this feature is absent in younger sediments. The anomalies are photochemically generated. They require (1) a sufficient flux volcanic sulfur to the atmosphere; (2) the absence of an ozone layer, which would provide photochemical shielding; and (3) a reducing atmosphere, which allows multiple exit pathways for sulfur such that isotopic heterogeneity can be preserved (Zahnle et al. 2006). The existence of the MIF-S record thus constrains Archean oxygen to a maximum of part per million levels (Pavlov and Kasting 2002; Zahnle et al. 2006).

The currently prevailing interpretation of Proterozoic oxygen history is (1) the Great Oxidation event in the earliest Paleoproterozoic, which is coeval with low-latitude glaciation; (2) peak levels for a couple of hundred million years in the Paleoproterozoic; (3) a decrease to a fraction of a percent, which is maintained for most of the Proterozoic (Lyons et al. 2014); then (4) a second oxygenation to perhaps 1% of modern levels in the Neoproterozoic. The exact time of the Neoproterozoic oxidation is not well constrained, but it may well occur coeval with another set of low-latitude glaciations in the Cryogenian. The first large metazoa in the fossil record, which likely required percent O_2, appear in the Ediacaran (Och and Shields-Zhou 2012). The Paleoproterozoic peak in oxygen is linked to abundant organic carbon burial causing an oxygen source, which is required to explain the Lomagundi carbon isotope excursion. Mesoproterozoic oxygen levels are constrained by a variety of trace metal systems to a fraction of a percent, and imply an anoxic, ferruginous, and locally euxinic ocean, for much of the Proterozoic (Lyons et al. 2014).

A most remarkable aspect of the 2.4 Ga Great Oxidation is how late it is. There are numerous lines of evidence for the origin of oxygen-producing photosynthesis several hundred

million years earlier (see Lyons et al. 2014, for a recent discussion). The motivating question becomes: why was the rise of atmospheric oxygen delayed following the advent of oxygen production?

Sources and Sinks of Atmospheric Oxygen

The oxygen cycle begins with a fast biological cycle, closed either within the biosphere or by atmospheric chemistry. A slow geologic cycle involves burial and subsequent oxidative weathering of organic carbon.

It is a common misconception to simply equate atmospheric oxygen to oxygen production by photosynthesis. The problem is, of course, that in the presence of abundant oxygen, the vast majority of the carbon fixed (reduced from CO_2 to organic carbon, and represented schematically as CH_2O) is oxidized on short timescales by aerobic respiration:

$$CO_2 + H_2O \underset{\text{aerobic respiration}}{\overset{\text{oxygenic photosynthesis}}{\rightleftharpoons}} CH_2O + O_2 \qquad (1)$$

That is, the modern oxygen production cycle is largely closed by biology. A long-term source of oxygen to the atmosphere requires burial of organic carbon in sediments and sedimentary rock, leaving the O_2 in the atmosphere. Oxidation of organic carbon during weathering is, equivalently, a sink for atmospheric oxygen. The reservoir of sedimentary organic carbon is 1×10^{21} mol, implying a time-integrated oxygen source of ~30 times the atmospheric inventory (Catling and Claire 2005).

Where high oxygen, aerobic respiration, and closure of the oxygen production by biology is one end member, the other end member is anoxia, wherein fermentation and methanogenesis decompose organic matter and ultimately closure of the cycle is via atmospheric chemistry. Net methanogenesis can be represented schematically

$$CH_2O \rightarrow \tfrac{1}{2}CO_2 + \tfrac{1}{2}CH_4 \qquad (2)$$

so the net effect of photosynthetic production and decay of organic matter is

$$\tfrac{1}{2}CO_2 + H_2O \rightarrow O_2 + \tfrac{1}{2}CH_4 \qquad (3)$$

That is given anoxia, there should be a large and stoichiometrically balanced flux of oxygen and methane from the biosphere to the atmosphere. The closure of the system is by net methane oxidation, which is photochemically mediated:

$$\tfrac{1}{2}CH_4 + O_2 \rightarrow H_2O + \tfrac{1}{2}CO_2 \qquad (4)$$

The rate of net methane oxidation has a nonlinear dependence on oxygen and ozone levels (described below). High atmospheric methane is expected.

An additional, and important, net source of oxygen is hydrogen escape to space (Hunten and Donahue 1976). High in the atmosphere, any hydrogen bearing compounds may be photolyzed, freeing hydrogen atoms light enough to escape Earth's gravity. For Earth-like, hydrogen-poor, atmospheres the rate-limiting step is upward diffusion of hydrogen-bearing compounds from the homopause (the level at which the atmosphere ceases to be well mixed, ~100 km for Earth). The escape flux thus depends directly on both the total hydrogen mixing ratio at the homopause and on gravity (the latter because diffusion upwards is a buoyancy flux). Because water condenses at atmospheric temperatures, it is scarce at the homopause, and methane likely contributed the most hydrogen for escape (Catling et al. 2001). Schematically hydrogen escape can be represented

$$\begin{aligned} CH_4 &\rightarrow 4H(\textit{to space}) + C \\ C + O_2 &\rightarrow CO_2 \end{aligned} \qquad (5)$$

The oxygen source arises as two moles of oxygen are produced for each mole of methane (Eqs. 1–3) but only one oxygen is used associated with hydrogen escape (Eq. 6). Taking a representative methane mixing ratio of 100ppmv, for the first half of Earth history, the oxygen flux would be 0.7×10^{12} mol $yr.^{-1}$ and the total oxygen source is 1.6×10^{21} mol, equivalent to 50 times the modern atmospheric oxygen inventory (Catling et al. 2001; Catling and Claire 2005).

Major oxygen sinks arise from the oxidation of crustal rocks and volcanic gases. Catling and Claire (2005) estimate the excess of oxidized iron (Fe^{3+}) and sulfate in rocks and sediments to be equivalent to a time-integrated oxygen sinks of around 2.5×10^{21} mol and 0.5×10^{21} mol respectively, together 100 times the present atmospheric O_2 inventory.

Mass balance requrires that time-integrated oxygen sources and sinks balance: oxidized reservoirs (atmospheric O2 and, dominantly, the oxidized crust) are balanced by a combination of burial of organic carbon and hydrogen escape.

Photochemistry, Ozone, and a Model for the Great Oxidation

Ozone, O_3, is a photochemical product of O_2, so the generation of a stratospheric ozone layer is intimately connected to the rise of oxygen as a major atmospheric gas. Establishment of an ozone layer requires a threshold level of oxygen. Once established, the ozone layer provides photochemical shielding of the troposphere, thus reducing the efficiency of methane oxidation and facilitating the accumulation of atmospheric oxygen. Thus, the formation of the ozone layer is the mechanism of the Great Oxidation (Goldblatt et al. 2006).

The reaction sequence for ozone production (Chapman 1930, Entry ▶ Ozone and Stratospheric Chemistry) is

$$O_2 + h\nu(\lambda < 240\,\text{nm}) \rightarrow O + O \quad (6)$$

$$O + O + M \rightarrow O_3 + M \quad (7)$$

$$O_3 + h\nu(\lambda < 320\,\text{nm}) \rightarrow O_2 + O \quad (8)$$

$$O_3 + O \rightarrow 2O_2 \quad (9)$$

Ozone production requires sufficient oxygen levels to produce odd oxygen via Eq. 6. In photochemical models, some ozone production can be seen at ~1 ppm O_2, whereas a modern-like ozone layer forms at 1% of present oxygen levels (Kasting and Donahue 1980).

Methane oxidation rates, as with much atmospheric chemistry, depend on the availability of OH^- radicals. The main source of OH^- is photolysis of water vapor which, given the decrease in atmospheric temperature with altitude, is found dominantly in the troposphere. The existence of the ozone layer and consequent UV shielding of the troposphere reduces tropospheric OH^- availability and slows down much of the atmospheric chemistry.

Thus, with an ozone layer, the effective rate constant for methane oxidation is lower, which drastically changes the dynamics of oxygen. Given the same stoichiometrically balanced flux of methane and oxygen from the biosphere, the oxygen level necessarily should increase so that the photochemical sink balances the source. Equivalently, the lifetime of oxygen is extended.

Two rather distinct stable states of oxygen exist: a low oxygen stable state with around a part per million oxygen and a high oxygen stable state of near a percent. There is a very nonlinear transition between these: the Great Oxidation (Goldblatt et al. 2006).

Carbon Dioxide

Carbon has a variety of valence states; in the atmosphere, carbon dioxide (CO_2) is the main oxidized species and methane (CH_4) the main reduced species. Carbon dioxide has likely been the dominant greenhouse gas throughout Earth history, with methane a popular candidate for second place. In terms of both budget and processes, there is a fundamental split between the cycles of inorganic (oxidized) and organic (reduced) carbon. The main link between these is oxygenic photosynthesis, reversed in oxidizing conditions by aerobic respiration (Eq. 1) or in anaerobic conditions by methanogenesis and subsequent atmospheric methane oxidation (Eqs. 2 and 4). The link between organic carbon and oxygen is so strong that atmospheric methane and the organic carbon budget are considered alongside oxygen (section "Sources and Sinks of Atmospheric Oxygen").

Atmospheric Evolution, Table 2 Global carbon budget. Atmospheric CO_2 was 403 ppmv at the time of writing. Mantle reservoirs are from Anderson and Poland (2017) and Le Voyer et al. (2017), but method-dependent uncertainties are a factor of a few. Other reservoirs from Kump et al. (2009) and Wallmann and Aloisi (2012) (error for rock sedimentary reservoirs is not stated, but will be non-trivial)

Reservoir	Size (10^{12} kg C)
Biomass (live)	**600**
Land	600
Ocean	6
Soils and sediment	**4100**
Organic	1600
Inorganic (carbonate)	2500
Ocean (inorganic)	**39,000**
Atmosphere	**870**
Methane	1.7
Carbon dioxide	868
Methane hydrates	**2400 ± 1200**
Sedimentary rock	$\mathbf{7.5 \times 10^7}$
Organic	1.5×10^7
Inorganic (carbonate)	6×10^7
Mantle	$\mathbf{(7.0 \pm 1.7) \times 10^8}$
MORB source	$(3.8 \pm 1.5) \times 10^8$
OIB source	$(3.2 \pm 0.8) \times 10^8$
TOTAL	$\mathbf{\sim 7.8 \times 10^8}$

The carbon budget is given in Table 2. Carbon dioxide is a minor species today, but the vast size of geological reservoirs of inorganic carbon make a much higher inventory in the deep past easy to motivate. Indeed, the carbon dioxide inventory of Venus' atmosphere is essentially equivalent to the geological C on Earth (see section "Comparative Planetology"). On Earth, the inorganic carbon (limestone) reservoirs are largely biogenic. On shorter timescales, the intermediate-sized ocean reservoirs provide rapidly exchangeable carbon; this has dominated CO_2 change through Quaternary glacial cycles.

Atmospheric carbon dioxide is controlled by a hierarchy of processes, depending on the timescale. On subannual timescales, higher rates of photosynthesis during the summer and respiration during the winter, especially from northern hemisphere land biota, give a hemispheric annual cycle of 10 ppm. On annual to centennial timescales, the dominant processes changing CO_2 now are anthropogenic fossil fuel burning and cement production (CHAPTER-REF?), which are increasing CO_2 by 2 ppm per year (https://scripps.ucsd.edu/programs/keelingcurve/). More generally, annual to millennial control on CO_2 is via ocean carbonate chemistry (changes in the speciation of inorganic carbon in the ocean) (Ridgwell and Zeebe 2005; Zeebe and Wolf-Gladrow 2001). This, in turn, is very heavily modulated by life and, on $\gtrsim 10^5$yr timescales, by geological activity. Presence of widespread and cumulatively vast deposits of biogenic calcium carbonate rock throughout

Earth history provides a prima facie case for the combined role of life, ocean chemistry, and geology in controlling CO_2.

Control of CO_2 by Ocean Chemistry

Carbon dioxide readily dissolves in seawater. The equilibrium dissolved carbon dioxide is given by Henry's Law

$$[CO_2] = k_H CO_2 \tag{10}$$

There is a similar amount of dissolved molecular CO_2 in the ocean as atmospheric CO_2. Once in solution, however, the total amount of dissolved inorganic carbon (DIC) partitions between CO2, H2CO3 (carbonic acid), HCO_3^- (bicarbonate ion), and CO_3^{2-} (carbonate ion). For Henry's law, only the dissolved CO_2 matters (i.e., that is all the atmosphere "sees") so the sum of these species, the DIC, is 50 times larger than dissolved CO_2 alone. The equation for the partitioning are

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \tag{11}$$

$$\begin{aligned} H_2CO_3 &\rightleftharpoons H^+ + HCO_3^- \\ HCO_3^- &\rightleftharpoons H^+ + CO_3^{2-} \end{aligned} \tag{12}$$

which give three equations with five unknowns. Two more constraints are needed. First is that DIC is a conserved quantity (conservation of mass of carbon atoms):

$$\mathrm{DIC} = [CO_2] + [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}] \tag{13}$$

The second conserved quantity is alkalinity, which accounts for conservation of charge. Ions in the ocean may, conceptually, be split into two groups. First, those from the dissolution of salts and strong acids; negative changer from Cl~ and others *almost* balances positive charge from Na^+, Mg^{2+}, Ca^{2+}, and others. These are referred to as conservative ions. Second, alkalinity is the net negative charge provided by species which exchange protons at $pH > 4.5$, which balances the net charge from conservative ions. For instructive purposes (in terms of the equations above), we can define alkalinity

$$\mathrm{Alk} = [HCO_3^-] + [CO_3^{2-}] \quad (\ldots - [H^+] + \ldots) \tag{14}$$

The first two terms on the right-hand side are the "carbonate alkalinity," which dominate. The bracketed term is small, but included to show, conceptually, how the Eq. 12 are balanced. In the real ocean, borate contributes at percent levels and there are additional minor contributing species.

Zeebe and Wolf-Gladrow (2001) provide an excellent textbook description of these processes.

Specifying any two parameters in the carbonate system (Eqs. 12–14) is sufficient to determine the whole system. DIC and alkalinity are the conserved quantities and have clear physical meaning (total carbon and charge balance), so make the most sense to use. Figure 3 shows the partitioning of carbon between different reservoirs. What should be immediately obvious is that pCO_2 – hence the contribution of inorganic carbon to the greenhouse effect – cannot be determined directly from the DIC: knowledge of alkalinity as needed. That is, ocean chemistry is fundamental to the abundance of the dominant noncondensible greenhouse gas in Earth's atmosphere.

Calcium Carbonate Formation

Ocean chemistry is linked to sediments and sedimentary rock via the formation and dissolution of $CaCO_3$:

$$Ca^{2+} + CO_3^{2-} \rightleftharpoons CaCO_3 \tag{15}$$

This has important consequences for pCO_2 and climate on millennial and longer timescales.

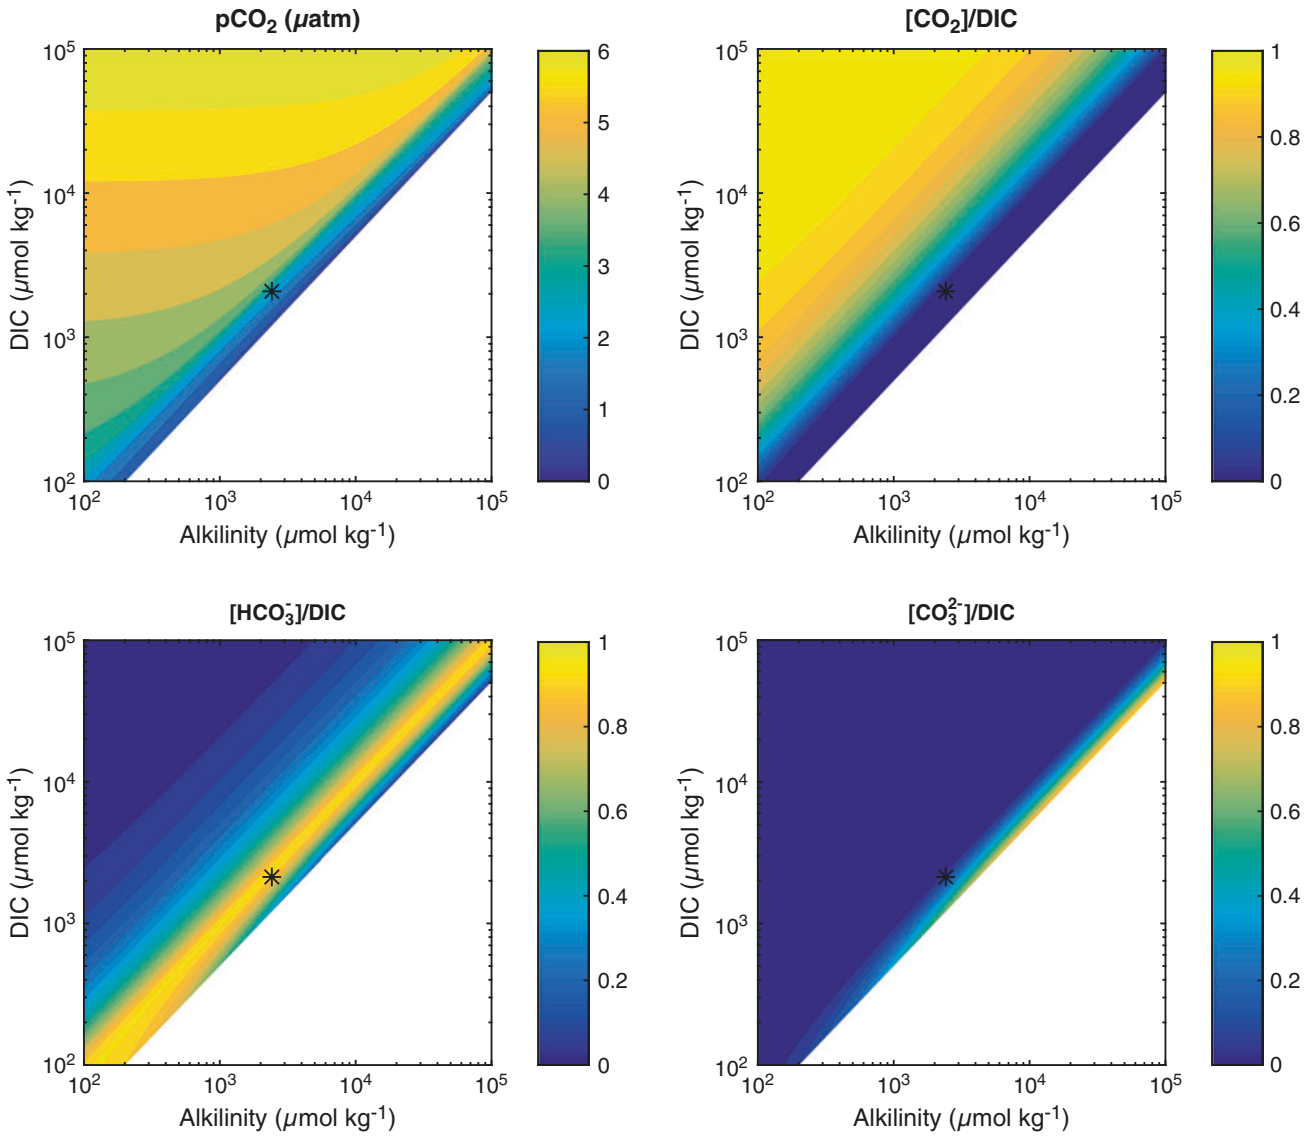
The position of solution with respect to equilibrium in Eq. 15 can be expressed as the calcite saturation, Ω_{calc}

$$\Omega = \frac{[Ca^{2+}][CO_3^{2-}]}{k_{sp}} \tag{16}$$

As an approximation, carbonates will decompose when $\Omega_{calc} < 1$ whereas formation requires supersaturation, perhaps $\Omega_{calc} \approx 30$ for chemical precipitation (also referred to as authigenic formation) or Ω_{calc} of 1–3 for biologically mediated formation. Variation in $[CO_3^{2-}]$ dominates over variation in $[Ca^{2+}]$, hence the ratio of alkalinity to DIC has a controlling influence on $CaCO_3$ precipitation: a high alkalinity to DIC ratio gives high $[CO_3^{2-}]$ and therefore high Ω_{calc}.

Calcium carbonate formation removes two units of alkalinity for each unit of DIC. The immediate effect, therefore, is to shift the partitioning of DIC away from $[CO_3^{2-}]$ and toward $[CO_2]$, consequently reducing the system's propensity to precipitate more calcite and increasing atmospheric pCO_2. On longer timescales, however, it is more important to think of this process as removing inorganic carbon from the atmosphere-ocean system, to be discussed further below.

Carbonate sediments are ubiquitous throughout the geological record. Their relatively continual formation places an empirical constraint on Ω_{calc}, implying that there have only been minor variations in the ratio of alkalinity to DIC through most of Earth history (Walker 1983). The fundamental question of what operates this control remains somewhat open. The amount of limestone ($CaCO_3$ in sedimentary rock) is vast: 5×10^{21} mol (Table 2). Were this in the atmosphere, Earth would have a 42 bar CO_2 atmosphere and a surface far too hot for life. The role of limestone



Atmospheric Evolution, Fig. 3 Atmospheric carbon dioxide and dissolved species concentrations as a function of DIC and Alk. There is a tendency to think of the total amount of carbon in the atmosphere-ocean determining the strength of the CO_2 greenhouse, but quite clearly alkalinity exerts equal leverage. Figures made with the Zeebe code (Zeebe and Wolf-Gladrow 2001)

formation – which is biologically controlled on Earth – in maintaining habitable conditions is evident.

Geological Control of Alkalinity: The Carbonate-Silicate Thermostat

An ocean of pure water would not mediate carbonate deposition. Rather fortunately in this regard, Earth's ocean is impure, containing dissolved ions from the chemical weathering of crustal rocks. As alkalinity balances the overabundance of cations among these salts, the cation flux determines long-term rates of carbonate deposition.

Weathering of crustal silicate rocks can be represented with the following series of reactions, using simplified stoichiometry. Atmospheric CO_2 dissolves and hydrates to become carbonic acid, which reacts with silicate rock (represented $CaSiO_3$):

$$2(CO_2 + H_2O \rightarrow H_2CO_3) \tag{17}$$

$$CaSiO_3 + 2H_2CO_3 \rightarrow Ca^{2+} + 2HCO_3^- + SiO_2 + H_2O \tag{18}$$

Two units of CO_2 are removed from the atmosphere and two units of both DIC and Alk are added to the ocean for each unit of silicate weathered. Given that CO_2 exchange between atmosphere an ocean is rapid, DIC will be removed by gas

flux to the atmosphere. Increasing Alk then dominates in the ocean, and a shift in DIC from bicarbonate to carbonate ions causes carbonate deposition,

$$2HCO_3^- \rightarrow CO_3^{2-} + CO_2 + H_2O \quad (19)$$

$$Ca^{2+} + CO_3^{2-} \rightarrow CaCO_3 \quad (20)$$

removing two units of both alkalinity and DIC from the ocean. The net stoichiometry of all of these is

$$2CO_2 + 2H_2O + CaSiO_3 \rightarrow SiO_2 + CO_2 + 2H_2O + CaCO_3 \quad (21)$$

$$CO_2 + CaSiO_3 \rightarrow SiO_2 + CaCO_3$$

This system is known as the Urey reactions (Urey 1952). Thus, silicate weathering followed by carbonate deposition leads to removal of inorganic carbon from the atmosphere-ocean system.

In a seminal paper, Walker et al. (1981) described a negative feedback on the long-term climate of Earth. Carbon dioxide is a greenhouse gas, so higher atmosphere-ocean carbon should result in a warmer planet and faster reaction rates. Likewise, a warmer planet would have higher rainfall which would enhance weathering. Warming would lead to carbon dioxide draw-down, providing a negative feedback on global temperatures. The WHAK feedback (known for Walker, Hays, and Kasting) remains the dominant paradigm for temperature regulation on Earth.

Its utility notwithstanding, there are various nuances and complications of the behavior of this system, such that one should look beyond the idea of a set point temperature toward which Earth is regulated. These include system dynamics, the mechanics of weathering, and the role of life.

Any dynamical model (there are many) will ultimately balance a volcanic CO_2 source with weathering-motivated carbonate deposition. Decreasing outgassing rate or increasing the reaction coefficient for weathering will then give a colder steady state; decrease these far enough and glaciation will ensue. Cold temperatures curtail weathering, atmospheric CO_2 accumulates and Earth warms; thus limit-cycle behavior can emerge (Mills et al. 2011; Abbot 2016).

Weathering does not occur uniformly. Rates are highest where there is fresh volcanic rock, young mountains, and warm and wet conditions. Fifty percent of global chemical weathering occurs on 9% of the surface (Hartmann et al. 2009). Broadly, felsic rock (e.g., granite) is less susceptible to weathering than mafic rock (e.g., basalt) (Ibarra et al. 2016), so weathering can be dominated by fresh exposures of mafic, volcanic rock. Today, basalts are responsible for 30–35% of the global CO_2 sink by weathering, dominated by tropical volcanic island arcs (Dessert et al. 2003). In the past, migration of large igneous provinces (flood basalts) through the humid tropics may have been responsible for major cooling; hypothesis attributes Cenozoic cooling (Kent and Muttoni 2013) and the Neoproterozoic snowball (Goddéris et al. 2003) to this mechanism, for example. For much of the continental interiors, where there is little variation in elevation, chemical weathering is limited by the availability of fresh rock and is not temperature dependence; only in mountainous areas, where exposure of fresh rock is rapid, are weathering rates temperature dependent (West et al. 2005).

Life is deeply implicated in the control of alkalinity, and therefore atmospheric CO_2. In soils, pCO_2 is elevated above atmospheric levels by respiration (Berner et al. 1983). Furthermore, fungal hyphae and plant roots penetrate rock, excreting organic acids which enhance weathering. The evolution of lichens (probably in Neoproterozoic time), a symbiosis of algae which provide a photosynthetic source of carbon and energy, and fungus which extracts nutrients, may have marked the beginning of very efficient, photosynthetically driven, enhancement of the weathering (Berner 1992). The evolution of nonvascular plants (mosses) in the Ordovician, and vascular plants in the Devonian further enhanced alkalinity supply by a factor of 2–10 (Lenton et al. 2012). Enhanced weathering has been linked to various glaciations (e.g., Berner 1997; Royer 2006; Lenton et al. 2012). In the ocean, organisms precipitate $CaCO_3$ at much lower Q than authigenic precipitation (Zeebe and Wolf-Gladrow 2001). The biota thus causes atmospheric CO_2 to be lower than it would be on an otherwise equivalent but sterile planet.

Proxy Constraints on, and History of, Atmospheric CO_2

With CO_2 as the main noncondensible greenhouse gas and a fainter Sun in the past, simple theoretical treatment of silicate-weathering feedback would call for pCO_2 to be high in the Archean and decrease over time to modern values. Since the proposal of high CO_2 as the resolution to the faint young Sun problem, there has been a consistent mismatch between climate model estimates of how much CO_2 should be required, and proxy estimates of how much is in the atmosphere.

For the Neoarchean and Proterozoic, paleosol constraints have been used for some decades. Soils are necessarily in contact with the atmosphere, so can be used as an atmospheric proxy. The absence of siderite can be used to exclude very high pCO_2 (Rye et al. 1995). Models can be used to quantify pCO_2, e.g., Sheldon (2006) suggests $23^{\times 3}_{\div 3}$ times the present level, but key parameters (e.g., soil formation rate) are very poorly constrained, making such model interpretations very challenging.

Recently, calcium isotopes have been used to more directly constrain the carbonate system via [Ca]/Alk; still, this does not uniquely constrain pCO_2, and a supplemental assumption about pH is necessary. A nominal assumption of pH of

7 would give around 30,000 ppmv CO_2. However, if another carobonate system parameter can be determined independently, then an actual constraint on pCO_2 will be available (Blattler et al. 2017).

For the Phanerozoic, a variety of proxies exist and give a somewhat consistent picture: pCO_2 decreases from around 5000 ppmv in the Silurian to less than 1000 ppmv in the Carboniferous, then varies between a few hundred and a few thousand ppmv until the present day (Royer 2006).

Water

Water is unique among Earth's atmospheric gases in that the control on its abundance is physical: equilibrium between vapor and a large condensed reservoir known as "the ocean." This physical control is via the saturation vapor pressure: the amount of vapor in equilibrium with a condensed reservoir depends exponentially on temperature. At the mean surface temperature of $\overline{T}_s = 15°\mathrm{C}$, the saturation vapor pressure of water is 1.7 kPa, implying that water comprises just under 2% of the atmosphere. In reality, it is somewhat less: the atmosphere cools with height, so the saturation vapor pressure decreases strongly with altitude, and in general, the atmosphere is subsaturated with water vapor. Spatial variations are important: Earth's warm tropics are very moist and the cold polar regions quite dry; water vapor is not well-mixed.

Water vapor content has changed by several orders of magnitude, covarying with temperature. In times when Earth was much colder, for example during Paleo- and Neoproterozoic Snowball Earth episodes with $\overline{T}_s \approx -40°\mathrm{C}$, the corresponding saturation vapor pressure was 100 times lower than today. During hyperthermal periods, such as the Cretaceous warm period with $\overline{T}_s \approx 30°\mathrm{C}$, the corresponding saturation vapor pressure was 2.5 times higher than today. Over these range of temperatures, which characterize most of Earth history, the expectation is that water vapor has varied by more than two orders of magnitude, between a trace to a minor constituent of the atmosphere.

Based on these arguments, three qualitatively different atmospheric water inventories, corresponding to different climate states, can be inferred to have existed through Earth history: cold and dry, with trace water in equilibrium with an ice surface (snowball Earth); intermediate climate with strong meridional gradients of temperature and water vapor, so that water is a minor (percent level) constituent in the tropics but trace at the poles (e.g., present day); and warm and moist in equilibrium with a warm ocean, small meridional temperature gradients, and water vapor as a minor constituent throughout.

When water becomes a major constituent, there are further qualitative changes to system behavior: transition to a hot and water-dominated atmosphere occurs above a threshold solar constant. That is, a liquid water ocean is stable only up to a limit on the energy supplied to the planet, after which a "runaway greenhouse" occurs, the ocean evaporates, and the atmosphere becomes water dominated (Simpson 1927; Komabayashi 1967; Ingersoll 1969). Given a water vapor column of 30 kgm^{-2}, corresponding to a saturated atmosphere with a surface temperature of 300 K, the atmosphere is optically thick at all thermal wavelengths. Consequently, only radiation from the atmosphere can reach space, and none from the surface, limiting outgoing thermal radiation. If more energy is absorbed by the planet, there will be a nonlinear transition of the atmosphere as the entire ocean evaporates (see reviews by Nakajima et al. 1992, Goldblatt and Watson 2012). Modern calculations of the radiation limit in clear-sky conditions give 283 Wm^{-2}, which corresponds to the sunlight that would be absorbed by a cloud-free planet at Earth's orbit (Goldblatt et al. 2013). Clouds are net reflectors, so increase the threshold insolation to at least 1.1 times the present solar constant (Leconte et al. 2013; Wolf and Toon 2014; Popp et al. 2016). As the solar constant increases, Earth will transition to a water-dominated atmosphere in around a billion years. Likewise, Venus receives 1.9 times the sunlight that Earth does, and the composition of the Venusian atmosphere is consistent with a postrunaway state. Whether Venus had oceans which evaporated at some point in the past, or never condensed any, is model dependent (Hamano et al. 2013).

Additionally, impact energy could be sufficient to evaporate the oceans and give a water-dominated atmosphere. This undoubtedly occurred during accretion. During the end-Hadean late heavy bombardment, statistics indicate that there would have been zero to four impacts sufficient to evaporate the oceans (Zahnle et al. 2007). The timescale of an impact-generated steam atmosphere would be a few thousand years (Zahnle et al. 2007). Likewise, early in the evolution of a planetary system, tidal heating of the planet could induce a runaway greenhouse (Barnes et al. 2013).

Discussion

Atmospheric Homeostasis, Vernadsky's "Biosphere," and the Gaia Hypothesis

The most remarkable observation of Earth history is the continual lineage of a single genesis of life spanning four billion years. Indeed, deep in the Archean record, the evidence for life is in general commensurate with the maximum that could be expected, given the preservation of the sedimentary record (Nisbet and Sleep 2001). Life requires temperature to be in a somewhat limited range, by necessity maintained for the entire length of the record. Three alternate explanations for this long-term homeostasis may be offered: luck,

abiological regulation, or an explanation based on the action of life itself.

Luck is a somewhat irrefutable option. Further disentanglement becomes difficult due to observer bias: our position as observers of this history is contingent on history itself: conditions must have been such that the long evolution to organisms with the science of geology and printing presses to make encyclopedia could occur. Our ability to pose the question requires continual habitability, so the observation itself is bias; such is the *weak anthropic principle* (Watson 1999).

Abiological regulation is supported by evidence of chemical feedback processes contributing to climate regulation, with the negative feedback on temperature via the silicate weathering and carbonate deposition cycle (Walker et al. 1981) the seminal contribution. A purely abiological model would have these geochemical mechanisms regulate temperature to a level at which life is plausible, allowing life to adapt to the environment. There is little doubt that this represents part of the explanation, but the entanglement of life in these geochemical mechanisms, enhancing both weathering and carbonate deposition, makes isolation to only abiological processes rather difficult. Life and nonlife processes are deeply entwined on Earth.

Biological control was a part of Vernadsky's original enunciation of the biosphere. Vernadsky (1926) described the biosphere as composing both living and nonliving parts, the atmosphere being the type example of the latter. He saw life as the dominant geological force, and that the planetary scale influence of life has increased with time – i.e., that the biota controlled the atmospheric composition, and that the control has become stronger has evolved to increasing complexity and dominance. Written in Russian and French, Vernadsky's original and visionary work on the biosphere was largely lost to anglophone science until David Langmuir's 1970's translation circulated in the late twentieth century and was eventually published in 1998 (but see also Vernadsky 1945).

In Western science, biological regulation was proposed by Lovelock (1972) with the *Gaia hypothesis:* "homoeostasis by and for the biosphere." A modern statement of this is "Organisms and their environment evolve as a single, self-regulating system" (Lovelock 2003). Thus, not only are organisms selected for their environmental fitness but are selected for their ability to modify the environment in beneficial ways (Lenton 1998).

It is plain that biology is deeply and intimately involved in the control of Earth's atmospheric composition. The question of whether this has directionality – whether the biota regulates – is probably the single most important open question in the study of atmospheric evolution of Earth. Significant theoretical development is needed and, ultimately, experiments to detect life on planets outside the solar system may provide the sample size to resolve the question empirically.

Comparative Planetology

Science progresses best with a sample size greater than one. Thus, as in seeking to understand the evolution of our own atmosphere, much is to be learnt from looking outward. In our solar system, primary comparisons are to our neighbors, Venus and Mars and further information come from including the giant planet moons (nomenclature and orbit type – planet, moon, dwarf planet – do not affect the geophysics).

The first, and obvious issue, is whether or not a planet actually has an atmosphere. Earth, Venus, Mars, and Titan do, whereas Ganymede, Calisto, Io, Mercury, and many smaller bodies do not. Presence of an atmosphere may be empirically determined via the "cosmic shoreline": a power law relating threshold insolation to escape velocity to the fourth power. Stellar energy drives atmospheric loss, whereas planetary mass holds the atmosphere down (Zahnle and Catling 2017).

Venus is the most Earth-like planet, with similar size and bulk composition. Venusian atmosphere has a 90 bar surface pressure (Earth is 1 bar), with a composition of 97.5% CO_2 and 3.5% N_2 and a surface temperature of 700 K. There is no ocean and water is only a trace atmospheric constituent.

Venus' current atmosphere is understood on the basis that it experienced a runaway greenhouse in the past (Walker 1975). The present insolation at Venus' orbit is well in excess of the runaway greenhouse limit, so if a Venusian ocean ever condensed after accretion, it later evaporated. Much of the hydrogen from the water was lost to space, evidenced by strong enrichment of D/H relative to Earth (Donahue et al. 1982). The timescale for loss of an Earth-size ocean via hydrodynamic escape is a few hundred million years (Watson et al. 1981). Accumulation of oxygen, however, may throttle hydrogen escape (Wordsworth and Pierrehumbert 2014), and extensive hydration of the surface rocks is another potential sink for water (Matsui and Abe 1986).

The carbon reservoir in Venus' atmosphere is of comparable size to the carbon stored in carbonate and organic carbon rocks on Earth. If there was an ocean on Venus, carbonates would have most likely been deposited, but these would have thermally decomposed during the runaway greenhouse (the equivalent process is used in industrial cement manufacture in lime kilns on Earth).

Venus gives two primary lessons that pertain to Earth. First, is contingency in planetary evolution. Venus' present state is only possible to understand through the presence of atmospheric water in the past, even though it is absent today. Second, is Earth's future: solar constant increases with time, so Earth should reach the runaway greenhouse threshold in a billion years. Venus' past informs us directly or what Earth's future: the end of the world will be a runaway greenhouse, lime-kiln, inferno.

Mars, by contrast, has a rather feeble atmosphere: 0.006 bar of CO_2, supporting a mean surface temperature around 220 K. Mars' mass and insolation are such that it is only marginally on the atmospheric side of the cosmic shoreline. Yet, there is abundant evidence in Mars' geological record for liquid water in the first billion years of the solar system, despite a dimmer Sun. It is not obvious whether early Mars was always warm, or only episodically so (Wordsworth 2016), but almost any solution requires both a thicker atmosphere and much stronger greenhouse effect in the past.

Mars and Venus together provide two primary lessons pertinent to Earth. First, that major variations in planetary atmosphere mass and composition, and thus climate, through time are the norm for terrestrial planets. Long-term consistency of any of these should be seen as an exceptional result, requiring exceptional evidence and explanation. Second, both have CO_2 dominated atmospheres which can be explained by photochemical equilibrium without any biology in stark contrast to Earth, whose atmospheric composition is to a large extent a biological construct. Life's alteration of Earth is of first order importance.

Outlook

Humanity is in the midst of a great age of discovery, as planets around other stars are discovered and characterized: "the age of exoplanets." Life has had a dominant role in altering the atmospheric composition of Earth, distinguishing us significantly from uninhabited planets. The composition of exoplanet atmospheres will soon be able to be determined remotely via spectroscopy, making *atmospheric analysis* the viable method of detecting life on other planets via *their influence on the atmosphere* (Lovelock 1965; Hitchcock and Lovelock 1967; Sagan et al. 1993). Life detection will require the detection of atmospheric disequilibrium and the exclusion of any abiotic cause. There is, however, no simple formula for what the composition of an atmosphere should be, so determining whether an observed atmosphere represents a living planet will only be achievable through a deep understanding of the processes determining atmospheric composition. Understanding Earth's atmospheric evolution is thus fundamental to learning our place in the universe.

Atomic Absorption, Inductively Coupled Plasma Optical Emission Spectroscopy, and Infrared Spectroscopy

Michael A. Rutzke
College of Agriculture and Life Sciences Nutrient Analysis Lab, Cornell University, Ithaca, NY, USA

Definition

Analytical spectroscopy is about measuring and recording the observations that occur when matter (atoms, ions, and molecules) interacts with or is exposed to thermal heating and/or electromagnetic radiation (light).

Introduction

The interactions that occur when matter interacts with electromagnetic radiation in the infrared and microwave range (thermal heating) and/or the visible range (light) allow us to identify the chemical species in a sample and to investigate their structures and physicochemical properties. This is possible because matter emits photons with energies equal to the energy differences between the initial and the final states that occur after stimulation of the matter. A stimulating source can be thermal, electrical, chemical, physical, or electromagnetic. This chapter will focus on stimulations (excitation) due to electromagnetic and thermal heating. These excited transitions are quantized – meaning atoms, ions, and molecules exist only in discrete states associated

with specific energies. Because each atom, ion, or molecule has a unique pattern of discrete energy states, we can use these properties to determine their presence and abundance and to measure their physicochemical properties. This information allows us to understand better the structure and physicochemical properties of geological material.

Electromagnetic radiation has many useful properties including velocity, wavelength, amplitude (intensity), polarization, and phase, but of these analytical spectroscopy is based on variation in the wavelength (or equivalently, frequency) of light.

Atomic spectroscopy utilizes the electromagnetic spectrum from 130 nm (ultraviolet, UV) through the visible spectrum up to 800 nm (infrared, IR). Atomic spectroscopy is simple because we are dealing with the energy released from a single atom, where each element gives a different emission pattern. An example of an emission spectra is shown in Fig. 1.

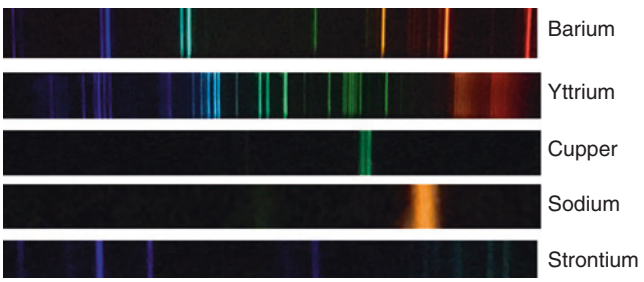
By comparison, the spectra obtained when one does molecular spectroscopy are more complicated because molecules contain two or more atoms. Molecular spectroscopy uses the electromagnetic spectrum from 800 nm to 1 mm. Molecular spectroscopy is a very popular technique used by organic chemists and geochemists as well. This branch of spectroscopy characterizes and measures vibrational and rotational energies in a molecule. It can also be used to measure the bond strengths of atoms in a molecule.

Basic Principles of Spectroscopy

The wavelength of light (λ, in m) is directly determined using a Michelson interferometer or a grating. The frequency (v, in s^{-1}) of the wave is determined by dividing the speed of light (3×10^8 m/s) by the wavelength.

$$v = \frac{c}{\lambda}$$

The total kinetic energy of a system is the summation of the electronic energy, vibrational energy, rotational energy, and the translational (thermal) energy.



Atomic Absorption, Inductively Coupled Plasma Optical Emission Spectroscopy, and Infrared Spectroscopy, Fig. 1 Examples of ICP-OES spectra for 5 different metals. (Photograph taken by Michael B. Rutzke)

The Maxwell-Boltzmann equation, given below, predicts the ratio of the excited states of the electronic, vibrational, or rotational energy to those in the ground state as a function of the temperature.

$$\frac{N_b}{N_a} = \left(\frac{g_b}{g_a}\right) e^{-\frac{\Delta E}{kT}}$$

where $\frac{N_b}{N_a}$ is the ratio of excited atoms to ground-state atoms, g_b is the number of excited states having equal energy, and g_a is the number of ground states having equal energy. The ratio $\frac{g_b}{g_a}$, known as the degeneracy, is typically 2–3; T is the absolute temperature in degrees Kelvin. k is the Boltzmann constant: $k = 8.617 \times 10^{-5}$ eV/K when ΔE is in volts. When ΔE is in Joules then the Boltzmann constant K is (1.381×10^{-23} J/K).

$$\Delta E = \frac{1240}{\lambda}$$

ΔE is in eV when λ is in nm. The ratio of excited- to ground-state atoms ($\frac{N_b}{N_a}$) in Na, which has a degeneracy of 2 and which emits 589.0 nm light at 2,500 K, is 1.14×10^{-4}. At 5,000 K, the ratio is 1.5×10^{-2}. Because of the exponential relationship, doubling the temperature increases the number of excited Na atoms by 128 times.

In Zn, which has a degeneracy of 3 and which emits 213.9 nm light at 2,500 K, the ratio of excited- to ground-state atoms is 6.17×10^{-12}. At 5,000 K, the ratio is 4.27×10^{-6}, a 705,000-fold increase in excited Zn atoms for a doubling of the temperature.

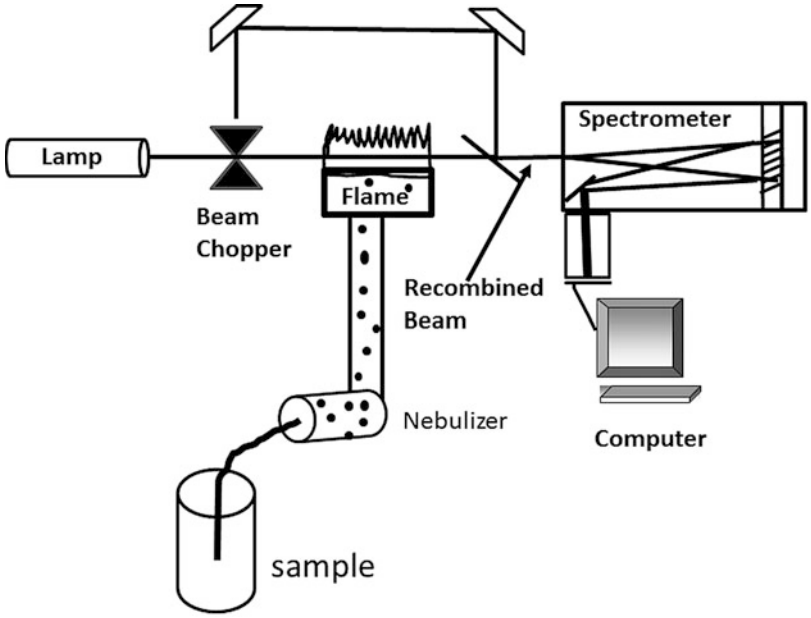
Since ΔE is inversely proportional to the wavelength, the number of atoms or molecules in the excited state will be dramatically higher with elements or molecules emitting radiation at longer wavelengths and with increasing temperature. This is why it is important to use a high-temperature excitation source for emission spectroscopy when analyzing elements emitting with short wavelengths.

Atomic Spectroscopy

Atomic Absorption Spectroscopy (AAS)

In March of 1952, Alan Walsh invented the popular technique known as atomic absorption spectroscopy. This was a major breakthrough in analytical chemistry for the analysis of elements. Prior to the invention of AAS, most elemental analysis was done using flame atomic emission spectroscopy (AES) or slow and labor-intensive chemical methods (Dawson and Price 1999). AAS had the ability to analyze about 50 elements in complex matrixes with minimum sample preparation one element at a time.

Atomic Absorption, Inductively Coupled Plasma Optical Emission Spectroscopy, and Infrared Spectroscopy,
Fig. 2 Schematic diagram of an atomic absorption spectrometer



AAS is an analytical method based on the absorption of discrete wavelengths of light by adequately spaced free atoms in the gaseous ground state. The wavelength coverage for this technique is generally for elements that absorb UV and visible light. The concept is rather simple. Adequately spaced free atoms in the gaseous ground state absorb very narrow absorption lines from a radiating light source (lamp) emitting at that specific wavelength. The detector records a decrease in signal from the lamp that is dependent on the concentration of the element in the sample.

There are basically two ways to generate free well-spaced atoms for AAS. (1) The most popular method uses a nebulizer to aspirate the sample into a flame. This is referred to as flame AAS or (2) to vaporize the sample using a graphite tube that is heated with electricity. This is referred to as thermal vaporization. This method is very sensitive and uses about 1–200 μl of sample but is prone to matrix interferences. Matrix interferences occur when the composition of the calibration standards and the sample behaves differently in the flame. This can result in the atomization rate of the sample and standard to be different.

AAS instrumentation is rather simple (Fig. 2). Flame AAS uses a nebulizer (similar to a paint sprayer) which converts the sample into very fine mist that is mixed with air and usually acetylene to produce a hot flame about 2,500 K. At this temperature, most compounds can be degraded to individual elements, producing adequately spaced free atoms in the gaseous ground state. The beam from the lamp passes through a rotating beam chopper that is synchronized with the electronics and serves as the reference beam. This mechanism alternately routes the beam around the flame or allows the beam to pass through the flame where some of the beam of light is absorbed by the sample. The two beams of light are recombined and pass into a spectrometer to a detector. The readout is then processed by a computer.

The amount of radiation absorbed by the analyte element is given by *Beer's law*:

$$A = \log\left(\frac{I_o}{I}\right)$$

where A is the absorbance, I_o is the intensity of radiation incident on the flame, and I is the intensity of radiation exiting the flame. The concentration of the element of interest is directly proportional to the absorption.

In some circumstances, the elements in the flame will reform more stable compounds. For example, when samples containing Ca are heated in the flame, the Ca will combine with PO_4^{-2} to form calcium pyrophosphate which will not dissociate at this flame temperature. Also refractory elements such as Al, Mo, Ti, W, and Zr, in the presence of the flame, can combine with oxygen to form thermally stable oxides. The flame is prone to chemical and matrix interferences (West et al. 1973; Boss et al. 1989).

Flame Emission Spectroscopy

It is possible to operate the AAS instrument in emission mode (flame AES). At these low temperatures, only elements of low excitation temperatures can be measured as predicted by the Maxwell-Boltzmann equation. These include the elements of Na, K, Ca, Sr, and a few others.

In flame emission spectroscopy, most samples are introduced as an aerosol. Many of the elements in the sample upon coming in contact with the hot flame (2,400 K) quickly become desolated, vaporized, and atomized. Thermal

collisions with these hot gasses cause the valance electrons of free elements to be excited. When the excited electrons relax to a lower energy state or ground state, they emit light. The emitted light then passes into a spectrometer and is digitally processed by a computer.

In general, AAS is less prone to spectral interferences than emission spectroscopy, but both AAS and AES are prone to chemical interferences and matrix interferences. AAS is a good technique for the determination of a single element in a sample if the standards and samples are closely matched and the flame parameters are optimized for that element.

Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES)

Background and History of Development of Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) Technology

The modern ICP-OES used today was first explored by Velmer Fassel and Stanley Greenfield in 1962. The lower power (1–2 kW) design by Fassel eventually became the instrument of choice (Montaser 1998).

The first generation of commercial ICP-OES instruments was introduced in 1974. These instruments were an ideal substitute for the popular flame AAS and flame AES spectrometers. This is because the ICP-OES has multielement determination capabilities, is more sensitive, and is less prone to matrix interferences (Dubuisson et al. 1998; Larson et al. 1975; West et al. 1973). The ICP-OES torch operates at temperatures up to about 7,000 K. At this temperature, the entire sample including calcium pyrophosphate and metal oxides is dissociated. Also at this temperature, there are enough energies of excitation for elements emitting from 135 nm to be analyzed.

Principles of Inductively Coupled Plasma Optical Emission Spectroscopy

Unlike flame AES, which combusts fuel to create the high temperature for excitation, ICP-OES uses an inductive-coupling process to heat argon to 10,000 K. This is the temperature of the surface of the sun. This process is similar to the heating of water in a microwave oven, which involves the radiative transfer of microwave energy to the water molecules. In the case of the ICP-AES radio frequency, energy is transferred to electrons which are accelerated in the magnetic field.

The ICP-OES uses an inert argon plasma between 6,000 and 10,000 K which quickly desolvates, vaporizes, and atomizes the sample. The plasma torch consists of three open-ended concentric quartz or ceramic tubes centered in a metal coil termed the load coil. A stream of argon flows through the middle and outer tube. A radio frequency (RF) power is applied to the load coil creating a magnetic field oscillating at 27 or 40 MHz. The collisions of the electrons with argon neutrals produce Joule heating and create secondary argon ions and electrons. The process converts 1% of the argon stream to ions. At this point, the plasma is stable and self-sustaining for as long as the RF field is applied. The concentration of argon ions in the central channel which is in contact with the sample is about 0.1%. Fig. 3 shows the components of the plasma.

Thermal Equilibrium Models and Excitation Mechanisms

The ICP-OES is a useful analytical tool because it operates at steady state. This means that the plasma has a continuously stable and reproducible output. The observation zone of the ICP-OES is about 7,000°K, which at this temperature dramatically increases the ratio of the element in the excited state to the ground state as compared with a flame. But in addition unlike other excitation sources, the ratio of the elements in the excited state to ground state is much higher in the ICP plasma than what the Boltzmann equation predicts. As a result, the emission observed is also increased over what would be expected at this temperature. There is general agreement that excitation is dependent primarily on the number and temperature of the electrons. The electrons when accelerated in a magnetic field acquire enough kinetic energy to excite the analyte upon collision. It is believed that electron impact is the primary excitation mechanism in the observation zone of the plasma (Hasegwa et al. 1992; Heiftje et al. 1985).

The ICP-OES plasma can be configured in one of the two ways shown in Fig. 4: radial viewing or axial viewing. In normal operation, samples are introduced as an aerosol. Figure 3 shows a picture and diagram of a ICP-OES plasma. Figure 4 shows how the chemical state of the sample changes as it travels through the plasma. The light emitted from the ICP is then transferred into a spectrometer where the signals are recorded and then processed by a computer. The two most popular spectrometers use a Rowland circle or an Echelle design. The main differences between manufacturers of ICP-OES are the design, of the spectrometer, the type of detector used, the RF field used (27 or 40 MHz), and the operating system.

The ICP-OES does suffer from spectral interferences (see Fig. 5). This is the result of the spectrometer not having a high enough resolution to separate the peaks. These interferences can be corrected for by measuring the interfering element at another wavelength, developing a mathematical equation to define the interference and then subtracting it out.

In a radial-viewed plasma, the matrix effects are much less than flame AAS or AES because the plasma is hot enough to atomize and vaporize all the sample. The axially viewed ICP-AES is about ten times more sensitive than the radial-viewed ICP-OES but unfortunately exhibits worse matrix interferences (Brenner and Zander 2000). This is most noticeable when

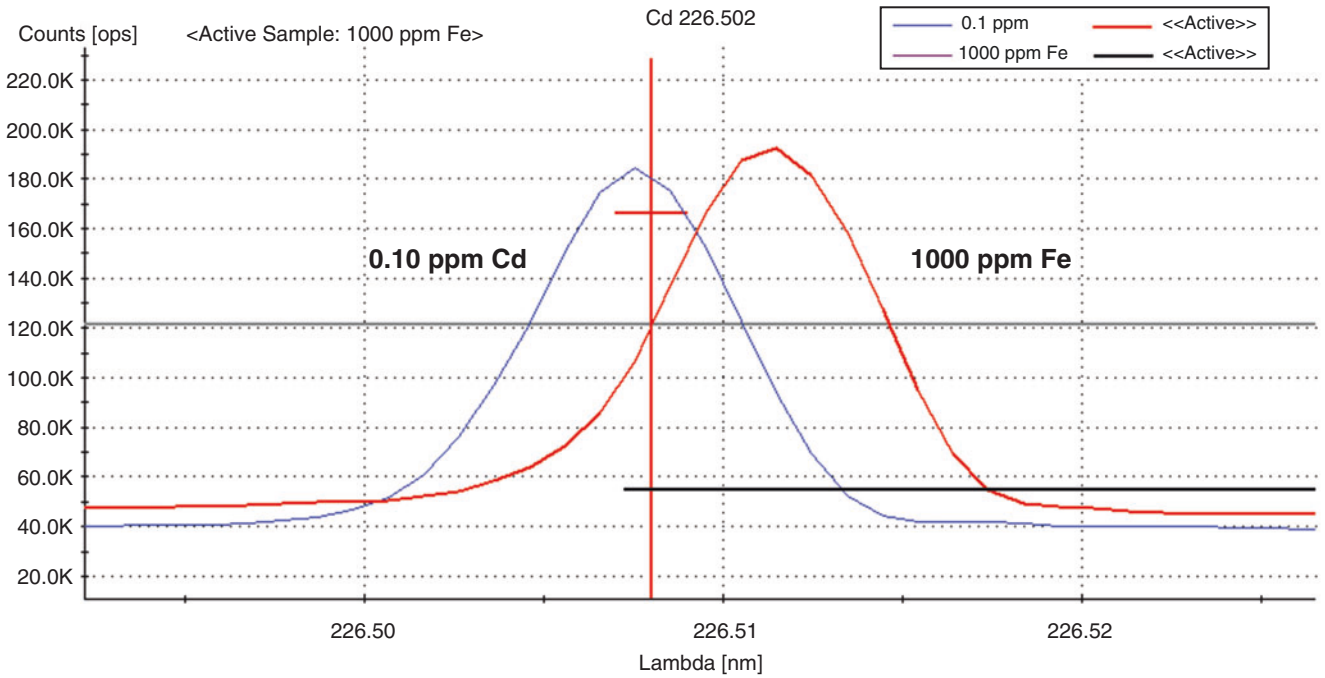
samples contain high concentrations (500–1,000 ppm) of Ca, Na, Mg, K, or La. These elements reduce or enhance the emission intensities from trace elements, including Zn, Cd, Mn, Fe, Cr, and Ni by as much as 17%. Emission from easily ionized elements, like K, Li, and Na, is enhanced by other easily ionized elements, and these elements also show self-enhancement. Self-enhancement results when the ratio of the analyte signal to analyte concentration increases with increasing analyte concentration. This results in positive curvature when analyte emission is plotted against analyte concentration.

Over all, the ICP-OES continues to be a popular technique for the analysis of geological materials.

Molecular Spectroscopy

In addition to translational energy and energy of excited electrons that form the basics of atomic spectroscopy, energy is also stored in molecules through their vibration and rotational states.



Atomic Absorption, Inductively Coupled Plasma Optical Emission Spectroscopy, and Infrared Spectroscopy, Fig. 5 A 1000 ppm Fe interfering with Cd analysis

Infrared (IR) radiation was discovered serendipitously by Sir William Herschel in 1800. He noticed that light after passing through a prism could heat a blackened thermometer outside the zones of the red visible spectrum. This demonstrated that there is radiation we can't see with our eyes.

Infrared (IR) spectroscopy is a very broad field that usually measures the absorption of the wavelengths of radiation between 0.75 and 200 μm in solids, liquids, and gasses (Wehling 2010). Unlike atomic spectroscopy which reports in wavelengths, IR spectroscopy displays are usually reported in wavenumbers ($\tilde{\nu}$, in cm^{-1}), which is the number of wavelengths per unit distance. The wavenumber range would be 13.333 cm^{-1} (0.75 μm) to 50.0 cm^{-1} (200 μm) (http://www.impublications.com/wavenumber-wavelength-converter). The wavenumber has the advantage in that the energy is linearly proportional to wavenumber while it is inversely proportional to wavelength. The disadvantage is that wavenumber often has two meanings ($\tilde{\nu} = \frac{1}{\lambda}$ or $\nu = \frac{c}{\lambda}$), and the one used must be clearly stated.

$$E = \frac{hc}{\lambda} = hc\tilde{\nu}$$

where E is the energy of the system, h is Planck's constant, ν is the frequency, and $\tilde{\nu}$ is the vibrational frequency (cm^{-1}).

The IR spectrum is complex because a molecule has many degrees of freedom to absorb energy. Each atom (n) in the molecule has ($3n$) degrees of freedom. The total degrees of freedom of a molecule is given by the product of the number of atoms (n) times the number of directions each atom can move in space. This corresponds to the Cartesian coordinates (X, Y, Z). The degrees of freedom in a molecule include three degrees of freedom for translation, three degrees of freedom for rotation of a nonlinear, or two degrees of freedom of rotation for a linear molecule. The remaining degrees of freedom are for vibrational energies. The vibrational degrees of freedom for a linear molecule is $3n - 5$. In this case, you subtract the three degrees of freedom for translation and the two degrees of freedom for rotation. In the case of a nonlinear molecule to calculate the vibrational degrees of freedom, you subtract the three degrees of freedom for translation and the three degrees of freedom for rotation. The equation is $3n - 6$.

When matter is exposed to quantized bands of IR radiation, the radiation will be absorbed by the molecule, increase the energies of vibrations of the atoms in the molecule, and also cause the molecule's rotational energy to increase.

The two types of molecular vibrations are stretching and bending. There are two types of stretching motions: symmetrical and asymmetrical. In symmetrical stretching, the distance between the atoms increases or decreases equally. Asymmetrical stretching involves the simultaneous vibration of two adjacent bonds that increase or decrease unequally. The bending vibration consists of a change in the bond angle between bonds with a common atom or group of atoms. These bending movements include rocking, scissoring, wagging, and twisting. The only vibrations of molecules observed in the IR are those that have a rhythmic change in their dipole moment.

Factors Affecting the Frequency of Vibration

A molecular vibration can be thought of as a harmonic oscillator. The following equation helps explain the factors that govern the energy levels of the vibration.

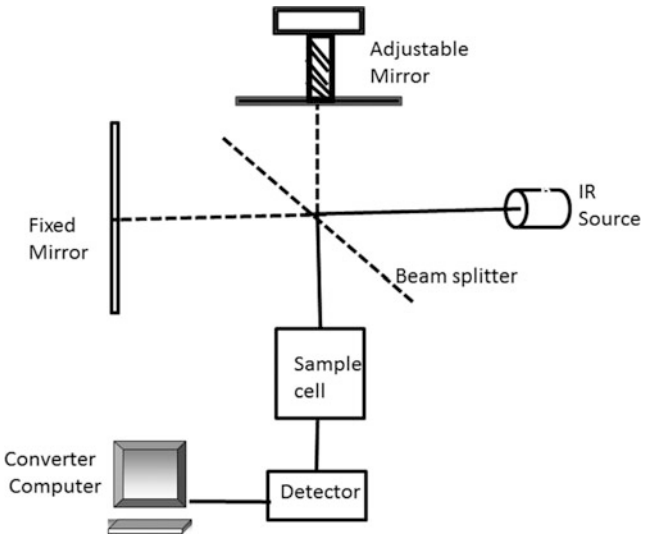
$$E = \frac{h}{2\pi}\left(v + \frac{1}{2}\right)\sqrt{\frac{f(m_1 + m_2)}{m_1 m_2}} \text{ and } \widetilde{\nu}$$
$$= \frac{1}{2\pi c}\sqrt{\frac{f(m_1 + m_2)}{m_1 m_2}}$$

where v is the vibrational quantum number, $\widetilde{\nu}$ = the vibrational frequency (cm^{-1}) h = Planck's constant, c = speed of light in cm/sec, f = force constant of the bond (dynes/cm), and m_1 and m_2 are the masses of the individual atoms involved in the vibration. This equation shows that the vibration energy and the frequency of vibration are proportional to the square root of the strength of the bond and inversely proportional to the square root of the reduced mass $\left(\frac{m_1 m_2}{m_1 + m_2}\right)$ of the molecular system in grams (Wehling 2010).

IR spectroscopy is useful to geologists because it can help them identify the structure of molecules. For example, a = C–H stretch occurs at 3,078 cm^{-1}. A coupled C = C–C = C occurs at 1,640 cm^{-1}. Because most molecules have a unique pattern, it is possible to identify unknown compounds with the aid of standards. These spectra can also be used to measure bond strengths. For example, the force f for a single bond is 5×10^5 dynes per cm, a double bond is 1×10^6 dynes per cm, and a triple bond is 1.5×10^6 dynes per cm.

IR Instrumentation

There are basically two types of instruments used. In the 1980s, IR spectrometers were double-beam dispersive grating spectrometers. They were similar to UV/VIS absorption spectrometers adapted for IR absorption. Most instruments used today are Fourier transform infrared spectroscopy (FTIR) (see Fig. 6). The principle of operation is as follows. The polychromatic IR beam after leaving the IR source strikes a beam splitter sending half the light to a stationary mirror and the other half of the light to a moveable mirror. The mirrors are originally adjusted so the path length of the recombined beams is equal at the detector. When the moveable mirror is moved, the path length of the beam changes. As the beam passes back through the beam splitter, it recombines with the beam from the stationary mirror. The recombined ray will develop constructive and destructive interference patterns and then pass through the sample where the sample absorbs its characteristic frequencies. These interactions generate a pattern of fluctuating optical interference fringes producing what is termed an interferogram. The interferogram is imaged on to a detector like a CCD camera which converts it to a digital electrical signal which is then processed by a computer using a mathematical equation to construct the image.



Atomic Absorption, Inductively Coupled Plasma Optical Emission Spectroscopy, and Infrared Spectroscopy, Fig. 6 Fourier transform infrared spectroscopy (FTIR)

Summary

The fields of atomic and molecular spectroscopies continue to contribute greatly to geology by determining the concentration and composition of components that make up geological materials. The instrumentation used today is well established and reliable.

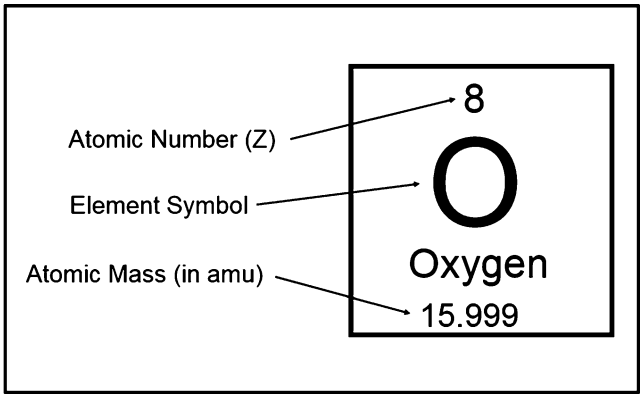
Atomic Number, Mass Number, and Isotopes

Russell S. Harmon
North Carolina State University, Raleigh, NC, USA

Definitions

The primary building blocks of atoms are protons, neutrons, and electrons. It is convenient to describe the composition of an atom in terms of the number of protons and neutrons in its nucleus (Fig. 1). The term *atomic number*, conventionally denoted by the symbol *Z*, indicates number of protons present in the nucleus of an atom, which is also equal to the number of electrons in an uncharged atom. The number of neutrons is represented by the *neutron number* (*N*). Because the mass of these nuclear particles is each approximately equal to one unified atomic mass unit (u), the sum of the protons plus neutrons is designated as the *mass number* (*A*). The mass of the electron is more than 1800 times smaller than the proton mass and, therefore, can be neglected in calculating the mass number. For any element, the mass number is equal to the atomic weight rounded off to the nearest integer value.

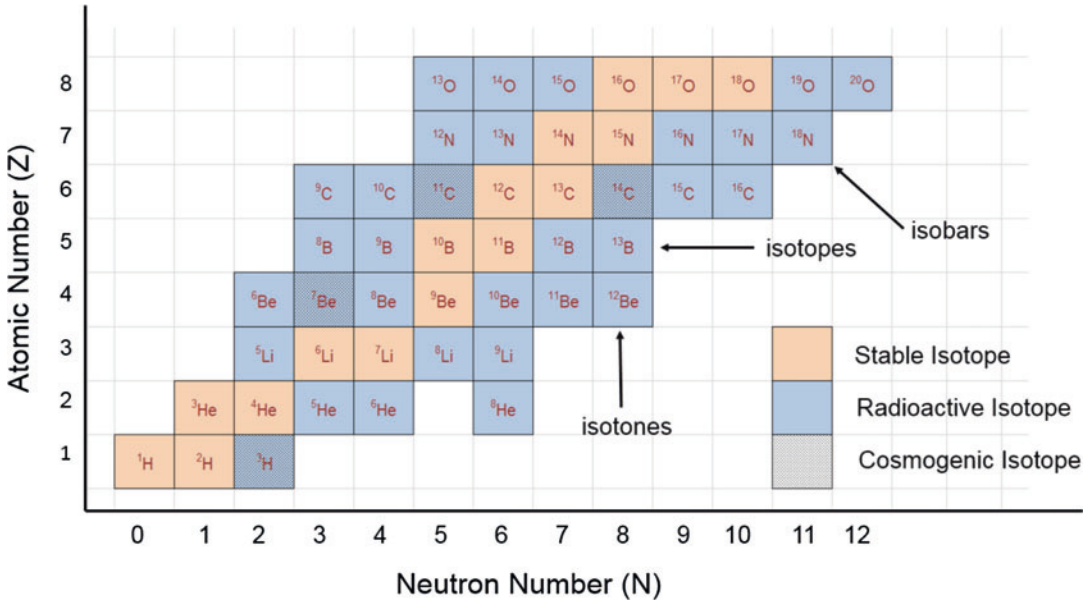


Atomic Number, Mass Number, and Isotopes, Fig. 1 Atomic number as displayed in the periodic table of the elements

Nuclear Structure and Stability

The proton has a positive charge that is equal in magnitude, but opposite in polarity, to the charge of an electron. The number of protons defines how many extranuclear electrons an atom can have under conditions of electronic neutrality. It is the number of electrons and their distribution about the nucleus that determines the chemical properties of an atom, whereas it is the composition of the nucleus that is responsible for the phenomenon of radioactivity. The modern periodic table of the elements is based on the fact that the properties of the elements are repetitive functions of their atomic number.

The term *nuclide* denotes any of the more than 1300 different atomic species characterized by a distinct combination of protons and neutrons, only about 270 of which are stable (i.e., non radioactive). The nuclear composition of any nuclide can be represented by the relationship $A = Z + N$. The two numbers Z and A completely describe any nuclear configuration, which can be conveniently written by means of a shorthand notation consisting of the chemical symbol of the element, with Z written as a subscript and A written as a superscript. For example, consider the element nickel (Ni), which has an atomic number of 28 and consists of five naturally occurring isotopes of masses 58, 60, 61, 62, and 64. Therefore, the notation ${}_{28}{}^{61}\mathrm{Ni}$ identifies the particular nuclide of nickel with 28 protons, an equal number of electrons, and 33 neutrons. Variation in A and at constant value of Z accounts for the occurrence of *isotopes*; nuclides with similar chemical characteristics but different masses depend on physical properties (e.g., ${}^{14}\mathrm{N}$ and ${}^{15}\mathrm{N}$), like diffusion rate. Approximately three-quarters of naturally occurring elements are mixtures of two or more isotopes. Nuclides having the



Atomic Number, Mass Number, and Isotopes, Fig. 2 Partial chart of the nuclides. Stable isotopes are shown in *orange* shading and radioactive isotopes in *blue* shading, and cosmogenic isotopes are denoted by the *stippled* pattern overlay

same A, but different Z, are called *isotones* (^{9}Be and ^{10}B), whereas nuclides having the same A, but different Z and N, are called *isobars* (e.g., ^{3}H and ^{3}He). As illustrated in Fig. 2, which is a plot of atomic number against neutron number, almost all elements occur in nature as mixtures of two or more isotopes. In some cases, this mixture includes cosmogenic isotopes that exist only because they are produced in the Earth's atmosphere, soil, or rock as a consequence of in situ interactions of high-energy cosmic rays with atomic nuclei (Fig. 2). *Atomic weight* is a term commonly used in physics, chemistry, and engineering to indicate the average mass of a chemical element, in unified atomic mass units.

Certain combinations of protons and neutrons produce stable nuclei, whereas other nuclear configurations are unstable and ultimately revert to a stable state through the process of radioactive decay. Nuclear stability is attained for low atomic numbers when the number of protons is approximately equal to the number of neutrons (i.e., at $Z/N \approx 1$). Above calcium ($Z = 20$), no stable nuclide exists with equal numbers of protons and neutrons, for as Z increases, the repulsive Coulombic forces increase at a greater rate than the attractive nuclear forces. Thus, the presence of additional neutrons is required to increase the average distance between protons within the nucleus and, thereby, reduce the Coulombic force according to the inverse-square law. For the heaviest stable nuclei, the Z/N ratio is >1.5. However, there is a limit to the number of excess neutrons that a nucleus can contain and remain stable. Beyond ^{209}Bi, the heaviest stable nuclide, with 83 protons and 126 neutrons, a neutron excess introduces instability and leads to beta decay (i.e., a type of radioactive decay in which a neutron is transformed into a proton, or vice versa, inside an atomic nucleus with the emission of an electron or positron or by electron capture). Such a process is known as *nuclear transmutation*, as the original element becomes a new chemical element as a consequence of the decay process (e.g., $_{53}{}^{131}\mathrm{I} \rightarrow_{54}{}^{131}\mathrm{I} + \mathrm{e}^{-} + \bar{\nu}_e$). Beyond ^{209}Bi, no combination of protons and neutrons is stable, and for A above ~230, there is an increasing instability relative to alpha decay.

The cosmic abundance of the elements varies systematically with atomic number. Only 12 elements, all with $Z < 27$, exhibit appreciable abundance (H, He, O, C, Ne, Fe, N, Si, Mg, S, Ar, Ca). Elements with a low atomic number (<40) exhibit an exponential decay in abundance, whereas elements of higher atomic number are of relatively constant abundance. The relative abundance of elements above 28 is less variable than elements of lower atomic number. Notably, elements of even neutron number and atomic number are more abundant than adjacent elements of odd atomic number. Additionally, certain combinations of neutrons and protons in the nucleus – 2, 8, 28, 50, 82, and 126 (called *magic numbers*) – produce particularly stable nuclear configurations that are characterized by high nuclide natural abundance and a large number of stable isotopes or isotones relative to neighboring nuclides. These observations provide strong support for a nuclear shell model, analogous to the well-known extranuclear electron shell model, on which *magic numbers* represent the number of particles required to give complete shell occupancy.

Summary

The atomic number designates the number of protons in an element's nucleus and because that determines its electronic structure, its chemical behavior. The mass number of a nuclide is equal to the number of protons and neutrons in the nucleus; variation in the number of the latter produces results in different isotopes of that element.

Authigenesis

Norbert Clauer
Laboratoire d'Hydrologie et de Géochimie de Strasbourg, CNRS - Université de Strasbourg, Strasbourg, France

Definition

Often used by sedimentologists and low-temperature mineralogists and geochemists to describe in situ (on site) mineral precipitation in "soft" rocks, "authigenesis" is derived from Greek "indigenous." Generally, it results from a discrete and long-lasting process that involves pore fluids of local origin or introduced from elsewhere. However, authigenesis occurs not only in sediments and at low-temperature (<150 °C), that is to say under diagenetic conditions. Its consequences can be very important economically; for instance, industrial clay and metal deposits, as well as mineral precipitation related to hydrocarbon maturation and trapping, may result from authigenic processes.

Some Complementary Aspects of the Definition

Based on the above definition, authigenesis can occur at any time after sediment deposition, depending on the reactivity of the mineral components (organics are also able to interfere or even contribute, but they will not be considered here) that interact with fluids of local or remote origin. In turn, this definition excludes mineral crystallization from massive high-temperature recrystallized or metasomatic concentrations. Fairbridge and Bourgeois (1978) segmented authigenesis into (1) an early occurrence immediately after sediment deposition (= syndiagenetic), (2) a continental weathering of sediments in contact with the atmosphere after initial burial (= epidiagenetic), and (3) a deep-burial episode of host sediments (= anadiagenetic).

In fact, the meaning of "authigenesis" depends mainly on what the user wants to highlight of a mineral crystallization at a given sediment site or even of tectono-thermally affected metasediments that are basically excluded from the above, somewhat restrictive definition. In fact, metasediments can also host authigenic minerals with the difference that the fluids responsible for in situ mineral crystallization were activated by a remote tectonic or igneous activity. In a broad sense, authigenesis can last for millions of years and induce any mineral precipitation at a given time in a sedimentary or low-grade metamorphic environment (Fairbridge 1981). It is also to be kept in mind that discrete authigenic reactions are dependent on chemical (chemistry of interacting fluids, mineral reactivity, biological contribution) and physical (rock porosity, fluid temperature, water/rock ratio) conditions during mineral crystallization, and that they may determine economic impacts.

Where to Expect Authigenesis and of Which Minerals?

In Continental Aerial Environments

Authigenesis occurring during subaerial exposure of varied rock types to atmosphere results from weathering processes driven by rainwater infiltration or runoff. Precipitation of chemical elements removed from outcropping rocks by surface and subsurface fluids that are often acidic favors nearby or remote mineral precipitation that might clog up the pore system of the host rocks. Various types of authigenic clays have been reported during continental weathering (Wilson 1999; Velde and Meunier 2008), the removed elements also generating massive authigenic duricrusts typical for semiarid regions that may host authigenic hematite and goethite nodules (Ramanaidou et al. 1996). The nature of such crusts depends on the major constitutive elements: calcretes

consisting mainly of calcium are the most common; when iron is included they become ferricretes or silcretes when silica is most incorporated. The climate is naturally a determining driving force of these authigenic precipitations: humid climates accelerate weathering and even dissolution of the most fragile rock-constitutive minerals, and they favor elemental release as solutes into the associated fluids, whereas seasonal evaporation is needed to agglomerate the elements into crusts (Girard et al. 2002).

In Marine Environments

Oceans are the most favorable places for varied authigenic mineralization, in fact wherever local conditions are in chemical disequilibrium. About 30–40 years ago, glauconite authigenesis was very extensively studied (e.g., Odin 1988). Along the western African Coast, it resulted from deposition of continental ferrous smectite that was oxidized and supplied with potassium in situ to trend towards glauconite. Useful as stratigraphic markers, glauconite grains represent the classic example of clay authigenesis in oceans that was also described at other places such as the oceanic ridges with local advective supply of hydrothermal fluids. There, original authigenic nontronite (= Fe-smectite; Bailey 1980) can also be changed into glauconite by addition of potassium, sometimes together with Mn-oxides precipitating in the black smokers of spreading centers (e.g., Hess et al. 1991). Pacific deep-sea red clays also host authigenic minerals, such as phillipsite, a zeolite of sedimentary origin involving volcanic rocks (Honnorez 1978; Clauer 1982), as well as Fe-Mn crusts and nodules in the eastern Atlantic and southern Pacific oceans (e.g., Glasby et al. 2015). These nodules were once the topic of extensive exploration and even of deep-sea mining projects (e.g., Sharma 2015). Metal authigenesis was also described in present-day Red Sea deposits by direct metallic precipitation from overlying acidic brines and in situ crystallization of pyrite framboids (Fig. 1a; Pierret et al. 2000) and other metal-type minerals (e.g., Anschutz and Blanc 1995).

In Buried Sediments

After deposition, sediments are progressively buried, which modifies their physical and chemical characteristics, including those of their pore system. Temperature increases, pore space is reduced, and pore waters are expelled, all inducing new conditions altering the detrital mineral and organic components, which favors precipitation on site of new minerals. For instance, pyrite "balls" crystallized on site in "nests" built by detrital minerals of Triassic sandstones at 2000-m depth in the eastern Paris Basin, before some were wrapped by an authigenic illite veil of a later generation (Fig. 1b; Blaise et al. 2016). Their idiomorphic shape testifies for on-site formation, even if under conditions different than those of the Suakin Depth of the Red Sea (Fig. 1a).

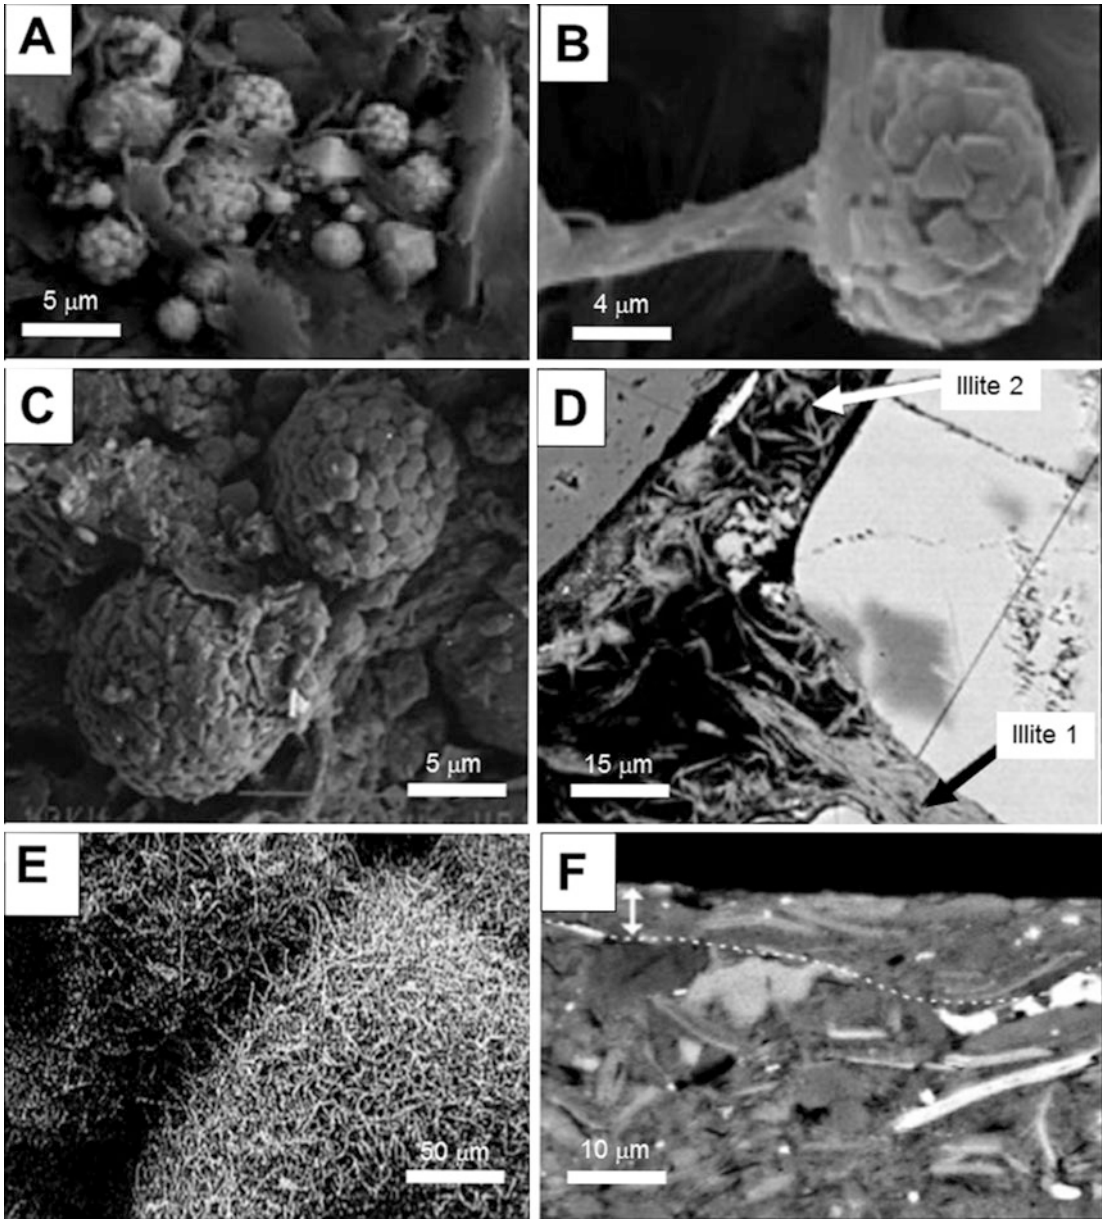
Paleocene Atlantic Ocean sediments drilled during the Deep Sea Drilling Project contain fuzzy, flake-like detrital smectite crystals that interacted with their pore system after deposition. Probably in thermodynamic disequilibrium with the initial depositional environment, the smectite particles were dissolved progressively and replaced in situ by diagenetic, lath-like authigenic crystals, surprisingly of the same smectite type (Clauer et al. 1990).

Combined with concomitant alteration of the initial detrital particles, authigenic processes can last for long times, especially when sediment burial is slow. Interestingly, the intensity of illite authigenesis differs in interlayered shaly and sandy units of a sedimentary sequence, partly because there is less pore fluid and a different chemistry, in the former than in the latter layers at similar depths (e.g., Clauer and Lerman 2012). Illite is an excellent tracer of hydrocarbon maturation in shaly source rocks and trapping in sandy or carbonate reservoirs, both buried at several thousands of meters (Pevear 1999). For instance, illite precipitated in situ at the same time in oil reservoirs located about 500 km apart in the North-Sea Viking Graben, of stratigraphically different sandstones buried at different depths (Clauer and Liewig 2013). Detailed observation may even show successive illite authigenic episodes in the same host rocks, the initial covering quartz grains as "palisades" and the second growing "fibers" into the pore space (Fig. 1c) that literally form a fiber "meadow" on detrital quartz grains (Fig. 1d).

Authigenesis of another clay is of importance for economical reasons, namely, that of kaolinite for the porcelain industry. Of course, kaolinite concentrations are not always authigenic, deriving also from continental weathering followed by river transport and deposition, or from hydrothermal cooling related to late magmatic events (e.g., Murray 1988). However, numerous studies in northwestern Spain have identified kaolinite authigenesis in sediments and plutonic basement rocks (Galán and Martín Vivaldi 1972). Authigenesis of uraninite has probably an even more important economical impact. Numerous studies of illite authigenesis in uranium-bearing Proterozoic sediments from Canada and Australia helped understanding of the combined precipitation of illite and uraninite. For instance, the description of successive episodes of hydrothermal illite authigenesis in the sedimentary cover and in main faults of the underlying basement allowed reconstruction of the evolution pattern of major uranium deposits of Australia (Clauer et al. 2015). Illite authigenesis was the signature of the major episodes of uranium concentration, whereas illite was lacking during episodes of minor uraninite recrystallization into coffinite.

In Volcanic Ash Beds

Volcanic ash layers sandwiched in sediment accumulations witness volcanic episodes. Those of the East Slovak Basin



Authigenesis, Fig. 1 (**a**) Authigenic pyrite framboids in a "nest" of detrital clay particles from a Triassic sandstone of the Paris Basin; (**b**) Authigenic pyrite framboid wrapped in a younger authigenic illite veil (both from Blaise et al. 2016); (**c**) Authigenic pyrite framboid from Suakin Depth of the Red Sea due to rain out from brines above (from Pierret et al. 2000); (**d**) Two authigenic illite generations grown in the pore system of an oil reservoir. Illite 1 grew as a "palisade" on quartz grains, while illite 2 fibers grew into the pore space (from Clauer and Lerman 2012); (**e**) Authigenic illite fibers grown into the pores between quartz grains. The black dot to the left top is the impact of a removed quartz grain, the pore spaces are the black holes to the lower left and upper right (unpublished, courtesy of J. Cocker, ARAMCO); (**f**) Side micro-picture of a fracture in a gouge with illite authigenesis: in the upper part between the void on the top and the dashed line, the authigenic illite fibers are thinner and more flexible than those of detrital origin below the dashed line (from Laurich et al. 2014)

showed that the original volcanic glass was altered progressively after deposition into an authigenic smectite (Kováč et al. 1997). Further addition of potassium by interstitial fluids from surrounding shales progressively modified this smectite into illite (Honty et al. 2004). In fact, illitization did not start at the same time in most of the regionally scattered bentonite beds and did not last the same time interval (Clauer et al. 2014a). The main driving force of illitization and probably of other authigenic processes is the changing chemical composition of the interacting fluid, coupled with the temperature increase resulting from progressive burial (Clauer et al. 2014b).

In Hydrothermal Environments

Authigenesis was also described in rocks percolated by hydrothermal fluids driven by close or remote tectonic activities. For instance, gouges represent plausible locations where illite authigenesis is expected in tectono-thermal contexts. These gouges are characterized by an intense grinding of their components but also by significant fluid flow. Recent ultra-fine observations of such gouge volumes have identified authigenic illite crystals as small as a few nanometers along shear zones representing favorable channels for circulation of the migrating fluids (Fig. 1e; Laurich et al. 2014).

Fluids flowing in gouges originated necessarily away from where their interactions are visible. This aspect becomes somewhat controversial in the case of illite authigenesis, as its precipitation is clearly contemporaneous with an identified tectonic activity (for instance in case of rifting) but located sometimes far from this activity. In Triassic sandstones from Paris Basin, illite authigenic crystals provided similar to identical isotopic ages at varied places in the basin (Blaise et al. 2016) despite widely dispersed locations, sometimes within faults. The fact that illitization was contemporaneous with major adjustments of the basement connects the authigenesis process to fluids released by tectono-thermal events from within or outside the basin. This connection is again of economic importance as the described illite authigenesis also relates to varied authigenic metal deposits next to the outcropping plutonic basement in the center of the Paris Basin and on its western side (Cathelineau et al. 2012).

Authigenesis at Crystal Scale

Mineralogical, crystallographic, chemical, and isotopic studies of authigenic illite from bentonite beds of the East Slovak Basin were privileged for a time, because the lack of detrital crystals in these rocks ensures that the observation and analysis of illite is not hindered or obscured. Studies of separated nanometer-sized illite crystals (<0.02 μm) defined an authigenic process with nucleation and crystal growth (e.g., Środoń et al. 1992; Eberl et al. 1998). Illitization was described as successive pulses of variable duration in the entire basin, with changing intensities at similar temperatures (Clauer et al. 2014a).

Summary: "Authigenesis" Needs to be Precisely Defined for Any Use

In the previous entry of authigenesis in this Encyclopedia of Geochemistry, Fairbridge (1999) questioned *sensu stricto* mineral authigenesis when interacting with "deep burial interstitial fluids that reflect more or less remote source rocks from which they have been expelled." There is nothing to argue about this statement except that it incites thinking that in situ minerals crystallized from remote fluids are not authigenic. This conceptual discrimination may raise debates that can be avoided by defining precisely the meaning of the somewhat ambivalent authigenic wording because of its potential wide applicability.

In summary, authigenesis is a discrete, often long-lasting process that favors new mineral crystallization on site, by involving the associated detrital minerals, especially those altered by the interacting fluids that can be local or derived from distance. And last but not least, mineral authigenesis can have very important economical consequences, especially if it involves metals and/or hydrocarbons.

Barium

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Element Data
Atomic Symbol: Ba
Atomic Number: 56
Atomic Weight: 132.9054 g/mol
Isotopes and Abundances: ^{130}Ba 0.11%, ^{132}Ba 0.10%, ^{134}Ba 2.42%, ^{135}Ba 6.59%, ^{136}Ba 7.85%, ^{137}Ba 11.23%, ^{138}Ba 71.70%
1 Atm Melting Point: 727 °C
1 Atm Boiling Point: 1845 °C
Common Valences: 2+
Ionic Radii: 149 pm (6-fold)
Pauling Electronegativity: 0.89
First Ionization Energy: 502.9 kJ/mol
Chondritic (CI) Abundance: 2.42 ppm
Silicate Earth Abundance: 6.6 ppm
Crustal Abundance: 390 ppm
Seawater Abundance: 30 to 150 nmol/kg
Core Abundance: ~0

Properties

Barium derived its English name from the Greek *barys*, meaning heavy. It is the heaviest stable alkaline earth and unusually abundant for an element with such a high atomic number. Barium, Pb, and Te are the only elements heavier than Zr (atomic number 40) with CI chondritic abundances greater than 2 ppm (Palme (in press), ▶ "Cosmic Elemental Abundances," this volume). This is due in large part to the unusual abundance of ^{138}Ba, which has a magic number of neutrons (82). In pure form, Ba is a silvery, slightly golden metal, but, as is the case with other alkaline earths, it tarnishes quickly upon exposure to the atmosphere.

History and Use

German-Swedish chemist Carl Scheele first recognized that barite (barium sulfate) contained an unrecognized chemical element in 1774. Barium was subsequently isolated and named by English chemist Humphry Davy in 1808.

The uses of barium are quite limited. In the late nineteenth and early twentieth century, it was used to produce oxygen in the Brin process. At present, the most common use of barium, in the form of barium sulfate, is as a component of drilling fluids ("mud") in the petroleum and natural gas industry to increase fluid density. Because of its insolubility, low toxicity, and strong X-ray absorption, barium sulfate is also used as a radiocontrast agent in medical X-ray gastrointestinal procedures. Barium has more limited uses in paints, plastics, alloys, glasses and optics, fireworks and flares, and fluorescent lamps. Barite ($BaSO_4$) is the principal source of industrial barium.

Geochemical Behavior

Barium is a refractory element with a 50% nebular condensation temperature of 1455 K. It is also a lithophile element and consequently its abundance in the silicate Earth relative to other such elements should be the same as in chondritic meteorites. As a consequence of its large ionic radius, it is a highly incompatible element and one of the large ion lithophile elements that cannot be readily accommodated in most igneous minerals. Biotite, alkali feldspar, and apatite are principal exceptions and the principal hosts of Ba in granitic rocks. As a result, Ba is strongly concentrated in the Earth's continental crust relative to the mantle. Barium is also a

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

relatively fluid-mobile element and abundances in igneous rocks are readily disturbed by weathering and metamorphism. High concentrations of Ba relative to fluid-immobile incompatible elements such as Th and La in subduction-related magmas provide evidence of the role fluids as well as subducted sediments in such magmatism (Kay 1980; Plank (2016), ▶ "Subduction Zone Geochemistry," this volume).

Barite is a common but minor component of many sedimentary rocks and hydrothermal deposits. Witherite ($BaCO_3$) is a rare mineral associated with low temperature hydrothermal deposits. Benitoite ($BaTiSi_3O_9$) is a very rare mineral occurring in association with blueschist facies metamorphic rocks.

In the oceans, Ba is present as the Ba^{2+} ion and has a nutrient-like distribution with low concentrations (35–45 nM) in surface waters and higher concentrations (~100–200 nM) in deep water, and an average concentration of 110 nM (Chan et al. 1976, 1977; DeBaar et al. (in press), ▶ "Ocean Biochemical Cycling and Trace Elements," this volume). However, Ba is not bioutilized nor does it appear to be taken up by phytoplankton. Rather it appears that Ba is precipitated as barite in microenvironments associated with decaying organic matter and opal in surface waters, despite general undersaturation (Bishop 1988; McManus et al. 1998). Absorption on particulate matter may also contribute to Ba removal in surface waters. Barium is then partially remobilized in deep water. As is true for nutrients, this results in Pacific and Indian deep waters, which are relatively old, being richer in Ba than the young deep waters of the Atlantic Ocean. While Ba is cycled internally in the ocean, its residence time is long, ~10,000 years (Chan et al. 1976), compared to bioutilized elements, although much shorter than conservative elements.

Despite partial redissolution in deep water, barite is a common component of marine sediments. Marine sediment Ba concentrations vary from several hundred ppm to over 2500 ppm and are highest beneath regions of high biological productivity. Dymond et al. (1992) suggested Ba in sediments might make a useful proxy for paleoproductivity; however, McManus et al. (1998) showed that under suboxic diagenetic conditions, which are common where biological productivity is high, Ba can be mobilized and diffuse out of sediments. Ba/Ca ratios in corals have been used to reconstruct changes in the upwelling of nutrient-rich deep waters and coastal waters (e.g., Lea et al. 1989; LaVigne et al. 2016).

Barium Isotopes

^{138}Ba is produced by radioactive decay of ^{138}La, but the fraction of radiogenic ^{138}Ba is almost always trivial as a consequence of very high $^{138}Ba/^{138}La$ ratio in terrestrial and meteoric materials and the long half-life of ^{138}La (~10^{11} years). Thus, there have been very few studies of this decay system, with the focus instead on Ce isotopes as ^{138}Ce is also produced by ^{138}La decay. Andreasen and Sharma (2007) and Carlson found that carbonaceous chondrites are slightly enriched in r-process (rapid neutron capture) nuclides ^{135}Ba and ^{137}Ba produced in supernovae compared to the Ba in ordinary chondrites and terrestrial materials. Moynier et al. (2015) found small mass-dependent fractionations among chondrite components, but found that all whole-rock terrestrial igneous and meteorite samples were isotopically identical within 50 ppm per atomic mass unit. More recently, Seibert and Munker (2017) reported small but significant variations in $\delta^{134/137}Ba$ in subduction-related volcanics.

Several studies have found significant mass-dependent fractionation of Ba isotopes in seawater, with $\delta^{138/134}Ba$ in deep waters 0.3–0.4‰ lower than surface waters (Horner et al. 2015; Hsieh and Henderson 2017) as a consequence of preferential incorporation of absorption of light isotopes on particulates in surface waters. This process maintains seawater $\delta^{138/134}Ba$ that is several tenths of per mil heavier than river water (Cao et al. 2016; Hsieh and Henderson 2017).

Biological Utilization and Toxicity

Barium has no known biological function and is toxic; ingestion or exposure can lead to a large number of adverse health effects including serious adverse neurological, cardiovascular, and gastrointestinal effects. Toxicity likely results from its biochemical similarity to potassium and consequent interference with potassium ion regulation. The no-observed-adverse-effect level (NOAEL) in humans is estimated to be 0.21 mg barium/kg body weight per day (Choudhury and Cary 2001). Because of its insolubility, barite represents a lesser hazard than other forms of Ba.

Summary

Society has found only limited uses for Ba, but it has proved quite useful to geochemists in understanding a range of phenomena including subduction zone volcanism and ocean circulation. The limited studies of Ba isotopes to date suggest that they have potential as a tracer of the carbon cycle and ocean in both modern and ancient oceans.

Core Abundance: ~0
(Earthref.org 2016; McDonough 2004; Palme et al. 2014)

Properties

Beryllium, the lowest atomic number alkaline earth element, is a steel-gray, brittle, lightweight metal. It is most commonly encountered in a small number of silicate and oxide minerals and occurs as a low abundance, lithophile trace element in most geologic systems.

History and Use

Beryllium was discovered by Louis-Nicolas Vauquelin in 1798 in the oxide form via extraction from emerald and beryl. In 1828, Friedrich Wohler and Antoine Bussy independently isolated Be metal via reaction between potassium and $BeCl_2$. As a low density, high-strength metal, Be is commonly used in metal alloys, in particular in beryllium copper, which is used in non-sparking tools, golf clubs, springs, as well as in a range of structural applications in aircraft, spacecraft, and satellites. It is transparent to X-rays and as such is used as X-ray window material in analytical instruments such as electron microprobes. Its small thermal neutron capture cross-section makes it useful as a moderator in nuclear reactors (Trujillo et al. 2011).

Geochemical Behavior

Beryllium abundances in the solar system and in meteorites are low, consistent with its origins as an element that was not formed during the Big Bang, and is destroyed by nucleosynthetic processes in the interiors of stars. Beryllium forms only via late-stage cosmic ray spallation reactions in the interstellar medium (Stegman and Walker 1992; Shearer 2002). During nebular condensation, Be is incorporated into early, Ca-Al rich phases as a refractory trace element (Lauretta and Lodders 1997). In terms of its geochemical behavior, Be shows systematics less like those of alkaline earth elements and more like that of Al (Grew 2002). In aqueous systems, Be is consistently low in abundance, albeit with some variation: Be abundances in ridgecrest hydrothermal fluids are enriched by a factor of 10^3 over seawater (0.09–0.8 ng/g vs. 0.2 pg/g Be; Measures and Edmond 1982), though even enriched hydrothermal solutions are 10^3 times lower in Be than terrestrial rocks.

Be abundances in mid-ocean ridge basalts (MORBs) and basalts from volcanic arcs range from 0.1 to 1.0 ppm; basalts from intraplate settings are an order of magnitude higher in Be, ranging from 0.8 to >10 ppm (Ryan and Langmuir 1988; Ryan 2002; Ryan and Kyle 2004). Differentiated arc lavas, marine sediments, and crustal rocks range from 1 to 3 ppm Be (Ryan 2002), consistent with recent estimates for Be in the continental crust (e.g., Rudnick and Gao 2014). During magmatic and hydrothermal processes, Be shows strong similarities in its mineral/melt distribution patterns to neodymium, with an inferred partition coefficient, D_{Be}, between 0.03 and 0.06 for basaltic melting and crystallization; however, in terms of ionic radius, Be^{2+} is closest to Al^{3+} and appears to substitute for Al in crystal lattices. D_{Be} is ≈0.3 for plagioclase, 0.05 for pyroxene, and <0.003 for olivine in basalts, while in more siliceous magmas D_{Be} approaches 1.0 for all phases (Monaghan et al. 1988; Brenan et al. 1998; Ryan 2002). The most economically significant beryllium mineral is beryl ($Be_3Al_2[Si_6O_{18}]$), which is found commonly in pegmatites and less frequently in metamorphic associations. Emerald, aquamarine, and morganite are, respectively, deep green, pale blue–green, and pink gem varieties of beryl. Other beryllium minerals of note are chrysoberyl ($BeA1_2O_4$), bertrandite ($Be_4Si_2O_7(OH)_2$), and phenakite (Be_2SiO_4) (Grew 2002).

Isotopic Systematics

Beryllium has only one stable isotope, ^{9}Be. However, the cosmogenic radionuclides ^{10}Be and ^{7}Be have become important as tracers for a wide variety of geologic, environmental, and cosmochemical processes. Variations in atmospherically produced ^{10}Be, which is concentrated in sediments at the Earth's surface, have been used to study marine sedimentary processes (i.e., the dating of sediments and studies of sedimentary rates or rates of growth for marine Mn nodules); soil development and erosion; and climate change, while ^{7}Be is used to trace short-term (<1 year duration) processes at the Earth's surface (Bierman et al. 2002; Morris et al. 2002; Kaste et al. 2002). In situ ^{10}Be production and decay rates have been used to estimate weathering rates on bare rock surfaces, as well as to estimate cosmic ray exposure ages (and thereby solar system travel times) for silicate meteorites (Morris et al. 2002). Significant ^{10}Be abundances have also been observed in fresh, zero-age lavas from several volcanic arcs and are believed to reflect chemical inputs to arc source regions from subducted marine sediments (Tera et al. 1986).

Biological Utilization and Toxicity

Beryllium compounds are generally toxic to humans. Inhalation of Be or its compounds can lead to chronic beryllium disease, a debilitating lung disorder, with no minimum "safe" level for exposure (Taylor et al. 2003).

Beryllium Isotopes

Paul R. Bierman[1] and Eric W. Portenga[2]

[1]Department of Geology, University of Vermont, Burlington, VT, USA

[2]Department of Geography and Geology, Eastern Michigan University, Ypsilanti, MI, USA

Definition

Beryllium (atomic number 4) has twelve isotopes, but only three are routinely measured: ^{7}Be, ^{9}Be, and ^{10}Be. ^{9}Be is a stable isotope that is found naturally in geological materials typically at $\mu g\ g^{-1}$ levels and is considered in the ▶ Beryllium chapter. ^{7}Be is a short-lived radionuclide ($t_{1/2} = 53$ days) and ^{10}Be is a long-lived radionuclide ($t_{1/2} = 1.38$ Myr) produced both in the atmosphere and in earth materials by cosmic-ray interactions. ^{10}Be produced in the atmosphere is termed "meteoric" ($^{10}Be_m$), whereas *in situ* ^{10}Be ($^{10}Be_i$) is produced within geological materials primarily within the uppermost few meters of Earth's surface (Lal 1988). Although both ^{7}Be and ^{10}Be have been used in geological, geomorphological, and geographical studies, we focus here on ^{10}Be. We consider both $^{10}Be_i$ and $^{10}Be_m$; $^{10}Be_i$ has been used to solve many more problems in Earth Science than $^{10}Be_m$, and our review reflects this.

^{7}Be Production, Delivery, and Analysis

^{7}Be is produced in the atmosphere by spallation reactions and delivered to Earth's surface with precipitation and as dry fallout. It is particle-reactive and thus sorbed to particle surfaces and incorporated in grain coatings which are stable at neutral and basic pH. As a result, ^{7}Be is often used to monitor very short-term sediment transport down hillslopes and in drainage networks (Wallbrink and Murray 1993) and as a tracer of air movement in the atmosphere and water movement in the oceans. ^{7}Be is usually measured by decay counting, but recently it has been measured by accelerator mass spectrometry (AMS). Because of ^{7}Be's very short half-life in comparison to ^{10}Be, it is of limited utility in studying all but the shortest near-surface processes and thus not

considered further in this review. We refer the reader to other papers for more information on ^{7}Be (e.g., Kaste et al. 2002; Landis et al. 2012).

^{10}Be Production and/or Delivery

Primary cosmic rays, mostly protons, enter Earth's atmosphere where many are deflected by Earth's magnetosphere. Protons that penetrate the atmosphere interact with atmospheric gases by spallation reactions, producing a variety of cosmogenic nuclides (e.g., ^{14}C, ^{7}Be, ^{10}Be$_{m}$) as well as a cascade of secondary neutrons that attenuate with increasing atmospheric depth and interact with rock and sediment at Earth's surface (Lal and Peters 1967); as a result, the production of ^{10}Be$_{i}$ at Earth's surface varies with latitude and elevation (Lal 1988). Production rates of ^{10}Be$_{i}$ have been estimated using both models and empirical measurements made in surfaces of otherwise known age (Borchers et al. 2016). These rates are scaled to different latitudes and elevations using a variety of schemes, both model-based and empirical (e.g., Lal 1991; Stone 2000). The delivery rate of ^{10}Be$_{m}$ depends on atmospheric production, mixing, rainout by precipitation, and dry fallout (Graly et al. 2011; Heikkilä et al. 2008) and has been estimated by measurements of samples from otherwise dated surfaces (Reusser et al. 2010).

^{10}Be$_{i}$ production decreases with depth in earth surface materials according to the material density and the attenuation length of cosmic ray neutrons (160 g cm^{-2}; Gosse and Phillips 2001); the only nuclide production at depths greater than a few meters is by muons which have many times longer attenuation lengths than neutrons and induce little nuclide production relative to spallogenic production of ^{10}Be$_{i}$ (Heisinger et al. 1997). ^{10}Be$_{i}$ accumulates in rock and soil on landscapes, and nuclide production is eventually balanced by nuclide loss due both to radioactive decay and surface erosion.

Sample Selection, Preparation, and Measurement

The near-ubiquity of the mineral quartz (SiO_2) in rocks at Earth's surface, its simple chemical formula, and its resistance to physical and chemical weathering make it an ideal mineral from which ^{10}Be$_{i}$ can be isolated and measured. Weak acid etches and sometimes heavy-liquid density separations remove carbonate and nonquartz minerals so as to isolate and purify quartz (Kohl and Nishiizumi 1992), which is dissolved in HF after ^{9}Be-carrier solution is added. Anion- and cation-exchange column chemistry isolates beryllium from solution (Corbett et al. 2016). ^{10}Be$_{m}$ can be removed from any substrate using either acid leaching or total fusion (Barg et al. 1997; Stone 1998).

AMS is required for ^{10}Be measurements because it can reliably separate the common isobar, ^{10}B. ^{10}Be/^{9}Be ratios of process blanks (e.g., only ^{9}Be-carrier) are measured and used for background correction. All ratio measurements are normalized to standard materials with consensus ^{10}Be/^{9}Be ratios; the nominal ratios of standards have changed over time in part because of changes in the accepted half-life of ^{10}Be (Nishiizumi et al. 2007); thus, most ^{10}Be data published prior to 2008 require recalculation. It is assumed that purified quartz contains no ^{9}Be; however, some samples include naturally occurring ^{9}Be which must be quantified or calculations will be inaccurate (Portenga et al. 2015).

Applications of In Situ ^{10}Be

Exposure Dating

The concentration of ^{10}Be$_{i}$ in rock and sediment exposed at Earth's surface can be used to calculate a duration of rock exposure – an exposure age – if the following assumptions are met: (1) the surface has not eroded since initial exposure, (2) the surface has not been buried after initial exposure, and (3) the exposed surface did not inherit any ^{10}Be$_{i}$ from one or more prior periods of exposure. Exposure ages are useful because they allow dating of landforms which cannot be dated by other means; primarily, exposure ages have been measured on boulders to date ice cap, ice sheet, and alpine glacial moraines around the world. Interpretation of boulder ages as the age of the underlying moraine is not always straightforward because both the boulders and the moraines on which they sit erode, lowering measured exposure ages. Alternatively, boulders can carry ^{10}Be$_{i}$ from prior periods of exposure; in this case, calculated exposure ages can overestimate the age of the landform (Briner et al. 2016; Heyman et al. 2011).

Paleoseismic studies have benefited from ^{10}Be$_{i}$ measurements. Fault scarps have been directly dated and the dates used to calculate rates of offset (Bierman et al. 2014). Numerical ages of offset surfaces have been determined using ^{10}Be$_{i}$ and those surfaces then used as strain gauges (Matmon et al. 2005). Rock falls likely related to paleo-earthquakes have been dated (Rinat et al. 2014) as have precariously balanced rocks which, through the application of numerical models, have been used to constrain maximum prior ground motion (Balco et al. 2011).

Terraces, both riverine and coastal, have been dated with ^{10}Be$_{i}$ using several different approaches. For bedrock strath terraces, outcrops can be dated directly (Reusser et al. 2006) and incision rates calculated. For alluvial terraces, depth

profiles can be measured and the inherited $^{10}Be_i$ estimated from samples collected at depth (Anderson et al. 1996).

Erosion Rate Estimates

If a rock outcrop surface has experienced constant erosion as it is exhumed through the uppermost few meters of Earth's surface, the production of ^{10}Be in that rock is balanced by nuclide loss through radioactive decay and erosion (Lal 1991). Thus, the rate of rock erosion can be deduced from the measured $^{10}Be_i$ concentrations, which are inversely proportional to erosion rate. Important assumptions inherent in this method are that (1) the erosion rate is constant in time, (2) the rock surface from which a sample is collected has a simple exposure history and has not been episodically buried for any significant amount of time prior to sample collection, and (3) erosion is by granular disintegration of the rock surface and not by removal of decimeter-scale rinds or slabs. Measuring $^{10}Be_i$ in outcrop samples gives erosion rates for points on a landscape and may not be representative of regional landscape erosion. Landscape-wide erosion rates have been derived by measuring $^{10}Be_i$ in sand collected from stream channels, a technique that assumes that the $^{10}Be_i$ in river sand is representative of $^{10}Be_i$ eroded from all quartz-bearing lithologies upstream of the sample collection site (Brown et al. 1995).

The bedrock and fluvial sediment techniques of measuring erosion rates have been used to assess landscape dynamics in a variety of landscapes around the world (Portenga and Bierman 2011). For example, $^{10}Be_i$ erosion rates have been used to assess landscape stability and relief generation (Bierman et al. 2014), infer uplift along tectonic, climate, and vegetation gradients (e.g., Olen et al. 2016), to understand passive margin escarpment retreat (Vanacker et al. 2007), and to assess the impact of human land use on landscapes (Portenga et al. 2016; Reusser et al. 2015).

Techniques have been devised to measure paleo-erosion rates of river catchments (Schaller et al. 2004). Deriving paleo-erosion rates relies on knowing the burial age of sediment from which quartz is extracted and the accumulation rate of sediment overlying any given sample. With this knowledge, the amount of $^{10}Be_i$ lost to radioactive decay can be determined as well as the amount of $^{10}Be_i$ produced during sample burial.

Landscape History and Sediment Tracing

$^{10}Be_i$ can also be used to infer landscape histories and to trace the movement of sediment across Earth's surface and the source of such sediment. In Greenland, Nelson et al. (2014) measured $^{10}Be_i$ in both glacial and fluvial sediment and used the measured concentrations to suggest that most of the sediment shed from Greenland today originated from under the ice sheet and not from deglaciated areas outside the ice margin. Bierman et al. (2016) used Nelson et al.'s results in conjunction with $^{10}Be_i$ measurements in quartz isolated from 7.5 Myr of marine sediment off the coast of Greenland to demonstrate a long history of erosion and ice cover on the continent. Perg et al. (2003) used $^{10}Be_i$ concentrations to identify the source of sediment in the littoral zone along California's Pacific coast, whereas Nichols et al. (2007) did the same in the Mojave Desert working out a sediment budgets for an arid region sediment system and thereby calculating sediment residence times (many kyr) and virtual sediment velocity (dm/yr) down desert piedmonts.

In many landscapes, erosion rates calculated from the measured concentration of $^{10}Be_i$ in river sediment are compared to the present-day rate of sediment export from watersheds to assess the impact of human land use. Such comparisons often show contemporary rates of sediment yield exceed long-term rates of sediment generation (Hewawasam et al. 2003) although there are situations where contemporary sediment yield is lower than long-term rates (Kirchner et al. 2001) likely because infrequent but large-magnitude sediment transport events are missing from the contemporary record.

By sampling rock and saprolite below soil cover, $^{10}Be_i$ has been used to estimate soil production functions – the rate at which rock weathers to soil parent material under different thicknesses of regolith. Such functions have been defined so far in North America and Australia and typically show the highest soil production rates at intermediate depths of regolith cover (Heimsath et al. 2009).

Applications of Meteoric ^{10}Be

$^{10}Be_m$ is typically present in concentrations orders of magnitude higher than the concentration of $^{10}Be_i$ and was thus measured more frequently during the early years of AMS. Initial applications of $^{10}Be_m$ were focused on estimating erosion rates and ages of soils (Pavich et al. 1984). Soon, improvements in AMS detection limits and questions about the retention of $^{10}Be_m$ in soils (Monaghan et al. 1983) slowed the pace of $^{10}Be_m$ research. Since 2010, $^{10}Be_m$ has undergone a renaissance, with numerous different applications.

$^{10}Be_m$ has been used to estimate the rate at which fine-grained soil moves down hillslopes. McKean et al. (1993) developed the first interpretive model that allowed $^{10}Be_m$ measured in hillslope soils to be interpreted as a sediment transport rate. His work in California was followed by similar sampling and analysis in the eastern United States which examined slope-aspect dependence of sediment transport and production in Pennsylvania (West et al. 2013) as well as comparing $^{10}Be_m$ to $^{10}Be_i$ in soils of the southern Appalachian Mountains (Jungers et al. 2009).

In the absence of quartz-bearing lithologies, some suggest that landscape dynamics may be assessed by normalizing measured concentrations of $^{10}Be_m$ to that of the reactive phase of ^{9}Be, both of which are adhered to the surfaces of sediment grains in streams (von Blackenburg et al. 2012). This technique requires representative concentration estimates of $^{10}Be_m$ in sediment grain coatings, ^{9}Be in parent bedrock sources, ^{9}Be weathered from minerals and adhered to sediment grain coatings, and ^{9}Be weathered from minerals and dissolved in stream water. Making such estimates is not trivial and may require many measurements collected over the course of many years. The ratio of $^{10}Be_m$ to ^{9}Be dissolved in sea water has been used as a proxy for terrigenous mass fluxes to global oceans (von Blackenburg and Bouchez 2014). Data from these studies suggest that late-Cenozoic global climate change has not significantly altered the magnitude of continental weathering processes on a global scale.

Human impacts on landscapes have been examined using $^{10}Be_m$. Brown et al. (1988) used $^{10}Be_m$ measurements in fluvial sediment to develop a mass and isotope balance approach, termed the erosion index, to understand land-use impacts in the eastern North America at the watershed scale. More recently, Reusser and Bierman (2010) used $^{10}Be_m$ as a sediment tracer to show downstream dilution of sediment released from a mega-landslide exacerbated by deforestation, and Portenga et al. (2017) paired measurements of $^{10}Be_m$ with bulk sediment luminescence to identify sediment sources and trace sediment transport in a gully-affected landscape.

$^{10}Be_m$ has been used at the plate tectonic scale to understand better the source and timescale of melt generation and igneous rock formation in subduction zones and to show that sediment can be subducted to mantle depths. Down-going oceanic slabs are covered with a mantle of marine sediment rich in $^{10}Be_m$. This hydrous material either melts or releases $^{10}Be_m$ in solution such that it enters magma. If transit times are short enough (less than several ^{10}Be half-lives), ^{10}Be can be measured in rock samples collected at Earth's surface (Morris et al. 2002).

Summary and Conclusions

Advances in ^{10}Be isotope extraction, analysis, and data interpretation over the last three decades have allowed Earth Scientists to study the processes that shape Earth's surface over hundreds to tens of thousands of years. Few other geological techniques operate over centennial-millennial timescales; thus, ^{10}Be bridges the knowledge gap between periods of historical observation and geological timescales. The examples of ^{10}Be applications in Earth Sciences presented above are by no means a comprehensive summary of the literature. What these examples do illustrate, however, is the wide variety of questions and topics that can be addressed with ^{10}Be. In time, this broadening of applications and consideration of new and different approaches beyond simple exposure ages, and erosion rates will allow an even greater understanding of the Earth system.

Biogenic Methane

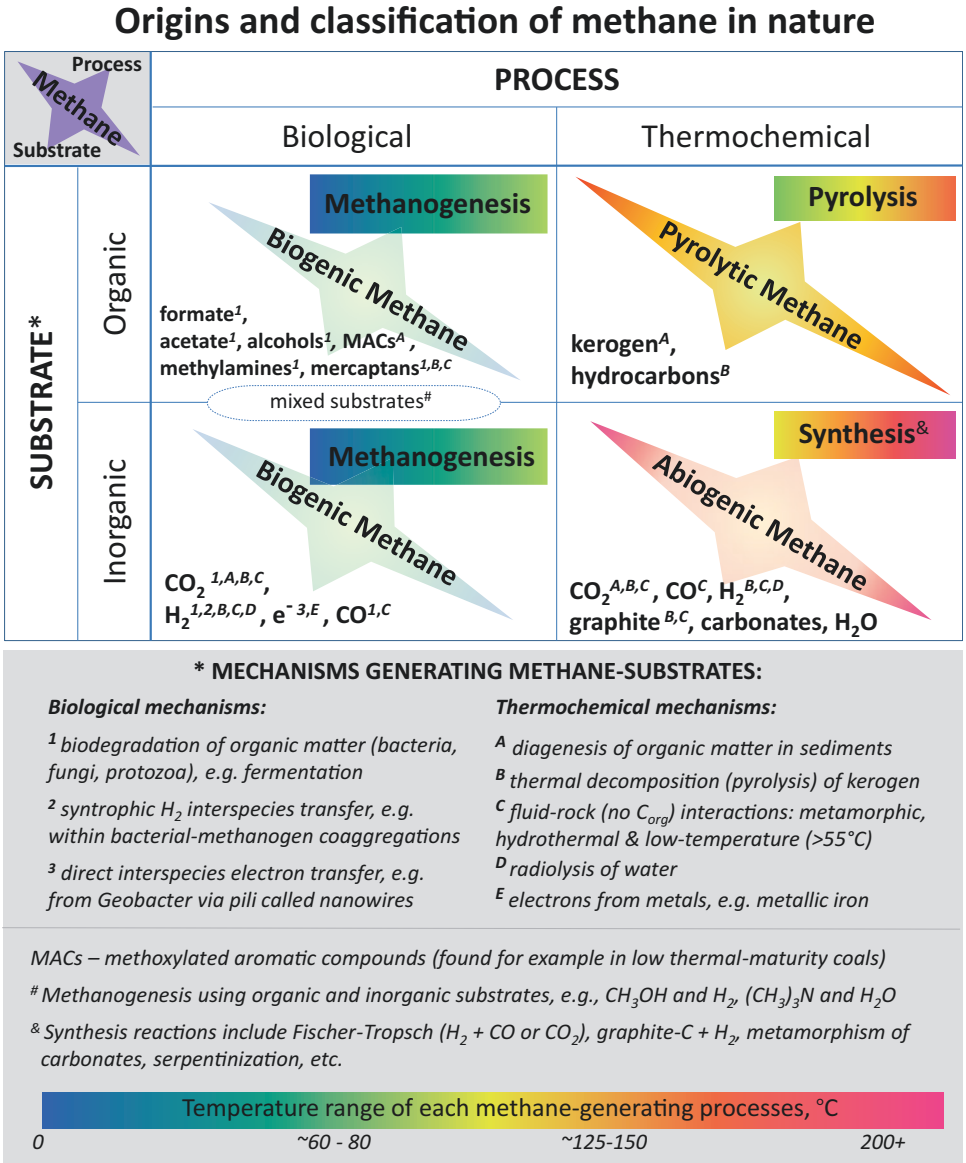
Dariusz Strąpoć
Geoservices, Schlumberger, Roissy, France

Definition

Biogenic methane is generated via a process called microbial methanogenesis, which is uniquely performed by methanogenic Archaea, the methanogens, namely several subbranches of Euryarchaeota on the 16S rRNA-based phylogenetic tree of life, i.e., *Methanomicrobiales, Methanosarcinales, Methanococcales, and Methanobacteriales* (Pace 2009). Microbial methanogenesis is the main terminal process of subsurface anaerobic organic-matter biodegradation (Head et al. 2003). Therefore, methanogenesis is important in the global carbon cycle, contributing to the terminal mineralization of organic matter. Figure 1 provides a summary of processes (biological and thermochemical) and substrates (organic and inorganic) for methane generation in nature and clarifies associated terminology. Accepted synonyms: microbial methane.

Methanogenic Pathways

The predominant biogenic methane generation pathways are CO_2-reducing and acetoclastic methanogenesis. Some environmental conditions, such as variations in salinity and pH or substrate specificity, can promote other methanogenic



Biogenic Methane, Fig. 1 Classification and proposed nomenclature of methane according to its process of origin (X-axis) and directly utilized substrates (Y-axis; schematic explanation in the upper left corner field). The grey box below the diagram explains (i) origins of substrates for methanogenesis (1–2 and A–C), (ii) other subscripts, and (iii) temperature range used as the *color bar* behind each of the three processes (methanogenesis, pyrolysis, and synthesis). Despite small overlaps, all three processes have characteristic temperature ranges. Note that biogenic methane can be generated from inorganic substrates produced by thermal mechanisms and, conversely, methane can be also produced thermally from biologically formed substrates (pyrolytic methane). The term "thermogenic methane" has been replaced by "pyrolytic methane." The latter term both points to a thermal origin and refers to the substrate of organic carbon. Additionally, the pyrolysis or cracking process (thermal breakdown of larger organic molecules) is, in essence, directly opposite to synthesis, another thermochemical process, which forms abiogenic methane (the lower right field)

pathways, including methanol-utilizing pathway (Strąpoć et al. 2010a). In CO_2-reduction methanogenesis, the reaction $CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$ provides energy. This pathway utilizes: (i) Ni/Fe-containing hydrogenases (Thauer et al. 2010) coupled with coenzyme F_{420} (Mills et al. 2013) and (ii) sulfide- or heterosulfide-bound coenzymes CoB and CoM (for schematic illustration of all major methanogenic pathways and involved enzymes see Fig. 1 in Borrel et al. 2013). In acetoclastic methanogenesis, methanogens split and disproportionate an acetate molecule into one methane and one carbon-dioxide molecule ($CH_3COOH \rightarrow CH_4 + CO_2$). Methanol-utilizing methanogenesis can proceed via two reactions: $4CH_3OH \rightarrow 3CH_4 + CO_2 + 2H_2O$ or $CH_3OH + H_2 \rightarrow CH_4 + H_2O$.

Laboratory geochemical studies have also reported the ability of methanogens to utilize a wider variety of substrates, typically containing methyl groups (e.g., methylsulfides or methylamines), formate, and alcohols other than methanol. See Table 1 in Whitman et al. (2006) for a list of methanogenic reactions with standard free energies. Some methanogens can also convert carbon monoxide (CO) to methane (e.g., *Methonosarcina acetivorans* Moran et al. 2008). Although some methanogens are universalists and able to utilize a wide variety of substrates [e.g., *Methanosarcina barkeri* can use CO_2/H_2, acetate, methanol, methylamines (Hutten et al. 1980)], others are specialists limited to one substrate, e.g., acetate (*Methanosaeta*), methanol (*Methanolobus* or extremothermophilic *Methanopyrus*), or two substrates, e.g., CO_2 or formate (*Methanocospusculum*). Further advancements in understanding microbial methanogenesis have been enhanced by full genome sequencing, e.g., of an obligate methylotroph *Methanococcoides methylutens* (Guan et al. 2014) and studies on functional genomics (Lupa 2010). Comprehensive textbook resources include Ferry's (1993) *Methanogenesis: Ecology, Physiology, Biochemistry & Genetic*s and Whitman et al.'s (2006) *Prokaryotes*.

Additionally, Mayumi et al. (2016) recently discovered that methoxylated aromatic compounds (e.g., methoxybenzenes and -benzoates) can be used as a sole substrate by a methanol-/methylamines-utilizing *Methermicoccus shengliesis*. This means that methanogens can directly and independently of bacterial consortia utilize methoxy groups attached to aromatic rings within a kerogen structure, e.g., of low thermal-maturity coals. This implies that other relatively reactive moieties (not only methoxy groups) containing N, O, and S heteroatoms attached to kerogen structure could possibly serve as direct methanogenic substrates.

In most ecological niches abundant in organic carbon, methanogenic substrates are generated by organic-matter-degrading anaerobic or facultative bacteria, e.g., fermenters, within specific microbial consortia. Fermentative bacteria and methanogens often form syntrophic partnerships, in which methanogenic removal of bacterial by-products maintains thermodynamically favorable reactions or prevents fouling of the system. A classic example is the H_2 interspecies transfer between propionate-oxidizing *Pelotomaculum thermopropionicum* and CO_2-reducing *Methanothermobacter thermoautotrophicus* (Ishii et al. 2005) within cellular coaggregations. In guts of termites and other arthropods, H_2 for methanogens is symbiotically provided by anaerobic protozoa (i.e., ciliates) that possess H_2-producing organelles – hydrogenosomes (Wrede et al. 2012). Anaerobic H_2-producing representatives of another Kingdom of Eukaryotes, Fungi, also form syntrophic relationships with methanogens, e.g., in rumens of herbivores (Bauchop and Mountfort 1981) or within shallow coal beds (Guo et al. 2017).

Syntrophic bacteria can also donate electrons directly to the methanogens via interspecies extracellular electron transfer using pili termed nanowires, e.g., from ethanol-metabolizing *Geobacter metallireducens* assisting *Methanosaeta* or *Methanosarcina harudinacea* with CO_2-reduction ($8H^+ + 8e^- + CO_2 \rightarrow CH_4 + 2H_2O$) (Rotaru et al. 2014; Kouzuma et al. 2015). In turn, the *Geobacter* requires the by-products of its ethanol metabolism (electrons and acetate) to be harvested and converted to methane by the methanogen partner. The high efficiency of microbial conversion of electrical current to methane could be utilized as temporary energy storage (Cheng et al. 2009). Electromethanogenesis (or bioelectrosynthesis if molecules other than methane are synthesized by a microbe, e.g., formate by *Methanococcus maripaludis*) can be associated with metal corrosion (Deutzmann et al. 2015) and is often observed in petroleum facilities (Uchiyama et al. 2010).

Methanogenic substrates may also originate from inorganic processes, e.g., CO_2 from thermolysis of carbonates, H_2 from water radiolysis (Blair et al. 2007), olivine serpentinization (Sleep et al. 2004), or other low-temperature reactions between water and minerals (e.g., spinels; Mayhew et al. 2013; see Fig. 1). Such reactions involve mafic rocks or carbonates and include minerals such as calcite, dolomite, siderite, serpentine, ferrous hydroxide, olivine, talc, and graphite (Sherwood Lollar et al. 1993). Additionally, recent experiments show that even at low temperatures (above about 50 °C), H_2 can be generated from water-mafic rock reactions (e.g., Mayhew et al. 2013). Such abiotic H_2 supply allows CO_2-reducing methanogen to thrive in some extreme environments. Certain methanogens (including specific thermophiles) are known to be lithoautotrophs (e.g., *Methanobacterium thermoautotrophicum*, Zeikus et al. 1980) that obtain energy and synthesize their biomass from inorganic substrates such as CO_2 and H_2. These CO_2-reducing lithoautotrophic methanogens fix carbon following the reductive acetyl-CoA pathway (Berg et al. 2010). However, there are also lithoheterotrophic CO_2-reducing

methanogens, which require organic molecules as a carbon source, e.g., *Methanothermobacter tenebrarum* requires acetate (Kouzuma et al. 2017).

Ecology of Microbial Methanogenesis

Methanogens originated during the Archaean era before 2.5 Ga ago or even as early as 3.5 Ga ago (Ueno et al. 2006) prior to Earth's oxygenation, when biogenic methane was an important component of the atmosphere (Izon et al. 2017). After the atmosphere's oxygenation, methanogens retracted to and became widespread in a variety of anoxic environments, some of which (e.g., hydrothermal vents or deep lithosphere) resemble early Earth environments. Different methanogens thrive over a wide range of temperature, pressure, nutrient supply, salinity, and pH. The minimum requirements for microbial methanogenesis include: (i) anoxic conditions (very low/no O_2); (ii) low levels of other electron acceptors (oxidizers) such as sulfate, nitrate, and multivalent metals [e.g., Fe(III), Mn(IV)], and (iii) a supply of one or more methanogenic catabolic substrates (see section on "Methanogenic Pathways"). Among methanogens, there are halophiles (*Methanohalophilus mahii*; Paterek and Smith 1988) and hyperthermophiles, which are able to thrive at temperatures up to 122 °C (*Methanopyrus kandleri*, Takai et al. 2008) at pressures simulating deep subsurface (20–40 MPa).

Typical environments of significant active biogenic methane generation are marshes and lake and sea floor sediments (Colwell et al. 2008), permafrost (Kraev et al. 2017), hydrate or clathrate intervals (Milkov 2005), seafloor hydrothermal vents or smokers (*Methanocaldococcus indicus*, L'Haridon et al. 2003; *Methanocaldococcus jannaschii*, Ver Eecke et al. 2012), terrestrial hot springs, and onshore sediments beneath ice sheets (Wadham et al. 2012). Over geological time, methanogen ecological versatility within near-surface environments led to their perseverance in sedimentary basins and fractured crystalline lithosphere down to ~3–4 km (Inagaki et al. 2015; Moser et al. 2005). Methanogens are also common colonizers of biota and inhabit animal digestive tracts (i.e., rumen) or guts of arthropods such as termites. Anthropogenic accumulations of organic matter, i.e., dump sites and wastewater treatment plants (e.g., Rotaru et al. 2014), have become another common niche for methanogens.

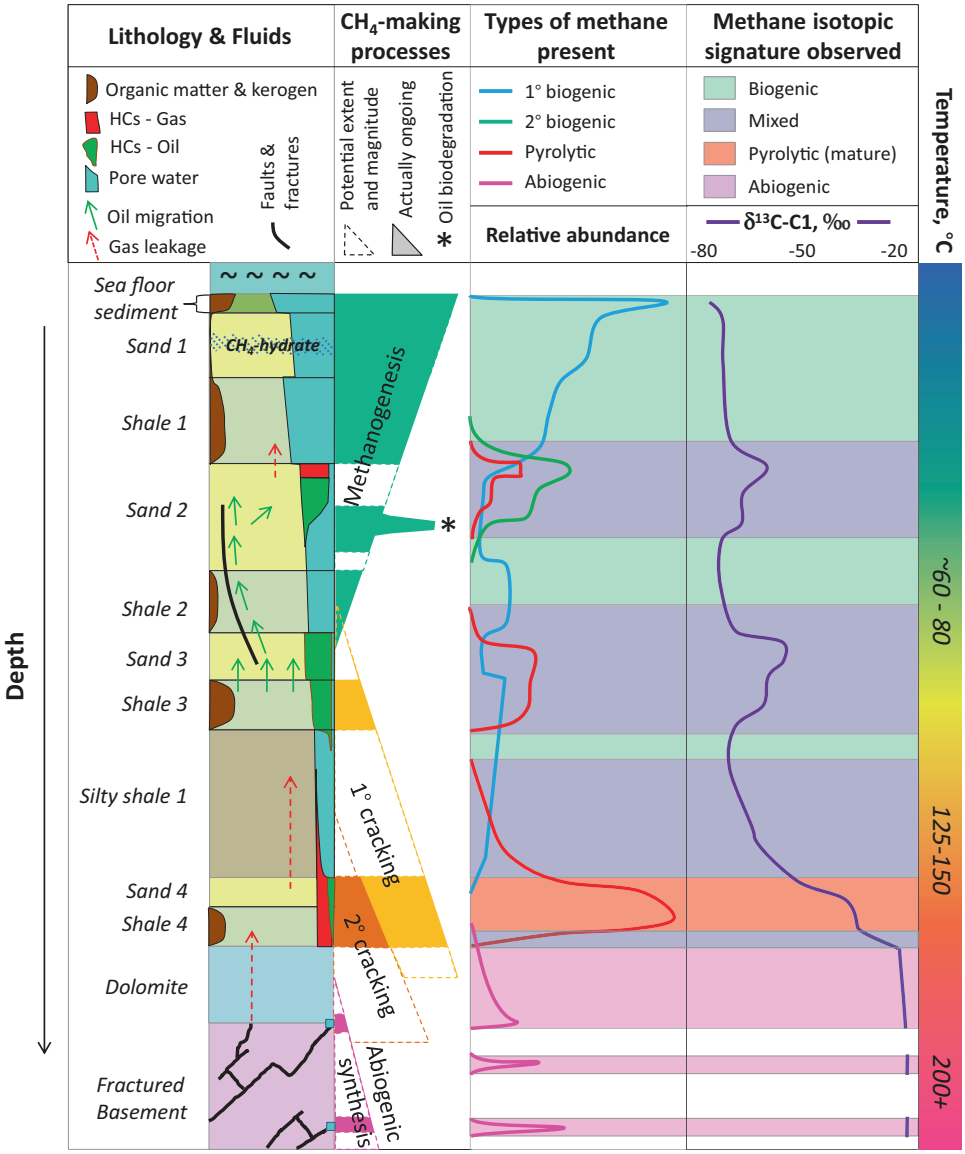
Intriguingly, methane has been detected on other planetary bodies as well, i.e., Mars or Saturn's largest moon – Titan. Models show that since 3.5 Ga ago approximately 360 thousands of viable objects (minimum 3 m diameter) or $120*10^6$ t of rocks got transferred from Earth to Mars (and 60 times more the other way) (Worth et al. 2013). Yet, it remains to be proven that such a violent, long trip and "transplantation" can be survived by any microbe. Probability of transfer of any viable objects from Earth or from Mars to the Jovian or Saturnian moons in the last 3.5 Ga was from very low to zero (Worth et al. 2013).

Biogenic Methanogenesis in the Subsurface

Evidence of past and present-day subsurface biogenic methane generation is found throughout the world in a wide range of sediments and rocks. Primary biogenic methane, derived from thermally immature organic matter, can be generated at significant rates down to ~3 km depth, corresponding roughly with 60–80 °C (e.g., Zeikus et al. 1980; Head et al. 2003), depending on the local geothermal gradient. However, viable methanogens have been found even deeper, e.g., a *Methanobacterium* inhabiting a fault down to 5 km (Moser et al. 2005). As the burial progresses, small fractions of this biogenic methane (~10 moles or ~0.25 m^3 of methane at surface conditions per cubic meter of sedimentary rock on average, Strąpoć et al. 2017) can remain adsorbed on kerogen and clay minerals (despite competitiveness with water and CO_2 molecules as modeled by Jin and Firoozabadi 2014) and get buried within rocks to beyond geopasteurization temperatures where microbial cells disintegrate. Primary biogenic methane preservation is documented within boreholes drilled into sedimentary basins worldwide, based on isotopic and molecular characteristics of recovered gas. Presence of methane at concentrations greater than >99% of total hydrocarbon gases and with $\delta^{13}C_{methane} < -60‰$ is diagnostic and has been found even in low-TOC rocks (shales and siltstones) or sandstones that are devoid of petroleum. Such consistent presence of primary biogenic methane has been observed (Inagaki et al. 2015) even down to depths of 10 km (Strąpoć et al. 2017; Jacquet et al. 2017), in cases where neither pyrolytic nor abiogenic methane overwhelmed the system.

Pyrolytic methane is also generated from organic material in sufficiently buried or heated formations. This pyrolytic methane often migrates or leaks and therefore mixes with pre-existing primary biogenic methane retained in surrounding formations. The two types of methane can be distinguished, and their mixing ratio can be estimated using diagnostic isotopic signatures (see following section and silty shale 1 on Fig. 2). The preservation of the primary biogenic methane, during burial below the habitable lithosphere, and its mixing with pyrolytic methane, is also clearly illustrated by modeling gas evolution in a passive coastal margin such as the northern coast of the Gulf of Mexico (Archer et al. 2012; see also associated video simulation at http://geosci.uchicago.edu/~archer/spongebob_passive/del13.movie.gif).

Secondary biogenic methane generation occurs when pyrolytic hydrocarbons generated from kerogen are expelled from organic-rich formations and migrate towards shallower,



Biogenic Methane, Fig. 2 Schematic depth profile of a subseafloor sedimentary column above igneous basement used to illustrate methane-forming processes, distribution of types of methane, and observed $\delta^{13}C$ of bulk methane present. Each process requires favorable conditions (i.e., temperature) and presence of substrate (e.g., organic matter) to be active. Estimated temperature range is the same as on Fig. 1. Methanogenesis requires habitable conditions and a substrate, e.g., note a spike of activity of secondary biogenic methane generation in a water-oil transition zone in Sand 2, which experienced a charge of hydrocarbons from deeper and hotter intervals. Also, observe the presence of primary biogenic methane below habitable temperatures adsorbed on sediments as a result of burial history (below Shale 2). If a subsequent charge of thermally generated hydrocarbons arrives, a mixed signature and origin of methane is observed (e.g., via leakage in Silty shale 1). Pyrolytic methane can be derived from thermolysis of kerogen (Shales 3 and 4) or secondary cracking of oil and gas (in Sand 4 and Shale 4). Finally, abiogenic methane can be synthesized via metamorphic reactions (e.g., in fractured ultramafic basement) and mix by leaking with other types of methane (see bottom of Shale 4)

cooler, and more porous formations inhabited by microbial methanogenic consortia. Biodegradation of such migrated oil or gas occurs within the oil-water or water-gas transition zones leading to the secondary biogenic methane generation (Fig. 2). This process leaves behind biodegraded oil (so-called heavy oil, e.g., in Bohai Bai, China, Qiang et al. 2016) or, in extreme cases, a recalcitrant tar-like residue rich in asphaltenes, e.g., Canadian oil sands (Aitken et al. 2004).

Alternatively, secondary biogenic methane can be generated from biodegradation of the kerogen itself, e.g., within shallow coals or organic-rich shales. Specifically, rock formations previously geopasteurized and subsequently exposed to lower temperatures and depths via erosional or tectonic uplift can be recolonized by microbial consortia. The recolonization occurs via contact with or access by meteoric or shallower pore waters containing microbial consortia, e.g., via outcrops of highly fractured coals and shales, and diluting the prohibitively high salinity of basinal brines (Strąpoć et al. 2008; Martini et al. 2008). Multiple biogenic methane reactivation events in the same formation have been documented as well. For example, alternating burial and uplift-erosion events in the Black Warrior Basin (Pashin 2007) exposed coal to freshwater recharge and led to the recolonization by microbial consortia.

Accumulations of Biogenic Methane

Methanogenesis would likely occur in any rock formation, provided that at some time in geologic history it fulfilled the minimum requirements: delivery/accommodation of methanogens (can be as small as 0.4 μm, Strąpoć et al. 2008)

and of substrate for energy and for biomass. Microbial methanogenesis has been extremely widespread across geologic time and space within the lithosphere. Additionally, over geologic time scales biogenic methane can migrate laterally and vertically or leak from its parent formation and accumulate elsewhere, e.g., sandstone channels above coal beds in Alberta basin (Bachu and Michael 2003). In the case of seafloor sediments on continental shelves, large amounts of predominantly biogenic methane are locked in the methane hydrates or clathrates (Archer 2007), a vast organic carbon pool spread out worldwide. In the high latitudes on shore, large amounts of methane are trapped within or beneath the permafrost.

As a result, some of the accumulations of biogenic methane are preserved in significant volumes and are exploited as an energy resource. Examples include widespread biogenic coalbed methane (CBM) accumulations (see Strąpoć et al. 2011, for global review), specifically, the Powder River and San Juan Basins in the USA (Formolo et al. 2008) and the Sydney Basin in Australia (Faiz and Hendry 2006), among others. Examples of significant biogenic methane accumulations in shale formations include the Western Canada Sedimentary Basin (Cokar et al. 2010) and the Illinois and Michigan Basins in USA (Martini et al. 2008; Strąpoć et al. 2010b). In addition to these so-called unconventional CBM and shale gas accumulations, biogenic methane also commonly occurs in more conventional reservoirs where more porous and permeable rocks, such as sandstone, are capped by a seal rock, e.g., the Cook Inlet Basin, where the Beluga field-reservoir consists of reworked fluvial sediment with sufficient dispersed organic matter as a substrate for methanogenesis (Strąpoć et al. 2010a). Recent discoveries of vast and economically significant accumulations of biogenic methane include the Levant Basin, in the eastern Mediterranean (~$1x10^{12}$ m^3 or 37 Tcf, Durham 2013; basin models by Wygrala et al. 2014 and Schneider et al. 2016), offshore Myanmar (Pinyo et al. 2016), northern Adriatic (Belopolsky et al. 2012), in the Qaidam Basin in China (lacustrine sediments), and in Hangzhou Bay (last two ~2.3×10^{11} m^3 or 8 Tcf; Pang et al. 2005; Li and Lin 2010), among others. The scale of these accumulations confirms and elucidates the importance of biogenic methane as a large pool of organic carbon. Our estimates of the biogenic methane pool size within the lithosphere, including methane hydrates, are similar or higher than another large organic carbon pool on Earth: the soil (~1500 pG or $1500*10^{15}$ g, Scharlemann et al. 2016).

Fate of Biogenic Methane and Impact on Climate

A large fraction of the subsurface-generated biogenic methane leaks or migrates, reaching near-surface sediments and eventually might be released to the atmosphere. Methane hydrates and permafrost provide a large volume-buffer storage of methane. However, the stability of these mostly biogenic methane storages can be very sensitive to climatic changes. Destabilization of methane hydrates, e.g., due to other climate drivers, such as astronomical cycles, have been shown to have a positive feedback on the climate warming, e.g., during the Paleocene-Eocene Thermal Maximum (Archer 2007) or Early Jurassic (Kemp et al. 2005) but could also respond to current anthropogenic climate warming caused by greenhouse gas emissions. In general, leaking methane is anaerobically or aerobically oxidized to CO_2 by microbes within shallow sediments, water columns (Carini et al. 2005), or soils. A fraction of carbon from the leaking methane is incorporated into biomass (e.g., in wetlands, Segarra et al. 2015, even up to 85% in shallow coastal sediments of Gulf of Mexico, Coffin et al. 2015).

Half of any methane leaking all the way to the atmosphere is oxidized to CO_2 within the first 9 years. Currently, at approximately 1.8 vol. ppm with preindustrial estimates of 0.4–0.8 vol. ppm, methane is a very potent greenhouse gas, absorbing 24 times more heat than CO_2 (Wuebbles and Hayhoe 2002). Biogenic methane contributes approximately two-thirds of global emissions of methane to the atmosphere, about half of which is anthropogenically induced: livestock guts (rumen, Hook et al. 2010), waste deposition or processing sites, and rice paddies. The natural sources are dominated foremost by wetlands, followed by termites and oceanic degassing (Bousquet et al. 2006). Climate warming may convert vast permafrost areas rich in organic carbon into additional high-methane-flux wetlands (Camill 2005) and, on slightly longer time scales (~millennial), destabilize global methane hydrates (Archer 2007). Furthermore, human activity adds industrial methane emissions to the atmosphere with the main sources being the fossil fuel industry (16% of global emissions) and incomplete burning of biomass and biofuels (Bousquet et al. 2006).

Stable Isotopic Composition of Methane

The stable isotopic composition of methane can be used to determine if the gas is biogenic or was generated via thermochemical processes (pyrolysis or abiogenic synthesis, Fig. 1). The stable isotopic composition of C and H in methane is expressed as two ratios, ^{13}C to ^{12}C and ^{2}H (or D – deuterium) to ^{1}H. These ratios are expressed relatively to the international standards (primary reference or scale-defining materials, Brandt et al. 2014) via the delta notation, $\delta^{13}C$ and $\delta^{2}H$, respectively. Biogenic methane is strongly depleted in ^{13}C relative to the standard and relative to other nonbiological methane sources. Whereas $\delta^{13}C$ of biogenic methane ranges from −120‰ to −50‰ (typically −80‰ to −60‰; Fig. 2), abiogenic methane or pyrolytic methane

derived from subsurface thermal defragmentation of kerogen and/or hydrocarbons ranges from −50‰ to −20‰. δ^2H, on the other hand, helps to distinguish methanogenic pathways, specifically the main ones including CO_2-reduction versus methanol- and acetate-utilizing (acetoclastic) pathways. The latter two are characterized by δ^2H more negative than −300‰, whereas the CO_2-reduction one by δ^2H similar in range to the pyrolytic methane (between −250‰ and −150‰, Whiticar 1999).

Abiogenic methane typically has isotopically distinct signatures (both C and H enriched in heavy isotope). However, as a caution, the final observed isotopic signature of methane depends on: (i) the isotopic composition of the substrate (e.g., $\delta^{13}C_{CO2}$ in subsurface can vary between −30‰ and +20‰, typically −10‰ to +10‰); (ii) the isotopic fractionation factor, which could depend on enzymatic pathway but also on temperature (e.g., $\varepsilon^{13}C_{CO2\text{-}CH4}$ for CO_2-reducing methanogens typically is between 60‰ and 80‰ or $\alpha^{13}C_{CO2\text{-}CH4}$ 1.060–1.080, Conrad 2005, but can be as low as 10‰ under hyperthermophilic and in situ pressure conditions, Takai et al. 2008) or other environmental stress;, and, finally, (iii) methane-alteration processes, such as mixing, diffusive transport (Prinzhofer and Pernaton 1997), and microbial oxidation at shallower depths (e.g., microbial anaerobic methane oxidation, Biddle et al. 2012; Segarra et al. 2015), with the latter two processes promoting $^{12}CH_4$ over $^{13}CH_4$.

Thermochemical Methanogenesis

Certain conditions in nature lead to generation of methane without involving methanogens. These thermochemical processes could be either (i) thermal decomposition of organic matter (e.g., kerogen or hydrocarbons) called pyrolysis or (ii) hydrothermal and metamorphic methane-synthesizing mineral-fluid interactions (e.g., during serpentinization or H_2 reaction with graphite, Sherwood Lollar 1993) or via Fischer-Tropsch type reactions at higher pressure and temperature regimes in deep lithosphere (Horita and Berndt 1999; Fig. 1). Additionally, there are synthetic and industrial methods of obtaining methane, e.g., Fischer-Tropsch synthesis from syngas (H_2 + CO) or photocatalysis from: (i) CO_2 via UV-illuminated rhodium particles (Zhang et al. 2017) or (ii) CO using iron molecular catalyst and visible light (Rao et al. 2017), both at ambient temperatures.

Summary

Biogenic methane is formed by microbial methanogens (methanogenic *Archaea*) using a variety of substrates, alone or in syntrophy with bacteria, fungi, or protozoa, in a variety of anoxic environments or microenvironments, ranging in scale from worldwide sedimentary basins and fractured upper lithosphere to the guts of termites or corroded petroleum pipeline. Adaptability and versatility of methanogens contributed to their omnipresence in anoxic environments throughout geologic time and led to widespread accumulations of biogenic methane within the lithosphere. Examples include methane hydrates, background primary biogenic methane in worldwide sedimentary basins, and economically important shallow coalbed methane or recently discovered vast conventional reservoirs. About two-thirds of global methane emissions to the atmosphere are of biogenic origin and half of those are linked to anthropogenic activities such as farming and waste management. From the early stages of life on Earth, microbial methanogenesis acted as a conduit between inorganic and organic carbon pools. Biogenic methane within the lithosphere is a significant fraction of the global organic carbon pool and can impact both short- and long-term carbon and climate cycles.

Biogeochemistry

Hilairy Ellen Hartnett
School of Earth and Space Exploration and School of Molecular Sciences, Arizona State University, Tempe, AZ, USA

Definition

Biogeochemistry is the scientific discipline that explores the physical, chemical, biological, and geological processes that control the composition of and changes to Earth's surface environments.

Introduction

A fundamental premise within biogeochemistry is that the influence of life, in particular microbial life, is so pervasive that Earth's surface geochemistry cannot be understood

without considering the biological components and processes (Schlesinger and Bernhardt 2013). Indeed, no surface environment on Earth has been demonstrated to be uninhabitable. The key biogeochemical processes involve elements that are necessary for or are affected by metabolism – especially C, H, N, O, S, but also many other major and trace elements. Biogeochemistry addresses both biotic and abiotic reactions and involves both organic and inorganic species. The science of biogeochemistry spans the marine, aquatic, terrestrial, and atmospheric sciences, it operates over a wide range of temporal and spatial scales, and it involves significant complexity due to the interactions and feedbacks among the many elemental cycles. Biogeochemistry regularly looks both backwards through the historical and geological records to understand underlying cycles and patterns but also strives to make predictions about future changes in Earth elemental cycles. Given that Earth is fundamentally an inhabited planet, biogeochemistry also has implications for understanding the controls on the distribution of life on other planets. Increasingly, biogeochemistry also examines the role of humans in altering elemental cycles and the coevolution of humans and their environment in the future.

Spatial and temporal scales in biogeochemistry. A fundamental challenge in biogeochemistry is that the relevant spatial and temporal scales range over many orders of magnitude – from the submicron-scale cells and nanometer-scale molecules that operate on the millisecond timescales of chemical reactions, to planetary-scale elemental cycles that operate over centuries to millennia. A single biogeochemical process, for example, photosynthesis, can exhibit day-to-night (diel) patterns, seasonal (summer/winter) variations, interannual (climatic) trends, and very long-term (glacial/interglacial) cycles. Evolutionary timescales are also relevant as the photosynthetic biochemistry has evolved over billions of years of Earth history. Many biogeochemical patterns, for example, seasonal variations, may be difficult to discern without detailed process studies that examine both shorter and longer temporal scales. At very long time frames, patterns found Earth's rock record have such long integration times that it is difficult to determine specific causative processes. For example, the seemingly rapid rise in atmospheric O_2 at ~2.5 billion years ago was likely a result of both slow secular H_2 loss from the Earth's mantle and the rapid biological production of O_2 via photosynthesis (Lyons et al. 2014). Steady-state approximations are often appropriate for processes and cycles that operate on long time scales (e.g., the carbonate-silicate weathering cycle that controls atmospheric CO_2 on geologic time scales; Berner et al. 2003) but non-steady-state conditions (e.g., the rapid increase in CO_2 over the last 200 years which is not balanced by rock weathering) are also possible.

Thermodynamic considerations. Biogeochemistry is based in the fundamental physical laws of thermodynamics. Chemical reactions tend toward equilibrium (energy minimization), and biological processes cannot subvert this. All biological reactions are thermodynamically favorable ($\Delta G_r < 0$); although, they may be kinetically inhibited. Biology can overcome kinetic barriers through enzymatic reactions, but it cannot force reactions to "run uphill." Biological systems take advantage of favorable redox gradients to gain energy from their environment; they must have continuous input of energy in order to maintain their reduced carbon molecules or their very biomass will tend (albeit, perhaps slowly) toward equilibrium. The evolutionary revolution of photosynthesis, whereby organisms harvest solar energy as photons, allowed biology to capture additional energy beyond that supplied geochemically, which could then be used to fix CO_2 into organic molecules.

Stoichiometry is another fundamental principle within biogeochemistry – the concept that the elemental composition of molecules can be extended to explain the elemental composition of biomass, communities, and even ecosystems. The classical Redfield ratio (C:N:P::106:16:1) in phytoplankton (Redfield 1958) describes the C:N:P content of phytoplankton; that same elemental ratio is reflected in the nutrient content of the surface ocean. Like a limiting reagent in a chemical reaction, ecological stoichiometry posits that availability of limiting nutrients control ecosystem structure and function (Sterner and Elser 2002). The Redfield ratio concept has been extended to include larger organisms and beyond C, N, and P to include other major elements (e.g., Ca, S) and a host of trace elements (e.g., Fe, Mo, Ni, etc.). It has been demonstrated that often Fe is a limiting nutrient in marine systems because algae require Fe for photosynthesis. Different organisms can have different stoichiometric ratios depending not only on their food sources but also on the plasticity of their metabolisms and the range of metal cofactors their enzymes utilize.

Coupled biogeochemical cycles. Biogeochemistry fundamentally addresses the global cycles of biologically relevant elements, especially carbon, oxygen, nitrogen, hydrogen, and sulfur, but also such elements as calcium, iron, silicon, mercury, and many others. Importantly, each cycle is considered a closed loop and the science of biogeochemistry seeks to determine how they are related and how they interact.

Carbon is centrally important for all life on Earth and thus the cycling of carbon is at the heart of biogeochemistry. Carbon exists in organic and inorganic forms, it has a wide range of stable redox states, and it can exist in in solid, dissolved, and gaseous phases. The fundamental biological processes that produce and consume organic carbon are

$$\text{Photosynthesis: } CO_2 + H_2O \rightarrow \text{organic carbon } (\text{“}CH_2O\text{”}) + O_2, \text{ and}$$
$$\text{Respiration: } O_2 + \text{organic carbon } (\text{“}CH_2O\text{”}) \rightarrow CO_2 + H_2O.$$

In these equations, the complex organic matter produced that includes proteins, carbohydrates, and lipids is

abbreviated as "CH_2O," a very rough approximation of the stoichiometry of a carbohydrate. The respiration equation assumes aerobic respiration, but the process can also proceed through a range of anaerobic metabolisms. Of course, this abbreviated organic matter also contains N, P, S, and trace metals in addition to C, H, and O. The full stoichiometric equations for photosynthesis and respiration allow the interactions of coupled elemental cycles to be examined. For example, plants require nitrate or ammonium and the amount of O_2 produced during photosynthesis varies depending on which N species is utilized. Respiration reactions also reflect significant biogeochemical complexity. Aerobic respiration of N-containing organic matter will generate ammonia (which can be subsequently oxidized to nitrate in the presence of O_2). Anaerobic carbon oxidation by NO_3^{2-} (e.g., denitrification) generates N_2 but can also produce a range of other species (NH_4^+, NO, N_2O, and NO_2^-) depending on the specific consortia of organisms present. The biogeochemical cycling of carbon also includes an inorganic cycle that is tied to the biological production of carbonate ($CaCO_3$) shells, abiotic carbonate precipitation in soils, and the weathering of carbonate rocks. The speciation of dissolved CO_2 and carbonate in water is a primary control on the pH of natural waters, and the coupling of the organic and inorganic carbon cycles is critical for understanding the sources and fate of CO_2 in the atmosphere. Humans are influencing the carbon cycle directly through the production of CO_2 from fossil fuels and indirectly via the downstream impacts on biological and geochemical cycling of this added C. There are many documented examples of carbon cycle feedbacks between human activities and biogeochemical systems. In coastal marine systems, increased CO_2 is contributing to ocean acidification, and lower pH is causing decalcification of organisms like oysters and mussels; this in turn is affecting shellfish productivity (Barton et al. 2012). In terrestrial systems, recent work has demonstrated that plants grown under elevated CO_2 are nitrogen poor relative to plants grown under ambient CO_2; this has significant implications for the nutritional value of future food crops (Huang et al. 2015; Sardans et al. 2017).

Nitrogen and phosphorus each have relatively small, rapidly cycling pool coupled to a large, but slowly cycling geologic reservoir (the atmosphere and crustal rock for N and P, respectively). Both the N and P cycles are tightly coupled to the carbon and oxygen cycles (Ingall and Jahnke 1994; Galloway et al. 2008). The global nitrogen cycle is coupled to photosynthesis and respiration, but also depends on nitrogen fixation (the conversion of N_2 gas to ammonium, NH_4^+, or nitrate, NO_3^{2-}) which occurs naturally through a bacterial process or due to lightning. Like carbon, nitrogen has a wide range of stable forms and redox states; one of which, N_2O, is a potent greenhouse gas and a catalyst of stratospheric ozone destruction. The global phosphorus cycle is somewhat simpler in that P is a rock derived element and its global cycle, unlike that of carbon and nitrogen has no source through biological fixation. Rivers convey the dominant flux of P from the land to the ocean, and on long time scales P is buried in marine sediments and returned to land via rock uplift.

Human activity has a profound and direct impact on both N and P cycles. Human N_2 fixation via industrial fertilizer production and fossil fuel burning now rivals natural N_2 fixation rates. Humans have directly enhanced P fluxes from the land to the ocean through the mining phosphate rocks for industrial use and fertilizer production. Geologic (rock-derived) P is a nonrenewable resource and current rates of P mining are unsustainable in the long term, suggesting P scarcity could become a significant foodsecurity issue by the latter half of the twenty-first century (Vaccari and Strigul 2011; Neset and Cordell 2012). Pollutant nitrogen and phosphorus from agricultural runoff and other waste is increasing coastal primary production rates and causing eutrophication (oxygen depletion due to excess organic matter production and subsequent decomposition). Recent work has shown that eutrophication also causes coastal waters to be more susceptible to ocean acidification since CO_2 produced by decomposition further decreases the oceans ability to buffer CO_2 from the atmosphere (Cai et al. 2011). Ecosystems respond rapidly and strongly to increases in N and P; as humans continue to alter the N and P cycles, it is important for biogeochemists to understand and predict how CO_2 in the atmosphere may respond to alterations in the biosphere and changes in N and P.

Atmospheric, terrestrial, and marine biogeochemistry. Atmospheric processes can affect climate due to changes in the concentration of greenhouse gases. Changes in atmospheric trace gas composition can affect ozone (O_3) levels and sulfate aerosols. The atmosphere also influences primary productivity though the deposition of nutrients, including: nitrogen oxides (NO, NO_2^-, $NO_3^=$), ammonia and ammonium (NH_3 and NH_4^+), and sulfate $\left(SO_4^=\right)$ on the Earth surface. In the lower atmosphere (troposphere), important processes include the conversion of N_2 to fixed nitrogen species (e.g., NO, NOx), uptake and release of CO_2, and the accumulation and consumption of O_2. In the upper atmosphere (stratosphere), the important processes are reactions that consume ozone (O_3), and reactions that affect sulfate aerosols which have a cooling effect on Earth's climate. The loss of stratospheric ozone in particular has been linked to human activity and the production of halogenated trace gases; this ozone loss (through the chemical cycling of NO) leads to increased UV radiation which causes cancer and cataracts in humans and may decrease primary production in the southern ocean. Human impacts on the atmosphere are quite pronounced because the atmosphere mixes rapidly, and many species are reactive on short time scales.

On land, the biogeochemical processes of rock weathering and soil development are important for nutrient supply and for carbon cycling. Nutrients and CO_2 are in turn key requirements for primary production. Land plants account for 50% of global net primary production (~60 Tg C $year^{-1}$; Schlesinger and Bernhardt 2013). Most of the organic carbon produced is delivered as plant detritus to soils where it is decomposed relatively efficiently back to CO_2. Soil C has a continuum of turnover times, with small rapidly cycling pools (months), is dominated by pools with turnover times of decades to millennia. Traditionally, these are defined as fast, slow, and passive. Agricultural activities have increased decomposition rates and thus move soil organic carbon back into the atmospheric CO_2 pool.

Marine biogeochemical cycles are dominated by algal production and microbial consumption. Marine primary production is about equal in magnitude to terrestrial primary production (~51 Tg C $year^{-1}$; Schlesinger and Bernhardt 2013). Like terrestrial production, the majority (~95%) of the marine production is rapidly decomposed by bacteria and converted to CO_2. However, the small amount of organic carbon that escapes degradation can be exported from the surface ocean to be buried in marine sediments. Decomposition in the sediments also consumes organic carbon and ultimately less than ~1% of marine primary production is permanently buried. This small burial flux, however, is the key to maintaining our atmospheric oxygen concentrations. Each mole of organic carbon atom that is buried was originally produced via photosynthesis along with an equimolar amount of oxygen. If that carbon escapes reoxidation, the oxygen produced with that organic carbon contributes to the atmosphere oxygen pool. This leads to a long-term negative feedback between the carbon and oxygen cycles. Low oxygen conditions promote carbon burial by inhibiting decomposition, and over long time scales oxygen can build up in the atmosphere. High O_2 leads to the more efficient oxidation of organic matter, reducing carbon burial and consuming atmospheric O_2 (Berner et al. 2003).

Models. Given the vast range in temporal and special scales as well as the range of ecosystems and metabolisms encompassed by biogeochemistry, conceptual models and numerical models are critical tools for exploring rates and processes. The simplest models are 1D mass-balance or box models with inventories for each box or reservoir and fluxes into and out of (and between) each box. These can be one or two box models or more complex models with many boxes. The most complex models are fully dynamic, 3D global circulation models (GCM) that conserve motion and mass and have parameterized chemical reactions for each species of interest. Biogeochemical modules that dynamically trace a wide range of elements and processes have been developed to run on top of these GCMs. Such coupled models are computationally intensive, but they allow us to faithfully reproduce past patterns in elemental cycles and they are necessary if we want to make predictions about future biogeochemical cycles.

Summary

Biogeochemistry and the science of global change. As Earth enters the Anthropocene (the epoch in which humans have become a dominant force on the Earth), the influence of humans on the planet's chemistry is clear. Human activities alter the cycling of C, N, P, and many other elements in the atmosphere, in soils, and in aquatic and marine environments. Biogeochemistry not only reveals changes in Earth's biological systems and patterns in the past it also provides a context for understanding change in the future. As the human population grows and the level of development improves for many countries, we have the potential to deplete resources, pollute waterways, and increase atmospheric greenhouse gases, or we can use the tools that biogeochemistry provides to develop an understanding of the connections and feedbacks among human activities and global biogeochemical cycles. The science of global change is ultimately a transdisciplinary one that must integrate biogeochemistry with human-systems science to help us to make informed, sustainable decisions about how we manage our environments and utilize resources to attain a thriving, positive future.

Biological Pump

Sarah L. C. Giering[1] and Matthew P. Humphreys[2]
[1]Ocean Biogeochemistry and Ecosystems, National Oceanography Centre, Southampton, UK
[2]Ocean and Earth Science, University of Southampton, Southampton, UK

Definition

The biological pump is the collection of marine biogeochemical processes that convert dissolved inorganic matter in the surface ocean into biomass and transport this to the ocean interior, where the biomass is returned to its original dissolved inorganic forms.

Introduction

The concentrations of elements vary throughout the global ocean. Concentrations of dissolved inorganic carbon (DIC – the sum of the aqueous CO_2 (<1%), bicarbonate (~90%), and carbonate ion (~10%) concentrations) and nutrients are greater in deep waters relative to the near-surface, and in older water masses relative to younger ones. Some trace metals, on the other hand, have higher concentrations in surface waters. The biological pump is an important process that contributes to these gradients.

The biological pump begins in the sunlit upper ocean, called the euphotic zone. Here, photosynthesizing organisms convert DIC and nutrients into biomass, in the form of particular organic matter (e.g., carbohydrates, lipids, and proteins) and biominerals (e.g., calcium carbonate and silica). This biomass is constantly reworked in a complex web of trophic interactions, and is mostly converted back into an inorganic form within the surface ocean. However, a fraction of the organic matter is "exported" from the surface ocean into the deeper interior. There, these particles may dissolve or be processed by the resident biota, ultimately converting them back into their inorganic forms ("remineralization"). Most remineralization occurs in the upper 1000 m of the water column, although a fraction of the organic matter also reaches the deeper waters and seafloor sediments.

Export

"Export flux" is the rate per unit area at which biomass exits the surface ocean through a reference depth. A fixed reference depth of 100 m is often used for studies that are based on modeling or remote sensing. A dynamic reference depth, such as the base of either the mixed layer or the euphotic zone, is more appropriate to capture particle dynamics and compare export across different ecosystems (Buesseler and Boyd 2009). The ratio of export flux to primary production is called "export efficiency." Three processes can drive export from the surface layer: sinking, active transport, and physical transport.

Sinking

The euphotic zone overlaps with the surface mixed layer, which is physically separated from the interior ocean by a density gradient sustained by winds and air-sea heat and freshwater fluxes. Nevertheless, a fraction of the organic matter passes through this density gradient in the form of sinking particles or through active transport. Sinking particles are a major pathway for biomass transfer to depth. These particles range in diameter from a few micrometers to several centimeters, and particles >0.5 mm across are called "marine snow." Each particle's sinking speed is determined by its

density and drag, with larger particles generally sinking faster. The incorporation of biominerals, such as biogenic silica produced by diatoms, increases density and can thus increase the sinking speed. Large particles are produced primarily through aggregation, which occurs through "coagulation" or biologically mediated repackaging (Burd and Jackson 2009). Coagulation requires particles to stick together to form a larger particle. "Stickiness" is currently not well understood but may be mediated by cell shape (e.g., whether plankton cells have spines or form chains) and the presence of exopolymers (e.g., transparent exopolymer particles) (Burd and Jackson 2009). Aggregation can further occur through feeding and repackaging by larger zooplankton and fish, which results in growth (i.e., biomass accumulation) and the production of fecal pellets (Steinberg and Landry 2017). The sinking of carcasses, in particular those of jellyfish and mammals, could be a significant contributor to export, but remains poorly quantified.

Active Transport

Larger zooplankton and fish export organic matter through vertical migration (Steinberg and Landry 2017). Many larger zooplankton feed in the mixed layer at night and retreat to a depth of several hundred meters during the day, in a process called "diel vertical migration." While resting at depth, migrating animals continue to respire, excrete, and release fecal material, and may die. Migrating animals thus actively export organic matter. The fraction of total export driven by diel vertical migration could be up to 40% (Brierley 2014). On seasonal timescales, some zooplankton species transport organic matter deeper still as they overwinter at over 1 km depth (Steinberg and Landry 2017). There is an additional nondiurnal contribution to active transport by krill, fish, and marine mammals.

Physical Transport

Physical transport can occur in areas of deep water formation, such as in the subpolar North Atlantic and the Southern Ocean. There, cold air takes up heat from warm, poleward-flowing surface waters, thus increasing their density and allowing them to sink to depths of up to 4 km. In the subtropical gyres, wind-driven downwelling can subduct surface waters into the interior (Carlson et al. 2010; Fontela et al. 2016). On smaller spatial scales, export via "detrainment" (i.e., the "mixed layer pump") can occur where stratification is unstable. A prominent example occurs during the onset of spring stratification at high latitudes (Dall'Olmo and Mork 2014). Rising air temperatures allow weak stratification to develop, promoting surface layer carbon fixation through phytoplankton production. During this time, unstable weather conditions (e.g., strong winds) can induce short-term mixed layer deepening, thus mixing the new biomass to greater depth. Once stratification strengthens again, this biomass remains isolated from the surface ocean. Export through detrainment has occurred if the biomass is not mixed back to the surface (or "entrained") during subsequent mixing events. These different types of vertical water mass transport can carry nonsinking organic matter and biominerals into the deep ocean.

Remineralization and Transfer

Most exported biomass is converted back into a dissolved inorganic form in the interior ocean through a set of processes together called remineralization. The remineralization rate, coupled with the vertical and horizontal transport, thus influences the distribution of dissolved inorganic matter, as well as its residence time in the interior ocean.

Sinking is the most effective export process for transporting biomass beyond a few hundred meters' depth, as active and physical transport are often restricted to the upper water column. Sinking particles can also penetrate density gradients and thus travel through different water masses, potentially reaching the seafloor. The "transfer efficiency" quantifies the fraction of organic matter exported from the surface layer that subsequently reaches a deeper reference depth (typically chosen between 500 and 2000 m).

Vertical Profiles

For sinking particles, transfer efficiency is a function of sinking speed and remineralization rate: fast remineralization and slow sinking retains matter near the surface ocean, while slow remineralization and fast sinking allow organic matter to be transported much deeper. Assuming that remineralization rate (r) and sinking speed (v) are constant with depth, flux (F_z) at a depth (z) can be calculated from a reference flux (F_{z0}) as:

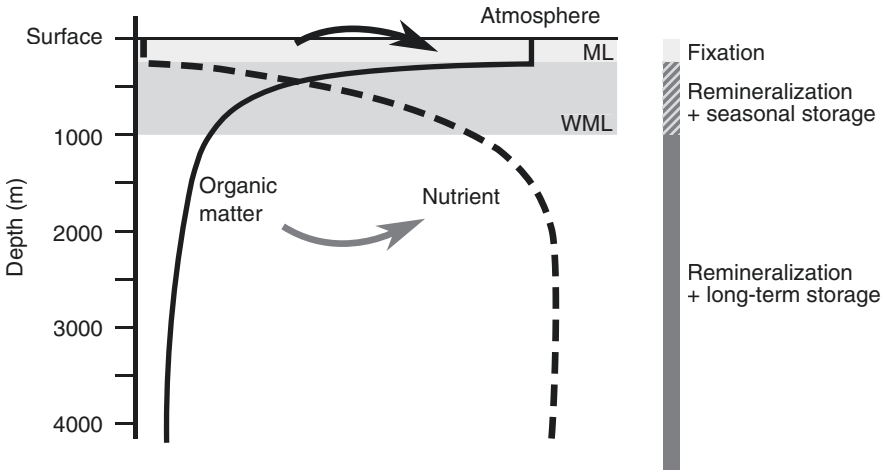
$$\mathrm{F_z} = \mathrm{F_{z0}e^{-(rz)/v}} \tag{1}$$

Observations of particle flux profiles suggest that particle flux is better described by an empirical power-law function known as the "Martin curve" (Martin et al. 1987):

$$\mathrm{F_z} = \mathrm{F_{z0}(z/z_0)^{-b}} \tag{2}$$

This power-law function implies that particle sinking speeds increase, and/or remineralization rates decrease, with depth. For carbon, "Martin's coefficient" b varies regionally with a global average of 0.86, while other elements have different values due to varying remineralization and transfer rates (Boyd et al. 2017).

As particles sink, they undergo transformation: remineralization and dissolution returns biomass into its dissolved components, while adsorption onto sinking particles removes



Biological Pump, Fig. 1 Idealized depth profiles of organic matter (solid line) and inorganic nutrients (dashed line). Mixed layer (ML) and winter mixed layer (WML) are illustrated by the green and blue areas, respectively. "Long-term" refers to time scales of up to about 1000 years. Arrows indicate fixation (black) and remineralization (gray)

dissolved elements from the water and transports these to the sediments. The unique combination of chemical and biological processes affecting each element thus drives its distinct vertical profile.

Depletion of an element in the surface layer indicates biological uptake, and such elements can limit primary production (they are "bio-limiting"). These elements are rapidly remineralized near the surface ocean, leading to increased concentrations of their dissolved form at depth ("nutrient-type profile"; Fig. 1). Prominent examples are N, P, Si, Fe, Cd, and Zn (Johnson et al. 2017). Elements that follow the nutrient-type profiles but only show slight surface depletion are called "bio-intermediates," such as Sr which is only used by relatively rare planktonic organisms. Other bio-intermediate examples are C, Ba and Ca.

The adsorption of ions onto sinking particles removes dissolved elements from the water column. This process is more pronounced in surface waters, where particle concentrations are high, and in older, deeper water masses. Adsorption results in decreasing concentrations with depth ("scavenged profile"), with examples being Pb, Mn, Sn, and Co. Short residence times of reactive elements (less than the ocean mixing time) further means that their source of origin influences their distribution, leading to unique depth profiles. Elements whose residence time is longer than the ocean mixing time show nearly uniform concentrations throughout the ocean and have a "conservative profile." Examples are Na, Mg, and Ca (Johnson et al. 2017).

Remineralization

Remineralization occurs via metabolic processes and dissolution. Exported organic matter provides the main energy source for organisms living beneath the sunlit surface. While microbes are principally responsible for remineralization, much of the rapid decrease in organic matter fluxes in the region just below the surface ocean (Fig. 1) is attributed to zooplankton (Giering et al. 2014). Zooplankton fragment large, fast-sinking particles into slow-sinking or suspended particles, thus facilitating shallow microbial remineralization. The metabolic requirements of microbes and zooplankton therefore determine the rate and processes responsible for remineralization.

Metabolic requirements vary for different elements, driving vertical decoupling. Compounds and elements that are essential to life are preferentially metabolized, so the majority of these are remineralized near the ocean surface. Remineralization is thus faster for macronutrients than for metals and approximately follows N > organic C > P > metals (Boyd et al. 2017).

Fresh aggregates are characterized by a high amount of labile compounds, such as essential amino acids and polyunsaturated fatty acids. Deep-sea organisms preferentially metabolize these labile compounds. Therefore, as organic matter "ages" (i.e., is processed), its lability decreases, and the contribution of saturated fatty acids and heterotrophic biomarkers increases (Lee et al. 2004). Eventually, the complex compounds are degraded into their inorganic forms and released as metabolic waste products. Organic nitrogen is converted to ammonia and then to nitrate by nitrifying bacteria. Organic phosphorus is excreted as phosphate. Organic carbon undergoes extensive reworking but is eventually respired as DIC.

Biominerals such as calcium carbonate and biogenic silica are produced along with organic matter. As they have little metabolic value to the deep-sea biota, their remineralization is determined by abiotic dissolution. The silica cycle illustrates how the biological pump influences elemental distributions in the ocean. The appearance of diatoms, which have high silicon requirements, led to a drop in silicic acid concentrations from ~1 mM to today's concentrations of ~70 uM, and resulted in a nutrient-type distribution for the past 50–100 million years (De La Rocha 2007).

Biological Carbon Pump

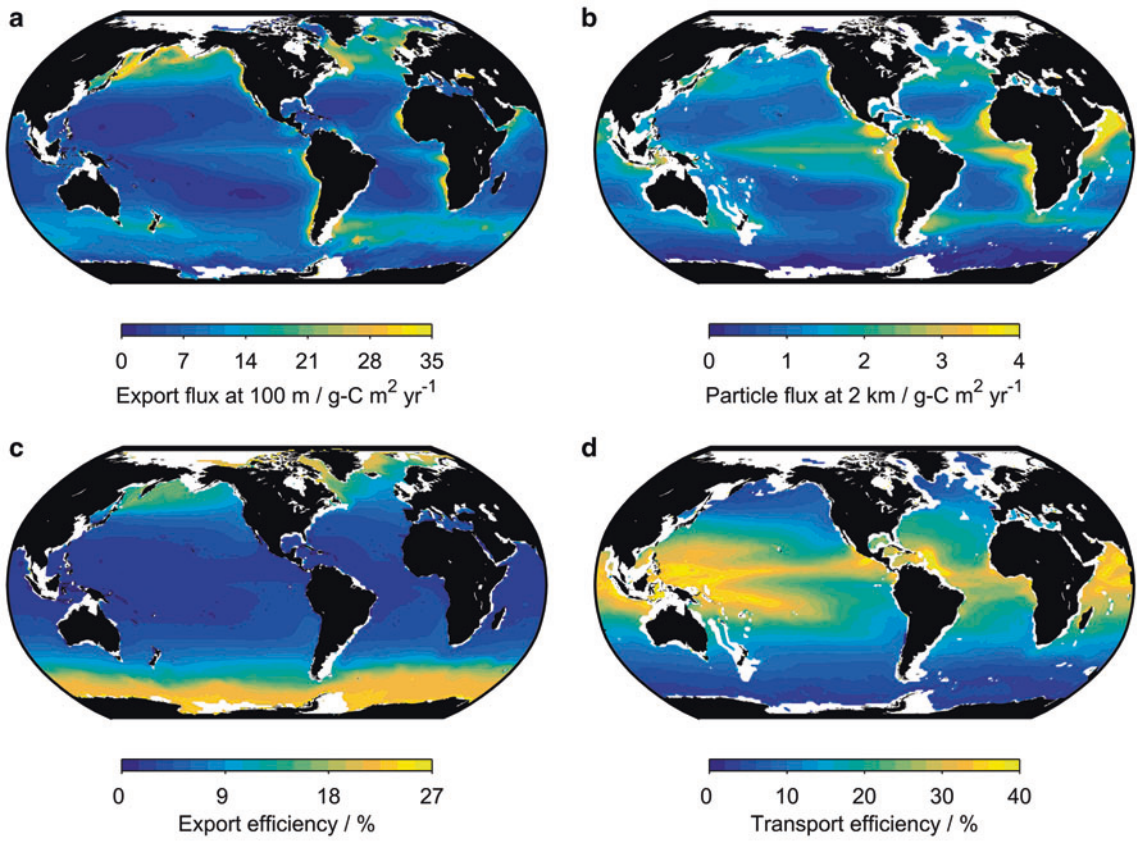
The biological carbon pump transports 5–20 Gt carbon annually from the surface into the interior ocean (Henson et al. 2011), and keeps, according to models, the atmospheric CO_2 concentration much lower than without ocean biology (Parekh et al. 2006). However, its effect on surface layer CO_2 uptake differs depending upon the type of particulate material produced in the surface ocean.

The soft-tissue pump converts DIC into organic matter in the surface layer. This acts as a sink for atmospheric CO_2: More CO_2 can be added to the water, through air-sea exchange, to replace the DIC that was converted into organic matter. The carbonate "counter" pump converts DIC into particulate inorganic carbon (i.e., $CaCO_3$) through near-surface calcification. Although this process also takes up DIC from the seawater, it reduces the total alkalinity of seawater (Wolf-Gladrow et al. 2007). Alkalinity controls the capacity for seawater to store DIC. The loss of alkalinity during calcification results in a reduction of the DIC storage capacity that is greater than the uptake of DIC. The net effect of calcification is therefore to drive the sea surface towards being a source of CO_2 to the atmosphere.

In the context of the biological carbon pump, the appropriate reference depth for export is the base of the winter mixed layer, because of the effect on isolation time from the atmosphere. DIC produced through remineralization above this depth will be mixed back up to the surface during the winter, where it is back in contact with the atmosphere, and thus promotes CO_2 outgassing. DIC produced beneath the winter mixed layer is considered to be isolated from the atmosphere until upwelling brings it back to the surface. The final isolation time depends on the location of particle export and depth of remineralization, and can be on the order of whole-ocean mixing (i.e., about 1000 years).

Global Pattern

While there is still much uncertainty about the absolute magnitude of export, remineralization, and transfer, general global patterns have been identified (Henson et al. 2012; Siegel et al. 2014). Export flux is typically higher at high latitudes, in the equatorial Pacific, and in upwelling regions (Fig. 2a). Where



Biological Pump, Fig. 2 Global map of satellite-derived estimates of (**a**) export flux at 100 m depth, (**b**) particle flux at 2000 m depth, (**c**) export efficiency (flux at 100 m depth/depth-integrated primary production), and (**d**) transfer efficiency (flux at 2000 m/flux at 100 m) (Redrawn from Henson et al. 2012). These maps show the approximate global patterns of each variable, but uncertainties for exact values at any specific location are high

primary production is strongly seasonal, export flux peaks during and after the phytoplankton bloom and is lowest during winter (Siegel et al. 2014). High-latitude regions can have high export efficiencies (Fig. 2c), while low-latitude systems generally retain a large fraction of the organic matter in the surface ocean. Inversely, transport efficiency has been shown to increase towards the tropics (Fig. 2d), leading to highest annual deep particle fluxes near the equator (Fig. 2b) (Henson et al. 2012).

Climate and Bioengineering

Various "geo-engineering" techniques have been proposed to offset the impacts of the anthropogenic increase in atmospheric CO_2. Some aim to increase the ocean's capacity to take up and store carbon by enhancing the biological carbon pump. For example, iron addition could promote carbon fixation in areas where iron limits primary production, like the Southern Ocean. Experiments have confirmed that this approach can boost primary production, thus enhancing CO_2 uptake (Lampitt et al. 2008). However, for long-term CO_2 storage, the newly produced organic carbon must be transported below the winter mixed layer. An artificially fertilized, diatom-dominated bloom in the Southern Ocean exported more than half of its biomass to deeper than 1000 m, providing successful long-term DIC storage (Smetacek et al. 2012). However, little carbon was exported to the ocean interior in a similar experiment in the Subantarctic Atlantic Ocean, despite a short-term increase in primary production near the surface (Martin et al. 2013). This spatial variability in efficiency, coupled with concerns about disruptive effects on ecosystems, has led to skepticism that this technique could mitigate the adverse effects of anthropogenic CO_2 (Strong et al. 2009).

Summary

Through the biological pump, dissolved inorganic matter is converted into biomass in the surface ocean, and exported to the interior via sinking, active transport or physical transport. At depth, this biomass is processed (fragmented and/or repackaged) by deep-sea organisms and remineralized. Essential elements are remineralized near the surface ocean and thus have "nutrient-type" vertical profiles (increasing concentration with depth). Non-essential elements exhibit a variety of profiles including decreasing concentrations with depth ("scavenged") and uniform distributions ("conservative"). The storage of carbon in the interior ocean sustained by the biological carbon pump plays an important role in regulating the atmospheric CO_2 concentration. The biological pump thus sustains life in the deep sea and drives the spatial distributions of many elements throughout the global ocean.

Definition

Thermal maturity consists of temperature/time-driven disproportionation reactions that convert sedimentary organic matter into light and heavy fractions of petroleum and finally into hydrocarbon gas and pyrobitumen or graphite. Different geochemical scales commonly used to describe the extent of thermal maturation include vitrinite reflectance (R_o), programmed pyrolysis (e.g., Rock-Eval) T_{max} and production index, and biomarker maturity ratios (e.g., Peters et al. 2005).

Introduction

Geochemists divide thermal maturation into three stages: diagenesis, catagenesis, and metagenesis. Temperature and vitrinite reflectance values at the transitions between these stages vary depending on the burial heating rate and type of organic matter and are thus only approximate. Diagenesis consists of chemical, physical, and biological changes in the organic matter during and after sediment deposition and lithification at temperatures below ~80 °C (R_o <0.6%). Diagenesis occurs prior to thermogenic oil and hydrocarbon gas generation but can include formation of microbial methane. Catagenesis includes thermal alteration of organic matter during burial at ~80–150 °C (R_o ~0.6–2.0%), which may require millions of years. The depth interval of catagenesis corresponds to the oil window or principal zone of oil formation. Metagenesis cracks organic molecules to gas and pyrobitumen at ~150–200 °C (R_o ~2.0–4.0%), prior to greenschist metamorphism (>200 °C). Because common thermal maturity parameters are measured using irreversible reactions, uplifted petroleum source rocks may show higher maturity than expected based on their present-day burial depth.

Vitrinite reflectance is a popular maturity parameter based on organic petrography or rock samples (e.g., Peters and Cassa 1994). Vitrinite phytoclasts are fine particles of higher-plant organic matter that are rare or absent in some rocks, so biomarkers or other parameters are required to assess their maturity (Peters et al. 2005). Because R_o cannot be determined on oil samples or rock extracts, geochemists commonly describe their thermal maturity in terms of equivalent R_o, which can be inferred from biomarkers or other compounds, such as methylphenanthrenes (Peters et al. 2005), or calculated based on time-temperature burial history (e.g., Sweeney and Burnham 1990).

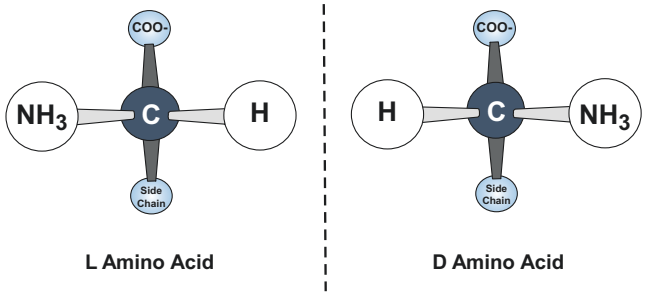
Certain biomarker stereoisomer ratios are among the most common measures of thermal maturity because, unlike R_o and other parameters, biomarkers are nearly ubiquitous in crude oil and sedimentary rock. Stereoisomers have the same molecular formula and the same bonds between atoms but different spatial arrangements of the atoms around each asymmetric carbon atom. Asymmetric carbon atoms are surrounded by four different substituents, thus allowing mirror-image molecules having the same molecular formula, such as L or D amino acids (Fig. 1). Stereoisomers include enantiomers (mirror-image structures having one or more asymmetric carbon atoms) and diastereomers (epimers), which differ at certain asymmetric centers, but may be identical at others.

Methods and General Approach

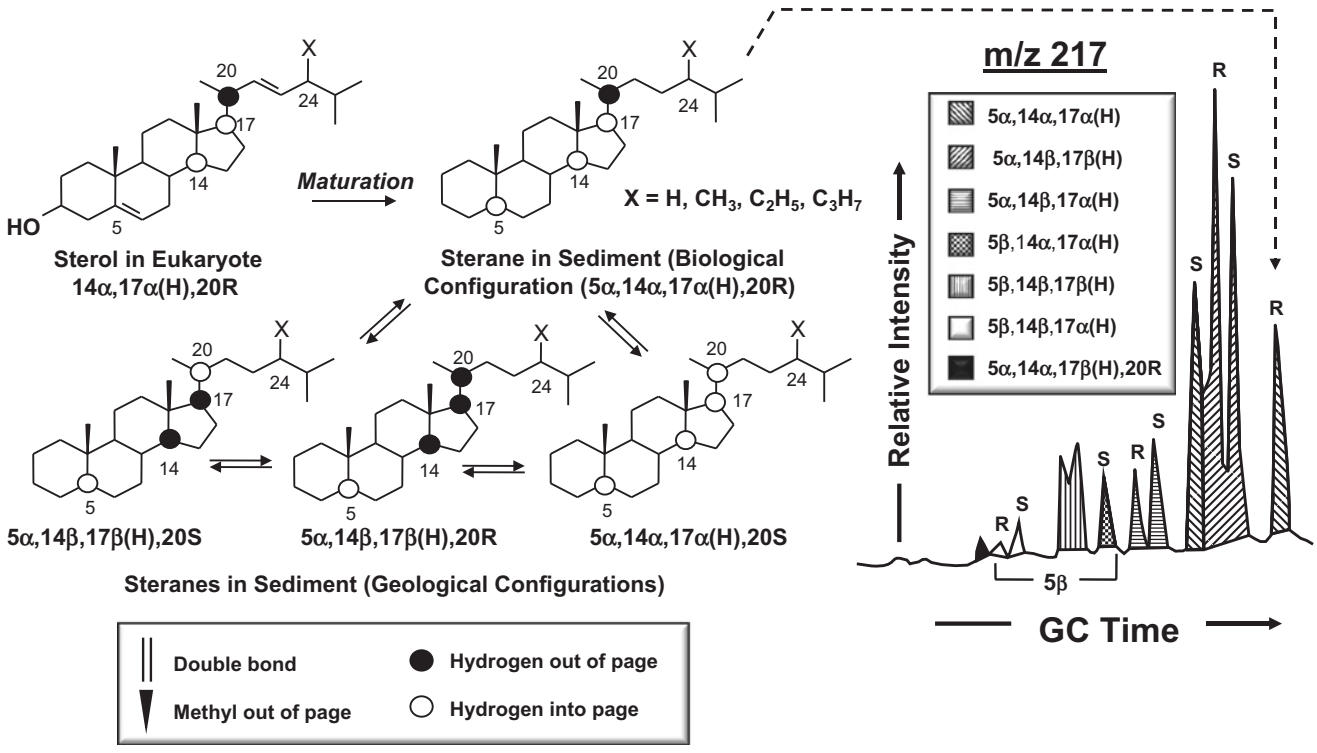
Gas chromatography-mass spectrometry (GC-MS) generates mass chromatograms, which detect steranes and other

biomarkers by focusing on the principal mass fragment ion that is diagnostic for that class of biomarkers (e.g., Fig. 2; m/z 217 for steranes). The following discussion focuses on steranes as examples of key biomarkers used to assess thermal maturity. Steranes in sediments and petroleum originate from sterols in once-living organisms (Peters et al. 2005). Three asymmetric centers in sterols (C-14, C-17, and C-20) are always in the "biological" configuration: 14α,17α(H),20R, i.e., αα20R. During thermal maturation, the biological configuration can undergo stereoisomerization to more stable "geological" configurations by formation of a carbocation and migration of a hydrogen ion. The biological and three key geological stereoisomers are readily quantified by gas chromatography-mass spectrometry (m/z 217; Fig. 2, far right). Two common sterane maturity ratios are: (1) 100 × αα20S/(αα20S + αα20R), also called %20S, and (2) 100 × (ββ20S+ββ20R)/(ββ20S+ββ20R+αα20S+αα20R), also called %ββ. X = H, CH_3, C_2H_5, and other groups. These ratios are normally measured for the C_{29} sterane homolog, which is called stigmastane (X = C_2H_5).

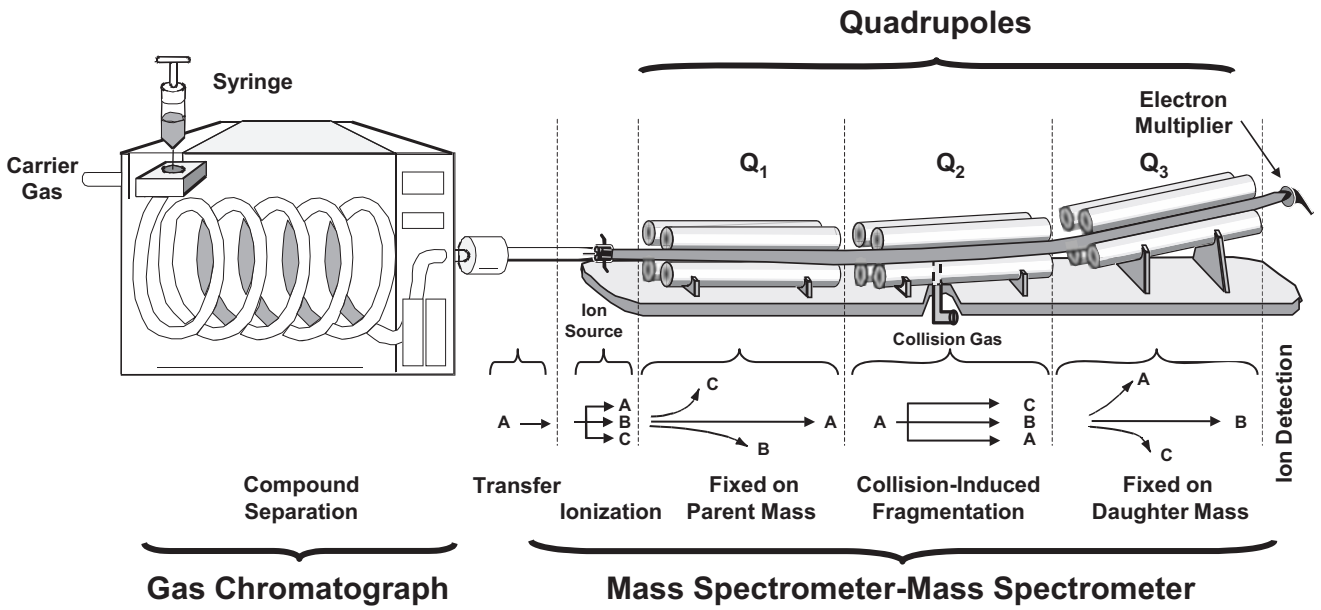
However, sterane homologs at C_{27}, C_{28}, C_{29}, and C_{30} in oil or extract samples can interfere with each other on mass chromatograms, resulting in inaccurate assessment of stereoisomer ratios. Gas chromatography-mass spectrometry-mass spectrometry (GC-MS-MS) eliminates interference among homologs by means of precursor-product (also called



Biomarker: Assessment of Thermal Maturity, Fig. 1 Inversion of one asymmetric carbon atom (epimerization) in an amino acid results in a type of stereoisomer called an enantiomer, which is a molecule having a nonsuperimposable mirror image (indicated by *dashed line*). Nearly all living organisms have amino acids in the L configuration. In molecules having more than one asymmetric center, inversion of all asymmetric centers leads to the enantiomer (mirror image). Inversion of one or more, but not all asymmetric centers, yields a diastereomer. Biomarkers in petroleum and source rock extracts have many asymmetric centers and therefore many diastereomers and enantiomers are possible for each



Biomarker: Assessment of Thermal Maturity, Fig. 2 Steranes in petroleum originate from sterols in once-living organisms (*top left*). During early diagenesis, steranes retain the original biological stereochemistry at positions C-14, C-17, and C-20 (αα20R). During catagenesis, steranes undergo stereoisomerziation at these and other positions, resulting in some proportion of thermally more stable geological stereioisomers (mass chromatogram at *right*; Seifert and Moldowan 1979). The extent of each reaction varies depending on the specific atomic geometry at each asymmetric center but can also be influenced by temperature and catalysis by minerals



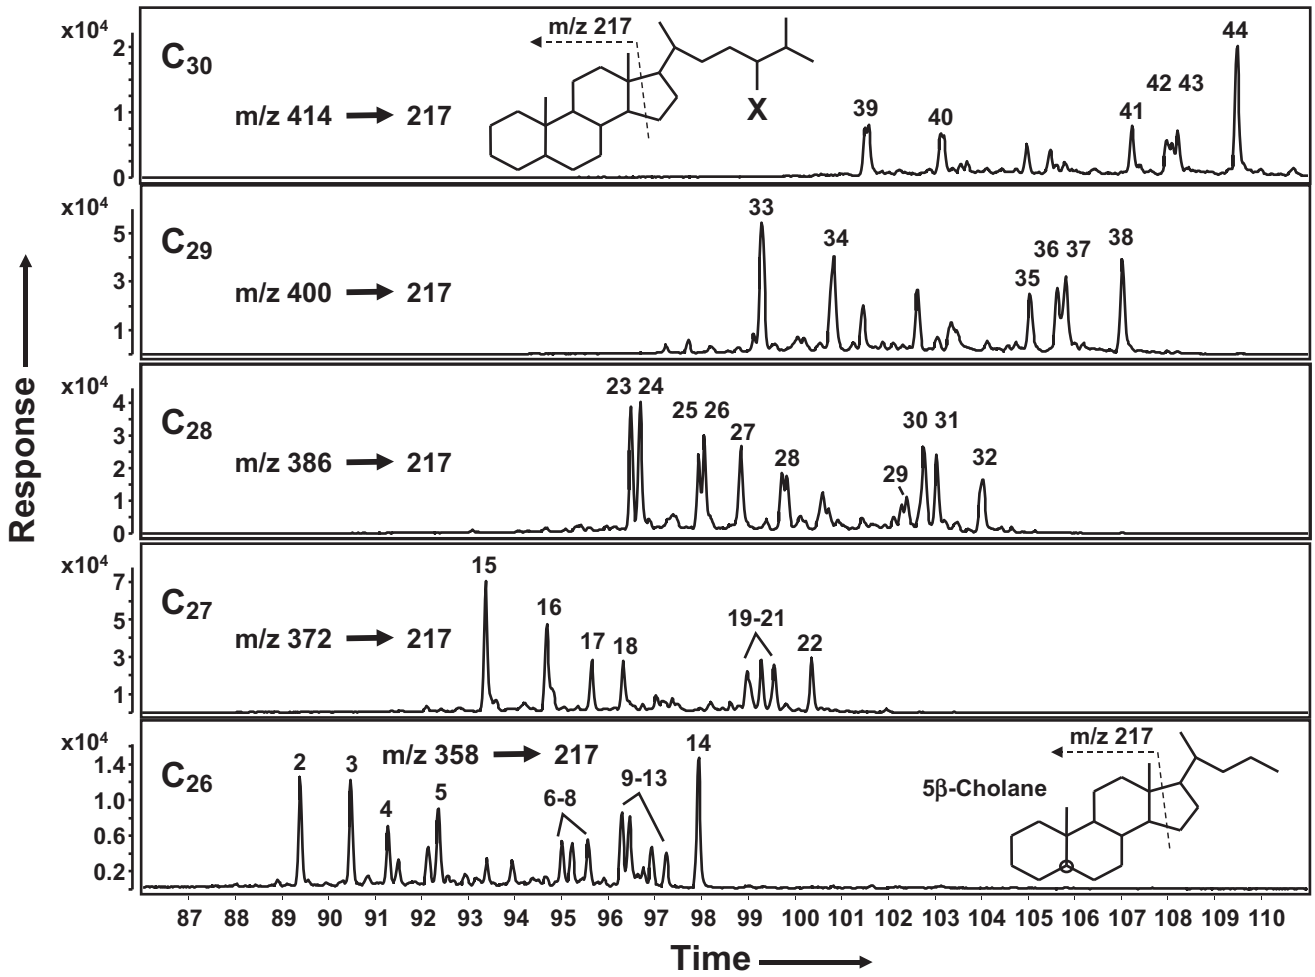
Biomarker: Assessment of Thermal Maturity, Fig. 3 Schematic view of a gas chromatograph equipped with a triple-quadrupole mass spectrometer consisting of three sets of quadrupole rods (GC-MS-MS; not to scale). Three quadrupoles allow highly selective precursor-product detection (e.g., only product ion B from precursor compound A). The gas chromatograph separates compound A, which undergoes ionization in the ion source at 70 eV. The first quadrupole (Q1) focuses the molecular ion of A, which is the precursor of additional ion products by collision-induced fragmentation in Q2. Q3 focuses the diagnostic product ion B, thus removing interference by other ions created in Q2

parent-daughter) ion monitoring. For example, C_{29} steranes can be monitored using triple-quadrupole mass spectrometry (Fig. 3) by allowing only ions having a precursor mass (M+) of m/z 400 to enter the second or collision quadrupole for further fragmentation. The third quadrupole focuses only on the appropriate product mass for steranes (m/z 217), thus resulting in a mass chromatogram that is unique for C_{29} steranes (Fig. 4).

Parameters

Various saturated and aromatic biomarker ratios can be used to assess thermal maturity of crude oils or source rock extracts (Peters et al. 2005). Most ratios are expressed as the product (B) divided by the reactant (A) plus the product, i.e., B/(B + A). These ratios are based on two reaction types: (1) stereoisomerization at asymmetric carbon atoms in saturated biomarkers and (2) cracking and/or aromatization, including so-called side-chain scission reactions in aromatic biomarkers. It is more likely that relative stability of the short versus long side-chain compounds is the basis for these cracking parameters. Relative stability is the basis for several other saturated biomarker maturity parameters, such as C_{23} tricyclic terpane/C_{30}-hopane, diasteranes/steranes, Ts/Tm [18α-trisnorneohopane/17α-trisnorhopane, usually presented as Ts/(Ts + Tm)], and 18α,30-norneohopane/17α-30-norhopane [abbreviated as C_{29}Ts/C_{29}Hop or C_{29}Ts/(C_{29}Ts + C_{29}Hop)]. The latter two and many other maturity parameters are not stereoisomerizations but are based on the relative kinetic and/or thermodynamic stability of the components toward C─C bond cracking. Thus, Ts/(Ts + Tm) progresses from zero in immature samples to one (or 100%) at late oil-window maturity due to greater relative stability of Ts compared to Tm. Such parameters, termed irreversible, become important for maturity estimation from before the peak to the end of the oil window, a maturity range in which sterane and hopane stereoisomer ratios have maximized at some value between zero and one.

Stereoisomerization ratios are preferred because the reactant in thermally-immature sediments is 100% in the biological configuration, whereas the product geological configurations are absent. In reality, even stereoisomer ratios cannot be described strictly by simple conversion of A to B. For this reason, kinetics derived for these presumed reactions cannot be reliably used to calibrate basin and petroleum system models (Walters et al. 2012). Four of the most commonly used ratios are based on isomerization of hydrogen atoms around asymmetric carbon atoms at C-20 [%20S/(20S + 20R)] and C-14 and C-17 [%ββ/(ββ + αα)] in the steranes, C-22 in the hopanes [%22S/(22S + 22R)], and both C-17 and C-21 in the hopanes [%ββ/(ββ + βα + αβ)], as indicated in Fig. 5. Other saturated biomarker maturity parameters supplement these isomerization ratios, such as the moretane/17α-hopane [17ß,21α/17α,21ß].



Biomarker: Assessment of Thermal Maturity, Fig. 4 Gas chromatography-mass spectrometry-mass spectrometry (GC-MS-MS) of a crude oil mixture (Stanford-1) in precursor-product mode (M+ → m/z 217) differentiates sterane epimers by carbon number, thus reducing interference seen in GC-MS. Stanford-1 is a blend of several oil samples and some pure synthetic compounds blended to include most biomarkers in crude oils derived from source rocks deposited in various depositional environments. *Dashed arrows* in the upper inset identify the m/z 217 product ion. X = H, CH_3, C_2H_5, and C_3H_8 for the C_{27} to C_{30} homologs (precursor ion, M+ = m/z 372, 386, 400, and 414, respectively). 5β-Cholane (*lower right*) is a C_{24} sterane not abundant in crude oil that is used as an internal standard to quantify peaks. Peaks 35–38 (Table 1) can be used to generate two C_{29} sterane stereoisomer ratios used to assess the thermal maturity of crude oil and source rock extracts (Fig. 5): %20S/(20S + 20R) and % ββ/(ββ + αα). Peaks 23–26 were recently identified in Peters et al. (2014)

Another biomarker cracking ratio is based on the conversion of monoaromatic (MA) to triaromatic (TA) steroids (Fig. 5). The TA/(MA + TA) ratio is less commonly applied for maturity assessment than isomerization ratios because (1) quantification of aromatic steroids can be difficult and (2) thermally immature samples may not start with 100% of the presumed reactant. Some additional aromatic maturity parameters are based on ratios of aromatic steroids with short versus long side chains (commonly described as side-chain cleavage reactions). These aromatic steroid side-chain scission parameters are similar to Ts/Tm in that they extend the application of biomarker maturity estimates from the middle to well into the late-oil window, where stereoisomeriztion ratios are ineffective.

Data Interpretation

Biomarker ratios can be used to assess the relative thermal maturity of crude oils and source rock extracts, particularly when the samples are genetically related based on oil-oil or oil-source rock correlation using source-related biomarker and stable carbon isotope ratios (Peters et al. 2005). Figure 6 shows the relative thermal maturity of nine genetically related crude oils based on two C_{29} sterane stereoisomer ratios from GC-MS-MS.

Assessment of thermal maturity relative to the oil window or vitrinite reflectance using biomarker ratios (Fig. 5) is not as straightforward as relative maturity assessment (Fig. 6). All relationships between reaction extent and the stage of oil

Biomarker: Assessment of Thermal Maturity, Table 1 Identification of biomarker peaks from Fig. 4, including peaks 35–38 that are used to generate two C_{29} sterane stereoisomer ratios in Fig. 5 and 6. Peaks are quantified using the C_{24} sterane 5β-cholane internal standard (peak 1 not shown in Fig. 4), which is measured from the m/z 330 to 217 precursor-product transition with calibration using the Stanford-1 external standard (Peters et al. 2005)

Peak	Identification	Carbon number
1	5β-Cholane	24

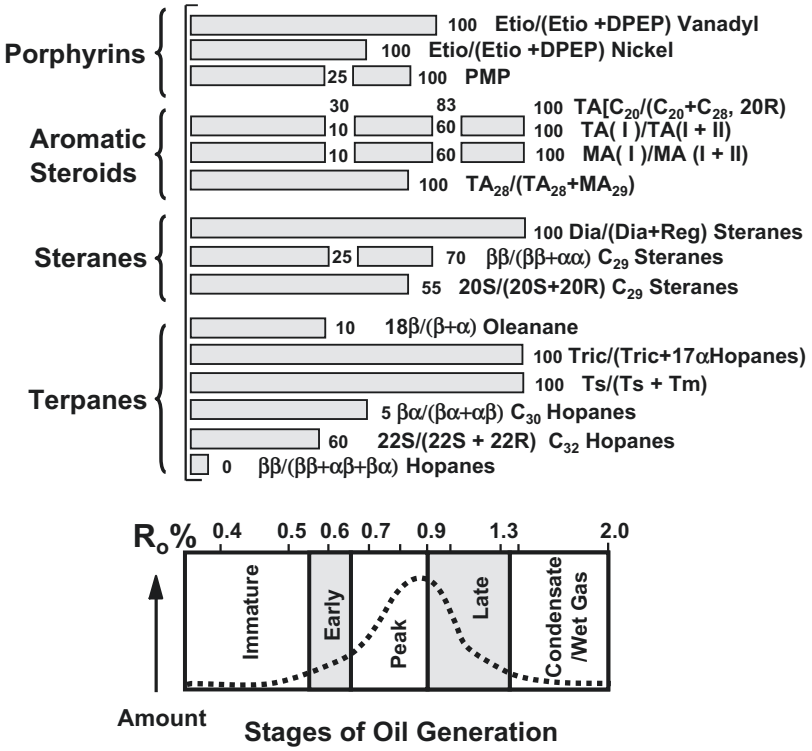
generation or vitrinite reflectance (R_o) are approximate. Readers are cautioned against inferring equivalent R_o from a single biomarker ratio. Reflectance inferred from multiple biomarker ratios may show variations of ±0.1% R_o.

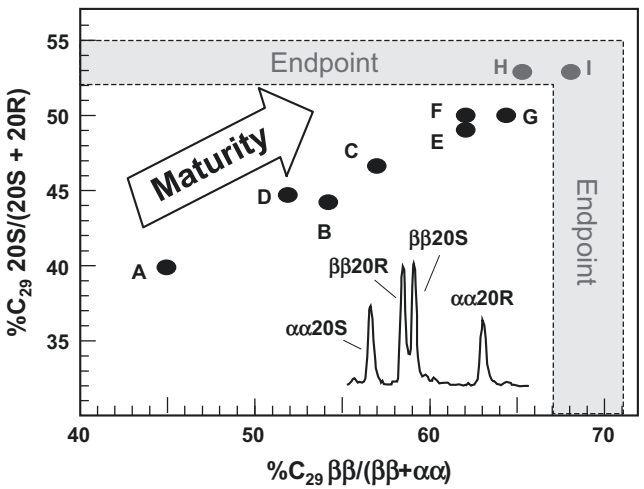
The most reliable approach to assess thermal maturity from Fig. 5 is to start by using stereoisomer ratios based on fast reactions (e.g., C_{32} hopane %22S/(22S + 22R). For example, if a sample achieved the endpoint for %22S/(22S + 22R) (~60%), this nominally represents maturity equivalent to at least the beginning of the oil window (R_o ~0.6%). All samples in Fig. 6 have achieved endpoint for this ratio. Next, proceed to the ratio for a slower reaction, such as C_{29} sterane %20S/(20S + 20R). If the endpoint for %20S/(20S + 20R) has been achieved, then proceed to an even slower reaction, such as C_{29} sterane %ββ/(ββ + αα). If this ratio did not achieve endpoint (~70%) for a sample (e.g., sample H in Fig. 6), then the thermal maturity is bracketed by the endpoints for %20S/(20S + 20R) and %ββ/(ββ + αα)], which approximately corresponds to the peak of the oil window or R_o ~0.9% (Fig. 5). If the sample achieved endpoint for %ββ/(ββ + αα), e.g., sample I in Fig. 6, then further assessment requires use of ratios from even slower reactions such as mono- or triaromatic side-chain cleavage parameters: MA(I)/MA(I + II) or TA(I)/TA(I + II), which are based on stereoisomerization. We do not recommend that maturity assessment begin with ratios based on such slow reactions, because (1) reactions controlling these ratios are complex and the initial amounts of reactant and product may not be 100% and 0%, respectively and (2) these robust ratios may not even respond at low maturity, thus resulting in no systematic trend. Nevertheless, ratios for these slow reactions can show systematic variations with maturity in some cases and it is preferable to consider as many biomarker maturity parameters as possible to corroborate interpretations.

Supporting Analyses

Perhaps the most straightforward biomarker maturity parameters rely simply on biomarker concentrations in oil and rock extract samples. Biomarker concentrations can be measured by GC-MS or GC-MS-MS by introducing calibration factors determined through analysis of an external standard, where the abundance of the ion being measured for each biomarker (e.g., m/z 217 for steranes by GC-MS or the m/z 400 → 217 transition for C_{29}-steranes by GC-MS-MS) is calculated based on its known concentration in the standard. Biomarker concentrations steadily decrease from a maximum before the beginning of the oil window to zero at or before the end of the oil window, depending on which biomarker is being measured. One such biomarker concentration that is commonly used in this way is that of the ααα20R-C_{29}-sterane (sometimes named stigmastane) when



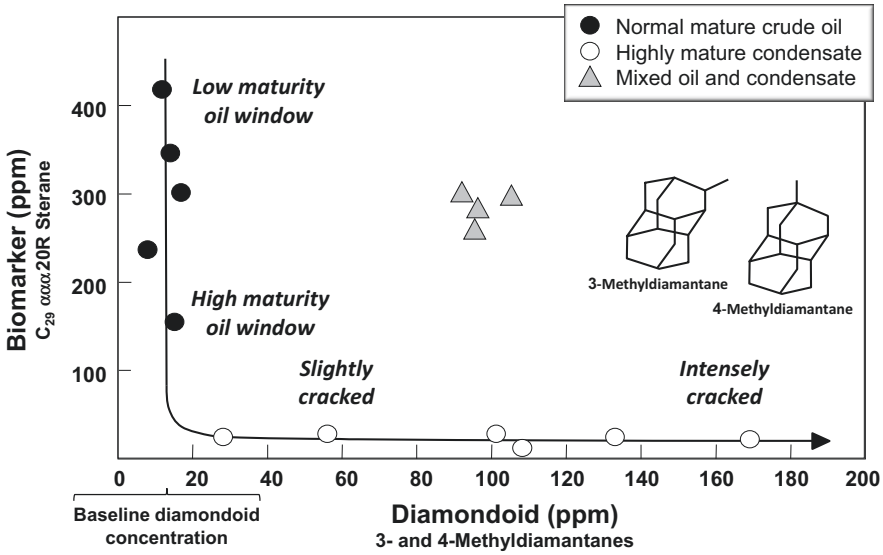
Biomarker: Assessment of Thermal Maturity, Fig. 5 Approximate ranges of some biomarker maturity parameters relative to equivalent vitrinite reflectance (R_o) and the oil generation window (modified from Peters and Moldowan 1993). *Solid bars* show the range for each ratio relative to the stages of oil generation. Each ratio reaches a constant percentage indicated at the end of the bar, which normally does not change with further maturity. This ratio is the maximum value for most of the parameters, except 18ß/(18α + 18ß)-oleanane, ßα/(αß + ßα)-hopanes (C_{30}) and ßß/(ßß + αß + ßα)-hopanes, where 10, 5, and 0 are minimum values, respectively. Intermediate values are shown for a few ratios within the bars to indicate earlier stages of maturity (Reprinted with permission by ChevronTexaco Exploration and Production Technology Company, a division of Chevron U.S.A. Inc.)



Biomarker: Assessment of Thermal Maturity, Fig. 6 Relative thermal maturity for nine genetically related crude oil samples based on two C_{29} sterane stereoisomer ratios. Inset shows peaks used for the C_{29} sterane ratios from GC-MS-MS analysis (m/z 400 → 217; peaks 35–38 in Fig. 4). The %20S and %ββ ratios require two and four peaks, respectively. Sample A is the least mature. Sample G is less mature than samples H and I. Sample I is more mature than H because it has achieved endpoint for both ratios. Complete maturity assessment of sample I requires additional biomarker ratios that respond at higher levels of thermal maturity

plotted versus the sum of the concentrations of two diamondoids; 3- and 4-methyldiamantanes (Dahl et al. 1999). Diamondoid concentrations are measured by adding deuterated diamondoids to the oil or extract sample before analysis (diamondoid methods and applications are reviewed by Moldowan et al. 2015). This method accounts for maturity from the beginning of the oil window extending into the gas window, i.e., from R_o ~0.6 to 4.0% or more. The ααα20R-C_{29}-sterane reaches negligible concentrations at approximately the maturity where oil begins to crack to gas and pyrobitumen is being formed. On the other hand, the diamondoids are thermally very stable and actually become more concentrated after significant oil cracking begins. Thus, Fig. 7 can be used to determine relative maturities of oil samples both within and far beyond oil-window maturity.

Additional maturity measurements help to validate biomarker maturity assessments. For example, vitrinite reflectance or programmed pyrolysis T_{max} and production index for rock samples help to verify biomarker interpretations based on the corresponding rock extracts. Nonbiomarker maturity parameters, such as the methylphenanthrene index (Radke and Welte 1983), can be used to corroborate biomarker assessment of oil maturity.



Biomarker: Assessment of Thermal Maturity, Fig. 7 The biomarker-diamondoid method can be used to assess thermal maturity of crude oil or source rock extract samples. Oil samples having maturities within the oil window show significant C_{29} sterane (stigmastane) concentrations and low concentrations of diamondoids (3- and 4-methyldiamantanes). Diamondoids increase rapidly from baseline concentrations after significant oil cracking begins. Oil samples showing mixed maturity signals, i.e., elevated stigmastane and elevated 3- and 4-methyldiamantane concentrations (*triangles*), represent mixtures of both oil-window (e.g., black oil) and postmature components (e.g., light oil or condensate) that result from multiple charge events in the petroleum reservoir (Figure adapted from Dahl et al. (1999))

Summary

In general, the relative thermal maturity of genetically related oil or source-rock extract samples can be readily assessed using various biomarker maturity ratios. Maturity ranking may not be possible for samples that are contaminated, heavily biodegraded, or so highly mature that specific biomarkers are low (<3–5 ppm) or absent. However, highly mature samples can still be evaluated using the quantitative biomarker-diamondoid method. Estimates of maturity relative to the oil window or vitrinite reflectance using biomarker ratios may not be as straightforward as relative maturity assessment. Biomarker maturity ratios are limited in the effective maturity ranges that they cover. Therefore, the most reliable maturity assessments are based on multiple biomarker ratios from progressively slower reactions, which bracket the maturity of each oil or rock extract sample. Stereoisomer ratios are preferred because the initial amount of reactant in the biological configuration is 100%, while that of the product is 0%.

Definition

Biomarkers. Complex organic compounds which retained structural similarities to biological precursors identified in living organisms.

Lipids. Small molecules that originate from biochemical subunits, including fats, waxes, sterols, etc. These molecules can be extracted by organic solvents.

Coal. Combustible black sedimentary rock formed by humification of plant materials. According to increased maturation, coals are classified as lignites, subbituminous coals, bituminous coals, and anthracites, respectively.

Introduction

Organic geochemical methods have become important tools for the reconstruction of paleovegetation, environmental changes, and transformation processes of organic matter during diagenesis. The application of gas chromatography and mass spectrometry techniques on extractable organic matter (i.e. lipids) from low-rank coals or compounds released during pyrolysis has been used to gain information about coal-forming vegetation. Biomarkers were successfully used for the taxonomical differentiation of plant families. Effects of humification, microbial activity, and diagenetic pathways on biomarker composition have been derived from coal-bearing sequences subjected to increased thermal maturation.

Lipids (especially hydrocarbons) are minor constituents in lignite and subbituminous coals. However, their composition provides information on paleovegetation and paleoclimate, especially if combined with the results of paleontological studies. The diagnostic biomarkers decrease in intensity with increasing maturity, and they largely disappear in butuminous coals. Instead information about thermal transformation processes (diagenetic pathways) of biomarkers can be derived from these coals.

Biomarkers and Paleovegetation

Besides pollen assemblages, changes in paleovegetation are reflected by biomarker composition of coals. Several attempts have been made to interpret *n*-alkane distribution patterns in terms of floral changes. However, the potential outcomes are controversially discussed. More specifically, terpenoids were found to contain diagnostic biomarkers for the reconstruction of the coal-forming vegetation.

Terpenoids (isoprenoids) represent the largest and most diverse class of biomolecules among the compounds produced by plants. Plants employ terpenoid metabolites for a variety of basic functions in growth and development but use the majority of terpenoids for more specialized chemical interactions and protection in the abiotic and biotic environment. They defend many species of plants, animals, and microorganisms against predators, pathogens, and competitors. Based on the number of isoprene units, the terpenoid biomarkers are subdivided into sesquiterpenoids, diterpenoids, and triterpenoids.

n-Alkane Distribution

Different types of plants produce leaf wax *n*-alkanes with differing carbon chain lengths. Leaf wax of vascular plants (grasses, sedges, trees, and shrubs) is dominated by long chain (C_{29}–C_{31}) *n*-alkanes, whereas *Sphagnum* leaf wax is characterized by medium chain length (C_{23}–C_{25}) *n*-alkanes (Nott et al. 2000; Pancost et al. 2002). The potential of using biomarker *n*-alkanes as surface moisture proxies by comparing changes in the ratios of *n*-alkanes with already observed changes in water table depths and humification indices in a peat core from Minden Bog in southeastern Michigan (USA) has been documented by Nichols et al. (2006).

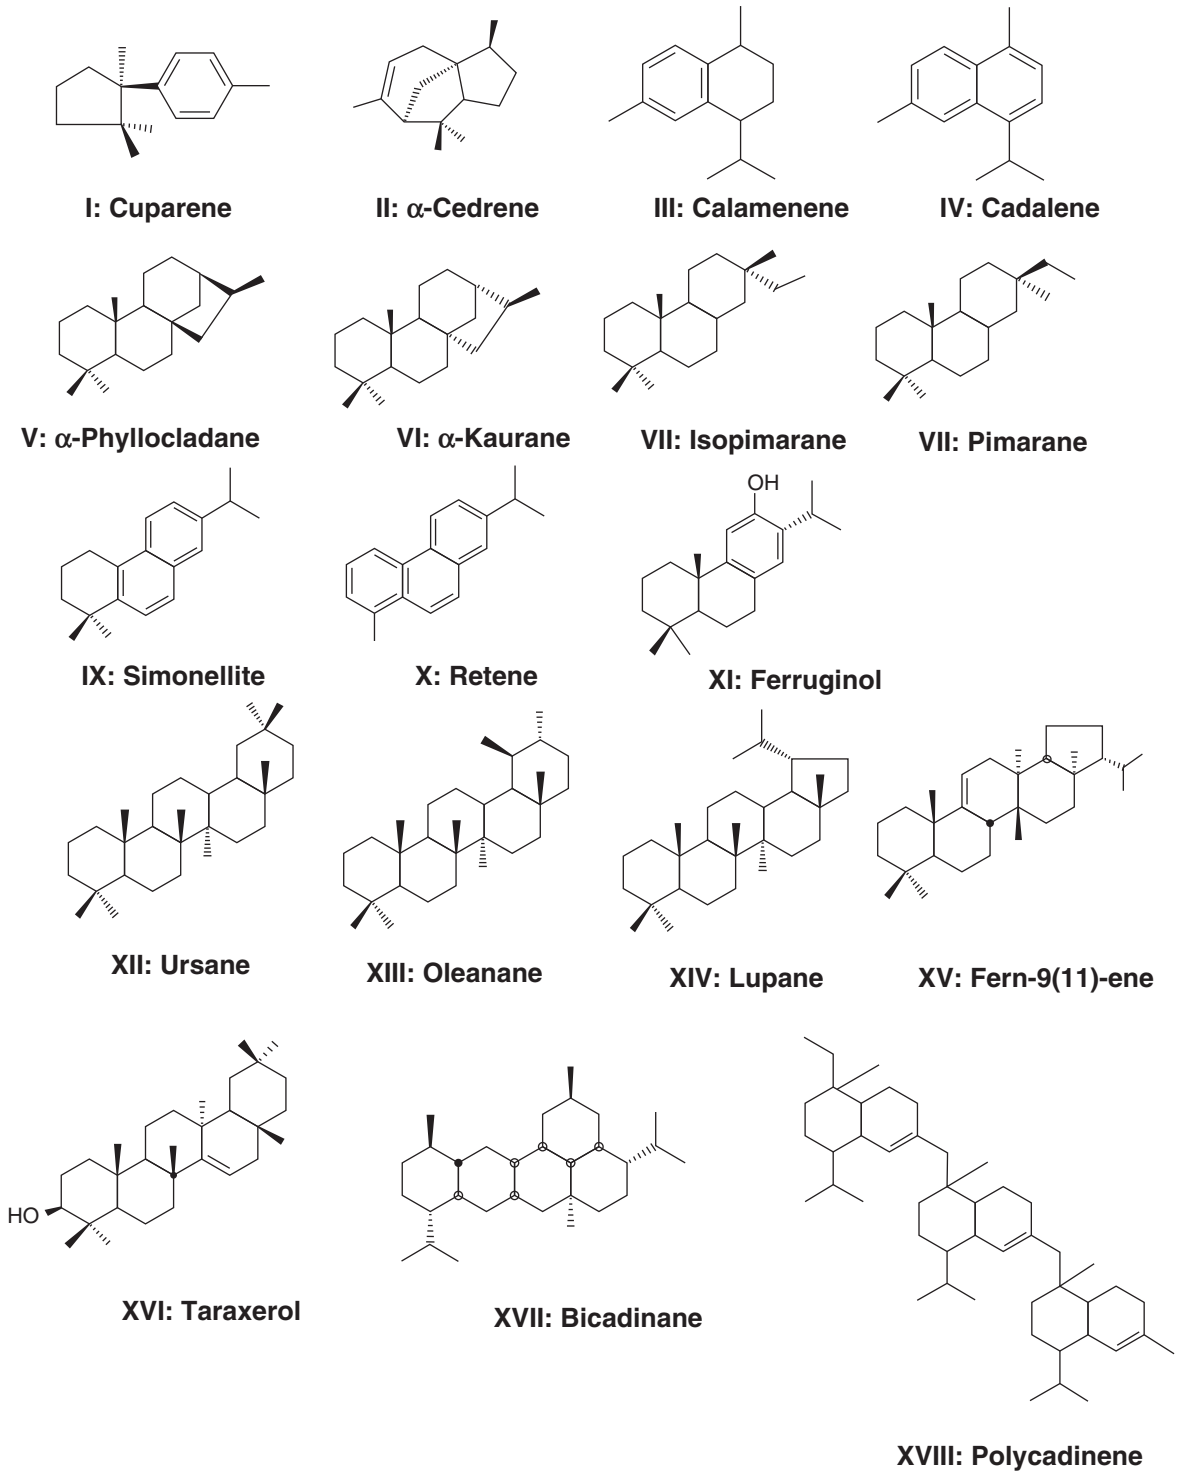
Recently, the combination of hydrogen isotopic compositions of low (C_{23}, C_{25}) and high molecular weight (C_{31}, C_{33}) *n*-alkanes with *n*-alkane ratios revealed differences in hydrology and the relative contribution of aquatic to terrestrial plants in a Quaternary peat bog of northwestern China (Seki et al. 2009).

Sesquiterpenoids

Sesquiterpenoids (C_{15}) include more than 2,500 compounds. Besides the origin of several bicyclic

sesquiterpanes (i.e., drimane) through biodegradation or thermal cleavage of pentacyclic triterpenes, the occurrence of mono- and bicyclic sesquiterpanes in crude oils derived from terrestrial sources has been reported (Alexander et al. 1983; Philp 1985).

Monocyclic bisabolanes and biosynthetically related compounds (cuparene (**I;** Fig. 1) and α-cedrene (**II;** Fig. 1); Otto and Wilde 2001) have been identified in a fossil resin and montane wax derived from conifers of the family Cupressaceae (Grantham and Douglas 1980). Besides this well-established



Biomarkers: Coal, Fig. 1 Terpenoid compounds of different structural types discussed in the text

precursor/product relationship, sesquiterpenoids are less specific for the identification of contributions of different gymnosperm families.

Bicyclic sesquiterpenoids are widely distributed in higher plants, and related hydrocarbons were found in oils and source rocks. Cadinanes are common constituents of conifers. However, these sesquiterpenoids are also known as catagenic products of polycadinenes, biomarkers specific for the angiosperm family Dipterocarpaceae (van Aarssen et al. 1990). Based on the identification of cadalane-type **(III, IV;** Fig. 1) sesquiterpenoids in fossil resins of the Oligo/Miocene *Taxodium*-rich oxbow lake clays, the origin of these sesquiterpenoids from Taxodiaceae was concluded (Otto et al. 1997; Vávra and Walther 1993).

Diterpenoids

Tetracyclic diterpenoid hydrocarbons include the phyllocladane- (**V;** Fig. 1) and kaurane-type (**VI;** Fig. 1) compounds (Fig. 2). They have been proposed as biomarkers for the Podocarpaceae and Araucariaceae families, respectively (Noble et al. 1985). The determination of the diagenetic molecular signatures of extant representatives of Araucariaceae through artificial maturation by confined pyrolysis confirmed the predominance of saturated tetracyclic diterpenoids including phyllocladanes and kauranes (Lu et al. 2013). However, the identification of phyllocladanes in Upper Carboniferous coals suggested their synthesis already in the ancient conifers of the order Voltziales (Schulze and Michaelis 1990). The occurrence of phyllocladanes in *Taxodium* peat from the Okefenokee swamp (Georgia, USA) and in the Miocene Oberpfalz coal (Germany), built up by Taxodiaceae-dominated vegetation, provided evidence for the correlation of phyllocladanes and Taxodiaceae (Dehmer 1989). Phyllocladanes may, therefore, originate from different conifer families. Only in Pinaceae, phyllocladanes have not been found (Otto and Wilde 2001). Therefore, a significant contribution of Pinaceae to peat formation can be excluded based on the predominance of tetracyclic diterpenoids in the hydrocarbon fractions.

Tricyclic diterpenoids may provide complimentary information about the peat-forming vegetation. Isopimaranes (**VII;** Fig. 1) and pimaranes (**VIII;** Fig. 1) are common constituents of conifers (Fig. 2a). They have been detected in recent species of Pinaceae, Cupressaceae, and Taxodiaceae (Otto and Wilde 2001). Recently, the higher pimarane/16α (H)-phyllocladane ratios in Lower and Middle Miocene lignites in comparison to Upper Miocene coals of Serbia were interpreted to imply a higher contribution of Pinaceae to coal formation, consistent with palynological data (Stojanović and Životić 2013).

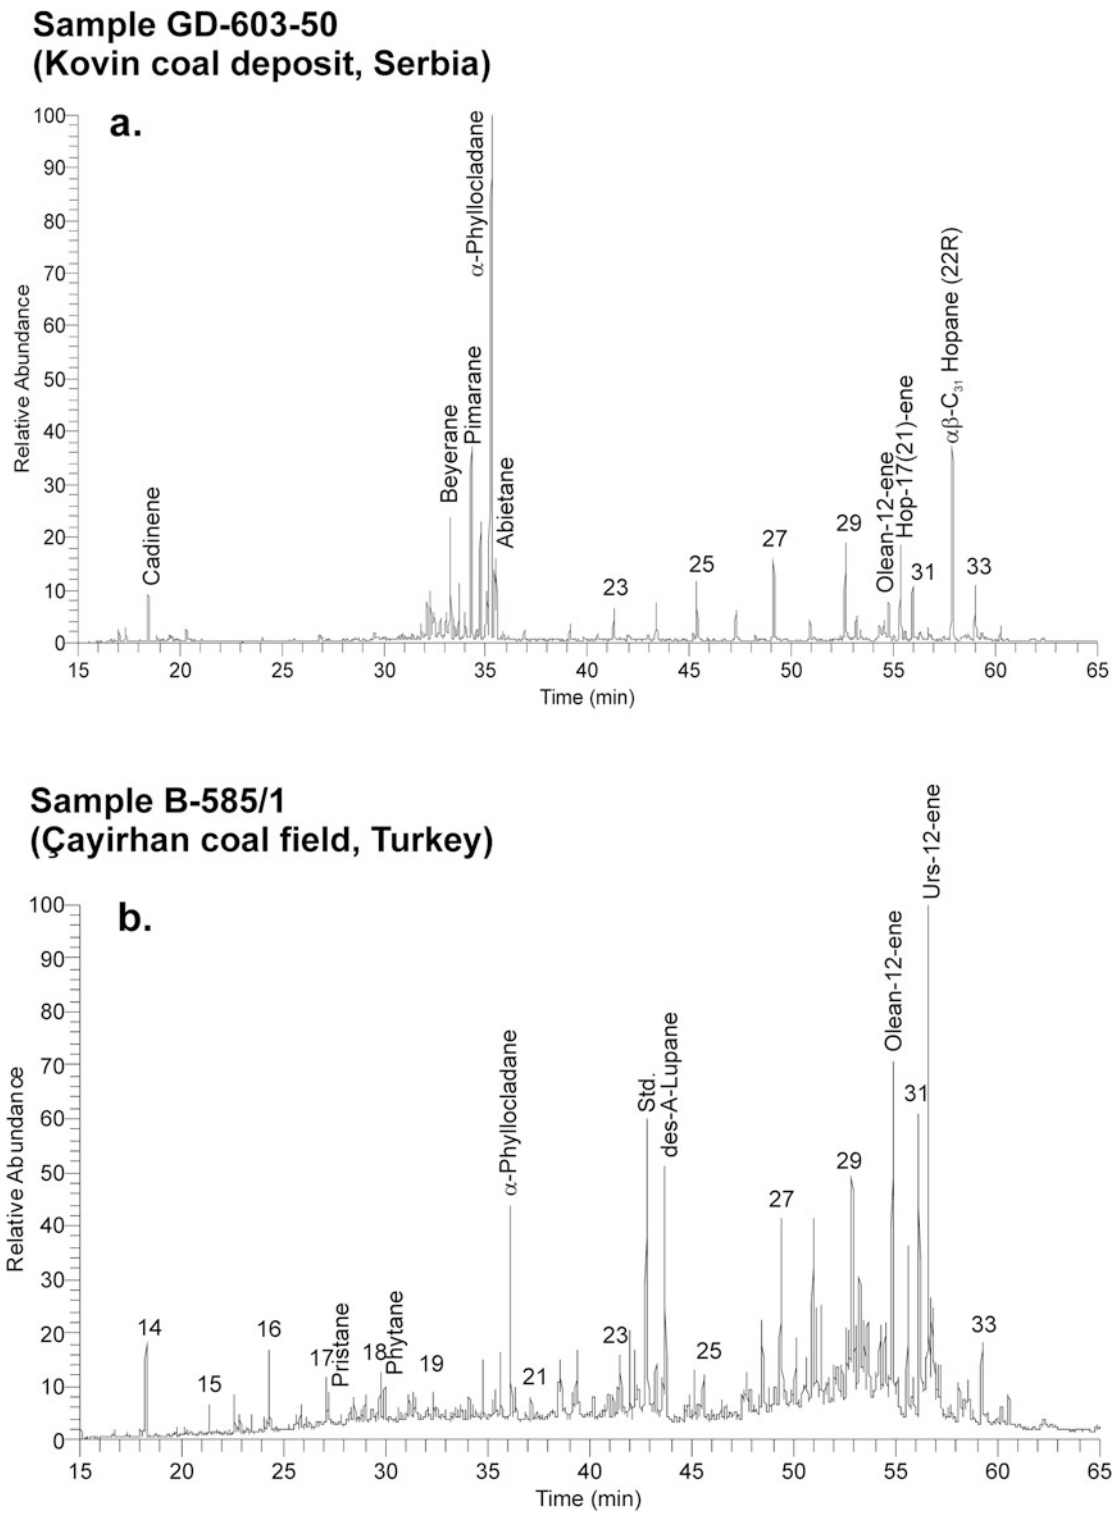
Additional indication about the role of Pinaceae is based on abietane-type compounds. Diterpenoids of the abietane type (Fig. 2a) have been identified in many sediments and coals (Simoneit et al. 1986). As abietic acid only occurs in Pinaceae species, their diagentic products simonellite (**IX;** Fig. 1) and retene (**X;** Fig. 1) were often referred to as biomarkers for Pinaceae. However, abietane-type diterpenoids in the geosphere may also derive from phenolic derivatives. The phenolic abietane ferruginol (**XI;** Fig. 1) has been described in most conifer families, especially Cupressaceae, Taxodiaceae, and Podocarpaceae, but seems to be absent in Pinaceae (Otto and Wilde 2001). Therefore, only nonaromatic abietanes can be considered as diagenetic products of abietic acid, specific for conifers of the Pinaceae family.

Triterpenoids

Deciphering precise precursor/product relationships for triterpenoids often suffers from largely unknown compound transformation routes, as well as the occurrence of nonspecific precursors in higher land plants (Regnery et al. 2013).

For example, oxygenated pentacyclic triterpenoids of the ursane (**XII,** Fig. 1), oleanane (**XIII;** Fig. 1), and lupane (**XIV;** Fig. 1) types occur in almost all angiosperm taxa (Fig. 2b), and their attribution to individual plant families is difficult (Medeiros and Simoneit 2007). With respect to lupanes (Fig. 2b), only correlation with angiosperms of the Betulaceae family is convincing, since the lupane precursors betulin, lupeol, and betulinic acid are the dominant pentacyclic constituents of *Betula* bark (Hayek et al. 1989). Betulin is also found in the bark of other genera belonging to the Betulaceae family, including *Alnus*, *Corylus*, and *Carpinus* (Hayek et al. 1990).

Based on pollen assemblages in several lignite deposits, ferns are considered to significantly contribute to peat formation. The presence of des-A-fernenes (Loureiro and Cardoso 1990), as well as fernenes of either Δ^7, Δ^8, or $\Delta^{9(11)}$ (**XV;** Fig. 1) (Paull et al. 1998), are considered as characteristic biomarkers. Fern-8-enes (C_{29}–C_{31}) and fern-9(11)-enes (C_{29}–C_{30}) have been identified in the aliphatic hydrocarbon fraction of Late Triassic subbituminous coals, mudstones, and plant fossils from the Telford Basin, Australia. These hydrocarbons were found to be related to pteridosperms (seed ferns) of the genus *Dicroidium* (Paull et al. 1998). However, fernenes have also been found in modern sediments where the input from ferns has been excluded (i.e., deep-sea sites, Antarctic saline lake; Peters et al. 2005). Previous paleobotanical studies on coals from Euramerican Pennsylvanian (Late Carboniferous) coal basins indicate a major change in coal-swamp floras, especially at the Westphalian–Stephanian (≈Kasimovian–Gzhelian) boundary. Biomarker studies at the Westphalian/Stephanian of the Saar–Nahe Basin (Germany) revealed that aromatized arborane/fernane derivatives are prominent constituents of the extracts of cordaitean macrofossils and can therefore be regarded as biomarkers for this group of gymnosperms (Auras et al. 2006).



Biomarkers: Coal, Fig. 2 Gas chromatograms (total ion current) of the saturated hydrocarbon fractions of (**a**) one Upper Miocene lignite sample from the Kovin deposit (Serbia), dominated by hydrocarbons derived from resinous compounds of conifers, and of (**b**) Middle Miocene lignite from the Çayirhan coal field (Turkey), containing high contents of angiosperm-derived triterpenoid hydrocarbons. *n*-Alkanes are labeled according to their carbon number. *Std* Standard (deuterated *n*-tetracosane) (**b** adopted from Bechtel et al. 2014)

In surface sediments and sediment cores from the Angola and Cape basins (southeast Atlantic), high concentrations of taraxerol (**XVI;** Fig. 1) have been found corresponding with maxima in the relative abundance of pollen from mangrove trees. Therefore, Versteegh et al. (2004) concluded that taraxerol can be used as a lipid biomarker for mangrove input. Taraxerol was also found to be the main component in the examined mangrove sediments in coastal areas of the Bragança peninsula in North Brazil (Koch et al. 2003). However, taraxer-14-ene has been suggested as a marker for Ericaceae based on biomarker data recovered from a peat deposited in a Dutch ombrotrophic bog (Pancost et al. 2002).

Cadalane-Type Biopolymers

Polymers of cadalanes (i.e., bicadinanes (**XVII;** Fig. 1), polycadinenes (**XVIII,** Fig. 1)) have been found in the angiosperm dammar resins of the family Dipterocarpaceae, a tropical hardwood (van Aarssen et al. 1990). These resins were identified to be responsible for much of the crude oil found in Southeast Asia and Australia (Murray et al. 1994).

Biomarkers and Paleoclimate

In several studies it was found that an alternance of humid and dry periods is reflected and the aquatic plant *n*-alkane proxy Paq (Ficken et al. 2000; Nott et al. 2000; Nichols et al. 2006) were used to estimate the relative contributions of mosses and aquatic macrophytes vs. higher plants, the former predominating in humid periods. In addition $n\text{-}C_{27}/n\text{-}C_{31}$ could be used to estimate the relative contributions of shrubs and trees vs. herbaceous plants to peat formation (López-Dias et al. 2013). Alterations in the chain length distributions of plant wax *n*-alkanes in lacustrine and peat deposits have been further related to differences in growing season temperatures of the source regions (Zheng et al. 2009).

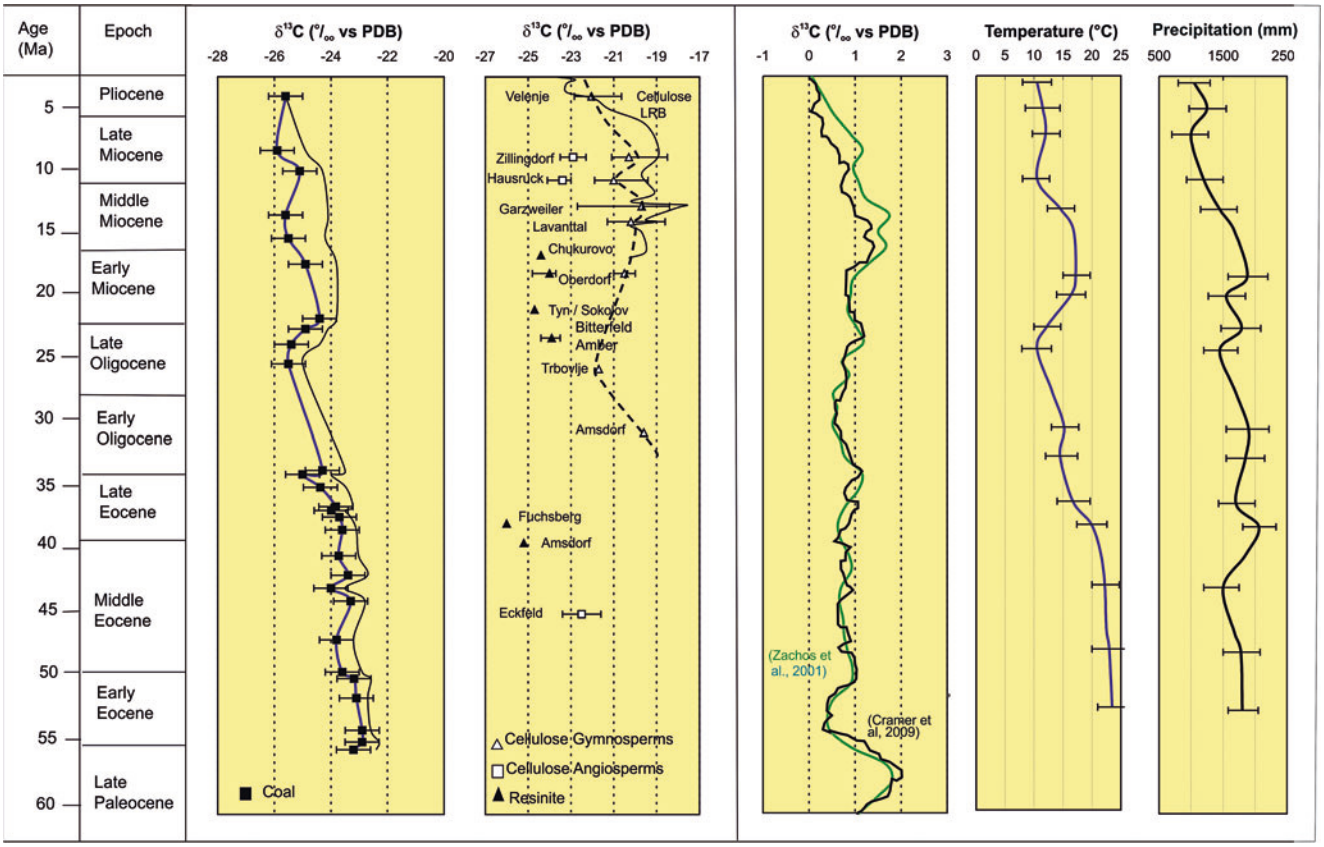
Recently, the distribution of bacterial branched glycerol dialkyl glycerol tetraethers (brGDGTs) has been investigated from 96 peatlands around the world with a broad mean annual air temperature (MAAT) and pH range (Naafs et al. 2017). It could be shown that the degree of cyclisation of brGDGTs is positively related to pH, and the degree of methylation of brGDGTs is positively correlated with MAAT. Based on the peat-specific calibrations (Naafs et al. 2017), the potential exists to use brGDGTs in peats and lignite to reconstruct terrestrial climate during the Cenozoic.

The presence of biomarker characteristic for plant families of specific climatic requirements is useful as paleoclimatic proxy. Such reconstructions are limited by the scarcity of source-specific plant biomarkers. The increasing relative abundance of biomarkers from gymnosperms versus angiosperms in low-rank coals is suggested to reflect cooler and drier climatic conditions during periods of peat accumulation. The retene/cadalene ratio has been used to reconstruct changes in the paleoflora and paleoclimate during Jurassic in the Paris Basin (France). In this study, the increase in the retene/cadalene ratio around the *cordatum* Zone was interpreted to reflect the rising proportion of Pinaceae indicating an increase in aridity at the end of the Lower Oxfordian (Hautevelle et al. 2006).

A significant change in the ratios of diterpenoids specific for gymnosperms versus angiosperm-derived triterpenoids has been obtained from studies on numerous lignites and subbituminous coals throughout the Cenozoic of central Europe (Fig. 3; Bechtel et al. 2005, 2008). Conifer biomarkers were found to predominate in Upper Oligocene and younger coal seams, whereas Eocene coals are derived from angiosperm-dominated vegetation. The results are in agreement with paleobotanical records, indicating that broad-leaved evergreen vegetation extended to almost 60°N during the Paleocene and Eocene. At the end of the Eocene, a decrease in both mean annual range of temperature and mean annual temperature resulted in northern European vegetation represented by temperate deciduous and coniferous forests (Wolfe 1980).

Stable carbon isotopes on cellulose from tree rings and fossil wood have been used to reconstruct changes in Earth's carbon cycle (Arens et al. 2000; Feng and Epstein 1995). Besides that, $\delta^{13}C$ values of tree ring cellulose reflect changes in humidity and air temperature (Hemming et al. 1998). However, the reconstruction of paleoclimate based on carbon isotope ratios of coal and fossil wood requires the correction for the effects of species variations (especially with respect to gymnosperm versus angiosperm contributions) and for microbial activities (Fig. 3; Bechtel et al. 2008). The interfering processes can be resolved by combining detailed molecular information on wood and coal composition with stable isotope data (Poole et al. 2006).

Recently, the stable isotope composition of leaf wax *n*-alkanes in coals and sediments was used to decipher environmental changes. In most studies, $\delta^{13}C$ values have been interpreted with respect to changes in the contribution of C3 versus C4 plants during the Cenozoic (Makou et al. 2007). Relatively little attention has been given to the fact that $\delta^{13}C$ values may be influenced by changing gymnosperm/angiosperm contributions. The analysis of hydrogen isotope composition of leaf wax lipids is a promising tool to reconstruct hydrological changes during Earth's history (Sachse et al. 2012). δD most likely records the hydrogen isotopic composition of plant growth water and thus may act as a proxy for local aridity (Seki et al. 2009).



Biomarkers: Coal, Fig. 3 Variation of $\delta^{13}C$ of terrestrial organic matter during the Cenozoic of central Europe corrected for the effect of liptinite and hopanoid contents, gelification index and varying contributions of angiosperms to peat formation on $\delta^{13}C$ of coal (*thin solid line*), as well as after additional correction for the effect of changing $\delta^{13}C$ values of atmospheric CO_2 on $\delta^{13}C$ of C3 plants (*bold line*), $\delta^{13}C$ of fossil wood, extracted wood cellulose (Data from the Lower Rhine Basin according to Jordan 1995), and resinites, carbon isotope records from benthic foraminifera (Zachos et al. 2001; Cramer et al. 2009), as well as estimates about the variability of mean annual temperatures and precipitation in central Europe during the Tertiary based on compilations of paleobotanical data (Blumenstengel et al. 1996; Bruch 1998; Eissmann 1994; Haas et al. 1998; Kolcon and Sachsenhofer 1999; Krutzsch et al. 1992) (Figure modified according to Bechtel et al. 2008)

Biomarkers and the Environment of Peat and Coal Deposition

The biomarker composition of peat, lignite, and coal provides not only insight into the paleovegetation contributing to the organic matter accumulated in the deposits but also to the environmental conditions during the deposition of organic matter.

The pristane/phytane ratio is among the most widely used molecular parameter for reconstruction of the paleodepositional environments in both marine and terrestrial environments. An explanation for the usability of this ratio as a parameter for the reconstruction of redox conditions during deposition of sediments was provided by Didyk et al. (1978). According to their explanation, phytol originating from the phytyl side chain of chlorophyll is oxidized in sediments under aerobic conditions to phytenic acid, which is decarboxylated to pristene. The pristene is subsequently hydrated to pristane. Under anaerobic conditions phytol is at first hydrated to dihydrophytol und subsequently further reduced to phytane. According to this concept after diagenesis of the organic matter, high pristane/phytane ratios indicate oxidizing conditions during sediment deposition, while low ratios will result when reducing conditions prevailed. The concept has been shown to be valid for many sediments and also crude oils (Didyk et al. 1978). However, an additional bacterial origin of acyclic isoprenoids must be considered (Tornabene et al. 1979), and also tocopherols were recognized as possible sources of pristane in sediments (Goossens et al. 1984). Due to the knowledge about multiple sources of pristane and phytane, ten Haven et al. (1987) argued for a restricted usability of the pristane/phytane ratio as an indicator for paleoenvironmental conditions of sediment deposition. However, the conflicts regarding the usability of the pristane/phytane ratio as indicator for paleoenvironmental conditions are largely related to the marine environment. Later, also for the terrestrial environment, concern about the assumption that chlorophyll is the common source for pristane and phytane

arose when phospholipids of archaeol were detected in methanogenic archaebacterial biomass (Tomoaia-Cortisel et al. 1992). Upon cleavage of the ether bonds of archaeol, one would expect the formation of phytane during diagenesis (Pancost and Sinnighe Damste 2003). Since methanogenic archaea are known to be active in peat, archaeol has to be considered as additional source of phytane in peat bogs, and the pristane/phytane ratio during diagenesis would be depending on the methanogenic activity in the former peat bog. Archaeol was additionally detected in the marine environment as constituent of anaerobic methanotrophic archaea with the particular attribute to provide a very light carbon isotopic signature of $\delta^{13}C = -104.29‰$ (Orphan et al. 2001).

However, by use of compound specific carbon isotopic measurements ($\delta^{13}C$) on individual compounds, it should therefore be possible to distinguish whether phytane is coming from phytol ($\delta^{13}C \sim -29‰$) or from archaeol originating either from methanotrophic archaea with $\delta^{13}C \sim -100‰$ (Orphan et al. 2001) or from archaeol originating from methanogenic archaea, which has not been analyzed yet with respect to its carbon isotopic composition. In case that the biomass of methanogens and methanotrophs would contribute significantly to the total organic matter in peat, one would expect lower $\delta^{13}C$ values for phytane than for pristane, originating in the terrestrial environment preferentially from the chlorophyll of higher land plants. The pristane/phytane ratio in coal might consequently reflect both the paleo-redox conditions during deposition of former peat bogs and the intensity of methane formation and oxidation during deposition and early diagenesis.

In only very few studies of coals, the $\delta^{13}C$ values have been determined simultaneously on pristane and phytane. In 12 coal samples from the Eocene Fushun Basin in NE China, the $\delta^{13}C$ values of pristane and phytane were on average −27,37‰ and −28,22‰, respectively (Strobl et al. 2014). Phytane is only by 0.85‰ more depleted in ^{13}C compared to pristane which argues for a similar precursor (i.e., chlorophyll) for both compounds. Schwarzbauer et al. (2013) determined $\delta^{13}C$ values of both pristane and phytane on 34 Late Paleozoic coals from all over the world, and on average phytane was by 1.07‰ more depleted in ^{13}C than pristane which confirms the dominating origin of both compounds from chlorophyll but also a minor contribution of methanogens and methanotrophs to the total biomass.

For the terrestrial environment, numerous examples have been provided showing the usefulness of the pristane/phytane ratio for the reconstruction preferentially of paleo-redox conditions in peats, lignites, and subbituminous and bituminous coals.

In three seams of middle Eocene subbituminous coals from Markushegy (Hungary), the values of the pristane/phytane ratio varied from values of 0.6 to 4.8 with decreasing ratios in the uppermost parts of the seams and in the shaly layers, which is in agreement with the establishment of reducing conditions due to increasing levels of the (ground)water table (Bechtel et al. 2007). Moreover, the pristane/phytane ratio provided a significant correlation with the abundance of inertinite macerals present in the coals, supporting the assumption that inertinite macerals in peat deposits and mires are formed preferentially under dry and oxic conditions under participation of fungi (Moore et al. 1996).

In solvent extracts of samples from the Upper Oligocene Trbovlje coal seam from Slovenia, the pristane/phytane ratio has been shown to correlate inversely with the amount of hop-17(21)-ene (Bechtel et al. 2004). This also confirms the influence of redox conditions during deposition of peat on the pristane/phytane ratio since hop-17(21)-ene is most likely originating from anaerobic (iron-reducing) bacteria (Wolff et al. 1992,) which can be expected to become more active in the peat together with intensifying anaerobic conditions.

In bituminous coals from the Saar-Nahe Basin,the pristane/phytane ratio increased significantly in coal seams of the Upper Carboniferous approaching to the Permian in accordance with the well-known shift to a drier climate (Vliex et al. 1994).

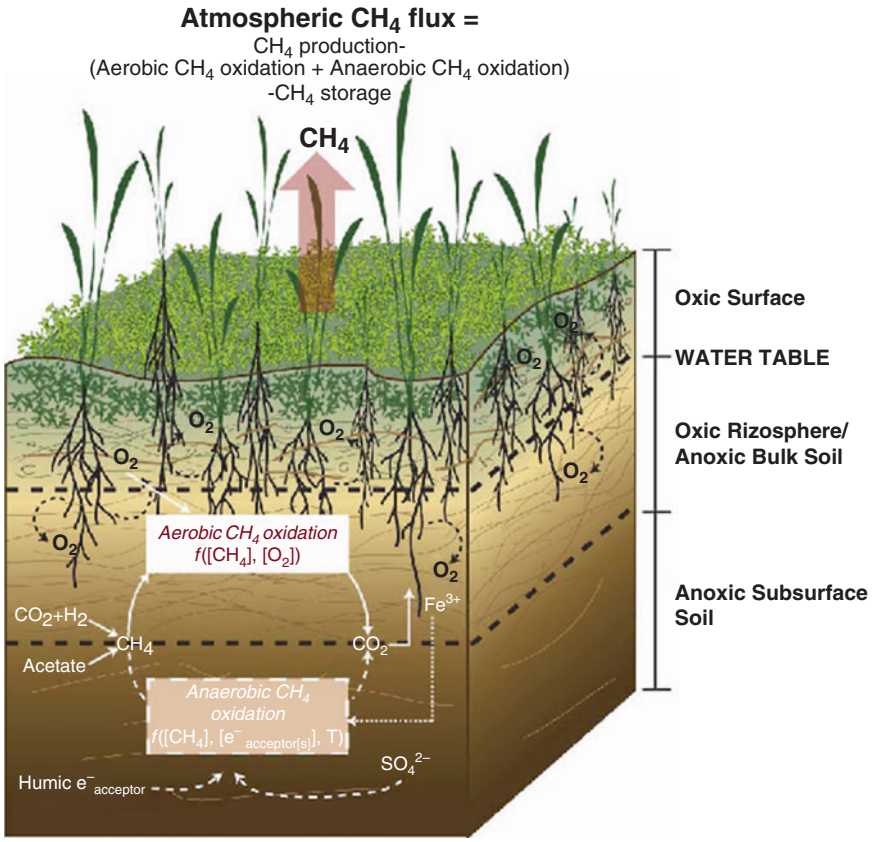
These examples show that the pristane/phytane ratio is a useful parameter for the reconstruction of paleo-redox conditions in peat, lignite, and subbituminous coals. However, several studies have shown that at higher rank of coals (approximately >0.5% vitrinite reflectance (Rm)), a maturity effect superimposes the redox effect on the pristane/phytane ratio. Among the first application of the pristane/phytane ratio in coal studies was reported by Radke et al. (1980), showing that in a set of 26 hard coals from the Ruhr district (Germany), covering a wide rank range (0.63–1.7% Rm), the pristane/phytane ratio varies significantly depending on the rank of the coal. In the range of 0.63–0.88% Rm, pristane/phytane ratio increases from values of 8 to 10 followed by a decrease from values of approximately 10 to 1 concomitant with further increasing rank of coals from 0.88% to 1.7% Rm. This observation is explained by an asynchronous formation of pristane and phytane from kerogen with pristane being generated earlier and phytane later during coalification. The tendency of increasing pristane/phytane ratios up to a rank of 0.8% Rm and decreasing pristane/phytane ratios together with further increase of the rank was later confirmed on Pennsylvanian coals from the Kittanning formation in Eastern Ohio, USA (Dzou et al. 1995). In their study absolute amounts of both compounds were determined, and results have shown that the phytane concentration remained largely constant over the rank range from 0.5% to 1.8% Rm, while changes in the pristane/phytane ratio were mostly attributed to concentration variations of pristane.

Biomarkers for Carbon Cycling in Peat Bogs

Approximately 30% of the global terrestrial carbon is stored in peat bogs dominated by *Sphagnum moss* and is thus an

important factor in the global carbon cycle (Smith et al. 2004). Ten percent of the total methane flux to the atmosphere has been suggested to originate from peat bogs (Smith et al. 2004). However, methane oxidation is well known to reduce the potential atmospheric methane emissions from both peatlands (Kip et al. 2010) and freshwater wetlands (Segarra et al. 2015). In ombrotrophic peat bogs, methanogens grow heterotrophically on acetate or other multi-carbon substrates and are expected to have $\delta^{13}C$ values similar to those of the used carbon source (Pancost et al. 2000a). The analysis of preferentially *Sphagnum* peat cores from ombrotrophic bogs taken from four northern European sites revealed the presence of archaeol and *sn*-2-hydroxyarchaeol which were suggested to be appropriates biomarker for methanogens (Pancost et al. 2011). Lim et al. (2012) proposed later the use of archaeol as biomarker for the methanogen biomass in water-saturated soil. The carbon isotopic composition of the archaeol and *sn*-2-hydroxyarchaeol was not determined in these studies, but both compounds revealed to be useful biomarkers. However, Pancost et al. (2000a) could find in two Holocene peat bogs from the Netherlands and Ireland neither molecular nor isotopic evidence for the activity of aerobic methane-oxidizing bacteria (methanotrophs) indicating the need for research to find additionally appropriate biomarkers for methane-oxidizing bacteria in peat deposits. Anaerobic methane oxidation is well known from the marine environment and generally coupled to sulfate reduction being available in high abundance (Pancost et al. 2000b; Orphan et al. 2001). However, the importance of both aerobic and anaerobic methane oxidation is also well known in peatlands and has been reviewed by Smemo and Yavitt (2011).

According to Fig. 4 in peat-forming wetlands, the zone of anaerobic methane oxidation is covered by a zone of aerobic methane oxidation, and both zones might migrate within the soil profile depending on the variation of the amount of precipitation over time. Possible electron acceptors for the anaerobic methane oxidation are sulfate, humic matter, and ferric iron, with sulfate being in general less available in peat-forming environments. In case that iron(III) is used as electron acceptor, iron(II) will be generated which can be reoxidized upon lowering of the water table. Humic substances might serve in this process as chelators for iron(III) which makes it available for iron reduction (Lipson et al. 2010). The internal recycling of iron(III) might be an effective process supporting the anaerobic methane oxidation. However, so far quantification of the proportion of anaerobic versus aerobic methane oxidation in peat-forming environments is not possible, and the knowledge of specific biomarkers might help to solve this problem.



Biomarkers: Coal, Fig. 4 Conceptual model of CH_4 cycling in the profile of *Sphagnum* sp. and *Carex* sp. covered peat-forming wetland indicating the relationship between water table depth, plant rooting zone, and redox status. *Solid boxes* and *arrows* represent known processes and controls of CH_4 fluxes, *dashed black arrows* represent O_2 fluxes from plant roots, and *dashed white boxes* and *arrows* represent recently quantified or hypothesized processes and controls. Factors controlling net atmospheric CH_4 flux rates from peatland ecosystems are illustrated by the equation at the *top* of the figure (Adopted from Smemo and Yavitt 2011; licensed under CC BY 3.0)

To establish biomarkers for methane oxidizing bacteria in peat deposits, van Winden et al. (2010) carried out incubation experiments with $^{13}CH_4$ and *Sphagnum* moss spp. It was not possible to identify an unambiguous biomarker for methanotrophs in peat moss, but particularly hopenes (hop-17(21)-ene and 2-methylhop-17(21)-ene) provided high degrees of ^{13}C-labeled incorporation into the individual lipid molecules. However, pure cultures of methanotrophs contained no hop-17(21)-ene but diploptene instead, leading to the conclusion that hop-17(21)-ene can be generated from diploptene through isomerization under acidic conditions (van Winden et al. 2012). Kip et al. (2010) carried out laboratory experiments with *Sphagnum* mosses from pools, lawns, and hummocks in nine *Sphagnum*-dominated peatlands from all over the world and tested their capacity to oxidize methane. A symbiosis between mosses and methanotrophs developed in all experiments, and ^{13}C labeling of methane has shown that methane-derived carbon was incorporated not only into hopanoids but also into steroidal plant lipids.

Zheng et al. (2014) investigated Holocene sediments from the Tibetan Plateau and used archaeol and *sn*-2-hydroxyarchaeol as biomarkers for methanogens. Lower concentrations of both compounds in the interval from 6 to 4 ka were interpreted as a result of lower methanogenic activity during this period associated with drier environmental conditions. In this profile also diploptene and the stable carbon isotopic composition ($\delta^{13}C$) of diploptene have been determined, and increasing amounts of diploptene were associated with decreasing $\delta^{13}C$ values of the diploptene supporting that the additional (light) diploptene might come from the biomass of methanotrophs. More recently, several bacteriohopanepolyols and further functionalized hopanoids in *Sphagnum* peat from Bissendorf Moor, Germany, have been reported to be biomarkers for aerobic methane-oxidizing bacteria (Talbot et al. 2016), but these compounds will not survive progressing diagenesis and will undergo further changes during coalification. The influence of potential electron acceptors (nitrate, sulfate, and ferric iron) on anaerobic methane oxidation has been studied by sealed incubation experiments using peat from Michigan Hollow (Gupta et al. 2013). The results have shown that these inorganic electron acceptors were not involved in the redox processes, and a putative organic electron acceptor has been suggested to be responsible for the anaerobic methane oxidation observed in the experiments (Gupta et al. 2013). In peat bogs, the availability of sulfate and nitrate is generally low and their contribution to anaerobic methane oxidation expected to be low, but iron(III) is available as possible electron acceptor and due to internal oxidation–reduction cycles iron (and also manganese) might be recycled for reuse in the anaerobic oxidation of methane (Smemo and Yavitt 2011). Further studies should be carried out, therefore, for the identification of biomarkers indicative for iron-reducing bacteria in the peatland environment.

Biomarkers and Thermal Maturity of Coals

The thermal maturity or rank of coals has for a long time been determined preferentially by the use of optical methods such the determination of the mean random vitrinite reflectance (Rm) or by the use of fluorescence light microscopy. An attempt to determine the thermal maturity of coals based on parameters derived from the composition of compounds extractable from coals by organic solvents has been reported by Radke et al. (1980). The development of glass capillary columns made it possible to separate all methylphenanthrene (MP) isomers present in coal extracts into individual peaks and revealed changing relative intensities of the compounds with the rank in a set of 24 Upper Carboniferous coals from the Ruhr area in Germany. Radke et al. (1982) developed the so-called methylphenanthrene index (MPI-1) according to the following equation:

$$\mathrm{MPI\ 1} = 1.5(2\text{-MP} + 3\text{-MP})/\mathrm{P} + 1\text{-MP} + 9\text{-MP}$$

with P phenanthrene, *2*-MP 2-methylphenanthrene, *3*-MP 3-methylphenanthrene, *1*-MP 1-methylphenanthrene, and *9*-MP 9-methylphenanthrene.

A linear correlation was observed in the rank range represented by vitrinite reflectance values ranging from approximately 0.6% to 1.5% Rm which allowed the determination of a "calculated vitrinite reflectance" (Rc) using equation $\mathrm{Rc} = 0.63 \times \mathrm{MPI\ 1} + 0.42$.

Moreover, the methylphenanthrene ratio (MPR) (representing the relative intensities of 2-MP/1-MP) revealed a linear correlation with the measured vitrinite reflectance of the coals.

Having more data points available from further coal samples of other provinces (Tertiary and Cretaceous age), the correlation equation slightly changes to $\mathrm{Rc} = 0.60 \times \mathrm{MPI\ 1} + 0.40$ for coals in the rank range of 0.65–1.35% Rm, and a further correlation between the MPI 1 and the Rm was defined for coals of higher rank (>1.35% Rm) from which also an equation for the calculation of the vitrinite reflectance was proposed: $\mathrm{Rc} = -0.61 \times \mathrm{MPI\ 1} + 2.30$ (Radke et al. 1982).

The change of the distribution pattern of phenanthrene and four of its methylphenanthrene isomers was explained to result from different reactivity at the ring carbon. At lower rank (~0.65% Rm), the isomers 1-MP and 9-MP dominate quantitatively over 2-MP and 3-MP since these positions at the phenanthrene ring are favored for methylation. With increasing rank (up to 1.35% Rm), rearrangement reactions occur leading to an increasing abundance of the thermodynamically more stable isomers 2-MP and 3-MP. Upon further

increase of the coal rank (>1.35% Rm) and under the influence of the associated higher temperatures, the MPI-1 is lowered continuously due to demethylation of methylphenanthrenes under formation of the parent compound phenanthrene (Radke et al. 1982). In principal, this explanation has recently been confirmed by the estimation and application of thermodynamic properties of aqueous phenanthrene and methylphenanthrene isomers at higher temperature (Dick et al. 2013). Ab initio quantum chemical calculations (DFT) led to the identification of possible transition states and to the determination of activation energies for reactions of the compounds in aqueous solutions, and according to the data the MPR, defined as the ratio 2-MP/1-MP, was suggested to be more closely related to thermal maturity than MPI-1 (Szczerba and Rospondek 2010).

Further studies revealed that the MPI-1 is a robust chemical maturation indicator but can be affected by organic matter type in coals and sediments (Radke et al. 1984, 1986). Apart from the MPI-1, additional maturity parameters for sediments and rank parameters for coals based on relative proportions of alkylated naphthalenes, phenanthrenes, and dibenzothiophenes have been developed, and the influence of organic matter type on each parameter has been tested (Radke et al. 1986). The alkylated naphthalenes revealed to be particularly useful for the maturity assessment of type II_B kerogens, while the alkylated phenanthrenes are more appropriate as rank parameters for type III kerogen including coal.

Kvalheim et al. (1987) applied multivariate analysis methods (principal component analysis followed by factor rotation) to the relative proportions of phenanthrene and the methylphenanthrene isomers obtained from 15 coals from different provinces covering different ages from Cretaceous to Carboniferous and a wide rank range from 0.53% to 1.29% Rm. The results have shown that the variation of rank correlates rather with the distribution of the methylphenanthrene isomers and less with the relative abundance of the phenanthrene. Therefore, they proposed to apply the methylphenanthrene distribution factor (MPDF) as an alternative maturity indicator, MDPF = (2−MP + 3−MP)/(2−MP + 3−MP + 1−MP + 9−MP), with the following linear regression equation: Rc = − 0.166 + 2.2423 × MPDF.

Boreham et al. (1988) investigated the aromatic hydrocarbon compositions of 94 coals and sediments with terrestrial organic matter from eight Australian basins and ages ranging from Tertiary to Carboniferous. MPI-1 values and MPDF values were calculated from the peak areas in the gas chromatograms. From the linear regression analysis at reflectance levels ranging from 0.3% to 1.7% Rm, the relationship between Rm (%) and MPI-1 results in a significant correlation coefficient of $r = 0.84$ and the following equation for the determination of the calculated vitrinite reflectance, Rc = 0.7 × MPI-1 + 0.22, which differs from the relationship proposed previously by Radke et al. (1982). The correlation coefficient between Rm and the simultaneously determined MPDF value was much lower ($r = 0.64$), but the formula for the linear regression line between MPDF and Rm was similar to the formula proposed by Kvalheim et al. (1987). For higher rank levels (>1.7% Rm), the following equation results: Rc = −0.55 × MPI-1 + 3.0 which also differs from the equation proposed by Radke et al. (1982). Attempts to explain the observed changes in the regression equation for the calculation of Rc from MPI-1 values using coals from different basins and ages have later been provided by Heppenheimer et al. (1992) showing that one of the methylphenanthrene isomers (1-MP) is increased significantly in relation to the other isomers and explained this observation by the abundance of coniferous resinite contributing retene, pimanthrene (1,7-dimethylphenanthrene), and 1-MP as diagenetic products of abietic acid and pimaric acid to the aromatic hydrocarbon fraction. Thereby, 1-MP is added to the distribution profile of the MPs expectable according to the usual isomerization and methylation reactions. Norgate et al. (1999) investigated the aromatic hydrocarbon composition of 22 Eocene bituminous coals from the Buller Coalfield, New Zealand. The calibration of the measured MPI-1 values and vitrinite reflectance values provided the following equation for the calculated vitrinite reflectance: Rc = 1.1 × MPI-1 + 0.07 ($R^2 = 0.71$). The calibration values in this equation differ significantly from the values determined in previous studies (Radke et al. 1982; Boreham et al. 1988). The deviation is explained by the fact that the investigated set of Buller coals is partly composed of perhydrous coals with a higher hydrogen/carbon atomic ratio compared to coals of similar rank which results in a lowering of the MPI-1 values (Norgate et al. 1999). Nevertheless, considering the aforementioned exceptions, the MPI-1 parameter has been established as a reliable maturity/rank parameter for coals and sediments with type III kerogen.

Summary

Based on the relative contents of sesqui-, di-, and triterpenoids in coal, the contribution of gymnosperms versus angiosperms to peat formation can be deduced. The occurrence of some of the terpenoid biomarkers is diagnostic for specific plant families (e.g., Cupressaceae, Betulaceae, ferns, mangrove trees, Dipterocarpaceae) in the peat-forming vegetation. However, deciphering precise precursor/product relationships often suffers from largely unknown compound transformation routes, as well as the occurrence of non-specific precursors in higher land plants.

Biomarkers characteristic for plant families of specific climatic requirements are regarded as useful paleoclimatic proxies. Based on the peat-specific calibration of the effects of changing pH and air temperature on the distribution of brGDGTs, there is a clear potential to use these biomarkers in

peat and lignite to reconstruct past terrestrial climate. Stable carbon isotopes on cellulose have also been used to reconstruct changes in Earth's carbon cycle, as well as in humidity and air temperature. Interfering processes (i.e., species variations, microbial activities), inhibiting the reconstruction of paleoclimate based on carbon isotope ratios of coal and fossil wood, can be overcome by combining molecular information of coal composition with stable isotope data. Recently, the stable isotope (C, H) composition of leaf wax *n*-alkanes in coals and sediments was used to decipher changes in paleovegetation, atmospheric CO_2 content, and humidity.

The pristane/phytane ratio is a valuable parameter for the reconstruction of paleo-redox conditions of lignites and subbituminous coals of lower rank. Due to the maturity effect and potentially different precursors, pristane/phytane ratios should be only applied to coals of identical rank and if both isoprenoids show similar $\delta^{13}C$ values. The $\delta^{13}C$ values of biomarkers originating from archaea and bacteria are useful to identify their specific role in the carbon cycling in peat and the contribution of wetland to methane emission.

The thermal maturity of coals can be successfully assessed by the isomerization of methylphenanthrenes. Different correlation equations have been postulated in order to relate the ratios in the relative proportions of methylphenanthrene isomers to vitrinite reflectance data. Significant correlations have been found in the range of 0.6–1.7% Rm.

Definition

Biomarkers	Biomarkers or biological markers are the complex organic compounds which are comprised of carbon, hydrogen, and other elements. Biomarkers are usually found in oil, bitumen, rocks, and sediments, and they usually show little changes in terms of molecule structure from their parent organic molecules in living organisms.
Petroleum	Petroleum is a complex mixture of liquid, gas, and solid hydrocarbons with small amounts of other substances and may include crude oil, natural gas, and natural asphalt that form naturally in sedimentary rocksfrom the remains of organisms.

Introduction

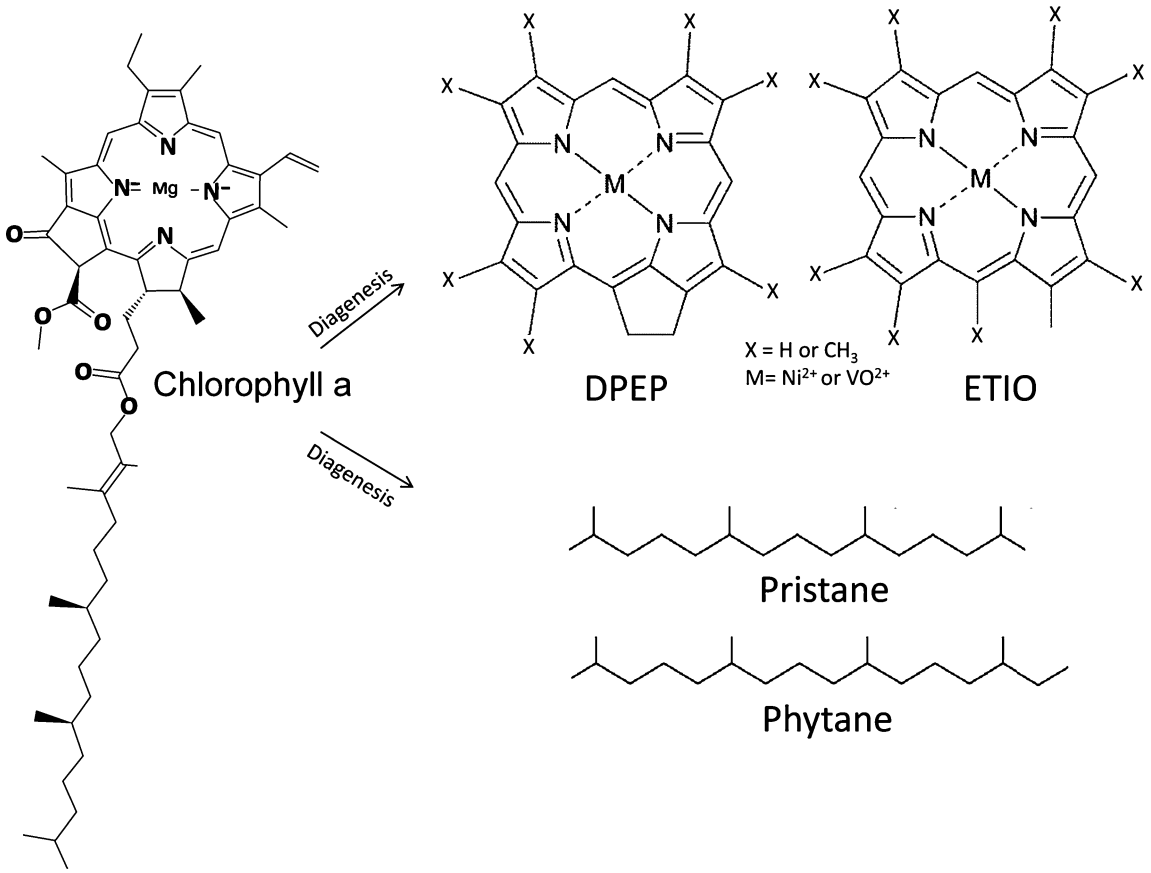
The term "biomarker" refers to a molecular fossil, which is an organic chemical that can be identified as originating from a particular biologically synthesized organic molecule. It is distinct from the broader term, "biosignature," which is used in the context of the search for evidence of extraterrestrial life and refers to any evidence of life (Biosignatures Workshop 2000). Biomarkers in geological environment, e.g., in sediments, rocks, and soil extracts, are unambiguously related to enzymatic synthesis in living organisms (Eglinton et al. 1964; Eglinton and Calvin 1967). Lipids, proteins, and carbohydrates are three main macromolecules of living organisms, and are also the potential biomarkers. Lipids include fats and waxes. They are the most probable candidates for evidence of extraterrestrial life due to their preservation in sediments over long periods. Most lipids on Earth come from cellular components. Lipids are known for their stability in sediments and for having a wide variety of diagnostic structural signatures (Engle and Macko 1993). In contrast, proteins and carbohydrates can be rapidly recycled by other living systems and consequently are extremely poorly preserved in sediments over geological timescales (Nagy 1982). Typically, biomarkers undergo a little or no structural change during diagenesis at a low temperature and they inherit most of the carbon skeleton from their original natural products (compounds produced by living organisms). This structural similarity explains why biomarkers can be used as "molecular fossils."

Treibs (1936) first defined the biomarker concept by his pioneering work on the identification of porphyrins in crude oil and their origin from chlorophyll in plants (Fig. 1). Biomarkers have a presence in both the biosphere and geosphere. Biomarkers and their products include most of the organic materials in the geosphere that are amenable to mass spectrometric analysis. Biomarkers have a variety of applications and are used extensively in exploration for petroleum resources (Peters et al. 2005). They are a powerful tool for paleoenvironmental interpretation in Earth history (Eglinton 1964; Eglinton and Calvin 1967; Summons and Walter 1990). Biomarkers can reveal (1) genetic relationships between an oil sample and the potential source rock, (2) geological age, (3) the lithology of the source (carbonate vs. shale vs. coal, etc.), (4) depositional environments (lacustrine, hypersaline, fluvial-deltaic, and marine) of the source rock, and (5) thermal maturity of the source rock and petroleum during petroleum generation (Peters and Moldowan 1993).

Petroleum consists largely of components derived from lipids and can be stable in the subsurface for billions of years (Peters et al. 2005). Since petroleum forms under a variety of geological conditions, each petroleum sample tends to have a unique biomarker fingerprint. The composition of petroleum varies widely due to origination from (1) different source rocks deposited in different depositional environments; (2) the thermal regime during burial, maturation, and oil generation; and (3) different migration pathways and in-reservoir alterations. In addition, the constituents of petroleum undergo changes in chemical structure due to biodegradation or weathering. However, relative to some other compound classes in petroleum, biomarkers are more resistant to biodegradation.

Analytical Methods for Biomarkers

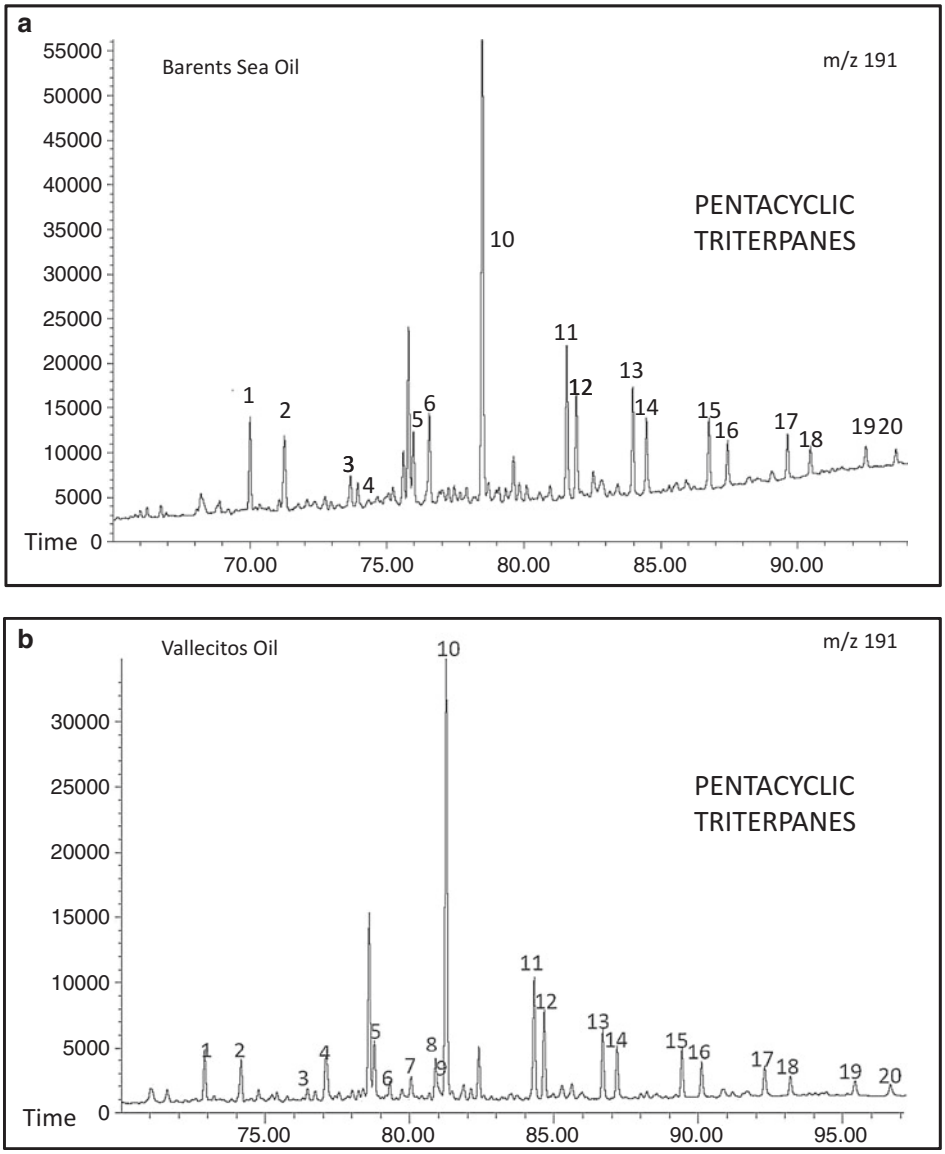
The principle methods of analyzing the biomarkers in petroleum are gas chromatography-mass spectrometry (GC-MS) or gas chromatography-mass spectrometry-mass spectrometry (GC-MS-MS). Analyses are typically performed on the saturated hydrocarbon fraction or the aromatic hydrocarbon fraction, which are the most abundant in petroleum. Isotope ratio gas chromatography-mass spectrometry (IRGC-MS) will be another important research tool widely used in both academia and the oil industry, which can help geochemists interpret the biosynthetic origin of organic compounds, reconstruct ancient geological environment, identify the thermal maturity of the oil, and build the correlation between oil and source rock samples. It can also predict the characteristics



Biomarkers: Petroleum, Fig. 1 Chlorophyll a is a pigment used by most photosynthetic organisms to release chemical energy during photosynthesis. The molecular structure of chlorophyll a is composed of a chlorin ring (four nitrogen atoms surround a central magnesium atom), several said chains, and a hydrocarbon tail. The tetrapyrrole ring and phytyl side chain in chlorophyll a can be converted to several biomarkers during sedimentary burial and thermal maturation, including deoxophylloerythroetioporphyrins (DPEP), etioporphyrins (ETIO), pristane, and phytane. X is hydrogen or an alkyl group and M is commonly nickel (Ni^{2+}) or vanadyl (VO^{2+}) in petroleum

of a source by the carbon isotope fractionation on individual hydrocarbons, which were generated by the source rocks through geological processes. In certain circumstances, it is only possible by using IRGC-MS instead of other methods to detect excess carbon isotopic fractionation compared to that which might be available from abiotic synthesis, and determine what source rocks are present and the level of exposure to thermal stress in mixtures of highly degraded or thermally altered hydrocarbons. Certainly, this would be an added piece of information for petroleum exploration.

Since petroleum is an extremely complex natural mixture of hydrocarbons, its chemical characterization remains an extremely challenging task to analytical scientists. Concentrations of individual biomarkers in petroleum typically range from <1 to 500 ppm, making them some of the most abundant, structurally defined compounds. To increase the accuracy of biomarker analysis, a series of separations is typically conducted before the analysis. First, silica-gel chromatography is applied to separate oil into saturates and aromatics. Second, the zeolite ZSM-5 or other molecular sieves might be used to remove normal alkanes (*n*-alkanes or paraffins) from the saturate fraction. Before removing normal alkanes, saturate fractions can be spiked with internal standards and then subjected to gas chromatography-mass spectrometry (GC-MS), which is the widely-used method to generate accurate analytical profiles for chemical fingerprinting of petroleum (Seifert and Moldowan 1979). The rapid development of organic geochemistry and its important application in petroleum exploration since the 1960s was mainly due to the application of GC-MS, especially after its computerization in the late 1970s. The commercial availability of GC-MS and associated data systems in the mid-1970s helped scientists extend biomarkers studies with a wide variety of purposes. GC-MS is routinely used to analyze biomarkers in whole oils or more commonly, the saturated and aromatic hydrocarbon fractions of oils. Modern GC capillary columns with nonpolar stationary phases are sufficient to resolve many biomarkers, including epimers. A mass spectrometer is used for detection, providing molecular "fingerprints" that identify the eluting compounds. In other words, gas chromatography



Biomarkers: Petroleum, Fig. 2 (**a**) Terpane mass chromatograms (m/z 191) for the crude oils from Barents Sea Basin. (**b**) Terpane mass chromatograms (m/z 191) for the crude oils from Vallecitos syncline in California

(GC) is used for biomarker analysis to provide the significant advantage of separating the different structures of biomarkers while a mass spectrometer (MS) can be accurately used to detect and identify those different structures. Electron ionization (typically 70 eV) is the most commonly used ionization technique, where classes of biomarkers yield characteristic ion fragments. For example, all hopanes and most other triterpanes and diterpanes yield a characteristic ion with mass-to-charge ratio (m/z) of 191 (Fig. 2a, b; Table 1), while steranes yield characteristic ions with m/z 217 (Fig. 3; Table 1). The m/z 217 ion is diagnostic for all steranes. Since the biomarkers with complicated structure and low concentrations require more sensitive and precise analysis in the biomarker studies, the development of analytical methodologies and combinations between these methods become very important for applications of the biomarker in both sediments and petroleum. To enhance sensitivity, the biomarkers (terpanes) in branched, cyclic, and aromatic fractions are analyzed by selected ion recording-gas chromatography mass spectrometry (SIR-GCMS). Figures 2a, b and 3 show SIM mass chromatograms for terpanes (m/z 191) and steranes (m/z 217) in saturated hydrocarbon fractions of the Barents Sea Basin (He et al. 2012) and Vallecitos Syncline in the western part of the San Joaquin Basin (He et al. 2014). The biomarker distributions of the Barents Sea oils show characteristics of sourcing from a marine shale, such as high C_{26}/C_{25} tricyclic terpane ratios, low $C_{19}/(C_{19} + C_{23})$, low C_{22}/C_{21}, high C_{24}/C_{23}, and low C_{29}/C_{30} hopane ratios. Characteristic distribution of extended homohopane homologs (relatively low C_{33}, C_{34}, and C_{35} homohopane peaks) on the m/z

Biomarkers: Petroleum, Fig. 3 Sterane mass chromatograms (m/z 217) for the crude oil from Vallecitos syncline in California

191 ion chromatogram (Fig. 2a) indicates that the source rock was deposited under dysoxic to oxic depositional conditions. The Kreyenhagen oil samples have slightly different biomarker distributions on the m/z 191 ion chromatogram (Fig. 2b). The biomarker analysis indicates little terrigenous organic matter input, and a clay-rich source rock (shale) by the ratio of C_{29}hopaneover C_{30} hopane ($C_{29}/C_{30} < 0.6$). The extended homohopane distribution of Kreyenhagen oil, a decrease in the concentration of extended homohopane homologs C_{31} to C_{35} with poor preservation of C_{35} homohopane, indicates that Eocene Kreyenhagen source rocks in the San Joaquin Basin were deposited in a dysoxic to the oxic open marine environment.

Since the mass spectrometer has high sensitivity, specificity, and capability to precisely elucidate the molecular structure of a particular compound, it has been widely used as the most powerful detector for gas chromatography. Mass fragmentography serves as a satisfactory tool for obtaining specific fingerprints for classes and homologous series of compounds which were originally identified by traditional

chemical structure elucidation techniques, such as nuclear magnetic resonance (NMR), X-ray crystallography, and GC coelution with authentic standards. Gas chromatography-mass spectrometry-mass spectrometry (GC–MS-MS) in the parent-daughter mode reduces interference and thus allows more definitive genetic oil-oil or oil-source rock correlations and thermal maturity assessments than is possible using conventional GC-MS. GC-MS resolves and identifies many of the major saturated and aromatic biomarkers, but the detection of steranes by GC-MS is often problematic due to the co-elution of specific sterane isomers and homologous series. Quantitative metastable reaction monitoring (MRM-GCMS) using a double focusing magnetic sector mass spectrometer and GC-MS-MS using other multisector mass spectrometer systems, such as a triple quadrupole have been used to analyze steranes (regular steranes, such as cholestanes, ergostanes and stigmastanes, diasteranes, dinosteranes), as well as certain terpanes (bicadinanes, tetracyclic polyprenoids, terrestrial diterpanes), since these GC-MS-MS methods resolve the co-elution problems. This type of biomarker analysis has enriched the application of biomarker science. By the use of GC-MS-MS many additional biomarkers have been found and well-studied to enhance the possibilities of understanding ancient depositional environments besides improving petroleum correlation studies. It is supposed that many biomarkers remain to be discovered. The development of the GC-MS is responsible for the growth of biomarker analysis and GC-MS-MS further refines the detection of biomarkers by eliminating interfering compounds.

The compound specific isotope analysis (CSIA) is another breakthrough applied in recent biomarker studies. The CSIA could be thought as a new analytical method that opens new insight and applications based on the GC-MS and GC-MS-MS. CSIA requires fairly precise separation of the compounds and high-resolution analysis to attain accurate measurements, but it is a key to extend a wide range of biomarker analysis of petroleum and source rock extracts. It can be both challenging and encouraging to develop more sensitive identification tools of biomarker analysis, particularly for petroleum with relatively low concentrations of biomarkers at high maturity levels or when severely altered by secondary alteration processes.

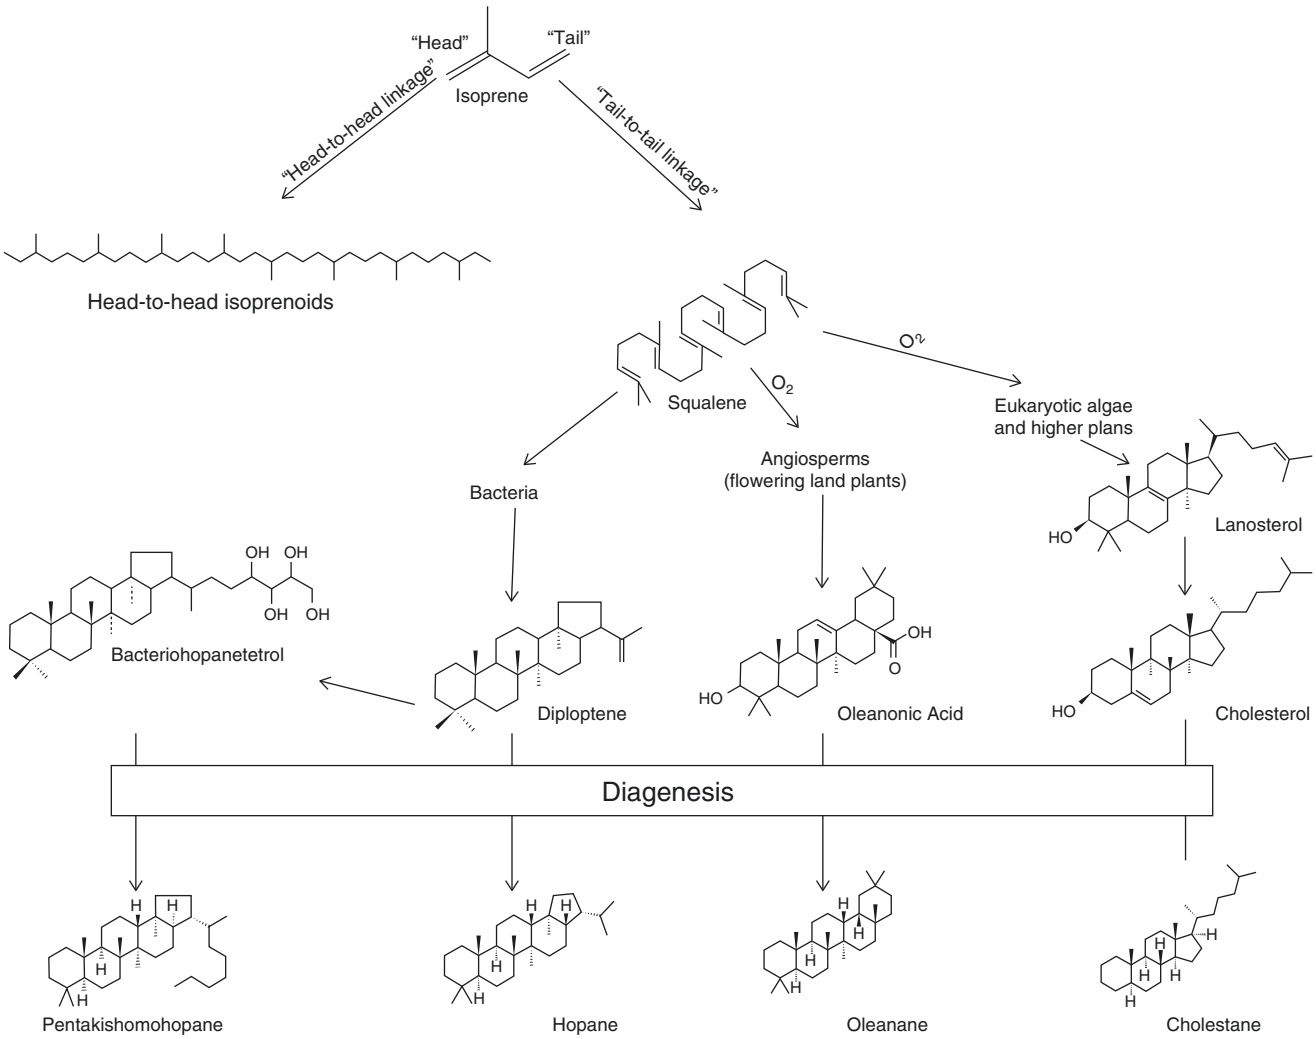
Biosynthesis of Biomarker Precursors

A landmark paper by Alfred Treibs (Treibs 1936) demonstrated an organic origin of petroleum when he showed the link between chlorophyll in photosynthetic autotrophs and porphyrins in petroleum (Fig. 1). This work marked the birth of organic geochemistry and laid foundations for the field of biomarker research. Chlorophylls from plants are the most abundant tetrapyrroles in the biosphere. Other tetrapyrroles include hemes in the blood of many animals. Tetrapyrroles preserved in sediments are so complex that they can only have come from chlorophylls or hemes. As discussed above, biomarkers encode abundant information about ancient biodiversity, sediment depositional environment, types of ancient organic matter, and food chain associations. While porphyrins are the first recognized biomarkers, those derived from terpenes by diagenesis are overwhelmingly the most commonly recognized and utilized today.

In general, lipids are a complex variety of organic compounds that are defined by their insolubility and immiscibility in water. Lipids have several biological functions such as constructing cell membranes, storing energy and as signaling molecules. The two main categories of the hydrocarbon skeletons of lipids produced in biosynthesis are: (1) acetogenic lipids having straight normal or simple branched (e.g., iso-, anteiso-) hydrocarbon chains built from C_2 (acetate) subunits; (2) polyisoprenoids, which are built from C_5 (isoprene) subunits by C─C covalent bonds, and are not readily broken down or depolymerized. Importantly, many features of naturally occurring lipids, such as stereochemistry and nonrandom distribution, cannot be explained by abiogenic synthesis. The biosignatures of these compounds can be recognized since abiotic synthesis produces a composition which is out of balance and different from what biotic synthesis produces.

The normal alkanes (*n*-alkanes) are the most abundant individual hydrocarbons in petroleum. Most are biosynthetically produced as functionalized compounds, such as fatty acids, and then converted into *n*-alkanes in diagenesis at a moderate temperature. While Fischer-Tropsch synthesis, which is an abiotic process, is also able to produce these straights-chain hydrocarbons with functionality (McCollom et al. 1998), the distribution of such abiotically produced *n*-alkanes is dramatically different from those produced by biotic synthesis. Fischer-Tropsch synthesis products show a smooth distribution of *n*-alkanes, as expected from abiotic synthesis. In contrast to biogenic synthesis, there is no outstanding excess or lack of any particular homolog such those distributions usually produced by enzymatic synthesis. The key factors which most likely control the distribution of the homologs in abiogenic synthesis lie in the conditions of the synthesis, namely as temperature, pressure, and catalysis.

Petroleum shows multiple expressions of biological synthesis. As discussed above, several *n*-alkanes have a relatively high abundance above the envelope of *n*-alkane peaks shown on the *n*-alkane distribution of the petroleum composition and indicate preferential biosynthesis of their precursors. Fatty acids are almost entirely even carbon-numbered, and if exposed to oxidative depositional conditions they yield predominantly odd carbon-numbered alkanes; whereas predominantly reducing conditions results in predominantly even carbon-numbered alkanes. The combined envelope of *n*-alkanes in an oil sample can, therefore, be considered a type of biosignature, but individual *n*-alkanes are generally not considered biomarkers in themselves. The isoprenoids, such as pristane and phytane, are the



Biomarkers: Petroleum, Fig. 4 Isoprene is an unsaturated pentahydrocarbon and it is produced biologically in animals, plants, and humans. The isoprene skeleton can be found in naturally occurring compounds called terpenes (known as isoprenoids), which can be viewed as multiples of isoprene subunits. The isoprenoids are derived from isoprene. Squalene is composed of six isoprene subunits linked head-to-tail except between the third and fourth subunits where they are linked tail to tail. Biosynthetic modification of squalene in living organisms yields various hopanoids and steroids, which can be further altered during burial to form some of the common biomarkers found in petroleum

classical biomarkers having structures with regularly repeating isopentenyl subunits (Fig. 4). Pristane and phytane are often the most abundant biomarkers in a petroleum sample. Branched hydrocarbons in petroleum show a greater relative abundance than those formed by Fischer-Tropsch synthesis and is another feature showing the biological attribute of petroleum. In fact, the positions of single methyl groups in simple methyl-branched alkanes indicate a positional preference along the carbon chain at the two and three positions, and those positions may have their own biological functions as a key biosignature, most likely due to the link between these lipids and primitive living organisms (Kenig et al. 1995).

Many biomarkers have taxon specificity and are important because they can be used to identify the organic inputs from various domains, kingdoms, families, and even individual species. Most precursors that give rise to biomarkers (e.g., steroids and pentacyclic triterpenoids) have a common biosynthetic precursor -squalene- a C_{30} acyclic isoprenoid composed of six isoprene units (Fig. 4). Under anaerobic conditions, bacteria can cyclize squalene to produce diploptene, which is a pentacyclic triterpenoid. Diploptene can then be biosynthetically modified to yield many other biomarker precursors in organisms. When these organisms die, their remains may be deposited in surficial sediments.

Most functional groups, such as hydroxyl groups and isolated double bonds, are lost or chemically reduced when these compounds undergo sedimentary burial. However, biomarkers in the geosphere commonly retain the carbon skeletons of their

biological precursors. For example, the addition of D-pentose to diploptene during biosynthesis yields C_{35}-bacteriohopanetetrol, which is a structural component of bacterial cell membranes. The defunctionalized product, C_{35} hopane (pentakishomohopane), is common in rock extracts and petroleum. The hopanoids (e.g., hopanes, hopene, and benzohopanes) are generated mainly from hopane polyols, which can be found in bacterial membranes, and have a general application in petroleum as biomarkers for aerobic bacteria (Fig. 4). Since the principal biological function of the most abundant petroleum biomarkers (steranes and hopanes) is as cell-membrane constituents, many biomarkers only appear after catagenesis, the process of kerogen breakdown by heating to generate petroleum. The heating necessary for catagenesis usually occurs by sufficiently deep burial of the rock containing the kerogen, but other processes can also result in catagenesis, such as volcanic intrusions and heating by hydrothermal vents.

Most organisms can biologically synthesize the acyclic molecule, squalene, which can be cyclized into the pentacyclic triterpene, hopane, by cyclase (Fig. 4). In bacteria, its derivative, hopene, can be further converted to bacteriohopane by adding a 5-carbon chain derived from the sugar ribose (Flesch and Rohmer 1988). Because bacteria constitute such a large fraction of Earth's biomass, hopane molecules with their persistency and thermodynamic stability have been said to comprise the most abundant large-molecule repository of carbon on Earth (Ourisson and Albercht 1992). Hundreds of hopanoids products can be further produced by degradation and by rearrangement of hopene (C_{30}) and bacteriohopane (C_{35}) through catalytic and thermal effects during diagenesis and catagenesis. Hopanoid products have been well identified in soils, sediments, other organic matter, and oil (Ourisson et al. 1984). However, even though the postdepositional degradation and rearrangement can alter the biochemistry (usually does not completely erase it), hopanoids have a fixed stereochemistry derived from enzymatic synthesis. They can still be recognized as biomarkers although they are partially altered.

Unlike prokaryotes, such as bacteria, eukaryotes are unicellular or multicellular organisms, including algae, protozoa, fungi, plants, and animals, whose cells contain a membrane-bound nucleus and complex organelles. Eukaryotic organisms use oxygen to synthesize tetracyclic triterpenes, precursors to the steroids instead of other triterpenoids (Fig. 4). Lanosterol is a precursor for many sterols. Cholesterol is one of the most common sterols in plants and animals and is the precursor for cholestane in petroleum. Prokaryotic hopanoids and eukaryotic steroids are key structural elements in prokaryotic and eukaryotic cellular membranes, which could explain the ubiquity and relative abundance of their hopane and sterane products in petroleum. Higher land plants synthesize many other biochemicals from squalene, including oleanolic acid and β-amyrin, to name a couple that can be precursors for the oleanane in petroleum (Fig. 4).

Archea possesses a cell wall and has a unique way of joining isoprenoids to form a "head-to-head" linkage (Fig. 4). This unique pattern of the isoprenoid linkage appears to be Archea-specific, reflecting a distinctly ancestral chemical differentiation from bacteria and eukaroytes, the other two domains of life (Chappe et al. 1982).The long hydrocarbon chains with head-to-head linkage could possibly include the short side hydrocarbon chains and rings. Archea uses acyclic isoprenoids to make phospholipids, which may help archean membranes from leaking at high temperature. Archea, bacteria, and photosynthetic eukaryotes are known to produce smaller isoprenoid chains, like pristane and phytane. Although acyclic isoprenoids play a significant role in forms of life and can be useful to indicate even very primitive life, they are not taxon-specific for tracking any particular domain due to their various original sources.

Biomarkers as Source and Environmental Indicators

Biomarkers are useful in petroleum exploration and production geochemistry because they carry information about organic matter input, depositional environment, age, and thermal history of the petroleum source rock, as well as the extent of alteration of petroleum in the reservoir rocks (Peters et al. 2005). For example, diagenesis and catagenesis of chlorophyll yields three common constituents in petroleum: porphyrins, and the acyclic diterpanes, pristane, and phytane (Fig. 1). Some porphyrins can be related to specific organisms in the source-rock depositional environment.

Certain steranes and triterpanes in petroleum and rock extracts are also diagnostic for specific biota. Dinoflagellates produce the dinosteranes. 24-*n*-Propylcholestane indicates input from marine Chrysophyte algae (Moldowan et al. 1990). Highly branched isoprenoids are derived from diatoms. Saturated equivalents of botyrococcene (botryococcane) are produced by the freshwater green algae *Botryococcusbraunii*. Botryococcane in petroleum from Minas Field in Indonesia indicates that it originated from a source rock that was deposited in a lacustrine environment conducive to Botryococcus blooms (Moldowan and Seifert 1980). Oleananes, lupanes, and taraxeranes are biomarkers of flowering plants and are also present in the source rock (Ekweozor and Udo 1988; Moldowan et al. 1994). Bicadinanes are derived from dipterocarpaceae tree resins (Cox et al. 1986). Retene, cadalene, and tetracyclic diterpanes indicate conifer input to the source rock (Noble et al. 1985).

An abundance of C_{35}-homohopanes in petroleum (relative to C_{31}-C_{34}-homohopanes) indicates source rocks deposited under anoxic conditions. High abundance of 28, 30-bisnorhopane in petroleum also indicates a reducing environment. 30-Norhopanes (the C_{29}/C_{30}-hopane ratio) have been widely used as a proxy for carbonate source rock. Oil

from carbonate source rock usually has a relatively low diasterane/sterane ratio and high concentrations of 2-α-methylhopanes (Summons et al. 1999). The pristane/phytane ratio can be used to support inferences about the redox conditions of the depositional environment (ten Haven et al. 1988). High concentrations of gammacerane in oils originate from tetrahymanol, which is a triterpanoid produced by anaerobic green-sulfur bacteria in source rocks, often deposited under hypersaline conditions and a stratified water column (Sinninghe Damste et al. 1995). Isorenieratane in petroleum originates from isorenieratene in green sulfur bacteria, which are anoxygenic phototrophs (Summons and Powell 1987). Thus, isorenieratane in petroleum and rock extracts indicates photic zone anoxia when the source rock was deposited.

Kerogen represents ~90% of the organic carbon in sedimentary rocks. Functionalized forms of biomarkers may still occur in extracts from thermally immature petroleum source rocks and low-maturity petroleum, but the defunctionalized saturate and aromatic biomarkers dominate under thermal conditions associated with oil generation. Hopanoids in the geosphere occur insignificant amounts, which is as much or more than the total mass of organic carbon in living organisms. Depending on the depositional setting, the sterol concentration may be more or less than that of the hopanoids. Some biomarkers contain heteroatoms. For example, sulfur can be incorporated into biomarkers during early burial under anoxic, marine conditions. Nitrogen and metals, such as vanadium and nickel, are common in low-maturity petroleum that contains porphyrins. Oxygen can be introduced into biomarkers as acid groups during microbial biodegradation.

Age-Diagnostic Biomarkers

Biomarkers can reveal the age of the source rock (Peters and Moldowan 1993). Steranes and hopanes occur in old Precambrian rocks and in much younger Tertiary rocks. Therefore, their presence in petroleum yields little information about the age of the source rock. However, some precursors originated with the evolution of new biota during the Phanerozoic and can be used as age-diagnostic biomarkers. Age-diagnostic biomarkers are important because they help to identify the origin of petroleum that may have migrated many kilometers from its source rock. Some compounds in petroleum and rock extracts cannot be identified as biomarkers based only on their chemical structures. For example, crude oils with abundant odd-carbon numbered *n*-alkanes in the range *n*-C_{11} to *n*-C_{19} and low amounts of pristane, phytane, and *n*-alkanes above *n*-C_{20} may have originated from *Gloeocapsomorpha prisca*, an extinct green algae that flourished during the early Paleozoic.

Gloeocapsomorpha prisca is the main contributing organism to many lower Paleozoic hydrocarbon source rocks. Evidence of *G. prisca* rarely occurs in post-Ordovician sediments. Source rocks enriched by *G. prisca* and oil derived from them show a distinctive geochemical characteristic of saturated fractions dominated by *n*-alkanes up to C_{19} with a pronounced odd-carbon number predominance. This particular alkane distribution suggests that oil might have been generated from source rocks of Ordovician or lower Paleozoic age. It is predominated by compounds with less than 20 carbons and with a strong odd-carbon predominance for *n*-alkanes (*n*C_{15}, *n*C_{17}, *n*C_{19}). The distribution of *n*-alkanes and low presence of the isoprenoids pristane and phytane results from source facies dominated by a single organism, *Glaecapsamorpha prisca* (*G. prisca*), which proliferated in carbonate banks of the Ordovician.

Sterane biomarkers are derived from steroids which are important constituents of eukaryotic cell-membranes. Steroids have been synthesized by various organisms from Precambrian to present times. C_{28}- and C_{29}-steranes are common constituents from green algae and C_{27}-steranes are prevalent in red algae in marine environment. However, these associations are not exclusive of all species of these groups. Regular steranes consist primarily of C_{27}, C_{28}, and C_{29} carbon numbers. Moldowan et al. (1985) and Grantham and Wakefield (1988) recognized that the ratio of C_{28} to C_{29} steranes varies with the geological age of marine source rocks and that the regular C_{28}/C_{29}-sterane ratio can be used to assess age of oils generated from marine source rocks. Variation in the C_{28}/C_{29} ratio is interpreted to be the result of diversification of sterane-producing organisms, including diatoms, coccolithophores, and dinoflagellates in the Jurassic and Cretaceous periods, particularly those that generate C_{28} compounds over geological time. Caution was emphasized by Peters et al. (2005) in using this ratio without other support due to the certain exceptions, such as land plant sources which have a high concentration of C_{29}-steranes.The ratio of C_{28}/C_{29} regular steranes is best suited for discriminating Palaeozoic from Tertiary sources and is only applicable to open marine organic facies.

Eukaryotic steroids are the most common biomarkers in geological record. The C_{30}-sterane 24-*n*-prophylcholestane (24-*npc*) derived from marine algae is commonly used as an indicator of ancient marine sedimentary depositional environments. The 24-*n*-propylcholestanes are diagnostic markers for marine algae of the older Sarcinochrysidales and brown tide algae (Moldowan et al. 1990). These C_{30}-steranes first appeared in Phanerozoic and their source algae evolved between Early Ordovician and Devonian. The 24-isopropyl/24-*n*-propylcholestanes ratio is used to assess the age of marine source rocks or oils generated from a marine source, particularly for Late Proterozoic (Vendian) to Ordovician sources. The modern precursors of 24-isopropylcholestane are found almost exclusively in marine porifera (sponges) referred to as Demospongiae (McCaffrey et al. 1994). Marine Chrysophyte algae biosynthesizes the 24-*n*-propylcholesterols, which are

related to the 24-*n*-propylcholestanes (Moldowan et al. 1990). The Demospongiae were proposed as the precursors of 24-isopropylcholestane based on the prevalence of 24-isopropylcholesterols in their natural products (McCaffrey et al. 1994). High concentrations of 24-isopropylcholestane (relative to 24-*n*-propylcholestane) were found in some Vendian-Cambrian rock extracts and petroleum, implying that sponges or related organisms were relatively more abundant in Vendian-Cambrian than at other geological times (McCaffrey et al. 1994). High 24-isopropylcholestane ratios appear to result from input of stomatoporids, the dominant reef-building organisms during Late Proterozoic and Early Cambrian. The stomatoporids may have a relationship to modern Porifera (sponges) containing abundant sterols having the 24-isopropylcholestane skeleton.

Dinoflagellates are single-celled eukaryotes whose nucleus lacks histones and having chromosomes that remain condensed throughout the cell division cycle.They are a major part of the marine microplankton flora, which has been around at least since the Late Proterozoic. Dinosterols (natural lipid precursors) and related compounds occur abundantly in modern dinoflagellates although dinosterols have been detected at low abundances in a few of marine diatom species. Consequently, dinosterane, the corresponding saturate hydrocarbon, is a specific marker for dinoflagellates. A relationship between cyst-forming dinoflagellates and pre-Triassic ancestors was constructed by molecular fossil evidence provided by Moldowan and Talyzina (1998). It has been shown in many studies that dinoflagellates are an important source of Mesozoic and Cenozoic marine oil and gas and they are widely accepted as important oil-generating algae. Dinosteranes and triaromatic dinosteroids are used to distinguish marine Jurassic or younger sources, where they occur abundantly and ubiquitously, from marine Paleozoic oils or extracts where they are much less abundant or absent, while Triassic abundances and occurrences are intermediate in magnitude and frequency. Thus, abundant dinosteranes or triaromatic dinosteroids suggest a Triassic or younger age of crude oils and rock extracts.

Tracking of dinosteranes and dinosteroids biomarkers in fossils has been valuable for documenting time-dependent changes in the fossil record. Although the pre-Triassic record contains only equivocal occurrences of dinoflagellates, comparative ultrastructural and molecular phylogenetic evidence from acritarchs (organic-walled microfossils thought to be algal cysts or resting stages) indicates a possible Precambrian origin for the lineage. Thus, it has often been proposed that the dearth of Paleozoic fossil dinoflagellates was due to a lack of preservation or recognition and that the relatively sudden appearance of dinoflagellates in the Mesozoic is an artifact of the record. However, new evidence from a detailed analysis of fossil records and from the biogeochemical records indicates that dinoflagellates did indeed undergo a major evolutionary radiation in the early Mesozoic. Moldowan et al. (1996) reported that triaromatic dinosteroids, which are derived almost exclusively from dinoflagellates, have not been detected in samples from Carboniferous and Permian, but occur sporadically in pre-Carboniferous rocks enriched in acritarchs. A combined dinoflagellate and acritarch species count appears to mirror the occurrence of the dinosteroids. Moldowan and Talyzina (1998) suggested that abundant triaromatic dinosteroids in some Paleozoic rocks and even Proterozoic strata could be related to marine acritarchs, potentially derived from dinoflagellates, which are potentially primary producers in Paleozoic oceans. This might indicate that dinoflagellates could have existed long before the appearance of dinoflagellate cyst fossils in the Triassic.

The C_{26}-sterane, 24-norcholestane, has also been demonstrated to be a useful constraint on geological age and depositional environment (Holba et al. 1998). The 24-norcholestanes are more abundant in oils and rocks younger than Paleozoic even though the source of the 24-norcholestanes is still unproven. The oldest occurrence of 24-norcholestanes probably has a dinoflagellate origin. According to the study by Moldowan and Talyzina (1998) acritarchs that are dinoflagellate ancestors were present as far back as the Early Cambrian. The 24-norcolestanes, along with 24-nordiacholestanes, are used to assess the age of source rocks and oils generated from both marine and non-marine sources. They are best suited for separating Tertiary from Cretaceous, and older than Cretaceous sources. There is still a debate on the relationship between 24-norcholestanes and specific modern taxa because traces of 24-norcholesterol have been observed in both living marine algae and invertebrates, suggesting an origin in eukaryotes which may or may not have prokaryotic symbionts. 24-Norsterols or 24-norsteranes (derived from 24-norsterols in diagenesis) may originate from dinoflagellates in temperate and tropical areas (Rampen et al. 2007). The presence of 24-norcholestane in recent sediment extracts and diatom blooms (Nichols et al. 1990), ancient diatomaceous sediments (Suzuki et al. 1993), and petroleum generated from siliceous sources indicates that diatoms may also be a source of 24-norsteroids. However, in recent studies both diatoms and dinoflagellates are now believed to generate the 24-norcholestanes found in both sediments and petroleum. The temporal evolution and expansion of both dinoflagellates and diatoms can explain the observed stepwise increases in 24-norcholestane concentrations in the sediment record and provide a rationale for their use as age-diagnostic biomarkers.

Highly-branched isoprenoids (HBIs) alkanes and alkenes with 25 carbons have been reported to occur widely in both recent and ancient sediments. These compounds are useful paleoenvironmental biomarkers. Generation of HBIs has been most likely controlled by some environmental factors, but a detailed understanding of these remains unclear. These unusual highly branched hydrocarbons have only been observed in

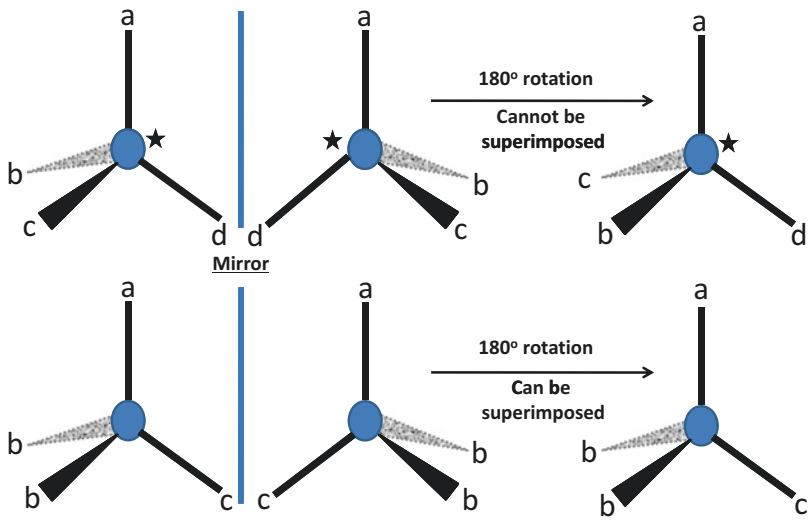
certain diatoms indicating that organic matter in the sediments includes diatoms. Diatoms (Bacillariophyta) are unicellular eukaryotic algae and they use water and light to stimulate their photosynthesis. Diatoms exhibit a great diversity within marine environments including benthic, planktonic, marine, and freshwater species that produce C_{25} HBIs. Diatoms are believed to have originated in the Jurassic and became dominant in Cretaceous and younger periods. In order to determine the timing of the origin of the HBI biosynthetic pathway, Sinninghe Damste et al. (2004) studied the fossil record. They believed that HBI biosynthesis evolved in the Upper Turonian (~90 Ma) according to their data in the study. It also has been observed that the HBI first occurred in sediments of Upper Turonian from the Guyana Basin (French Guyana) in the Canje Formation. There is no occurrence of C_{25} HBIs earlier than Upper Turonian, whereas C_{25} HBIs have widespread occurrence in younger marine sediments (Younger than Upper Turonian age). The HBI occurrence in petroleum shows the great similarity to how the HBI biosynthetic pathway evolved (Peters et al. 2005). For example, the petroleum from the Maracaibo Basin (Venezuela) has a Cenomanian/Turonian age of source rock. Also, it has been documented as the oldest petroleum containing the C_{25} HBI alkane above the detection limit. The close match between sediments and petroleum makes the C_{25} HBI a probable candidate of age-related biomarker. It could be inferred that petroleum containing the C_{25} HBI alkane must be sourced by sedimentary rocks with an age of Upper Turonian or younger. Thus, highly branched isoprenoids with high concentrations of C_{25} HBIs (more than 100 ppm as a detection limit) indicates a Late Cretaceous or younger marine source. HBIs are present in most of the modern coastal sediments and are very common in many lake sediments.

The oleananes are probably derived from pentacyclic triterpenes in angiosperms (flowering plants) (Moldowan et al. 1994). The earliest fossil of angiosperms are found in Early Cretaceous rocks. Therefore, the presence of oleanane suggests that organic matter has been sourced from land plants, specifically angiosperms (Philp and Gilbert 1986) of mid-Cretaceous age or younger. A nonzero oleanane index in these samples indicates some contribution from land plants (angiosperms) to the source rocks where these oils were generated. Angiosperms diversified and spread rapidly in the Late Cretaceous (Moldowan et al. 1994) and came to dominate the terrestrial biota by the end of the Cretaceous. Thus, oleanane is present, though in some cases in reduced quantities, in a majority of crude oil samples from the Cretaceous reservoirs in the world. Higher concentration of oleanane strengthens an interpretation of a tertiary source; the source rock most likely has tertiary age if oleanane is greater than 20% of the sum of oleanane + αβ-hopane. At low concentrations (i.e., less than 3% of the C_{30}-αβ-hopane peak), other compounds unrelated to oleanane can be mistakenly identified as oleanane. The presence of oleanane does not rule out a pre-mid-Cretaceous source because oils generated from older strata could have migrated through post-mid-Cretaceous strata. If the post-mid-Cretaceous strata are immature and rich in biomarkers, compounds such as oleanane can be entrained by the migrating oil. Conversely, the absence of oleanane does not rule out a post-mid-Cretaceous source. Highly mature material or sources dominated by marine organic matter will have low concentrations of oleanane.

Several considerations must be kept in mind when using age-related biomarkers to assess the age of source rock and petroleum samples. In general, it is recommended to look at more than one age-related biomarker to improve the confidence in the age identification. Age-related biomarkers are also affected by source facies, biodegradation, secondary processes in the reservoirs, and maturity. It is not easy to build the relationship between a biomarker parameter ratio and the source rock maturity because many factors such as heating rate, source rock lithofacies, and source rock organic facies (kerogen type) could variously impact identification of that relationship. As a result, it always happens that the exact maturity (i.e., vitrinite reflectance equivalent) associated with a given value for a biomarker parameter ratio could vary from basin to basin with different depositional settings. Most significantly, the concentrations of biomarkers in petroleum dramatically decrease with increasing thermal maturity, and many age-related biomarkers would reach their terminal values. Hence, any given biomarker parameter ratio is applicable within its own limitations.

Biomarker Stereochemistry

Stereochemistry refers to a way in which the atoms of a molecule are spatially arranged. Biological compounds have stereochemistries that give them the capability of fulfilling specific functions in organisms, such as membrane stabilization. The vast majority of biomarkers have some kind of stereospecificity. Spatial arrangement is the key concept in understanding chirality and stereochemistry. Molecules display their own spatial preference based on the kinetics and energetics of their formation. Enzymatic synthesis plays an important role by placing constraints on the three-dimensional shape of the biosynthesized natural products, since only specific molecular shapes are biologically active. Therefore, molecules with a unique spatial arrangement of atoms in three-dimensional space have different chemical-physical properties from molecules having exactly the same composition (empirical formula). Chirality has received wide attention in organic chemistry and also is an important biosignature of biomarkers. It helps to explain the physical and theoretical reasons behind the biomarker structure and is related to the origin of biomarkers via enzyme-assisted synthesis. A molecule with a chiral center has a non-superimposable mirror image. In reality, a carbon atom with four different surrounding atoms bonded to it is treated as



Biomarkers: Petroleum, Fig. 5 It is shown the comparison of chiral and achiral molecules. The center atom is commonly carbon atom in petroleum, a, b, c, and d are different either atoms or atom groups attached to the carbon atom. The chiral molecule has a stereocenter which is designated with an asterisk. Rotation of its mirror image does not generate the original structure. In contrast, the mirror image of the achiral molecule can be superimposed on the original structure after the 180° rotation

chiral molecules if it cannot be superimposed upon itself after 180° rotation (Fig. 5). Many biomarkers, such as steranes and hopanes, have multiple chiral centers which can be preserved through diagenesis. They have multiple quaternary asymmetric carbon atoms (carbon atoms bonded to four different groups) in their carbon backbone structures, which allow them to be recognized by the mass spectrometry. Epimerization is the process during which one asymmetric carbon center is converted to its chiral counterpart. With relatively mild diagenetic conditions, biomarkers with asymmetric centers (tertiary asymmetric carbon atoms bonded to only one hydrogen atom), such as acyclic isoprenoids and amino acids, generate a racemic mixture, a 50:50 mixture of enantiomers, of both the biologically and geologically produced antipodes via epimerization.

Isomers are molecules that have the same chemical formula but a different structural arrangement of atoms in space. Many different types of isomers are important in organic geochemistry. Molecules are identical in a two-dimensional view but can be differentiated stereochemically in three dimensions can be designated as enantiomers, diastereomers, or epimers. Usually biosynthesis produces one isomer exclusively, known as homochirality; for example, amino acids are biosynthesized exclusively as the L-enantiomer rather than the D-enantiomer. Internal rotational and vibrational energies cause these molecules to twist and writhe in space instead of being static. In general, lipids having carbon atoms as asymmetric centers (centers with four different groups attached by four single bonds) are biosynthesized as one or the other antipode.

However, once organisms die, the biological configurations of these compounds may not be stable in the biosphere and geosphere. Certain asymmetric centers can be inverted during diagenesis. As a result, amino acids in ancient organic matter containing tend to epimerize into a racemic mixture (50:50 mixtures) of Land D amino acids. Biomarkers encode valuable information about diagenetic and thermal conditions by suffering postmortem stereochemical changes. Enantiomers receiveless attention during biomarker analysis, because it is not easy to resolve them by the available analytical technology. However, compounds with multiple asymmetric centers can be resolved as diastereomers due to the inversion of some of the asymmetric centers. Asymmetric centers carrying a hydrogen atom (tertiary carbon centers) tend to invert but asymmetric quaternary carbon centers (carbon atom bound to four different groups other than hydrogen) cannot. Inversion at asymmetric centers is called stereoisomerization. During the process of the stereoisomerization, the formation of thermodynamically more stable geological epimers from less-stable biological epimers takes place. However, it does not usually generate a 50:50 mixture of the two configurations because some of the multiple asymmetric centers are involved and some of them are not free to invert. It is impossible for quaternary centers to complete the stereoisomerization during diagenesis, and disruption of these centers may lead to rearranging and destroying the base molecular structure. Acyclic isoprenoids readily isomerize very early in their burial and steroids can form pairs of diastereoisomers at former sites of unsaturation (double bonds). Certain hydrogen atoms at ring junctions are prone to isomerize and even the whole steroid backbone can rearrange. This backbone rearrangement is particularly catalyzed in the presence of acidic clays in the enclosing sediment. Whereas such rearrangements are often suppressed in the carbonate sediments due to the different type of diagenesis in carbonate rocks. Thus, stereoisomerization reactions can be used not only as thermal maturity indicators but also as depositional environment indicators.

Thermal maturity describes the extent of heat-driven reactions that convert sedimentary organic matter into petroleum. Petroleum is a complex mixture of metastable products that

evolve toward greater thermodynamic stability during maturation. Exploration success for petroleum can be improved by identifying areas within sedimentary basins where thermal maturity is favorable for the occurrence of crude oil. Thermal stress parameters are the most commonly utilized parameters for evaluating the maturity of organic matter. The effect of temperature leads to conversion of relatively unstable compounds to thermodynamic more stable compounds based on either rearrangement or decomposition. The mechanism of rearrangement or decomposition proceeds via aromatization, dealkylation, isomerization, and alkylation, and these chemical changes can be enhanced by catalytic activity.

Organic matter from bacterial and plant debris in sediments is generally converted into kerogen and bitumen by means of biological, physical, and chemical alterations and without pronounced effects of temperature during diagenesis. After progressive diagenesis, catagenesis and metagenesis can commence upon deep burial and organic matter is converted into petroleum and, ultimately, to gas and graphite (Peters et al. 2005). Since the changes are progressive during the long geological periods of burial in the sediments, most biomarkers comprise mixtures dominated by the most thermodynamically stable stereoisomers. For example, during the thermal process, cleavage and reformation of the bonds result in two configurations where the asymmetric center is with or without an attachment to a ring. Therefore, with increasing maturity, these reactions lead to the enrichment of the thermodynamically more stable isomers. The extents of such conversions can be used as maturity indicators.

Summary

Petroleum occurs naturally in complex mixtures. It contains more than 20,000 hydrocarbon compounds having a broad structural and chemical diversity. Those compounds are predominantly comprised of aliphatic hydrocarbons, aromatic hydrocarbons, and many other constituents with heteroatoms (N, O, S) and with different volatilities.

Biomarkers are important compounds in petroleum, whose basic structure provides an unambiguous link with formerly-living organisms. Their basic molecular structures are primarily inherited from the parent organic molecules with little or no change.

Further, their structures undergo few changes during diagenesis and catagenesis. The most important biomarkers are hydrocarbons. Crude oils exhibit different biomarker fingerprints. The high specificity of some biomarkers in petroleum and source rocks toward specific classes of organisms and different types of depositional environments allows the interpretation of paleoenvironmental conditions at the time of sedimentation, thermal maturity, type of organic matter in the source rock, and genetic relationships between petroleum and source rocks. In addition, biomarker analysis can also provide important information about migration pathways from the source rock to the reservoir based on oil-to-oil and oil-to-source rock correlation. Biomarkers provide information of great importance in forensic investigations to determine the source of spilled oil, differentiate and correlate oils, and monitor the degradation process and weathering of oils because they resist biodegradation and weathering.

[2]Nuclear Magnetic Resonance Facility, Oregon State University, Corvallis, OR, USA

Definition

A *polymer* is "a chemical compound or mixture of compounds formed by polymerization and consisting essentially of repeating structural units" (Merriam-Webster 2017). As the original meaning of the term polymer does not include any reference to molecular size, Staudinger and Fritschi (1922) introduced the word *macromolecule* to describe large covalently bonded organic chain molecules containing more than 10^3 atoms. By convention, the term macromolecule is reserved for organic molecules; it does not cover inorganic geopolymers such as obsidian. The official definition (IUPAC 2006) of the term macromolecule regards a molecule as having a high relative molecular mass if the addition or removal of one or a few of the units has a negligible effect on the molecular properties. Also, when a molecule has a high molecular mass *and* comprises the multiple repetitions of units derived from molecules of low relative molecular mass, it may be described as either macromolecular or

polymeric. *Supramolecular assemblies* of amphiphilic subunits share the element of monomer repetition and the element of potentially large molecular size, but here the monomers are not covalently linked. Size, biological functionality, and shape of supramolecular assemblies in geosystems depend on the presence and ionic composition of the supporting aqueous phase.

Types of Macromolecules in Geosystems

Biomacromolecules include a wide range of species such as cellulose, hemicellulose, lignin, protein, DNA, RNA, resins, glycogen, and many others. Many of these macromolecules play important roles in geophysical systems. These roles can be separated into four broad categories based on the propensity of the respective molecule to maintain some form of biogeochemical functionality in the environment: (i) providers of energy, carbon, nutrients, and biophysical functionality, (ii) conservation of information and signaling, (iii) extracellular catalysis, and (iv) residuum with no obvious biological function.

Biomacromolecules as a Source of Energy, Carbon, and Nutrients

Globally, two major biomacromolecule production environments can be distinguished. (a) In terrestrial systems, vascular plants predominate and consist largely of carbon-rich biomacromolecules such as cellulose, lignin, and tannin (Table 1). A detailed description of these compounds has been offered by Kögel-Knabner (2002). Dead plant matter from the shoot is dropped on the soil surface, while root derived debris and exudates enter the subsurface mineral soil. Mesofauna, fungi, bacteria, and archaea constitute the decomposer community involved in the conversion of dead plant matter to smaller intermediate compounds and ultimately to end products such as CO_2, HCO_3^-, and CH_4. Terrestrial systems receive variable amounts of rainwater which percolates through the soil and so generates a constant vertical removal vector for all soluble organic compounds, requiring those organisms who wish to feed on such compounds to be alert, selective, and efficient. Because terrestrial systems are overwhelmingly aerobic environments, fungi specialized on producing O_2 – requiring oxidative enzymes are particularly important for decomposition processes. (b) In the oceans, phytoplankton produce a nitrogen – rich biomass (Table 1), where bacteria and archaea recycle the constituents of dead organisms in the water column. Any debris that escape degradation sink to the underlying sea floor, where the scarcity of oxygen means degradation can only continue with the help of electron acceptors (such as nitrate, sulfate) that allow for lesser energy yields than oxygen. Vascular plants and their unique macromolecular constituents (lignin, tannin, crystalline cellulose) are largely absent, as are the fungal decomposers that are specialists on such materials.

As long as oxygen is present, microbial decomposition is vigorous in both terrestrial and marine systems and even organic debris encapsulated in aggregates or adsorbed to mineral surfaces will eventually be mineralized (Hedges and Oades 1997). Preservation of organic debris over geological time scales requires the absence or profound impediment of prokaryotic life. For instance, deep burial of anoxic sediments may lead to elevated pressure and temperature and thus prevent decomposer activity.

Biomacromolecules as Information Carriers

The nucleic acids, DNA and RNA, are the primary information carrying macromolecules.Nucleic acids are normally protected from the extracellular environment inside cells or the capsid of viruses. However, they can be found in the environment as the result of cell lysis or excretion by live cells (Lorenz and Wackernagel 1994). In the environment, nucleic acids are subject to degradation by nucleases, which is a relatively rapid process. DNA is degraded in aquatic

Biopolymers and Macromolecules, Table 1 Relative composition of vascular plants, algae, bacteria, and fungi, modified after Kleber et al. (2007)

	Vascular plants	Algae	Bacteria	Fungi
	% dry matter			
Lignin	5–30			
Cellulose	15–60

Lipids	Minor	2–10	10–35	1–42
Noncellulosic carbohydrates	Minor	40	4–32	8–60
	Ratio			
C:N ratio	20–50 (tree leaves) 25–80 (herbaceous plants)	6	5–8	≈10

systems with a half-life of minutes to hours. In contrast, rapid binding to soil minerals can result in persistence of nucleic acids for many hours, days, or weeks (Lorenz and Wackernagel 1994). Organisms in the soil can utilize this genetic information when they take up the nucleic acids by transformation. Transformation of environmental DNA has been implicated in gene transfer and the emergence of antibiotic resistance in the environment (Berglund 2015). Proteins can also carry information, albeit not genetic in nature. Signal peptides are often used in quorum sensing, a mechanism that is thought to coordinate activities between groups of microorganism (Miller and Bassler 2001; Hibbing et al. 2010).

Biomacromolecules as Catalysts

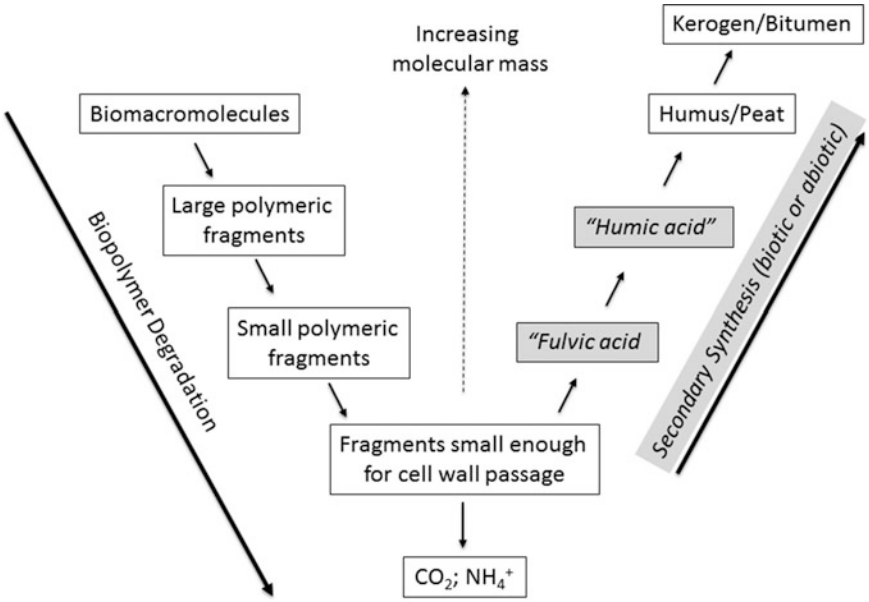
Proteins account for the majority of catalytic macromolecules in the extracellular environment. As polymers of amino acids, these macromolecules incorporate a wide range of functional groups, such as amines, carboxylic acids, and aromatics. The wide range of functional groups in proteins contributes to their varied functions and behavior. Most catalytically active proteins (or enzymes) fold into complex three-dimensional structures that form an active site where important functional groups are optimally positioned to carry out catalysis. Denaturation or unfolding of an enzyme typically results in its loss of function. RNA is also capable of carrying out catalytic function (Fedor and Williamson 2005), with the ribosome being one of the most important examples. However, the extent to which RNA contributes to soil catalytic processes has not been fully determined.

Proteins can associate with soil mineral surfaces resulting in various outcomes (Gianfreda et al. 2011). In some cases, binding of proteins to minerals has resulted in loss of catalytic activity, implying that either the active site has been occluded or the protein has unfolded. In other cases, proteins bound to minerals have retained their catalytic activity and have also been found to have improved thermal stability (Huang et al. 2005). These and similar observations have suggested the hypothesis that mineral association by proteins results in their reduced degradation and extended persistence in the environment (Burns et al. 2013). The hypothesis is further supported by the observation of mineral associated proteins preserved in the environment for time periods in excess of four million years (Demarchi et al. 2016). Yet, it is important to note that not all minerals will reduce protein degradation. Reactive metal oxides, such as birnessite, have been shown to readily degrade proteins (Reardon et al. 2016; Russo et al. 2009). In another case (Johnson et al. 2006), the phyllosilicate montmorillonite was observed to cleave a pathogenic prion protein, although the pathogenic subunit remained intact and infective. This is particularly interesting, because montmorillonites generally are thought to bind and preserve protein (Gougeon et al. 2003), rather than contribute to its degradation. Thus, while many protein mineral interactions result in thermal stabilization, and perhaps protection from degradation, this is not true of all such interactions. Biophysical properties of the particular proteins involved in the interaction and the local environmental conditions likely contribute to these interactions and the resulting outcomes.

The tendency of proteins to interact with soil minerals, regardless of the eventual outcome of these interactions, has complicated their study (Quiquampoix and Burns 2007). Their wide range of biophysical properties results in complex interactions with minerals and involve an array of molecular level forces (Norde 2008). Thus, a given mineral can exhibit strong affinity for one protein but modest affinity for another. Further, environmental conditions, such as pH, can have a significant influence on affinity (Reardon et al. 2016). Many studies of soil protein require extraction of protein from the mineral for subsequent downstream analysis. However, the complexity of these interactions can hamper protein extraction. Methods intended to extract total protein from minerals have been developed; however, the actual efficiency of extraction is typically well below 100% (Chourey et al. 2010; Wu et al. 2014; Keiblinger et al. 2012).

Residual Carbon: Macromolecularity as a Condition for Persistence

The realization that molecular complexity and degree of polymerization are linked to slow decomposition can be traced back to the early decades of the twentieth century (Waksman 1936) and received strong support from the work of Martin and coworkers (Haider and Martin 1975; Haider and Trojanowski 1975; Martin and Haider 1971; Martin et al. 1982). These scientists introduced ^{14}C into the molecular structure of phenolic acids and artificially prepared phenolic polymers. This allowed them to identify the molecular origin of the carbon in the $^{14}CO_2$ that evolved during decomposition of these molecules. In a seminal publication, Haider and Martin (1975) showed how linkage into polymeric structures was able to retard the decomposition of organic carbon in 12-week incubation experiments. As a result, macromolecularity has long been considered one of the major factors determining the persistence of organic C in geosystems. This perception contributed to attempts to predict the persistence of organic C based on the molecular properties of organic substrates (reviewed by Derenne and Largeau 2001). One significant outcome of this view is the traditional model of kerogen formation (Fig. 1) as the result of initial depolymerization followed by partial recondensation of decomposition fragments into operationally defined "humic substances" (Hedges 1988).



Biopolymers and Macromolecules, Fig. 1 Classic view of the biopolymer degradation and abiotic condensation pathways (Modified after Hedges 1988). *Gray shadowing*: fraction or mechanism currently debated. Fulvic acid and humic acid are operationally defined fractions obtained by an alkaline extraction procedure, their actual physical existence in geosystems has not been verified in observations using independent methodology. While demonstrable in laboratory settings, secondary synthesis of small fragments into larger, operationally defined "humic substances" has so far not been shown to be of quantitative relevance for organic matter accumulation in geosystems

Two major developments have altered this view. The advent of supramolecular chemistry inspired Wershaw (1993) to conceptualize decaying organic matter as a collection of relatively small amphiphilic molecules assembled into micellar or hemimicellar associations held together by noncovalent interactions among the component molecules, a view that has steadily gained traction (Kleber et al. 2007; Piccolo 2001; Sutton and Sposito 2005). Concomitantly, analytical techniques such as solid state nuclear magnetic resonance spectrometry (SS-NMR) and synchrotron spectromicroscopy (STXM-NEXAFS) have allowed the community to observe the chemical characteristics of organic compounds in situ and independent of operational extraction procedures. This has led to the development of alternate models to explain the survival of fragmented organic matter without the need for a recondensation step. The biodegradation/sorption model proposed by Hedges and Keil (1999) posits that some degradation intermediates escape microbial uptake and are leached into the soil where they partition between the aqueous phase and the surrounding mineral surfaces. These organic materials escape remineralization due to protective sorption/aggregation without the need to invoke spontaneous condensation reactions. Based on in situ observations using modern spectrometric techniques (Keiluweit et al. 2012; Kelleher and Simpson 2006; Lehmann et al. 2008; Masoom et al. 2016; Myneni et al. 1999), this concept has since been further refined into the soil continuum model (Lehmann and Kleber 2015), which conceptualizes soil organic matter as a continuum of progressively decomposing organic compounds whose persistence depends on interactions with the mineral phase. Recent evidence for the ability of mesofauna and symbiotic microorganisms to decompose even industrial polymers (Yang et al. 2014, 2015, Yoshida et al. 2016) emphasizes the insight of Jenkinson (1981) that "in the long run, no fraction of organic matter can withstand decomposition" and that the molecular peculiarities associated with kerogen formation (Vandenbroucke and Largeau 2007) arise from the combined effects of exclusion of decomposer organisms, anoxia, heat, and pressure following burial and not as a consequence of polymerization reactions during humus or peat formation.

Summary

Biomacromolecules are synthesized by organisms to perform numerous functions inside and outside of the cell. Historically, emphasis was placed on the decomposition, alteration, and persistence of macromolecules in geosystems. The concepts and pathways involved in the early stages of macromolecule transformations are currently revised based on new information made available by innovative methods for in situ observation of chemical processes at the submicron scale. Extracellular functions of biomacromolecules such as catalysis, signaling, and transfer of genetic information are receiving increasing attention and constitute an exciting realm of future research.

Bismuth

Cristiana L. Ciobanu and Nigel J. Cook
School of Chemical Engineering, The University of Adelaide, Adelaide, SA, Australia

Element Data
Atomic Symbol: Bi
Atomic Number: 83
Atomic Weight: 208.9804
Isotopes and Abundances: Bi^{209} (100%) – several other isotopes are short-lived intermediate products of U^{238} (Bi^{210} and Bi^{214}), U^{235} (Bi^{211} and Bi^{213}), and Th^{232} (Bi^{212}) decay. Bi^{209} is a rare primordial isotope, discovered in 2003, that decays via α-decay with a half-life greater than a billion times the age of the universe.
1 Atm Melting Point: 544.52 °C
1 Atm Boiling Point: 1837 °C
Common Valences: +3 (0, +5)
Ionic Radii: 3+: 101 pm
Pauling Electronegativity: 2.02
First Ionization Potential: 703 kJ mol^{-1}
Chondritic (CI) Abundance: 0.11 ppm
Silicate Earth Abundance: 0.003 ppm
Crustal Abundance: 0.025 ppm
Seawater Abundance: 0.015 μg/l
Core Abundance: ~0.03 ppm

Properties

Bismuth is a brittle, diamagnetic, reddish white metal which tarnishes to a brassy color and is a poor conductor of heat and electricity. Chemically, bismuth is similar to metalloids antimony and arsenic, albeit with greater metallic character. The metal burns upon heating with oxygen to give the oxide Bi_2O_3 (Bi_2O_5 is unstable).

Bismuth is most commonly found in the +3 oxidation state in minerals, rarely as Bi^{5+}. Bismuth readily forms chloride ($BiCl_5^{2-}$ and $BiCl_6^{3-}$), oxide, and hydroxide complexes, notably $Bi(OH)_{3(aq)}$ (Tooth et al. 2013; Etschmann et al. 2016). Bismuth is the most ionic of the Group VA elements and tends to form strong bases in aqueous solutions.

Bismuth is a moderately volatile chalcophile element and is typically enriched in sulfide-bearing meteorites. A subordinate lithophile character is reported but remains poorly documented.

History and Use

Known since ancient times [from the German, *Weisse Masse* (white mass), later *Wismuth*, or possibly via Arabic *bi ismid* (having the properties of antimony), and translated in the sixteenth century to the New Latin name *bisemutum*].

Bismuth has a remarkably low toxicity relative to lead, and bismuth alloys are increasingly used instead of lead in a variety of applications, including water pipes, ceramic glazes, fishing weights, solders, and gunshot. More than half the annual production of bismuth (13,600 tonnes in 2015; USGS 2016) is, however, used for manufacture of compounds for the cosmetics, pigment, and, increasingly, pharmaceutical industries. Bismuth-based compounds, notably tellurides and selenides alloyed with antimony and, most recently, sodium bismuthinides, have attracted considerable interest as thermoelectric materials and topological insulators on account of their semiconducting properties.

Bismuth production, sufficient to meet world demand, comes largely as a by-product of lead (and in China, also tungsten) mining. Two mines, one each in Bolivia and China, have exploited bismuth ore. China and Vietnam are currently the world's most important suppliers.

Geochemical Behavior

Bismuth concentrations in most rock types are low, around or below minimum limits of detection. The element is, however, typically enriched in felsic rocks (~0.9 ppm in rhyolite,

0.27 ppm in granites), although concentrations tend to vary from example to example. Concentrations are an order of magnitude lower in mafic or intermediate rocks. It is therefore unsurprising that the greatest concentrations of bismuth minerals are found in pegmatites associated with granites, in hydrothermal deposits associated with granites, and in skarn deposits formed via intrusive-related metasomatism. Concentrations of bismuth in sedimentary rocks vary; they are highest in recent pelagic sediments (0.56 ppm) and shales (0.26 ppm) and low in sand- and limestones (averaging 0.03 ppm). Coals are typically relatively enriched in bismuth (average 5 ppm). Metamorphic rocks appear typically low in bismuth.

Mineralogy

Bismuth is one of a number of elements (the others are Cu, Ag, As, Se, Ag, Sb, Te, Pb, and U) which build an anomalously large number of distinct minerals in which it is an essential component. Bismuth is second only to tellurium in terms of mineralogical diversity (Christy 2015).

Bismuth is found as native metal but more commonly as a relatively large number of sulfides, the most abundant of which is the mineral bismuthinite (Bi_2S_3). Bismuthinite forms a solid solution with stibnite (Sb_2S_3). There are currently around 210 approved bismuth minerals. Bismuth sulfosalts (and selenosalts) (Moëlo et al. 2008) are a particularly diverse group and make up around half this number. Among the most common sulfosalts of bismuth are bismuthinite derivatives, lillianite homologues, and cosalite. These may contain lead, copper, and/or silver and can be classified into a number of homologous series on the basis of related crystal structures (Makovicky 1997, 2006). Additional bismuth sulfosalts are described and named each year. Other primary bismuth minerals include Te- and/or Se-bearing chalcogenides (e.g., tetradymite, Bi_2Te_2S), also making up an extensive homologous series of structurally related species (Lind and Lidin 2003; Cook et al. 2007; Ciobanu et al. 2009a), and bismuthides (e.g., maldonite, Au_2Bi). Secondary bismuth species include oxides (most common: bismite, Bi_2O_3), carbonates (most common bismutite, $Bi_2(CO_3)O_2$), and less abundant vanadates, molybdates, arsenates, and tungstates. There are three bismuth silicates (all rare). Bismuth can also substitute into common sulfide minerals, notably galena (via the coupled substitution $2Pb^{2+} \rightleftharpoons M^{+} + (Bi,Sb)^{3+}$ where M is typically Ag). Bismuth also substitutes into the copper Cu-(Fe)-sulfides bornite, chalcocite, and chalcopyrite (at up to concentrations of hundreds or even thousands of ppm; Cook et al. 2011). Since bismuth can cause copper to become brittle, copper concentrates containing greater than statutory concentrations of bismuth may be liable to severe financial penalties when sold to smelter.

Economic Geology and Mining

Apart from pegmatites, bismuth is most commonly found in polymetallic sulfide ore deposits of hydrothermal origin, associated with silver, copper, lead, zinc, tin, and sometimes molybdenum and tungsten.

Bismuth has a low melting point relative to most other metals. The role of bismuth melts has been demonstrated in a number of ore deposits, notably to scavenge gold from hydrothermal fluids and contribute to its concentration in ore. Empirical and experimental evidence for the scavenging of gold by bismuth melts (Tooth et al. 2011) help explain the strong association often observed between gold and bismuth minerals in skarns and some "orogenic" gold deposits, as well as the presence of gold in some bismuth minerals (Ciobanu et al. 2009b).

Biological Utilization and Toxicity

There is no natural biological utilization. Considered as a "green" heavy metal, the replacement of lead by bismuth in some applications is seen as a way to mitigate environmental problems caused by heavy metal pollution. Bismuth has low toxicity to humans, and a number of bismuth-based drugs have been developed as treatments for various health conditions. In high concentrations, bismuth may however be damaging to health (Yang and Sun 2011).

Black Shales and Sapropels

Kay-Christian Emeis
Department of Earth Sciences, Hamburg University, Hamburg, Germany

Synonyms

Bituminous rock; Organic-rich shale; Sapropelites

Definition

Black shales are organic carbon-rich sediments or sedimentary rocks. Black shales are important source rocks of fossil fuels (petroleum and natural gas) (Tissot and Welte 1984) and in some cases host economically viable metal accumulations (Vine and Tourtelot 1970). Sapropels are a geologically young analogue of black shales and offer high-resolution archives to decipher the interplay of paleoclimate and paleoceanography with biogeochemical and biological conditions in marine black shale depositional environments of the more distant geological past (Emeis and Weissert 2009).

Characteristics

Black shales and sapropels represent paleoenvironmental conditions that caused an unusually efficient transfer of mainly marine nonliving biomass into the geosphere and thus have been a key regulation on the global carbon cycle throughout Earth history. The sequestration of organic carbon in the geosphere is a small sink in the contemporaneous global carbon cycle (estimated at 0.2*10^15 g C annually), but this small flux has over Earth history accumulated an enormous amount of organic carbon in the geological sediment record (estimated at 1.2*10^22 g C). The long-term organic carbon sink for CO_2 is of the same magnitude as chemical weathering in regulating atmospheric CO_2. The fossil reduced carbon (in the form of kerogen, insoluble organic matter dispersed in sediment, originating from buried remains of marine plankton or land plants) is a minor constituent in most sedimentary deposits (constituting between 0.0 and 0.5 percent by weight), but organic carbon concentrations in black shales and their variants commonly exceed 1% by weight and can reach up to 50%. Such organic-rich sediments and sedimentary rocks are typically fine-grained (sand-silt-clay or mud) and dark, and the organic matter is interspersed in a matrix of clastic or biogenic origin. Enrichment of metals is commonly associated with high sulfide concentrations.

Black shale depositional environments range from lakes to the open ocean but cluster in:

(a) Open-ocean settings where the biological productivity in the sea surface was high (recent analogues are upwelling areas)
(b) Young ocean basins dissected by sills with impeded deepwater recharge (a recent analogue is the Black Sea)
(c) Hemipelagic settings over continental margins that lead to concentrations of allochthonous organic matter (of marine and also of terrestrial provenance) by physical transport
(d) Vast epeiric seas created during periods of high global sea level and warm climates in Earth history (no large recent analogue)

Such environments are conducive to enhance organic carbon burial via two interlinked controls that regulate the rate of organic carbon sequestration in marine environments:

biological productivity in the sea (or lake) surface fueled by nutrients originating from enhanced weathering of continents and oxygen depletion in deep waters or in oceanic oxygen-minimum zones preventing settling and sedimenting organic matter from being oxidized. In the Mesozoic Era (252 to 66 million years ago), extended (up to several million years duration) periods of coeval deposition of black shales in all ocean basins are thought to represent global oceanic anoxic events (Schlanger and Jenkyns 1976).

The interplay between climate, oceanography, and biogeochemistry in the origin of black shales is exceptionally well preserved in sapropels – layers of organic-rich sediments intercalated in late Cenozoic sediments of the Mediterranean realm (and in some other silled basins) (Rohling et al. 2015). Here, changes in the climate and hydrology of the Mediterranean Sea and its North African catchment, predominantly related to insolation-driven changes in African monsoon runoff into the Eastern Mediterranean (Rossignol-Strick et al. 1982) but also linked to global sea level/ice sheet fluctuations (Grimm et al. 2015), caused a dramatic change in the oxygenation of Eastern Mediterranean deep waters. Deepwater ventilation was inhibited when warming and freshening of Eastern Mediterranean sea surface layers caused stratification of the water column; the aging deep waters then became anoxic from continued mineralization of organic matter, leading to enhanced preservation of organic carbon (over a few thousand to ten thousand years). Increased surface water productivity likely contributed to sapropel deposition in some cases although there are differences between sapropels, and it can be hard to distinguish between increased productivity and preservation (Rohling et al. 2015).

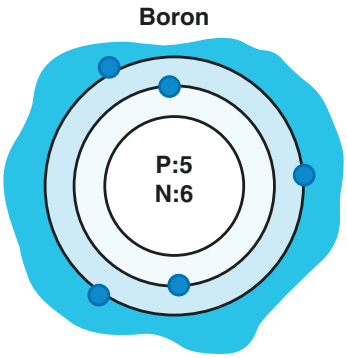
Properties

Boron is a metalloid with a rhombohedral crystal structure. This element belongs to the group 13 and period 2 of the periodic table (Fig. 1). Boron has sixteen known isotopes of which two are stable, ^{10}B and ^{11}B, of relative atomic mass 10.01293695(41) and 11.00930536(45) (source of data: National Institute of Standards and Technology): http://www.nist.gov/pml/data/comp.cfm. Geochemists measure the relative variations in the ^{11}B/^{10}B of terrestrial and extraterrestrial materials as per mil deviations from the isotopic composition of a synthetic boric acid (international reference: NIST SRM-951a; Atom%: ^{11}B = 80.173 ± 0.013; ^{10}B = 19.827 ± 0.013) according to Catanzaro et al. (1970):

$$\delta^{11}B = \left(\frac{{}^{11}B/{}^{10}B_{\text{sample}}}{{}^{11}B/{}^{10}B_{\text{reference}} - 1} \right) \times 10^3 \qquad (1)$$

The electronic configuration of boron is $1s^2 2s^2 2p^1$ while valence states are possibly +4, +3, +2, and +1, the oxidation



Boron, Fig. 1 Schematic illustration of the atomic configuration of ^{11}B

state +3 being by far the most common one. Its nonbonded atomic radius is 1.92 Å, its covalent radius is 0.84 Å, along with a strong electronegativity of 2.04 on the Pauling scale and an electron affinity of 26.989 kJ.mol^{-1} (Coursey et al. 2010; Haynes 2015). Amorphous and β-rhombohedral boron have a density of 2,350 kg.m^{-3} while the α-rhombohedral phase has a density of 2,460 kg.m^{-3}. Boron, as the metalloid element, does not react with water under standard conditions. Boron salts, however, are soluble in water, with boric acid H_3BO_3 showing a solubility of 57 g.L^{-1}, borax having a solubility of 25.2 g.L^{-1}, and boron trioxide (B_2O_3) having a solubility of 22 g.L^{-1}. Boron has a specific heat capacity of 1,026 J.kg^{-1}.K^{-1}.

History and Use

The name Boron originates from the Arabic word "buraq" and the Persian word "burah"; however, the English word "Boron" resulted from a combination of the words "borax" (the main boron ore) and "carbon" that indicates both its natural source and resemblance to carbon. In nature, boron does not occur in its elemental form but is bound to oxygen. According to Wisniak (2005), boron compounds such as borax ($Na_2[B_4O_5(OH)_4].8H_2O$) may have been known for about 6,000 years, Babylonians most likely being the first to have used borax brought from the Far East followed by Egyptians, Chinese, Tibetans, and Arabians. Borax has been used to decorate Chinese pottery dated to the third century. In Europe, as early as in the twelfth century, borax was used by silversmiths to strip precious metals such as gold. Medical prescriptions have been recorded in Coptic Papyruses describing a borax-based recipe for the treatment of eye diseases (Travis and Cocks 1984).

In 1702, Wilhelm Homberg transformed borax into a snow-white powder known today as metaboric acid (HBO_2). The element itself was discovered independently in June, 1808, by the English chemist Sir Humphry Davy and French chemists Joseph-Louis Gay-Lussac and Louis Jacques Thénard. Davy (1808) obtained boron by electrolysis while Gay-Lussac and Thénard (1808) isolated the element through a reduction of boric acid (H_3BO_3) with potassium. Neither of these discoveries allowed boron to be truly purified as synthesized compounds contained less than 50 wt% of boron. Boron was isolated and purified with better chemical yields by Moissan (1895), who reduced boric anhydride (B_2O_3) with magnesium in a thermite-type chemical reaction. Weintraub (1911) was the first to obtain a high-level of purity (near 99%), but pure boron phases were not obtained until the late 1950s. Pure boron is either dark brownish gray (amorphous powder or poorly crystallized phase) or silver-gray in color with a metallic, lustrous brilliance (polycrystalline phase).

Natural Abundance

Boron is a lithophile element according to Goldschmidt's classification (Goldschmidt 1926), meaning that it forms very strong covalent bonds with oxygen and thus commonly occurs in silicate mineral phases despite its low crustal abundance (≈10 ppm).

Ordinary and carbonaceous chondrites contain indistinguishable amounts of boron, together ranging from 0.3 to 1.4 ppm (Shaw et al. 1988; Zhai and Shaw 1994). This range was obtained by analyses of 36 fragments of meteorites by gamma-ray neutron activation analysis. CI chondrites contain 0.78 ppm of boron on average (Lodders 2010). The boron content of carbonaceous chondrites results from a weighted linear combination of the matrix (0.69 ppm) and chondrules (0.23 ppm; Zhai and Shaw 1994). The mean boron content of the matrix of carbonaceous chondrites has been used to calculate a normalized Solar System abundance of 16.9 ± 2.2 atoms/10^{6}Si. Large variations in $\delta^{11}B$, from −50 ± 10‰ to +40 ± 10‰, were documented for chondrules (Chaussidon 1995) whereas more restricted variation ($\delta^{11}B = 25 \pm 15‰$) has been observed for the Allende CV3 meteorite. Chaussidon and Robert (1995) suggested that these variations in boron isotope composition reflect synthesis of boron in the presolar cloud via spallation processes involving nebular hydrogen and cosmic rays. These isotopic heterogeneities are at least partly preserved in chondrules that formed at early stages in the evolution of the solar system. Cosmic ray spallation can explain the greater abundance of the heavy isotope of boron, as for lithium.

Menard et al. (2013) estimated a primitive mantle B concentration of 0.26 ± 0.04 ppm, based on analyses of peridotite xenoliths from Mongolia and Russia and fresh lavas from the active volcano of Piton de la Fournaise, Réunion Island. Mid-ocean ridge basalts contain 0.5 to 1.3 ppm of boron, as determined by ion microprobe (Chaussidon and Jambon 1994), and upper continental crust contains an average boron concentration of 17 ppm (Rudnick and Gao 2005).

In seawater, with pH of ~8, boron occurs as trigonal boric acid H_3BO_3 (≈90%) and tetrahedral borate ion $B(OH)_4^-$ (≈10%; relative abundance of these species is from Hemming and Hanson 1992). Average seawater abundance is 4.5 ppm; consequently it is the 11th most abundant element (Brown et al. Open University 1989) dissolved in seawater (O_2 gas excluded), showing conservative vertical profiles and similar contents in Earth's oceans. Its abundance and homogenous distribution in seawater is also related to its long residence time of about 10 to 14 My calculated by Broecker and Peng (1982), Lemarchand et al. (2000), and Simon et al. (2006). Spivack and Edmond (1987) suggested a longer residence time of 20 My, based on the ratio of the total amount of dissolved boron in the oceans and the global average river input, and assuming that the boron cycle is at steady state.

River water contains low concentrations of dissolved boron, ranging from 1 to 200 ppb, with an average value of 10.2 ppb. Global variations in the B concentrations of lake waters are very large and, not surprisingly, the concentrations are higher in more saline lakes. For example, boron concentrations of Dead Sea surface waters range from 38 to 44 ppm (Vengosh et al. 1991), whereas in fresher lakes in Australia, boron concentrations range from 0.3 to 17 ppm (Vengosh et al. 1991).

Minerals and Ores

Several silicate minerals contain abundant tetrahedral boron (e.g., danburite, $CaB_2Si_2O_8$; datolite, $CaBSiO_4(OH)$) or trigonal boron (grandidierite, $(Mg,Fe)Al_3BSiO_9$), each of these phases occurring as an accessory mineral in metamorphic rocks. Tourmaline (rhombohedral), by far the most abundant borosilicate, has the generalized formula of $(X)(Y_3)(Z_6)T_6O_{18}(BO_3)_3V_3W$ (Hawthorne 1996).

However, the most common sources of boron are boron salts (borax, kernite or rasorite, ulexite, and colemanite) deposited during the evaporation of water bodies (e.g., saline lakes) in a volcanic context (Fig. 2). The most important mines are in Turkey (Mustafakemalpascha Mine, West-Anatolia), California (city of Boron, Kern County; Rio Tinto Boron Mine, Fig. 3), Chile (Atacama Desert), Argentina (Tincalayu, Sijes, and Porvenir), Russia (Dalnegorsk), Tibet, and Italy (Siena Province). In these occurrences, the primary B-rich minerals are kernite or rasorite ($Na_2B_4O_7.4H_2O$), borax ($Na_2[B_4O_5(OH)_4].8H_2O$), ulexite ($NaCaB_5O_6(OH)_6.5H_2O$),

Boron, Fig. 2 Borax crystals

Boron, Fig. 3 Rio Tinto Boron Mine (35°02'34.63"N – 117°40'21.19"0), city of Boron, Kern County, California, USA. GoogleEarth® satellite view (15 km above sea level)

and colemanite ($Ca_2B_6O_{11}.5H_2O$). Italy was the first country exploiting boron ores, as early as 1830, and the present-day annual world production is about one million tons of B_2O_3 (source: USGS).

Geochemical Behavior

Birth of oceanic lithosphere and its recycling in subduction zones constitute two important geological processes responsible for chemical and heat exchange between Earth's mantle and oceanic crust. In subduction zones, the creation of volcanic island arcs constitutes an opportunity to identify and quantify the respective amounts of fluids and solids that exchange between the mantle wedge and the subducted slab. Island-arc magmas are commonly interpreted as resulting from the partial melting of the mantle wedge metasomatized by liquids (aqueous fluids, silicate melts) or solids (sediments, altered oceanic basalts) derived from the subducted lithospheric plate. Those "contaminants" are also considered to play a significant role in generating the geochemical "signatures" of arc magmas (Gill 1981). As emphasized by Straub and Layne (2002) and Rosner et al. (2003), boron is a highly mobile element toward the aqueous phase along with an incompatible behavior during processes of partial melting. Moreover, boron is highly concentrated in oceanic sediments and hydrothermally altered oceanic crust compared to fresh rocks derived from upper mantle melting. Consequently, boron can be considered as a key tracer of slab contribution to island-arc volcanic rocks (Morris et al. 1990; Ryan and Langmuir 1993; Leeman and Sisson 1996; Bebout et al. 1999). Moreover, the hydrothermally altered oceanic crust and the subducted sediments constitute two geochemical reservoirs of highly contrasted boron isotope compositions.

The main dissolved boron species in waters are the neutral trigonal boric acid and the tetrahedral borate anion (Culberson and Pytkowicz 1967; Felmy and Weare 1986). Boric acid acts as an electron acceptor in aqueous solution, accepting a hydroxide ion from water to form $B(OH)_4^-$. The molar proportions of the dissolved boron species are strongly dependent upon pH. At pH above 7, boric acid is the dominant species whereas borate ions prevail under acidic conditions. The two boron species coexist in most natural surface waters. High concentrations in solutions (>0.1 M of boric acid), and at slightly acidic (pH = 6) to alkaline (pH = 11) pH, can lead to the formation of polymeric species such as $B_3O_3(OH)_4^-$, $B_5O_6(OH)_4$, $B_3O_3(OH)_5^{2-}$, and $B_4O_5(OH)_4^{2-}$ (Choi and Chen 1979).

Boron has a strong affinity with water because its salts have high-solubility products. The temperature dependence of the solubility product (K_{sp}) of minerals, based on experiments, can be expressed by the following equation:

$$\ln K_{sp} = (-\Delta H^o/R).(1/T) + \Delta S^o/R \quad (2)$$

where ΔH^o and ΔS^o are the standard enthalpy and entropy of the chemical reaction, T the temperature, and R the gas constant. In the case of boron salts such as borax, its dissociation in water is expressed as follows:

$$Na_2B_4O_5(OH)_4.8H_2O \Leftrightarrow B_4O_5(OH)_4^{2-} + 2Na^+ + 8H_2O \quad (3)$$

According to the mass action law, the corresponding solubility product of borax is:

$$K_{sp} = [Na^+]^2.\left[B_4O_5(OH)_4^{2-}\right] \quad (4)$$

Its temperature dependence has been determined experimentally as follows:

$$\ln K_{sp} = -16.10^3/T + 47.7 \quad (5)$$

For example, at the mean temperature at Earth's surface, near 15 °C, the K_{sp} of borax is $10^{-3.43}$.

In the oceans, borate ions are absorbed by clays, explaining the high concentrations of B in shales deposited on the seafloor. At seafloor spreading centers, seawater interacts with oceanic crust at temperatures ranging from a few tens of degrees to 450 °C. At temperatures >350 °C, boron is leached from basalts and gabbros whereas at temperatures <150 °C, boron is trapped within clays such as smectites (Seyfried et al. 1984). The net flux of boron from the oceanic crust to the oceans was estimated at $2.3.10^{14}$ kg B.year^{-1} (Simon et al. 2006).

In contrast with the low boron concentrations in river water (mean concentration of 10 ppb), high concentrations of dissolved boron have been documented in some hydrothermal waters linked to active volcanoes. Hot spring waters in Japan have boron contents ranging from 0.35 to 200 ppm (Musashi et al. 1991) while they vary within a more narrow range (0.4 to 9 ppm) in Iceland (Aggarwal et al. 2000). Geysers from Yellowstone National Park, Wyoming, USA, have boron concentrations of 35 to 730 ppb (Gemery-Hill et al. 2007).

Boron compounds are released to water in municipal sewage from perborates in detergents and in wastewaters from coal-burning power plants, copper smelters, and industries using boron (e.g., metallurgy). Borate levels from 1 to 10 ppm, far higher than the natural background of a few ppb, have been measured in runoff waters from areas where boron-rich fertilizers or herbicides are used (e.g., Butterwick et al. 1989). Xiao et al. (2013) reviewed the potential use of boron isotopes to track pollution of surface and groundwaters. Sodium perborate is the main source of water pollution resulting from human activity, and it is synthesized by

decomposition of sodium tetraborate decahydrate (a type of borax) by the following reaction:

$$Na_2B_4O_7.10H_2O + 2NaOH + H_2O + 4H_2O_2 \rightarrow 4(NaBO_3.4H_2O) \quad (6)$$

Biological Utilization and Toxicity

The highest naturally occurring concentrations of boron are observed in soils developed from marine evaporites and clays. It is very difficult to remove boron from soils except by leaching with huge amounts of boron-free water.

As early as 1910, boron was recognized as an essential element in the functioning of the higher plants (Agulhon 1910; Warington 1923). Boron is a micronutrient required for the growth and development of vascular plants, marine algae, diatoms, and cyanobacteria (Dembitsky et al. 2002). Boron as H_3BO_3 is absorbed by plant roots from soil water, then stored in roots, stalks, and cell walls of many plants. Boron also plays a key role in maintaining the structural integrity of plasma plant cell membranes (Hu and Brown 1997). Boron deficiency in soils is responsible for a yellowing of plant leaves. Plants contain from a few ppb and up to 400 ppb, the highest concentrations corresponding to aquatic plants. Plants are able to adapt, through genetic responses, to high concentrations of boron in soils.

Boron is generally not considered poisonous to animals; however, exposure to high levels of boron in diets could negatively affect general metabolism or even can be lethal. For example, Sisk et al. (1988) reported that goats that ingested 3.6 g of boron fertilizer per kg of body weight developed diarrhea, weakness, ataxia, and signs of depression and died, usually within a few hours. Human exposure to boron, typically as borates or boric acid, can occur through ingestion of food and water, or through use of pesticides containing boron compounds (and inhalation of boron-containing powders or dusts), or by use of boron-rich cosmetics, or medical preparations. The primary health effects associated with inhalation exposure of humans to boron are acute respiratory inflammation. Human beings ingest about 2 mg of add a blank boron per day, largely in fruits, green vegetables, nuts, beans, and drinking water. Boron does not accumulate in soft tissues but in bones where it assists in maintaining healthy bones, thus a boron deficiency can contribute to the development of arthritis. Boron has been also recognized as useful to healthy brain functions such as memory and hand-eye coordination. In excess, boric acids and borates are toxic for most living organisms. Poisoning of human beings may result either by accidental ingestion or an excessive use of boric acid ointment for the treatment of burns (Pfeiffer et al. 1945). Normal levels of boron in soft tissues, urine, and blood generally range from less than 0.05 ppm to no more than 10 ppm. In cases of boron poisoning of human beings, the concentration of boric acid in brain and liver tissues has been measured at as high as 2,000 ppm (Moseman 1994).

Summary

Boron compounds such as borax have been known and used by humans of different cultures for several thousand years. In early times, the uses of borax were diverse, in the decoration of potteries, the cleaning of precious metals such as gold, or even medical prescriptions for the treatment of eye diseases. The most important modern use of boron is in the production of borosilicate glasses used as thermal shock-resistant containers as well as the manufacturing of high-quality optical glasses for telescopes. Boron also forms hard alloys (BC and BN) with nitrogen and carbon. In nuclear power plants, the light stable isotope of boron (^{10}B) is employed as a neutron absorber due to its high neutron cross-section. Despite its relative low abundance in solid Earth's envelopes, the affinity of boron for aqueous solutions and the large magnitudes in isotopic fractionation that take place between minerals and fluids make it a powerful geochemical tracer. The resulting highly contrasted isotopic compositions of reservoirs that constitute its natural geochemical cycle allow the possibility of quantifying water-rock interactions. In combination with lithium, it is also useful to calculate the amounts of recycled hydrothermally altered rocks and sediments in subduction zones.

Properties

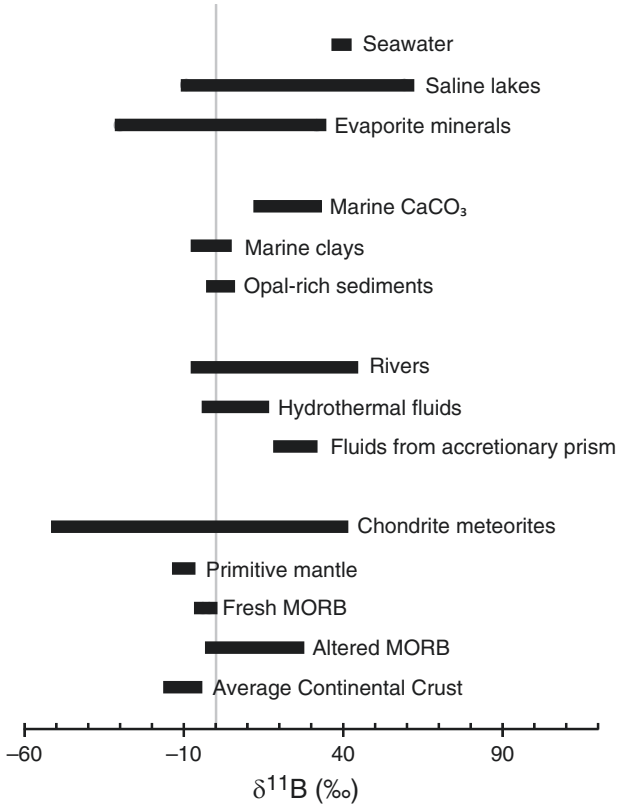
Boron, a group 13 metalloid, has two natural occurring stable isotopes, ^{11}B (11.00930536[45]) and ^{10}B (10.01293695[41]), with relative abundances of 0.199(7) and 0.801(7), respectively, and hence occurs approximately in a 4:1 ratio (source of data: National Institute of Standards and Technology, http://www.nist.gov/pml/data/comp.cfm). Numerous radioisotopes of boron also occur with masses from ^{7}B to ^{17}B, but their half-lives are all <1 s. As with other stable isotopic systems, natural isotope variation is described using delta notation, i.e., the per mil variation from the ^{11}B/^{10}B ratio of the synthetic boric acid international reference material NIST SRM-951 (atom%: ^{11}B = 80.173 ± 0.013; ^{10}B = 19.827 ± 0.013; Catanzaro et al. 1970). This can be described by the following equation:

$$\delta^{11}B = \left(\frac{{}^{11}B/{}^{10}B_{\text{sample}}}{{}^{11}B/{}^{10}B_{\text{reference}}} - 1 \right) \times 10^3 \qquad (1)$$

In natural systems, boron is almost exclusively found bound to oxygen in either tetrahedral (e.g., borate ion, $B(OH)_4^-$) or trigonal complexes (e.g., boric acid, $B(OH)_3$). Natural fractionation of the two isotopes is governed principally by their distribution between such complexes, with a tendency for ^{11}B to be incorporated preferentially in the stronger bonded trigonal molecules (e.g., boric acid in seawater). Boron is very soluble and hence fluid mobile and exhibits a dynamic speciation at low temperature. These features, coupled with its relatively light mass (10.806–10.821) and the large mass difference between its isotopes (~10%), combine to cause a very wide range in natural isotopic compositions (from −50 ‰ to +60 ‰; Barth 1993; Fig. 1).

History and Use

F.W. Aston made the first determinations of the isotopic composition of naturally occurring boron in 1920 using what was then known as a "positive ray spectrograph" and what is now known as mass spectrometry (Aston 1920). Due to its utility in tracing low-temperature geochemical processes, relative to other nongaseous stable isotope systems (e.g., Li, Ca, Cu, Co, etc.), boron isotope research in the Earth sciences has a relatively long history with the first measurement of natural materials in the early 1960s (e.g., McMullen et al. 1961). Like many isotopic systems, technological developments have led the expansion in the use of boron isotopes as a geochemical tracer with significant growth in the 1980s with the improvement and development of thermal ionization techniques (e.g., Zeininger and Heumann 1983), and a more recent expansion with plasma-based analytical methods in the 2000s for both bulk and in situ measurements (e.g., Lécuyer et al. 2002; Foster 2008; Fietzke et al. 2010).



Boron Stable Isotopes, Fig. 1 Boron isotopic composition of some terrestrial and extraterrestrial materials (Sources are either as in text or from Barth 1993)

Geochemical and Isotopic Behavior

Figure 1 shows the large range (>100 ‰) of δ^{11}B observed in terrestrial and extraterrestrial materials. The building blocks of the terrestrial planets, the carbonaceous chondrites, have a relatively low boron concentration (~0.8 μg/g; Lodders

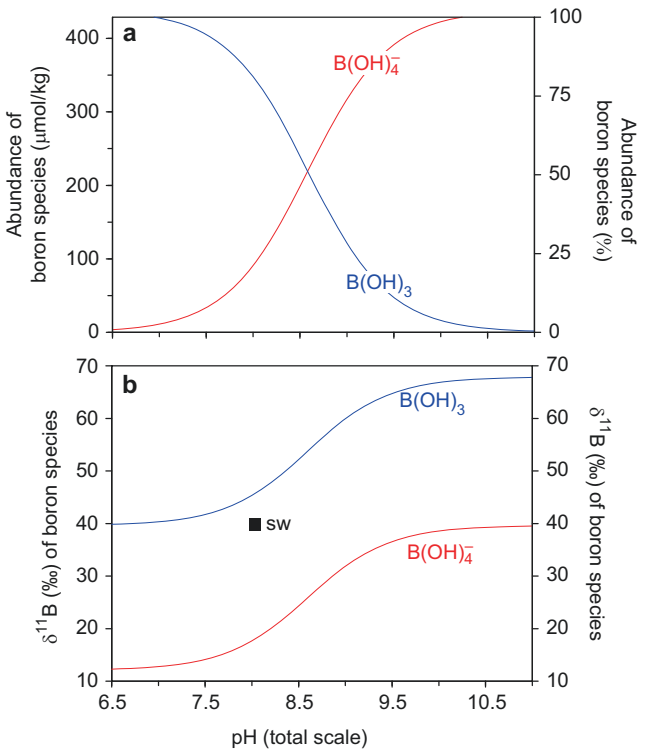
2010), and chondrules exhibit an isotopic variation that spans nearly the entire range of observed values in terrestrial materials (from −50 ± 10 ‰ to +40 ± 10 ‰; Fig. 1; Chaussidon 1995), while more restricted variations ($\delta^{11}B$ = +25 ± 15 ‰) have been observed in the Allende CV3 meteorite. This is thought to be the result of the synthesis of B via spallation processes involving nebular hydrogen and cosmic rays (Chaussidon and Robert 1995). This process also offers an explanation of why ^{11}B is more abundant than ^{10}B, in a similar fashion to lithium.

In contrast to the chondrites, the boron content of the Earth's mantle is relatively low (~0.3 μg/g; Menard et al. 2013), and its isotopic composition is ≈−10 ‰ (Chaussidon and Marty 1995). Unaltered (i.e., fresh) mid-ocean ridge basalts (MORB) have ~1 μg/g B with a $\delta^{11}B$ in the range −10 to −2 ‰ (e.g., Spivak and Edmond 1987). Alteration through reaction with seawater increases their B content (up to 120 μg/g) and drives the $\delta^{11}B$ up (−2 to +26 ‰; Smith et al. 1995). The mean $\delta^{11}B$ of the continental crust is hard to define but is most likely in the range −15 to −5 ‰ (Ishikawa and Nakamura 1993). Tourmaline is the most common boron-bearing mineral (borosilicate) in the continental crust and has $\delta^{11}B$ values ranging from −30 ‰ to +37 ‰ reflecting the nature of the fluids and rock types it is associated with (Marschall and Jiang 2011). The isotopic composition of the common ores of boron (hydrated sodium and calcium borates such as borax, kernite or rasorite, ulexite, and colemanite) depends on the nature of their parent fluid. Borates from marine evaporite deposits have $\delta^{11}B$ values that range from +18 ‰ to +32 ‰, in average much higher than those measured in nonmarine evaporation borates (−30 ‰ $< \delta^{11}B <$ +12 ‰), thus reflecting their highly isotopically contrasted source reservoirs, which are seawater (today $\delta^{11}B$ = +39.6 ‰; Foster et al. 2010) and the continental crust ($\delta^{11}B \approx$ −15 to −5 ‰), respectively.

The isotopic composition of boron is also fractionated in the terrestrial weathering environment with ^{10}B preferentially retained in secondary clays (Schmitt et al. 2012). As a consequence, river water has low boron concentrations (1 to <40 ng/g) and has a $\delta^{11}B$ (−6 to +43 ‰) that is typically heavier than average continental crust (Lemarchand et al. 2002). The flux-weighted mean $\delta^{11}B$ of riverine boron supply to the oceans is +10 ‰ (Lemarchand et al. 2002). Freshwater lakes have variable boron contents (0.3 to 44 μg/g) and also exhibit a wide range in $\delta^{11}B$ from −4.4 to +59 ‰ (Vengosh et al. 1991). Additional fractionations can occur in the terrestrial realm through the uptake and fractionation of boron in plants (Xu et al. 2015).

Boron has a long residence time in the oceans (10–20 million years; Simon et al. 2006) and is both uniform in concentration (4.5 μg/g; Lee et al. 2010) and isotopic composition ($\delta^{11}B$ = 39.61 ‰; Foster et al. 2010). Boron is also supplied to the ocean via hydrothermal fluids with $\delta^{11}B$ = −2.5 to +14.5 ‰ and fluids expelled from accretionary prisms (+25 ± 5 ‰; Smith et al. 1995). Since the boron isotopic composition of the ocean is significantly heavier than these inputs (Fig. 1), other processes must operate that preferentially remove ^{10}B to isotopically enrich the remaining boron. Three major sinks have been recognized: (1) the alteration of oceanic crust (see above; Smith et al. 1995), (2) the adsorption of boron onto clays such that marine clays have $\delta^{11}B$ = −6 to +2.8 ‰ (Ishikawa and Nakamura 1993), and (3) coprecipitation of boron in calcium carbonate and biogenic silica (Fig. 1; Ishikawa and Nakamura 1993).

The magnitude of fractionation via adsorption to clays and coprecipitation with calcium carbonate is a well-described function of pH (Palmer et al. 1987; Zeebe and Wolf-Gladrow 2001). This pH sensitivity arises because of the pH dependency of speciation of aqueous boron species: at low pH, trigonal boric acid ($B(OH)_3$) dominates, and at high pH, boron is predominantly in the tetrahedral borate ion ($B(OH)_4^-$) complex (Fig. 2). Due to the structural differences between the two aqueous forms of boron found in seawater, there is a large isotopic fractionation between them, with ^{11}B preferentially incorporated into boric acid. The isotopic exchange between these species can be described by the reaction:



Boron Stable Isotopes, Fig. 2 The variation of concentration (**a**) and isotopic composition (**b**) of borate ion ($B(OH)_4^-$) and boric acid ($B(OH)_3$) with changing seawater pH (total scale) at typical surface ocean conditions (T = 25 °C, S = 35 psu). Also shown in (**b**) is the $\delta^{11}B$ of total boron in seawater (39.61 ‰; Foster et al. 2010)

$$^{10}B(OH)_3 + {}^{11}B(OH)_4^- \Leftrightarrow {}^{11}B(OH)_3 + {}^{10}B(OH)_4^-, \quad (2)$$

with the isotopic fractionation, α_B (also written $^{11-10}K_B$ and α_{B4-3}), given as:

$$\alpha_B = \frac{{}^{11}_{10}R_{B(OH)_3}}{{}^{11}_{10}R_{B(OH)_4^-}}, \quad (3)$$

where $^{11/10}R$ is the $^{11}B/^{10}B$ ratio of each dissolved species. At any given pH, the sum of total boron in seawater and its $\delta^{11}B$ can be described by the following reaction:

$${}^{11}_{10}R_{B_{sw}} \times [B]_{sw} \Leftrightarrow {}^{1110}R_{B(OH)_3} \times [B(OH)_3] + {}^{11}_{10}R_{B(OH)_4^-} \times [B(OH)_4^-]. \quad (4)$$

It follows therefore that as the abundance of each species changes with pH so does their isotopic composition (Fig. 2). There have been numerous attempts to define α_B, and recent direct measurements place its value in seawater at 1.0272 ± 0.0006 to 1.0260 ± 0.0010 at 25 °C (Klochko et al. 2006; Nir et al. 2015). At present, the temperature sensitivity of α_B is uncertain, but it is likely to be small (Rae et al. 2011). It has been experimentally determined and observed through isotopic measurements of natural materials that both boron absorbed to clays (e.g., Palmer et al. 1987) and boron coprecipitated with $CaCO_3$ are isotopically lighter than seawater (Sanyal et al. 2000; Fig. 1). This arises due to the preferential absorption of the charged and isotopically light borate ion species to clay particles in seawater and to the growing surfaces of $CaCO_3$. The latter behavior forms the basis of the boron isotope pH proxy (see below and Foster and Rae 2016).

Applications to Geochemical Studies

Boron Isotopes as a Tracer of Human Activities

Xiao et al. (2013) reviewed the potential use of boron isotopes to track pollution of surface and groundwaters. Sodium perborate is the main source of boron pollution in water resulting from human activity. The synthesis of sodium perborate operates through the decomposition of sodium tetraborate decahydrate (a kind of borax) as follows:

$$Na_2B_4O_7.10H_2O + 2NaOH + H_2O + 4H_2O_2 \rightarrow 4(NaBO_3.4H_2O) \quad (5)$$

As this chemical reaction does not involve any boron isotope fractionation (e.g., Barth 1998), the product of this reaction preserves the isotopic composition of its source, making it possible to track boron pollution in natural waters under the condition that reservoirs involved have distinct $\delta^{11}B$ values.

Warner et al. (2014) also recently proposed the use of boron isotopes to trace contamination of groundwater and rivers by hydraulic fracturing fluids (HFF) from oil and gas operations. Distinct boron isotopic fingerprints for HFF relate to either the process of hydraulic fracking liberating the light isotope from clay surfaces, boron associated with the liberated hydrocarbons or trapped brine, and/or from chemical additives to the fluid.

Phase Partitioning

Fractionation of Boron Isotopes Between Mineral and Fluid: The Case of Tourmaline

Boron isotopes are valuable to track processes of mass transfer between Earth's surficial and rock reservoirs. Both the solubility of most boron-bearing minerals and the incompatible behavior of this element during magmatic processes enable its isotopic composition to fingerprint dehydration and water-rock interaction during lithospheric subduction, metamorphic reactions, and magmatic activity along with associated hydrothermal circulations. Tourmaline is a mineral of predominant interest as it is stable over a wide range of pressure and temperature. The fractionation of boron in tourmaline relative to the aqueous fluids in which it forms was first identified to be temperature dependent by Palmer et al. (1992) and more recently defined as $\Delta^{11}B(\text{tourmaline-aqueous fluid}) = -4.20(10^3.T^{-1}) + 3.52$, by Meyer et al. (2008), with no dependence on pressure (at least between 200 and 500 MPa). These experimentally determined tourmaline-fluid isotope fractionation factors are employed, for example, to quantify the evolution of fluids involved in the genesis of large ore deposits (e.g., Bast et al. 2014).

Fractionation of Boron Isotopes Between $CaCO_3$ and Seawater: The $\delta^{11}B$-pH Proxy

The pH of the ocean, like its CO_2 content, is determined by the ratio of total alkalinity (the charge balance, TA) to the sum of dissolved inorganic carbon species (DIC): as the CO_2 content of the water increases, its pH decreases. Reconstructions of ocean pH in the past therefore offer the ability to trace the CO_2 content of the oceans through time. This is useful because (i) the partitioning of CO_2 between the ocean and the atmosphere is thought to govern atmospheric CO_2 change on glacial-interglacial timescales, and (ii) on a global-scale, the CO_2 content of the oceans determines the CO_2 content of the atmosphere, thereby allowing pH reconstructions to constrain the CO_2 content of the ancient atmosphere (e.g., Martínez-Botí et al. 2015).

The boron isotopic composition of marine $CaCO_3$ is well-defined proxy of ocean pH because it is predominantly the borate ion that is incorporated into the growing $CaCO_3$ (Hemming and Hanson 1992) resulting in the $\delta^{11}B$ of $CaCO_3$ ($\delta^{11}B_c$) varying as a strong function of pH (at pH = 8.2, +0.1 pH units = +1 ‰ $\delta^{11}B$), as defined by Zeebe and Wolf-Gladrow (2001):

$$\mathrm{pH} = \mathrm{p}K_B^* - \log\left(-\frac{\delta^{11}B_{sw} - \delta^{11}B_c}{\delta^{11}B_{sw} - \alpha_B\delta^{11}B_c - \varepsilon_B}\right). \quad (6)$$

where $\delta^{11}B_{sw}$ is the boron isotopic composition of seawater, α_B is defined above and $\varepsilon_B = (\alpha_B - 1) * 1000$. pK_B^* is the dissociation constant of boron in seawater which is a function of temperature, pressure, and salinity.

Although biogenic marine $CaCO_3$ largely conforms to this simple inorganic model a number of complications arise. For instance, life processes in some, but not all (e.g., Rae et al. 2011), $CaCO_3$ secreting organisms modify either the pH around themselves or internally in the calcifying space (e.g., coral; McCulloch et al. 2012), such that $\delta^{11}B$ of the marine carbonate is offset from the $\delta^{11}B$ of borate ion ($\delta^{11}B_{borate}$). The existence of such "vital effects" therefore requires species-specific calibrations to account for the $\delta^{11}B_c \neq \delta^{11}B_{borate}$ and allow pH to be reconstructed (e.g., Henehan et al. 2013).

Despite these limitations, $\delta^{11}B$ in carbonates can reconstruct past pH with a typical accuracy of around ±0.02 pH units, and under favorable conditions, this translates into reconstructions of ancient atmospheric CO_2 with an uncertainty of ±20 ppm (Foster 2008).

Tracing the Recycling of Subducted Oceanic Crust

Island-arc magmas are commonly interpreted as resulting from the partial melting of the mantle wedge metasomatized by liquids (aqueous fluids, silicate melts) or solids (sediments, altered oceanic basalts) derived from the subducted lithospheric plate. Those "contaminants" are also considered to play a significant role in generating the geochemical "signatures" of arc magmas. As emphasized by Rosner et al. (2003), boron is a highly mobile element in the aqueous phase with an incompatible behavior during processes of partial melting. Moreover, boron is highly concentrated in oceanic sediments and hydrothermally altered oceanic crust compared to fresh rocks derived from upper mantle melting. Consequently, boron can be considered as a key tracer of slab contribution to island-arc volcanic rocks. Moreover, the hydrothermally altered oceanic crust and the subducted sediments constitute two geochemical reservoirs of highly contrasted boron isotope compositions. As a result, $\delta^{11}B$ values of volcanic arc rocks reflect their relative contributions during their petrogenesis, albeit modified by fractionation that occurs during dehydration of the subducted slab (Leeman et al. 2004).

Summary

The stable isotopes of boron exhibit a very wide range in natural and extraterrestrial materials. This is virtue of their light mass, large mass difference between ^{11}B and ^{10}B, and the geochemical behavior of B itself. As a consequence, however, the boron isotope system has great utility in the Earth sciences, and the use of boron to trace low-temperature geochemical and extraterrestrial processes has a long history and is continuing to grow.

Element Data
Atomic Symbol: Br
Atomic Number: 35
Atomic Weight: 79.901–79.907
Stable Isotopes: ^{79}Br: 50.5–50.8%
^{81}Br: 49.2–49.5%
1 Atm Melting Point: 266 K
1 Atm Boiling Point: 332.7 K
1 Atm of Nebular Condensation[a]: 546 K
Valence State: $4s^2p^5$
Common Valences: −1, 0, +1, +3, +5
Common Ions: Br^-, BrO^-, BrO_3^-, BrO_4^-
Ionic Radius[a]: 196 pm
Pauling Electronegativity: 2.96
First Ionization Potential: 1139.9 kJ/mol
Chondritic (CI) Abundance [b]: 3.26 ppm
Silicate Earth Abundance [cb]: 50–75 ppb
Crustal Abundance[d]: 0.88 ppm
Oceanic Crust[e]: 0.17 ppm
Depleted Mantle[e]: 0.02 ppm
Seawater Abundance[f]: ~67 ppm
Evaporites[g]: 151 ppm
Sediments + Pore Water[h]: 97 ppm
Troposphere[i]: 0.016 ppbv
Core Abundance[j]: ~0.7 ppm

Properties

Bromine is the third halogen element located in the group XVII of the periodic table with an electronic configuration of [Ar] $3d^{10}$ $4s^2$ $4p^5$. It has 35 protons and has two stable isotopes. Bromine is a minor component on Earth, mostly concentrated in the hydrosphere (oceans). There is an increasing interest in geochemistry to study Br because of its high volatility during volcanic eruptions, as Br contributes to the destruction of the stratospheric ozone. It is also considered as an excellent tracer of geochemical processes such as recycling processes in subduction zones.

History and Use

The etymology of Br derives from the Greek "bromos" meaning stench due to a pungent, irritating odor. Bromine was discovered in 1826, simultaneously by Antoine-Jérôme Balard in Montpellier, France, and by Carl Löwig in Heidelberg, Germany, thought it was used during antiquity as the main ingredient of the Tyrian purple famous pigment derived from snails' secretions.

Bromine does not occur as a free element in nature; it is naturally concentrated in bromide salts present in evaporites and ore deposits, in seawater, and therefore easily workable for human uses. Traces of Br are also found in crustal and mantle rocks. Gaseous Br species such as bromoform organobromides and other Br-radicals are present as traces in the atmosphere and stratosphere.

Bromine compounds are commonly used in agricultural chemicals, in pesticides, in chemical intermediates such as disinfectants for swimming pools. Silver bromide AgBr is a chemical used in film photography. Bromine compounds are also used in lamps, dyestuffs, and cosmetics. Halons are flame-retardants in fire extinguishers, and they are added to furniture foam, plastic casings for electronics, and textiles to make them less flammable.

Isotopes

Bromine has two stable isotopes (^{79}Br, ^{81}Br), both having similar abundances. Variations in Br isotope data are reported in the standard delta notation:

$$\delta^{81}\mathrm{Br} = \frac{\left(\frac{^{81}\mathrm{Br}}{^{79}\mathrm{Br}}\right)\mathrm{sample} - \left(\frac{^{81}\mathrm{Br}}{^{79}\mathrm{Br}}\right)\mathrm{standard}}{\left(\frac{^{81}\mathrm{Br}}{^{79}\mathrm{Br}}\right)\mathrm{standard}} * 1000$$

The composition of the ocean water is used as the reference and defined as SMOB for Standard Mean Ocean Bromine analog to SMOC for chlorine. Bromine isotopes have not yet been intensely investigated because of technical difficulties (Eggenkamp 2014). Bromine isotope signatures allow for predicting the equilibrium fractionation between different oxidation states of Br oxyanions. Up to now they have been measured to study seawater, pore fluids, brines, and evaporates.

Mineralogy and Geochemistry

All halogen elements are characterized by the s^2p^5 outer shell configuration, with one missing electron in the last electron shell.

Elemental Br can be produced as a liquid or gaseous diatomic molecule Br_2. It commonly occurs as aqueous monovalent ions or salts, such as NaBr and AgBr in which the bromine atom has a −1 charge and oxidation number. They have the same face-centered cubic crystalline structure than NaCl. Bromine is always found associated with chlorine or iodine. Bromine forms numerous interesting covalent compounds as well, including two oxides: BrO_2 and Br_2O. Due to a large ionic radius, Br is incorporated in rock-forming minerals as traces.

Geochemistry of Bromine in Terrestrial Reservoirs

From a geochemical point of view, Br is classified as a lithophile element (McDonough and Sun 1995); it is considered as volatile with a nebular condensation temperature of 546 K (Lodders 2003). Br exhibits a similar geochemical behavior than Cl and I in most igneous processes, and differs from fluorine (strongly lithophile). Bromine is depleted compared to chondritic material in the bulk silicate Earth such as Cl and I (McDonough and Sun 1995). Halogen abundances decrease with respect to their size F<Cl<Br<I; Br natural abundances are low, ranging from ppb to several ppm, depending on the contexts.

Quantifying the distribution of Br in the deep Earth's major reservoirs is still difficult today due to the challenge of analyzing very low Br abundances and due to the limited access to natural deep mantle samples. Recent studies have attempted to constrain the geochemical behavior of bromine in igneous processes and bromine global cycling. The initial Br content for the Earth is still unknown, such as its origin that could be from a solar, a chondritic, or a cometary source or from a combination of the latter (Marty 2012). The bulk silicate Earth content would range from 0.05 to 0.075 ppm wt. when the CI chondrites (volatile-rich meteorites) contain 3.26 ppm wt. Br, but these calculations are based on the composition of mid ocean ridge basalts and on the assumption that Br/Cl has a constant value for the whole mantle, which may not be true.

Bromine in Upper Crust, Oceans, and Atmosphere

The chemistry of Br in the stratosphere is the object of strong attention because it is roughly 45 times more effective than chlorine for destroying ozone (Daniel et al. 1999). While the presence of Br in the atmosphere mostly results from anthropic activity (agricultural pesticides, biomass burning, automobiles, etc.), there are also natural sources such as seawater ice and seawater evaporation, cyanobacterias, phytoplankton, volcanic activity, etc. Bromine reacts with ozone and reduces its production through chain reactions as long as it is present as a reactive species (von Glasow and Crutzen 2014).

Similarly to the other halogen elements Br is strongly concentrated in Earth's differentiated crust, sediments, and hydrosphere.

Oceans are the major superficial reservoirs for Br, where marine phytoplankton and sea ice algae are the main source of bromoform and dibromomethane involved in ozone depletion. The role of organisms is determinant for Br chemistry also in terrestrial ecosystems forming organo-bromine compounds in soils (Vainikka and Hupa 2012).

Evaporites are the principal mineral sources for Br, and they are mined for Br commercial exploitation. They result from the evaporation of seawater and/or terrestrial lake waters. Although bromide salts (NaBr, KBr) are not present as individual minerals in evaporates, Br is concentrated in halite NaCl.

Bromine is significantly present in fluid inclusions from crustal minerals and is used to determine the origins of ore forming brines and to map hydrothermal processes (Leisen et al. 2012).

Bromine in Igneous Processes and in the Mantle

Bromine is found as traces in apatite, amphibole, biotite (e.g., O'Reilly and Griffin 2000; Teiber et al. 2013), in phengite, lawsonite (Pagé et al. 2016), and in serpentine-group minerals (Sumino et al. 2010; John et al. 2011; Kendrick et al. 2013).

The difficulty of measuring trace amounts of bromine in igneous samples explains that trace element geochemistry of Br in the mantle is currently poorly constrained. Halogens are thought to play a central role in the evolution of magmatic systems and associated ore deposits (e.g., Liu et al. 2014).

The magmatic abundances of Br are determined from analysis of volcanic glasses where Bromine is ranging from tens of ppb to a few ppm (Schilling et al. 1980; Jambon et al. 1995; Kendrick et al. 2012a; Kendrick et al. 2012b).

Bromine is expected to be incompatible during partial melting and differentiation. Br, Cl, and I are not strongly fractionated during partial melting or fractional crystallization and are expected to behave similarly in magmas; therefore, halogen ratios Br/Cl and Br/I provide crucial information on halogen sources, crystallization, degassing, and contamination processes (Pyle and Mather 2009; Aiuppa et al. 2009).

A few experimental studies probe Br behavior in silicate melts. The measured solubility of Br in hydrous silicate melts is similar to that of Cl and can reach a few wt.% in hydrous silicic melts (Bureau and Métrich 2003). Partitioning results show that Br concentration in silicate melts in equilibrium with aqueous vapor decreases together with pressure (Bureau et al. 2000; Bureau et al. 2010) that highlights the strong volatility of Br compared to Cl. The global volcanic bromine input to the atmosphere is very difficult to measure; estimates

would range from 5 to 15 Gg/a HBr (Pyle and Mather 2009). HBr and BrO have been measured in volcanic plumes in significant amounts (e.g., Bobrowski et al. 2003; Aiuppa et al. 2005; Kutterolf et al. 2015). Furthermore, HBr, the most common Br species released by volcanoes, reacts in plumes where it is converted into BrO, (Oppenheimer et al. 2006) meaning that volcanic vents should be regarded not only as passive providers of bromine but as "reaction vessels" (Mather 2016).

Bromine is recycled in the Earth's mantle with sediments, altered oceanic crust, and serpentinites. These last are transferred at depth where major fluid-rock interactions occur. Bromine is successively stored and released during serpentinization and deserpentization processes (John et al. 2011). It is a conservative fluid tracer. The Br content found in the arc-volcanic material may be highly influenced by the fluid release of deserpentinizing slabs as evidenced by Br/Cl, F/Cl, and I/Cl ratios that are used to understand their transfers and cycling in subduction settings (e.g., Kendrick et al. 2012b; Pagé et al. 2016). Deep Br-rich marine pore fluids are also found in exhumed peridotites, showing that Br is preserved in the down going hydrous peridotite that retained the pore fluids in a closed system up to at least 100 km (Sumino et al. 2010).

There is a real debate about potential deep recycling of Br. Is all Br subducted finally mobilized in arc magmatism (e.g., Kendrick et al. 2012b), is it retained within the subcontinental lithospheric mantle (Broadley et al. 2016), or is it cycling across the whole mantle? Experiments show that although most of the Br is mobilized by fluids escaping the down going slabs, a significant part of Br could be subducted deeper in the mantle (Bureau et al. 2010), implying that high pressure melts are ideal deep vectors and potential repositories. Indeed, Br speciation in hydrous melts at high pressure (7.6 GPa) indicates that Br anions form NaBr complexes in the hydrous melts and possibly BrOH complexes (Cochain et al. 2015).

Hydrous high pressure mineral phases may transfer bromine and other halogen in the deep mantle. The deep recycling of Br is also supported by the presence of Br-rich fluid inclusions trapped in diamonds (Johnson et al. 2000; Burgess et al. 2002).

Biological Utilization and Toxicity

In pharmacology, potassium bromide KBr is used as a sedative and can treat epilepsy. Bromine is mostly known as a toxic and corrosive reddish brown liquid/vapor. It is very reactive and poisonous, causing burns. Dibromide (Br_2) and a wide variety of organobromine compounds are used in industry. Among organobromine compounds, "halons" for haloalkanes, consisting of alkanes linked with halogens such as organobromides (i.e., bromomethane CH_3Br bromochloromethane, CH_2BrCl bromochlorodifluoromethane, CF_2ClBr, etc.), have been intensively produced, and they have a particularly harmful bad effect on the atmosphere chemistry. Therefore, organobromine is now a significant pollutant substance, and some uses are being phased out.

Summary and Conclusions

In geochemistry, determination of Br abundances combined with those of other halogen elements Cl, F, and I is extremely useful to understand how element transfer and store at depth. The geodynamical cycle of Br is linked to the cycle of water, fluids being efficient vectors for Br transport. The study of Br helps to understand hydrothermal geology, ore deposition processes, fluid–rock reactions, and subduction recycling. But today, the storage of bromine in the deep reservoirs is totally indeterminate. Further investigation would be useful to better constrain the extent of Br heterogeneity in the mantle and its cycling. Experimental studies (i.e., partitioning of Br between minerals from mantle rocks) would certainly help to determine if bromine is possibly stored at depth or not and to characterize the real bromine abundance of the Earth.

Cadmium

Monica Vasiliu and David A. Dixon
Department of Chemistry, University of Alabama, Tuscaloosa, AL, USA

Element Data
Atomic Symbol: Cd
Atomic Number: 48
Atomic Weight: 112.411
Isotopes and Abundances: ^{106}Cd 1.25%, ^{108}Cd 0.89%, ^{110}Cd 12.51%, ^{111}Cd 12.81%, ^{112}Cd 24.13%, ^{113}Cd 12.22%, ^{114}Cd 28.72%, ^{116}Cd 7.47%
1 Atm Melting Point: 594.1 K
1 Atm Boiling Point: 1038 K
Common Valences: +2, +1
Ionic Radii: (+II) 103 ppm, (+I) 114 ppm
Pauling Electronegativity: 1.69
First Ionization Energy: 867.8 kJ/mol
Chondritic (CI) Abundance: 686 ppb
Silicate Earth Abundance: 0.04 ppm
Crustal Abundance: 0.11 ppm
Seawater Abundance: 0.11 ppb
Core Abundance: 0.15 ppm

Properties

Cadmium (Emsley 1991, 2001; Anthoni 2006; Anders and Grevesse 1989; McDonough 2005) is a lustrous, silvery-white metal with a bluish tinge on the surface and tarnishes in air. It is very ductile and malleable and is soft enough to be cut with a knife. Cadmium is soluble in acids but not in alkaline solutions. In many ways, cadmium is similar to zinc but forms more complex compounds.

Cadmium was not considered to be radioactive until 1970 when, as a surprise, ^{113}Cd was shown to be an α-emitter with a very long half-life (9×10^{15} years). The consequence of this radioactivity is negligible as only one atom is lost per minute in a 10 g piece of cadmium metal.

History and Use

At the beginning of the 1800s, apothecaries made zinc oxide by heating a naturally occurring form of zinc carbonate called cadmia, also named calamine. Sometimes the resulting product was yellow instead of being pure white. And Friedrich Stromeyer of Göttingen University traced the discoloration to a component in the mineral that he could not identify. In 1817, he separated a brown oxide, purified unknown element, and named it cadmium after the mineral from which it came. Karl Meissner in Halle, and Karl Karsten in Berlin, working on the same problem, reported their discovery of cadmium 1 year later. A significant amount of research led to the conclusion that cadmium is present in all zinc ores but has no effect on the performance of zinc compounds. Cadmium was partly removed when zinc metal was smelted because cadmium is more volatile than zinc and was lost in the atmosphere.

Cadmium is a poison and is known to cause birth defects and cancers so its use is more limited. Around 80% of the cadmium that is produced is used in rechargeable Ni-Cd batteries. These batteries are slowly being phased out and replaced with nickel hydride batteries. The remainder of the cadmium is mainly used for pigments (yellow, orange, and red), coatings, and plating and as stabilizers for plastics.

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

Cadmium films about 0.05 mm thick were used to electroplate steel to protect it against corrosion. It is still used today to protect critical components of airplanes and oil platforms. Cadmium absorbs neutrons and is used in rods in nuclear reactors to control atomic fission.

Geochemical Behavior

Cadmium is naturally occurring in the Earth's crust and always occurs in combination with zinc. The only mineral containing significant quantities of cadmium is greenockite (cadmium sulfide). It is also present is small amounts in sphalerite (ZnS) in which CdS is a significant up to 3% impurity. Almost all commercially produced cadmium is obtained as a by-product of zinc, lead, or copper extractions and refining.

Naturally, a cadmium is released into the environment with half being released into rivers through weathering rocks and some released into the air by forest fires and volcanoes. The remainder of the released cadmium is from human activities including manufacturing. In some cases, cadmium is washed onto soil used to grow crops and to feed animals.

Biological Utilization and Toxicity

Cadmium is toxic, carcinogenic, and teratogenic. On average the human intake is 0.05 mg/day, but it accumulates and stays in the body for around 30 years; the human body stores about 50 mg of cadmium.

Before the dangers of cadmium were fully understood, welders and some other metal workers were at risk of becoming ill. For example, in 1966 welders working on the Severn Road Bridge in England became ill from breathing cadmium fumes.

Although it has not been proven, there are suggestions that cadmium could be essential for some species, as it can stimulate metabolism. Marine organisms absorb cadmium rapidly so that little cadmium is found in the surface layers of the oceans.

Cadmium can never be totally excluded from the diet and can be found in food like offal, shellfish, and rice. Some fungi such as the mushroom *Amanita muscaria* and other food crops (lettuce, spinach, cabbage, and turnip) have the ability to absorb cadmium. Smoking adds to the body burden because tobacco plants absorb it as well.

Caesium

Gray E. Bebout
Department of Earth and Environmental Sciences, Lehigh University, Bethlehem, PA, USA

Element Data
Atomic Symbol: **Cs**
Atomic Number: **55**
Atomic Weight: 132.90545 u
Isotopes and Abundances: ^{133}Cs, ~100%
1 Atm Melting Point: 28.5 °C
1 Atm Boiling Point: 670.8 °C
Common Valences: 1+
Ionic Radii: 12-fold: 188 pm
Pauling Electronegativity: 0.79
First Ionization Energy: 375.4 kJ/mol
Chondritic (CI) Abundance: 0.188 ppm
Silicate Earth Abundance: 7.7 ppb
Crustal Abundance: 2 ppm
Seawater Abundance: 2 nmol/kg
Core Abundance: ~0

Properties

Caesium, a reactive silvery-gold metal belonging to the group IA on the periodic table, is one of the alkali elements and considered as a "lithophile" element as defined by Goldschmidt. Caesium, atomic number 55, has a standard atomic weight of 132.90545 and an electronic configuration of [Xe]6 s^1. The lone 6 s electron is relatively easily removed; this first ionization potential of Cs is 375.4 kJ/mol. Caesium is highly ionic in character and the ionic radius of Cs^{1+} is

188 pm in 12-fold coordination. Caesium has a 1 atm melting point of 28.5 °C. Caesium has only one naturally occurring isotope, the stable ^{133}Cs. However, there are 40 known isotopes of Cs, with atomic masses of 112–151. The longest-lived radioisotope of Cs is ^{135}Cs, with a half-life of 2.3 million years. All but three of the other radioisotopes of Cs have half-lives of less than 2 weeks, many of them well under 1 h.

Caesium nearly always is bonded by electrostatic forces as Cs^{+1} with various anions and it is, in general, highly soluble in aqueous solutions, for example, during weathering and in the oceans. Caesium, with an ionic radius similar to that of K^+, tends to show geochemical behavior similar to that of K^+ and therefore in silicate rocks to occur in greatest concentrations in K-rich minerals such as illite (a clay mineral), muscovite and biotite (both micas; phengite is a Si-rich muscovite), and alkali feldspars. Concentrations of Cs in silicate minerals are ordinarily at trace levels in the ppm range, commonly lower than 100 ppm but in some rocks as high as 100 s of ppm (see, for example, the ion microprobe analyses of coexisting metamorphic minerals in Bebout et al. 2007, 2013). In the crust, it is a main constituent in nonabundant minerals such as pollucite, a tectosilicate (zeolite group mineral), and lepidolite (a Li-rich mica), both found in Li-rich pegmatites.

History and Uses

Caesium was discovered, along with Rb, by Gustav Kirchhoff and Robert Bunsen in 1860 by spectroscopic study of mineral waters. Its name derives from the Latin *caesius*, meaning sky blue, referring to the color of its emission spectrum. "Caesium" is the name adopted by the International Union of Pure and Applied Chemistry while the American Chemical Society uses "Cesium," which is also common usage in North America. Nonradioactive Cs is used in drilling fluids in the oil industry (the largest current use) and also in atomic clocks and various electronics applications.

The radioactive isotope ^{137}Cs has been used as a tracer in hydrologic studies, in applications similar to those of ^{3}H; both of these isotopes are produced largely by nuclear testing. With the initiation of nuclear testing in 1945, Cs isotopes were released into the atmosphere where it is absorbed readily into solution and is returned to the surface of the earth as a component of radioactive fallout. ^{137}Cs is a particularly dangerous fission product because of its high yield during fission, moderate half-life (30.17 years), high-energy decay pathway, and chemical reactivity. Because of these properties, ^{137}Cs is a major contributor to the total radiation released during nuclear accidents. Despite its prevalence in spent nuclear fuel and nuclear waste, ^{137}Cs is extremely rare. Its half-life is too short for it to persist from natural fission sources, and on earth it is a synthetic isotope only, presently showing decline in concentration in surface reservoirs due to the cessation of major nuclear bomb testing.

Abundances

The solar system abundance of Cs is estimated at 0.371 Atoms/10^6 Si; (Lodders et al. 2009), based on study of meteorites. The bulk Earth Cs concentration is believed to be 0.035 ppm (McDonough 2003) and Hofmann and White (1982) estimated a concentration of 7.7 ppb in the primitive mantle. Seawater contains 2 nmol/kg of Cs and shows concentrations as high as 368 nmol/kg of seawater in seafloor hydrothermal fluids (Palmer and Edmond 1989). Caesium concentration in the continental crust is estimated as being near 2 ppm, with greater amounts (4.9 ppm) concentrated in the more felsic upper continental crust (Rudnick and Gao 2014) and 2.2 and 0.3 ppm concentrations in the middle and lower continental crust, respectively. Fresh NMORB contains ~0.01 ppm and is enriched by up to ~20X during seafloor alteration (see Bebout 2014 and references therein), with Cs enrichments showing strong correlation with enrichments of K and Rb (see Bebout 2014). Seafloor sediments can contain far greater concentrations of Cs, with the GLOSS (global subducting sediment) composition containing ~3.5 ppm or about 350X the concentration in fresh NMORB (see Plank 2014).

General Behavior in Fluid/Melt-Mineral Systems

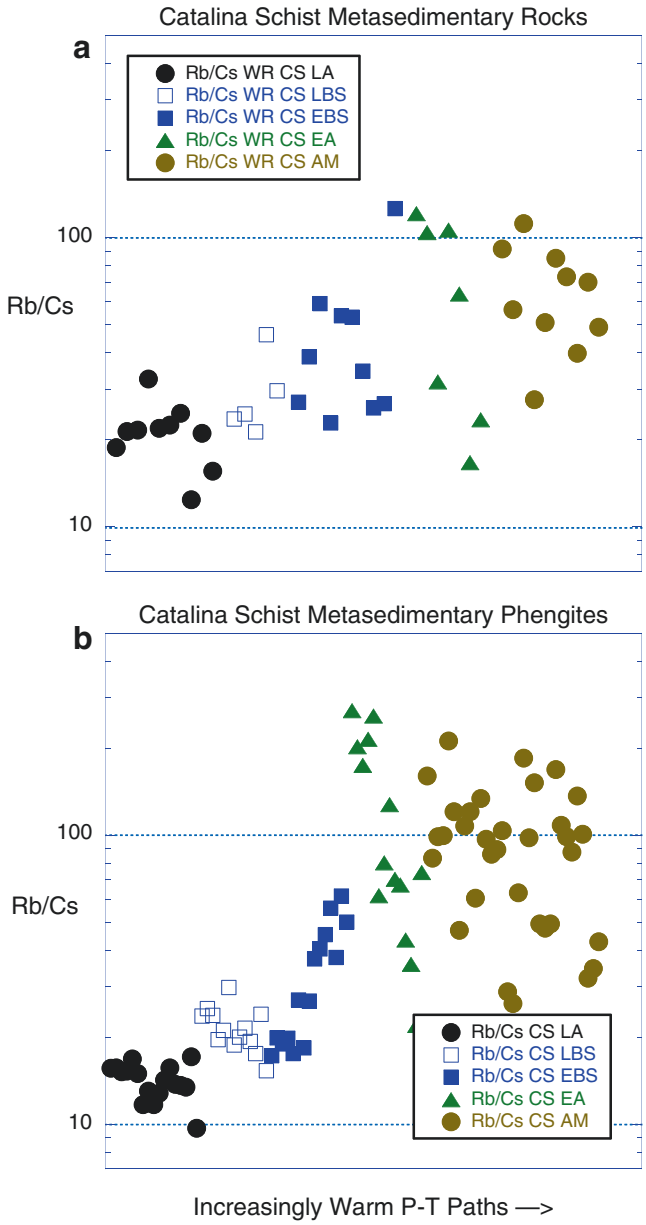
Caesium is commonly thought of as belonging to the group of large-ion lithophile elements (LILE), along with K, Rb, Sr, and Ba, and showing the most similarity in behavior with K and Rb. It shows strong incompatibility during melting in the mantle and is partitioned into basaltic melts. Its great tendency to partition into fluids and melts is reflected in its tendency to be enriched in late-stage differentiation products in more felsic igneous systems. Economically important Cs deposits are commonly in pegmatitic systems reflecting this late-stage differentiation. During metamorphism of sedimentary rocks, Cs concentrations are largely governed by reactions involving phyllosilicates capable of housing this element as highly coordinated atoms in interlayer sites. However, Cs has shown some tendency to become mobilized in H_2O-rich fluids, during devolatilization reactions, to a greater extent than other LILE and charged molecules residing in these sites (e.g., K^+, Rb^+, and NH_4^+ see Bebout et al. 1999, 2007). Although significant loss of Cs to fluids can occur during low- to medium-grade metamorphism, and during

partial melting reactions, significant fractions of the protolith Cs can be retained even during partial melting, including those that result in destabilization of its preferred mineral host, the micas. Caesium, on the average, shows somewhat greater tendency than K^+ and Rb^+ to be mobilized into aqueous fluids and depleted in devolatilizing rocks, thus whole-rock Rb/Cs and K/Cs can be strongly increased by devolatilization (see the discussion of Rb and Cs on Earth by McDonough et al. 1992; also see Rudnick and Gao 2014). In seafloor basaltic rocks, Cs concentrations are enriched along with K during hydrothermal alteration and, as for metasedimentary rocks, strongly influenced in their behavior by the abundance of potassic mineral phases, particularly the clays and micas.

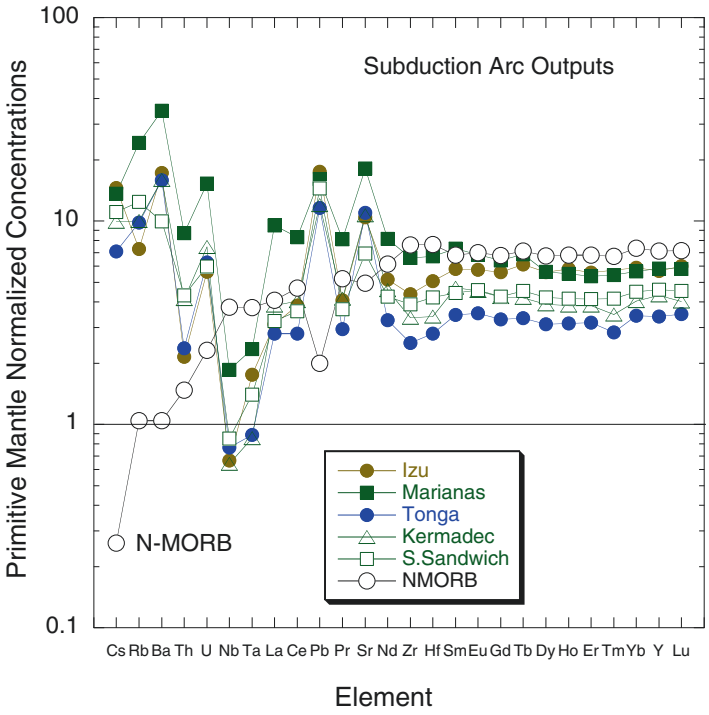
Subduction Zone Cycling of Caesium

Subduction of Cs, along with Rb^+ and NH_4^+ is strongly tied to the stability and reactions involving K-rich micas such as phengite (Si-rich muscovite). In subduction zones with typical relatively "cool" thermal structure, much of the LILE inventory in both sedimentary and basaltic rocks could be retained to depths beneath volcanic arcs (and perhaps beyond, into the deeper mantle; see Bebout et al. 2013). Figure 1 illustrates the strong dependence of Cs retention in subducted sediments on the thermal structure of the subduction zone. On this figure, whole-rock (Fig. 1a; data from Bebout et al. 1999) and phengite (Fig. 1b; data obtained using an ion microprobe; see Bebout et al. 2007) Rb/Cs are plotted against metamorphic grade in the Catalina Schist paleo-accretionary complex, exposed on Santa Catalina Island, California. From the left to the right on this diagram, rocks experienced increasingly warmer P-T paths during their subduction into this evolving paleo-margin (all at pressures of ~8–11 kb, corresponding to ~24–33 km depths). The increase in Rb/Cs, with increasing grade, is associated with loss of Cs at relatively constant Rb concentration.

Caesium enrichments in volcanic lavas are one characteristic of these rocks believed to reflect additions to mantle-wedge melting regions by aqueous fluids or silicate melts derived in subducting slabs (Elliott 2003). In Fig. 2 (from Bebout 2014), element concentrations in arc volcanic rocks and in mid-ocean ridge basalts are normalized to concentrations in the primitive Earth mantle. High- and ultrahigh-pressure metamorphic rocks, representing deeply subducted oceanic slab sections (oceanic crust and overlying sediment), contain a complementary record of Cs release, mobility during devolatilization reactions, and metasomatic enrichment in metabasaltic and metaultramafic rocks (Bebout 2014).



Caesium, Fig. 1 Ratio of Rb to Cs concentration in whole-rock samples (**a**) and phengites (siliceous white micas; **b**) in subduction-zone-metamorphosed sedimentary rocks in the Catalina Schist (from Bebout et al. 1999, 2007). From *left* to *right* on this diagram, the metamorphic units experienced increasingly higher-temperature P-T paths during prograde metamorphism in the evolving paleo-subduction zone (*LA* lawsonite-albite, *LBS* lawsonite blueschist, *EBS* epidote blueschist, *EA* epidote amphibolite, *AM* amphibolite). Bebout et al. (2007) presented Cs and Rb concentrations in all coexisting minerals in these samples, demonstrating the strong partitioning of both elements into phengite. Also showing whole-rock (and phengite) losses was (**B**), which like Cs is highly concentrated in the micas. In these rocks, Ba^{+2} also is strongly concentrated in the phengite (at considerably higher concentrations of 1000 s of ppm) but does not show evidence of loss across this range in grade



Caesium, Fig. 2 Chemical characteristics of subduction zone outputs: erupted lavas. Data are normalized to primitive mantle from Hofmann (1988). Data for arc basalt outputs are from Elliott (2003). Note the large enrichments in Cs in arc lavas, relative to mid-ocean ridge basalts, accompanied by enrichments in Rb and Ba. These enrichments are generally attributed to additions to mantle-wedge arc magma source regions by hydrous fluids or silicate melts derived in subducting slabs and overlying sediments

Caesium Behavior During Partial Melting in the Continental Crust

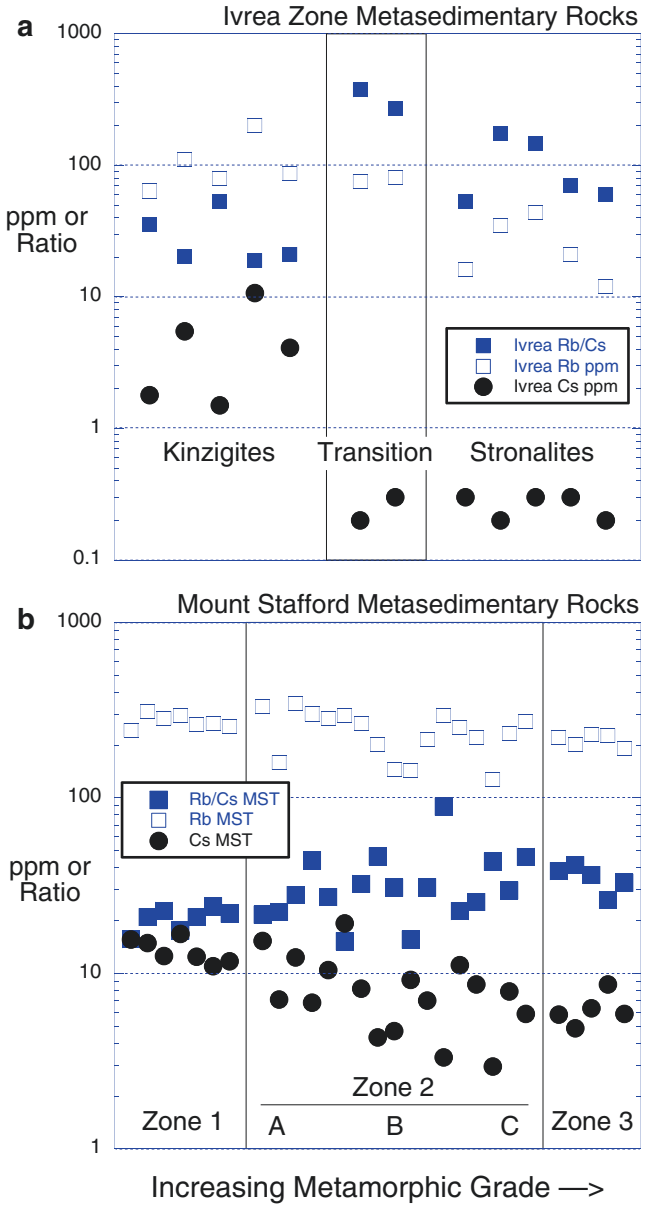
Partial melting in the continental crust shows a tendency to similarly disrupt the Rb/Cs of metasedimentary rocks, as related to the preferential loss of Cs, relative to Rb, during partial melting. Figure 3a shows the apparent effect of partial melting reactions (at pressures of 4–8 kb; corresponding to ~12–24 km depths) on Rb and Cs concentrations, and Rb/Cs, in the Ivrea Zone, Italy (data from Bea and Montero 1999). Figure 3b shows the change in the concentrations of the two elements, and Rb/Cs, as related to a series of partial melting reactions experienced at pressures of 2–4 kb (corresponding to ~6–12 depths) and now exhibited in Zones 1–3 at Mt. Stafford, Australia (from Palya et al. 2011). Rubidium shows only very modest change but Cs shows considerable loss, producing the increase in Rb/Cs. In such rocks, partial melting reactions can be driven by infiltration by H_2O-rich fluids (H_2O-saturated melting) or can involve partial or complete breakdown of hydrous mineral phases such as the micas, the latter in many cases the dominant mineral hosts for both Rb and Cs. In rocks experiencing complete mica breakdown, these elements can be partly retained in feldspars, particularly the alkali feldspars. A combination of devolatilization and partial melting, and ascent of relatively low Rb/Cs felsic magmas to shallow levels, likely contributes to the elevated Rb/Cs of middle and lower continental crust, ~30 and ~37, respectively, as compared with the Rb/Cs of upper continental crust (~17; see Rudnick and Gao 2014).

Biological Utilization and Toxicity

Caesium has no biological role, although it can to some extent replace potassium in the body because of the chemical similarity of the two elements and can be uptaken by plants affected by potassium nutrition (White and Broadley 2000; Fujiwara 2013). Ingestion of any caesium compound is in general to be avoided; however, it is unlikely that humans would be exposed to enough ^{133}Cs to experience health effects that can be related to this stable isotope. Because of the similarity in behavior of caesium with potassium, the radioactive isotopes ^{134}Cs and ^{137}Cs (present in the biosphere in small amounts as a result of radiation leaks) are very toxic. Both isotopes emit beta radiation and gamma radiation. ^{137}Cs is also used in some medical applications (e.g., brachytherapy).

Summary

Caesium, of interest to researchers in many scientific fields, shows strong similarity in behavior with potassium but also some intriguing differences in behavior compared with this



Caesium, Fig. 3 Caesium and Rb concentrations, and Rb/Cs, in whole-rock metasedimentary samples experiencing partial melting reactions at middle to deep levels of the continental crust. (**a**) Data for migmatites of the Ivrea Zone, Italy (Val Strona di Omegna), investigated by Bea and Montero (1999). (**b**) Data for metasedimentary rocks exposed at Mt. Stafford (North-Central Australia), from Palya et al. (2011). On both diagrams, metamorphic grade increases from left to right (see the labeled zones described in detail by Bea and Montero (1999), and Palya et al. 2011)

and other LILE. It is a trace element in most environments of interest to humans, but it serves as an extremely useful tracer of a large number of processes in the hydrosphere, biosphere, and lithosphere. Because of the hazards associated with radioactive ^{137}Cs, caesium receives attention in not only the scientific community but also from the medical community and more broadly in society.

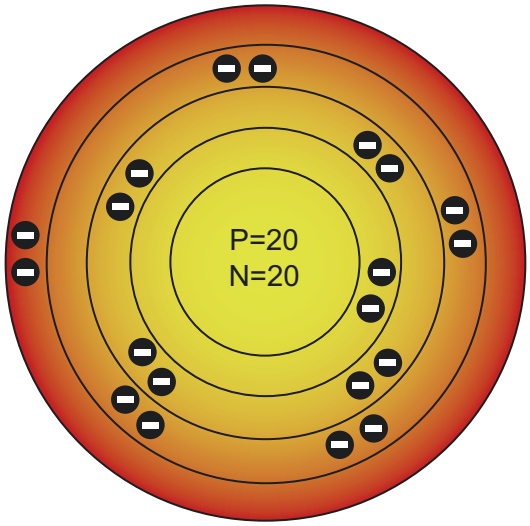
Properties

Calcium is a metal (alkaline earth) with a silvery color and a cubic crystal structure. This element belongs to group 2 and period 4 of the periodic table (Fig. 1). Calcium has 25 known isotopes of which 5 are stable (source of data: National Institute of Standards and Technology: http://www.nist.gov/pml/data/comp.cfm).



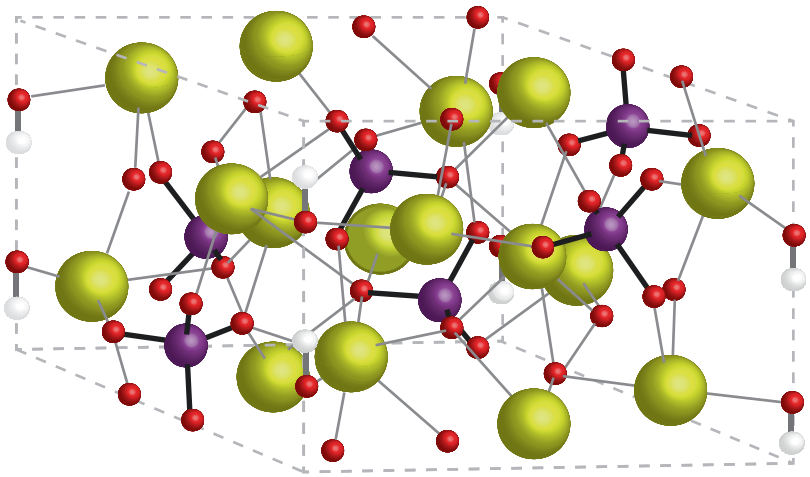
Calcium, Fig. 1 Schematic illustration of the atomic configuration of ^{40}Ca

Geochemists measure the relative variations in the ^{44}Ca/^{40}Ca of terrestrial and extraterrestrial materials that result mainly from chemical equilibrium and kinetic effects. Some of this variation also results from the β decay of ^{40}K (decay constant = 4.962×10^{-10} year^{-1}) to ^{40}Ca (Dickin 2005). For example, ^{40}K–^{40}Ca measurements were performed to quantify the contribution of crustal silicates to the marine calcium cycle (Caro et al. 2010).

The electron configuration of calcium is $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$, while its valence state is +2, forming ionic bonds with nonmetal elements. Its nonbonded atomic radius is 197 pm; its covalent radius is 174 pm, along with a strong electronegativity of 1.00 on the Pauling scale and an electron affinity of 2.369 kJ.mol^{-1} (Coursey et al. 2010; Haynes 2015). Calcium has a density of 1,550 kg.m^{-3} at 20 °C. Calcium salts are more or less soluble in water; indeed, at 25 °C, the solubility products of calcite (trigonal $CaCO_3$), aragonite (orthorhombic $CaCO_3$), gypsum ($CaSO_4.2H_2O$), anhydrite ($CaSO_4$), and antarcticite ($CaCl_2.6H_2O$) are $10^{-8.48}$, $10^{-8.34}$, $10^{-4.58}$, $10^{-4.36}$, and $10^{-4.09}$, respectively. Hydroxyapatite, the biomineral constituting the skeleton of vertebrates, has a much lower solubility product of $10^{-54.45}$ (Fig. 2). Calcium is also characterized by a specific heat capacity of 653 J.kg^{-1}.K^{-1}.

History and Use

The name calcium originates from the Latin word “calx” that means “the ashy remaining substance after burning,” i.e., the “lime.” In nature, calcium does not occur in its elemental form but bounds to oxygen or halogens (fluorite CaF_2). Calcium compounds, such as quick lime (CaO), slaked



Calcium, Fig. 2 Crystal lattice of hydroxyapatite. Atomic symbols: *Yellow* calcium, *dark gray* carbon, *red* oxygen, *white* hydrogen, *purple* phosphorus

lime ($Ca(OH)_2$), limestone ($CaCO_3$), gypsum ($CaSO_4.2H_2O$), anhydrite ($CaSO_4$), and hydroxyapatite ($Ca_5(PO_4)_3(OH)$), have all been known and used by human beings for several thousands of years. The Romans heated calx (limestone) to produce a decarbonation reaction leaving calcium oxide as the solid residue. While gypsum is a common component of wallboard for buildings and concrete for the construction of highways and bridges, it has also been used for centuries in the field of fine arts. Alabaster, which is the translucent variety of gypsum, is a sought-after mineral used for ornamental stonework and sculptures. Anhydrite is commonly used to produce industrial sulfuric acid.

Despite the use of calcium compounds for centuries, the element calcium was not isolated and identified until electricity was under control. Calcium as a metal species was first isolated by Sir Humphry Davy (1808). Calcium forms alloys with magnesium, aluminum, copper, and lead. Calcium bromide ($CaBr_2$), a white powder, has many uses and is present in fire retardants, drilling fluids, cooling agents in freezing mixtures, food preservatives, and medication for the treatment of anxiety. Quicklime (CaO) is, for example, used in water purification devices for drinking water production. Calcium favors the growth of symbiotic and nonsymbiotic nitrogen-fixing bacteria, which are critical for the growth of legumes.

Natural Abundance

Calcium is a lithophile element according to Goldschmidt's classification (Goldschmidt 1926); it is one of the most important rock-forming element (after Si, Al, and Na) at the Earth's surface with a crustal abundance of 41,500 ppm. Several minerals, rare to common, contain from ≈8 to 40 mol% of Ca (Table 1).

CI meteorites contain 9,110 ppm on average (Palme et al. 2014). In most chondrites, calcium is hosted by diopside ($CaMgSi_2O_6$), chlorapatite ($Ca_5(PO4)_3Cl$), and merrillite ($Ca_9Na(Mg,Fe)(PO_4)_7$) and also occurs in minor amounts in feldspars or orthopyroxene. Despite the strong lithophile property of calcium as mentioned above, it may occur as sulfides such as oldhamite ((Ca,Mg,Fe)S) in the reduced sulfide-rich enstatite chondrites. It is also worth noting that calcite, dolomite, and gypsum have been observed in Cl and C2 chondrites.

Calcium, Table 1 Molar content of calcium in the most common of Earth's crust minerals and biominerals

Mineral	Chemical formula	Ca mol%
Calcite, aragonite	$CaCO_3$	40.04
Dolomite	$CaMg(CO_3)_2$	21.73
Anhydrite	$CaSO_4$	29.44
Gypsum	$CaSO_4.2H_2O$	25.47
Anorthite	$CaAl_2Si_2O_8$	14.41
Wollastonite	$CaSiO_3$	34.50
Diopside	$CaMgSi_2O_6$	18.51
Hydroxyapatite	$Ca_5(PO_4)_3(OH)$	07.98
Fluorite	CaF_2	51.33
Antarcticite	$CaCl_2.6H_2O$	26.67

Of special interest are the calcium-aluminum-rich inclusions (CAIs), considered to belong to the first solid grains that condensed in the nebular disc surrounding the protosun. Pb-Pb dating of these CAIs indicates that they formed 4,568.2 My ago, the oldest age obtained for any solar system object so far (Bouvier and Wadhwa 2010).

Palme and O'Neill (2014) have estimated the upper primitive mantle CaO content at 3.78 wt%. Mid-ocean ridge basalts contain between 11.39 and 11.46 wt% of CaO according to measurements of fresh basaltic glass (Gale et al. 2013; White and Klein 2014). Wedepohl (1995) calculated that the CaO content of the bulk continental crust is close to 5.5 wt‰. The upper continental crust contains an average CaO concentration of 3.59 ± 0.2 wt% (Rudnick and Gao 2005).

Seawater calcium abundance is in the range 412–420 ppm; consequently it is the fifth most abundant element after Cl,

Na, Mg, and S (Bruland et al. 2014) dissolved in seawater (O_2 gas excluded). The calcium content increases from the ocean surface down to depths of 2,000–3,000 m and then decreases again down to the seafloor (de Villiers 1998). The calcium content was found to be closely related to carbonate alkalinity according to the temperature and pH dependence of calcium carbonate solubility in seawater. However, de Villiers (1998) observed that the deep ocean contains higher amounts of dissolved calcium than predicted by the thermodynamics of calcium carbonate dissolution. The Ca excess occurring at these intermediate depths could correspond to the calcium contribution from hydrothermal systems located at the axis of mid-ocean ridges (de Villiers 1998).

Dissolved calcium abundance and its rather homogeneous distribution in seawater are related to its relative high residence time close to 1 My. Consequently Ca is considered as a "conservative" element in seawater.

The world's average polluted river water contains 14.7 ppm of calcium, with anthropogenic contributions corresponding to 9% of the total concentration. The main non-anthropogenic calcium fluxes to rivers result from the dissolution of calcium and magnesium carbonates (≈70% of the total flux), evaporites such as gypsum or anhydrite (≈10% of the total flux), and Ca-feldspars or Ca-pyroxenes hosted by basaltic or ultrabasic rocks (≈20% of the total flux).

Most lakes contain from a few ppm to a few dozens of ppm of dissolved calcium. The highly alkaline saline Mono Lake, USA, has only a $[Ca^{2+}] \approx 6$ mg.L^{-1} for a pH of 9.8 and a salinity S of 81 g.L^{-1} (Domagalski et al. 1990). Acid lakes are generally characterized by higher concentrations of dissolved calcium, typically in the range 50–100 ppm (Lake Ontario, Canada).

Geochemical Cycling

The long-term (My scale) calcium geochemical cycle is basically defined by four reservoirs, which are (1) the upper continental crust, (2) the marine biomass made of calcifying organisms, (3) the marine sediments, and (4) the oceanic crust. Connecting fluxes are contributed by (1) the rivers; (2) the dissolution and precipitation of sediments (carbonates and sulfates); (3) the primary production of calcifying organisms with the most important planktonic producers being the coccolithophores, the foraminifera, and the euthecosomatous pteropods (Fabry et al. 2008); and (4) the seawater-basalt interactions associated with hydrothermal activity located at mid-ocean ridges.

The two net input Ca fluxes to the oceans are the river and hydrothermal fluxes. The first one is obtained by multiplying the world river flux (3.74×10^{16} kg of water per year) by the average river Ca content of 14.7 ppm, which gives a calcium flux of 5.5×10^{11} kg.year^{-1}. The second flux corresponds to the release of dissolved calcium at mid-ocean ridges during the hydrothermal alteration of clinopyroxene (diopside; (Ca, Mg)Si_2O_6) into amphibole (tremolite; $Ca_2Mg_5(Si_8O_{22})(OH)_2$) (6) and Ca-plagioclase (anorthite; $CaAl_2Si_2O_8$) into Na-plagioclase (albite; $NaAlSi_3O_8$).

This hydrothermal flux was estimated close to 1×10^{11} kg of Ca per year (Alt et al. 1986; Bednarz and Schmincke 1989). Consequently, the total input flux to the oceans is about 6.5×10^{11} kg.year^{-1}.

Assuming that the calcium geochemical cycle is close to steady state, output fluxes from the oceans to other solid reservoirs should more or less balance the net input flux estimated above. A first output flux is the precipitation of calcium carbonate in the tensile fractures that develop in the oceanic crust during its off-axis cooling.

Alt and Teagle (1999) calculated a flux of about 1.4×10^{11} kg Ca.year^{-1}. A second flux corresponds to the subduction of sediments that operates at a rate of 0.5 km^3. year^{-1} with a present-day carbon content of 8,200 ppm. These data allow the calculation of an average carbon flux of 1.2×10^{10} kg.year^{-1}. The biogenic contribution to this C flux is evaluated at 15% of the total sedimentary flux, thus corresponding to a Ca flux of 1.7×10^{11} kg Ca.year^{-1}.

Consequently, the difference between the net input and output flux is 3.4×10^{11} kg Ca.year^{-1}. Such an apparent "missing output Ca flux" could be explained by the oceanic primary productivity involving the calcifying organisms. Indeed, the dissolution of carbonated skeletons from dead organisms does not match the rate of calcification in the oceans. According to Langer et al. (1997), the total present-day $CaCO_3$ production in the world oceans is 3.27×10^{12} kg. year^{-1}, which corresponds to a flux of 1.31×10^{12} kg Ca. year^{-1}. A part of this flux could have contributed to the progressive integration of carbonates into the upper continental crust through the accumulation of carbonates in passive margins. The amount of Ca trapped into carbonates (limestones and dolomites) (Taylor and McLennan 1985) was estimated close to 1.8×10^{20} kg Ca. The apparent "missing output flux of Ca" from the oceans could be thus explained by the storage of carbonates in passive margins during the last 530 My (≈ the Phanerozoic) at a rate of 3.4×10^{11} kg of Ca.year^{-1}.

It is also worthy to note that the budget of Ca^{2+} in the oceans is linked to the carbon cycle through the dissolution and precipitation (8) of carbonates. One mole of carbon is trapped during carbonate precipitation, but one mole is released as CO_2. The dissolution of $CaCO_3$ tends to buffer the pH of the oceans when atmospheric pCO_2 is rising.

Strong connections operate between Earth's climate modes and geochemical cycles. Such relationships are evidenced by secular variations in seawater chemistry over the Phanerozoic, which have been recorded in the composition of marine evaporites (halite) and biogenic carbonates

such as corals and foraminifera. The "greenhouse" climatic conditions of both Jurassic and Cretaceous were characterized by low molar Mg/Ca ratios (≈1) that favored the precipitation of calcitic cements (the so-called "calcite" seas), while the "icehouse" Tertiary has been a period of high Mg/Ca ratios (from 3 to 5) that produced inorganic aragonite cements in the so-called "aragonite" seas (Gothmann et al. 2015).

On the continents, massive precipitation of calcium carbonates (travertines) may occur associated with geothermal waters. In most cases, geothermal waters originate from meteoric waters that infiltrate the continental crust through fissures and cracks and that are heated up at the contact of magma chambers beneath volcanoes or slowly cooling plutonic rocks such as granites. Carbonate precipitation then occurs as a result of the degassing of carbon dioxide when calcium concentrations higher than 100 $mg.L^{-1}$.

Biological Utilization and Toxicity

Calcium is of primordial importance for the growth of skeletons of many invertebrates (e.g., mollusks, foraminifera, coccolithophores, corals, bryozoans) and all vertebrates. Calcium ions are the most important messengers between cells in living organisms. Calcium oxalates, such as weddellite ($Ca(C_2O_4).2(H_2O)$) and whewellite ($Ca(C_2O_4).(H_2O)$), are present in soils and play an important role in the availability of nutrients to plant roots (Graustein et al. 1977).

In the oceans, phytoplankton developed the remarkable ability to regulate the concentration of Ca^{2+} in the intracellular cytosol. Over geological times, most taxonomic groups were thus able to cope with variations in seawater chemistry (Müller et al. 2015). For example, coccolithophores were abundant during the Cretaceous, a warm period most likely characterized by high levels in seawater dissolved calcium abundance (Müller et al. 2015).

Calcifying marine organisms is commonly considered to be highly sensitive to a decrease in oceanic pH because calcification rates are expected to decrease. However, in situ observations, laboratory experiments, and paleontological records indicate that numerous marine organisms are capable of adjusting their physiological functions to deal with an increase in seawater acidity (Findlay et al. 2009). For example, McCulloch et al. 2012) have shown that cold-water scleractinian corals have a strong resilience to oceanic acidification.

Calcium is the most abundant of the metallic elements in the human body. The average adult body contains about 1 kg of calcium, 99% of which is located in the hydroxyapatite mineral constituting the skeleton. While old bone is regularly eliminated by osteoclasts, new bone is mineralized by osteoblasts in fibroblasts that secrete and mineralize the bone matrix. The mineralized extracellular matrix is mainly composed of type I collagen and osteocalcin (a noncollagenous protein), matrix Gla protein, osteopontin, bone sialoprotein, bone morphogenetic proteins (BMPs), transforming growth factor-beta (TGF-β), and hydroxyapatite.

If calcium is crucial for living organisms including human beings, intake of calcium in excess may provoke arterial calcification and may also increase the risk of cardiovascular diseases in elderly persons. Even healthy kidneys have a restricted capability for eliminating excessive calcium derived from the diet. So high calcium intakes in adults should be avoided since they have relatively limited or no positive consequences for bone mineral density (Anderson and Klemmer 2013).

Summary

This lithophile element is one of the most important rock-forming elements of the Earth. The budget of Ca^{2+} in the oceans is linked to the carbon cycle through dissolution and precipitation of $CaCO_3$.

Calcium is a critical component of skeletons of many invertebrates and all vertebrates, and its ions are the most important messengers between cells, resulting in Ca being the most abundant of the metallic elements in the human body.

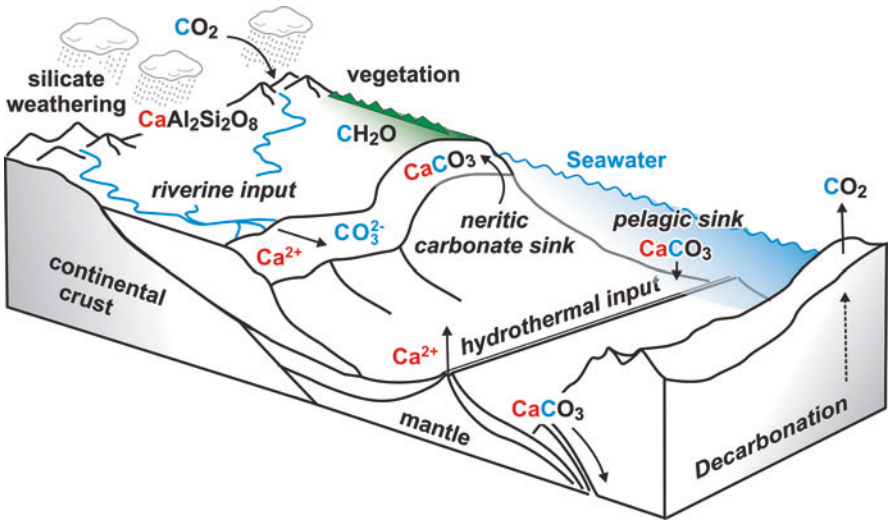
Introduction

Calcium (Ca) is the fifth most abundant element and dissolved ion, respectively, in the Earth's crust and the oceans. Ca is also an essential nutrient for marine and terrestrial organisms where it regulates metabolic processes (i.e., calcium homeostasis) as well as the production of skeletal structures (i.e., bones and calcitic shells). Importantly, Ca has six naturally occurring isotopes (^{40}Ca, ^{42}Ca, ^{43}Ca, ^{44}Ca, ^{46}Ca, and ^{48}Ca), where ^{40}Ca is the most abundant and also produced by the radioactive decay of potassium ^{40}K with a half-life of ~1.277 billion years (Byr). Due to its numerous isotopes and a high mobility in near-surface environments, Ca represents a valuable tracer for earth system processes and biogeochemical pathways. The isotope studies of Ca are thus relevant for a better understanding of global elemental cycles and mutual interactions between lithosphere, hydrosphere, and biosphere. In this contribution, we present the stable Ca isotope variations as delta values ($\delta^{44/40}$Ca, in per mil) normalized to NIST 915a; and the radiogenic ^{40}Ca isotope anomalies are expressed as epsilon units (εCa, in parts per ten thousand).

The global biogeochemical cycle of Ca is tightly linked to other major elemental cycles, including the global carbon (C) cycle, which is facilitated through processes such as continental weathering, hydrothermal exchange at



Calcium Isotopes, Fig. 1 A schematic diagram showing the links between the global Ca and C cycles in the earth surface environments, including the main sources and sinks of Ca^{2+} and C O_3^{2-} ions in the modern oceans (Modified after Husson et al. 2015)

mid-ocean ridges, and/or the formation and deposition of marine carbonates (see Fig. 1). The majority of Ca delivered to the oceans by rivers is primarily derived from the dissolution of continental crust, which contains Ca-bearing carbonate and silicate minerals, expressed by simplified chemical formulas $CaCO_3$ and $CaAl_2Si_2O_8$, respectively. Although carbonates are more soluble, it is the dissolution of silicates that consumes carbon dioxide (CO_2) from the atmosphere, which in turn regulates the Earth's climate over geological time, according to the following simplified reaction (cf., Berner and Berner 1997):

$$\begin{aligned} &CaAl_2Si_2O_8\ (\text{silicate}) + CO_2\ (\text{gas}) \\ &\quad \Rightarrow CaCO_3\ (\text{carbonate}) + Al_2O_3 + 2SiO_2 \end{aligned} \qquad (1)$$

A reversed process of this reaction is the "decarbonation" of limestones in the subduction zones, where the increasing temperature decomposes carbonate minerals and liberates CO_2 gas which can be then reintroduced back into the atmosphere via volcanic systems (see Fig. 1). The tight coupling between the global Ca and C cycles in terrestrial and marine environments highlights the importance of Ca isotope studies for a better understanding of the global C cycle and its role in the modulation of atmospheric CO_2 levels.

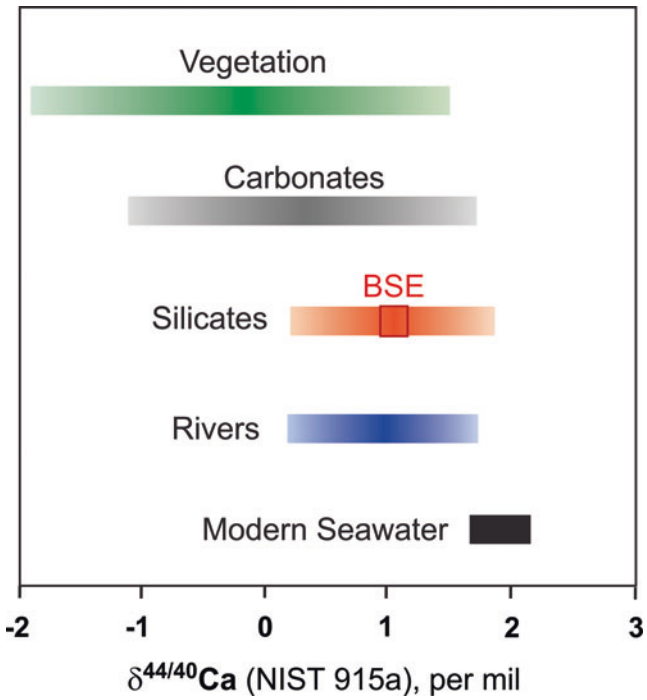
Stable Calcium Isotope Variations and Global Ca Cycle

The stable, or mass-dependent, isotope fractionation of Ca in nature is expressed as delta (δ) notation based on the measured isotope ratios of $^{44}Ca/^{40}Ca$ (or alternatively also $^{44}Ca/^{42}Ca$) in a sample relative to a standard, according to the following relation:

$$\delta^{44/40}Ca = \left(\frac{\left(^{44}Ca/^{40}Ca\right)_{\text{sample}}}{\left(^{44}Ca/^{40}Ca\right)_{\text{standard}}} - 1 \right) \cdot 10^3 \qquad (2)$$

where the reported delta values ($\delta^{44/40}Ca$) are in "per mil" (‰, parts per thousand), and here normalized to a standard NIST 915a. The recent compilation of $\delta^{44/40}Ca$ values from major geological and biological reservoirs (Fantle and Tipper 2014) shows an overall range of about 4 ‰ for various terrestrial and marine samples (see Fig. 2; $n > 2600$ measurements), where the isotopically heaviest Ca reservoir on Earth is the ocean water ($\delta^{44/40}Ca \approx 1.9$ ‰). In contrast, the isotopically lightest Ca is associated with vegetation (i.e., terrestrial plants) and/or biologically precipitated marine carbonates (i.e., calcitic and aragonitic shells). This points to a critical role of organisms and the biosphere in fractionating the stable Ca isotopes in the Earth's surface environments, due to a preferential incorporation of lighter Ca isotopes by plants and animals, which is a common feature of the stable isotope systems of other bioessential elements including carbon (Hoefs 2015). Nevertheless, pure abiotic processes such as (i) the inorganic precipitation of $CaCO_3$ and $CaSO_4$ minerals due to an oversaturation of natural waters, and/or (ii) the adsorption of dissolved Ca^{2+} ions on clays and exchangeable sites of particles can also lead to a significant fractionation of stable Ca isotopes at low temperatures (Fantle and Tipper 2014 and references therein).

The magnitude of stable Ca isotope fractionation in nature diminishes with an increasing temperature (being proportional to $1/T^2$ at high temperatures), and thus igneous silicate Ca reservoirs exhibit much narrower range of $\delta^{44/40}Ca$ values (about 2 ‰) compared to marine carbonates and/or the organically complexed Ca (see Fig. 2). Nevertheless, recent studies of Ca isotope fractionation in high-temperature



Calcium Isotopes, Fig. 2 A compilation of the published Ca isotope data from terrestrial samples (more than 2600 measurements) presented on a common delta scale: $\delta^{44/40}$Ca relative to NIST 915a (Modified after Fantle and Tipper 2014). *BSE* Bulk Silicate Earth (After Huang et al. 2010)

geological settings revealed systematic behavior of the $\delta^{44/40}$Ca proxy in certain igneous rocks and silicate minerals (Schiller et al. 2016 and references therein). Specifically, there is a general coupling between Ca isotopes and Ca and Mg contents in ultramafic rocks (i.e., dunite, peridotite, komatiite), where $\delta^{44/40}$Ca values become higher (i.e., heavier) with decreasing CaO and increasing MgO contents, but such trend has not been documented for felsic and mafic rocks (Schiller et al. 2016 and references therein). Complementary to this isotopically heavy Ca source in ultramafic rocks is the isotopically light Ca present in serpentinized slab mantle rocks, suggesting that perhaps dehydration of slab-mantle serpentinite can produce fluids with high $\delta^{44/40}$Ca that could be then imparted to ultramafic rocks via metasomatisms (Schiller et al. 2016 and references therein). Moreover, the Ca isotope analysis of mineral separates from mantle xenoliths and/or granitic rocks revealed systematic differences in $\delta^{44/40}$Ca signatures of individual minerals, which have been interpreted to reflect either a high temperature equilibrium isotope fractionation or isotope effects generated by igneous differentiation processes (Schiller et al. 2016 and references therein). Overall, the average $\delta^{44/40}$Ca of silicate rocks is close to 1 ‰, which is also our best estimate for the Ca isotope composition of the *bulk silicate Earth* (BSE), the latter constrained by the analysis of mineral separates from mantle xenolithes and bulk mafic rocks (cf., DePaolo 2004; Huang et al. 2010).

Apart from the unanticipated and relatively large (up to 0.8 ‰) high-temperature fractionation of Ca isotopes in the Earth's mantle, another intriguing and currently unresolved aspect of the terrestrial Ca isotope cycle is the fact the mean $\delta^{44/40}$Ca signature of the global riverine Ca flux of about 0.9 ‰ overlaps with that of the silicate Ca reservoir ($\delta^{44/40}$Ca of ~1 ‰) but is systematically higher than the mean $\delta^{44/40}$Ca of carbonates ($\delta^{44/40}$Ca of ~0.6 ‰; Fantle and Tipper 2014). This finding is unexpected considering that previous studies suggested that the majority (>75%) of Ca in the global riverine flux should be derived from carbonates (Gaillardet et al. 1999; Berner and Berner 2012). Hence, one would expect that the mean $\delta^{44/40}$Ca signature of the global riverine flux to be much lower and closer to carbonate sources, i.e., somewhere between 0.6 and 0.7 ‰, based on a simple isotope mass-balance constraints using available data (cf., Fantle and Tipper 2014). Accordingly, either the current estimates of silicate vs. carbonate contributions of Ca to the global riverine flux are incorrect (i.e., the silicate-derived Ca contribution is underestimated), or there is an ongoing fractionation of Ca isotopes during the weathering and transport of Ca^{2+} ions that shifts the riverine $\delta^{44/40}$Ca to higher values relative to those observed in the source rocks (Fantle and Tipper 2014).

Radiogenic Calcium Isotopes in Geological Reservoirs

The radiogenic, or mass independent, isotope variation of ^{40}Ca in nature is expressed as an epsilon (ε) notation in parts per ten thousand (10^4), relative to the Earth's mantle reservoir, according to the following relation (Marshall and DePaolo 1982):

$$\varepsilon_{Ca} = \left[\left({}^{40}Ca/{}^{n}Ca \right)_{sample} / \left({}^{40}Ca/{}^{n}Ca \right)_{mantle} - 1 \right] \cdot 10^4 \quad (3)$$

where n is 44 or 42, and the Ca isotope ratios of sample and mantle are after an "internal normalization" following an exponential law for the correction of an instrumental fractionation during the isotope analysis. The radiogenic isotope of calcium, ^{40}Ca, is the product of radioactive decay of potassium ^{40}K, with a half-life of 1.277 billion years; however, only about 89.5% of the ^{40}K decay results in the production of ^{40}Ca and the remaining 10.5% produce ^{40}Ar. Due to the relatively short half-life of ^{40}K compared to the age of the Earth, minerals and rock that crystallized in Precambrian and had high initial K/Ca ratios (e.g., the continental crust containing K-rich minerals like potassium feldspar and biotite) can accumulate significant amount of the radiogenic ^{40}Ca over time, thus yielding positive epsilon ε_{Ca} values.

The potential of a radiogenic ε_{Ca} tracer for the earth system evolution studies has been explored by Kreissig and Elliott (2005) to distinguish between two possible end-member scenarios for the early crustal growth (i.e., "steady-state" vs. "continuous" growth models) and concluded that Ca isotope data provide little support for the "steady-state" model. However, this study also found that the radiogenic Ca isotope proxy is not a robust tracer of crustal growth due to its sensitivity to secondary processes such as potassium metasomatism and/or the Ca isotope exchange during metamorphic events. More recent studies, performed both in laboratory (Ryu et al. 2011) and natural settings (Farkaš et al. 2011; Hindshaw et al. 2011), applied the ε_{Ca} proxy to investigate the weathering processes in granitic rocks and the associated release of a radiogenic ^{40}Ca from K-rich minerals (i.e., feldspar and biotite), with implications for mineral weathering, soil formation, and the sources of bioavailable Ca^{2+} for plants at base-poor granitic sites.

Future Directions in Ca Isotope Research

Aside from the abovementioned problem regarding the unexpectedly high $\delta^{44/40}Ca$ in the global riverine flux, compared to what is anticipated based on the estimates of carbonate vs. silicate partitioning of Ca in the world's rivers (Fantle and Tipper 2014), there are also unresolved issues related to the interpretation of Ca isotope variability observed in igneous rocks (Schiller et al. 2016 and references therein) and marine sedimentary archives (Fantle and Tipper 2014); the latter relevant for the reconstructions of past changes in the oceanic Ca cycle. Numerous studies aimed to constrain the Ca isotope evolution of seawater over different time intervals (e.g., Heuser et al. 2005; Farkaš et al. 2007; Payne et al. 2010; Blättler et al. 2011), using various marine archives such as bulk carbonate sediments, calcitic shells, marine barite, and phosphate. As pointed out by Fantle and Tipper (2014), such different approaches and recording phases have led to some conflicting results and uncertainties in terms of the reconstructed $\delta^{44/40}Ca$ evolution of the past seawater. Since then, more work has been done on Ca isotopes in the marine Ca cycle, particularly with the emphasis on "deep times" including Paleozoic and Neoproterozoic (e.g., Blättler and Higgins 2014; Kasemann et al. 2014; Du Vivier et al. 2015; Husson et al. 2015; Farkaš et al. 2016), yet the uncertainty with respect to the reconstructed $\delta^{44/40}Ca$ of paleo-seawater remains, and thus a more systematic research towards a better understanding of a marine $\delta^{44/40}Ca$ proxy in different mineral archives and depositional environments (e.g., *open* vs. *restricted* settings) is currently of a high priority. First pioneering studies addressing these issues have been recently performed, specifically Holmden et al. (2012a) investigated the effects of submarine groundwater (SGD) and a "local elemental cycling" on the marine $\delta^{44/40}Ca$ proxy in a modern shallow-lagoon environment; and Hinojosa et al. (2012) utilized a "multiple-archive" approach (i.e., based on marine carbonates and phosphates) to constrain the Ca isotope composition of paleo-seawater. More work following these directions is needed, including laboratory-controlled precipitation and culturing experiments (cf., Tang et al. 2008), to realize the full potential of the Ca isotope proxy for the paleoceanographic and earth system evolution studies.

Finally, due to the different residence times of Ca and C in the oceans (i.e., 10^6 vs. 10^5 years, respectively), the marine $\delta^{44/40}Ca$ and $\delta^{13}C$ proxies are expected to respond differently to perturbations in the oceanic Ca and C cycles, assuming that these occurred in an "open ocean" settings (cf., Holmden et al. 2012b; Farkaš et al. 2016). Hence, any positive or negative $\delta^{13}C$ excursion recorded in marine archives should recover much faster compared to a time needed for the recovery of a possible accompanying $\delta^{44/40}Ca$ excursion, due to an order of magnitude longer residence time of Ca in the oceans compared to C. Accordingly, future detail studies that will use a coupled $\delta^{44/40}Ca$ and $\delta^{13}C$ proxy approach might help to clarify if the observed C isotope excursions in marine carbonates are indeed an evidence of past changes in the *global* marine C cycle, or rather reflect diagenetic and/or *local* scale processes. The latter involving a locally enhanced bioproductivity and/or a mixing of different water masses (e.g., seawater, groundwater) and carbonate sediments (i.e., facies migration) within a basin, linked to eustatic sea-level fluctuations (cf., Holmden et al. 2012b; Husson et al. 2015; Farkaš et al. 2016).

Advances in Ca Isotope Analysis

Analytical challenges associated with a precise and accurate measurements of stable and radiogenic Ca isotopes have been recognized by the community for decades (cf., Boulyga 2010; Fantle and Tipper 2014), and it was really the development of a new generation of mass spectrometers (both TIMS and MC ICP MS) over the last ca. 10–15 years which opened up the possibilities to fully explore the research potential of Ca isotopes. Although, most of the instrumental and analytical issues are now resolved and well understood, the main limitation for a rapid expansion of the field of the Ca isotope biogeochemistry lies in the relatively time-consuming sample preparation (i.e., chemical purification of Ca) and the necessity for a longer analytical runs (i.e., ca. 1.5 h for TIMS). Fortunately, recent advances in semiautomated sample purification systems (cf., Romaniello et al. 2015; Husson et al. 2015) promise to significantly speed up this sample preparation step, thus allowing a higher and more efficient sample throughput, and possibly also a more rapid expansion of the field in the near future.

Summary and Conclusions

Calcium is the fifth most abundant element in the Earth's crust, and due to its numerous isotopes (^{40}Ca, ^{42}Ca, ^{43}Ca, ^{44}Ca, ^{46}Ca, and ^{48}Ca), it is also a valuable isotope tracer in many geological and biological systems. The natural variations in the Ca isotope composition can be produced by either mass-depended fractionation processes (i.e., $\delta^{44/40}$Ca and $\delta^{44/42}$Ca variations) or via a radioactive decay of potassium ^{40}K, which generates radiogenic ^{40}Ca isotopes (i.e., ε_{Ca} variations). Thus far, available studies documented approximately 4 per mil variation in $\delta^{44/40}$Ca in different terrestrial and marine samples, where the largest anomalies towards light Ca are produced due to a biological cycling of Ca both on land (i.e., plants, vegetation) and in the oceans (i.e., marine carbonates). In contrast, the isotopically heaviest Ca reservoir on Earth is the ocean water, which is thus complementary to the isotopically light Ca accumulated in marine carbonates. Relatively large Ca isotope variations (>0.5 per mil) have been documented in terrestrial igneous rocks, including ocean island basalts, granites, and mantle-derived rocks; thus implying that Ca isotopes can be also significantly fractionated during high-temperature processes.

Importantly, the biogeochemical cycle of Ca on Earth is tightly linked with the global C cycle and therefore the atmospheric CO_2, via processes such as continental weathering of carbonate/silicate rocks, hydrothermal reactions at mid-ocean ridges and off-axis centers, and the precipitation of shallow- and deep-water marine carbonates. Future detail Ca isotope studies on marine carbonate archives could thus help to better understand the functioning of the global C cycle and the origin of C isotope anomalies recorded in marine carbonate sediments.

Calorimetry

Masaki Akaogi
Department of Chemistry, Gakushuin University, Tokyo, Japan

Definition

In major areas in Earth Science, particularly geochemistry, petrology, and mineralogy, one of fundamental theoretical frameworks is thermodynamics which is expressed by thermodynamic functions: Gibbs energy, Helmholtz energy, enthalpy, entropy, heat capacity, etc. Calorimetry means experiments to measure heat changes which lead to the thermodynamic quantities. A calorimeter is an instrument used to measure the heat change associated with change of a substance. The heat change at a constant pressure is equal to enthalpy change. Calorimetric measurements are generally divided into two categories (Sorai 2004). The first one is measurement of heat capacity, and the second is measurement of heat of reaction.

Heat Capacity Measurement

The heat capacity is defined as absorbed heat energy divided by the associated temperature change in a substance, and customarily two different heat capacities are defined, C_p and C_v, relating to temperature change at constant pressure and to that at constant volume, respectively. The heat capacity is a function of intrinsic energy related to atomic motion or lattice vibration of the substance. At a temperature range between near 0 K and about room temperature, C_p is measured using adiabatic calorimetry and thermal relaxation calorimetry. The standard entropy at 298.15 K ($S^0_{298.15}$) of a pure crystalline substance is obtained by integrating C_p/T with T between 0 and 298.15 K. A latent heat of transition is also measured in the heat capacity measurement. For C_p measurement at temperature above room temperature, two methods can be adopted: differential scanning calorimetry up to about 2000 K and high-temperature drop calorimetry up to about 2500 K. Among the above techniques, the adiabatic calorimetry is most accurate but requires a sample of at least several grams, as well as in the high-temperature drop calorimetry. Instruments for differential scanning calorimetry and thermal relaxation calorimetry are commercially available and need a sample of only about 10–20 mg, though the methods are somewhat less accurate than the other two methods. However, it is generally not feasible to get a large amount of natural homogeneous samples or to synthesize pure materials of several grams, particularly at high pressure and high temperature.

Reaction Calorimetry

The second method of calorimetry used in Earth Science is reaction calorimetry, which is generally solution calorimetry to measure heat associated with dissolution of a substance in a solvent at a constant pressure, mostly atmospheric pressure. The experimental solution calorimetry is divided into two types: hydrofluoric acid solution calorimetry and high-temperature oxide melt solution calorimetry. In the former measurement, a sample is dissolved in HF at around 323 K, and in the latter a sample is dissolved in oxide melt such as lead borate and sodium molybdate at 1000–1100 K, in order to measure heat of solution of a substance. The heats of formation, transition, and reaction are calculated from the measured heats using thermochemical cycles. The heats of mixing of solid solutions and of glasses and heat associated with order-disorder transition can also be measured. Oxide melt solution calorimetry needs a sample of only several to several 10 mg and is widely used to various inorganic compounds including silicate minerals, metal oxides, hydrous phases, high-pressure phases, nanomaterials, etc.

Summary

Measurements of heat capacity and heat of reaction are fundamental experimental techniques to obtain the important thermodynamic quantities. A limited number of laboratories perform calorimetric measurements because the methods are specialized. For minerals and related inorganic substances of

geochemical, petrological, and mineralogical interests, calorimetrically measured data and derived data from them are summarized in several publications (e.g., Robie and Hemingway 1995; Navrotsky 1997, 2014).

Carbon

Adrian Jones
Department of Earth Sciences, University College London, London, UK

Element Data
Atomic Symbol: C
Atomic Number: 6
Atomic Weight: 12.0107
Isotopes and Abundances: ^{12}**C**: ~98.89%, ^{13}**C:** ~1.11%, ^{14}**C** $\sim 10^{-12}$
Atm Melting Point*: 3550 °C
1 Atm Boiling Point*: 4492 °C (101 kPa)
Common Valences: −4, 0, +2, +4
Ionic Radii: 30 pm (4+)
Pauling Electronegativity: 2.5
First Ionization Energy: 1086 kJmol^{-1}
(*continued*)

Chondritic (CI) Abundance: 3.65 wt%
Silicate Earth Abundance: 50–500 ppm
Crustal Abundance: ~1800 ppm
Seawater Abundance: ~28 ppm
Core Abundance: unknown 0.2–2%

Properties

Carbon has three isotopes, two are stable ^{12}C (98.89%) and ^{13}C (1.11%) plus a radioactive isotope ^{14}C ($\sim 10^{-12}$). The systematics of carbon isotopes yield important information about their environments and are discussed separately (Cross reference #1). ^{12}C is the standard which defines mass number 12 containing 6 protons, 6 neutrons, and 6 electrons.

The melting point of carbon is extremely high and varies with pressure*; in a carbon arc, it sublimes above ~5,530 °C, which is higher in temperature than any known metal. Consequently, carbon may have been the first element to condense from gas to solid in the protoplanetary nebula as nanodiamond or graphite, although oxidized forms are also abundant in the universe. The ability of hydrocarbons to bond with themselves is known as catenation and leads to more complex forms, such as cyclohexane, or even benzene. Hydrocarbons are hydrophobic. Some are abundant in the solar system as sampled widely in primitive undifferentiated meteorites like chondrites (Sephton 2002). Carbon-rich lakes of methane occur on Titan, and polycyclic aromatic hydrocarbons (PAHs) are abundant in nebulae. In carbonaceous chondrites, the average carbon abundance is 3.65 wt%, whereas in the bulk Earth estimates for carbon vary from 50 to 500 (Zhang and Zindler 1993; Marty 2012) and much of Earth's carbon from ~0.2 to 2 wt%, maybe in the core (Wood et al. 2013).

History and Use

Carbon (*from* Latin *carbo* meaning charcoal or coal), the element with atomic number 6, is the fourth most abundant element in the universe but is less abundant in the *differentiated* Earth. Carbon occurs naturally in pure elemental form, the two most famous crystalline allotropes of carbon are diamond (cubic, density 3.51 gcm^{-3}), the hardest known mineral, and graphite (hexagonal, density 2.266 gcm^{-3}), one of the softest and most refractory substances known. Other carbon allotropes of native carbon include crystalline lonsdaleite, chaoite, fullerenes, and graphene, plus several noncrystalline forms of glassy ("vitreous") carbon, nanofoam ("carbon aerogel"), and carbine (Hazen et al. 2013, Table 1).

In diamond, each carbon atom is bonded to four adjacent carbon atoms in tetrahedral coordination, with a C—C distance of ~1.54 A°, and C—C—C angles close to ideal 109.5°. This tetrahedral covalent bonding configuration reflects the hybridization of one 2 *s* and three 2*p* orbitals from each carbon atom to form four sp^3 orbitals. The framework structure of diamond leads to its superlative physical and chemical properties, including being the hardest known material (10 on *Moh's scale of hardness*). The absence of conduction electrons make diamond an insulator, yet paradoxically it is an excellent thermal conductor with ~five times better thermal conductivity than copper, which some jewellers can detect by touch. Diamond forms naturally at depths on Earth below ~150 km and is stable to temperatures and pressures greater than at the centre of the Earth (Oganov et al. 2013).

The optical properties of diamond feature the widest transparency of all known solids, extending from the UV (225 nm) to the far infrared, even at very high temperatures and radiation intensities. The combination of unique properties, including hardness and brilliance, have led to its preeminence as a gemstone. The best diamond gemstones are graded for qualities of the "four c's"; cut, color, clarity (absence of inclusions), and carat weight. One carat equals 1/5 g. The main impurity in "Type I" natural diamond is nitrogen, trapped in the lattice as single atoms, aggregates or clusters capable of changing color toward yellow and brown. The specific nitrogen residency in diamond provides a useful way of categorizing diamond, with nitrogen-free "Type II" diamond being the rarest (Cartigny 2005). A nitrogen-induced optical absorption in diamond around 270 nm has been identified in interstellar clouds. Diamond formed by shock during hypervelocity impact cratering usually contains the hexagonal polymorph called lonsdaleite, as at the 35 Ma Popigai impact crater in Siberia (Jones et al. 2016).

Since the 1950s, diamond synthesized at high pressures and temperatures (HPHT) replicates all of the mechanical properties of natural diamond suitable for industrial uses, but usually with different absorption and luminescence lines inherited from nickel and cobalt-rich metal solvents. Diamond can also be grown dynamically from low-pressure gas by chemical vapor deposition (CVD).

"Carbonado" is a variety of black or dark polycrystalline diamond, which is slightly porous, found only in Brazil and the Central African Republic, and possibly of nonterrestrial origin (Garai et al. 2006).

In graphite, graphene, fullerenes, and several types of amorphous and glassy carbon, the carbon atoms are covalently bonded in planar three-coordination, with typical C—C distances of ~1.42 A°, and C—C—C angles close to 120°. This trigonal coordination results from hybridization of carbon electrons where the *2 s* orbital mixes with two *2p* orbitals to form three sp^2 orbitals. Graphite is formed of electronically neutral, monatomic flat carbon layers, which bonds through relatively weak van der Waals attractions between the layers, separated by 3.41 A°. The layered structure leads to highly orientation-dependent or anisotropic properties and the weak interlayer bonding leads to uses as a lubricant and as pencil "lead." Graphite is highly refractory and its very high-temperature stability, >4,800 K, make it useful as a heater or in nuclear reactors as a neutron moderator.

Individual one atom-thick two-dimensional carbon layers when meticulously separated are known as graphene, a pure carbon allotrope ~200 times stronger than steel, with unique electronic and mechanical properties (Geim and Novoselov 2007) that can produce lightweight composite structures which can be transparent, flexible, and yet impermeable even to helium.

Geochemical Behavior

Carbon shows remarkable chemical flexibility with the ability to bond to itself and with more than 80 other elements, most commonly in 2-, 3-, and 4-coordination. Carbon has oxidation numbers ranging from −4 to +4 and can behave as a cation, as an anion, and as a neutral species in mineral phases with a spectacular variety of crystal structures, chemical bonding, and physical and chemical properties (Hazen et al. 2013). Carbon occurs in solids, liquids, and gases in variable amounts throughout the Earth, from the atmosphere and oceans to the crust-mantle and core, as both a major element and trace element. Carbon on Earth also moves, and is fundamental to life, it belongs to the boundary matter between living and nonliving matter, and is central to the science of organic chemistry. Carbon transforms and moves between near-surface reservoirs in the *carbon cycle* (Berner 2004) and carbon also moves deep below the surface through rocks over geological timescales, as studied by the Deep Carbon Observatory (https://deepcarbon.net) extending the biosphere on Earth to the deep subsurface (Colwell and D'Hondt 2013; Schrenk et al. 2013). Evidence for the connection between the Earth's conventional *carbon cycle* and the *deep carbon cycle* is provided in the form of volcanic degassing, where volatile gases deliver carbon as CO_2 to the atmosphere, and subducting plates return solid carbon back into the mantle; the carbon flux of this geological process is enormous but slow and is globally estimated to be largely in balance (Kelemen and Manning 2015).

Carbon Minerals

By far the most abundant carbon minerals in the Earth's crust are carbonates, whose crystal structures incorporate $(CO_3)^{2-}$ anions, with an equilateral triangle of oxygen atoms around the central carbon atom. Most C—O bond distances are

between 1.21 and 1.30 A^{O}, and O—C—O angles are ~120°. Two types of rhombohedral carbonates, calcite and dolomite ($CaMg(CO_3)_2$), account for at least 90% of crustal carbon as massive sedimentary and metamorphic formations (Reeder 1983). In the calcite structure ($CaCO_3$), each Ca^{2+} cation is coordinated to six $(CO_3)^{2-}$ groups and each $(CO_3)^{2-}$ group is coordinated to six Ca^{2+} cations.

Calcite appears most commonly in sedimentary rocks where it occurs as the principal mineral of limestone, and as natural cement in siliceous sandstone and shales. In the present day, calcite is deposited within shallow marine settings, but the distributions of carbonate minerals have varied through Earth history, principally as a consequence of evolving feedback between the geosphere and biosphere (Hazen et al. 2008). Calcite is also common in metamorphic rocks such as marble and calcareous gneiss. Calcite and other carbonate minerals also crystallize in unusual carbonate-rich igneous volcanic rocks called carbonatites (Jones et al. 2013). Approximately 200 of the ~300 known carbonate minerals also include water in their structure. These include mixed anionic forms such as carbonate sulfates, carbonate silicates, and carbonate phosphates. The common copper carbonates are also hydrous including highly colored varieties like green malachite and blue azurite, which form in the oxidized zones of copper deposits.

Carbides, such as cohenite $(Fe, Co, Ni)_3C$, are refractory materials formed where carbon bonds to a less electronegative element, represented by ~10 different naturally occurring minerals. These are scarce in the Earth's crust, but familiar from meteorites and may represent a significant volume fraction of carbon in Earth's deep interior especially the core (Wood et al. 2013).

Organic Carbon and Energy

Carbon forms a variety of minerals which incorporate organic molecules into their structure, including organic molecular crystals, carbon minerals with organic anions, clathrate silicates, and clathrate hydrates. These can have both biological and nonbiological origins. The water-based clathrates are also known as gas hydrates or clathrate hydrates, and are remarkable compounds which form at low temperatures (<0 °C) and elevated pressures (>6 MPa). They are widely distributed around the globe in deep-offshore marine environments and have attracted growing interest because of their enormous potential for methane-based energy. The unnamed main form of "methane ice," which occurs in oceans and deep permafrost regions, is a large cubic 3D H_2O framework with two types of cages partially filled with methane (CH_4) molecules holding on average ~0.17 moles of methane per mole of water, with a density close to 0.9 gcm^{-3} (Max 2003).

A major category of carbon materials concerns carbon deposits in the crust, which are related to energy resources, namely coal and hydrocarbons. Coals are combustible sedimentary rocks derived from organic matter and are composed primarily of carbon, plus other volatile elements like hydrogen, oxygen, sulfur, and nitrogen. The sequence of coal formation by *carbonization* occurs over long geological timescales, accompanied by burial, increasing in grade from peat to lignite, then subbituminous coal, bituminous coal, and finally anthracite. Mature coal deposits sometimes hold unusual crystalline hydrocarbon phases and other organic materials (Sephton and Hazen 2013).

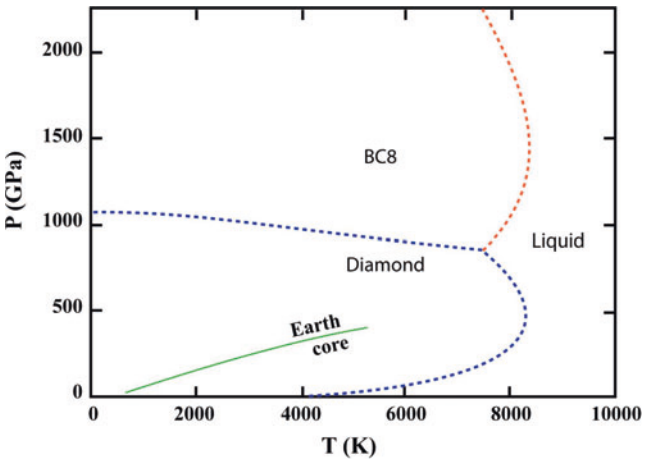
Deep deposits of hydrocarbons represent perhaps the most economically important component of the deep carbon cycle. Most are considered to have a purely biological origin, but there are some challenges to this paradigm, which include similar methane-rich hydrocarbons observed to form in ultramafic rocks like serpentinites (Schrenk et al. 2013), suggesting that alternative nonbiogenic pathways to form hydrocarbon gas deposits are also possible.

Conventional natural oil and gas resources reside in sedimentary basins, and the hydrocarbons of interest consist entirely of carbon and hydrogen, forming a large number of organic compounds. Their empirical formulae differ between types of gaseous hydrocarbons in the series of linear structured hydrocarbons; the amount of bonded hydrogen decreases in the series of alkanes, alkenes, and alkynes, with self-bonding of carbon preventing saturation of the hydrocarbon by the formation of double or triple bonds. Liquid components of petroleum include a complex mixture primarily of linear and cyclic hydrocarbons from C_3 to C_{10}, as well as numerous other molecular species, while solid hydrocarbons include such broad categories as paraffin waxes (typically from C_{18} to C_{40}).

Summary

Carbon (atomic number 6) is the fourth most abundant element in the solar system. Its abundance on Earth is much less well known. It exists everywhere in the atmosphere and oceans, through the crust and mantle in the deep subsurface all the way to the core. A major global concerted effort is underway (the *Deep Carbon Observatory*) to quantify the reservoirs and fluxes of carbon below the surface, to find out how deep life can exist on our planet, and to evaluate how all this additional carbon impacts, if at all, on the measurable and observable *carbon cycle*.

Diamond is the most spectacular form of native elemental carbon. Used since ancient times as a gemstone, not only does it have brilliant optical properties and unmatched hardness, but sophisticated advances in synthesis, including low-pressure chemical vapor deposition (Roy 1987), are leading



Carbon, Fig. 1 Phase diagram for elemental carbon at high temperatures and pressures

to new uses of diamond in industry. Diamond is also at the forefront of experimental research into defining the limits of extreme pressure and temperature. Two opposing diamonds are used to generate very high static pressures in the megabar range a small experimental device called a "diamond anvil cell," permitting simultaneous heating by laser to thousands of degrees (Lazor et al. 1992). Diamond is the deepest known mineral from Earth, and may also be the oldest, but it is currently impossible to date. By contrast 1-atom thick-layered carbon, graphene, was only isolated in 2004 and is emerging as an important industrial material.

Carbon exists in many forms on Earth, not just as allotropes some of which like diamond are actually rare, but also as hundreds of inorganic minerals and organic compounds or hydrocarbons. Dispersed carbon may also be present deep in the Earth as a nonstoichiometric component in high-pressure silicate minerals and dissolved as CO_2 in silicate melts (Ni and Keppler 2013).

Carbon is essential to life on Earth and can exist in gaseous, liquid, and solid forms. Its mobility in dissolved aqueous fluids is particularly important, not only in the oceans and hydrosphere but in the way tectonic plates are subducted at plate boundaries over geological time (Fig. 1).

Definition

The biochemical and geochemical cycling of the organic and inorganic forms of carbon through Earth processes is referred to as the global carbon cycle. The carbon cycle considers the flow of carbon across four reservoirs: atmosphere; continental, including the biosphere, freshwaters, and soils; ocean; and geosphere (Fig. 1). Processes influencing the transfer of carbon between reservoirs occur over short (active) and long (geologic) timescales. The global carbon cycle is closely linked to the cycles of other elements (e.g., oxygen, nitrogen, phosphorus, and sulfur) because of the important role these elements play in biological and geological processes. Studies of the carbon cycle encompass contemporary, historical, and geologic timescales. Analyses of the rock and sediment records aim to understand how the carbon cycle has varied in the past in response to global transformations and earth system cycles and provide useful analogues for understanding future change. Ice cores provide a record of atmospheric concentrations of carbon dioxide (CO_2) and methane (CH_4) over the past 400,000 years. Interest in the carbon cycle has grown in recent decades due to increasing concentrations of atmospheric CO_2 from anthropogenic combustion of fossil fuels and associated effects on global climate change.

Inorganic Carbon

The main reservoirs of inorganic carbon in the Earth's crust are sedimentary rocks, which hold ~60,000,000 Pg (1 Pg = 10^{15} g) (Hedges and Keil 1995). This oxidized carbon occurs primarily as carbonate minerals (calcite and dolomite) in limestones (80%) and shales (14%) (Hunt 1996). These rock reservoirs are isolated from surficial processes by deep burial and only affect biological cycles on geologic timescales. In contrast, surficial reservoirs, although considerably smaller in size, are more dynamic on biological timescales. The largest of these "active" reservoirs is dissolved inorganic carbon (DIC) in seawater (~40,000 PgC) (Hedges and Keil 1995). Approximately 25% of all marine DIC is stored in the upper kilometer of ocean above the permanent thermocline (Hedges 1992) with most exchange between the atmosphere and ocean taking place in the mixed layer (25–200 m). DIC is also stored in the deep ocean, and exchange between the deep ocean carbon pool and the atmosphere through the process of upwelling occurs at ~1,000 year timescales. Other major reservoirs of inorganic carbon at the Earth's surface include soil carbonates (1,100 PgC) and atmospheric CO_2 (828 PgC).

At geologic timescales, inorganic carbon is transferred between the geosphere and atmosphere by geochemical (weathering) and geothermal (tectonic) processes (Eqs. 1 and 2). Rock weathering produces dissolved bicarbonate (HCO_3^-), which is delivered to the ocean by rivers and groundwater where it is precipitated as calcium carbonate ($CaCO_3$) and other carbonate minerals. There is a positive feedback between weathering and tectonics because subduction processes cause the outgassing of CO_2 from the mantle, thereby increasing atmospheric CO_2 and temperature. Tectonic processes also increase weathering by increasing the amount of land available to weathering through uplift and mountain building. These processes are summarized in the following equations with the forward reaction described on top and the reverse reaction on the bottom:

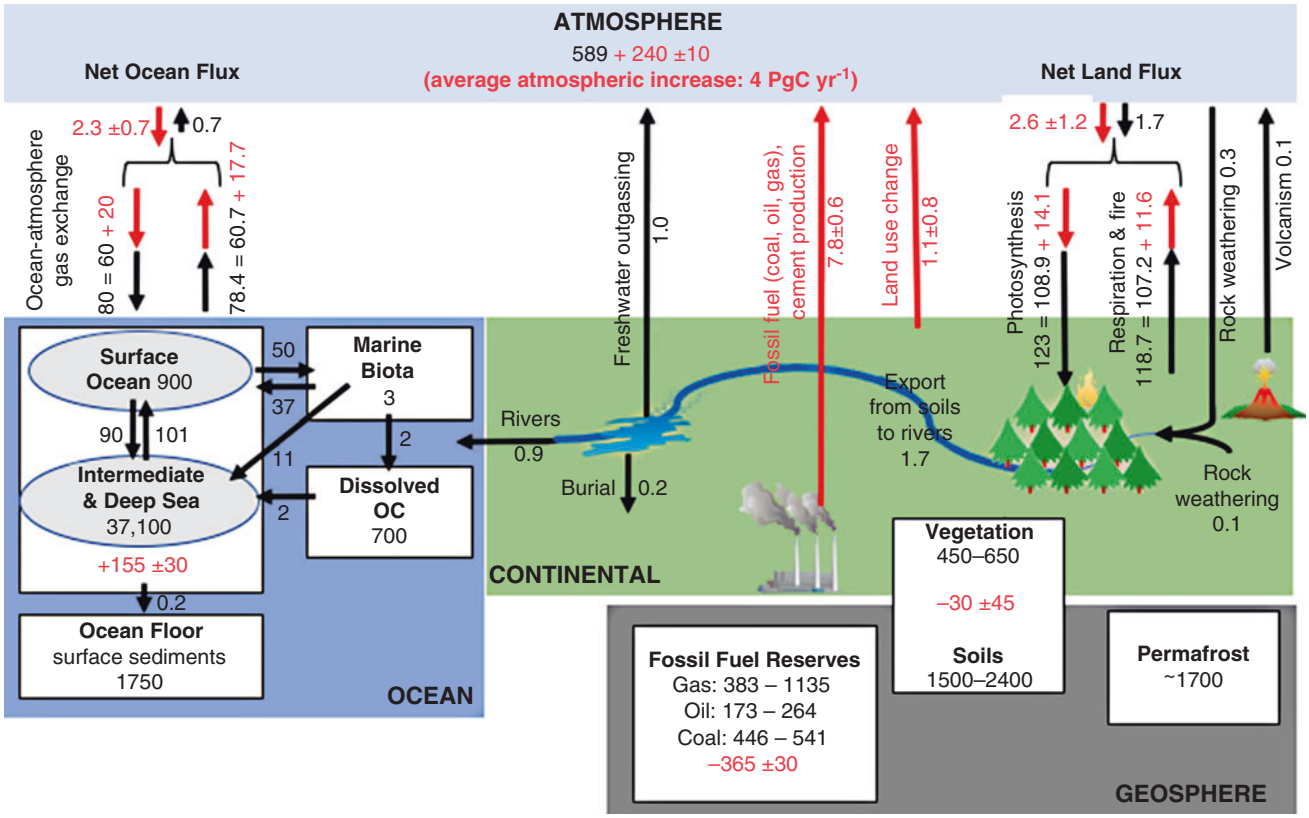
$$CO_2 + CaSiO_3 \underset{geochemical}{\overset{weathering}{\rightleftarrows}} CaCO_3 + SiO_2 \quad (1)$$

$$CO_2 + MgSiO_3 \underset{geochemical}{\overset{weathering}{\rightleftarrows}} MgCO_3 + SiO_2 \quad (2)$$

Organic Carbon

Organic carbon (OC) is present in both living and nonliving systems and ultimately fuels all of Earth's biogeochemical processes. Understanding the formation, cycling, and preservation of OC is essential for understanding the cycling of all bio-elements between living and nonliving reservoirs, the formation of economically important petroleum and coal deposits, and predicting how human activity may change the natural balance of these systems.

Much of the OC formed during photosynthesis or by chemosynthetic autotrophs is decomposed by heterotrophic organisms. Heterotrophic processes occur in the water column of marine and aquatic environments, as well as in sediments, soils, and rocks. Organic matter (OM) diagenesis



Carbon Cycle, Fig. 1 Simplified schematic of the global carbon cycle, with a focus on the relatively fast-cycling reservoirs. *Numbers* represent reservoir mass, also called "carbon stocks" in PgC and annual carbon exchange fluxes (in PgC year^{-1}). *Numbers* and *arrows* indicate reservoir mass and exchange fluxes estimated for the time prior to the Industrial Era (~1750). *Red* reservoir numbers denote cumulative changes of anthropogenic carbon over the Industrial Period 1750–2011. *Red arrows* and *numbers* indicate annual anthropogenic fluxes averaged from 2000 to 2009. By convention, a positive cumulative change means that a reservoir has gained carbon since 1750. Unless otherwise specified, these values pertain to total C, while values in the text are provided for organic and inorganic C pools (Figure adapted from Ciais et al. (2013) and references therein. *Symbols* courtesy of Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/imagelibrary/))

occurs under low temperature (<50 °C) and low pressure and primarily through biological processes that occur in surface sediments. The OC preserved following diagenesis is subject to further alteration by the processes of catagenesis and metagenesis, which occur at higher temperatures and pressures and lead to the formation of petroleum and natural gas.

$$\underset{\text{oxidative weathering}}{\overset{\text{photosynthesis and organic burial}}{CO_2 + H_2O + \text{light} \rightleftarrows CH_2O + O_2}} \quad (3)$$

The major fluxes between organic pools are driven by marine and terrestrial primary production (Fig. 1). The active (surficial) pools of OC include soil humus, land and marine plant tissue, seawater dissolved OC (DOC), and surface marine sediments (Hedges and Keil 1995). Photosynthesis, the harvesting of light energy to convert inorganic carbon to reduced (organic) forms in the tissue of plants, is the primary mode of primary production. However, chemosynthesis by microbial organisms, which uses chemical energy rather than sunlight, is also important. The fixation of carbon by plants over the Earth's history accounts for the oxygen in the atmosphere; thus the cycles of carbon and oxygen are closely linked over geologic time. In fact, to maintain current atmospheric oxygen levels, rapid cycling of carbon in the surficial pools is required. These pools exchange on relatively short timescales (10^2–10^4 years). In contrast, OC that remains in the sedimentary system cycles slowly (~10^8 year). Over geologic time, sedimentary reservoirs only become exchangeable through uplift, followed by oxidative weathering of OC by exposure to the atmosphere (Eq. 3).

Global gross primary production on land (123 PgC year^{-1}) is dominated by nonwoody plant tissues such as leaves, grasses, and herbaceous plants (Schlesinger 1997). The highest gross terrestrial production and storage as biomass occurs in the tropics (56%), while polar regions are considerably less productive (0.5%; Taube 1992). Forests are the most productive continental biomes; deserts and tundra are the least productive, reflecting global patterns of temperature and

precipitation. Marine primary productivity (~50 PgC $year^{-1}$) is dominated by open water (pelagic) phytoplankton productivity because open water constitutes ~75% of the total ocean area. However, when normalized to area, coastal and upwelling areas together account for nearly two-thirds of the total oceanic productivity because a greater supply of nutrients is available to support phytoplankton in these areas. Other primary producers along the coasts (i.e., seagrass, marsh plants, macroalgae, mangroves) provide locally important sources of OC (Canuel and Hardison 2016).

Delivery of OC (as dissolved and particulate fractions) from the land to coastal marine environments by rivers accounts for 0.4 PgC $year^{-1}$ (Meybeck 1982). However, there remains considerable uncertainty in the ability to adequately quantify carbon exchange from land to the coastal ocean and in understanding the processes influencing the fate of terrigenous carbon in coastal sediments (Hedges and Keil 1995). Generally, the total annual riverine OC load to the ocean is proportional to annual total river flow, which is dominated by a small set of rivers that transport the bulk of the freshwater from land to sea (Schlesinger 1997). However, seasonal and annual/interannual variations in hydrology as well as large events such as storms and hurricanes influence the input, dispersion, and cycling of sediment OM in coastal environments, thus making it difficult to trace terrigenous OM. In addition, molecular and isotopic evidence suggests that OC in seawater and marine sediments is marine, rather than terrestrial, in source, suggesting that remineralization of terrestrial material must occur in rivers prior to delivery to the coastal ocean (Cole et al. 2007) or in the marine environment. Eaolian (air) OC flux from the land to the sea approximates 0.1 Pg C $year^{-1}$, but this estimate remains uncertain (Zafiriou et al. 1985).

Organic Matter Preservation and Geologic Processes

Only ~0.1% of global net primary production (NPP) is ultimately preserved within sediments; however, it is this OC that eventually becomes part of the sedimentary record and available to be transformed into fossil fuels. The remaining 99.9% of global NPP is remineralized to inorganic carbon, nutrients, and water. Remineralization represents a sink for oxygen, linking the global cycles of OC and oxygen. Microfauna, bacteria, and fungi (on land) are responsible for the breakdown of OM.

The rates and extent of decomposition are influenced by environmental, biological, and physical factors. There must be a sufficient supply of labile OM to be degraded, and the depth-integrated rate of OM remineralization in marine sediments correlates closely with carbon flux to the sediment surface (Henrichs 1993). Interestingly, the fraction of OC that is *not* remineralized is also highly correlated with the carbon flux to the sediment surface. Thus, the efficiency of OM decomposition appears to be lower in systems that receive the highest input of OC compared to systems with lower accumulation rates (Henrichs and Reeburgh 1983). Second, like most metabolic processes, decomposition rates are proportional to temperature, resulting in global patterns of decomposition rates (e.g., higher degradation rates in the tropics than in tundra systems) (Schlesinger 1997). Oxygen is also a controlling factor for decomposition. Recent evidence suggests that oxygen exposure time rather than oxygen concentration may be an important determinant of the extent to which OM is decomposed (Hartnett et al. 1998).

Physical and chemical "protection" of OM also plays a key role in controlling preservation. Protection by binding to inorganic ions, clays, and organic residues decreases the surface area of OM that is exposed to bacteria for degradation. This protection or encapsulation of OM explains why compounds that appear to be labile, or readily available for decomposition, have been found in sedimentary OC deposits. Preservation of OC occurs predominantly in anoxic marine sediments. More than 80% of preserved OC is located in deltaic-shelf environments associated with fine-grained sediments (Berner 1982), which supports the physical or chemical protection model since these sediments provide the most potential surface area with which OM can bind. This has likely been true for millions of years, as current petroleum deposits are found in areas that were formerly coastal, fine-grained sediments. Major depositional environments include lacustrine environments (open, closed lakes), peat swamps and coal, and continental margins, enclosed or silled basins, and the Black Sea (Hedges and Keil 1995).

Sedimentary rocks are the largest geologic reservoir of OC and make up ~99.5% of the total global OC. Sedimentary OC occurs primarily as kerogen, coal beds, and petroleum reservoirs, which ultimately come from biogenic processes or sources. Kerogen is amorphous, highly insoluble particulate OM that is thought to form by two pathways – selective preservation and geopolymerization – both of which occur under low temperature and pressure conditions. Petroleum, naturally occurring fluids (liquid and gases) that evolve from kerogen, is formed primarily from the remains of microbes (algae and bacteria) although some types of petroleum are formed from higher plants. In contrast, coal is a solid and is formed from the remains of higher plants. The most common type of coals, humic coals, is formed through the processes of peatification and coalification, which involve both biological and geochemical processes. The OC in ancient sedimentary rocks provides these economically important fossil fuels as well as a molecular record of life, which has allowed the construction of evolutionary trees and an understanding of the geologic timing of past events and the response of natural systems to tectonic, environmental, and biological change.

Summary

The global carbon cycle involves exchange of OC between surface and subsurface (buried) reservoirs on timescales of less than 1 year to millions of years. These fluxes are driven by the production and cycling of OC through biological, physical, and geological processes. The global OC cycle is intimately linked with other global cycles and is sensitive to human-induced perturbations. In 2016, concentrations of atmospheric CO_2 (~400 ppm) and CH_4 (1,834 ppb) reached a new milestone in human history, and the last time the Earth experienced atmospheric concentrations of CO_2 that were this high was during the Pliocene (~3 million years ago). Understanding changes in the size and composition of carbon reservoirs and changes in these reservoirs through space and time is essential for predicting Earth system responses to anthropogenic activities as well as responses in the associated cycles of other biologically important elements.

$^{13}C/^{12}C$ ratios; Carbon isotope stratigraphy; Stable carbon isotopes

Definition

The stable carbon isotopes ^{12}C and ^{13}C comprise 98.89% and 1.11% respectively of the carbon on Earth (Craig 1953). Measurements of these isotopes are expressed as ratios to the more common ^{12}C in a sample ($^{13}C/^{12}C$) and reported in the $\delta^{13}C$ notation relative to the Vienna Pee Dee Belemnite (VPDB) standard in per mil (Coplen 1996). There is also an unstable nuclide – radiocarbon (^{14}C) – that is much rarer, with a natural abundance of ~1 part per trillion (Chanton et al. 2014).

Introduction and Main Applications

The stable carbon isotopes measured on the carbonate and organic carbon fractions in sediments or carbonate tests from planktonic and benthic organisms and molecular compounds (biomarkers) isolated from them are classical proxies in marine sciences. This chapter focusses on main applications of carbon isotopes in marine and climate sciences, which include reconstructions of the global carbon cycle, chemostratigraphy, tracing of water masses, and surface water productivity in the modern and past ocean, reconstructing early life, and likewise are relevant to applied forensic applications in numerous archaeological (sub)disciplines.

Carbon Isotopes

Isotopes are atoms with the same number of protons but different numbers of neutrons. Traditional nomenclature denotes isotopic species as ${}^{A}_{Z}\mathrm{E}$, in which Z is the element's atomic number (e.g., number of protons) and A is the mass number (i.e., sum of protons and neutrons). For example, carbon atoms always contain six protons ($n = 6$), but this atom can contain either six, seven, or eight neutrons ($m = 12$, 13, or 14, respectively). With this in mind, the characteristic atomic weight for any particular atom is the average of the relative mass contributions of the atom's isotopic species, which for carbon is equal to 12.0107 (Coplen 1996).

Isotopic Nomenclature and Fractionation Mechanisms

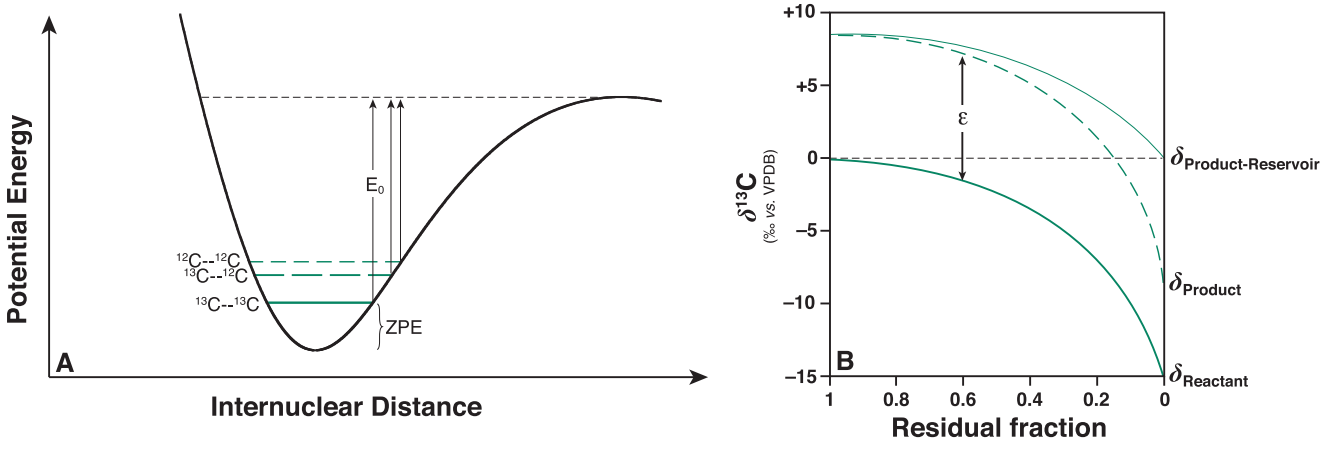
Selective relative enrichment (discrimination) of discrete isotopic species, such as ^{12}C and ^{13}C, between compounds or coexisting phases (e.g., gaseous vs. aqueous carbon dioxide) is called "fractionation." There are two main important types of isotope fractionation – equilibrium and kinetic. Equilibrium isotope fractionation occurs via isotopic exchange when there is a relative separation (discrimination) of isotopes between substances in chemical equilibrium as a result of the reduction in vibrational (zero point) energy when a more massive isotope (e.g., ^{13}C) is substituted for a less massive isotope (e.g., ^{12}C). As such, isotopic exchange reactions occur if the isotope distribution of two or more substances changes, with no change in reactants or products. In contrast, kinetic fractionation is the consequence of rate dependent, incomplete, or nonreversible reactions, such as distillation ("rain out") and biology processes (Chen and Marcus 2005). In such systems, reaction dynamics are sensitive to atomic mass in one or more of the reactants. For instance, products show disproportional incorporation of lighter isotopes compared with reactants because molecules with the heavier isotope form stronger bonds and have higher dissociation energies compared with molecules with lighter isotopes (Fig. 1a, b). Thus, the energy required to achieve molecular dissociation is much lower for ^{12}C–^{12}C bonds compared with ^{13}C–^{12}C bonds (Matsson et al. 2005).

Isotopic exchange reactions are well described by generic equilibrium dynamics:

$$aA_1 + bB_1 = aA_2 + bB_2$$

Here, subscripts 1 and 2 represent the respective abundances of the light and heavy isotopic species of substances A and B, such that the equilibrium constant for such a reaction would be:

$$K = \frac{\left({}^{A_2}/_{A_1}\right)^a}{\left({}^{B_2}/_{B_1}\right)^b}$$



Carbon Isotopes, Fig. 1 (**a**) Schematic potential energy curve for the interaction of two carbon atoms in a stable molecule or amid two molecules in a solid/liquid. (**b**) Coeval $\delta^{13}C$ values of two discrete substances as a function of the residual fraction of the reactant for a Rayleigh process. ZPE (E_0) = Zero point energy

According to statistical mechanics, the equilibrium constant can be expressed by partition functions (Q) of these respective substances:

$$K = \frac{\left(Q_{A_2}/Q_{A_1}\right)}{\left(Q_{B_2}/Q_{B_1}\right)}$$

Accordingly, partition functions are defined by:

$$Q = \sum_i \left[g_i\, e^{(-E_i/kT)}\right]$$

where associated functions are summed for every potential level (E_i), g_i is equal to statistical weight of different i^{th} levels, k is the Boltzmann constant, and T is temperature in Kelvin (Stern et al. 1968).

The fractionation factor α mathematically describes isotopic discrimination, where $\alpha = R_A/R_B$. R is the isotopic ratio of interest (e.g., $^{13}C/^{12}C$), and A and B are discrete compounds or phases. The equilibrium constant (K) is related to the fractionation factor (α) by the equation $\alpha = K^{1/n}$, where n equals the number of atoms exchanged. For isotope exchange reactions involving a single atom, $K = \alpha_{A\text{-}B}$. As an example, consider exchange of ^{13}C and ^{12}C between carbon dioxide and Ca-carbonate:

$$^{13}CO_2 + Ca^{12}CO_3 < - - - > {}^{12}CO_2 + Ca^{13}CO_3$$

This reaction would have an isotopic fractionation factor for aragonite equal to (Emrich et al. 1970).

$$\alpha_{CaCO_3-CO_2} = \frac{\left(\frac{^{13}C}{^{12}C}\right)_{CaCO_3}}{\left(\frac{^{13}C}{^{12}C}\right)_{CO_2}} = +10.63 \text{ (at } 25^{*}C).$$

For calcite, which is common in many marine settings, the isotopic fractionation factors will be different (Romanek et al. 1992; Turner 1982).

Based on available experiments and theoretical data, $\alpha_{CaCO3\text{–}CO2}$ can be calculated from ambient temperature with the equation (Horita 2014):

$$10^3 \ln\alpha_{CaCO_3-CO_2} = -1.637\left(^{10^6}/_{T^2}\right) + 7.290$$

Note that the addition of 10^3 is convenient for conversion of fractionations into more customary per mil (‰) deviations, which are straightforward to compare with conventional delta (δ) values vis-à-vis epsilon values:

$$\varepsilon_{CaCO_3-CO_2} = 10^3(\alpha_{CaCO_3-CO_2} - 1) = 10^3\left(^{R_B}/_{R_A} - 1\right)$$

Delta (δ) notation is defined by the equation:

$$\delta_{SA}(‰) = 10^3\left(\frac{(R_{SA} - R_{ST})}{R_{ST}}\right)$$

where R is the isotope ratio and subscripts SA and ST represent sample and standard respectively.

Carbon isotope ratio measurements are compared to an international isotopic reference material called Vienna Peedee Belemnite (VPDB) with an R equal to 0.011237 (Coplen 1996). As such, a sample substance's measured $^{13}C/^{12}C$ ratio is used to calculate stable carbon isotope values ($\delta^{13}C$):

$$\delta^{13}C_{Sample} = 10^3\left(\frac{\left(\frac{^{13}C}{^{12}C}\right)_{Sample} - \left(\frac{^{13}C}{^{12}C}\right)_{VPDB}}{\left(\frac{^{13}C}{^{12}C}\right)_{VPDB}}\right)$$

In conjunction with the epsilon equation above, the stable carbon isotopic fractionation (α) between two substances can be calculated (*c.f.*, Table 1):

$$\alpha_{A-B} = {}^{R_B}/_{R_A} = {}^{(\delta^{13}C_A+1000)}/_{(\delta^{13}C_B+1000)}$$
$$\approx \delta^{13}C_A - \delta^{13}C_B = \Delta\delta^{13}C_{A-B}$$

Carbon Isotopic Measurements

Isotope ratio mass spectrometry (IRMS) provides measurements of the absolute abundance of stable carbon isotopes in natural or synthetic materials. Over the last few decades, advances in IRMS instrumentation now allow for accurate and highly precise stable carbon isotope measurements of bulk and molecular samples. Further, recent IRMS

technologies now support coupled instrumental techniques, which are configured to incorporate a range of differing peripheral (front-end) techniques such as elemental analysis (EA, Muccio and Jackson 2009), gas chromatography (GC; Sessions 2006), and high performance liquid chromatography (HPLC, Godin et al. 2007). Ultimately, these peripheral techniques use oxidation to convert diverse carbon compounds into carbon dioxide for IRMS detection (*c.f.*, Sessions 2006; Muccio and Jackson 2009). Following gasification, samples are compared to a reference gas calibrated with recognized international isotope reference materials (Table 2). This approach thus normalizes measured (raw) $\delta^{13}C$ values to a common reference scale shared between laboratories worldwide.

Current theoretical sensitivities of IRMS for combustion-interface carbon isotope measurements are about 0.025 nmol for samples with natural ^{13}C distribution abundances, although realized detection thresholds are much higher at 1–5 nmol (~50 ng of typical hydrocarbons [Sessions 2006]) for on-column injections. Precision of $\delta^{13}C$ values measured from samples with >5 nmol C is presently ca. 0.1–0.3‰ (1σ standard deviation). Comprehensive review of IRMS instrumentation and techniques are well beyond the scope of this chapter. The reader is directed toward recent literature reviews (c.f., Brand 2004; Sessions 2006; Muccio and Jackson 2009) and other contributions in this encyclopedia.

Carbon Isotopes, Table 2 Reported $\delta^{13}C$ values of NBS-reference materials against VPDB

NBS-19	Marble	+1.9
NBS-20	Limestone	−1.1
NBS-21	Graohite	−28.1
NBS-22	0il	−30.0

Distribution of Carbon Isotopes in Nature

Stable carbon isotopic compositions are widely used as geochemical proxies to reconstruct changes in the global carbon cycle. Two main carbon reservoirs exist, the reduced biogenic organic carbon reservoir (organic matter) and the oxidized carbonate reservoir, covering a wide range of stable carbon isotopic signatures from less than −100‰ to greater than 10‰, depending on the carbon source (Figs. 2 and 3). The lowest $\delta^{13}C$ values are related to microbially produced methane (CH_4) (Grossman et al. 2002) in, e.g., gas-hydrate bearing sediments along continental slopes and related carbonate biohermes, marine seep systems, and Arctic permafrost (e.g., Claypool and Kvenvolden 1983; Whiticar 1999, and references therein). The highest values (>10‰) occur in dissolved inorganic carbon (DIC) associated with methanogenesis (Claypool and Kaplan 1974; Hudson 1977).

Differences in the organic carbon isotopic composition ($\delta^{13}C_{org}$), both at the bulk and the molecular level, are controlled by complex biosynthetic pathways, including the fractionation during the production of biomass, e.g., photosynthesis, in the marine and the terrestrial biosphere (e.g., Degens et al. 1968). Bulk organic carbon from terrestrial C3 plants, the most common type of vegetation on Earth, is lower in $\delta^{13}C$ with mean values of about −27‰. Bulk $\delta^{13}C_{org}$ values for marine algae scatter around −21‰. Terrestrial vegetation from arid climate zones utilizing the C4 and Crassulacean Acid Metabolism (CAM) photosynthetic pathway, mainly Savannah grasslands,

Carbon Isotopes, Fig. 3 Carbon cycle dynamics along the land-river-ocean continuum (modified from Canuel et al. 2012). Average $\delta^{13}C$ values, reservoir sizes, and fluxes are also shown for reference (Siegenthaler and Sarmiento 1993; Hedges et al. 1997; Rabouille et al. 2001)

shows averaged bulk $\delta^{13}C_{org}$ values of about −12‰. Within all these organisms, at the molecular scale, most lipids are ^{13}C–depleted (lower $\delta^{13}C$ values) as compared to starch ($\Delta\delta^{13}C_{Starch–Lipid}$ = 6.0‰), sugars ($\Delta\delta^{13}C_{Sugar–Lipid}$ = 5.5‰), proteins ($\Delta\delta^{13}C_{Protein–Lipid}$ = 5.0‰), and therefore bulk biomass ($\Delta\delta^{13}C_{Bulk–Lipid}$ = 4.0‰), as a consequence of biochemical (enzymatic) differences during production and transport through an organism (Hobbie and Werner 2004; Bowling et al. 2008).

Carbon Isotopes and the Emergence of Life

Physiochemical and biological processes create distinctive carbon isotopic signatures in biogenic material that trace the occurrence of life. In consequence, $^{13}C/^{12}C$ variations in sedimentary geologic archives are often used to reconstruct the origin(s) and evolution of life because of its characteristic discrimination against heavier isotopes. For instance, numerous studies adopt $\delta^{13}C$ values of fossil organic matter (kerogen) in sedimentary rocks to resolve the antiquity of life as we understand it based on remarkably persistent kinetic isotope effects associated with enzymatic carboxylation reactions (e.g., photosynthetic assimilation via ribulose bisphosphate carboxylase) as compared to inorganic carbon species, such as carbon dioxide and (bi)carbonate (Schidlowski and Aharon 1992; Havig et al. 2017).

Other disciplines, including paleontology and archeological fields, similarly utilize characteristic carbon isotopic discriminations imparted by plants and higher animal-derived biomass in order to more fully understand the evolution of life and behavior. For example, many previous studies interpret $\delta^{13}C$ values of dental bioapatite derived from early humans with respect to vegetable versus meat-based dietary preferences during our species' evolution (Cerling et al. 2011; Sponheimer et al. 2013; Loftus et al. 2016). These same values also create an explicit link between our ancestors and their environments, which then can be contextualized by plant lipid $\delta^{13}C$ analyses of the matrix across an archeological horizon in order to shed light on community patterns, resource use, and (pre)historical behavior (Magill et al. 2016). The analysis of biochemical "residues" similarly provide new dimensions in archeological investigations of diverse materials, such as pottery (potsherds), soils, sediments, and biogenic remains in order to link lipid residues with their organic and environmental sources (Dudd and Evershed 1998; Dunne et al. 2016). Thus, combined bulk and molecular analyses are especially powerful because they can disentangle source-specific inputs within otherwise complex mixtures of lipids.

Carbon Isotopes in Shallow Seawater

The dissolved inorganic carbon (DIC) $\delta^{13}C$ of seawater ($\delta^{13}C_{DIC}$) is dynamically coupled to the global carbon cycle via the partitioning of the main carbon reservoirs between the ocean, atmosphere, and terrestrial biosphere (Fig. 3). $\delta^{13}C_{DIC}$ is not uniform in the modern ocean, nor constant over time (e.g., Sundquist and Visser 2004). The global seawater $\delta^{13}C_{DIC}$ composition is mainly controlled by three processes: photosynthesis, microbial decay of algal organic matter, and physical fractionation during gas exchange at the air-sea interface (Broecker and Maier-Reimer 1992). Marine surface

water is generally enriched in ^{13}C because photosynthesis of marine phytoplankton favors the light ^{12}C over the heavy ^{13}C, leading to lower $\delta^{13}C$ values for organic matter ($\delta^{13}C_{org}$) relative to ambient seawater $\delta^{13}C_{DIC}$ (Garlick 1974). This process is limited by the availability of nutrients, in particular nitrate and phosphate (Broecker and Peng 1982).

Most marine organisms exhibit $\delta^{13}C$ values in their carbonate shells, which were formed not in full equilibrium relative to ambient seawater (Fig. 1). The reason for this is manifold but metabolic effects, including the photosynthetic activity of algal symbionts, kinetic fractionation tied to growth rates, and carbonate ion concentrations are critical (McConnaughy 1989; Rohling and Cook 1999). These effects, together with species-specific differences, are summarized as 'vital effects' (e.g., Wefer and Berger 1991). Intriguingly, previous studies suggest that, if these vital effects are corrected for, isotopic mass-balance calculations can be used for reconstructions of biophysical factors, such as the concentration and the composition of Earth's atmospheric carbon dioxide (e.g., alkenones; Pagani 2014).

In most places, modern sea surface waters $\delta^{13}C_{DIC}$ is about 2–3‰ heavier than the deep-water values of about 0‰ due to biological activity in the photic zone (Kroopnick 1985; Raven and Falkowski 1999; Sarmiento and Gruber 2006). In addition, changes of the $\delta^{13}C_{DIC}$ in the ocean are influenced by increasing anthropogenic pCO_2 causing a decline in the ^{13}C content of DIC relative to ^{12}C – a phenomenon called the "Suess effect" (Keeling 1979; Quay et al. 1992).

Remineralization of organic matter and nutrients within thermocline subsurface water recycle isotopically light ^{12}C. Due to upwelling and wind-mixing of shallow waters, this light ^{12}C and nutrient-rich subsurface water can be remobilized back into the surface waters thereby stimulating primary productivity and influencing the carbon isotopic composition of calcareous shells (e.g. Broecker and Peng 1982).

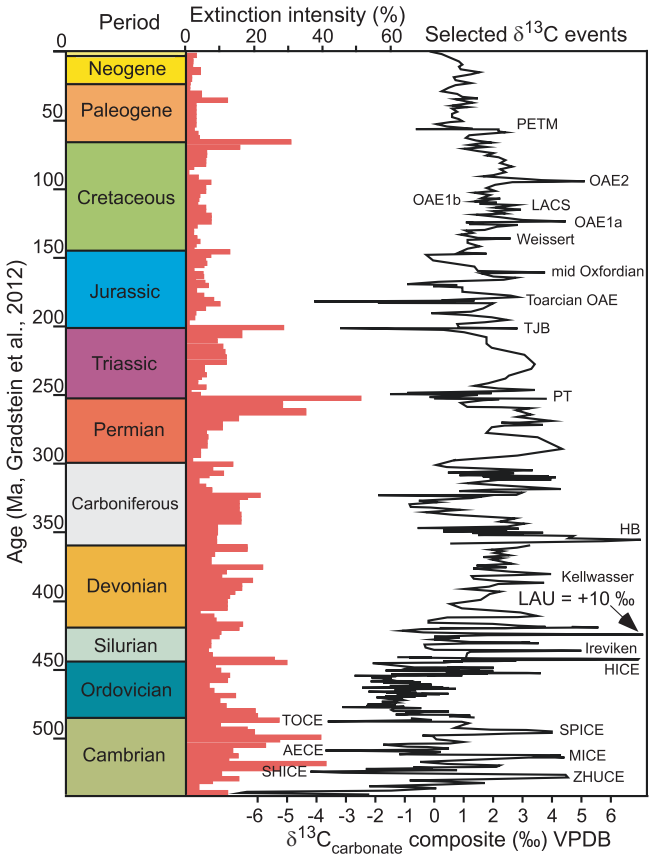
Tracing of Seawater Masses, Surface Water Productivity, and Ecology

The $\delta^{13}C_{DIC}$ in water is widely used as a tracer for seawater masses. Although changes in surface water productivity and mixing influence $\delta^{13}C_{DIC}$, other processes, including water mass formation, respiration, ocean circulation, and vital effects, determine the $\delta^{13}C_{DIC}$ value and therefore can be used as tracers for water masses (e.g., Ravelo and Hillarie-Marcel 2007). Deep water captures the $\delta^{13}C$ signature from its surface water sources. North Atlantic Deep Water (NADW) has therefore relatively high $\delta^{13}C$ values (~1.11‰) whereas Antarctic Bottom Water (ABW) is relatively low (~0.4‰), reflecting the major differences in surface water $\delta^{13}C_{DIC}$ in both high latitude source regions (Kroopnick 1985). Variations in deep water $\delta^{13}C$ can, therefore, be used to trace the history of deep water currents. This approach is also referred to as "aging" of deep water (Rohling and Cook 1999), where the relative age of deep water provides a measure for ocean circulation.

The $\delta^{13}C$ difference between shallow and deep dwelling planktic foraminifera ($\Delta\delta^{13}C$) provides a well-established proxy for thermocline productivity and the depth of the shallow water mixed layer (e.g., Wefer et al. 1999). Increasing $\Delta\delta^{13}C$ values reflect more stratified surface water masses due to increasing contrasts between shallow and deep waters, and vice versa. A comparable approach is used to reconstruct productivity via changes in benthic foraminifera $\Delta\delta^{13}C$ of epifaunal and infaunal species (Zahn et al. 1986). Here, the $\delta^{13}C$ differences are mainly controlled by pore water geochemical gradients and the intensity of organic matter degradation, the latter being a function of organic matter supply (flux) to the sea floor (McCorkle et al. 1990). Large $\Delta\delta^{13}C$ values represent less organic matter flux, and thus less primary productivity, and vice versa. Benthic foraminifera $\Delta\delta^{13}C$ gradients can, however, be biased by the variability in new production of organic matter (fresh phytodetritus), which influences the stable isotope signal. This effect, constrained by variable primary productivity and organic matter fluxes at seasonal time scales, is referred to as the "Phytodetritus" or "Mackensen effect" (Mackensen et al. 1993). Furthermore, the carbon and oxygen isotopic composition of calcite tests of planktic foraminifera is used for reconstructing depth habitats and thus the ecology of extant and extinct species (e.g., Pearson et al. 1993).

Chemostratigraphy and Carbon Isotope Excursions (CIE)

The history of the global carbon cycle and climate through time is preserved in the carbon isotope record of marine and terrestrial sediments (Fig. 4). The application of organic and inorganic carbon isotope ratios as chemical fingerprints for stratigraphic correlations was pioneered in the late 1970s with the studies of Berger et al. (1978), Weissert et al. (1979), and Scholle and Arthur (1980), more recently summarized in Weissert et al. (2008), Saltzman and Thomas (2012), Wendler (2013), and Jarvis et al. (2015). The most robust Phanerozoic archives of marine carbon isotope signatures are from individual pristine preserved fossils and bulk carbonate from marine sediments (e.g., Joachimski and Buggisch 1993; Veizer et al. 1999; Grossman et al. 2008; Saltzman and Thomas 2012, and references therein). Carbon isotope fluctuations of several per mil are also reported from hemipelagic sediments, shallow water carbonates, and terrestrial sediments. Due to multiple local influences, however, they may differ in their absolute isotope values and ranges from their



Carbon Isotopes, Fig. 4 Phanerozoic carbon isotope record, extinction events, and selected global events (CIEs) based on Gradstein et al. (2012) and references therein, Caplan and Bustin (1999), Munnecke et al. (2003), Wagner et al. (2007), Korte and Kozur (2010), and McAnena et al. (2013). Extinction intensity represents the fraction of genera that are present in each interval of time but do not exist in the following interval (Modified after Rohde and Muller (2005) and Sepkoski (2002). *PETM* Paleocene Eocene Thermal Maximum, *OAE* Oceanic Anoxic Events, *LACS* Late Aptian Cold Snap, *TJB* Triassic Jurassic Boundary, *PT* Perm-Trias Event, *HB* Hangenberg Event, *LAU* Lau Event, *HICE* Hirnantian Event, *TOCE* Top Cambrian Excursion, *SPICE* Steptoean Event, *MICE* Mingxinsi Event, *AECE* Archaeocyathids Event, *SHICE* Shiyantou Event, *ZHUCE* Zhujiaqing Event

corresponding pelagic sediment records, complicating their use in stratigraphic correlation across wider areas (Weissert and Breheret 1991; Saltzman and Thomas 2012; Jarvis et al. 2015).

The long-term trend in Earth's climate is interrupted by series of transient events, identified by distinct positive or negative carbon isotope excursions, CIEs (Fig. 4). These CIEs, combined with longer trends in the global carbon isotope record, are used in chemostratigraphy to identify chemical events (e.g., Zachos et al. 2001; Weissert et al. 1998), which can be correlated within and across shallow, hemipelagic, and pelagic marine and the terrestrial environments (e.g., Gröcke et al. 1999; Herrle et al. 2004). Well-documented examples of CIEs representing major perturbations of the global carbon cycle are reported from, e.g., the Mesozoic-Paleogene greenhouse (Paleocene–Eocene thermal maximum PETM, Early Jurassic and Cretaceous Oceanic Anoxic Events, OAEs, Jenkyns 2003), and the Paleozoic (Saltzman and Thomas 2012, Fig. 4). In contrast to the large Paleozoic fluctuations of >10‰, the Mesozoic and Cenozoic amplitudes are with >2‰ much smaller. Many CIEs coincide with widespread environmental perturbations including severe and short-term global warming (hyperthermal events), ocean acidification, shoaling of the carbonate compensation depth (CCD), enhanced marine organic carbon burial linked to widespread ocean anoxia, major crisis or extinction of biota on land and in the ocean, and sudden shifts in Earth's hydrological cycle and climate (e.g., Leckie 2009; Stanley 2010; Beerling and Woodward 2001). Understanding how the Earth system responded to and recovered from these past extreme events remains a major focal point of Earth Sciences, adding to the discussion on anthropogenically induced global warming (Stanley 2010).

The magnitude of 2 to >10‰ and rapidity of CIEs in the Phanerozoic, combined with evidence for massive environmental change, has stimulated intense interdisciplinary research about the underlying trigger and feedback mechanisms. Positive CIEs are reported for multimillion to orbital time scales and are, among other possible mechanisms (Fig. 4), commonly associated with periods of globally enhanced marine carbon burial, leading to the concept of Oceanic Anoxic Events (Schlanger and Jenkyns 1976, Scholle and Arthur 1980) and global cooling (e.g., Kuypers et al. 1999). Recent studies, combining geochemical with biotic data and biogeochemical modeling, have shown that global cooling can cause perturbations to marine ecosystems and biogeochemical cycles at scales comparable to those associated with global warming (McAnena et al. 2013). Sharp negative CIEs, either isolated within the chemostratigraphic record or in combination with positive CIEs, have been recorded throughout the Phanerozoic sedimentary record (e.g., Saltzman and Thomas 2012) and have become a focal point for Earth System research. Negative CIEs have been related to a large number of mechanisms, including rapid dissociation of metastable marine methane hydrate, build-up and release of isotopically "light" carbon in stratified epicontinental seas, thermogenic release of methane related to the placement of volcanic dykes into coal-bearing strata or thermal maturation of other organic-rich sediments, extensive biomass burning, mobilization of labile carbon pools from terrestrial permafrost, ventilation of marine dissolved organic carbon, and others (for further information on mechanisms see, e.g., Cohen et al. 2007; deConto et al. 2012). Correlations of smaller magnitudes of >1.0‰ within less than 100 kyrs have been successfully used in regional epicontinental settings of the late Cretaceous (Menegatti et al. 1998; Herrle et al. 2004; Jarvis et al. 2015). In contrast to the large amplitudes, the factors controlling small scale variations of <0.5‰ are far less understood. Among

others, coccolith distribution and depletion in marl–limestone alternations, diagenetic effects of pore waters, sedimentation, and cementation have been identified to play a role (Jarvis et al. 1988, 2015; Mitchell et al. 1997).

Processes Limiting the Use of C within Chemostratigraphy

Major processes affecting the absolute values in both organic and inorganic matter are surface water productivity (Arthur et al. 1988), input of organic matter from land (Jarvis et al. 2015), remineralization in the water column (Sinninghe Damste and Köster 1998), mineralogy, and carbonate and organic composition of the sediments (cements, carbonate producers such as calcareous nannofossils composition and abundances; Beltran et al. 2007; Jarvis et al. 2015), early and late diagenetic processes (Mitchell et al. 1997; Allan and Matthews 1982; and Immenhauser et al. 2003), CO_2 (Kump and Arthur 1999), and sea-level changes (Jenkyns 1996). Furthermore, it has been shown that mineralogy can impact on carbon isotopic stratigraphy (e.g., Swart 2008). Paired organic and inorganic carbon isotope records might help overcome this problem (Menegatti et al. 1998; Jarvis et al. 2015). Parallel shifts, in both organic and inorganic carbon isotopes, are often a robust signal in different marine records as it is documented for example for the early Aptian carbon isotope event. For this event, a consistent >4–6‰ shift is observed in organic and inorganic carbon isotopes from shallow marine Cretaceous Arctic marsh records and subtropical pelagic and shallow marine records (Menegatti et al. 1998; Herrle et al. 2015).

Besides the chemical and physical alteration of the carbon isotope signals, the impact of orbital forcing on the carbon cycle, which is most dominant within the 400 kyr cycle in the Cenozoic and Mesozoic $\delta^{13}C$ records (Pälike et al. 2006; Gale et al. 2011), can make correlations difficult if major $\delta^{13}C$ shifts of >2‰ are absent. Thus, instead of correlating single peaks, longer intervals (>0.5–1 Ma) are needed to be studied together with biostratigraphic and/or chronostratigraphic makers (Herrle et al. 2004). The absolute $\delta^{13}C$ values might be obscured but the form and shape of isotope profiles are a robust feature in many long- and short-term records (Herrle et al. 2015; Jarvis et al. 2015). Thus, using longer records, the form and the shape are the basis for a reliable high-resolution chemostratigraphic approaches (Jarvis et al. 2015).

Conclusions

Stable carbon isotopes are commonly used for a wide range of applications in marine sciences and climate research. Applications include reconstructions of the global carbon cycle including short-term perturbations, chemostratigraphy, and tracing of water masses and surface water productivity in the modern and past ocean. The development of carbon isotopes at the bulk sediment, foraminifera shell, and compound-specific (molecular) level, especially when combined with complementary evidence from biota, nutrients, ocean chemistry and redox, and modeling, has opened new pathways to unravel the complex interplay between fluctuations of main carbon pools between the atmosphere, the living biosphere, and carbon buried in the sediments, and their interactions with and impact on global climate at multiple temporal and spatial scales.

Carbonate Compensation Depth

Ryan J. Woosley
Department of Ocean Science, University of Miami, Rosenstiel School of Marine and Atmospheric Sciences, Miami, FL, USA

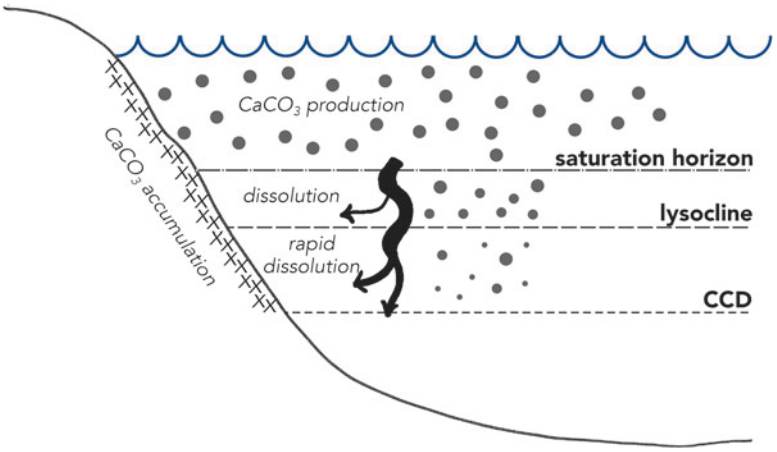
Definition

Calcifying organisms in the surface supply $CaCO_3$ to deep waters when they die, and their tests or shells fall through the water column. As a result of respiration, increasing pressure, and decreasing temperature, waters become increasingly undersaturated with respect to $CaCO_3$ with depth, allowing the tests to dissolve more readily. The depth in the water column at which the rate of calcium carbonate supplied from the surface equals the rate of dissolution is called the carbonate compensation depth (CCD). If the sea floor lies above the CCD, these $CaCO_3$ tests can accumulate in the sediments; if the sea floor lies below the CCD, $CaCO_3$ will be absent from the sediments. In this way, the CCD can be thought of as a "snowline" marking the separation between carbonate-rich sediments and carbonate-deficient sediments. This gives rise to an alternative definition of CCD as the depth at which the carbonate content of the sediments is 0% by weight. This is a more practical definition because measuring the carbonate content of sediments is much easier than measuring rates of supply and dissolution in the water column.

There are actually at least two different CCDs because there are two common crystalline polymorphs of $CaCO_3$ produced in the surface. Pteropods (cone-shaped mollusks) secrete the more soluble form, aragonite, while foraminifera (zooplankton) and coccolithophores (phytoplankton) secrete the more stable form, calcite. The aragonite compensation depth (ACD) is typically about 3,000 m shallower than the calcite compensation depth (Morse and Mackenzie 1990). Studies generally focus on the calcite compensation depth because it marks the complete dissolution of carbonates from the sediments. The system is further complicated by high-magnesium calcites, which are actually more soluble than aragonite, can also be produced as a by-product of osmoregulation (Woosley et al. 2012), and likely begin to dissolve shallower in the water column; however, very little is known about their contribution to the carbon cycle.

Factors Controlling CCD

The depth of the CCD is mainly controlled by two factors: the degree of undersaturation with respect to calcite or aragonite and the flux of $CaCO_3$ debris from the surface. The saturation state (Ω) is the ratio of the ion concentration product ($[Ca^{2+}][CO_3^{2-}]$) to the apparent solubility constant and represents how close the water is to thermodynamic equilibrium. Surface waters are generally supersaturated ($\Omega > 1$). The degree of supersaturation decreases with depth as a result of decreases in the solubility of the minerals with increasing pressure and decreasing temperature, as well as increased total CO_2 from remineralization of organic matter, until the water reaches saturation ($\Omega = 1$), a depth called the saturation horizon. Below the saturation horizon, the saturation state continues to decrease and the waters become undersaturated ($\Omega < 1$), allowing $CaCO_3$ to dissolve. At some depth at or below the saturation horizon, there is a rapid increase in the rate of dissolution; this is called the lysocline. Below the lysocline, the percent of $CaCO_3$ found in sediments decreases rapidly until the CCD is reached. The saturation horizon, lysocline, and CCD are shown schematically in Fig. 1. In a thermodynamically controlled ocean, the depth of the saturation horizon, lysocline, and CCD would all be very similar. But because the kinetics of $CaCO_3$ dissolution are complex and nonlinear, the lysocline and CCD can be 200–1000 m deeper than the saturation horizon. The majority of dissolution occurs at the sediment-water interface because $CaCO_3$



Carbonate Compensation Depth, Fig. 1 A schematic showing the relationship between the saturation horizon, lysocline, and carbonate compensation depth (CCD) in the ocean. The location of the three levels varies by location as a result of differences in $CaCO_3$ production at the surface and the degree of undersaturation at depth

particles generally fall through the water column faster than they can dissolve. There is some evidence of dissolution above the aragonite saturation horizon, which is thought to be dissolution of high-magnesium calcites.

Spatiotemporal Variability

The position of the CCD varies spatially as the result of differences in the magnitude and type of production at the surface and saturation state at depth. Specifically, the CCD is deeper in the Atlantic (~5,000 m) than in the Pacific and Indian (~3,500–4,500 m) due to a lower saturation state in the subsurface Pacific and Indian as a result of higher total CO_2 concentrations from organic matter remineralization. The CCD is also deeper in the tropics due to high productivity in the surface resulting in a higher flux of $CaCO_3$ to the deep and shallower near the continental margins due to increased organic matter remineralization decreasing the saturation state.

The position of the CCD also varies greatly (~2,000 m) over geologic time scales. This variability has major implications for the global carbon cycle because it determines how much carbon is stored long term (millions of years) in deep-sea sediments and how much is actively cycled through the ocean, atmosphere, and biosphere (~1,000-year time scales).

Buffering Anthropogenic CO_2

Currently, the uptake of anthropogenic CO_2 by the oceans is resulting in a decrease in pH and CO_3^{2-} concentration, a process termed ocean acidification. These changes to the inorganic carbon system cause the saturation horizon, and in turn the lysocline and CCD, to shoal. Lowering of the saturation state in the surface ocean may also lead to a decrease in $CaCO_3$ production at the surface and thus reduce the supply of $CaCO_3$ to sediments, causing the CCD to shoal. If the CCD shoals, carbonate sediments that were formally below the CCD will become exposed to corrosive waters and begin to dissolve. The dissolution of $CaCO_3$ consumes CO_2 according to the following reaction:

$$CO_2 + H_2O + CaCO_3 \rightarrow Ca^{2+} + 2HCO_3^{-}. \quad (1)$$

This reaction reflects the "neutralizing capacity" of the deep ocean by increasing the alkalinity (or buffering capacity) and will play a major role in returning atmospheric CO_2 concentrations to "natural" levels once fossil fuel burning ceases (Morse and Mackenzie 1990). However, this re-equilibration will take thousands of years (Broecker and Takahashi 2011).

Definition

Carbonic acid, H_2CO_3, forms from the dissolution of CO_2 in water and plays a key role in weathering, biological production, formation and deposition of sediments, and the carbon cycle. Carbonate minerals, primarily calcite, aragonite, and dolomite precipitating from these solutions, constitute the second most abundant class of sedimentary rocks.

Introduction

Carbonate rocks, consisting mainly of the minerals calcite ($CaCO_3$) and dolomite [$CaMg(CO_3)_2$], are the second most abundant class of sedimentary rocks, after terrigenous clastics, on land and on the ocean floor. The widespread occurrence of carbonate rocks in the geologic record is attributable to the following factors:

1. CO_2 gas has a relatively high solubility in water, higher than molecular oxygen and nitrogen.
2. CO_2 hydrolyzes in water, making the bicarbonate and carbonate anions (discussed in more detail in section "CO_2-Carbonic Acid-Carbonate System and Seawater") that react with divalent and monovalent metals.
3. Among the divalent cations, calcium combined with the carbonate anion makes a solid of low solubility.

Calcium is the fifth and carbon the 15th most abundant elements in the Earth's crust, and their presence in natural waters accounts for the formation of mineral $CaCO_3$ by inorganic and biogenic processes in many environments.

Twenty-seven carbonate minerals are listed in Table 1 to provide the reader with an appreciation of the wide variety of minerals in this mineral group. In terms of their abundance, calcites with Mg in their structure ($Ca_{1-x}Mg_xCO_3$) and aragonite ($CaCO_3$) are more abundant in the extant younger sedimentary mass, whereas dolomite and nearly pure calcite are more abundant in the geologically older sequences. Figure 1 shows the mass of calcite and dolomite in the preserved sedimentary carbonate mass. A long-standing and unresolved geologic problem is how much of the extant dolomite in the sedimentary record is of primary origin, that is, a direct precipitate from seawater, and how much is secondary formed from alteration of calcite and aragonite. Some scientists have proposed that both the calcite/dolomite preserved mass distribution and the original composition of inorganic and biogenic calcite and aragonite phases have varied cyclically during the Phanerozoic (the past 545 Ma) reflecting major changes in seawater composition during this eon (see, e.g., Mackenzie and Andersson 2013).

Ca-carbonates are primarily inorganic and biogenic products of the marine environment. $CaCO_3$ is a first precipitate in an evaporative sequence of seawater, and later precipitates are Na and K chlorides and sulfates. In continental waters, however, the anions HCO_3^- and CO_3^{2-} are usually more abundant than Cl^- and SO_4^{2-}, and the minerals precipitating are the various carbonates of Na, as shown in Table 1. Much of the information in this article is based on the books by Morse and Mackenzie (1990), Mackenzie and Lerman (2006), and Mackenzie and Andersson (2013).

CO_2-Carbonic Acid-Carbonate System and Seawater

This section presents some of the basic physical-chemical relationships relevant to understanding the behavior of CO_2 in aqueous solution in the Earth's surface environments. Readers are referred to the books by Broecker and Peng (1982), Morse and Mackenzie (1990), Mackenzie and Lerman (2006), Zeebe and Wolf-Gladrow (2001), and Millero (2013) for a detailed development of the subject material.

***Dissolution and Dissociation of CO_2 in Water*:** Dissolution of carbon dioxide in water is the first step that enables photosynthetic production of organic matter in aqueous environments, precipitation of carbonate minerals from aqueous solutions, and chemical weathering of the Earth's crust and sediments. Carbon dioxide dissolves in water and reacts with it producing negatively charged bicarbonate and carbonate ions. In pure water the electrical charges are balanced by the hydrogen ion or in natural or experimental more complex aqueous solutions by other metal cations and the hydrogen ion. Dissolution and dissociation of the gaseous species $CO_2(g)$ in water are represented by the following reactions:

$$CO_{2(g)} = CO_{2(aq)} \quad (1)$$

$$CO_{2(aq)} + H_2O_{(l)} = H_2CO_{3(aq)} \quad (2)$$

$$H_2CO_{3(aq)} = H^+_{(aq)} + HCO_{3\,(aq)} \quad (3)$$

$$HCO_3{}^-_{(aq)} = H^+_{(aq)} + CO_3{}^{2+}_{(aq)} \quad (4)$$

Carbonate Minerals and the CO_2-Carbonic Acid System, Table 1 Carbonate minerals[a,b]

	Mineral	Composition	Occurrence[b]
1	Calcite	$Ca_{1-x}Mg_xCO_3$, $0 \leq x \leq 0.25$	A major rock-forming mineral in sedimentary environments. Calcite is a common constituent of sedimentary rocks, limestone in particular, much of which is formed from the shells of dead marine organisms. Approximately 10% of sedimentary rock is limestone. Calcite is the primary mineral in metamorphic marble. It also occurs as a vein mineral in deposits from hot springs, and it occurs in caverns as stalactites and stalagmites. Calcite may also be found in volcanic or mantle-derived rocks such as carbonatites, kimberlites, or rarely in peridotites. Calcite is often the primary constituent of the shells of marine organisms, e.g., plankton (such as coccoliths and planktonic foraminifera), the hard parts of red algae, some sponges, brachiopods, echinoderms, some serpulids, most bryozoa, and parts of the shells of some bivalves (such as oysters and rudists) The largest documented single crystal of calcite originated from Iceland, measured 7 × 7 × 2 m and 6 × 6 × 3 m and weighed about 250 t
2	Aragonite	$CaCO_3$	Aragonite is the high pressure polymorph of calcium carbonate. As such, it occurs in high pressure metamorphic rocks such as those formed at subduction zones. Aragonite and calcite precipitate in hot springs as travertine deposits. Aragonite forms naturally in almost all mollusk shells, and as the calcareous endoskeleton of warm- and cold-water corals (Scleractinia). Several serpulids have aragonitic tubes. In some mollusks, such as pteropods, the entire shell is aragonite; in others, aragonite forms only discrete parts of a bimineralic shell (aragonite plus calcite). The nacreous layer of the aragonite fossil shells of some extinct ammonites forms an iridescent material called ammolite. Aragonite also forms in the ocean and in caves as inorganic precipitates called marine cements and speleothems, respectively. Aragonite is not uncommon in serpentinites where high Mg in pore solutions apparently inhibits calcite growth and promotes aragonite precipitation
3	Vaterite	$CaCO_3$	Vaterite occurs in mineral springs, organic tissue, gallstones, and urinary calculi. Vaterite can be produced as the first mineral deposits repairing natural or experimentally induced shell damage in some aragonite-shelled mollusks (e.g., gastropods). Subsequent shell deposition occurs as aragonite
4	Ikaite	$CaCO_3 \cdot 6H_2O$	At the Ikka Fjord, Greenland, Ikaite, occurs in spectacular towers growing out of the fjord floor toward the surface water, where they are naturally truncated by waves. The Ikaite towers are created as the result of a groundwater seep, rich in carbonate and bicarbonate ions, entering the fjord bottom. Ikaite has also been reported as occurring in high-latitude marine sediments in Antarctica, Sea of Okhotsk, and Saanich Inlet, British Columbia, Canada. In addition it has been reported in a deep sea fan off the Congo. The most recent occurrence has been reported by Dieckmann et al. (2008). Ikaite directly precipitates in sea ice in the Weddell Sea and throughout fast ice off Adélie Land, Antarctica
5	Monohydrocalcite	$CaCO_3 \cdot H_2O$	Monohydrocalcite has been observed in air conditioning systems, and in moonmilk deposits in caves, both probably formed from spray of carbonate-rich fluids. It is well known in Robe on the Limestone Coast of South Australia as a component of beach sands of Lake Fellmongery and Lake Butler, where it is believed to be formed from algal spume. Other lacustrine deposits include Lake Issyk-Kul, Lake Kivu, and Solar Lake, Sinai
6	Magnesite	$MgCO_3$	Magnesite occurs as veins in and an alteration product of ultramafic rocks, serpentinite, and other magnesium-rich rock types in both contact and regional metamorphic terrains. Magnesite is also present within the regolith above ultramafic rocks as a secondary carbonate within soil and subsoil, where it is deposited as a consequence of dissolution of magnesium-bearing minerals by carbon dioxide within groundwater
7	Barringtonite	$MgCO_3 \cdot 2H_2O$	Found with nesquehonite on the surfaces of olivine basalts
8	Nesquehonite	$MgCO_3 \cdot 3H_2O$	Bases of stalactites and incrustations, the remainder of which consisted of lansfordite. Anthracite coal deposit
9	Lansfordite	$MgCO_3 \cdot 5H_2O$	Small stalactites attached to carbonaceous shale
10	Pokrovskite	$MgCO_3 \cdot Mg(OH)_2 \cdot 0.5H_2O$	Alteration of ultramafic bodies of dunite and serpentinite
11	Artinite	$MgCO_3 \cdot Mg(OH)_2 \cdot 3H_2O$	Artinite is found along with hydromagnesite and other minerals as a low-temperature alteration product as veinlets or crusts in serpentinized ultrabasic rocks
12	Hydromagnesite	$4MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O$	Associated with the weathering products of magnesium containing minerals such as serpentine or brucite. It occurs as incrustations and vein or fracture fillings in ultramafic rocks and serpentinites. It occurs in hydrothermally altered dolomite and marble. It commonly appears in caves as speleothems and "moonmilk," deposited from water that has seeped through magnesium-rich rocks. It is the most common cave carbonate after calcite and aragonite
	Giorgiosite	$4MgCO_3 \cdot Mg(OH)_2 \cdot 4–6H_2O$	In white powdery crusts on lava

(*continued*)

Carbonate Minerals and the CO_2-Carbonic Acid System, Table 1 (continued)

	Mineral	Composition	Occurrence[b]
13	Dypingite	$4MgCO_3{\cdot}Mg(OH)_2{\cdot}5H_2O$	Alteration product in serpentines
14	Strontianite	$SrCO_3$	Strontianite is an uncommon low-temperature hydrothermal mineral formed in veins in limestone, marl, and chalk, and in geodes and concretions. It occurs rarely in hydrothermal metallic veins but is common in carbonatites
15	Witherite	$BaCO_3$	Witherite forms in low-temperature hydrothermal environments
16	Siderite	$FeCO_3$	Siderite is commonly found in hydrothermal veins and is associated with barite, fluorite, galena, and others. It is also a common diagenetic mineral in shales and sandstones, where it sometimes forms concretions, which can encase three-dimensionally preserved fossils. In sedimentary rocks, siderite commonly forms at shallow burial depths and its elemental composition is often related to the depositional environment of the enclosing sediments https://en.wikipedia.org/wiki/Lagoon
17	Dolomite	$CaMg(CO_3)_2$ or $Ca_{0.5}Mg_{0.5}CO_3$	A major sedimentary rock-forming mineral. Modern dolomite formation has been found to occur under anaerobic conditions in supersaturated saline lagoons. Vast deposits of dolomite are present in the geological record, but the mineral is relatively rare in modern environments
18	Ankerite	$Ca(Fe,Mg)(CO_3)_2$	Ankerite occurs with siderite in metamorphosed ironstones and sedimentary banded iron formations. It also occurs in carbonatites. In sediments it occurs as authigenic, diagenetic minerals and as a product of hydrothermal deposition
19	Natron	$Na_2CO_3{\cdot}10H_2O$	Geologically, the mineral natron and the historical natron are formed as transpiro-evaporite minerals, i.e., crystallizing during the drying up of salt lakes rich in sodium carbonate. The sodium carbonate is usually formed by absorption of carbon dioxide from the atmosphere by a highly alkaline, sodium-rich lake brine. Pure deposits of sodium carbonate decahydrate are rare, due to the limited temperature stability of this compound and due to the fact that the absorption of carbon dioxide usually produces mixtures of bicarbonate and carbonate in solution
20		$Na_2CO_3{\cdot}7H_2O$	*No known occurrences in nature*
21	Thermonatrite	$Na_2CO_3{\cdot}H_2O$	As efflorescences on soil in arid regions and in saline lakes
22	Natrite	Na_2CO_3	Locally abundant in deep drill holes in pegmatites occurring in differentiated alkaline massifs, in sodalite xenoliths associated with an intrusive alkalic gabbro-syenite complex
23	Nahcolite	$NaHCO_3$	In lava tunnels. It occurs as a hot spring and saline lake precipitate or efflorescence, in differentiated alkalic massifs, in fluid inclusions as a daughter mineral phase, and in evaporite deposits
24	Wegscheiderite	$Na_2CO_3{\cdot}3NaHCO_3$	As a replacement of trona in a lacustrine deposit. Lacustrine deposits
25	Trona	$Na_2CO_3{\cdot}NaHCO_3{\cdot}2H_2O$	Trona is found in alkaline saline lakes. Trona also occurs in magmatic environments, where it forms by autometasomatic reactions of late-magmatic fluids or supercritical fluid-melt mixtures with earlier crystallized rocks
26	Pirssonite	$Na_2CO_3{\cdot}CaCO_3{\cdot}2H_2O$	Lacustrine clay beds. In oil shales; in sediments of a salt pan
27	Gaylussite	$Na_2CO_3{\cdot}CaCO_3{\cdot}5H_2O$	Forms as an evaporite from alkali lacustrine waters. Also occurs rarely as veinlets in alkalic igneous rocks

[a]Morse and Mackenzie (1990), Mackenzie and Andersson (2013), Railsback (2002)
[b]Anthony et al. (1997–2003), Mindat (1993–2016), and Wikipedia articles by mineral name https://en.wikipedia.org/wiki/[mineralname]

Although aqueous uncharged CO_2 can include the species $H_2CO_{3(aq)}$, this species constitutes only a small fraction, about 1/400, of CO_2 in solution. As such the use of either $CO_{2(aq)}$ or $H_2CO_{3(aq)}$ for all of the aqueous species CO_2 is acceptable without a loss of meaning or accuracy (Millero 2013).

For each of the mass action Eqs. 1, 2, 3, and 4, one can write a thermodynamic equilibrium constant, using H_2CO_3* to represent both undissociated aqueous carbon species in solution – $H_2CO_{3(aq)}$ and $CO_{2(aq)}$ – which have values at 25 °C and 1 atm total pressure as follows (Morse and Mackenzie 1990):

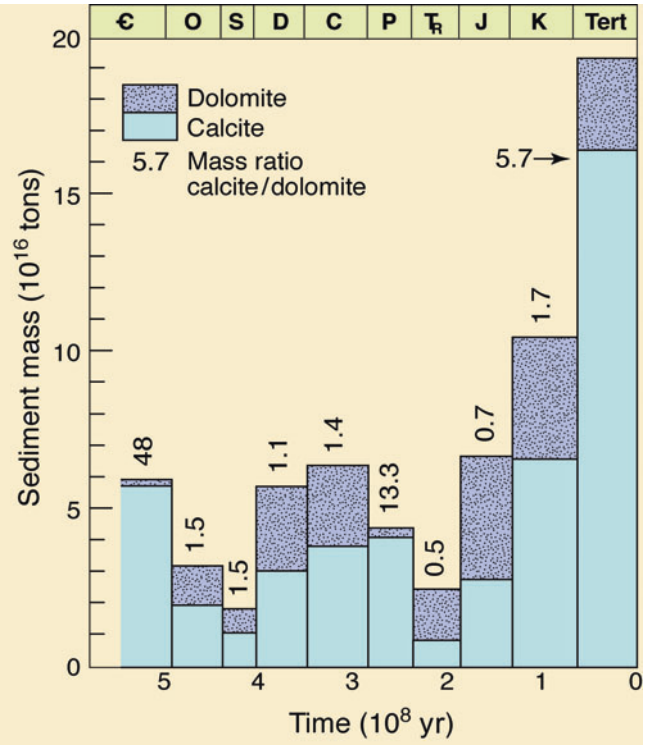
$$K_o = \{H_2CO_3^*\}/P_{CO2} = 10^{-1.47} \quad (5)$$

$$K_1 = \{H^+\}\{HCO_3^-\}/\{H_2CO_3^*\} = 10^{-6.34} \quad (6)$$

$$K_2 = \{H^+\}\{CO_3^{2-}\}/\{HCO_3^-\} = 10^{-10.33} \quad (7)$$

where curly brackets designate thermodynamic activities of the chemical species (dimensionless quantities), and P_{CO2} is the partial pressure of CO_2, taken as an ideal gas and replacing its fugacity that is also dimensionless. The activities are also denoted as, for example, a_{H^+}, for the activity of the hydrogen ion, and a_{ion} for other species.

The activities of aqueous species and solids are referred to a standard state, chosen as a normal temperature and pressure



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 1 Period-averaged preserved (extant) mass distribution of calcite and dolomite and mass ratio of calcite/dolomite through Phanerozoic time (After Mackenzie and Morse (1992))

(NTP) of 25 °C and 1 atm pressure, usually replaced by 298 K and 1 bar. Pure solids and solutes have an activity of 1 in a standard state. For solutes it is a 1 m (molal) solution, such that at infinite dilution the activity coefficient of the solute is equal to one. Thus, mass action equations written in terms of equilibrium constants are expressed as activities of the chemical species of interest and are a function of only pressure and temperature.

Because of the difficulties in determining the values of activity coefficients in seawater or compositional modifications of such, another standard state has been developed, that of the composition of seawater at the salinity $S = 35‰$ (g dissolved solids in 1 kg of solution; however, S in seawater is now taken as a dimensionless number because it is measured using a salinometer, which is based on electrical conductivity), 25 °C, and 1 atm total pressure. Thus for calculations of seawater CO_2-carbonic acid system chemistry, "apparent" or stoichiometric constants have been adopted and these vary with pressure, temperature, *and* composition (salinity). In seawater the mass action equations and the CO_2-carbonic acid system stoichiometric equilibrium constants (K-primes) have a similar formulation as the thermodynamic constants, but the expressions are written in terms of the concentrations of the dissolved inorganic carbon chemical species, have different values, and are functions of salinity as well as temperature and pressure. As an example, for an average seawater salinity of 35‰ and at a temperature of 25 °C and a total pressure of 1 bar (= ~1 atm), the stoichiometric constants and their values corresponding to Eqs. 5, 6, and 7 are Morse and Mackenzie (1990)

$$K'_0 = [H_2CO_3^*]/P_{CO2} = 2.84 \times 10^{-2} \quad (8)$$

$$K'_1 = [H^+][HCO_3]/[H_2CO_3^*] = 1.39 \times 10^{-6} \quad (9)$$

$$K'_2 = [H^+][CO_3^{2}]/[HCO_3] = 1.19 \times 10^{-9} \quad (10)$$

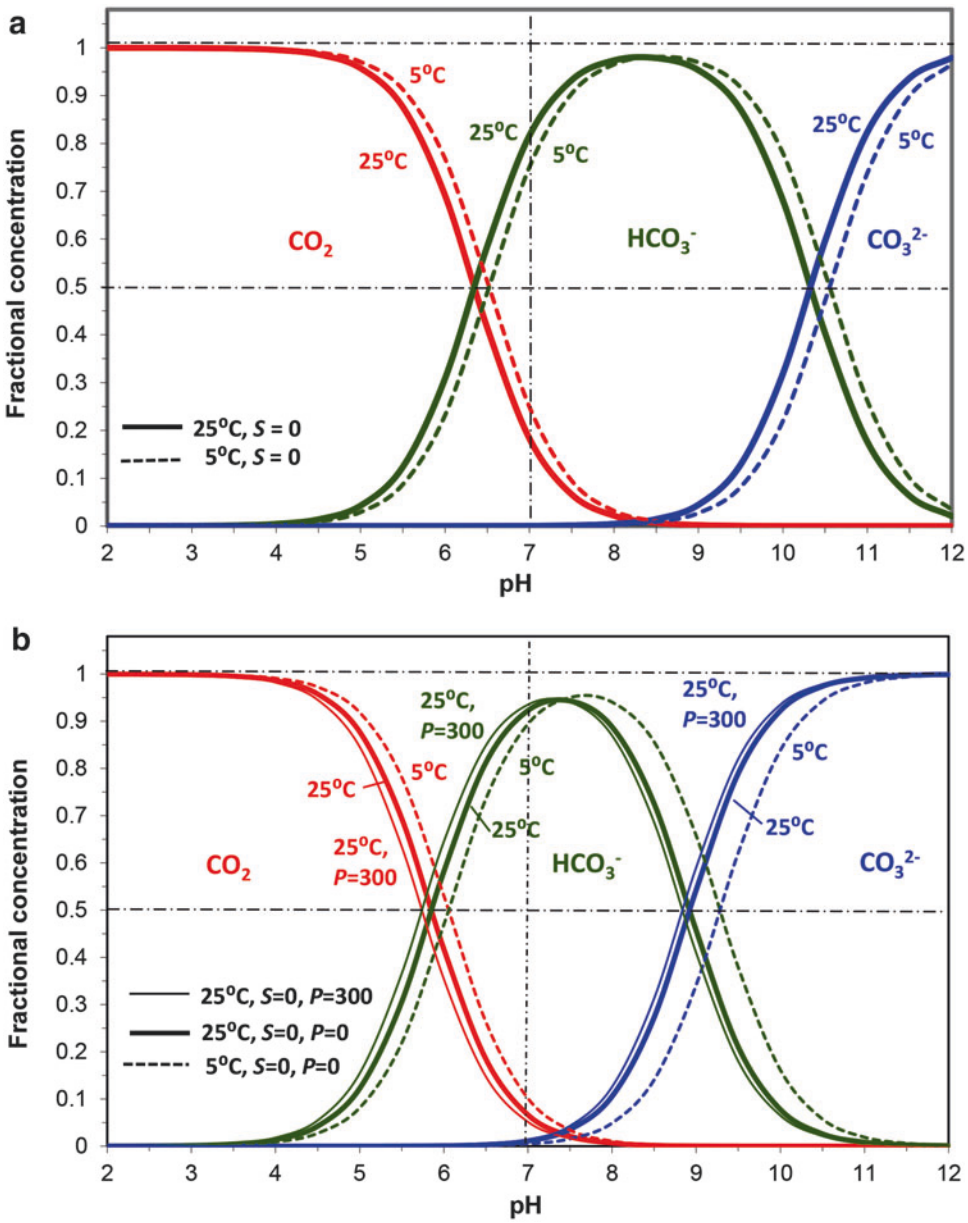
where brackets denote concentrations of the chemical species in mol per 1 kg seawater.

***Dissolved Inorganic Carbon*:** Because of the formation of the aqueous ions HCO_3^- and CO_3^{2-} from CO_2 in solution, the total concentration of dissolved inorganic carbon is the sum of all the inorganic carbon species, $CO_{2(aq)}$, HCO_3^-, and CO_3^{2-}. This parameter is termed dissolved inorganic carbon, to distinguish it from dissolved organic compounds, and it is usually denoted as ΣCO_2 or DIC:

$$DIC = CO_{2(aq)} + HCO_3^- + CO_3^{2-}. \quad (11)$$

The relative distribution of DIC chemical species is commonly shown as a function of pH in a plot known as a Bjerrum diagram (Fig. 2). The individual values of the three fractions of DIC (CO_2 plus H_2CO_3 as CO_2, HCO_3^- and CO_3^{2-}) are shown in the figure for different sets of conditions, as a function of the solution pH, between pH = 2 and 12, at two temperatures of 5 and 25 °C, and 1 bar total pressure and for seawater $S = 35‰$ and 1 and 300 bar total pressure. In a very dilute solution of zero ionic strength (Fig. 2a), HCO_3^- is the dominant DIC species over the pH range from roughly 6.5 to slightly more than 10. This is the range in pH of many natural waters. In addition, in dilute waters, lower temperature favors relatively higher concentrations of undissociated CO_2 and lower concentrations of the carbonate anion, CO_3^{2-}; that is, the equal concentration points of 50% shift to the left, toward lower pH values.

The effects of salt concentration and pressure on the distribution of the dissolved carbon species are shown in Fig. 2b. Notice first that HCO_3^- is still by far the dominant species in seawater over its pH range of slightly above 7 (deep ocean waters) to slightly above 8 (surface ocean waters). In addition, at 5 and 25 °C, the effect of a mean seawater salinity of 35‰ on the abundance of the various DIC species is pronounced: from a dilute solution of salinity 0–35‰, the abundance of the bicarbonate ion, HCO_3^-,



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 2 Bjerrum diagram showing (**a**) Fractional concentrations of dissolved inorganic carbon species in pure water (salinity $S = 0‰$) as a function of pH at 5 ° and 25 °C. (**b**) Fractional concentrations of dissolved inorganic carbon species in seawater ($S = 35‰$) at 5 and 25 °C at atmospheric pressure, and at a pressure of 300 bar (After Mackenzie and Lerman (2006))

decreases at the expense of the other two species of $CO_{2(aq)}$ and CO_3^{2-}. However, the effect of pressure is small at a mean ocean water salinity of 35‰: a total pressure increase from atmospheric to 300 bars of pressure has only a small effect on the shift in the relative abundance of the DIC chemical species.

***Total Alkalinity*:** One other variable of the CO_2-carbonic acid system that is important to seawater carbon chemistry is that of total alkalinity. For seawater, the difference between the charges of the conservative cations and anions is equal to the algebraic sum of the charges of the H^+-dependent ions, and this difference is called the total alkalinity of the solution, denoted [TA]:

$$2[Ca^{2+}] + 2[Mg^{2+}] + [Na^+] + [K^+] - [Cl^-] - 2[SO_4^{2-}] = [HCO_3^-] + 2[CO_3^{2-}] + [B(OH)_4^-] + [OH^-] - [H^+] \quad (12)$$

and for the major species in seawater that contribute to the total alkalinity:

$$[TA] = [HCO_3^-] + 2[CO_3^{2-}] + [B(OH)_4^-] + [OH^-] - [H^+]. \quad (13)$$

The determination of TA and DIC in ocean waters is a powerful tool to use to trace water masses in the ocean and to obtain estimates of primary productivity and the dissolution

and precipitation of carbonate minerals. Also if the values of these two variables are known, the pH and pCO_2 of seawater can be calculated. Alternatively, the pH can be measured in solution instead of being calculated.

Saturation State: It is also possible to write reactions and equilibrium constants for the solution (dissolution) and precipitation of minerals in aqueous solutions. The carbonate minerals are especially important minerals found in the ocean as the skeletons and tests of marine organisms and as cements in marine sediments. Calcite (hexagonal $CaCO_3$), aragonite (orthorhombic $CaCO_3$), and dolomite [hexagonal $CaMg(CO_3)_2$] are important marine minerals. The latter mineral is not found in great abundance in modern environmental settings, but it is an important carbonate mineral found in ancient rocks deposited in the marine environment (Fig. 1). The mass action equation for both calcite and aragonite is written

$$CaCO_3 = Ca^{2+} + CO_3{}^{2-}, \tag{14}$$

and at 25 °C and 1 atm total pressure, the thermodynamic equilibrium constants are

$$K_{cal} = \left\{Ca^{2+}\right\}\left\{CO_3{}^{2-}\right\} = 10^{-8.46} \tag{15}$$

and

$$K_{arag} = \left\{Ca^{2+}\right\}\left\{CO_3{}^{2-}\right\} = 10^{-8.3} \tag{16}$$

and in seawater of $S = 35‰$ under the same P and T conditions

$$K'_{cal} = \left[Ca^{2+}\right]\left[CO_3{}^{2-}\right] = 10^{-6.37} \tag{17}$$

and

$$K'_{arag} = \left[Ca^{2+}\right]\left[CO_3{}^{2-}\right] = 10^{-6.19}. \tag{18}$$

Despite the two minerals having the same composition, they differ in their atomic structure, and thus the K values for the two minerals differ. These K values basically represent the solubilities of the two minerals. The larger K value for aragonite than for calcite implies that aragonite is a more soluble mineral than calcite and is unstable relative to calcite under the environmental conditions specified above. However for these minerals to dissolve, the aqueous solution in which the minerals are bathed must be undersaturated with respect to the two minerals. This implies that the product of the activities or concentrations of Ca^{2+} and $CO_3{}^{2,-}$, termed the ion activity product (*IAP*) or ion concentration product (*ICP*), respectively, in the solution must be smaller than the K values for the minerals; that is, the ratio of *IAP/K* or *ICP/K′* must be <1. In general, in a solution at equilibrium, $\Omega = 1$:

$$\Omega = IAP/K \text{or } ICP/K' = 1 \text{ at saturation.} \tag{19}$$

In a supersaturated solution $\Omega > 1$, and in an undersaturated solution, $\Omega < 1$.

Both calcite and aragonite contain other elements in minor or trace amounts, and this affects their solubilities. Strontium is especially important in aragonite and magnesium in calcite. Indeed Mg can be so plentiful in biogenically and inorganically produced calcite that a special term has been applied to the calcites containing more than about 4 wt.% Mg, the magnesian calcites, that generally have greater solubilities than pure calcite, and for some magnesian calcite compositions, even than aragonite. The general mass action equation and thermodynamic equilibrium constant for calcites with Mg in them is written as

$$Ca_{(1-x)}Mg_x(CO_3) = (1-x)Ca^{2+} + xMg^{2+} + CO_3{}^{2-} \tag{20}$$

and

$$K_{Mg-calcite} = \left\{Ca^{2+}\right\}^{(1-x)}\left\{Mg^{2+}\right\}^{(x)}\left\{CO_3{}^{2-}\right\} \tag{21}$$

where x is the mole fraction of $MgCO_3$.

For dolomite the mass action equation is

$$CaMg(CO_3)_2 = Ca^{2+} + Mg^{2+} + 2CO_3{}^{2-} \tag{22}$$

and

$$K_{dol} = \left\{Ca^{2+}\right\}\left\{Mg^{2+}\right\}\left\{CO_3{}^{2-}\right\}^2 = \sim 10^{-17}. \tag{23}$$

To our knowledge the K', that is, the stoichiometric constant, for dolomite has never been determined experimentally in seawater because of the difficulty in doing experiments involving this phase at low temperatures due to its slow reactivity in aqueous solution.

Thermodynamic and Thermophysical Data for Major Carbonate Minerals

This section discusses a number of fundamental thermophysical and thermodynamic data for the major sedimentary carbonate minerals calcite, aragonite, dolomite, and magnesite that are germane to their occurrences on Earth. Table 2 gives the molecular mass of each mineral, its molar volume, and density at ambient conditions (25 °C and 1 atm total pressure, rounded to 298 K and 1 bar). Also given are the coefficients of volume expansion as a function of temperature $\alpha_V = (1/V)(\partial V/\partial T)_P$ K^{-1}, and the coefficient of isothermal compressibility $\beta_T = -(1/V)(\partial V/\partial P)_T$ bar^{-1}.

[i]Bass (1995, p. 49)

The coefficient of adiabatic compressibility in Table 2 $\beta_{ad} = -(1/V)(\partial V/\partial P)_{ad}$ is related to β_T by the relationship $\beta_{ad} = \beta_T C_V/C_P$ bar^{-1}, where C_V and C_P are heat capacities of the mineral at constant volume and pressure, respectively, in J mol K^{-1}. Heat capacities at constant pressure, C_P, are given in Table 3 for different temperatures. Heat capacity at constant volume, C_V, is calculated from the thermodynamic relationship $C_P - C_V = TV\alpha_V{}^2/\beta_T$, where all the parameters are as defined above, and the ratios C_P/C_V for each mineral at different temperatures are given in Table 3.

The essential thermodynamic data that are needed for computation of mineral equilibria above the standard conditions of $T = 298$ K and $P = 1$ bar are summarized in Table 3 for temperatures from 298 to 900 K at 1 bar total pressure. The Gibbs standard free energy of formation of a mineral is designated $\Delta G_{T,1}$ (kJ/mol) and molar volume is $V_{T,1} = V_{0,1}[1 + \alpha_V(T - 298)]$($cm^3$/mol), where the coefficient of thermal expansion α is given in Table 3.

The equilibrium constant of a reaction, log K, is defined in terms of the Gibbs standard free energy change for the reaction, $\Delta G_{r\,T,1} = \Delta G_{T,1}$ (products) – $\Delta G_{T,1}$ (reactants), as

$$\log K_{T,P=1} = -\frac{\Delta G_{rT,1}}{2.3RT} \tag{24}$$

where ΔG in kJ mol^{-1} and $R = 8.314 \times 10^{-3}$ kJ mol^{-1} K^{-1}.

For solids at higher pressures, by integration of Eq. 24,

$$\log K_{T,P} - \log K_{T,1} = -\frac{\Delta V_{rT,1}(P-1)}{2.3RT} \tag{25}$$

where the values of $V_{T,1}$ of the individual minerals are given in Table 3, P is pressure in bars, and the gas constant $R = 83.14$ cm^3 bar mol^{-1} K^{-1}. If isothermal compressibility β_T of the reacting phases needs to be taken into account at pressures in the megabar range, then Eqs. 24 and 25 become:

$$\left(\frac{\partial \log K}{\partial P}\right)_T = -\frac{1}{2.3RT}\left(\frac{\partial \Delta G_{rT,1}}{\partial P}\right)_T = -\frac{\Delta V_{rT,1}(1-\beta_T P)}{2.3RT} \tag{26}$$

$$\log K_{T,P} - \log K_{T,1} = -\frac{\Delta V_{rT,1}}{2.3RT}\left((P-1) - \frac{\beta_T(P^2-1)}{2}\right) \tag{27}$$

Carbonate Mineral Stability in the System $CaCO_3$-$MgCO_3$

Determination of the univariant temperature-CO_2 curve for the calcite-dolomite-magnesite system was made by Harker and Tuttle (1955) at high to moderate temperatures and pressures. The order of decomposition with increasing temperature was shown to be magnesite, dolomite, and calcite. The location of the calcite-dolomite and dolomite-magnesite solvi along the $CaCO_3$-$MgCO_3$ binary join (Fig. 3) was established through the collective work of a number of investigators (e.g., Graf and Goldsmith 1955; Goldsmith and Heard 1961). The top of the calcite-dolomite solvus was located by Goldsmith and Heard (1961) at 1,075 °C, giving a composition of $Ca_{0.57.5}Mg_{0.42.5}CO_3$, a slightly calcium-rich phase. Note in Fig. 3 that the composition of calcite in terms of its Mg

Carbonate Minerals and the CO_2-Carbonic Acid System, Table 3 Thermodynamic data for four carbonate minerals at 298.15 $\leq T \leq$ 900 K and $P = 1$ atm ($\approx$1 bar). $\Delta G_{T,1}$ and C_p from Robie and Hemingway (1995). Others as explained in the text

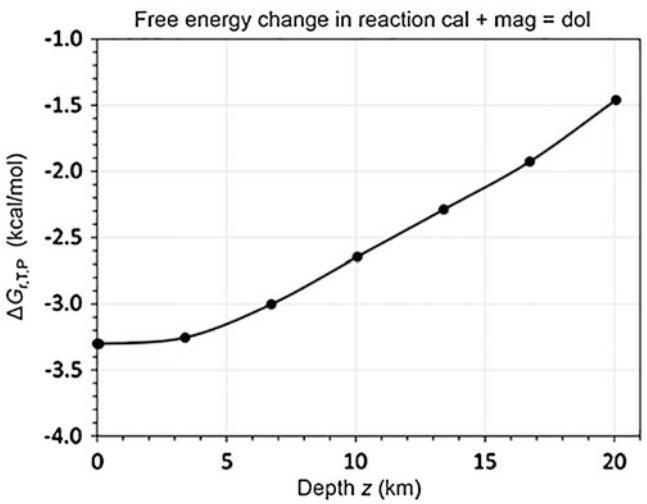
Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 3 Subsolvus relationships for the $CaCO_3$-$MgCO_3$ join. The top of the calcite-dolomite immisibility gap occurs at 1075 ºC. At this temperature, the phase composition is $Ca_{57.5}Mg_{42.5}(CO_3)_2$. *Dotted line* represents limit of detectable ordering in the dolomite structure. *C* calcite, *M* magnesite, and *D* dolomite (After Graf and Goldsmith (1958) and Goldsmith and Heard (1961); figure modified in Mackenzie and Andersson (2013))



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 4 Free energy change of the reaction calcite + magnesite = dolomite with increasing T and P

content at the Earth's surface temperature and pressure in equilibrium with dolomite contains only a couple of mol% Mg in solid solution. All calcites containing more Mg than this are unstable relative to nearly pure calcite $CaCO_3$. Calcium-rich, somewhat disordered dolomite, protodolomite, is commonly found in younger sediments and, with aging of the rock, progressively converts to a stoichiometric dolomite with distinct ordering (Land 1985).

From the Earth's surface and down the *P-T* gradient, dolomite is a more stable phase than calcite and magnesite. This is illustrated in Fig. 4 for the free energy of the reaction

$$CaCO_3 + MgCO_3 = CaMg(CO_3)_2,$$

where the value of $\Delta G_{r\ T,P}$ is <0, indicating that the dolomite phase is more stable than the two reactant phases (data in Table 3).

Stability of the Calcites: Calcites constitute major and very important biogenic and inorganic constituents of modern marine sediments, Pleistocene, and older rocks as skeletal clasts and cements. These phases can contain up to 25 mol% $MgCO_3$, and higher Mg content phases have been produced in the laboratory and observed sparingly in nature. Calcites with more than a few percent $MgCO_3$ are usually referred to as magnesian calcites or magnesium calcites (Mg calcites). Generally, for the same $MgCO_3$ content, calcites comprising the skeletons and tests of organisms have greater concentrations of sodium, sulfate, water, hydroxide, and bicarbonate and tend to have larger cell volumes and greater carbonate anion and cation positional disorder in their structure than natural or synthetic mineral phases. Chemical and microstructural heterogeneities especially characterize biogenic magnesian calcites, and dislocations and plane defects are common in their crystals. All of these characteristics may affect the thermodynamic and kinetic properties and reactivity of these phases in aqueous solution.

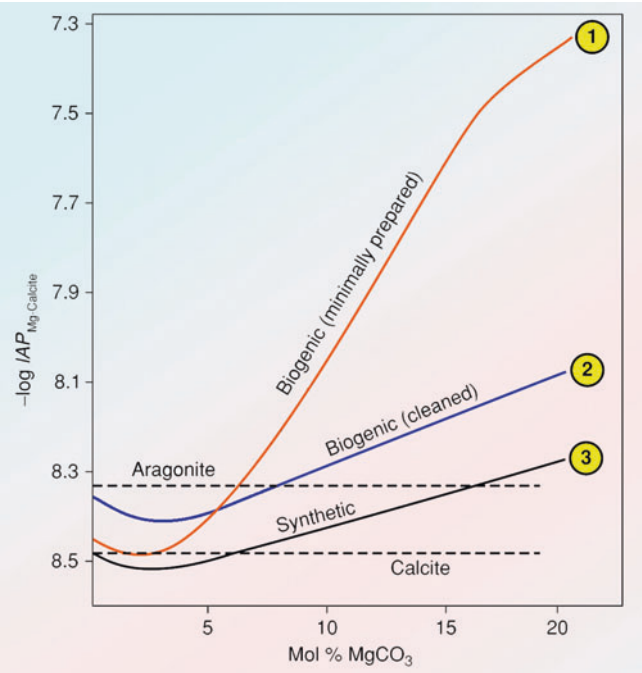
The solubility of calcites depends on their $MgCO_3$ content, in addition to other chemical constituents, and environmental parameters. The solubility of calcites can be expressed as a function of their $MgCO_3$ content and the ion activity product (*IAP*) of a solution in equilibrium with the solid (Plummer and Mackenzie 1974):

$$Ca_{1-x}Mg_xCO_3 = (1-x)Ca^{2+} + xMg^{2+} + CO_3{}^{2-} \quad (28)$$

$$IAP_{\text{calcite}} = K_{sp} = \{Ca^{2+}\}^{1-x}\{Mg^{2+}\}^{x}\{CO_3{}^{2-}\}, \quad (29)$$

where curly brackets in the latter expression denote the *activities* of the ions in aqueous solution, x is the mole fraction of $MgCO_3$ in the solid, and K_{sp} is the solubility product. For pure calcite, the mole fraction of $MgCO_3$ is zero. The generalized trend in solubility with $MgCO_3$ content of calcite phases at 25 °C and 1 atm total pressure appears reasonably well defined (Fig. 5) owing to the work of Plummer and Mackenzie (1974), Thorstenson and Plummer (1977), Walter and Morse (1984), Bischoff et al. (1987, 1993), and Busenburg and Plummer (1989). Bertram et al. (1991) have made estimates of the change in solubility with temperature demonstrating that as with pure calcite, the magnesian calcites have retrograde solubility (solubility decreases with increasing temperature).

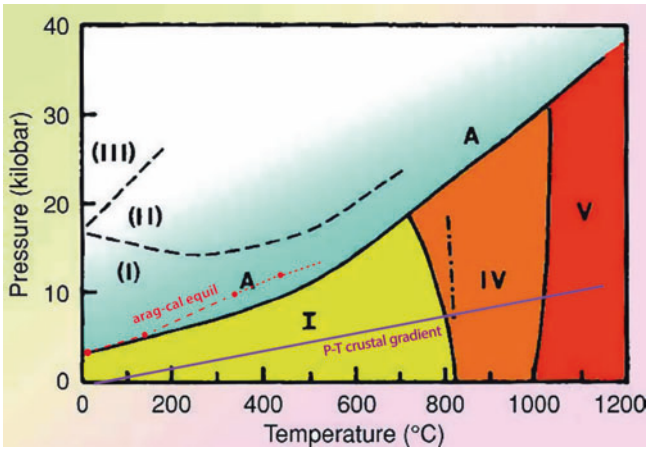
The *thermodynamic solubility product* of pure calcite at 25 °C and 1 atm is about $10^{-8.46}$. The solubilities of the compositions of other calcites with Mg in them expressed in terms of IAP exhibit a minimum of around two mole percent $MgCO_3$, beyond which their solubility increases nearly linearly with increasing $MgCO_3$ content. There appear to be three recognizable trends in the solubility-composition data: one for abiotic solids that are well crystallized, compositionally homogeneous, and chemically pure (Fig. 5, curve 3), and the other for biogenic phases and abiotic solids that exhibit substantial lattice defects, carbonate positional disorder, and substitution of such foreign ions as sulfate and sodium (Fig. 5, curve 2). The third solubility-composition curve is that of Plummer and Mackenzie (1974) for biogenic materials subjected to minimal cleaning procedures in the laboratory before use in dissolution experiments designed to determine the solubilities of these phases (Fig. 5, curve 1). This curve may best reflect the effective solubility of the biogenic magnesian calcites in nature as a function of $MgCO_3$ content. It is this latter curve that is most used by scientists today when they report the saturation state of an aqueous solution with respect to a Mg-calcite composition.



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 5 Solubility of the magnesian calcites as a function of the $MgCO_3$ in the phase. See text for further explanation (After Bischoff et al. (1993); figure modified in Mackenzie and Andersson (2013))

Biogenic and some abiotic calcites are unstable in aqueous solutions relative to synthetic phases of similar $MgCO_3$ content. Their solubilities differ by roughly 0.15 pIAP units (pIAP = −log IAP), or about 4.6 kJ mol^{-1} (1.1 kcal mol^{-1}). This difference arises because of physical and chemical differences between the two types of solids. The complex microarchitecture, greater positional disorder of the $CO_3{}^{2-}$ anion group, and chemical impurity of the biogenic phases and some biogenic calcites result in higher solubilities of these solids. It is likely that the solubility-composition curve 3 for pure, compositionally homogeneous, and structurally well-ordered calcite phases represents the true metastable equilibrium solubility of magnesian calcites in aqueous solution at 25 °C and 1 atm.

Stability of Aragonite: The most abundant naturally occurring orthorhombic carbonate is aragonite, the dimorph of calcite. At near Earth surface pressure and temperature, aragonite is found as the biogenic component of many common invertebrate skeletons, as sediments derived from the physical and biological disintegration and erosion of these skeletons, as cements in modern marine sediments and Neogene limestones, in some carbonate cave deposits and travertine precipitated by hot springs, and often as a replacement mineral in igneous and metamorphic rocks and ore deposits (Speer 1983; Table 1). Although aragonite has larger cation sites, the phase is denser than calcite and hence is stable relative to calcite at elevated pressure and temperature (Fig. 6). The solubility product of aragonite at 25 °C and 1 atm is about $10^{-8.30}$. Aragonites exhibit only limited solid solution, primarily with Pb and Sr. Plumbian aragonites with up to 2.5 mol% are common, and strontian aragonites occurring in hot springs may contain up to 14 mol% $SrCO_3$ (Speer 1983). The limited solid solution of Sr is of importance because of the fact that the degree of



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 6 Stability fields of aragonite and different polymorphs of calcite as a function of temperature and pressure. *A* aragonite, *I* through IV: calcite polymorphs with metastable fields shown by parentheses; *dash-dot line* at 800°C represents aragonite-calcite transition encountered on experimental cooling runs; *solid line* at lower temperature represents transition encountered on experimental heating runs (After Carlson (1980); figure modified in Mackenzie and Andersson (2013)). Calcite is the stable phase along the *P-T* gradient in Earth's crust. An equilibrium between aragonite and calcite, as shown by the *red dashed line*, would require pressures higher than those along the *P-T* gradient

solid solution varies among different groups of organisms having aragonitic shells, and the Sr content of some skeletal species has been used to obtain the Sr/Ca ratio or the temperature of the water from which the organism precipitated its skeleton.

Because aragonite is unstable relative to calcite at near Earth surface pressures and temperatures, with time and changes in environmental conditions, such as exposure to meteoric waters or burial in the subsurface, abiotic and biogenic aragonite can be converted to calcite or dolomite. Thus the original texture of the aragonite can be altered and the chemical and isotopic information contained in the phase lost. Rocks older than Neogene contain very little aragonite because of diagenetic reactions that lead to leaching of the components of the phase from the rock or its recrystallization to another mineral. Scant aragonite has been found in rocks as old as Pennsylvanian in age. The recrystallization process can lead to a loss of information concerning the environment of formation of a biogenic or abiotic aragonitic precipitate.

Stability of Dolomite: The mineral dolomite is a major constituent of especially ancient carbonate rocks. Dolomite was named in honor of Dieudonné Dolomieu (also known as Déodat Dolomieu), a geologist who worked in the Pyrenees and Alps in the eighteenth century and first described the mineral's characteristics and occurrence. Dolomite is distinguished from calcite and the other rhombohedral carbonates by its stoichiometry. Ideal dolomite has equal numbers of Ca and Mg atoms, and the Ca and Mg are segregated in distinct lattice planes. These planes are oriented normal to the *c*-axis, each alternating with *c*-normal trigonal CO_3 groups that are also in essentially planar orientation. For geologists, dolomite has been the center of an unending debate regarding its mode of formation in surface environments, its past abundance relative to other sedimentary carbonates, and its overall significance in the geologic record (e.g., Land 1985; Machel and Mountjoy 1986; Hardie 1987; McKenzie 1991; Mackenzie and Morse 1992; McKenzie and Vasconcelos 2009). The stability relations for dolomite in the $CaCO_3$-$MgCO_3$ system are shown in Fig. 4. In many aqueous solutions, including seawater, the solution is found to be oversaturated with respect to dolomite, but the phase does not spontaneously precipitate. This conundrum is probably at least in part a result of the kinetics of the dolomite precipitation reaction, which are very slow due to the difficulty in forming such a well-ordered phase from solution at near Earth surface *T* and *P*. Arvidson and Mackenzie (1997, 1999) have shown experimentally that increases in temperature and saturation state of a solution with respect to dolomite increase the rate of precipitation of dolomite. Field data tend to support the experimental observations since most unequivocal *primary* dolomite forming in the modern marine environment and that which is observed in the rock record has formed from compositionally modified seawater solutions with higher dolomite saturation states and at warmer temperatures than the global mean average of today.

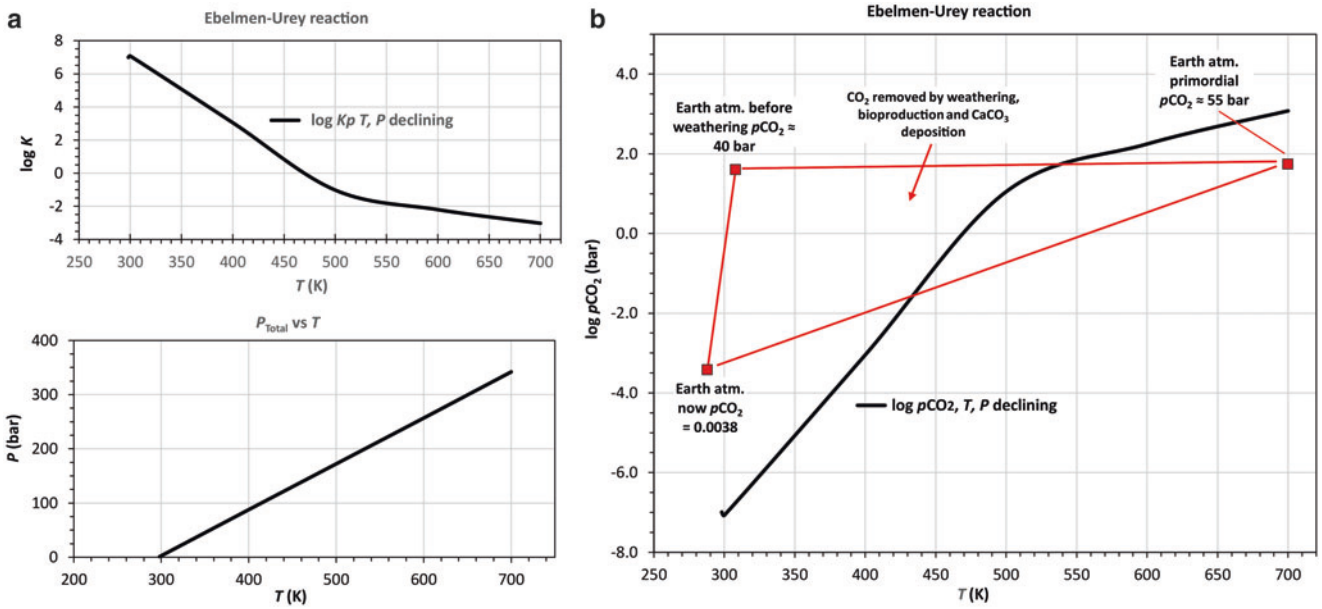
Importance of Reaction of Calcium Silicate, Calcium Carbonate, and CO_2 in Earth History

The connection between the world of silicate minerals in the Earth's igneous crust and the sedimentary carbonates is represented by the reaction

$$CaSiO_3 + CO_2 = CaCO_3 + SiO_2, \qquad (30)$$

where $CaSiO_3$ is a shorthand notation for the silicate minerals containing the 1st (O), 2nd (Si), and 5th (Ca) most abundant elements by mass in the Earth's crust, CO_2 is gas, and the products are solid calcite and amorphous silica which recrystallizes to quartz with time. The reaction was introduced by Urey (1952), and it was known as the Urey reaction until Berner and Maasch (1996) produced evidence that the chemist and mining engineer Jacques-Joseph Ebelmen thought of this reaction in 1845–1847. Since then, the name has been deservedly changed to the Ebelmen-Urey reaction.

After the Earth had formed and was still hot, all the volatiles occurred as gases in the primordial atmosphere at about 700 K – above the critical temperature of water of 647.14 K and other gases, atmospheric pressure was 342 bar, comprising mostly H_2O, CO_2, N_2, HCl, and H_2S



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 7 (**a**) log K of reaction (30) at decreasing T (K), and P (bar). (**b**) Model decrease of atmospheric pressure P (bar) with decreasing temperature T (K). (**c**) p_{CO_2} from Eq. 31 calculated for atmospheric pressure P (bar) and T (K) decreasing as shown in (**b**). The triangular section of CO_2 decrease on the cooling Earth from Mackenzie and Lerman (2006)

(Mackenzie and Lerman 2006). As the Earth cooled, water condensed to liquid, and CO_2 and other gases dissolved in the primordial ocean. Subsequently, the weathering reactions, deposition of limestone, and biological production and burial of organic matter have further reduced the atmospheric CO_2 content. Two paths of the depletion of the atmosphere in CO_2 are schematically shown in Fig. 7 where they are compared to p_{CO_2} from the equilibrium constants of reaction (30):

$$\log K_{T,P} = \frac{a_{CaCO_3}\, a_{SiO_2}}{a_{CaSiO_3}\, p_{CO_2}} \tag{31}$$

where a are the activities of pure solids ($a > 1$ at $P > 1$ bar) and p_{CO2} is partial pressure of CO_2 ideal gas.

Log $K_{T,P}$ for reaction (30) at the T and P values of the crustal geothermal-geobaric gradient were computed from the data of Robie and Hemingway (1995), such as those cited in Table 3. For solids $CaSiO_3$ (wollastonite), $CaCO_3$ (calcite), and SiO_2 (glass), the molar volume change in the reaction, $\Delta V_{solid,T,P}$ is as given in (Eq. 27), using α_V (K^{-1}) and β_T (bar^{-1}) from Table 3. At the highest point of $T = 700$ K and $P = 342$ bar, the solid activities are: $a_{CaSiO_3} = 1.27, a_{CaCO_3} = 1.25$, and $a_{SiO_2} = 1.17$. For the solids, the volume change of the reaction is small, $\Delta V_{solids\ T,P} = 24$–$25$ cm^3 mol^{-1}. Much bigger volume change is associated with the reactant CO_2 that decreases from 24,666 cm^3 mol^{-1} at 298.15 K, 1 bar, to 178 cm^3 mol^{-1} at 700 K, 342 bar (NIST 2016). The equilibrium constant at a higher pressure is

$$\log K_{T,P} = \log K_{T,P=1} - \left(\frac{V_{sil} + V_{cal} - V_{wol} - V_{CO_2}}{2.303RT}\right)_{T,P} \times (P-1) \tag{32}$$

where V (cm^3 mol^{-1}) is molar volume at the temperature and pressure shown and gas constant $R = 83.14$ cm^3 bar mol^{-1} K^{-1}.

The relationships in Fig. 7c indicate that p_{CO_2} in the earlier Earth's atmosphere was lower than the equilibrium value of reaction (30–32) at the temperature above about 550 K. As the Earth cooled below 530–430 K, the equilibrium value of p_{CO_2} should be smaller that the atmospheric value. Under these conditions reaction (30) could be driven to the right and Ca-silicate converted to carbonate.

Accretion of the Earth, according to different models, might have lasted about 40 million years (Hanks and Anderson 1969; Wood et al. 2006). If life on Earth existed as early as 3.9 billion years B.P., the temperature of the atmosphere was likely to be below 50 °C or 325 K. This would imply that 325 K in Fig. 7c was reached some 600 million years after Earth's accretion, and most of the removal of atmospheric CO_2 by biological production and $CaCO_3$ formation occurred over a very long time stretch of Earth's history. In all, in the course of Earth's history 2.85×10^{20} kg CO_2 were removed

Carbonate Minerals and the CO_2-Carbonic Acid System, Table 4 Precipitation and dissolution rates of three major carbonate minerals

Precipitation $R_p = k_p(\Omega - 1)^n$ (Zhong and Mucci 1989)	Rate constant (k) (μmol m–2 h − 1)	Reaction order (n)
1. Calcite	$10^{-0.20}$	2.80
2. 15 mol% Mg-calcite	$10^{-0.20}$	2.80
3. Aragonite	$10^{1.00}$	2.36
Dissolution $R_d = k_d(1 - \Omega)^n$ (Walter and Morse 1985)	Rate constant (k) (μmol g–1 h−1)	
5. Calcite	$10^{2.82}$	2.86
6. 15 mol% Mg-calcite	$10^{2.62}$	3.34
7. Aragonite	$10^{2.89}$	2.48

from the atmosphere, leaving there 0.001% of the original mass, including the anthropogenic additions.

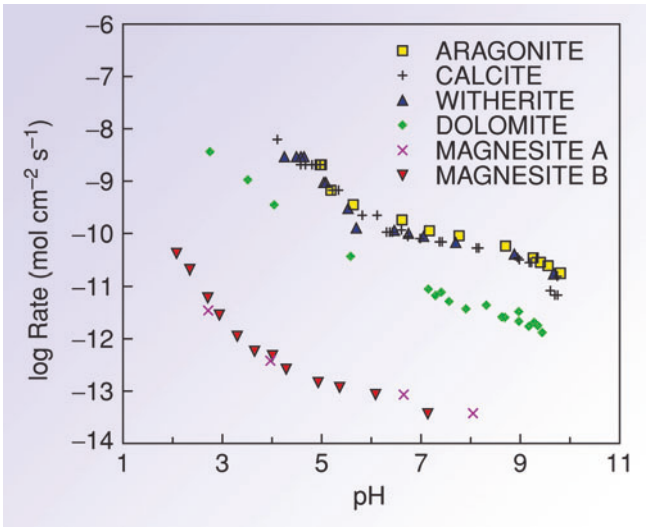
Carbonate Mineral Dissolution and Precipitation Rates

The relationships between the dissolution (R_d) and precipitation (R_p) rates of calcite, Mg-calcite, and aragonite at 25 °C in seawater are summarized in Table 4.

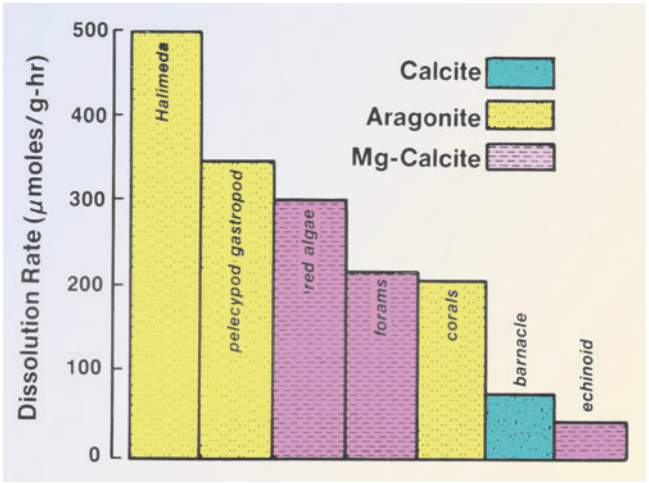
The dissolution rate is also a function of the pH. When a mineral dissolves in a partly closed system, such as in sediment pore water, of initially $\Omega < 1$, the solution can approach $\Omega = 1$ as dissolution progresses and the dissolution rate slows down. Mean dissolution rate $\overline{R}_d$ in the interval between the initial $\Omega < 1$ and final $\Omega = 1$ is:

$$\overline{R}_d = \frac{1}{1-\Omega}\int_{\Omega}^{1} k(1-\Omega')^n d\Omega' = \frac{k(1-\Omega)^n}{n+1} \quad \mu\text{mol g}^{-1}\text{h}^{-1} \tag{33}$$

The rates of dissolution of several carbonate minerals at 25 °C as function of pH are shown in Fig. 8. It should be noted that the rates are a strong function of pH, and that aragonite has the fastest dissolution rate and magnesite the slowest. There is also a considerable variation in the dissolution rate of the biogenic $CaCO_3$ phases (Fig. 9). The taxonomic nature of the carbonate-secreting organism evidently affects the crystal structure of the skeleton and hence its dissolution rate. Even though red algae particles of a Mg-calcite composition of ~20 mol% $MgCO_3$ are more soluble than the aragonitic green algal *Halimeda* sp., the rate of dissolution of the *Halimeda* is about 67% faster than that of the red algae. Pickett and Anderrson (2015) studied the dissolution rates of various biogenic Mg calcites in natural seawater at elevated pCO_2 values. They found that the rates increased with increasing Mg content, and that the relative dissolution rates were observed to be a function of both Mg content and



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 8 Logarithmic rates of dissolution of several important carbonate minerals in distilled water at 25 °C and 1 atm as a function of pH. Notice the slower rates of dissolution for dolomite and especially magnesite. Also that aragonite dissolves faster than calcite (After Chou et al. (1989); figure modified in Mackenzie and Andersson (2013))



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 9 Dissolution rates of disintegrated skeletons of various marine organisms of different carbonate mineralogies (After Walter and Morse (1985); figure modified in Mackenzie and Andersson (2013))

microstructure (surface area). Measured rates of dissolution increased with increasing pCO_2 treatment for all substrates and ranged from 2.5 to 18 umol g^{-1} h^{-1}.

CO_2-Carbonic Acid-Carbonate System of Ocean Waters

Discussion of the CO_2-carbonic acid-carbonate system of seawater is a treatise in itself (see, e.g., Broecker and Peng

1982; Andersson 2014). Here we look at two important aspects of the system in ocean water so the reader can gain an impression of the variables involved and their distribution and an appreciation of application of knowledge of the system to a major environmental problem, that of ocean acidification (OA).

Saturation State of Central Pacific Ocean Water Column: Surface ocean water is generally supersaturated with respect to the minerals aragonite and calcite ($CaCO_3$). Deeper-ocean waters are undersaturated with respect to aragonite and calcite, and the saturation depth is shallower for aragonite than that for calcite because aragonite is more soluble and hence $K'_{arag} > K'_{cal}$. The decrease in the degree of saturation with increasing depth is primarily due to an increase in CO_2 concentration due to bacterial decomposition of sinking organic matter and concomitant decrease in the CO_3^{2-}-ion concentration at the lower temperature of deep water and an increase in the value of K'_{cal} and K'_{arag} with increasing pressure. The depth where supersaturation changes to undersaturation varies among the major oceans (deepest in the Atlantic, shallower in the Indian, and shallowest in the Pacific oceans) and with latitude and location within an ocean (Broecker and Peng 1982; Morse and Mackenzie 1990).

Figure 10 shows generalized depth profiles of temperature, calcite and aragonite saturation states, dissolved inorganic carbon (DIC), total alkalinity, and dissolved calcium in waters of the Central Pacific. Notice the rapid decline with increasing depth of the degree of saturation of ocean water with respect to aragonite and calcite down to a depth of about 500 m and then the slow but steady decline to greater depths (Fig. 10b). The saturation depth of the more soluble aragonite is at about 500 m and that of calcite is at 3,000 m. The undersaturation of ocean waters at depth with respect to carbonate phases (Fig. 10b) accounts for the dissolution of $CaCO_3$ particles settling from the surface ocean layer and the return of calcium and total alkalinity to solution in this pump-like process. The increase in DIC with depth is mainly due to the microbial-mediated oxidation of organic matter sinking through the water column and at greater depth, the dissolution of $CaCO_3$.

It is of interest at this point to obtain a feel for how fast $CaCO_3$ dissolves in ocean waters and how quickly a hypothetical state of carbonate saturation in the oceanic water column might be reached. For the entire 5,500-m water column of Fig. 10, the average values of the degree of saturation are $\Omega_{cal} = 1.5$ and $\Omega_{ar} = 0.95$. However, below the saturation depth of 500 m for aragonite, the picture is very different: $\Omega_{ar} = 0.685$ from 500 to 5,500 m. To raise the degree of saturation with respect to aragonite to $\Omega_{ar} = 1.0$ within this depth range, total alkalinity (TA, Fig. 10c) would have to increase by a factor of 1.5. Equating this increase in TA as due to dissolution of $CaCO_3$ in ocean-floor carbonate sediments, the mass of the dissolved $CaCO_3$ would be 620 kg $CaCO_3/m^2$ or 21 cm/m^2 of solid $CaCO_3$. The mean rate of aragonite dissolution, using Eq. 7 in Table 4 for $\Omega_{ar} = 0.685$ and $\overline{R}_d$ from Eq. 33, is 6.91×10^{-3} kg yr^{-1}. The time to dissolve the mass of aragonite of 620 kg m^{-2} is

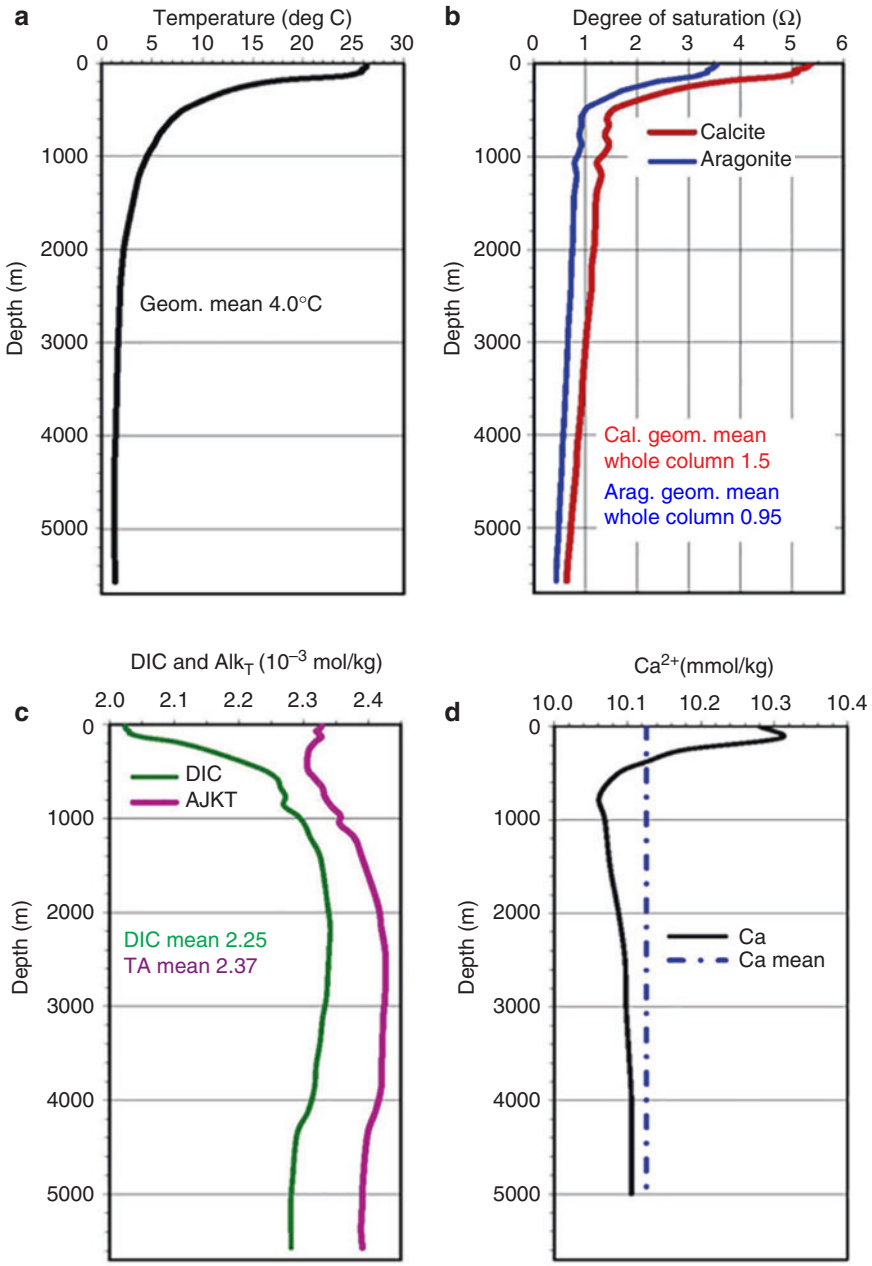
$$t = \frac{\text{Mass } CaCO_3 \text{ dissolved}}{\text{Dissolution rate}} = \frac{620 \text{ kg m}^{-2}}{6.91 \times 10^{-3} \text{kg year}^{-1}} \approx 90,000 \text{ year} \quad (34)$$

The preceding calculation assumes that Ω_{ar} rises in the course of aragonite dissolution from 0.685 to 1. The turnover time of the global ocean is much shorter ≥1,000 years, and this may assure that the undersaturation value is maintained at 0.685, making the dissolution rate in Eq. 33 faster. Therefore the time of dissolution of 620 kg aragonite/m^2 in Eq. 34, needed for the theoretical saturation, would be considerably shorter, about 26,000 years. If the dissolution rates determined in the laboratory (Table 4) hold in the ocean, the mass of $CaCO_3$ that is needed to bring the entire water column to saturation with respect to aragonite would be smaller than, or comparable to, the thickness of $CaCO_3$ deposited over such periods of time at an estimated rate of about 3 cm/10^4 years (Hay et al. 1988).

Ocean Acidification: Carbon dioxide is one of the concentration variables in the definition of DIC, where $DIC = HCO_3^- + CO_3^{2-} + CO_2$ (Eq. 11). CO_2 exchange between surface ocean water and the atmosphere is mainly controlled by the partial pressure difference of gaseous CO_2 between surface waters and the atmosphere and an exchange coefficient that is mainly a function of wind speed. Carbon dioxide is naturally exchanged between seawater and the atmosphere by physical factors and biological productivity that draws down CO_2 and respiration that produces CO_2, determining whether surface seawater acts as a source or sink of CO_2. Prior to the eighteenth century, the oceans appear to have been a net source of CO_2 that eventually was consumed in plant productivity on land (Lerman et al. 2011; Mackenzie et al. 2011). With the burning of fossil fuels of coal, oil, and gas and land use changes (mainly deforestation), the situation was reversed. CO_2 emissions to the atmosphere from these anthropogenic activities led to accumulation of CO_2 in the atmosphere, and in the early part of the twenty-first century, storage of 26% of the anthropogenic CO_2 emissions in ocean waters (Fig. 11). This has led to the second problem of anthropogenic CO_2 emissions – the first being global climate change – that of ocean acidification (OA).

As CO_2 from anthropogenic emissions of CO_2 have been absorbed by ocean waters, the pH has decreased, and consequently the CO_3^{2-}anion has decreased in concentration leading to a reduction in the carbonate saturation state of surface seawater:

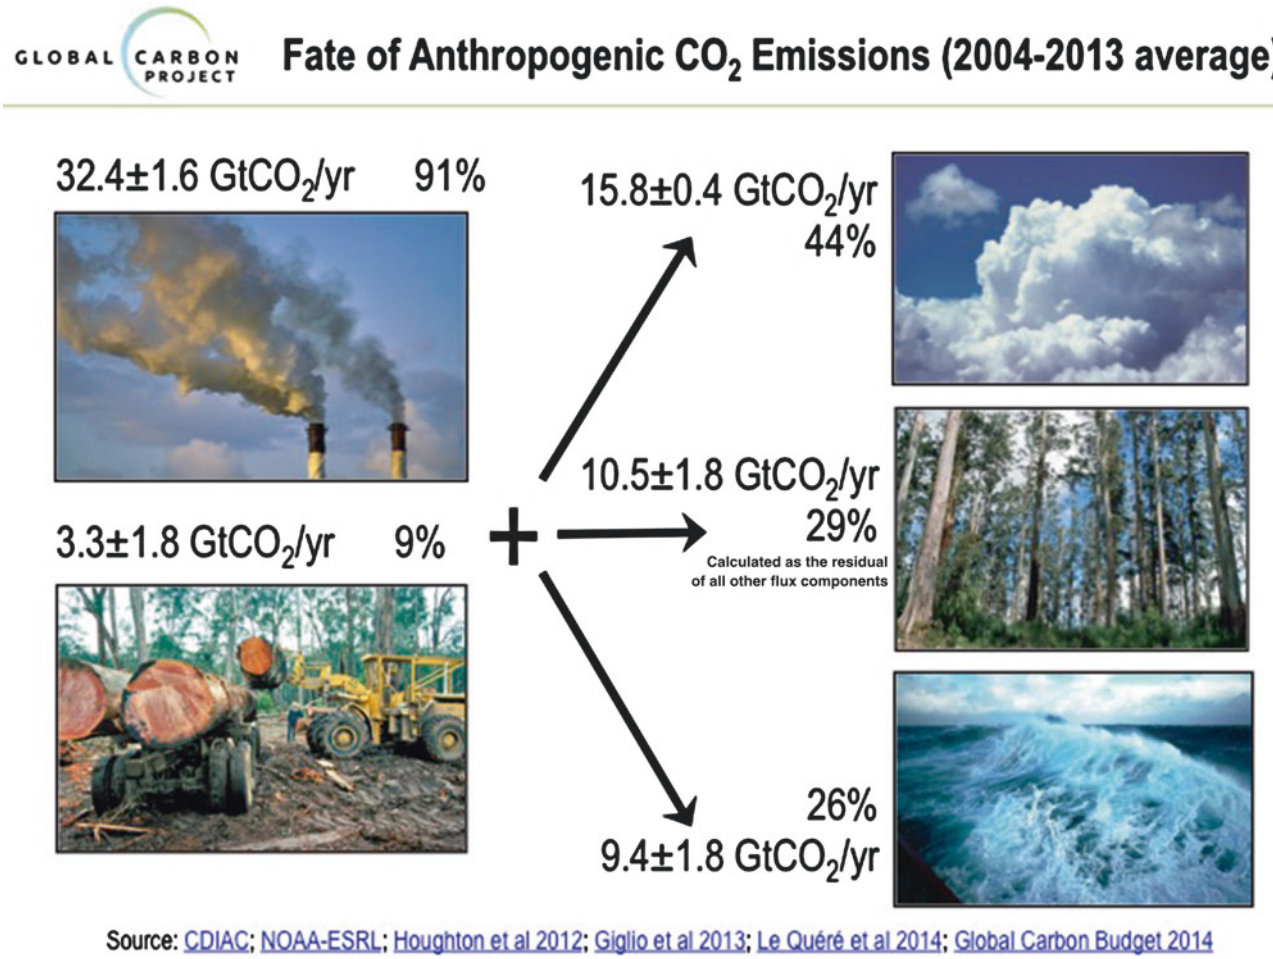
$$2CO_2 + CO_3^{2-} + 2H_2O = 3HCO_3^- + H^+ \quad (35)$$



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 10 Central Equatorial Pacific, W168.75°, S0° (WOCE Section P15S/14S, NOAA CGC-96, 6 March 1996, http://cdiac.ornl.gov/oceans/RepeatSections/clivar_p15s.html). Water depths calculated from pressure (Chapman 2006). (**a**) Temperature. (**b**) Degree of calcite and aragonite saturation (Ω) from *T*-*S*-*P* and carbonate-system parameters (Zeebe and Wolf-Gladrow 2001). (**c**) Dissolved inorganic carbon (DIC) and total alkalinity (TA). (**d**) Ca^{2+} concentration

Figure 12 shows the depth to which anthropogenic CO_2 has penetrated the oceans integrated over the time period 1800–1994. Notice in particular the "hot spot" of penetration in the high North Atlantic where North Atlantic deep water forms and sinks.

Experimental work and direct observations (e.g., Sabine et al. 2004; references in the legend of Fig. 11) have shown that lowering of the pH of seawater decreases the rate of calcification of a skeletal organism. This has been observed for pelagic and benthic foraminifera, coralline red algae, and of most concern, hermatypic corals, among others. In a world affected by OA, there is much concern for coral reefs and other carbonate ecosystems of the world as skeletal organisms' ability to calcify will be diminished. Also, with lowered seawater pH, particles produced by the disintegration of organism shells and tests will be more susceptible to dissolution in the more acidic seawater. It is possible that because of these two effects of anthropogenic CO_2 uptake by surface ocean waters, coral reefs will cease to accrete, and there will be net loss of $CaCO_3$ from their structural edifices. This implies potential loss of these structures as refuges for fish, barriers to storm surges, sources of beach sand, and an aesthetic environment for all to appreciate.



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 11 Fate of anthropogenic CO_2 emissions from the fossil fuels of coal, oil, and gas and that of land use changes (deforestation). The sinks are the atmosphere, ocean waters, and by difference the land. Fossil-fuels have a lower $^{13}C/^{12}C$ ratio than CO_2 in the preindustrial atmosphere and their emissions dilute it (After Le Quere et al. (2015); see "Isotopes in Carbonates in Interpretation of Earth History" section)

Isotopes in Carbonates in Interpretation of Earth History

The heavier isotopes of an element are usually more abundant than the light ones (with the exception of ^{11}B and ^{7}Li among the common elements). Isotope concentrations in different materials are denoted as abundance ratios, $R = {}^{\text{heavy}}X/{}^{\text{light}}X$, in a sample relative to the ratio in a standard as

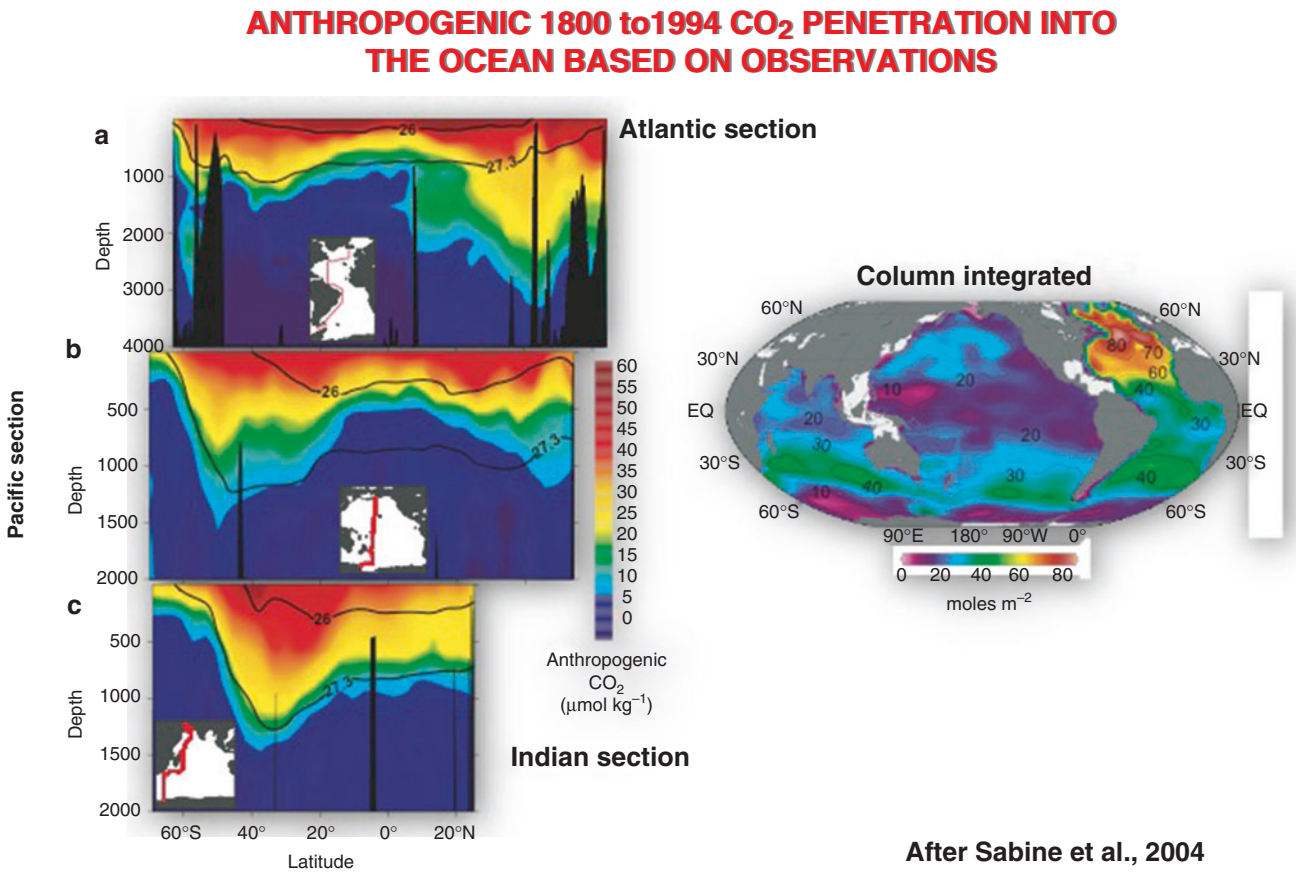
$$\delta X = \left(\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1\right) \times 1000 \quad (‰)$$

For details of the notation of the isotope abundance, the reader may refer to such textbooks as Faure and Mensing (2004). An equilibrium constant of an isotope exchange reaction between two phases, X_1 and X_2, is usually denoted

$$\alpha_{1-2} = \frac{1 + \delta X_1}{1 + \delta X_2}$$

$$\ln \alpha_{1-2} = \ln \frac{1 + \delta X_1}{1 + \delta X_2} \approx \delta X_1 - \delta X_2$$

and the quantity $1000\ \ln\alpha_{1-2}$ is the fractionation factor of the isotope ratio $R = {}^{\text{heavy}}X/{}^{\text{light}}X$ between phases 1 and 2. Of the main components of $(Ca, Mg)CO_3$, calcium (atomic number $Z = 20$) has seven naturally occurring isotopes, one radioactive cosmogenic ^{41}Ca of half-life



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 12 Anthropogenic CO_2 penetration into the world's oceans from 1800 to 1994. Notice in particular the deep penetration and amount of anthropogenic carbon in waters of the region where the North Atlantic deep water forms and sinks (After Sabine et al. (2004))

Carbonate Minerals and the CO_2-Carbonic Acid System, Table 5 Stable isotopes of Ca, C, O, and Mg and their abundances in atomic %

Mass	% atomic abundance	Mass	% atomic abundance	Mass	% atomic abundance	Mass	% atomic abundance
^{40}Ca	96.941	^{12}C	98.93	^{16}O	99.757	^{24}Mg	78.7
^{42}Ca	0.647	^{13}C	1.07	^{17}O	0.038	^{25}Mg	10.13
^{43}Ca	0.135			^{18}O	0.205	^{26}Mg	11.17
^{44}Ca	2.086						
^{46}Ca	0.004						
^{48}Ca	0.187						

102,000 years, and six stable isotopes. Carbon ($Z = 6$) has two stable and one radioactive ^{14}C of half-life 5,730 years. Oxygen ($Z = 8$) and magnesium ($Z = 12$) each has three Table 5:

The most abundant isotope of calcium, ^{40}Ca, is also produced by decay of ^{40}K (Weatherill 1966). Fantle and Tipper (2014) have shown that for average bulk crustal rocks, the rate of ^{40}Ca addition from the decay of ^{40}K is less than 0.3‰ over 1 billion (10^9) years. Translating the addition rate of ^{40}Ca to Ca in the limestone and dolomite masses in Fig. 1, we use the following data: in carbonate rocks (Fig. 1), calcite makes 4.5×10^{20} and dolomite 2.1×10^{20} kg; mean K concentration in Eastern Kansas limestones of 0.22 wt.% K (Runnels and Schleicher 1956); ^{40}K atomic abundance fraction of K 1.17×10^{-4}; decay half-life of ^{40}K to ^{40}Ca 1.47×10^9 years; and ^{40}Ca atomic abundance fraction of Ca 0.97. Taking the limestones as pure $CaCO_3$ (40.0 wt.% Ca) and dolomites as $CaMg(CO_3)_2$ (21.7 wt.% Ca), the mass of Ca

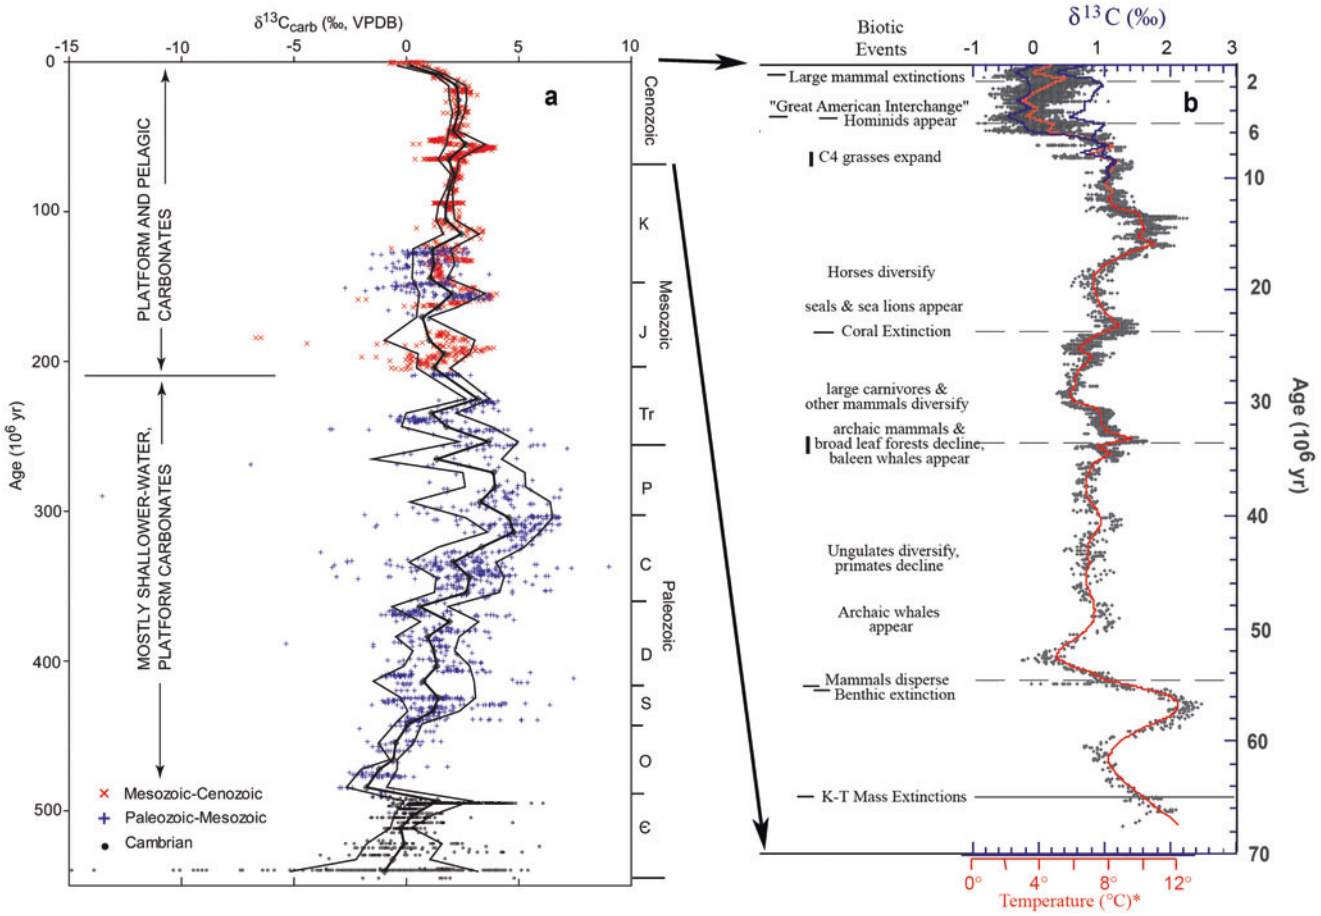
in sedimentary carbonates is 2.24×10^{20} kg. The mass of ^{40}Ca in the carbonate reservoir is

$$\begin{aligned}&\left(2.24 \times 10^{23}\text{g Ca}/40.078\text{g Ca/mol}\right)\\&\quad\times\left(0.969\text{ mol fraction}^{40}\text{Ca}\right)\times\left(39.963\text{ g}^{40}\text{Ca/mol}\right)\\&\quad=2.17\times10^{20}\text{kg}.\end{aligned}$$

The result is that 82,000 kg ^{40}Ca/year are added to 2.17×10^{20} kg ^{40}Ca in the carbonate rocks in the sedimentary record. Thus the residence time of ^{40}Ca in carbonate rocks with respect to its production from $^{40}K - 2.17 \times 10^{20}$ kg/8.24×10^4 kg/year is very long, 2.6×10^{15} years, indicating that a change in the ^{40}Ca isotopic composition of carbonates is insignificant, in the absence of local strong K sources. The fractionation factors of the four isotopic ratios in some natural environments and processes are given in Table 6.

The main goals of studying the isotope fractionation in natural environments is to establish relationships between the fractionation and climate parameters, such as temperature or paleotemperature (Epstein et al. 1951, 1953), partial pressure of atmospheric CO_2, history of seawater, and diagenesis of carbonate sediments (references in Table 6 and others cited therein). The record of $\delta^{13}C$ in Phanerozoic carbonates and Cenozoic carbonates is shown in Fig. 13b. A number of long-term trends can be distinguished in the Phanerozoic (Lerman and Clauer 2007):

- A secular increase in the $\delta^{13}C$ during the 180 Ma from the Ordovician to the Carboniferous-Permian boundary broadly coincides with the emergence of higher plants and massive storage of organic carbon of lower $\delta^{13}C$ as coal in the Carboniferous.
- The next 100 Ma include glaciations of Gondwana near and above the Carboniferous-Permian boundary and a major extinction at the Permian-Triassic transition. This time represents a slightly declining trend, with much scatter, of the carbonate $\delta^{13}C$. However, some detailed $\delta^{13}C$ profiles across the Permian-Triassic boundary have provided internally consistent trends and information for the modeling of changes in atmospheric CO_2 and O_2 at that time (Berner 2006).
- From the Jurassic to the Miocene, a period from about 200 to 20 Ma, there is a slight increase in the $\delta^{13}C$, although it is smaller than an increase in the Paleozoic over a similar length of time. Within the Jurassic to the Miocene data, there are periods of elevated $\delta^{13}C$ values that lasted about 5–10 Ma and shorter periods of $\leq$1 Ma that are associated with oceanic anoxic events (Katz et al. 2005).
- The decrease in the $\delta^{13}C$ of carbonates at least during the last 30 Ma to the present represents a trend that may



Carbonate Minerals and the CO_2-Carbonic Acid System, Fig. 13 (**a**) $\delta^{13}C$ values of Phanerozoic carbonates. Cambrian to Jurassic (*black* • and *blue* +) data from Veizer et al. (1999; courtesy of J. Veizer); Jurassic to Recent (*red* ×) from Katz et al. (2005). VPDB scale. Stratigraphic time scale from Gradstein et al. (2004). *Thick line*: consecutive 10-Ma-interval means (5-Ma in the most recent 10-Ma interval); *thin lines* are ±1 standard deviation (From Lerman and Clauer (2007)). (**b**) $\delta^{13}C$ values of Cenozoic carbonates (Modified from Zachos et al. (2001))

indicate a smaller biological fractionation between the carbonate carbon and organic carbon in the ocean. It has been variably proposed that a greater weathering of old organic matter has increased the delivery of isotopically lighter inorganic carbon forming from the remineralization of ^{13}C-depleted organic matter and it has been, consequently, one cause of the decreasing $\delta^{13}C$ values of marine carbonates. The rise of ^{13}C-enriched terrestrial grasses and the rapid radiation of ^{13}C-enriched diatoms also probably contributed to the depletion of ocean water in ^{13}C and hence to this trend in the carbon isotopes precipitated from the ^{13}C-depleted seawater (Katz et al. 2007). Finally in Fig. 13b, Zachos et al. (2001) relate the changes in $\delta^{13}C$ of the last 65 million years to the important biological, climatic, and orbital changes of the Earth.

Summary

Dissolved CO_2 in aqueous solution in the form of carbonic acid and carbonate ions has played a key role in processes at the Earth's surface over its entire history. Weathering reactions and subsequent precipitation of carbonate sediments together with biological production and burial of organic matter have removed 2.85×10^{20} kg of CO_2 from the atmosphere, leaving there 0.001% of the original mass. Cycling of CO_2 between dissolved forms in the ocean, gaseous form in the atmosphere, and carbonate sediments continues to exert a major control on Earth's climate. Dissolved carbonate exerts a major control on the pH of seawater and other natural waters. Burning of fossil fuels and other anthropogenic activities is increasing the amount of dissolved CO_2 in the ocean and reducing ocean pH,

threatening carbonate-secreting organisms such as corals. Carbonate minerals, primarily calcite and dolomite precipitating from these solutions, constitute the second most abundant class sedimentary rocks.

Cerium

Catherine Chauvel
ISTerre, University Grenoble Alpes, CNRS, Grenoble, France

Element Data
Atomic Symbol: **Ce**
Atomic Number: **58**
Atomic Weight: 140.115 g/mol
Isotopes and Abundances: ^{136}Ce *0.186%*, ^{138}Ce 0.251%, ^{140}Ce 88.449%, and ^{142}Ce 11.114%
1 Atm Melting Point: 795 °C
1 Atm Boiling Point: 3443 °C
Common Valences: +3 and +4
Ionic Radii: 3+: 101 pm, 4+: 87 pm
Pauling Electronegativity: 1.12
(*continued*)

Chondritic (CI) Abundance: 0.6379 ppm
Silicate Earth Abundance: 1.675 ppm
Crustal Abundance: 63 ppm
Seawater Abundance: $\approx 1*10^{-6}$ ppm
Core Abundance: ~0

Properties

Cerium is a reactive and gray metal that tarnishes in air and burns when heated. It usually occurs in substitution to major elements in minerals.

History and Use

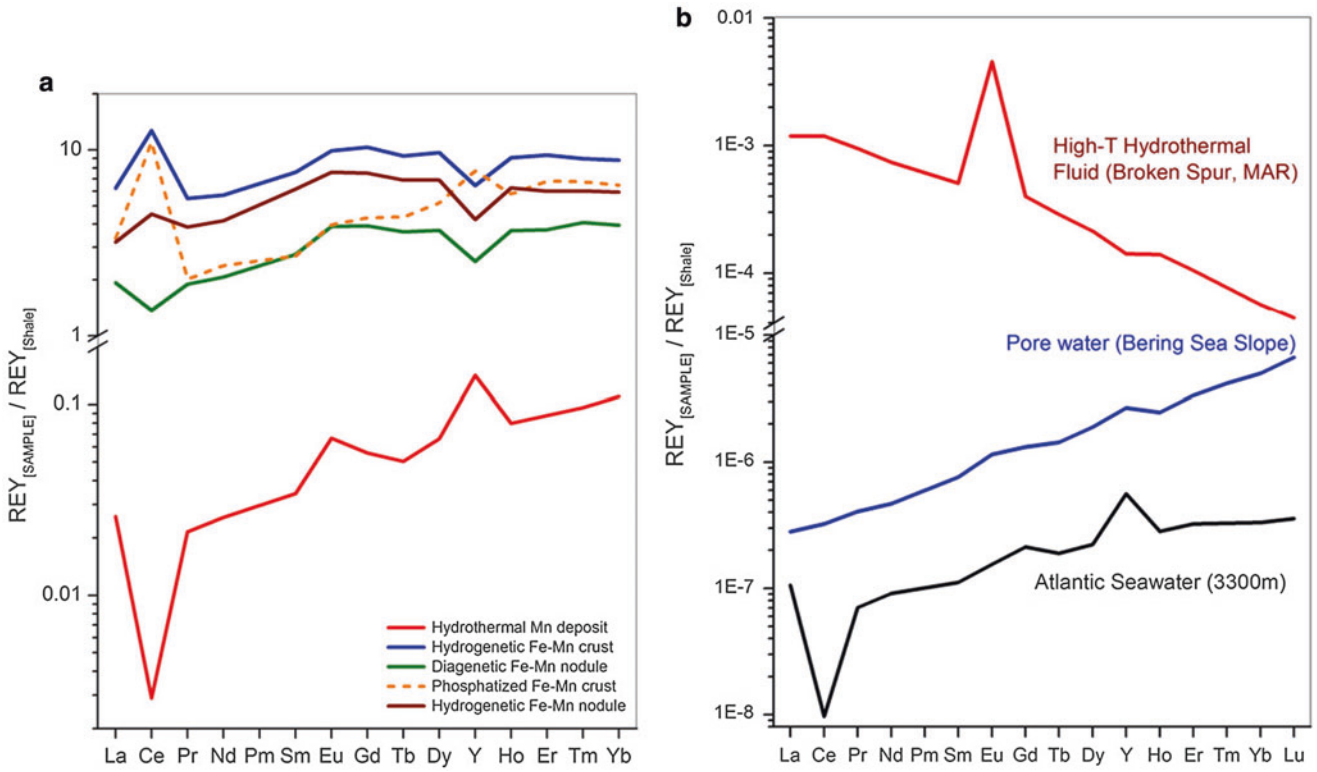
Cerium was discovered in Bastnäs (Sweden) in 1803 by J. J. Berzelius and W. Hissinger and was named after asteroid Ceres. Cerium is the most abundant of the lanthanide metals (also called rare earth elements), a group of 15 similar elements between lanthanum and lutetium in the periodic table and behaves cosmochemically as a refractory lithophile element.

Cerium has been used for a long time in industry: it is a key constituent of lighter flints; it provides special properties to some stainless steels; it is added to some special glasses and it is a key constituent of polishing powders. It is also used in catalytic converters.

Geochemical Behavior

Cerium is the most abundant rare earth element, but it is still rarely a constituent of mineral phases on Earth. Nevertheless, two common REE minerals exist: monazite ((Ce,La,Nd,Th)PO_4) and bastnäsite ((Ce,La,Y)CO_3F). During partial melting and fractional crystallization of magmas, it behaves as an incompatible element and is concentrated in melts. It is therefore enriched in basalts relative to their mantle source and enriched in continental crust relative to Earth's mantle. Together with the other REE, it is widely used in geochemistry to trace geological processes.

In contrast to other REE, Ce can have two valences: in the Earth's interior, it is almost exclusively in the +3 as most REE but can be in the +4 in oxidizing environments at the Earth's surface, and consequently, it can be decoupled from other REE in those environments. The decoupling is quantified as the Ce anomaly (Ce_N/Ce_N^*) with $Ce_N^* = 0.5La_N + 0.5Pr_N$ and all concentrations normalized to a reference reservoir that



Cerium, Fig. 1 Typical patterns of (**a**) marine hydrothermal Fe–Mn deposits, diagenetic Fe–Mn nodules, hydrogenetic Fe–Mn nodules, hydrogenetic Fe–Mn crusts, and phosphatized hydrogenetic Fe–Mn crusts, and (**b**) high-temperature hydrothermal (black-smoker) fluids, seawater, and marine porewater (From Bau et al. (2014) and references therein)

can be the primitive mantle or another reservoir. During supergene weathering in tropical climates, negative cerium anomalies occur in altered soil materials, and precipitation of cerianite ($(Ce,Th)O_2$) leads to the formation of positive anomalies in other soil layers (Cotten et al. 1995). Similarly, seawater is characterized by a strong negative Ce anomaly, while Fe–Mn nodules have positive Ce anomalies (see Fig. 1) (Bau et al. 2014).

Geochronology and Isotope Geochemistry

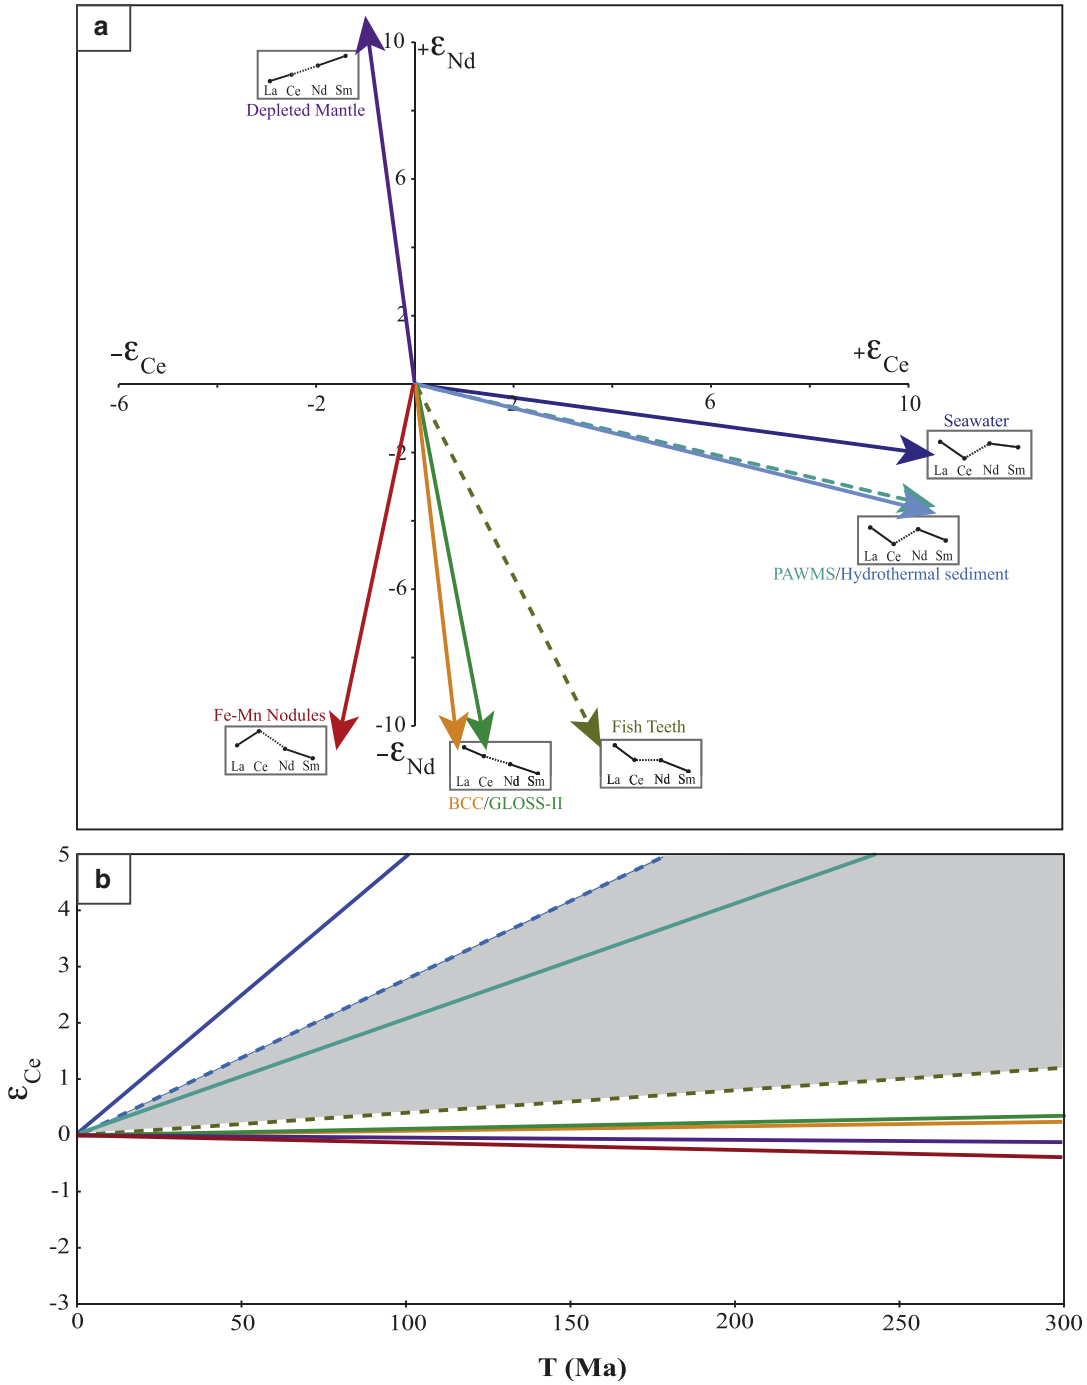
Cerium has four isotopes, and one of them, ^{138}Ce (0.251%), is produced by the radioactive decay of ^{138}La with a half-life of ≈292.5 Ga. Because of the very long half-life and the analytical difficulties related to the low abundance of ^{138}Ce, the decay system has hardly been used in geochronology. However, with the arrival on the market of more precise and accurate mass spectrometers, new perspectives are now open.

In the field of isotope geochemistry, it could be an interesting tool to distinguish the type of sedimentary material involved in the source of island arc volcanic rocks. A pioneer study published by Bellot et al. (2015) demonstrates that coupling Ce and Nd isotopes could help distinguish hydrogenetic deposits from hydrothermal or detrital materials. As shown in Fig. 2, different types of sediment evolve on very different evolutionary paths as time goes past; in addition, distinct Ce isotopic compositions can be acquired within a relative short time (less than 200 Ma), an age that corresponds to the oldest subducted oceanic plate in the Pacific.

Coupled Ce and Nd isotopic studies of planetary materials and of early Earth rocks could also be very interesting because of the constraints it could provide on the nature of the material that accreted to form planets and on the nature of the dominant processes during the early stages of Earth evolution.

Biological Utilization and Toxicity

Cerium has no known biological role and has low to moderate level of toxicity.



Cerium, Fig. 2 Schematic diagram showing the isotopic trajectories of various Earth reservoirs in Ce–Nd isotopic spaces. ε_{Ce} and ε_{Nd} measure the deviation in 10^4 of Ce and Nd isotopic compositions relative to chondritic references (i.e., $\varepsilon_{Ce} = ([^{138}Ce/^{142}Ce]/[^{138}Ce/^{142}Ce_{CHUR}] -1)*10^4$) (See Bellot et al. (2015) and references therein for further details)

Chalcophile Elements

Sarah-Jane Barnes
Sciences de la Terre, Université du Québec à Chicoutimi, Chicoutimi, QC, Canada

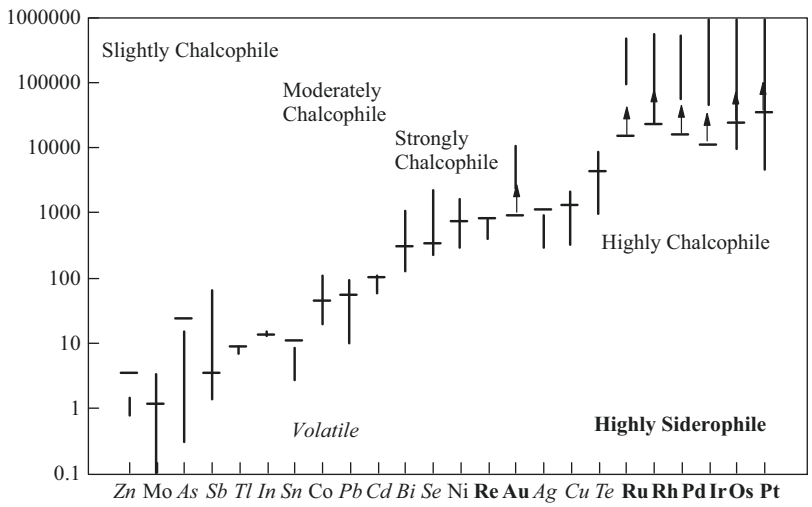
Definition

The term chalcophile (derived from the Greek for copper-loving) was originally introduced by Goldschmidt (1923) to describe the group of elements that are concentrated in sulfide minerals in meteorites. Traditionally this group is defined as the elements Ag, As, Bi, Cd, Cu, Hg, In, Pb, S, Sb, Se, Te, Tl, and Zn. Goldschmidt classified the other elements in meteorites into two groups: those associated with Fe alloy as siderophile (iron loving) and those concentrated in silicates minerals as lithophile (rock loving). Subsequently Goldschmidt applied his classification to the whole Earth and modified it to include two new groups of elements: atmophile, those concentrated in the atmosphere and biophile elements, those concentrated by organic processes (Goldschmidt 1930).

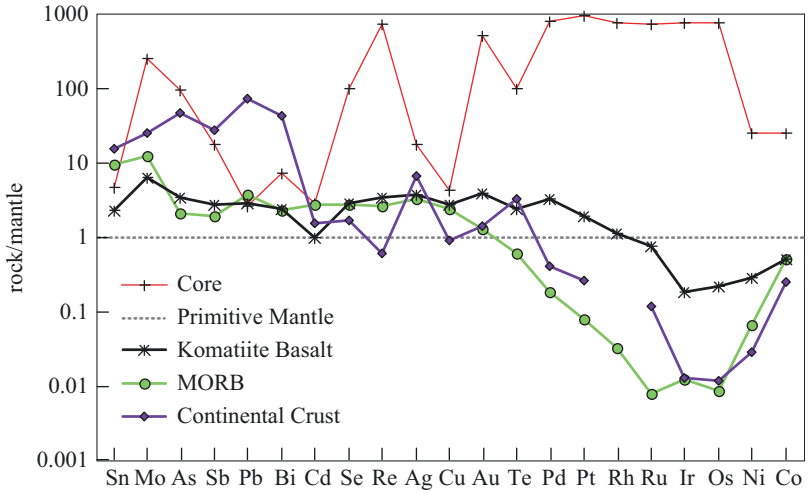
Distribution in Terrestrial Rocks

Whereas the concepts outlined by Goldschmidt are useful, as is evidenced by the fact the terms, siderophile, chalcophile, and lithophile are in daily use by geochemists, the behavior of an element depends on the composition of the system, oxygen fugacity (fO_2), temperature, and pressure (Li and Audétat 2015); thus, its behavior may vary depending on the context. Lodders (2003) outlined the behavior of the elements during condensation of the elements to form the solar system, and under these low fO_2 conditions, the chalcophile group is restricted to Ag, Cd, Hg, In, Pb, S, Se, Te, and Zn. Low fO_2 conditions would also have prevailed during the segregation of the earth's core and consequently many elements behaved in a siderophile manner. Current estimates of the core composition show enrichment of up to 1000 times primitive mantle (Fig. 2) for elements such as the platinum-group elements (PGE; Ru, Rh, Pd, Os, Ir, Pt). In contrast at the oxygen fugacities found in the Earth's mantle and crust, Fe alloy is very rarely present and many elements that are siderophiles in meteorites and during core segregation partition into sulfide minerals rather than Fe alloy and thus behave as chalcophile elements.

The partition coefficients between sulfide droplets and mid-ocean ridge basalts (MORB) give an indication of how chalcophile each element is under crustal conditions (Fig. 1). Elements with partition coefficients between 1 and 10 may be described as slightly chalcophile (Zn, Mo, As, Sb, Tl, In, and



Chalcophile Elements, Fig. 1 Partition coefficients between mafic magma and sulfide liquid. — indicates partition coefficients between MORB and sulfide droplet; I indicates range of values from experiments conducted at *f*O2 between −2 FMQ +2; ↑ indicates minimum partition coefficients; italics indicates the element is volatile; bold indicates that the element is highly siderophile (Data from Barnes and Ripley (2016) and references therein, plus Li and Audétat (2015))



Chalcophile Elements, Fig. 2 Concentrations of chalcophile elements in the core, komatiitic basalt, MORB, and the continental crust normalized to primitive mantle and plotted in order of incompatibility with komatiitic basalt (Data for the core from McDonough and Sun (1995); mantle from Lyubetskaya and Korenaga (2007); MORB form Arevalo and McDonough (2010); continental crust from Rudnick and Gao (2003); komatiitic basalt from this work (median of 52 samples from the Cape Smith Fold Belt northern Quebec))

Sn,), those with partition coefficients in the range 20–100 as moderately chalcophile (Pb, Co, Cd), those with a partition coefficient in the 100–1000 range as strongly chalcophile (Bi, Se, Ni, Re), and those with partition coefficients above 1000 as highly chalcophile (Au, Cu, Te, Ru, Rh, Pd, Os, Ir, Pt).

Among the group that behave as highly chalcophile elements under crustal conditions are the PGE which together with Au and Re are commonly referred to as highly siderophile elements because of their very high partition coefficients into Fe alloy (Harvey and Day 2016 and references therein). The highly siderophile elements attract a great deal of interest because of their potential to investigate the early history of planetary formation. In particular the relatively high concentrations of the highly siderophile elements in the Earth's mantle suggest that it is not in equilibrium with the core and that, during late meteorite bombardment, highly siderophile elements were added to the mantle (Dale et al. 2012).

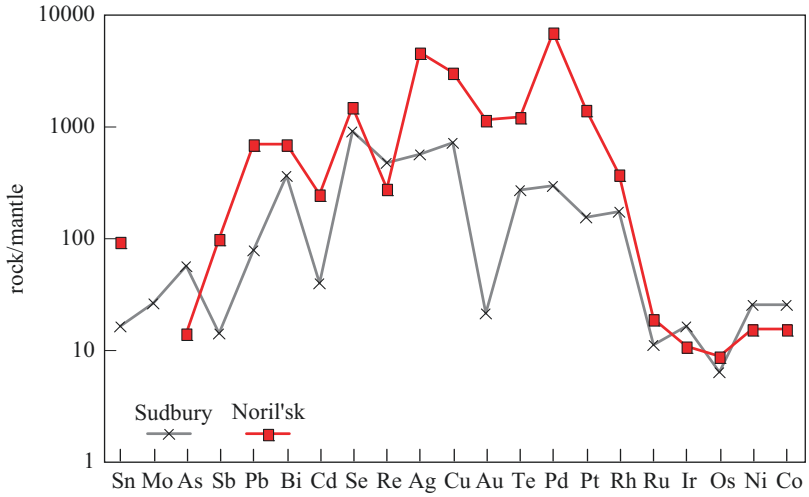
The behavior of the chalcophile elements during mantle melting can be considered by inspection of a mantle-normalized plot of average MORB and komatiitic basalts (Fig. 2). The elements are plotted in approximately decreasing normalized abundance in komatiitic basalt. For komatiitic basalt most of the chalcophile elements from Sn to Pt are present at the two to three times mantle concentrations. Moderately incompatible lithophile elements such as Sm are present in these rocks at similar to slightly higher levels (three to four times mantle); thus most of the chalcophile elements behave as incompatible elements and sulfide phases do not appear to control the behavior of the chalcophile elements at the high degrees of partial melting required to produce komatiitic basalts. In contrast the Ir-platinum-group elements (IPGE, Os, Ir, Ru, and Rh), Ni, and Co are present at less than one times mantle and behave as compatible elements.

The concentrations of the chalcophile elements in MORB show a wider range of values. Tin and Mo are present at close to ten times mantle, most of the chalcophile elements (As to Cu) show a lower degree of enrichment in the range of twice to three times mantle. Tellurium, Au, Ni, and Co are present at 0.1–1 times mantle exhibiting compatible behavior, and the PGE are extremely depleted at 0.01–0.1 times mantle. The variations in the behavior of the chalcophile elements in MORB are generally attributed to the presence of residual sulfides in the MORB source. The PGE exhibit extreme depletion because of their very high partition coefficients into sulfides, whereas the moderately chalcophile elements exhibit a much smaller degree of depletion because the sulfide phases will affect their bulk partition coefficients less (Patten et al. 2013). Tin and Mo at ten times mantle show an enrichment similar to incompatible lithophile elements, suggesting that the presence of sulfide phases has a negligible influence on these elements.

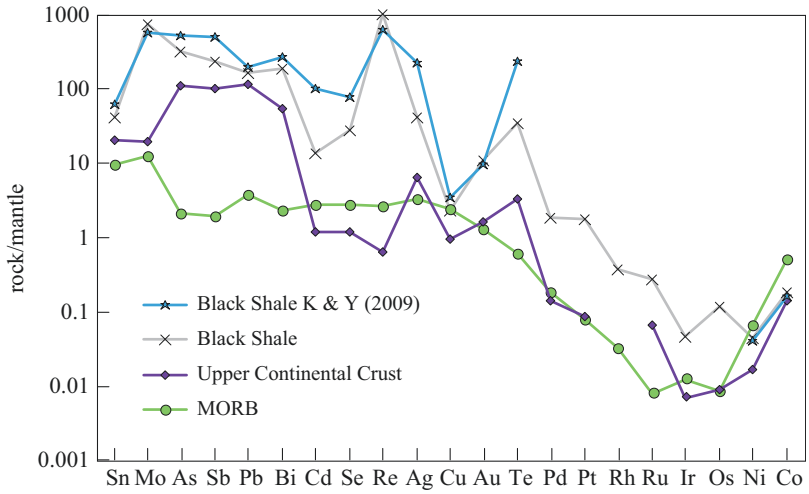
The average continental crust is depleted in most moderately to strongly chalcophile elements and like MORB is particularly depleted in PGE (Fig. 2). However it is enriched at 10–100 times mantle in the slightly to moderately chalcophile elements Sn to Pb and in the strongly chalcophile elements Bi and Ag (Fig. 2).

Naturally all of the chalcophile elements are concentrated into magmatic sulfide liquids when they segregated from mafic magmas, and the Ni and PGE ore deposits that form from the liquids are enriched in all of these elements (Barnes and Ripley 2016). Most of the chalcophile elements are enriched by a factor of 100–1000 relative to mafic magma Fig. 3. The slightly chalcophile elements are less enriched with enrichment factors of approximately 10 reflecting their lower partition coefficients (Figs. 1 and 3).

During crystallization of magma, the silicate liquid may become saturated in a magmatic-hydrothermal fluid.



Chalcophile Elements, Fig. 3 Mantle-normalized concentrations of chalcophile elements from the two largest magmatic Ni-sulfide deposits, Sudbury and Noril'sk (Data from Dare et al. (2011) and Zientek et al. (1994))



Chalcophile Elements, Fig. 4 Comparison of mantle-normalized concentrations of chalcophile elements in black shales with the upper continental crust and MORB (Data from Ketris and Yudovich (2009), this work of literature survey, Hu and Gao (2008), and Arevalo and McDonough (2010))

Some chalcophile elements and S partition into these fluids. For example, fluid inclusions from Cu-Mo porphyries are enriched in Cu, Mo, Zn, Ag, Tl Au, Pb, and Bi (John et al. 2010). The fluids then react with country rocks and the chalcophile elements are deposited along with sulfides as a result of the reactions (Keith et al. 1997; John et al. 2010; Richards 2011).

At low pressures the silicate magma or a magmatic-hydrothermal fluid may become saturated with a vapor. Some chalcophile elements preferentially partition into the vapor phase. Based on their condensation temperatures during the formation of the solar system, Lodders (2003) defined Hg, Tl, In, Cd, Se, S. Sn, Te, Pb, Bi, Sb, Ag, Cu, As, and Au as volatile. Volcanic gasses and sublimates have been found to be enriched in these elements (Hinkley et al. 1994; Zelenski et al. 2013). Another effect of the vapor is that magmatic sulfide droplets in the magma may lose S during magma degassing. The loss of S destabilizes the sulfides and some of the chalcophile elements partition into the vapor.

Black shales are also enriched in many chalcophile elements (Fig. 4). [Some black shales, such as those in southern China, show much greater degree of enrichment than the median (Xu et al. 2013).] Relative to the upper crust (a potential source of the clastic component of the shales), the median black shale is enriched by a factor of 2 to 10 for most of the elements (Ketris and Yudovich 2009). Molybdenum, Cd, Se, Ag, and Te show larger enrichments in the range of 30–100, and Re shows the most extreme degree of enrichment at 1000. Ketris and Yudovich (2009) did not provide estimates for the PGE. But based on a survey of the literature, the PGE are also enriched in black shales at approximately ten times crustal values (Fig. 4). The origin of the enrichment of the metals in black shales has been much debated with one school of thought favoring the precipitation of the metals from seawater in anoxic basins (Xu et al. 2013) and the

other school suggesting that the metals are derived from hydrothermal fluids (Orberger et al. 2003). Recently models involving both processes have become popular (Slack et al. 2015).

Over the past few years, the concentrations of chalcophile elements in pyrites from black shales have become the focus of intense study as a means of exploration for Au deposits (Large et al. 2011). In this model the chalcophile elements are precipitated by organic matter and pyrite and incorporated into the pyrite during diagenesis. During greenschist facies metamorphism, the pyrite recrystallizes and releases many of the chalcophile elements to metamorphic fluids which can migrate to low pressure zones where they precipitate Au and other chalcophile elements.

Summary

The chalcophile elements can be divided into slightly, moderately, strongly, and highly chalcophile based on their partition coefficients between silicate and sulfide melts. Some of the highly and strongly chalcophile elements (PGE, Au, Re) are also highly siderophile, and thus most of the budget of these elements is found in the Earth's core. The slightly chalcophile elements Sn, Mo, As, Sb, and Pb together with Bi are enriched in the continental crust. Black shales are an important reservoir of most chalcophile elements in the Earth's crust. MORB is slightly enriched in most chalcophile elements except the highly chalcophile elements. In the Earth's crust highly chalcophile elements are only found in significant quantities in magmatic sulfide deposits.

Chelation

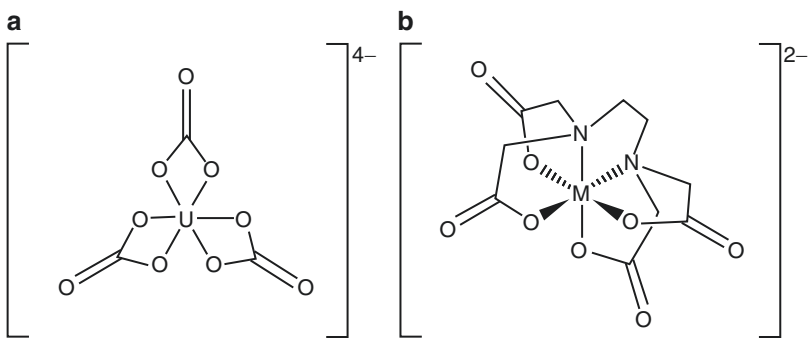
Corey D. Pilgrim
Department of Chemistry, University of California, Davis, Davis, CA, USA

Definition

Chelation is the complexation process by which a metal ion is bound to more than one atom in a single ligand. The ligand in question is said to be polydentate and is described by how many bonds are formed to the metal (e.g., a bidentate ligand has two bonds or a tridentate ligand has three bonds). The term chelation uses the Greek root *chela*, which is descriptive of the claws of lobsters and crabs, and is used because the resulting chelate complexes look as if the metal ion is caught between the pincers of the ligand. The favorable process of the replacement of monodentate ligands with polydentate ligands is known as the "chelate effect."

Chelation plays a prominent role in both inorganic chemistry and geologic processes. Water-solvated metal ions do not exist as discrete species in solution; they order the solvent molecules around themselves in different spheres of interaction (Richens 1997). Usually, these water molecules orient such that the negatively charged end of the dipole is attracted to the positively charged metal ion. These solvent molecules are thus coordinating as monodentate ligands around the metal center. Most geochemically important coordination complexes involve the interaction between Lewis acids and Lewis bases, such that the electrons in the coordinating ligand are donating to the electron poor metal center. Chelation occurs when a ligand, with multiple sites that act as Lewis bases, replaces the monodentate ligands around the metal center. This can result in interesting complexes forming – as an example, carbonate is a geologically abundant, bidentate, hard Lewis base which likes to coordinate with metal centers (interestingly, it can even form tricarbonate complexes with the early actinides, Fig. 1a). Another example of a chelating ligand is the molecule ethylenediaminetetraacetate (EDTA). This ligand is a hexadentate ligand that can coordinate a metal center through the lone electron pairs found on the four oxygen and two nitrogen atoms (Fig. 1b). EDTA can fill all octahedral sites around a metal center, effectively surrounding the ion in a cage. EDTA is used medically to trap toxic metals that have been digested by humans. It is also used as a complexometric titrant to determine the metal ion content in mixed solutions. Replacement of lower coordination number ligands by these higher coordination number ligands is known as the chelate effect.

The chelate effect, the process of exchanging lower coordinated ligands for higher coordinated ones, is an entropically favored process. When the higher coordinating ligand displaces the lower coordinating ligand, more species are in solution, where there are then more available translational, vibrational, and rotational modes of freedom. This increases the entropy (ΔS) of the system through the increase in



Chelation, Fig. 1 (**a**) Triscarbonato uranyl complex, with the axial "–yl" oxygens omitted for clarity. (**b**) Deprotonated ethylenediaminetetraacetate, chelated around a generic M^{2+} metal center

disorder. This process must overcome the enthalpy (ΔH) of the initial complex – the net gain in disorder must be greater than the change in the amount of energy that is stored in the coordinating bond between the Lewis acid–base pairs. When looking at coordination compounds, a few specific donor atoms have prevalence, most notably oxygen and nitrogen. The effects of replacing an oxygen – metal bond from a lower coordinating ligand with another oxygen – metal bond from a higher coordinating ligand are almost negligible, and the entropy of the exchange can be considered as the dominant thermodynamic process involved. However, a careful study of the enthalpy differences must be done if the donor atoms are different.

Chemical Bonds

Barry R. Bickmore and Matthew C. F. Wander
Department of Geological Sciences, Brigham Young University, Provo, UT, USA

Definition

Linus Pauling famously described a chemical bond as "whatever is convenient to the chemist to define as a bond" (Pauling 1960). In the simplest terms, a chemical bond is merely an attraction between atoms in a substance containing an aggregation of two or more atoms. However, while all bonds are based on the attraction between positively charged protons and negatively charged electrons, quantum mechanical effects governing the spatial distribution of electrons give rise to a wide range of bond properties and a continuum of bond types. The standard types include covalent, metallic, ionic, hydrogen, and van der Waals bonds (Gillespie and Popelier 2001).

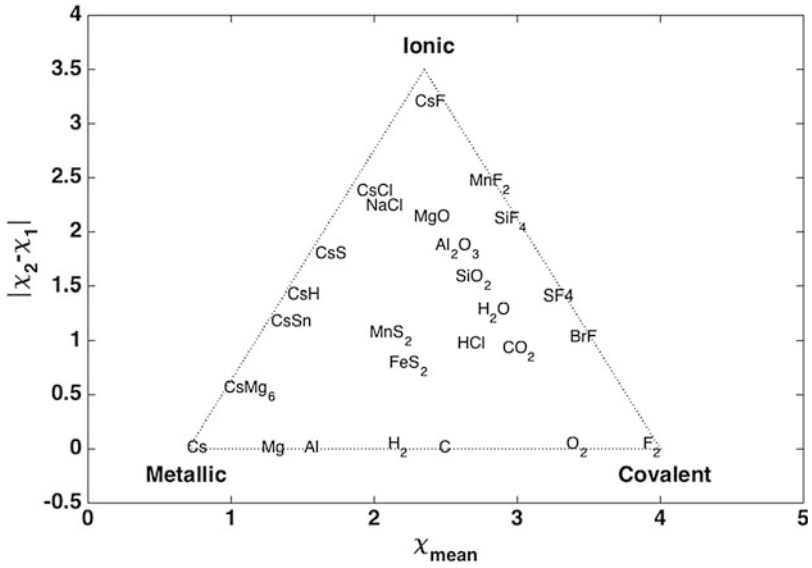
Traditional Valence Bonds

The strongest chemical bonds (covalent, metallic, and ionic) are sometimes called "valence bonds," due to the fact that they are formed when partially filled *valence atomic orbitals* combine to create molecular orbitals (Albright et al. 2013). The average spatial distribution of electrons (the electron probability density or electron density) around a free atom can be described in terms of atomic orbitals, which form three-dimensional standing wave patterns about the nucleus. As atoms approach one another, their atomic orbitals mix to create molecular orbitals, which form three-dimensional standing wave patterns about multiple nuclei. The resulting redistribution of the bonding electron density causes a net attraction between the atomic centers, but the bond properties depend strongly on the details of the redistribution (Gillespie and Popelier 2001). These details will be discussed here with reference to the *electronegativity* of the participating atoms. (*Electronegativity* is a single-parameter summary of the electron-attracting power of atoms.)

Ionic bonds form between atoms with widely different electronegativity values (metals with nonmetals). In these bonds, molecular orbitals concentrate most of the bonding electron density around the more electronegative atoms, resulting in some atoms with a net negative charge (anions) and others with a net positive charge (cations), which if sufficiently large can behave as separate ions. An ideal ionic bond would involve a cation and anion that can be treated as two point charges, but in real ionic systems, some sharing of valence electrons occurs, the molecular orbitals are not fully spherically symmetrical about the atomic centers, and there is always some orbital overlap, or sharing, of electrons. Therefore, even bonds between atoms with the most disparate electronegativity values are not considered fully ionic (Rohrer 2001).

Covalent bonds form between atoms with similar, high electronegativity values (nonmetals). Here molecular orbitals distribute, or share, the bonding electron density more or less evenly between the atoms involved, with an accumulation of electron density in the overlap region between atomic centers (Popelier 2000). Although fully ionic bonds do not exist, fully covalent bonds do exist between atoms of the same element. Given that covalent bonds involve atoms that tend to hold tightly to their valence electrons, the molecular orbitals form with their associated electron density concentrated very locally, around neighboring atoms. This makes the bonds very localized and directional, i.e., the angles between bonds to a given atom are relatively tightly constrained (Gillespie and Hargittai 1991).

Metallic bonds form between atoms with similar, low electronegativity values (metals). These atoms hold relatively weakly to their valence electrons, and the molecular orbitals formed spread out to encompass a very large number of atoms. Thus, metallically bonded systems are often described as positively charged atoms (nuclei + core electrons) held together by a "sea" of valence electrons shared between all the atoms. When so many atomic orbitals combine, a large number of closely spaced (in terms of energy) molecular orbitals become available, with a relatively small gap (or no



Chemical Bonds, Fig. 1 A van Arkel–Ketelaar triangle, illustrating the continuum of bond types between the ionic, covalent, and metallic limits. The *x*-axis represents the mean electronegativity (χ_{mean}) of the two atoms involved in the bonds in each of the substances plotted. The *y*-axis represents the difference in the two electronegativity values (χ_1–χ_2)

gap) between the filled and unfilled levels. This leads to the high thermal and electrical conductivity of metals, because a relatively small excitation of a bonding electron takes it into molecular orbitals that are comparatively empty and extend throughout the substance. The delocalization of the bonding electrons also results in considerably less directionality and force in the bonds, which explains the malleability of metallic solids (Burdett 1997; Rohrer 2001).

The different types of valence bonds form a continuum, in which the degree of ionicity can be roughly estimated in terms of electronegativity differences between atoms, and covalency/metallicity can be roughly estimated in terms of the average electronegativity of the bonded atoms (Rohrer 2001). Figure 1 shows a van Arkel–Ketelaar triangle, which schematically illustrates this point. However, bonding character can also be affected by factors such as pressure and temperature (Burdett 1997; Batsanov and Batsanov 2012).

One defining attribute of valence bonds is bond order. Bond order refers to the number of valence electron pairs involved in an individual bond, whether shared or transferred (IUPAC 1997; Brown 2002). (In cases where antibonding electron pairs exist, these are subtracted from the bond order.) The bond in an $F_{2(g)}$ molecule, for example, has a bond order of 1, because the electrons from two half-filled atomic orbitals are shared in one bonding molecular orbital. The electrons from three half-filled atomic orbitals are shared in $N_{2(g)}$ molecules, so the bond order is 3. In a $CsF_{(g)}$ molecule, an electron from a half-filled atomic orbital in Cs is transferred to a half-filled orbital on the F, creating an ionic bond with a bond order of 1. The orders of bonds incident to a given atom in a stable substance must sum to the atomic valence of the atom. The atomic valence is equivalent to the number of H atoms to which it can bond. Given that bond lengths are highly correlated with bond orders (Brown 2002), this creates stringent constraints regarding the combinations of bond lengths that are possible in a stable structure. Although atomic valence values are necessarily integers, bond orders can have non-integer values, especially in condensed phases with extended networks of valence bonds. For example, in corundum (α-Al_2O_3) Al has a valence of 3, while O has a valence of 2. The Al-O bonds have bond orders of ~0.5, so that each Al is bonded to six O atoms, and each O is bonded to four Al atoms. Non-integer orders for individual bonds are possible because molecular orbitals, which must contain an integral number of electrons, can encompass multiple atoms (Brown 2002; Albright et al. 2013).

At least for covalent bonds with integer bond orders, the force constants used to describe bond vibrations are proportional to the bond order (Johnston 1966). This gives rise to another defining attribute of bonds, i.e., the inverse relationship between bond length and strength.

Bonds can also profitably be characterized in terms of bond energy (E_{bond}), which is the average energy per mole of bonds released when molecules are separated into their constituent atoms. A similar quantity can be obtained from dividing the atomization energies of solids by the number of bonds per formula unit (Sanderson 1976). For a bond between two given elements, of a given bond order, E_{bond} values are relatively transferable. Therefore, it is possible to roughly estimate enthalpies of formation by summing bond energies. It is important to note that, for the same bond order, E_{bond} can vary by hundreds of kJ/mol for bonds between different elements. For example, the bond energy for the single bond in $F_{2(g)}$ is 158.67 kJ/mol, whereas that for

$Cs_{2(g)}$ is 43.919 kJ/mol and that for $CsF_{(g)}$ is 517.1 kJ/mol (Luo 2007). However, bond energies are not strictly proportional to bond order, although there is a relationship between the two.

Hydrogen Bonds as Valence Bonds

Hydrogen bonds (H-bonds) are the weaker of conjugate bonds formed between H and two or more highly electronegative atoms such as N, O, or F and are usually designated as X–H. . .X, where X represents the more electronegative atoms, the solid line represents a strong, polar covalent bond, and the dotted line represents an H-bond. The electron density involved in the strong bond is shifted toward the more electronegative atom, creating a dipole between the two atoms, resulting in a relatively weak electrostatic attraction between the positively charged H and any other electronegative atoms in the vicinity. Thus, the H is bonded strongly to one comparatively electronegative atom and much more weakly to one or more others. Due to the fact that H atoms have only one electron, along with their small size, shifting its electron density toward the anion results in a relatively high positive charge density.

Hydrogen bonds are often treated as simple electrostatic dipole interactions, rather than valence bonds, but in fact, it has been shown that even weak hydrogen bonds have some covalent character, so there is no reason to treat them as anything but weak valence bonds that may be assigned a bond order. In fact, when H-bonds are shorter, the adjacent stronger bonds become longer, as one would expect for a valence bond (Steiner and Saenger 1994; Steiner 2002).

The typical asymmetry of X–H. . .X bonds is likely to be a product of the small size of H atoms. Symmetric H-bonds, in which the two bonds to H have equal bond orders of 0.5, do exist. However, they are quite rare because bond order falls off exponentially with distance. Therefore, an X–H–X configuration with two 0.5 order bonds draws the X atoms considerably closer to one another than would typically be the case for nonbonded atoms, whereas an asymmetric X–H. . .X configuration results in a considerably longer X–X distance (Brown 2002). However, symmetric H-bonds become more common at high pressure (Steiner 2002), because X atoms are forced together by compression.

London Dispersion (van der Waals) Forces

London dispersion (van der Waals) forces originate due to oscillations in the instantaneous electron distribution around atoms. The average electron distribution is generally very symmetrically disposed about the nucleus, but at any given instant this may not be the case, creating a small dipole moment. As atoms approach one another, their oscillations synchronize to maximize attraction. This oscillation is correctly accounted for with electron correlation calculations and is in itself a type of standing wave behavior. A very weak molecular state is created in these cases, which explains why an attraction between filled shells is possible (Housden and Pyper 2007; Krapp and Frenking 2007). This is why noble gases, with filled valence shells, can condense into liquid at very low temperatures.

Bonds and the Distribution of Elements

A number of factors contribute to the distribution of the elements in the Earth, as described by the traditional *Goldschmidt classification* (Faure 1998), but one such factor has to do with bond energies. As noted above, bonds of the same order can vary widely in bond energy with the bond character. Elements with very low electronegativity (e.g., the alkali and alkali earth metals) favor highly ionic bonds with fractional bond orders (i.e., bond order < 1), so they naturally bond easily to O in network solids. Oxygen is the most abundant element in the Earth and the second-most electronegative, and some of the more electronegative elements, such as the halogens, often substitute for O. Therefore, these elements are classified as *lithophile* and are enriched in the crust and mantle. Some of the more electronegative elements, such as C and N, favor covalent bonds with one another, having high bond orders (1 or greater). This results in fewer bonds and discrete molecules rather than network solids. A number of elements with moderately high electronegativity favor covalent bonds with similar elements and low to moderate bond orders, so these tend to congregate in sulfides, and are classified as *chalcophile*. A number of metals with moderately low electronegativity favor metallic bonds with one another, with low bond orders. These tend to form metallic solids and are classified as *siderophile*, because they readily bond with Fe and are enriched in the core.

Summary and Conclusions

Chemical bonds can usefully be characterized in terms of bond order, bond energy, and bond type. Bond orders constrain suitable combinations of bond lengths incident to atoms in stable configurations, and bond energies for bonds of the same order vary widely as a function of bond type. It is impossible to classify a given chemical bond as exclusively one type, however, because van der Waals interactions are present between all neighboring atoms, and even in cases where van der Waals interactions dominate (e.g., noble gas dimers and condensed phases), molecular orbitals play some role. This is why there is a continuum between the

different bond types, based on the affinity for electrons of the bonded atoms. The relationships between bond order and bond energy for different atom pairs are one of the determining factors affecting the distribution of elements in the Earth.

Chemical Weathering

Jérôme Viers and Priscia Oliva
CNRS/IRD, Paul Sabatier University, Toulouse, France

C

Definition

Chemical weathering may be defined as the *spontaneous* and *irreversible* thermodynamic process that causes degradation of the mineral phases under the prevailing environmental conditions at the surface of the Earth. If one must differentiate the weathering in the continental and marine environments, chemical weathering is usually considered to be the solid/solution interactive process occurring in contact with the atmosphere. By extension, in the language of the specialists of the critical zone, chemical weathering may be defined as that set of processes which alter a rock into a layer of chemically and physically transformed superficial material (i.e., regolith) which is susceptible to evolve (soil or karst) with time following biogeochemical processes.

Introduction

While this process of chemical modification can be easily formalized by writing on paper, for example, the chemical reaction of dissolving a mineral (1), the reality is much more complex because it actually encompasses a set of chemical, physical, or biological complex interactions:

$$CaAl_2Si_2O_8 s + 4H^+ aq = Ca^{2+} aq + Al_2Si_2O_5(OH)_4 s \quad (1)$$

The physical process that causes the dissolution of calcium feldspar (1) is a process of hydrolysis corresponding to the replacement of a cation (Ca^{2+}) on the mineral surface by a proton (H^+). This first step in chemical weathering is the surface protonation of the mineral. The presence of protons in the etching solution is explained by chemical equilibria involving the distribution of CO_2 (atmospheric) between the aqueous and gaseous phases, e.g.:

$$CO_{2(g)} + H_2O = H^+ + HCO^-_{3(aq)} \quad (2)$$

In the conditions at the Earth's surface, chemical weathering processes occur mainly in contact with acidic solutions that result from natural acidification of rainwater in reaction (2) and subsequent acidification of solutions in the soil environment due to microbial activity (decomposition of organic matter) and root respiration (atmospheric CO_2 enrichment of the soil). In certain geological environments

(sulfide-rich volcanic or metamorphic formations), production of acid can be generated by the oxidative dissolution of sulfides such as:

$$FeS_2 s + 15/4 O_2 g + 7/2 H_2 O aq = 2SO_4^{2-} aq + Fe(OH)_3 s + 4H^+ aq \quad (3)$$

The principal reactions of chemical weathering are hydrolysis (1), oxidation (3), and the dissolution of ionic compounds. Chemical weathering processes in saline or alkaline environment exist but are very minor at the natural environment's surface conditions. The products of these reactions may be both dissolved compounds and secondary solid phases, which may be either well or poorly crystallized. The reaction is said to be incongruent when we have both aqueous and solid phases and congruent when having only dissolved compounds. The principal secondary minerals that form in the conditions at the surface across the critical zone are clay minerals or metal oxyhydroxides which are more stable from a thermodynamic perspective than are the primary minerals. Both secondary phases and residual primary minerals (inherent minerals) constitute soils mineralogical assemblage.

The products of chemical weathering can then be transported by surface water: we speak of transportation for dissolved compounds in solution (Ca^{2+}, HCO_3^-, small organic molecules, etc.) and particulate matter (or sediments) for either mineral or organic solid compounds. Geochemists have conventionally considered that the boundary between the dissolved phase and the particulate phase is defined by membranes filtration of water with the empirical pore diameter being 0.45 or 0.2 micrometers. Data on concentrations (dissolved and particulate) combined with the water discharges of rivers are therefore used to define, respectively, the chemical and physical erosion fluxes. This process of chemical weathering of rocks associated with their physical dismantling and potential material transport by inland waters is responsible for about 15 billion tons of sediment exported from the continents to the oceans annually (Milliman and Farnsworth 2011).

Chemical Weathering: A Major Geological Process

Chemical weathering is a fundamental "geological" process because it plays a major role in the global geodynamic of our planet; this role is complex because it occurs at highly variable scales of time and space.

- At the scale of the weathering front (a zone of transition between the rock and soil) or the soil itself, chemical weathering is accompanied by the release of nutrients (e.g., major elements such as K or Ca, and trace elements such as Fe or Co) essential to the functioning of the continental ecosystems. The soil which is a product of chemical weathering appears here as a fundamental natural resource, nonrenewable on the scale of humanity. It provides numerous economic functions (agricultural production, materials production in quarries, etc.), cultural (recreational, archaeological sites, etc.), or environmental (regulation of water flow, retention of contaminants, etc.). Yet in many parts of the world, soils are subjected to very high stressors (e.g., contamination, salinization, desertification, etc.) and are often irreversibly lost for any use by society.
- On a global scale, chemical weathering plays an important but complex role in regulating the climate of our planet. This role stems from the fact that the chemical weathering of silicate rocks consumes atmospheric CO_2 because the calcium and bicarbonate ions (produced in reactions (1) and (2) above) are carried to the ocean by rivers where they are precipitated (usually biologically) as calcium carbonate (4):

$$Ca^{2+} + HCO_3^- = CaCO_3 + H^+ \quad (4)$$

In the early 1980s, Walker et al. (1981) proposed a negative feedback loop between the climate and the chemical weathering of continental surfaces: an increase in the partial pressure of CO_2 (pCO_2) from the atmosphere induces an increase in air temperature and accelerates the hydrological cycle. This change of physical parameters enhances the chemical weathering of silicate rocks which in turn lowers pCO_2 and therefore regulates the Earth's climate.

However, the links between climate and weathering today appear much more complex than envisioned by Walker et al.; therefore, in recent decades, chemical weathering has undergone numerous studies conducted via different approaches.

The Different Approaches Used to Study Chemical Weathering

The chemical weathering processes can be studied in differing ways:

- They can be studied under controlled laboratory conditions. Many studies have been conducted to examine this process in conditions near to and far from thermodynamic equilibrium. These studies were intended to better understand the reactions occurring on the mineral surface during dissolution and thus gain a better understanding of the parameters controlling the kinetics of dissolution. They allowed the proposal of the empirical laws of chemical weathering (e.g., transition state theory; Berner 1995 and references therein) that revealed the importance of many factors: mineral surfaces, temperature, chemical affinity, proton activity, organic compound).

- Laboratory research on chemical weathering has a long history (about a century), and the nature of these involved processes is still undergoing debate within the scientific community. Most experiments in dissolution yield chemical weathering rates up to four orders of magnitude greater than those estimated from field studies. This discrepancy between the experimental and natural chemical weathering rates is called the "dissolution rate conundrum" (Maher et al. 2006). Under natural conditions, a progressive loss of reactive surface sites for silicate weathering over time is observed. It may be attributed to the inhibitory effect on mineral dissolution due to the presence of Al^{3+} or organic ligands in solution or to surface coating by the secondary phases precipitates in a natural context which are rare in dissolution experiments (Oelkers et al. 1994). Indeed, experimental conditions still remain far from natural circumstances (e.g., duration, fluid / mineral ratios, fluid composition) (White and Brantley 1995). The saturation state of the solution appears to be a key parameter as it controls the effects of microstructures and microtextures on chemical weathering (Chardon et al. 2006 and references therein).
- Chemical weathering processes can be studied in situ by considering the weathering products constituting the regoliths and soils. Mineralogical and/or chemical composition of the regolith represents an integrated view of all the processes that have occurred over time to form this regolith. One approach allows for the establishment of mass balances for chemical elements using references called invariant elements such as zirconium or titanium. This approach has the merit of being able to estimate the flow of chemical elements and, therefore, rates of loss or enrichment of elements throughout the soil profile. However, it often remains impossible to transform these fluxes into chemical erosion rates because the age of a given soil is often very difficult to narrow down.
- A third method is the "watershed" approach. This approach involves studying the fluxes of chemicals leaving the watersheds. These studies involve the hydrological and chemical monitoring of water during the course of continental surface drainage. This approach can be conducted on large river basins (Amazon, Congo, Lena, etc.) or small watersheds. The "large pool" approach offers the advantage of being inclusive of processes over large areas; the "small pool" approach offers the advantage of often working on more homogeneous systems (e.g., as for lithology) rendering the least complex object for study. Over watersheds of varying lithology, chemical erosion rates associated with silicate rocks may be understood by "direct" (Garrels and McKenzie 1967) or 'indirect' methods, the latter by the use of inverse methods of calculation (e.g. Gaillardet et al. 1999). All of these studies allowed highlighting of the roles of certain parameters on the weathering: mineralogy of exposed rocks, surface ages, precipitation/dissolution of clay minerals, presence of easily changeable accessory minerals, movement and time that water resides in the soil, physical erosion, vegetation, anthropogenic disturbance (fertilizer) (Oliva et al. 2003; Perrin et al. 2008).
- More recently, there are several works studying chemical weathering from numerical models (Duffy et al. 2014). These studies seek to examine/simulate chemical weathering occurring today (MacKenzie watershed, Beaulieu et al. 2011) or in the past (Goddéris et al. 2014). This is, for example, the case of the WITCH model based on the law of weathering kinetics (Beaulieu et al. 2011). In recent years, this type of model has been coupled with global dynamic models of vegetation because vegetation plays an important role with regard to the flow of water (in the soil and the soil interface/atmosphere). Vegetation plays a more direct role in the dissolution of minerals because of root activity and the release of organic acids in soil (Drever and Vance 1994). In the future, one challenge will be to model the effects on the evolution of biodiversity on the cycle of elements because vegetation is not only a sink or reservoir for carbon but is this for all of the other chemical elements (Mg, Si, Ca) (Chave 1999; Viers et al. 2005). Recent field and laboratory tests have also shown that the dissolution of phytoliths (siliceous particles produced in the plant and then recovered in the soil) showed faster dissolution kinetics than the secondary minerals (clay) and therefore could play an important role in the silicon cycle on the surface of the Earth (Derry et al. 2005; Fraysse et al. 2009). This is another poorly known effect of the role of vegetation on chemical erosion rates and more generally on the cycle of elements.

Unifying Natural and Experimental Chemical Weathering Rates

During the last decade, one of the major scientific questions circulating about chemical weathering was to understand the existing disparities between the field measurements of natural "chemical weathering rates" and the measurements carried out in the laboratory, the objective being to attempt unification of this dual information. The most significant results were obtained from multidisciplinary approaches in geochemistry and mineralogy (Ferrier et al. 2010) or by focusing on the molecular-level mineral-water interface by means of new observational tools and analyses of mineral surfaces with high resolution [e.g., Raman spectroscopy, high-resolution and energy-filtered TEM, in situ atomic force microscopy (AFM)] as defined in the publications of Hellmann et al. (2012) or Ruiz Agudo et al. (2012). These methods have identified the mechanisms of interface-coupled dissolution-reprecipitation mechanisms during chemical weathering. These results put into question the currently accepted leached-layer model of

chemical weathering (Oelkers et al. 2009; Schott et al. 2012) which involves preferential removal of weakly bonded cations (e.g., Na^+ and K^+) from the surface regions of silicates, which precedes the removal of the more strongly bonded cations (e.g., Al^{3+} and Si^{4+}) at acidic pH values resulting in apparent incongruent dissolution for silicate minerals.

Concurrently, Rasmussen et al. (2011) using a more traditional approach (measurement of the ground flux versus thermodynamic calculations on the basis of Na export) on a set of data very well documented across the Rio Icacos watershed were able to quantify the activation energies (E_a) for the weathering of feldspars comparable to those data given in the literature for the experimental dissolution of albite. These results indicate that to correctly quantify E_a dissolution from field data, certain parameters (i.e., water availability, erosion) rather neglected up to that point, must be considered. It's about the physicochemical and regolith soil data, particularly the availability of water to perform mineral weathering. Rasmussen et al. (2011) calculated an average apparent activation energy of 69 $kJ.mol^{-1}$ Na for positive annual water balance zones and 136 $kJ.mol^{-1}$ Na for water-limited locations, respectively. This suggests that water availability is the dominant factor limiting rate kinetics for albite weathering in the cool climate of the water-limited systems.

The Effect of Water Availability and Time Duration for the Presence of Water

The availability of water is proposed as the factor limiting the rate of chemical weathering in weathering systems by many authors (Maher 2010). Long transit times of water (>1 decade) are consistent with a kinetic control of the weathering by thermodynamics through the precipitation of secondary phases or activity of microorganisms, while the short times that water is present are synonymous with control by the processes of transport and hydrology. Thus, some authors consider that the dependence of chemical weathering on time, which is often considered to be the major parameter in the models of landform contour evolution, is in fact a result of mechanisms controlled by hydrological processes (water availability, time period that water is present, etc.). The concept of a hydrological thermostat ("hydrologic thermostat") was established to describe the role of hydrological processes in the regulation of chemical weathering and associated with the consumption of CO_2 (Maher and Chamberlain 2014). The flow (*runoff*) appears as the most relevant parameter to describe the flux of weathering in comparison with the temperature in many environments. The most important flow of weathering measured at present corresponds to the environments of volcanic islands (Goldsmith et al. 2010; Schopka et al. 2011) in which deeply circulating hydrological systems (table) can play a major role (Schopka and Derry 2012).

Summary and Conclusions

Numerous studies conducted over the past two decades on chemical weathering are related to its ability to remove CO_2 from the atmosphere because that can condition our Earth's climate (West 2012). Understanding the links between the climate and tectonics in the geological history of our planet inevitably involves taking the carbon cycle into account and thus, chemical weathering. Certainly the study of current systems helps to better establish some parametric laws between weathering and climate. However, the relationship between climate, tectonics, erosion, and the sets of potential feedback is still a major subject of study. The study of the role of mountain ranges and flood plains of major rivers in weathering (such as those currently in the Amazon watershed) will remain a preferred subject of study over the coming years (Moquet et al. 2011; Bouchez et al. 2012).

Chlorine

Mark A. Kendrick
Research School of Earth Sciences, Australian National University, Canberra, ACT, Australia

Element Data

Atomic Symbol: Cl
Atomic Number: 17
Atomic Weight: 35.453
Isotopes and Abundances: stable ^{35}Cl (75.76%) and ^{37}Cl (24.24%) and radioactive ^{36}Cl ($t_{1/2} = 301.3$ ka)
1 Atm Melting Point: 171.65 K
1 Atm Boiling Point: 239.11 K
Common Valences: −1, 1, 3, 5, 7
Ionic Radii: 1.8 Å
Pauling Electronegativity: 3.16
First Ionization Potential: 1256.2 kJ mol^{-1}
Chondritic (CI) Abundance: 680 ppm
Silicate Earth Abundance: 15–30 ppm
Crustal Abundance: 140–470 ppm
Seawater Abundance: 19,300 ppm
Core Abundance: <20 ppb?

Properties

Chlorine is a diatomic toxic green-yellow gas at room temperature with a bleach-like smell. However, Cl is characterized by an S^2P^5 outer electron shell configuration and is highly electronegative, meaning it rarely exists in its elemental form in nature. Chlorine most commonly forms the chloride ion with a valence of -1, but it can exist in a number of different valence states. Chloride forms strong ionic bonds in salts and substitutes for the OH group in many hydrous minerals. Hydrogen chloride [$HCl_{(g)}$] is a diatomic gas at room temperature and forms hydrochloric acid $HCl_{(aq)}$ when dissolved in water.

History and Use

Elemental $Cl_{2(g)}$ was first produced by the Swedish scientist Carl Wilhelm Scheele in 1774. Scheele isolated $Cl_2(g)$ by heating hydrochloric acid with the mineral pyrolusite (MnO_2) but believed the resulting gas was an oxide he named "dephlogisticated muriatic acid air." Later experiments showed that this gas would not decompose during reaction with charcoal, phosphorus, or ammonia, and by 1810 Sir Humphrey Davy concluded the gas was an element (Davy 1811). The name chlorine is derived from the Greek word chloros meaning green-yellow (Davy 1811).

Chloride in common salt has been used in cooking and food preservation since prehistoric times. Salt is produced commercially by the evaporation of seawater or mining. Chlorine gas is produced for industrial purposes by electrolysis of salt solutions or molten sodium or magnesium chloride. Chlorine is used to kill bacteria in drinking water and swimming pools and in the manufacture of a wide range of products including paper, paints, textiles, and plastics. PVC (polyvinyl chloride) alone is used extensively in the building and automotive industries. The high electronegativity of Cl means Cl or Cl compounds are used as oxidizing agents or in substitution reactions involved in the manufacture of many pharmaceuticals and some insecticides. In the past Cl was used to make chloroform ($CHCl_3$) which is a toxic but powerful anesthetic, chlorofluorocarbons (CFCs) were used as refrigerants and aerosol propellants before being linked to destruction of stratospheric ozone, and Cl gas was used as a highly toxic chemical weapon in World War 1.

Distribution in the Cosmos and on Earth

The solar photosphere contains 4.8 ppm Cl, making it the eighteenth most abundant element in the solar system (Lodders 2003). Chlorine is moderately volatile with a 50% condensation temperature of 954 K at 10^{-4} bar (Lodders 2003). Chlorine has a concentration of ~680 ppm in CI chondrites compared to an estimated concentration of ~15–30 ppm in the Earth's theoretical primitive mantle (McDonough and Sun 1995). Chlorine is depleted on Earth relative to other elements of similar volatility, and because Cl has a low compatibility in Fe-Ni alloys and is therefore expected to have a low concentration in the Earth's core, it is suggested that Cl was probably lost during Earth's accretion either with the early atmosphere or with crustal components removed by collisional erosion (Sharp and Draper 2013).

Chlorine is a strongly incompatible element and is concentrated in the Earth's surface reservoirs. Seawater with 1.9 wt. % Cl (~3.5 wt % salt) contains a bit less than half, and evaporites with up to 60 wt. % Cl contain about a quarter of the total Cl in the Earth's surface reservoirs (Schilling et al. 1978).

Chlorine has a residence time of 100s of Myr in seawater, suggesting a constant concentration; however, depending on the amount of Cl stored in evaporites, seawater salinities could have been very different (more saline) in the distant geological past (Hay et al. 2006). Sedimentary formation waters have salinities that commonly range from ~1 up to ~30 wt. % salt, but can include even higher salinities (Hanor 1994). Average continental crust has been variably estimated to contain 130–470 ppm Cl compared to ~1–5 ppm Cl in the depleted mantle (Rudnick and Gao 2003; Shimizu et al. 2016). Primitive mid-ocean ridge and ocean island basalt glasses contain ~30–2000 ppm Cl (Schilling et al. 1978; Michael and Cornell 1998; Kendrick et al. 2015). The average Cl content of altered ocean crust is not well constrained but could be as high as 100–500 ppm (Sano et al. 2008). High concentrations of Cl are common in metamorphic environments characterized by low fluid-rock ratios, and parts of the oceanic crust and lithosphere contain amphibole and serpentine with wt. % levels of Cl (Sharp and Barnes 2004; Kendrick et al. 2013; Kendrick 2017). The long-term exchange of Cl between the Earth's mantle and surface reservoir over time is an area of active research.

Significance in Geochemistry

Chlorine is undersaturated in typical submarine basaltic lavas and behaves as a lithophile element in the mantle. However, $HCl_{(g)}$ is degassed from subaerial volcanoes and has a significant influence on climate and ozone depletion (Kutterolf et al. 2013). Chloride is the dominant anion in geofluids, including magmatic fluids exsolved in the crust. Chloride acts as an important ligand enabling the transport of metals in hydrothermal solution (Yardley, 2005).

In sedimentary environments with a high water-rock ratio, fluid chlorinity is often considered to be conservative and can be used to infer a fluid source or migration pathway. In some cases the movement of saline formation waters (oil field brines) is linked with hydrocarbon migration. In higher-temperature metamorphic environments with lower fluid-rock ratios, the concentration of Cl in a geofluid is not conservative. Fluid salinity provides important evidence for hydrothermal phase separation and the Cl content of metamorphic minerals track the involvement of saline fluids in metamorphic processes (Kendrick 2017).

Chlorine Isotopes

Chlorine stable isotope ratios reported relative to standard mean ocean chloride vary by ~10 ‰ on Earth. Chondrites and samples from the terrestrial mantle typically have δ^{37}Cl of slightly less than seawater (0 ‰), suggesting that Cl was isotopically uniform in the inner solar nebular (Sharp et al. 2013). Minor variations in mantle δ^{37}Cl, including maximum δ^{37}Cl of up to +3 ‰, have been attributed to the subduction of sediments (John et al. 2010). However, the majority of materials from the Earth's surface including sediments have δ^{37}Cl of less than seawater, and the mechanisms for isotope fractionation are not well understood (Barnes and Straub 2010). The Moon exhibits much greater variation in δ^{37}Cl with maximum values of +25 ‰ attributed to fractionation during lunar degassing of metal-halides from anhydrous magmas at low atmospheric pressures (Sharp et al. 2010). The short-lived ^{36}Cl isotope ($t_{1/2}$ = 301.3 ka) is used in dating groundwater and cosmogenic exposure dating of landforms formed by lava flows or glacial erosion surfaces ranging from tens of thousands of years to about 1 Ma (Ivy-Ochs and Kober 2008).

Biological Utilization and Toxicity

Chlorine gas is a respiratory irritant, and it can be detected by a bleach-like odor at concentrations of less than 1 ppm; it causes immediate chest pain, vomiting, and shortness of breath at concentrations of ~30 ppm; and is fatal within minutes at concentrations of more than ~1000 ppm (About Chlorine 2016). In contrast, chloride is the dominant anion enabling cellular level electrochemistry, meaning that Cl is an essential element for life.

Chlorine Isotopes

Magali Bonifacie
Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Université Paris Diderot, Paris, France

Introduction

Chlorine has 24 isotopes with mass numbers ranging from ^{28}Cl to ^{51}Cl. There are only two stable isotopes: ^{35}Cl and ^{37}Cl with respective proportions of 75.76% and 24.24% (Berglund and Wieser 2011). The longest-lived radioactive isotope is ^{36}Cl (half-life of 301,000 years); all other isotopes having half-lives of less than 1 h. Variations of the chlorine isotope ratio ($R = {}^{37}Cl/{}^{35}Cl$) are expressed in the δ-notation with $\delta^{37}Cl = \left(R_{sample}/R_{standard} - 1\right) * 1000$. The international reference standard for chlorine is the terrestrial ocean Standard Mean Ocean Chloride (SMOC), with $\delta^{37}Cl = 0$ ‰ (Godon et al. 2004a; Kaufmann et al. 1984).

History and Overview

Chlorine undergoes volatile and incompatible behavior during silicate melting and is water soluble. For these reasons, geological processes (including partial melting, magma degassing, hydrothermal activity, and weathering) have mostly concentrated Cl at the Earth's surface, particularly in the ocean, evaporites, and crustal brines. The most common and stable oxidation state of chlorine is -I, with chloride (Cl^-) being the main anion of most geological fluids.

Chlorine stable isotopic variations in geological samples were first reported in formation waters from the Gulf of Mexico (Kaufmann et al. 1984). Since then, chlorine stable isotopes have been used as a tool for tracing the origin and fate of fluids and rocks from the Earth's surface and interior (e.g., fluid movement in sedimentary basins, magma degassing, cycling of the subducted lithosphere into the mantle). Excluding volcanic fumaroles, the large majority of terrestrial samples analyzed to date have δ^{37} Cl between −2 and +2 ‰ (Fig. 1) requiring precise analytical methods to be able to identify and interpret small variations.

Stable Chlorine Isotope Measurements

Though chlorine isotopic compositions were, in the 1990s, measured via thermal ionization mass spectrometry (TIMS), δ^{37}Cl measurements are now mostly performed via gas source isotope ratio mass spectrometry (GS-IRMS) on gaseous methyl chloride. This requires prior precipitation of soluble chlorides Cl^- into $AgCl_{(s)}$, followed by the formation of $CH_3Cl_{(g)}$, via AgCl reaction with excess $CH_3I_{(g)}$ (Eggenkamp 1994). This method allows to reach the best precision on δ^{37}Cl measurements that are typically about ± 0.04 ‰ and ± 0.3 ‰ (1σ) when using either dual-inlet (Godon et al. 2004a; Bonifacie et al. 2005) or continuous-flow (Sharp et al. 2007) introduction modes. The determination of δ^{37}Cl of silicate bulk rocks and minerals requires an additional step of Cl extraction from the silicate network, usually made via pyrohydrolysis (Bonifacie et al. 2007a), before AgCl precipitation. Only recently, δ^{37}Cl values of rocks and minerals have been determined in situ with secondary ion mass spectrometry (SIMS) in Cl-rich terrestrial basaltic to andesitic glasses (Godon et al. 2004c; John et al. 2010; Layne et al. 2009) or melt inclusions (Manzini et al. 2017) but also in some extraterrestrial samples as chondritic sodalites (Sharp et al. 2007) or Cl-rich apatites from the Moon or Martian meteorites (Boyce et al. 2015; Sharp et al. 2010b; Williams et al. 2016). However, the uncertainty associated with δ^{37}Cl measurements by SIMS is still relatively large ± 0.5 ‰ (1σ) for samples with percent-level Cl (Williams et al. 2016) and larger for lower Cl-content samples.

Chlorine Isotope Fractionations

Many physical and chemical processes are likely to segregate isotopes of a single element according to their mass and following either thermodynamic equilibrium laws or kinetic processes. Theoretical studies based on ab initio calculations

(15) Eastoe et al. (2001), Kaufmann et al. (1993), Stotler et al. (2010). (16) Koehler and Wassenaar (2010). (17) Bonifacie et al. (2007a), Sharp et al. (2007, 2013). (18) Williams et al. (2016). (19) Sharp et al. (2010b), Boyce et al. (2015)

have reported equilibrium fractionations between different Cl-bearing molecules of geochemical or environmental importance including chloride salts (e.g., NaCl, KCl, RbCl), gas-phase molecules (such as HCl and Cl_2 or molecule of interest in atmosphere as ClO, $ClONO_2$), dissolved species, and $FeCl_2$ and $MnCl_2$ as analogs for Cl-bearing silicates (Czarnacki and Hałas 2012; Richet et al. 1977; Schauble et al. 2003). Their main conclusions are (i) Cl isotope equilibrium fractionations are limited to only a few per mil when Cl is under –I oxidation state (the majority of geological samples) with fractionation decreasing with increasing temperature, (ii) the magnitude of fractionation is predicted to increase with the increasing oxidation state of Cl (e.g., ClO_4 is 75 ‰ enriched relative to chloride at 25 °C), and (iii) silicates are predicted to be enriched compared to coexisting brines (from about 2 ‰ to 3 ‰ at 25 °C). Experimental work to constrain equilibrium fractionations have been limited to chloride salt precipitation (Eggenkamp et al. 2016; confirming the theoretical predictions of less than 0.5 ‰ fractionations at 22 °C) or gaseous HCl in equilibrium with aqueous chloride (Sharp et al. 2010a; confirming the predicted ~1.5 ‰ gas enrichment at 50 °C). On the other hand, kinetic fractionations are suggested to occur at low temperature during processes such as (i) diffusion (^{35}Cl diffusing faster than ^{37}Cl; Desaulniers et al. 1986; Eggenkamp and Coleman 2009; Richter et al. 2006), (ii) ion filtration (this process results from a fluid flow forcing solute ions such as Cl^- through a negatively charged low-permeability medium/membrane such as clays – ^{35}Cl being more efficiently repelled than ^{37}Cl, the solution passing through the membrane is enriched in ^{37}Cl, and the solution on the inflow side is Cl-enriched but ^{37}Cl depleted; (Campbell 1985; Phillips and Bentley 1987)), or (iii) HCl dynamically escaping from an acid solution (Sharp et al. 2010a). Eggenkamp (2014) presents a detailed and up-to-date review of the aforementioned and other known Cl isotope fractionations.

Key Research Findings and Applications as a Geochemical Tracer

Multiple studies have used $\delta^{37}Cl$ values to trace the origin of salinity and the hydrodynamic history of saline fluids found in the continental crust, brines in sedimentary basins (e.g.,

Eastoe et al. 2001; Kaufmann et al. 1993), or crystalline waters from old cratons (e.g., Shouakar-Stash et al. 2007; Stotler et al. 2010). In contrast to most chemical tracers that are prone to changes upon water-rock interactions, chlorine is mainly conservative, therefore Cl isotopes are used to identify fluid circulation in sedimentary basins and quantify diffusion in aquifers (e.g., Eggenkamp 1994; Giunta 2015; Lavastre et al. 2005).

Over the last decade, δ^{37}Cl values have been increasingly used to constrain the source and/or degassing of terrestrial and extraterrestrial rocks and magmas. Notably, since chlorine isotopes are thought to not fractionate during high-temperature dehydration of the subducting slab (Bonifacie et al. 2008b; Selverstone and Sharp 2013), δ^{37}Cl is used to better constrain the deep-Earth cycling of halogens and the origin of mantle chemical heterogeneity. Since the work constraining the Cl composition of the depleted mantle (Bonifacie et al. 2008a; Sharp et al. 2007), several studies have used δ^{37}Cl values for tracing the source of ocean island basalts (Halldórsson et al. 2016; John et al. 2010), back-arc basalts (Layne et al. 2009; Barnes et al. 2009), or arc magmas (e.g., Barnes and Straub 2010; Barnes et al. 2009).

Chlorine shows a unique combination of geochemical properties that can inimitably trace the history of magmas from their origin through their differentiation, degassing, and interactions with meteoric or hydrothermal fluids. Notably, chlorine is among the last volatiles degassed (mainly as HCl) from magmas, is chemically nonreactive (unlike most other main volatile elements), and is highly hydrophilic. Fumaroles, geothermal waters, and rocks of various arc volcanoes have been investigated in order to trace the source of magmas [for instance, the Poas volcano (Rodríguez et al. 2016; Sharp et al. 2010a), the Soufrière de Guadeloupe (Li et al. 2015), or the Mount Etna (Rizzo et al. 2013) or along an active arc setting (e.g., Barnes et al. 2009; Chiaradia et al. 2014; Li et al. 2015)]. Some studies also presented a time-related evolution of δ^{37}Cl in springwaters and fumaroles to test their relevance for volcanic surveillance (Li et al. 2015; Rodríguez et al. 2016). In parallel, the highly ^{37}Cl-enriched apatites of lunar basalts (with δ^{37}Cl up to +25 ‰) have been explained as resulting from the degassing of metal halides from an anhydrous mantle (Sharp et al. 2010a) or alternatively from the degassing of a lunar magma ocean early in the Moon's history (Boyce et al. 2015).

Summary and Future Directions

Because of the unique characteristics of chlorine when compared to most other abundant and geochemically important volatiles or mobile elements on Earth, δ^{37}Cl are increasingly used to reveal the origin and fate of terrestrial and extraterrestrial reservoirs. However, before reaching their full potential as a geochemical tracer, there is still a need of strengthening our fundamental knowledge on Cl isotope systematics (mainly further determination of isotopic fractionations between Cl species in various conditions and improvements of analytical methods in order to determine precise δ^{37}Cl on Cl-poor samples). Another promising aspect is the recent advance in measuring bromine stable isotope compositions in low Br-content geological samples (Louvat et al. 2016). Because Br shares most chemical characteristics with Cl (although slightly more reactive), the coupled used of Cl and Br stable isotopes should undoubtedly unravel important features of the halogen geodynamics.

Chondrites

Sara Russell
Department of Earth Sciences, The Natural History Museum, London, UK

Definition

Chondrites are the most common type of *meteorites*, making up around 80% of all known meteorite falls. Chondrites are stony meteorites and most are dark brown, gray, and/or black in color. Chondrites are accreted material from nebular components formed within the dusty cloud that circulated around the young Sun. They avoided igneous differentiation and so contain approximately solar proportions of the elements. Therefore, they likely originated on minor planets (mainly asteroids) which were not large enough to generate heat to melt. Most chondrites preserve an original texture from the time of their accretion. This texture consists of ~mm sized spherical silicate balls called chondrules surrounded by a submicron sized material called matrix (Fig. 1). In some chondrites, metal and/or sulfides are common and in some can be found refractory inclusions, including calcium-aluminum-rich inclusions (CAIs). Less heated chondrites typically contain primordial organic material and presolar grains that formed around ancient ancestral stars.Organic material can be complex and includes polyaromatic hydrocarbons. More details about chondrites and their classification can be found in Krot et al. (2013); Scott and Krot (2013); and Grady et al. (2014).

Alteration of Chondrites

As well as classifications of chemical class, chondrites are classified according to the degree of alteration (aqueous interaction and/or heating) they experienced on their parent asteroid. This is called the petrological scale and chondrites are numbered from 1 to 6 (Van Schmus and Wood 1967). According to this classification scheme, petrological types 2 and 1 show increasing amounts of aqueous alteration from 2 to 1, and types 3 to 6 show increasing amounts of changes due to heating. Type 1 chondrites only rarely contain anhydrous minerals; typically silicates have been entirely transformed to clays. Type 2 chondrites contain visible chondrules but also abundant phyllosilicate minerals. Type 3 chondrites are petrologically pristine, with clearly defined chondrules composed of anhydrous olivine, pyroxene, metal, and minor minerals, and containing glass in chondrule mesostasis. A continuum exists from type 3 to type 6 chondrites that have lost almost all their petrological texture and chondrules are barely visible. Meteorites that have been completely melted but retain a chondritic bulk composition are occasionally termed "Type 7 chondrites."

Chondrites are often affected by shock processing, most commonly while on their parent body. This can result in the formation of veins and mineralogical effects such as planar deformation features. A classification system for shock in ordinary chondrites was devised by Stoffler et al. (1991).

Another process that can affect chondrites, especially finds rather than falls, is terrestrial *weathering*. The most obvious effects of terrestrial weathering are oxidation of native iron to form oxides. Weathering also affects bulk chemistry and the silicate mineralogy of the sample, with CCs most easily affected (Bland et al. 2006).

Classification

Chondrites are cateogorized according to their chemical and isotopic properties, with the three main types or *classes* being ordinary chondrites, carbonaceous chondrites, and enstatite chondrites (Fig. 1).There are rare chondrites that do not fit into these classes: the Rumuruti type chondrites (R chondrites) and the Kakangari type chondrites (K chondrites). Additionally, a few chondrites do not fall into any of these types and are classified as ungrouped. These classes are further subdivided into *groups*, as outlined below. In addition, the chondrite is assigned a *petrologic type*, which is an indication of the type of asteroidal processing it has experienced.

Ordinary Chondrites (OC): Ordinary chondrites are the most common type of meteorite and around 95% of all chondrite falls are OCs. OCs are composed of chondrules rich in olivine and pyroxene, with minor silicates, oxides, sulfides,

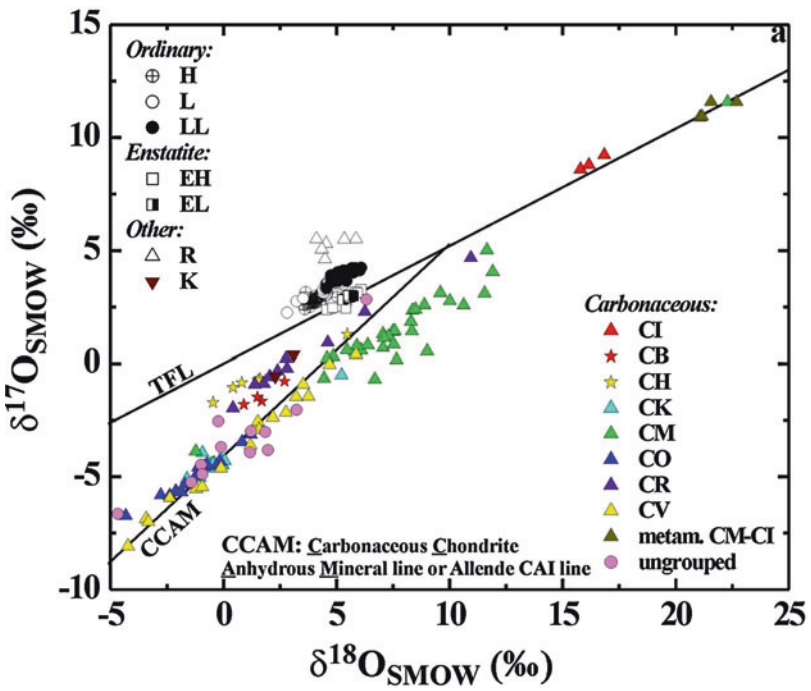
and metal, surrounded by fine grained matrix that is composed of chondrule-like fragments and sometimes amorphous material. Ordinary chondrites are typically petrological types 3–6. They contain metal in the form of Fe-Ni in varying proportions. Ordinary chondrites are further subdivided into three groups, H, L, and LL, according to their metal content and composition of silicates. H chondrites contain 15–20% free metal (a Fe-Ni alloy) and the olivine composition is $Fa_{16–20}$; L chondrites contain 7–11% free metal and their olivine composition is $Fa_{21–25}$; LL chondrites contain 3–5% free metal and olivine of $Fa_{26–32}$. Ordinary chondrites have oxygen isotope compositions distinct from terrestrial samples (Fig. 2). The JAXA Hayabusa mission returned material from an S type asteroid, which is remarkably similar to LL chondrite material (Nakamura et al. 2011). Therefore, S type asteroids are likely to be the source of most ordinary chondrites.

Chondrites, Fig. 1 The Parnallee meteorite that fell in India in 1857. This type 3 ordinary chondrite (LL) contains distinct rounded chondrules surrounded by a fine grained matrix. Natural History Museum specimen number BM 34792. The specimen is approximately 16 cm across

Carbonaceous Chondrites (CC): Although a minor contribution to known meteorites, carbonaceous chondrites have been extensively studied as they have suffered on minimal heating while on their parent bodies, and their petrological types are usually 1–3. The term carbonaceous is misleading; they typically contain no more than a few percent carbon and often much less. Carbonaceous chondrites are exceptionally diverse in texture and chemistry. The CCs are divided into classes, represented by a letter that usually refers to the type specimen of that class.

CV meteorites, which contain large chondrules of up to several mm in size and rather abundant white CAIs (around 5 vol%) which are irregular or rounded in shape and can be up to cm in size.

CK meteorites contain textural and oxygen isotope similarities to the CV meteorites, but they are more oxidized. CK are the only carbonaceous chondrites that are mostly typically metamorphosed, with petrological types 4–6 most common. Some researchers believe CV and CK are the same or related group (e.g., Greenwood et al. 2010).



Chondrites, Fig. 2 Oxygen isotope composition of chondrites. On a three-isotope oxygen diagram, $^{17}O/^{16}O$ ratio vs. $^{18}O/^{16}O$ ratio, both normalized to the Standard Mean Ocean Water value, chondrite groups occupy distinct regions. CCs typically plot below the terrestrial fractionation line; most non-CCs above it. $\delta^{17,18}O = [(^{17,18}O/^{16}O)_{sample}/(^{17,18}O/^{16}O)_{SMOW}-1] \times 1{,}000$ (From Scott and Krot 2013)

CO chondrites have a similar bulk chemistry to CVs and a similar abundance of CAIs, but both chondrules and CAIs in these meteorites are much smaller, around ~100 μm typically.

CM chondrites contain small chondrules and abundant matrix (around 50%). They are nearly always petrological type 2 and have experienced significant aqueous alteration.

CI chondrites have been extensively aqueously altered, which has destroyed much of their original texture and mineralogy. These chondrites have no (or very rare) chondrules and consist almost entirely of water-formed minerals such as phyllosilicates, sulfides, carbonates, and oxides. CIs are the most chemically primitive chondrites, and their bulk composition resembles that of the Sun, apart from volatile species such as H and He (e.g., Lodders 2003).

CR chondrites contain large chondrules similar in size to those in CV chondrites, but they only rarely contain CAIs. Iron nickel metal is abundant. Matrix makes up around 50% of the rock.

CH chondrites are very enriched in metal, have very small chondrules (~20 microns), and also contain CAIs. CH chondrites are exceptional among meteorite groups in that they do not contain true matrix, but instead the chondrules are closely packed. They are highly depleted in volatile elements.

CB chondrites contain large amounts of metal and are subdivided into two chemically similar textural types. CBa meteorites have extremely large chondrules (>cm in size), large metal grains, and are depleted in CAIs. CBb meteorites contain smaller chondrules (mm in size) and contain CAIs.

The CR, CB, and CH chondrites contain geochemical similarities to each other (e.g., they all have elevated $^{15}N/^{14}N$ compared to other chondrite groups) and are referred to as a clan.

Carbonaceous chondrites are darker in color than most other meteorites, and spectroscopically they resemble some C type or related asteroids such as G, B, or D. These asteroids are therefore the likely source for carbonaceous chondrites. Carbonaceous chondrites may preferentially originate in the outer regions of the main asteroid belt. There have been suggestions in the literature that CI chondrites may have a cometary source (e.g., Gounelle et al. 2010).

Enstatite chondrites (EC): Enstatite chondrites are highly reduced rocks that are rich in Fe, Ni-metal, and sulfides. Enstatite ($MgSiO_3$) is common, and Fe is almost absent in silicates. ECs are divided into two groups: the EH meteorites that contain chondrules around 0.2 mm in diameter and high abundance of metal and EL meteorites that contain larger chondrules (~0.5 mm) and less free metal. Enstatite chondrites have similar isotopic compositions to the Earth (Fig. 2). They are spectrally similar to many E-type asteroids.

Kakangari type chondrites (K): These are matrix-rich chondrites that are highly reduced.

Rumuruti type chondrites (R): Rumurutiite meteorites are enriched in matrix and are very oxidized with essentially no free metal.

Oxygen Isotopes

Measurements of the ratios of the three stable isotopes of oxygen (^{16}O, ^{17}O, and ^{18}O) are an essential tool in understanding the relationships between meteorite classes and groups (Fig. 2). On a graph of $^{17}O/^{18}O$ as a function of $^{18}O/^{16}O$, most terrestrial objects fall on a mass-related fractionation line of slope ~0.5, whereas meteorites fall off this line, with each group occupying a distinct oxygen isotope field. Meteorites with similar oxygen isotopic composition may have formed on the same or related asteroids, whereas differences may indicate an origin on separate parent bodies (e.g., Clayton 1993).

Ages of Chondrites

While the exact timing of accretion of chondrites has not been measured, age dates for many chondritic components have been reported, with Pb-Pb data giving the most accurate absolute ages. CAIs have ages of around 4567 Myr while chondrules tend to give similar or younger ages by a few Myr (e.g., Connelly et al. 2012). A minimum age of the accreted parent body can be determined from the age of alteration products that formed on the asteroid; for example, Mn-Cr isotopic data suggests that chondrites accreted and carbonates formed ~3Myr after the formation of the constituents of chondrites (e.g., Fujiya et al. 2011).

Summary and Conclusions

Chondrites are an invaluable tool for the geochemist, as they provide information about the original material from which terrestrial planets accreted. There is a great diversity in geochemistry, isotope compositions, and texture among chondrites, which likely reflects a diversity among the asteroids that are the source of most chondrites. Increased astronomical observations along with recent and upcoming sample return missions are helping us to refine our understanding of the sources of chondrites.

Chondrules

Rhian Jones
School of Earth and Environmental Sciences, The University of Manchester, Manchester, UK

Definition

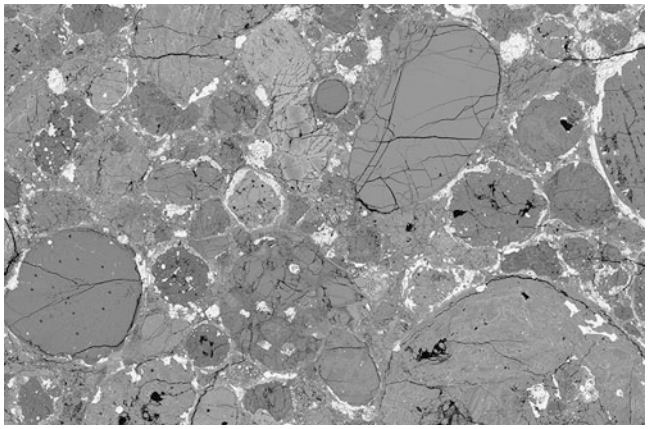
Chondrules are the most abundant component of chondrite meteorites. The term chondrule comes from the ancient Greek word for the kernel of a grain of wheat, χονδρος (chondros), which chondrules roughly resemble in size and shape. Chondrules are rounded, millimeter, or submillimeter stone particles. They are among the oldest solid materials in the solar system. Shapes and textures of chondrules indicate that they formed from molten droplets which were floating freely in the gas of the protoplanetary disk at the time of cooling and solidification. After formation, chondrules accreted with other materials to form asteroids, from which chondrite meteorites are derived. There is debate about the heating process that melted chondrules and the environment in which they formed. Properties of chondrules can be used to infer physical and chemical conditions within the protoplanetary disk in the first few million years of solar system history.

Chemistry and Mineralogy of Chondrules

Chondrules constitute up to 80% by volume of ordinary (O) and enstatite (E) chondrites and approximately 50% of carbonaceous (C) chondrites (Scott and Krot 2014, Zanda 2004). This high abundance has been used to estimate that chondrules made up about 10^{24} g of material in the early solar system (Desch et al. 2012), and thus they provide an important record of materials that remain from the protoplanetary disk environment. The description of chondrules presented here considers only the primary properties of chondrules, i.e., properties that pertain to their formation and history prior to incorporation into the asteroid parent bodies of their host chondrites. Most chondrites have undergone secondary processing after accretion to their parent asteroids, to varying degrees, including aqueous alteration, heating that resulted in metamorphism, and/or shock resulting from impacts. Primary properties of chondrules must often be deduced by considering the nature of any alteration and disentangling effects that may have altered or erased primary signatures. Chondrules occur in all chondrite groups except for the CI chondrites, which have undergone complete aqueous alteration of the initially anhydrous assemblage, to the extent that any chondrules that were originally present have been obliterated.

The basic chemical and mineralogical properties of individual chondrules are similar, but they differ in detail. Chondrule chemistry varies widely both within and among chondrite groups and classes (Jones et al. 2005; Jones 2012). Average major element contents for bulk chondrules (Fe, Mg, Si, Ca, Al) are similar to solar or CI chondrite abundances, and there is little fractionation among refractory elements (e.g., Ca, Al, Ti, Mg, rare earth elements). However, bulk compositions of individual chondrules are variable, for example, within a single chondrite the ratio of refractory elements to Si can vary by about a factor of 3, and the Fe/Si ratio can vary by more than an order of magnitude. Abundances of moderately volatile elements (e.g., Mn, Na, K, S) are also highly variable among individual chondrules.

In all chondrite groups, there is a range of chondrule textures (Connolly and Desch 2004; Lauretta et al. 2006; Jones 2012; Scott and Krot 2014) (Fig. 1). The dominant silicate minerals are olivine ($(Mg,Fe)_2SiO_4$) and pyroxene



Chondrules, Fig. 1 The Semarkona ordinary chondrite: back-scattered electron image, ~9 mm across. Chondrules are round or have rounded outlines. Individual chondrules have different textures, as well as different chemical compositions. The most abundant minerals are olivine and pyroxene, for which darker shades of *gray* correspond to higher Mg/(Mg + Fe) ratio. *White* grains are metal and/or sulfide (Image by J. Lewis)

($(Mg,Fe,Ca)_2Si_2O_6$): individual chondrules have varying ratios of olivine/pyroxene, from 100% olivine to 100% pyroxene, and an interstitial feldspathic phase that may be crystalline feldspar ($CaAl_2Si_2O_8$-$NaAlSi_3O_8$) or glass. Chondrules also contain varying amounts of Fe-Ni metal and/or sulfide minerals. In most chondrules, olivine and pyroxene grains have regular crystal forms: these chondrules are described as having porphyritic textures. Olivine and pyroxene can also show a range of morphologies that are a function of growth rate including hopper morphologies, elongate barred grains (usually bars of olivine), radiating needles, and cryptocrystalline textures. Two common types of chondrules are defined based on their textures and chemical characteristics (Brearley and Jones 1998). Type I chondrules are chemically reduced: olivine and pyroxene have a high atomic Mg/(Mg + Fe) ratio, commonly around 0.99, and they contain abundant metallic iron, commonly kamacite ($Fe_{\sim 0.95}Ni_{\sim 0.05}$). Type II chondrules are more oxidized: olivine and pyroxene have lower atomic Mg/(Mg + Fe) ratios than type I chondrules, and olivine and pyroxene grains usually show strong growth zoning (igneous zoning), e.g., Mg/(Mg + Fe) ratios from around 0.8 to 0.7 in ordinary chondrites. Compared with type I chondrules, type II chondrules contain less metallic iron but more iron sulfide (typically troilite, FeS), and they have higher abundances of moderately volatile elements than type I chondrules (Na, Mn, P, S).

The majority of olivine and pyroxene grains in chondrules crystallized from melt as the droplet cooled. There is also a population of identifiable grains called relict grains which were inherited from previous generations of chondrules and did not melt during the heating event (Jones 2012). These include MgO-rich olivine (forsterite) in type II chondrules and relict grains of MgO-rich olivine in type I chondrules. Relict grains termed dusty olivine are grains of FeO-rich olivine that were incorporated into type I chondrules. During the heating event that melted the type I chondrule, the FeO-rich olivine grain underwent reduction, and small blebs of Fe metal precipitated which give the grain a dusty appearance in transmitted or reflected light. Chemical compositions and oxygen isotope compositions of relict grains are consistent with formation in previous generations of chondrules and provide evidence that there were multiple heating episodes in the chondrule-formation region. Further evidence for repeated heating is found in igneous rims on chondrules: these represent a second episode of heating that melted a dusty rim that was deposited after the host chondrule solidified.

There are significant differences in the chondrule populations among the different chondrite classes and groups (Jones 2012). These include properties such as mean chondrule sizes and the distribution of different textural types of chondrules. There are chemical differences between chondrules of similar textural type that occur in different chondrite groups, and abundances of relict grains in chondrules of the same textural type vary among chondrite groups. Also, chondrules from O, C, and E chondrites have different oxygen isotope compositions. Differences in chondrule properties specific to individual chondrite groups indicate that the disk was chemically heterogeneous and that chondritic asteroids accreted from localized batches of materials.

Oxygen Isotope Compositions of Chondrules

Oxygen isotope compositions of early solar system materials are an important record of relationships among different components of chondrites, as well as among different chondrite groups. In an oxygen three-isotope diagram ($\delta^{17}O$ vs. $\delta^{18}O$, where $\delta^n O = [(^nO/^{16}O)_{sample}/(^nO/^{16}O)_{SMOW} - 1]^*10^3$ and SMOW = standard mean ocean water), mass-dependent isotopic fractionation results in a distribution of compositions along a line of slope 0.52, an example of which is the terrestrial fractionation line, TFL. Oxygen isotope compositions of chondrules in O, E, and C chondrites lie above, along, and below TFL, respectively (Clayton 2003; Krot et al. 2006; Yurimoto et al. 2008; Scott and Krot 2014). Chondrules have significantly higher values of $\delta^{17}O$ and $\delta^{18}O$ than calcium-aluminum inclusions (CAIs), which have $\delta^{18}O$ values around −40‰, close to values inferred for the sun. For bulk chondrules, $\delta^{18}O$ values are typically in the range −10 to +7‰. Oxygen isotope compositions of chondrules in C chondrites lie on arrays that have a slope close to one on the oxygen three-isotope diagram, which indicates mixing of

isotopic reservoirs that were related by non-mass-dependent processes. Isotopic self-shielding, possibly within the protoplanetary disk or in its precursor molecular cloud, could have led to an isotopically heavy ice component that evaporated in the region of chondrule formation and became incorporated into chondrule materials (Clayton 2003; Krot et al. 2006; Yurimoto et al. 2008).

Chondrule Precursor Material

Since chondrules are solidified melt droplets, the precursor material from which they formed has largely been erased during melting. Relict grains are a direct record of precursor material that would have been present as grains tens of micrometers across in the precursor assemblage. The remainder of the precursor material was probably a fine-grained mixture of silicates, metal, and sulfide grains (e.g., Jones et al. 2005), although in chondrule-formation models that involve collisions between molten planetesimals, the predominant precursor material would have been molten. Matrix in chondritic meteorites consists of a fine-grained assemblage of silicate, oxide, metal, and sulfide materials (Scott and Krot 2014), but it is not chemically equivalent to material needed for chondrule precursors. Chondrules and matrix show chemical complementarity in that their combined chemistry is similar to solar abundances, suggesting that each chondrite group formed in a chemical reservoir of broadly solar composition, after condensation of refractory, common, and moderately volatile elements.

A group of chondrules described as aluminum-rich chondrules spans the compositional gap between CAIs and the common ferromagnesian chondrules (Connolly and Desch 2004). Relict fragments of CAIs are observed in these chondrules (Krot et al. 2009). Oxygen isotope compositions of chondrules from C chondrites also show clear relationships to CAIs and other types of refractory inclusions. Hence, fragments of CAIs are plausible components of chondrule precursor material.

Thermal Histories of Chondrules

Thermal histories of chondrules have been deduced from their textures and mineralogy, as well as from analogue experiments (Desch and Connolly 2004; Hewins et al. 2005; Lauretta et al. 2005; Jones et al. 2005; Desch et al. 2012). The ambient temperature prior to heating was below the temperature at which sulfur condensed from the solar nebula gas, <400 °C. Peak temperatures for chondrule formation were close to the temperature of complete melting of the chondrule material, around 1500–1600 °C. The duration of heating at the peak temperature was short, seconds to minutes, in order to retain moderately volatile elements such as Na and S that would evaporate during an extended period of melting. Retention of Na also requires a high gas density. After melting, chondrules cooled at rates that range from around five to several hundreds of degrees per hour. These cooling rates are constrained by laboratory experiments that reproduce chondrule textures, as well as considerations such as the development of igneous growth zoning in olivine and dissolution rates of relict grains. The wide range of cooling rates is responsible for production of different chondrule textures because morphologies of olivine and pyroxene grains are a function of growth rate, which is a function of undercooling. Chondrule cooling rates are significantly slower than cooling rates that would result from black-body radiation of isolated molten droplets into free space, indicating that they formed in a gas of higher density (Alexander and Ebel 2012).

Ages of Chondrules

Chondrules formed within the first few million years of solar system history. Absolute ages of chondrules determined by high-precision Pb-Pb radiometric dating range from 4567 to 4565 Ma (see Krot et al. 2009; Wadhwa 2014). Ages are also measured based on chronometers that use extinct short-lived radioisotopes that were present in the early solar system, such as ^{26}Al which decays to ^{26}Mg with a half-life of 0.75 My. Most ^{26}Al ages for chondrules are within 1–3 million years after the CAI formation age (4567 Ma) (Krot et al. 2009; Desch et al. 2012; Kita and Ushikubo 2012). Hence, chondrule formation appears to have begun contemporaneously with CAI formation and persisted throughout the time period when planetesimals were accreting. Most measured chondrule ages are younger than the time scales of differentiation on the earliest planetesimals (Wadhwa 2014). It is possible that chondrule formation occurred prior to formation of those bodies and that earlier generations of chondrules no longer exist because the bodies in which they were incorporated have been melted.

Chondrules in the metal-rich CB and CH chondrite groups differ from other O, C, and E groups. Chondrules in the CB_a chondrites are unusually large (up to cm sized), whereas those in the CB_b and CH chondrites are small (mean diameters 0.5 and <0.1 mm, respectively). These meteorites have a high proportion of non-porphyritic chondrules (Scott and Krot 2014). They likely formed in a large impact plume that resulted from a collision involving a metal-rich body. Ages of chondrules in CB chondrites are significantly younger than typical chondrules in most chondrite groups, 4563 Ma, so they probably formed after the nebular gas had dissipated (Desch et al. 2014; Wadhwa 2014).

Chondrule-Formation Models

Chondrule-formation models must take into account the chemical, isotopic, and physical properties of chondrules and the constraints those properties impose. A variety of models has been proposed to account for the rapid heating and cooling events that chondrules experienced, but no single model is clearly preferred. Models include heating in a shock front as a result of gas drag combined with radiant heat, heating in the X-wind that lofted chondrules above the nebular midplane in the magnetocentrifugal outflow, lightning within the disk, collisions involving partially or completely molten planetesimals, and collisions involving solid planetesimals (e.g., Connolly and Desch 2004; Desch et al. 2012; Johnson et al. 2015). For the shock model, chondrule formation could have occurred in the bow shock of a planetesimal moving through the disk in an eccentric orbit or in the shock front associated with gravitational instabilities in the disk. A chondrule-formation process has not been detected directly in astronomical observations of protoplanetary disks around young stellar objects.

Summary

Chondrules formed from partially to fully molten liquid droplets that solidified into approximately spherical, (sub) millimeter-sized beads. They formed within one to three million years of the formation of the first solids in the solar system. Chondrules have approximately chondritic chemical compositions and consist predominantly of olivine, pyroxene, a feldspathic phase, metal, and sulfide. Chemical, isotopic, and physical properties of chondrules vary among the different chondrite groups. Chondrule cooling rates inferred from their textures and mineralogy are between a few to several hundred degrees per hour. Models for the mechanism that resulted in chondrule formation include heating within shock fronts and collisions between either solid or partially molten planetesimals during the early stages of formation of the solar system.

Chromium

Monica Vasiliu and David A. Dixon
Department of Chemistry, University of Alabama, Tuscaloosa, AL, USA

Element Data
Atomic Symbol: Cr.
Atomic Number: 24.
Atomic Weight: 51.9961.
Isotopes and Abundances: ^{50}Cr 4.35%, ^{52}Cr 83.79%, ^{53}Cr 9.50%, ^{54}Cr 2.36%.
1 Atm Melting Point: 2130 ± 20 K.
1 Atm Boiling Point: 2945.
Common Valences: 2, 3, 4, 6.
Ionic Radii: (+II) 84, (+III) 64, (+IV) 56, (+VI) 44 ppm.
Pauling Electronegativity: 1.66.
First Ionization Potential: 6.76 eV.
Chondritic (CI) Abundance: 2660 ppm.
Silicate Earth Abundance: 2625 ppm.
Crustal Abundance: ~100 ppm.
Seawater Abundance: 0.2 ppb.
Core Abundance: 0.90%.

Properties

Chromium (Emsley 1991, 2001; Anthoni 2006; Anders and Grevesse 1989; McDonough 2005) is a lustrous, brittle, hard, and very corrosion-resistant metal. It has a silver-gray color with a blue tinge and it can be highly polished. It does not tarnish in air, but when heated it burns forming the green chromic oxide. Chromium is unstable in oxygen as it immediately reacts to form a thin oxide layer that is impermeable to oxygen and protects the metal below. Chromium dissolves in HCl and H_2SO_4 but not in H_3PO_4. None of the natually occurring chromium isotopes are radioactive.

History and Use

Chromium was discovered in 1797 by Louis Nicolas Vauquelin while experimenting with a material known as Siberian red lead, the mineral crocoite ($PbCrO_4$). He produced chromium oxide by mixing crocoite with hydrochloric acid. Although he believed a method for isolating chromium didn't yet exist, Vauquelin showed in 1798 that he was able to obtain metallic chromium by simply heating chromium oxide in a charcoal oven.

Chromium can be polished to form a very shiny surface and is often plated to other metals to form a protective and attractive covering. Chromium is added to steel to harden it and to form stainless steel, an iron-based alloy that contains at least 10% chromium. Other chromium-steel alloys are used to make armor plate, safes, ball bearings, and cutting tools. Chromium compounds are also used to anodize aluminum, a process which coats aluminum with a thick, protective layer of oxide. Chromite, chromium's primary ore, is used to make molds for the firing of bricks because of its high melting point, moderate thermal expansion, and stable crystal structure.

Crocoite or lead chromate is also known as chrome yellow and has been used as a yellow pigment in paints. Chromic oxide (Cr_2O_3), also known as chrome green, is the ninth most abundant compound in the Earth's crust and is a widely used green pigment. Ruby (variety of corundum, Al_2O_3) and emerald (variety of beryl, $Be_3Al_2(SiO_3)_6$) owe their colors to chromium compounds. Potassium dichromate ($K_2Cr_2O_7$) is used in the tanning of leather, while other chromium compounds are used as mordants (materials which permanently fix dyes to fabrics). Chromium(IV) oxide (CrO_2) is used to manufacture magnetic tape.

Geochemical Behavior

Chromium is not found free in nature and is found mainly as chromite. This ore is found in many places including South Africa, India, Kazakhstan, and Turkey. Chromium metal is usually produced by reducing chromite with carbon in an electric-arc furnace or reducing chromium(III) oxide with aluminum or silicon.

Chromium enters the air, water, and soil in the chromium (III) and chromium(VI) oxidation states through natural processes and human activities. Most of the chromium in air will eventually settle and end up in waters or soils. Chromium in soils strongly attaches to soil particles and as a result it will not move toward groundwater. In water, chromium will absorb on sediment and become immobile. Only a small part of the chromium that ends up in water will eventually dissolve.

The main human activities that increase the concentrations of chromium(III) are steel, leather, and textile manufacturing. The main human activities that increase chromium(VI) concentrations are chemical, leather, and textile manufacturing and electro painting, as industrial examples. These applications will mainly increase concentrations of chromium in water. Through coal combustion, chromium will also end up in air, and through waste disposal, chromium will end up in soils.

Sodium dichromate is a corrosion inhibitor and was added to the Columbia River water used to cool the nuclear reactors, which produced plutonium for nuclear weapons at the

Hanford site in Washington, USA. Some of this material spilled or leaked from pipes leading to soil contamination. Large holes of at least 26 m deep and more than 5000 m^2 at the top were dug down to the groundwater. Approximately two million tons of contaminated soil containing an estimated 129 tons of concentrated chromium was removed and transported to a lined landfill at Hanford. The most contaminated soil is mixed with cement to prevent additional leaching. This led to the reduction of risk to a key salmon spawning region in the Columbia River.

Biological Utilization and Toxicity

Chromium(III) is an essential trace element for organisms including humans, who consume approximately 1 mg a day, because it can disrupt the sugar metabolism pathway, for example, leading to heart conditions, when the daily dose is too low (Vincent 2013). Like other metals that organisms require in trace amounts, chromium can be quite toxic, especially chromium(VI) (chromates (CrO_4^{2-})), which can alter genes, for example, causing cancer. Humans can be exposed to chromium through breathing, eating, or drinking and skin contact with chromium or chromium-containing compounds. The level of chromium in air and water is generally low; however, conytaminated well water may contain the dangerous hexavalent chromium(VI). Food consumption is the main route of chromium(III) uptake, as chromium(III) occurs naturally in many vegetables, fruits, meats (kidneys), yeasts, and grains (brewer's yeast, wheat germ). Various methods of food preparation and storage may alter the chromium content of food; for example, food stored in steel tanks or cans can absorb chromium.

Crops contain biological control systems that arrange the chromium uptake to be low enough not to cause any harm, but when the amount of chromium in the soil rises, this can lead to higher concentrations in crops. Acidification of soil can also influence chromium uptake by crops. Plants usually absorb only chromium(III). This may be the essential kind of chromium, but when concentrations exceed a certain value, negative impacts on animal health can still occur.

Chromium is not known to accumulate in the bodies of fish, but high concentrations of chromium, due to the disposal of metal products in surface waters, can damage the gills of fish that swim near the point of disposal. In animals, chromium can cause respiratory problems, a lower ability to fight disease, birth defects, infertility, and tumor formation.

Definition

Chromium has four naturally occurring stable isotopes (^{50}Cr, ^{52}Cr, ^{53}Cr, and ^{54}Cr) with natural abundances of 4.35%, 83.79%, 9.50%, and 2.36%, respectively. Among these, ^{50}Cr, ^{52}Cr, and ^{54}Cr are nonradiogenic, while ^{53}Cr is the radiogenic product of ^{53}Mn, an extinct nuclide with a half-life of 3.7 Myr. Chromium isotope variations in terrestrial samples are reported using the ratio $^{53}Cr/^{52}Cr$, expressed in conventional delta notation ($\delta^{53}Cr$) relative to NIST SRM 979, a metallic Cr standard from the National Institute of Standards and Technology. In meteorite samples, the ratio $^{54}Cr/^{52}Cr$ is sometimes used to report nuclear synthetic anomalies (conventionally reported in epsilon notation). Chromium isotopes have a wide range of applications in cosmochemistry, geochemistry, and environmental remediation efforts.

Introduction

The earliest work on Cr isotopes was largely focused on cosmochemical processes, namely the application of the short-lived ^{53}Mn-^{53}Cr radiochronometer to date early solar system events (e.g., Birck and Allègre 1984). Other early

work was been driven by the need to monitor hexavalent Cr as an environmental contaminant, which has resulted in a well-developed framework for understanding low-temperature mass-dependent Cr isotope systematics. Building on this foundation, there has been a surge of recent work focused on using Cr isotopes as a paleoredox proxy. Most recently, work has also focused on improving our understanding of Cr cycling on the modern Earth surface and on developing a global isotope mass balance for the Cr system. Given the broad scope of Cr isotope work, we will touch only briefly on each of the primary applications for the system and then highlight aspects of the Cr system that have drawn recent attention.

Methods

Chromium isotopes can be measured either by thermal ionization mass spectrometry (TIMS) or by multicollector inductively coupled plasma source mass spectrometry (MC-ICP-MS). Typically a tracer containing known concentrations of two isotopes (most commonly ^{50}Cr and ^{54}Cr) is added to samples prior to sample preparation. This method, known as the "double-spike" method, can be used to correct for any fractionation during sample preparation or analysis based on the known and measured ^{50}Cr/^{54}Cr ratio. Due to isobaric interferences with ^{51}V, ^{49}Ti, and ^{56}Fe, and the relatively small range of Cr isotopic variation seen in nature, chemical purification of samples is required prior to analysis. This is typically accomplished via column chromatography using cation or anion exchange methods (e.g., Schoenberg et al. 2008; Yamakawa et al. 2009), followed by additional column purification to remove remaining Fe, Ti, and V. Analysis on TIMS is relatively straightforward – Cr is ionized at ~1200–1400 °C, which is below the temperatures required to efficiently ionize Fe. Interferences during MC-ICP-MS analysis can be much more problematic, in particular polyatomic interferences associated with the use of Ar as a plasma gas. These require the measurement of Cr on the "shoulder," instead of in the center of a flat peak as is typical of most systems. Additionally, these analyses typically must be conducted with a high mass resolution instrument in order to distinguish Cr and Fe peaks (Weyer and Schwieters 2003).

Cosmochemistry

Early work on chromium isotope systematics in natural materials focused on mass-independent effects, i.e., radiogenic effects on ^{53}Cr, and nucleosynthetic effects on ^{54}Cr. Mass-independent Cr isotopic composition are typically expressed in ε notation (deviation of the isotopic ratio of the sample from the standard multiplied by 10,000). In contrast to mass-dependent measurements, measured isotope ratios are corrected for the mass-dependent fractionations that occur naturally and during sample preparation and instrumental analysis by assuming a natural ratio for two isotopes (often least affected by mass-independent effects) of the same element. In the case of Cr, ^{50}Cr and ^{52}Cr are usually used for normalization.

The decay product of short-lived nuclide ^{53}Mn (half-life 3.7 Myr) is ^{53}Cr (Kaye and Cressy 1965). Due to the relatively short half-life, the change in parent/daughter ratio was extremely large during the early evolution of the solar system, and thus short-lived nuclide systems are sensitive to tracking events during this period. Further, because the parent isotope is extinct, examination of the change in daughter isotopes (differentiation between Mn and Cr leads to varying Mn/Cr ratio and thus different ^{53}Cr ingrowth) can further provide age information. ^{53}Mn-^{53}Cr is one of the few short-lived chronometers that have achieved prominence (Birck and Allègre 1985, 1988; Rotaru et al. 1992; Lugmair and Shukolyukov 1998), which is partially due to the relatively high abundances of both Mn and Cr in many solar system objects. These applications are explored further by McKeegan and Davis (2014) and Qin and Wang (2017).

In a second application of mass-independent fractionation, anomalies in ^{54}Cr/^{52}Cr relative to terrestrial rocks have been reported for both bulk meteorites and individual meteorite components (Birck and Allègre 1984; Papanastassiou 1986; Rotaru et al. 1992; Podosek et al. 1997; Trinquier et al. 2008; Qin et al. 2011). These are thought to be the result of incomplete mixing of nuclides synthesized in different nucleosynthetic sources with distinct isotopic signatures. Such isotope anomalies have been found for a range of other elements in addition to Cr (further discussed by Qin and Carlson (2016)). These isotope anomalies have been very useful for identifying the sources of materials accreted into the early solar nebula. Anomalies at the whole meteorite scale are especially useful for understanding heterogeneity in the solar nebula, can act as fingerprints of specific meteorites, and can be used to probe the genetic relationship between different meteorite groups.

High-Temperature Terrestrial Settings

Mass-dependent fractionation of Cr under high-T settings is much less constrained compared to that under low-T settings. This limits the application of Cr isotopes to trace geological and planetary processes. Such studies are also important for constraining the Cr isotope inventories of major terrestrial reservoirs, which often serve as the basis for the application of Cr isotopes in low-T settings. An early study by Schoenberg et al. (2008) found a limited variation in the Cr isotopic

composition of different types of igneous rocks and marine sediments, and the bulk silicate earth (BSE) value of δ^{53}Cr was therein estimated to be -0.124 ± 0.101‰. These authors argued for a homogeneous mantle source and limited Cr isotopic fractionation during partial melting and magma differentiation (Schoenberg et al. 2008). Chondrites show a similarly limited range of variations (Qin and Carlson 2016; Bonnand et al. 2016b; Schoenberg et al. 2016). A recent Cr isotopic study by Xia et al. (2017) on mantle xenoliths from various locations showed much larger variation (δ^{53}Cr ranging from -1.36‰ to 0.75‰), than found by Schoenberg et al. (2008). Although some of the variations are likely due to secondary processes such as metasomatism and these results suggest some mantle heterogeneity, the variation is mainly caused by interaction of mantle peridotites with silicate melts long before they were brought to the surface. This study also confirmed that partial melting does not lead to significant Cr isotopic fractionation. The most recent estimate of the BSE value is -0.14 ± 0.12‰ (Xia et al. 2017), in concert with the previously determined value (Schoenberg et al. 2008). Studies on subducted continental and oceanic crusts showed that dehydration does not fractionation Cr isotopes, probably due to limited dissolution of Cr(III) in the fluids or limited amounts of fluid generated (Shen et al. 2015; Wang et al. 2016a). However, serpentinized oceanic crusts have been shown to be significantly isotopically heavier than BSE (Wang et al. 2016a; Xia et al. 2017) and the missing isotopically light source warrants future studies.

Further insights on high-T Cr isotopic behavior can be gained from the study of intermineral isotopic fractionation of mantle minerals. Based on first-principle calculations, Moynier et al. (2011) made theoretical estimations of Cr isotopic fractionation between co-existing minerals under conditions of planetary core-mantle segregation. The differences between most Cr(II) and Cr(0)-bearing minerals are minor at high temperatures, but the difference between those with Cr(III) and Cr(0) can be much larger. Farkaš et al. (2013) observed that chromites of different origins all have slightly heavier Cr isotopic compositions (with an average δ^{53}Cr value of -0.079 ± 0.129‰) than the BSE value. This finding was confirmed in a later study by Shen et al. (2015). Lunar mare basalts show Cr isotopic variation correlated with MgO content, likely due to spinel crystallization (Bonnand et al. 2016a). More modeling and laboratory observations are needed to further characterize mineral-scale Cr isotope heterogeneity.

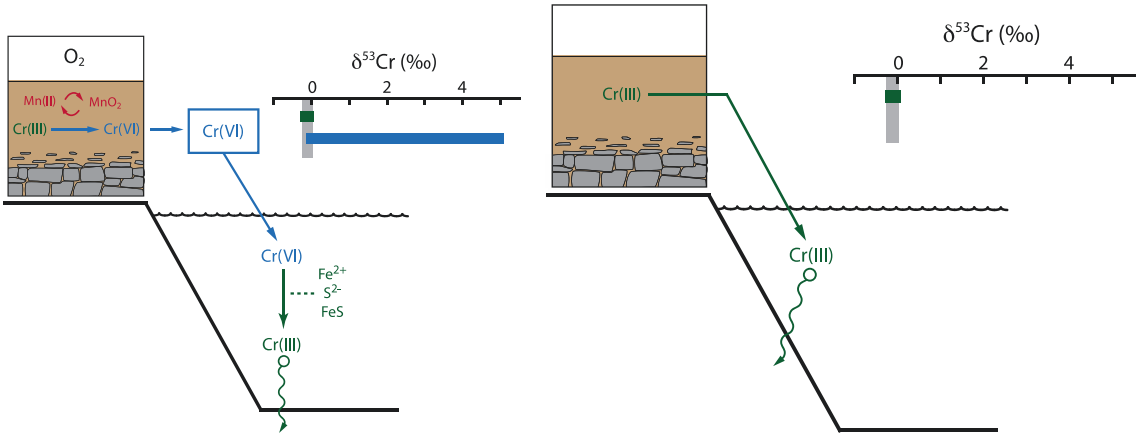
Environmental Applications

Chromium has two major species in the natural surface environment – trivalent and hexavalent – denoted as Cr(III) and Cr(VI), respectively. Cr(VI) is carcinogenic and soluble in aquatic solution, while Cr(III) is sparingly soluble and can act as a micronutrient (Bartlett and Kimble 1976, 1979; Rai et al. 1987, 1989; Fendorf 1995). The major source of Cr (VI) to the environment is from industrial activities such as electrical plating and leather tanning (e.g., Megharaj et al. 2003), although geogenic pollution can also occur in areas covered with Cr-rich ultramafic bedrocks (e.g., Bartlett and James 1979; Oze et al. 2007).

The reduction of Cr(VI) to insoluble Cr(III) can remove Cr(VI) from groundwater (e.g., Cheung and Gu 2007; Dhal et al. 2013). Natural attenuation (Palmer and Puls 1994), active remediation (e.g., the use of permeable reactive barriers (Blowes et al. 1997, 2000; Puls et al. 1999; Wilkin et al. 2005) and biostimulation (Oliver et al. 2003; Cheung and Gu 2007; Dhal et al. 2013)) has been used to remove potentially dangerous levels of Cr(VI) from groundwater. Cr isotopes are a key tool used to monitor the effectiveness of these techniques. Light isotopes are preferentially reduced (and removed from groundwater) relative to heavy ones, leading to systematically increasing δ^{53}Cr in the remaining Cr(VI) thereby creating a means to track the extent of reduction and removal of Cr from this soluble pool (e.g., Ellis et al. 2002; Basu and Johnson 2012). The preferential reduction of light isotopes is linked to weaker chemical bonds in lower mass isotopes (Urey 1947; Bigeleisen 1965).

Numerous laboratory and field studies have been conducted to determine the fractionation factor during reduction (α). The α values determined in the lab range from as high as 0.9996 (-0.04‰) to as low as 0.9920 (-8‰) (see Qin and Wang 2017 for a more detailed review), in contrast to the narrower range observed in the field, which range from ca. 0.3‰ to ca. -2‰ (Berna et al. 2010; Izbicki et al. 2012). Lower fractionations derived from field studies likely result from a diffusion-reaction process, where Cr(VI) must diffuse into isolated reduction zones and the isotopically fractionated Cr(VI) can then diffuse back into solution (e.g., Clark and Johnson 2008). This systematic change in δ^{53}Cr during reduction can be described by a Rayleigh distillation model whereby groundwater δ^{53}Cr will become increasingly heavy as mobile Cr (VI) is reduced (e.g., Ellis et al. 2002; Scott et al. 2004; Abe and Hunkeler 2006).

Interpretation of Cr isotope data from field samples requires a clear understanding of several nonredox-dependent processes. Significantly, adsorption of Cr(VI) to mineral surfaces does not induce Cr isotope fractionation (Ellis et al. 2004) and therefore does not interfere with the use of Cr isotopes in tracking reduction. However, isotope exchange between remaining Cr(VI) and previously formed Cr(III) (Altman and King 1961) can lead to large isotope fractionations (Schauble et al. 2004; Wang et al. 2015). The



Chromium Isotopes, Fig. 1 Schematic of Cr cycle as a paleobarometer for atmospheric oxygen level. Large Cr isotope fractionations are expected in an oxic world (left hand side), while limited fractionations are expected in an anoxic world

timescale and impact of isotope exchange depends on the Cr concentrations and the relative masses of dissolved Cr (VI) and exposed Cr(III). Therefore, field conditions must be taken into account to assess uncertainties related to isotope exchange when using groundwater δ^{53}Cr to detect and quantify the extent of Cr(VI) reduction. Furthermore, additional complications can arise from solubilization of Cr(III) by organic ligands and reoxidation of previously formed Cr (III) (e.g., Bartlett and James 1979; Buerge and Hug 1998), which are still poorly understood. In sum, the Cr isotope system is useful redox proxy that can move forward our understanding of hexavalent Cr contamination. However, potential complications regarding isotope exchange, ligand mobilization, and oxidation continue to pose challenges and offer future research opportunities.

Cr Isotopes as a Paleoredox Proxy

More recently, Cr isotopes have emerged as a tracer of Earth's atmospheric oxygenation (e.g., Frei et al. 2009, 2013; Crowe et al. 2013; Planavsky et al. 2014; Cole et al. 2016; Gilleaudeau et al. 2016). The simplest application of Cr isotopes as a paleoredox proxy relies on the basic idea that variability of δ^{53}Cr in sedimentary rocks requires mobile Cr (VI) on Earth's surface and that the oxidation of Cr(III) to Cr (VI), via Mn oxides, requires free oxygen. The isotopic variability of this mobile pool has been demonstrated in modern riverine and marine systems (e.g., Bonnand et al. 2013; Frei et al. 2014; Scheiderich et al. 2015; Wu et al. 2017; D'Arcy et al. 2016; Farkaš et al. 2013; Novak et al. 2014), while the potential to record these signals in sedimentary archives has also been demonstrated in modern systems (e.g., Reinhard et al. 2014; Gueguen et al. 2016; Pereira et al. 2016; Wang et al. 2016b). Oxidized and mobile Cr(VI) is isotopically enriched, while residual soils are isotopically depleted. Using this framework, a lack of variability in the δ^{53}Cr sedimentary record should be indicative of very low surface oxygen levels, not capable of inducing oxidative Cr cycling, while the onset of variability in the δ^{53}Cr record should mark a shift to oxidative terrestrial weathering of Cr and an oxidized surface environment (Fig. 1).

Initial paleoredox Cr isotope studies have focused on reconstructing this record of Earth's oxygenation using banded iron formations (BIFs) and ironstones as an archive for Cr (Frei et al. 2009; Planavsky et al. 2014). These sediments can provide an ideal sedimentary archive as they are likely to develop large authigenic (seawater-derived) Cr enrichments with little detrital input and should be well rock-buffered and therefore resistant to later diagenetic influence. Unfortunately, these formations are not common throughout the rock record, and while they indicate a shift to an oxidizing Earth surface by the early Neoproterozoic, these records lack necessary temporal resolution. Significantly however, the oxygen level at which surface Cr oxidation can proceed has been suggested as ~0.1% and 1% present atmospheric levels (PAL), based on kinetics of Mn oxidation and the lack of available Fe(II) in order to prevent reduction, respectively (Crowe et al. 2013; Planavsky et al. 2014). These estimates are below theoretical and experimental estimates for the minimum oxygen needs of the earliest complex animals (Sperling et al. 2013; Mills et al. 2014). As such, understanding the timing of this shift to and Earth system capable of the terrestrial oxidative weathering of Cr has major implications for understanding the rise of complex life and the relationship between biologic innovation and environmental factors.

A number of other sedimentary archives also have the potential to record shifts in the δ^{53}Cr record, including organic-rich black shales and carbonates, which are both

ubiquitous throughout the rock record. Work on shales has demonstrated that these sediments are capable of recording modern marine variability in δ^{53}Cr values in the recent sedimentary record (e.g., Reinhard et al. 2014; Gueguen et al. 2016), and this archive has been expanded into deep time, providing increased resolution in understanding the transition to an oxidizing Earth surface, just prior to the earliest evidence of complex life (Cole et al. 2016). Additional work on shales from the Cretaceous shows a negative δ^{53}Cr excursion, coincident with Ocean Anoxic Event II, suggesting that with new developments in our understanding of the Cr mass balance there is also potential to track marine redox changes in the sedimentary record (Wang et al. 2016c).

Others have focused on investigating δ^{53}Cr isotopes in carbonates, both in laboratory experiments and in modern settings, as well as in deep time records. Laboratory work has suggested that moderate fractions are possible during carbonate precipitation when Cr(VI) is incorporated in to the crystal lattice (Tang et al. 2007; Rodler et al. 2015). These abiogenic fractionations were observed to be ~0.3‰, while biogenic uptake can vary much more significantly, ranging from −0.5 to 0.3‰ in corals, and showing species-dependent variations in foraminiferal calcification (Rodler et al. 2015; Pereira et al. 2016; Wang et al. 2016b). Further, there has not yet been an investigation of Cr(III) incorporation into carbonates and the fractionations that could be associated with this process. Despite these complexities, the currently observed abiogenic fractionations are small enough that abiogenic carbonates could potentially record a shift in Earth's redox state (e.g., Frei et al. 2011; Gilleaudeau et al. 2016). Gilleaudeau et al. (2016) reported both unfractionated and some fractionated δ^{53}Cr values from bulk carbonate analyses as ~1.1 Ga, which if primary, would suggest oxygen levels above ~0.1–1% PAL by the late Mesoproterozoic. However, carbonate rocks can be susceptible to later diagenetic alteration, and trace metal signatures are frequently diagenetic in origin as these lithologies are somewhat poorly rock-buffered (e.g., Brand and Veizer 1980; Jahn and Cuvellier 1994).

In sum, the Cr isotope system, even in its relatively nascent state as a paleoredox proxy, has proven a sensitive and useful tool in shaping our understanding of Earth's redox evolution. With further developments in our understanding of modern systems, the Cr mass balance, and sedimentary archives, this system is poised to provide many new high-resolution insights into the redox story of Earth's oceans and atmosphere through time.

Summary and Conclusions

Chromium isotopes are now an established system being routinely measured in a wide range of applications. Work in this system has revealed important new insights in the fields of cosmochemistry, environmental remediation and monitoring procedures, and most recently in reconstructing Earth's redox evolution, which has been a major contribution to the ongoing debate about the relationship between environmental factors and the evolution of life on this planet.

Clapeyron's Equation

Masaki Akaogi
Department of Chemistry, Gakushuin University, Tokyo, Japan

Definition

We consider here that a substance changes from a reactant phase to a product phase and that both the phases are in equilibrium at pressure (P) and temperature (T). Clapeyron's equation expresses the stability relation between the reactant and product phases and gives a dP/dT slope of equilibrium phase boundary between the reactant and the product as a function of P and T. This equation is one of the most important equations for understanding thermodynamic stability relations in geochemical, petrological, and mineralogical processes. For example, when α-quartz SiO_2 is in equilibrium with coesite at certain P, T conditions, Clapeyron's equation gives the slope of the equilibrium quartz-coesite transition boundary in a P-T space where quartz is stable at relatively lower P and higher T and coesite at relatively higher P and lower T.

Clapeyron's Equation

When reactant and product phases are in equilibrium at P and T, and changes of entropy (ΔS) and volume (ΔV) accompany with the reaction at P and T, Clapeyron's equation is given as:

$$dP/dT = \Delta S/\Delta V \quad (1)$$

If the reaction reaches equilibrium state, $\Delta H = T\Delta S$, where ΔH is enthalpy of reaction. Therefore, Eq. 1 is rewritten as:

$$dP/dT = \Delta H/T\Delta V \quad (2)$$

Note that ΔS, ΔV, and ΔH are entropy, volume, and enthalpy changes at the P, T conditions considered. In principle, the values of ΔS, ΔV, and ΔH cannot be assumed as constants along the equilibrium phase boundary, and

therefore the slope is not constant. However, in solid-solid phase transitions in limited P, T ranges, ΔS, ΔV, and ΔH may generally be approximated as constants, resulting in a constant slope. In reactions involving vapor or liquid phase, the boundary is generally curved, because the vapor or liquid phase has higher entropy and is more compressible than the solid phase. Several textbooks on thermodynamics show a simple derivation of Clapeyron's equation from thermodynamic principles (e.g., Richet 2001).

It should be noted that Clapeyron's equation is applicable to the first-order phase transitions but cannot be applied to the second-order transitions in which both ΔS and ΔV are zero. Clapeyron's equation is useful for understanding stability relations of a substance and for constructing phase diagrams by combining with Schreinemaker's rule.

Summary

Clapeyron's equation is widely used in thermodynamics for materials of geochemical, petrological, and mineralogical interests. One of important applications of Clapeyron's equation in the fields is to evaluate dP/dT slopes of phase transition boundaries in silicates at high pressure and high temperature. In particular, dissociation reaction of spinel-type $(Mg,Fe)_2SiO_4$ to perovskite-type $(Mg,Fe)SiO_3$ and (Mg,Fe)O, called the post-spinel transition, which occurs at 660 km depth in the Earth's mantle, has a phase boundary with a negative dP/dT slope. The transition with the negative Clapeyron slope provides substantial resistance for subduction of slabs, resulting in significant effects on mantle dynamics and geochemical evolution of the mantle (e.g., Christensen 1995).

Clay Membranes

Ian C. Bourg
Department of Civil and Environmental Engineering and Princeton Environmental Institute, Princeton University, Princeton, NJ, USA

C

Definition

Clay membranes are clay-rich media (soils, sediments, or sedimentary rocks) that exhibit partial restriction of solute migration relative to that of water, i.e., semipermeable membrane properties.

Geochemical Importance

Clay membrane properties have the potential to significantly modulate the groundwater hydrology of clay-rich media, at least in some cases. They have been studied as a potential cause of erratic fluid pressures in sedimentary formations and, also, because of their potential impacts on well-bore stability, chemico-osmotic consolidation, water and nutrient fluxes in soils, and waste isolation using natural and engineered clay barriers (Takeda et al. 2014).

Phenomenology

Clay membranes give rise to two geochemical phenomena: hyperfiltration and osmosis. Hyperfiltration occurs when a hydraulic pressure gradient drives water flow across a clay membrane. For solutes that exhibit restricted migration through the membrane, the solute concentration of the permeate is depleted by a dimensionless factor σ known as the osmotic efficiency or solute reflection coefficient.

Osmosis occurs when a clay membrane separates two aqueous reservoirs with different concentrations of a solute. The associated gradients in chemical potential give rise to a diffusive flux of solute toward the dilute reservoir and of water toward the concentrated reservoir. If the porous medium separating the two reservoirs partially restricts solute migration relative to that of water, a net flux of solution (the osmotic flux) occurs toward the concentrated reservoir.

Reported values of σ in fine-grained sedimentary rocks range from 0 to 0.5, with a tendency of σ to increase with decreasing permeability and salinity (Takeda et al. 2014). Values of σ up to ~1.0 have been reported in compacted smectite or bentonite samples, with a strong dependence on salt concentration, counterion valence, and compaction (Kemper and Rollins 1966; Malusis et al. 2012).

Fundamental Basis

Porous media exhibit semipermeable membrane properties if their pores are sufficiently narrow that steric or electrostatic effects significantly hinder solute migration. In clay membranes, the predominant mechanism is the partial exclusion of anions from the electrical double layer (EDL), the region of interfacial water where electrolyte ions screen the negative surface charge of the clay particles. Anion exclusion restricts the migration of anions through the clay membrane and, therefore, that of cations because of the electroneutrality requirement.

Theories of the structure of the electrical double layer, such as the Gouy-Chapman model, predict that anion exclusion has a characteristic length scale d_a equal to twice the Debye length (Tournassat and Appelo 2011). At room temperature in a 0.1 M NaCl electrolyte, d_a equals ~2 nm on each pore wall, suggesting that anions are almost completely excluded from pores narrower than ~4 nm. The anion exclusion thickness d_a varies with the inverse square root of ionic strength and decreases significantly in the presence of multivalent cations.

In clay-rich sedimentary rocks, the largest pore-width mode observed by nitrogen adsorption or mercury intrusion porosimetry is often on the order of ~10 nm. This value is consistent with the observation that the anion-accessible pore space equals roughly half of the total pore space in many clay-rich rocks. Together, these observations suggest that most fine-grained sedimentary rocks have the potential to behave as clay membranes, particularly in aqueous chemistry conditions where the Debye length is large (low salinity, Na^+ as the predominant exchangeable cation) and where pores are small (low porosity, high content of smectite clay).

Mathematical Formulation

At the macroscopic scale, solution volumetric flux $\mathbf{J}_v$ (m s^{-1}) and solute molar flux relative to solution $\mathbf{J}^d{}_s$ (mol m^{-2} s^{-1}) in clay membranes are commonly described using the following pair of equations derived from non-equilibrium thermodynamics:

$$\mathbf{J}_v = L_{11}\nabla P + L_{12}\nabla \mu_s \tag{1}$$

$$\mathbf{J}^d{}_s = L_{21}\nabla P + L_{22}\nabla \mu_s \tag{2}$$

where $L_{12} = L_{21}$ based on Onsager's reciprocity rule. The most appropriate formulation of the L_{ij} parameters is not entirely settled, however, as noted below. One possible formulation yields the following expressions for $\mathbf{J}_v$ and for the net solute flux $\mathbf{J}_s = c_s\mathbf{J}_v + \mathbf{J}^d{}_s$ (Malusis et al. 2012; Takeda et al. 2014):

$$\mathbf{J}_v = -(\mathrm{k}/\mu)\left(\Delta P - \sigma\nabla\prod\right) \tag{3}$$

$$\mathbf{J}_s = (1-\sigma)c_s\mathbf{J}_\mathbf{v} - D_e\nabla c_s \tag{4}$$

where k is the intrinsic permeability of the porous medium (m^2), μ is the dynamic viscosity of the solution (Pa s), P is pressure (Pa), Π is osmotic pressure (Pa), D_e is the effective diffusion coefficient of the solute in the porous medium (m^2 s^{-1}), and c_s is solute concentration (mol m^{-3}). The osmotic pressure gradient ideally is given by Van't Hoff's relation: $\Pi = \nu RTc_s$, where R is the ideal gas constant (Pa m^3 mol^{-1} K^{-1}), T is absolute temperature (K), and ν is the number of constituents in the solute (e.g., $\nu = 2$ for NaCl).

Unresolved Issues

Several incompletely resolved issues exist in the study of clay membrane properties, particularly with regard to the choice of formulation for the L_{ij} parameters in Eqs. 1 and 2 (Bader and Kooi 2005; Malusis et al. 2012). For example, the common assumption that $\mathbf{J}_v$ is accurately described by Darcy's law if $\nabla\mu_s = 0$ yields an advective coefficient $L_{11} = \mathrm{k}/\mu$. The definition of the reflection coefficient can then be used to write $\sigma = -L_{12}/c_sL_{11}$, which yields $L_{12} = -\sigma\,(\mathrm{k}/\mu)\,c_s$. This formulation (used in Eq. 3) describes the osmotic flux of solution as an advective phenomenon (dependent on k) even though its fundamental origin is a difference in the diffusive fluxes of water and solute.

A second unresolved issue is whether a full characterization of clay membrane behavior requires two parameters: the reflection coefficient σ describing the tendency of the solute to resist *advection* through the membrane and an additional coefficient σ_d describing the tendency of the solute to resist *diffusion* through the membrane (Katchalsky and Curran 1965). Geochemical studies have often used the simplifying assumption $\sigma_d = \sigma$ while noting that the validity of this assumption is not entirely settled (Bader and Kooi 2005; Malusis et al. 2012).

A third important conceptual question is the manner in which Eqs. 1 and 2 should be solved in clay membranes of non-negligible thickness, where $\mathbf{J}_v$ and $\mathbf{J}^d{}_s$ are not inherently at steady state. Existing schemes rely on treating σ as invariant with time (Takeda et al. 2014), despite strong evidence that σ can vary significantly with time if salt diffusion and cation exchange occur in the membrane (Shackelford and Lee 2003).

A fourth important question is whether membrane efficiency (σ) can be correlated with other properties of the porous medium (Malusis et al. 2012). Experimental results suggest possible correlations with salinity, in agreement with the strong salinity dependence of EDL thickness, and permeability, in agreement with the expected sensitivity of both permeability and membrane efficiency to the width and connectivity of the largest pores (Takeda et al. 2014). Relatively little progress has been made on relating these results to the microstructure of clayey media, because of the difficulty of precisely characterizing the pore networks that control σ in these media and because the microstructure itself, in some cases, is sensitive to salinity (Tournassat and Appelo 2011).

Summary

Clay membrane behavior is relatively widely observed in sedimentary rocks and compacted clay barriers. Observations of this behavior reflect conditions where flow in a clay-rich medium is controlled by pores with a pore width on the order of ~10 nm or less. The osmotic efficiency of clay membranes decreases significantly with increasing salinity, pore width, and counterion valence. Significant conceptual questions remain unanswered with regard to the geochemical modeling of clay membranes.

Clay Minerals

Josh Wimpenny
Nuclear and Chemical Sciences Division, Lawrence Livermore National Laboratory, Livermore, CA, USA

C

Definition

Clay minerals are a diverse group of minerals that are fine grained and crystalline and ultimately form from the aqueous alteration of primary igneous minerals at or near the surface of the Earth. They have a layered structure, commonly consisting of repeating sheets of Si tetrahedra and Al octahedra. The wide diversity of clay minerals stems from the way that these sheets stack together and the identity of ions that commonly substitute into the clay mineral structure. Due to their unique layered structure and their effectiveness as ion exchangers, the formation of clay minerals can have a significant impact over the chemical and isotopic compositions of solid and fluid phases during weathering.

Introduction

Clay minerals are a highly diverse and abundant group of minerals that derive from the interaction of water with rock in the Earth's crust. Because clay minerals are often found in the clay-size fraction of sediments and soils (i.e., below 2 μm), the terms "clay" and "clay minerals" are often used interchangeably. However, the term clay minerals refers to a distinct group of minerals with a layered structure, rather than having grain-size significance.

Clay minerals are comprised of repeating aluminosilicate layers (or sheets), and the way that these sheets stack together helps to control their physical properties and chemical composition. Clay minerals form in a range of conditions (pH, temperature, pressure), and clay-rich sediments result from a range of different formation mechanisms, from solid-state alteration to dissolution and neoformation, to detrital inheritance (Singer 1980). Due to their layered structures, large surface area, and prevalence in the Earth's crust, the formation of clay minerals can have a significant impact over the chemical and isotopic composition of crustal rocks, sediments, and soils, and understanding how and when clay minerals have formed can shape our understanding of past weathering regimes and changes in the Earth's climate. Furthermore, the alteration of primary silicate minerals and formation of clay minerals have a significant impact on the chemical and isotopic composition of crustal fluids, including rivers, lakes,

and groundwaters, and, ultimately, help to control the past chemical composition of the Earth's oceans.

The unique physical and chemical properties of clay minerals mean that understanding how and why they form is critical in our understanding of natural processes, such as changes in past climate and crustal cycling, as well as facilitating our development of natural resources such as aquifers and oil and gas fields. Our utilization of clay minerals goes further still. Clay minerals are currently directly involved in many industrial applications and find their way into our homes where they are used on a daily basis, from ceramics to building materials to the production of paper, as well as in major engineering projects such as dams and landfill sites. Clay minerals are found in a wide range of environments, from soils and weathering profiles, to hydrothermal systems, to lake and estuaries and deep sea sediments. The ubiquitous occurrence of clay minerals on Earth has even helped to guide our ongoing exploration of the solar system. Recently, the Mars rover Curiosity was sent to a clay-rich region of the red planet because of the link between formations of clay minerals with liquid water. The finding of clay minerals on Mars suggests a distant past with a once water-rich environment that could have harbored life.

In this summary of clay mineralogy, we will discuss (i) the basics of clay mineralogy, (ii) the most common types of clay minerals and their uses, (iii) the ion exchange processes and their significance in influencing the chemical composition of rivers and the oceans, and (iv) the human uses for clay minerals.

Clay Mineral Structure and Ion Exchange

The basic structure of clay minerals consists of repeating sequences of Si-O tetrahedra (T) and Al-O octahedra (O) that form layers or sheets that bind together by sharing oxygens (Merkel et al. 2005). In tetrahedral coordination, the central cation is surrounded by four oxygen atoms, while in octahedral coordination, the central cation is surrounded by six oxygen atoms. The distinctive clay mineralogies and their chemical and physical properties are, to a first order, controlled by how these sheets of Si tetrahedra and Al octahedra stack together. For this reason, clay minerals are often described by the ratio of T:O layers in their structure. For example, the kaolin group of clay minerals is comprised of tightly packed alternating T-O units and so is called 1:1 clay minerals. Another common group of clay minerals, the mica group, consists of repeating T-O-T units and so is referred to as 2:1 clay minerals. The 2:1 clay minerals are some of the most common in the crust and include the highly abundant mineral smectite, vermiculite, and illite. The layer of oxygen atoms that bound the basal tetrahedral layer in a 2:1 clay mineral is often referred to as the siloxane layer (e.g., Sposito et al. 1999), and the characteristic spacing between adjacent tetrahedral layers is called the interlayer (Drever 1988).

While the basic structure of clay minerals is dominated by Si and Al, clay minerals can contain significant quantities of other cations due to structural substitution reactions. The most common is the replacement of Si^{4+} in the tetrahedral sheet by Al^{3+}, with a limit to ~15% substitution (Krauskopf and Bird 1967), and replacement of Al^{3+} in the octahedral sheet, in which both the identity of the exchanging cation and the amount of substitution can vary. The most common cations that exchange into the octahedral sheet are Mg^{2+}, Fe^{2+}, and Ca^{2+}. In these isomorphic substitutions, the charge of the replacing cation is less important than the length of the cation-oxygen bond. For this reason, these substitutions often result in a charge imbalance, which is typically negative and is considered to be permanent (Odom 1984; Drever 1988; Appelo and Postma 2005; Merkel et al. 2005). An example is the substitution of Mg^{2+} for Al^{3+} in the octahedral layer of pyrophyllite, resulting in the formation of the common smectite group mineral montmorillonite. This isomorphic substitution of cations into structural layers can be significant; in the case of montmorillonite, the clay can contain upward of 3 Wt % Mg (Mermut and Cano 2001). Isomorphic substitutions are not common in all clay minerals; they do not occur to any significance in the kaolin group minerals, and as a consequence, these minerals do not develop a significant charge imbalance.

Where isomorphic substitutions do occur, the resulting negative structural charge is balanced by adsorption of freely exchangeable positively charged cations from solution (e.g., Mg^{2+}, Ca^{2+}, Na^{+}, and H^{+}). Adsorption of cations onto clay minerals is typically described as occurring in one of two ways: inner-sphere or outer-sphere adsorption (e.g., Sposito et al. 1999; Strawn and Sparks 1999). Outer-sphere complexes contain a water molecule in between constituent ions of the complex, which are solvated (Sposito et al. 1999; Appelo and Postma 2005). Outer-sphere complexation usually occurs on the basal planes, or interlayer, of the clay mineral (Strawn and Sparks 1999). Inner-sphere complexation occurs when the water molecule is expelled and covalent bonding can occur (Appelo and Postma 2005).

There is a general order of chemical affinity for adsorption of cations from solution. Typically the divalent cations (e.g., Mg^{2+}, Ca^{2+}) have a stronger affinity for adsorption than the monovalent cations (e.g., Na^{+}, K^{+}). However, within cations of the same charge, those that have the smallest hydrated ionic radii typically have the strongest adsorption affinity. Adsorbed ions are commonly incorporated into the clay interlayer region where they electrostatically bond to the siloxane layers on the basal plane of Si-tetrahedral layers (Odom 1984; Drever 1988; Strawn et al. 2004; Merkel et al. 2005). This ensures net charge neutrality across the clay mineral structure. The uptake of exchangeable cations is

usually more important where there is the greatest charge imbalance, i.e., where isomorphic substitution has occurred, and the capacity for electrostatic uptake is greatest. The capacity of clay minerals for ion exchange or adsorption (the cation exchange capacity or CEC) is dependent on pH and the type of ions that already occupy exchange sites. In general, the expandable clay minerals such as smectite and vermiculite have higher CEC values than non-expandable minerals such as kaolinite and illite (Ma and Eggleton 1999).

Minerals in which substitution reactions do not occur and interlayer expansion is not important (e.g., kaolinite) can still be important adsorbing agents. Other important adsorption sites include surface hydroxyl sites that form at edge sites where the clay structure has been interrupted (Papelis and Hayes 1996) or silanol sites which can be amphoteric (Peacock and Sherman 2005).

Common Clay Minerals

As described, there is a diverse range of clay minerals, but they have, in general, similar structural components. In the following the main groups of clay minerals will be described, from the simple phases similar to layered double hydroxides to expandable clay minerals such as the smectite group. Basic physical properties of the main clay groups are given in Table 1, while chemical formulas of clay minerals from each group are given in Table 2. Illustrations of the structure of kaolin, smectite, and mica group minerals are shown in Fig. 1.

Gibbsite, Brucite, and Layered Double Hydroxides (LDH)

These minerals differ from what are typically thought of as phyllosilicates, because they do not consist of layers of both Si tetrahedra and Al octahedra, instead being more analogous to the octahedral sheet itself. The structure of these minerals is two closely packed layers of hydroxyl ions (hence layered double hydroxides) with cations in octahedral coordination between the two sheets (Drever 1988). In the case of brucite, this octahedral cation is Mg^{2+}, and each Mg^{2+} is coordinated by 6 OH^- ions, while each OH- ions is coordinated to 3 Mg^{2+} ions. In this way the charges balance with the formula Mg $(OH)_2$, and all of the octahedral sites are filled. In the case of gibbsite, the octahedral cations are Al^{3+}. Because Al is trivalent, it cannot be coordinated in the same way as Mg^{2+} without resulting in a charge imbalance. Hence in gibbsite every third octahedral site is left empty so it has a formula Al $(OH)_3$. Clay minerals in which the octahedral vacancies are all filled (e.g., brucite) are called trioctahedral, while those in which only two out of three octahedral sites are occupied are called dioctahedral.

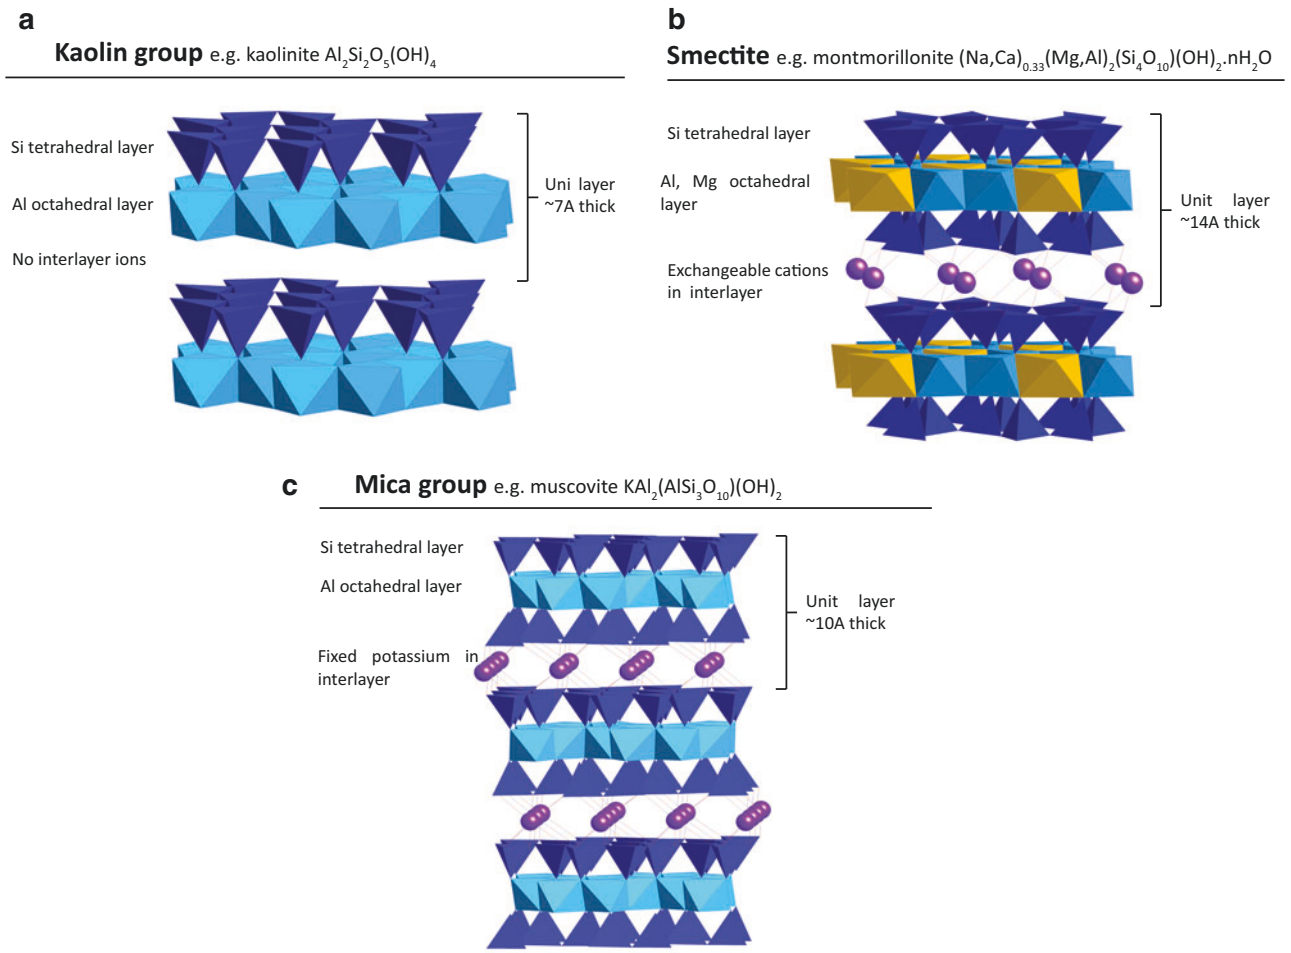
The dioctahedral mineral gibbsite is particularly relevant to further discussion, not only because of its analogous structure to the octahedral sheet in most phyllosilicates but because of its capacity for swelling and uptake of cations and anions into structural sites and the interlayer. By definition the dioctahedral clay minerals have one void in the octahedral layer that has potential to be filled, albeit the radius of the void limits the cation size. In simple minerals such as gibbsite, the voids have easy access for small cations including Li^+ and Mg^{2+}. The uptake of Li^+ into the octahedral vacancy in gibbsite would result in a charge imbalance; hence Li also takes its accompanying counterion such as Cl^-. Experiments have shown that reaction of LiCl solutions with gibbsite results in appreciable uptake of Li, and large swelling of the clay layers, as significant anions are required to maintain charge balance (e.g., Fogg and O'Hare 1999; Wimpenny et al. 2015). This interlayer expansion is an important quality

Clay Minerals, Table 1 Physical characteristics of clay mineral groups (Data taken from Drever 1988 and Appelo and Postma 2005)

	Kaolin group	Smectite group	Mica group	Chlorite
Structure	T-O (1:1)	T-O-T (2:1)	T-O-T (2:1)	T-O-T-(O) (2:2)
Layer charge	<0.01	0.5–1.2	1.4–2	variable
Unit layer	7A	Ranges depending on interlayer: 14A to 17A	10A	14A
Cation exchange capacity (CEC) meq/100 g	1–10	80–150	10–40	<10

Clay Minerals, Table 2 Examples and formulas of common clay minerals based on mineral group

Group	Mineral	Formula
Kaolin/ serpentine group	Kaolinite	$Al_2Si_2O_5(OH)_4$
	Serpentine	$Mg_3Si_2O_5(OH)_4$
Smectite	Pyrophyllite	$Al_2Si_4O_{10}(OH)_2$
	Talc	$Mg_3Si_4O_{10}(OH)_2$
	Montmorillonite	$(Na,Ca)_{0.33}(Mg,Al)_2(Si_4O_{10})(OH)_2.nH2O$
	Saponite	$Ca_{0.25}(Mg,Fe)_3((AlSi)_4O_{10})(OH)_2.nH2O$
	Hectorite	$Na_{0.3}(Mg,Li)_3(Si_4O_{10})(F,OH)_2$
	Beidellite	$(Na,Ca_{0.5})_{0.3}Al_2((Si,Al)_4O_{10})(OH)_2.nH2O$
Mica	Muscovite	$KAl_2(AlSi_3O_{10})(OH)_2$
	Phlogopite	$KMg_3(AlSi_3O_{10})(OH)_2$
	Paragonite	$NaAl_2(AlSi_3O_{10})(OH)_2$
Chlorite	Clinochlore	$Mg_5Al(AlSi_3O_{10})(OH)_8$
	Chamosite	$(Fe^{2+},Mg,Al,Fe^{3+})_6((Al,Si)_4O_{10})(OH,O)_8$



Clay Minerals, Fig. 1 Structure of the three major clay mineral groups: (**a**) kaolin, (**b**) smectite, and (**c**) mica. Figures show the stacking of Si tetrahedra and Al octahedra and characteristic basic spacing

of clay minerals that can have implications not only for the bulk clay chemical composition but also on the chemical composition of the fluid phase in which the clay is reacting (e.g., rivers and seawater).

Kaolin Group

Kaolin group minerals are one of the most common clay minerals during weathering and are particularly prone to formation in warm, humid climates (Dixon 1989). Kaolin minerals are all 1:1 phyllosilicates, with a unit structure comprising a single Si-tetrahedral sheet bonded to a single Al-octahedral sheet (analogous to gibbsite) by sharing oxygen atoms between adjacent Si and Al atoms (Murray 1991; Angove et al. 1997). These 1:1 layers stack together by hydrogen bonding and van der Waals forces. The way that these aluminosilicate layers stack together determines the distinct kaolin group minerals. For example, halloysite differs from kaolinite by having a layer of water molecules between the T-O unit layers. These minor differences can affect the dominant clay form; while kaolinite typically forms plates, halloysite forms characteristic nanotubes (Tan et al. 2015). Isomorphic exchange can occur in kaolin group minerals, but these reactions are not common, and minimal charge deficit is associated with the structure. One of the most common ions to be incorporated into structural sites in kaolinite is iron, although levels are still typically low (less than a Wt %), and it is difficult to tell whether the Fe is actually structurally incorporated into the clay, or is an artifact of a mixed kaolinite-smectite (Dixon 1989). In addition to isomorphic exchange being relatively unimportant, the bonding between the 1:1 layers in kaolin minerals is relatively strong, so that interlayer exchange cannot occur (Angove et al. 1997). The low-layer charge and no interlayer mean that the cation exchange capacity of kaolinite is much lower than expandable clays such as smectites (see later), typically ~1–10 $cmol_c/kg$ (Drever 1988). Any limited sorption capacity of kaolinites is usually caused by broken bonds at the layer edge (Bolland et al. 1976; Ma and Eggleton 1999) and the presence of

pH-dependent functional groups on the clay surface and edge sites (Papelis and Hayes 1996; Strawn et al. 2004; Merkel et al. 2005).

Smectite Group

The smectite group clay minerals are 2:1, or T-O-T, phyllosilicates. As described this means that they have two octahedral sheets bounding a single tetrahedral layer. Other common 2:1 phyllosilicates will be described later on and include micas and chlorite, although there are important structural differences between these minerals and smectite.

Due to the common occurrence of isomorphic substitution into the phyllosilicate structural layers in 2:1 clay minerals, there are a wide range of smectite group clays found in nature. For this reason, we will start with the simplest case, in which the tetrahedral and octahedral sheets are pure. If the octahedral sheet is similar to gibbsite ($Al(OH)_3$), the resulting clay mineral is called pyrophyllite and has the formula $Al_2Si_4O_{10}(OH)_2$. If the octahedral sheet is similar to brucite ($Mg(OH)_2$), the resulting clay mineral is called talc and has the formula $Mg_3Si_4O_{10}(OH)_2$ (Drever 1988). Common smectite group clay minerals and their chemical formula are shown in Table 2. Changes in their chemical composition relative to these end-member compositions result directly from isomorphic exchange, i.e., exchange of trivalent cations for Si^{4+}, divalent cations for Al^{3+}, and/or monovalent cations for Mg^{2+}.

A key property of smectite clay minerals that differentiate them from kaolin and other 2:1 group clay minerals is the relative expandability of the interlayer and the fact that the interlayer can be hydrated. The uptake of exchangeable cations results from the relative charge imbalance caused by isomorphic exchange into structural layers. The most common exchangeable cations in smectite minerals are Mg^{2+}, Ca^{2+}, Fe^{2+}, Na^{+}, and H^{+}, although other cations will also exchange (Odom 1984). Although many smectites contain abundant amounts of Mg^{2+}, the amount of Mg and Ca in the interlayer is usually very similar, and smectite minerals with both Mg and Ca are usually very common. The amount of water that can be incorporated into the smectite will depend on the identity of the interlayer species, for example, where Mg or Ca^{2+} is present, two layers of water molecules can be incorporated and the smectite will expand to ~14A (Drever 1988). In contrast, a smectite in which Na is the dominant cation in the interlayer can expand by up to 10 times its original size. In fact the swelling of Na-rich smectites can cause complete dissociation of individual smectite crystals, resulting in dispersion and the formation of a colloidal-like solution with an increased viscosity. For this reason, Na montmorillonites are in high demand in the oil industry as drilling muds (Murray 1991). Ultimately, the cation exchange capacity (CEC) of a smectite mineral will of course depend on its chemical composition, but is usually in the range of 70–130 meq/100 g (Odom 1984; Murray 1991). Most of this CEC is caused by charge deficiency resulting from structural substitution reactions (Odom 1984).

Vermiculites

Vermiculite is a mineral similar in structure to the smectite group minerals but has a greater charge across the interlayer. As a result, the interlayer is less readily expandable than in smectite minerals, and the amount of cation exchange is lower, although because of the higher charge, the CEC of vermiculite is greater than in most smectites.

Mica Group

Mica group clay minerals are also 2:1 clay mineral similar to smectites. However, the isomorphic substitution in mica group clay minerals typically occurs in the tetrahedral layer, where Si^{4+} is replaced by Al^{3+}. The resulting charge deficit is accounted for by incorporation of K+ into the interlayer. Because the charge deficit is derived from the tetrahedral layers, the K is held very tightly in the interlayer (Krauskopf and Bird 1967) and is generally not exchangeable. Common mica group minerals include muscovite, phlogopite, and biotite (see Table 2). Mica group minerals are also commonly referred to as illite. Most natural illites are actually mixed layers of muscovite-like minerals and smectite-like minerals (Drever 1988). Illites make up the bulk of ancient shales, and illitization reactions are common during late diagenesis of siliciclastic materials (Drever 1988; Milliken 2003).

Chlorite Group

Chlorite consists of a 2:1-layered structure similar to the structure of smectite and illite. However, a major difference in the structure of chlorite is that a structural charge imbalance remains even after uptake of exchangeable cations. In chlorites the negative charge is compensated for by the formation of a brucite-like layer within the interlayer region (Velde and Meunier 2008). This brucite-like layer is bonded to the basal tetrahedral layers by coulomb attraction and can be rich in Mg, Al, or Fe (Bailey 1972). Hence the structure of chlorite is essentially 2:1:1 or 2:2 (Drever 1988). Most chlorites are trioctahedral, containing Mg in both the structural octahedral layer and in the interlayer sheet. However, Fe-rich chlorites also exist and occur commonly in iron-ore deposits. Chlorites form in nature via diagenesis of mafic and ultramafic rocks at low- to medium-grade metamorphic conditions, or from the alteration of volcanic rocks. Chlorites have also been synthesized in the laboratory from hydrothermal alteration of montmorillonite and Al or Mg hydroxides (Slaughter and Milne 2013).

Clay Mineral Formation

Clay minerals ultimately form from the alteration of primary silicate minerals. These primary phases form from the crystallization of magma at high temperature and a range of pressures in the Earth's crust. After crystallization and cooling, these primary minerals may be exposed to surface conditions through uplift and erosion. In the low-temperature and low-pressure environment of the Earth's surface, minerals derived from igneous processes are unstable, with those minerals forming at highest temperature, such as olivine, being the least stable at surface conditions. Clay minerals are either direct or indirect alteration products of these unstable primary phases, forming through incomplete (or incongruent) weathering. The relative insolubility of aluminum compounds such as Al oxide (Appelo and Postma 2005) is a major reason that clay minerals are so ubiquitous throughout the crust.

The type of clay mineral that forms during weathering will be dependent on many factors including the type of primary mineral or rock that is being weathered, the fluid composition, the pH and temperature of that fluid, the water-rock contact time, and the influence of biological agents (Galan and Ferrell 2013). While clay minerals are more stable than primary igneous minerals at the Earth's surface, clay minerals themselves can continue to alter during weathering. With increasing intensity of alteration (i.e., temperature and water-rock contact time), clay minerals will tend to change from containing higher amounts of structural Si and other cations to containing higher concentrations of Al, for example, the transition from montmorillonite to kaolinite to gibbsite (Appelo and Postma 2005). Thus aluminum oxide minerals such as gibbsite are typically a product of the more extreme weathering environments.

Continuing alteration of clay minerals can often be associated with a change in the environment (e.g., solution composition, temperature and runoff, pH) such as that associated with a change in climate or progressive burial. This is most easily observed in weathering profiles such as in the study of laterites, which contain distinct layers with different clay mineralogies, caused by abrupt change in climate and subsurface processes such as a fluctuating water table. The formation processes of clay minerals are diverse, ranging from newly formed clays by direct precipitation from solution to solid-state alteration in which the previous clay mineral structure is retained in the new form (e.g., transformation by ion exchange) or in which structural reorganization takes place (e.g., during diagenesis). This diversity in formation mechanism is intuitive if we consider that clay minerals are found in a wide range of environments within the Earth's crust and subjected to changing chemical and physical conditions. A more detailed consideration of clay mineral formation mechanisms follows:

Direct Precipitation or Neoformation

The classic way to envisage the formation of a new mineral is via direct crystallization from a solution, which can also be termed direct precipitation or neoformation. This mechanism requires that a solution has a pH, temperature, and dissolved solid content that promotes precipitation of a new mineral. Based on knowledge of these parameters, it is possible to calculate how stable a mineral phase is in a solution by calculation of its saturation state. Such calculations can provide information about whether a mineral is more likely to dissolve or precipitate in a solution, i.e., whether it is undersaturated or oversaturated. It is important to realize that simply because a certain mineral is oversaturated in solution, it will not necessarily precipitate. The type of clay mineral that forms via neoformation will be dependent on many factors including precursor mineralogy, climate, drainage, and weathering time (Eberl et al. 1984). For example, a classic study in Hawaii, where the bedrock is all basalt, shows that different clay minerals predominantly form in different microclimates (Eberl et al. 1984 and references within). In this case, smectite formed on the drier part of the island, while gibbsite formed where rainfall was much higher. Thus clay minerals that are comprised of soluble cations such as Mg and Ca will only form where these cations can accumulate, such as in dry climates or regions where drainage is poor. In contrast, clay minerals that comprise mostly insoluble elements such as gibbsite will form where rainfall is high and drainage is good so Al will accumulate (Eberl et al. 1984).

At the extreme high-temperature end of the scale, clay minerals can form directly from magma-derived fluids. These fluids originate from deeper in the crust (e.g., a cooling magma chamber) and interact with crustal rocks, stripping out silica and aluminum and forming clay minerals at temperatures up to 450 °C (Kerr 1955). Hydrothermal alteration will typically cause clay formation on a limited scale, restricted to contact metamorphic zones in which temperature is elevated (>50 °C). The clay minerals that form will be controlled not only by temperature but also on the environment of formation, for example, a hydrothermal vent on the seafloor versus a continental extensional setting such as the Basin and Range in western United States.

Diagenesis and Solid-State Alteration

Solid-state alteration can take place either by ion exchange or by alteration of the structural layers in a clay mineral (Eberl et al. 1984). For example, the interlayer leaching of potassium from the interlayer of an illite will result in vermiculite formation (Wilson 1999); this is a common process in soils where the alteration of micas and chlorite can progress in sequence through vermiculite, smectitic mixed layers, degraded smectite, and finally amorphous compounds such as allophane (Chamley 2013). Such a progression is usually observed as one moves from the base to the top of a soil

profile. Other common solid-state alteration phases include products of igneous rock weathering such as that experienced by basaltic lavas or large-scale granitic intrusions. Typically the type of clay mineral formed will depend on the precursor igneous mineralogy and fluid composition and residence time. For example, plagioclase feldspar is typically replaced by kaolinite (e.g., Nesbitt et al. 1997), particularly in more intense weathering regimes where more mobile cations like Mg, Ca, and Na are removed from the rock. In humid tropical environments, highly altered weathering profiles called laterites develop on crustal rocks, for example, the Deccan traps flood basalts in India. Here clay minerals such as kaolinite replace the primary mineralogy, and as weathering progresses, all primary igneous textures are lost, suggesting that both transformation and neoformation of clay minerals occur.

As clay minerals are buried within the Earth's crust, they undergo transformation induced by changes in the pressure and temperature. Notably these changes in PT conditions will progressively expel water from a clay mineral structure and cause a decrease in porosity. In summarizing diagenetic alteration of clay minerals, authors have typically invoke a number of stages of alteration that will ultimately depend on the type of clay protolith. With progressive burial (i.e., increasing PT conditions), there is initial compaction, loss of interlayer cations and water, and a decrease in porosity (Segonzac 1970; Aoyagi and Kazama 1980), although recirculation of water can still occur and can cause retrograde or reverse weathering reactions to occur. In alkaline environments rich in K and Na, the diagenesis of dioctahedral smectite can result in the formation of mixed layer illite-smectite minerals. This reaction usually proceeds at ~60 °C (Perry and Hower 1970), and while the initial distribution of illite and smectite layers is random but with increasing temperature and pressure and increased illite proportion, the distribution of the illite-smectite layers becomes ordered. The reaction is thought to occur as increasing amounts of Al^{3+} substitute into the Si-tetrahedral layer of smectite. This results in an increasing charge across the interlayer, and interlayer K^{+} becomes dehydrated, i.e., resulting in the formation of illite (or mica). The identity of the clay mineral that forms from diagenetic reaction will depend on the chemical composition of the precursor mineral and fluid phases. For example, the burial of trioctahedral smectite (i.e., Mg^{2+}-rich montmorillonite) usually results in the formation of chlorite minerals (Galan and Ferrell 2013), while the diagenesis of kaolinite can result in transformation to a more ordered form called dickite, although dickite can also form from K feldspar and other Al-rich silicate minerals.

Further burial and compaction results in complete dehydration with the mixed layer smectite-illites converted to illite and chlorite. These reactions are not usually reversible. At even higher metamorphic grade, the chlorite and illite become ordered, and particle sizes increase to above what is typically considered to be clay sized (<2 μm).

Detrital Inheritance

While neoformation and solid-state alteration are the two main mechanisms by which clay minerals form, a third mechanism can account for large-scale clay deposits; this accumulation of clay minerals from disparate sources is often termed detrital inheritance. Inheritance is an important mechanism because of the stability of the clay mineral group at the Earth's surface, meaning reaction rates are slow and clay minerals can survive physical and/or chemical weathering in their original location and transport to a new accumulation zone. An obvious location for detrital inheritance is in soil profiles that have directly formed from weathering of a sedimentary sequence.

An important region of clay mineral inheritance is on the seafloor, where continental sediments are deposited via outflow from rivers and from aerial deposition. Riverine transport is one of the most important mechanisms, and accumulation of continental detritus, including abundant clay minerals, is common at the continental margin. As one would expect, the clay mineralogy of oceanic sediments usually corresponds to the dominant mineralogy and climate of the adjacent continental region (Eberl et al. 1984; Thiry 2000). Thus kaolin minerals are more common in the tropics, while illite and chlorite are more common at high latitudes, possibly due to their production during glacial weathering (Thiry 2000). As one moves further from the continent, the dominant clay mineralogy changes depending on clay settling time, which is related to the ease with which a clay mineral flocculates. Far out from the continental margin on the abyssal plain, the rate of clay mineral sedimentation is incredibly slow (cm per 1000 years). Here the sediment accumulation is comprised of mixed calcareous ooze and detrital clay minerals that are fine-grained Aeolian sediments and volcanic ash.

While all three mechanisms are important in the formation of clay mineral-rich sediments, they are not mutually exclusive processes; often they work in tandem, and it can be difficult to discern one process from another, i.e., at what point does transformation become neoformation? For example, detrital clay minerals often undergo ion exchange processes in the oceans; the exchange of Ca^{2+} in clay minerals for Mg^{2+} in seawater is such an effective process that it has implications for long-term CO2 drawdown, carbon storage, and climate change (Gislason et al. 1996).

Clay Mineral Isotope Geochemistry

Investigating the isotopic fractionation of stable isotope systems is an established technique within geochemistry that can provide a wide range of useful information about the

formation and chemical evolution of clay minerals. The fractionation of stable isotope systems is mass dependent and is also controlled by temperature (Urey 1947) and the bonding environment (Bigleisen and Mayer 1947). The isotopic composition of a clay mineral will depend on the isotopic composition of the precursor mineral and the fluid phase from which the clay forms. It will also be dependent on the temperature of the system (less fractionation at higher T) and whether the clay mineral forms in a system at equilibrium, or through a unidirectional or kinetic process. Furthermore, isotopic compositions can be altered post-formation in environments where the chemical properties of an element might change (e.g., change in redox conditions between Fe^{2+} and Fe^{3+}), or during re-equilibration at higher temperatures. For example, studies of O and H isotopes in clay minerals provide useful information about the conditions of clay formation and subsequent post-formation processes, because many clay minerals tend to retain their initial O and H isotopic compositions unless subjected to diagenetic or metamorphic conditions (Sheppard and Gilg 1996). For example, detrital clay minerals in the oceans often retain their continental H and O isotope signatures (Sheppard and Gilg 1996). The unique layered structure of clay minerals and importance of ion exchange and adsorption mean that careful isotopic analyses of clay minerals can also shed light on recent fluid interactions by isolating and examining the isotopic composition of interlayer ions in minerals such as smectite. Isotopic analyses have shown that interlayer cations and water rapidly exchange with fluid phases, meaning the interlayer reservoir can be isotopically distinct to the composition of the structural sheets (e.g., Savin and Epstein 1970; Wimpenny et al. 2015).

While the stable isotope systems of H, C, N, and O have been well established for many decades, advancing technology means a wide range of stable isotopic systems from Li all the way up to U can now be studied, many of which are influenced by clay mineral formation. The utility of these isotope systems varies, from understanding global weathering processes (e.g., Li, Mg), to tracing nutrient use (e.g., Fe isotopes), to understanding the transport and distribution of potentially toxic heavy metals (e.g., Cr, Cd, Hg). In all cases, to understand the geochemistry and isotopic composition of these elements in waters and sediments from the Earth's crust requires understanding of the way clay minerals influence their mass budget during weathering and, because their uptake and incorporation into clays usually occurs with an isotopic preference, how the formation of phyllosilicates influences their isotopic composition. Through a combination of field studies and experimental work, an increasing understanding of isotopic behavior has been gained detailing the sense and isotopic fractionation factor associated with elemental uptake or sorption into clay minerals.

While stable isotope systems can provide useful information about general clay mineral formation processes, radiogenic isotope systems can potentially provide information about when and from what parent material the clay mineral formed or originated. A problem with utilizing clay minerals as a dating tool is that they have often undergone burial and diagenesis which could influence the meaning of any obtained age (i.e., what event are we dating?). However certain chronometers such as the Ar-Ar and Rb-Sr systems have proved successful in dating clay mineral formation, particularly in the study of illite formation (e.g., Kelley 2002). For example, Clauer et al. (1997) used both Ar-Ar and Rb-Sr dating techniques to assess the timing of diagenetic illite formation in a sandstone reservoir rock from the North Sea.

Regardless of whether age dating results in reliable age determination, radiogenic isotope systems can also provide useful information about clay provenance. This is because different rock types often have different radiogenic isotopic compositions due to differences in age and/or the way elements partition into different minerals. Thus two different potential source terrains for an inherited clay sediment can be distinguished based upon their radiogenic isotopic composition. It is also important to understand the radiogenic isotopic characteristics of clay minerals when interpreting water-rock interactions. For example, the rubidium ion (Rb^+) commonly substitutes for K^+ in micaceous minerals due to similarity in ionic radius and charge. The relatively high concentration of Rb in micas means that their Rb/Sr ratio is also elevated, and because ^{87}Rb decays to ^{87}Sr over time, these minerals can develop highly radiogenic $^{87}Sr/^{86}Sr$ ratios. In glacial rivers where interlayer leaching of biotite is an important process, the Sr isotopic signal delivered to rivers is often far more radiogenic than the bedrock. This has important consequences for the evolution of Sr isotopes in the ocean during the Cenozoic.

Clay Minerals in the Solar System

The search for life outside of own planet has important implications for how we understand our own origin and the origin of life throughout the universe. Though we do not understand exactly how life on Earth started, we know that liquid water is a key prerequisite for life to begin, develop, and ultimately thrive over geological time. Thus the search for life, or past signs that life was once present, hinges on the ability to identify regions that have once known liquid water. As has already been discussed, clay minerals form due to the interaction of primary igneous minerals with water and are the most ubiquitous alteration minerals on Earth. Of the many planets and moons in our solar system, one of the most

promising places to look for the presence of clay minerals is on our neighbor, Mars. This comes from two lines of evidence: orbital observations from probes and satellites and pieces of Martian crust in the meteorite record.

Orbital observations (e.g. Ehlmann et al. 2008, 2011) have identified a diverse range of clay minerals on Mars surface with the most common clay minerals being Fe-Mg smectites and chlorite. The abundance of chlorite suggests the clays formed in closed system environments at temperatures ranging from ambient to hydrothermal (~400 °C). From these observations and stratigraphic relationships upon Mars, some estimates of the relative timing of clay formation have been made, with the most important period of clay mineral formation occurring between 4.1 and 3.1 billion years ago. These observations suggest that earlier in this period (4.1–3.7By), there was widespread hydrothermal alteration in the subsurface of Mars and, due to the presence of sedimentary structures, the presence of liquid water at the surface, if only as a short-lived phenomenon. As time progressed (3.7–3.1By), the formation of clay minerals is hypothesized to have declined, perhaps because heat sources for hydrothermal alteration (e.g., impacts, volcanism) also declined at this time. Younger terrains (<3.1By) are dominated by crystalline materials. These observations are indicative of Mars being water rich early in its history and transitioning to being increasingly arid.

Unfortunately, we cannot study the Martian crust here on Earth because a sample return mission from Mars is, as yet, not possible due to its extreme technical difficulty and prohibitive cost. Further investigation of Mars surface, the presence of clay minerals, and the possibility of discovering life can be addressed in one of two ways: the study of the Martian meteorite record and sending a remote controlled lander onto Mars surface. While a growing number of Martian meteorites have been identified, they are not ideal rocks in which to look for these chemical signatures. They are derived from impact so have been altered both during impact and ejection from Mars and on entry to the Earth's atmosphere. But perhaps more fundamentally, we have no control over where they came from; from remote observations, it is clear that some locations on Mars are more promising as once having known the presence of water.

These problems can be avoided by sending a rover to make remote measurements on Mars surface, with the caveat that instruments on a rover are far less sophisticated than instruments found in laboratories on Earth. In NASA's recent Mars Science Laboratory (MSL) mission, the rover Curiosity was sent to Gale Crater, an area where hydrated clay minerals and sulfates had been identified from orbit (Ehlmann et al. 2008; Ehlmann et al. 2011; Grotzinger et al. 2014). Recently, Curiosity traversed an area of Gale Crater, encountering sandstones and mudstones interpreted to have a fluvial origin (Grotzinger et al. 2015). Detailed analysis of a mudstone layer identified around 20% saponitic smectite, probably formed by aqueous alteration of primary olivine in a lacustrine environment. These initial analyses by Curiosity point to an environment that could conceivably have been habitable to basic life once in Mars history.

C

Clay Mineral Uses

There are a wide range of uses for clay minerals based on their unique mineralogical properties including grain size, surface area, adsorption, color, plasticity, and fire strength (Murray 1991). A brief summary of clay mineral uses is given in the following:

Kaolinites

They are relatively soft (1.5 on Mohs scale) so it is not abrasive and can be used in many industrial applications without causing degradation of machines. They are used in ceramics because they fire to a white color and don't shrink after firing (Murray 2000). The fact that kaolinite is highly dispersible and particles form micron-sized platelets that orient on coated surfaces means they are used to provide a sheened or glossy finish for paper. Calcining kaolinite drives off the hydroxyl groups from the structure. This meta-kaolin has dielectric properties and so has been used as a filler in electric wiring. Kaolinites have a diverse range of applications although their exact use will differ depending on specific properties of the deposit. For example, only kaolinites with the correct color can be used for ceramics. Kaolinites are used as the raw material for the production of fiberglass (Murray 1991) due to the health risks of asbestos.

Smectites

The high-charge, surface area, and cation exchange capacity mean smectites are highly absorbent. When mixed with water, the swelling properties of the clay give the fluid a high viscosity. The largest swelling properties are exhibited by Na montmorillonites. These can expand by up to ten times their original size when immersed in water (Murray 1991). These smectites can yield large volumes of drilling mud. While other smectite minerals such as Ca montmorillonite can be treated to exchange Ca for Na in the interlayer and increase the cation exchange properties and swelling volume, these clays are less useful than naturally occurring Na bentonite. High-swelling clays such as Na bentonites are also commonly used where water barriers are necessary, e.g., in the construction of dams, containment of chemicals in toxic waste dumps, landfill, and nuclear waste disposal sites. Blends of Ca and Na smectites are also typically used as absorbents in animal waste products such as cat litter.

Micas

The most commercially useful micas are muscovite and phlogopite. Both phlogopite and muscovite mica are used as electrical insulators. Dry ground mica has a wide variety of uses from dry wall filler, to an additive to paint, to a reinforcement material in plastics. Ground mica is also used in drilling mud for oil and gas wells where it prevents loss of circulation by filling cracks and reducing porosity in the well. Wet ground mica is used in pearlescent paints and the cosmetic industry where it is incorporated into a range of products from lipstick and nail polish to moisturizing lotion.

Mixtures of shale and chlorite are commonly used in construction, particularly in the production of bricks and cement (Virta 2013, USGS).

Summary

Clay minerals are ubiquitous in the weathering environment. Their diversity in chemical composition and unique physical and chemical properties stems from their layered structure and the ability to take up exchangeable ions from solution. Because clay minerals form from alteration of primary rocks and minerals near the surface of the Earth, they have a direct influence over the chemical evolution of the crust and provide a critical control over the chemical and isotopic composition of river and groundwaters that ultimately feed the oceans. For this reason, characterizing how elements and isotopic systems behave during incorporation into clay minerals will ultimately help us understand large-scale processes such as the impact of climate change, or tectonic shifts on past ocean chemistry. The association between clay minerals and water means that the presence of clay minerals can also guide our exploration of the solar system and the search for life on other worlds. Finally, understanding the physical and chemical properties of clay minerals has practical benefits to society; clay minerals are used widely in industry from drilling mud in oil field exploration to building supplies and plastics to uses around our homes such as in paints and coatings on paper. The utility of clay minerals stems from their unique physical and chemical properties; furthering our understanding of these minerals will both enhance future scientific studies and have important industrial implications.

Definition

Coal is a naturally occurring sedimentary carbonaceous rock composed of at least 50% organic matter by weight, and 70% carbonaceous material by volume, mostly from the diagenesis (chemical and physical alteration) of plant material in buried peat (Schopf 1956, 1966; Alpern and DeSousa 2002). Coal is a solid hydrocarbon. It is a rock that can burn. Coal does not have a distinct chemical formula, although it is dominated by complexly bound C, H, O, N, and S. Coal has an organic matrix but also contains inorganic (mineral) and fluid components. The chemical variability in coal is a result of (1) variability in the soils and weathered surfaces upon which the peat accumulated, (2) different types of plants and plant remains in peat, different types of peat mires, (3) the depositional history of the peat mire, (4) the syndepositional environments lateral to the peat which contributed inorganic sediment to the mire, (5) burial environments and history, (6) the long diagenetic history in which the peat was altered to coal, and (7) the exhumation history in which the coal was brought back to the surface or near-surface.

Coal Origins

Coal is physically, chemically, and thermally altered peat. *Peat* is partially decayed plant material, mineral matter, and water, which accumulates in anoxic swamps or mires (peat-forming wetlands). Peats generally have organic contents greater than 75%, inorganic mineral contents less than 25%, and water contents of 75–90% (Schopf 1966; Jarrett 1983; Clymo 1987; Alpern and deSousa 2002). Because they represent buried organic material, peats are natural carbon sinks and are an important component of the global carbon cycle (Gorham 1991; Yu et al. 2011). The plant material in peat varies, but in general, consists of organic compounds and plant tissues (wood, cortical tissues, roots, leaf cuticles, spores, pollens, etc.) which are composed of carbohydrates (mainly cellulose), lignins, proteins, lipids, waxes, and resins. Summaries of the chemistry of these tissues can be found in Bouška (1981), Given (1984), de Leeuw and Largeau (1993), and Krevelen (1993). The plants also contain inorganic

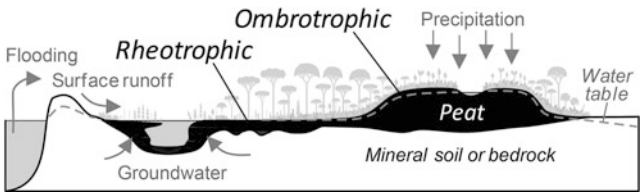
constituents, which are the precursors of some of the mineral matter in coal (see "Mineral Content").

The breakdown of plant parts through microbial and chemical activity while the peat is accumulating is termed *peatification.* Peatification involves oxidation, fermentation, gelification, methanogenesis, and humification, among other processes. Anaerobic transformation of carbon occurs through fermentation, which results in formation of low-molecular weight, acids, alcohols, and carbon dioxide (CO_2). In methanogenesis, bacteria convert cellulose (and other carbohydrates) into biogenic methane (CH_4). *Humification* is the physical and biochemical breakdown of plant tissues into humic substances (Stach et al. 1982; Krevelen 1993; Mitsch and Gosselink 2000). Most of the cellulose in plant debris is broken down by fungi and bacteria during peatification and only small amounts survive into low-rank coalification. Lignins, sporopollenins, cutans, suberans (periderm), resins, and algaenans are also degraded but can survive peatification and humification into coalification as different types of macerals (Stach et al. 1982; Given 1984; Teichmüller 1989; de Leeuw and Largeau 1993; Krevelen 1993; Hatcher and Clifford 1997). Biomarkers from organic compounds of these plant tissues have also been detected from organic geochemistry of the hydrocarbon fractions of the soluble organic matter of coals (Hatcher et al. 1982; Tissot and Welte 1984; Bustin et al. 1985).

Peat Mires

Not all peats form coal. Those peats which have a chance to become coal beds generally must be widespread, thick, and accumulate for thousands of years (or more). For thick peats to accumulate, plant production and plant-part accumulation must be greater than the rate of organic decay. Organic decay is slowed in most peats by maintaining waterlogged, anaerobic, acidic conditions. Maintenance of high water tables requires precipitation or groundwater contributions in excess of evaporation. Hence, climate plays a significant role in peat accumulation. Additionally, for thick peats to accumulate they must be protected from significant clastic sediment input or oxygenation (Moore and Shearer 2003; Clymo 1987; Stach et al. 1982).

Peat accumulates in a variety of different types of wetlands including bogs, fens, mires, and swamps. Two broad divisions based on chemistry and hydrology are (1) rheotrophic (minerotrophic) and (2) ombrotrophic (Mitsch and Gosselink 2000; Moore 1989; Clymo 1987). Rheotrophic peat-forming wetlands are groundwater sourced and tend to fill depressions in the landscape, while ombrotrophic mires are rainwater sourced and build up above the landscape (Fig. 1). These basic distinctions have profound influence on the resulting precursor peat chemistry, because topography-filling rheotrophic peats can be intermittently inundated by flood waters containing dissolved and suspended inorganic



Coal, Fig. 1 Two broad subdivisions of peat, the precursors of coal

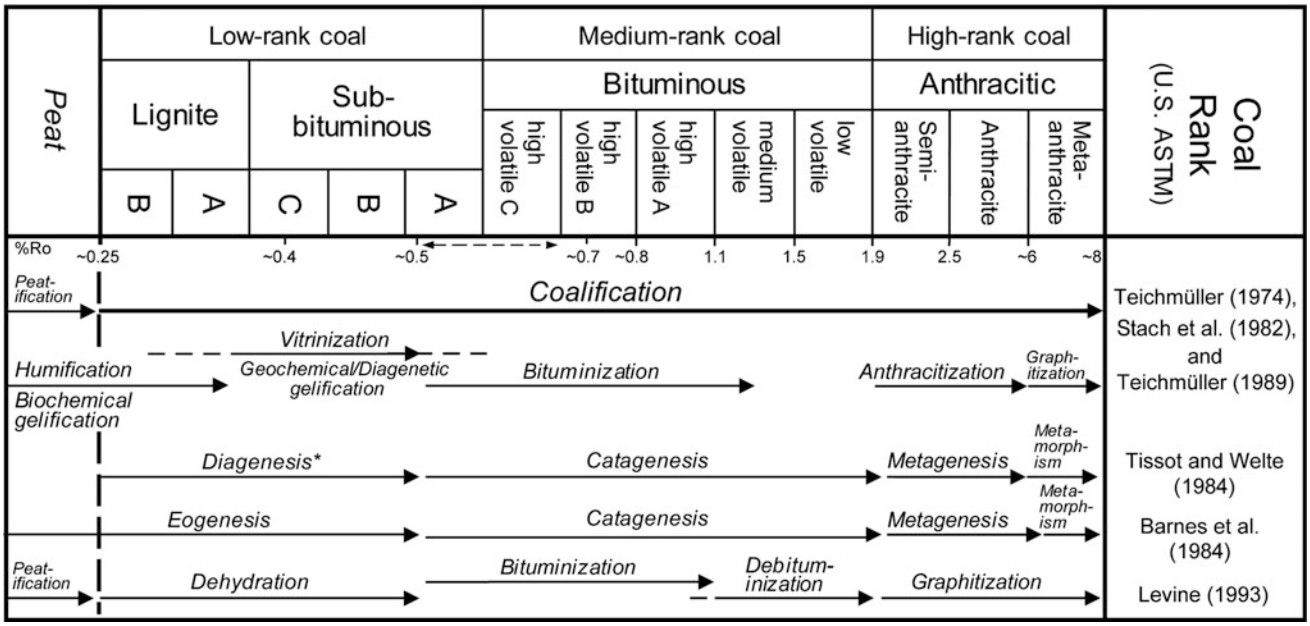
sediment, the precursors of mineral matter and much of the ash in coals. In contrast, ombrotrophic peats which build up above the level of bounding lakes or rivers are more sheltered from water-born sediment influx and receive only wind-born detrital minerals. Such peats will produce coals with low ash yields (Eble and Grady 1993; Neuzil et al. 1993; Staub 1991; Cecil et al. 1985). Different types of peat may grade into each other and succeed each other through time.

Peat Accumulation and Preservation

In order for thick peats to accumulate and be preserved, space must be generated for preservation. Relative to the accumulation and burial of peat, accommodation space can be generated (1) below the peat through compaction of underlying sediments or tectonic subsidence; (2) within the peat through biochemical processes resulting in auto-compaction; and (3) above the peat through base-level or sea-level rise. Optimal conditions for thick peat accumulation are when the rates of peat accumulation keep pace with the net rate of subsidence, sea-level change, and sedimentation (McCabe 1984; Butler et al. 1988; Diessel 1992; Bohacs and Suter 1997; Holz et al. 2002).

Peats Through Geologic Time

Time is another variable relative to coal. The oldest mires, and therefore oldest true peats, were in the Late Devonian, following the evolution of vascular plants on land. Although coals occur in rock strata from the Devonian Period through the Neogene Period, they are more common at certain times than others, because of changing global climatic and tectonic conditions. Also, plants have evolved through time, resulting in changes to the vegetative components of peats and the coals they form (Collinson and Scott 1987; Cross and Phillips 1990; Greb et al. 2006a). Different plants have different rates of decomposition and provide different chemical constituents (lignins, resins, etc.) to peat. Most plants contain inorganic elements which contribute to mineral matter in the peat and ultimately the coal formed from the peat. For example, Permian-age coals from southern continents (Australia, India) have higher inertinite (see "Coal Macerals") contents than Carboniferous-age coals from Europe and North America, because the precursor peats had different flora accumulating under different climates (Hunt and Smyth 1989; Taylor et al. 1989).



Coal, Fig. 2 Diagram showing stages of coalification cited in different reports relative to their approximate US coal rank (Note the term *diagenesis* was used by Tissot and Welte (1984) for the initial stages of coalification but in many reports it is used synonymously with the entire coalification process. %Ro vitrinite reflectance in oil. %Ro data from Teichmüller and Teichmüller (1982). In the US classification system, vitrinite reflectance values overlap between subbituminous A and high volatile bituminous C ranks, which is shown here as a *dashed line*)

Coalification

Coalification is the process by which peat is transformed into coal. The increasing alteration of coal is classified by rank (see next section). Coalification involves the breakdown of the original plant components in peat and the preservation of other more resistant plant components followed by reorganization of the biopolymers and geopolymers that survive (Hatcher and Clifford 1997). Historically, several processes were used to describe the transformation of peat and its constituent plant parts into coal and its components (Stach et al. 1982; Teichmüller 1974, 1989 in Fig. 2). More recent explanations have subdivided coalification into a series of stages relative to thermal maturation of source rocks (Tissot and Welte 1984; Barnes et al. 1984; Levine 1993; in Fig. 2). These stages approximate different processes which dominate coalification at different temperatures, although in some cases, they are overlapping. These processes are discussed further under *coal rank.*

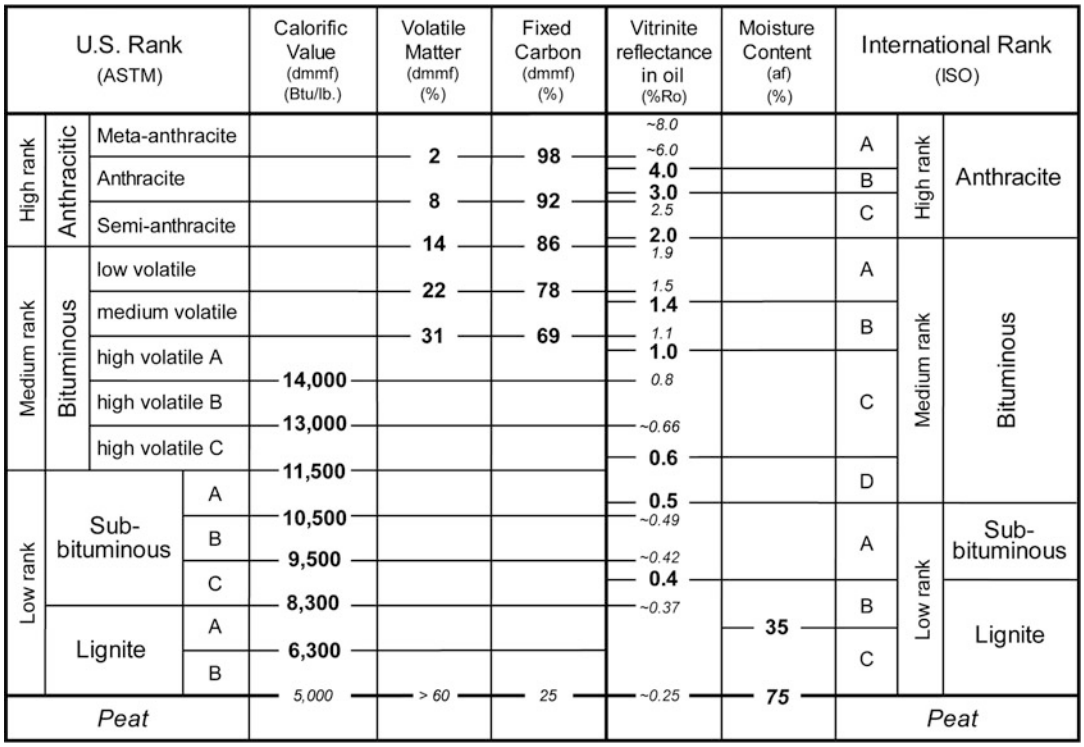
Not included in Fig. 2, are alterations to coal chemistry which may accompany igneous intrusions, hydrothermal fluids, and natural exhumation of deeply buried coal to the surface where it can be introduced (again) to near-surface and surface processes. A *telogenesis* stage is sometimes added to the coalification tract to include these processes (Barnes et al. 1984; Bustin et al. 1985). The diagenesis of coal is irreversible. Once a coal reaches its highest rank, it remains at that rank; however, minerals and elements within the coal may be oxygenated or react with minerals in groundwater during exhumation and telogenesis.

Coal Classification: Rank, Grade, and Types

Different countries and, in some cases, industries classify coal in different ways. Three general means of classification are based around parameters of (1) rank, (2) grade or quality, and (3) type or macroscopic and microscopic characterization.

Coal Rank

Coal rank is the terminology used to classify coal based on its relative coalification. In general, increasing coalification results in the loss of moisture and compounds rich in hydrogen and oxygen and the relative enrichment of carbon. Krevelen (1993) provides a good summary of different global classification schemes and the parameters upon which they are based. In the US classification scheme, calorific value is used to subdivide low-rank through medium-rank coals, and volatile matter or fixed carbon content is used for higher medium rank and high-rank coals (Fig. 3, ASTM 2014). Calorific value is a measure of the amount of energy produced from coal when it is combusted. Volatile matter is a measure of the nonwater gases formed from a coal sample during heating under oxygen-free conditions. Fixed carbon is a calculated value of the amount of nonvolatile carbon remaining



Coal, Fig. 3 Comparison of US and international rank subdivisions of coal. Critical values of defining parameters (calorific value, volatile matter, fixed carbon) for the US system (ASTM 2014) and defining parameters (vitrinite reflectance, moisture content) for the international system (ISO 2005) are shown in *bold*. Typical vitrinite reflectance values for US coal ranks and for the peat-lignite subdivision also shown for comparison (Data from Teichmüller and Teichmüller 1982). In the US classification system, vitrinite reflectance values overlap between subbituminous A and high volatile bituminous C ranks (Data from ASTM 2014; Schweinfurth and Finkelman 2003; ISO 2005; Diessel 1992; Given 1984; Stach et al. 1982). *dmmf* dry, mineral-matter-free basis, *af* ash-free basis)

in a coal sample after combustion of the sample. In the international system, moisture content is used to subdivide low-rank coals, while the reflective properties of vitrinite (a coal maceral discussed in a following section) are used to subdivide medium- and high-rank coals (Fig. 3, ISO 2005).

Ash yield and the percentage of vitrinite reflectance are used for further subdivisions and modifiers. Vitrinite reflectance can be used to compare the two classifications (Fig. 3).

Lignites are the lowest rank of coals. They are brown in color and have an earthy, crumbly texture. The boundary between what is termed peat and what is termed lignite is transitional, but having 75% or less moisture content (weight %) is a common parameter for lignite (UNECE 1998; Alpern and DeSousa 2002; ISO 2005). The dominant processes during the lignite stage of coalification are physical compaction, dewatering (dehydration stage in Fig. 2), and biogeochemical gelification (Fig. 2). Moisture content decreases dramatically from peat to lignite and subbituminous ranks as the coal is compacted by increasing burial. Additional moisture is lost through the loss of methoxyl ($–OCH_3$), hydroxyl (–OH), carboxyl (COOH–), and carbonyl (C=O) functional groups. Compaction from moisture loss is also associated with increasing hardness and development of fracture or joint sets in the coal called cleats (Taylor et al. 1998; Mukhopadhyay and Hatcher 1993; Krevelen 1993; Levine 1993; Teichmüller 1989; Given 1984; Hatcher et al. 1982; Stach et al. 1982). The carbon structure of lignites is dominated by catechol-like carbon rings (Hatcher and Clifford 1997). Catechols have two hydroxyl groups linked to an aromatic carbon (benzene-like) ring.

Subbituminous coals are the second division of low-rank coals (Figs. 2 and 3). In appearance and physical properties they are transitional between lignites and bituminous coals. Subbituminous C coals in the US rank system are brown and earthy like lignites, whereas subbituminous A coals are gray to black and shiny like bituminous coals. During coalification of subbituminous coals, moisture loss continues, but biochemical gelification is replaced by geochemical gelification, also termed vitrinization (Fig. 2). Vitrinization involves homogenization, compression, decarboxylation (loss of –COOH), and dewatering (dehydration) of low-rank huminite macerals to form vitrinite macerals (Mukhopadhyay and Hatcher 1993; Krevelen 1993; Teichmüller 1989; Given 1984; Stach et al. 1982; Schopf 1948). Continued loss of oxygen-bearing functional groups transforms the carbon structure of subbituminous coals from catechol-like structures

to phenols and alkylated phenols (Hatcher and Clifford 1997). Phenols have one hydroxyl group linked to a carbon ring.

In the transition from subbituminous B to A and bituminous C rank (US rank system), the color of coal changes, from brown to black. This color change is caused by chemical (diagenetic) gelification of humic substances and marks the beginning of the bituminization or catagenesis stage of coalification (Fig. 2). Bituminization involves the generation and entrapment of hydrocarbons from thermal processes, depolymerization of the coal matrix, and increased hydrogen bonding (Teichmüller 1974, 1989; Stach et al. 1982; Bustin et al. 1985; Levine 1993).

Bituminous coals are black, shiny, and generally hard. Bituminous coals begin with abundant volatile matter (high volatile bituminous coals) but with increased rank, volatile matter is lost (medium volatile and low volatile bituminous coals). In the high volatile bituminous rank, bituminization continues and transforms the molecular phase of the coal from a water-based to bitumen-based system (Teichmüller 1989; Levine 1993). The high volatile bituminous rank is approximately equivalent to the oil-forming window of hydrocarbon generation in source rocks (Teichmüller 1974, 1989; Hunt 1979; Levine 1993; Mukhopadhyay and Hatcher 1993). Coalification from the uppermost high volatile A through low volatile ranks is dominated by thermal degradation and repolymerization (cracking) of the molecular components of the coal and expulsion of low-molecular weight hydrocarbons, especially thermogenic methane. This is the thermogenic gas window in coals (Teichmüller 1974, 1989; Tissot and Welte 1984; Barnes et al. 1984; Bustin et al. 1985; Levine 1993; Mukhopadhyay and Hatcher 1993). Thermogenic gas is generated at burial temperatures of 150–220 °C (Hood et al. 1975; Quigley and Mackenzie 1988; Stolper et al. 2014).

At the bituminous stage of coalification, aromaticity increases through the condensation of phenols to heterocyclic aromatic compounds and benzene-like structures (Hatcher and Clifford 1997).

High volatile bituminous coals (high volatile B and C) are classified using gross calorific value in the US system. Calorific value, however, does not systematically change above the high volatile A bituminous rank, so other parameters are used to classify higher rank coals. Medium volatile and low volatile bituminous ranks in the US system are defined based on volatile matter or fixed carbon (Fig. 3, ASTM 2014). The international system uses vitrinite reflectance to subdivide bituminous coals (Fig. 3, ISO 2005).

Anthracitic coals are high rank coals (Figs. 2 and 3). They are shiny (glassy) and break with a conchoidal fracture. The anthracitic rank is characterized by a sharp decrease in hydrogen content and the H/C ratio. From the semianthracite to anthracite rank, coalification involves condensation of small aromatic ring to larger ordered structures (Stach et al. 1982; Krevelen 1993; Levine 1993). Most coals do not reach anthracitic rank, which requires high heat, generally considered to be greater than 200–250 °C (Bostick 1979; Hunt 1979; Price 1983), from very deep burial, tectonic metamorphism, or contact metamorphism. It is commonly thought that further heating would transform meta-anthracite coal to graphite, a crystalline form of carbon. However, the activation energy for the formation of graphite may be too high to be formed in nature by heating alone, and significant strain energy appears to be required to produce natural graphite from anthracitic coals (Wilks et al. 1993; Bustin et al. 1995; Bustin 1999).

Heat related to burial depth and geothermal fluids is considered the leading cause for coal rank changes (Teichmüller 1989; Daniels et al. 1990; Hower and Gayer 2002; Ruppert et al. 2010). The maximum heat achieved and the duration of that heating event are important factors in maturation and rank changes (Lopatin 1971; Bostick 1979; Teichmüller 1989).

Coal Grade

Coal grade is generally an economic or technological classification reflecting the relative quality of a coal for a particular use. For example, the grade of coals used to generate steam in electric power utilities (called *steam coals*) usually is a reference to a coal's ability to combust with minimal leftover material and minimal emitted pollutants, based on government regulation. Likewise, coal used to produce steel, referred to as metallurgical coal, or *met-coal*, has very specific grade requirements. The coal must be very low in ash (generally $<10\%$) and sulfur ($<1\%$), have volatile matter contents between about 20% and 30%, and have a favorable balance of volatile and inert components. Element concentrations are important as well, as certain elements (e.g., phosphorous) are deleterious (e.g., Zimmerman 1979; Stach et al. 1982). In many cases, different coals are blended to achieve the grade and quality needed for a specific use.

Coal Types

The term "type" relative to coal description and classification unfortunately has many different uses (e.g., O'Keefe et al. 2013), but in coal science, type refers to the general appearance of a coal, which is based on the manner in which the coal (or parts of the coal) was deposited. Shearer and Moore (1999) provide a brief summary of maceral-based and botanical-based type classifications. Stach et al.'s (1982) classification (based in part on Stopes 1919; Schopf 1960) has two types: humic and sapropelic. *Humic* coals are banded coals and are most abundant. The humic type is divided into four lithotypes (vitrain, clarain, durain, and fusain) based on appearance (Table 1). A single humic coal bed may contain all four lithotypes. *Sapropelic* coals are nonbanded coals that form in standing water (ponds, lakes) within peatlands. Sapropelic coals are subdivided into cannel and boghead coals, based on whether the dominant organic material is pollen and spores (cannel), or algae (boghead) (Table 1).

Coal, Table 1 Coal types and their dominant microlithotypes and maceral content. Many different types of macerals can be found in microlithotypes, and many microlithotypes can be found in lithotypes

Coal type	Lithotype (macroscopic)	Appearance	Dominant microscopic components	
			Microlithotype	Macerals
Humic (banded)	Vitrain	Bright, black, shiny and brittle bands, usually with fissures. Tends to break into small cubes	Vitrite	Vitrinite/huminite
	Clarain	Semi-bright (between vitrain and clarain), black, and very finely (mm-scale) interlayered bands of vitrain, durain, and sometimes fusain	Clarite, clarodurite	Vitrinite/ huminite, inertinite
	Durain	Dull, black to gray-black bands with rough surface. Bands have less fissures than vitrain. Tends to break into lumps	Durite, durolaclarite	Inertinite, vitrinite/huminite
	Fusain	Silky lustre, black to gray-black, fibrous bands. Soft and friable, sometimes like charcoal	Inertite, vitrinertite	Inertinite, vitrinite/huminite
Sapropelic (nonbanded)	Cannel	Dull to greasy lustre, black, very hard nonbanded coal. Breaks with conchoidal fracture	Liptite	Sporinite (a liptinite group maceral)
	Boghead	Similar to cannel but brownish	Liptite	Alginite (a liptinite group maceral)

Data from Stach et al. (1982)

Sapropelic coals are far less common than humic coals and may occur as layers or benches, within an otherwise humic coal. Further subdivisions of sapropelic coals are shown in Hutton and Hower (1999).

Relative to geochemistry, different coal types begin with different weight percentages of carbon (C), hydrogen (H), and oxygen (O). For example, humic coals are initially rich in oxygen and poor in hydrogen, whereas sapropelic boghead coals are rich in hydrogen and poor in oxygen. Ratios of H/C to O/C change along different paths for sapropelic and humic coals through medium volatile bituminous rank (Krevelen 1952, 1993; Tissot and Welte 1984; Levine 1993).

Different countries and industries may have their own "type" classification and in some cases, existing classifications are added, or subdivided further, based on local or regional needs. For example, Hagemann and Hollerbach (1980) subdivided German lignite classes into four lithotypes based on texture and the ratio between ground mass and identifiable plant remains, and varieties of lithotypes based on color and hue, evidence of gelification, the presence of organic inclusions, and surface texture.

Coal Microlithotypes

Each coal type is composed of microlithotypes (Table 1). *Microlithotypes* are microscopic associations of macerals (see next section) with a minimum band width of 50 microns (ICCP 1963). Microlithotypes can be mono-, bi-, or trimaceralic depending whether they contain one, two, or three of the maceral groups. A fourth microlithotype group, termed carbominerite, can also be identified for microlithotypes which contain more than 25% mineral matter. Humic coal lithotypes commonly consist of vitrite, clarite, vitrinertite, duroclarite, or inertite microlithotypes. Sapropelic coal lithotypes tend to consist of liptite, vitrinertoliptite, and durite microlithotypes (ICCP 1963; Stach et al. 1982; O'Keefe et al. 2013). End-member microlithotypes (vitrite, liptite, and inertite) represent coal that is dominantly (>95%) composed of vitrinite, liptinite, and inertinite, respectively. Coal with varying proportions of different macerals is classified accordingly to their composition. For example, the bimacerite clarite is composed of >95% vitrinite and liptinite, while durite is composed of >95% inertinite and liptinite.

The chemistry of micolithotypes can influence the physical behavior of coals (e.g., Suárez-Ruiz and Crelling 2008). For example, the relative composition of inertinites from microlithotypes can be used as an indicator of coke strength in coking coals (Brown et al. 1964). It also influences the ability to grind (Hower et al. 1987; Moore and Shearer 1999) and break (Esterle et al. 2002), which influence coal processing for electrical and commercial uses.

Coal Macerals

Macerals are microscopic components of coal that are distinguished and classified based on petrographic properties, observed in reflected light on polished surfaces. They are the building blocks of microlithotypes. Macerals represent the altered remains and byproducts of the original plant material and are analogous to the sediment grains and cements that compose a clastic sedimentary rock. The current maceral classification and the plant parts from which they originate are shown in Fig. 4.

Low-rank Macerals			Higher-rank Macerals			Origin
Group	Subgroup	Maceral	Group	Subgroup	Maceral	
Huminite	Humotelinite	Texinite →	Vitrinite	Telovitrinite	Telinite	Plant cell walls (with visible structure)
		Ulminite →			Collotelinite	Plant cell walls (gelified, structureless)
	Humotelinite	Attrinite →		Detrovitrinite	Vitrodetrinite	Small particles of attritus (huminitic particles)
		Densinite →			Collodetrinite	Mottled groundmass (originally attritus)
	Humocollinite	Corpohuminite →		Gelovitrinite	Corpogelinite	Primary and secondary cell infillings from humic gels
		Gelinite			Gelinite	Crack infillings of amorphous humic matter
Liptinite		Sporinite			Sporinite	Outer membranes of plant spores and pollen
		Cutinite			Cutinite	Outer coatings (cuticles) of leaves, roots, stems
		Suberinite			Suberinite	Suberinized cell walls of cork in bark and roots
		Resinite			Resinite	Plant resins, balsams, latexes, fats, and waxes
		Alginite			Alginite	Algae (mostly planktonic)
		Bituminite			Bituminite	Amorphous degraded material of algal or bacterial origin
		Exsudatinite*			Exsudatinite	Secondary crack-filling material after oil generation
		Liptodetrinite			Liptodetrinite	Mechanically degraded particles and residues of liptinites
		Chlorophyllinite			X	Chlorophyll-derived material in peat through lignite rank
Inertinite		Fusinite			Fusinite	Fusinization of plant cell walls (fires, decarboxylation, etc.)
		Semifusinite			Semifusinite	Weakly humified and dehydrated plant tissues
		Funginite			Funginite	Fungal spores, sclerotia, and other fungal tissues
		Secretinite			Secretinite	Oxidation of resin and possibly humic gels
		Macrinite			Macrinite	Dehydrated flocculated humic matrix substances
		Inertodetrinite			Inertodetrinite	Fusinization of tiny varied inertinite precursors
		X			Micrinite	Secondary coalification residues of liptinitic substances

Coal, Fig. 4 Terminology of macerals and their suspected origins. *Arrows* show direct relationship between low rank maceral and higher rank macerals (Data from ICCP 1971, 1998, 2001; Stach et al. 1982; Scott 2002; Sýkorová et al. 2005; Pickel et al. 2017)

Macerals were originally defined based on their relative reflectance in incident light (Stopes 1935). They are classified intro three broad groups: liptinites, vitrinites, and inertinites. For low-rank coals, the precursor of vitrinite is referred to as huminite. Different macerals have different coalification tracks, or different rates at which hydrogen, carbon, and oxygen contents change in the macerals with rank, although in general, macerals increase in aromaticity from liptinite to vitrinite to inertinite, and aromaticity increases within each maceral group with rank. Different macerals also have different volatility. Vitrinite, liptinite, and a portion of semifusinite tend to be volatile, while inertinite macerals tend to be inert. Also, some macerals may be more likely to be associated with mineral matter. For example, fusain contains many pores, which are often filled with mineral matter (Masterlerz and Bustin 1993; Krevelen 1993; Given 1984; Stach et al. 1982).

Huminite-Vitrinite

Huminite and vitrinite group macerals are largely derived from woody and structurally resistant plant tissues (Fig. 4). Huminite group macerals in low-rank coals are the precursors of vitrinite macerals in higher-rank coals and vitrinite group macerals are the dominant macerals in most humic medium- and high-rank coal beds. These macerals are defined by structural features representing the degree of gelification of the precursor plant material. They have high oxygen contents and low carbon contents relative to the other maceral groups, but carbon content increases with rank (Sýkorová et al. 2005; ICCP 1998; Stach et al. 1982).

Huminite and vitrinite macerals increase in aromaticity through coalification, which influences their reflectivity. Vitrinite macerals are gray in reflected light, but their reflectance increases uniformly through coalification, providing a parameter that can be used to measure rank in coal (Fig. 2), and thermomaturity in organic-rich shales containing particles of vitrinite and bitumen. Bitumen is a thermomaturation product of kerogen in organic-rich petroleum source rocks (Hunt 1979; Tissot and Welte 1984; Teichmüller 1989; Littke 1999).

Inertinite

Inertinite group macerals are the oxidized remains of woody and other plant tissues, as well as humic gels and coprolites (Fig. 4). Different macerals in the inertinite group are defined based on the presence or absence of original plant structure. The term implies that these macerals are chemically more inert than other macerals, particularly in carbonization (making coke for steel) processes. They tend to be carbon-rich and hydrogen-poor. The carbon content depends on the origin of the maceral and extent of desiccation or redox processes it underwent during peatification. Inertinite macerals are highly reflective and appear white in reflected light, but they become difficult to distinguish petrographically at anthracite rank because all macerals have the same high reflectance by that stage of coalification (Stach et al. 1982; Teichmuller 1989; ICCP 2001).

Liptinite

Liptinite group macerals are black or brown in reflected white light and fluoresce under blue or ultraviolet light. They are

derived from cutans (waxes), resins, spores, and pollens in plants (Fig. 4) and as such, they tend to be hydrogen rich. Liptinites are involved in two coalification jumps. The first occurs in high volatile bituminous B and C coals when they begin to expulse liquids. The second occurs at or near the boundary of high volatile and medium volatile coals, where they lose their fluorescent properties, and their reflectance becomes similar to vitrinite (Stach et al. 1982; Teichmüller 1974, 1989; Pickel et al. 2017).

Coal Molecular Structure

There is no singular molecular chemical model for coal because coals are chemically and physically microheterogenous, both between different coals and within individual coals. Coals are aromatic (consist chiefly of aromatic [pentagonal rings] of carbon) compounds, and more than 100 molecular models have been proposed for the "basic" coal molecule. Mathews and Chaffie (2012), Mathews et al. (2011), and Marzec (2002) provide summaries of these models. Most modern models illustrate coal as a complex macromolecular network, which changes with rank. Levine (1993) summarized the macromolecular coal model as a (1) three-dimensional macromolecular matrix fraction composed mostly of single or polycyclic aromatic carbon structures fringed by H- and O-bearing functional groups and cross-linked by H- and O- bridge structures; and a (2) molecular fraction formed by tightly bound oils and asphaltenes of medium- to high-molecular weight and lower molecular weight compounds either physically entrapped or loosely bound to the matrix. The lower molecular weight fraction includes H_2O, CH_4, and CO_2, which change with rank.

Mineral Content

Coal is also comprised of minerals, separate or entrapped within the organic coal matrix. Mineral matter occurs as nonmineral inorganics and discrete inorganic crystalline and noncrystalline particles or masses. The minerals in a coal may have originated in the original peat (detrital, authigenic, biogenic) or may have been introduced, remobilized, or transformed within the coal at any time during post-peat coalification (Table 2). More than 120 minerals and inorganic compounds have been documented in coals worldwide (Schweinfurth and Finkelman 2003; Ward 2002; Vassilev and Vassileva 1996; Finkelman 1981). Table 3 shows some of the minerals which have been reported from coal.

Minerals in coal commonly occur as single crystals or concentrations of crystals within the coal matrix or in voids (fractures, cleats, rotted roots, etc.) within the coal. Authigenic minerals (Table 2) tend to be very fine grained (microns) and embedded in the coal matrix, often occurring within cell-sized voids of individual macerals. In contrast, diagenetic minerals (Table 2) tend to be coarser crystalline, macroscopic concentrations in cleat and fracture fills. This distinction is significant as cleat-filling minerals are generally easier to remove from coal prior to utilization than authigenic minerals (Rao and Gluskoter 1973; Mackowsky 1982; Renton 1982; Ward 1989; Krevelen 1993). The amount, particle size, and type of mineral matter in coal influence a wide variety of uses, including combustion for steam for electrical energy production and the production of metallurgical coke to make steal. Understanding mineral components is not only important for the practical processes and maintenance of combustion equipment but also chemical reactions during combustion, and the resultant composition of emissions and solid residues, especially in countries where the chemical composition of the emissions or residues is regulated.

Silicate Minerals

The most common minerals in coal are silicates, especially quartz and assorted clays (Table 3). Quartz is a common detrital mineral in flood waters and can also be deposited in peats from wind-blown sediment and volcanic ash falls (e.g., Neuzil et al. 1993; Ruppert et al. 1993). Biogenic opaline quartz accumulates from plant phytoliths and in sponge spicules in peat (Andrejko et al. 1983; Davis et al. 1984; Ruppert et al. 1993). Although most quartz in coal is syngenetic, diagenetic quartz-filling cleats are also reported in high-rank coals (Ward 2002; Spears 1987; Renton 1982).

Feldspars are minor mineral constituents in coals. Most feldspars are detrital in origin. Micas are rare, but detrital micas, which were weathered by acidic peat waters, may be the source for many clays, especially chlorite, in coal beds (Staub and Cohen 1978; Davis et al. 1984; Vassilev and Vassileva 1996).

Clay minerals are the most common silicate minerals in coal, and total clays often constitute the majority of mineral matter in coal. Kaolinite and illite are two of the most common clays in coals, but different types of clays are common in different coals in different basins (Table 3). Clays are common constituents of flood waters, so are common detrital additions to peats. Authigenic clays in peat can be sourced from (1) inorganic constituents in the original plant material, which become amorphous inorganics in the peat, which in turn, are altered to clays (Renton et al. 1979); (2) weathering of volcanic ash (Stach et al. 1982; Ward 2002); (3) from altered detrital muscovite (Staub and Cohen 1978; Davis et al. 1984); and from leaching and alteration of bedrock and underlying soil materials (Spears 1987). Kaolinite is favored in acidic peats, whereas smectite-dominated mixed layer clays dominate in neutral pH conditions. Smectite can

Coal, Table 2 Terminology used to describe the relative timing of mineral formation, deposition, or emplacement in peat and coal, and some of the sources and processes involved

Timing of mineral emplacement				Source/Origin		Dominant processes and products
Non-mineral inorganics	Higher Rank Coals ← Lignite ← Peat	Syngenetic (Primary)	*Early (During peat accumulation)*	Authigenic	Peat pore fluids	Dissolved salts and other inorganics in peat pore waters
Inorganic mineral particles (Crystalline and non-crystalline)					Biogenic	Inorganic elements in organic compounds in peat
				Allogenic Detrital	Clastic Epiclastic	Aqueous: Sediment deposited in peat from adjacent waters
						Aeolian: Air-born dust and sediment in peat
					Ash falls	Deposition of volcanic ash in peat
			Both Early and Late	Authigenic	Biogenic	Inorganic components of plants (e.g. pytholiths) and animals (e.g. spicules) produced through biologic/metabolic activity
					Chemical precipitates (pore filling)	Alteration of detrital and biogenic minerals in peat
						Bacterial reduction of sulfates sourced from peat processes and from marine flood waters
			Late (after burial)			Pre-compactional minerals formed from soluble ions during biochemical gelification at low temperatures
		Diagenetic (Secondary)		Epigenic	Chemical precipitates and transformations (cleat filling)	Transformation of minerals in coal through interactions with fluids and gases produced by coalification processes or from geothermal fluids at increasing burial temperatures and pressures
						Remobilization of minerals and ions in coal and fluids with increasing heat, pressure, and fluid chemical evolution, resulting in mineral deposition in cleats and fractures
						Metamorphism from igneous intrusions or geologic metamorphism at higher anthracitic ranks
		Telogenetic (Tertiary)			Chemical precipitates	Oxidation of minerals in coal at the surface after exhumation
						Mineralogical reactions associated with burning coal at the surface after exhumation

From data in Mackowsky (1982), Ward (2002). A telogenesis stage is added here to show processes at the surface which can precipitate minerals in coal

later be transformed to illite during diagenesis. Kaolinite and illite can also be formed by diagenetic transformations and are common in cleat and fracture fills in coal beds (Rao and Gluskoter 1973; Renton et al. 1979; Renton 1982; Spears 1987; Vassilev and Vassileva 1996).

Carbonate Minerals

Siderite, calcite, dolomite, and ankerite are common, and sometimes abundant constituents of the mineral fraction of coals (Table 3). In anaerobic, alkaline peat sediments, iron can accumulate as siderite (Postma 1977, 1982; Shotyk et al. 1992), possibly from CO_2 released by organic decay (Gould and Smith 1979; Ward 1989). Concretionary masses of calcite in coal beds, called coal balls, are found in some coal basins. Many coal balls preserve the cellular structure of plants in the peats in which they formed so are early syngenetic (e.g., Stopes and Watson 1909; Phillips 1980; Scott et al. 1996). Syngenetic dolomite may be introduced to peats if peats are

buried by marine waters (Stach et al. 1982). Carbonates can also be diagenetic. Calcite, and to a lesser extent, dolomite and ankerite are common fracture- and cleat-filling minerals formed in medium- and high-rank coals (Rao and Gluskoter 1973; Mackowsky 1982; Ward 1989, 2002). Some cleat-filling calcite cements may also result from telogenesis and precipitation from meteoric groundwater during exhumation (e.g., Kolker and Chou 1994).

Sulfide and Sulfate Minerals

Sulfur occurs in three forms in coal: (a) organic sulfur from the organic compounds in the coal; (b) sulfide minerals; and (c) sulfate minerals (usually hydrous iron and calcium sulfates) produced by oxidation of pyritic sulfides. At least 24 sulfate minerals and 19 sulfide minerals have been identified in coals (Ward 1989, 2002; Casagrande 1987; Davis 1982; Finkelman 1981). Pyrite and marcasite are the most

Coal, Table 3 Some of the minerals found in coals. Occurrence and abundance varies within and between coal beds. Not all minerals are found in all coals

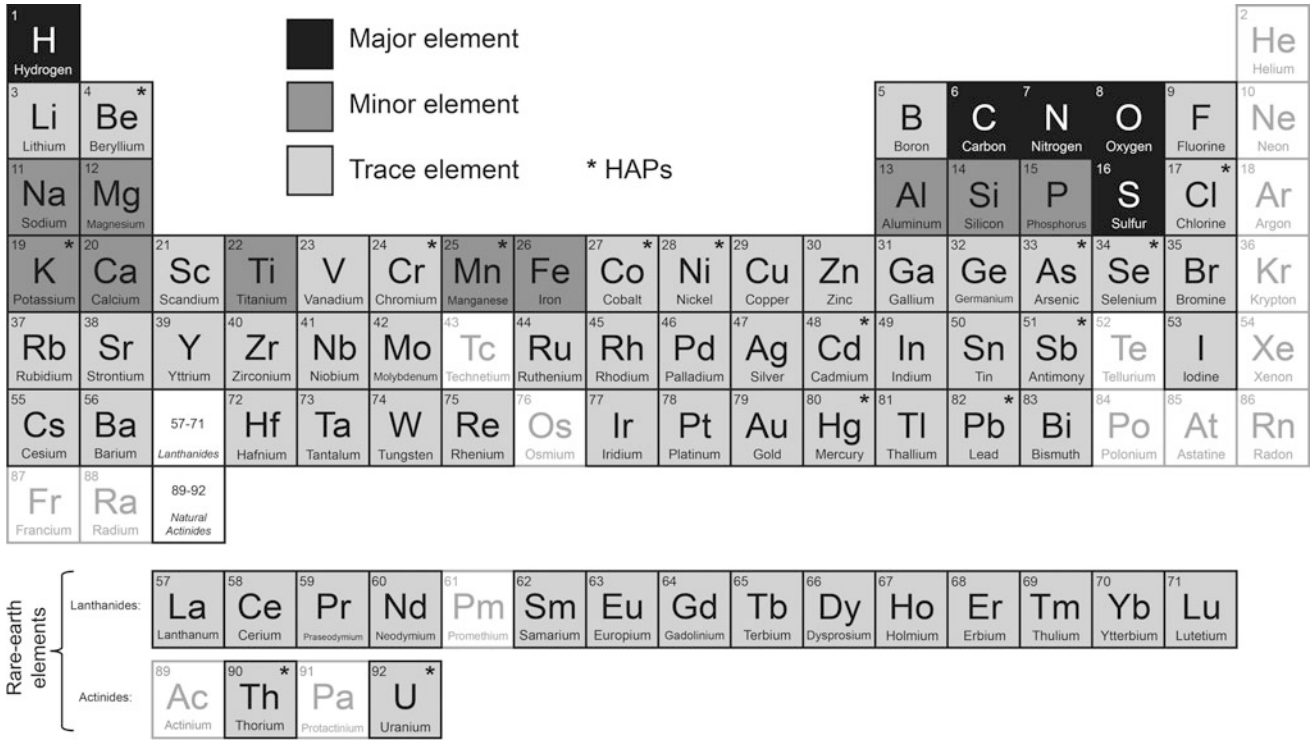
From data in Rao and Gluskoter (1973), Finkelman (1981), Mackowsky (1982), Renton (1982), Vassilev and Vassileva (1996, 2000), Hower et al. (1999), Ward (2002), Schweinfurth and Finkelman (2003)

common sulfide minerals in coal (Table 3). These may be authigenic or diagenetic. Authigenic pyrite can form in peat while the peat is accumulating, or in peats buried by marine waters (e.g., Casagrande 1987). Authigenic pyrite may occur as single crystals or clusters of crystals in individual macerals of coal. Diagenetic (epigenetic) pyrite tends to fill veins and cleats in coal and be more coarsely crystalline (Rao and Gluskoter 1973; Mackowsky 1982; Vassilev and Vassileva 1996). Additional diagenetic sulfide minerals include sphalerite, galena, and chalcopyrite, especially from coals which have encountered hydrothermal fluids (Mackowsky 1982; Finkelman 1981, 1985). Many of the sulfate minerals found in coal (e.g., coquimbite, jarosite, melanterite, rozenite, szomolmokite) result from exposure of sulfide minerals in coal at the surface (e.g., Rao and Gluskoter 1973).

Pyrite (FeS_2) breaks down with potentially deleterious consequences in many parts of the coal mining and utilization cycle. Weathering of mined exposures of coal and high-sulfur stratum, or abandoned spoil piles with significant pyrite concentrations, can result in acid-mine drainage (ARC 1969; NRC 1990; Brady et al. 1998; Greb et al. 2006b; Finkelman and Greb 2008). In boilers and furnaces, pyrite breaks down into elemental iron and sulfur, which can lead to corrosion and fouling. Each element combines with oxygen to form oxides. Iron oxide becomes part of the bottom or fly ash. Sulfur dioxide (SO_2) is emitted in the gas stream, which can react with water vapor to form sulfurous acid (H_2SO_3), which oxidizes to sulfuric acid (H_2SO_4), a major component of acid rain (EIA 1997, 2001; U.S. EPA 2004; Greb et al. 2006b). Many different types of mitigation are employed to



Coal, Fig. 5 Periodic table of naturally occurring elements, showing the elements reported from coal. Not all elements are found in all coals (After Schweinfurth and Finkelman 2003, Fig. 9)

remove or reduce pyrite from mined coal and to reduce or limit sulfurous emissions during and following combustion. Many techniques are also available for limiting acid-mine drainage from mine sites, and from mitigating drainage from mine sites which were abandoned before modern regulations in developed countries.

Major, Minor, and Trace Elements

Figure 5 shows the elements that have been reported in coal. Although coal does not have a unique chemical structure, the major elements (more than 1%) in the coal matrix are carbon (C), hydrogen (H), oxygen (O), nitrogen (N), and sulfur (S) (Fig. 5). The relative percentage of carbon increases with rank, while oxygen and hydrogen decrease with rank. Major elements are mostly organically associated, although they are found in inorganic (mineral) associations as well. Minor elements (1.0–0.01%) in coal are Na, Mg, Al, Si, P, K, Ca, Ti, Mn, and Fe (Fig. 5). Most of the minor elements are associated with the mineral constituents in coal, although phosphorus (P) is also organically associated. Minor elements are relatively common in coal but do not occur in all coal seams and occur in different concentrations in different seams (Finkelman 1981, 1985; Schweinfurth and Finkelman 2003; Swain 2013).

Trace elements (Fig. 5) are elements which occur in concentrations of 100 parts per million or smaller. Not all coals contain these elements, and concentrations of these elements vary greatly among and within coal beds. Similar to mineral matter, trace elements may be introduced during peatification or at any stage of coalification. Most appear to be syngenetic. From the peat through lignite stage of coalification, fresh cations may be introduced from groundwater and by ion exchange with carboxyl acids or their salts. Organic acids in peat and low-rank coals provide a large capacity for ion-exchange and complexation of metal ions into organometallic compounds (Rashid 1974; Nissenbaum and Swain 1976; Miller and Given 1986; Given and Miller 1987; Mitsch and Gosselink 2000; Li et al. 2010). Some trace elements are also epigenetic and are introduced with epigenetic minerals.

An important aspect of trace elements is their chemical association. Trace elements can be organically bound to the coal matrix or associated with mineral matter. The elements B, Be, Ga, Ge, and Sb are usually organically bound. The elements As, Cr, Ni, Se, Ti, U, and V, among others, may be either organically bound or occur in mineral matter, depending on the coal. Most of the other trace elements in coal shown in Fig. 5 are associated with mineral matter (Gluskoter et al. 1977; Miller and Given 1986; Given and Miller 1987; Goodarzi 1988; Finkelman 1995; Swaine

2013). In fact, some elements tend to have associations with certain minerals. For example, Cr, Hf, Rb, Ti, and Zr are commonly associated with aluminosilicate minerals like micas, feldspars, and clays (e.g., Suárez-Ruiz and Crelling 2008). Be, Cr, Mn, and Ni are commonly associated with the clay mineral chlorite. As, Cd, Co, Hg, Ni, Sb, and Se are commonly associated with the sulfide minerals pyrite and marcasite (e.g., Schweinfurth and Finkelman 2003). Understanding the chemical association of trace elements in a coal can aid in (1) determining if the elements can be or need to be removed or diminished from the coal prior to utilization, (2) where the elements will end up (emissions, solid residues) during and following coal utilization, and (3) determining the best mechanisms for mitigating any potential technological or environmental issues an element may have in the utilization process based on best practices and regulations.

Of the trace elements which can occur in coal, there are 15 which are listed as hazardous air pollutants (HAPS) by the US EPA (Fig. 5) although currently, mercury (Hg) is the only element of the 15 regulated and monitored from coal-fired power plant emissions in the United States (U.S. EPA 1998, 2016a). Many of the other HAPS (As, Cd, Co, Hg, Pb, some Se, and Sb) are commonly associated with sulfide minerals (see previous section), so removal of (or at least reducing) sulfide minerals from the coal prior to combustion in preparation plants aids in mitigation.

Coal Utilization

The majority of chemical testing of coal beds is conducted to (1) determine how a particular bed will react during its prospective use; (2) what and how much solid, particulate, and gaseous products may be produced from its use; and (3) address any technological or environmental issues resulting from coal utilization. Globally, coal is mostly combusted to generate steam to provide electrical power. Hence, much of the geochemical analysis of coal is aimed at understanding combustion characteristics and potential environmental issues of coal combustion. Environmental issues depend on the coal, the local environment (climate, pH, moisture, etc.), combustion technology, and the type of pollution control systems used in the process. A variety of coal-combustion emissions (SO_2, NO_x, etc.) are regulated in developed countries (e.g., U.S. EPA 1998). Concerns about CO_2 emissions and global climate change have also sparked limits on carbon emissions in some countries (Houghton et al. 1990; UN 1998; Stocker et al. 2013; U.S. EPA 2016b; EU 2016). Other than emissions, the chemistry of solid combustion residues and by-products is also important for determining potential by-product uses or for mitigating potential groundwater issues related to disposal of combustion residues in landfills (Adriano et al. 1980; U.S. EPA 1999, 2015; Izquierdo and Querol 2012). More information and references concerning environmental chemistry and issues of coal utilization, including various emissions, and solid residues, can be found at government agencies charged with their regulation and in Greb (2006).

Coal also has *nonfuel* uses. The principle nonfuel use of coal is to make metallurgical coke, which is used to make steel. A by-product of metallurgical coke are coal tars, which can be used to produce a wide array of aromatic chemicals. The pitch fraction of the tar can also be used to make an array of specialty carbon materials such as graphite and carbon fibers. Coal can also be gasified to make synthesis gases and other chemicals and can be liquefied to make synthetic fuels (Miura 2000; Schobert and Song 2002). More information about the commercial chemistry of coal and coal by-products can be found in Bouška (1981), Given (1984), Berkowitz (1985), and Krevelen (1993).

Conclusions

Coal is a complex material composed of an organic matrix, as well as inorganic and fluid constituents. Coal is diagenetically altered peat. Much of the chemistry of a particular coal is inherited from its peat precursor, but overprinted by its diagenetic history. This results in variability between and within coal beds. Coal chemistry changes with rank, which is largely a function of burial and thermal diagenesis. Variability in coal composition can generally be seen and analyzed at different scales, from the whole seam or benches of a seam, to bands in the seam (type), to microscopic bands and associations (microlithotype), to macerals (microscopic particles), to sub-maceral elemental composition. Understanding a coal's composition requires an understanding of a particular coal from its genesis as peat, through its geologic history to exhumation and exposure. How detailed the analysis of a particular coal is, generally depends on the coal's end use. Most chemical analyses on coals are done to determine parameters which influence the technological utilization of the coal, and to plan for any environmental or regulatory considerations of that particular use. Such considerations involve more than the coal itself, but also the equipment used and regulations, which vary considerably around the globe.

Element Data
Atomic Symbol: **Co**
Atomic Number: **27**
Atomic Weight: 58.933195 g/mol
Isotopes and Abundances: ^{59}Co 100%
1 Atm Melting Point: 1495 °C
1 Atm Boiling Point: 2927 °C
Common Valences: 2+, 3+
Ionic Radii: 65 pm (2+, 6-fold coordination)
Pauling Electronegativity: 1.88
First Ionization Energy: 7.88 eV
Chondritic (CI) Abundance: 513 ppm[a]
Silicate Earth Abundance: 102 ppm[a]
Crustal Abundance: 26.6 ppm[b]
Seawater Abundance: ~3–300 pmol/kg[c]
Core Abundance: 0.25%[d]

Properties

Cobalt (chemical symbol, Co) is a d-block transition metal, bluish white. It appears in the first long period of the periodic table between iron and nickel. Cobalt shares many chemical and physical properties with these two elements. Naturally occurring Co consists of a single stable isotope: ^{59}Co, whereas ^{60}Co is an artificial isotope that is an important γ-ray source. Cobalt has two main oxidation states (2+ and 3+). The common oxidation state for simple compounds is Co^{2+}. Depending upon geometry and environment, Co ionic radii vary between 56 pm and 90 pm. Cobalt is a transitional, compatible, and siderophile (chalcophile and lithophile in the Earth's crust) element, has a high melting point of 1495 °C, and is ferromagnetic. Cobalt has an electronegativity of 1.88 on the Pauling scale and displays a first ionization potential of 7.88 eV. More details can be found in Blackman (2006), Raveau and Seikh (2012), and Haynes (2015).

History and Use

Cobalt has been utilized by the society since the Bronze Age, mainly to impart a rich blue color to glass and ceramics. Its name derives from the German word kobald (goblin or evil spirit) and Greek word cobalos (mine), because Co minerals fooled miners with their bright colors. However, it was only isolated as a pure metal by Swedish chemist Brandt in 1735. Demand for Co remained subdued until the turn of the twentieth century and the development of cobalt-chromium alloys. Indeed, the demand for Co increased considerably after the Second World War, driven by the use of high-purity Co in jet engines and gas turbines. Cobalt demand has further accelerated in the past 30 years. Indeed, it reflects the increased use of Co as an essential constituent of materials used in high-technology industries including rechargeable batteries, superalloys, and catalysts. Cobalt, like Fe, can be magnetized and so is used to make magnets. It is alloyed with Al and Ni to make particularly powerful magnets. Other alloys of Co are used in jet turbines and gas turbine generators, where high-temperature strength is important. Cobalt metal is sometimes used in electroplating because of its attractive appearance, hardness and resistance to oxidation, and thus corrosion. Cobalt salts have been used for centuries to produce brilliant blue colors in paint, porcelain, glass, and pottery. Cobalt is one of the elements defined as a critical metal to clean energy over the next 5–15 years, because of its use in lithium ion batteries: each electric-powered vehicle will demand 9.4 kg of Co (Crundwell et al. 2011). Although Co does not get a ton of press, it is a pretty important metal in this day and age. The artificial radionuclide ^{60}Co is widely used in cancer treatment, as a tracer, and for radiotherapy.

Geochemical Behavior

Cobalt is often associated with Ni, Ag, Pb, Cu, and Fe-Mn ores, from which it is most frequently obtained as a by-product (Gunn 2014). The main known ore deposits are found in Katanga (Democratic Republic of Congo) (Decrée et al. 2015), whereas some recent discoveries evidenced that central Pacific Ocean may have Co-rich deposits (i.e., manganese nodules and Co-rich ferromanganese crusts) (Josso et al. 2017) at relatively shallow depths. Almost 50% of the world's cobalt supply in 2014 was mined in the Democratic Republic of Congo. Mining and smelter activities in Katanga have contaminated soil, water, and urban environments (Pourret et al. 2016).

Cobalt forms a number of minerals: cobaltite [CoAsS], skutterudite [$CoAs_{3-x}$], erythrite [$Co_3(AsO_4)_2.8H_2O$], spherocobaltite [$CoCO_3$], and heterogenite [CoO(OH)]. It is widely distributed in igneous and sedimentary rocks and minerals. Cobalt is also present in meteorites (i.e., iron-nickel metal contains a few tenths of a percent cobalt). Its average content in the Earth's crust is approximately 25–30 ppm, though widely distributed, stands only 33rd in order of abundance, and is less common than all other transition metals except scandium. It is, however, more dispersed in the crust than either of those elements, and concentrated mineral deposits are consequently rare. The average Co contents of CI chondrites estimated in a few studies are quite consistent, ranging from 500 ppm to 513 ppm. The bulk Earth has a Co content of 880 ppm, lower than that in the metallic core (0.25%). Cobalt contents in the bulk continental crust vary significantly from 15 ppm to 30 ppm. In particular, Co is most abundant in ultramafic rocks with an average concentration of 110 ppm. During differentiation of a basaltic magma, most of Co enters the ferromagnesian minerals. Cobalt content of these minerals depends on the total number of Fe-Mg lattice sites and is independent of the Fe/Mg ratio. Cobalt is strongly coherent with Mg in granitic rocks and behaves like Mg in its partition relations between metamorphic minerals. The acceptance of both Co and Mg is more selective at lower grades of metamorphism. These aspects have been further reviewed by Gunn (2014), McDonough (2014), Palme et al. (2014), and Rudnick and Gao (2014).

Cobalt is also a naturally occurring element in air, soil, plants, and water. The mean concentration of Co in the open ocean is very low (~40 pmol/kg) which in part reflects its short residence time. Co^{2+} is the principal aquatic species in seawater (Bruland et al. 2014). There has been considerable speculation on its mode of uptake in deep-sea manganese nodules and crusts. Cobalt tends to be associated with either Mn or Fe oxyhydroxides (Brown and Calas 2012). Cobalt may substitute as exchangeable Co^{2+} in marine manganates and then be oxidized to Co^{3+} by Mn^{4+}, whereas Co^{3+} may substitute for Fe^{3+} in Fe oxyhydroxide minerals. Cobalt may also be incorporated in birnessite as Co(II) at pH 7 and Co(III) above pH 8. The aqueous speciation and chemistry of Co in terrestrial environments is now an important focus of research, as the solution speciation of Co has a critical influence on its biological activity in the environment. Although there is a lack of comprehensive data on aqueous Co concentrations in soil porewaters, groundwater, and surface waters, natural Co concentrations vary mostly from 0.006 μg/L to 0.43 μg/L (Gaillardet et al. 2014). Cobalt is considered as moderately mobile with a mobility 10 times less than that of Na. Cobalt chemistry is dominated by the Co(II) oxidation state in the aqueous phase of terrestrial environments primarily due to the extremely low solubility of Co(III). There is no universal agreement on the importance of Co (II) complexation in the solution phase of terrestrial environments and, furthermore, on the nature of the major binding inorganic and organic ligands. The kinetics of Co (II) complexation to, and dissociation from, natural organic

complexing ligands are such that the speciation of Co is likely to significantly diverge from estimates based on thermodynamic equilibrium calculations. As a result, an accurate understanding of Co bioavailability, toxicity, and transport in terrestrial aquatic environments will only be achieved when thermodynamics can be reconciled with reaction kinetics.

Biological Utilization and Toxicity

Cobalt is an essential trace element in life and plays an important role in biochemical reactions essential for life, notably in the coenzyme cobalamin (Co chelated to four N atoms at the center of a porphyrin-like structure, Chivers 2014). Cobalamin has a complex biochemistry, and there is a number of cobalamin-dependent enzymes. Cobalamin-dependent enzymes influence nodulation and N_2 fixation in legume plants that can be used to supply nitrogen in crops (Underwood 1977). Cobalt deficiency affects nodule development, function, and nitrogen fixation. Cobalamin, also called vitamin B-12, is essential for human and animal health, nutrition, and growth. The amount needed is very small. Dietary Co intake is estimated to range 5–40 μg/day in the general human population (Simonsen et al. 2012).

Understanding the factors which affect Co uptake by plants across a range of soil types is essential for food quality as well as for possible remediation of contaminated sites. The relevant pedogenic processes contributing to Co uptake from soils by plants includes total, extractable, and exchangeable soil Co concentrations, pH and other soil chemical parameters, microbial variations, as well as anthropogenic inputs. In soils, Co is fixed by Mn-oxides in a non-extractable form, and its bioavailability is inversely proportional to the Mn content of the soil (Collins and Kinsela 2010).

High and frequent Co exposures can affect nervous system and cause an *axonopathy* (Flora 2014). Chronic inhalational intake of cobalt dust can lead to diffuse-inflammatory reactions of the bronchial mucosa and chronic respiratory tract disorders (Banza et al. 2009; Cheyns et al. 2014). In large doses, some Co forms are carcinogenic. Some plant species, also called metallophytes, have adapted to natural and contaminated Co-rich soils (Faucon et al. 2007). Among these metallophytes, some are able to hyperaccumulate Co in plant shoots (>300 ppm, without toxicity symptoms and growth inhibition) (Lange et al. 2017).

Summary

Cobalt production hugely increases in the last decade as the global demand for Co increases. However, its exploitation becomes a new urgent environmental issue, especially in region such as Democratic Republic of Congo. Cobalt has been suggested to be a potentially dangerous pollutant, and the United States Environmental Protection Agency classifies Co in the priority list of environmental risk elements. A better understanding of Co biogeochemical behavior may support to assess the risk to the environment and to human health and to assist in developing new remediation tools.

Colloids

Jean-François Boily
Department of Chemistry, Umeå University, Umeå, SE, Sweden

Definition

Colloids are (in)organic (poly)molecular particles in which at least one dimension is of the order ~1–1000 nm in length. They may occur as individually dispersed and/or aggregated particles of a given substance suspended in another substance. They cannot be separated by conventional forms of filtration or centrifugation.

Introduction

Colloidal suspensions consist of particles of one phase (solid, liquid, gas) in a second continuous phase. Particles are ~1–1000 nm (or even ~10 μm) wide in at least one direction, can be amorphous or crystalline, and be composed of inorganic, organic, or biological materials. Colloids of interest to Earth Sciences can be dispersed in solids, liquids, and gases, with representative examples shown in Table 1. Notable examples of colloids of biogeochemical importance include clays, fine silt, condensed Al(III) and Fe(III) (oxyhydr)oxides, as well as humic substances. Biocolloids are of organic nature and can include bacteria, viruses, protozoae, including macromolecular breakdown products and exudates.

Colloids, Table 1 Colloidal systems according to states of matter[a]

Dispersed phase	Dispersing medium	Colloidal system	Examples
Gas	Liquid	Foam	Gas bubbles in water and magmas
	Solid	Solid foam	Pumice
Liquid	Gas	Liquid aerosol	Fog
	Liquid	Emulsion	Water-in-oil emulsions
	Solid	Gel	Fluid inclusions
Solid	Gas	Solid aerosol	Atmospheric mineral "dust"
	Liquid	Sol, suspensions	Mineral particles in aquatic environments
	Solid	Solid sol	Opals

[a]After Yariv and Cross (1979)

In contrast to dissolved substances in homogeneous solutions, colloids can undergo Brownian motion due to collisions with molecules of the host medium. Many can also scatter light (Tyndall effect) when suspended in light-transparent media. Stable colloidal suspensions, namely those that do no settle effectively, are stabilized by strong solvation forces from the dispersing medium, thus effectively overcoming gravitational forces. Destabilized colloids can however agglomerate and settle if this fine balance of forces is compromised. Note that "flocculation," "agglomeration," and "coagulation" are terms that are often used interchangeably in the literature. Still, "coagulation" can be more specifically used to refer to the near irreversible aggregation of tightly packed colloids into a "coagulum," while "flocculation" can pertain to loose and open colloidal aggregates that can be readily dispersed by external forces.

Because colloids can expose reactive functional groups capable of removing molecules from the host medium, they can play key roles in the (bio)geochemical cycling of elements and mass transport in nature. For instance, the biogeochemical cycling of elements can be strongly coupled to the occurrence and reactivity of high specific surface area iron (oxyhydr)oxide colloids (Raiswell and Canfield 2012). Colloidal transport through waterways of Earth's surface or through porous/fissured media of Earth's upper crust represents an additional important vector affecting mass transport.

In this article an overview of representative colloids and colloidal processes of central interest to Earth Sciences is presented. It briefly highlights settings from Earth's atmosphere and low-temperature environments to those relevant to magmatic settings.

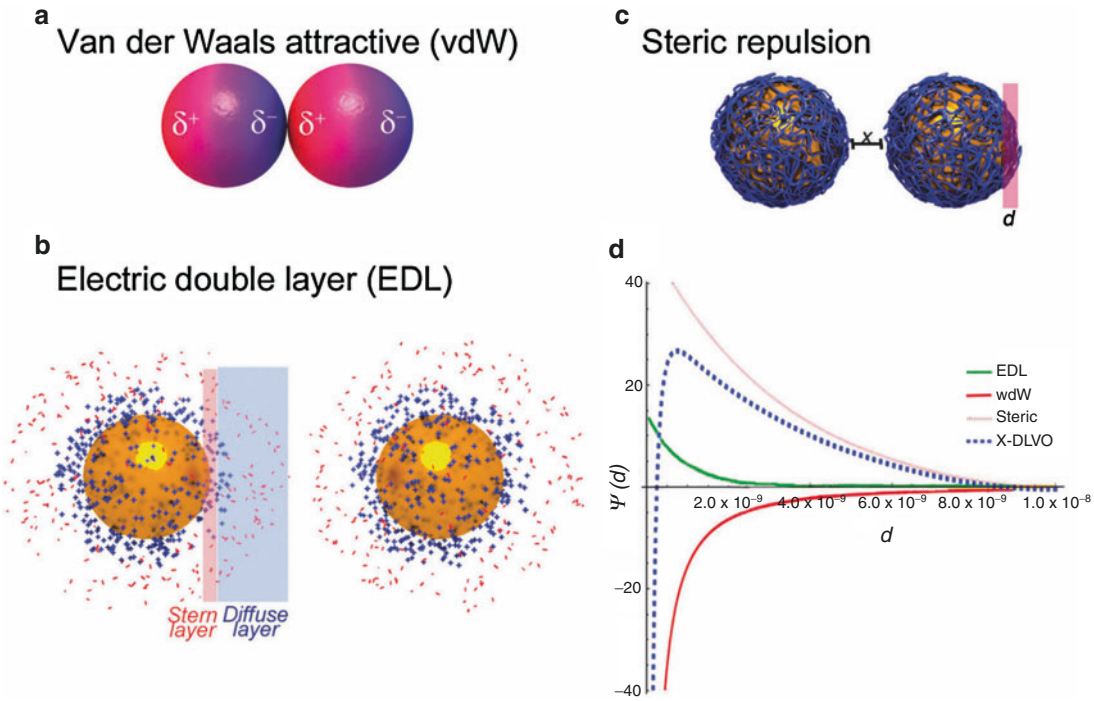
Colloidal Suspension Properties

Colloids form (i) chemically by *condensation* of new phases from molecular units (e.g., hydrolysis and precipitation of Al(III)), or (ii) by physical or chemical *comminution* (dispersion) of host materials into smaller fragments. As these are materials with high surface area to bulk mass ratios, surfaces play a determining role on the behavior of colloids. These particles can then be subjected several forces that can even overcome gravitational forces and suspend particles temporarily or indefinitely, namely with suspension times from seconds to years. The concept of colloidal stability ratio (W) accounts suspension stability in terms of the the ratio of the rates of diffusion-controlled to interaction force-controlled interparticle collision (*cf.* Hunter 1981). In thermodynamic parlance, the total Gibbs free energy of colloidal suspensions can be given by a balance of attractive and repulsive contribution (Fig. 1; Moore et al. 2015):

$$\Delta G_{\text{total}} = \Delta G_{\text{repulsive}} + \Delta G_{\text{attractive}} \quad (1)$$

Each of these latter terms can be broken into components referring to distinct physicochemical phenomena including solvation, electrostatic (electric double layers), steric, polymer flocculation, and hydrophobic contributions.

In vacuum or inert air, van der Waals attractive force can drive aggregation as a means to minimize surface energies of colloidal particles. These energies can however also be decreased via adsorption of solvents, such as water, which in turn form *excluded volumes* that hinder particle-particle collisions. Adsorption reactions involving potential-determining ions and counterions (e.g., Na^+ and Cl^-) can also generate an electric double layer (EDL) repelling charged particles from one another. The magnitude and sign of the EDL potential as well as its thickness affect colloidal stability. This is classically expressed by DLVO theory (Derjaguin, Landau, Verway and Overbeek (Verwey and Overbeek 1948) by accounting for the interplay of electrostatic repulsion of the EDL and of van der Waals attraction between particles. Stable colloidal suspensions thus result from dominant electrostatic repulsion between particles. Stability may however be compromised by changes in salinity because weakly- to non-binding ions (e.g., Na^+, Cl^-) can effectively contract EDL thickness. This can be accounted by the Debye screening length (Hunter 1981), which can range from



Colloids, Fig. 1 Colloidal interactions. (**a**) Van der Waals attractive forces. (**b**) Electric double layer formed at charged particle surfaces. (**c**) Steric repulsion caused by sorbed macromolecules. (**d**) Potential energy distance curve (DLVO, *blue dashed*) broken down for contributions from van der Waals (*red*), electric double layer (*green*), and steric (*pink*). (Taken from Moore et al. (2015)

~300 nm at 0.001 M to ~11 nm at 0.7 M, the latter being close to seawater. Thus, when fluvial colloids are discharged into estuarine environments, or when water evaporates from a colloidal suspension, the contraction of the EDL enables attractive to van der Waals forces to drive particle flocculation and sedimentation. At the same time, colloidal stability can be compromised by changes in pH or binding of foreign species (e.g., metal ions, natural organic matter) affecting the magnitude and sign of EDL potentials, and therefore electrostatic contributions to colloidal stability.

Additionally, adsorption of polymeric-like molecules, such as possibly natural organic matter, can present possibilities for *steric stabilization*. Particle-particle interactions can be inhibited by an an osmotic pressure effect driving water molecules between interpenetrating polymeric units of approaching particles. Loss of degrees of freedom of polymers between particles also result in a lost of entropy, and thus induce a thermodynamically unfavorable condition for colloidal stability.

Examples of Colloids on Earth

Colloids are of widespread occurrence in terrestrial environments. Predominant forms of sedimentary rocks (shales, sandstones and limestones) in fact cover ~73% of modern-day continents and can be made up of considerable portions of colloidal particles. In soils, they can be generated by the physicochemical breakdown of host rock, or by precipitation from aqueous solution (e.g., via hydrolysis of Al(III) and Fe(III)). Gravitation of colloids from upper soil horizons to accumulative horizons in the lower portion of soils is an additional process contributing to mass transfer across soil profiles. Likewise, the transport of colloids in porous or fissured environments of Earth's upper crust is key to the understanding on nutrient, metal, radionuclide and contaminant transport.

Sedimentation of colloidal suspensions in open waterways can be strongly affected by particle density, size, and water movement. For instance, while an important quantitity of matter collected by rivers is deposited as sediments at estuaries, fines such as clays, silt, and organic matter are transported further to oceans. Additionally, particles may remain in suspension or be resuspended by wave, tidal, and flood activities in spite of favorable physicochemical conditions for flocculation.

Opals are another example of sedimentary deposits consisting of colloidal particles. These mineraloids can be refered as *colloidal crystals* and consist of (hexagonal, cubic) close-packed colloidal particles of hydrated SiO_2 spheres of ~150–300 nm in size. They can form from evaporated silica-rich solutions that have leached through sandstones. Subsequent compaction and partial dehydration of the silica spheres produce opals with various degrees of organisation, with gemstone-like attributes.

Gas bubbles represent another form of colloidal entity strongly relevant to Earth sciences. Bubbles expelled by biotic, diagenetic, and igneous processes can be dispersed in the form of a foam. Water-based foams can, for instance, reduce the permeability of porous media, such as soils and sediments. Air bubbles can also be captured in freezing soils or (sea) water (Deville 2017), which are in turn used for tracking paleoclimates. Nucleation and growth of bubbles in magmas are also key to understand explosive in relation to effusive volcanic eruptions. Gas bubbles in pumice, a vecicular volcanic glass, are also viewed as colloids (Table 1).

Finally, the atmosphere can also be considered as a colloidal system. Colloids in these systems are more often refered to as solid or liquid aerosols. A notable example is water droplet formation from the condensation of atmospheric water vapor (*e.g.*, fog, cloud, mist, droplets), and with droplet sizes in the ~1–100 100 μm range. Atmospheric mineral dust particles ejected from volcanoes, blown from deserts, and, more recently, produced by industry play integral parts to atmospheric processes, and most notably in ice nucleation (Hoose and Möhler 2012). Deposition of iron-bearing particles to the oceans is, moreover, a key input to ocean productivity and biogeochemistry (Tagliabue et al. 2017).

Summary

Colloids are inorganic and organic fines of diverse compositions and sources. They are of widespread occurrence in continental, oceanic, and atmospheric environments. The high surface-to-bulk mass ratio of these particles is especially responsible for their large chemical reactivity and for their important roles in the biogeochemical cycling of elements in nature and even in atmospheric processes.

Definition

Complexes are compounds that form in solutions due to interactions between ions or neutral molecules forming coordinating bonds between them. Coordination complexes commonly form between positively charged cations (e.g., Ca^{2+}, Mg^{2+}, Na^{+} and Cu^{2+}), which act as a central atom and are bound to negatively charged anion species (e.g., Cl^{-}, SO_4^{2-}, HCO_3^{-} and F^{-}) or neutral species (e.g., H_2O and NH_3), also referred to as ligands. The types of bonds that form may be ionic due to Coulombic forces or covalent due to sharing of electrons between atoms or other types of interactions such as dipole-dipole interactions (See entries ▶ "Chemical Bonds" and ▶ "Van der Waals Force"). Ligands that form more than one bond with a central metal atom, thus occupying more than one coordination site, are called chelates (See entry ▶ "Chelation"). Many organic ligands act as chelates forming multiple bonds with a metal, such as porphyrin a ring shaped tetradendate ligand which binds metals in the center via 4 bonds (See entry ▶ "Porphyrins"). Complexes that form with more than one metal center are referred to as multi- or polynuclear complexes (Stumm and Morgan 1996).

Complex Formation and Coordination Chemistry

A general chemical reaction for complex formation can be written with an acidic electron accepting group (the metal) and a basic electron donating group (the ligand), much in the same sense as that of acid–base chemistry (See entry ▶ "Acid–Base Reactions") but defined as:

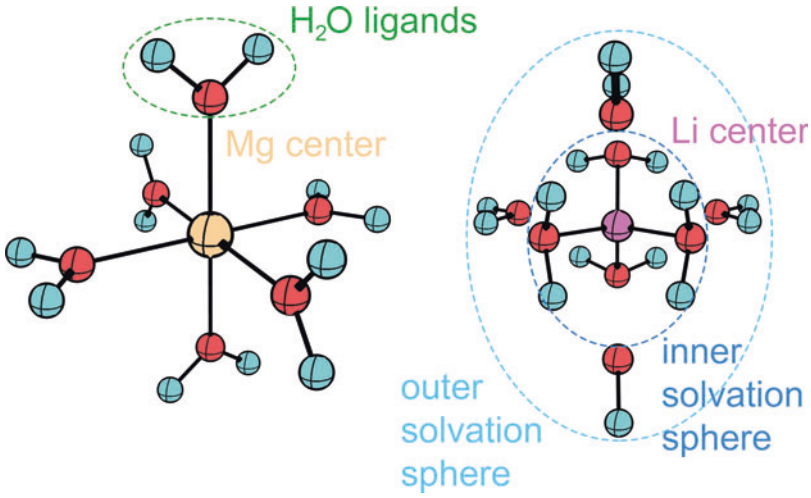
$$mM^{i+} + nL^{j-} = (M_mL_n)^{(mi+nj)} \quad (1)$$

where, M is a metal of charge i + and L is a ligand of charge j-, m and n being stoichiometric constants.

In aqueous solutions metals will form a coordination complex with water molecules, which form an inner sphere of hydration of varying coordination depending upon the metals type (See entry ▶ "Aqueous solutions"). For instance, at most ionic strengths Mg^{2+} forms an octahedrally coordinated inner sphere complex with 6 molecules of H_2O ($Mg(H_2O)_6^{2+}$, see Bock et al. 1994), whereas, Li^{+} forms a tetrahedrally coordinated inner sphere complex with 4 molecules of H_2O ($Li(H_2O)_4^{+}$, see Rudolph et al. 1995) (Fig. 1). The water molecules bound to the inner sphere of a complex are often omitted, for instance, $Mg^{2+}_{(aq)}$ would refer to the $Mg(H_2O)_6^{2+}$ complex and the subscript (aq) is commonly used to designate an aqueous complex. Thus, a knowledge of coordination chemistry is needed to understand the chemical environment of an aqueous complex.

Inner-Sphere and Outer-Sphere Complex Formation

The inner sphere constitutes ligands that are directly bonded to the metal center in the inner coordination environment. Beyond the coordination environment of the inner sphere of a complex the solvent or solutes may also be ordered around a complex forming an outer sphere coordination environment due to electrostatic interaction between the central cation and solvated anions or dipole-dipole interactions with water. As the types of interactions leading to the formation of an outer sphere complex are often weaker than inner sphere interactions, the structure of the outer sphere is often not considered until higher ionic strengths are reached where ion pairing becomes more important (See entry ▶ "Debye-Hückel Equation"). However, considering the second solvation sphere of an aqueous complex is often important in order to accurately predict the vibrational spectra of the complex (e.g., $Li(H_2O)_4^{+}.4H_2O$, Fig. 1; Pye et al. 1996). Inner and outer



Complexes, Fig. 1 Molecular models of aqueous complexes of octahedral $Mg(H_2O)_6^{2+}$ (on the *left*) and tetrahedral $Li(H_2O)_4^{+}.4H_2O$ (on the *right*) showing both the inner sphere and outer sphere solvation of the lithium ion

sphere complexes are also important to the complex structure that forms at mineral surfaces at the water-mineral interface where a minerals surface charge affects the adsorption of aqueous metals and ligands forming surface complexes (See entries ▶ "Surface Geochemistry" and ▶ "Gouy-Chapman Theory").

For example, sulphate may form an outer-sphere complex with magnesium or ion pair (Eq. 2). As the concentration of sulphate in solution increases it may exchange with a water bound to the inner sphere of the hexaaquomagnesium complex, thus going from being bound as an outer-sphere complex to a inner-sphere complex or contact ion pair (Eq. 3):

$$\left[Mg(H_2O)_6\right]^{2+} + SO_4^{2-} = \left[Mg(H_2O)_6\right].SO_4 \qquad (2)$$

$$\left[Mg(H_2O)_6\right].SO_4 = \left[MgSO_4(H_2O)_5\right] + H_2O \qquad (3)$$

The ligand-exchange reactions shown in Eqs. 2 and 3 simplify the solvation structure, as the sulfate ligand may also be solvated and bound as an outer-sphere complex via it's solvation sphere. Rates of ligand exchange between the inner and outer spheres are often quite rapid in aqueous solution (See entry ▶ "Kinetics of Geochemical Processes").

Complex Speciation and Stability

The addition of many solutes and ligand types to an aqueous solution may lead to various metal complexes forming in solution, the distribution of these complexes or aqueous species is known as the aqueous or complex speciation of the solution. Simply varying the pH of an aqueous solution may lead to the formation of various metal hydrolysis products (i.e., the formation of soluble metal hydroxides and oxide complexes). The hydrolysis of cations has been reviewed in detail by Baes and Mesmer (1976). Complex speciation affects many environmental processes from the solubility of minerals (See entry ▶ "Solubility"), to the transport of metals in hydrothermal fluids and their eventual deposition as an ore deposit (See entries ▶ "Hydrothermal Solutions" and ▶ "Ore Deposits").

The thermodynamic stability of aqueous complexes can be measured and is defined by an equilibrium constant for reactions such as those represented by Eq. 1 (See entry ▶ "Equilibrium constant"). Ligand substitution reactions can be written in a stepwise or cumulative manner and formation constants defined as K (Eqs. 4, 5, and 6) or β (Eq. 7), respectively:

Stepwise complex formation and constants:

$$M^+ + L^- \overset{K_1}{=} ML^0 \text{ where } K_1 = \frac{\left[ML^0\right]}{\left[M^+\right]\left[L^-\right]} \qquad (4)$$

$$ML^0 + L^- \overset{K_2}{=} ML_2^- \text{ where } K_2 = \frac{\left[ML_2^-\right]}{\left[ML^0\right]\left[L^-\right]} \qquad (5)$$

$$ML_{(n-1)}^{(2-n)} + L^- \overset{K_n}{=} ML_n^{(1-n)} \text{ where } K_n = \frac{\left[ML_n^{(1-n)}\right]}{\left[ML_{(n-1)}^{(2-n)}\right]\left[L^-\right]} \qquad (6)$$

Cumulative complex formation and constant:

$$M^+ + nL^- \overset{\beta_n}{=} ML_n^{(1-n)} \text{ where } \beta_n = \frac{\left[ML_n^{(1-n)}\right]}{\left[M^+\right]\left[L^-\right]^n} \qquad (7)$$

The cumulative formation constant is related to the stepwise formation constant by the expression:

$$\beta_n = K_1 \cdot K_2 \ldots \cdot K_n \qquad (8)$$

The concentration of aqueous complexes as defined by the formation constants above (Eqs. 4, 5, 6, and 7) does not account for species activity, which is affected by the ionic strength of a solution where ion pairing increases with increasing ionic strength (See entries ▶ "Activity and Activity Coefficients" and ▶ "Debye-Hückel Equation").

Complex stability is affected by the strength of bonds which form, and as metals can be treated as hard or soft Lewis acids and ligands as hard or soft Lewis bases, the stability and reactions between complexes can be treated similarly to Lewis acid–base chemistry (Pearson 1963; Stumm and Morgan 1996) (See entry ▶ "Acid–Base Reactions"). Pearson's HSAB (Hard Soft Acid Base) principles can be used to determine the relative strength of bonds that form between metals and ligands (Liu et al. 2014; Pearson 1963).

Temperature and pressure of a system also affect complex stability. With increasing temperature the dielectric constant of water decreases making it less polarizable, which leads to a decrease in the coordination number of waters solvating an ion (Seward and Driesner 2004). Increasing pressure in a system may also lead to change in coordination environment of a complex due to changes in the solvent structure again leading to a dehydration of an ion (Seward and Driesner 2004). These changes in ion hydration and solvent structure inherently lead to a change in water activity affecting the water-rock interactions and complex formation and stability at higher temperatures and pressures.

Complex Speciation in the Environment

The formation of aqueous complexes affects many natural processes, from mineral solubility to metal transport in hydrothermal solutions. Formation waters occurring deep within the aquifers of sedimentary basins range in composition from fresh to extremely saline, and their composition can affect the diagenesis of minerals within the basin (See entry ▶ "Diagenesis"). Hydrothermal fluids found much deeper in the Earth's crust and potentially originating from the mantle or other sources can vary in composition significantly (See entry ▶ "Hydrothermal Solutions"). Hydrothermal fluids can transport high concentrations of various metals through complexation with ligands such as Cl^-, HS^- and OH^-. For example, the formation of gold complexes in hydrothermal solutions containing Cl^-, Br^-, HS^- and $NH_{3(aq)}$ ligands (Liu et al. 2014), where Au^+ preferentially binds with HS^- ligands to form a $Au(HS)_2^-$ complex.

The chemistry of Earth's oceans is affected by the complex speciation between a number of dissolved metals and ligands found in seawater. For instance, the ionic strength (I) of seawater (I = c. 0.69 m) leads to significant ion pairing and formation of complexes of $MgHCO_3^+$, $MgCO_3^0$, $MgSO_4^0$, $NaHCO_3^0$, $NaCO_3^-$, $NaSO_4^-$, $CaHCO_3^+$, $CaCO_3$, $CaSO_4^0$ and KSO_4^- in excess of 0.01 millimolal in solution. The pH of seawater is influenced by this complex speciation and in particular the equilibrium established between the bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) ligands, dissolved CO_2 and various metals (See entry ▶ "Carbon Cycle").

Understanding complex speciation is important to contaminant transport in shallow groundwater environments where toxic or radioactive metals have been mobilized in surface and groundwaters. For example, the persistence of methylmercury complexes (e.g., CH_3Hg^+, CH_3HgS^-, $(CH_3)_2Hg^0$, CH_3HgOH^0 and CH_3HgCl^0) in the environment, of which the neutral complexes are highly mobile increasing their bioavailability (Stumm and Morgan 1996).

Summary and Conclusions

Complex formation and speciation is important to understanding the distribution and transport of metals in the environment. The formation of aqueous complexes affects the solubility of minerals and transport of dissolved solutes in the environment from the Earth's oceans to formation waters in sedimentary basins and hydrothermal fluids. Complex stability is affected by the concentration and type of ligands available to bond with metals, as well as the temperature and pressure of a system. Further information about complex formation, structure and bonding can be found in most inorganic chemistry text books discussing crystal field theory and ligand field theory (e.g., Shriver and Atkins 1999).

Compound-Specific Isotope Analysis

Yi Ge Zhang
Department of Oceanography, Texas A&M University, College Station, TX, USA

Definition

Compound-specific isotope analysis (CSIA), as opposed to bulk analysis, determines the isotopic signatures (for example, $^{13}C/^{12}C$, D/H, $^{15}N/^{14}N$, $^{18}O/^{16}O$) at the molecular level. The separation and purification of organic compounds can be achieved by gas chromatography (GC) or liquid chromatography (LC). The analysis of stable isotopes requires an isotope ratio mass spectrometry (IRMS).

Analytical Methods: GC-IRMS

Traditionally, CSIA refers only to the stable isotope measurements of the molecules separated by GC. The system usually consists of a GC, a chemical reaction interface, and an IRMS (Sessions 2006; Summons 2000). Individual compounds are separated by the GC, followed by quantitative conversion at the interface, and continuous-flow isotopic analysis using the IRMS. The interface either diverts or removes the interfering compounds such as the solvents and H_2O.

Early CSIA focused on stable carbon isotopes (Hayes et al. 1989; Matthews and Hayes 1978). Organic molecules can be rapidly and quantitatively combusted to CO_2, done by metal oxides (e.g., CuO, NiO) with the presence of catalysts (e.g., Pt) at high temperature (900–1200 °C). The oxidizing reagents are regenerated by flushing the combustion reactor with O_2 after analysis (Merritt et al. 1995). The solvent peak is usually diverted by backflushing the reactor with a He flow. And the impurities in the CO_2 stream (H_2O, S, and N oxides) are removed by Nafion™, a selectively permeable membrane of the sulfonated fluoropolymer (Leckrone and Hayes 1997), and by passing the combusted gas through the elemental copper at a lower temperature. CO_2 is then analyzed in a gas source IRMS, which usually consists of an electron-impact ionization source, a magnetic-sector analyzer, and several Faraday cup detectors which receive analog signals of the ion currents.

Compound-specific nitrogen isotope measurement is also based on combustion/reduction, which produces NO_x then reduced to N_2 (Merritt and Hayes 1994). Notably, a bacterial method which could be used to convert organic N to N_2O significantly reduces the amount of N required for accurate measurements (Sigman et al. 2001). Hydrogen isotope analysis is usually achieved by pyrolysis using carbon-lined reactors heated to > 1440 °C (Burgoyne and Hayes 1998). In the IRMS ion source, H_2 reacts to form H_3^+ and therefore the "H_3-factor" must be determined and corrected for (Sessions et al. 2001). Oxygen isotope measurements also rely on pyrolysis and reduction, which transfers O from organic material to CO.

Recent Developments

GC-IRMS has greatly expanded our ability to analyze compound-specific isotopes on GC-amenable molecules. However, many higher molecular weight, more complex compounds cannot be directly vaporized in the traditional GC. Further, the process of combustion/pyrolysis destroys the position-specific isotope signatures. Nonetheless, recent efforts have made interesting developments to tackle these issues.

Compound Separations Without a GC

A large number of nonvolatile biochemical such as nucleic acids, proteins, polar lipids, and carbohydrates cannot be separated by the traditional GC. To tackle this problem, a variety of offline preparative procedures (e.g., prep LC) were developed to fraction-collect and purify the compounds of interest, for further "bulk" analysis. The stable isotope

measurements can be achieved on the conventional elemental analyzer (EA)-IRMS or the spooling wire microcombustion (SWiM-IRMS)(Sessions et al. 2005) and nano-EA-IRMS (Polissar et al. 2009), both of which significantly reduce the quantities needed for isotope ratio monitoring. For example, the precision on the SWiM-IRMS is about 0.4‰ for ~2 μg C (Pearson et al. 2016).

High-Temperature GC-IRMS

An alternative approach to volatize the larger compounds is to increase the temperature of the GC oven, from ~320 °C to a maximum of ~450 °C. Studies have shown that if connections are all air-tight by using metal ferrules, high-temperature resistant components as well as sensitive systems that discriminates the analytes from high column bleeding, the GC-MS system can detect *n*-alkanes with more than 100 carbon atoms (Sutton and Rowland 2012). Measuring these high molecular weight compounds on GC-IRMS is being experimented as this entry is written in 2016.

Site-Specific Isotope Measurements

The conversion of C, H, N, or O to analyte gases is required by CSIA based on the traditional gas source IRMS. The isotopic value, however, is an average over all elemental positions within its molecular structure. Intramolecular variations in isotopic signatures are missing in this approach.

Innovations in the technology, including the utilizations of high-sensitivity detectors capable to quantify low-intensity multiply substituted ion beams using both improved IRMS (Eiler et al. 2013) or IR absorption spectroscopy (Ono et al. 2014). Position-specific intramolecular isotopic distributions are now being reported from several molecules, including ethane (Webb et al. 2013) and propane (Piasecki et al. 2016).

Selected Applications in Geoscience

The Alkenone-$\delta^{13}C$ Method for pCO_2

One of the earliest applications of CSIA was to measure the $\delta^{13}C$ of biomarkers associated with photosynthesis, such as porphyrins (Hayes et al. 1989; Popp et al. 1989) and alkenones (Jasper and Hayes 1990), as a proxy for atmospheric CO_2 levels. This methodology stems through the isotopic fractionation models of C3 plants during photosynthesis (Farquhar et al. 1982, 1989). Compared with the traditional bulk organic carbon measurements, CSIA provides isotopic evidence from the substance with a clear photosynthetic origin. Alkenones are then favored over porphyrins because they are only produced by a few species of the haptophyte algea in the modern ocean (Conte et al. 1994).

The alkenone-^{13}C based pCO_2 estimates have covered most of the Cenozoic era, which reveals a long-term decline of the greenhouse gas forcing from the Paleogene into the Neogene (Pagani et al. 2005; Zhang et al. 2013). Specific time intervals are also targeted, with pCO_2 often found to be tightly coupled to major climate change events (Bijl et al. 2010; Pagani et al. 2011). Alkenone-derived reconstructions largely agree with other proxy-based CO_2 estimates (Palmer et al. 2010), but occasionally show low sensitivity to CO_2 changes (Badger et al. 2013). Efforts are being made to constrain the physiology of the haptophyte algae and how they are going to affect carbon isotope fractionations (Bolton et al. 2016; Henderiks and Pagani 2007).

^{13}C–Depleted Biomarkers and Methane Cycling

CSIA is widely used to trace biogeochemical processes (Freeman et al. 1990). For example, massive amount of methane produced in the deep ocean are oxidized anaerobically before they can reach the sea surface. Anaerobic oxidation of methane (AOM) has been suggested by geochemical data in the 1970s (Reeburgh 1976). However, for a long time the microorganisms responsible for this process could not been identified. In 1999, Hinrichs et al. noticed that the biomarkers associated with archaea in a gas hydrate site offshore of northern California are extremely depleted in ^{13}C. The $\delta^{13}C$ of these biomarkers, including archaeol, hydroxyarchaeol, and *sn*-2-hydroxyarchaeol, ranges between −100 and −110‰, indicating that the carbon source of the archaea has a methenotrophic origin (Hinrichs et al. 1999). Later, microscopic evidence was provided to confirm the role of archaea in the AOM process, and showed that a consortium of archaea and sulfate reducing bacteria that commonly perform sulfate reduction – anaerobic methane oxidation in marine sediment (Boetius et al. 2000).

Summary

Compound-specific isotope analysis has broad utilities in tracing sources and revealing the biogeochemical processes that involves isotopic fractionation. The field has greatly expanded from measuring carbon isotopes of GC-amendable compounds to employing a variety of approaches to separate and purify compounds, including those that cannot be separated by the traditional GC, for isotope measurements of C, N, H, O, S, and other light elements. Position-specific isotope analysis is also being explored that adds a whole new dimension to CSIA. CSIA is widely applied in organic geochemistry, biogeochemistry, geobiology, paleoclimatology, forensic geoscience, and petroleum science and technology.

Copper

Xingcheng Liu and Xiaolin Xiong
Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China

Element Data
Atomic Symbol: Cu
Atomic Number: 29
Atomic Weight: 63.546 u
Isotopes and Abundances: ^{63}Cu 69.15%, ^{65}Cu 30.85%
1 Atm Melting Point: 1084.6 °C
1 Atm Boiling Point: 2562 °C
Common Valences: 2+, 1+
Ionic Radii: 1+: fourfold: 60 pm, sixfold: 77 pm; 2+: Fourfold: 57 pm, sixfold: 73 pm
Pauling Electronegativity: 1.9
First Ionization Energy: 745.5 kJ mol^{-1}
Chondritic (CI) Abundance: 131 ppm
Silicate Earth Abundance: 20–30 ppm
Crustal Abundance: 27 ppm
Seawater Abundance: 0.4–5 nmol/kg
Core Abundance: 125 ppm

Properties

Copper (Cu) is a reddish metal with an atomic number 29, standard atomic weight of 63.546, and melting point of 1357.8 K at 1 atm. It was moderately volatile during the Earth formation by accretion of solid material condensed from the solar nebula. As a siderophile element, it partitioned into the core during the separation of metallic core from molten silicate mantle. In the silicate Earth, it behaves as a chalcophile element and usually forms stable sulfides; chalcopyrite ($CuFeS_2$) is the most common copper-bearing sulfide. In nature, copper is the 26th most abundant element in the Earth's crust, with concentrations ranging from 26 ppm in the lower continental crust to 28 ppm in the upper continental crust; the concentration in the oceanic crust is lower at 44 ppm. Concentrations in MORB range from 60 to 80 ppm, in arc basalts from 50 to 100 ppm, and in oceanic island basalts from 80 to 120 ppm (White 2013).

History and Use

Cu was the first metal people learned to smelt and this discovery ended the Stone Age in many parts of the world. The discovery that alloying it with tin produced bronze, a stronger metal, led to the Bronze Age.

Due to its high electrical conductivity, tensile strength, ductility, creep resistance, corrosion resistance, low thermal expansion, and high thermal conductivity, copper is extensively used in building construction, power generation and transmission, electronic product manufacturing, and the production of industrial machinery and transportation vehicles nowadays (Doebrich 2009). Besides the pure metal, copper is often alloyed with zinc, tin, gold, and nickel in industrial applications.

The US Geological Survey estimates the global mine production and consumption of Cu is over 18 and 20 million metric tons in 2015, respectively. Major producing countries include Chile, China, and Peru.

Geochemical Behavior: Magmatic Processes

Copper dissolves in silicate melts (natural magmas) dominantly as Cu^{1+} and perhaps in very minor amounts as Cu^{2+}. Copper is believed to dissolve in silicate melts mainly as $CuO_{0.5}$. The solubility of Cu in sulfur-free silicate melts increases with increasing temperature and increasing oxygen fugacity (Liu et al. 2015 and references therein). Zajacz et al. (2012, 2013) also suggest that Cu dissolves in silicate melts dominantly as Cu–O complex, while Cu–S and Cu–Cl complexes are not significant; thus, its solubility is enhanced only slightly by the presence of chlorine (Cl) and sulfur (S) in the melts.

In magmatic evolution, the geochemical behavior of Cu is controlled by the partition coefficients between silicate minerals, Fe–Ti oxides, sulfides, and magmas. The partition coefficients (given in Table 1) suggest that Cu is highly incompatible in silicate minerals (generally <0.2), incompatible to moderately compatible in Fe–Ti oxides, and highly compatible in sulfides. It should be noted that the partition coefficients are generally controlled by compositions of silicate melts, temperature, pressure, and oxidation state. Thus it's important to know the chemical and physical environmental conditions while applying the partition coefficients to predict the geochemical behavior of Cu.

Geochemical Behavior: Hydrothermal Processes

In contrast, the behavior of Cu in fluids (volatile phases) is a different story. The presences of S and Cl significantly enhance the solubility of Cu in the geological fluids. According to direct Cu K-edge X-ray absorption near-edge structure (XANES) spectra, Berry et al. (2006) suggest that Cu^{+} is stable in high-temperature brines in synthetic

Copper, Table 1 Partition coefficients of Cu between mineral and silicate melts

fluid inclusions. In addition, Cu typically occurs as $CuCl_2^-$ ($\pm Cu(HS)_2^-$) in natural hydrothermal systems, in which the partition coefficients of Cu between volatile phases and silicate melts range from dozens to several hundreds (Simon and Ripley 2011; Pokrovski et al. 2013). This means that Cu will be transported into brines or vapors from ascending magma in magmatic–hydrothermal processes if the magmatic aqueous fluids are present. The mass transfer of Cu from magmas to volatile phase(s) is the most important process in the development of a porphyry Cu deposit (Audétat and Simon 2012, and references therein).

Ore Deposits

Most copper is extracted from ore deposits as copper sulfides. Porphyry Cu deposits and sediment-hosted Cu deposits contain most portions of the world's Cu resources. Porphyry ore deposits supply over 70% of the world's copper. They dominantly formed above subduction zones and most of them are genetically related to intermediate to felsic calc-alkaline magmas, which provide metals and fluids (e.g., H_2O, CO_2, Cl, and S) for the ore formation. However, the most important controlling factor(s) is still debated.

Individual copper deposits may contain millions of tons of copper and generally are developed by using open-pit mining methods (Doebrich 2009).

Natural Waters

Copper exists in natural waters mainly as Cu^{2+} and is readily complexed by hydroxyl and carbonate. Surface water concentrations of dissolved Cu are 63.55 ppt in the open ocean and 1.48 ppb in the rivers (global average) (Bruland et al. 2014; Gaillardet et al. 2014). The Cu^{2+} in surface waters is buffered by a strong Cu-binding class of organic ligands, called L_1, which chelates nearly 99.8% Cu^{2+} and reduces the Cu^{2+} concentration to a nontoxic condition for phytoplankton. Without organic complexation, the dominant species of Cu would be $Cu(CO_3)^0$ and approximately a factor of 20 lower than the total dissolved concentration (Bruland et al. 2014 and references therein).

Biological Utilization and Toxicity

$Cu^{2+}$and Cu^+ can participate in a wide spectrum of interactions with proteins to drive diverse structures and biochemical reactions. As life evolved, more complex roles for Cu arose, concurrent with the elaboration of mechanisms to tightly regulate acquisition and distribution of Cu and provide protection against Cu toxicity (Festa and Thiele 2011). It is an essential and required trace element in plants and animals but can be toxic to some microorganisms at relatively low concentrations. Defects in Cu homeostasis lead to human disease. On the other hand, excess Cu intake induces toxicity for human.

Summary

Humans have been using copper for several thousands of years. As an industrial material, it is significant and widely used in modern society. As a trace element in Earth, it also provides insight into the crust–mantle differentiation, the formation of ore deposits, and the redox history of magmas.

Copper Isotopes

Paul Savage
Department of Earth and Environmental Sciences, University of St Andrews, St Andrews, UK

Synonyms

Copper stable isotopes; Cu isotopes

Introduction

Copper has two stable isotopes, ^{63}Cu and ^{65}Cu, with relative abundances of 69.15% and 30.85%, respectively. A transition metal, Cu is moderately siderophile and strongly chalcophile (around 2/3 of Earth's Cu is thought to be stored in its core). Copper is redox-sensitive and is present in three oxidation states in terrestrial environments: native Cu^0, Cu^+ and Cu^{2+}. Copper is both economically important and an essential micronutrient. For all these reasons, isotopic variations of Cu have the potential to inform us of processes, sources, and phenomena in all disciplines of the geosciences. A more detailed review of the myriad applications of Cu isotopes is given by Moynier et al. (in press).

Analysis

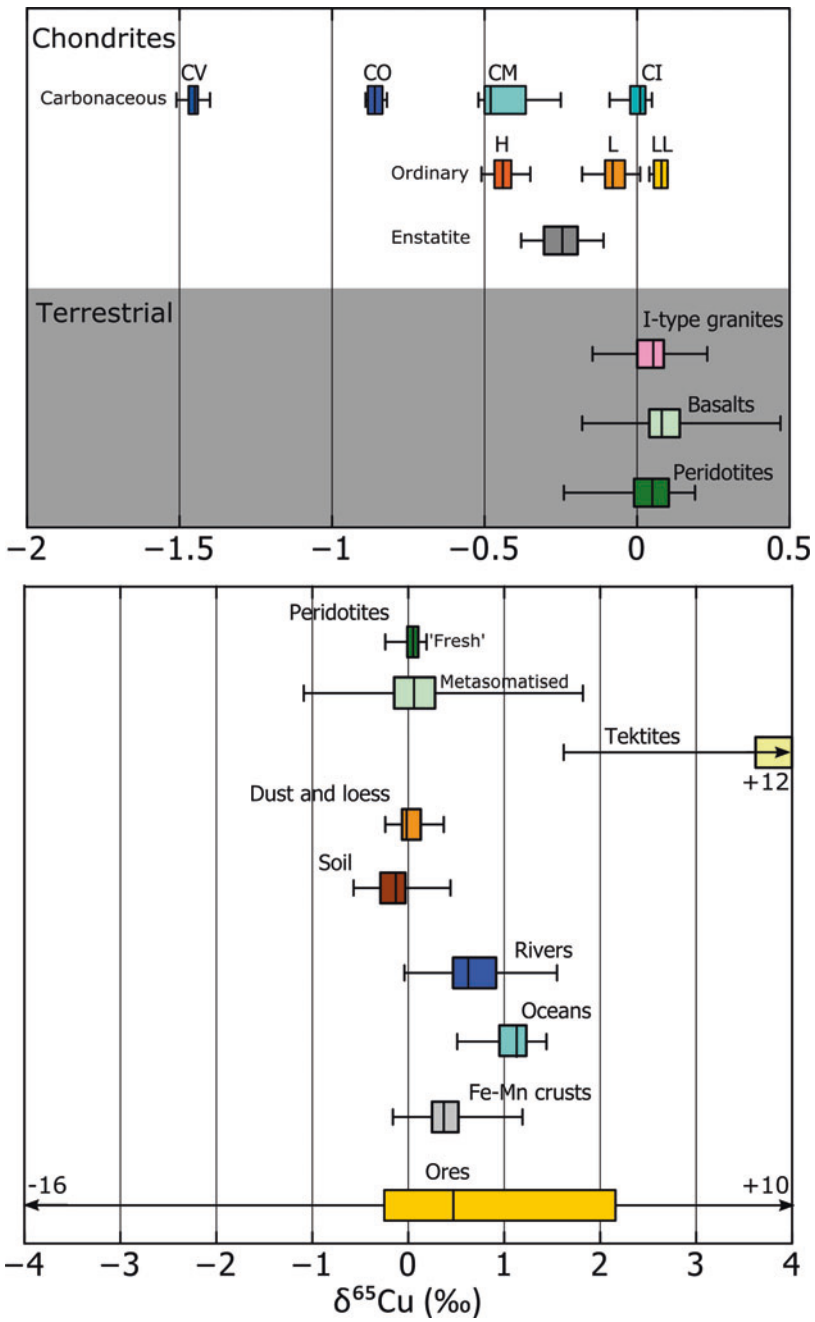
As with many other stable isotope systems, accurate, precise, and routine measurement of Cu isotope ratio was made possible with the advent of Multi-collector Inductively-Coupled-Plasma Mass Spectrometry (MC-ICPMS) and precisions of <50 ppm are now attainable. This is usually by solution analysis, whereby copper is isolated from a dissolved sample using ion exchange chromatography (Marechal et al. 1999); however, some in-situ laser ablation isotope analyses has been made (Ikehata and Hirata 2013). Variations in Cu isotopes are represented using the delta notation as $\delta^{65}Cu$ in permil (‰; Eq. 1), relative to the pure Cu standard NIST976:

$$\delta^{65}\mathrm{Cu} = \left[\frac{\left(^{65}\mathrm{Cu}/^{63}\mathrm{Cu}\right)_{\mathrm{sample}}}{\left(^{65}\mathrm{Cu}/^{63}\mathrm{Cu}\right)_{\mathrm{NIST976}}} - 1\right] \times 1000 \qquad (1)$$

(N.B. while this standard is still utilized in Cu isotope analysis, it is now commercially unavailable and a number of replacements have been characterized, e.g., Moeller et al. 2012; however, δ^{65}Cu values should remain relative to NIST976 using a precalibrated standard, to allow for direct comparison of all Cu isotope data).

Meteorites

The chondritic meteorites display significant variability in Cu isotope abundances. Carbonaceous chondrites (CC) define the largest range, from CI (0.02 ± 0.12) to CV (-1.45 ± 0.04) and each group has a distinct average (Fig. 1; Luck et al. 2003). Ordinary chondrites (OC) define a smaller range; nevertheless, the groups H, L, and LL again have distinct δ^{65}Cu, becoming more enriched in ^{65}Cu with decreasing Fe content (Fig. 1). Both CC and OC δ^{65}Cu



Copper Isotopes, Fig. 1 *Box* and *whisker plot* showing representative ranges of various Cu isotope reservoirs – see text for data sources. *Top panel* – high-temperature and extra-terrestrial samples. *Bottom panel* – impact-generated and critical zone (low temperature) samples

values vary systematically with oxygen isotope anomaly ($\Delta^{17}O$), which Luck et al. (2003) interpreted as revealing the presence of two, possibly three, distinct Cu isotope reservoirs in the early solar system, which mixed in varying proportions by nebula processing. Unlike carbonaceous and ordinary, enstatite chondrite groups (EH and EL) have similar Cu isotope compositions, which fall in the middle of the primitive meteorite range (-0.25 ± 0.09; Fig. 1). Savage et al. (2015a) used these data, in part, to define the bulk Earth $\delta^{65}Cu$ based on the observation that for many other isotope systems, enstatite chondrites and terrestrial materials appear identical.

In terms of iron meteorites, the first Cu isotope analyses by Luck et al. (2005) showed that IIIAB (magmatic), IA, and IIICD (silicate-bearing) iron meteorites showed similar, limited compositional ranges which broadly fell within the chondrite array ("magmatic" irons are thought to represent the cores of asteroids, and "silicate-bearing" possibly represent impact-generated melt-pools). A subsequent study by Bishop et al. (2012) showed that the silicate-bearing irons' Cu isotope and $\Delta^{17}O$ compositions correlate – as with the chondrites. The same could be true for the magmatic irons; as these meteorites have no silicates (and thus minimal oxygen to measure), Bishop et al. (2012) suggested that their Cu isotope compositions could instead be used to indicate genetic links with other meteorites. Most recently, large (negative) Cu isotope variations (-5.84 to -0.24) have been measured in the volatile element-poor IVB meteorites (Chen et al. 2016). These meteorites have high Ni/Cu ratios, and these negative enrichments are interpreted as resulting from variable exposure to galactic cosmic rays, whereby neutron capture forms excesses of ^{63}Ni, which decays quickly to ^{63}Cu.

Igneous Rocks

Two recent estimates of the copper isotope composition of the bulk silicate Earth (BSE; i.e. the mantle and crust) place it at 0.07 ± 0.10 and 0.06 ± 0.20 (Savage et al. 2015a; Liu et al. 2015, respectively). Both estimates were based on representative suites of mantle peridotites and ultra-mafic and mafic mantle-derived melts (e.g. komatiites, mid-ocean ridge basalts, ocean-island basalts) and are identical within error. Copper isotopes do not appear to fractionate greatly as a result of magmatic differentiation, even in systems where sulfide fractionation is occurring (Savage et al. 2015b). There appears to be a small enrichment (+0.1 ‰) in heavy Cu as differentiation approaches rhyolitic compositions, which agrees with the few analyses of I-type granites available in the literature (Li et al. 2009; Fig. 1). Metasomatism appears to have a strong effect on Cu isotope compositions, as evinced by much larger Cu isotope variations seen in metasomatized peridotites (Savage et al. 2015b; Liu et al. 2015; Fig. 1). This raises the possibility that Cu isotopes could be used to characterize the nature of a metasomatic agent.

Planetary Accretion and Differentiation

Savage et al. (2015a) noted that the Cu isotope composition of BSE is heavy compared to estimates for bulk Earth and suggested that fractionation occurred during Earth's differentiation. This isotope difference could reflect metal-silicate equilibration during core formation; however, experiments performed by Savage et al. (2015a), as well as analyses of individual metal, silicate, and sulphide grains from iron meteorites (Williams and Archer 2011) suggest that metal-hosted Cu is isotopically heavier than co-evolving silicates. This seems to rule out core formation as explaining the positive $\Delta^{65}Cu_{BSE\text{-}bulk\ Earth}$ ($\delta^{65}Cu_{BSE} - \delta^{65}Cu_{bulk\ Earth}$), as an isotopically heavier core implies a negative $\Delta^{65}Cu_{BSE\text{-}bulk\ Earth}$. Savage et al. (2015a) argued that either 1) the $\Delta^{65}Cu_{BSE\text{-}bulk\ Earth}$ implies that the majority of mantle Cu was delivered post-core formation, by a CI-like impactor (cf. Schonbachler et al. 2010); or 2) this missing light Cu is stored in sulfides, either in the mantle or a reservoir that was subsequently admixed into the core. Further experimental constraints on the partitioning behavior of Cu isotopes are required, but there is great potential for Cu isotopes to reveal information about the formation of Earth and other rocky bodies.

Impact-Driven Loss of Cu

Some of the largest Cu isotope variations measured in natural samples are recorded in tektites, glasses formed by high-energy (i.e., meteorite) impact events. Values up to 12.5 ‰ have been measured in tektites from the across the globe (Fig. 1; Moynier et al. 2010; Rodovská et al. 2015), which have been interpreted as an effect of kinetic isotope fractionation – whereby the lighter isotope can escape to the gas phase more easily – in a diffusion-limited regime. Anomalously high Cu isotope compositions have also been measured in lunar soils (Moynier et al. 2006; Herzog et al. 2009), caused by micro-meteorite "gardening" and, potentially, lunar basalts (~0.5 ‰). Because igneous processes do not fractionate Cu isotopes resolvably, the isotopically heavy composition of the latter sample group relative to Earth could be induced by volatile Cu loss, reflecting the violent nature of the Moon's birth (Day and Moynier 2014).

Low Temperature Environments

Mechanical weathering (to form dust, loess, clastic sediments) does not appear (as would be expected) to fractionate Cu isotopes – with aeolian dust samples showing limited Cu isotope variation and compositions close to BSE (Fig. 1;

Dong et al. 2013). However, compared to that seen in high-temperature terrestrial settings, a much wider range of Cu isotope compositions have been measured in such systems affected by chemical weathering and biological activity that occur in the "critical zone".

Weathering/leaching of primary Cu-bearing minerals generally involves oxidation (from Cu^{+} to Cu^{2+}) and results in the release of isotopically heavier Cu (by ~0.5–4.0 ‰) relative to the source. This has been shown via experiments (Fernandez and Borrok 2009) as well as measurements of soils and corresponding pore waters (Fig. 1; Mathur et al. 2012). Acid mine drainage solutions also have relatively heavy Cu isotope compositions, thought to be related to the oxidation of the source Cu (Kimball et al. 2009). These observations have been corroborated by ab initio calculations (Fujii et al. 2013). Biological utilization of Cu can also involve oxidation (i.e. through the reductase enzyme in the plant root system), and where this occurs, the biologically-complexed Cu is heavier than the source (Jouvin et al. 2012).

Redox reactions are thought to be the main control over the extremely large range of Cu isotope compositions seen in ore minerals. Specifically, "primary" (igneous) ore minerals have compositions close to that of BSE (~0.0 ± 0.5 ‰), whereas supergene ores show huge variability (−16.5 to +10 ‰; Mathur et al. 2009; Fig. 1). These large variations are likely due to multiple cycles of oxidation and reduction in the supergene environment, although Rayleigh fractionation, kinetic effects, and complexing ligand (Fujii et al. 2013) could also play a role.

Most Cu in the "critical zone" is organically complexed or sorbed onto the surface of Fe (oxy)-hydroxides (Vance et al. 2009). In regards to organically complexed Cu, experiments show that this pool is isotopically heavier than the free Cu ion and that the magnitude of isotope fractionation between the two pools increases as the stability constant of the complex increases (e.g. Ryan et al. 2014) – again, corroborated by ab initio calculations (Sherman 2013). Like organic complexation, sorbtion onto Fe-oxides causes a positive isotope effect, with the sorbed Cu showing around a 1 ‰ enrichment compared to the free metal pool (Pokrovsky et al. 2008).

Vegetation also has an impact on Cu isotopes in the critical zone. In general, plant material has an isotopically light Cu isotope composition compared to the surface pool. In a study by Weinstein et al. (2011) on lentil plants, light Cu was seen to be preferentially transferred up the plant, such that the youngest leaves were isotopically lighter than the root system. Comparison experiments between Strategy I plants (which involve a reduction step during Cu utilization) and Strategy II (no reduction), reveal that the latter have lighter isotope compositions than the former, identifying the importance of the reduction step in controlling Cu isotope compositions under Strategy I (Jouvin et al. 2012; Ryan et al. 2013). Any organic-rich soil horizon should therefore be isotopically light, and this has been observed in natural settings where decaying plant material was present (e.g., Bigalke et al. 2011).

In summary, weathering and Cu bio-utilization in the critical zone release isotopically heavy Cu to the solution – via oxidation of primary minerals, organic complexation, and/or preferential storage of light Cu in biomass. This suggests that the riverine and ocean Cu isotope compositions should be heavier than the continents – and this is indeed the case. Measurements of the isotope composition of dissolved riverine Cu give an average composition of ~0.7 ‰ (Fig. 1; Vance et al. 2008) and, given that riverine input dominates oceanic Cu, this will be close to average ocean δ^{65}Cu. The recent study of Little et al. (2014) modeled both the elemental and isotopic ocean Cu cycle and revealed a missing, isotopically heavy, Cu sink. One explanation could be that ^{65}Cu is preferentially sorbed on Mn-Fe oxides (e.g. Pokrovsky et al. 2008); however, Little et al. (2014) went on to measure such samples and found that they were isotopically light (~0.2 ‰; Fig. 1) relative to the oceans. This issue, as of writing, remains unresolved.

Biomedical Applications

The application of traditionally geochemical techniques to biomedicine is a new and exciting topic (Albarède 2015). Copper plays a vital role in the human body, thus Cu isotopes may be extremely important in this new field. Arguably the most promising application for Cu isotopes is in the early detection of some cancers. In patients with cancer, blood serum Cu is known to be anomalously high; however, changes in serum [Cu] are typically too ambiguous to be usable as a biomarker. However, Telouk et al. (2015) found a significant difference in the Cu isotope composition of blood serum from cancer patients compared to healthy patients, which, in their pilot study, was more explicit than the canonical cancer biomarker.

Cosmic Elemental Abundances

Herbert Palme
Forschungsinstitut und Naturmuseum Senckenberg, Frankfurt am Main, Germany

Definition

The average chemical composition of the solar system is identical to the composition of the Sun, representing more than 99.8% of the mass of the solar system. Solar abundance data obtained from absorption spectroscopy and complemented by the more accurate chemical data on CI chondrites, a small group of meteorites with solar abundances of non-volatile elements, define the *solar system element abundances*, which are known to within a few percent for most elements. Many stars have compositions similar to the average solar system composition, justifying the term cosmic element abundances. Solar system abundances are, however, much better known than the more loosely defined cosmic element abundances.

The Concept of Cosmic Abundances

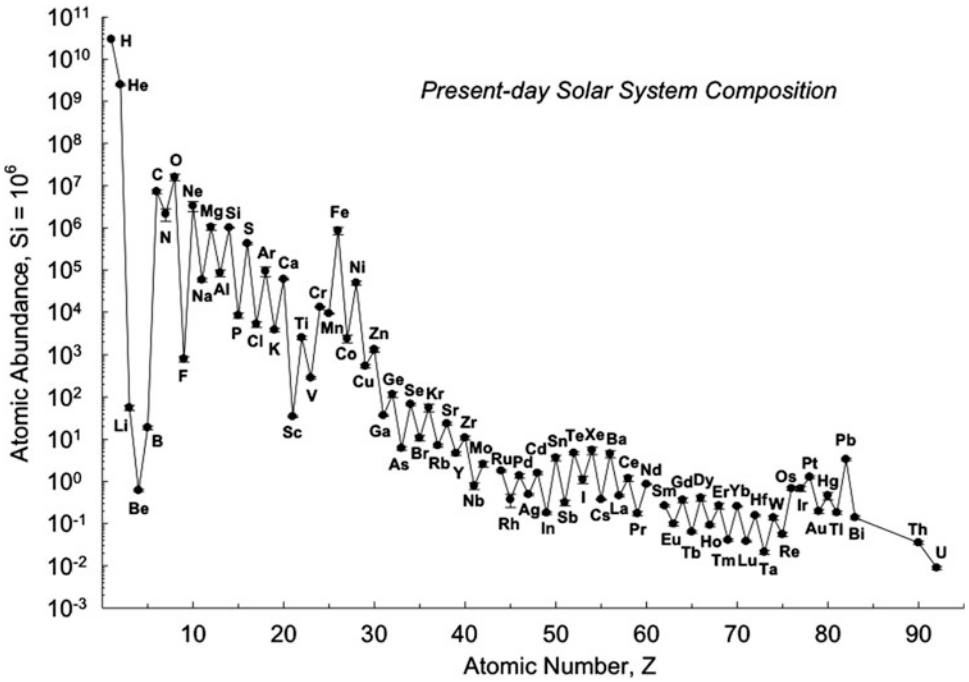
Three lines of evidence lead to the concept of cosmic abundances. (1) Since about 1920, it is possible to determine the abundances of most chemical elements in the photosphere of the Sun by using the absorption lines in the solar emission spectrum. Although this only allows determining the composition of the outer 200 km of the Sun, it is believed that the interior of the Sun has essentially the same composition. The same procedure can be applied to stars. Thus the chemical composition of numerous stars is known. (2) Undifferentiated or chondritic meteorites come from planetesimals that were never fully molten. These meteorites have compositions not very different from that of the solar photosphere. A precise match, i.e., agreement of most elements within the error bars between solar abundances and meteoritic abundances, is found for one specific group of meteorites, the CI chondrites. The agreement is for all elements heavier than oxygen and excluding the very volatile rare gases. Other groups of undifferentiated or chondritic meteorites deviate somewhat from the solar or CI abundances. (3) The Big Bang produced hydrogen (H), helium (He), and some lithium (Li), about 13.8 billion years ago. All other chemical elements were made later in stars by nuclear reactions. As a result the heavy element abundances in the universe increase continually with time. The parameter [Fe/H] of a star is called metallicity. It is the logarithm of the ratio of iron atoms divided by hydrogen atoms divided by the same ratio in the Sun. The metallicity of the 4.67 billion-year-old Sun is 1, and stars older than the Sun have metallicities lower than 1 and younger stars above 1. The relative abundances of metals (all elements heavier than H and He in the jargon of astronomers) are in most stars very similar to those in the Sun. This element pattern is in agreement with nucleosynthetic calculations. An important parameter is the stability of a nucleus or its binding energy. Elements with even mass or atomic number gaining stability from pairing energy of neutrons and/or protons are more stable and therefore more abundant than elements with uneven mass or atomic numbers. This is visible in Fig. 1, displaying the abundances of elements in the Sun versus atomic number.

The convergence of solar-observed photospheric abundances, measured meteoritic abundances, and calculations of nucleosynthesis to a single more or less constant element pattern is a strong indication for well-defined solar system abundances, which when extended to other stars become cosmic abundances. The only variable is the metallicity, the ratio of heavy elements to hydrogen, which continually increases with time.

Historical Background

During the 1920s and 1930s of the last century, Victor Moritz Goldschmidt and his colleagues measured and compiled chemical data of terrestrial rocks, meteorites, and individual phases of meteorites. Based on these data Goldschmidt set up a cosmic abundance table. Goldschmidt realized that most meteorites should be representative of average cosmic matter because they have not been affected by melting and crystallization, whereas the crust of the Earth, a product of mantle melting, is not representative of the Earth's bulk composition. Goldschmidt calculated the average concentrations of elements in cosmic matter by using a weighted mean of element abundances in meteorite phases: metal (2 parts), sulfide (1 part), and silicates (10) parts.

The German physicist Joseph von Fraunhofer (1787–1826) was the first to observe dark lines in the spectrum of the light emitted from the Sun. Some 50 years later, G. Kirchhoff (1824–1887) recognized that these lines are characteristic of chemical elements, and he correctly concluded that the outer cooler layers of the Sun absorb radiation from the hotter underlying parts. At the beginning of the twentieth century, C.H. Payne made the first attempts to



Cosmic Elemental Abundances, Fig. 1 Elemental solar system abundances as function of atomic number normalized to 10^6 Si atoms. The preponderance of H and He is obvious. The stability of ^{56}Fe and the higher stability of elements with even atomic numbers are clearly visible (Figure is from Lodders et al. 2009)

quantify the information contained in stellar and solar absorption lines. She recognized the large abundance of H in stars and gave the first estimates of the chemical composition of stellar atmospheres. Later N. H. Russell published the elemental abundances of 56 elements in the solar photosphere.

Goldschmidt's and Russell's lists had most of the major features of the solar system abundances as we know them today: the dominance of H and He; the strong decrease in abundance with increasing atomic number; the very low abundances of Li, Be, and B; and the pronounced abundance peak at ^{56}Fe (see Fig. 1).

Later compilations took into account improved analytical data of meteorites and of the solar photospheric spectrum (see Lodders et al. 2009 and Palme et al. 2014 for references).

Abundances of Elements in the Sun and in Meteorites

In Table 1, we have listed elemental abundances of the Sun and compare them to the abundances in CI chondrites which closely match the solar abundances for heavy elements. Solar and meteoritic abundances are calculated relative to 10^{12} hydrogen atoms, the scale used in astronomy. The Table is from Palme et al. (2014), and from Lodders et al. (2009). The solar abundances listed here are very similar to those in Asplund et al. (2009).

Table 2 contains the abundances of elements by mass in CI meteorites, chiefly the Orgueil meteorite. The table is from Palme et al. (2014), largely based on earlier compilations (Lodders et al. 2009). In the last column data are converted to atoms and normalized to 10^6 atoms of Si. The conversion from the astronomical scale (A_{ast}) based on 10^{12} H atoms to the meteoritical scale (A_{met}) based on 10^6 atoms of Si is according to Palme et al. (2014):

$$\log A_{ast} = \log A_{met} + 1.533$$

The CI chondrites match the solar element abundances within analytical uncertainties. Other groups of chondritic meteorites deviate somewhat from the solar composition. This is demonstrated in Fig. 2, where several abundance ratios are plotted for members of the major chondrite classes and compared with solar abundance ratios.

The major chondrite classes shown in Fig. 2 are carbonaceous chondrites with CI, CM, CO, and CV groups; ordinary chondrites with H, L, and LL groups; and enstatite chondrites with EH and EL groups. These are the most populated chondrite groups (e.g., Krot et al. 2003).

The element ratios plotted in Fig. 2 are representative of different cosmochemical components. Each of these

Cosmic Elemental Abundances, Fig. 2 Element/Si mass ratios of characteristic elements in various groups of chondritic (undifferentiated) meteorites. The refractory component is represented by Al; Mg represents the Mg silicates, Fe the metal component, and Na, Zn, and S the moderately volatile elements. Only CI chondrites fit with photospheric abundances indicated on the left side (Figure is from Lodders et al. 2009)

components has a characteristic formation temperature indicated by condensation temperatures of elements and phases involved. Condensation temperatures are calculated by assuming thermodynamic equilibrium between solids and a cooling gas of solar composition (see Lodders 2003, for details). The various cosmochemical components are in order of decreasing condensation temperatures:

Refractory component: The first phases to condense from a cooling gas of solar composition are Ca,Al-oxides, and silicates associated with many trace elements, such as the REE (rare earth elements), Zr, Hf, and Sc, and additionally refractory metals, e.g., W, Os, and Ir. The refractory component makes up about 5% of the total condensable matter. Variations in, e.g., Al/Si and Ca/Si ratios of bulk chondrites may be ascribed to the incorporation of variable amounts of early condensed refractory phases.

Mg silicates: The major fraction of condensable matter is associated with the three most abundant elements heavier than oxygen: Si, Mg, and Fe. In the relatively reducing environment of the solar nebula, Fe condenses almost entirely as metal alloy (FeNi), while Mg and Si form forsterite (Mg_2SiO_4) which converts to enstatite ($MgSiO_3$) at lower temperatures by reaction with gaseous SiO. Variations in Mg/Si ratios of bulk meteorites are produced by the incorporation of various amounts of early-formed forsterite.

Metallic iron condenses as a FeNi alloy at about the same temperature as forsterite, the sequence depending on total pressure. Variations in the concentrations of Fe and other siderophile elements in meteorites are produced by the incorporation of variable fractions of metal.

Moderately volatile elements have condensation temperatures between those of Mg silicates and FeS (troilite). The most abundant element of the moderately volatile elements is sulfur. The amount and the relative abundances of these elements in meteorites are probably the result of removal of volatiles during condensation.

Highly volatile elements have condensation temperatures below FeS and above water ice The group of highly volatile elements comprises elements with very different geochemical affinities, such as the chalcophile Pb and the lithophile I. Similar processes as those invoked for the depletion of moderately volatile elements are responsible for variations in these elements. In addition, heating on small parent bodies may lead to loss of highly volatile elements by evaporation.

Ultra volatile elements have condensation temperatures below that of water ice. This group includes H, C N, O, and the noble gases.

In summary, Fig. 2 gives some indication for the range of elemental variations in chondritic meteorites. We assume that minor compositional variations among chondritic meteorites are produced by nebular processes that occurred before accretion of planetesimals. Planetary melting processes, such as core formation or partial melting, lead to rocks with completely different compositions.

The bulk composition of the terrestrial planets is essentially solar with similar numbers of Mg, Si, and Fe atoms and about one tenth of Al atoms. This characteristic composition prevails, with more or less variability in kilometer-sized asteroids, meter-sized chondritic meteorites, submillimeter- to millimeter-sized micrometeorites, micrometer-sized interplanetary dust particles, and sub-micrometer-sized particles, possibly interstellar dust. The major variables are the ratio of metallic to oxidized Fe and variations in the depletion of volatile elements.

Summary

The abundance pattern of chemical elements in the Sun and many other stars is determined by the Big Bang making H and He and by later production of heavy elements in the interior of stars, a process that is still active. The pattern of heavy, non-volatile elements in unmelted, chondritic meteorites is the same as in the Sun, with one group of meteorites the CI chondrites fitting best. Other undifferentiated, chondritic meteorites have compositions deviating somewhat from solar. These meteorites were modified by solar nebula processes before planetesimal accretion. The solar system abundances, a combination of solar photospheric and meteoritic abundances, are known to within a few percent for each element. Extension to other stars leads to heavy element cosmic abundances which are less well known.

Cosmogenic Nuclides

Rainer Wieler
Department of Earth Sciences, Institute of Geochemistry and Petrology, ETH Zürich, Zürich, Switzerland

Definition

Cosmogenic nuclides are produced when primary or secondary particles of the galactic (or in some cases also the solar) cosmic radiation interact with atomic nuclei in extraterrestrial or terrestrial material. Cosmogenic nuclides are observable mainly for noble gas isotopes and radioactive nuclides, whose abundances in the target materials are otherwise extremely low. In this article, we discuss production and applications of cosmogenic nuclides in meteorites and other extraterrestrial samples (Wieler 2002; Eugster et al. 2006; Herzog and Caffee 2014) as well as in terrestrial samples (Gosse and Phillips 2001; Dunai 2010; Granger et al. 2013). In solid matter, the cosmic-ray flux has a mean attenuation length of roughly 50 cm. Hence, cosmogenic nuclides in meteorites are primarily used to determine exposure ages, i.e., the time spent as meter sized or smaller body in interplanetary space before falling on Earth or in some cases also the residence time in the uppermost few meters of their larger parent body. Cosmogenic nuclides in terrestrial rocks allow determining ages or erosion rates of geologic surfaces and nuclides produced in the atmosphere and subsequently being deposited in terrestrial archives provide records of, e.g., past solar activity and geomagnetic field variations.

Introduction

On Earth, cosmogenic nuclides are produced both in the atmosphere and in situ in solid samples at the Earth's surface. Cosmogenic radionuclides produced in the atmosphere (together with contributions from nuclear power plants and nuclear bombs) are used to study atmospheric dynamics and the hydrological cycle. Nuclides produced in the atmosphere will eventually also be deposited in the geosphere or hydrosphere as "meteoric nuclides." Meteoric nuclides which found their way into archives such as ice or sediment cores allow us to determine the past flux of the cosmic radiation entering the Earth's atmosphere. Such archives are therefore used to investigate the physics of the sun, the heliosphere, and the geomagnetic field. Meteoric radionuclides also allow us to study processes near the Earth's surface such as subduction of oceanic crust or sediment dynamics. A particularly important cosmogenic nuclide produced in the atmosphere is ^{14}C, which ultimately may find its way into organic matter. The nuclide ^{14}C is the basis of the most widely used radiometric dating method. On the Earth's surface, the cosmic-ray flux is several orders of magnitude lower than in interplanetary space. Production rates and concentrations of cosmogenic nuclides produced at the Earth's solid surface are thus much lower than in meteorites, which presents considerable analytical challenges. Nevertheless, cosmogenic radionuclides and noble gases produced in situ in terrestrial surface rocks have become a very widely used tool in Earth surface sciences, allowing, e.g., to determine the time since a rock has been exposed on the Earth's surface or long-term erosion rates of landscapes.

Production of Cosmogenic Nuclides

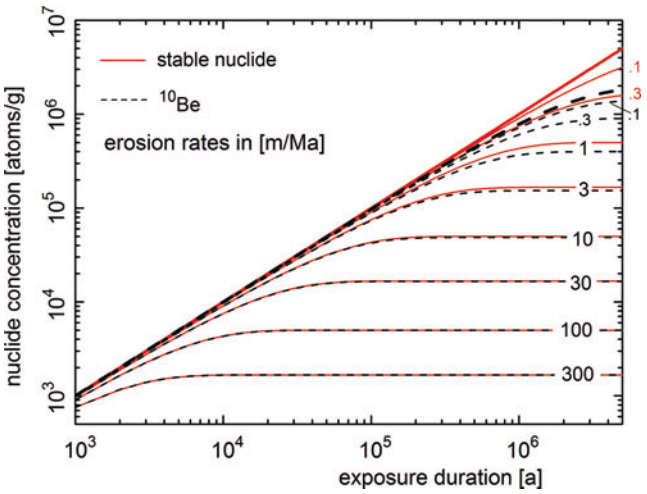
Cosmogenic nuclides are produced either when target atoms interact with high-energy cosmic-ray particles (mainly between 100 MeV–10 GeV) or when they capture low-energy neutrons ("thermal" or "epithermal" neutrons, i.e., ~0.025 eV and 0.5 eV–0.1 MeV, respectively). A detailed account of cosmogenic nuclide production is given by Gosse and Phillips (2001). Primary cosmic-ray particles (mostly protons and alpha particles) need to be distinguished from secondary particles, the latter being created in the cascade of nuclear reactions initiated by primary particles. Secondary particles include high-energy protons and neutrons as well as thermal and epithermal neutrons. On the Earth also secondary cosmic-ray muons are of some importance. These can be considered as heavier brothers of the electron with a half-life on the order of a microsecond. In meteorites production by primary and secondary particles is important (Eugster et al. 2006; Herzog and Caffee 2014). In contrast, the cosmogenic nuclide production in terrestrial rocks is largely dominated by secondary neutrons, since hardly any cosmic-ray protons arrive at the Earth's surface. Muon-induced reactions become important at depths below several meters, because the mean attenuation length of muons in matter is much larger than that of neutrons. As discussed further down, the analysis of several cosmogenic nuclides in the same or adjacent samples will often allow us to constrain the "shielding" of a meteorite sample during cosmic-ray exposure, i.e., the size of the meteorite before it becomes ablated upon passage through the Earth's atmosphere and the depth of the sample within this "meteoroid." This is because production rates of different cosmogenic nuclides vary with depth in different ways. Analyses of several nuclides are also used to better constrain exposure and erosional histories of terrestrial samples. Most widely studied nuclides are the rare isotopes of helium, neon and argon (^{3}He, ^{21}Ne, ^{38}Ar) and the radioactive nuclides ^{10}Be ($T_{1/2}$ = 1.387 Ma), ^{14}C (5730 a), ^{26}Al (0.717 Ma), ^{36}Cl (0.301 Ma) and ^{53}Mn (3.74 Ma). Complete lists of nuclides measured in meteorites and terrestrial samples are given by Eugster et al. (2006) and Dunai (2010), respectively.

In meteorites, important parameters governing production rates are energy-dependent particle fluxes at the sample site, energy-dependent cross sections of all important reactions, and the major target element composition of the sample (e.g., Leya and Masarik 2009). The particle flux depends on the primary cosmic-ray proton flux, which varies with the solar cycle but usually is assumed to be constant over longer time scales. The flux seen by a sample also depends on its shielding and on the composition of the meteorite as a whole. A high Fe concentration, for example, leads to a higher production of secondary neutrons, while neutrons are more efficiently slowed down in meteorites relatively rich in H and C. Production rates are usually considerably higher from target elements with only a slightly higher mass than the product nuclide. For example, the production of ^{21}Ne from Mg is about 2.5–3 times higher than that from Si and some two orders of magnitude higher than that from Fe (Leya and Masarik 2009). A good knowledge of the major target element composition of a given sample is thus a prerequisite for an accurate production rate estimate.

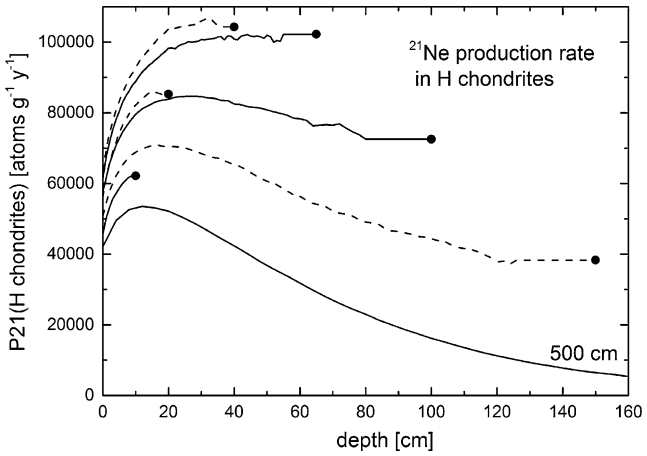
Production rates on the Earth depend largely on the shielding of a sample by the atmosphere (i.e., the sample's altitude) and the modulation of the primary proton flux by the Earth's magnetic field (the geomagnetic latitude). For example, at a given latitude, production rates at sea level are some 15–20 times lower than at 4000 m altitude, and at the equator, production rates are ~2.5 times lower than at latitudes >60° (Lal 1991; Balco et al. 2008; Lifton et al. 2014). This is because near the poles virtually all cosmic-ray protons reach the upper atmosphere unhindered by the Earth's magnetic field, whereas at lower latitudes lower energy protons will be deflected (Gosse and Phillips 2001; Beer et al. 2012). For the relatively short-lived nuclide ^{14}C (which is also produced in situ in rocks) and for samples with high erosion rates, the position of the geomagnetic poles in the past (polar wandering) may have to be considered. For longer-lived nuclides, it is usually assumed that the average position of the geomagnetic poles coincides with the geographic poles, as these nuclides integrate production over at least several ten thousand years unless erosion rates are very high (see below). Time-integrated production rates of a sample will crucially depend on the rock's erosion history, as a sample now at the immediate rock surface will in the past have been shielded by overlying material. The production rate in the past will therefore have been lower than the present day surface value, and this effect will be more pronounced with higher erosion rates (Lal 1991; Gosse and Phillips 2001; Dunai 2010, see Fig. 1). This is the reason why cosmogenic nuclides very often are used to constrain erosion rates rather than exposure ages.

Models to calculate production rates in meteorites are based on large libraries of measured cross sections for proton- and neutron-induced reactions as well as nuclear model codes used to extend or interpolate measured data (Leya and Masarik 2009). This needs especially to be done for neutron-induced reactions to compensate for the many gaps in the measured data. The spectra of primary and secondary protons and neutrons as function of meteorite radius and sample depth are calculated by nuclear codes using Monte Carlo techniques (Leya and Masarik 2009). The primary galactic cosmic-ray proton flux is calibrated by fitting modelled concentrations of radionuclides (e.g., ^{10}Be) to measured values in well-studied meteorites, for which the preatmospheric geometry can be reliably reconstructed and which have exposure ages long enough for the radionuclide concentration to have reached its equilibrium value, where production and radioactive decay match (in practice after some 4–5 half-lives of the nuclide). Figure 2 shows modelled production rates of ^{21}Ne (P21) as a function of depth in spherical meteorites of H-chondritic composition and radii between 10 and 500 cm. The increase of P21 from the meteorite surface up to depths varying between ~15 and 40 cm reflects the development of the cascade of secondary protons and neutrons. At large depths, the decrease of P21 approximately reflects the mean attenuation length of the cosmic-ray flux of ~50 cm.

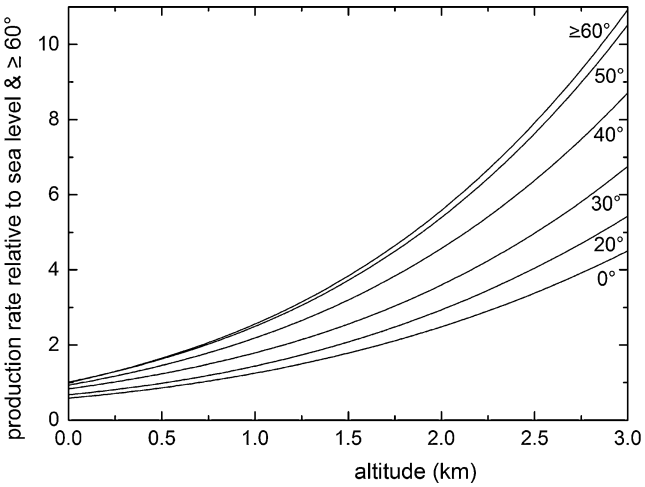
Because meteorites suffer large ablation losses or split into multiple fragments upon atmospheric passage, preatmospheric meteorite size and sample depth will hardly ever be known a priori. However, analyses of several cosmogenic nuclides on the same sample (or a series of samples) combined with model calculations may allow one to constrain the shielding of a given sample and hence its production rates.



Cosmogenic Nuclides, Fig. 1 Nuclide concentrations at the top of eroding surfaces. Exposure duration in years since onset of erosion with constant rate [m/Ma]. *Red solid lines* are valid for stable nuclides, *dashed lines* for ^{10}Be. The two *thick lines* represent non-eroding surfaces. A hypothetical production rate of 1 atom per gram per year is adopted; hence concentrations need to be multiplied with the actual local production rate. Concentrations of ^{10}Be are only sizably affected due to radioactive decay for erosion rates not exceeding ~3 m/Ma. In eroding surfaces also stable nuclides reach a steady-state concentration which depends on the erosion rate (Figure adapted from Lal (1991) and Dunai (2010))



Cosmogenic Nuclides, Fig. 2 Production rate of ^{21}Ne in meteorites of H-chondritic composition with radii of 10, 20, 40, 65, 100, 150, and 500 cm, calculated with the nuclide production model by Leya and Masarik (2009). Wiggles near the centers of the meteorites are the result of poor statistics in the model calculations due to relatively low volumes considered



Cosmogenic Nuclides, Fig. 3 Cosmogenic nuclide production rates relative to values at sea level and high latitude (≥60°, SLHL) according to the classical scaling scheme proposed by Lal (1991). Production rates at 3000 m altitude and high latitude are ~11 times higher than the SLHL values; production rates at sea level and the equator are ~60% of the SLHL values. Other scaling schemes are mentioned in the text

A widely used shielding parameter is the ratio ^{22}Ne/^{21}Ne, which decreases with increasing shielding, since production of ^{21}Ne by secondary neutrons is higher than that of ^{22}Ne. Other shielding indicators are based on ratios of a stable to a radioactive nuclide, which may vary little over a certain shielding range (Herzog and Caffee 2014). If the radionuclide can be assumed to be in saturation, the production rate of the stable nuclide can be determined. A well-known such combination is ^{26}Al-^{21}Ne. The combination of radioactive ^{81}Kr with stable Kr isotopes even yields shielding-corrected exposure ages by a single Kr isotope analysis (e.g., Leya et al. 2015). None of these shielding corrections is perfect, however. They may be valid over a limited size and depth range only, some of them require multiple analyses and analytical precision is often also a problem. ^{81}Kr concentrations, for example, are very low, and in many cases, also corrections for non-cosmogenic stable Kr isotopes are very substantial. In summary, production rates usually have considerable uncertainties, in favorable cases perhaps 10%, but often 20% or more.

A major issue when studying cosmogenic nuclide production at the Earth's surface is proper "scaling" of production rates determined at one geographical location to altitude and latitude of any sample site of interest. In contrast to meteorites, the moment in time when a sample at the Earth's surface had been freshly exposed to cosmic rays can independently be deduced in favorable cases (Dunai 2010; Granger et al. 2013). For example, the eruption age of a lava flow can be determined by radiometric dating. Production rates of cosmogenic nuclides at the sample site can then be deduced, although care is required to properly assess potential erosion of the calibration sample or effects such as episodic cover by snow or vegetation. Also partial shielding from cosmic rays by surrounding mountains, other obstacles or inclined surfaces need to be considered (Gosse and Phillips 2001; Dunai 2010). Fortunately, topographic shielding is only significant in "rather spectacular" landscapes (Dunai 2010), because the angular cosmic-ray flux seen by a sample strongly decreases towards the horizon. For relatively young samples, also the paleopole positions may have to be taken into account. In the case of in situ ^{14}C, it may not even be necessary to know the actual exposure age of a sample. Similar to production rate determinations of radionuclides in meteorites, it may suffice if one reliably can assume the sample to have been exposed for longer than some four or five half-lives of ^{14}C, i.e., for more than ~25 ka. Potential uplift of a calibration sample – leading to increasing production rates with time – should hardly be a concern, since suitable calibration samples mostly have rather low exposure ages in order to minimize uncertainties due to erosion. By convention, production rates determined at a calibration site are scaled to sea level and high latitude (>60°) as described in the next paragraph, and these "SLHL" values are reported. At 60°or higher, production rates will not increase with latitude any further.

Scaling schemes are largely based on measured neutron fluxes in the atmosphere. Figure 3 shows scaling factors according to the classical study by Lal (1991). A recent model uses analytical approximations to fluxes of cosmic-ray neutrons as well as protons and muons modeled by Monte Carlo techniques (Lifton et al. 2014). Various online calculators and computer codes are available to scale production rates to latitude and altitude of samples of interest (Vermeesch 2007; Balco et al. 2008; Lifton et al. 2014). It is highly recommended to always report the scaling scheme

used in a particular study. Dunai (2010) provides a checklist of further information recommended to be reported. Because pressure regimes are not identical to standard atmospheric values everywhere on Earth, corrections for such persistent anomalies may be required. The best-known case is Antarctica, where today pressures at all elevations are a few ten hPa lower than standard values and production rates accordingly some 25–30% higher (Stone 2000). When calculating exposures ages of antarctic samples, it is usually assumed that this anomaly has persisted over millions of years.

Production rates of cosmogenic nuclides in the atmosphere are also calculated with physical models. Required proton and neutron flux spectra are obtained with extensive computer codes (Masarik and Beer 2009; Kovaltsov and Usoskin 2010; Beer et al. 2012). Similar to the Earth's surface, production rates increase with geomagnetic latitude. However, because of atmospheric mixing, concentrations of atmosphere-derived cosmogenic nuclides in terrestrial archives such as ice cores depend much less on the latitude than is the case for in situ produced nuclides.

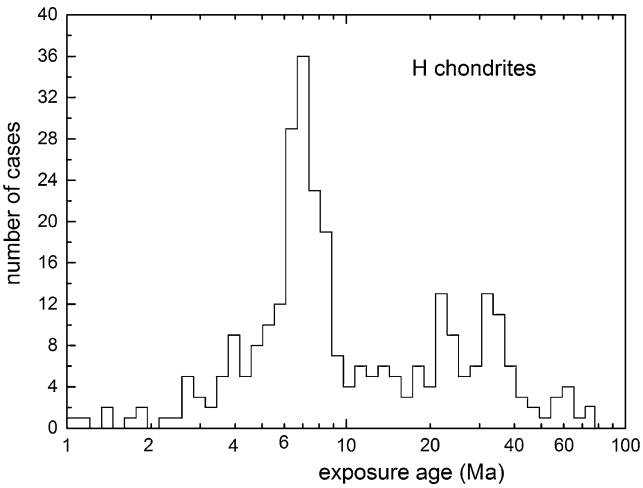
Analytical Aspects

Cosmogenic noble gases are measured by noble gas mass spectrometry; radionuclides are mostly analyzed by accelerator mass spectrometry (AMS) (Christl et al. 2014). For routine analyses of meteorites, often whole-rock samples are measured, whereas mineral separates are the rule in terrestrial studies, with quartz being the most important by far. A major reason for this is that meteoric radionuclides can be removed in a controlled way from quartz by etching off grain surface layers (Kohl and Nishiizumi 1992). Meteoric ^{10}Be in an untreated quartz separate is orders of magnitude more abundant than in situ produced ^{10}Be. Noble gases are usually extracted by heating samples in single or multiple steps, sometimes combined with in vacuo crushing, e.g., to partly remove or correct for non-cosmogenic ^{3}He or ^{21}Ne (Niedermann 2002). Preparation for radionuclide analyses of rock samples requires several steps of chemical treatment, first to obtain clean mineral separates (Kohl and Nishiizumi 1992) and next to extract the nuclides (Gosse and Phillips 2001). Similar procedures – though nuclide and sample specific – are used for meteoric radionuclide separation from terrestrial archives (Beer et al. 2012). Cosmogenic and non-cosmogenic noble gases can usually not be separated quantitatively from each other, or in many cases are not separated at all, e.g., in meteorite analyses. Corrections for non-cosmogenic contributions may be minor in many cases, e.g., for meteorites with low concentrations of primordial or solar-wind-implanted noble gases, but often non-cosmogenic noble gases are the limiting factor deciding whether or not concentrations of cosmogenic noble gases in a sample may be determined. This is particularly a problem for terrestrial samples and is the main reason why often much lower exposure ages can be determined with radionuclides than with noble gases. On the other hand, stable noble gas isotopes are useful to determine very old exposure ages in very slowly eroding arid landscapes.

Cosmogenic Nuclides in Extraterrestrial Samples

Two classical applications of cosmogenic nuclides in meteorites are to determine their cosmic-ray exposure age and their terrestrial age, i.e., the time they spent in interplanetary space as roughly meter-sized objects and the time they fell on Earth and became essentially shielded from cosmic rays by the atmosphere. Exposure ages longer than ~5–6 Ma (some 4–5 half-lives of ^{10}Be) are determined with stable noble gas isotopes, often together with radionuclide analyses to constrain shielding of and hence production rate in a sample, as explained above. With some exceptions, exposure ages of stony meteorites fall in the range of below one Ma to about hundred Ma, whereas iron meteorites often have exposure ages of several hundred Ma, with a highest value of some two Ga (Marti and Graf 1992; Herzog and Caffee 2014). Figure 4 shows the exposure age distribution of the H chondrites, one of the largest stony meteorite classes.

In arid areas meteorites weather only slowly, hence terrestrial ages of meteorites from hot deserts are often in the ten to several ten thousand year range, whereas many meteorites found in Antarctica have been on Earth since several hundred



Cosmogenic Nuclides, Fig. 4 Cosmic-ray exposure age distribution of H chondrites (Graf and Marti 1995). About 45% of all H chondrites show an exposure age of 7–8 Ma, indicating one (or perhaps two) major collision(s) in the asteroid belt 7–8 Ma ago. Minor peaks at ~24 Ma and 33 Ma are the result of further major collisions in the asteroid belt. Exposure age distributions of other meteorite classes are shown by Herzog and Caffee (2014). Often also these histograms show a clustering of ages typical for the respective class

thousand years, with the highest reported values being ~3 Ma (Jull 2006; Herzog et al. 2015). Terrestrial ages are determined with radionuclides of suitable half-lives. An additional noble gas analysis may confirm that the exposure age of the sample had been long enough to bring the radionuclide concentration in saturation at the time of fall. Carbon-14 is the main nuclide used for stony meteorites; ^{36}Cl is used for iron meteorites and for stony meteorites with long terrestrial ages. Also pairs of radionuclides are used for shielding corrections, e.g., ^{14}C–^{10}Be or ^{36}Cl–^{41}Ca (Jull 2006; Herzog et al. 2015). The atmosphere can be assumed to completely shield a fallen meteorite from further cosmogenic nuclide production, since production rates on Earth are very much lower than in space.

Meteorites from the asteroid belt are delivered to Earth through resonances, for example, the 3:1 mean-motion resonance with Jupiter. A meteorite with a semimajor axis of ~2.5 astronomical units will complete three orbits in the time Jupiter revolves around the sun once. Such resonances result in chaotic eccentricities and inclinations, and the meteorite may collide with the Earth within one Ma or so (Wisdom 1987; Gladman et al. 1997). Since most meteorites have much longer exposure ages, they must therefore spend most of their lifetime as meter-sized bodies in the asteroid belt. After having been released from larger parent bodies by a collision, they slowly move towards a resonance largely due to non-gravitational forces, e.g., the Yarkovsky effect, the anisotropic emission of infrared photons (Bottke et al. 2002).

Cosmic-ray exposure ages are important to evaluate whether meteorites may be paired or source paired, i.e., whether they belonged to the same meteoroid prior to breakup in the atmosphere or were ejected from their parent body by the same event, respectively. Identification of paired meteorites is especially important for the numerous desert finds. Identical terrestrial ages are a further pairing criterion, and in some cases, short-lived cosmogenic radionuclides (half-lives on the order of months or years) provide evidence for a (common) recent fall date. Care is required not to overinterpret cosmogenic nuclide data, however. Identical exposure ages of two meteorites are by far not a sufficient pairing criterion by themselves. For example, about 20% of all H chondrites – belonging to many hundred different falls - have an exposure age of about 7–8 Ma (Fig. 4). On the other hand, the 7–8 Ma H chondrites indeed very likely originate from one (or perhaps two) major collisions in the asteroid belt (Graf and Marti 1995).

By now, exposure age distributions of most major meteorite classes are known, and it is clear that different classes have different distributions (Herzog and Caffee 2014). Most of them show clusters similar to the 7–8 Ma peak in the H chondrite histogram. This means that a small number of collisions produced a very large fraction of the known meteorites, which indicates that we sampled only a tiny portion of the potential meteorite parent bodies in the asteroid belt (Wieler and Graf 2001).

Sometimes, exposure ages derived for different samples of the same meteorite or by different nuclides in the same sample are clearly discrepant. This often indicates a "complex" exposure history, which means that not all cosmogenic nuclides were acquired during the recent exposure stage prior to fall but that some of them testify of earlier irradiations in different settings (Herzog and Caffee 2014). For example, a meteorite may have been broken up on its way to Earth. Particularly interesting are complex exposure histories where the first stage happened near the surface of the parent body. In such cases, cosmogenic nuclides allow us to study the dynamics of the parent body regolith. This can often only be done with stable noble gas nuclides, as radionuclides potentially acquired on the parent body may have completely decayed during the transfer of the meteorite to Earth. Differences in nominal cosmic-ray exposure ages indicate that different samples from a regolith breccia had spent variable times near the surface of their parent body (perhaps at different depths) before compaction into the present-day meteorite (Wieler 2002). Complex exposure histories are also reported for single grains or single chondrules in some meteorites, which contain sometimes orders of magnitude higher concentrations of cosmogenic noble gases than the parent meteorite as a whole. It remains controversial whether this indicates – at least in some cases – an irradiation by a high fluence of solar energetic particles from the very early sun (Woolum and Hohenberg 1993) or simply a prolonged irradiation by galactic cosmic rays in the parent body regolith (Roth et al. 2011). Most lunar meteorites contain cosmogenic noble gases acquired on the parent body, indicating a shallow excavation depth (Herzog and Caffee 2014; Herzog et al. 2015). In contrast, martian meteorites show hardly any signs of a parent body exposure, hence must have been excavated from larger depths (Herzog and Caffee 2014). Also in situ analyses of cosmogenic nuclides by spacecraft have a considerable potential to study the evolution of the morphology of planetary surfaces, in essence similar to what is now routinely done on Earth (e.g., Farley et al. 2014).

Not only noble gases and radionuclides but essentially the isotopes of all other elements are also produced by cosmic-ray interactions. Until recently, however, the resulting shifts in isotopic composition have in most cases remained unnoticed. Exceptions were gadolinium and samarium which both contain isotopes with very large cross sections for thermal neutron capture. These elements have been used to study the depositional history of the lunar regolith with samples from Apollo drill cores (Russ et al. 1972; Hidaka and Yoneda 2007) and cosmic-ray exposure histories of large meteorites (Bogard et al. 1995). The very high precision of present-day analyses now reveal tiny isotopic anomalies in several other elements as results of cosmic-ray effects. Some of these elements are important for cosmochemistry, and the cosmogenic isotopic shifts are large enough to require a proper

correction. The foremost example is tungsten, measured to date early solar system events by the Hf-W method (Kleine et al. 2009). Cosmic rays modify not only the abundances of the radiogenic isotope ^{182}W (from decay of ^{182}Hf) but also W isotopes used to correct for instrumental mass fractionation (or sometimes to study potential primordial isotopic anomalies). The effects are largest in samples with long exposure ages, especially lunar samples and iron meteorites (Leya et al. 2000). The knowledge of an exposure age alone does often not permit a proper correction, however, because the magnitude of isotopic shifts may also substantially depend on the shielding of the sample. Isotopes of platinum are an excellent monitor to correct tungsten isotopes in iron meteorites for cosmic-ray effects, because W and Pt are both modified by thermal and epithermal neutrons (Kruijer et al. 2013).

Cosmogenic Nuclides in Terrestrial Rocks

Considerably later than in meteoritics in situ produced cosmogenic nuclides also became an important tool in Earth surface sciences. This delay is due to the fact that nuclide concentrations on Earth are orders of magnitude lower than in meteorite samples. Yet, since the late 1980s terrestrial applications proliferate and led to what is often called a revolution in Earth surface science. Publication and citation rates of Earth science studies involving cosmogenic nuclides increased by orders of magnitude in the past 20–25 years (Dunai 2010). Cosmogenic nuclides allow us to study and quantify processes and timescales in geomorphology in a qualitatively new way.

Two major applications are dating the ages of geologic surfaces (exposure dating) and determinations of erosion or denudation rates. The two questions are often intertwined, as is illustrated in Fig. 1. Concentrations of stable nuclides (e.g., ^{21}Ne) and the radionuclide ^{10}Be ($T_{1/2} = 1.38$ Ma) in a sample presently at the immediate surface of the Earth are shown as a function of exposure duration and for different (time-independent) erosion rates. A hypothetical production rate of 1 atom per gram per year is adopted. Concentrations as displayed therefore need to be multiplied with the actual local production rate at a sample site. The concentration of a stable nuclide in a non-eroding surface increases linearly with time, but in an eroding surface, also stable nuclides will eventually reach equilibrium. The higher the erosion rate, the sooner the equilibrium concentration will be reached and the lower it will be. This is because the cosmic-ray neutron flux seen by the sample had always been lower than the present-day value at the very surface as long as it was shielded by overlying material (Lal 1991). For erosion rates larger than some 3 m/Ma, radioactive decay has no discernible additional effect on the ^{10}Be concentration. For very high erosion rates of 300 m/Ma (0.3 mm/a), erosional saturation is reached already after some 7000 a, whereas for low erosion rates of 0.3 m/Ma, stable nuclides will not have reached their steady-state concentrations even after ~5 Ma and ^{10}Be hardly so. The figure also illustrates that with a single nuclide, essentially only a minimum exposure age (assuming no erosion) or a maximum erosion rate (assuming an infinite exposure age) can be determined. Analyses of two nuclides with different half-lives (e.g., ^{10}Be and stable ^{21}Ne or ^{10}Be and ^{26}Al) in principle allow the determination of both erosion rate and exposure age. Such data pairs also permit to recognize "complex" exposure histories, i.e., when a sample already contained "inherited" nuclides from a previous exposure stage under a different geometry or when a sample had been buried for a certain time (Lal 1991; Granger 2006; Dunai 2010). However, analytical uncertainties often limit the accuracy of erosion rate/exposure age data pairs.

Some of the numerous studies using in situ produced cosmogenic nuclides to determine exposure ages and erosion rates are reviewed, e.g., by Morris et al. (2002), Dunai (2010), Balco (2011) and Granger et al. (2013). Classical examples include dating of glacial moraines and other glacially overprinted landscapes, studies of other erosional surfaces such as river terraces or slowly eroding desert landscapes, and dating of lava flows or fault scarps induced, e.g., by earthquakes. Careful fieldwork is obviously crucial, and sampling strategies need to take into account the specific requirements for cosmogenic nuclide studies.

Cosmogenic radionuclides may not only allow us to derive the time when a rock became exposed to the cosmic radiation but also the moment a sample became completely shielded from cosmic rays. This can occur when sediments are washed into caves or when rocks are covered by water, ice, sediment deposits, volcanic flows, etc. The principle of "burial dating" is somewhat analogous to terrestrial age determinations of meteorites with cosmogenic radionuclides, except that in the terrestrial case, two radionuclides with different half-lives are required (Granger 2006; Dunai 2010). If the concentration ratio of the two nuclides at the time the sample became buried can be assumed to be known, the measured ratio will yield the burial duration. Well suited is the couple ^{10}Be-^{26}Al, since their preburial concentration ratio can often reliably be assumed to be close to the production rate ratio. While for samples that experienced a simple exposure history followed by a rapid burial, the burial event can be dated, for samples that experienced repeated episodes of exposure and burial, cosmogenic nuclides can only provide a lower limit for the total near-surface exposure (Granger 2006).

Cosmogenic nuclides do not only constrain erosion rates at a specific site but can also be used to derive erosion rates averaged over entire river catchments (von Blanckenburg 2005; Portenga and Bierman 2011; Willenbring et al. 2013). This is done by analyzing sediment samples from active river channels at the low end of a catchment of interest. To obtain accurate results, several conditions need to be fulfilled (Dunai 2010). These include that (i) erosion rates in the catchment are constant over

the period reflected by a nuclide studied, i.e., mass wasting processes did not contribute significantly to the overall erosion, (ii) all lithologies in the catchment are equally well represented in the sample analyzed (often a quartz grain separate), and (iii) transit times of sediments through the catchment are short compared to the erosional timescale. Even if not all these conditions are met, however, the method may still usefully constrain catchment wide erosion rates, though with limited accuracy (Dunai 2010). Relevant production rates averaged over the entire catchment are derived either from digital elevation models or – more simply – are taken to be equal to the production rate at the mean altitude (and latitude) of a catchment.

Catchment-wide erosion rates in the past are reflected in cosmogenic nuclide concentrations in sediment cores (Schaller et al. 2002; Charreau et al. 2011; Savi et al. 2014). These data may require a – sometimes large – correction for in situ nuclide production after sediment deposition. Limited knowledge of variables such as the extent of the paleo source region may also lead to considerable uncertainties, but the method can provide important data not to be obtained otherwise (Granger et al. 2013).

Meteoric ^{10}Be (and ^{14}C)

The two most important cosmogenic nuclides produced in the atmosphere and eventually incorporated into solid or liquid inventories are ^{14}C and ^{10}Be. Here we concentrate on meteoric ^{10}Be but also discuss ^{14}C in tree rings independently dated by dendrochronology. Beryllium-10 is produced mainly from atmospheric nitrogen and oxygen, ^{14}C from nitrogen, with a production maximum at ~10–12 km altitude (Masarik and Beer 2009; Kovaltsov and Usoskin 2010; Beer et al. 2012). Carbon-14 atoms combine with oxygen to form CO_2 , the major fraction of which becoming dissolved in the ocean while a smaller part quickly gets incorporated into plants. This carbon cycle is explained in more detail by Beer et al. (2012) and an understanding of its basics is required to properly use ^{14}C as dating tool or environmental tracer. Beryllium-10 atoms get adsorbed on aerosol particles which are deposited at the Earth's surface typically within less than a year (Morris et al. 2002; Beer et al. 2012). About two orders of magnitude more ^{10}Be is produced in the atmosphere than in situ in rocks. Therefore, in terrestrial samples, meteoric ^{10}Be usually completely dominates in situ produced ^{10}Be and needs to be removed carefully when the latter is of interest, as discussed above. The large amounts of meteoric ^{10}Be require, on the other hand, much lower sample sizes than in situ studies, or – alternatively – can be detected even when strongly diluted, e.g., upon subduction and recycling of sediment at convergent margins (Morris et al. 2002).

Because intensity and energy spectrum of the cosmic radiation entering the Earth's atmosphere are influenced by both the heliospheric and the geomagnetic fields, analyses of meteoric ^{10}Be in ice cores and ^{14}C in tree rings provide a paleo-cosmic-ray record, which is used to investigate the physics of the sun, the heliosphere, and the geomagnetic field in the past several ten thousand to several hundred thousand years (Beer et al. 2012). High solar activity leads to stronger cosmic-ray attenuation and hence lower nuclide production and vice versa. Six "Grand minima" (several consecutive solar cycles with very low activity maxima such as the "Maunder Minimum" in the seventeenth century) are recorded both in ^{14}C and ^{10}Be records over the last 1200 years. Such minima occur in clusters, and four clusters in the past ~7.5 ka are revealed by the ^{10}Be data (Steinhilber et al. 2010). The ^{14}C and ^{10}Be records over the last 10 ka agree very well with each other, which means that the observed variations are indeed caused by periodic changes in the cosmic-ray intensity in the past and are not a "transport" effect, i.e., caused by variations in atmospheric transport processes of ^{14}C and ^{10}Be or ocean storage of ^{14}C (Beer et al. 2012).

To derive solar magnetic field intensity changes over timescales of more than a few hundred years, variations in radionuclide concentrations caused by variations in the geomagnetic field need to be corrected for, as the latter dominate the overall variability on these timescales. This can be done by conventional paleomagnetic techniques, e.g., by measuring the magnetic properties of dated samples. A second method is to combine ^{14}C and ^{10}Be data, which helps to reduce the effects of noise in the data. While this is far from trivial, the overall agreement between the two different paleofield reconstructions in the past 50 ka is satisfying (Beer et al. 2012). Beryllium-10 data from ice or sediment cores (sometimes stacked data from many cores) are also used to derive the geomagnetic field intensity in the past several ten thousand to several hundred thousand years (Frank et al. 1997; Beer et al. 2012). Even the Brunhes-Matuyama magnetic field reversal ~780 ka ago has been observed in the Epica Dome C ice core in Antarctica (Raisbeck et al. 2006).

Meteoric ^{10}Be is also used to date sediments, for example, ferromanganese crusts at ocean floors. Beryllium-10 in sediments is used to derive paleodenudation rates over millions of years and catchment-wide modern erosion rates (Willenbring and von Blanckenburg 2010a, b; von Blanckenburg et al. 2012; Granger et al. 2013). In these cases, also the concentration of the non-cosmogenic stable ^{9}Be isotope needs to be determined. One of the first applications of meteoric ^{10}Be has been its use as tracer of subduction zone processes: cosmogenic ^{10}Be found in island-arc volcanic rocks and other mantle-derived rocks has been recycled from marine sediments incorporated into arc lavas during subduction (Morris et al. 2002). In such studies, ^{10}Be is also combined with U-series studies to better constrain timescales and mechanisms of the transfer from the slab to the mantle.

Beer et al. (2012) give an overview of further applications of radionuclides in studies of the atmosphere, hydrosphere,

and geosphere. Such work includes analyses of many nuclides not discussed so far, with a wide range of half-lives, e.g., Tritium, ^{36}Cl, ^{39}Ar, ^{81}Kr, ^{85}Kr, and ^{129}I. Some of these nuclides are predominantly anthropogenic, produced during nuclear bomb testing or deriving from nuclear power or reprocessing plants.

Summary

Cosmogenic nuclides are very widely studied in cosmochemistry and geochemistry. They allow us to study the transport of meteorites from their parent bodies to Earth and sometimes their previous history near the parent body surface. Cosmogenic nuclides are a tool to judge whether different meteorite specimens, e.g., found in a desert, may belong to a common fall or may have been released from their parent body by the same event. While in the past mostly bulk meteorite samples were analyzed, more recently much attention is given to single phases, such as individual chondrules or calcium-aluminum-rich inclusions. It is still debated whether or not such studies allow us to recognize irradiation of meteoritic matter by an intense flux of solar particles in the early solar system. Analytical advances also allow us to analyze cosmogenic nuclides in other tiny samples such as single presolar grains in meteorites, interplanetary dust particles, and material from sample return missions, e.g., from the regolith of the asteroid Itokawa sampled by the Japanese Hayabusa probe. Since some three decades, cosmogenic nuclides are having a tremendous impact in Earth surface sciences. Fields such as geomorphology, glaciology, paleoseismology, or volcanology profit from the unprecedented possibility to quantify geomorphic processes and timescales. Progress is driven by continuous analytical developments, allowing, in particular, the analysis of ever smaller amounts of cosmogenic radionuclides by new generations of accelerator mass spectrometers. Apart from cosmogenic nuclides produced in situ in rock samples, meteoric radionuclides – produced in the atmosphere before being deposited at the Earth's surface – have long since been and continue to be important tools in paleoclimatology and paleomagnetic studies. More recently, the potential of meteoric radionuclides as tracers and as tools to study large scale erosion has been recognized. A continuing challenge in many applications of cosmogenic nuclides in cosmochemistry and geochemistry is a reliable and accurate determination of relevant production rates. Further progress depends on both theoretical and experimental work.

Critical Points

William H. Casey[1] and Peter A. Rock[2]
[1]Department of Chemistry and Department of Earth and Planetary Sciences, University of California, Davis, CA, USA
[2]College of Math and Physical Sciences, Department of Chemistry, University of California, Davis, CA, USA

Definition

The point in phase space where the distinction between liquid and vapor disappears.

Elaboration

If you heat water in a closed volume, the temperature and pressure are initially fixed by equilibrium between a liquid and vapor. Beyond a certain temperature and pressure, however, the meniscus that separates the two phases disappears, and they become indistinguishable. If one draws a curve in

Prof. Peter A. Rock is deceased.

P-V space that identifies the region where both a liquid and vapor coexist, the *critical point* lies at the maximum where the slope is zero:

$$\left(\frac{\partial P}{\partial V}\right)_{T=T_c} = 0 \quad \text{and} \quad \left(\frac{\partial^2 P}{\partial V^2}\right)_{T=T_c} = 0 \qquad (1)$$

As this point is approached, the two phases, gas and liquid, begin to closely resemble one another on a molecular scale. The critical point for pure water is at 374.2 °C and 218.3 atm.

Near the critical point, the structure of these phases is very sensitive to small changes in temperature and pressure, and these changes are reflected in the macroscopic properties. Density, for example, changes considerably with small variations in pressure and temperature because the relative proportions of the two phases, liquid and vapor, fluctuate widely.

To illustrate the sensitivity of fluid properties near the critical point, consider that the critical point for pure CO_2 is at 31.8 °C and 72.9 atm, which are easily accessible in a laboratory. At these conditions a change in pressure of 1 part in 50,000 causes the CO_2 fluid density to increase by 10%. The density of critical CO_2 is 0.5 g/cm^3 so that 1 torr of CO_2 corresponds to an inch-thick layer. This one-inch-thick layer of CO_2 exhibits a 10% greater density at the bottom of the column than at the top simply due to the weight of the gas.

Likewise, the enthalpy of vaporization goes to zero at the critical point, and it can be seen that the isothermal compressibility

$$\beta \equiv -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T \qquad (2)$$

becomes infinite at the critical point. Correspondingly, the heat capacity, C_p, for the substance reaches large values near the critical point. Near-critical fluids also exhibit curious properties, such as critical opalescence, where light scatters into a dazzling display as the fluid reaches a certain molecular density because the molecular structures reach a characteristic length similar to the wavelength of visible light. Stated differently, the refractive index varies widely near the critical point along with the other bulk properties.

Addition of other components, such as CO_2, NaCl, or H_2, to H_2O dramatically affects the critical point of the solution. For these systems, a curve of critical points is defined in *P-T-X* space (*X is* a composition variable) that is generally nonlinear. The critical curve for the CO_2-H_2O system, for example, is a saddle with two maxima near end-member compositions and a minimum at intermediate values. The critical point for a saturated NaCl-H_2O mixture is at almost 600 °C and approximately 390 bars pressure, significantly higher than the value for pure H_2O.

Understanding the thermodynamic properties of mixed volatile fluids (e.g. CO_2-H_2O; H_2-H_2O) is important for predicting phase assemblages in rocks, for interpreting the compositions of fluid inclusions in minerals, and for predicting the effect of volatile gases on magma. Establishing these thermodynamic properties has been a major success in geochemistry during the last 50 years, and thermodynamic models have recently been extended to 6.0 GPa and 1200 °C based upon molecular-dynamic estimates of the dielectric constant of water (Sverjensky et al. 2014).

Critical Zone

Justin B. Richardson
Dept. of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Synonyms

Earth's critical zone

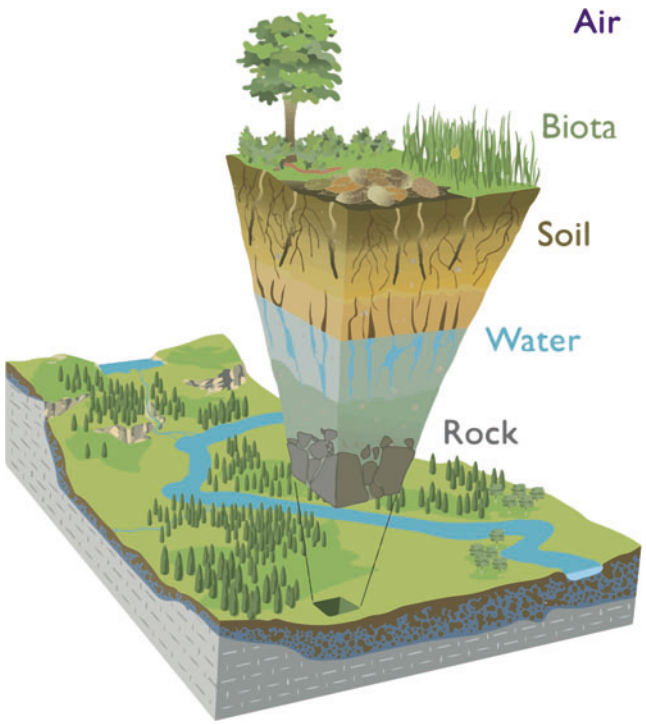
Definition

The critical zone, the near-surface terrestrial environment from the bottom of circulating groundwater to the top of vegetation, hosts the complex interactions involving rock, soil, water, air, and living organisms that regulate life-sustaining resources.

Introduction

The term "critical zone" was first applied to the surface terrestrial environment by Dr. Gail Ashley (1998) in a presentation at the Geological Society of America. In her work, Dr. Ashley introduced the concept of the critical zone when

she wrote that a "holistic approach is needed to understand the three-dimensional complex linkages involving physical, chemical, and biological processes" and a study of geologic and surface processes that are "crucial for life" (Ashley 1998). In 2001, the United States National Research Council's Committee on Basic Research Opportunities in the Earth Sciences noted the future importance of the critical zone concept as integrative of disciplines and required to address interconnected problems (NRC 2001). The National Research Council defined the critical zone as "*the heterogeneous, near surface environment in which complex interactions involving rock, soil, water, air and living organisms regulate the natural habitat and determine availability of life sustaining resources*." Brantley et al. (2007) provided an alternative definition of the critical zone as "*the fragile skin of the planet defined from the outer extent of vegetation down to the lower limits of groundwater*," and many others have followed. In all definitions, the critical zone is recognized as a location of complex biogeochemical and physical processes that supports the terrestrial biosphere (Fig. 1) (White and Sharkey 2016). Study of the structure and function of the critical zone explicitly includes study of processes evolving at all timescales from that of the geologist to that of the meteorologist, and explicitly includes atmospheric (i.e., climate), geologic (e.g., volcanic, tectonic), and biologic (e.g., microbes, plants, organisms, humans) changes throughout Earth's deep and recent history (NRC 2001). Critical zone science can provide information for sustainable adaptation to human perturbations (e.g., intensive land use and climate change).



Critical Zone, Fig. 1 An illustration of the Critical zone conceptual model modified from Chorover et al. (2007) (Artwork by R. Kindlimann)

Essential Concepts

The critical zone paradigm is a new integration of existing fields of natural sciences (Fig. 1). One of the essential aspects of this paradigm is that the term "critical" reflects that nearly all terrestrial life, including humans, depends on the critical zone (Giardino and Houser 2015; NRC 2001), establishing a clear link between Earth's surface processes and geosystems with humans (Brantley et al. 2007; Richter and Billings 2015). Land use and climatic impacts are affecting processes that govern biomass productivity, soil formation, geochemical cycling of elements, and water resources (Hooke et al. 2012). For this reason, it is essential for developing predictive abilities of how attributes, processes, and outputs of the critical zone will respond to projected climate and land-use changes. Some of the central scientific concepts that have been investigated through critical zone science are: (1) formation and distribution of weathered bedrock, (2) sustainability of water and soil resources, (3) tracing the movement of energy and reactive material, and (4) integration of processes across spatial and time scales and with respect to anthropogenic uses and perturbations.

Understanding the biological, chemical, and physical properties controlling bedrock and surficial deposit weathering is a central topic for critical zone science and for parallel efforts in geobiology and geochemistry (Pope 2015). The formation of weathered bedrock has been investigated by Earth scientists for more than 170 years (see Ebelmen 1845; Gilbert 1909). Critical zone science has generated renewed interest in the distribution, structure, and residence of weathered rock, features whose spatial distribution are generally considered to be difficult to measure (Holbrook et al. 2014). The architecture of the weathered bedrock of the critical zone has been shown to be a combination of tectonic, topographic, and weathering processes combined (e.g., Brantley and Lebedeva 2011; St. Clair et al. 2015). Weathering of bedrock may influence sustainability issues, in particular, the feedback between weathering rates and atmospheric CO_2 concentrations (Raymo 1989). Bedrock composition can also directly control the aboveground ecosystem. Hahm et al. (2014) found differences in forest productivity were directly linked to major and minor element composition of the underlying bedrock. The architecture and distribution of fractures is not only important for element cycling, but is also key for reservoirs of materials and energy in the critical zone. For example, the thickness and structure of the weathered bedrock in the critical zone controls many hydrologic properties such as water table elevation, plant-available water, and discharge rates to streams and rivers (Brooks et al. 2015).

Soil and water sustainability is a fundamental component of critical zone science. Much of the framework of critical zone science is built upon principal themes of soil science (e.g., state factor model of Hans Jenny 1941) and hydrology (e.g., subsurface and surface flow by Freeze 1972). Critical zone science focuses on soil sustainability through estimating soil formation rates (e.g., soil formation on a hillslope by Riggins et al. 2011), modeling nutrient cycling (e.g., soil-vegetation cycling rates in a temperate forest by Kraepiel et al. 2015), and quantifying erosion and denudation rates (e.g., sediment transport from following a storm by Foster and Anderson 2016). In addition, water sustainability is considered through snowpack (e.g., snow accumulation in the southern Sierra Nevada by Kirchner et al. 2014), belowground water storage (e.g., water table recharge along a hillslope by Dralle et al. 2014), surface and subsurface flow (e.g., depth of preferential flow rates through soils by Thomas et al. 2013), plant-availability (e.g., plant ecohydrological strategies in seasonally dry ecosystems by Vico et al. 2015), and evapotranspiration losses (e.g., evapotranspiration along an elevation gradient in southern Sierra Nevada mountains by Goulden et al. 2012). While many of these efforts run parallel with traditional soil and hydrological sciences, their integration with other disciplines for broader theoretical understanding and quantitative modeling is pivotal for critical zone science. For an example of greater integration, Bales et al. (2011) observed that during severe droughts in the Sierra Nevada Mountains, California, the majority of water lost from soils and trees can be sourced from water stored in weathered bedrock. In addition, Wilson et al. (2016) linked tillage practices in agroecosystems with soil erosion, which influences crop productivity, carbon storage, and net income from a parcel of land. Critical zone science has built upon existing soil and water sustainability concepts with greater integration as a holistic system (Richter and Billings 2015).

Tracing the movement of material and energy is important for quantifying and modeling local and global critical zone processes, particularly those that are reactive. The movement of materials through soil and unconsolidated material has been a topic of concern for many disciplines. Materials of interest include nutrients (e.g., Davis et al. 2014), inorganic colloids (e.g., Trostle et al. 2016), organic carbon (e.g., Stielstra et al. 2015), trace metals and metalloids (e.g., Ma et al. 2011), and pollutants (e.g., Ma et al. 2014). The movement of these materials through the critical zone controls natural phenomena such as chemical weathering, erosion, nutrient cycling, and anthropogenic issues, such as acid-mine drainage, eutrophication of surface waters, atmospheric CO_2 concentrations, and contamination of drinking water (Li et al. 2017). Studies of material movement range from empirical studies and process-based models to quantify their movement. Li et al. (2017) described four areas in which reactive transport models may substantially contribute to critical zone science as testable hypotheses: (1) evapotranspiration-chemical weathering controlled by reactive gases, (2) water availability-chemical weathering-atmospheric CO_2-temperature linkages at the global scale, (3) soil moisture influences on carbon stabilization in soil, and (4) plant root controls on soil formation and function. Understanding the movement of energy in the critical zone is important for investigating thermodynamic controls from climate on physical, biological, and chemical processes. Rasmussen et al. (2011) proposed the structure and evolution of the critical zone can be described using climatic and biotic forcings as a single environmental energy and mass transfer (EEMT) parameter with energy flux units (e.g., J m−2 s−1). This concept has many potential applications and may be applied across any chosen spatial and temporal scales. Further coupling the movement of materials and energy are current areas of study with many future implications for understanding the critical zone.

Linking critical zone processes across time and spatial scales is a principal goal of critical zone science. Many chemical reactions occur at molecular microsystems (mineral surfaces, root surfaces, macropores, rock fractures), and critical zone scientists are working to measure their effect on larger scale processes (soil formation, hillslopes development, watersheds ecosystem services). For example, Brantley et al. (2011) notes that as rocks and minerals weather, their size decreases and surface area increases, exerting a control on the rate of chemical weathering in the soil profile with potential influences at the watershed scale in Puerto Rico and Pennsylvania. Moreover, mechanisms occurring in a soil profile or at an acre scale can be coupled with regional and global scale estimates. In addition to size and spatial scales, the other most arduous endeavors for Earth Scientists has been linking short-term processes (hours, days, years) with longer-term changes (decades, centuries, and millennia). Monitoring efforts have been fundamental for quantifying short- and long-term biogeochemical and physical processes of the critical zone. For example, a short-term observation may be daily monitoring for peak streamflow during melt season in a snow-dominated watershed (Chen et al. 2016). As a long-term example, Richter et al. (2000) observed that the impact of atmospheric nitrogen was dominant in biological nitrogen fixation over 40 years, by comparing soils collected and archived from 1962 through 1997 at the Calhoun Experimental Forest. Coupled numerical models, such as Flux-Penn State Integrated Hydrologic Model (Flux-PIHM) (Shi et al. 2013) and Terrestrial Integrated Modeling System (TIMS) (Niu et al. 2014), are the leading edge on combining processes over multiple time scales to evaluate the relative influences of different critical zone parameters, and hold out the capacity to support predictions of critical zone processes in the past and future. Furthermore, coupled numerical models are capable of using contemporary processes to

investigate changes over geologic time scales (thousands to millions of years).

Current Investigations

The critical zone is studied at a number of Critical Zone Observatories (CZOs), where multiple scientific communities work in tandem to understand coupled processes, through both field and theoretical approaches. Teams of researchers monitor surface and subsurface water, meteorological conditions, soil properties, and vegetation. In addition, researchers undertake sampling campaigns of vegetation, soils, sediments, regolith, and bedrock. Information generated through monitoring and from sampling campaigns is synthesized to investigate complex systems at CZOs.

While individual CZOs each develop novel approaches to quantify critical zone processes, observatories aim to complete comparable measurements as a network. A key aspect is to use common measurements in which sampling is guided by overarching hypotheses and further developed to reflect site conditions, but materials and methods are implemented in a similar manner across the CZO network (White et al. 2015). Although cross-CZO data comparisons are a substantial goal, many lines of inquiry are site-specific and utilize approaches based on the principal of "best technique and sampling design" at each individual CZO. Thus, even though CZOs are individual entities, data is collected to be comparable with local, regional, and global monitoring efforts. Cross-CZO comparisons that are generalizable across space and time may be modeled using common measurement data and are paramount for creating integrated processes theories needed to expand predictive modeling (i.e., Earth-casting) (White et al. 2015; Richter and Billings 2015).

The United States National Science Foundation (NSF) has funded 10 CZOs across the United States and nine of these still receive funding (White et al. 2015). The NSF CZO program began in 2007 with support of three CZOs: Susquehanna-Shale Hills CZO in Pennsylvania, the Southern Sierra CZO in California, and the Boulder Creek CZO in Colorado. In 2009, three additional observatories were added: Luquillo Mountains CZO in Puerto Rico, Christina River Basin CZO in Delaware and Pennsylvania, and the Jemez River Basin/Santa Catalina Mountains CZO in Arizona and New Mexico. In 2013, four new observatories were selected for funding: Eel River CZO in northern California; Reynolds Creek CZO in Idaho; the Intensively Managed Landscape CZO in Illinois, Iowa, and Minnesota, and the Calhoun CZO in northern South Carolina. Measurements at the NSF-funded CZOs include a common set of variables that quantify Critical zone architecture and evolution, fluxes across the Critical zone boundaries, and changes in storage of the major critical zone reservoirs. The CZOs have recognized that many of the details of overarching science questions can best be addressed if a core set of variables is measured across the CZOs, and if those core measurements are made using the same or readily comparable methods. In 2014, the CZO National Office was created to spur network level research and outreach activities.

There have been many international projects to conduct critical zone research globally. Although some observatories worldwide are not called CZOs, scientists across the international research communities have adopted the framework and nomenclature of "critical zone science," because the paradigm is compelling for addressing environmental sustainability and accelerating interest in Earth surface sciences (White et al. 2015; Richter and Billings 2015). International CZOs and similar projects have identified objectives of determining changes to the critical zone in response to human pressures, and each program has its own approach and strategy. The European Commission funded SoilTrEC in 2009. The SoilTrEC network consisted of four CZOs: Koilaris River Basin in Crete, Damma Glacier in Switzerland, Slavka Forest in the Czech Republic, and in Fuchsenbigl, Austria. Germany has also established the TERENO network, a set of four observatories: Eifel/Lower Rhine Valley, Harz/Central German Lowland, Northeastern German Lowland, and Bavarian Alps/pre-Alps Observatories. Additional CZOs in France and through a United Kingdom-China partnership are in development. Through internationally funded meeting and workshops, there are 60 countries conducting research at 21 funded CZOs as of 2015 (White et al. 2015).

Conclusions

Critical zone science is a new paradigm focusing on integration of existing fields of natural sciences: a systems approach needed to understand the three-dimensional complex linkages involving physical, chemical, and biological processes at the Earth's surface. The term "critical" reflects that nearly all terrestrial life depends on the critical zone. Critical zone science aims to develop predictive abilities, which are essential to understand the past and future effects of climate and land-use. The central scientific concepts investigated through critical zone science are the formation of weathered bedrock, water and soil resources, the movement of energy and reactive material, and integration of natural processes across spatial and time scales. The critical zone is studied at Critical Zone Observatories (CZOs), where multiple scientific communities monitor and conduct sampling campaigns to synthesize the complex interactions systems. Critical zone research is conducted globally as international research communities have adopted the framework and nomenclature to renew interest in Earth surface processes and their sustainability.

Crystal Chemistry

Dana T. Griffen
Geology Department, Brigham Young University, Provo, UT, USA

Definition

Crystalline materials consist of periodically repeating arrays of atoms with compositions that can be represented by definite chemical formulas (which may be variable within certain compositional limits). Crystal chemistry addresses the interdependence of crystallography and chemistry and the attendant consequences and phenomena. Thus, crystal chemistry is concerned with the symmetry and dimensions of the unit cell, the positions of atoms within the unit cell, the kinds of atoms found at each crystallographic site, and relationships with similar phases through such phenomena as solid solution, exsolution, polymorphism, and so forth. For earth scientists, the crystals of interest are minerals. Although the boundaries between crystal chemistry, materials science, and certain areas of solid-state physics and solid-state chemistry are quite blurry, we shall approach the subject from the viewpoint of geology – that is, mineralogical crystal chemistry.

Stereochemistry

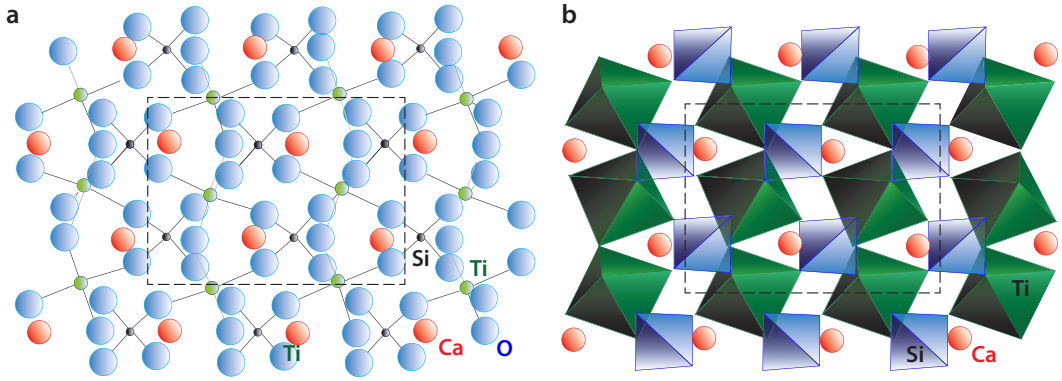
Atoms

Virtually everything of interest in crystal chemistry is related in some way to the spatial and chemical relationships among atoms or ions in a crystal. (The terms "cation" and "anion" are used hereafter to suggest atoms with lesser or greater electronegativity, respectively. No implication of fully ionic charges or fully ionic bonds is intended. Ionic size is discussed under ▶ ionic radii.) In general, ions may be viewed as soft spheres, with cations smaller than anions and surrounded by them; the number of ions bonded to a cation or anion is the coordination number. That the coordination numbers of cations should depend on their sizes relative to the surrounding anions and that bond lengths should equal the sums of the ionic radii are ideas formalized early in the twentieth century. They were stated in the first of five rules by Linus Pauling (1929), and these came to be known as Pauling's rules. For decades, they were taken as the basis for understanding inorganic crystal structures. Because they are often cited even in current literature, it is worthwhile to consider them as relevant concepts that are discussed in the paragraphs below.

Coordination Polyhedra

Imagining cations surrounded by anions leads to the concept of coordination polyhedra, envisioned by connecting the anions about a cation (Gibbs 1982). Figure 1 illustrates this concept using the crystal structure of the common mineral, titanite ($CaTiSiO_5$). Figure 1a is a "ball-and-stick" depiction of the structure and has the advantage of showing the positions of each atom; even so, it is somewhat confusing, and the coordination numbers and geometric relationships can be extracted only by careful study. Figure 1b is a polyhedral drawing, anions are assumed to be at each corner of each polyhedron, cations are presumed to lie within (although not necessarily at the precise center of) each polyhedron, and the coordination numbers and geometric relationships are immediately obvious. For atoms that have large coordination numbers and/or irregular coordination polyhedra, such as the Ca atoms in titanite, it is often advantageous to show them simply as independent spheres.

The frequent occurrence of 3-, 4-, 6-, 8-, and 12-coordination in crystalline solids leads to the recognition of regular coordination polyhedra (see Table 1 and Fig. 2). "Regular coordination" need not mean geometrically ideal, indeed, coordination polyhedra are most often distorted in



Crystal Chemistry, Fig. 1 (**a**) The crystal structure of titanite ($CaTiSiO_5$) represented as a "ball-and-stick" illustration. (**b**) The same crystal structure represented as a polyhedral diagram with the SiO_4 tetrahedra and TiO_6 octahedra shaded; the Ca polyhedra are irregular, and the Ca atoms are left as independent spheres for clarity

some way, but it implies representation by some type of regular solid. Coordination numbers such as 5, 7, 9, and 10 do occur, although much less frequently for cations with radii below about 1.0 Å, and with some exceptions, no attempt is made to represent these by polyhedra with simple shapes.

Figure 2e, f look very similar, but note that the triangles of anions on the top are rotated 60° with respect to one another. Figure 2e represents hexagonal close packing of anions (the layer sequence is . . .ABABA. . .), and Fig. 2f represents cubic close packing (. . .ABCABC. . .). Many minerals have crystal structures that are based on one of the two types of close packing. For example, olivine is based on a distorted hexagonal close packed array of oxygens with Si in some of the tetrahedral interstices and Mg or Fe^{2+} in some of the octahedral interstices; the pyroxene structure is based on very distorted cubic close packing.

Polyhedral Arrangements

Representing crystal structures, or parts thereof, as assemblages of linked polyhedra not only simplifies envisioning the structure but leads to crystallochemically useful ways of classifying minerals. Silicates, for example, are classified on the basis of tetrahedral polymerization – that is, the extent to which tetrahedra are linked (or "share corners") in the structure. (See ► Silicate Minerals)

Consideration of the extent to which corners can be shared, that is, the number of cations bonded to an anion, leads to another important crystallochemical principle. Pauling's second rule states that the sum of electrostatic bond strengths reaching an anion is equal to the charge (oxidation number) of the anion with the sign reversed. Electrostatic bond strength is defined as

$$\mathrm{EBS} = \frac{\mathrm{cationoxidationnumber}}{\mathrm{cationcoordinationnumber}} \qquad (1)$$

Crystal Chemistry, Table 1 The regular coordination polyhedra

Type	No. of corners	No. of edges
Triangle	3	3
Tetrahedron	4	6
Octahedron	6	12
Cube	8	12
Cuboctahedron	12	24

and is the proportion of the formal charge of the cation allotted to each coordinating anion. The rule seems a reasonable requirement, and there are many structures for which it works perfectly. Consider the common garnet, grossular, $Ca_3Al_2Si_3O_{12}$. There is only one crystallographically unique oxygen atom, and it is bonded to one Si, one Al, and two Ca atoms, which are 4-, 6-, and 8-coordinated, respectively. The bond strengths are therefore

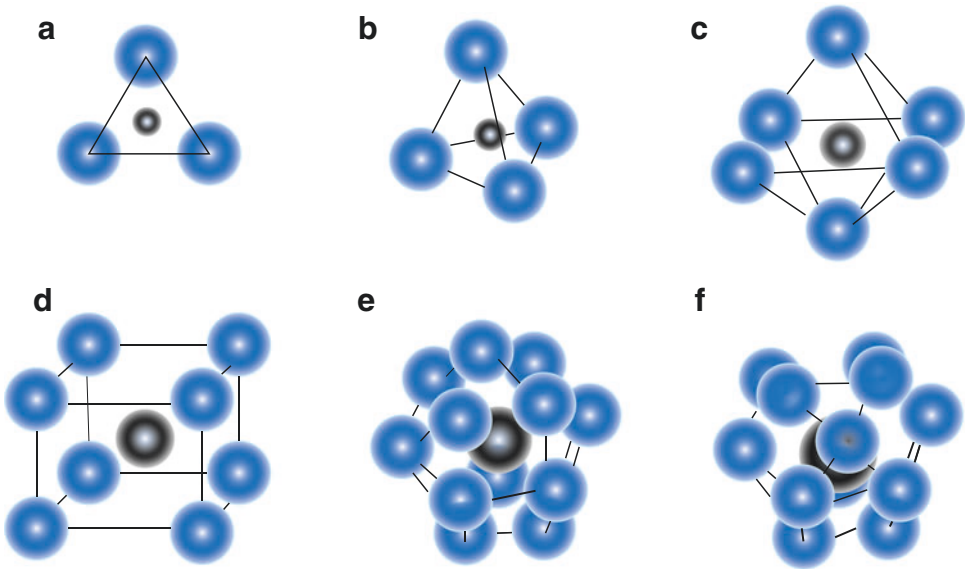
$$\mathrm{EBS_{Si}} = \frac{4}{4} = 1; \quad \mathrm{EBS_{Al}} = \frac{3}{6} = \frac{1}{2}; \quad \mathrm{EBS_{Ca}} = \frac{2}{8} = \frac{1}{4}$$

Thus,

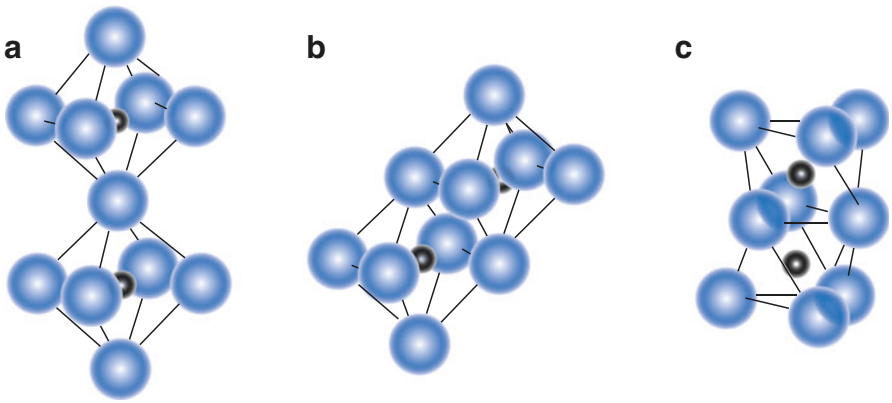
$$\sum \mathrm{EBS} = 1 + \frac{1}{2} + 2\left(\frac{1}{4}\right) = 2$$

which is the oxidation number of oxygen with the sign reversed.

Very often, Pauling's second rule fails, however. Sometimes the failure is minor, in that the deviations in Σ EBS are not large, and the average over the anions is correct. In other cases, the deviations are quite large. The problem is that the rule tacitly assumes that all of the bond lengths about a cation are identical, and this is most often not the case. Because shorter bonds are obviously stronger than longer ones for the same cation–anion pair, dividing the oxidation number by the



Crystal Chemistry, Fig. 2 Regular coordination polyhedra. (**a**) Triangular coordination. (**b**) Tetrahedral coordination. (**c**) Octahedral coordination. (**d**) Cubic coordination. (**e**, **f**) Two types of 12-coordination, one based on hexagonal close packing (**e**) and one on cubic close packing (**f**)



Crystal Chemistry, Fig. 3 The effects on cation–cation distances of sharing polyhedral elements. (**a**) Shared octahedral corner (one anion). (**b**) Shared octahedral edge (two anions). (**c**) Shared octahedral face (three anions)

coordination number does not yield a proper bond strength. A popular approach to "correcting" this problem has been the development of empirical bond-strength–bond-length relationships of the form

$$s = \mathrm{e}^{(r-r_0)/B} \tag{2}$$

or

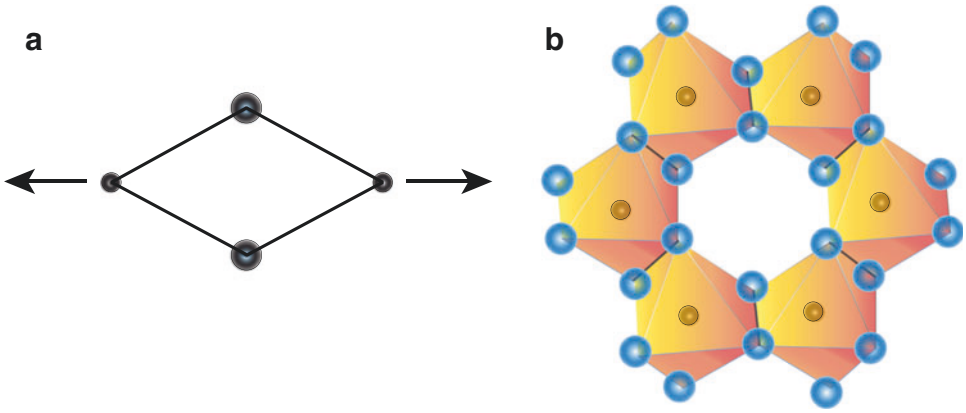
$$s = \left(\frac{r}{r_0}\right)^{-N} \tag{3}$$

where s is often called bond valence, r is bond length, and r_0, B, and N are adjustable parameters (e.g., Brown and Shannon 1981). Using this approach, it is generally possible to obtain bond–valence sums that are very close to the oxidation number of the anion. It also facilitates the recognition of hydroxyls in a structure that has been refined by X-ray diffraction; the bond–valence sum about a hydroxyl should be close to 1 rather than 2. Even using a refinement such as the bond–valence approach, the sums are often not quite perfect, for the same reasons that the first rule of Pauling lacks rigor: Variations in bond strength, like variations in bond length, result not only from the ionic effects assumed by the models but also from the effects of covalence.

Shared Polyhedral Elements

Figure 3 shows pairs of octahedra sharing a corner (i.e., one anion), an edge (two anions), and a face (three anions). It is evident that the cation–cation distance decreases in the order shared corner-edge-face. The third and fourth of Pauling's rules state that the sharing of polyhedral edges and (particularly) faces tends to decrease the stability of a structure and that this effect is largest for small, highly charged cations, which tend not to share polyhedral elements with one another. The usual rationale is based on cation–cation repulsions, which, it will be seen from Fig. 3, increase as edges and faces are shared.

The sharing of polyhedral elements is extremely common, however. It is true that the size and charge of the cations have an



Crystal Chemistry, Fig. 4 (**a**) The direction in which the shortening of shared polyhedral edges increases the cation–cation distances, thereby reducing cation–cation repulsion. (**b**) A part of the octahedral sheet in muscovite. The shared octahedral edges are shown by heavy *lines*

effect (e.g., SiO_4 tetrahedra never share faces, although BeO_4 tetrahedra are known to), but the sharing of octahedral edges occurs in many minerals (olivines, pyroxenes, amphiboles, micas, and many more), and octahedral faces are even shared in some (e.g., corundum, hematite, and dumortierite). In the case of shared edges, one structural compensation that occurs is that the shared edges tend to shorten, thereby lengthening the cation–cation distance and perhaps positioning the anions so as to increase the negative charge density between the cations (Fig. 4a). Figure 4b shows part of a sheet of octahedra in muscovite. Note that the shared octahedral edges (heavy lines) are shorter than the unshared edges. In the case of shared faces, not only do edges shorten, but the cations typically move away from the shared face if it is opposite to an unshared face.

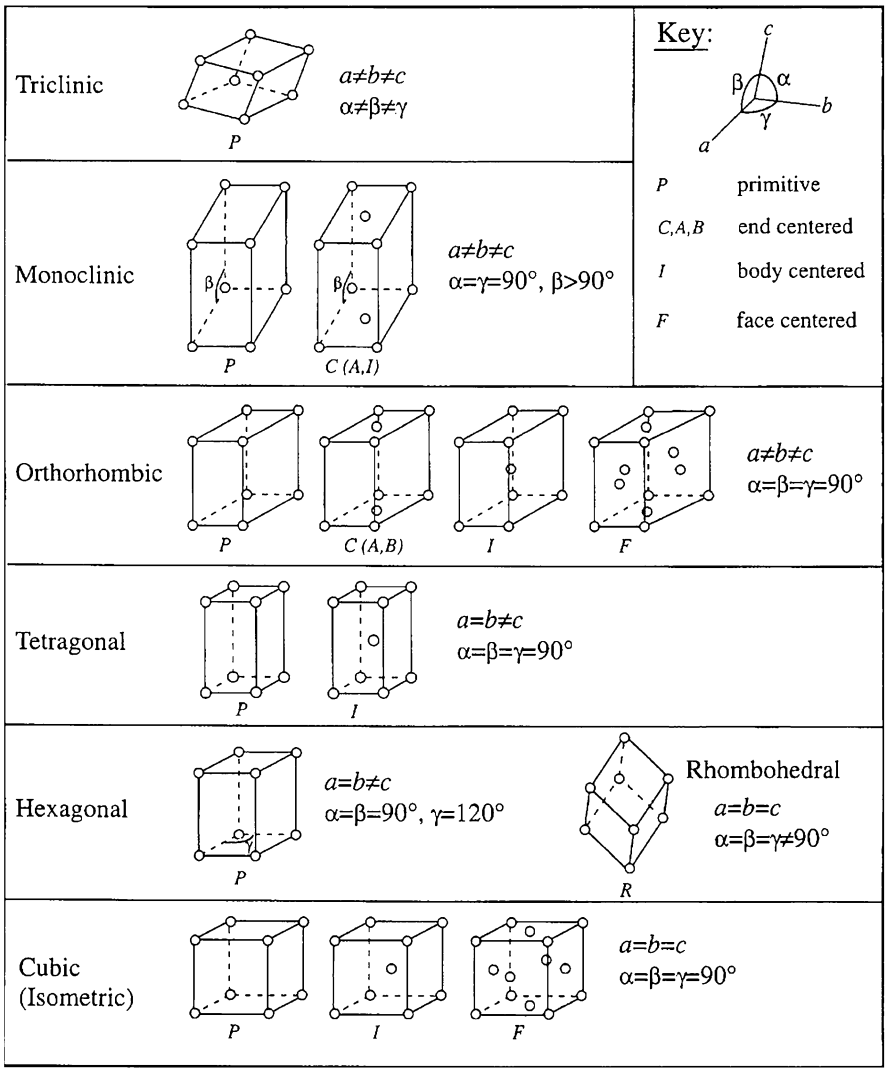
Pauling's fifth and last rule is known as the rule of parsimony and states that the number of essentially different kinds of constituents in a crystal structure tends to be small. If "constituents" are interpreted as coordination polyhedra, and if "essentially different kinds" means that differently distorted polyhedra with the same number of anions are considered "the same kind," then this rule is acceptable, although of doubtful practical significance. Consider this example: Anorthite contains eight symmetrically unique sites containing Si, eight containing Al, and eight containing Ca. Each of the Si sites is geometrically somewhat different from all of the others, and the same is true for each Al and each Ca site. Twenty-four unique kinds of coordination polyhedra are not a small number. Nevertheless, if it is conceded that all of the tetrahedral (Si and Al) sites are very similar, as are all of the Ca sites, then there are only two kinds of "constituents" in anorthite – tetrahedra of oxygens with either Si or Al in the centers and an irregular Ca polyhedron.

Why Are Some Structures Stable While Others Do Not Occur?

Pauling's rules served for many years as the basis for rationalizing the steric details of crystal structures. Even with the recognition of their important limitations, they have proven too useful to crystal chemists to be abandoned altogether. Nonetheless, they and the various modifications and amendments that have been added over the years are tools for rationalization of what is observed, not for prediction of what might be observed. At least two kinds of crystallochemical predictions are of interest: (1) Given a certain type of structure, what are the limits of chemical substitution that the structure will tolerate, and (2) given a certain proposed stoichiometry, what kinds of crystal structures are stable? The first is perhaps the easier to approach, because the atomic substitutions envisioned will impose roughly predictable variations on bond lengths, nonbonded distances, and interatomic bond angles, and there is a substantial body of literature documenting the acceptable ranges of values for these sorts of parameters. The second question is more interesting and much more difficult to deal with. Recent and current research, both on the general question and on predictions for specific minerals and other inorganic compounds, has focused on bond topology (connectivity, particularly of the strongest bonds in a structure), the predictive use of bond–valence theory, the application of molecular orbital theory (at various levels of approximation, applied both qualitatively and quantitatively) to "molecular" fragments of crystal structures, band theory, experimental methods such as vibrational spectroscopy (Berry and Vaughan 1985), Landau theory (Tolédano and Tolédano 1987), and others.

Crystallography and Crystal Symmetry

By definition, a crystal consists of an arrangement of atoms that is periodically repeated in three dimensions. The smallest parallelepiped that possesses within both the symmetry and stoichiometry of the overall arrangement is called the unit cell, and the entire crystal consists of unit cells related to one another by translation alone. The corners of the unit cell are surrounded by identical groups of atoms, and form a lattice, the definition of which is an array of points in space arranged such that each one has an identical and indistinguishable environment. There may be other points that are surrounded



Crystal Chemistry, Fig. 5 The 14 Bravais lattices, arranged by crystal system

by groups of atoms identical to those around the corners of the unit cell; if so, the lattice is referred to as a centered lattice, and if not it is called a primitive lattice. Combining both primitive and centered lattices, there are only 14 symmetrically unique possibilities. These are called the Bravais lattices, after Auguste Bravais (1811–1863), and they are illustrated in Fig. 5. Note that each lattice is represented in Fig. 5 by a single unit cell, the edges of which define three crystallographic axes a, b, and c separated by three interaxial angles α, β, and γ.

Rotational Symmetry

Consideration of the data in Fig. 5 reveals that each type of lattice can be mapped into itself by at least one symmetry operation. Depending upon the arrangement of the atoms about the lattice points, this will be true also of the unit cells (i.e., of the entire crystal structure). Although it is easy to conceive of an atomic arrangement that would yield no symmetry, there are very few minerals that fall into that category; the overwhelming majority show symmetry of some sort.

Rotational symmetry elements are lines (axes of symmetry) around which an arrangement of atoms may be rotated so as to exactly reproduce itself. Proper rotation axes are those that map right-handed objects into right-handed objects, and improper rotation axes map right-handed objects into left-handed ones. Proper symmetry operations are represented symbolically by Arabic numerals, and improper symmetry operations are represented by Arabic numerals with a bar over them. The constraints imposed by the definition of a lattice (given above) limit the types of rotations that may occur in a crystal structure (and in the resulting macroscopic crystal) to those shown in Table 2. It can be shown that the sixfold rotoinversion is equivalent to a triad with a mirror plane perpendicular to it (symbolized $3/m$), but $\overline{6}$ is usually used. The symbol m (rather than $\overline{2}$) is used for a mirror plane.

Crystal Classes

Not only are the types of rotational symmetry in crystals limited but so are the compatible combinations of symmetry elements. First, it is possible for a crystalline atomic arrangement or a macroscopic crystal to have only one kind of rotational symmetry. If there are two symmetrically different kinds, however, then there must also be a third that is symmetrically distinct from the other two. Symmetrically distinct or different here means that the operation of any one of the symmetry elements does not map the other two into each other. Among these three symmetry elements, all may be proper, or one can be proper and two improper. Given these constraints, there are only 32 permissible groups of symmetry elements (including those groups made up of but a single symmetry element), and these are called the crystal classes or crystallographic point groups. They are a subset of the infinite set of noncrystallographic point groups that are not restricted to one-, two-, three-, four-, and sixfold symmetry. The 32 crystal classes are given in Table 3. The symbols in the table are called Hermann–Mauguin symbols, and they specify the particular symmetry required for the class. A fuller explanation is beyond the scope of this article but may be found in any introductory text on mineralogy or crystallography or in Hahn (1987).

Table 3 also lists the defining symmetry for each of the crystal systems; this is the minimum symmetry that must be possessed by a crystal to place it in a particular crystal system.

Crystal Chemistry, Table 2 Permissible rotational symmetry operations

Symbol	Names	Rotation angle
1	Onefold rotation axis monad	0°, 360°
2	Twofold rotation axis diad	180°
3	Threefold rotation axis triad	120°
4	Fourfold rotation axis tetrad	90°
6	Sixfold rotation axis hexad	60°
$\overline{1}$	Center of symmetry inversion center	0° or 360° + inversion
$\overline{2} = m$	Mirror plane of reflection	180° + inversion
$\overline{3}$	Threefold rotoinversion bar-three	120° + inversion
$\overline{4}$	Fourfold rotoinversion bar-four	90° + inversion
$\overline{6}$	Sixfold rotoinversion bar-six	60° + inversion

Symmetry is a more rigorous requirement for membership in a crystal system than is the geometry of the unit cell (Fig. 5). To illustrate, it is possible to superimpose on a cubic lattice a periodic arrangement of atoms that negates all of the inherent symmetry of the lattice; thus one would have a metrically cubic unit cell with no symmetry, and it would belong to the triclinic system. Although this is highly unlikely, because the non-cubic arrangement of atoms would impose asymmetrical atomic interactions that would lower the symmetry of the lattice, it does sometimes happen that experimental measurements of a unit cell (by, e.g., X-ray diffraction) show it to be within experimental error of the geometry of a higher crystal system than the atomic arrangement allows.

The external symmetry of a macroscopic crystal is completely described by the rotational symmetry elements of the 32 crystal classes. For the crystal chemist, the more interesting issue is the symmetry of the arrangement of atoms, and this sometimes involves symmetry elements that combine both rotation and translation.

Translational Symmetry Elements

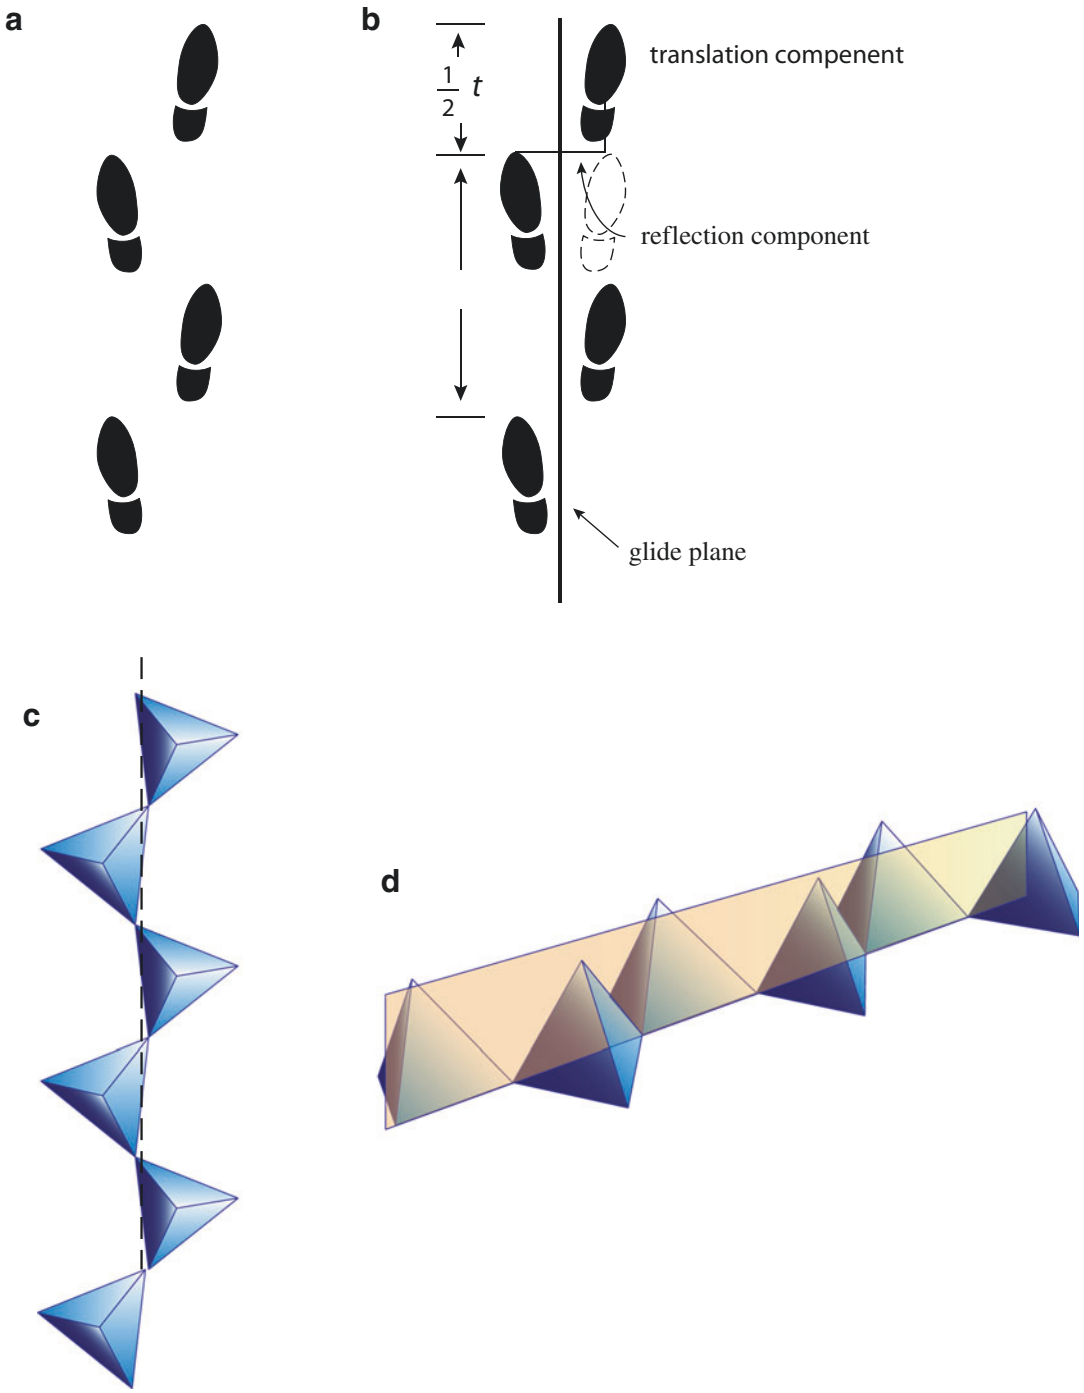
Figure 6a shows a set of footprints. It is obvious that there is some symmetrical relationship between the set of right footprints and the set of left ones, but it is more complicated than a simple reflection. Figure 6b shows the symmetry relationship to be a reflection followed by a translation of one-half the repeat distance parallel to the mirror plane. This is called a glide plane, and the glide plane that relates successive tetrahedra in the pyroxene chain is shown in Fig. 6c, d. Because the translation component of the glide plane is parallel to the *c* crystallographic axis in the case of pyroxenes, it is called a *c*-glide; the other axial glide planes are *a*-glides and *b*-glides. Two other types of glide planes may be found in some atomic arrangements: diagonal glides, in which the glide component is one-half the vector sum of two axial translations, and diamond glides, in which the glide component is one-fourth the vector sum or difference of either two or three of the axial translations; they are labeled *n*-glides and *d*-glides, respectively.

The final type of translational symmetry element is the screw axis, which is a rotation (two-, three-, four-, or sixfold) followed by a translation. Figure 7 illustrates a screw axis.

Crystal Chemistry, Table 3 The 32 crystal classes

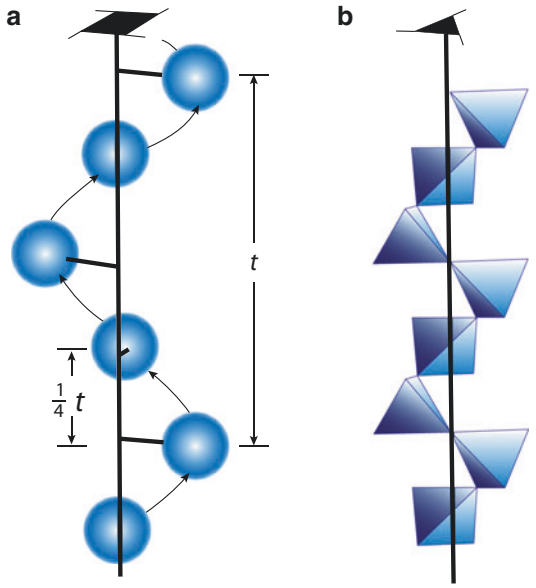
System	Minimum symmetry			Hermann-Mauguin symbols for crystal classes				
Triclinic	None	1	$\overline{1}$					
Monoclinic	1 diad[a]	2	m	$\frac{2}{m}$				
Orthorhombic	3 ⊥ diads[a]	222	mm^2	$\frac{2}{m}\,\frac{2}{m}\,\frac{2}{m}$				
Tetragonal	1 tetrad[a]	4	$\overline{4}$	$\frac{4}{m}$	422	4 mm	$\overline{4}$2m	$\frac{4}{m}\,\frac{2}{m}\,\frac{2}{m}$
Hexagonal	1 hexad[a]	6	$\overline{6}$	$\frac{6}{m}$	622	6 mm	$\overline{6}$m2	$\frac{6}{m}\,\frac{2}{m}\,\frac{2}{m}$
(Trigonal)	(1 triad[a])		3	$\overline{3}$	32	3 m	$\overline{3}\,\frac{2}{m}$	
Cubic	4 triads[a]		23	$\frac{2}{m}\overline{3}$	432	$\overline{4}$32	$\frac{4}{m}\overline{3}\,\frac{2}{m}$	

[a]May include a permissible combination of proper and improper axes



Crystal Chemistry, Fig. 6 (**a**) Although there is clearly some symmetry relationship between the right and left footprints, it is not pure reflection. (**b**) A reflection followed by a translation of one-half the repeat distance parallel to the mirror plane is called a glide reflection, and the symmetry element is a glide plane. (**c**) The tetrahedral chain of Si-containing tetrahedra in pyroxene (diopside, in this case). Oxygen atoms are implied at the corners of the tetrahedra. The chain runs parallel to the *c* crystallographic axis, so this is a *c*-glide (*dashed*). (**d**) The *c*-glide in diopside seen in perspective

The types of possible screw axes are 2_1, 3_1, 3_2, 4_1, 4_2, 4_3, 6_1, 6_2, 6_3, 6_4, and 6_5. If the subscript is less than one-half of the Arabic numeral representing the rotation, the screw axis is right-handed (i.e., a rotation to the right followed by translation); if it is greater than one-half of the rotation numeral, the screw axis is left-handed; if it is equal to one-half of the rotation numeral, the screw axis is neutral, because right- and left-handed rotations yield identical results. Table 4 shows the translation distances, in fractions of the repeat distance along the axis, for each type of screw axis.



Crystal Chemistry, Fig. 7 (**a**) A schematic 4_1 screw axis consisting of successive 90° right-handed rotations followed by translations of one-fourth the repeat distance parallel to the rotation axis. (**b**) The helical chain of tetrahedra found in quartz; tetrahedra are related by a 3_2 screw axis

Crystal Chemistry, Table 4 Translational components of screw axes

Rotation	Translation[a]			
	$\frac{c}{2}$	$\frac{c}{3}$	$\frac{c}{4}$	$\frac{c}{6}$
180°	2_1			
120°		3_1, 3_2		
90°	4_2		4_1, 4_3	
60°	6_3	6_2, 6_4		6_1, 6_5

[a]2_1 screw axes may be in other directions than parallel to *c*, depending on crystal system. All three-, four-, and sixfold screw axes are parallel to *c*; in the cubic system, a fourfold screw axis parallel to *c* requires one parallel to *a* and *b* as well

Space Groups

The combination of 14 Bravais lattices, 32 crystal classes, and glide planes and screw axes leads to 230 unique combinations of crystallographic symmetry elements that describe the symmetry of crystals on the atomic level (Burns and Glazer 1990). They are called space groups and are enumerated, diagrammed, and thoroughly explained in Hahn (1987). The determination of the space group of a particular mineral does not specify its atomic arrangement (i.e., crystal structure) but places limitations and requirements on the possible locations of atoms. For example, although tremolite and sanidine have entirely different crystal structures, they crystallize in the same space group and therefore possess identical symmetry properties.

The notation used for space groups provides the type of Bravais lattice, the crystal system, the crystal class, and the translational symmetry elements present and is best understood by analyzing an example. The space group of the clinopyroxenes, such as diopside, is *C*2/*c*. The first letter, always in upper case, is the Bravais lattice type – a *C*-centered lattice in this case. 2/*c* is the crystal class with translational symmetry elements replacing rotational symmetry elements, if applicable; in this case, a *c*-glide replaces the mirror plane that is normal to the diad. Thus the crystal class is 2/*m* and the crystal is monoclinic, but the atoms that would be related by a mirror plane are instead related by a glide operation.

Crystallochemical Phenomena

Polymorphism and Phase Transformations

Polymorphism is the existence of two or more different crystal structures with identical chemical compositions. (Technically, if only two structures exist for a given composition, they should be referred to as dimorphs, but the almost universal practice is to call them polymorphs.) Transformations between phases provide important information about the conditions of formation or the thermobaric history of a rock, and they can be described in several different ways (Price and Ross 1992; Hazen and Finger 1982):

1. Transformations in which atomic bonds are broken and rearranged (i.e., in which the topology is changed) are called reconstructive transformations. They are generally sluggish, often leading to the metastable persistence of phases under conditions of thermodynamic instability (Lasaga and Kirkpatrick 1981). For example, Al_2SiO_5 exists as the minerals kyanite, andalusite, and sillimanite, all of which have fields of stability in pressure–temperature (P–T) space and each of which possesses a quite different bond topology; nevertheless, all of these can be found in rocks that have been exposed at the Earth's surface, because the energy required to break and reform the bonds is unavailable under ambient conditions. Transformations that involve only shifts in atomic positions without the breaking of bonds leave bond topology unchanged and are called displacive transformations. These phase transitions are typically rapid and easily reversible. A good example is the β–α quartz transformation, which occurs around 573 °C at atmospheric pressure. When that temperature is reached from either above or below, the atomic transformation occurs immediately, regardless of the rate of temperature change; thus, β-quartz does not exist in rocks under surface conditions.
2. Another way of characterizing phase transformations is to examine changes in coordination polyhedra. If the number of anions around a cation changes as a result of the transition, then it is a change in primary coordination. Again, the Al_2SiO_5 polymorphs provide an example, and the change is apparent if the coordination numbers are written as upper

left superscripts in the chemical formulas: Kyanite is $^{[6]}Al^{[6]}Al^{[4]}SiO_5$, andalusite is $^{[6]}Al^{[5]}Al^{[4]}SiO_5$, and sillimanite is $^{[6]}Al^{[4]}Al^{[4]}SiO_5$. If no primary coordination numbers change, but the dispositions of polyhedra are altered (i.e., if the numbers and/or types of atoms in the second coordination sphere change), then this is a change in secondary coordination. The transition between quartz and tridymite, wherein all Si atoms in both phases are tetrahedrally coordinated, but the arrangements of tetrahedra are quite different, is of this type. If coordination numbers do not change, but the chemical species within polyhedra are rearranged, then the change is an ordering transformation. For example, two polymorphs of $KAlSi_3O_8$ are sanidine and microcline; they differ in the way in which Al and Si are ordered within the available tetrahedral sites.

3. Phase transformations can also be defined in thermodynamic terms based on the behavior of derivatives of the Gibbs free energy (G), defined as

$$G - H - \mathrm{TS} \tag{4}$$

where H is enthalpy, T is temperature, and S is entropy. Molar volume and entropy are first derivatives of G, and heat capacity, compressibility, and thermal expansion coefficient are second derivatives. If the first derivatives of G are discontinuous at the transformation temperature, the transformation is a first-order transition. If the first derivatives are continuous but the second derivatives are discontinuous, the transformation is of second order. If the second derivatives (particularly heat capacity, C_P) tend to infinity at the transition temperature, it is called a lambda transformation. Reconstructive transformations tend to be first order, displacive transformations are often second order, and the α–β quartz transition may be a lambda transformation.

4. If the new phase nucleates at discrete locations in the host phase and grows from these, the transformation is called a discontinuous phase transition. If, on the other hand, the transformation occurs simultaneously throughout the host by structural modulation of the parent atomic arrangement, the transformation is a continuous phase transition.

A single example of the information available from the study of phase transformations must suffice. Consider the Ca-poor clinopyroxene, pigeonite. At high temperature, it crystallizes in space group $C2/c$, so that all of the tetrahedral chains (see Fig. 6c, d) are identical. As the temperature decreases, the site in which the small amount of Ca present is concentrated contracts, causing different rotations in what had previously been two symmetrically identical tetrahedral chains. This yields symmetrically different SiA and SiB chains and lowers the symmetry to $P2_1/c$. The transformation is rapid and displacive. Because either chain in the $C2/c$ structure can become the SiB chain in the $P2_1/c$ structure, the "choice" is made differently in different parts of the crystal, and when the microdomains of consistent "choice" meet, they are out of phase with one another. This antiphase domain texture can be observed by transmission electron microscopy and provides information on the thermal history of the sample.

C

Solid Solution and Exsolution

Many minerals exist in ranges of compositions that are limited by three factors:

1. The crystal structures of all compositions exhibited by a mineral must be topologically identical (i.e., they may differ only by small distortions).
2. The atoms (or ions) that substitute for one another must have roughly the same radii.
3. Electrostatic neutrality must be retained by the substitutions.

If all three requirements are met and a range of compositions is in fact observed, the mineral is said to exhibit solid solution. The requirement for similarity in radii is important but only approximate; a rule of thumb often stated is that the radii should be within 15% of each other. Electrostatic neutrality may be maintained either by substituting ions that have identical oxidation numbers or by substituting ions in combination with one another (coupled substitutions) so that overall neutrality is maintained.

Consider, for example, the feldspars. The plagioclase feldspars consist of the solid solution series $NaAlSi_3O_8$–$CaAl_2Si_2O_8$ (albite to anorthite). The crystal structures are topologically identical; the effective ionic radii of Na and Ca in 7-coordination are 1.12 Å and 1.06 Å, respectively; and the substitution $Na^+Si^{4+} \leftrightarrow Ca^{2+}Al^{3+}$ meets the requirement for electrostatic neutrality. Thus, to a first approximation, the plagioclase feldspars display a complete solid solution series between the two end members. The alkali feldspars are those with compositions between albite and $KAlSi_3O_8$ (compositionally called orthoclase, although it can exist in several polymorphs). Like Na, K is monovalent, but its radius is 1.46 Å. At high temperature, atomic vibrations make the effective sizes of Na and K similar, and complete solid solution occurs. As temperature decreases, however, the size difference becomes important, and at low temperatures, there is only limited solid solution; that is, a small amount of K can substitute in crystals of albite-rich composition, and a small amount of Na can substitute in crystals of K-rich composition. Between the K and Ca end members, solid solution is even more restricted.

If alkali feldspar crystallizes at high temperature as a homogenous phase in a magma, and then the temperature is slowly lowered (as, e.g., in a cooling pluton), the feldspar becomes unstable because of the substantial crystallographic

strains required to accommodate both K and Na in the same lattice. The result is a solid-state migration of K and Na, which separate into regions of high K and regions of high Na concentration. If the bulk composition is nearer the K end member, then a K-rich feldspar becomes the host to exsolution "stringers" or lamellae of an Na-rich phase; if it is nearer the Na end member, then the reverse occurs. Although feldspars have been used for illustration, solid solution is extremely common for many important mineral families, and exsolution occurs when solid solution behavior for end members differs significantly over the temperature range experienced by the mineral.

Other Phenomena

Among the many other phenomena that arise from the crystal chemistry of minerals are color, elastic and vibrational properties, ordering of atomic species in preferred crystallographic sites, polytypism, twinning, compositional zoning, hydration and surface phenomena, and others. Space does not permit more than this brief enumeration, but the bibliographic listings include works that delve into all of these areas and more (Boisen and Gibbs 1985; Burdett 1995; Deer et al. 2013; Griffen 1992; Kieffer and Navrotsky 1985; Jaffe 1988; Vaughan and Pattrick 1985).

Crystal Field Theory

Hans Keppler
Bayerisches Geoinstitut, University of Bayreuth, Bayreuth, Germany

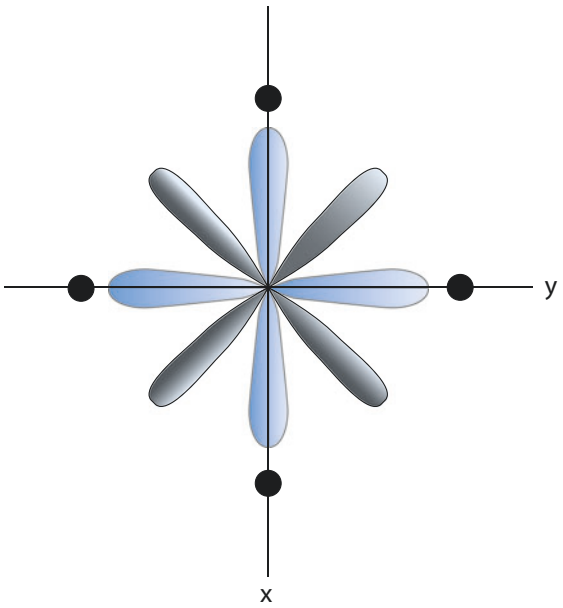
Crystal field theory is a model describing the interaction between the electric charges of a cation and the surrounding anions. A more sophisticated version of this model, which includes covalent bonding effects, is the ligand field theory. Very frequently, however, the terms crystal field theory and ligand field theory are used synonymously. Crystal field

Originally published in: Marshall CP, Fairbridge RW (eds) Encyclopedia of Geochemistry, Springer Netherlands, 1999.

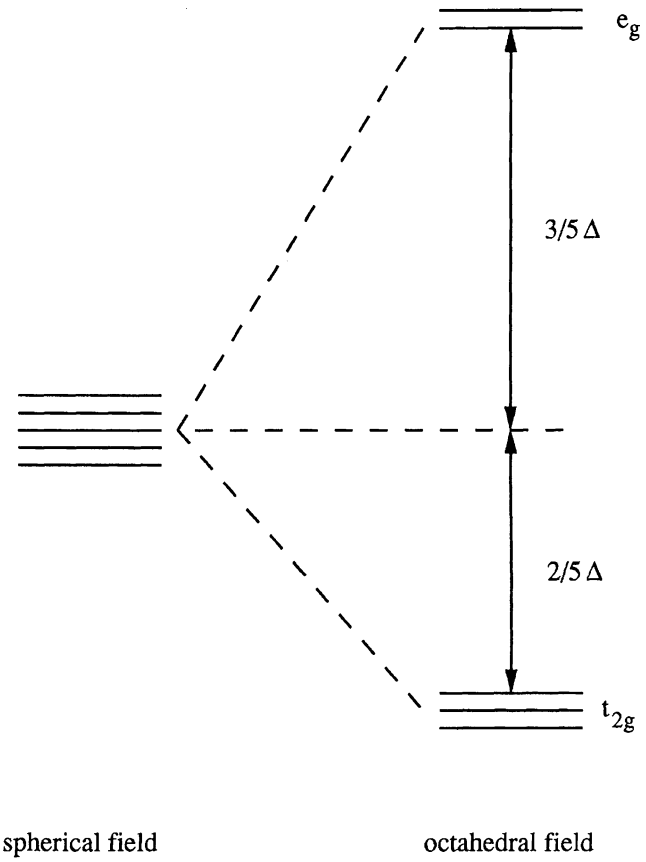
theory can be used to extract thermodynamic properties (crystal field stabilization energies) from optical spectra of minerals and other substances. By considering crystal field stabilization energies, many features of the geochemistry of transition metals can be explained.

The basic idea of crystal field theory is related to the fact that the charge distribution of the d- and f-orbitals in cations is not spherically symmetrical. This means that the repulsive electrostatic forces between the electrons in these orbitals and the surrounding anions (ligands) depend on the relative orientations of the anions. This is shown schematically in Fig. 1. If one considers the charge density of d-orbitals in the *xy*-plane of a Cartesian coordinate system, the d_{xy} orbital has maximum charge density (maximum probability to find an electron) between the coordinate axes. The $d_{x^2-y^2}$ orbital, on the other hand, has the maximum charge in the direction of the coordinate axes. If the cation is surrounded by six anions in octahedral coordination, these anions can be grouped in the directions of the coordinate axes (four in the *xy*-plane, one in $+z$, and one in $-z$ direction), as shown in Fig. 1. Obviously, the electrostatic repulsion between these anions and the $d_{x^2-y^2}$ orbital will be stronger than the repulsion between the anion and the d_{xy} orbital. Therefore, the energy of an electron in the $d_{x^2-y^2}$ orbital will be higher than in the d_{xy} orbital. In vacuum or in a spherically symmetrical field, however, the energies of these orbitals are equal – they are said to be degenerate. Therefore, the effect of the electrical field of the anions is to split the d-orbitals into groups of different energies. The magnitude of this splitting is called the crystal field splitting Δ. A detailed analysis shows that an octahedral field splits the five d-orbitals into two levels, the t_{2g} level (d_{xy}, d_{xz}, d_{yz} orbital) and the e_g level ($d_{x^2-y^2}$, d_{z^2} orbital). The magnitude of the splitting follows the so-called center of gravity rule, which means that the average energy of the five orbitals must equal the energy of the orbitals in a spherically symmetric field. This condition is only fulfilled if relative to a spherically symmetrical field the t_{2g} levels are lowered in energy by $2/5\Delta$ while the e_g levels are raised by $3/5\Delta$. This situation is schematically depicted in Fig. 2.

The type and magnitude of the crystal field splitting depend on the geometry of the coordination polyhedron. It can be shown, for example, that in a tetrahedral environment, the effect of the crystal field splitting is opposite to the octahedral case, i.e., the energies of d_{xy}, d_{xz}, and d_{yz} are raised, while the energies of $d_{x^2-y^2}$ and d_{z^2} are lowered. Other things being equal, the magnitude of the crystal field splitting in a tetrahedral field will be 4/9 of that in an octahedral field. Furthermore, if the symmetry of the coordination polyhedron is lower than cubic, i.e., if the coordination tetrahedron or octahedron is distorted, additional splittings of energy levels can be induced. For example, $d_{x^2-y^2}$ and d_{z^2} orbitals no longer



Crystal Field Theory, Fig. 1 Orientation of the $d_{x^2-y^2}$ (*light blue*) and d_{xy} (*dark*) orbitals of a cation relative to the *xy*-plane of a Cartesian coordinate system. The positions of anions surrounding the cation in octahedral coordination are indicated as *black dots*. Four of these anions are in the *xy*-plane, one is above in $+z$, and one below in $-z$ direction



Crystal Field Theory, Fig. 2 Splitting of the energies of d-orbitals in an octahedral environment. Δ is the crystal field splitting

need to have the same energy in a distorted octahedral or tetrahedral environment.

Crystal field theory was originally derived for cations in a crystal lattice (Bethe 1929). However, exactly the same formalism can be applied to cations in liquids (silicate melts, aqueous solutions) and even gases. The effects described by crystal field theory are almost completely due to interactions within the first coordination shell, so that the medium and long-range order in the phase considered is not important.

The splitting of d-orbital levels by interaction with the charges in the first coordination sphere has important consequences if the d-orbital shell is not completely filled. Consider, for example, an ion with three d-electrons, such as Cr^{3+}, in an octahedral environment. In the ground state of the ion, the three electrons will occupy the d_{xy}, d_{xz}, and d_{yx} orbitals (the t_{2g} level, Fig. 2). The $d_{x^2-y^2}$ and d_{z^2} orbitals are empty. This has the following consequences:

1. Relative to Cr^{3+} in a spherically symmetric electrostatic field, the energy of the octahedrally coordinated Cr^{3+} ion will be lowered. Since the t_{2g} level is lowered by $2/5\Delta$ and there are three electrons in this level, this effect stabilizes the octahedral Cr^{3+} by $6/5\Delta$. This energy is called the crystal field stabilization energy (CFSE). CFSE is often in the order of the free energy of chemical reactions (several 10 or 100 kJ/mol). In the case of ions which have very large CFSE, such as octahedral Cr^{3+} or Ni^{2+}, one can often predict the direction of a reaction or the approximate value of an equilibrium constant by considering the CFSE of the ions in the phases involved. Such considerations have been very fruitful for predicting the partitioning of transition metal ions between different sites in a crystal (e.g., tetrahedral and octahedral sites in spinel) as well as for predicting the partitioning between different phases (minerals and silicate melts). However, it is important to note that the CFSE amounts only to a maximum of 20–30% of the total bonding energy, which means that other effects can also be important.
2. Since the three electrons in Cr^{3+} occupy those orbitals which have the weakest interaction with the anions, while the orbitals that are closest to the anions are empty the effective ionic radius of octahedral Cr^{3+} is lower than expected for a spherically symmetrical charge distribution. Crystal field theory can therefore explain irregularities in the ionic radii of transition metal ions.
3. If the Cr^{3+} ion interacts with electromagnetic radiation, electrons can be promoted from the t_{2g} into the e_g level. This gives rise to absorption bands in the near-infrared, visible, and ultraviolet region of the electromagnetic spectrum. These spectra can be used to detect the oxidation state and coordination number of transition metals. Moreover, the crystal field splitting and crystal field stabilization energy can easily be obtained from such spectra. A fully quantitative interpretation of the spectra requires a modification of the simple electrostatic model of crystal field theory that allows for some covalent bonding effects. This model is often called ligand field theory. Covalent bonding implies that the electrons are not completely localized at the cation any more, but they can be "smeared out" over the anions. This effect will reduce the interelectronic repulsion, because the average distance between the electrons increases. The Racah parameter B is a measure for interelectronic repulsion and can be obtained from optical absorption spectra. If there is some covalent bonding, the Racah parameter will be reduced relative to the value for the free ion in vacuum. In order to obtain both the crystal field splitting and the Racah parameter from spectroscopic data, the Tanabe–Sugano diagrams (Tanabe and Sugano 1954) are used which are plots of the energies of the possible states of an ion as a function of Δ and B.

If the d-electron levels are completely filled, the CFSE is zero, and no optical absorption due to transitions within the d-orbital levels can occur. Ions with incompletely filled f-orbitals (lanthanides and actinides) are in principle subjected to crystal field effects. These effects, however, are relatively small, since the f-electrons are strongly shielded from the surrounding electrostatic fields. Therefore, crystal field theory is primarily a tool for understanding the chemistry and geochemistry of transition metal ions which contain partially filled d-orbitals.

A special situation can arise, for example, for octahedrally coordinated cations having four d-electrons, such as Cr^{2+} or Mn^{3+}. In these cations, three electrons will occupy the t_{2g} level, while one electron is in the e_g level, i.e., either in the $d_{x^2-y^2}$ or the d_{z^2} orbital (see Fig. 2). In an undistorted octahedron, the energies of the $d_{x^2-y^2}$ orbital and the d_{z^2} orbital are identical. This means that there are two possible ground states (states with lowest energy) of the ion, depending on which one of the two e_g orbitals contains an electron. This is often expressed by saying that the ground state of these ions is degenerate. However, if the octahedron is slightly distorted, the degeneracy is lifted, since then the two orbitals will have different energy. Since the e_g electron can then reside in the orbital with the lower energy ($d_{x^2-y^2}$ or d_{z^2}, depending on the type of distortion), generally this effect will lower the total energy of the system. Therefore, the coordination polyhedron of ions with a degenerate ground state, such as octahedral Cr^{2+} or Mn^{3+}, will always be distorted. This is known as the Jahn–Teller effect. As a consequence of this effect, cations such as Cr^{2+} or Mn^{3+} will prefer the more distorted sites in

crystal structures, if several sites of approximately equal size are available.

In most coordination environments, the crystal field splitting is small compared to the energy necessary to cause spin pairing of electrons. This means that if five electrons are present in an octahedrally coordinated cation, three will occupy the t_{2g} and two the e_g-level (Fig. 2). Any additional electrons will then enter these orbitals with antiparallel spin. However, in some cases the crystal field splitting can become so large that spin pairing is induced. In this case, up to six electrons will first enter the t_{2g} level, and only after that the e_g level can be filled with additional electrons. This means that for some cations, two different electronic configurations are possible, depending on the magnitude of the crystal field splitting: the high-spin configuration (where the vectorial sum of the electron spins is maximum) for low Δ and the low-spin configuration for high Δ. Certain ligands, such as sulfide, can cause Δ to be very large; therefore, many transition metal sulfides are in the low-spin state. Oxides and silicates under normal conditions are in the high-spin state. It is possible, however, that they convert into the low-spin state at extreme pressures prevailing in the lower mantle. Since the high-spin to low-spin transition changes the configuration of the outer electron shell, this could completely change the geochemical behavior of the elements involved.

A good introduction into the theoretical background of crystal field theory is the book by Figgis (1966). Symmetry aspects are discussed by Cotton (1971). Geochemical applications can be found in Burns (1985, 1993) and Rossman (1988).

Debye-Hückel Equation

Jay R. Black
School of Earth Sciences, The University of Melbourne, Melbourne, VIC, Australia

Definition

Named after Peter Debye (1884–1966) and Erich Hückel (1896–1980) for their work pioneering the understanding of aqueous electrolyte solutions, the Debye-Hückel equation defines the activity coefficient (γ) of an aqueous ion as a function of the ionic strength of solution. Models that incorporate Debye-Hückel's theory and equations enable geochemists to predict the complex speciation of solutes in aqueous solutions from thermodynamic principles (See ▶ "Activity and Activity Coefficients"; ▶ "Aqueous Solutions"; ▶ "Complexes"; ▶ "Geochemical Thermodynamics").

Debye-Hückel Models

There are a number of theoretical expressions of the Debye-Hückel model, the primitive Debye-Hückel model describes long-range Coulombic forces between dissolved ions where the solvent acts as a structureless dielectric continuum and solutes are defined as hard spheres with a charge at the center (See "Electrolyte Theory"). Coulombic interactions between dissolved ions tend to promote ordering of negatively charged anions around positively charged cations, and vice versa, leading to a decrease in the thermodynamic free energy of the system (See ▶ "Free Energy") compared to if the dissolved ions were distributed randomly in solution. If ions are considered to be point charges then Coulombic interactions between ions will lead to a Boltzmann distribution of ions around one another and the Debye-Hückel limiting law is defined as:

$$\log_{10}\gamma_i = -Az_i^2\sqrt{I} \quad (1)$$

where A is a constant that is dependent on temperature and pressure, z_i is the charge on the ion (i) and I is the ionic strength defined by the equation:

$$I = \frac{1}{2}\sum_i m_i z_i^2 \quad (2)$$

where, m_i is the molal concentration of the ion (i). Equation 1 is only valid for very low ionic strengths ($I < 10^{-3}$ molal) due to the assumption of ions being point charges. The Debye-Hückel model can be extended to higher ionic strengths by considering that ions have a finite diameter, yielding the equation:

$$\log_{10}\gamma_i = \frac{-Az_i^2\sqrt{I}}{1 + B\mathring{a}\sqrt{I}} \quad (3)$$

where B is a constant that is dependent on temperature and pressure and $\mathring{a}$ is the distance of closest approach equivalent to the hydrated radius of the ion in Angstroms.

Equation 3 is generally valid for $I <= 0.1$ molal for monovalent ions, but lower ionic strengths for multi-valent ions and mixed electrolyte solutions. The parameter $\mathring{a}$ can be varied for different ionic species, as would be expected due to different ionic complexes having different hydrated radii, however doing so violates the assumption of the Debye-Hückel model that all ions are hard-spheres of the same diameter and thermodynamic relationships can no longer be satisfied (See ▶ "Geochemical Thermodynamics"). As such, some variations of Eq. 3 assume the $B\mathring{a}$ term is constant regardless of ion type, e.g., where $B\mathring{a} = 1$ it is known at the Güntelberg equation. Varying $\mathring{a}$ for different ions is often used in the implementation of the Debye-Hückel model in various thermodynamic databases for geochemical modeling programs (e.g., WATEQ: Truesdell and Jones 1974; EQ3/6: Wolery and Jarek 2003).

W. M. White (ed.), *Encyclopedia of Geochemistry*,
https://doi.org/10.1007/978-3-319-39312-4

At higher ionic strengths the primitive Debye-Hückel models become inaccurate due a number of effects and underlying assumptions. Real solutes are not hard-spheres with a central charge and the hydration state of ions can change with increasing ionic strength and vary between different ionic complexes (i.e., different values for $\mathring{a}$). Ion association (See ▶ "Complexes") becomes increasingly important at higher ionic strengths and hard-core effects become important (Pitzer 1973). Attempts to expand the Debye-Hückel model further to account for ion association at higher ionic strengths have included an extra ionic strength dependent term:

$$\log_{10}\gamma_i = \frac{-Az_i^2\sqrt{I}}{1 + B\mathring{a}\sqrt{I}} + bI \quad (4)$$

where b is a constant that may or may not be ion specific. Various expansions of the Debye-Hückel equation of this nature are collectively referred to as specific ion interaction theory, one form of which is the Davies (1962) equation.

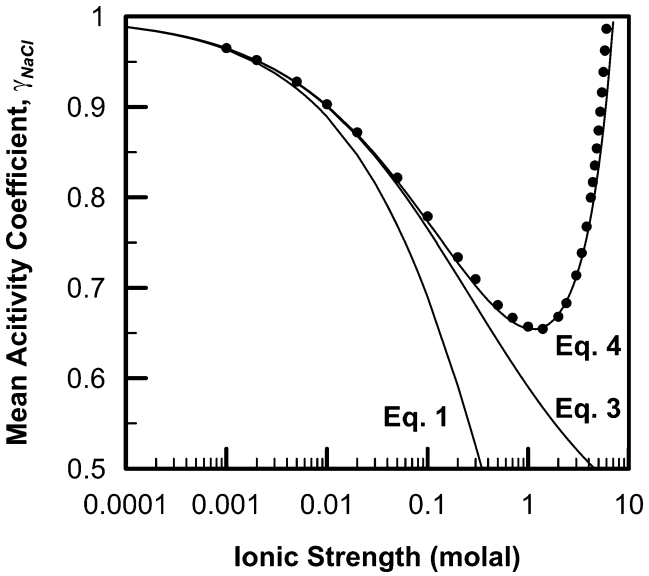
Care must be taken when computing the value for the constant A depending upon whether the form of the Debye-Hückel model being used is written as ln γ or $\log_{10}\gamma$ and similarly care must be taken with the units of the constant A being on the same length scale used for parameter $\mathring{a}$. Analytical expressions for the constants A and B from 25 °C to 600 °C and 0.001–5 kbar pressure can be found in Helgeson and Kirkham (1974).

Model Comparison to Experiments

Activity coefficients for individual ions cannot be measured, as such, measured values for the mean activity coefficient of NaCl (γ_{NaCl}) at various ionic strengths are plotted in Fig. 1 (Robinson and Stokes 1965; Haynes 2015–2016) and compared to calculations using the Debye-Hückel models presented here (Eqs. 1, 2, 3, and 4). Since Eqs. 1, 3 and 4 calculate activity coefficients for individual ionic species (Na^+ and Cl^-), the mean activity coefficient is determined using the following equation:

$$\gamma_{NaCl} = \sqrt{\gamma_{Na^+}\gamma_{Cl^-}} \quad (5)$$

At high enough dilutions Debye-Hückel models fit measured activity coefficients for solutes very well, however, the monotonic decrease of the activity coefficient predicted by Eqs. 1 and 3 with increasing ionic strength is no longer observed in solutions of high ionic strength ($I >$ c. 1.2 molal) where the activity coefficient exponentially increases (Fig. 1). Debye-Hückel models such as that presented in Eq. 4 can be empirically fit to experimental data (e.g., Fig. 1).



Debye-Hückel Equation, Fig. 1 Mean activity coefficients for NaCl at 25 °C as a function of ionic strength. Experimental data plotted as circles (Robinson and Stokes 1965; Haynes 2015–2016). Results using Eqs. 1, 2, 3, and 4 and with Eq. 5 are plotted as lines using: $\mathring{a}_{Na} = 4$; $\mathring{a}_{Cl} = 3.5$; $b_{Na} = 0.075$; $b_{Cl} = 0.015$ (Truesdell and Jones 1974)

Summary and Conclusion

The Debye-Hückel equation and models derived from the underlying electrolyte theory allow geochemists to model the behavior of ionic solutes in dilute aqueous solutions. The expanded version of the Debye-Hückel equation presented in Eq. 4 fits experimental data for NaCl up to much higher ionic strengths (close to the solubility limit for NaCl, Fig. 1). However, the most successful specific ion interaction theory models expanding on the Debye-Hückel equation are those of Pitzer (1973). Pitzer's equations account for secondary and tertiary ion-pair interactions through a virial expansion of the Debye-Hückel model and can successfully model systems containing single and multiple electrolytes to high ionic strengths. For further reading see Pitzer (1973) and implementation of the Pitzer equations to geochemical modeling (Wolery and Jarek 2003).

Density Functional Theory

David A. Dixon
Department of Chemistry, University of Alabama, Tuscaloosa, AL, USA

Definition

Density functional theory is an approach to solving the Schrödinger equation for the motion of electrons in molecules (as well as atoms) based on the concept that the energy is a functional of the density. In principle, it is an exact theory if the density and the functional are known. In practice, the exact form of the functional is not known. This method is another way to solve the Schrödinger equation for the electronic motion of electrons in atoms and molecules in addition to molecular orbital theory. It has been extensively applied to both molecules and solids and is probably the most common method in use today for electronic structure calculations.

Overview

Density functional theory (DFT) can be used to determine the ground state energy of the system as well as to predict a wide range of properties including structures, spectra, energetics, and charge distributions (Parr and Wang 1989; Dreizler and Gross 1990; Labanowski and Andzelm 1991; Seminario and Politzer 1995; Laird et al. 1996; Springborg 1997; Sholl and Steckel 2009). Rather than solving the Schrödinger equation explicitly as in molecular orbital theory, one uses a theorem (Hohenberg and Kohn 1964) which states that the exact energy is a functional of the density ρ. This means there is a one-to-one correspondence between the electronic energy and the electron density. The foundation for the use of DFT methods in computational geochemistry was the realization that the external potential is determined, within an additive constant, by the electron density (Kohn and Sham 1965). Since the wave function is a functional of the electron density, it follows that the density also determines the ground state wave function and all other electronic properties of the system. Because ρ determines N (the number of electrons) and v (the external potential) and hence all the properties of the electronic ground state, we can write the energy to explicitly depend on v:

$$E_v[\rho] = T[\rho] + V_{ne}[\rho] + V_{ee}[\rho] = \int \rho(r)v(r)dr + F_{HK}[\rho] \quad (1)$$

where

$$F_{HK}[\rho] = T[\rho] + V_{ee}[\rho] \quad (2)$$

We write $V_{ee}[\rho] = J[\rho] + E_{xc}[\rho]$, where $J[\rho]$ is the classical repulsion and $E_{xc}[\rho]$ is a nonclassical term referred to as the "exchange-correlation energy." The first and second terms correspond to the kinetic energy of the electrons and to the classical Coulomb electronic-nuclear attraction term, respectively. The $E_{ne}[\rho]$ and $J[\rho]$ terms are given by their classical expressions (Eqs. 3 and 4), and the factor of ½ in the $J[\rho]$ functional allows for the integration over all space for both variables:

$$E_{ne}[\rho] = \sum_a \int \frac{Z_a \rho(r)}{|R_a - r|} dr \quad (3)$$

$$J[\rho] = \frac{1}{2} \iint \frac{\rho(r)\rho(r')}{|r - r'|} dr dr' \quad (4)$$

The last term, E_{xc} the exchange-correlation energy, contains all of the many-body contributions to the energy. If the form of this term were known exactly, then one could solve for the total energy using Eq. 1, but, the exact form of this term is not known, so it is necessary to use some approximation for E_{xc}. The last term contains the exchange energy $K[\rho]$ and the correlation energy. For a noninteracting uniform electron gas, $T[\rho]$ and $K[\rho]$ are given by Eqs. 5 and 6:

$$T[\rho] = C_F \int \rho^{\frac{5}{3}}(r) dr \quad (5)$$

$$K[\rho] = -C_x \int \rho^{\frac{4}{3}}(r) dr \quad (6)$$

with the coefficients C_F and C_x given by

$$C_F = \frac{3}{10}\left(3\pi^2\right)^{\frac{2}{3}} \tag{7}$$

$$C_x = \frac{3}{4}\left(\frac{3}{\pi}\right)^{\frac{1}{3}} \tag{8}$$

The second Hohenberg-Kohn theorem provides the energy variational principle, $E_0[\rho_0] < \mathrm{E}_0[\rho]$ for $\rho_0 \neq \rho$; the exact energy for the ground state is obtained for $\rho_0 = \rho$. This is analogous to the variational principle for wave functions from molecular orbital theory.

Although DFT has been around since the mid-1960s, it is only recently (since ~ 1990) that its application to chemical, including geochemical, problems has become popular. This was because of the development of new approaches to solve the DFT equations implemented in software used by chemists coupled with exchange-correlation functionals that could be applied for use in chemical molecular problems. In addition, DFT works very well for many chemical systems with a reduced computational cost. For about the same cost of doing a Hartree-Fock calculation, DFT usually includes a significant fraction of the electron correlation energy. Note that DFT is *not* a Hartree-Fock method, nor is it (strictly speaking) a post-Hartree-Fock method. The wave function is constructed in a different way (the spin and spatial parts are different to those developed in Hartree-Fock theory), and the resulting orbitals are often referred to as "Kohn-Sham" orbitals.

The computer programs that actually solve the DFT equations have much in common with Hartree-Fock electronic structure programs, and chemical theorists initially adapted their Hartree-Fock programs to perform DFT computations, although there were a number of codes that were developed just for DFT. Like Hartree-Fock, the DFT equations must be solved self-consistently, making DFT another type of self-consistent field (SCF) method. Instead of focusing on wave functions and orbitals, DFT focuses on the electron density, although molecular DFT calculations usually employ orbitals to get the density. As it includes an approximate treatment of electron correlation, it should be more accurate than Hartree-Fock theory. There are many different variations of DFT, depending on the particular treatment of correlation and exchange, i.e., the choice of the exchange-correlation functional. The main drawback of DFT is that as the exact form of the exchange-correlation functional is not known, improvements to the functional are not straightforward. This contrasts with other *ab initio* electronic structure methods, where one can keep improving the results until the electronic Schrödinger equation is solved exactly. The reason DFT is broadly used is that it tends to give very accurate results much more cheaply than many competing MO-based methods, especially for molecules containing transition metals.

Functionals

The two input computational parameters for the solution of the Schrödinger equation for a system using DFT are the exchange-correlation functional and the functions used to represent the electrons, the one-particle basis set. At the present time, there is no formal systematic way of choosing the functional, and the most popular ones in the literature have been derived by careful comparison with experiment as well as meeting the formal criteria for a functional (Scuseria and Staroverov 2005). Examples of commonly used functionals are given in Table 1. The selected examples of DFT exchange-correlation functionals consist of (1) local spin density approximation (LSDA), (2) generalized gradient approximations (GGA), (3) meta GGA (mGGA), (4) hybrid GGA (HGGA), and (5) hybrid meta GGA (HmGGA) functionals. We note that Perdew and coworkers have called the hierarchy of functionals the "Jacob's ladder of functionals"(Perdew and Schmidt 2001; Tao et al. 2003; Perdew et al. 2005). The first level of approximation usually used is the local density approximation, and this is usually taken as Slater exchange together with the correlation energy of the uniform electron gas. This functional depends only on the density. The LSDA for the exchange-correlation functional in DFT is well known for its accuracy in predicting properties such as lattice parameters and bulk moduli in metallic systems. However, the LSDA results for electronic properties are of lower quality, because of intrinsic deficiencies, including missing self-interaction corrections and the absence of the derivative discontinuity in the exchange-correlation potential.

The functional can be improved by incorporating gradient (nonlocal) corrections to the exchange and correlation energy (GGA). A third type of functional, called hybrid GGA (HGGA), is a gradient-corrected functional that includes some components of HF exact exchange. For molecules, hybrid exchange-correlation functionals often show improvement in the prediction of energetics over those from GGA functionals because the hybrid functionals help to delocalize the exchange hole. Hybrid functionals have proven to be equally good at predicting a range of physical properties, but such calculations in the solid state are computationally expensive due to the need to calculate Hartree-Fock exchange (Kudin et al. 2002). Commonly used GGAs are B88P86, PBE, and PW91. B3LYP is the most commonly used HGGA by a wide margin.

Weak interactions such as those involving van der Waals interactions or hydrogen bonding are important for geochemical applications. As hydrogen bonding has some electrostatic

[a]Long range corrected exchange correlation functional.

D

or dipolar component, a number of functionals can provide reasonable hydrogen bond energies, although if there are a large number of such interactions, the total error may not be small. On the other hand, most common DFT functionals do not handle dispersion corrections properly. One approach is to add in a set of atom-pairwise empirically based corrections as developed by Grimme and coworkers, the –D3 correction, for example (Grimme 2006; Grimme et al. 2010). Another approach is to add on a more formally developed correction based on the electron density a van der Waals nonlocal functional, which is added to commonly used exchange and correlation components, such as the VV10 functional (Vydrov and Van Voorhis 2009, 2010). These different types of corrections have been evaluated (Hujo and Grimme 2011, 2013; Mardirossian and Head-Gordon 2014).

The use of approximate exchange-correlation functionals allows one to solve the density functional equation exactly for an approximate energy expression, whereas molecular orbital methods solve an exact expression for the energy approximately. An advantage of many DFT functionals without exact exchange is that they formally scale as N^3 as compared to the N^4 scaling of Hartree-Fock theory and the N^5–N^7 scaling of common correlation methods. Thus, DFT methods, if derived without the inclusion of Hartree-Fock exchange, are computationally much cheaper than Hartree-Fock-based methods and exhibit a much better scaling with the size of the molecule. In fact, the Hartree-Fock method is a special case of DFT with the exchange term computed exactly and the correlation term equal to zero.

Other Features of DFT

An important use of DFT is to predict spectroscopic properties. The prediction of infrared and Raman vibrational spectra including intensities for molecules follows the second derivative methods developed for molecular orbital theory. UV-vis spectra can be calculated using time-dependent density functional theory (TD-DFT) (Bauernschmitt and Ahlrichs 1996; Casida et al. 1998). Nuclear magnetic resonance chemical shifts can be calculated using the gauge invariant atomic orbital (GIAO) approach (Wolinski et al. 1990) with density functional theory (Schreckenbach and Ziegler 1995, 1996, 1997). It is also possible to include relativistic effects in the zeroth-order regular approximation (ZORA) for the NMR chemical shifts (Wolff and Ziegler 1998; Wolff et al. 1999; Autschbach and Ziegler 2004).

As DFT developed as a broad-based chemical tool for predicting structures and energetics, there has been a continued development of the method for providing insights into chemical bonding and reactivity. This approach is often called conceptual DFT (Geerlings et al. 2003, 2014; De Proft et al. 2014). For example, it provides formal definitions of hardness and softness, the basis of hard-soft acid/base theory as well as electronegativity.

Solid State and Plane Waves

DFT calculations on solids are done with periodic boundary conditions. Plane waves are usually used rather than the Gaussian-type orbitals used in molecular calculations although the latter can be used in solid-state calculations. Plane waves are used in the electronic structure because they fit more naturally with the Bloch states and they are expanded in Wannier functions. In addition, they do not have the problems that Gaussian orbitals have in calculating diffuse parts of the wave function. The periodic calculations can be performed using the projector augmented wave (PAW) method, which deals with the full wave functions and allows the treatment of all elements in the periodic table (Blöchl 1994). Such calculations usually employ pseudopotentials so that calculations are only performed on the valence electrons as the contracted size of the inner shell orbitals makes it difficult to calculate these electronic states using plane waves. Ultrasoft pseudopotentials (Vanderbilt 1990) are broadly used and, for example, allow first-row transition metal elements to be dealt with in an economical manner.

Several approaches to improving the quality of band gaps including LSDA + U, which relies on LSDA-optimized lattice parameters, and many-body perturbation theory in the framework of the Green's function (GW) method have been developed (Grossman et al. 2001; Onida et al. 2002). Although these approaches predict improved band gaps, just like hybrid functionals, they are computationally demanding and are usually applied only to small systems. By using a screened hybrid functional that includes nonlocal Hartree-Fock exchange but decomposes the Coulomb operator into short-range and long-range components, such as that in the HSE functional (Heyd et al. 2003), it is possible to accurately and efficiently predict semiconductor and insulator band gaps (Prodan et al. 2007).

Conclusions

Density functional theory is an important tool for predicting the properties of geochemical systems based on their electronic structure. It is important to choose a properly benchmarked exchange-correlation functional together with an appropriate basis set. DFT can provide a broad

range of structural, energetic, and spectroscopic predictions that can be used to obtain detailed insights into geochemical systems at the molecular level. DFT is currently the most popular computational electronic structure method for geochemical applications, especially for predictions in the solid state or at extended interfaces. DFT can also provide qualitative insights into molecular reactivity through the use of conceptual DFT.

Diagenesis

Isabel P. Montañez[1] and Laura J. Crossey[2]
[1]Department of Earth and Planetary Sciences, University of California, Davis, CA, USA
[2]Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, NM, USA

Synonyms

Diagenesis classified by setting and evolutionary stage of sedimentary basins: Eogenetic or *eodiagenesis* (near surface and shallow burial), *mesogenetic* or *mesodiagenesis* (deeper burial), and *telogenetic* or *telodiagenesis* (uplifted succession) (Choquette and Pray 1970).

Diagenesis classified by process: Syndiagenesis (biogeochemical processes at the sediment-water interface through shallow burial), *anadiagenesis* (dominantly physicochemical processes under deeper burial or orogenic conditions), and *epidiagenesis* (biogeochemical processes associated with fluid flow during uplift) (Fairbridge 1967).

Catagenesis (late, deep-burial diagenesis, referred by some as "burial metamorphism" as it incorporates the earliest stage of metamorphism).

Definition

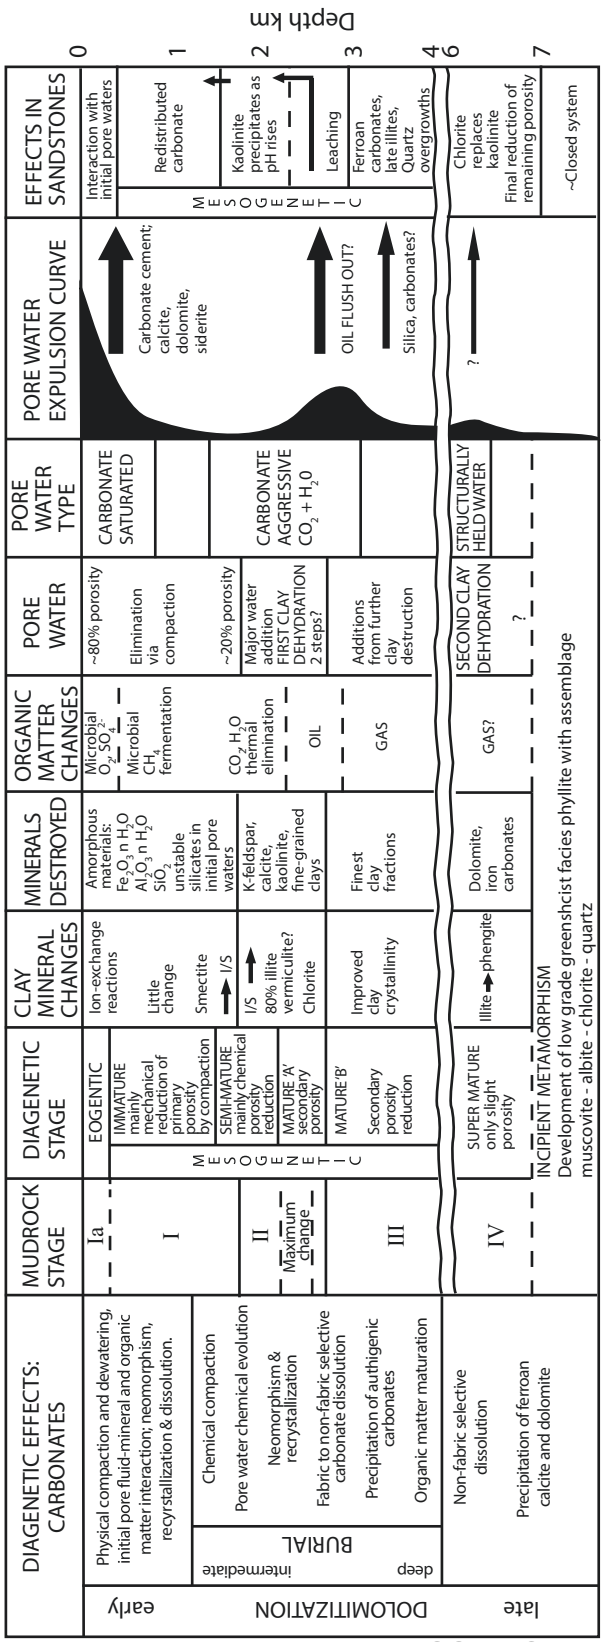
Diagenesis is the sum total of physical, chemical, and biological processes that occur in sediments and sedimentary rocks from immediately after deposition through to the metamorphic realm. No universal definition exists for diagenesis and the term has evolved since it was defined nearly 150 years ago (de Segonzac 1968). It is generally agreed that diagenetic processes occur under Earth surface conditions (~0–30 °C and 1 bar of pressure) to temperatures of ≤250 °C and pressures of up to 2.5 kb (7 km) involving a broad range of fluid compositions from fresh water to concentrated brines (Fig. 1). Diagenesis involves both the conversion of sediments into sedimentary rock and the subsequent changes that occur prior to entering the metamorphic realm. There is no distinct boundary between the culmination of diagenesis and the onset of metamorphism nor between early diagenesis and weathering. The process of diagenetic conversion begins at the sediment-water interface in marine and terrestrial depositional sites, which have sufficient accommodation space to accumulate and preserve sediments, and continues to influence mineral and organic matter throughout its burial in sedimentary basins and associated tectonic history. Given the high reactivity of many minerals and organic matter within sediments and sedimentary rocks and the evolving nature of pore fluid temperature and chemistry, diagenesis is a continually active process with a protracted history of physical and chemical processes that lead to dissolution, chemical transformation of mineral components, precipitation of new mineral cements, and maturation of organic matter. Many resources such as coal, oil, gas, and ore deposits result from diagenetic processes.

D

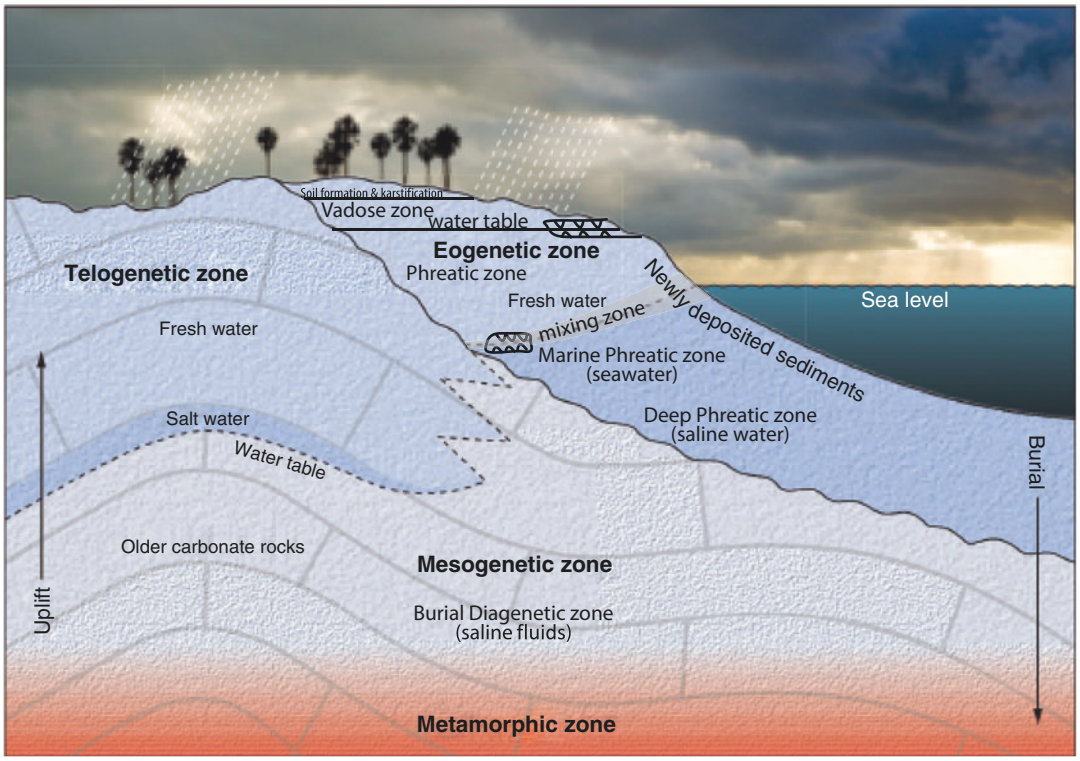
The Diagenetic Cycle

The diagenetic cycle begins immediately following deposition on the ocean, lake, or channel/floodplain floor and continues through shallow- to deep-burial, and for many sediments ends with exposure above sea- or base-level where erosion, chemical weathering, and other diagenetic processes take place. Water and organic matter decomposition are the agents of diagenesis providing the fuel for the chemical and microbial processes that act on newly deposited detrital siliciclastic materials and chemically precipitated minerals, such as carbonates, amorphous silica, and evaporites (Ali et al. 2010). The course of diagenesis is dictated by sedimentary factors such as particle size and mineralogic composition, fluid-rock ratio, fluid chemistry and flow rates, organic matter content, the presence of microbial communities, as well as environmental conditions (temperature, fluid chemistry, pressure). In turn, diagenetic processes can change the chemical properties of the pore fluids over time, causing additional changes to mineralogy, fluid composition, and petrologic properties. Figure 1 summarizes many aspects of diagenesis. Figure 2 places these processes in a schematic cross section and provides a framework for the conditions under which diagenesis occurs.

- The ***early diagenetic realm*** (eogenesis or eogenetic zone, Fig. 2) occurs during burial to a few hundred meters and involves changes to the sediment, organic matter it hosts, and the interstitial fluids (pore water) by surface-related processes under near surface temperatures (≤30 °C). Diffusion of gases (e.g., oxygen, carbon dioxide, hydrogen sulfide, and methane) can also influence the geochemical environment. Early diagenesis typically involves dewatering of fine-grained sediments by gravitational compaction, bioturbation by burrowing organisms, dissolution of unstable minerals, diffusion of dissolved cations (e.g., Ca^{2+}, Mg^{2+}, Fe^{2+}, Mn^{2+}, Sr^{2+}), anionic species and gases (e.g., SO_4^{2-}, HCO_3^-, O_2, CO_2, CH_4, H_2S) through the sediment, bacterial decomposition of organic matter, transformation (neomorphism or recrystallization) of



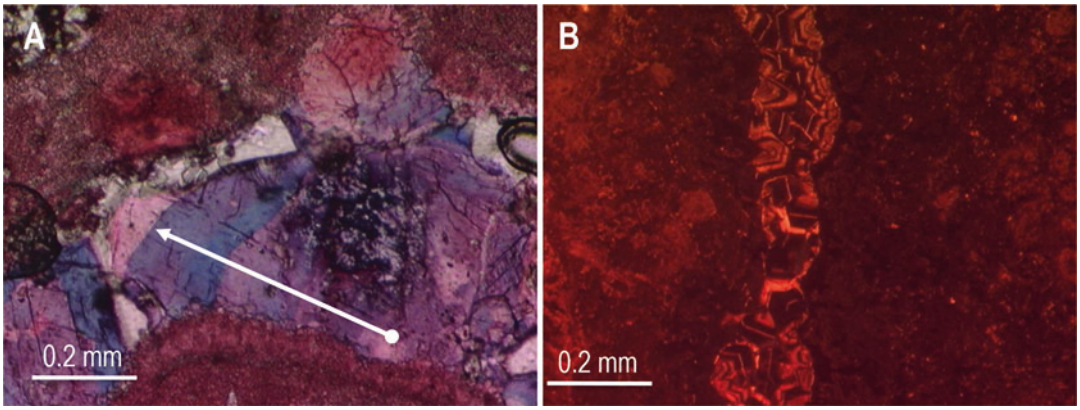
Diagenesis, Fig. 1 Matrix illustrating different aspects of diagenesis. The matrix is arranged with increasing depth (temperature) toward the bottom, and different sedimentary components in the columns (Modified from Burley et al. (1985))



Diagenesis, Fig. 2 Summary of diagenetic realms. Sediments deposited in Earth surface environments pass through the diagenetic cycle post deposition, which can include the eogenetic zone (early diagenetic realm), the mesogenetic zone (burial diagenetic realm), and the telogenetic zone (exposure) (Modified from Ali et al. (2010))

unstable minerals, and precipitation of authigenic carbonates, oxides, hydroxy-oxides, aluminosilicates, sulfates, and sulfides. Sedimentation rate controls the degree of physical compaction and dewatering of sediments as well as the depths of bioturbation and cation/molecule diffusion rates. Most early diagenetic chemical reactions are driven by the reactivity of metastable minerals (e.g., amorphous silica, aragonite, high Mg-calcite, dolomite) or phyllosilicates. Many early diagenetic processes involve the kinetic boost by bacteria, referred to as bacterial mediation. Empirical studies of the early diagenetic realm involve outcrop studies and coring of marine and lake sediments and analysis of sediment mineralogy, texture, and grain size distribution, pore-water chemistry, and in recent years, the composition of associated microbial communities.

- Sediments continue to undergo geochemical modification in the ***burial diagenetic realm*** (mesogenesis or mesogenetic zone, Fig. 2) involving processes that are no longer directly related to the surface including chemical compaction (pressure solution), dissolution, precipitation of authigenic minerals (i.e., cementation), and organic matter maturation. This diagenetic realm is commonly partitioned into the intermediate burial (between 500 and 2000 m depth) and deep burial ($\geq$ 2 km) zones. Elevated temperature and pressure play a major role in driving the physicochemical reactions in the burial diagenetic realm. The chemical composition of pore waters evolves with depth, typically becoming more saline, due to fluid-rock interactions such as dewatering of clays and dissolution of buried evaporites. Maturation of organic matter releases organic acids and contributes toward lowering pH and changing redox conditions of interstitial fluids (Surdam and Crossey 1987; Harrison and Thyne 1992). Consequently, minerals, which were initially stable in the shallow diagenetic realm, become metastable with burial driving dissolution and precipitation of authigenic minerals such as calcite, dolomite, anhydrite, silica, zeolites, and clay mineral transformations. Overall, cementation is thought to dominate over dissolution in the burial diagenetic realm (Ali et al. 2010).
- Exposure of sedimentary rocks above base level by tectonic uplift (telogenesis) or sea-level fall exposes them to atmospheric processes and physical erosion and chemical weathering. Meteoric (fresh, dilute) waters can penetrate deeply into exposed or tectonically uplifted sedimentary rocks through permeable units or fracture porosity and develop extensive karst and dissolution features in carbonate-dominated successions (telogenetic zone, Fig. 2).



Diagenesis, Fig. 3 Photomicrographs of carbonate. (**a**) Stained (Alizarin *Red* and potassium ferricyanide) thin section showing calcite cement sequence (paragenesis) in a calcite spar cement that occludes a primary pore developed between grains (*pink*); thin marine cement and freshwater cement rims (*pink* staining are developed on grains. *White* triangular cement lining pores are dolomite. (**b**) Cathdoloumінescent zoning in calcite cement occluding porosity in a fracture (or between grains). The alternating bright luminescent and nonluminescent banding of the cement records the migration of multiple generations of calcite-precipitating fluids

- Tectonic forces and sea level fluctuations lead to cycling of sediments and sedimentary rocks between the diagenetic realms resulting in multiple cycles of dissolution, cementation, mineral transformation, and recystallization until a steady state or equilibrium is reached. The extent and nature of diagenesis will reflect the reactivity of the initial sediment, its fluid-rock interaction history including fluid-rock ratios and exposure time to each diagenetic zone.
- Where multiple diagenetic events have influenced a sedimentary rock, the paragenetic sequence of these events (Fig. 3) can be reconstructed by integrating microscope (thin sections to scanning electron microscopy) and geochemical studies of the sedimentary rocks and their fluid inclusion waters as well as associated organic matter. Diagenetic transformation of sedimentary rocks can substantially impact their porosity and permeability and in turn their fluid conduit and aquifer or reservoir potential (Montañez 1997).

Methods Applied to Study of Siliciclastic and Carbonate Rocks

Petrographic study of thin sections employing the optical microscope forms the basis for understanding the composition (mineralogy), spatial and textural relationships between detrital grains, authigenic minerals, and pore geometries (Fig. 3). Optical examination is aided by specialized preparation (impregnation of the rock with colored epoxy to highlight porosity) and staining techniques for recognition of specific carbonate minerals (Fig. 3a) and feldspars as well as calcite cements of differing Fe^{2+} concentration (Nelson and Read 1990; also see Humphries (1992) for a guide to thin section preparation methods). Cathodoluminescence study of thin sections (Fig. 3b) is commonly used to further identify textures and to define a paragenetic sequence for a given sample or suite of samples. A paragenesis is the sequence in which different minerals or generations of a given mineral (e.g., calcite) were precipitated. Carbonate cements exhibit varying shades of brown, red, yellow, and orange under cathodoluminescence due to incorporation of varying amounts of Fe^{2+} and Mn^{2+} into the crystal lattice. Cathodoluminescent zoning in carbonate cements reflects the Mn^{2+} to Fe^{2+} ratio of a given generation of carbonate cement, and in turn that of the fluid from which it precipitated. Authigenic feldspar overgrowths and cements are nonluminescent, whereas detrital cores and grains exhibit blue luminescence. Discrete generations of carbonate cements typically are identified by their coupled staining and cathodoluminescence (Fig. 3).

X-ray diffraction (XRD) is the preferred method for structural identification of fine-grained minerals, particularly in mudrocks. Moore and Reynolds (1989) provide a summary of preparation and analysis: Brindley and Brown (1984) and Newman (1987) provide detailed descriptions of clay minerals.

Geochemical analysis may include elemental and isotopic (both stable and radiogenic) approaches. While a comprehensive survey of all methods is beyond the scope of this overview, several common techniques will be mentioned. Electron microbeam techniques are powerful tools for in situ chemical and mineralogical examination of sedimentary rocks of all types. Scanning electron microscopy (SEM) is widely used to understand three-dimensional morphology, pore geometries, sequence of mineral growth, and more recently, microbe/mineral interactions (Banfield and Nealson 1997). Electron microprobe analysis (EMPA) provides quantitative chemical analyses of phases typically of 10 micron and greater size though specialized instruments may target smaller regions. This tool is generally restricted to major and minor element analysis. The secondary ion microprobe (SIMS) has gained

wide use in geoscience applications (see review in Stern 2009) and provides quantitative trace element and stable isotopic analyses in spatial context. Methods involving laser ablation in tandem with inductively coupled plasma mass spectrometry are providing new approaches to both elemental and isotopic analysis of sedimentary materials with excellent opportunities for application to diagenesis research (see examples in Rasbury et al. 2012). Integration of petrographic features with elemental and isotope analysis (carbon, oxygen, sulfur, and nitrogen) of authigenic phases, at times coupled with fluid inclusion study, has been effective in understanding conditions of formation and paleofluid composition in some cases (see summaries in Sharp 2007). Banner (2004) provides a comprehensive overview of applications of radiogenic isotopes to sedimentary systems.

Carbonate Diagenesis

Carbonates are minerals with a structural CO_3^{2-} group and Ca^{2+}, Mg^{2+}, or a combination of these two elements. Weight percent Fe^{2+}, Mn^{2+}, and Sr^{2+} occur in less common carbonates. Most carbonate sediments form in marine settings commonly with coexisting polymorphs of aragonite and low- ($\leq$5% $MgCO_3$) to high-Mg calcite (5–20% $MgCO_3$), as well as rarely dolomite (Moore 1989). Terrestrial carbonates form as low-Mg calcite and siderite in lacustrine, wetland, and spring deposits, low-Mg calcite and sphaerosiderites in soils, and low- to high-Mg calcite and aragonite in travertines and cave speleothems. This entry focuses on marine carbonates given their prevalence in the modern and geologic record; see reviews by Ford and Pedley (1996) and Capezzuoli et al. (2014) for freshwater carbonates.

Carbonate mineralogy in the marine realm is determined thermodynamically by mineral stability (solubility) and kinetically by substrate mineralogy, biological effects, differences in precipitation rates, and the presence/absence of organic compounds and inorganic inhibitors (e.g., SO_4^{2-}, PO_4^{3-}, Mg^{2+}) (Burton 1993). Biological effects include microbial mediation and vital effects. With the exception of low-Mg calcite, all of these carbonate mineralogies are thermodynamically metastable (high Mg-calcite, aragonite, non-stoichiometric dolomite) at Earth surface conditions and will convert to stable low-Mg calcite or stoichiometric dolomite during subsequent exposure to evolved marine pore waters, introduction of meteoric fluids, and/or interaction with saline brines during burial (Walter 1985).

Early Diagenetic Realm

For shallow-water carbonates, extensive diagenesis occurs proximal to the sediment-fluid or atmosphere interface due to repeated flushing by seawater or freshwater (eogenetic zone, Fig. 2). Their metastable mineralogy makes them highly susceptible to post-depositional mineralogical and geochemical alteration as the pore fluid chemistry evolves with fluid mixing and chemical reactions (Moore 1989; James and Choquette 1990). Diagenesis at the sediment-seawater interface begins with boring by endolithic algae, sponges, and fungi, which replace primary skeletal carbonate with clay-size carbonate precipitates (micrite), a process called micritization. Within the first few centimeters to meters of burial, dissolution of high-Mg calcite and aragonite releases bicarbonate (HCO_3^-) that along with fluid CO_2 degassing promotes neomorphism and recrystallization of grains, carbonate cementation, and calcite overgrowths on biotic templates. Neomorphism involves the molecular-scale replacement of an unstable phase of carbonate by thermodynamically more stable low-Mg calcite. Recrystallization of grains and early cements involves the wholesale dissolution of the original carbonate and simultaneous precipitation of a more stable phase resulting in a possible volume change and loss of original textures. Recrystallization occurs in both carbonates and siliciclastic deposits. These early diagenetic processes lead to preservation of much of the original fabric and retard compaction in shallow-water marine carbonates. Dissolution of aragonitic fossils and matrix creates secondary moldic or vuggy porosity.

In contrast to shallow-water carbonates, the predominance in deep-sea sediments of stable low-Mg calcite causes delay in dissolution and cementation. The presence of small amounts of calcite overgrowths and cements on shells and shell recrystallization indicates localized regions of carbonate dissolution and diffusion/advection to areas of calcite cementation (Moore 1989). Oxidation of organic matter buried with carbonate sediments provides HCO_3^- to pore fluids for carbonate precipitation. Pore water profiles of the oxygen ($\delta^{18}O$) and calcium ($\delta^{44}Ca$) isotopic composition and trace element concentrations are used to model the rates of carbonate recrystallization in deep-sea sediments (Fantle et al. 2010). Gravitational compaction of deep-sea sediments in the shallow burial realm (within the first 200 m of burial) is a major influence on lithification and leads to substantial loss of porosity (from ~80% to $\leq$50–60%).

The diagenetic evolution of carbonate sediments, which were deposited on the slopes surrounding shallow-water carbonate platforms, falls between that of deep-sea sediments and shallow-water marine carbonates. This reflects the mixing of a pelagic low-Mg calcite source with a platform-shed source of reactive aragonite and high-Mg calcite as well as overall higher concentrations of organic matter (Swart 2015). Thus, periplatform carbonates may undergo extensive dissolution and cementation during initial burial making them more resistant to compaction than deep-sea sediments.

Meteoric diagenesis: The vast majority of carbonates are deposited during sea level highstands when shallow water platforms are inundated (Ali et al. 2010). These carbonates

are subsequently exposed to freshwater, which is undersaturated with respect to carbonates, during subsequent drop in base level whether driven by eustasy or tectonic uplift (telo- or epidiagenesis). Meteoric diagenesis occurs over a series of near-surface (eogenetic) diagenetic zones (Fig. 2) including soil formation and karstification and vadose, phreatic, and mixing zones (see reviews by Moore 1989; James and Choquette 1990). Overall, freshwater reactions with metastable carbonates result in extensive stabilization (through neomorphism or recrystallization) of carbonate grains, superimposed generations of dissolution and low-Mg calcite cementation, as well as substantial redistribution of pore space. The degree of diagenetic alteration is dictated by the reactivity of the initial mineralogy, the pore fluid chemistry, fluid-rock ratios, and flow rates.

Diagenesis in the freshwater undersaturated vadose zone is characterized by seepage flow through intergranular porosity and conduit flow through solution-enlarged fissures (Fig. 2). Vadose waters are typically CO_2-charged and chemically aggressive given exchange with the atmosphere and with soil-formed CO_2. Rapid conduit flow leads to extensive, non-mineral selective dissolution. Rates of calcite precipitation are far slower than fluid flow rates, thus as dissolution proceeds fluids become oversaturated with respect to low-Mg calcite and precipitate cements down-flow (Moore 1989). Freshwater that percolates slowly through the vadose zone by diffuse flow promotes mineral-controlled diagenesis, which is controlled by the differing solubilities of the carbonate polymorphs. Aragonite is 1.5 times more soluble than low-Mg calcite at a given temperature, whereas high-Mg calcite, whose solubility increases with Mg content, can be up to an order of magnitude more soluble than low-Mg calcite (Walter 1985). Dissolution of more soluble carbonate under the slow diffuse flow rates leads to oversaturation with respect to low-Mg calcite proximal to the site of dissolution driving widespread fabric-retentive neomorphism, recrystallization, and precipitation of vadose calcite cements (e.g., pendant and meniscus cements, crystal silt, fine crystalline equant cements unevenly lining primary porosity). The end-product can be wholesale transformation of metastable carbonates to thermodynamically stable low-Mg calcite while retaining much primary texture and fabric. This conversion process, however, is slow (on the order of 10^6 year) reflecting the overall low water-rock ratios of the vadose zone.

The water table (Fig. 2) delineates the boundary between the vadose and underlying saturated phreatic zone. High flow rates and turbulent exchange at the water table promotes CO_2 dissolution into water or high CO_2 degassing rates making this region a dynamic zone of dissolution and low-Mg cementation (Moore 1989; James and Choquette 1990). The phreatic zone hosts the bulk of dissolution and cementation by freshwater. Exposure of marine carbonates due to sea level fall leads to deep penetration of meteoric water given that the freshwater phreatic lens will develop to depths of ~40 times the height of the water table above sea level (Ghyben–Herzberg principle). Diagenetic processes in the shallow phreatic zone are orders of magnitude faster than in the vadose zone reflecting overall higher flow rates and fluid-rock ratios. In this zone, low-Mg calcite cements form isopachous rims of equant to bladed crystals on grains and within moldic porosity and microspar cements partially to fully occlude porosity. Relatively rapid flow rates lead to large-scale transport of dissolved carbonate and Ca^{2+} down-flow resulting in extensive dissolution updip and cementation downdip.

Mineralogic stabilization within the phreatic zone (Fig. 2) occurs rapidly (10^4–10^5 year) relative to the vadose zone. Once stabilized, subsequent diagenetic modification is limited to minor cementation within conduits that focus fluid flow. The mixing zone (Fig. 2), at the interface between the freshwater phreatic zone and the underlying deep phreatic zone with saline continental or marine interstitial fluids, is a chemically active region given that physical and diffusive mixing of waters leads to nonlinear changes in carbonate mineral saturation. The mixing zone is a region of abundant secondary porosity and subsurface karst development (e.g., Boulder zone in the Tertiary Florida aquifer or the ceynotes of the Yucatan Peninsula). The different zones of meteoric diagenesis have characteristic stable (O and C) isotopic and trace element signatures that when coupled with stratigraphic and petrographic studies have been used to reconstruct the diagenetic history of carbonate successions. The reader is directed to Moore (1989) and Swart (2015) for a comprehensive review of the geochemistry of meteoric diagenesis. The deep phreatic zone (Fig. 2) is a shallow burial locale of substantially slower diagenesis given the slow fluid flow rates and low fluid-rock ratios. Low-Mg calcite and dolomite cements that form in this zone are typically large and blocky reflecting their slow growth rates under very low saturation states.

The meteoric diagenetic realm is dynamic with fluctuations in base level, whether driven by eustasy or tectonics, that induce repeated large-scale vertical migration of the marine, vadose, phreatic, and mixing zones through a sedimentary succession over time (Read and Horbury 1993). Throughout Earth history, sea level has fluctuated 10 s to 100 s of m over a spectrum of timescales (10^4–10^7 -year) driven by orbitally forced waxing and waning of ice sheets, atmospheric pCO_2 variability, and tectonic and mantle processes. These shifts in the meteoric diagenetic zones impart a mineralogic and geochemical signature that is characteristic of the magnitude of relative sea-level fluctuations and the climate regime under which they occurred (Read and Horbury 1993). Zonation in low-Mg calcite cements, discernible petrographically under transmitted light or by cathodoluminescence (Fig. 3) as well as by their geochemical compositions (Fe, Mn, Mg,

concentrations and $\delta^{18}O$ and $\delta^{13}C$ isotopic compositions), record changes in fluid conditions (redox, temperature, salinity) through time from which the spatial migration of the near-surface diagenetic zones can be reconstructed (Niemann and Read 1988; Nelson and Read 1990). In many cases, zoned phreatic cements capture multiple cycles of fluid change within a pore providing a strip chart of the eustatic fluctuations that affected a given carbonate succession (Read and Horbury 1993) even when deeply eroded by post-depositional processes (Bishop et al. 2009).

Intermediate-to-Deep Burial Diagenetic Realm

Ultimately, most sedimentary deposits are buried sufficiently (>1 km) by overlying sediments and rocks that they are introduced to the intermediate-to-deep-burial diagenetic realm (herein referred to as "burial diagenetic" or mesogenetic zone). The burial diagenetic zone (Fig. 2) begins proximal to the liquid oil window in hydrocarbon source rocks (Machel 2005). Formation temperatures are elevated above ~50 °C reaching conditions of over 100–200 °C, which enhances diagenetic reactions. The burial diagenetic realm is characterized by further chemical compaction and dissolution, mineral stabilization, and precipitation of cements. Depending on the clay mineral content and previous cementation history, chemical compaction can become a predominant process with the degree of pressure solution influenced by pore-water composition, mineralogy, degree of previous cementation, and the presence of organic matter. Grains or primary marine cements or earlier diagenetic precipitates, which were not previously stabilized, become thermodynamically metastable in the deep subsurface due to changing fluid conditions driving further recystallization and mineral replacement, including widespread dolomite replacement of limestone host rocks (Machel 2005).

Interstitial (formation) fluids in the deep-burial diagenetic environment range from brackish (< 35 weight percent) to hypersaline reflecting their interaction history with sedimentary rocks, including evaporites and siliciclastics, along their flow path and mixing with organic-rich fluids, which formed during hydrocarbon maturation. Fluid flow rates vary from near stagnant to moderately fast if an external hydraulic gradient is established by regional groundwater flow systems or dewatering of shale basins. At temperatures proximal to and within the oil window (~80–120 °C), thermal maturation of organic matter (decarboxylation) and other mineral reactions occurring in situ or in shale basins introduce organic-acid, CO_2-rich brines that can lead to extensive non-fabric-specific dissolution (Montañez 1994, 1997; Machel 2005). As these fluids evolve down-flow through wholesale dissolution and pressure solution, they become saturated and precipitate Fe- and Mg-rich calcite cements and Ca-rich dolomites (Montañez 1994). Dolomite, anhydrite, and silica (chert) replacement of limestones is common in the deep-burial diagenetic realm. Exposure of evaporite-rich deposits to hydrocarbon-bearing fluids at elevated temperatures promotes thermochemical sulfate reduction, which produces significant amounts of H_2S and water and precipitation of low-Mg calcite and pyrite, and possibly saddle dolomite (Swart 2015). At temperatures <80–100 °C, bacterial sulfate reduction dominates when dissolved sulfate is exposed to hydrocarbons.

Ultimately, tectonic processes may uplift deeply buried carbonate successions and expose them to meteoric conditions. For those carbonates, which were previously stabilized and lithified in near-surface to deep-burial diagenetic zones, the extent of dissolution and cementation in this telogenetic zone (Fig. 2) will be greatly reduced. Rather, diagenesis will occur as karstification and development of fluid conduits associated with fractures and joints.

Dolomitization

The origin of dolomite, particularly early diagenetic dolomite, remains elusive despite over a century of empirical and experimental studies. This reflects that dolomite ($CaMg(CO_3)_2$) is rare in modern environments but very common in ancient carbonate successions. Furthermore, constraints on the chemical and hydrologic conditions of dolomite formation are limited and the kinetics of dolomite precipitation are poorly understood (Machel 2004). Although seawater is ~1000 times oversaturated with respect to dolomite, it rarely forms in the marine realm given the need for a source and mechanism of steady Mg^{2+} supply (Swart 2015) and mechanism to overcome kinetic inhibitors (e.g., SO_4^{2-}). Thus, dolomite precipitation (i.e., primary dolomite) and replacement of $CaCO_3$ (i.e., dolomitization) at earth surface conditions require a mechanism to raise the saturation state of dolomite and provide the necessary high fluid-rock ratios for steady Mg^{2+} supply. Highly evaporative environments (arid climate tidal flats) and refluxing of evaporatively sourced brines through shallow-water carbonates (Montañez and Read 1992a), possibly in mafic parent-material or seasonally very dry soils (Capo et al. 2000) and fluids in which the alkalinity is increased by oxidation of organic matter provide such a mechanism for "early" dolomitization (Fig. 1; Machel 2004; Swart 2015). The fluid mixing zone at the interface between the freshwater phreatic lens and underlying deep phreatic zone has been invoked as a locale of dolomite formation (Fig. 2) given that fluid mixing leads to undersaturation with respect to calcite but high supersaturation with respect to dolomite. Dolomite, however, is absent from most modern-day mixing zones and ancient examples have been contested (Machel 2004; Swart 2015). Bacterial mediation is likely involved in the precipitation of many near surface dolomites (Vasconcelos et al. 1995), in particular in highly evaporative environments and/or organic-rich deposits. Early formed dolomites are typically poorly ordered and Ca-rich

(non-stoichiometric) and volumetrically minimal. These disordered and Ca-rich dolomites undergo stepwise recrystallization throughout burial, becoming more ordered and stoichiometric with time and with exposure to dolomitizing fluids (Montañez and Read 1992b). Progressive recrystallization overprints their original geochemical signature although a memory of the primary composition can be preserved.

Extensive dolomitization, however, likely occurs in the intermediate- (100 s m) to deep-burial realm (up to 1000s of m) (Fig. 1). This reflects the elevated temperatures needed to overcome kinetic inhibitors, the very high fluid-rock ratios, the hydrologic plumbing to provide the Mg^{2+} and CO_3^{2-} supply, and the time required to produce volumetrically large (massive) dolomites (Machel 2004). Normal seawater may be capable of extensive dolomitization at slightly elevated temperatures (50–80 °C) and moderate depths (few 100 meters) in regions of large-scale thermal circulation through isolated carbonate platforms (Kohout convection). Regional or basinwide dolomitization, however, likely develops through multiple generations of dolomite replacement of limestones and precipitation of dolomite cements (Montañez 1992, 1994). Hydrologic models invoked for regional dolomitization, in addition to thermal convection, include tectonically induced flow of basinal brines, funneled compaction flow, and rapid upward advection of hydrothermal fluids along faults (summarized in Machel 2004), although the latter process is likely limited in spatial scope. Integration of stratigraphy, petrographic (textures and cathodoluminescent zoning) features, and geochemical compositions of dolomite and its fluid inclusion waters has been effectively used to unravel the paragenesis of multigeneration massive dolomites (e.g., Montañez 1994) and to reconstruct the hydrology of dolomitizing environments (studies summarized in Machel 2004; Swart 2015; and Montañez 1992, 1994). Massive dolomites (dolostones) in the subsurface tend to have higher porosities than limestones making them excellent reservoirs (Montañez 1997). Enhanced porosity is attributed to (1) a 12% porosity increase during replacement given the smaller molar volume of dolomite relative to calcite, (2) dissolution of original calcite during burial dolomitization or during subsequent migration of low pH brines, and/or (3) thermochemical sulfate reduction.

Siliciclastic (Sandstones and Mudrock) Diagenesis

The diagenesis of siliciclastic grains encompasses the full range of grain sizes found in sedimentary systems. Siliciclastic systems usually are composed of a primary population of detrital grains and primary porosity. A summary of the controls on initial composition of clastic grains may be found in Johnsson (1993). Common physical diagenetic changes in siliciclastic sediments include compaction, bioturbation, and tectonic deformation. All three of these processes may result in the rearrangement of primary grains, hence influence the porosity and permeability of the unconsolidated sediment. Compaction acts to reduce primary porosity, and may reduce both inter- and intragranular volume. Deformation may result in crushing of primary grains as well as cross-cutting fractures in lithified rocks. Chemical diagenetic changes in siliciclastic systems involve fluid-rock interaction and result in mineral precipitation, dissolution, or recrystallization. Examples include recrystallization of metastable or unstable phases, precipitation of new, authigenic phases as grain replacement or intergranular cement, and dissolution of unstable phases resulting in secondary porosity. While many cements and mineral reactions appear to result from predictable, equilibrium processes, it is common for siliciclastic sediments and rocks to be in an overall state of chemical disequilibrium due to the presence of a wide range of primary constituents and the relatively low temperatures (hence slow reaction rates) particularly during early diagenesis. Figure 1 highlights some important depth-related changes in clastic rocks. Original grain composition, increasing temperature and pressure, the hydrodynamic conditions, and the presence of reactive organic matter all play an important role in determining the extent of diagenetic modification.

Early Diagenesis

During early diagenesis, the precipitation of carbonate minerals (especially, calcite, ankerite, and siderite), quartz, and aluminosilicates such as kaolinite, smectite and illite predominate. If oxidizing conditions are encountered (as through active meteoric recharge in the near-surface (eogenetic) environment), oxides and hydroxides of iron and manganese may form as well (these include ferrihydrite, goethite, limonite, todorokite, and pyrolusite). High water throughput or excess acidity during early diagenesis may also result in selective dissolution of primary grains (especially carbonates) or alteration of lithic and feldspar grains to produce secondary porosity in addition to authigenic clays. Some primary clastic assemblages, for example, volcanic materials including glass, result in high pH conditions that foster the formation of zeolites in addition to clay minerals. An extensive theoretical treatment of early diagenesis is provided in Berner (1980).

Burial Diagenesis

During burial, shales undergo dewatering including compaction-driven expulsion and loss of water from dehydration of silicates (clay minerals). In sandstones, authigenic growth of quartz (commonly as syntaxial overgrowths on existing clean quartz grain surfaces), kaolinite (often accompanying detrital feldspar alteration), smectite, illite, and calcite dominates. At greater depths, mixed-layer clays become

more illitic and chlorite, dolomite, and ankerite are more common. Detrital feldspars alter toward more sodic compositions (albitization). The geochemistry of authigenic phases, as well as of fluid inclusions within these minerals, provides information on the burial conditions.

Novel Approaches to Studying Diagenesis

The study of carbonate diagenesis is experiencing a rejuvenation with the introduction of new visualization, geochemical proxy and modeling approaches. Although petrographic and SEM study coupled with geochemical analysis of carbonate and siliciclastic rocks have become fundamental tools for reconstructing diagenetic pathways and environments, a new suite of stable (boron, sulfur, magnesium, calcium, lithium) and radiogenic (Sr, Nd, U) isotopes are being applied to carbonates to reconstruct paleo-seawater pH, oxygenation, and temperature as well as to place constraints on past carbon, sulfur, and magnesium cycling, weathering rates, and crystallization rates. Such studies have implications for the evolution of pCO_2 and pO_2 and life-environment interactions. With the advent of better methods for determination of trace element concentrations and their isotopic compositions through applications of ICP-MS, the use of trace metals as paleo-redox and paleoproductivity proxies has led to a rich literature (Lyons et al. 2014; Tribovillard et al. 2006; Gill et al. 2011; Jones and Manning 1994). Of particular interest for diagenetic studies is clumped isotope paleothermometry (Δ_{47}), which uniquely permits independent measurements of carbonate cement precipitation temperatures in carbonate and siliciclastic sedimentary rocks and the $\delta^{18}O_{fluid}$ in which they formed. Although the application of clumped isotope thermometry to diagenetic studies is only beginning, initial results show promise for constraining diagenetic conditions and the evolution of fluid-flow conduits (Huntington et al. 2011; Budd et al. 2013). These applications of sedimentary geochemistry require assessment of separate diagenetic effects from primary signals in rocks across the broadest range of time scales. A surge in computational power over the past two decades is permitting the integration of sedimentology, petrography, geochemistry, geodynamics, and structural geology into forward modeling of the diagenetic evolution of sedimentary successions and the impact of diagenesis on their petrophysical properties and hydrologic potential (e.g., Whitaker et al. 2014; Agar and Geiger 2015).

Summary

Diagenetic modification of freshwater and marine carbonates and siliciclastic deposits by physical and chemical processes is a dynamic process that begins immediately following deposition (0–30 °C) through to the metamorphic realm (~250 °C). Sediments are converted to sedimentary rocks, and permeability and porosity develop by the integrated effects of dissolution, cementation, mineral overgrowth, neomophism, and recrystallization. The extent of diagenetic modification is governed by the original grain composition and reactivity, temperature and pressure, hydrodynamic conditions, and the presence of reactive organic matter. Bacterial mediation is an important component of carbonate and siliciclastic diagenesis.

The diagenetic cycle includes the early (eogenetic) through burial (mesogenetic) diagenetic realms as well as the telogenetic zone associated with tectonic uplift or sea-level exposure of sedimentary rocks. Although dolomite has been shown to form at Earth's surface conditions with microbial mediation, extensive dolomitization occurs in the burial realm where kinetic inhibitors are overcome and elevated temperatures and high fluid-rock ratios promote the process. Maturation of sedimentary hosted organic matter through the diagenetic cycle has produced the world's coal, oil, and gas deposits. Modern diagenetic studies are coupling new visualization, geochemical proxy, and modeling approaches with fundamental petrographic and geochemical tools in order to (1) quantitatively constrain the diagenetic history of carbonate and siliciclastic successions, (2) assess the potential of sedimentary rocks as archives of past surface conditions, and (3) reconstruct the evolution of petrophysical properties and hydrologic conduits in sedimentary units, as well as their resource potential.

Diffusion

Yan Liang
Department of Earth, Environmental and Planetary Sciences, Brown University, Providence, RI, USA

Definition

Diffusion arises from random motions of particles in a fluid or solid. Here the particles can be neutral molecules or atoms, or charged cations or anions. The particle that diffuses through a medium or substance is called diffusant. Diffusion is a microscopic kinetic phenomenon that results in intermingling and homogenization of the chemical components in a substance. It is part of the mixing process that is not accounted for by the bulk flow or advection of the chemical system. The word "diffusion" originates from the Latin word "diffundere" which means to pour out or spread out.

Fick's Laws of Diffusion

The spreading of diffusant in a medium can be quantified by applying the laws of diffusion which are established through observations of natural phenomenon and laboratory diffusion experiments. During diffusion, random motions of the particles in a chemically heterogeneous phase will redistribute its constituent from regions of high concentration to low concentration, which eventually leads to homogenization of the phase. The amount of materials that move perpendicular through a unit cross-section area by diffusion or random motions of the particles in the medium is called diffusive flux. According to Fick's first law of diffusion, the diffusive flux for a component of interest, $\mathbf{J_i}$, is proportional to the concentration gradient of the component in the system. For one-dimensional diffusion, this can be written as

$$\mathbf{J_i} = -D_i \frac{\partial c_i}{\partial x}, \tag{1}$$

where D_i is the diffusion coefficient or diffusivity of component i; c_i is the concentration of component i; and $\partial c_i/\partial x$ is the concentration gradient of component i along the x direction. The diffusive flux has the units of mass per unit area per unit time. The concentration has the units of mass per unit volume. The diffusion coefficient has the units of length-squared per unit time, for example, $m^2\ s^{-1}$. The diffusive flux is a vector (along x direction in this case) and the negative sign in Eq. 1 is to ensure that material diffuses from regions of high concentration to low concentration, that is, along the direction of decreasing concentration gradient.

Fick's first law of diffusion was postulated by Adolf Fick in 1855, drawing on the analogy between the spreading of a solute in a solvent to Fourier's law for the diffusion of heat by conduction and Ohm's law for the flow of electric current in a conductor (Tyrrell 1964; Narasimhan 2004). It was based on observations of diffusion in a binary solution (salt and water in Fick's case). The term interdiffusion has also been used to describe diffusion in a binary liquid or solid (e.g., diffusion of salt in water or Fe-Mg diffusion in olivine). The diffusion coefficient obtained from a binary diffusion experiment is called the interdiffusion coefficient. Fick's first law has been used to define the diffusion coefficient and to study steady-state diffusion along a concentration gradient.

Fick's second law of diffusion is a statement of mass conservation for diffusive mass transfer in a medium. In one dimension, the diffusion equation can be written as

$$\frac{\partial c_i}{\partial t} = \frac{\partial}{\partial x}\left(D_i \frac{\partial c_i}{\partial x}\right), \tag{2}$$

where t is the diffusion time. When density variation in the system is small, the concentration in Eq. 2 can be replaced by the weight or molar fraction. This practice has been routinely used in studies of diffusion in silicate melts and crystals. When the diffusion coefficient is independent of concentration or spatial coordinate, the diffusion equation takes on the simple expression:

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial^2 c_i}{\partial x^2}. \tag{3}$$

For diffusion in three-dimensional isotropic media, the diffusion equation takes on the more general form in a Cartesian coordinate:

$$\frac{\partial c_i}{\partial t} = D_i\left(\frac{\partial^2 c_i}{\partial x^2} + \frac{\partial^2 c_i}{\partial y^2} + \frac{\partial^2 c_i}{\partial z^2}\right) = D_i \nabla^2 c_i, \tag{4}$$

where ∇^2 is the Laplacian operator. For diffusion in an axisymmetric sphere, the diffusion equation takes on the special form:

$$\frac{\partial c_i}{\partial t} = D_i\left(\frac{\partial^2 c_i}{\partial r^2} + \frac{2}{r}\frac{\partial c_i}{\partial r}\right), \tag{5}$$

where r is the radial coordinate. Equation 5 can be used to model diffusion in and around mineral grains and fluid or melt inclusions. Equations 2, 3, 4, and 5 are partial differential equations. Their solutions depend on the initial and boundary conditions. Analytical solutions to Eqs. 3, 4, 5, and 6 subject to various initial and boundary conditions can be found in the treatise *The Mathematics of Diffusion* (Crank 1975). For a variable diffusion coefficient, the diffusion

equation can be solved numerically using a finite difference method (Crank 1975).

Fick's laws of diffusion were originally developed for diffusion in fluids. These laws are directly applicable to diffusion in isotropic media such as melts, glasses, and minerals of isometric crystal system. The diffusion coefficient in an isotropic medium is independent of direction or orientation and can be treated as a scalar. For diffusion in anisotropic media, such as minerals of crystal systems other than isometric, the diffusion coefficient will depend on the direction of diffusion in the crystals. Diffusivities measured along different directions in the crystal may be different depending on the symmetry of the crystal. For example, for oxygen diffusion in quartz, Giletti and Yund (1984) found that diffusivities of oxygen parallel and perpendicular to the c axis of quartz differ by two orders of magnitude. Diffusion modeling in such systems may be simplified by using two diffusivities in the cylindrical coordinate:

$$\frac{\partial c_i}{\partial t} = D_{\perp c}\left(\frac{\partial^2 c_i}{\partial r^2} + \frac{1}{r}\frac{\partial c_i}{\partial r}\right) + D_{\parallel c}\frac{\partial^2 c_i}{\partial z^2}, \tag{6}$$

where $D_{\perp c}$ and $D_{\parallel c}$ are diffusivities perpendicular and parallel to the c axis of quartz. Equation 6 can be used to model diffusion in hexagonal, tetragonal, and trigonal crystal systems. For diffusion in orthorhombic crystal systems, diffusion coefficients measured along three orthogonal directions are needed to completely describe a diffusive flux. Shea et al. (2015) presented an example of three-dimensional numerical modeling of anisotropic Fe-Mg diffusion in olivine, which is a mineral in the orthorhombic crystal system. In general, a full description of the direction-dependent diffusivity for diffusion in anisotropic media requires a symmetric second order tensor (Nye 1985). In practice, due to the lack of sufficient diffusion data and complicated geometry of the crystals, simplifications are made in diffusion modeling of anisotropic minerals, for example, by using Eq. 2 or 5 with a single diffusion coefficient (Zhang 2010; Shea et al. 2015). A list of diffusion tensors for different crystal systems can be found in Nye (1985) and Zhang (2010).

Types of Diffusion

Depending on the chemical state of the system, the nature of the diffusants, the initial and boundary conditions, and simplifications involved, several types of diffusion can be identified: self diffusion, chemical diffusion, multicomponent diffusion, effective binary diffusion, thermal diffusion, and grain boundary diffusion.

Self diffusion or tracer diffusion takes place when the system of interest is at chemical, but not isotopic, equilibrium. There is no concentration or chemical potential gradient of any elements in the system. Self diffusivity of an element or component is determined by labeling some of the atoms in the diffusant using isotopic tracers, hence the name tracer diffusion. For example, to determine the self diffusivity of Mg in an olivine crystal, one can deposit a thin layer of ^{26}Mg-spiked olivine on the surface of the crystal and follow the spread of ^{26}Mg in the olivine grain.

Chemical diffusion or multicomponent diffusion takes place when the system of interest is out of chemical equilibrium. Many geological systems are made of two or more components. A silicate magma, for example, typically has seven or more major oxide components. Diffusion in such systems is referred to as multicomponent diffusion or chemical diffusion. During chemical diffusion, the concentration gradient of one component may affect the diffusive flux of another component. Lars Onsager generalized Fick's laws of diffusion in binary fluids to multicomponent systems by considering the rate of entropy production which can be written as a sum of scalar products between diffusive fluxes and driving forces for diffusion (e.g., de Groot and Mazur 1962; Hasse 1969). The driving force for chemical diffusion at a constant temperature and pressure is the chemical potential gradient. Since chemical potential of a component in a multicomponent substance (μ_i) is a function of temperature, pressure, and concentration, it is convenient to express diffusive fluxes in terms of concentration gradients of the components in the system. For a binary fluid, for example, Fick's first law can be written as

$$\mathbf{J_i} = -L_i\frac{\partial \mu_i}{\partial x} = -\left(L_i\frac{\partial \mu_i}{\partial c_i}\right)\frac{\partial c_i}{\partial x}, \tag{7}$$

where L_i is the phenomenological coefficient for diffusion. The term in the parentheses is identified as the diffusion coefficient. According to Onsager (1945), the diffusive flux of a given component in a multicomponent liquid can be expressed as a linear combination of concentration gradients of the independent components in the system. In a volume-fixed frame of reference, the one-dimensional diffusive flux of component i in an n component fluid or melt at constant temperature and pressure is given by (Onsager 1945):

$$\mathbf{J_i} = -\sum_{j=1}^{n-1} D_{ij}\frac{\partial c_j}{\partial x}, \tag{8}$$

where D_{ij} are elements of an $(n-1)$ by $(n-1)$ diffusion matrix with component n taken as the dependent variable. The index i in Eq. 8 takes on integers $1, 2, \ldots, n-1$. The diffusive flux of the dependent component n is constrained by the requirement of total flux conservation. The latter depends on the choice of reference frame. An important property of the diffusion matrix is that its eigenvalues are positive, which is

a prerequisite for stable solutions of the diffusion equations. For a ternary system, there are two independent components. The diffusion equations for the independent components 1 and 2 are

$$\frac{\partial c_1}{\partial t} = D_{11}\frac{\partial^2 c_1}{\partial x^2} + D_{12}\frac{\partial^2 c_2}{\partial x^2}, \tag{9a}$$

$$\frac{\partial c_2}{\partial t} = D_{21}\frac{\partial^2 c_1}{\partial x^2} + D_{22}\frac{\partial^2 c_2}{\partial x^2}, \tag{9b}$$

where D_{11} and D_{22} are the diagonal terms and D_{12} and D_{21} are the off-diagonal terms of the 2 × 2 diffusion matrix. For diffusion in an n component system, the diffusion equation for component i is

$$\frac{\partial c_i}{\partial t} = \sum_{j=1}^{n-1} D_{ij}\frac{\partial^2 c_j}{\partial x^2}. \tag{10}$$

Equations 9 and 10 are coupled diffusion equations because of the presence of the off-diagonal terms. A peculiar consequence of coupled diffusion is uphill diffusion, which happens when the spreading direction of a diffusant is in the opposite direction of its own concentration gradient (i.e., the diffusant can migrate from regions of low concentration to high concentration). Uphill diffusion is a transient phenomenon. It occurs when the net diffusive flux produced by concentration gradients of all other components in Eq. 10 is larger than and has the opposite sign relative to the diffusive flux produced by the concentration gradient of the component of interest. Examples of uphill diffusion in molten silicates can be found in Zhang et al. (1989), Watson and Baker (1991), Liang et al. (1996), Richter et al. (1998), and Guo and Zhang (2016). When elements of the diffusion matrix are constant and uniform, analytical solutions to the coupled diffusion equations can be constructed from solutions to the equivalent binary cases using the method of linear transformation (Toor 1964; Gupta and Cooper 1971). Exact solutions for multicomponent diffusion in ternary systems were derived by Fujita and Gosting (1956) and Kirkaldy (1958) for one-dimensional semi-infinite diffusion couples. A recent summary with additional examples can be found in Liang (2010).

Numerical values of the diffusion matrix depend on the choice of the dependent variable, units of concentration, and the frame of reference for the diffusive fluxes. The volume-fixed frame of reference is most suitable for studying chemical diffusion in the laboratory. For diffusive mass transfer in geological systems, mass-fixed frame of reference is most convenient. The difference between the two frames of reference is whether the sum of the volume fluxes or the mass fluxes is set to zero. For a general treatment of multicomponent diffusion, including coordinate transformation, the reader is referred to the textbooks or monographs by de Groot and Mazur (1962), Katchalsky and Curran (1967), Hasse (1969), Tyrrell and Harris (1984), Miller et al. (1986), Kirkaldy and Young (1987), and Kondepudi and Prigogine (1998). Relevant reviews or summaries in the geochemical literature include Anderson (1981), Lasaga (1998), and Liang (2010).

Effective binary diffusion is a simplified treatment of chemical diffusion in multicomponent fluids or solids. Here the multicomponent system is treated as a pseudo-binary system in which the component of interest is taken as the independent variable and all other components are taken together as the dependent variable (Cooper 1968). The diffusive flux of the component of interest (i) is assumed to follow a relation similar to Fick's first law of diffusion for binary fluids,

$$\mathbf{J_i} = -D_i^E\frac{\partial c_i}{\partial x}, \tag{11}$$

where D_i^E is the effective binary diffusion coefficient of component i. The diffusive flux defined by Eq. 11 is equivalent to that defined by Eq. 8 if the effective binary diffusion coefficient is given by (Cooper 1968):

$$D_i^E = \sum_{j=1}^{n-1} D_{ij}\frac{\partial c_j}{\partial c_i}. \tag{12}$$

Most diffusion coefficients for chemical diffusion in fluids, melts, and crystals reported in the geochemical literature were obtained using the effective binary approximation (see reviews by Watson and Baker 1991; Zhang et al. 2010). Unlike the diffusion matrix for a multicomponent system, the effective binary diffusion coefficients depend on the direction of diffusion in composition space, that is, they are sensitive to the specific diffusion experiments from which they are derived. This is shown by the composition derivatives in Eq. 12 and verified by many laboratory studies of chemical diffusion in molten silicates. For diffusion in a confined system or finite geometry, $\partial c_j/\partial c_i$ in Eq. 12 may change its sign during diffusion (Watson and Baker 1991; Liang 2010), and the effective binary diffusion coefficient may also vary as a function of time. Since D_i^E must be positive for the diffusion equation to be stable, Eq. 11 cannot be used to model uphill diffusion without additional assumptions (Richter 1993; Zhang 1993). For a detailed discussion on the usefulness and limitations of effective binary diffusion and its relation to multicomponent diffusion, the reader is referred to Cooper (1968), Liang (2010), and Zhang (2010).

Relationship between self diffusion and chemical diffusion Self diffusivity is a measure of the intrinsic mobility of the diffusing species. In the presence of chemical potential or

concentration gradient in a binary system, the intrinsic diffusivity for component 1 (D_1^I) is related to the self diffusivity of component 1 (D_1) through the expression

$$D_1^I = \left(1 + \frac{d\ln\gamma_1}{d\ln X_1}\right) D_1, \tag{13}$$

where γ_1 is the activity coefficient and X_1 is the molar fraction of component 1 in the binary system. The term in the parentheses is called the thermodynamic factor, which is identical to that for component 2 in the binary system. For chemical diffusion in a simple binary fluid or solid, the interdiffusion coefficient ($\tilde{D}$) is related to the intrinsic diffusion coefficients of the two components through Darken's equation

$$\tilde{D} = X_2 D_1^I + X_1 D_2^I = (X_2 D_1 + X_1 D_2)\left(1 + \frac{d\ln\gamma_1}{d\ln X_1}\right). \tag{14}$$

A comparable expression for interdiffusion of two counter ion species in a binary crystal or fluid is given by the expression (Helfferich and Plesset 1958; Barrer et al. 1963):

$$\tilde{D} = \frac{D_1 D_2 (X_1 Z_1^2 + X_2 Z_2^2)}{D_1 X_1 Z_1^2 + D_2 X_2 Z_2^2}\left(1 + \frac{d\ln\gamma_1}{d\ln X_1}\right), \tag{15}$$

where Z_1 and Z_2 are charge numbers of the two ions. When the abundance of component 1 is much smaller than that of component 2 ($X_1 << X_2$), the interdiffusion coefficient in Eq. 14 or 15 is mostly determined by the self diffusivity of component 1. Generalizations of Eqs. 14 and 15 to multicomponent geological fluids or solids can be found in Cooper (1965), Lasaga (1979), and Liang et al. (1997). In all cases, the diffusion matrix can be written as a product of a kinetic matrix and a thermodynamic matrix. Elements of the kinetic matrix are functions of self diffusivities of the components in the system, while elements of the thermodynamic matrix depend on activity-composition relationships of the components. Darken's equation and its generalizations have been used to study chemical diffusion in molten silicates and selected minerals (Chakraborty 2010; Ganguly 2010; Liang 2010).

Thermal diffusion is a general case of chemical diffusion in that the flow of heat drives a flow of matter. This transport phenomenon is often referred to as the "Soret effect" after the Swiss chemist Charles Soret. The driving force for thermal diffusion involves temperature gradient. For a multicomponent fluid, the diffusive flux for an independent component takes on a more general form (e.g., de Groot and Mazur 1962; Hasse 1969). With concentration in mass fraction, the diffusive flux for component 1 in a binary fluid is written as the sum of two parts – one proportional to the concentration gradient and the other proportional to the temperature gradient:

$$\mathbf{J}_1 = -\rho D_1 \left[\frac{\partial w_1}{\partial x} + S_T w_1 (1 - w_1)\frac{\partial T}{\partial x}\right], \tag{16}$$

where ρ is the density of the fluid; w_1 is the mass fraction of component 1 in the fluid; D_1 is the diffusion coefficient of component 1; and S_T is the Soret coefficient. The product $D_1 S_T$ is called the thermal diffusion coefficient, designated as D_T. The Soret coefficient or thermal diffusion coefficient can be either positive or negative, depending on the response of the component to the imposed temperature gradient. While the concentration gradient serves to homogenize a fluid, the presence of a temperature gradient across the fluid can result in mass separation. This is a key difference between thermal diffusion and chemical diffusion and can be demonstrated by setting the diffusive flux to steady state (i.e., $\mathbf{J}_1 = 0$ in a confined system). Equation 16 then is reduced to

$$\frac{dw_1}{dT} = -w_1(1 - w_1)S_T. \tag{17}$$

For steady-state thermal diffusion across molten silicates, it has been observed in the laboratory that SiO_2, Na_2O, and K_2O migrate towards the hot end (negative S_T), whereas CaO, MgO, FeO, and TiO_2 concentrate towards the cold end (positive S_T) of diffusion charges (Walker et al. 1981; Lesher 1986; Richter et al. 2009).

Grain boundary diffusion is a general case of diffusion in crystalline solids in which the boundaries between neighboring grains and dislocation pipes within the crystals serve as fast-pathways or short-circuits for the spreading of diffusant. Diffusion in polycrystalline materials is multipath and consists of both lattice diffusion (also called volume diffusion) and grain boundary diffusion. The mathematical treatment of diffusion in polycrystalline materials generally requires two independent diffusivities, one for diffusion in the crystal lattice and the other for diffusion along grain boundaries or dislocation pipes (Fisher 1951; Whipple 1954; Suzuoka 1961; Le Claire 1963). The structure of grain boundaries are relatively open compared to the structure of the crystal lattice. Diffusion along grain boundaries is typically orders of magnitude faster than diffusion within the crystal lattice. The grain boundary diffusivity is comparable to the diffusivity in the melt as the temperature approaches the melting temperature of the solid (Mishin et al. 1997). During diffusion, a particle may spend some fraction of time in the crystal lattice and the rest of the time in the grain boundary, wandering back and forth between the lattice and the grain boundary. Depending on their relative contributions to the bulk or net transport of diffusants through the polycrystalline material, three types or regimes of grain boundary diffusion are identified in the absence of grain boundary migration (Harrison 1961): A, B, and C. Types A and C are endmember cases in which volume diffusion is either dominant or insignificant, respectively,

whereas Type B is the intermediate regime and also the most complicated case of grain boundary diffusion. Type C diffusion happens when the diffusion time is too short for appreciable contribution of lattice diffusion, and the net mass transport of diffusants through the polycrystals can be solely accounted for by diffusion along grain boundaries. Type A diffusion is dominant when the diffusion time is long and the volume diffusivity (D_L) is large such that the diffusion length in the solid is much larger than the average grain size (d), that is,

$$\sqrt{D_L t} >> d. \tag{18}$$

The bulk diffusive flux in the polycrystalline material can be modeled by Fick's first law of diffusion (Eq. 1) with an effective diffusion coefficient (D_{eff}) that is a weighted average of diffusivities for the lattice and grain boundary diffusion (Hart 1957):

$$D_{eff} = f_{gb} D_{gb} + \left(1 - f_{gb}\right) D_L, \tag{19}$$

where D_{gb} is the grain boundary diffusivity; f_{gb} is the volume fraction of grain boundaries in the polycrystals. f_{gb} is proportional to the ratio between the grain boundary width and the average grain size. The boundary width is reasoned to be very small, on the order of several interatomic distances. Hence, grain boundary diffusion is more effective for diffusive mass transfer in fine-grained solids (larger f_{gb}) at low temperatures (smaller D_L). Type B regime is observed when significant concentration zoning is present in the crystals. The diffusion length in the crystal is smaller than the grain size. Depending on temperature, diffusion time, and grain size, the three regimes of grain boundary diffusion may coexist in different parts of a system. During grain growth or recrystallization, grain boundaries migrate in polycrystalline solids. The classification of grain boundary diffusion also depends on the grain boundary migration velocity. For additional reading on grain boundary diffusion, including mathematical treatment and summary of diffusion data in silicate and oxide minerals, the reader is referred to the review articles by Joesten (1991), Mishin et al. (1997), Watson and Baxter (2007), and Dohmen and Milke (2010).

Diffusion Coefficients

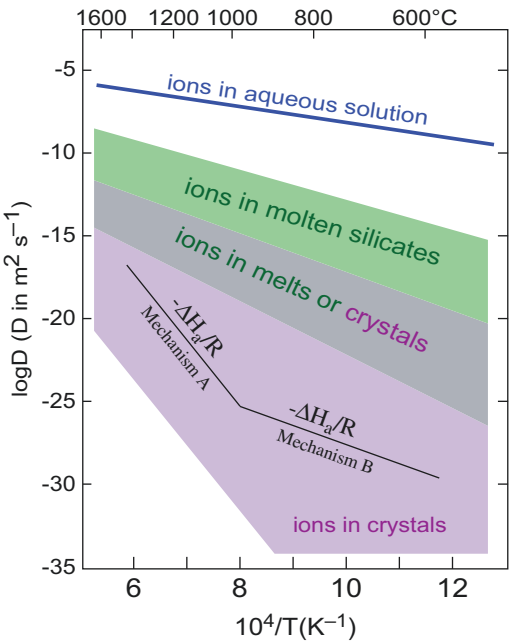
Diffusion is a thermally activated process. In general, both self diffusion and chemical diffusion coefficients in a substance or medium vary systematically with temperature, pressure, and composition. For a given composition, the diffusion coefficient of a component (D) in the medium follows the Arrhenius equation:

$$D = D_0 \exp\left(-\frac{E_a + PV_a}{RT}\right), \tag{20}$$

where D_0 is the pre-exponential factor for diffusion (in $m^2\ s^{-1}$); E_a is the activation energy for diffusion (in J mol^{-1}); V_a is the activation volume for diffusion (in $m^3\ mol^{-1}$); T is the temperature (in K); P is the pressure (in Pa); and R is the gas constant (8.314 J $mol^{-1}\ K^{-1}$). D_0 is related to the vibration frequency and jumping distance of the diffusing species in the medium. The sum $E_a + PV_a$ in the Arrhenius equation is called the activation enthalpy for diffusion (H_a). The linearized version of the Arrhenius equation can be used to determine the diffusion parameters (D_0, E_a, and V_a):

$$\ln D = \ln D_0 - \frac{E_a + PV_a}{RT}. \tag{21}$$

A set of diffusion coefficients of a component in the medium measured at a constant pressure but different temperatures generally defines a straight line in the plot of ln D against the reciprocal of the temperature (Fig. 1). Such a diagram is referred to as the Arrhenius plot or Arrhenius diagram. The intercept of the line is ln D_0 and the slope of the line in the Arrhenius plot is $-H_a/R$. The larger the activation energy for diffusion, the stronger the dependence of diffusion on temperature. The activation enthalpy obtained through a set of

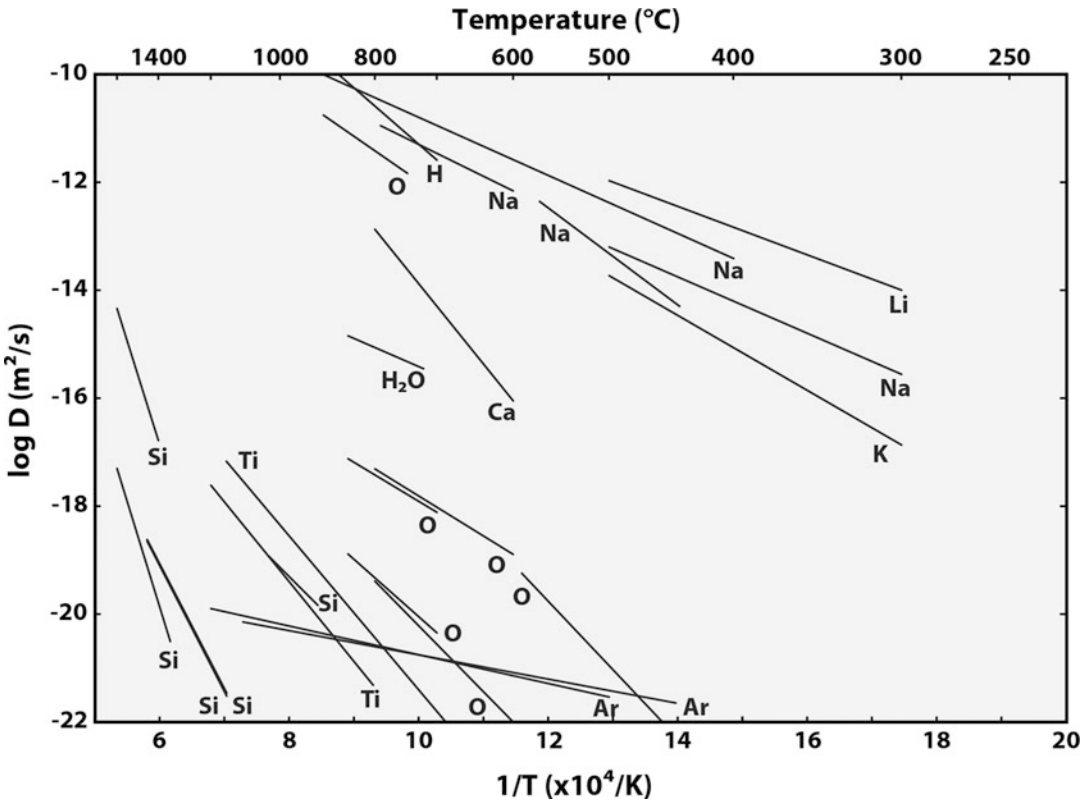


Diffusion, Fig. 1 Arrhenius plot illustrating the ranges of diffusivities of various cations and anions in aqueous solutions, molten silicates, and crystals. The change in the slope in this diagram may indicate a change in diffusion mechanism (A vs. B) (Modified from Watson and Baxter (2007) by E. Bruce Watson)

diffusion data collected at a constant pressure is often called the activation energy in the literature, which may cause confusion. Care should be exercised when comparing activation energies measured at different pressures. Deviation from the straight line in the Arrhenius plot, such as a change in the slope (black lines in Fig. 1), often suggests either a change in diffusion mechanism or inaccurate diffusion data. A family of straight lines is established in the Arrhenius plot if diffusion coefficients are measured over a range of pressures and temperatures. A comprehensive compilation of diffusivities and diffusion parameters for self diffusion and chemical diffusion of cations, anions, volatile species, and noble gases in silicate melts and crystals can be found in the monograph *Diffusion in Minerals and Melts* (Zhang and Cherniak 2010). A few first order features are highlighted below.

Depending on physical state of the substance and diffusing species, values of activation energy for diffusion in earth and planetary materials vary greatly. In general, diffusivities of ions (cations and anions) in aqueous solutions are considerably larger than those in molten silicates which, in turn, are larger than those in silicate or oxide minerals. Activation energies for diffusion in the minerals are generally larger than those for diffusion in the melts with which the minerals may reside (e.g., olivine and pyroxene vs. basalts, feldspars vs. rhyolites). Figure 1 is from Watson and Baxter (2007) and illustrates the enormous ranges of diffusivity and activation enthalpy for diffusion of cations and anions in geological fluids, melts, and minerals, from ~40 kJ mol^{-1} for interdiffusion in supercritical aqueous solution (Wark and Watson 2004) up to ~800 kJ mol^{-1} for tetravalent Hf diffusion in zircon (Cherniak et al. 1997a). Figure 2 highlights both the complexity and systematics of the Arrhenius relations for monovalent (H, Li, Na, and K), divalent (Ca and O), tetravalent (Ti and Si) ions and molecules (H_2O and Ar) in quartz under nominally anhydrous conditions. The general trends of increasing activation energy and decreasing diffusivity with increasing ionic charge and size are also observed for diffusion in other minerals and silicate melts, although exceptions are abundant. For example, diffusivities of trivalent REE in diopside and zircon vary systematically as a function of ionic radius (Cherniak et al. 1997b; Van Orman et al. 2001), whereas diffusivities of REE in enstatite and plagioclase appear to be insensitive to the size of REE (Cherniak 2003; Cherniak and Liang 2007).

Few studies have focused on the effect of pressure on cation diffusion in minerals and melts, as pressure has a negligible effect on diffusion under crustal conditions. However, pressure may play an important role in modulating diffusion rate under mantle conditions. For example, diffusivities of network-forming cations, such as Si and Al, in



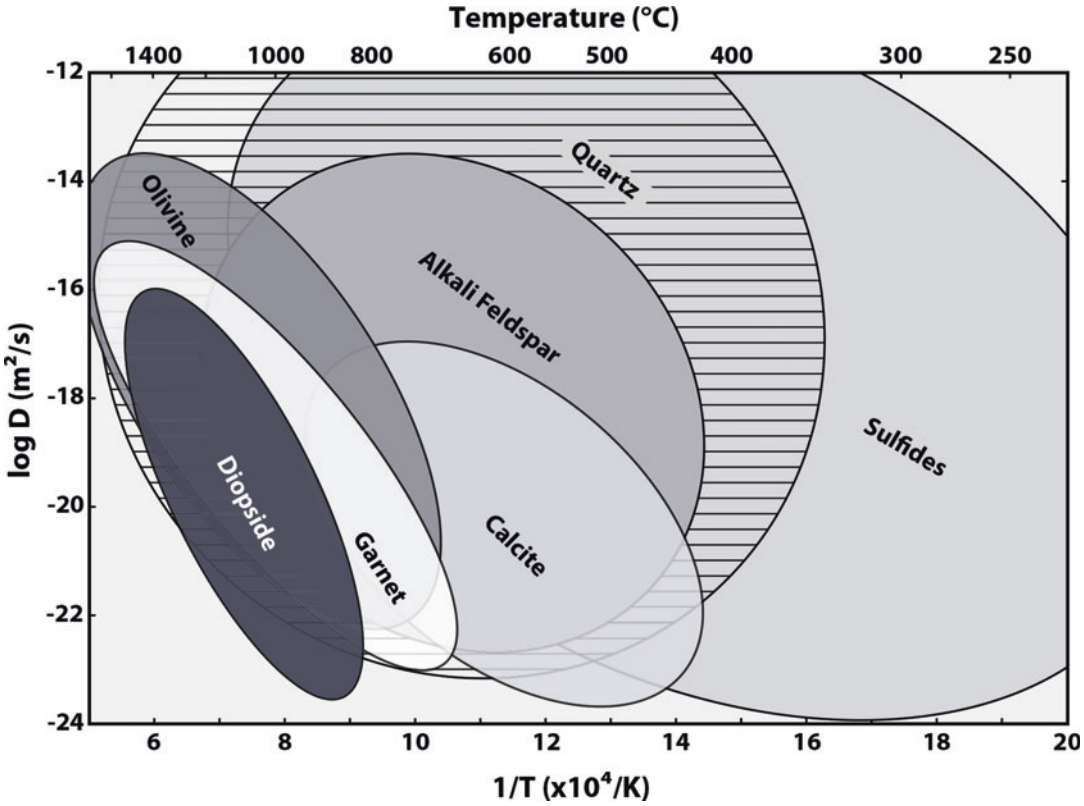
Diffusion, Fig. 2 Diagram summarizing Arrhenius relations for diffusion of various cations, anions (oxygen), and Ar in quartz under nominally anhydrous conditions (Adapted from Brady and Cherniak 2010)

highly polymerized melts increase with the increase of pressure (an apparent negative activation volume), which are attributed to changes in the melt structure with pressure (Kushiro 1983; Poe et al. 1997). Activation volumes (V_a) for cation diffusion in minerals are generally positive and range from less than 10^{-6} m^3 mol^{-1} to 20×10^{-6} m^3 mol^{-1} (Béjina et al. 2003; Chakraborty 2010). At 1200 °C, trivalent REE diffusivities in diopside (V_a ~10×10^{-6} m^3 mol^{-1}, Van Orman et al. 2001) and garnet ($V_a = 10 \times 10^{-6}$ to 20×10^{-6} m^3 mol^{-1}, Van Orman et al. 2002; Carlson 2012; Bloch et al. 2015) decrease by one and two orders of magnitude, respectively, when the pressure is increased from 1 to 4 GPa. The diffusion of divalent cations (Fe-Mg, Mn, and Ni) in garnet and olivine depends moderately on pressure ($V_a = 4\sim8 \times 10^{-6}$ m^3 mol^{-1}, Béjina et al. 2003; Holzapfel et al. 2007; Chakraborty 2010). Since diffusion coefficients decrease with the decrease of temperature and the increase of pressure, simultaneous changes in temperature and pressure along a geotherm can significantly reduce temperature-induced variations in diffusivity (Holzapfel et al. 2007; Watson and Baxter 2007; Liang 2017). Holzapfel et al. (2007) gave an example of Fe-Mg diffusion in olivine along a *P-T* path in the upper mantle. According to their calculation, the diffusivity of Fe-Mg in olivine increases from ~10^{-25} to 10^{-15} m^2 s^{-1} in the lithosphere (50–150 km depth) and then decreases gradually through the asthenosphere. Near the bottom of the upper mantle (400 km) the Fe-Mg diffusion coefficient is reduced to 10^{-16} m^2 s^{-1}. Without the competing effect of pressure, the Fe-Mg diffusivity in olivine would monotonically increase in the asthenospheric part of the upper mantle. Similar variations in diffusivity with depth are also expected for cation diffusion in other mantle minerals (Watson and Baxter 2007).

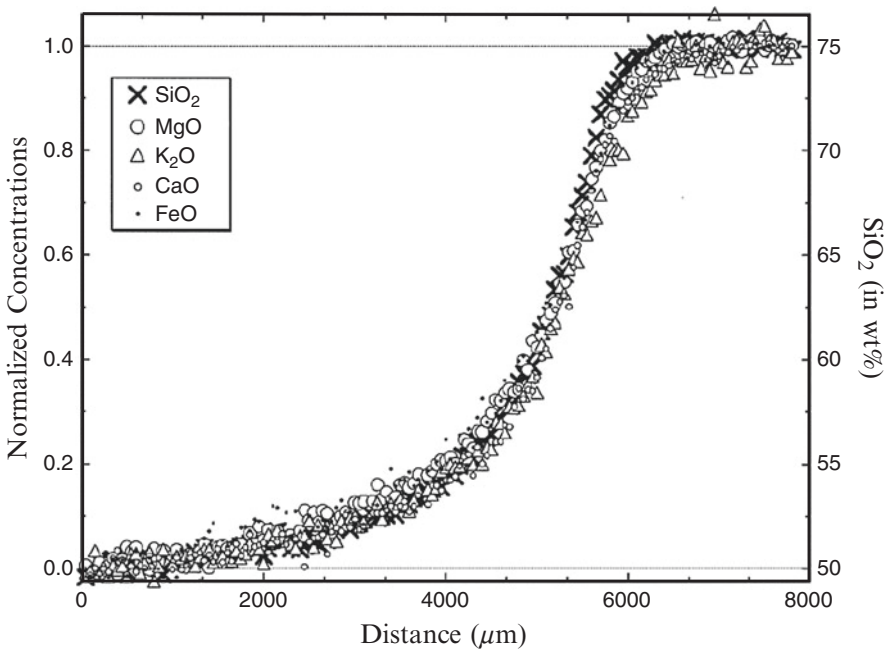
Diffusion in oxides and silicate crystals depends on diffusion mechanism and defect chemistry (Watson and Baxter 2007; Chakraborty 2008, 2010; Cherniak and Dimanov 2010; Van Orman and Crispin 2010). The mechanisms of diffusion in minerals are complicated and still not well understood in many cases. Because natural minerals typically are solid solutions and contain vacancies and impurities of various sizes and valences, diffusion of an ion in a mineral may take more than one mechanism. For the same ion, its diffusion mechanism in one mineral may not necessarily be the same as in another mineral. For example, Li diffusion in olivine follows two pathways: a fast path through interstitial sites and a slow path through octahedral sites in olivine (Dohmen et al. 2010), whereas Li diffusion in zircon appears to follow one mechanism (Cherniak and Watson 2010; Trail et al. 2016). When vacancies are involved, diffusion in minerals can be broadly divided into two regimes: a high temperature or intrinsic regime where diffusivity is proportional to vacancy abundance in the minerals, and a low temperature or extrinsic regime where the vacancy abundance is low and does not contribute significantly to the overall diffusion. For Fe-bearing minerals, vacancy abundance is sensitive to oxygen fugacity. Measured diffusivities then depend on oxygen fugacity (e.g., Fe-Mg diffusion in olivine, Chakraborty 2010). The activation enthalpy for diffusion in the intrinsic regime is higher than that for diffusion in the extrinsic regime. The two regimes of diffusion are illustrated as mechanisms A and B in Fig. 1. Diffusion in minerals also depends on mineral composition. Cation diffusion in feldspars, for example, is very sensitive to feldspar compositions: Mg, Pb, Sr, and Nd diffusivities in anorthite are one to two orders of magnitude smaller than those in oligoclase (Giletti and Casserly 1994; Cherniak and Watson 1994; Cherniak 1995, 2003; Van Orman et al. 2014). Finally, the presence of water and H species in minerals enhances oxygen diffusion but generally has very little effect on cation diffusion in minerals (Watson and Baxter 2007). Figure 3 is a broad-brush summary of cation and anion diffusion in minerals commonly observed in the earth and planetary materials (Brady and Cherniak 2010). The general trends and variations in diffusivities highlight the importance of mineral composition, mineral structure, temperature, and oxygen fugacity on diffusion in minerals.

Diffusion in silicate melts depends strongly on melt composition and melt structure (Watson and Baker 1991; Lesher 2010; Liang 2010; Zhang et al. 2010). Chemical diffusivities for cations in silicate melts are typically measured with metal oxides as independent components. In general, diffusivities decrease with the increase of SiO_2 and the decrease of alkali and water contents in the melt. For example, diffusivities of oxide components (including total water) decrease by over an order of magnitude from basalt to rhyolite, whereas the diffusivity of Li_2O only decreases by a factor of two and the diffusivity of CO_2 appears to be insensitive to melt composition (Watson and Baker 1991; Richter et al. 2003; Zhang and Ni 2010). Figure 4 displays an example of chemical diffusion between a basaltic melt and a rhyolitic melt (Richter et al. 2003). The steep gradients on the high SiO_2 or rhyolite side of the diffusion couple are due to the composition-dependent diffusivity in the melt, and can be reproduced by allowing the effective binary diffusion coefficients of the oxides to vary by factors of ~10–20 across the diffusion couple (Richter et al. 2003).

It has been demonstrated experimentally that isotopes of a number of elements (Li, Mg, Ca, K, Fe, and Ge) can be fractionated from each other during self diffusion, chemical diffusion, and thermal diffusion in aqueous solutions, molten silicates, iron-nickel alloys, as well as minerals such as pyroxene (e.g., Richter et al. 1999, 2003, 2006, 2009, 2014, 2016; Watkins et al. 2011, 2014; Watson et al. 2016). Richter and coworkers quantified this effect by relating diffusivity ratio of two isotopes to the reciprocal of their mass ratio through an empirical kinetic parameter β:



Diffusion, Fig. 3 Schematic Arrhenius diagram showing the approximate ranges of measured diffusion coefficients and temperatures for all elements (except H, He, Ar, and Li) in several common minerals or mineral groups (Adapted from Brady and Cherniak 2010)



Diffusion, Fig. 4 Variations of selected oxide abundances across a basalt-rhyolite diffusion couple. The diffusion experiment was conducted at 1450 °C and 1.3 GPa for 15.7 h. At the start of the experiment, compositions of the basalt (left) and rhyolite (right) are homogeneous and shown as thin gray lines. The measured concentration profiles are shown as open circles. The small dots are calculated diffusion profiles using composition-dependent effective binary diffusion coefficients (Adapted from Richter et al. 2003)

$$\frac{D_1}{D_2} = \left(\frac{M_2}{M_1}\right)^{\beta}, \tag{22}$$

where D is the diffusivity and M is the mass of isotope 1 or 2 of the element of interest. While the experimentally determined β values in silicate melts are small for cations (0.215 for Li, but <0.1 for Ca, Mg, Fe and Si), they give rise to kinetic isotope fractionations that are larger compared to the precision with which isotope ratios are routinely measured. The values of {\beta} in minerals are often larger than in melts (e.g., ~0.3 for Li in pyroxene), while they are much smaller for salts diffusing in water. But in every case the light isotope diffuses slightly faster than the heavy isotope. Compilations of β values in aqueous solutions, melts, and minerals can be found in Richter et al. (2009) and Watkins et al. (2017). Isotope fractionation by diffusion is becoming a powerful tool for identifying diffusion-dominated mass transfer process in natural samples and as a result there is a growing interest in its geochemical applications. Some examples involving measurements and diffusion modeling of both isotopic ratio and element concentration profiles in natural settings can be found in Teng et al. (2006), Chopra et al. (2012), Sio et al. (2013), and Richter et al. (2014, 2016), among others.

Methods for Measuring Diffusion Coefficients

Diffusion coefficients for earth and planetary materials reported in the literature are mostly obtained from laboratory experiments. The methods for measuring diffusivities vary considerably, depending on physical state of the matter (fluid, melt, glass, or solid) and availability of analytical methods. Regardless of experimental complexity and sophistication, the basic idea of all diffusion experiments remain the same: Given an initial perturbation in concentration or isotopic ratio on the surface or in part of the specimen of interest, monitor the spread of the diffusant in the specimen as a function of diffusion time by measuring concentration and/or isotopic ratio profile(s) in the experimental charge using a suitable analytical instrument, and retrieve diffusion coefficient(s) from the measured concentration profiles using solutions to diffusion equations pertinent to the experimental setup. For the convenience of mathematical treatment of diffusion data, diffusion experiments are typically arranged in an effective one-dimensional geometry using one of the three setups or methods: diffusion couple method, thin source method, and constant source method. In the diffusion couple method, two rods or slabs of uniform but different composition starting materials are juxtaposed against each other in a capsule. In the thin source method, a thin film of diffusant is deposited on the surface of a polished specimen. In the constant source method, concentration of the diffusant at the surface or interface of the specimen of interest is kept constant during the course of diffusion. The diffusion couple method has been widely used to study self diffusion and chemical diffusion in molten silicates. This method has also been used to study chemical diffusion in minerals (e.g., garnet, olivine, and spinel) that have relatively fast diffusion rates on the laboratory time scale (the high temperature region labeled "ions in melts or crystals" in Fig. 1). The thin source method has been more frequently used to study diffusion in solids (minerals and glasses). The constant source method has been used to study diffusion of trace elements in either melts or minerals. This method has also been used to study diffusional loss or gain of diffusant in mineral grains in spherical geometry. The length of diffusion profile and the abundance of diffusant largely determine the analytical method used in a diffusion study (e.g., electron microprobe, ion microprobe, laser-ablation inductively coupled mass spectrometry, Rutherford backscatter spectroscopy, and nuclear reaction analysis). Depending on diffusivity and experimental run duration (minutes to a month), typical diffusion lengths range from 100s ~1000s microns for diffusion in melts (e.g., basalt-rhyolite interdiffusion) to 10s microns ~ less than 100 nanometers for diffusion in minerals (e.g., Fe-Mg diffusion in olivine; REE diffusion in pyroxene). Experimental studies of diffusion in fluids at elevated temperatures and pressures are more challenging and require special setups and capsules (e.g., the differential solubility and diffusion cell of Watson and Wark 1997; Wark and Watson 2004). A common practice in laboratory diffusion measurements is the time series study, in which a set of diffusion experiments is carried out at the same temperature and pressure but for different annealing times. Diffusion coefficients obtained from a time series study should be identical to within experimental uncertainty if diffusion is the sole mass transfer mechanism. To determine activation energy and activation volume for diffusion, diffusion experiments are conducted over a range of temperatures and pressures. Diffusivities obtained from such experiments can be used to extract diffusion parameters for the Arrhenius equation (Eq. 20). Finally, it is worth noting that diffusivities in fluids, melts, and crystals can be calculated theoretically through atomistic simulations. Computer simulations can extend the temperature and pressure ranges beyond those accessible in the laboratory, making it a powerful tool for studying thermodynamic and transport properties (including diffusivity) of earth and planetary materials. So far, atomistic simulations have been mainly used to study diffusion of major elements in simple but geologically relevant materials and the results are promising. For detailed summaries of various methods used in diffusion studies, the reader is

referred to the review articles by Ryerson (1987), Cherniak et al. (2010), de Koker and Stixrude (2010), and Watson and Dohmen (2010).

Diffusion Length and Closure Temperature

Diffusion length is a measure of the length scale of a region that is affected by the spread of diffusant. The diffusion length, L_D, scales with the square root of diffusion time and is given by the simple expression:

$$L_D = \sqrt{Dt}. \tag{23}$$

For diffusion coefficients $D = 10^{-6}$, 10^{-11}, and 10^{-19} $m^2\,s^{-1}$, which are within the ranges for diffusion in fluids, melts, and solids (Fig. 1), the diffusion lengths are 5.6 km, 18 m, and 1.8 mm, respectively, for a diffusion time of one million years. Depending on time scales of geological processes, concentration variations in mineral grains may not be effectively homogenized by diffusion. Indeed, zoning patterns preserved in mineral grains offer valuable information on time scales of geological processes, such as magma residence time, magma ascent rates, and cooling rates (Dohmen et al. 2017). During cooling, the diffusivity decreases with temperature and time, and the diffusion length may be estimated using a time-integrated diffusivity:

$$L_D = \left[\int_0^t D(t)dt\right]^{\frac{1}{2}}. \tag{24}$$

With decreasing temperature, concentration profiles in the interiors of the mineral grain become progressively insensitive to variations in mineral surface concentration. In terms of diffusional loss or gain, the mineral effectively ceases diffusive exchange with its surrounding at some lower temperature limit. This lower temperature limit is called the closure temperature (Dodson 1973). At closure temperature, the diffusion length defined by Eq. 24 is comparable to mineral grain size. By considering diffusional loss to a large reservoir along a prescribed cooling curve, Dodson (1973, 1986) obtained an equation for the mean closure temperature (T_c) for an element in a mineral grain of effective radius d,

$$\frac{E_a}{RT_c} = G + \ln\frac{D_0RT_c^2}{E_a\dot{s}d^2}, \tag{25}$$

where $\dot{s}$ is the absolute value of cooling rate at the closure temperature; G is the spatial average of the closure function and depends on geometry of the mineral ($G = 4.0066$ for sphere, 3.29506 for cylinder, and 2.15821 for plane sheet). The closure temperature decreases with the decrease of the product of cooling rate and the square of the effective diffusion radius. The geometric function, G, in Dodson's equation was modified by Ganguly and Tirone (1999) to include the "memory effect" that arises from situations when diffusion has not affected the center of the crystal (i.e., cases of fast cooling and/or large grain size). In his original derivation, Dodson (1973) used a cooling curve along which the reciprocal of the temperature increases linearly as a function of time. Generalization of Dodson's equation can be made to other heating-cooling-upwelling scenarios (Gardés and Montel 2009; Watson and Cherniak 2013; Liang 2017) and to two minerals in a closed system (Powell and White 1995; Liang 2015). Combined with geothermometers and isotopic dating, closure temperatures can be used to constrain thermal history of igneous and metamorphic rocks (Mueller et al. 2010).

Summary

Diffusion is a kinetic phenomenon that arises when there are gradients in concentration, chemical potential or temperature in a substance. Many geological processes are rate-limited by diffusion. Fick's laws of diffusion form the basis for quantifying diffusion kinetics in earth and planetary materials. The types of diffusion that are important to understand diffusion kinetics include self diffusion, chemical diffusion, multicomponent diffusion, effective binary diffusion, thermal diffusion, and grain boundary diffusion. Diffusion is a thermally activated process. Diffusion coefficients for geologically relevant fluids, melts, and solids vary enormously and systematically. The temperature- and pressure-dependent diffusivities follow the Arrhenius equation. Diffusion in silicate melts and crystals also depends on composition and structure of the melts and the crystals. Methods for measuring diffusion coefficients depend on physical state of the matter and availability of analytical methods. Atomistic simulations are becoming a powerful tool for diffusion studies and have the potential to significantly improve our knowledge and understanding of diffusion of earth and planetary materials at temperatures and pressures inaccessible in the laboratory. The field of diffusion studies is expanding owing to the continuing improvement and development of experimental, computational, and analytical methods, theories for diffusion, and numerical models for diffusion-related mass transfer. Because the diffusion equations are time-dependent, they can be used to infer rates and time scales of geological processes. There is a growing interest in applying diffusion data and models to field observations of earth and planetary materials. Indeed, diffusion is a cornerstone that connects several branches of the earth and planetary sciences.

Dissolved Organic Matter (DOM)

Hilairy Ellen Hartnett
School of Earth and Space Exploration and School of Molecular Sciences, Arizona State University, Tempe, AZ, USA

Definition

Dissolved organic matter is a heterogeneous class of water-soluble compounds that contain reduced (organic) carbon from a variety of biological and geological sources with a wide range of chemical reactivity. Dissolved organic matter is a key component in the biogeochemical cycling of carbon.

Introduction

Dissolved organic matter (DOM) is operationally defined as any organic matter that is able to pass through a filter. It is described in contrast to particulate organic matter (POM) retained on the filter. Traditionally, glass fiber filters with a nominal pore size of 0.7 μm were the standard. Currently, smaller-sized filters (0.2 μm) are often used because they are readily available and they remove most bacteria, which can degrade a DOM sample. DOM is derived from many sources both external and internal to an aquatic system. Dissolved organic matter is a complex mixture of organic molecules made up of carbon, hydrogen, and oxygen as well as the heteroatoms nitrogen, phosphorous, and sulfur; thus DOM comprises dissolved organic carbon, nitrogen, phosphorous, and sulfur. This heterogeneity makes it difficult to define DOM composition. Dissolved organic matter is an important component of the global carbon cycle and is among the most reactive pools of organic material at Earth's surface.

(Hedges 2002; Hansell and Carlson 2015). In marine systems, DOM is the primary currency of the microbial loop as it provides a food and energy source to microbes. DOM also forms complexes with trace metals making the metals more soluble and more bioavailable. In addition, in freshwater systems, DOM influences aqueous geochemistry by contributing to acidification in low-alkalinity, weakly buffered systems; it can also impart color, taste, and odor to drinking water.

Marine dissolved organic carbon concentrations range from very low values in the deep ocean (~40 μM) to very high values (>300 μM) in coastal regions. Pore water DOM values tend to be higher as particulate organic matter (POM) decomposition within sediments can release DOM. In freshwater systems, DOM ranges from 40 to1000 μM and can reach mM levels in the most carbon-rich systems (e.g., wetlands, bogs, and swamps). The reactivity or bioavailability of DOM describes how well this carbon pool can support the growth of microorganisms. Due to its diverse molecular composition DOM can be highly reactive or quite recalcitrant.

Sample Collection and Bulk Quantification

The choice of filter for DOM sampling is important. Glass fiber filters and silver membrane filters are easily cleaned but suffer from large pore sizes and very high cost, respectively. Membrane filters, especially nitrocellulose and polypropylene filters, are inexpensive but often cause significant sample contamination because they leach carbon and are difficult to clean. Polyethersulfone filters (PES, Supor™) are membrane filters that can be cleaned with deionized water and are available with small pore sizes. The choice of filter is dictated by the specific needs of the sample and the environment in which it is collected. Ideally samples should be collected and stored in ashed (500 °C, 4 h) glass containers and stored cold and in the dark to reduce biological modifications of the sample. If samples are to be stored for long periods, acidification or freezing will reduce post-filtration alteration.

Bulk quantification of DOM is achieved by converting the organic molecules to CO_2 followed by infrared detection of the CO_2 molecule. The method requires (1) complete removal of inorganic carbon from the sample and then (2) complete oxidation of the reduced organic carbon. Inorganic carbon removal is achieved by reducing pH to <2, converting carbonate and bicarbonate to carbon dioxide, and sparging to remove CO_2 gas. The oxidation of organic carbon can be achieved by UV (light) or by persulfate (wet chemical), but most modern DOM analyzers rely on oxidation by high-temperature combustion (HTC). The HTC methods generally employ a platina-alumina catalyst and temperatures of ~720 °C, followed by nondispersive infrared detection of the CO_2. Dissolved organic nitrogen (the DOM molecules that contain N in addition to C, H, and O) can be quantified separately via HTC followed by chemiluminescent detection of the NO formed during oxidation.

In the 1980s, DOM analytical methods were plagued by uncertainty surrounding analytical blanks. A broad community intercomparison revealed that careful attention to sample collection and handling techniques, as well as a commitment to uniform use of standard reference materials, allows routine, high-precision (CV ~ 3–5%), accurate measurement of DOM concentrations down to <35 μM (Sharp et al. 2002).

Characterization

The specific molecular composition of DOM is important for understanding its reactivity and fate in the environment. The direct analysis of DOM composition can be challenging due to low concentrations of individual DOM components and the sheer number of molecules represented; however, great advances have been made in the last 20 years. Improvements in isolation and extraction techniques have helped the low concentration problem, but all methods isolate only a fraction of the DOM pool. It is important to recognize that no individual analysis technique can detect 100% of the carbon in a sample at the molecular level. Thus, multiple methods must be applied to fully characterize the classes of carbon compounds present or to quantify all the molecules in a sample. Biological and environmental samples are especially complex (Kujawinski 2011; Moran et al. 2016).

DOM is comprised of a wide range of biomolecules and organic moieties ranging from large bio- and geopolymers to low molecular weight monomers. A single natural dissolved organic matter sample can be comprised of thousands of different molecules (Sleighter and Hatcher 2007). The dominant classes of biomolecules include proteins and nucleic acids, carbohydrates (sugars), lipids (fatty acids, sterols, and alkenes), pigments, and an array of smaller primary and secondary metabolites. In marine systems, fresh, algal-derived DOM reflects the relative distribution of the biomolecules in plankton biomass; however, microbial and photochemical degradation of DOM rapidly obscures the molecular composition because partially degraded molecules become unrecognizable and difficult to classify. In the deep ocean, a majority of the DOM cannot be classified as individual biomolecules because they have been partially degraded and no longer fall into a given analytical window. In terrestrial aquatic systems, similar biomolecules predominate, but there are also significant contributions from degraded, soil-derived carbon and from land plants (lignin, as well as humic and fulvic acids). Dissolved organic matter can also include geological and anthropogenically derived compounds (i.e., petroleum-derived compounds, PAHs, pesticides, detergents and surfactants, pharmaceuticals, and other emerging contaminants).

Analytical methods that have been applied to characterize DOM at the molecular level include spectrophotometric and optical techniques, nuclear magnetic resonance (NMR) spectroscopy, 2D gas chromatography, and a wide array of mass spectrometry techniques with a variety of ionization techniques. Stable carbon and radiocarbon isotope analyses of DOM are also possible and reveal information about carbon source, reactivity, and fate in the environment. Mass spectrometry can be applied to both extracted and derivatized components as well as to bulk DOM. High-resolution mass spectrometry (e.g., FT-ICR MS and ToF-MS techniques) is an especially exciting field as it is now possible to identify virtually all of the molecules present in a given sample. This capability enables true proteomics and metabolomics analyses in complex environmental samples.

Optical techniques for DOM characterization are gaining popularity because they require little sample preparation, they are nondestructive, and they can characterize different pools of organic carbon. These techniques include UV-Vis absorbance and fluorescence spectroscopy. Some compound classes of the dissolved organic matter can absorb light (colored dissolved organic matter, CDOM); these molecules affect light penetration and therefore primary production. Only certain classes of organic molecules, generally those that are aromatic or highly conjugated, are also fluorescent (fDOM). Absorbance spectroscopy can be used to characterize the aromatic fraction of the DOM (e.g., specific UV absorbance at 240 nm, $SUVA_{254}$), which is related to humic content. Fluorescence is emerging as a powerful tool to characterize aromatic/humic components of the DOM as well as moieties that contain tryptophan-like and tyrosine-like fluorescence (Fellman et al. 2010). Modeling approaches (PARAFAC) have been developed that quasi-quantify contributions of different fluorescent components (Stedmon and Bro 2008). It is not yet well known what fraction of the DOM is comprised by CDOM and fDOM, and further research is required to determine how the reactivity of CDOM and fDOM relates to the bulk DOM reactivity.

Importance to the Carbon Cycle and Current Questions

Dissolved organic matter plays a major role in the carbon cycle. The marine DOM pool holds ~700 Pg of carbon, roughly equivalent to the atmospheric pool. This DOM is a fundamental component of the Earth's active carbon cycle, and the wide range in molecules present means that some fractions are labile and readily degraded by microbes, while other fractions are recalcitrant and can persist for thousands of years. The DOM pool is also in dynamic equilibrium with particulate organic carbon (POC), and the sorption of DOM to particles provides a measure of protection from microbial degradation. The specific mechanism of this sorptive protection is not well known.

Questions remain as to what controls DOM accumulation and removal in marine and terrestrial systems and how microbial and abiotic processes affect DOM composition. Terrestrial carbon, once thought to be highly refractory (non-labile), has been shown to be reactive on short timescales (days to weeks) in estuaries. Surface ocean carbon in excess of deep ocean concentrations holds a modern radiocarbon signature (recently produced) but seems to be semi-labile, possibly due to the more limited microbial diversity in surface waters relative to that in deep waters and coastal regions. DOM in surface waters can also be photooxidized which may influence the lability of the DOM. The vast, deep ocean pool of DOM is old, but small additions of labile and semi-labile material do occur upon solubilization of sinking biogenic POM, and this labile carbon may have a "priming" effect that induces DOM degradation. The complexity of dissolved organic carbon is enormous, and our understanding of the detailed cycling of dissolved organic carbon is still quite limited. New approaches that link microbial ecology with high-resolution geochemical analyses and informatics data are necessary to achieve predictive understanding of DOM cycling (Moran et al. 2016).

Summary

Dissolved organic matter is a complex mixture of organic molecules that occupies a central role in Earth's surface carbon cycle. The complexity of DOM composition has made it difficult to characterize at the molecular level, and we are only beginning to understand the interactions among microbes, metabolisms, and dissolved organic matter cycling.

Dolomite and Dolomitization

Jennifer A. Roberts
Department of Geology, University of Kansas, Lawrence, KS, USA

Definition

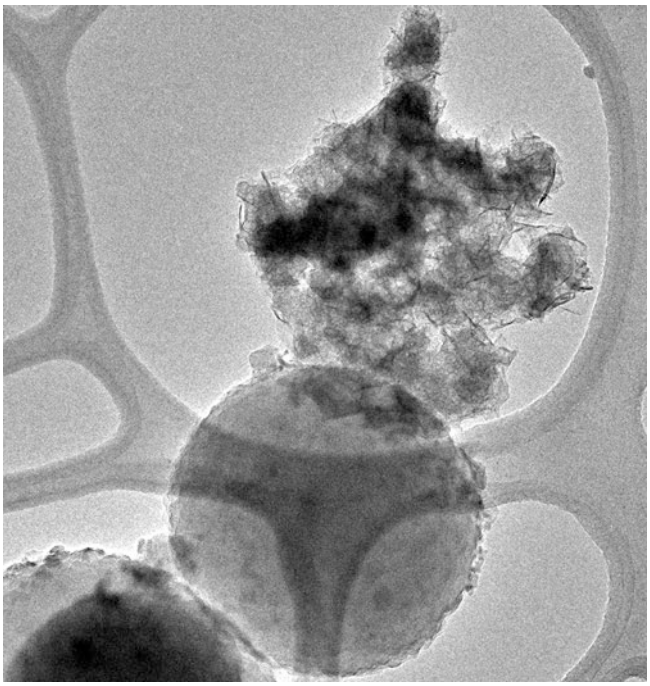
Dolomite is a trigonal–rhombohedral, ordered Ca, Mg carbonate mineral ($CaMg(CO_3)_2$) occurring primarily in sedimentary and metamorphic rocks. Dolomitization is the process in which Mg ions replace Ca ions in a calcium carbonate mineral.

Crystal Structure and Geochemistry

The crystal structure of dolomite is similar to calcite with Mg ions substituting for Ca in every other layer. To accommodate this substitution, due to differences in bond lengths between Ca–CO_3 and Mg–CO_3 (238 pm versus 208 pm, respectively), CO_3 in the Mg layer is uniformly rotated about the threefold axis relative to calcite (Reeder and Wenk 1983).

Stoichiometric dolomite (50:50 $CaCO_3$:$MgCO_3$) is part of a solid solution between calcite ($CaCO_3$), magnesite ($MgCO_3$), and ankerite ($FeCO_3$). Iron substitution as well as Mg substitution greater than ~10 mol% will lead to disordering and expansion of the unit cell (Antao et al. 2004; Carmichael and Ferry 2008). These disordered phases are thermodynamically metastable and over time, and with diagenetic alteration, through dissolution/re-precipitation are replaced by more ordered phases.

Dolomite stoichiometry can be measured using atomic absorption spectroscopy, inductively coupled plasma, and electron microprobe. Crystal structure and ordering of dolomite can be identified using X-ray diffraction (XRD) techniques; however, determination of stoichiometry requires the use of empirical curves that relate dolomite to calcite d_{104} to account for unit cell changes with substitution of $MgCO_3$ (e.g., Zhang et al. 2010). In mixed mineralogy samples and in samples where dolomite is in low abundance, XRD may not give unequivocal results of stoichiometry and ordering (e.g., Gregg et al. 2015), and techniques such as transmission electron microscopy (Fig. 1) with selected area electron diffraction (Zhang et al. 2010; Zhang et al. 2012a; Zhang et al. 2012b; Roberts et al. 2013), laser scanning Raman spectroscopy (e.g., Sun et al. 2014), synchrotron-based energy-dispersive X-ray diffraction, and infrared spectroscopy (Rodriguez-Blanco et al. 2015) may help confirm these results.



Dolomite and Dolomitization, Fig. 1 Dolomite precipitates abiotically at 25 °C on a carboxylated, polystyrene sphere in seawater approximating Silurian conditions (see Roberts et al. 2013 for experimental conditions). Sphere is 0.8 μm in diameter

Kinetics of Precipitation

Stoichiometric, ordered dolomite readily forms at temperatures above 100 °C (Arvidson and Mackenzie 1999); however, changes in temperature and solution chemistry significantly influence the stoichiometry of precipitated phases. Thermodynamic constants and isotopic fractionation factors have been developed for dolomite at high temperatures (80–250 °C; Baker and Kastner 1981; Sibley et al. 1987; Li et al. 2015) and extrapolated to lower temperatures where laboratory synthesis is hindered by slow reaction kinetics (e.g., Land 1998). Kinetic inhibition of dolomite precipitation at low temperature is attributed to lack of persistent solution supersaturation, low Mg:Ca ratios, sulfate inhibition, Mg-dehydration barrier, and lack of nucleation sites or critical nuclei (e.g., Baker and Kastner 1981; Hardie 1987; Zhong and Mucci 1989; Slaughter and Hill 1991; Brady et al. 1996; Arvidson and Mackenzie 1999; Wright and Wacey 2004).

There are many reports of microbially facilitated dolomite at low temperature (<80 °C) in which kinetic barriers such as solution supersaturation, sulfate inhibition, Mg desolvation, and nucleation sites are attributed to microbial metabolism and surfaces (e.g., Vasconcelos et al. 1995; Warthmann et al. 2000; Mazullo 2000; van Lith et al. 2003; Moreira et al. 2004; Roberts et al. 2004; Wright and Wacey 2004; Wright and Wacey 2005; Braissant et al. 2007; Bontognali et al. 2008; Sánchez-Román et al. 2008; Sánchez-Román et al. 2009; Kenward et al. 2009; Bontognali et al. 2010; Krause et al. 2012; Kenward et al. 2013; Meister et al. 2007; Petrash et al. 2015). These reports link microorganisms to dolomite formation; however, few studies have identified definitive mechanisms by which microbial activity or surfaces facilitate nucleation and subsequent precipitation at low temperature. Enhanced Mg incorporation into the calcite crystal structure has been linked abiotically to dissolved sulfide, which sorbs onto crystal surfaces and facilitates Mg dehydration (Zhang et al. 2012b). Dolomite and Mg-calcite precipitation has been linked also to exopolymeric substances found in microbial biofilms (Bontognali et al. 2008; Krause et al. 2012) in which carboxyl groups associated with these surfaces or other organic matter complex and dehydrate Mg (e.g., Zhang et al. 2012a; Roberts et al. 2013). Many of these reports are of disordered phases, although there are reports of ordered, stoichiometric dolomite forming at low temperature (e.g., Roberts et al. 2004; Kenward et al. 2009; Kenward et al. 2013; Roberts et al. 2013).

Geological Significance and Occurrence

A long-standing conundrum in the geosciences is the so-called dolomite problem. Modern dolomite is scarce and rarely forms on Earth today due to slow reaction kinetics (<50 °C); however, ancient low-temperature dolomite formed in large quantities in Precambrian oceans and throughout the Phanerozoic from so-called calcite seas, apparently dependent upon secular variation of seawater geochemistry (Hardie 1987). Temporal changes in seawater Mg:Ca ratios, pCO_2, and dissolved sulfate concentrations contribute to thermodynamic favorability of aragonite ($CaCO_3$) versus calcite ($CaCO_3$) and dolomite (Wilkinson and Given 1986). Ancient dolomite formed through both primary precipitation and replacement (dolomitization) of $CaCO_3$, presumably by Mg-rich fluids. In modern systems, primary dolomite is constrained to hypersaline environments, such as lagoons (e.g., Vasconcelos and McKenzie 1997) and sabkha environments (e.g., Wright and Wacey 2005), and evidence of ongoing dolomitization of $CaCO_3$ in low-temperature settings has not been reported.

Large-scale models of carbonate dolomitization, including mixing of seawater and groundwater, reflux dolomitization by mesohaline brines, and (hydro)thermal circulation of seawater, have varying evidence of their contributions to dolomitization (e.g., Machel 2004). These models underpin the prevalence of dolomite as a prolific petroleum reservoir. Its utility as a reservoir is attributed to the fact that dolomite preserves its porosity more readily with burial than other carbonate units (Schmoker and Halley 1982; Sun 1995) due to the increased resistance to mechanical and chemical compaction of dolomite compared to calcite (Gale et al. 2010).

History and Use

Giovanni Arduino, an Italian geologist, is credited with the first identification of the mineral now known as dolomite in 1779 (McKenzie and Vasconcelos 2009); however, Déodat de Dolomieu is credited with recognizing the mineral that makes up the mountains now known as the Dolomite Mountains of Northern Italy (de Dolomieu 1791; Zenger et al. 1994).

In addition to its utility as a petroleum reservoir, dolomite is also used as a paleothermometer and a tracer of seawater geochemistry. It is mined and used as a source of Mg and a pH buffer in soils and is used as a flux for smelting and ceramics.

Summary

Extensive research has been performed on kinetics of dolomite precipitation and dolomitization reactions. These efforts further refine models of large-scale dolomite formation that are found in ancient rock.

1 Atm Melting Point: 1412 °C
(*continued*)

1 Atm Boiling Point: 2567 °C
Common Valences: +3
Ionic Radii: 91.2 pm (CN6), 102.7 pm (CN8), and 122.8 pm (CN12)
Pauling Electronegativity: 1.22
First Ionization Energy: 573.02 kJ mol^{-1}
Chondritic (CI) Abundance: 0.254 ppm
Silicate Earth Abundance: 0.566 ppm
Crustal Abundance: 3.7 ppm
Seawater Abundance: 1.06 ppt
Core Abundance: ~0

Properties

Dysprosium (Dy), from the Greek *dysprositos* (hard to access), is a soft, ductile, dense (8.551 g cm^{-3}), bright silvery metal. Its electronic configuration is [Xe]4f^{10}6s^{2}. It is stable at room temperature and readily dissolves in mineral acids. It is a group 3 or IIIB inner transition element, with +3 being its only valence state in geological environments, and is one of the lanthanide rare earth elements (REE). In geochemical terminology, it is grouped with heavy rare earth elements (HREE; Gd-Lu). Dysprosium has seven natural, stable isotopes, listed above with their abundances.

More than 270 minerals contain lanthanides as essential structural constituents, but those with Dy as a major component are restricted to Y and HREE varieties, such as xenotime [$Y(PO_4)$], bastnäsite [$REE(CO_3)F$], allanite [$(REE,Ca,Y)_2(Al,Fe^{2+},Fe^{3+})_3(SiO_4)_3(OH)$], and britholite [$(REE,Ca)_5(SiO_4,PO_4)_3(OH,F)$]. In addition, Dy may be enriched in ion adsorption lateritic kaolinite–halloysite clay deposits that are mined for REE.

Details of properties, mineralogy, history, and uses of Dy were compiled from Goonan (2011), Chakhmouradian and Wall (2012), Zaimes et al. (2015), Gschneidner Jr (2016), Hammond (2016), and Meija et al. (2016a, b).

History and Use

Dysprosium was discovered in 1886 by Paul Émile Lecoq de Boisbaudran but not isolated until about 1950. Its major use is as a component for neodymium magnets. Due to a relatively high thermal absorption cross section, Dy_2O_3–nickel ceramic metals (cermets) have been used in nuclear reactor cooling rods. Other uses include as components in lasers, magnets, metallic coatings, ionizing radiation dosimeters, transducers, and infrared radiation sources.

Geochemical Behavior

The fundamental importance of Dy in geochemistry is that it is one of the small trivalent rare earth elements, among the most useful trace elements in all areas of geochemistry and cosmochemistry due to their coherent and systematic behavior as a group, largely a consequence of the "lanthanide contraction."

Dysprosium is typically a trace element in most rocks and minerals. It is classified geochemically and cosmochemically as a highly refractory lithophile element with a 50% $T_{condensation}$ of 1659 K at 10^{-4} bars (Lodders 2003). In most igneous systems, Dy is incompatible with bulk partition coefficients, $D < 1$. In aqueous systems, Dy normally has very low fluid/rock partition coefficients ($\ll 1$). As a result, Dy contents of clastic sediments typically reflect their average provenance abundances.

In seawater, Dy has very low concentrations (~ppt) and residence times (~740 year) with speciation dominated by Dy^{3+}, $DyCO_3^+$, and $Dy(CO_3)_2^-$. In other aqueous systems (e.g., magmatic, hydrothermal), Dy can reach ppm levels due to elevated temperatures, pH effects, and complexing with various ligands (e.g., F^-, Cl^-, OH^-).

Concentration and residence time data are from compilations in Taylor and McLennan (2009) and Nozaki (2001).

Biological Utilization and Toxicity

There are no documented biological uses for Dy, but in China REE have been added to fertilizers and to stock feed to promote growth. REE (including Dy^{3+}) likely substitute for Ca^{2+} in biological materials and processes. REE concentrations (including Dy) in human tissues and fluids are very low (tens of ppb to <ppb levels, respectively) due to very low concentrations in natural waters and low uptake rates throughout the food chain (Bulman 2003). At low levels of ingestion, there are no established toxic effects that pose a threat to human health.

Earth's Atmosphere

Daniele L. Pinti
GEOTOP, Research Center on the Dynamics of Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

The Earth's atmosphere is the outer layer of our planet. This layer contains gases, commonly referred to as *air*.

Overview

The atmosphere is retained by the Earth's gravity, although some of it is lost to outer space through thermal escape, known as *Jeans escape*. By volume, dry air contains 78.08% N_2, 20.94% O_2, 0.933% Ar, and 409 ppmv CO_2 (CO_2 data from the Mauna Loa Observatory, April 2017 at https://www.esrl.noaa.gov/gmd/ccgg/trends/monthly.html). The noble gases He, Ne, Kr, and Xe, together with CH_4 and H_2O (as water vapor), occur in trace concentrations (see Table 1). The total mass of the atmosphere is approximately 5.15×10^{18} kg, mainly concentrated in the first layer, called the *troposphere*, which extends from the topographic surface of the planet to 12 km above it.

The atmosphere is divided into five layers, from the surface to outer space: the troposphere (0–12 km), the stratosphere (12–50 km), the mesosphere (50–80 km), the thermosphere (80–700 km), and the exosphere (700–10,000 km). The exosphere merges with the solar wind. The current chemical composition of the atmosphere is the result of several extraterrestrial volatile sources – wet asteroids and comets – deeply modified by the activity of life. Due to these latter processes, the Earth's atmosphere can be classified as *habitable*. The most apparent effect of biological activity on Earth is the progressive accumulation of molecular oxygen (O_2) since the end of the Archean and the formation of the ozone (O_3) layer.

How the atmosphere formed has fascinated philosophers, scholars, and scientists for centuries, since ancient Greece. The advent of cosmochemistry and isotope geochemistry in the twentieth century provided valuable contributions to understanding how the Solar system formed and how rocky planets acquired their atmospheres and oceans. However, recent discoveries made by the Rosetta mission on comet 67P/Churyumov–Gerasimenko might revolutionize our theories of the Earth's formation and the evolution of its differentiated geochemical reservoirs.

History of the Origins

One of the first treatises on the physics of the atmosphere is *Meteorologica* by **Aristotle** (384–322 BC), the title of which comes from the ancient Greek μετέωρον (metéōron, "high in the sky"). In this work, Aristotle attempted to describe everything of a physical nature in the sky. One of the philosophical thoughts of Aristotle was that earthquakes resulted from winds within the Earth caused by the Earth's own heat, as well as heat from the Sun. Volcanoes, he thought, marked the points at which these winds finally escaped from inside the Earth into the atmosphere (Aristotle and Lee 1952). Prior to Aristotle, **Anaximander of Miletus** (611–549) speculated that the Earth began as fluid, some of which dried to become solid earth and some of which evaporated to become the atmosphere.

This vision, in which the atmosphere was derived from the degassing of the interior of the Earth, lasted for centuries. In one of the first treatises of geology, *Mundus subterraneus, quo universae denique naturae divitiae*, the German Jesuit and scholar **Athanasius Kircher** (1602 – 1680) illustrated the interior of the Earth with a central core from which conduits extend to the surface, with intermediate cavities (*pyrophylacies*) filled with fluids and gases. The conduits

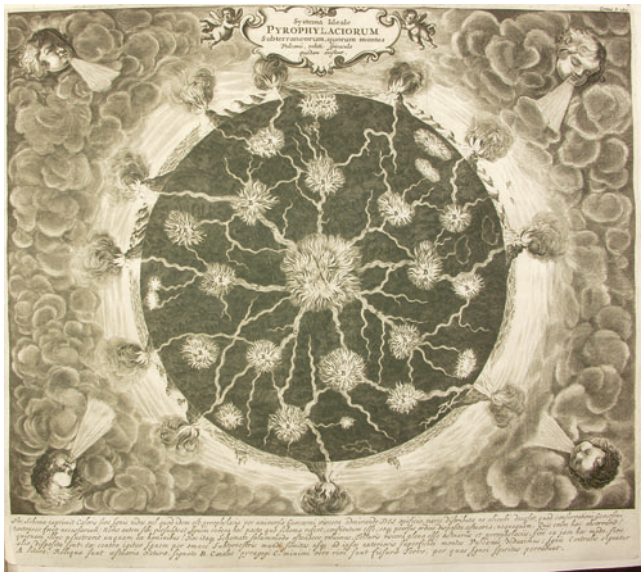
Earth's Atmosphere, Table 1 Twenty-first century elemental composition of dry air by volume (Data modified after Gatley et al. 2008)

Constituent (chemical symbol)	Volume %
Nitrogen (N_2)	78.0818
Oxygen (O_2)	20.9435
Argon[a] (Ar)	0.9332
Carbon dioxide[b] (CO^b)	0.0385
Subtotals	99.9970
Neon (Ne)	0.001818
Helium (He)	0.000524
Methane (CH_4)	0.00015
Krypton (Kr)	0.000114
Hydrogen (H_2)	0.00005
Nitrous oxide (N_2O)	0.00003
Xenon (Xe)	0.0000087
Subtotals	0.0026947
Eight trace gases, including CO, O_3, SO_2, NO_2, NH_3, and H_2O	0.0003053
Total	100.0000

Notes: Because Gatley et al. (2008) assumed that increases in CO_2 result from combustion and respiration processes, and the increase is perfectly correlated with a decrease in O_2, then the volume % of O_2 in the 2016 dry air should be 20.9417

[a]The amount of CO_2 reported was measured in 2008. The present-day value (April 28th 2017) is 409.48 ppmv (Mauna Loa Observatory at https://www.esrl.noaa.gov/gmd/ccgg/trends/monthly.html)

[b]NASA continues to use 0.9340 as the volume % for argon, as calculated at the beginning of the twentieth century



Earth's Atmosphere, Fig. 1 Kircher's vision of the *Mundus Subterraneus* and its interior, in which conduits extend to the surface, with intermediate cavities (pyrophylacies) filled with fluids and gases (From Kircher 1678)

were thought to reach the surface to form volcanoes from which the internal fire escaped to the atmosphere (Fig. 1) (Kircher 1678).

In 1833, the French physicist **André-Marie Ampère** concluded that the Earth's atmosphere resulted from the reduction of oxygenated bodies by metals, leading to the release of nitrogen originally combined with oxygen, also explaining the origin of oxygen in the atmosphere.

Mid-twentieth century, American geologist **William W. Rubey** (1951) wrote a seminal paper entitled *Geological History of Seawater. An attempt to state the problem,* in which he attempted to resolve the origin of the atmosphere and the oceans.

He noticed that the most common volatiles – H_2O, CO_2, Cl, N, and S – are too abundant in the atmosphere, hydrosphere, biosphere, and in ancient sediments to be produced by the weathering of the continental masses, which he assumed to be constant. For example, he estimated that only one hundredth of the 1.37×10^{21} kg of H_2O present in the hydrosphere and atmosphere could be derived from silicate rock weathering. Continents growth throughout the Hadean and Archean eons, reaching the present volume somewhere at the end of the Archean or in the Proterozoic, (e.g., Hawkesworth and Kemp 2006). The supply of volatiles from rock weathering would therefore be even lower than that estimated by Rubey. Furthermore, it is now recognized that the terrestrial mantle contains at least five times the amounts of hydroxides as the global ocean mass in high-pressure mineral phases, such as ringwoodite (Pearson et al. 2014), so any hypothesized source of water on Earth must be able to explain the occurrence of a total water amount of ~8–9 $\times 10^{21}$ kg.

Rubey (1951) noticed that the amount of volatiles "in excess" of those possibly formed by rock weathering was similar to the combined amounts found in gases escaping from volcanoes, fumaroles, hot springs, and in gases trapped in igneous rocks. He concluded that during the crystallization of melts, water and carbon dioxide were preferentially partitioned in the residual melt and then released during the last stages of magma differentiation. Intrusive rocks might have been the main sources of these volatiles, escaping to the atmosphere through hot springs. Again, the hypothesis of a volatile source from the interior of the Earth prevailed.

Modern Theories of Earth's Atmosphere Formation

The hypothesis that the volatiles forming the atmosphere and hydrosphere were degassed from the Earth's interior became even stronger with the advent of noble gas geochemistry. In 1969, American geochemist Harmon Craig and colleagues found ^{3}He anomalies in seawater samples taken at the proximity of the East Pacific Rise (Clarke et al. 1969). In the same year, anomalous helium isotopic compositions (^{3}He/^{4}He ratios) were found in the volcanic gases of Kamkatcha

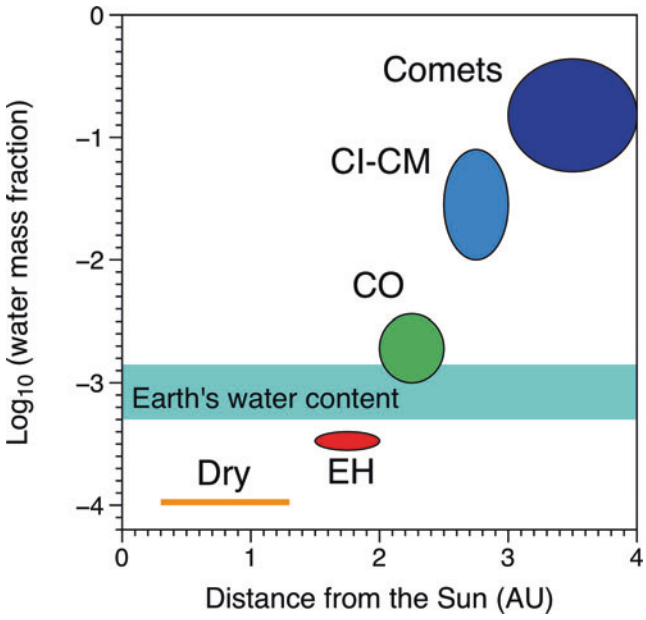
(Mamyrin et al. 1969). Mamyrin and his colleagues argued that the high $^{3}He/^{4}He$ ratios found was due to ^{3}He production from decay of tritium released during Russian tests. Later tritium measurements in the area dismissed this hypothesis.

^{3}He is a primordial isotope (of solar origin) trapped in the mantle during Earth's accretion from the protosolar nebula (PSN hereafter). It is extremely rare in the atmosphere and the hydrosphere. The presence of ^{3}He in seawater was a clear indication that volatiles are still degassing from the mantle, mainly at the mid-ocean ridges (presently, the ^{3}He flux at MOR is 4 ± 1 atoms $cm^{-2}s^{-1}$; Craig et al. 1975) and in minor amount in back-arc basins (0.6–1.6 atoms $cm^{-2}s^{-1}$; Lan et al. 2010). This degassing is the residual of a catastrophic degassing event which took place within 50–100 Ma of the Earth's formation (Marty 1989; Kunz et al. 1998). This hypothesis was reached after the discovery of the extinct radionuclides, particularly the ^{129}I-^{129}Xe system (e.g., Butler et al. 1963). ^{129}Xe is produced by ^{129}I, a short-lived nuclide with a half-life of 16 Ma. ^{129}Xe, normalized to the primordial ^{130}Xe isotope, is less abundant in the atmosphere ($^{129}Xe/^{130}Xe = 6.496$; Ozima and Podosek 1983) than in the mantle basalts ($^{129}Xe/^{130}Xe \leq 8.2$; Moreira et al. 1998). This means that atmospheric ^{129}Xe was outgassed from the mantle when the parent element was still present, and the two reservoirs were then essentially isolated from each other. Residual ^{129}I in the mantle would have continued to produce ^{129}Xe, creating the isotopic difference between the two reservoirs. This model is consistent with that of the evolution of $^{40}Ar/^{36}Ar$ in the atmosphere (e.g., Sarda et al. 1985). Like ^{3}He, ^{36}Ar is a primordial isotope. ^{40}Ar, present in negligible amounts at the time of terrestrial accretion, has been produced by the decay of ^{40}K, present in the continental crust throughout the Earth's history. The $^{40}Ar/^{36}Ar$ ratio in the atmosphere evolved from nearly zero (2×10^{-4}) to the present-day value of 298.6 by addition of radiogenic ^{40}Ar. All models which take continental crust growth into account predict that more than 80% of the ^{36}Ar was degassed very early in the Earth's history, while ^{40}Ar slowly built up in the atmosphere (Hamano and Ozima 1978; Turner 1989).

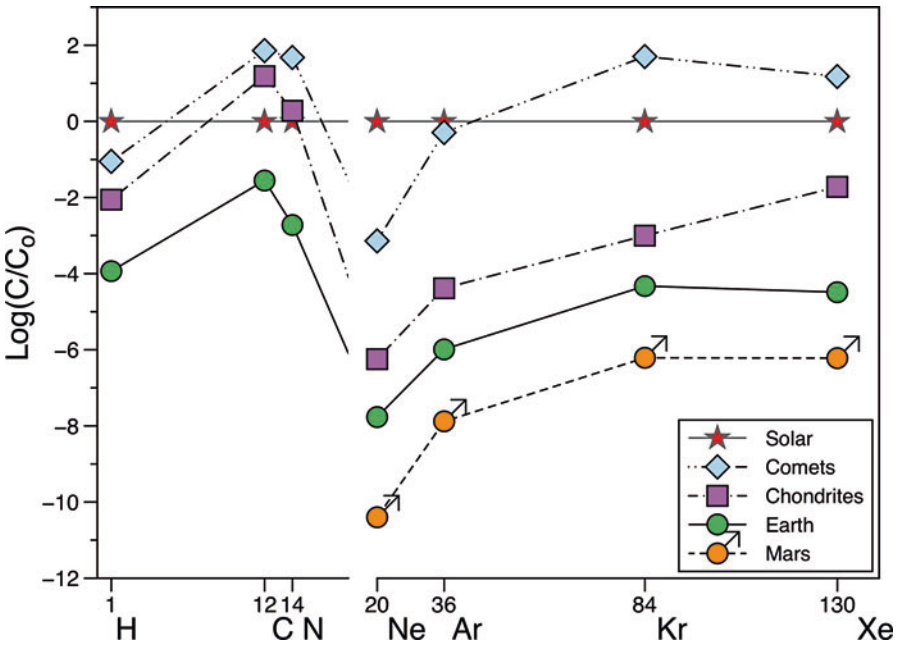
If the idea that the atmosphere was derived from volatiles added during Earth's accretion and then degassed from its interior is basically correct; the source of these volatiles is still not completely clear. The Earth's atmosphere, also made up of gases such as oxygen that were added more recently by the activity of life, does not have a solar composition, except for ^{3}He (and possibly ^{20}Ne; see below). The primary atmospheres enveloping the rocky planets were stripped by powerful stellar winds during the first phases of young Sun activity, known as the T-Tauri stage, and only survived in the giant planets of the Solar system. Earth retained a small amount of hydrogen and helium (^{3}He). Indeed, primitive magmatic rocks show $^{3}He/^{4}He$ ratios of up to 60 times (Stuart et al. 2003) the atmospheric ratio ($Ra = 1.382 \times 10^{-6}$; Sano et al. 2013), clearly indicating the occurrence of solar ^{3}He in the Earth's interior. These values are lower than the expected solar ratio of 108 Ra (Geiss et al. 1995), because of the ubiquitous atmospheric contamination of terrestrial rocks.

There is still debate as to whether ^{20}Ne on Earth is also from the PSN (Sarda et al. 1988). ^{20}Ne excesses over ^{22}Ne compared to the ratio in the present atmosphere ($(^{20}Ne/^{22}Ne)_{air} = 9.80$; Ozima and Podosek 1983) were measured in deep CO_2 well gases ($^{20}Ne/^{22}Ne$ up to 11.85 ± 0.04; Ballentine and Holland 2008) and in magmatic rocks from the lower, non-degassed mantle ($^{20}Ne/^{22}Ne$ up to 13 ± 0.7; Matsumoto et al. 1997). More recently, Yokochi and Marty (2004) gave a more precise value of 13.0 ± 0.2 for the Kola plume, while Mukhopadhyay (2012) gave a closer value of 12.88 ± 0.06. ^{20}Ne excesses could either be accounted for by protosolar Ne ($^{20}Ne/^{22}Ne = 13.8$; Benkert et al. 1993; $= 13.4$; Heber et al. 2007) trapped during the accretion of planetesimals or solar wind-implanted (SWI)-Ne ($^{20}Ne/^{22}Ne = 12.5$; Wieler 2002; Raquin et al. 2008). This latter Ne component is mainly recorded in gas-rich meteorites and may have been produced on the meteorite surface by irradiation by the solar wind.

Models of solar system dynamics suggest that the Earth formed in a region of the nascent Solar system too energetic to permit the trapping of volatile elements in the planetary embryos (Fig. 2). The accreting material was essentially dry (e.g., Wanke and Gold 1981). In his model, Javoy (1997) assumed that the Earth was made almost entirely of enstatite chondrites, the driest objects in the solar system, consisting of



Earth's Atmosphere, Fig. 2 Water content (as a mass fraction of the planetary body) in different objects of the solar system, compared to the Earth's water content, including the mass of the global oceans and five times this mass in the terrestrial mantle ($8–9 \times 10^{21}$ kg) (Redrawn from Dauphas and Morbidelli (2014))



Earth's Atmosphere, Fig. 3 Major volatile (HCN) and noble gas abundances in different objects of the solar system (Mars, CI-CM type chondrites, and comets) compared to abundances in the Earth's atmosphere (labeled "Earth"). Abundances are reported as the logarithm of the ratio of the abundances, normalized to the solar composition. Comet abundances are derived from noble gas-trapping experiments in amorphous ice (calculated at 55 K) (Owen and Bar-Nun 1995). Note the split in the X-axis for clarity (Data are from Dauphas and Morbidelli (2014))

only 0.01% water (Fig. 2). Drake and Righter (2002) suggested an unknown primitive meteoritic material as the building blocks of the Earth, something between ordinary and enstatite chondrites, and almost entirely dry. In conclusion, when the Earth arrived at the waning stages of accretion, it was basically depleted in any sort of volatile.

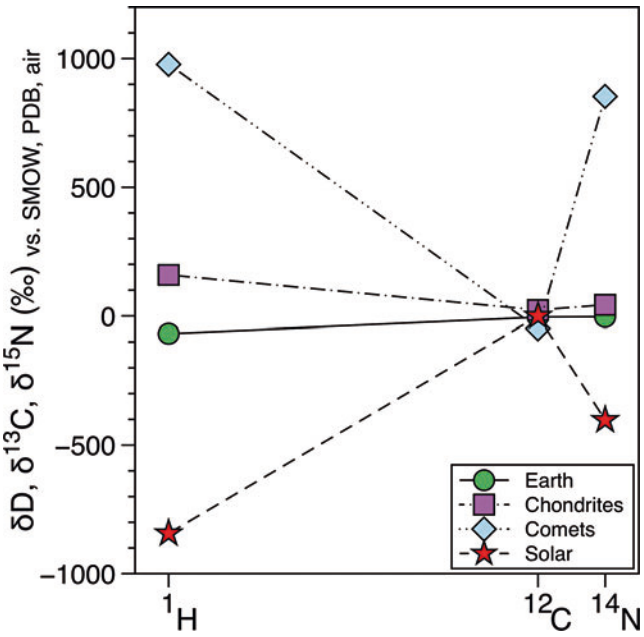
This ascertainment led to the late veneer theory (Chou 1978). Basically, wet bodies, akin to carbonaceous chondrites, brought the main volatiles and water to a dry proto-Earth at the end of accretion and after core formation (Wanke and Gold 1981). The late veneer theory also elegantly resolved another conundrum: the presence of platinum group elements (PGE) in the mantle. Indeed, it is expected that these highly siderophile elements (HSE) were all drained into the core during the differentiation of the Earth. In order to explain the mantle excesses of PGE, Morgan et al. (1981) postulated the need for a chondritic veneer (C1 type). The mass of chondritic material added to a dry proto-Earth was estimated to range between 0.12% and 0.74% of the whole mantle (Morgan et al. 1981; Dauphas and Marty 2002; Wang and Becker 2013). We will see in the last section that the late veneer did not contribute substantially to the volatile inventory of the hydrosphere-atmosphere, which was instead contributed by chondritic planetary bodies during the Earth's building stages.

Asteroids or Comets: The Long-Standing Controversy

The development of cosmochemistry and isotope geochemistry in the second half of the twentieth century provided a great deal of help in refining the model of Earth's atmosphere and hydrosphere formation.

By looking at the total atmospheric inventory of major gaseous species and noble gases, a complex formation scenario is revealed. In Fig. 3, the total inventories of ^{1}H, ^{14}N, ^{12}C, ^{20}Ne, ^{36}Ar, ^{84}Kr, and ^{130}Xe in the present-day Earth atmosphere, on Mars' surface, in volatile-rich carbonaceous chondrites (CI-CM class meteorites), and in comets are normalized to their solar abundances (data from Dauphas and Morbidelli 2014). Because noble gases are chemically inert, their abundances and isotopic ratios should provide solid constraints on the cosmic reservoirs from which the volatiles originated.

The major volatile elements (H, C, N) in the Earth's atmosphere are one to two orders of magnitude lower than in the chondrites and comets but show a similar pattern. However, the cometary pattern shows a slight enrichment in N with respect to C compared with the present-day Earth's atmosphere (i.e., the C/N ratio in comets is lower than on Earth; Fig. 3). Primordial noble gas isotopes are also depleted in the Earth's atmosphere compared with the other reservoirs, with mass-dependent depletion; Ne being the most depleted and Xe the least depleted compared to the solar abundance. The patterns of Mars and Earth are identical and very close to that of chondrites, except for Xe, which is depleted compared to that in chondrites. This is known as the *missing Xe problem*. Comets are more depleted in Ne and more enriched in Kr than Earth, but they show Xe depletion, like Mars and Earth. It is important to note that the cometary abundances reported in Fig. 3 (and in Dauphas and Morbidelli 2014) are those derived from noble gas-trapping experiments in amorphous ice (calculated at 55 K) (Owen and Bar-Nun 1995). The recent



Earth's Atmosphere, Fig. 4 Isotopic composition of major volatiles (HCN) in comets, CI-CM chondrites, and solar compared to those in the Earth (Redrawn from Dauphas and Morbidelli (2014))

Rosetta mission on comet 67P/Churyumov–Gerasimenko only allowed ^{36}Ar to be measured (Marty et al. 2016).

The similarity of the noble gas abundance patterns between the Earth and chondrites suggests that chondrites could be the main external carrier of volatiles (including water) on Earth. This is also supported by similar isotopic ratio patterns of major volatiles (R = ^{2}H/1H, ^{13}C/^{12}C, ^{15}N/^{14}N), as reported in Fig. 4 in delta notation ($\delta i(‰) = [R_{reservoir}/R_{std}]\text{-}1) \times 1000$, where the reference standard (std) is V-SMOW for H, PDB for C, and air for N). The isotopic composition of H, C, and N of Earth and of chondrites (data compiled from Dauphas and Morbidelli 2014) are comparable (Fig. 4), while clearly different from that of comets (except for C). Mars is not reported because its atmospheric isotopic composition is strongly fractionated toward higher values by massive loss of the hydrosphere-atmosphere system (Atreya et al. 2013).

These simple observations suggest that volatile-rich chondrites, such as carbonaceous chondrites, are the main carrier of water and of the atmophile elements on Earth. However, the depletion of Xe (the so-called *missing Xe problem*) calls for a possible contribution from comets. There are numerous hypotheses to explain the missing Xe, such as hidden reservoirs on Earth (in clays (Bernatowicz et al. 1984); in high-pressure phases in the mantle (Sanloup et al. 2005; Dewaele et al. 2016); in the core (Lee and Steinle-Neumann 2006)) or the progressive escape of Xe ions from the early Earth atmosphere, possibly through the interaction with UV light from the young Sun (Pujol et al. 2011). However, the contribution of cometary xenon cannot be excluded. Based on missing Xe, Dauphas (2003) calculated a maximum cometary mass accreted to the Earth of 3×10^{18} kg (i.e., 0.00005% of the Earth's mass). Comets could only have contributed 2–3% the total water budget on Earth by mass ($8–9 \times 10^{21}$kg).

There are two other convincing pieces of evidence that major volatiles and some of the noble gases were brought to Earth by chondritic bodies rather than by comets: the isotopic signature of the oceanic water on Earth and the very recent analysis of volatiles form the coma of the 67P/Churyumov–Gerasimenko comet (Marty et al. 2016).

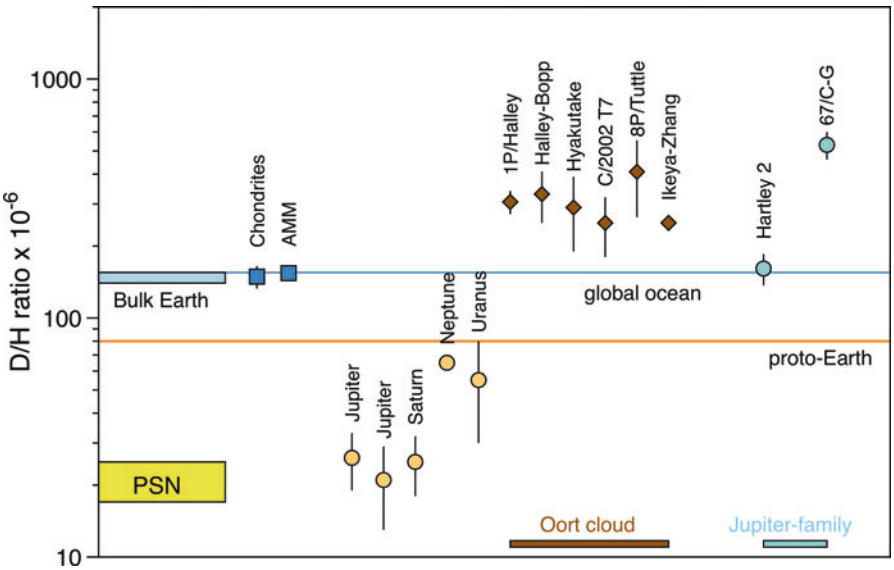
The water molecule has two elements, H and O. Hydrogen has two stable isotopes (^{1}H and ^{2}H, or D for deuterium), and oxygen has three stable isotopes (^{16}O, ^{17}O, and ^{18}O). The major hydrogen reservoir in the universe is atomic or molecular hydrogen. The isotopic composition of water in several objects of our Solar system, such as comets, chondrites, or planets, shows a systematic enrichment in deuterium, which can be determined by measuring the ^{2}H/^{1}H or D/H ratio (e.g., Robert 2001a) (Fig. 5).

Models of the PSN evolution indicate that once they had entered the nebula, interstellar ice grains vaporized, and the D/H ratio of the resulting deuterium-rich water vapor was lowered through isotopic exchange with molecular hydrogen. Water vapor successively condensed into microscopic icy grains, with decreasing D/H ratios, the closer they were to the Sun. This isotopic gradient reflects the fact that the closer to the Sun, the higher the temperature and the faster the isotopic exchange between water and molecular hydrogen. The D/H heliocentric gradient predicts that the D/H ratio for water condensed at Earth's distance (1 AU) from the Sun should be ~80×10^{-6} or $\delta D = -490‰$ depleted compared the global ocean (V-SMOW = 155.67×10^{-6} or $\delta D = 0‰$ by definition) (Robert 2001a; Fig. 5). The water isotopic composition of the bulk Earth is only slightly depleted compared to the global ocean ($149 \pm 3 \times 10^{-6}$ or $\delta D = -43‰$; Lécuyer et al. 1998) and is very different from the PSN value of $21 \pm 5 \times 10^{-6}$. Giant planets (which have primary atmospheres of solar composition) have D/H ratios ranging from 21 ± 8 to $65 \pm 2 \times 10^{-6}$ (δD from −865 to −580‰), while long period comets from the Oort cloud have D/H ratios much higher than bulk Earth (average D/H of $296 \pm 25 \times 10^{-6}$ or $\delta D = +900‰$; Robert 2001a, b; Hartogh et al. 2011).

Conversely, carbonaceous chondrites show an average D/H of $149 \pm 6 \times 10^{-6}$ ($\delta D = -43‰$; data compiled by Pinti 2005), which encompasses the bulk Earth value (Fig. 5). Antarctic micrometeorites (which have a CM-CR carbonaceous chondrite composition; Kurat et al. 1994) show an average value of $154 \pm 16 \times 10^{-6}$ or $\delta D = -11‰$ (Engrand et al. 1999, data compiled by Pinti 2005; Fig. 5).

The comparison of D/H ratios of water supports the hypothesis that chondrites are the main carrier of volatiles on Earth. However, defenders of the theory of cometary

E



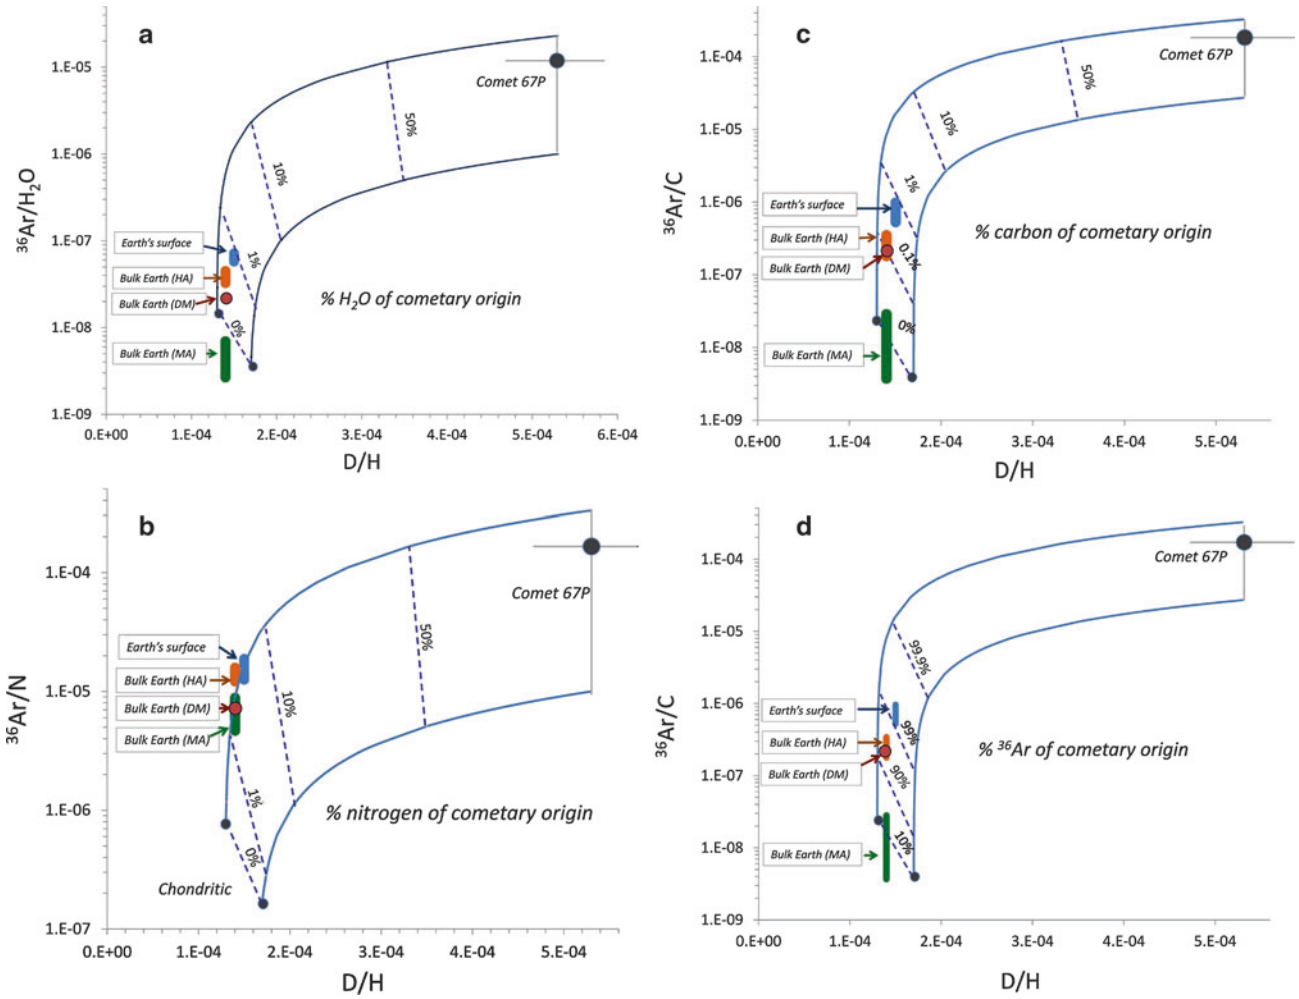
Earth's Atmosphere, Fig. 5 Variation in the D/H ratio in the solar system. Proto-Earth is the expected initial D/H ratio in the region where the Earth formed, based on isotopic exchange models between molecular H and water (Robert 2001a). The bulk Earth value range is from Lécuyer et al. (1998). Gaseous planets, protosolar nebula (PSN) and Oort cloud comet D/H ratios are compiled by Robert (2001b) and Hartogh et al. (2011). Chondrite and Antarctic Micrometeorite (AMM) data are from a literature compilation in Pinti (2005). D/H for the 67P/Churyumov–Gerasimenko comet is from Altwegg et al. (2015)

contribution to water and volatiles on Earth contested that comets formed within the Solar system, in the Kuiper belt (the short-period Jupiter-family comets), are the best candidate to have contributed to the Earth's wetness. Most of the data available are from Oort cloud comets that might have condensed water from the outer Solar system, where isotopic exchange is slow and deuterium is enriched in the water phase. The measurement of a "terrestrial" D/H ratio of $161 \pm 24 \times 10^{-6}$ or $\delta D = +34‰$ in the Jupiter family comet, 103P/Hartley 2, by the Herschel telescope refueled the debate (Hartogh et al. 2011). However, very recent D/H data obtained by in situ coma measurement of the Jupiter family 67P/Churyumov–Gerasimenko comet by the ROSINA mass spectrometer onboard the ROSETTA orbiter seems to have settled the controversy regarding the origin of water. Indeed 67P/Churyumov–Gerasimenko is a short-period comet, presumably originating from the Kuiper belt and yet has the highest D/H ratio among comets. Altwegg et al. (2015) measured a D/H of $530 \pm 70 \times 10^{-6}$ or $\delta D = +2400‰$ in the 67P/Churyumov–Gerasimenko comet (i.e., three times higher than in the bulk Earth; Fig. 5).

More interestingly, the first measurements of noble gas ^{36}Ar, together with major volatiles H, C, and N in the coma of 67P/Churyumov–Gerasimenko comet, allowed to calculate the contribution of chondritic versus cometary material to the Earth volatile inventory (Fig. 6; Marty et al. 2016). Figure 6 reports the $^{36}Ar/H_2O$ (a), $^{36}Ar/N$ (b), and $^{36}Ar/C$ (c, d) versus D/H mixing diagrams between cometary and chondritic (asteroidal) end-members (after Marty et al. 2016). Bulk Earth and Earth surface (hydrosphere + atmosphere) volatile compositions are also reported. From the mixing curves, the cometary % of H, C, and N are estimated to vary from less than 1% for H_2O and C to less than 10% for N. On the other hand, 10 to 90% of ^{36}Ar, and by extension the other heavy noble gases, Kr and Xe, could be of cometary origin. To reconcile these findings with a general model where carbonaceous chondrite material brought the main volatiles to Earth, Marty et al. (2016) suggested that 10% of cometary material could have been added during the Late Heavy Bombardment (LHB), bringing argon, but not substantially affecting the original amounts of major volatiles, brought much earlier by asteroids of chondritic composition.

Timing and Processes of the Earth's Atmosphere Formation

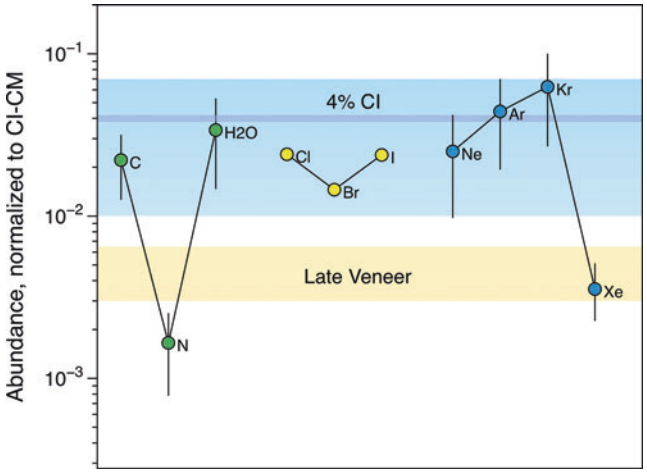
The major volatiles composing the early atmosphere and hydrosphere reservoirs on Earth were brought by asteroids of chondritic composition very early during the accretion of the Earth. There are several lines of evidence suggesting this scenario. First, models of Solar system formation indicate that only a few wet asteroids of carbonaceous chondrite composition, formed originally in the outer asteroid belt, were able to deliver water in the inner Solar system during the waning phases of the Earth's accretion (~70% of the Earth's mass accreted) (Morbidelli et al. 2000). Planetary formation models are also able to simulate the migration of wet planetary embryos from distances of up to 5 AU into the Earth's orbit, delivering water (Raymond et al. 2006). Volatiles added to the planet were partitioned preferentially into melt during the magma ocean episode (complete melt of the planet at the end of its accretion) or during the melt of its surface by the successive impacts. Volatiles, including water, were thus incorporated into the interior of the planet. This process would have been brief and happened very early in the history of the Earth. A model of catastrophic mantle degassing and secondary atmosphere formation based on ^{129}I-^{129}Xe



Earth's Atmosphere, Fig. 6 $^{36}Ar/H_2O$ (a), $^{36}Ar/N$ (b), and $^{36}Ar/C$ (c, d) versus D/H mixing diagrams, between cometary and chondritic (asteroidal) end-members. Bulk Earth composition, labeled differently, is from various literature sources (see Marty et al. (2016) for details on bibliographic references). Solid curves represent hyperbolic mixing lines between cometary and chondritic end-members, the curvature factor calculated using known elemental and isotopic compositions of the end-members. *Dotted lines* and associated numbers represent the percentages of volatiles of cometary origin in the mixture (From Marty et al. (2016))

indicated that mantle degassing was likely produced within the first 50 Ma after the Solar system formation (e.g., Kunz et al. 1998; Avice and Marty 2014), which is also the minimum age of the formation of the Earth (30–60 Ma) based on ^{82}Hf-^{182} W systematics (e.g., Kleine et al. 2002; Yin et al. 2002). Consequently, the delivery of volatiles must precede this episode of massive degassing. The impact of a Mars-sized object colliding with the Earth 50–100 Ma after the Solar system formation (Canup and Asphag 2001) could have been the trigger of the catastrophic volatile degassing, including water, from the terrestrial interior (Sleep et al. 2001; Pinti 2005).

The amount of carbonaceous chondrite material added to the mass of the Earth would have had to have been approximately 4% of the Earth's mass (Albarède et al. 2013) (Fig. 7) to explain the entire volatile inventory of the Earth (H, C, Ne, Ar, Kr, and halogens). N and Xe are more depleted on Earth than other volatiles and would require a much smaller amount of chondritic material to be added, equivalent to that of the late veneer (Fig. 7). To reconcile these diverging views, Marty (2012) suggested that the missing N is now partitioned into the core. The missing Xe could be related to late cometary contributions (Dauphas 2003) or to Xe-specific atmospheric loss through geological periods of time (Pujol et al. 2011). Mass balance results reported in Fig. 7 also place strong constraints on the timing of volatile delivery to Earth. Excesses of PGE in the mantle require a smaller contribution of chondritic (or cometary) material, probably less than 0.5%, while volatiles require 4% of accreted mass. To reconcile the volatile and PGE mass balances, we need to assume that volatiles were mainly brought prior to core differentiation. In this case, the accompanying PGE would have been totally segregated into the core, leaving the mantle depleted in these HSEs. The timing of core formation is highly variable and



Earth's Atmosphere, Fig. 7 Comparison of the CI-normalized concentrations of terrestrial volatile elements (amounts in the mantle + surface), with the amounts predicted by the conventional late veneer assumption (*pale brown*) and by the addition of 4% CI chondrites (*blue*) (Redrawn from Albarède et al. (2013))

isotopic model dependent. It varies from 30−≥60 Ma after Solar system formation based on ^{182}Hf-^{182}W systematics and possibly terminating within 80–200 Ma after Solar system formation, based on coupled Hf-W and Pb-Pb systems (Nimmo and Kleine 2015). Successive delivery of PGE by 0.5–1% of chondritic material and a smaller percentage of cometary material during a late veneer episode or even during the Late Heavy Bombardment could explain the current PGE excesses in the mantle (Dauphas and Marty 2002) and a late delivery of cometary Ar (and possibly Xe) without considerably affecting the inventory of major volatiles (Marty and Meibom 2007; Marty et al. 2016).

Summary

Resolving the origin of the Earth's atmophile elements has been an intriguing scientific problem for centuries. Development of geochemistry as an Earth science and planetary discipline, particularly isotope geochemistry (noble gases, radiogenic isotopes, and extinct radionuclides) and cosmochemistry, has been an exceptional tool for deciphering between different theories. If the scientific community generally accepts the fact that water and volatiles were brought to Earth by planetary bodies assimilated to CI-CM class carbonaceous chondrites, numerous questions remain unresolved. Among them we can mention, the mechanisms and timing of Earth's ingassing and successive degassing, and the relative contribution to Earth's volatile budget of the late veneer during the LHB compared to the early delivery from wet asteroids. If new volatile data from the ROSETTA mission seem to support the hypothesis of a chondritic origin of the main volatiles on Earth (the D/H ratio dismisses comets as the water carriers to Earth), a new line of questioning is also opened on the origin of the trace gases, particularly the heavier noble gases, Ar, Kr, and Xe. This points out of the importance of in situ measurements or home return samples in future space missions to asteroids (Osirix-Rex, Hayabusa 2) and comets, so as to obtain precise and pristine isotopic data to constrain a univocal mechanism and timing of atmophile arrival to our planet to form a stable atmosphere-hydrosphere system.

Earth's Continental Crust

Roberta L. Rudnick
Department of Earth Science, University of California, Santa Barbara, CA, USA
Department of Geology, University of Maryland, College Park, MD, USA

Definition

The continental crust is typically defined as that portion of the outer rocky layer of the Earth that extends vertically from the surface (subaerial or submarine) to the Mohorovicic discontinuity (or Moho) and laterally to the slope break on continental shelves (Cogley 1984).

Introduction

The continental crust has an average thickness of around 35 km (Hacker et al. 2015; Huang et al. 2013), considerably thicker than oceanic crust, which averages 6.5 km in thickness (White and Klein 2014). The lower density and greater thickness of the continental crust compared to oceanic crust causes it to ride higher on the mantle; consequently, a large proportion (70% by area) is exposed above sea level. Data for the physical properties of the continental crust are given in Table 1.

The continental crust is arguably the best-studied and understood region of the solid Earth, given that we live on the continental crust, that our species evolved on the continents, and that nearly all of the resources required to sustain our civilization derive from it. It thus has an importance disproportionate to its mass, which is only ~0.5% of the silicate portion of the Earth. Despite this proximity, however, there are still first-order questions about the continental crust for which no consensus answers exist. What is the average composition of the continental crust, and how might that composition changed over time? When and how did the continental crust form? How has the volume of continental crust changed over Earth history? What was the nature of the earliest crust on Earth, and how did that crust, which is no longer preserved, compare to the continental crust of today? Each of these major questions are addressed, in turn.

Composition and Structure

While the composition of the upper continental crust is derived by study of rocks exposed at Earth's surface, the structure and composition of the crust at depth have generally been inferred from geophysical data (specifically, seismic and heat flow data, e.g., Christensen and Mooney 1995; McLennan and Taylor 1996; Rudnick and Fountain 1995; Wedepohl 1995). Seismic refraction studies generally divide the crust into layers, varying in number from two to six (see compilations in Pasyanos et al. 2014; Rudnick and Fountain 1995). In general, geochemical models for the crust composition divide the crust into either two or three layers, comprising the upper and lower (e.g., Hacker et al. 2011; Taylor and McLennan 1985; Wedepohl 1995) or upper, middle, and lower continental crust (Gao et al. 1998; Hacker et al. 2015; Rudnick and Fountain 1995). In two-layer crust models the upper crust is generally considered the heat-producing layer, which does not extend below the upper 1/3 of the crust; the one exception is the study of Wedepohl (1995), which splits the crust into roughly equal proportions of upper and lower crust. In reality, it's unlikely that the crust is truly layered, and these hypothetical layers are used as a matter of convenience because many seismic refraction profiles report layers, and also to allow discussion of different portions of the crust.

The upper crust is the most accessible portion of the continental crust, and hence, its composition is the best constrained. Estimates of the composition of the upper continental crust are based on widescale surface sampling (e.g., Eade and Fahrig 1971, 1973; Gao et al. 1998; Shaw et al. 1967, 1976; Togashi et al. 2000), and analyses of fine-grained sediments or sedimentary rocks such as shales (Haskin and Haskin 1966; McLennan and Taylor 1980; Nance and Taylor 1976, 1977), loess (Chauvel et al. 2014; Park et al. 2012; Peucker-Ehrenbrink and Jahn 2001; Sauzéat et al. 2015; Taylor et al. 1983), and river sediments (Kamber et al. 2005), which provide natural averages for relatively insoluble trace elements in the crust that is exposed to weathering and erosion (see summary of methods in Rudnick and Gao 2003). In addition, the fine-grained matrices of glacial diamictites have recently been utilized to determine the major and trace element composition of the upper continental crust (Chen

Earth's Continental Crust, Table 1 Physical parameters of different portions of the continental crust

Data from Huang et al. (2013)

et al. 2016; Gaschnig et al. 2016), following on from the original approach of Goldschmidt (1933). Table 2 provides examples of these estimates of the upper continental crust.

All estimates of upper crust composition are felsic (SiO_2 = 66 to 70 wt.%, 1.6 to 2.5 wt.% MgO) with significant heat-producing element (HPE: K, Th, and U) concentrations (average heat production varies from 1.3 to 1.8 $\mu W\ m^{-3}$). The compositional estimate derived from river sediments and glacial diamictites shows the influence of chemical weathering (i.e., depletion of relatively soluble elements such as Mg, Ca, Na, Sr, and Mo), as both sample the uppermost crust (upper 1–2 m) that has experienced significant chemical modification due to weathering (Gaschnig et al. 2016; Kamber et al. 2005; Li et al. 2016). This strongly weathered signature probably does not extend through the entire upper continental crust. Excluding the elements thus influenced, all major element estimates fall within a factor of 1.7 of each other, and many trace element estimates fall within a factor of two. For three elements listed in the table (e.g., Br, Rh, Te), there is only one estimate of average upper crust composition, and our knowledge of the upper crustal abundances of these elements should be considered preliminary, at best. For some of the trace elements that show more than a factor of two difference between estimates, the variability reflects an outlier composition. For example, the Shaw et al. (1967, 1976, 1986) estimates for C, Sc, Cr, Cu, and Bi are all considerably lower than other estimates for these elements and may reflect the limitations of their study, as they describe: "few sampling areas, inadequate sampling within areas, lack of stratigraphic control" (Shaw et al. 1976). When these outliers are eliminated, all of the remaining estimates for these elements fall within a factor of two of each other. Other outliers are likely related to analytical issues (e.g., the La estimate of Eade and Fahrig 1973; the Nb and Ta estimates of Shaw et al. 1976; and the Sn estimate of Taylor and McLennan 1985), as discussed in Rudnick and Gao (2003). Similarly, the Ru value in Rudnick and Gao (2003), which derives from Peucker-Ehrenbrink and Jahn (2001), may be an analytical artifact (see discussion in Park et al. 2012). Elimination of these compromised values brings the overall variability of different estimates generally to within a factor of two. The exceptions include Be, B, S, Cl, Ni, V, As, Se, Mo, Sb, I, Ba, some of the heavy rare earth elements (HREE), Re, Hg, Tl, the platinum group elements (PGEs), and the elements mentioned above for which there is only a single estimate.

Estimates for the composition of the middle continental crust (that part of the crust between the upper and lower crust, generally defined seismically, see Huang et al. 2013; Rudnick and Fountain 1995) are based on the geochemistry of amphibolite-facies rocks (Gao et al. 1998; Huang et al. 2013; Shaw et al. 1994; Weaver and Tarney 1984) or granulites, corrected for loss of K, Rb, Cs, Th, and U that is associated with high-grade metamorphism (Rudnick and Fountain 1995). The values published in Rudnick and Gao (2003) are mostly averages of previous studies, with some exceptions noted by them. The estimates range from intermediate to felsic compositions (SiO_2 = 62 to 69 wt.%, Table 3), with magnesium numbers (Mg#'s = 100*Mg/(Mg + Fe_T), where "T" denotes all Fe as ferrous iron) that overlap with but range to higher values than observed in upper crustal estimates. Relative to the upper crust, there are very few trace element estimates yet made for the middle crust, and of those available, there is much greater variability among the estimates. Heat production ranges from 0.75 to 1.36 $\mu W\ m^{-3}$ and is generally below that of upper crust estimates. The middle crust is currently the least well-documented portion of the crust from a geochemical perspective.

In contrast to the middle crust, there have been a large number of investigations into the composition of the lower continental crust, though some of these lump middle and lower crust together (e.g., Hacker et al. 2011, 2015; Taylor and McLennan 1985), making direct comparison of compositions potentially misleading. Table 4 presents a subset of lower crustal compositions from the literature (see also Table 7 of Rudnick and Gao 2003). Many investigations use measured seismic velocities of the deep crust (i.e., that crust below the upper crust) and ultrasonic wave speeds of different types of deep crustal rocks determined in the laboratory to infer rock type, and combine these with geochemical data for granulite-facies rocks to derive lower crustal composition (e.g., Rudnick and Fountain 1995; Christensen and Mooney 1995; Wedepohl 1995; see review of methods by Rudnick and Gao 2003 and more recently, Huang et al. 2013). An alternative approach is to calculate equilibrium mineralogy and wave

Major elements recast to 100% anhydrous
Mg# = molar 100*Mg/(Mg + Fe_T)
[a]Calculated on a sedimentary rock-free carbonate basis
[b]Wedepohl's upper crust is largely derived from the Canadian Shield composites of Shaw et al. (1967, 1976). Values taken directly from Shaw et al. are shown in brackets
[c]Preferred values from Table 4 of Gaschnig et al. (2016), except for Be, Ga, In, Sn, and Tl data, which come from preferred values of Table 5 in the same reference
[d]Values taken from studies of individual elements: Li value from Sauzeat et al. (2015); N value from Johnson and Goldblatt (2015); platinum group elements and Re from Park et al. (2012)
[e]Total Fe as FeO
[f]Values of Kamber et al. (2005) and Gaschnig et al. (2016) reflect depletion due to chemical weathering of surficial layer
[g]Values of Shaw et al. are outliers
[h]Value from McLennan (2001)
[i]Values of Kamber et al. (2005) elevated due to anthropogenic input
[j]Value in Rudnick and Gao is analytical artifact
[k]Value in Taylor and McLennan is analytical artifact
[l]Value in Eade and Fahrig is an analytical artifact; see text for discussion of each of these outliers

speeds for granulite-facies rocks as a function of pressure and temperature to infer lithology and composition (Behn and Kelemen 2003; Hacker et al. 2011, 2015).

In nearly every seismic survey, the velocity of the continental crust increases with depth (see summaries in Christensen and Mooney 1995; Pasyanos et al. 2014; Rudnick and Fountain 1995). Temperature and pressure also increase with depth, and while P-wave velocities decrease with increasing temperature by $\sim -4 \times 10^{-4}$ km s^{-1} $°C^{-1}$, they increase with pressure (2×10^{-4} km s^{-1} MPa^{-1}; see references in Rudnick and Fountain 1995 for the temperature and pressure derivatives). Nevertheless, the in situ velocity of a given rock will either stay approximately the same (in areas of low heat flow) or will decrease (in areas of high heat flow) with depth in the crust (see Fig. 1 of Rudnick and Fountain 1995). Therefore, the increasing seismic velocity with depth reflects either metamorphic recrystallization, causing an increase in the bulk and shear moduli ($V_p = \sqrt{\frac{\kappa + \frac{4}{3}\mu}{\rho}}$, where K is the bulk modulus, μ is the shear modulus, and ρ is the density) and/or increasingly mafic compositions with depth, as seismic velocity increases with decreasing SiO_2 for rocks of a given metamorphic grade (Fig. 1). Despite this correlation between composition and seismic velocities, the latter may vary by over 10% for a given bulk composition depending on mineralogy (Fig. 1). Moreover, metapelitic rocks (metamorphosed mudstones and shales) show a huge range in seismic velocities, depending upon the original proportion of clay to quartz in the sample and the amount of melt

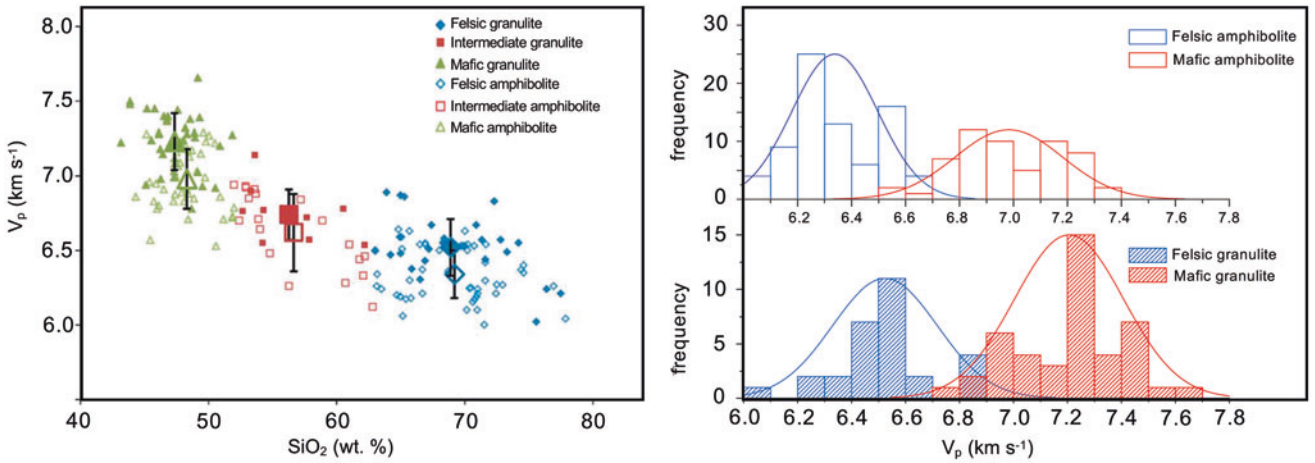
Major elements recast to 100% anhydrous
Mg# = molar 100*Mg/(Mg + Fe_T)
[a]Model CEC3
[b]Combined middle and lower crust
[c]Values taken from studies of individual elements: K, Th, and U from Huang et al. (2013); Li from Teng et al. (2008); N from Johnson and Goldblatt (2015); Cl and I from Muramatsu and Wedepohl (1998, mixing 62% felsic granulite with 38% mafic granulite; nb that lower crust represents approximately 50% of total crust)
[d]Value from McLennan (2001)
[e]Total Fe as FeO
[f]Corrected value from misprint in published paper, via personal communication from the author



Earth's Continental Crust, Fig. 1 (**a**) Correlation between SiO_2 content and laboratory measured room-temperature ultrasonic velocities of amphibolite- and granulite-facies rocks of different bulk composition: mafic = 45 to 52 wt.% SiO_2, intermediate = 52 to 63 wt.% SiO_2, felsic >63 wt.% SiO_2. (**b**) Histograms of the same data shown in panel **a** (Modified from Huang et al. 2013)

extraction they experienced during metamorphism. The elastic properties of quartz, the second-most common crustal mineral, are also quite unusual with respect to most crustal minerals, causing further uncertainty (Abers and Hacker 2016). Thus, constraining the proportion of metasedimentary rocks in the lower crust from seismic velocity is difficult (Rudnick and Fountain 1995).

This ambiguity in using seismic velocities to infer rock type forms the cornerstone of one of the current debates regarding the composition of the deep crust. Whereas most studies using seismic velocities to infer deep crustal composition have concluded that the crust becomes more mafic with depth (Christensen and Mooney 1995; Huang et al. 2013; Rudnick and Fountain 1995; Wedepohl 1995), an alternative hypothesis (driven by the relamination scenario, which is described in the next section) is that the lower crust is composed of relatively felsic rock types, including metapelites (Hacker et al. 2011, 2015). Heat flow data currently provide only broad constraints on the composition of the deep crust: heat production must decrease with increasing depth (see Jaupart and Mareschal 2014, for a recent review), and a felsic lower crust produces a surface heat flow that is at the upper bounds of those permitted by heat flow data (Hacker et al. 2011).

As can be seen from Table 4, the different compositional models for average lower crust vary from mafic to intermediate (48.6 to 64.4 wt.% SiO_2, MgO = 2.5 to 7.2 wt.%, and Mg# = 46 to 60). Interestingly, the two studies that consider the lower crust as the lower ⅔ to ½ of the crust fall at different ends of the compositional spectrum: the Taylor and McLennan (1985) lower crust is the most mafic (54 wt.% SiO_2, 6.3 wt.% MgO), whereas the Hacker et al. (2011) lower crustal model is the most felsic (64 wt.% SiO_2, 2.5 wt.% MgO). Heat production varies by a factor of seven among all models listed in Table 4, with the least radioactive crust being the relatively felsic composition of Weaver and Tarney (1984), who used the extremely HPE-depleted Scourian granulites to represent the lower crust.

Composition of the Bulk Continental Crust and Implications for Its Formation

The bulk continental crust is estimated, by all who have undertaken such an exercise, to be "intermediate" in composition (see Rudnick and Gao 2003 for the most recent review on the methods used to estimate crust composition and Hacker et al. (2015) and Huang et al. (2013) for updated perspectives on its average composition). If cast in terms of an igneous rock type, the bulk crust would be called "andesitic," sensu lato, in that all estimates have between 57 and 65 wt.% SiO_2 (Table 5). This intermediate composition distinguishes the continental crust from all other planetary crusts recognized in our solar system, which are dominated by basalt (Fegley 2014; McCoy and Nittler 2014; McSween and McLennan 2014). The significance of an "andesitic" continental crust on Earth is twofold: (1) it points to more protracted processes of crust formation on Earth compared to other planets, as andesite, unlike basalt, is not a primary melt of peridotitic mantle, and (2) the majority of andesites on Earth are generated in subduction zones (indeed, the type locality for andesite is the Andes), suggesting a link between generation of the continental crust and subduction, one of the defining processes of plate tectonics on Earth (e.g., Taylor 1977).

Despite the overall andesitic bulk composition of the continental crust, andesite (or its intrusive equivalent, diorite) is not a particularly common rock type within the crust, and the average andesitic composition reflects the fact that the continental crust is a mixture of a wide array of rock types, particularly mafic igneous rocks such as basalts and gabbros

Major elements recast to 100% anhydrous

[a]Model CEC[3]

[b]This paper presents several compositional models based on differing assumptions regarding matching composition to seismic velocities and heat flow constraints; shown here are the end-member compositions

[c]Values taken from studies of individual elements: N concentration from Johnson and Goldblatt (2015); Cl and I concentrations from Muramatsu and Wedephohl (1998); W concentration from König et al. (2011); Hg concentration from Canil et al. (2015)

[d]Total Fe as FeO

[e]Updated by McLennan (2001)

[f]Updated by Barth et al. (2000)

and felsic igneous rocks such as rhyolites and granites (Hacker et al. 2015; Rudnick and Fountain 1995). Indeed, many have argued that andesites themselves result from mixing of basalt and rhyolite (e.g., Eichelberger 1975; Kent et al. 2010; Reubi and Blundy 2009), though crystal fractionation is also an important process in generating evolved igneous rocks (Keller et al. 2015; Lee and Bachmann 2014; Yanagi and Yamashita 1994), and there is ongoing debate regarding the relative importance of partial melting versus crystal fractionation in generating evolved igneous rock types. Assuming that crust grows by mass transfer from the mantle via melt intrusion, and because the primary melt of mantle peridotite is basalt (or more Mg-rich lavas such as picrites or komatiites), processes in addition to mantle melting must have modified the crust. This mismatch between crustal building-blocks (mantle-derived basalts) and the crustal edifice (andesitic crust) has been termed the "andesite paradox" (Kelemen et al. 2003a) or the "crust composition paradox" (Rollinson 2008).

Processes that have been suggested to solve the crust composition paradox include weathering, slab melting, and preferential recycling of mafic to ultramafic rocks from the continental lithosphere into the mantle (see reviews of Hacker et al. 2015; and Rudnick 1995). Each of these processes is addressed, in turn.

The weathering hypothesis, whereby soluble elements such as Mg are lost from the continents, are taken up in altered oceanic crust, and then preferentially recycled back into the mantle when that crust subducts (Albarède 1998; Anderson 1982; Lee et al. 2008; Liu and Rudnick 2011), serves to deplete Mg (and possibly other soluble elements) from basaltic crust. The fact that most rocks of the continental crust have oxygen (Simon and Lecuyer 2005) and lithium (Liu and Rudnick 2011; Teng et al. 2004) isotopic compositions that are offset from those of primary mantle-derived magmas in the direction expected for a weathered regolith is prima facie evidence that weathering played a role in generating the continental crust that we see today. Estimates for the mass of continental crust lost to chemical weathering vary from >20% (Lee et al. 2008) to between 15% and 65% (Liu and Rudnick 2011).

Whereas the thermal structure of the majority of modern subduction zones is cool enough that melting within the slab is primarily confined to the water-laden sedimentary layer ± uppermost volcanic rocks (van Keken et al. 2011), this may not have been the case in the ancient past (although the question of when subduction initiated is very much an ongoing debate, as discussed below). In particular, higher heat flow expected in the Archean due to greater heat production may have led to dehydration melting of subducted, hydrated basaltic crust, generating Na-rich granitic rocks, the so-called tonalite-trondhjemite-granodiorites (TTGs, Martin 1986) that may then interact with mantle wedge peridotite before they cross the Moho (Martin and Moyen 2002). In this scenario, the igneous flux across the Moho is not basaltic, but rather tonalitic.

Removal of mafic lower continental crust may happen through a variety of processes that involve density sorting (see Hacker et al. 2011; Lee 2014). One popular hypothesis is that mafic to ultramafic lithologies that may be present in the deep crust may be denser than underlying mantle (e.g., if the crust is thickened so that eclogite forms) and can be lost from the base of the crust through density foundering (Arndt and Goldstein 1989; Herzberg et al. 1983; Jull and Kelemen 2001; Kay and Kay 1991), which is often referred to erroneously as "delamination." A more recent hypothesis suggests that subduction of compositionally stratified continental or differentiated arc crust leads to density segregation as the buoyant upper layers underplate the overlying crust, while the denser, deeper sections founder into the convecting mantle (the "relamination" hypothesis of Hacker et al. 2011; Kelemen and Behn 2016). Estimates for the cumulative mass of continental crust lost to lower crustal recycling vary from 0.3 to 4 times the present mass of the continental crust (Table 6).

Tectonic Setting of Crust Formation

Creation of continental crust is fundamentally an igneous process, as the crust grows by mass addition of melts from the mantle. Today, mantle melting occurs mainly in three distinct plate tectonic settings: rifts, where melts are generated due to adiabatic melting; convergent margins, where hydrous fluids/melts from the subducting slab flux the overlying mantle wedge; and intraplate settings, which are often attributed to mantle plumes. Debate centers on which tectonic environments have been most important in generating the crust that we see today.
