Just as there are many types of sediment samplers, there are also many ways to section the sediments. Most researchers use an extrusion system for recent sediments, whereby discrete intervals of sediment can be sliced off the core for further analyses (Fig. 3). However, for some paleolimnological analyses, researchers may want to keep the core intact until some preliminary analyses are completed, such as X-raying the sediment profile.

Fig. 3 An example of a vertical extrusion system used for sectioning recent sediment at close intervals. (A) A 1 cm slice of sediment has been extruded from the core tube. (B) The sediment section is sliced off and removed. Photographs courtesy of N. Michelutti (Queen's University).

Dating sediment cores

A critical factor in deciphering lake sediment histories is to establish an accurate depth-time profile (i.e. geochronology) of the sediment core. Without this information, it is not possible to place past environmental changes in a proper temporal perspective. Many approaches are available depending on the type of sediments, the location of the study lake, and the approximate age of the sediments themselves (Last and Smol, 2001a).

In some lakes, such as certain meromictic lakes, sediments may be annually laminated (i.e. varved; Zolitschka et al., 2015), and superficially may resemble annual tree rings. A typical biogenic varve is composed of a couplet of laminae representing 1 year of sediment accumulation. The reason why couplets form in some sediment profiles varies from lake to lake, but varves represent seasonal differences in the materials (biological, chemical, and/or mineral) reaching the sediment surface. If varved sediments can be identified, the paleolimnologist can often attain a very high degree of temporal resolution (e.g. even sub-annual changes in some cases by splitting varves into seasons). However, the annual nature of varves must first be confirmed using other dating techniques (see below), as false laminae and missing laminae may obscure the record.

In most cases, lake sediments are dated using radiometric techniques. For older sediments (e.g. on millennial scales), radiocarbon-14 (^{14}C) dating is often used. As ^{14}C has a radioactive half life of 5730 +/− 40 years, it is useful for dating sediments on millennial time scales up to approximately 45,000 years of age. In the older paleolimnological literature, many ^{14}C dates were described as "bulk dates," as the ^{14}C content of bulk sediment was often used for dating. However, over recent decades, advances in Accelerator Mass Spectrometry (AMS) technology have allowed paleolimnologists to date much smaller organic samples, such as a single seed or pine needle. As with all techniques, care must be taken to use the most appropriate material for dating, because a variety of potential error sources exists. For example, one of the most common problems with ^{14}C dating is the so-called "hard water effect," whereby "old carbon" from the local bedrock can dilute the ^{14}C content of a bulk sediment sample. Ideally, paleolimnologists try to radiocarbon date material such as terrestrial macrofossils (e.g. seeds, twigs), which are not affected by some of these problems.

As noted previously, there has been a shift in some areas of paleolimnology to focus on the more recent histories of lakes. Due to relatively long radioactive half-life of ^{14}C, it is not appropriate for dating recent sediments. Instead lead-210 (^{210}Pb), a naturally occurring isotope, is often the dating method of choice. ^{210}Pb has a half-life of about 22.3 years, and so it is ideal for dating sediments over the last century or so. In addition, other isotopes, such as cesium-137 (^{137}Cs), which is a by-product of nuclear explosions, can be used in some sedimentary sequences to further refine depth-time profiles. As stratospheric nuclear bomb testing became more common in the mid-1950s, a rise in ^{137}Cs can often be recorded in sediment profiles at this time. Bomb testing by the former Soviet Union and the USA peaked in 1963, and this is often seen as a peak in the ^{137}Cs profile, followed by a marked decline in concentrations, with the signing of the nuclear Test Ban Treaty in that year. However, in some parts of Europe and elsewhere, a second peak in ^{137}Cs can be found, marking the 1986 Chernobyl nuclear accident in the Ukraine.

Other dating methods include identifying ash layers (tephras) from known volcanic eruptions, as well as other episodic events, such as sedimentary charcoal from known forest fires. Accurate dating of sediment profiles remains a major challenge for many studies, and so, when possible, several dating methods should be used simultaneously to increase the confidence of the geochronology.

The "top-bottom" or "before and after" approach

As noted above, paleolimnologists often have the important advantage that they can set the time scales for analysis. Typically, many sediment sections in a core are analyzed for a suite of indicators. However, this is also quite time consuming, as many biological analyses are time intensive (e.g. isolation from sediments, taxonomy, microscopy, enumeration). For some research questions, though, it may be more important to study a larger number of lakes to obtain a regional assessment of environmental change. In such cases, detailed paleolimnological analyses are not practical due to time and resource restraints. Instead, paleolimnologists have developed a simple, regional assessment tool, which is often referred to as the "top-bottom approach."

The top-bottom approach is straight-forward and was originally developed to study the effects of recent human influences (e.g. acidification, Cumming et al., 1992) on lake ecosystems. In this approach, surface sediment cores spanning the last several hundred years, such as those collected with gravity corers, are taken from the lakes included in the study. However, in contrast to a standard paleolimnological assessment, where many sediment samples would be analyzed from each core, typically only two sediment samples are analyzed for indicators: the surface (or top) sediment sample, representing recent environmental conditions; and a sediment sample that predates the period of marked human impacts (or bottom sample). For example, if one was attempting to assess the differences in lakewater pH because of acidic precipitation for a region, the bottom sample should pre-date *ca* 1850 CE. By comparing ecosystem changes, as inferred from the paleolimnological indicators present in the surface sediment (i.e. recent) and deeper sediments (i.e. pre-impact), a regional assessment of environmental change can be attained. A major advantage of the top-bottom approach is that only two samples (not including samples to establish reproducibility) are analyzed for each core, as opposed to perhaps 20 or more sediment sections of a typical paleolimnological assessment of recent environmental change. The major disadvantage is that the top-bottom approach does not provide information on the timing of environmental changes – it is simply a "snapshot" approach.

Paleolimnological indicators

Lake sediments contain a wide array of physical, chemical, and biological indicators of past environmental change. Only the most commonly used indicators are discussed below, however details concerning these and other proxies are reviewed in Cohen (2003), Smol (2008), Last and Smol (2001a, b), Smol et al. (2001a, b), and Smol and Stoermer (2010).

Important information is contained in the physical structure and composition of the sediments themselves. For example, a simple visual inspection of the sedimentary sequence can provide information on color changes, texture, presence of laminae, etc. A variety of sediment logging and recording techniques are now available, especially with the advent of digital technology. In addition, radiography, X-ray, and other image analysis techniques can often reveal important bedding features that may not be visible with the naked eye (Francus, 2004). Other procedures that are commonly used include particle size analyses of the sediments, which provide important insights to help determine the process, and to some extent, the source of detrital sedimentation. Lake sediments also archive magnetic signals, which are used in a number of applications, including deciphering past erosion events.

Typically, one of the first analyses a paleolimnologist will undertake is to determine the relative proportions of water, organic matter, carbonate, and siliciclastic material (i.e. clastic sediment composed of silicon-bearing minerals such as quartz, feldspars, clay minerals) in the sediment sections. This is often done using weight loss techniques, by successively exposing the sediment to higher temperatures, and then use the differences in sample weights to estimate the percentage of the various fractions. For example, wet sediment can be dried in a drying oven set at approximately 80–100 °C, and the percentage of water can be estimated by weight loss. Combusting the same sediment in a muffle furnace at about 450 °C for a few hours will provide an estimate of the organic matter content. A further ashing to about 950 °C can be related to the carbonate content. The remaining material represents mainly siliciclastic sediments. These types of data have many applications, although they also have to be interpreted cautiously. For example, intuitively, one might expect that the percentage of organic matter in a sediment profile would be directly related to the amount of organic production occurring in the lake basin. Although to some extent this relationship holds, it is important to consider that these variables are typically expressed as percentages, and if, for example, human activities in a catchment have resulted in erosion as well as nutrient export, the siliciclastic material deposited in the lake due to the erosion may well obfuscate any signal of increased autochthonous production.

Lake sediments also archive a wide spectrum of geochemical information that can be used to interpret ecosystem changes. Typical approaches include analyses of various elements that can be used to track past biogeochemical changes in the lake and its catchment. Whilst wet chemical lab techniques are still typically used for detailed assessments, a variety of newer, non-destructive tracking techniques have become available (Rothwell and Croudace, 2015). Other geochemical data can be used to reconstruct past anthropogenic influences (Blais et al., 2015), such as mercury and lead, as well as other metals. Persistent organic pollutants, such as DDT or PCBs, also provide important records of contaminant trajectories to lake sediments. These pollution profiles can be strengthened by studying the past deposition of fly-ash particles, such as spheroidal carbonaceous particles and inorganic ash spheres, resulting from various industrial activities (Rose, 2015).

The isotopic composition of sediments provides additional paleoenvironmental information (Leng, 2006). These include isotopes of carbon that have been used in, for example, lake eutrophication work, sulfur isotopes to track the effects of anthropogenic acidification, oxygen isotopes in climatic and hydrologic change research, and nitrogen isotopes to reconstruct past changes in sources and cycling of nitrogen (and even past sockeye salmon or seabird populations). More recent approaches include determining the isotopic composition of specific indicators found in lake sediments, such as the carapaces of some invertebrates.

One of the most active areas of paleolimnological research, however, deals with biological indicators (Smol et al., 2001a, b). A central theme in ecology has always been the attempt to link the distributions of organisms to environmental conditions. A diverse array of biological indicators is preserved in lake sediments, either as morphological remains (e.g. diatom valves) or as biogeochemical fossils (e.g. pigments). It is therefore not surprising that biological paleolimnology has provided important insights into past ecosystem changes. Below, I summarize some of the dominant indicators.

Pollen grains and spores are amongst the most common morphological indicators used in paleoenvironmental studies. The study of pollen grains and spores is a large scientific discipline, called palynology, which has many applications besides paleolimnology, such as in archeology and forensic science. Plants can produce large numbers of pollen grains, which are often well preserved in sediments. Similarly, the so-called lower plants, such as mosses, produce spores that are also well represented in sediment profiles. Although most pollen grains and spores are from terrestrial vegetation, aquatic macrophytes also produce pollen. As different species of plants produce morphologically distinct pollen grains (often identifiable to the genus level, but sometimes even to the species level), it is possible to reconstruct, at least in a general way, the composition of past forests and other vegetation. This provides important information on past climate and soil development, as well as the succession of different plant species. Some pollen grains can also assist in dating sediment cores. For example, in northeastern North America, the arrival of European settlers, and their related activities of clearing forests and initiating European style agriculture, resulted in the increase in pollen grains from ragweed (*Ambrosia*).

Plants are also represented in sedimentary deposits by macroscopic remains, typically referred to as macrofossils, which include seeds, twigs, and pieces of bark. Although pollen grains can be transported long distances via wind and other vectors, plant macrofossils are less easily transported, and so they more accurately reflect local vegetation changes. In addition, as noted earlier, they are also important sources for material used in ^{14}C dating.

Algae and cyanobacteria (i.e. blue-green algae) represent major primary producers in most aquatic systems, and almost all of them leave reliable morphological and/or biogeochemical fossils. Foremost amongst these are the siliceous cell walls of diatoms

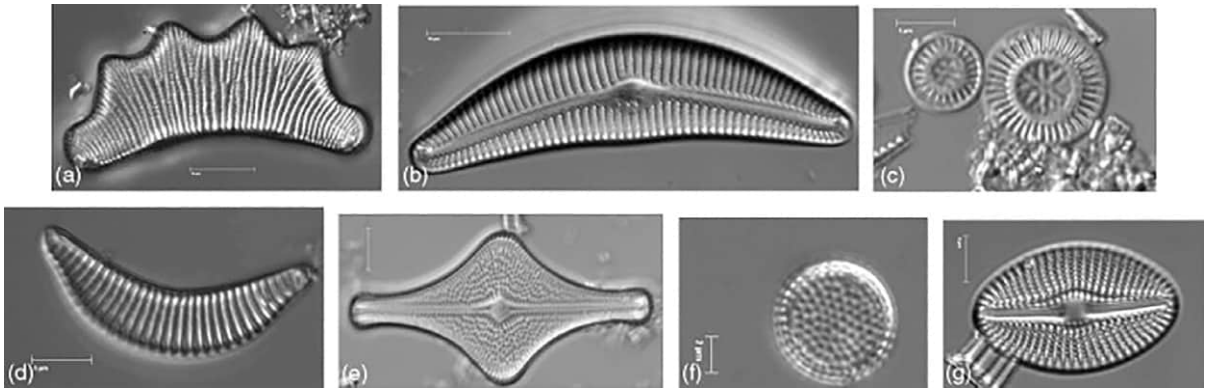

Fig. 4 Freshwater diatom valves. (A) *Eunotia*, (B) *Cymbella*, (C) *Discostella*, (D) *Semiorbis*, (E) *Brachysira*, (F) *Aulacoseira*, (G) *Diploneis*. Photographs courtesy of B. Ginn (Queen's University).

(Bacillariophyceae, Fig. 4), which are the most used indicators in paleolimnological studies, assessing a wide variety of environmental issues (Smol and Stoermer, 2010). A diatom cell wall is composed of two similar halves (or valves) joined together; two valves forming a full diatom cell are called a frustule. Diatoms, which include many thousands of species, often dominate the plankton and periphyton of most lake systems. They have many characteristics that make them ideal paleoindicators. For example, they are abundant and diverse, and their taxonomy is based on the size and sculpturing of the intricate glass cell walls that characterize individual species. As their cell walls are siliceous, they are very well preserved in most lake environments. The distributions of many diatom species are closely linked to specific limnological conditions, such as lakewater pH, salinity, nutrient levels, and so forth, and so are excellent paleoindicators.

Chrysophytes (classes Chrysophyceae and Synurophyceae) similarly can be tracked using siliceous microfossils. About 15% of chrysophyte taxa (including important genera such as *Mallomonas* and *Synura*) are characterized by an armor of overlapping siliceous scales. Similar to the diatom valves described above, these scales are species specific and can be used by paleolimnologists to track past populations of some groups. In addition to the scales, which are only produced by some taxa, all chrysophytes are characterized by the endogenous formation of siliceous resting stages, called stomatocysts (or statospores in the older literature). These cysts also appear to be species specific and are well preserved in sediments, However, unlike chrysophyte scales, the taxonomic identity of many cyst morphotypes have not yet been linked to the species that produced them, and instead cyst morphotypes are often simply referred to by temporary number designations.

Other algae also leave morphological microfossils, but are less widely used. These include vegetative or reproductive cells of certain green (Chlorophyta) algae (e.g. *Pediastrum* colonies), or the akinetes and heterocysts of some blue green algae.

All algal and cyanobacterial groups are also represented in lake sediments by a variety of biogeochemical indicators. Fossil pigments (e.g. chlorophylls, carotenoids, xanthophylls), which characterize certain groups, can be identified in sediments using high performance liquid chromatography (HPLC) or other techniques (such as visible range spectroscopy, VRS).

In addition to some of the primary producers described above, a large suite of zoological indicators is identifiable in sediments. Cladocera (Fig. 5) are represented in sediments primarily by their chitinized body parts: head-shields, shell or carapace, and post-abdominal claws. Trained taxonomists can determine the species affinities of many of these body parts. In addition, the sexual resting stages (i.e. ephippia) of Cladocera are commonly encountered.

Lakes are also the habitat for many insect larvae, with midges or chironomids (Chironomidae, Diptera) dominating many assemblages. Fossil chironomids can be identified via their chitinized head capsules (Fig. 6), which can often be classified to the generic level, or even species level. Chironomid head capsules are most often used in climate reconstructions and in tracking past

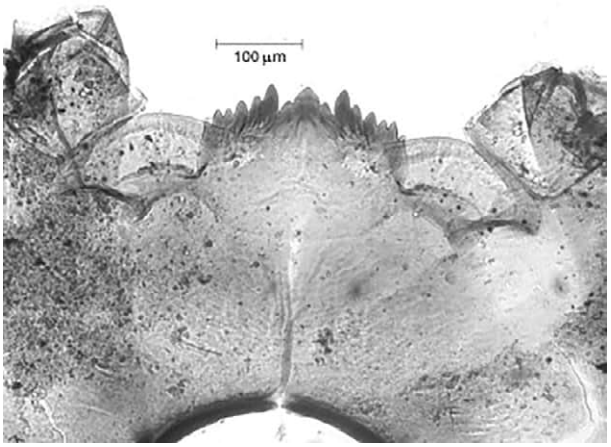

Fig. 6 A head capsule of the chironomid *Chironomus*. Photo courtesy of J. Sweetman (Queen's University).

deepwater oxygen levels. Other insect remains include the chitinized mandibles of *Chaoborus* (phantom midge) larvae. Because certain taxa cannot co-exist with fish predators, these mandibles have been used to document collapses of past fish populations (such as from lake acidification).

The Ostracoda (ostracods, also spelled ostracodes) is another widely used group of invertebrates in paleolimnological studies. Ostracods are characterized by two calcitic valves or shells that can be used to track a wide spectrum of environmental variables. Paleolimnologists not only focus on changes in species assemblages but also on the trace-element chemistry and stable isotope signatures of individual valves, as a memory of past limnological conditions is preserved in the chemistry and isotopic composition of ostracod valves.

In contrast to algal and invertebrate remains, vertebrates tend to be poorly represented in lake sediments. However, in certain environments, fish scales are common, and the inner ear bones of fish (i.e. otoliths) are increasingly being used in paleolimnological reconstructions.

New methodologies and proxies are constantly being developed. For example, there is growing interest in the application of ancient DNA analyses of lake sediments, especially for the study of taxa that do not leave distinct morphological fossils (Domaizon et al., 2017; Parducci et al., 2017). A variety of fecal markers, such as sterols and stanols, are being used to track past sewage inputs (e.g. Vane et al., 2010) as well as wildlife changes, such as seabirds and waterbirds (Hargan et al., 2018). In addition, cyanobacterial toxins, such as microcystins, are being tracked in sedimentary profiles (e.g. Zastepa et al., 2017), as are emerging stressors, such as microplastics (Yang et al., 2021). Applying "-omics" screening methods, which facilitate the visualization of small organic molecules (typically $<$1000 kDa) from sediments, is emerging as a promising way to identify new paleolimnological proxies (Bell and Blais, 2019). These approaches provide new perspectives to lake sediment studies by using high resolution mass spectrometry or nuclear magnetic resonance, along with data mining techniques, to characterize the molecular composition of organic matter in sediments in ways that can be applied to a range of environmental questions. Ongoing work appears to be promising. However, as with all proxies, issues with preservation must be considered carefully.

Determining the environmental optima of indicators

The previous section summarized some of the key indicators used in paleolimnology. However, in order to use, for example, diatom or chironomid species assemblages to infer environmental conditions, it is important to estimate the environmental optima of the indicator taxa. Some information on the ecological optima and tolerances of indicators is available in the scientific literature from previous biological surveys or similar studies. However, given the large number of taxa present, as well as the myriad of environmental variables that can influence species distributions, it can be a daunting task to link species distributions to environmental variables. The most used paleolimnological approach to provide estimates of the environmental optima of indicator taxa are to use surface sediment calibration sets (or sometimes referred to as training sets).

Surface sediment calibration sets have become common components of many paleolimnological studies. The approach is fairly straightforward. A set of calibration lakes is chosen (perhaps 80 or so in number) that reflect the gradients of limnological conditions that might be expected in the paleolimnological study being undertaken. For example, suppose the goal of the study is to reconstruct lakewater pH in a series of lakes affected by acidification. Lakes with present-day pH values ranging from 4.5 to 8.0 would represent a broad gradient in pH values. The first component of the calibration set would be a matrix of limnological and other environmental data available for the calibration lakes. The second step is to determine the distribution of indicator taxa in the 80 calibration lakes. This is done by taking surface sediment cores from each lake and identifying and enumerating the indicators in questions (e.g. diatoms) from the surface 0.5 cm or 1.0 cm of sediments (i.e. representing recently deposited biota). This represents

the second matrix of data required for developing the calibration set, namely the species matrix. The next step is to use a variety of statistical techniques to link the species distributions in the surface sediments to the measured environmental variables for the calibration lakes. Multivariate techniques, such as canonical correspondence analysis (CCA), are often used to determine which environmental variable exerts the greatest influence on species distributions (Birks et al., 2012). Transfer functions can then be constructed relating species distributions (e.g. diatom percentages) to the variables of interest (e.g. lakewater pH). The latter is typically done using statistical approaches such as weighted averaging regression and calibration. The resulting transfer functions linking species distributions to environmental variables are often quite robust.

Although quantitative approaches, such as those described above, have become commonplace in paleolimnological studies, many environmental inferences can still be accomplished using qualitative approaches. It is important not to forget basic ecology when undertaking paleolimnological reconstructions.

Paleolimnological applications

Paleolimnological approaches have now been used to assess a wide spectrum of limnological changes. Early work focused on long-term studies of lake ontogeny, however a considerable volume of more recent research has centered on determining the effects of human impacts on aquatic ecosystems. Much of this applied paleolimnology began in the 1980s with work on acidic precipitation, where paleolimnology was used to determine if lakes had acidified, and if so, when and by how much. For example, Fig. 7 shows a typical diatom stratigraphic profile for an acidified lake in Nova Scotia (Canada). The change in the dominant diatom taxa (shown as percentages) clearly shows a shift in species assemblage composition (beginning *ca* 1940, as estimated from ^{210}Pb dating) that is characteristic of more acidic waters. By using transfer functions developed from surface sediment calibration sets, the pH optima of the individual taxa can be used to provide quantitative estimates of past lakewater pH (as shown to the right of Fig. 7). These types of analyses had a critical role in demonstrating the effects of acid precipitation on lake ecosystems. Other water quality issues can be studied using similar approaches.

Another major research focus is to use paleolimnological approaches to study long-term changes in climate (Battarbee et al., 2004; Bradley, 2014), which has been receiving heightened attention with concerns about greenhouse gas induced warming.

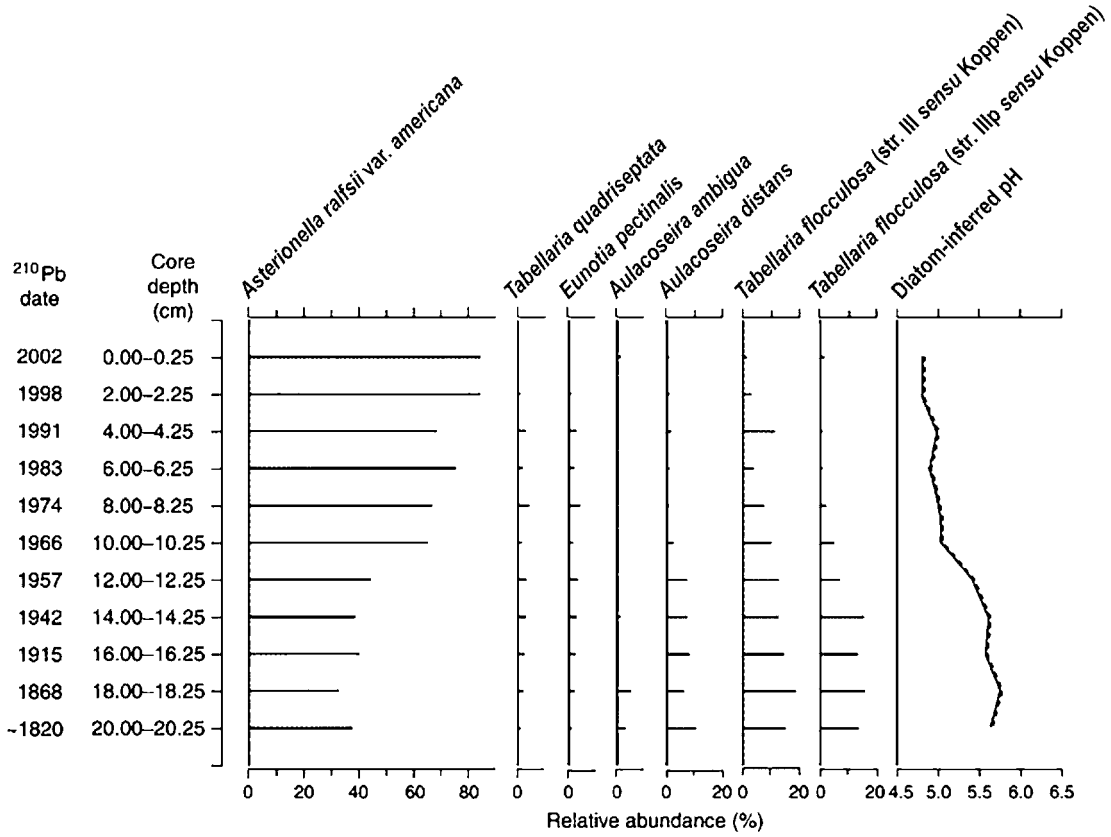

Fig. 7 A summary diagram of the dominant diatom changes (as percentages) in the recent sediments of Kejimkujik Lake (Nova Scotia, Canada). The dates of the sediment slices are estimated using ^{210}Pb dating (left of figure). To the right is the diatom-inferred pH profile, which was generated using a transfer function developed from diatoms preserved in the surface sediments of a calibration set of east coast lakes. Adapted from Fig. 3 from Ginn BK, Stewart LJ, Cumming BF, and Smol JP (2007) Surface-water acidification and reproducibility of sediment cores from Kejimkujik Lake, Nova Scotia, Canada. *Water, Air and Soil Pollution* 183: 15–24. Reproduced with the kind permission of Springer Science and Business Media.

As climatic variables influence, to some extent, all biological distributions, it is not surprising that indicators such as chironomids, diatoms, and other proxies have been shown to track climate variables, either directly (e.g. temperature reconstructions) or indirectly (e.g. via tracking past lakewater salinity changes which can be linked to past precipitation and evaporation ratios, past lake ice covers, etc.). Lake-based paleolimnological studies have been especially important in climatically sensitive polar regions (Pienitz et al., 2004), where some traditional proxies used in temperate and tropical regions are less effective in these cold extremes. Paleolimnology has played a key role in demonstrating the complexity of anthropogenic climate change when considering other environmental stressors.

Many new types of paleolimnological studies are being initiated, the majority of which are multi-disciplinary, which provide more robust environmental inferences. In addition, important synergies between different groups of scientists (e.g. the study of fossil DNA in cladoceran ephippia, working with archaeologists and conservation biologists, etc.) have heightened the interest in many paleolimnological approaches. As environmental problems continue to be identified, and as little monitoring data exist, paleolimnological studies will continue to provide critical information on environmental change in our multiple-stressor world.

Section introduction: Structures and Functions of Inland Waters—Lakes

Marie-Elodie Perga[a] **and Damien Bouffard**[b], [a]Faculty of Geoscience and Environment, Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland; [b]Surface Waters—Research and Management, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Kastanienbaum, Switzerland

A proper introduction needs to define the objects of attention. Yet, the term "lake," while tangibzle, cannot be simply defined. If the Oxford's dictionary qualifies a lake as a large area of water that is surrounded by land, it does not specify the blurred distinction between a shallow lake and a pond using more than a relative criterion for size or depth. Similarly, the distinction between large salty lakes and seas is based upon lakes not being directly connected to any ocean or marine basins. But coastal lakes or lagoons somewhat lie in between. Some confusion therefore arises from this floating definition of lakes so that undue reliance should not be put on their given names: remember that the largest lake in the World is named after a sea (the Caspian Sea). On the other end of the size spectrum, some shallow but relatively large waterbodies named ponds end up being larger than others bearing the name of lakes. Lakes are entangled within a hydrological continuum that defies the scientific practice of categorizing objects and, ultimately, definitions for lakes remain mostly operational.

Lakes can be as small as a couple of city blocks of Chicago, Melbourne or Torino (a few hectares, as for the lakes of the historical Experimental lakes Area, a place of major scientific achievements in the field of lake science), they can be as large as a nation (Lake Baikal has the size of Taiwan). Some can be crossed by foot (the average depth of Lake Tchad is 1.5 m) while others are as deep as the height of the Burk Khalifa tower (Lake O'Higgins-San Martín in Patagonia, 836 m depth). They lie at all latitudes, from 55°S (excluding permanently ice-covered Lakes of Antarctica) and beyond 78°N (with at least 1,000 lakes even further north), and altitudes from below sea level (the Dead sea is 431 m below sea level) up to 5200 m above sea level (recently discovered Kajin Sara lake in Nepal). Some are natural, carved millions years ago (ancient lakes of the East African Rift Valley), or were formed after the last deglaciation 15–10,000 years ago (many lakes of the Fennoscandian shield), or only over the last century due to current glacial retreat (about 1200 newly created lakes for Switzerland since the little ice age) (but see Branstrator, in press). Lakes can even be created within days (such as the landslide lake of Derborence in Switzerland, created almost overnight due a massive rockfall in 1749). They can expand, shrink or disappear within decades or millennia (the Aral Sea has lost 75% in surface area since 1960). An increasing number is man-made reservoirs, which currently represent one fifth of the global lake surface (Meyer et al., 2020). Some have uninhabited catchments while some Chinese lakes, such as Taihu, lie within watersheds of several tens of million inhabitants. Some high-altitude lakes, with almost no catchment, contain pure meteoric freshwaters (Crater Lake, United States) while some lakes have waters one order of magnitude saltier than the ocean (Lake Reta/Rose in Senegal with a salinity of 380 g L^{-1}). Due to such a singularity and variability of the millions of the World's lakes, there is no typical lake, neither in terms of structure, i.e., their physical, morphological, chemical or biological components, nor in the way they function, i.e., energy, water or matter movements across components or emergent properties. Each lake is idiosyncratic, only representative for itself. To our appreciation, lake science revolves around searching for commonality and universal principles that regulate the evolution of specific lake structures and functions. And it is of course an ongoing, exhilarating and somewhat endless work. Dealing with such a variability remains a major challenge of lake science, especially since the dynamics of natural but also anthropogenic forcing factors makes it a non-stationary target.

While 75% of the planet's land surface is experiencing measurable human pressure (Venter et al., 2016), lakes, which had always been prioritized locations for human settlements, are under an increasing and diversifying constellation of anthropogenic pressures (Dudgeon et al., 2006; Jenny et al., 2020). There is therefore a crucial stake in lake management, and many relevant case studies are provided in other sections of this volume. Since many of those pressures spread to a global scale, part of the lake science is dedicated to finding common trends in how lakes respond to those global disturbances. Yet, what matters for people is actually their local lake, from which they extract values and services. Lake management applies at the scale of the watershed and requires that the singularity of the local lake is accounted for. Therefore, if global predictions at large scales tell a lot on the evolution of the Earth system, the remaining unexplained variability might impede local projections and decisions for actions. There is then a need to address as much the global trends as to reduce the variability around those trend lines, so that predictions and understanding can be tailored to the local context. For climate change for instance, both data analysis and models attest to a general warming of lakes (O'Reilly et al., 2015), changes of mixing regimes (Woolway and Merchant, 2019), and shorter ice cover (Sharma et al., 2019). Yet, if two neighboring lakes, exposed to the same climate variability, might share trends for some thermal responses to climate warming, the commonality of their responses will decrease when observing their chemical or biological components (Dokulil, 2014; Farrell et al., 2020). While variability in the lake responses can be enormous, universality should be explored through the search of causal mechanisms (Wetzel, 2001). Yet, the predictive power and accuracy of deterministic models decrease when moving from the physical to the ecological or biological aspects of lakes (Soares and Calijuri, 2021). The idiosyncrasy of lakes' responses to

climate change ultimately comes from subtle differences in their hydrological settings, geomorphology, catchment land cover and land use and history (Dokulil, 2014; Leavitt et al., 2009) posing a serious integrative challenge to adaptive management planning.

Herein, we aimed at providing an entry point for the lake science that is being developed to elucidate the fundamentals of lake processes, as the building blocks to a better understanding of lakes' singularities. Summarizing the full knowledge acquired and stabilized in lake science would take much more than 38 chapters. It implied making some choices, and ours were guided by what we considered as topics to be key knowledge for the reader to fully embrace the multiple facets of the ongoing lake science, from geomorphology and geology to physics, biogeochemistry, ecology, trophodynamics and microbiology. All chapters approach their central topic from a functional perspective, linking the structure to the emergent functions, in order to enlighten processes that might drive within and amongst lake variability. So, even if each chapter can be read independently, many of them are by

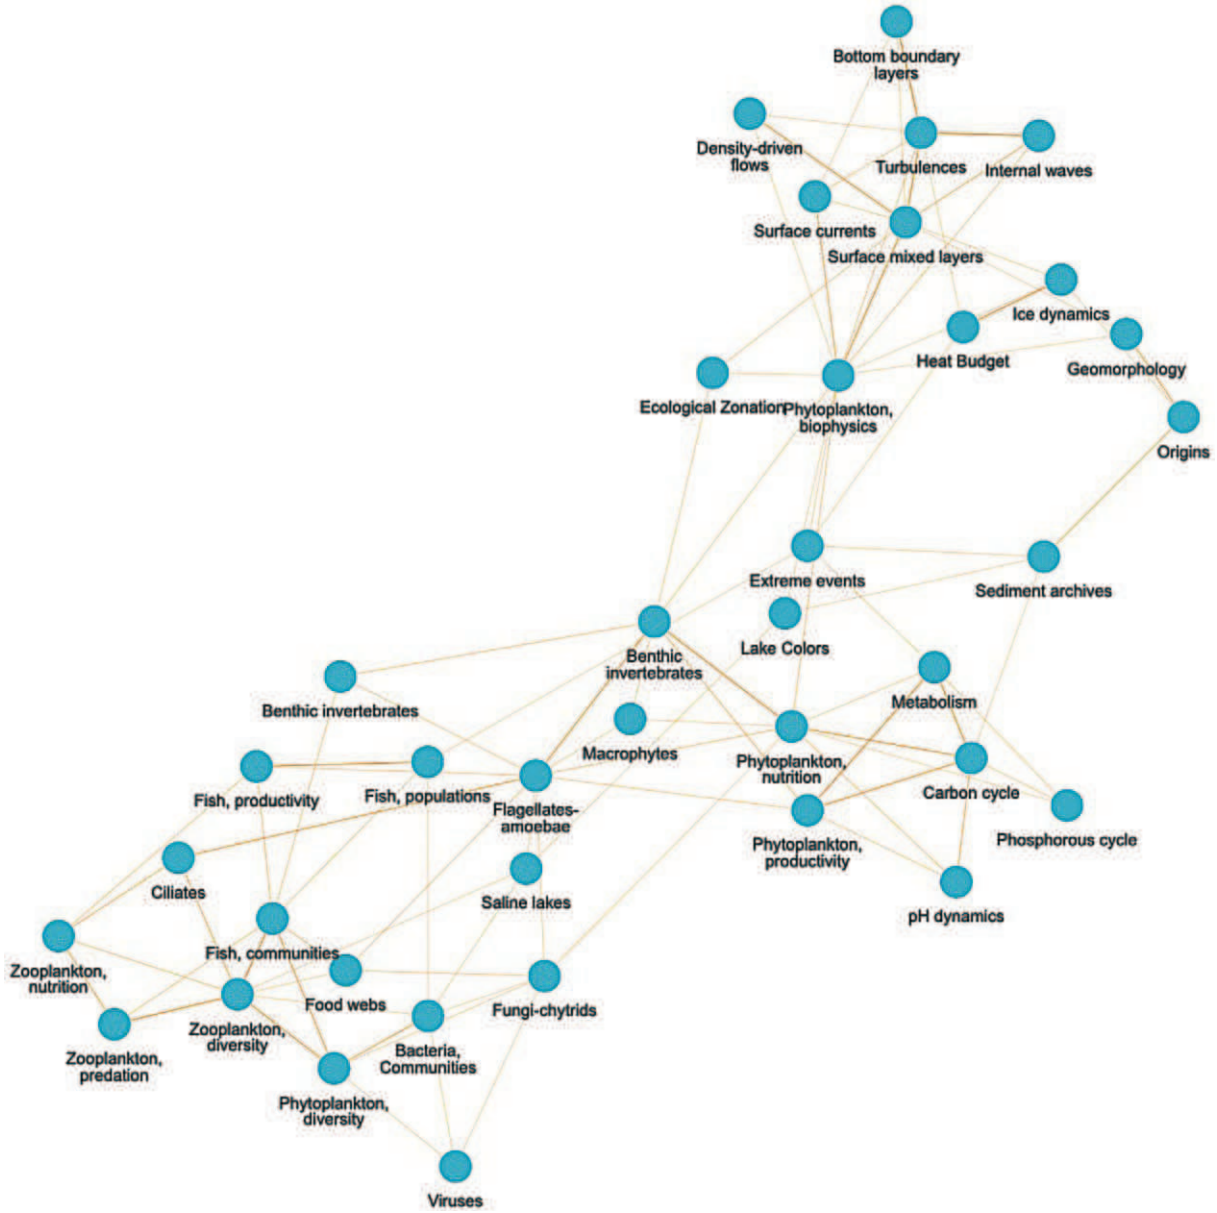

Fig. 1 Network of chapters connection based on text similarities. An interactive version available here (Supplementary Material in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00205-X). Bacteria, communities (Bertilsson and Mehrshad, in press); Benthic algae (Vadeboncoeur and Katona, in press); Benthic invertebrates (Strayer, in press); Bottom boundary layers (Henderson and Nielson, in press), Carbon cycle (Prairie and Cole, in press); Ciliates (Posch et al., in press); Density-driven flows (Peeters and Kipfer, in press); Ecological zonation (Lewis, in press); Extreme events (Dokulil, in press); Fish, communities (Mehner and Brucet, in press); Fish, populations (Winfield, in press); Fish, productivity (MacLeod et al., in press); Flagellates-amoebae (Sanders, in press); Food webs (Embke and Vander Zanden, in press); Fungi-chytrids (Van Den Wyngaert and Kagami, in press); Geomorphology (Timms, in press); Heat budget (Schmid and Read, in press); Ice dynamics (Kirillin and Leppäranta, in press); Internal waves (Boegman, in press); Lake colors (Odermatt and Gege, in press); Macrophytes (Hilt et al., in press); Metabolism (Zwart and Brighenti, in press); Origins (Branstrator, in press), pH dynamics (Finlay and Bogard, in press); Phosphorus cycle (Wilkinson and Albright, in press); Phytoplankton, biophysics (Mackay et al., in press); Phytoplankton, diversity (Pomati et al., in press); Phytoplankton, nutrition (Maberly et al., in press); Phytoplankton, productivity (Dokulil, in press); Saline lakes (Schagerl, in press); Sediment archives (Arnaud and Sabatier, in press); Surface currents (Toffolon, in press); Surface mixed layers (Wells and Troy, in press); Turbulences (Fernandez-Castro et al., in press); Viruses (Schweichhart, in press); Zooplankton, diversity (Thackeray, in press); Zooplankton, nutrition (Straile and Martin-Creuzburg, in press); Zooplankton, predation (Bertolo, in press).

essence connected. In order to guide the reader within the architecture of this section, we added an interactive reading map (Fig. 1/ Supplementary Material in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00205-X). This map was built using a text-mining approach on the content of the chapters. Major links were computed from the number of occurrences of the most frequent significant words from one chapter to the others. Clicking on one chapter in the interactive map will help the reader visualize which other chapters are naturally connected. This network reflects the complexity and diversity of lake science and calls for system analysis and integrative studies.

This introduction is also the opportunity to review the main research gaps in lake science as expressed by the scientists in this section. We invite readers to look at the domain specific research questions presented in the 38 articles and, here, we discuss the general trends.

16 chapters out of 38 pointed out the need for improved observations. There is in particular a lack of information regarding horizontal heterogeneities and we need to move away from the oversimplification that consists in viewing lakes as homogeneous blue dots as typically represented in geographical maps. The problem is clearly raised for the physical structure (lake thermal properties (Schmid and Read, in press) and turbulent fluxes (Fernandez-Castro et al., in press) or lake circulation (Toffolon, in press)) that would benefit for horizontally distributed observations. The littoral region is particularly undersampled and basic questions such as contribution of the benthic population to the whole lake metabolism and more generally the role of benthic algae remain largely underexplored (Hilt et al., in press; Vadeboncoeur and Katona, in press; Wilkinson and Albright, in press; Zwart and Brighenti, in press). Spatially resolved sediment cores might also bring a perspective on the long-term evolution of lakes accounting for their different habitats (Arnaud and Sabatier, in press). Many authors also pinpointed to seasonal or meteorological biases and suggested more investigation of winter limnology and ice-covered systems (Kirillin and Leppäranta, in press) as well as observations under all kinds of atmospheric forcing conditions (Dokulil, in press; Wells and Troy, in press). While global scale studies were not the central focus for most chapters, several authors also indicated geographical bias with most studies being conducted in Europe and North America (Pomati et al., in press; Schmid and Read, in press; Thackeray, in press; Zwart and Brighenti, in press). Remote sensing offers the opportunity to both improve the spatial resolution in large lakes, as well as to expand the geographical cover of monitored lakes worldwide (Odermatt and Gege, in press). Despite their large number, saline lakes are often left aside from large scale studies. Their specific ecosystem functioning remains to be understood (Schagerl, in press). Improved observations go also with technological development with as a short non-exhaustive list the generalization of eddy covariance techniques for boundary conditions (atmospheric and benthic; Henderson and Nielson, in press; Schmid and Read, in press; or e-DNA and genomic structures analysis; Mehner and Brucet, in press; Sanders, in press; Straile and Martin-Creuzburg, in press; Thackeray, in press; Winfield, in press).

Detailed observations are needed to improve our integrated approach of lakes. Linking the catchment to the lake seems to be a priority for future system-based analysis of lake functioning. Such a connection is for instance particularly relevant for explaining the evolution of the main biogeochemical cycles and in particular of the carbon cycle (Prairie and Cole, in press). It is also useful from a management view point to monitor the local anthropogenic effect for heat (Schmid and Read, in press), or any transported compounds that can alter the food web as endocrine disruptors or microplastics (Winfield, in press). Beside the catchment-to-lake perspective, a system-based integrative approach also requires connecting the main biogeochemical cycles together (Prairie and Cole, in press) as well as their response to environmental factors (Boegman, in press). Yet, all causal mechanisms are still not well established. The role of microorganisms such as parasites, fungi, bacteria or viruses and interactions on the dynamic of the benthic or pelagic lake food web (Bertilsson and Mehrshad, in press; Embke and Vander Zanden, in press; Sanders, in press; Schweichhart, in press; Vadeboncoeur and Katona, in press) or on the degradation and detoxification of pesticides, pharmaceuticals and microplastics (Van Den Wyngaert and Kagami, in press) are, for instance, still not quantitatively assessed.

Lakes are complex environmental systems and understanding and parameterizing all the interactions is a major stake to reach a better accuracy of ecological and biogeochemical models. The final identified research gap actually consists in dealing with such a complexity. Several authors called for a simplification of the complexity into something ultimately manageable to inform decision-makers with scientifically sound scenarios. The problem is for instance evident when it comes to predicting the evolution of the food web (Embke and Vander Zanden, in press). The Metabolic Theory of Ecology is seen as a potentially unifying approach to bridge fish individual to population scales (MacLeod et al., in press). Simple analytical models can also help identify the main processes driving the lake circulation (Toffolon, in press) without using complicated three-dimensional hydrodynamic models. The role of small- scale turbulence in the formation of patches of algae is also difficult to assess without reducing the degree of complexity based on theoretical arguments (Mackay et al., in press). The complexity can also be reduced by learning from past studies. Alkalinization is for instance a growing concern (Finlay and Bogard, in press) and lessons can be learnt, yet with new challenges, from past studies and actions to fight acidification. The complexity comes also from the fast changes our environment is facing. It is fundamental to evaluate the resilience of the different communities as a result of climate change (Pomati et al., in press; Posch et al., in press; Straile and Martin-Creuzburg, in press). While not mentioned by the authors, process-guided data-driven models represent an interesting opportunity to embrace the complexity (Hanson et al., 2020).

Some may find that crucial topics are missing for this table of content and we would have to agree. We first targeted a chapter on lake microclimates, as well as on the silicon cycle. We struggled to find authors for those fields, illustrating there are still many fields to explore. Some topics were also already well covered in the previous edition of the encyclopedia or in the section on fundamental principles (as for the nitrogen cycle and methane dynamics), and we will advise the curious reader to directly refer to them. Some might also regret there is no chapter dedicated to oxygen and in a sense we do too. Yet, the questions of oxygen concentrations and cycle are cross-cutting many of the chapters presented either in this section (they appeared in 33 of the 38 chapters), or in other sections of the encyclopedia. We are convinced at heart that solving the current challenges in lake science requires the interdisciplinary perspective demonstrated by the authors of the section's chapters. While highly semantical, this section calls for a stronger

interdisciplinarity (collaborative and integrative approach toward the same research goal) as opposed to a cross disciplinarity (collaborative but not integrative approach). This section should help by providing the needed common ground between the different disciplines. We have had a lot to read and review while editing this section. It was fascinating and we've learnt a lot.

Origins of Types of Lake Basins☆

Donn K Branstrator, University of Minnesota Duluth, Duluth, MN, United States

This article is an update of D.K. Branstrator, Origins of Types of Lake Basins, in Encyclopedia of Inland Waters, Academic Press, 2009, edited by Editor: Gene E. Likens, Academic Press, https://doi.org/10.1016/B978-012370626-3.00023-5.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Caldera Name for a lake basin that forms in the chamber where magma was ejected.
Cirque Name for a lake basin resembling an amphitheater that forms in mountainous areas by glacial activity.
Fluvial Associated with a river.
Graben Name for a lake basin that forms when tectonic plates shift and produce a gap in the ground.
Karst Name for a lake basin that forms when limestone bedrock dissolves.
Kettle Name for a lake basin that forms when glacial ice is folded under soil then melts.
Moraine A glacially carried mound of soil.
Oxbow Name for a lake basin that forms in the meander of a river.
Reservoir Name for a lake basin that forms when humans dam a pre-existing river.

☆*Change History:* August 2021. DK Branstrator updated the entire article.

Introduction

Lake basins originate through a wide variety of natural and anthropogenic processes. Some of these processes are gradual and usually imperceptible (tectonic movement, fluvial erosion) while others (meteorite impact) are quick and extraordinary. To the human observer, most lakes are permanent features of the landscape. On a geologic time scale, by contrast, most lakes are fleeting and all are ultimately ephemeral. Although we have few opportunities to witness a lake's origin, the same set of lake-forming processes at work historically continue unimpeded today.

Earth's distribution of lakes is strikingly nonrandom (Fig. 1). Most lakes lie at northern latitudes and within the footprint of recent glaciation. By contrast, lakes of great depth are scattered across Earth's surface, including East Africa, revealing that the

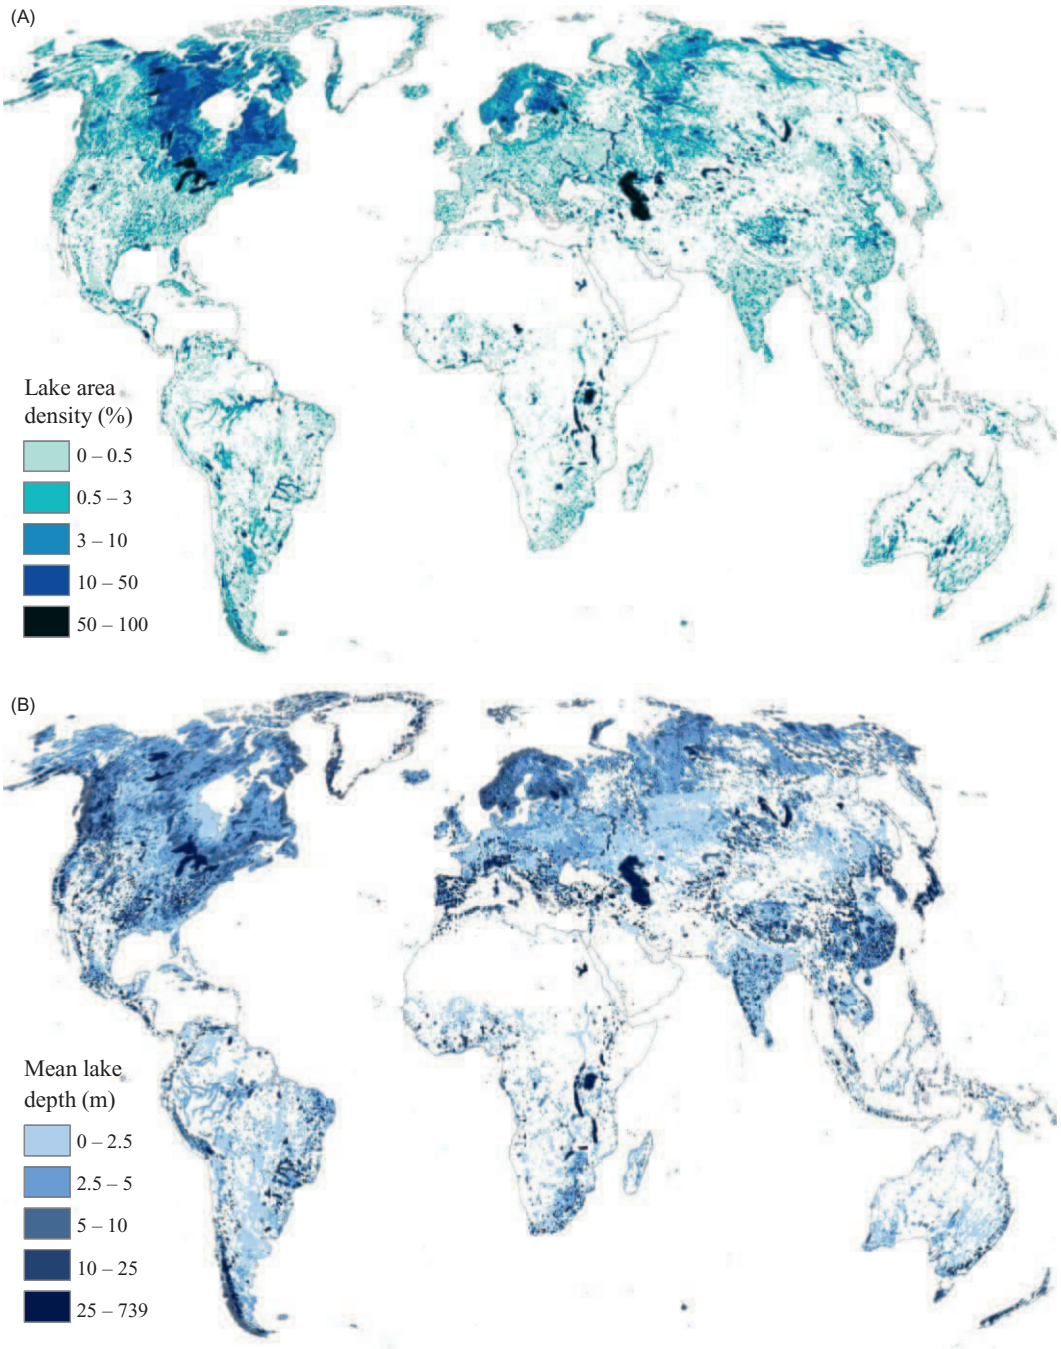

Fig. 1 Patterns of global lake distribution. (A) Lake area density given as percent area covered by lakes within a 25 km radius. (B) Average depth of all lakes within a 25 km radius, weighted by their partial area within that radius. Both maps include reservoirs from the Global Reservoir and Dam (GRanD) database. From Messager ML et al. (2016) Estimating the volume and age of water stored in global lakes using a geo-statistical approach. *Nature Communications* **7**: 13603, Reprinted by permission.

geomorphological processes producing extreme depth or volume can differ from those producing large numbers. Earth's distribution of human-made lakes is also patchy. Their origins are driven by necessity for their services (e.g., irrigation, power, and recreation) and access to water for impoundment.

Three elements are common to the origin of all lakes including (1) an environmental force, (2) a body of terrain reshaped by that force into a closed depression (basin), and (3) a water supply. The first element in the origin of a lake, an environmental force, is generally used by scientists to guide the broad classification of lake basins. G. E. Hutchinson provided one of the most extensive surveys available on the origins of lake basins in the first volume of his four-volume series, *A Treatise on Limnology* (Hutchinson, 1957). There he describes the formation of numerous distinct types of lake basins resulting from 11 principal environmental forces, including glacial, tectonic, volcanic, fluvial, organism behavior (including humans), chemical, wind, landslide, shoreline, meteorite, and organic accumulation.

The second element in the origin of a lake concerns the specific process by which an environmental force reshapes terrain into a closed depression (basin). This is the element conventionally used by scientists to name distinct types of lake basins. For example, in the case of glacial force, different names are given to basins scoured in bedrock versus those impounded by moraine. Scientists have also found it useful at times to organize lake basins quite broadly according to whether the terrain-shaping process works destructively, constructively, or obstructively. Destructive processes (glacial scouring) excavate depressions, constructive processes (moraine deposition) build rims that define depressions, while obstructive processes (landslide) build rims that barricade preexisting flows. An individual lake basin may be molded by more than one process. Because Earth's terrain is so richly varied in its composition of soil, rock structure, and topographic relief, ceaseless opportunities exist for unique outcomes in the bathymetry and shoreline structure of lake basins.

A lake district refers to a set of lakes that share a principal originating force and that reside geographically in a defined setting on the landscape. Although individual basins in a lake district are generally of similar age and origin, they can differ exceptionally in size and shape. For example, the English Lake District basins shown in Fig. 2 originated at about the same time by glacial scouring. Their different shapes and bathymetries illustrate how the interplay between an environmental force and the terrain under influence can change rapidly across short distances.

The third element in the origin of a lake is the water supply. Unlike the first two elements, water is not always present at a lake basin's inception. Water derives variously from ice, rivers, precipitation, groundwater, wetlands, and preexisting lakes. Water sources to lakes may shift through time. For instance, most glacial lakes that were filled originally by melt water are now maintained by alternative supplies (precipitation, groundwater). Scientists find it useful to differentiate between lakes connected to rivers (drainage lakes) versus those whose hydrology is reliant exclusively on precipitation and groundwater (seepage lakes). On a regional scale, water supply can be unstable, resetting the hydrologic origin of a lake long after its geologic birth. One prominent example of this phenomenon is Lake Victoria (Africa), which originated several hundred thousand years before present but was dry as recently as about 15,000 years ago (Johnson et al., 2000).

Certain types of lake-building processes can be expected to dominate over others at any moment in Earth's history. In today's inventory of natural lakes whose surface areas are ≥ 0.01 km^2 (1 ha), approximately 90% have basin origins that trace to glacial, tectonic, or fluvial forces (Table 1). Of these, glacial force far outweighs the importance of all others. This contemporary bias owes to recent and widespread glaciation during the Pleistocene when ice sheets covered nearly 25% of Earth's continents. As climate change warms Earth, glacial force is giving rise to an increasing number and size of proglacial lakes that are forming at the margins of retreating ice. In addition, as human population size burgeons, human force is giving rise to an increasing number of human-made impoundments. Both forces are notably shifting the contemporary inventory of lake types.

With global human demand for freshwater on the rise, increasing efforts are being made to inventory the distribution, size, and number of Earth's lakes. Estimates of numbers of natural lakes of various sizes down to 0.1 km^2 (10 ha) in surface area have been made by different scientists using different approaches. The total number of natural lakes ≥ 0.1 km^2 in surface area as estimated by three different studies are 1.42 million (Messager et al., 2016), 1.55 million (Lehner and Döll, 2004), and 2.30 million (Downing et al., 2006). When smaller natural lakes are included, the total number grows substantially to 304 million lakes ≥ 0.001 km^2 in surface area (Downing and Duarte, 2009). The total number of human-made impoundments (e.g., reservoirs and farm ponds) has been estimated at 77 million (Downing and Duarte, 2009), bringing the total number of all lakes (natural and human-made) to 381 million. A variety of data bases that offer global lake statistics are available to the public including HydroLAKES (https://www.hydrosheds.org/page/hydrolakes) and the Global Reservoir and Dam database (http://globald amwatch.org/grand/), also known as GRanD.

Types of Lake basins

Scientists have long appreciated that a lake's physics, chemistry, and biological potential are predictable end products of its origin. Trained scientists can infer much about a lake's current limnology by knowing its originating process. In this article, 22 specific processes that produce distinct types of lake basins (hereafter simply referred to as lakes) are enumerated and described. They are organized and presented by principal environmental force as summarized in Table 2. Organic accumulation is the only principal environmental force discussed by Hutchinson (1957) that is not considered here.

	Area (km^2)	Length (km)	Max. depth (m)	Mean depth (m)	Volume (m^3) (10^6)	Area of drainage basin (km^2)
1. Windermere	14.8	17	64	21.3	314.5	230.5
2. Ullswater	8.9	11.8	62.5	25.3	223.0	145.5
3. Derwent Water	5.3	4.6	22	5.5	29	82.7
4. Bassenthwaite Lake	5.3	6.2	19	5.3	27.9	237.9
5. Coniston Water	4.9	8.7	56	24.1	113.3	60.7
6. Haweswater	3.9	6.9	57	23.4	76.6	26.6

Fig. 2 Fourteen of the largest ice scour lakes in the English Lake District (shown blackened above) and their physical characteristics (associated table). Stippling shows surrounding relative elevation with the darker regions higher than the lighter regions. From Burgis MJ and Morris P (1987) *The Natural History of Lakes.* Cambridge: University of Cambridge, Reprinted by permission.

Table 1 Estimates of the global number and area of natural lakes ≥ 0.01 km^2 in surface area organized by principal environmental force.

Principal force	*Number of lakes*	*Percent of total lakes*	*Total lake area (km^2)*	*Percent of total lake area*
Glacial	3,875,000	74	1,247,000	50
Tectonic	249,000	5	893,000	35
Fluvial	531,000	10	218,000	9
Volcanic	1000	$<<1$	3000	$<<1$
Coastal	41,000	<1	60,000	2
Miscellaneous	567,000	10	88,000	4
Total	5,264,000	$\sim$100	2,509,000	100

A more recent study by Downing and Duarte (2009) estimates that Earth presently holds 27 million natural lakes that are ≥ 0.01 km^2 in surface area, about five times more than the total number of lakes shown here. In addition, it is estimated that Earth presently holds 277 million smaller natural lakes that are 0.001–0.01 km^2 in surface area, and 77 million human-made lakes, for a total of 381 lakes that are ≥ 0.001 km^2 in surface area.

Table 2 Common types of lakes organized by principal environmental force.

Principal force	*Lake type*	*Process of basin origination*
Glacial	Ice scour	D: Glacier excavates a depression.
	Moraine dam	C: Glacier pushes or deposits terrain to make a rim.
	Kettle	D: Stagnant glacier block displaces soil to make a depression.
	Ice dam	O: Lobe or wall of glacier prevents drainage.
	Ice basin	D,O: Depression or cavity in glacier prevents drainage.
	Thaw	O,C: Permafrost prevents drainage and soils heave to make a rim.
Tectonic	Fault block	D,C: Fracture, faulting and warping define a depression and rim.
	Reverse drainage	O: Uplift and tilting prevent drainage.
	Newland	C: Uplift of ocean floor exposes a submarine depression.
Volcanic	Volcanic crater	D: Magma chamber empties to define a depression.
	Volcanic dam	O: Volcano or cooled lava barricades a flow.
Fluvial	Plunge pool	D: Waterfall excavates a depression.
	Oxbow	D,O: Coupled erosion and deposition close a river segment.
	Fluvial dam	O: Fluvial sediments barricade a flow.
Organism behavior	Beaver pond	O: Wood and mud barricade a flow.
	Reservoir	O: Human-constructed dam barricades a flow.
	Farm pond, Mine pit	D: Human excavates a depression.
Chemical	Solution	D: Bedrock dissolves to make a depression.
Wind	Deflation	D: Wind excavates a depression.
Landslide	Landslide dam	O: Gravity moves terrain which barricades a flow.
Shoreline	Coastal	C: Sediments deposited from longshore currents close a bay.
Meteorite	Meteorite crater	D: Meteorite impact excavates a depression.

The terrain-shaping process at origination is coded as destructive (D), constructive (C), or obstructive (O).

Glacial

Glaciers transform Earth's surface through a variety of erosive and depositional processes resulting from their physical constitution, their forward motion (advance), and their recession through melting (retreat). Glaciers form through the compaction and transformation of snow and other precipitation. During the Pleistocene, glaciers reached heights of 2 km above Earth's surface, establishing enormous weight loads on the landscape. Under gravitational force imposed by their own mass, glaciers creep internally and slide along terrain, aided by relief in the landscape. Rock debris is commonly incorporated into glacial ice through abrasion and quarrying (plucking) at the basal surface. Liquid water developing on or in glaciers is heavier than ice and tends to sink and layer along the glacial sole. This lubrication further aids advance and erosive action.

As Earth's deglaciation continues at alarming rates, scientists are being presented with unprecedented opportunity to see and study glacial force as an originator of lakes. Proglacial lakes (defined below) are one type of glacial lake that is already increasing rapidly in number and size. Carrivick and Tweed (2013) review the trends which offer a glimpse of what Earth is poised to experience in the way of new and larger proglacial lakes, and the resulting environmental consequences. One spectacular example of a new proglacial lake is Lake Tasman located at the foot of the Tasman Glacier in the Southern Alps, New Zealand. Ponds that were precursors to Lake Tasman first appeared in the early 1970s. By 2008 the lake was already about 7 km length and more than 200 m deep.

Ice scour

These lakes are excavations in bedrock caused by the crushing and removal of loose debris. The depressions are generally carved during glacial advance, and deepened over cycles of retreat and readvance. In addition to the scouring effect of pure glacial ice, erosion is facilitated by protruding rock debris and melt water issuing through basal channels. Notable lakes with significant ice scouring in their origins include the Laurentian Great Lakes (Canada, United States), Great Bear Lake and Great Slave Lake (Canada), the fjord lakes in Norway, several lakes in the English Lake District (Fig. 2), Lago Maggiore (Italy), Lac Léman (France, Switzerland), Lake Te Anau (New Zealand), and innumerable small lakes carved in the pre-Cambrian shield in Canada and Europe.

Glaciers tend to preferentially exploit weaknesses in rock structure and composition. As a result, the shorelines and subsurface contours of ice scour lakes often follow preexisting fracture and transitional zones in the bedrock. An acute example of bedrock control on scouring activity is provided by a set of lakes in Minnesota (United States) where glaciers excavated the soft slate layered between resistant columns of diabase sill (Fig. 3). Quite impressive is that the long axes of these lakes lie oblique to the southerly direction of glacial advance.

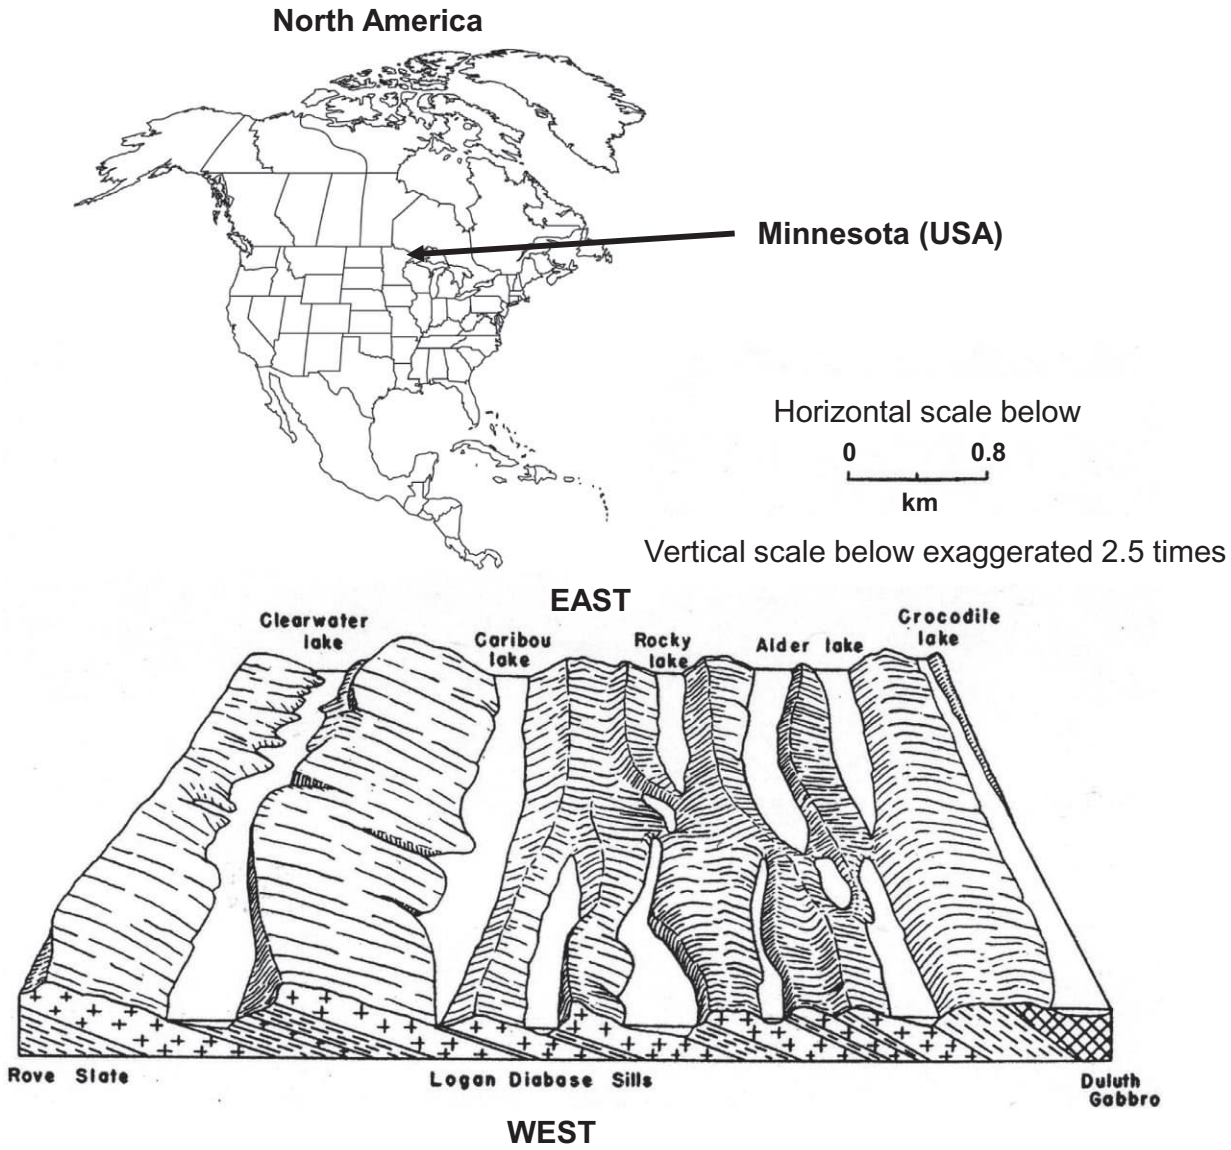

Fig. 3 Examples of some ice scour lakes in Minnesota (United States) that were carved in slate (metamorphic rock) resting between diabase sill (igneous rock). The alternating slate (–) and sill (+) are overlain by lakes (no pattern). Forested sill generally forms the terrestrial landscape separating the lakes. Adapted from Zumberge JH (1952) *The Lakes of Minnesota: Their Origin and Classification, University of Minnesota Geological Survey Bulletin 35*. Minneapolis: University of Minnesota. Continental map courtesy of Graphic Maps, Woolwine-Moen Group, Reprinted by permission.

A stunning type of ice scour lake called a cirque (tarn) originates at the snow line in mountainous relief. Cirques derive from relatively small glaciers and are characteristically bowl-shaped and bounded on the upslope shore by a steep headwall of rock. The erosive power of freezing and thawing on a seasonal basis is believed to enhance local corrosion of the lake floor and walls.

Moraine dam

Advancing glaciers push terrain at their leading edge whereas retreating glaciers deposit previously held debris as they melt. Both processes erect mounds of rock and soil on the landscape loosely referred to as moraines. Moraine dam lakes commonly reside in former river valleys with the moraine serving as a rim to complete the lake. Examples include Lake Mendota in Wisconsin and Mille Lacs Lake in Minnesota (United States), the latter lake being almost half bounded by moraine deposits (Fig. 4). Ice scour and moraine building processes regularly labor in concert to forge glacial lakes. As a result, many cirque lakes are impounded by a moraine at their downslope edge, and a vast number of lakes categorized as ice scour depend to some degree on moraine rims to maintain their current depths. The Finger Lakes in New York (United States) were joint products of ice scour and moraine building processes.

Kettle

Advancing and retreating glaciers commonly fracture and strand ice blocks. Ice blocks that become partially or fully buried in soil or in the sediment of an outwash plain can originate kettle lakes (Fig. 5). In this process, the dimensions and extent of inlay of the ice strongly dictate the lake's shape and bathymetry. Kettle lakes are characteristically deep relative to surface area and they can have complex bathymetry where two or more blocks of ice strand adjacent to one another. Kettle lakes abound in North America, Europe, and Asia. Lakes in the prairie pothole region in Canada and the lakes surveyed by pioneering limnologists E. A. Birge and C. Juday in Wisconsin (United States) are primarily kettles.

Ice dam

When glaciers themselves represent barricades that obstruct water flow they originate ice dam lakes. In regions of notable relief, an ice dam lake typically occurs where the lobe of a glacier extends down a main valley to barricade a tributary river entering from a lateral valley. The Märjelensee (Switzerland) is a well-known example. These lakes are highly transitory and can drain rapidly if the dam hemorrhages.

Lake Missoula (United States) was an ice dam lake of the Clark Fork River that grew to a depth exceeding 600 m and had a volume the combined size of present day Lake Ontario and Lake Erie (Canada, United States). The ice dam ruptured and reformed dozens of times over thousands of years. Upon rupture events, lost water produced massive floods that scoured the region of present day eastern Washington state.

Ice dam lakes also form on flatter terrain when the edge of a glacier prevents the drainage of its own melt water. Here the lake forms through ponding in front of the glacier and is more specifically termed a proglacial lake. Isostatic rebound of the recently

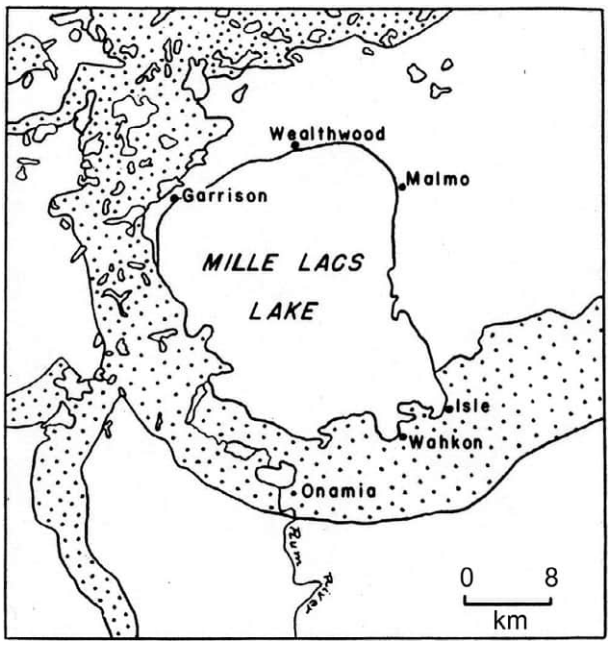

Fig. 4 An example of a moraine dam lake in Minnesota (United States). Stippling shows the moraine. Geographic reference as in Fig. 3. uncovered terrain may tilt it toward the glacier and enhance the ponding effect. Lake Agassiz was a large proglacial lake that covered several hundred thousand square kilometers during its life (Fig. 6). The lake changed its configuration and reach many times as the glacier retreated northward and the lake periodically drained (Teller et al., 2002). Vestiges of Lake Agassiz include Lake of the Woods (Canada, United States) and Lake Winnipeg (Canada).

Ice basin

Ice basin lakes reside either on or in a glacier. They originate when melt water, obstructed from exiting a glacier, pools either in a surface depression or internally in a glacial cavity. The depressions and cavities form as a result of glacial movement, fracture, fluvial erosion, and heat from the sun and Earth. In the case of surface depressions, the entire lake is cupped in ice. In the case of internal cavities, the lake commonly resides at the floor of the glacier and is bounded by land underneath and by ice on the walls and ceiling. Lake Vostok (Antarctica) is an example of the latter, residing some 4000 m below the Antarctic ice sheet. It is a huge lake that is several hundred meters deep at various locations with a surface area of about two thirds that of present day Lake Ontario (Canada, United States).

Thaw

Thaw (thermokarst, cryogenic) lakes have fascinated scientists for decades. These lakes cover vast coastal areas in the arctic regions of Eurasia and North America. They are best classified as periglacial because their origins depend on near-glacial conditions, but not glaciers themselves. A thaw lake originates when melt water in the surface layer of permafrost is prevented from draining downward by a deeper layer of frozen permafrost which serves as the lake floor. The surface area of a thaw lake may be quite small at first and polygon shaped. The soil rims that contain these lakes arise above fracture zones in the permafrost where annual freeze-thaw cycles lead to vertical expansion and soil upheaval. Contiguous thaw lakes will coalesce, resulting in large and small lakes in the same general area (Fig. 7).

Tectonic

Earth's exterior layer is comprised of a network of about a dozen relatively rigid, crustal plates that form a shell around the planet. The boundaries of these plates are zones of active slip, collision, and separation that generate what are called tectonic forces. Tectonic forces that translate upward to Earth's surface deform bedrock through fracture, rifting (separation), and warping (uplift and subsidence), resulting in the formation of mountains, oceans, and some of Earth's largest, deepest, and oldest lakes.

Fault block

Fault block lakes form where uplift and subsidence create vertical offset in adjacent blocks of fractured land. In cases where a single fault or fault complex is active, the process leads to a half-graben. This type of lake has characteristic steep-walled bathymetry on the fault side and an angled floor that slopes gradually to the opposite shore where vertical offset is minimal or nonexistent. Where multiple fault lines occur with wide parallel spacing, both sides of a land block can experience vertical offset and create a trough-shaped lake called a graben. Grabens generally contain precipitous bathymetric contours along both main shorelines (Fig. 8). Well-known examples of fault block lakes include Lake Baikal (Russia), Lake Ohrid and Lake Prespa (Europe), Lake Issyk-Kul (Kyrgyzstan), Lake Tahoe (United States), and several lakes in the Central African Rift Valley District (Fig. 9), including Lake Tanganyika, Lake Malawi, Lake Edward, Lake Albert, and Lake Rudolf. Fault block lakes are characteristically flanked by massive, steep escarpments that crest hundreds to thousands of meters above lake level (Fig. 9). Some fault block lakes that have been filled with water continuously for millions of years now house remarkably thick sediment layers such as those in Lake Baikal (~8 km thick) and Lake Tanganyika (~5 km thick). Such extraordinary sediment accumulations can only be explained if subsidence is ongoing. Evidence shows this to be the case which means that the longevity of these lakes depends in part on continual processes of origination.

Reverse drainage

Reverse drainage lakes result from uplift and tilting that redirect drainage. Two well-known examples include Lake Kyoga and Lake Victoria in Africa (Fig. 9). These lakes were created when uplift around the plateau's western margin reversed flow in the Kafu, Katonga, and Kagera Rivers (Kendall, 1969). All three major rivers historically flowed east to west across the plateau but now flow west to east over much of their course, flooding what were once old river channels and riparian plains in the formation of these two lakes. The dendritic shoreline of Lake Kyoga and the angles of its bays with respect to the main arm of the lake are vestiges of an ancestral fluvial state and a history of drainage that once flowed east to west (Fig. 9).

Newland

Newland lakes originate when the sea floor is uplifted and becomes exposed. The Caspian Sea, Aral Sea, and Lake Okeechobee (Florida, United States) are examples. Not long ago, the Aral Sea was listed among the largest lakes by surface area on Earth. Diversion of its major inlets for irrigation progressively reduced its volume to a mere fraction of its historic size and the remaining water is now divided into several smaller lakes (for more information see chapter on Saline lakes).

Volcanic

Volcanism is responsible for a variety of lake types that can be divided relatively naturally into two groups. One group includes those forming directly in the volcanic chamber where magma exited. The other group includes lakes that result from obstruction imposed by the volcanic mountain itself or the expelled magma. Volcanic lakes are generally small but often deep and they comprise some of Earth's most aesthetically pleasing and noteworthy aquatic ecosystems.

Volcanic crater

Volcanic crater lakes originate in the cavities from which magma was ejected. Small volcanic crater lakes (maars) and large ones (calderas) have representatives across Earth, including many in the Eifel region (Germany), the Auvergne region (France), Indonesia, and central Africa. Because of their origin, these lakes generally have a small aspect ratio (maximum width:maximum depth), which can inhibit complete mixing (turnover) of the lake's water mass on an annual basis. Lake Nyos (Cameroon) is a maar with an aspect ratio of 9:1. In its recent history, Lake Nyos remained partially unmixed long enough to become supersaturated with carbon dioxide gas. A catastrophic episode of mass release of the gas in 1986 killed about 1700 humans and 3000 cattle (Kling et al., 1987). Crater Lake (United States) is a magnificent example of a caldera. At about 600 m depth, it is one of the top 10 deepest lakes on Earth. Lake Tazawa and Lake Okama (Japan), and Lake Taupo (New Zealand) are other examples.

Volcanic dam

Volcanic dam lakes originate as a result of drainage that is blocked by either a volcanic mountain or its expelled lava. One example is Lake Kivu which lies on the western side of the Central African Rift Valley (Fig. 9). In the origination of this lake, seven major volcanoes dammed a drainage pattern that historically flowed north into Lake Edward. Drainage in the watershed now accumulates in Lake Kivu with excess water in the lake flowing south to Lake Tanganyika. Lake Lanao (Philippines) is another example of a volcanic dam lake.

Fluvial

Running water plays a profound role in sculpting Earth's surface. Its dual ability to erode and construct, akin to glacial, tectonic, and volcanic forces, engender fluvial force with a wide range of originating processes.

Plunge pool

As the name implies, a plunge pool lake originates at the base of a waterfall where the destructive energy of falling water excavates a hollow large enough to hold water long after the river has perished. A number of lakes in eastern Washington (United States) provide examples including Dry Falls Lake.

Oxbow

An oxbow (billabong) lake originates through the coupled influence of erosion and deposition in what are often wide, gently sloping floodplains. The general process, illustrated in Fig. 10, is one whereby a meandering loop in a river is eventually abandoned as the river cuts a newer, more direct path through the bank. The old river course is sealed at both ends with sediment deposits. Oxbows are commonly serpentine or crescent shaped, which reflects their position in the old river channel. Innumerable examples of oxbows exist that can best be appreciated from aerial views (Fig. 10).

Fluvial dam

Fluvial dam lakes originate when deposited silt creates a barrier that impounds drainage. Most common among this spectrum of lakes is a lateral lake that originates when a tributary is obstructed from entering a main river by a levee at the confluence. Lateral lakes are frequent on the Danube River (Europe) and the Yangtze River (China). A second type of fluvial dam lake is called a

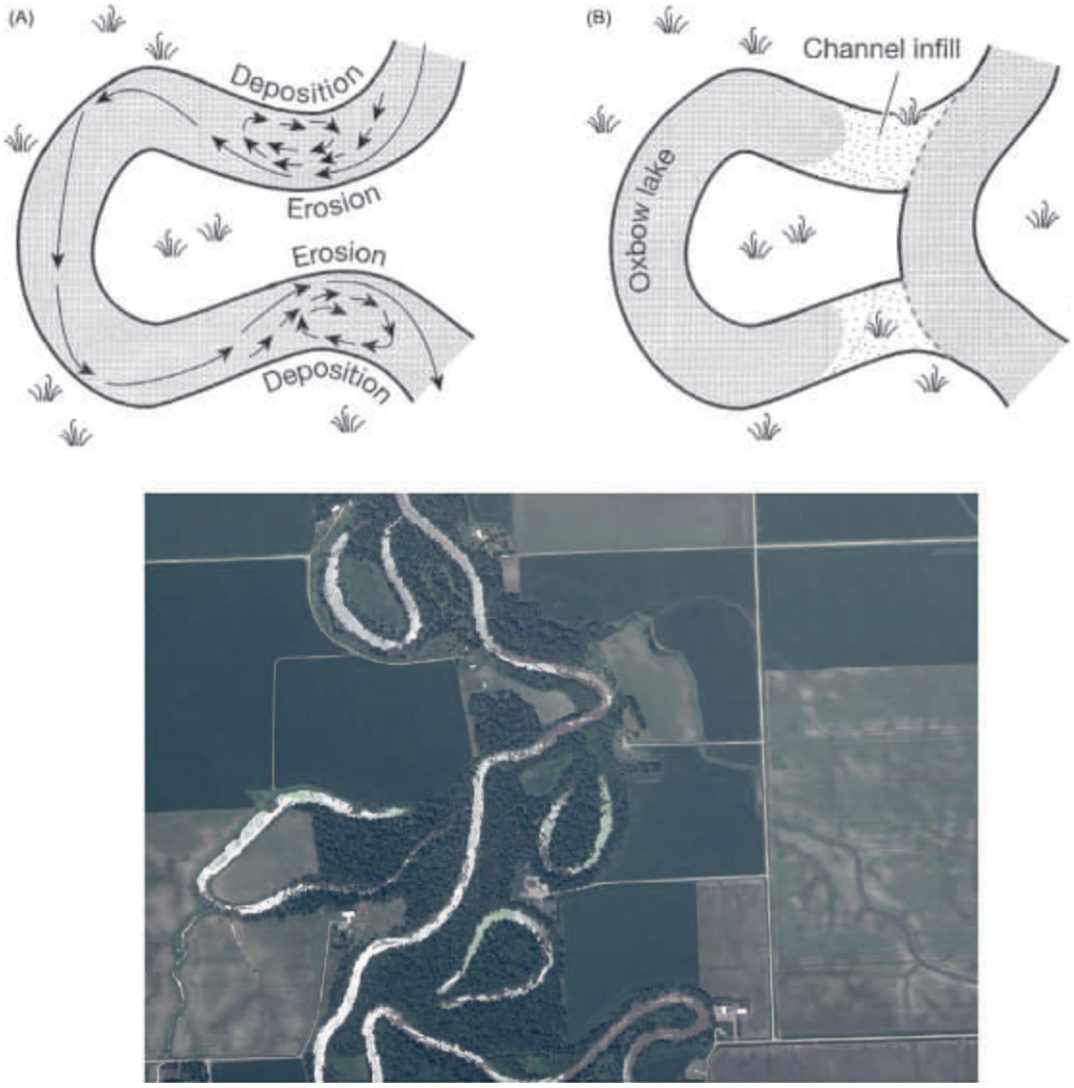

Fig. 10 Diagram of an oxbow lake during the (A) precursor phase and (B) late phase of origination. Color inset: Aerial photograph of four oxbow lakes flanking the Red River at the border of Minnesota and North Dakota (USA). *(A) Kalff J (2002) Limnology: Inland Water Ecosystems. Upper Saddle River: Prentice Hall, Reprinted by permission. (B) U.S. Department of Agriculture, Farm Service Agency, Aerial Photography Field Office, Reprinted by permission.*

floodplain lake. This type originates when a levee develops along the edge of a main river and obstructs seasonal floodwater of the main river from reentering. The volume of a floodplain lake can shift by an order of magnitude on a seasonal basis in relation to rainfall. Floodplain lakes are common throughout low-latitude, riparian regions of South America.

Organism behavior

Beaver pond

Beavers are industrious ecosystem engineers that transform land surfaces from terrestrial to aquatic. Their dams are built of wood and mud for purposes of habitat expansion and predator protection. Beaver dams may reach 4 m in height and extend for up to 0.5 km in length, giving their aquatic impoundments the dimensions of small lakes. The European beaver (*Castor fiber*) was extirpated by trappers over most of its native range by 1900 and is now being reintroduced. A dire fate of similar proportions reduced the abundance of the American beaver (*Castor canadensis*) from an estimated 60–400 million individuals only two centuries ago to 6–12 million today. The remarkable numbers of beaver at one time suggest that their ponds may have once contributed significantly to lake numbers on a global scale.

Reservoir

Reservoirs are human-made impoundments that block the natural flow of rivers and submerge formerly terrestrial surfaces. They are generally built for purposes of water supply (irrigation, drinking), power generation, flood control, or recreation. Modern, highly engineered reservoirs can store enormous volumes of water and control its passage at the outlet with great precision. The numbers and sizes of reservoirs have been growing at rapid rates since World War II. One of the largest is Bratsk Reservoir (Russia) with a volume that exceeds Lake Tahoe (United States).

Farm pond, mine pit

Humans have long been excavating Earth to retain water for agricultural purposes. These lakes, called farm ponds, are widespread globally and may be more important in their contribution to the total surface area of freshwater than once thought. Humans also excavate Earth during mining operations for rocks, metals, and gems. These depressions are called mine pits and once abandoned they can fill naturally with groundwater. Some mine pit lakes are remarkably deep. The Portsmouth Mine Pit Lake in Minnesota (United States) has a maximum depth of 150 m and a surface area of 0.5 km^2, making it the state's deepest inland lake.

Chemical

Solution

Solution (karst, doline) lakes form through a process of chemical dissolution of bedrock. The breakdown of limestone ($CaCO_3$) by natural levels of acidity in the groundwater is the most common chemical reaction involved. A solution lake generally originates as a subsurface cavern which progressively collapses under the strain of overlying soils. Solution lakes have been known to appear suddenly, and disastrously, where large underground cavities collapse all at once. Subsurface outlets and cracks in solution lakes may be sealed by residual rock, soil, or the hydrostatic pressure of the water table, including the ocean in coastal locations. They are common in the Balkan Peninsula, the European Alps, and Florida (United States).

Wind

Deflation

Deflation (playa, pan) lakes originate through erosive wind forces that remove loose terrain. The process is facilitated by an arid climate and a lack of vegetative cover, and may be aided further in some instances by intermittent fluvial erosion and animal occupation (ungulates) which can help loosen sediment and reduce its grain diameter. Deflation lakes may dry up on a seasonal basis if precipitation and runoff are unable to maintain their evaporative losses. They are common throughout arid regions in Australia, Africa, and North America. One notable example is Lake Alablab (Kenya).

Landslide

Landslide dam

A landslide is a gravitationally pushed, mass movement of debris. When one obstructs the passage of a river it originates a landslide dam lake. Because landslide debris is typically unconsolidated it erodes rapidly. These lakes are generally short-lived compared to other lake types. Two examples include Lake Janet in Glacier National Park (United States) and Lake Waikaremoana (New Zealand).

Shoreline

Coastal

Coastal lakes originate when a bay or indentation in the shoreline of a lake or ocean becomes closed to the main body of water by a bar (spit) of sediment deposited through longshore currents. It is a process similar to that which creates fluvial dam lakes. Maritime examples of coastal lakes are common in France, Australia, and New Zealand. Lake Nabugabo (Uganda) is an example of a freshwater coastal lake which was cut off from Lake Victoria. The western edge of the state of Michigan (United States) is rich with coastal lakes sealed off from Lake Michigan (Fig. 11).

Meteorite

Meteorite crater

The most bizarre of all originating processes, and one of the rarest at this moment in Earth's history, is that related to the impact of a meteorite. In this case, the catastrophic destruction and dispersal of terrain leaves a hollow called a meteorite crater lake. Examples include Pingualuit Crater Lake in Québec (Canada) and Laguna Negra (Argentina).

Fig. 11 Aerial photograph of Stoney Lake (United States), a coastal lake of Lake Michigan (background). Aerial Graphics, L.L.C., Grand Rapids, Michigan (United States), Reprinted by permission.

Knowledge gaps

- How environmental forces that originate lakes will respond to climate change including increased heating (glacial force), changing weather (fluvial force and wind force), and changing water demand (human force).
- Approaches to inventory lakes (particularly small lakes) on a global scale with accurate estimates of depth and volume.
- Approaches to track the ever changing geography of lakes (size and presence), particularly in remote areas.

Conclusion

Most lakes originate through nonliving processes but they occasionally involve the behavior of animals such as beaver, ungulates, and humans. Although a relatively limited number of recognized processes originate lakes, the path followed by any particular lake will always be unique and inherently richer and more variable than a classification scheme can convey. Understanding the origin of a lake not only serves to document the natural history of its landscape but also provides valuable context for the investigation of its past and contemporary limnology.

Geomorphology of Lake Basins

B Timms, University of Newcastle, Callaghan, NSW, Australia

This is a reprint of B. Timms, Geomorphology of Lake Basins, In Encyclopedia of Inland Waters, Edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00024-7.

Glossary

Arcuate Gilbert delta – A delta arched in plan and composed of a wide block of sediments up to the water surface.
Homopycnal inflows – Incoming water and lake water of same density, so thorough mixing of the two.
Hyperpycnal inflows – Incoming water more dense than lake water, so it flows along the bottom of the lake.
Hypopycnal inflows – Incoming water less dense than lake water, so it flows on the surface.

Introduction

Mapping is basic human activity, born in antiquity and developed today to embrace complex, multilayered geographic information systems. Maps of lakes are of more intrinsic value than terrestrial maps, because they show features below the water surface the eye cannot see. Moreover, they can be used to compute various parameters of value in understanding the structure and functioning of lakes. This chapter is devoted to explaining these parameters and to expand upon the role of lake geomorphology in limnology.

Morphometric Parameters

In the past, mapping lakes was a laborious task. Lake shorelines had to be established by such methods as transverse, stadia or plane table surveys, all time consuming, and spot depths by lead lines at fixed positions. Today, outlines of shores are easily obtained from aerial or satellite images and depth profiling done by echosounders. Exceptions include shallow ephemeral lakes, like many in Australia, which are best mapped when dry using modern terrestrial surveying equipment. Once, the basic data had to be processed by hand to produce a map, but nowadays almost all stages can be computerized. In all cases scale is important, the finer the scale, the more accurate the map. The parameters derived from these maps can be divided into those taken directly or indirectly from the map and those that are derived by computation from the primary parameters.

(a) Primary Parameters
  (i) *Lake length*. This is the length of the line connecting the two most remote points on the shoreline. It should not cross land (so in an oxbow lake the line is curved), but it may cross islands. Such measurements are of intrinsic geomorphic value only. Of more use limnologically is the *maximum effective length*, which is defined by the longest straight line over water on which wind and waves can act. While the two values are similar in large deep lakes like Africa's Lake Victoria, in island-studded lakes like Sweden's L.Vänern, the maximum effective length is 69%of the maximum length. Knowledge of this parameter is important in geomorphic studies on shorelines and in studies on seiches and stratification in physical limnology.

(ii) *Lake width* is defined by a straight line at right angles to the maximum length and connecting the two most remote shorelines. Again, of more value is the maximum effective width, which does not cross land. This, and the mean width are of use mainly in hydromechanical studies.

(iii) *Lake depth* is the maximum known depth of a lake, and is the single most important geomorphic parameter of a lake. The world's deepest lake is Lake Baikal in Siberia (1620m deep) and many large glacial, volcanic, and tectonic lakes exceed 200m in depth. By contrast, most lakes on flood plains or formed by wind are shallow, rarely exceeding 5m in depth. The limnological consequences of this are paramount and discussed later. *Mean depth* (lake volume/lake area) is also worth noting and has been used many times to explain varying productivities between lakes (e.g., the deeper the lake the less productive it is). Of the various other depth-related parameters, *relative depth*, which is the ratio of the maximum depth to the mean diameter of the lake, is useful in explaining stability of stratification in lakes. For large shallow lakes like the wind-stirred Lake Corangamite in Victoria, Australia, the value is 0.09%, while the nearby meromictic West Basin Lake in a volcanic crater, the relative depth is 3.0%.

(iv) *Direction of major axis*. It is important to know this in geomorphic and hydrodynamic studies as lakes may be aligned to dominant wind direction and hence be more subject to wind than others. For instance, in the eastern inland Australia, only those lakes with an axis near N-S grow spits under the influence of winds from the NW that close off the southeast corner (see later).

(v) *Shoreline length* is easy enough to measure by a map measurer, but is very much influenced by map scale. It is used to calculate shoreline development, a parameter used in littoral studies.

(vi) *Lake area*, once determined by planimetry, but now easily done with a computer, and hardly affected by map scale, is another of the most basic lake parameters. The world's largest lakes are of tectonic and of glacial erosion origin. At the individual country scale, lakes are often listed by area with an explanation for any pattern based on geomorphic distinctiveness of the district/mode of origin. For instance in New Zealand, geology and climate explain the dominance of large piedmont glacial lakes on the South Island, and many somewhat smaller volcanic lakes on the North Island. If the area occupied by a lake fluctuates (because it is terminal or used for water supply) then it is useful to know the area at any depth and this is visualized in a *hypsographic curve* (**Figure 1(a, c)**).

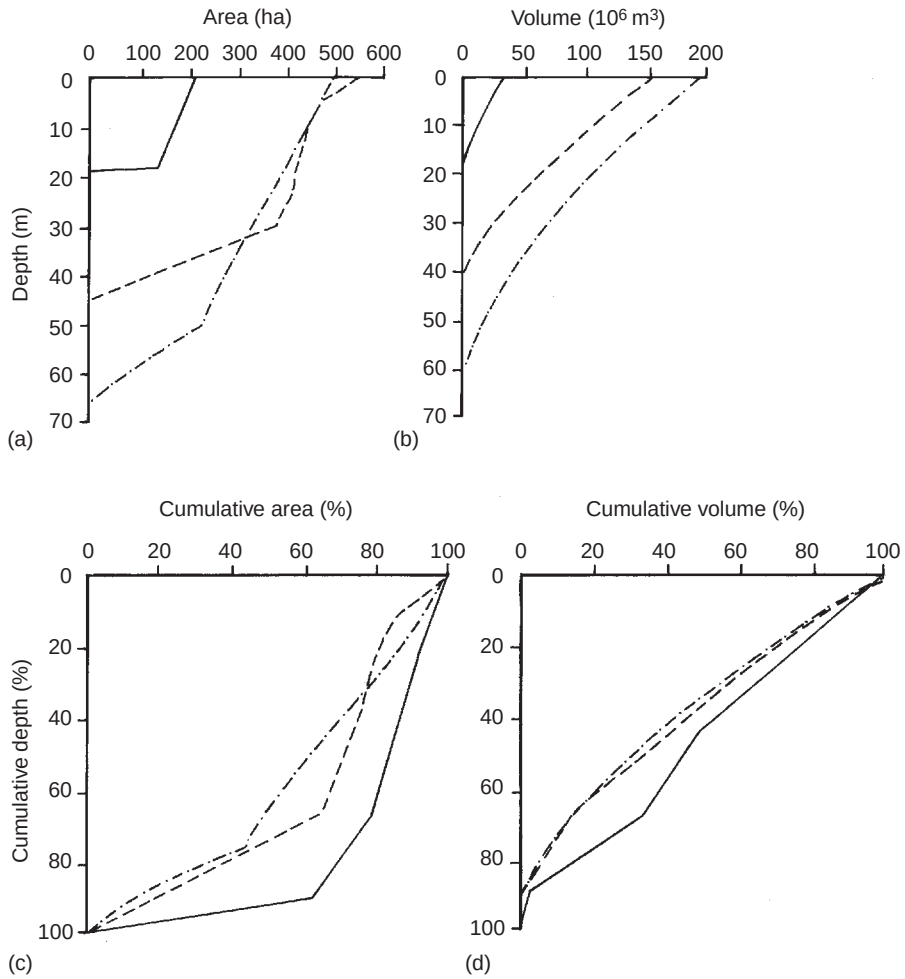

Figure 1 Absolute hypsographic (a) and volume curves (b), and relative hypsographic (c) and volume curves (d) for three maar lakes in Victoria, Australia.

(vii) *Lake volume* is calculated from summing the volumes between each contour, though for increased accuracy different formulae are used according to lake form. This is another parameter often quoted for lakes, particularly if they are large. Most impressive in this instance is Lake Baikal's massive volume of 23 000 km^3, representing one-fifth of the world's fresh water. Visualization of volume at any depth, particularly useful in lakes and reservoirs that fluctuate in depth, is achieved by a *volume/depth curve* (**Figure 1(b, d)**). In this respect, volume percentages derived from cumulative curves for reservoirs are widely quoted in the media in dry countries like Australia, where water reserves are precarious and precious.

(viii) *Insulosity* is the percentage of the lake area occupied by islands. Though some lakes have minor islands, like subsidiary cones in crater lakes, their insulosity values are of no consequence. It is mainly in glacial ice scour lakes and other lakes with highly irregular shorelines where there are many islands that this parameter exceeds ca. 10% and assumes importance. While its worth is intrinsically geomorphic, it is sometimes equated to the value of a lake for recreation, where humans require high shoreline–waterway interaction, as in Swedish lakes Vänern and Mälaren. On the other hand, sailors and waterskiers require open water for their recreation activities, so small, lakes without islands are favored. Thus, there is no relationship between insulosity and recreational use of a lake!

(ix) *Watershed to lake area/volume.* This is easy to calculate from maps and is used as an estimate of terrestrial inputs as in eutrophication studies and also as water renewal ratios for some in-lake processes.

(b) Common Derived Parameters

(i) *Shoreline development* (D_s) is a measure of the irregularity of the shoreline; its accuracy is dependent on map scale. Essentially, it is the ratio of the length of the shoreline to the length of the circumference of a circle of area equal to that of the lake. It is an index of the potential importance of littoral influences on a lake. Perfectly circular lakes have a D_s of 1.0, average lakes have values between 1.5 and 2.5, while lakes and reservoirs with much indented shorelines have values exceeding 3 (**Figure 2**). Expressed in relation to lake types, volcanic vent lakes have minimal D_ss, and lakes in dammed valleys and in ice-scoured terrain have the highest values.

(ii) *Volume development*. This index (D_v) is used to express the form of a basin, and is defined as the ratio of the volume of a lake to that of a cone of basal area equal to the area of the lake and depth equal to the maximum depth of the lake. Lakes with a D_v of 1.0 are perfectly cone-shaped and uncommon. Values <1.0 indicate a trumpted-shaped lake and are rare and values $>$ca. 2.5 indicate a beaker-shaped lake and are also uncommon (**Figure 2**). Most lakes have values somewhat greater than unity. The unusual values may be related to lake type, e.g., doline lakes usually have D_vs near 1 and claypans and maar lakes may have D_vs near 3, but sometimes D_vs may be the result of peat growth/marl deposition/shoreline slumping/erosion in the littoral, leading to values near 1. In all cases the index is a surrogate for the role of the sublittoral in a lake's limnological processes, the lower the value the greater the sublittoral influence.

(iii) *Slope* is the angle, usually expressed as a percentage of repose of the bottom sediments and can be determined directly from an echogram or from a contour map using appropriate measurements and formulae. Slopes of near 0% (profundal areas) to 20% (sublittoral slopes) are common, but occasionally values approach the maximum of 90% in a steep-shored crater, glacial erosion and lakes due to earth movements. This parameter is used mainly in sedimentological studies and to lesser extent in benthic studies in choosing suitable stations. *Mean slope* is an average for a whole lake and is derived from a contour map and application of formulae. Not surprisingly, mean values are much more subdued than slopes at designated contours and commonly range from $<1\%$ to 10%, but may exceed 25%in some lakes, e.g., Lake Barrine, a small maar in north Queensland, Australia, has a mean slope of 30%. Perhaps in interlake comparisons, visual inspections of comparative hypsographic curves (**Figure 1**) are just as instructive as are figures for mean slope, and far less troublesome to prepare.

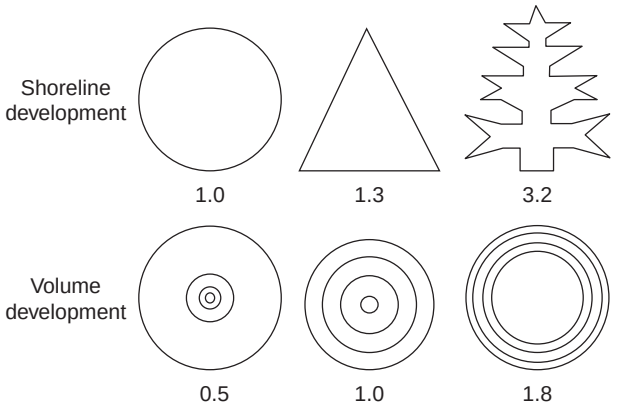

Figure 2 Graphical representation of shoreline development for three lakes of different shape, and of volume development for another three lakes of different volume distribution. In the latter, concentric lines represent depth contours.

(iv) Sometimes a derived parameter can be established for a special need. For example *Ratio of epilimnion sediment area to epilimnion volume* has been usedmore effectively than parameters based on whole lake volume in eutrophication studies because it more accurately accounts for nutrient recycling in a lake.

Lake Shapes

Many lakes have characteristic shapes determined by their mode of origin that are only partly described by their parameters. The ratio of length over width can give information on whether a lake is rectangular, circular or ellipitical and high D_ss can indicate a dendritic lake, but a simple descriptive word is usually better. *Circular* lakes (D_s near 1) are uncommon, but can be found in volcanic vents, in some deflation basins and in lakes due to meteoric impact. *Subcircular* lakes are more common and are associated with a variety of origins: volcanic craters, deflation basins, dolines, cirques, kettle-holes to name the more common ones. *Ellipitical* lakes are a special subgroup of these and are generally associated with wind deflation. *Subrectangular* elongate lakes generally are of structural origin or result for glacial erosion in valleys (piedmont lakes). Markedly *dendritic* lakes result from flooding of dissected valleys as in some coastal lagoons, some landside lakes and in many reservoirs. It is these in which D_s is high (>3). *Triangular* lakes also usually arise from flooding, usually either on floodplains or along coasts. These may be confused with circular lakes on length/width ratios, but not by their descriptor. *Lunate* (or newmoon shaped) lakes result from river meandering to form oxbows, and sometimes from asymmetrical placed subcones in volcanic craters. Highly *irregular* lakes are possible from the fusion of lake basins and in glacially scoured areas. These also may have high D_ss.

Changes with Time

Over geological time, lakes are temporary landscape features (but see later), filling with sediment and/or eroding at the outlet. Consequently lake morphometry changes with time, imperceptibly in well-watered areas, but at the other extreme, oscillating widely in terminal lakes in arid areas. The most obvious changes are lake level fluctuations and their concomittent shoreline changes. Sedimentation is less obvious, except for delta construction.

Lowered lake levels, of whatever cause, result in stranded beaches, spits and deltas. Worldwide, piedmont glacial lakes provide many examples, perhaps none better than New Zealand's Lake Wakatipu with its 10 strandlines cut into a major bench and deltaic fronts at 50m above present lake level The terminal lakes of Tibet have numerous elevated shorelines attesting to a more fluvial past, as do most of the world's large lakes in endorheic regions. Interesting as these landforms may be, and useful in aging a lake, it is the changes with decreasing depth in physicochemical processes in the lake such as thermal and chemical stratification, that are important limnologically.

In some lakes, levels have been elevated since initial formation, drowning shoreline features and river channels. Coastal marine lagoons, tied to changing sea levels, provide many examples including Lake Macquarie near Sydney, Australia, where drowned river channels and spits are clearly discernable (**Figure 3**). As in lakes with lowered levels, raised levels may change physicochemical processes, and in addition, there may be hydrodynamic changes associated with changed inflows.

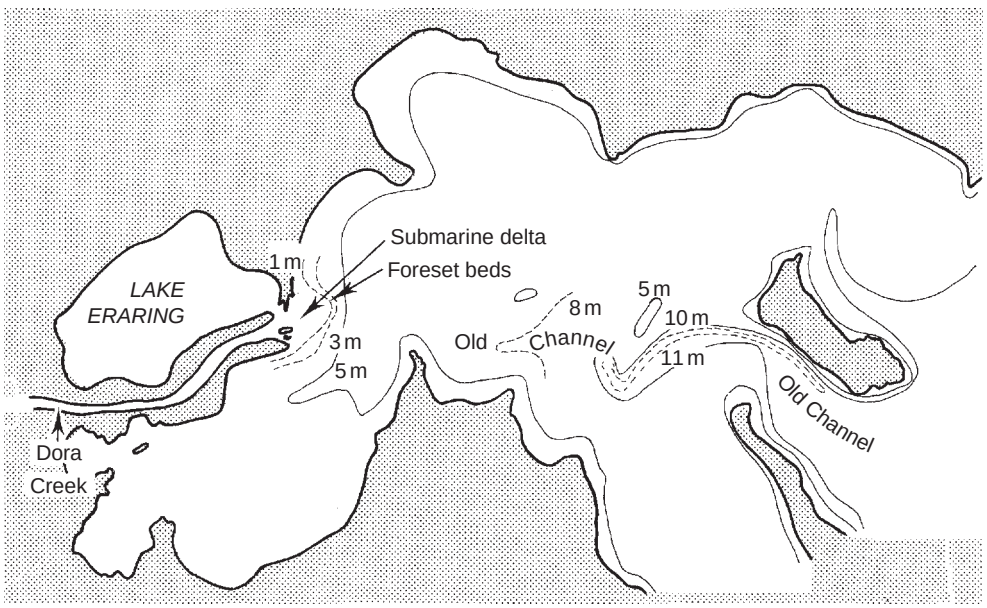

Figure 3 The western bay of Lake Macquarie, near Sydney, Australia, a drowned coastal valley, showing the former river course and a lobate delta.

All lakes accumulate sediment, either mainly from stream inflows, or biological production in the lake itself, or occasionally from overland flows and rarely by showering ash from volcanic eruptions (as in lakes around Taupo and Rotorua in New Zealand). Rates are highly variable and depend on geomorphic type, catchment size and erodability, and trophic status (and proximity to a volcano!). The most rapid accumulation is by delta building in lakes with large inflows in mountainous areas. Well-known examples include the deltaic plain at the head of Lake Geneva and the surficial sediments that divide Thuner See and Brienzer See at Interlaken, both in Switzerland. Deltaic form depends on the relative densities of lake and river water and lake currents. Arcuate Gilbert deltas due to homopycnal flows are perhaps the most common type in piedmont glacial lakes, lobate deltas associated with hypopycnal inflows in coastal marine lagoons (Figure 3), and alluvial fans in shallow desert lakes. No matter the deltaic form, lake surface area and volume are reduced, but probably with minimal influence on limnological processes in large lakes.

On the other hand, lake floor sedimentation due to submarine delta building by hyperpycnal inflows (as in Lake Pukaki in New Zealand) and by chemical or biological deposition decrease lake depth and hence may influence physicochemical processes, particularly if the sediments of productive lakes consume oxygen during stratification. Rearrangement of bottom sediments due to slumping or bioturbidation are of little geomorphic consequence, but may upset layering and hence interpretations of lake/catchment history recorded in sediment cores.

Ancient Time plus Size

While differing geomorphology, as measured by the above parameters, influences lake ecology, there are many other factors involved, one of which is geological time. Most lakes exist for hundreds to thousands of years, perhaps even a few hundred thousand years, but some persist for many millions of years, and cognisance of this, together with their size (volume, perhaps area), allows greater understanding. Scale is indeed important in limnology.

By considering a new coefficient, Touchart divides lakes into four broad groups. He estimates the scale of a lake, by taking the logarithm of the product of the age (expressed in millennia) by its volume (in cubic kilometres). Lakes with values 4–8 are almost exclusively large old structural lakes such as Baikal, Caspian, Tanganyika (values of 8), Victoria (7), Issyl-Kul, Aral, Titicaca (6), Balkhash, Tahoe (5), and Biwa, Toba, Taupo (4), among others. Most of these are largely independent of morphoclimatic hazards and have high biological endemism. For instance in Lake Baikal there are 255 species of gammarid amphipods in 35 genera, 34 of which are endemic. New Zealand's Lake Taupo is an exception, going back perhaps only a million years, but subject to many catastrophic reincarnations as recent as 1800 years ago). Biodiversity is low as a consequence of this Recent age, and also it small size (623 km^2) and being on an isolated island.

The next group usually have values 1–4 and are medium sized, largely of morphoclimatic heritage, i.e., shaped largely by the Würm glaciation. Examples include, Lakes Superior, Great Bear (4), Ontario, Winnipeg (3), Constance, Geneva (2), Te Anau, Wakatipu (both NZ)(1) among a host of others. They are often large (>10 000 km^2) and deep (200–500 m), and formed by glacial erosion. Life expectancy is in the order of only thousands/tens of thousands of years. Biodiversity is lower and morphodynmaic processes (delta-building, sedimentation) in their basin are relative important in limnological processes. These are the lakes most common in the Temperate Zone of the Northern Hemisphere where limnology developed, so they are the 'standard' lakes of text books. To a large degree both of these classes of lakes are dominated by their shear size, so that morphometric parameters other than area and depth are generally unimportant in influencing limnological processes.

A third group of lakes are small (Touchart coefficients of 1 or less) and largely influenced by current morphodynamic processes or recently inherited ones. These include fluviatile lakes, karstic lakes, aeolian lakes, and landside lakes in the first subgroup and many small glacial and volcanic lakes in the second. All are subject to changing shape and dimensions and many have a particularly precarious existence (e.g., landslide lakes). It is in these lakes where key abiotic variables (e.g., Secchi depth) are related in varying degrees to lake morphology and catchment area.

Touchart's fourth group of lakes also have coefficients of 1 or less; they are the lakes (reservoirs) of human origin. They are of variable size (in area, some challenge lakes with coefficients of 4), but are recent in origin and have a short life span. Moreover, their morphometry is forever changing and their catchments dominate their limnological processes.

Touchart largely omits consideration of short-term changing morphology, partly seen in reservoirs, but absolutely characteristic of intermittent lakes. Such lakes are uncommon where most limnologists live in Europe and North America, but prevalent in the drier parts of Asia, Africa, South America and especially Australia. Some are of very ancient lineage, e.g., Lake Chad, Lake Eyre, but lack ancient/endemic biodiversity because intermittent lakes are useless evolutionary loci. Others (e.g., seasonal lakes due to flooding; shallow lakes due to wind deflation) are temporary landscape features and if they lie in a distinct basin, are best depicted with inverse contours (i.e., bottom at 0m, highest level at x metres/centimetres to account for their fluctuations in water level (Figure 5). Most abound in geomorphic expressions of their shallowness and variability, so that a consideration of their geomorphic parameters together with their hydrologic variability can explain some ecological features.

Parameters of the Geomorphic Lake Types

Structural (Tectonic) Lakes

As shown above, many of these like Lakes Baikal and Tanganyika, are especially large, deep and old, so that they have special limnological features, that are expressed most meaningfully by their Touchart coefficients. Such lakes have D_vs a little above unity

(1.2–1.5) and moderate D_s (1.3–3.4). Many older tectonic lakes of moderate depth (e.g., Caspain Sea, Aral Sea) have D_v s <1, while the shallow intermittent ones vary according to hydrological condition. For instance in Lake Eyre D_v decreases from 1.68 when 'full'(=5.7mdeep) to 1.55 at 4mdeep to 1.43 at 1m deep, while D_s decreases from 4.7 when full (it spreads up entering creeks to give a highly indented shoreline) to much lower values when contained well within the vast salt flats. The limnology of Lake Eyre is different when full to when near empty, largely because of differing water salinities but the consequences of its differing geomorphic parameters contribute too. Lake Chad also has differing geomorphologies at different water levels, and probably so do many other shallow arid zone lakes. In addition, tectonic lakes in terminal basins have many stranded beach features useful in deducting past histories, as in many Tibetan lakes to give one set of numerous possible examples.

Meteoritic Impact Lakes

These are rare, but impressive because of their roundness ($D_s = 1$).Depths vary, but LakeUngava (=Chubb) in Quebec Province, Canada, is 251m deep and diameter about 3 km. Intermittent Lake Acraman in South Australia, although not quite round is notable because of its huge size (diameter 22km).

Volcanic Lakes

Like structural lakes, there is no one set of parameters which characterize all volcanic lakes, though some subtypes have characteristic features. One group are the maars and calderas; generally these have low D_ss (near 1), high D_vs (near 2), high littoral slopes and low profundal slopes. In an analysis of 15 Australian maars, D_s averaged 1.14 (lowest 1.01) and D_v 1.91 (highest 2.8) (**Figure 4**). Such lakes are typically dominated by their limnetic zone and have physicochemical processes not too dissimilar to the classic large lakes of limnological literature. On the other hand shallower lakes on Victorian lava fields are not that different (except for their saline waters) to shallower lakes elsewhere. These are dominated by shallow water and littoral processes due to low maximum and mean depths, low littoral slopes and often high shoreline developments. Again, the basic geomorphic differences between the various types of lakes are expressed in depth and size, and perhaps there is scope in the Touchart system to differentiate lakes with coefficients <1 within his third type.

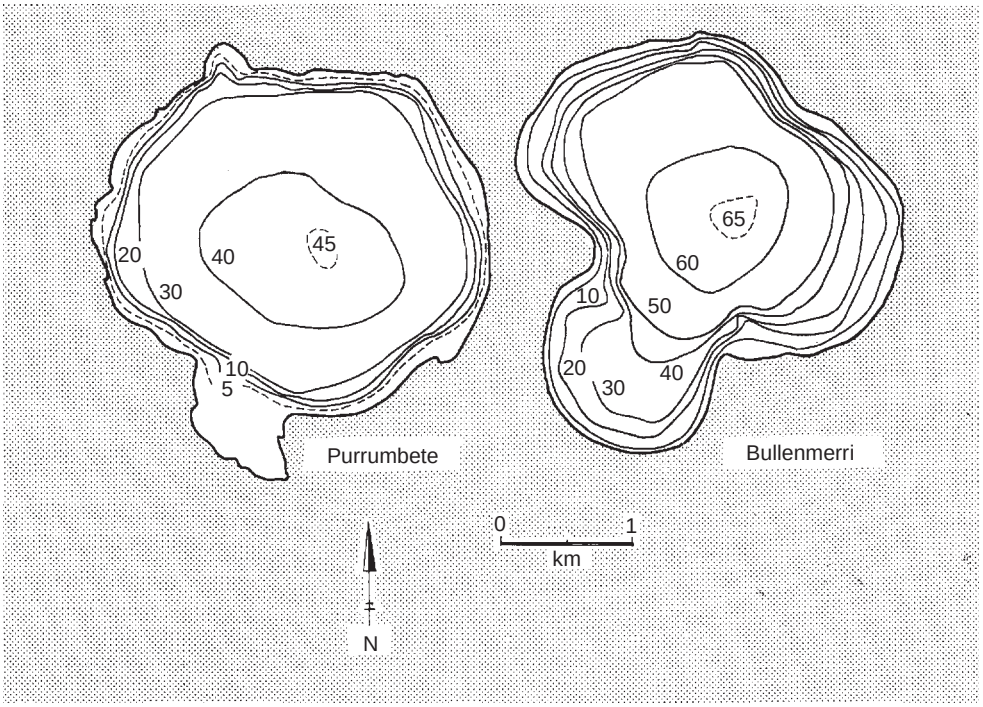

Figure 4 Bathymetric map of two maar lakes in western Victoria, Australia. Lake Purrumbete lies almost wholly within its crater, while Lake Bullenmerri lies within three adjoining craters. Both have a D_s a little >1 and a D_v near 2.

Glacial Lakes

Again there is a wide variety of limnologies better explained by the size-age coefficient of Touchart (group 2, see above) than by geomorphic parameters alone. Nevertheless for the piedmont lakes due to glacial erosion, waters are deep, and D_vs are high. For 10 such large lakes on the South Island of New Zealand, 7 are deeper than 200 m and the average D_v is 1.75. Shore and littoral features are unimportant compared with the contribution of large and deep limnetic region. Cirque lakes for another group, but their geomorphic parameters are hardly unique and influencial. The smaller kettles and the like are dominated by their small overall size and hence littoral processes.

Fluviatile Lakes

Almost all of these are small, and even if >10 km^2 are still shallow and hence belong to Touchart's group 3 and so littoral dominated. Two common types have some characteristic parameters: most oxbows are lunate-shaped with a curving maximum length and moderate D_ss (<2.5), while most blocked valley lakes are dendritic with higher D_ss (2–4). Some, e.g., the bog lakes of the Waikato, New Zealand have shorelines much smoothed by growth of littoral vegetation so that D_ss are low, as are D_vs.

Solution Lakes

As for fluviatile lakes most of these, especially dolines, are small and shallow, and though uvalas and poljes may be larger in area, they are still shallow. Perhaps the parameter of most interest is their D_v – this is often 1 or less, indicating a cone or trumpet-shaped basin. Unlike the previous fluviatile lakes, but like kettles, they may have multiple deeper subbasins.

Aeolian Lakes

Lakes formed, or largely moulded by wind action, are generally shallow (<5 m, often <1 m deep), relatively small (<100 km^2, often <1 km^2) and have sandy shores, so that shore processes are most important in their limnology. Hence spits, beaches, islands, and deltas feature in their evolution and their basin orientation is both a consequence of their development and/or a causal driver in their further evolution. Orientation to wind and effective maximum lengths for wave generation are basic controllers of their geomorphology. Many lakes in southwestern Western Australia and elsewhere are rounded or ellipitical and difference in orientation and size between areas is related to different wind directions and/or rainfall distribution. On the other side of Australia, only those lakes orientated with their major axis N-S, develop spits in the southeastern corner in an attempt at lake compartmentalization (see later) (Figure 5). These spits increase D_s, which increases the habitat for shorebirds. Under unidirectional or

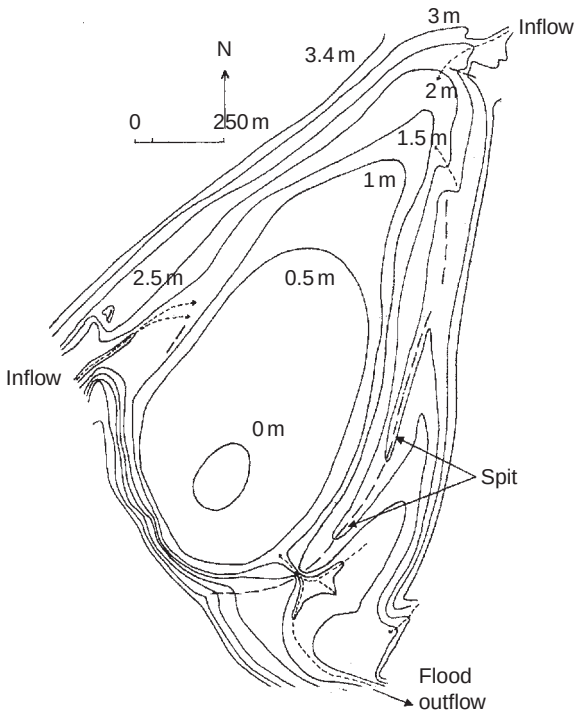

Figure 5 Bathymetric map of Lake Yumberarra, Outback Queensland, Australia. Key: beach ridges long dashes; creek channels, short dashes. Depth contours inverted from normal pattern, as this is more convenient in shallow intermittent lakes with highly variable water levels.

bidirectional winds, shallow lakes may completely segment (i.e., form separate compartments), creating smaller lakes with more shorelines and increasing the important of littoral processes.

Coastal Lakes

Although most coastal lakes are due to sea-level rise, their geomorphology is variable due to different inherited features. A few are in fjords, so may be deep and steep-sided, while most are in drowned valleys, so dendritic or triangular, and those on low coasts may be elliptical. Australia's southeast coast has numerous coastal lakes of many subtypes, as does the Landes coast of France, the Cape Cod coast of North America, the Baltic coast to name a few others. Their active depositional environment encourages delta and spit formation, and lake compartmentilization in low coasts, so that shorelines are longer than those inherited. Given most lie in windy environs, basin orientation, and effective lengths are particularly important for those lake processes dependent on wave generation.

Lakes as Recorders of Earth Surface Dynamics From Yearly to Plurimillennial Time-Scales

Fabien Arnaud and Pierre Sabatier, Environment Dynamics and Territories of the Mountain (EDYTEM), CNRS, Université Savoie Mont-Blanc, Chambéry, France

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Accumulation (of sediment) When the transporting medium is not competent enough to ensure the transport of erosion products, they may accumulate in a so-called depocenter. Within their watershed, lakes are often such a final sink in which erosion products and the information they bear are trapped. Moreover, because lake bottoms are generally quiet, this accumulation of sediment is regular enough to preserve the chronological succession of information, just like pages in a book. This is why lake sediment can be considered as "natural archive."

Anthropocene The Anthropocene is a neologism forged by Paul Crutzen to designate the moment in the history of the Earth when humans emerged as a new geological force. The international commission on Stratigraphy is currently addressing the question of making the Anthropocene an official geological Era which should have started in 1950 CE with the first worldwide dispersal of artificial radionuclides due to a period of intense nuclear weapons atmospheric tests.

Erosion cycle The erosion cycle designates the succession of any processes leading to the movement of matter teared from the Earth surface and subsequently deposited. It is commonly divided in four phases: weathering, grabbing, transport and accumulation of sediment.

Grabbing Any process permitting the extraction of weathered matter (cf. weathering) from a rock or a soil, usually through a meteoric agent: rain, wind, waves.

Holocene The Holocene is the most recent geological epoch; it conventionally started 11,700 years ago with the termination of the Pleistocene Stage 4 glacial period. It is hence the most recent interglacial stage of the Pleistocene, but also the period that has witnessed the rise of organized human civilizations which eventually became one of the driving forces of the Earth dynamics. This growing influence of humans led several scientists to propose the Holocene epoch is now over and should be replaced by the Anthropocene Era.

Natural archive A natural archive is the common name given to Earth surface systems that have the capacity to record environmental conditions through time. They are the study object of paleosciences.

Paleosciences A corpus of scientific approaches aiming at reconstructing past Earth dynamics.

Transport (of sediment) Once weathered and grabbed, erosion products need a sufficiently competent flow of matter in order to be carried away from their source area; this is generally stream water, but may also be wind, avalanche, glaciers, humans etc.

Weathering Physical or chemical reworking of rocks that generate an outgoing flux of dissolved and/or particulate matter toward the Earth Critical Zone; it includes in particular all processes of soil formation from non-weathered bedrocks.

Introduction

Lakes are defined as in-land bodies of standing water. As such they represent zones of drastically reduced water velocity along stream courses and thus—almost—perfect sediment traps. Indeed, whereas, in most cases, the amount of water flowing in a lake is almost equal to the amount flowing out of it (+/– evaporation), most of the solid charge brought by stream water is trapped within the lake. This is nicely exemplified at the outlet of Lake Geneva where the alpine Rhône river gets out of the lake free of any sediment and is met by its tributary Arve river which is by contrast extremely turbid. Whereas both streams originate from a high-altitude glaciated area producing massive amounts of sediment, the difference in particles load is only explained by the presence of Lake Geneva which traps most of the sediment coming from the Upper-Rhône River catchment area (Fig. 1).

The quantity and quality of river's solid charge depend on a multitude of processes acting within a given catchment area. They hence potentially bear a lot of information about the evolution of inland areas, both submitted to natural and human-triggered forcing mechanisms. This information is subsequently stored in stratigraphic order at the bottom of lakes within sediment strata. This is why lakes are particularly interesting archives of the Earth Critical Zone dynamics (Fig. 2).

The Earth Critical Zone (ECZ) is a conceptual space defined as the thin active layer at the surface of the Earth where all the energy, matter and information exchanges that are necessary to sustain life do operate (Banwart et al., 2013). It has been defined by the US National Research Council as spanning the whole space from the top of the canopy down to the base of groundwater (Gaillardet et al., 2018). Among the recent advances in environmental sciences, the concept of ECZ theorizes the fact that social-ecological systems strongly depend on the imbrication of biotic and abiotic processes that interact at various time scales, from the second to several millennia. It is hence crucial to better know all those interacting processes, their kinetic and long-term interactions in order to understand global changes and their potential effects on planet Earth habitability (Lade et al., 2020). In this chapter, we will detail how some of the information stored in lake sediment can be extracted in order to reconstruct the evolution of the ECZ along with the complex interactions driving its dynamics.

Production and export of eroded matter within the Earth Critical Zone

Erosion processes are the main path for matter and thus information to be transferred within the Earth critical zone. They may be schematized into four phases (Fig. 3): weathering, grabbing, transport and accumulation.

Main forcing factors of weathering, grabbing and transport process may be climate- (temperature, precipitation, wind) and/or human-triggered (land-use, including agro-pastoral activities and civil engineering, such as urbanization or dam building, for instance). They are also related to natural functioning of the ECZ, such as vegetation changes or geodynamics. As a consequence, the quantity and quality of eroded material potentially bring information about all those processes.

Documenting climate-triggered changes in erosion patterns

Streams are one of the most efficient sediment conveyors on Earth and as such, they play a key role in the erosion cycle (Aksoy and Kavvas, 2005). Reconstructing changes in river-borne sediment flux and origin from lake sediment might hence reflect the history of

Fig. 1 *Left panel*: this Sediment plume entering the Cayuga Lake, New York, United States, illustrates the huge amount of sediments that are transferred from catchment areas toward Lake basins. *Right panel*: the Arve river, loaded with glacial sediment from Mont-Blanc Massif, joins the Rhône river at the output of Lake Geneva. When it enters the lake, some 80 km upstream, the Rhône river was as much loaded as the Arve river, but Lake Geneva acted as a perfect sediment trap and only let the clear water pass through.

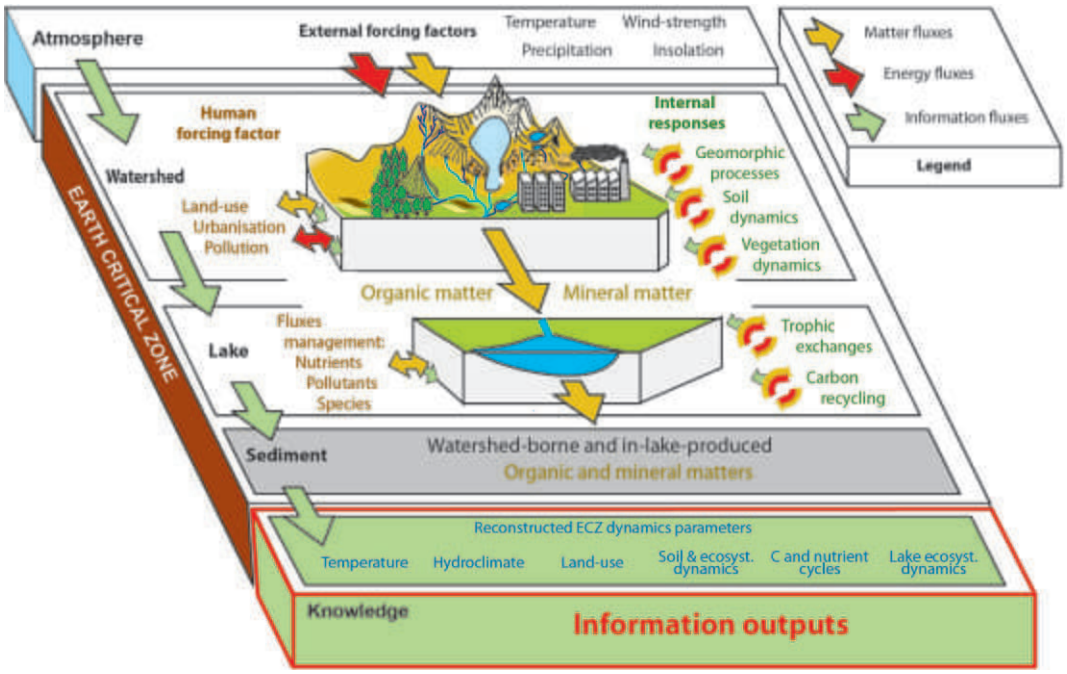

Fig. 2 Conceptual view of matter, energy and information fluxes through the Earth Critical Zone and toward a lake basin. Lake floors accumulate matter from the catchment that carries information about the ECZ dynamics. Limnogeology is the science that permits to reveal this information, hence turning mud into information.

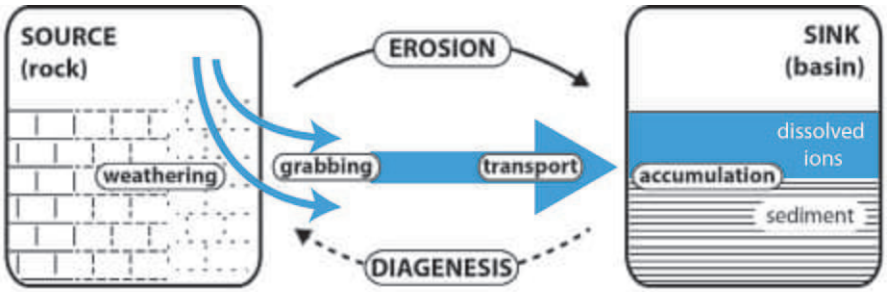

Triggering factors		Erosion processes			
		Weathering	Grabbing	Transport	Accumulation
Climate	Temperature	Hydrolysis Frost/unfrost	**Permafrost stability** **Glacier dynamics**	Snow cover cycle	Dilution (authigenic productivity)
	Precipitation	Hydrolysis	**Glacier dynamics** **Heavy rainfall**	**Hydrological flux** **Fluvial morphology**	Terrigenous input
	Wind		Wind erosion	Air-borne transport	Aeolian deposit
Land cover		**Hydrolysis**	**Soil (de)stabilisation**	Fluvial morphology	Buffering effect (riparian forest)
Geodynamics		Rejuvenation	**Earthquake-triggered destabilisation**	Hydrosystem destabilisation	Sediment reworking

Fig. 3 Schematic view of the erosion cycle (upper panel) and its processes as well as triggering factors (lower panel). Modified after Arnaud F, Poulenard J, Giguet-Covex C, Wilhelm B, Révillon S, Jenny JP, Revel M, Enters D, Bajard M, Fouinat L, Doyen E, Simonneau A, Pignol C, Chapron E, Vannière B and Sabatier P (2016) Erosion under climate and human pressures: An alpine lake sediment perspective. *Quaternary Science Reviews* **152**: 1–18. https://doi.org/10.1016/j.quascirev.2016.09.018.

the in-land hydrology (Arnaud et al., 2012, 2016). Dust mobilization and emission by wind into the atmosphere may also be important erosive mechanisms (Shao et al., 2011). Since the dust flux can contribute >10% of the global river sediment flux, dust deposition from the atmosphere plays an important role in the biogeochemistry of the ECZ (Derry and Chadwick, 2007) and can be imprinted within lake sediment (Sabatier et al., 2020).

Most methods used to record erosion fluxes from lake sediment archives lie upon the geochemical contrast of this river-borne fraction, named "allochthonous" or "terrigenous," compared to the in-lake produced matter, named "autochthonous." In this chapter, we will focus on the use of the terrigenous fraction, as a marker of the Critical Zone dynamics. For the use of the autochthonous fraction, refer to the "Paleolimnology" chapter. However, a good knowledge of the mineral autochthonous fraction is required in order to well-distinguish it from the terrigenous one. The autochthonous fraction preserved in lake sediment can be made of bio-precipitated skeletons, typically made of carbonate or silicon and/or of organic matter. In tempered hard-water lakes, the mineral autochthonous fraction is largely dominated by bio-chimio-precipitated carbonates (see chapters on "drivers and implications of lake pH" and "the lacustrine carbon cycle"). In high altitude and/or high latitude, colder conditions preclude the precipitation of calcite and the autochthonous fraction is commonly dominated by biogenic silica (mostly diatoms remains) and organic matter.

Whatever the composition of the autochthonous fraction, measuring the evolution of a marker of one the two fractions permits assessing the erosion-borne contribution to the sediment flux. The magnetic susceptibility of sediments generally increases with higher erosion-derived material contribution and is commonly used as such a marker. Inversely, one may measure chemical proxies of organic matter, such as the total organic carbon, the abundance of chlorophyll-like pigments or the bromine content, which are often negatively correlated to the erosion-triggered sediment input.

Recording airborne erosion through dust deposit

Recent advances about very high altitudes lakes systems in granitic contexts with a low to very low watershed/lake surface ratio leading to low local erosive inputs by stream allow to reconstruct past airborne dust fluxes (Fig. 4; Jiménez-Espejo et al., 2014; Sabatier et al., 2020). These lakes present very low accumulation rates, generally 1–2 m for the entire Holocene with a strong in situ organic matter component. Hence, they can be considered as rain gauge lakes where the sediment is a mixture of autochthonous organic matter and atmospheric inputs. Tracers such as clay mineralogy allows to assess the arid dust contributions (palygorskyte) and their origins (ratio Illite/Kaolinite and Chlorite/Kaolinite) (Sabatier et al., 2020; Scheuvens et al., 2013). Other techniques such as mineral geochemistry and Sr/Nd isotopic composition allow quantitative reconstructions of past dust flux and dust origin fingerprinting.

Recording glacier fluctuations

A classic example of a direct relationship between climate and erosion is given by the reconstruction of glacier fluctuations from lake sediments. The amount of glacial sediment produced by glacier erosion is indeed related to the surface of the glacier (Dahl et al., 2003; van der Bilt et al., 2016). As a consequence, reconstructing the flux of glacier-eroded material into a lake permits to reconstruct past glacier fluctuations.

In this case, the cold lake water precludes the precipitation of carbonates. The terrigenous input is hence assessed through the relative proportions of terrigenous fraction and in-lake produced organic matter. This can be done using any of the techniques exposed above, magnetic susceptibility being among the most cost- and time-efficient and thus the most used ones (van der Bilt et al., 2016). Recent development in spectrocolorimetry also brought promising results by accurately assessing the fluctuation in organic matter content (Fouinat et al., 2017).

Such an approach has been extensively used in Scandinavia where large ice-cap glaciers have tongues flowing onto ancient glacier valley (van der Bilt et al., 2016). When those valleys get dammed, often relatively low in the catchment area, the lakes hence trap efficiently the glacier-derived terrigenous flux (Fig. 5). Moreover, their moderate altitude permits the development of primary producers whose organic matter will dilute the erosion flux whereas the surrounding forested environment provides sufficient organic macroremains for dating. On the contrary, the method is sometimes hard to apply in inner mountain ranges where glacier-fed lakes are located higher in altitude and surrounded by steep slopes. Steep slopes reduce the glacier surface and short distance between the glacier and the lake may indeed lead to a hard-to-interpret non-buffered signal. Moreover, the scarcity of datable organic macroremains in high altitude lake sediments may make them hard to date. However, applying a detailed sedimentological study may in such cases permit to construct accurate glacier fluctuations chronologies (Fouinat et al., 2017).

Erosion and paleohydrology

Large rivers may bring huge amount of sediment to lake basins (Fig. 5). In such cases, the evolution of the terrigenous input may reflect changes in regional paleohydrological conditions, assuming there is a positive feedback between more humid conditions and both accentuated erosion in the lake catchment area and more efficient transport (Arnaud et al., 2016; Wessels, 1998). Hence, high resolution continuous paleohydrological reconstructions can be established, provided one may verify that hydrology is the prime forcing factor of changes in erosion flux. This is often the case in the early times of the Holocene, because the emergence of agro-pastoralism, a human-triggered perturbation of the erosion cycle, may alter the climate-erosion relationship (Arnaud et al., 2016). As early human perturbations of the erosion rarely affected large surface areas, the choice of a large and deep lake, fed by a large catchment area will hence be more favorable for climate reconstruction than a small lake, more sensitive to human disturbances. At high altitude, landscapes are losing their interest for human activities such that highest altitude lake records are directly connected to climate changes, especially if there is a glacier in their catchment area (Arnaud et al., 2016; Fig. 6). However, in

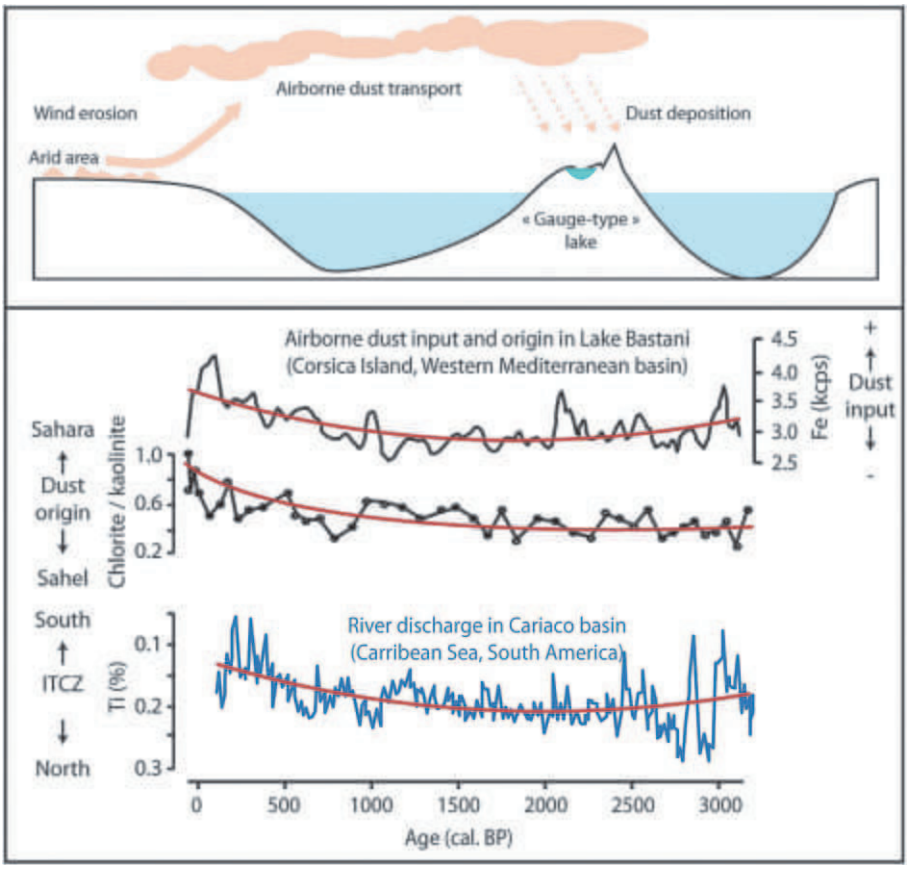

Fig. 4 (A) Schematic principle of the record of wind-driven erosion from arid area in gauge-type lake through dust deposition signal. (B) Example from Lake Bastani, Corsica (Sabatier et al., 2020), where the sediment geochemistry gave a record of dust input, while clay mineralogy gave a signal of dust origin (Sahel vs. Sahara desert). The river discharge in Cariaco Basin (Haug, 2001) illustrates how such a signal enables paleoclimatic interpretations: the increase in dust and the change in its origin reflects the independently evidenced southward migration of the Intertropical Convergence Zone (ITCZ). Modified after Sabatier P, Nicolle M, Piot C, Colin C, Debret M, Swingedouw D, Perrette Y, Bellingery M-C, Chazeau B, Develle A-L, Leblanc M, Skonieczny C, Copard Y, Reyss J-L, Malet E , Jouffroy-Bapicot I , Kelner M, Poulenard J, Didier J, Arnaud F and Vannière B (2020) Past African dust inputs in the western Mediterranean area controlled by the complex interaction between the intertropical convergence zone, the North Atlantic oscillation, and total solar irradiance. *Climate of the Past* 16: 283–298, https://doi.org/10.5194/cp-16-283-2020.

any case, it is crucial to critically assess the climatic interpretation of fluctuation in erosion fluxes. This must first be done through a deep sedimentological investigation in order to track any sign of non-climatically induced changes. In particular, any change in the composition of the terrigenous fraction must be documented and interpreted regarding the local geological setting.

One must always keep in mind that any paleo-reconstruction depends on an array of assumptions that are often impossible to be verified altogether. As a consequence, they must be interpreted very cautiously. Beyond the study of the sediment itself, it is hence crucial to confront results to independent markers, both within the same core and from independent regionally close archives. Indeed, even if precipitation may vary following more regional patterns than temperature, they are still coherent over large areas and all records based on the same assumptions should hence react together.

Geological record of flood chronicles

While they generally appear as quiet bodies of standing waters, lakes are also subject to violent sedimentation events. An abundant literature has been dedicated to the identification and documentation through time of geological deposits deriving from flood events (Gilli et al., 2013; Schillereff et al., 2014; Støren and Paasche, 2013). Potentially mobilized techniques are here very numerous, however they all lie upon the same concept of seeking for anomalous layers interbedded within the so-called "continuous sedimentation." By contrast, such layers are often called "instantaneous deposits" or "event layers" (see the chapter on "Sedimentology"). Naked eyes have been, and still are, the first tool used to identify such layers (Fig. 7). Laser grainsizers were largely used in sedimentology lab since the late 1990s'. They offered a precise description of sediment layers that was since then used to document and characterize flood layers (Arnaud et al., 2002; Wilhelm et al., 2012a). Magnetic parameters, among which

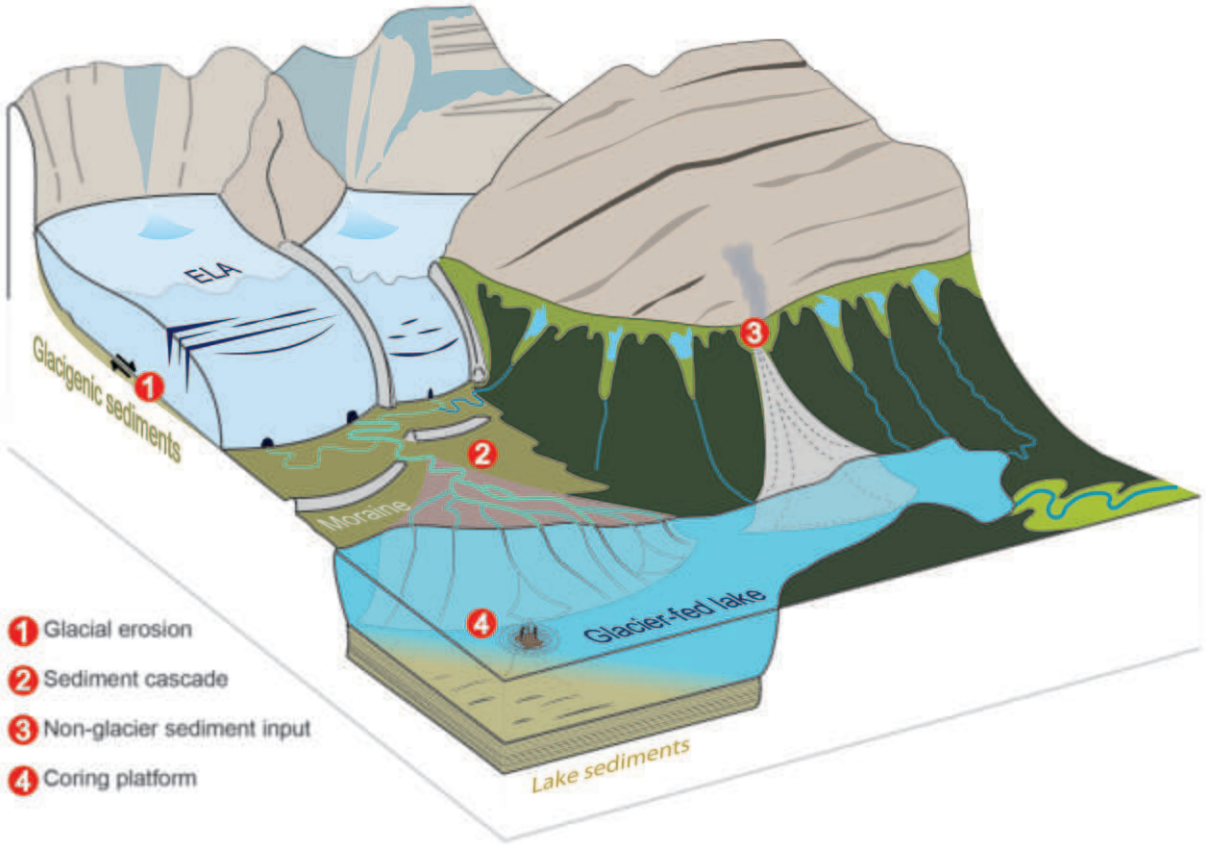

Fig. 5 Schematic view of a lake basin fed by a partially-glaciated catchment area (van der Bilt et al., 2016).

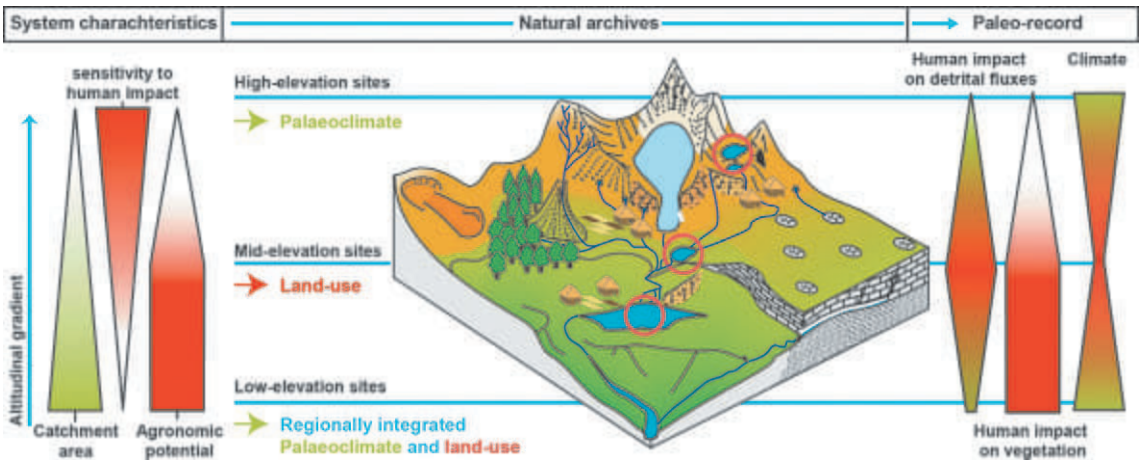

Fig. 6 Schematic representation of lake sediment sensitivity to climate and human forcing factors depending on the setting in a mountainous landscape (Arnaud et al., 2016). Arnaud F, Poulenard J, Giguet-Covex C, Wilhelm B, Révillon S, Jenny JP, Revel M, Enters D, Bajard M, Fouinat L, Doyen E, Simonneau A, Pignol C, Chapron E, Vannière B and Sabatier P (2016) Erosion under climate and human pressures: An alpine lake sediment perspective. *Quaternary Science Reviews* **152**: 1–18. https://doi.org/10.1016/j.quascirev.2016.09.018.

magnetic susceptibility is the easiest to measure, were also intensively used since the years 1980s' (Støren et al., 2016). Since years 2000s' the multiplication of XRF core scanners enabled the efficient acquisition of high resolution geochemical logs hence marking a major milestone in the development of new approaches (Wilhelm et al., 2012b). These new methods enable the detection of much thinner layers (Fig. 7) along with the measurement of their composition. It was then possible to reveal information about their source area, but also about their grainsize which reflects flood intensities (Wilhelm et al., 2012b). Even more recently, hyperspectral image of sediment cores surface was applied to the detection and characterization of unconsolidated sediment, hence opening new promising perspectives (Jacq et al., 2020).

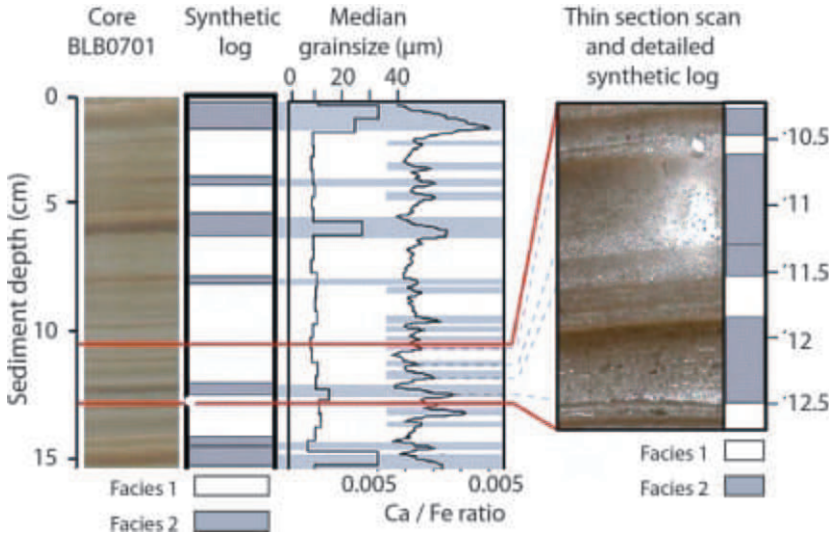

Fig. 7 Identification of flood-triggered deposits in a sediment core at various scales. From left to right: visual identification of interbedded coarser sediment layers, facies determination based on visual observation, grainsize increases (5 mm-step), XRF core scanner-based geochemical identification of coarser sediment layers that are enriched in calcium vs. iron and microscopic observation on embedded thin section showing complete flood-triggered sequences of layers: (i) basal coarsest grains, (ii) gradual upward decrease in grainsize and (iii) final "clay cap", here marked as a brown opaque layer. Modified after Wilhelm B, Arnaud F, Enters D, Allignol F, Legaz A, Magand O, Révillon S, Giguet-Covex C and Malet E (2012a) Does global warming favour the occurrence of extreme floods in European Alps? First evidences from a NW Alps proglacial lake sediment record. *Climatic Change* **113**: 563–581. https://doi.org/10.1007/s10584-011-0376-2.

Erosion processes are essential links between the occurrence of a flooding event and the transfer of this information toward the sediment accumulation. However, this link may be biased by a number of intermediate processes within the catchment area, the watershed or the lake itself. Sedimentologists thus developed a panel of techniques and concepts in order to verify the climatic relevance of hence reconstructed past floods chronicles. The two main potential misinterpretations are the false attribution of a given deposit to an actual flooding event and the false attribution of an apparent change in flood deposits recurrence rate to a change in climatic conditions.

How to relate an instantaneous deposit to a flooding event?

Attributing a given sediment layer (or sequence of layers) to a single flooding event that occurred maybe hundreds or thousands of years ago is a quite challenging task. In particular, one must remember that various processes may trigger the occurrence of instantaneous deposits. For instance, earthquakes induced deposits in lake sediment records which might be mistakenly interpreted as flood-triggered (Arnaud et al., 2002). In order to trustfully attribute an instantaneous deposit to a flooding event, it is important to study the sedimentology in detail. In particular, facies recognition is crucial as it permits to identify and characterize the different sedimentation patterns that are recurrent throughout a given sediment accumulation and thus to sort the huge amount of information stored in it. To do so, naked eyes are the primary tool, but they must be supported by quantitative information about grainsize, chemical and/or mineralogical composition and/or colorimetry. Among those parameters, the size distribution of particles is often a good indicator of the triggering mechanism.

Floods can generate turbid currents that flow on the bottom of the lake (Hsü, 1989; Lambert et al., 1984). According to the historical experiment of Hjulström (1935), in such a case, one given current velocity permits the deposition of one given particle size. This results, within a single flood-triggered deposit, in a succession of well-sorted layers of various particle sizes. Within the thickest sequences, it is possible to measure an increasing particle size from bottom to top at the base of the sequence that mirrors the increasing current velocity at the beginning of the flood event (Figs. 7 and 8). Then the deposited grainsize diminishes toward the top of the sequence as the velocity drops. In most cases, a clay cap then tops the summit of the sequence while the flood-triggered lake water turbidity settles over some days, weeks, or even months in the case of extreme floods within large and deep lakes. This whitish clayey top layer is hence often one the most convenient markers to identify a flood as a triggering mechanism. On the contrary, subaqueous slides generate matrix-supported flows which can be assimilated to subaqueous avalanches. Resulting deposits are made of a mixture of fine and coarse grains. The difference between those deposit types can be revealed by several grain-size parameters. The representation proposed by Passega in the 1960s' (Passega, 1964), i.e., a bi-plot of Q99 vs. Q50 is one them, which can be particularly useful when the event layers are thick enough to perform several grainsize measurement in them.

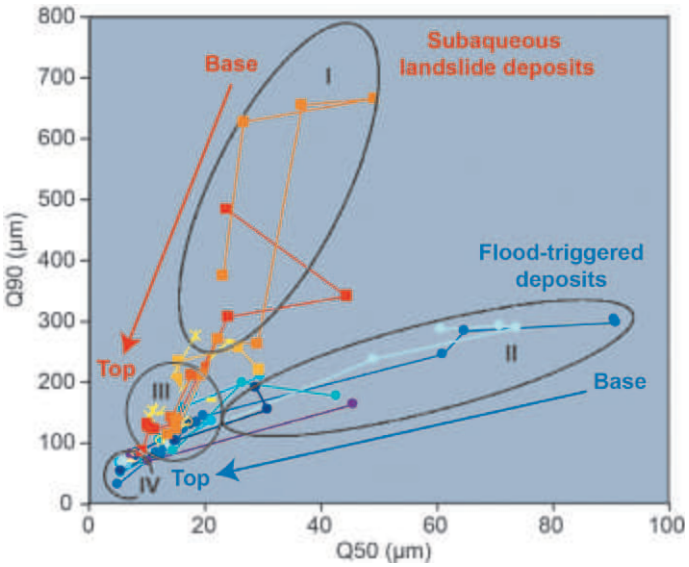

Fig. 8 Q50 vs. Q90 bi-plot, inspired from Passega (1964), from 12 subaqueous landslides deposits (in red and orange) and nine flood-triggered deposits (in blue) from Lake Anterne (Northern French Alps). Each same-color linked dots set corresponds to a single event deposit sampled every 5 mm from base to top. Note that all flood-triggered points are aligned along the same line (from sectors II, to III and IV) which is close to the 1:1 line. By comparison, samples from subaqueous landslide deposits are aligned from the high Q90 and low Q50 sector I to sector III and never reach sector IV (low Q90, low 50). See Arnaud et al. (2002) for further details.

In some cases, generally when deposits are particularly thin or, on the contrary particularly thick, sedimentological investigation are not sufficient to clearly determine the triggering mechanism of instantaneous deposits. The geometry of the deposit, at the lake basin scale, then brings essential information. Flood deposits will forcedly originate from the lake inlet and flow toward the lake bottom following the steepest slopes. On the contrary gravity reworking may originate from anywhere in the lake and will slide in mass toward the lake bottom. The geometry of a given deposit maybe determined using geophysical approaches, like reflection seismic, when it is thick enough (typically >20 cm). It may also be determined using an array of numerous cores which will have to be carefully correlated in order to determine in which of them the layer is present or not (Wilhelm et al., 2012a,b).

An increase in flood deposit frequency does not necessarily track an actual increase in flood frequency

Human land-use affected erosion processes as early as in the Neolithic period through deforestation, livestock tumbling and early cropping. Later on, deep ploughing, stream damming and soil artificialization further reinforced the human pressure on erosion fluxes. This resulted in more efficient runoff erosion, increasing both the frequency of recordable flood events and the amount of displaced sediment for a given flood intensity. In the geological record, this may result in an apparent increase in flood-layers frequency and thicknesses, independently of any climatic change. This point is still tricky for Holocene geologists which may only rely on comparison with independent markers, such as pollen, to infer the human origin of observed changes in flooding patterns. Few studies however went further by showing human-reinforced flood patterns resulted in a disruption in the grainsize-thickness relationship among flood-layers. In a human-disturbed catchment area the erodibility of soil is higher. As a consequence, a flood event of a given magnitude is able to transport more sediment, resulting in thicker deposits than it would have been without human soil disturbance (Giguet-Covex et al., 2011). However, the maximum transported grainsize is far less impacted as it depends on the river stream velocity (Hjulström, 1935) and thus on river discharge (Hsü, 1989). As a consequence, the observation of an increase in flood-layers thickness, without a marked rise in maximum grainsize is a good marker for human-triggered soil destabilization (Giguet-Covex et al., 2012).

Human disturbance of Earth Critical Zone dynamics

As stated above, human activities emerged all along the Holocene as one of the major triggering mechanisms of erosion patterns. Lake basins all around the globe witnessed this emergence which chronicle has been archived within their sediment. The effect of agro-pastoralism upon erosion was probably empirically known by the very first farmers. It was later well-known during Hellenistic period and stated for instance in Plato's dialogues *Critias* relating the dramatic loss of fertile soil due to bad land-use management. However, it has only been possible to document scientifically the history of Human-enhanced erosion in the last decades of the 20th century. Following the pioneer works by Franck Oldfield and John Dearing, notably in Papua New Guinea (Oldfield et al., 1980), lake basins appeared as particularly good candidate to record such an history. The rich information contained in lake

sediment further permits to acquire information about human land-use (pollen) as well as its effect both on land and within the lakes themselves from the same archive. Quantities of biotic and abiotic markers were then developed until recently when the development of organic geochemical markers (Dubois and Jacob, 2016) as well as lake sediment DNA (Giguet-Covex et al., 2019) was propagated, extending the range of investigation permitted by the study of lake sediment.

From erosion record to soil development history

At the difference of their geological substratum, soils are highly dynamic even at a human-life time-scale. Their current state results from a dynamic equilibrium between the weathering of underlying rocks and the erosion of the soil surface. In the absence of human forcing factors, the balance between those two processes tends to reach a steady state, hence maintaining a stable layer on which ecosystems may grow. Human activities might break this balance by soil surface destabilization. Studying past erosion fluxes permits to reconstruct the evolution of soils and downstream to identify periods of human-triggered soil disturbances. This can be done not only by recording the total amount of eroded material, but also by identifying its provenance source in the lake catchment area, as well as its weathering degree.

When the geology of the catchment area is diverse enough, the provenance source may be tracked using mineral geochemistry, or mineralogy. Isotopic indicators of rock ages are here particularly efficient. In several cases, major elements also proved to be quite good markers of provenance, however, they are also strongly affected by weathering processes and may hence not be used alone to track the sediment provenance.

Chemical weathering is the dominant process of soil formation. It results in the selective removal of the most mobile elements (e.g., potassium). More developed soils? Are hence depleted in such elements, when compared the bedrock from which they were formed. This degree of depletion can be assessed using a ratio of mobile over immobile (e.g., aluminium or titanium) elements. When applied to terrigenous lake sediment this may be used to track the degree of evolution of the soils that were eroded at a given time (Arnaud et al., 2012). This permitted to show that human soil disturbance results in apparent rejuvenation of soils evidenced by a relative enrichment in mobile elements in eroded material. Some isotopic markers, such are lithium, bore or uranium (Rothacker et al., 2018) are currently under development to track the weathering degree of eroded soils (Fig. 9).

Soils are basically made of organo-mineral complexes. Soil evolution is thus strongly linked to the evolution of organic matter. Just as for the mineral fraction, the study of the organic compounds of eroded material trapped in lake sediment brings a lot of information about soil evolution. Rather simple techniques, such the microscopic identification of organic matter types, may be completed by more sophisticated ones. Element concentration of carbon, hydrogen and oxygen in variously refractory and oxidizable organic matter fractions is extensively used in petroleum geology. It applies also perfectly to characterize the degree of maturity of organic matter in soils and downstream in lake sediment. Hence it has been shown that a human-triggered erosion event following a deforestation starts with a flux of fresh organic matter from the litter and while the erosion is eroding deeper and deeper horizons, the organic matter signal tends to be dominated by more and more refractory fractions. Inversely when human pressure weakens, or at least a new equilibrium is reached, the refractory organic matter is retained in the soil and the eroded organic matter then originates from soils of upper and fresher horizons. Using molecular organic geochemistry opens possibilities for even more detailed investigation of past soil dynamics. For instance, branched glycerol dialkyl glycerol tetraethers (brGDGTs) have recently been proved to be markers of soil pH, which is a key parameters of soil evolution, particularly in regard with organic matter dissolution and fluxes.

Tracking land-use changes

Because they are highly integrative archives, lake sediments bear information about catchment reactions but also about what caused these reactions. Pollen are of course the main and most anciently used marker of vegetation dynamics that may be acquired from lake sediment. They have long been the only way to get valuable information about human land-use, through the filter of vegetation changes. However, pollen fly in the air and are thus not strictly representative of a given catchment area. Over the last decade, a number of studies proved lake sediment DNA (sedDNA) to be a valuable complementary information source about vegetation changes (Capo et al., 2021). Sediment DNA data are not yet quantitative, but they differ from pollen information by a different taxonomic resolution and a drastically different taphonomic behavior. Indeed, taxonomic resolution of DNA results highly depends on DNA sequence libraries that are still under development. In the case of graminae and in general, non-tree species, sedDNA taxonomic resolution may be more precise than what is allowed by pollen. It has recently been understood that catchment-derived sedDNA is strongly linked to erosion processes. Indeed, most of terrestrial DNA arriving into lake sediment has been freshly eroded from soil where it was stored under the form of organo-mineral complexes, hence protected from bacterial degradation. As a consequence, terrestrial SedDNA signal tracks the dynamic of the lake catchment area only. This also implies that a certain amount of catchment erosion is necessary to properly transfer the environmental signal that is transported by SedDNA toward the lake bottom (Giguet-Covex et al., 2019).

One of the greatest advances that was made possible by SedDNA is to provide taxonom<–specific information about livestock (Giguet-Covex et al., 2014). The identification, alongside pollen, of coprophilous fungi had permitted to complete the vegetation data with an assessment of the livestock pressure upon a lake catchment area. However, this did not allow to identify which mammal species generated the feces that permitted the development of fungi (Etienne et al., 2012). With SedDNA this information is completed at a higher taxonomic level, permitting to attest the former presence of livestock as well as the relative composition of herds. Hence in a near future it will probably be possible to analyze the long-term effects of livestock farming upon the environment with a detail that had never been reached before.

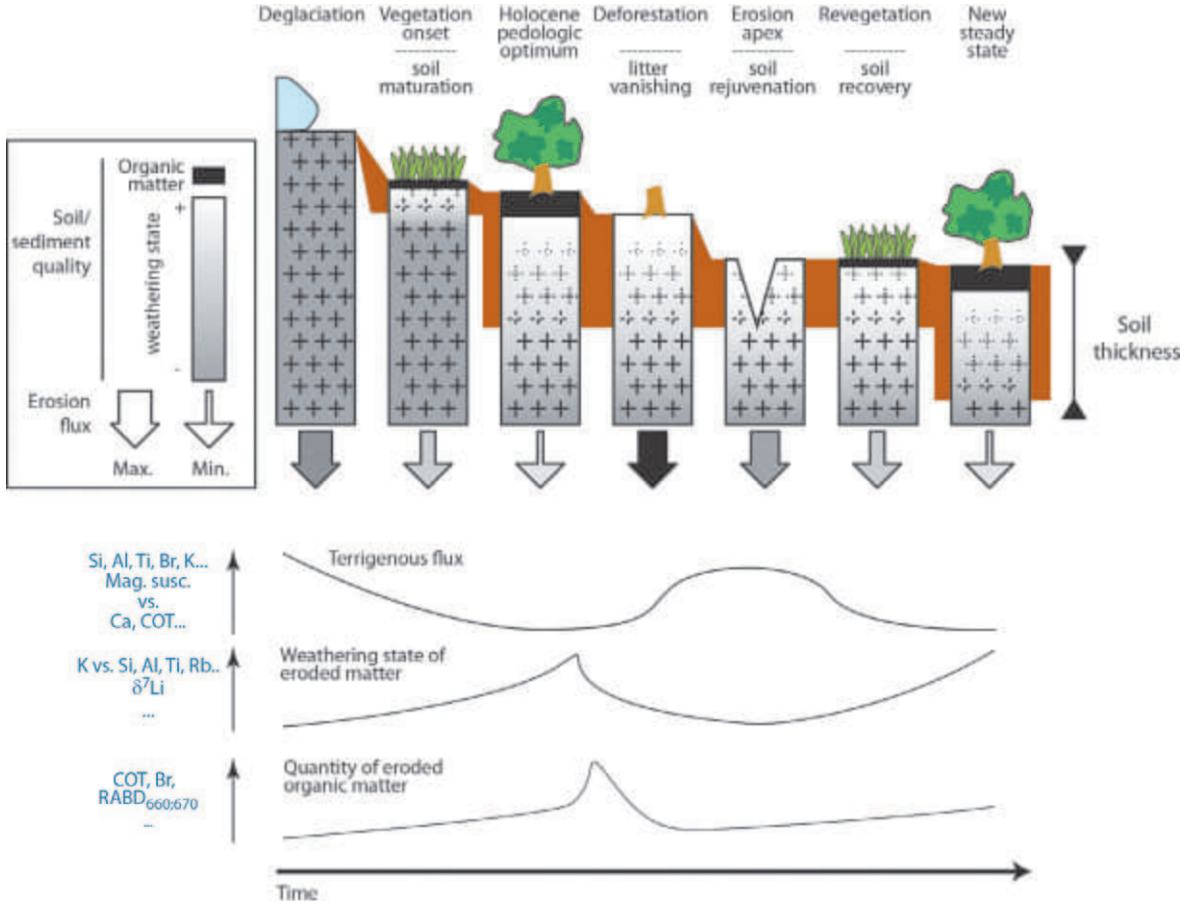

Fig. 9 Schematic representation of soil evolution following the last deglaciation (upper panel) and the corresponding theoretical record in lake sediment (curves in lower panel). Shades of grey and crosses materialize the weathering state, from bedrock (darker grey with solid crosses) to the most weathered terms (lighter grey with dotted crosses); black color represents the soil litter rich in organic matter. The soil itself is the layer overlying the non-weathered bedrock. Its thickness varies through time, as it is underlined by the brown surface. Arrows materialize the output of material due to erosion: their thickness represent the flux, whereas their color illustrates the nature of eroded material, as for soil state: shades of grey represent the degree of weathering and black represents the litter. Without human action, soil thickness tends to increase through time whereas the uppermost layer is more and more depleted in mobile elements and enriched in organic matter. Human-induced deforestation results in increasing erosion. First the litter is removed, inducing a peak organic matter transfer to the lake. If the process continues, the erosion reaches less and less depleted soil horizons, hence eliminating thousand years of soil formation within only some decades. Inspired from Bajard M, Poulenard J, Sabatier P, Develle A-L, Giguet-Covex C, Jacob J, Crouzet C, David F, Pignol C and Arnaud F (2017) Progressive and regressive soil evolution phases in the Anthropocene. *Catena* 150, 39–52. https://doi.org/10.1016/j.catena.2016.11.001.

Direct and indirect pollutions

Among human-triggered threats upon ECZ, the dispersion of extracted or man-made substances is particularly damaging for ecosystems' and downstream, humans' health. As local sediment sinks, lakes have the capacity to record the history of dispersion of those substances.

Metals were dispersed throughout the Earth environment as early as metallurgy was invented. Numerous reconstructions of metal contamination chronicles have been published over the last decades, providing a comprehensive scheme of world history of human-triggered metal dispersion. In lake sediment, the attribution of a metal peak to human activities is made difficult by the presence of the sediment matrix which can be metal-rich on its own. It is then necessary to assess the contribution of human-spread vs. naturally-present metals (see Dunnington et al., 2020 for a methodological review). The isotopic composition of some metals can be helpful to identify the origin of contamination. Lead is particularly interesting and has been extensively for such a purpose, as it is the most stable element of several radioactive decay chains. However, case studies using zinc, mercury, copper and silver, just to cite some, can be found in the literature. In case, studying both the temporal evolution of metal contamination and its potential sources permitted to better identify the causes of contamination, which is the primary stage for reducing human impact upon the environment.

Over the 20th century the chemical industry produced thousands of artificial compounds used for manufacturing processes or helping agriculture to face natural plagues. Most of them happened to be persistent in the environment, causing various threats upon ecosystems health. Those chemical species are often referred as persistent organic pollutants (POPs). They include among

others all kind of pesticides, fire delayers, solvents, fossil fuels etc. Reconstructing the concentration of those POPs in lake sediment series permits to better understand their contamination histories and pathways. It was hence possible to show that Polychlorinated biphenyl (PCBs), a fire delayer used in electric transformers until its production was progressively banned between 1978 (in the United States) and 2001 (worldwide) may move from a surface area, such as a lake or soil, toward another ECZ compartment by a succession of evaporations under warm conditions and condensations under cold conditions (Naffrechoux et al., 2015). Lake sediment-based POPs contamination history may also evidence combined effect of pollutants. It has hence been shown that the use of a powerful herbicide, the glyphosate since 1990s, was responsible in vineyards of a drastic rise in soil erosion (due to the destruction of herbs-associated rhizosphere that is an agent of soil stabilization) which downstream led to the remobilization of insecticide, such as DDT that had been applied for decades and then banned since 1973 but stored in agricultural soils (Sabatier et al., 2014). This last example shows the ECZ is a complex reactive layer in which all process may interfere together, leading to strong and potentially harmful retroactions (Fig. 10).

Even the mountains can be shaken: recording how inner-Earth dynamics affects the ECZ over human time-scale

The Earth Critical Zone is also the interface between inner and outer Earth dynamics. As such it may be affected by geodynamics, even at a human life time-scale when paroxysmal events, such as volcanic eruptions and earthquakes, occur. The strongest of those events may be particularly threatening for life beings and especially for human societies. Because they are rare at human time-scale, it is necessary to document them beyond the historical period in order to assess their returning period in a given place. In this aim, only geological records can be mobilized. Among them, lake sediment may record volcanic eruptions and earthquakes through three mechanisms: (i) atmospheric fall-out, (ii) in-lake reworking processes, (iii) indirect post-event terrigenous fluxes.

Atmospheric fall-out of volcanic products

This way of recording is quite obvious and generally simple to apply. In most cases volcanic deposits are clearly different from the continuous lake sedimentation and may be identified by visual observation or any mineralogical (including magnetics) or mineral geochemistry approaches. However, the documentation of past volcanic events can be disturbed by post-depositional reworking of the volcanic deposits. Such a reworking may occur within the lake itself, under the form of subaqueous slides, or within the catchment area where volcanic products may accumulate during the eruption and be more or less abruptly released in the following

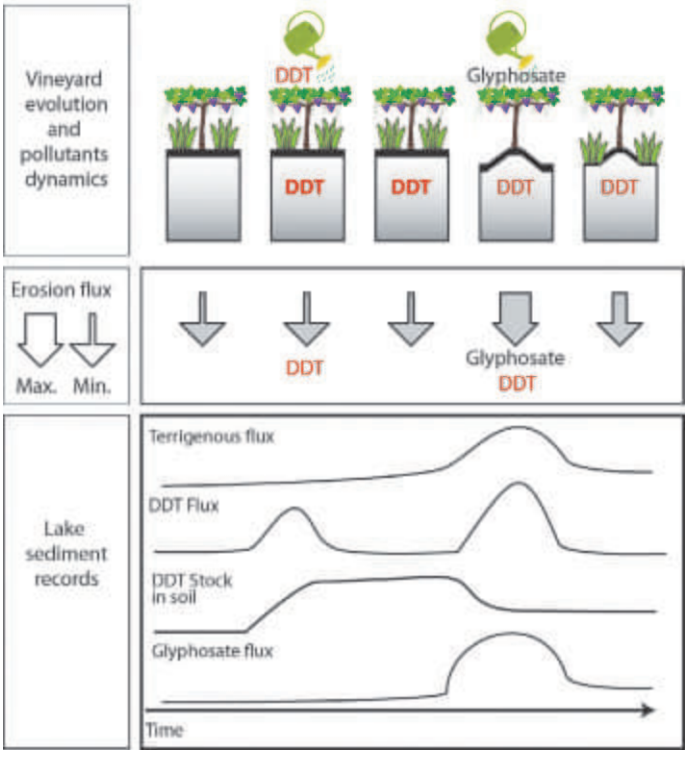

Fig. 10 Schematic representation of DDT spreading, incorporation in soil and Glyphosate-triggered released from a Vineyard (upper panel), the resultant impact in terms of erosion and pollutant fluxes (middle panel) and the corresponding theoretical record in sediment (lower panel). Inspired from Sabatier P, Poulenard J, Fanget B, Reyss JL, Develle AL, Wilhelm B, Ployon E, Pignol C, Naffrechoux E, Dorioz JM, Montuelle B and Arnaud F (2014) Long-term relationships among pesticide applications, mobility, and soil erosion in a vineyard watershed. *Proceedings of the National Academy of Sciences of the United States of America.* https://doi.org/10.1073/pnas.1411512111.

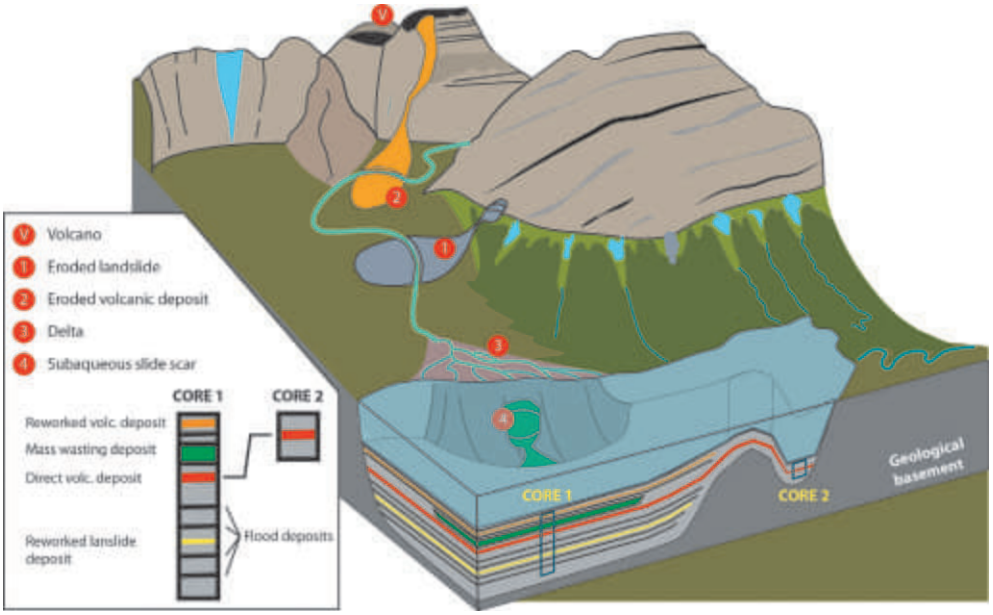

Fig. 11 Schematic representation of a lake sediment basin connected to a volcanic catchment-area submitted to regular earthquakes.

day to years through erosional processes. A detailed sedimentological study of the whole lake basin is then required in order to demonstrate that the volcanic-triggered layers came purely from the atmosphere and were thus strictly contemporaneous of an eruption (Fig. 11).

Earthquake-triggered in-lake reworking processes

Earthquake-triggered mass-wasting deposits are very common in lakes, making them natural seismographs (Strasser et al., 2013). They are favored by a high terrigenous sedimentation flux and the presence of a delta at the tributary inlet. Indeed, higher sedimentation rates result in less stable delta slopes, hence favoring the triggering of subaqueous slides (Wilhelm et al., 2016). Several triggering mechanisms may be invoked for those slides, but earthquakes are the more common ones. The main difficulty here is to distinguish those mass wasting deposits from flood triggered deposits. There is no universal recipe to do such and a detailed sedimentological study is here also required. The texture of the deposit is a meaningful information as mass wasting deposits are less well-sorted than flood deposits (Arnaud et al., 2002). The Earthquake may also trigger internal lake motions that can be large enough to resuspend sediment at the whole basin scale and ultimately lead to a typical homogenous sediment deposition layer called "homogenite" (Chapron et al., 1999). When deposits are thick enough, the geophysical imagery of the lake sediment pile brings usually precious information about the deposits shape and downstream, about their triggering mechanisms (van Rensbergen et al., 1999).

Indirect post-event terrigenous fluxes

When a powerful earthquake hit a mountainous region, it often generates massive landslides (Keefer, 2002). Those landslides result in river dams that are more or less abruptly eroded (Wang et al., 2015). When such a dam breaks, the resulting outburst may be recorded in lakes under the form of a specific layer due the sudden arrival of terrigenous sediment (Zhang et al., 2019). It may also occur that the excess in eroded material in the river course gets eroded slowly, hence increasing the sedimentation rate over several years.

One must finally notice that any combination of processes may occur (Zhang et al., 2019). For instance, an earthquake may generate a rock slide, triggering a snow avalanche, itself triggering a destabilization of a lake delta as well as a tsunami-like wave that will erode the shores of the lake, far from the delta. The sedimentologist studying lake basin must be aware of those potential mechanisms. It is necessary to propose falsifiable hypothesis in order to lead the required measurement which will finally lead to a careful interpretation of the lake basin sedimentological behavior.

Conclusion/synthesis

We aimed in this chapter at providing a non-exhaustive, but yet large overview of the strong potential of lake sediment studies when it comes to reveal the history of in-land social-ecological systems and interactions within the ECZ. Lake sediment may indeed be seen as the Swiss knife of natural archives as they are submitted to a quasi-infinite number of forcing factors, acting both outside and

within the lake itself. This diversity of forcing factors has long been seen as a weakness because of the complexity of the resulting archives. However, no other natural archive has seen more developments of new investigation techniques than lakes over the last decades. Scientists interested in the evolution of any aspect, biotic or biotic, natural and human-triggered, over recent or pluri-millenial periods, etc. of the ECZ may hence rely on a vast scientific literature and an extended methodological toolbox in order to find in lake sediments the stored information they are looking for.

Remaining challenges

- Modelling the processes from catchment area to sediment deposition.
- Developing spatial approaches based on multiple cores.
- Developing an integrated approach of main triggering mechanisms that affect the critical zone dynamics (climate, humans, geodynamics, ecological responses).

Saline Lakes

Michael Schagerl, Department of Functional and Evolutionary Ecology, University of Vienna, Vienna, Austria

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Athallassic Not related to the sea, no connection to the sea during recent geological times.
Brine Highly concentrated saline solution.
Chemocline Interface that separates the upper water layer of standing water bodies from a deeper layer containing higher concentrations of dissolved solids.
Endorheic basin (internal drainage basin) Landlocked with no outflow.
Halocline A subtype of chemocline caused by a strong, vertical salinity gradient.
Heliothermy Heating from direct solar radiation.
Meromictic lake The water body does not fully mix during overturn.
Mixolimnion Upper water layer of meromictic lakes, which circulates during overturn.
Monimolimnion Deep water layer of meromictic lakes not involved in circulation during overturn.
Open lake (also called flow-through or exorheic lake) The lake drains into another water body; the water ultimately flows into the sea.
Polymictic lake The water body mixes frequently during the year.
Pycnocline Interface where the density gradient is greatest.
Saline lake Athallassic water body with salinity >3‰.
Salinity Amount of salt dissolved in water.
Terminal lake (also called closed or endorheic lake) Waters do not drain into the ocean and are mainly reduced by evaporation.

Introduction: What are saline lakes

Lakes are large standing water bodies occupying continental basins. Most lakes are of tectonic origin, amongst these also the largest saline lake of the world, the Caspian Sea. Based on Hammer's (1986) categorization, saline lakes have a salinity ≥3‰, reaching up to 350‰ in saturated brines (the salinity of seawater is around 35‰). Freshwater lakes show a salinity <0.5‰. The range between 0.5 and 3.0‰, referred to as subsaline, is a transitional zone in which both freshwater organisms and halophiles can co-exist (Fig. 1).

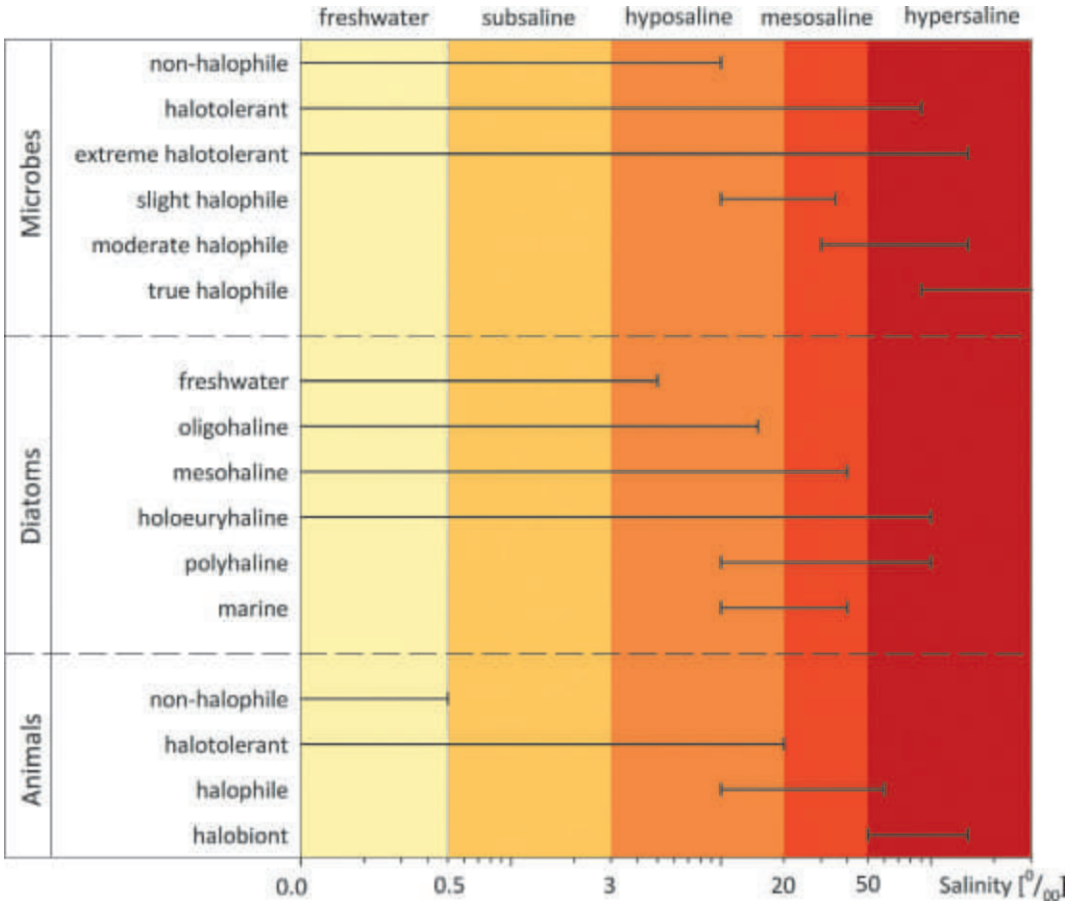

Fig. 1 Hammer's (1986) categorization of saline lakes versus classification of organisms inhabiting saline lakes. Microbes—combined data (Oren, 2006; Mesbah and Wiegel, 2011; Banciu and Sorokin, 2013); diatoms (Carpelan, 1978); Animals (Williams, 1978). Conversion factor 1 M NaCl to salinity = 58.5‰.

In contrast to thalassic water bodies such as lagoons, which are connected to the sea, athallassic lakes are located in hydrologically closed basins. Many saline lakes are permanent, but some are also ephemeral water bodies termed playa lakes or salt pans (Renaut and Gierlowski-Kordesch, 2010).

How is salt content measured?

Today, the salt content of the oceans is provided in "practical salinity units" (PSU). PSU measurements are based on conductivity, which is an unspecific measure of the total ion content of solutions. The principle behind the measurement is a drop in voltage caused by the resistance of the water (conductivity = resistance^{-1}). Because conductivity is affected by temperature, it is reported as specific conductivity at 25 °C. The conductivity unit μS cm^{-1} is mainly used in waters with low ion content, whereas salinity is a common measure for saline waters. Salinity is a unitless parameter because it was originally defined as a measure of the mass of dissolved salts in a given mass of solution. In limnology, salinity is usually reported in ‰ or parts per thousand (ppt), I therefore have retained ‰ for better readability. Early measurements until the 19th century were performed gravimetrically, but this method has several disadvantages including additional dissolved substances other than salt and the loss of volatile compounds. Today, conductivity meters are the standard instruments because they are easy to handle, robust and sensitive. Another unit in use is total dissolved solids (TDS), which is expressed as milligrams dissolved solids (particle size <2 μm) per liter water. TDS is sometimes also reported as parts per million (ppm). A rule of thumb for converting the parameters is salinity [‰] = 0.7 × conductivity [mS cm^{-1}], and TDS [ppm] = salinity [‰] × 1000.

Genesis and geochemistry

The genesis and persistence of salt lakes depend on following conditions: (1) endorheic basins lacking significant water loss by (sub)surface discharge; (2) balance of inflow (with only low precipitation) and evaporation (with only low seepage) is maintained

over longer periods; (3) an inflow sufficient to sustain the lake. Favorable regions for the formation of saline lakes are arid basins in the rain shadow of high mountains acting as a precipitation trap. As water loss is restricted to evaporation, solutes are retained in these lakes, which become increasingly saline over time. Because a significant outflow is lacking, such water bodies are also termed closed lakes or terminal lakes. In contrast, open lakes are located in open drainage basins with a balanced in- and outflow, which also results in a low concentration of solutes.

Salt lakes not only cover a wide salinity range (Fig. 2), but also show a high variability in brine composition. Generally, three main categories are recognized, namely carbonate (HCO^3/CO_3^{2-}), sulfate (SO_4^{2-}) and chloride (Cl^-) brines (Fig. 2), but in many cases a combination exists. Eugster and Hardie (1978) defined eight major brines types, which reflect both the type of bedrock and the chemical reactions of brines.

The geochemistry of a saline lake is defined by an allogenic and an autogenic step. The first step is chemical weathering of bedrock and soil. Meteoric water becomes enriched in solutes, which are defined by the lithology of the catchment area. The second step is autogenic and caused mainly by evaporation at the lake surface, followed by mineral precipitation (sediments are termed evaporites) due to oversaturation of solutes. The remaining solutes characterize the chemical conditions of the saline lake. This so-called brine evolution was first described in a flow chart by Eugster and Hardie (1978) and later revised by Deocampo and Jones (2014) (Fig. 3). The principle behind brine evolution is the different solubility of evaporites. Evaporites with low solubility such as calcite or gypsum precipitate first. This makes brines with an elevated Ca^{2+} content an exception. Other evaporites such as trona ($Na_3(HCO_3)(CO_3)\cdot 2H_2O$) or halite (NaCl) show very high solubility products. Accordingly, most saline lakes with an elevated salinity have only Na^+ as the dominant cation (Fig. 4; in few cases Mg^{2+} also plays a significant role). Regarding the anion composition, saline lakes are quite diverse.

The pH depends on the brine composition and is mostly neutral to slightly basic (mainly SO_4^{2-} and Cl^- solutes). Some lakes are however highly acidic with pH < 3 (usually a mixture of SO_4^{2-}/Cl^- with very low buffer capacity (e.g., lakes of SW-Australia) (Mernagh et al., 2016), others quite alkaline with pH > 9.5. The elevated pH is usually combined with a very high buffer capacity due to a combination of Na^+ and HCO^3/CO_3^{2-}. Such lakes are called soda (or alkaline-saline) lakes.

Physical properties

Terminal lakes are prone to water level changes (Fig. 5; Odada et al., 2006), which are often linked to large variations in lake area especially in plain basins (Fig. 6). Lake morphology, latitude, altitude, and wind exposition are key parameters for defining the mixing regime. Moreover, optical properties also influence the mixing pattern, with low transparency increasing the stability of thermal stratification. The mixing regime can also change because of climate change. Woolway and Merchant (2019) assume less frequent mixing in the future in response to global warming, but this holds true only for open lakes. In contrast, terminal lakes will respond individually depending on the local climate.

Mixing patterns

All mixing types are present, with polymixis and meromixis being frequently observed (Fig. 7).

Polymixis is quite common, because many lakes are shallow and wind-exposed. A prime example is Lake Nakuru (Kenya), where thermal stratification develops during daytime, followed by full circulation at night due to wind-induced mixing and convection

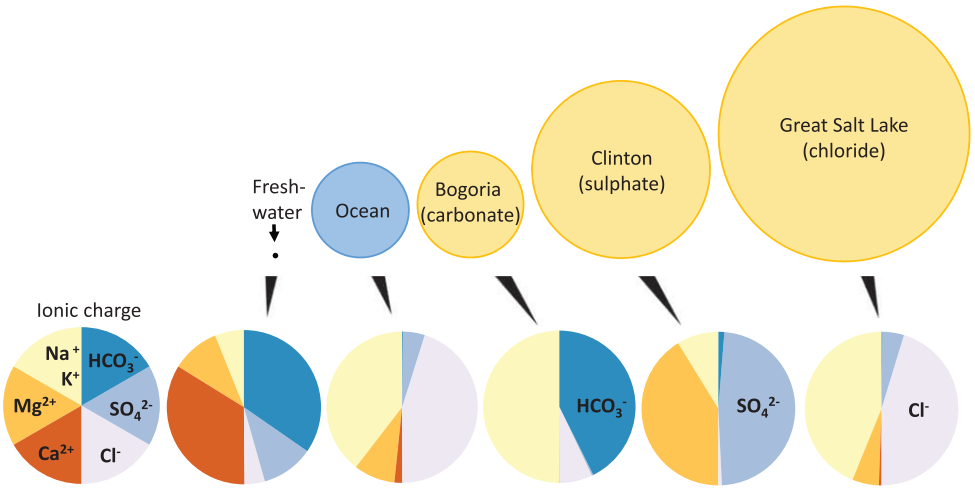

Fig. 2 Salinity ranges of freshwater, oceans and saline lakes classified according to their chemical composition. The circle areas correspond to salinity levels on a relative basis and to ion composition (meq L^{-1}).

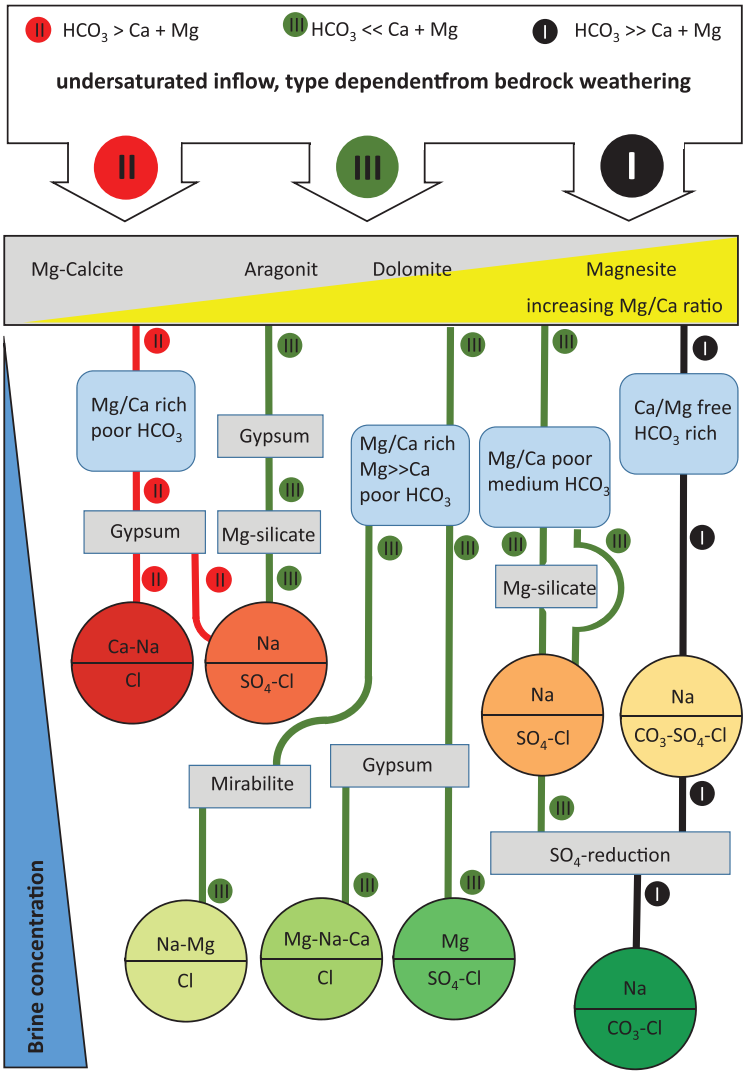

Fig. 3 Brine evolution diagram. From the lithology of the catchment area and weathering of the bedrock, three types of inflow chemistry can be distinguished, which map the general route for brine composition. Water evaporation is followed by evaporites precipitation due to oversaturation of solutes. The remaining solutes characterize the brine composition of the lake. Modified from Eugster, HP and Hardie LA (1978). Saline Lakes. In Lerman A (ed.) *Lakes: Chemistry, Geology, Physics*, pp. 237–293. New York, NY: Springer New York. 10.1007/978-1-4757-1152-3_8, and Renaut RW and Gierlowski-Kordesch EH (2010). *Lakes*. In James NP and Dalrymple RW (eds.) *Facies Models*. pp. 541–575. Geological Association of Canada.

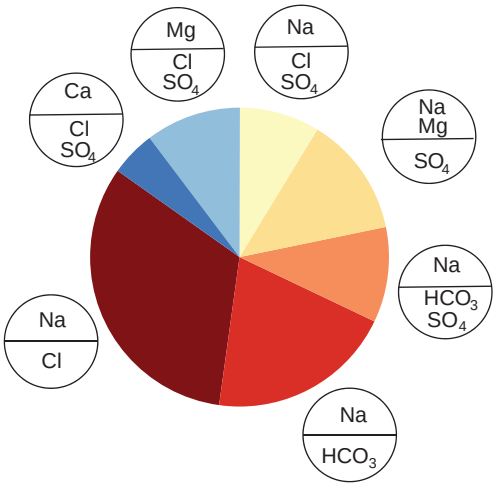

Fig. 4 Saline lakes of the world show a high variability in brine composition. Ions are considered as major ions, if they contribute more than 30% based on mmol L^{-1} (unpublished data combined with Hammer, 1986, $n = 184$).

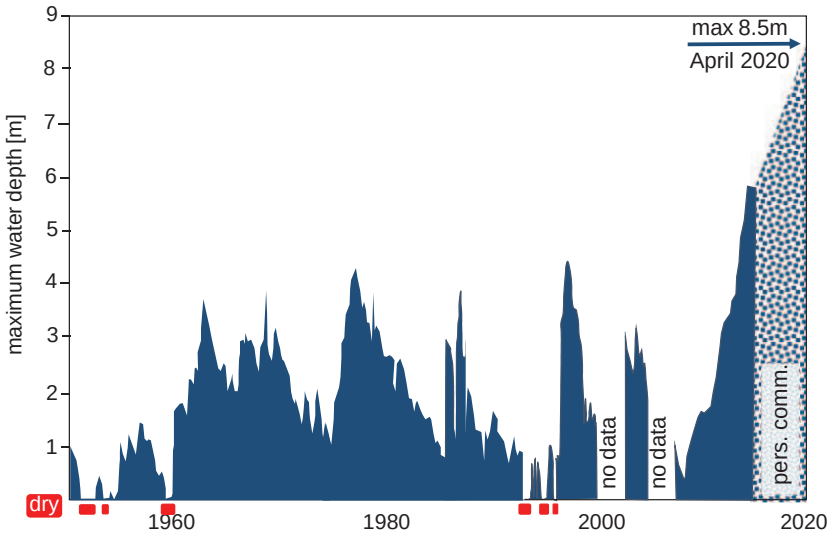

Fig. 5 Variability of water levels of Lake Nakuru (Kenya). Red bars indicate times of desiccation. Data from Odada EO, Raini J and Nedetei R (2006) *Lake Nakuru [Online]*. LakeNet—World Lake Basin Management Initiative. Available: http://www.worldlakes.org/uploads/18_Lake_Nakuru_27February2006.pdf (Accessed 30th September2015); Vareschi E (1987) *Saline Lake Ecosystems*. In Schulze E-D and Zwölfer H (eds.) *Potentials and Limitations of Ecosystem Analysis*, pp. 347–364. Berlin Heidelberg: Springer. 10.1007/978-3-642-71630-0_17, and own observations.

from surface cooling (MacIntyre and Melack, 1995). Such a diurnal pattern causes oxygen depletion in near-bottom zones, especially in hypertrophic systems with high respiration, which in turn facilitates phosphorus release from the sediments.

Meromixis is due to big differences in density of the mixolimnion and the monimolimnion (Fig. 7). The chemocline of saline systems is also referred to as a pycnocline or halocline. In many cases, the chemocline shows increased turbidity because particles are caught in this density gradient. The monimolimnion is separated over long periods from the atmosphere, making it anoxic and a sink for dissolved matter in its reduced form; it becomes further enriched with solutes and gases such as methane. Meromixis can be traced back to ectogenic (outside the system) and endogenic processes (within the system). With regard to salinity gradients, ectogenic meromixis is caused either by surface or subsurface inflow of freshwater into saline lakes or by saltwater inflow into freshwater lakes. Endogenic meromixis is induced by salt exclusion during surface ice formation. The salinity gradients between the monimolimnion and mixolimnion can be considerable. In Lake Bonney (Antarctica) for instance, the surface layer is of freshwater while near-bottom zones have a salinity >100‰ (Torii, 1975). The Vestfold Hills is an ice-free area in Antarctica with many meromictic lakes. All these lakes show increased temperatures with depth due to heliothermy (Fig. 7), but the vertical density gradient is maintained by the strong vertical salinity gradients, leading to permanent stratification lasting up to decades (Gibson, 1999). The lakes are covered with ice for 8–11 months, with ice thickness being inversely related to salinity at the surface layer. The monimolimnion of permanently ice-covered Lake Vanda (Antarctica) is the remnant of a former saline lake. The freshwater layer (with regular mixing) reaches down to around 55 m. A deep-layer chlorophyll maximum is located at the depth of the chemocline. Below the chemocline, salinity increases to >120‰, which stabilizes the water body despite an inverted temperature gradient between 0 °C at the surface and >20 °C in near-bottom zones (Fig. 7) (Schutte et al., 2020). Large saline lakes such as the Caspian Sea (Western Asia) and Lake Van (Turkey) are also meromictic; their stability of the water column is highly influenced by water level and the strength of the winter.

The mixing regime may change within short periods, e.g., due to human impact. One example is the Great Salt Lake (GSL), which was well mixed until the late 1950s, when the lake was subdivided into two basins by a railway causeway construction. Since this separation, only the southern basin is fed by freshwater inflows, which led to a steep increase in salinity from South toward North (Baxter and Zalar, 2019; Null and Wurtsbaugh, 2020). The northern arm is now fed via surface water from the southern arm (salinity about 80–170‰), whereby the solute further concentrates to saturation (270‰). The saturated brine sinks down to near-bottom zone, where it flows back to the deep layer of the southern arm, which ultimately created a meromictic water body. The Dead Sea is an example for a reverse shift from mero- to holomictic conditions. Before 1979, the lake was meromictic with a dense monimolimnion and a more diluted mixolimnion due to regular freshwater recharge. Today, because of reduced inflow (the lake level falls by about 1 m $year^{-1}$), the lake is warm monomictic with active halite precipitation of about 0.1 m $year^{-1}$ (Lensky et al., 2005).

Optical properties

Turbidity of saline waters is often increased compared to their freshwater counterparts because of particle resuspension, and due to extremely high numbers of microorganisms. Increased turbidity may also reflect the precipitation of oversaturated brines. Lake Van

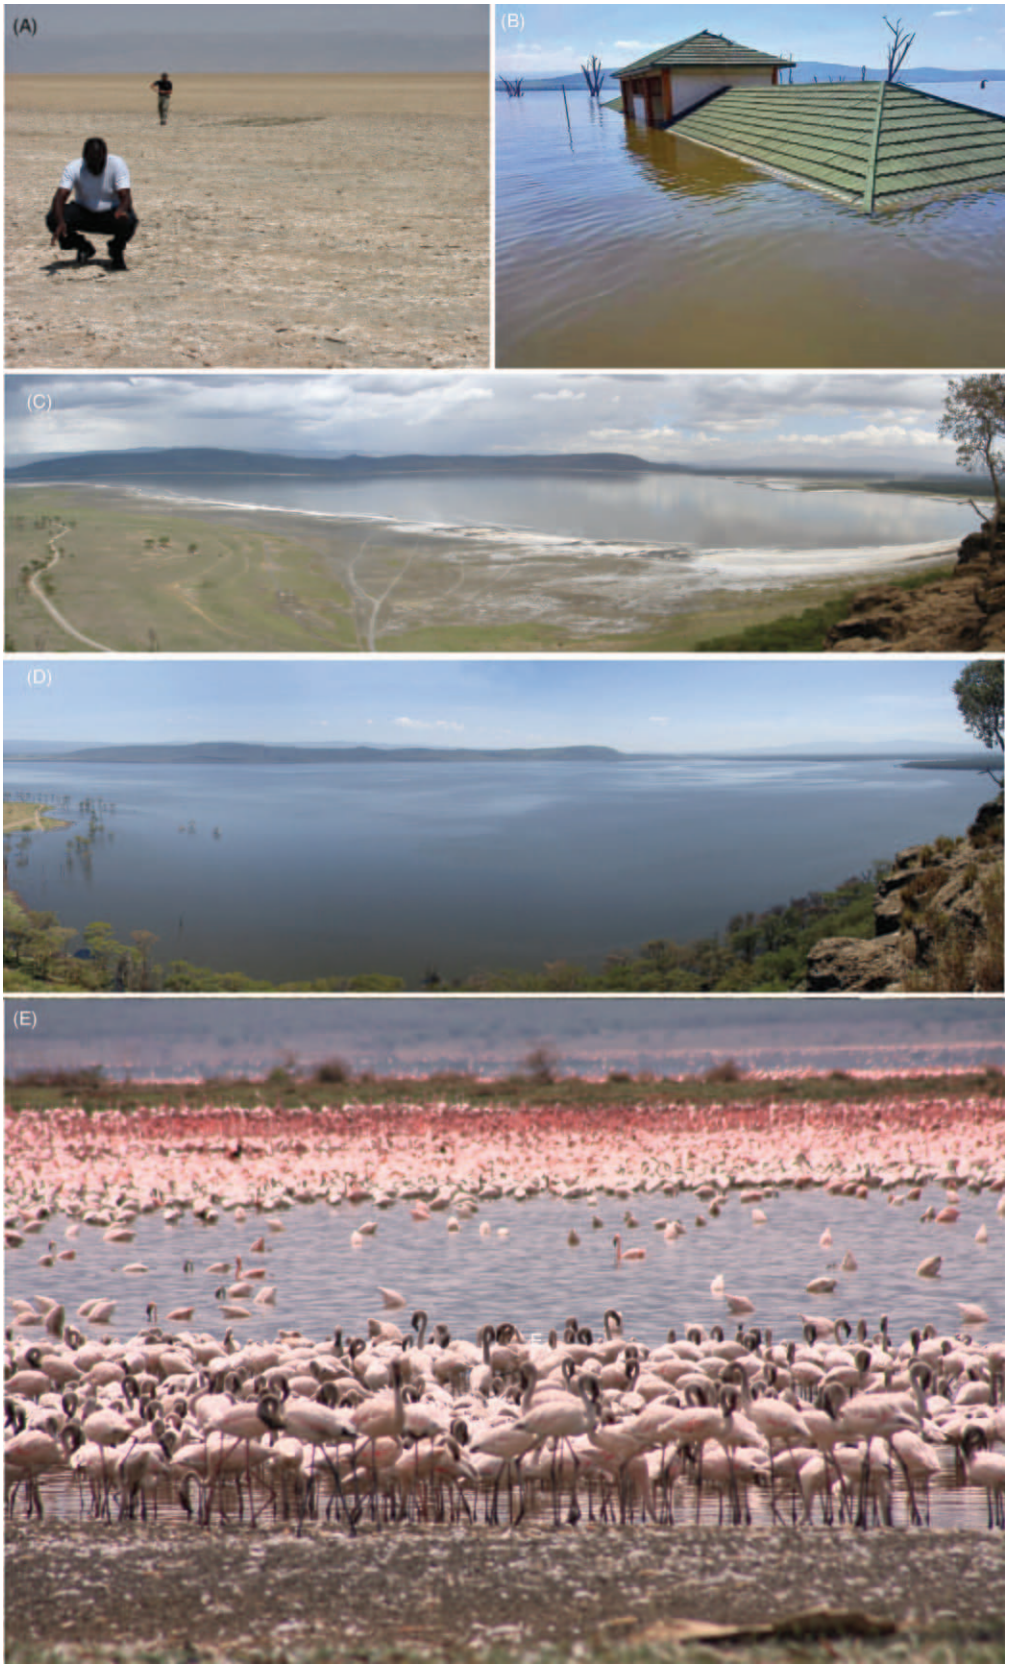

Fig. 6 Impression of alkaline saline lakes. (A) dried ephemeral Lake Eyasi (Tanzania; 2010). (B) Increased lake levels of Nakuru flooding buildings at the entrance of the Nakuru National Park in 2020 (Kenya, photo S. Oduor). (C) Amplifier Lake Nakuru in 2009 and (D) in 2013 from exactly the same viewpoint. (E) Huge flocks of flamingos at Lake Bogoria 2013 (Kenya).

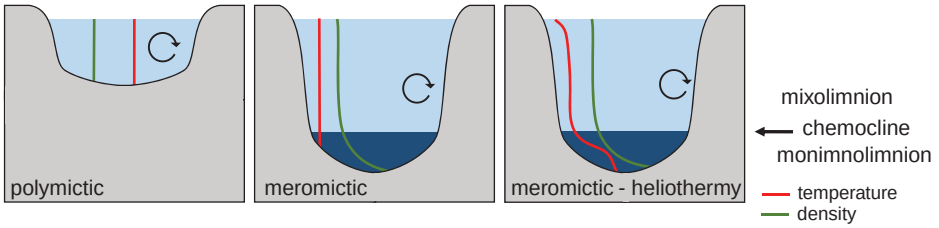

Fig. 7 Saline lakes are often polymictic due to their shallowness and wind exposure. Another common type is meromixis, because salt water has a higher density compared to freshwater. In very cold regions, an inverted temperature gradient might persist over longer periods.

is characterized by regular aragonite precipitation, a feature visible even on satellite images. This so-called "whitings" are the result of additional Ca^{2+} input from surface waters to the solute, which is already supersaturated with $CaCO_3$. Dissolved organic matter (DOM) also deserves mention. Saline lakes as terminal water bodies accumulate recalcitrant DOM, which may reach concentrations of >300 mg L^{-1}. During an extreme drought, Jirsa et al. (2013) reported DOC values up to 1 g L^{-1} in Lake Nakuru (Kenya). The DOM pool of meromictic Lake Sonachi (Kenya) is fed and modified by autochthonous microbial production, decomposition and photodegradation, with the chemocline acting as a hotspot of DOM transformations (Butturini et al., 2020).

Worldwide distribution

Lake water storage is about 0.013% of the global water, with large lakes >500 km^2 storing 92% of the water volume. The global volume of saline lakes almost approaches that of freshwater lakes, with the Caspian Sea alone contributing 93% to inland saline waters (Table 1). Saline lakes are found worldwide in semi-arid land-locked regions. About 10% of the global land area are endorheic basins (Fig. 8).

Eurasia

Eight out of the 10 largest saline lakes are located in Eurasia (Table 1). The Caspian Sea, and the dramatically shrunk Aral Sea, both located in the Aralo-Caspian Depression, are remnants of the Paratethys and dominated by Na^+ and $Cl^-/SO_4{}^{-2}$. Many small lakes, amongst them also soda lakes, are located in the Kulunda Steppe. Large saline lakes also exist in China within the endorheic Qinghai-Tibet Plateau, with Qinghai Hu being the 7th largest in the world. The Iranian Plateau hosts Lake Urmia, which was formerly listed amongst the 10 largest saline lakes in the world. Its volume, however, dropped considerably from around 35 km^3 in the mid-1990s to 2 km^3 in 2018 (Schulz et al., 2020), mainly driven by climatic conditions. The Middle East also hosts saline lakes, amongst them Lake Van and the Dead Sea.

The Dead Sea in the Syro-African Depression is the lowest place on Earth, currently 430 m below sea level. The ongoing drop in water level is associated with a change in the chemical composition of the brine and has led to a change in the mixing regime. The lake is hypersaline with around 350‰ and contrary to most other saline lakes has a very special brine with $CaCl_2$ as the dominant solute. This can be explained by the lake's history: after a lagoon was disconnected from the sea and ultimately became landlocked, the brine composition changed due to evaporation of seawater, hydrothermal springs, freshwater recharge and evaporite precipitation.

Table 1 Largest saline lakes of the world and the respective brine type. Compiled from various sources.

Lake	*Continent*	*Volume (km^3)*	*Brine type*
Caspian Sea	Asia	79,000	Na-SO_4-Cl
Issyk Kul	Asia	1730	Na-SO_4-Cl
Van	Asia	206	Na-CO_3-Cl
Turkana	Africa	204	Na- CO_3
Dead Sea	Asia	136	Na-Mg-Ca-Cl
Balkash	Asia	118	Na-SO_4-CO_3
Qinghai Hu	Asia	85	Na-SO_4-Cl
Karakul	Asia	78	Mg-$NaSO_4$-Cl
Aral Sea	Asia	27	Na-Cl-SO_4
Pyramid	North America	26	Na-CO_3-SO_4-Cl
Mar Chiquita	South America	25	Na-SO_4-Cl
Eyre	Australia	23	Na- Cl
Great Salt Lake	North America	19	Na-Mg-Cl
Salton	North America	7	Na-SO_4-Cl
Mono	North America	4	Na- CO_3-SO_4-Cl

Fig. 8 Global distribution of endorheic basins (red area).

In Europe, continental saline lakes and salt pans are common in Spain (Comin and Alonso, 1988), with some are being located in the Pannonian Basin (Boros and Kolpakova, 2018).

Africa

Soda lakes are common in the Eastern branch of the East African Rift (Schagerl, 2016). The characteristic alkaline brines reflect chemical weathering of volcanic bedrock, dominated by silicate hydrolysis (Deocampo and Jones, 2014). Lake Natron is the world's most important breeding site of Lesser Flamingos (*Phoeniconaias minor*) being a flagship species of these lakes. A special case is Lake Turkana (Kenya/Ethiopia), which had a salinity of about 2.5‰ in the 1980s (Källquist et al., 1988). Although the lake is threatened by the construction of hydropower dams accompanied by receding water levels, no current data are available. Even recent reviews (Ojwang et al., 2016) refer to the above values, which date back 30 years. Lack of lake monitoring is symptomatic for most saline lakes, especially those in developing countries.

Southern Africa also contains many saline water bodies. Most of them are ephemeral hypo- to mesosaline salt pans, and all of them are understudied. Seaman et al. (1991) provided a detailed overview of their location and chemical composition(mainly Na^+, Cl^-). Saline lakes are also located in the Sahara and in Egypt.

North America

In the rain shadow of the Pacific Coastal Mountain Range, the North Western Region and the Great Basin contain many salt lakes of different chemistry. The Great Basin contains the largest saline lake of North America, the Great Salt Lake (GSL), but also Mono Lake and the artificial Salton Sea, which are amongst the best studied saline lakes worldwide. The current lake was formed about 13,000 years ago, is the remnant of the paleolake Lake Bonneville (see "Mixing patterns" section).

The Great Plains harbors four additional endorheic basins, extending from Saskatchewan to New Mexico. The Prairie Pothole Region in the North is one of the largest inland wetland systems and a critical habitat for migratory waterfowl. The large number of lakes, many of them saline, are highly diverse biogeochemically, with Mg^{2+}/Na^+ and SO_4^{-2} being the most prominent brines. Since the mid-1990s, this region has received more precipitation, which resulted in an increased number of permanent water bodies and the dilution of saline lakes. Other endorheic basins of the Great Plains are the Mid-Continental and South Western Region, and the Chihuahuan Regions. Mexico also has some saline lakes, but they are not well studied (Alcocer and Hammer, 1998). A few lakes are also historical sites: the capital of the Aztec Empire, Tenochtitlan (today Mexico city), was built on islands of the ancient Lake Texcoco. Today, only remnants of the water body remain. The Aztecs were also known to have consumed the alkaliphilic cyanobacterium *Limnospira* (formerly *Spirulina, Arthrospira*) in pre-Hispanic times. The first outdoor cultivation facility for *Limnospira* was installed in the solar evaporator El Caracol in the late 1960, initially for Na_2CO_3 and $NaHCO_3$ extraction, but production ceased in the early 1990s.

South America

Saline lakes are mainly found in Altiplano and the Pampas. The Altiplano is a cold, high-altitude desert with some ephemeral water bodies and a few lakes. The terminal Lake Poopó is the remnant of the paleolake Lake Tauca and fed by the major outflow river of freshwater Lake Titicaca. In the past decades, Lake Poopó greatly suffered from water abstraction, mining and cropping practices. Besides Lake Poopó, Lake Tauca covered two other basins, which are nowadays mostly dry and listed amongst the largest playas worldwide: Salar de Coipasa and Salar de Uyuni, the latter considered to be the largest lithium brine resource in the world.

The Pampas harbors the 2nd-largest lake of South America after Lake Titicaca, namely Mar Chiquita (Table 1). The large water level fluctuations are correlated with wide salinity ranges between 25‰ and 360‰ (Bucher, 2019). Major eolian erosion and salt transport were observed in this lake, especially in periods of receding water level. The Salinas Grandes Basin with an area of 4700 km^2 and many ephemeral water bodies is also located in this region.

Australia

Six regions (including one in Tasmania) with mainly ephemeral lakes are distinguished. Mernagh et al. (2016) provide a review of Australian salt lakes and their mineral systems, with a special focus on mineral exploitation. Na^+ and Cl^- brines—reflecting their oceanic origin—usually dominate these lakes, but there are a few exceptions. The largest region is in the Australian desert with playa Lake Eyre. The endorheic basin of South-Western Australia contains many small saline lakes, some of them highly acidic, others saline-alkaline (Bowen and Benison, 2009).

Western Victoria also contains interesting salt lakes: Lake Corangamite is the largest permanent salt lake in Australia. The playa Lake Tyrrell is a depression of about 150 km^2, which is covered by water during winter. Due to chemical processes percolating in the aquifer in winter (mainly ferrolysis and pyrite oxidation), the water becomes acidic (Long et al., 2009). Other lakes in this region differ in chemistry due to weathering of volcanic rock, yielding high loadings of HCO_3^-/CO_3^{2-} and therefore being highly alkaline.

Antarctica

A few areas located mostly along the east and south coast remain free of snow and ice year-round. Permanent lakes are located in these so-called "oases," some of them saline (Burton, 1981). Saline water bodies are known from the Soya coast, the Vestfold Hills and the dry valleys of Southern Victoria Land (see "Mixing patterns" section). Stable isotopes analyses revealed that seawater (either via direct connection or windborne) is the origin of the brines in most of these water bodies (Matsubaya et al., 1979). A chain of three lakes is present in the Taylor Valley, with Lake Bonney and Lake Fryxell being saline. Recently, an airborne transient electromagnetic sensor survey indicated that liquid brines below the glaciers drain into these lakes (Mikucki et al., 2015), most probably originating from ancient seawater and weathering processes.

Amplifier lakes

Saline terminal lakes are especially prone to climate change because a balance between water supply and evaporation is mandatory for their existence. Amplifier lakes respond rapidly to moderate climate shifts: prolonged periods of rainfall will result in rising water levels, until a spillway is reached. If evaporation rates over longer periods exceed water supply, they will ultimately dry out. Olaka et al. (2010) demonstrated that especially alkaline-saline lakes with a high surface to volume ratio respond strongly to regional climatic shifts. Examples include Lake Abbe and Lake Nakuru in East Africa (Figs. 7 and 8) (Trauth et al., 2010). They are climate sentinels that react with short delay to environmental changes, analogous to glaciers. Lake levels of amplifier lakes are considered to record current climatic conditions, but they can also provide a basis for paleoclimatic reconstructions (De Cort et al., 2013), including those related to human evolution (Junginger and Trauth, 2013).

Organisms

Biology and physiological adaptations

Compared to other aquatic systems, saline lakes provide unique conditions that force organisms living there to develop specific adaptations. The considerations here include not only increased salinity as the fundamental stressor, but also other factors derived from an increased salt content. Depending on the brine composition, highly alkaline or acidic conditions might prevail, the density of the surrounding water might be increased and in cold regions the water temperature may sometimes be well below 0 °C. Salt lakes are classified based on salinity levels, but classification systems also have been developed based on preference of organisms for certain salt levels (Fig. 1). According to Williams (1978), halobiontic animals ("salt living") inhabit water bodies >50‰ salinity, halophilic species ("salt loving") show a preferred occurrence between 10‰ and 60‰, and halotolerant organisms prefer freshwater but tolerate salinities up to 20‰. Non-halophilic taxa are true freshwater species, which are found only below 0.5‰. Other classification systems have been developed based on other organism groups, e.g., metazoans, diatoms and microbes.

Independently of their phylogeny, organisms have developed three specific strategies to cope with extreme conditions. Avoiders escape unfavorable living conditions. Conformers adjust their metabolic processes to the respective conditions without any internal regulatory mechanisms; their internal conditions resemble those of the surrounding water. Regulators maintain the internal environment by using regulation mechanisms (homeostasis).

In saline lakes, organisms are exposed not only to increased salinity, but also to substantial shifts in salt concentration within very short periods. High salt concentrations (hypertonic conditions) of the surrounding medium cause serious problems if no protection mechanisms are developed: biological membranes are water-permeable, which would lead to continuous water loss through osmosis, resulting in plasmolysis and/or shriveling. Moreover, the increased ionic strength of the surrounding brines might cause an influx of ions into the cells. Besides morphological adjustments, Archaea and bacteria are conformers and have developed two major strategies to overcome osmolysis, namely "all-salt-in" and "low-salt-in-organic-solute-synthesis" (Oren, 2011; Sorokin et al., 2014). In the former strategy, KCl is accumulated in cells, which also requires adjustment of intracellular enzymes to overcome the problem of protein precipitation. The latter strategy includes synthesis of hydrophilic organic substances of low molecular weight such as certain amino acids (osmolytes, compatible solutes). Osmolytes—in contrast to KCl—do not interfere with metabolic activities, so no modification of enzymes is necessary. Although there are gaps in our knowledge, osmolytes are also common in eukaryotic algae (Oren, 2007) and protozoa (Gunde-Cimerman et al., 2018).

Rotifers can reach incredibly high numbers (Burian et al., 2016) and are of interest for aquaculture, but very little is known about their adaptations to salinity. *Brachionus plicatilis* is omnipresent in saline lakes between 3‰ and around 100‰ (Hammer, 1986). Lowe et al. (2005) suggested that *Brachionus* is a regulator based on Na^+/K^+ ATPase transporters. Crustaceans are quite common in saline lakes, with the branchiopod *Artemia salina*, also referred to as brine shrimp, surviving salinities between 3‰ and >250‰ (Croghan, 1958). *Artemia* is a regulator. A data compilation of worldwide copepod occurrence revealed that >25 species are found at salinities >100‰, and 12 species survive >200‰ (Anufriieva, 2015). Most copepods are probably conformers synthesizing osmolytes. *Ephydra* is another genus characteristic of saline lakes. The brine fly has Malpighian tubules for osmoregulation. The system is partly modified into a lime gland, where carbonates precipitate (Herbst and Bradley, 1989).

Vertebrates also occupy saline lakes. As opposed to invertebrates, fish are often lacking in this environment. This is because endorheic water bodies are quite isolated compared to their open counterparts, hampering movement and migration. From another perspective, however, isolation might boost endemism in such water bodies, similar to isolated mountain ranges. Hammer (1986) compiled a list of fish species naturally populating saline lakes of the world. This list reveals a clear pattern: increasing salinity results in decreased species number. Moreover, only five species tolerate >80‰. Generally, teleosts are slightly hypoosmotic to the surrounding water, which causes permanent water loss. This water loss is compensated by drinking. Gills, kidneys and the intestinal epithelium are highly involved in osmoregulation (Evans et al., 2005; Brauner et al., 2012). An additional challenge is the alkaline water of saline-alkaline lakes. The cichlid *Alcolapia grahami* (Magadi Tilapia) is adapted to such extreme conditions; its blood pH is adjusted to considerably higher levels compared to other fish. Wood et al. (2002) assumed that around 50% of the metabolic costs are traceable to acid-base regulation. *Alcolapia* drinks copiously to maintain ion balance. To escape the problem of stomach neutralization, it has developed a pyloric bypass in the gut. The bypass acts like a valve: it is closed during eating and open when drinking (empty stomach). Other physiological adaptations include obligate ureotely (Randall et al., 1989), with urea excretion across the gills. Many bird species developed salt-secreting glands in addition to kidneys to cope with salt water drinking, an essential feature for surviving in dry and salty environments.

Biodiversity and ecology

The biodiversity of photoautotrophs and heterotrophic eukaryotes in saline lakes is assumed to be low compared to the sea and to freshwater systems (Timms, 2020). It decreases continuously along a salinity gradient (Williams, 1998). This traditional view, however, needs to be scrutinized. The use of molecular taxonomic markers revealed an unexpectedly high diversity of Archaea (Menéndez-Serra et al., 2020) and other microorganisms (Alexe et al., 2017; Harding and Simpson, 2018). Additional explanations for these apparently contrasting patterns involve the application of traditional versus modern tools as well as organismic size. The number of easily recognizable taxa such as vertebrates and invertebrates is reduced with increasing salinity (Vareschi, 1987; Afonina and Tashlykova, 2020), whereas microorganisms have a "hidden" diversity (Lanzén et al., 2013). Saline lakes continue to provide unexpected new insights into microbial community composition. Just two examples are provided here. The Blood Falls is an iron-rich, blood-red, cryo-concentrated brine discharging at the glacier tongue of Taylor Glacier, which flows into Lake Bonney. This subglacial brine hosts a very stable, but previously undetected microbial community (Campen et al., 2019). Huge carbonate towers exceeding 40 m in height, built by calcifying cyanobacteria, have been discovered in Lake Van (Kempe et al., 1991).

From the classical point of view, food webs of saline lakes have a low complexity because the species inventory is limited. The evidence, however, is mounting that this statement falls short because the importance of the microbial community in both abundance and biodiversity has been largely neglected. As mentioned by Padisák and Naselli-Flores (2020), food webs of extreme environments are not necessarily simple, they are just considerably different from freshwater systems. Microbes are involved in element cycling of saline lakes (Banciu and Sorokin, 2013) and show extremely high abundances. Moreover, viruses might play a pivotal role in saline lakes (Peduzzi et al., 2014).

Saline-alkaline lakes up to mesosaline conditions rank amongst the most productive ecosystems of the world (Oduor and Schagerl, 2007). In addition to an elevated nutrient supply, high concentrations of inorganic carbon boost primary production. Key factors for community development can be categorized into allogenic environmental conditions and autogenic factors including

biological interactions (Schagerl and Burian, 2016). For saline lakes as terminal water bodies, water level with all its associated conditions is the overall allogenic key variable: changes in water levels impact the mixing regime and optical properties, the stability of the sediment-water interface, and geochemistry.

Economic concerns and threats

Commercial fishing is practiced in only a few mesosaline large lakes such as the Caspian Sea and Issyk-Kul. Another source of revenue is tourism. Beyond the environment itself, the associated organisms attract visitors. Because of their unique avifauna, some lakes have been designated as Ramsar Wetlands. Especially in lakes without fish, birds are at the top of the trophic cascade and feed on invertebrates and phototrophs. Microorganisms inhabiting the lakes are also in the focus of companies. The organisms synthesize valuable compounds and can be cultivated outdoor at extreme conditions, which precludes infections by contaminants. The chlorophyte *Dunaliella salina* is commercially exploited for ß-carotene and lutein production. *Limnospira* is cultivated in open pond systems and sold under the trade name "*Spirulina platensis*" as a food supplement. In addition, various health benefits such as anticancer and anti-inflammatory effects have been documented. Heterotrophs and their enzymes are already in use for industrial purposes; enzymes are robust against organic solvents, high temperature and salt content (Oren, 2010). Apart from these examples, other promising taxa still wait to be studied (Krienitz et al., 2016). Near the shore of saline lakes, health spas treat skin disorders, the most prominent examples being the Dead Sea and Lake Manitou (Saskatchewan). By far the largest source of income, however, is the mining and mineral industry. Besides halite, other evaporitic minerals are also mined. Trona and borax are used in the glass industry, and lithium is essential for various industrial purposes, e.g., for lithium-ion batteries.

The threats to saline lakes can be subsumed under direct anthropogenic impacts in the catchment and lake area, and climate change. Williams (2002) assumed substantial changes to the natural status of these lakes by 2025, with permanent water bodies showing a decrease in size paired with an increase in salinity, and ephemeral lakes having extended dry periods. His prediction was recently verified for several lakes (Wurtsbaugh et al., 2017; Tussupova et al., 2020). Although frequent water level changes are a typical feature of terminal lakes, human impact greatly speeds up this process. Global warming specifically affects saline lakes because they are a priori prone to climate change.

The Aral Sea is a very prominent warning example of human interference. Prior to 1960, this lake was ranked amongst the three largest saline lakes worldwide. Due to expanding irrigation, water was abstracted from the lake's main tributaries, dramatically decreasing its volume by 90% and triggering salinization (Fig. 9; Micklin, 2016). This disaster exposed former lake sediments to air, and the resulting dust deposition causes severe human health problems. Moreover, deflation substantially reduced the area of arable land due to salinization.

Lake Texcoco was once a very large lake in Mexico. The Aztecs already began to drain some areas, a practice that was later continued by the Spanish conquerors. Today, the expanding metropolis of Mexico City is located on the former lake area, and only negligible remnants of the lake remain.

The Dead Sea is being altered by human activities and is facing an ongoing reduction of its volume. In the 1970s, the southern part was separated from the northern basin and since then used as evaporation ponds for salt extraction. The water level has been receding by around 1 m per year in recent decades, mostly because of water diversion for irrigation, industrial and domestic use combined with high evaporation (Bookman, 2020). Because of its morphology, only about 20% of the initial volume was lost, and an annual halite precipitation of 0.1 m helped counteract the volume decrease.

Lake Urmia has faced a dramatic decline in water level for two decades. Within 8 years, the lake shrunk by about 60% and lost 90% of its original volume, which severely threatens the overall functionality of the system. The reasons for this decline are not fully understood, but Schulz et al. (2020) were able to prove climate change as the main trigger, additionally boosted by water abstraction of major inflows.

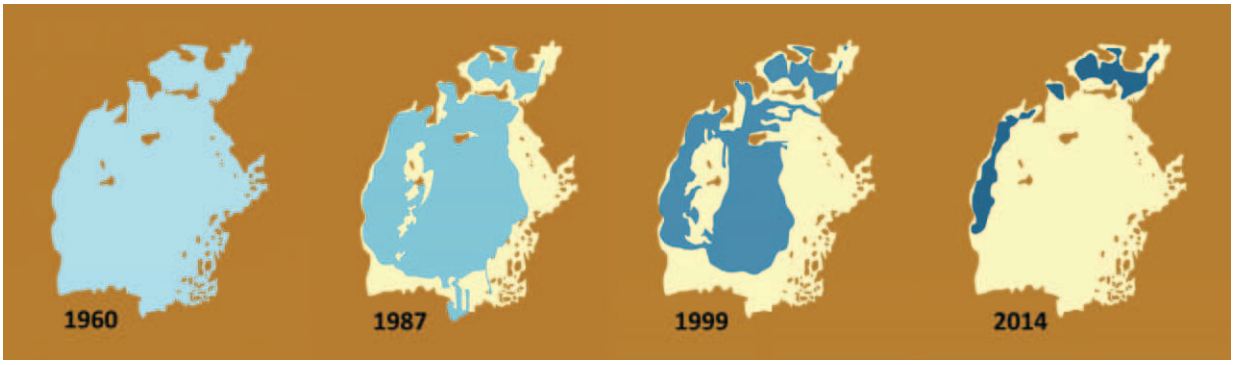

Fig. 9 The disaster of the Aral Sea. Modified from Micklin P (2016) The future Aral Sea: Hope and despair. *Environmental Earth Sciences* 75: 844. doi: 10.1007/s12665-016-5614-5.

Soda ash mining poses a threat to saline-alkaline lakes. Lake Abijata (Ethiopia) is dramatically shrinking due to water abstraction of inflows combined with soda ash production directly at the lake (Fetahi, 2016). The biology of the lake has completely changed: fish disappeared, which then triggered the loss of piscivorous birds. Other migrating birds such as flocks of flamingos no longer visit the lake because the plankton community also shifted from *Limnospira* toward other components.

The hypersaline lakes and subsurface brines of the Atacama Desert are ranked amongst the largest lithium exploitation sites worldwide. It is very likely that the biodiversity and stability of these sensible systems are highly endangered, but no environmental impact assessments and environmental protection measures have yet been performed (Gajardo and Redón, 2019). Australian salt lakes also face mineral exploitation (Timms, 2005).

In a few cases, lake restoration efforts have been successful. From the 1940s onwards, Los Angeles extracted water from tributaries of Mono Lake, resulting in a significant decrease of its volume paired with salinization. The lowered water level impaired organisms and their interactions, and also endangered the stability of tufa formations. To counteract this development, conservation efforts were undertaken, e.g., by reducing water diversion from the inflows. These efforts have already resulted in a rise of the water level.

Conclusion

Saline lakes are located in endorheic basins of all continents, including cold regions with ice-cover and high altitudes. They are often present in semi-arid to arid climates, which makes them and their tributaries an integral part of the water supply for certain land animals such as migratory birds. Contrary to the common belief outside the limnology community, they are extremely diverse in geochemistry and salinity. They represent complex and dynamic hydrological systems controlled by allogenic and autogenic factors such as tectonic activity and climatic conditions, catchment area lithology, mineral precipitation due to the different solubilities of evaporates, and biology. Organisms inhabiting these systems have adapted to brine concentrations at the limit of solubility. With increasing salinity, the biodiversity of eukaryotes drops. A few more recent studies, however, indicate that saline lakes hold a hidden diversity of prokaryotes, especially of Archaea. Due to their elevated nutrient supply combined with exceptionally high concentrations of inorganic carbon, saline-alkaline lakes rank amongst the most productive ecosystems worldwide. As terminal water bodies, saline lakes are prone to climate change and pollution, which is already illustrated by various dramatic examples. This urgently calls for comprehensive protection measures in most regions of the world.

Knowledge gaps

- Physiological adaptations to salinity and geochemistry
- Food web studies including the microbial loop and viral shunt
- Hidden biodiversity of eu- and prokaryotes
- Role of microbes in element cycling and system productivity
- Benthic-pelagic interactions
- Even regular basic measurements obtained by monitoring programs are missing

Acknowledgment

This chapter is dedicated to Aharon Oren, who is one of the leading scientists in the microbial ecology and prokaryote taxonomy of saline systems. His competence, enthusiasm, kindness and candidness have inspired many people, including the author of this chapter.

Heat Budget of Lakes

Martin Schmid[a] **and Jordan Read**[b], [a]Eawag: Swiss Federal Institute of Aquatic Science and Technology, Kastanienbaum, Switzerland
[b]U.S. Geological Survey, Water Resources Mission Area, Middleton, WI, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie-Elodie Perga and Damien Bouffard.

Glossary

Albedo Fraction of incoming shortwave radiation reflected at the lake surface.
Energy flux Rate of energy exchange across an arbitrary or physically meaningful boundary (e.g., a lake surface).
Equilibrium temperature Lake surface temperature at which the net lake surface heat flux would be zero for given meteorological conditions.
Heat flux A thermal energy flux.
Incoming longwave radiation Thermal radiation at wavelengths >3000 nm directed from the atmosphere to the lake surface.
Incoming shortwave (solar) radiation Radiant energy with wavelengths between ~300 and ~3000 nm, emitted by the sun and reaching the lake surface after passing through the atmosphere.
Lake surface heat fluxes Heat fluxes between the lake surface and the atmosphere.
Latent heat flux Heat flux between the lake and the atmosphere due to evaporation or condensation.
Outgoing longwave radiation Thermal radiation at wavelengths >3000 nm emitted from the lake surface.
Sensible heat flux Heat flux between the lake and the atmosphere due to thermal conduction.
Surface mixed layer Nearly homogeneous water layer extending from the lake surface to a depth determined by recent turbulent mixing, in classical limnology also referred to as the epilimnion.

Introduction

The dynamics of heat fluxes determine lake water temperatures and stratification, which in turn impact water quality and biota. Changes in lake heat budgets are the most direct and primary effect of climate change on lakes, and the monitoring, modelling, and prediction of heat fluxes has a long history in limnology with continued growth in applications for present-day management and understanding of lakes. Due to the importance of heat fluxes to lake ecosystem functions and the need to project the response of lakes to climate change, numerous book chapters (see Wetzel and Likens, 2000) and reviews on the topic exist (Henderson-Sellers, 1986) as well as tools to support heat flux calculations (Woolway et al., 2015). Here we summarize current knowledge of lake heat fluxes and identify new future research challenges for the field of limnology.

Concepts

Components of the heat budget

Short-term temperature changes in lakes are the result of imbalance in heat losses or gains, most of which occur at the lake surface (Fig. 1). The timing and magnitude of surface energy fluxes vary in response to atmospheric conditions and the properties of the lake surface. Energy is also lost or gained to the lake below the surface, including from sub-surface inflows, sediment heat exchange, and the attenuation of penetrative radiation within the water column. The heat content of the lake (U_{tot}) is defined by the temperature and volume of the water, as well as other water properties that impact water density or specific heat. Any changes to thermal energy are driven by coincident imbalance in energy fluxes (H_X) which are positive when entering the lake:

$$U_{tot}/A = H_S + H_A + H_W + H_E + H_C + H_F + H_D$$

Where A is the surface area of the lake. Heat fluxes include downward shortwave (H_S) and longwave (H_A) radiation, outgoing longwave radiation (H_W), latent (H_E) and sensible (H_C) fluxes, advected energy (H_F), and sediment heat flux (H_D).

Accurate measurements of water temperature and volume (used to estimate U_{tot}) can be combined with detailed measurements or estimates of energy fluxes (H_X) to define seasonal patterns in lake heat budgets and temperature regimes. As an example, the seasonality of the components of the lake surface heat fluxes for a temperate and a tropical lake are displayed in Fig. 2. The values of missing or uncertain heat flux measurements can be inferred by quantifying the remaining elements of the heat budget and solving for the residuals, such as using temperature and measured energy fluxes to estimate evaporation (Lenters et al., 2005; Winter et al., 2003), or conversely, process-based lake temperature models predict temperatures by including measured or estimated heat fluxes in an energy budget model (Hipsey et al., 2019). A wide range of equations have been used in process-based models to parameterize lake surface heat fluxes. Henderson-Sellers (1986) summarized available parameterizations for all surface heat fluxes, and specific sets of equations can be found, e.g., in Livingstone and Imboden (1989), Fink et al. (2014), Woolway et al. (2015), and Hipsey et al. (2019).

Shortwave radiation

Downwelling shortwave radiation (H_S) quantifies the direct energy from the sun as the sum of all wavelengths in the range of ~300–3000 nm including near-ultraviolet, visible light, and near-infrared radiation. As such, H_S varies according to latitude, cloud cover, elevation, and any landscape features that may block the sun's rays from reaching the lake surface (e.g., tall buildings, mountains, and tree canopies). A portion of incoming radiation is reflected by the lake surface, and this loss is defined as the albedo. The shortwave albedo varies according to location (including latitude and elevation), time and day of year, and surface water conditions (e.g., presence of waves or ice cover). Empirical formulations or look-up tables are available for estimating time-varying albedo (Cogley, 1979) but it is common to assume a constant value (e.g., Lenters et al., 2005). After reflection of a fraction of incoming shortwave radiation, shortwave radiation wavelengths beyond the range of visible light are non-penetrative and are

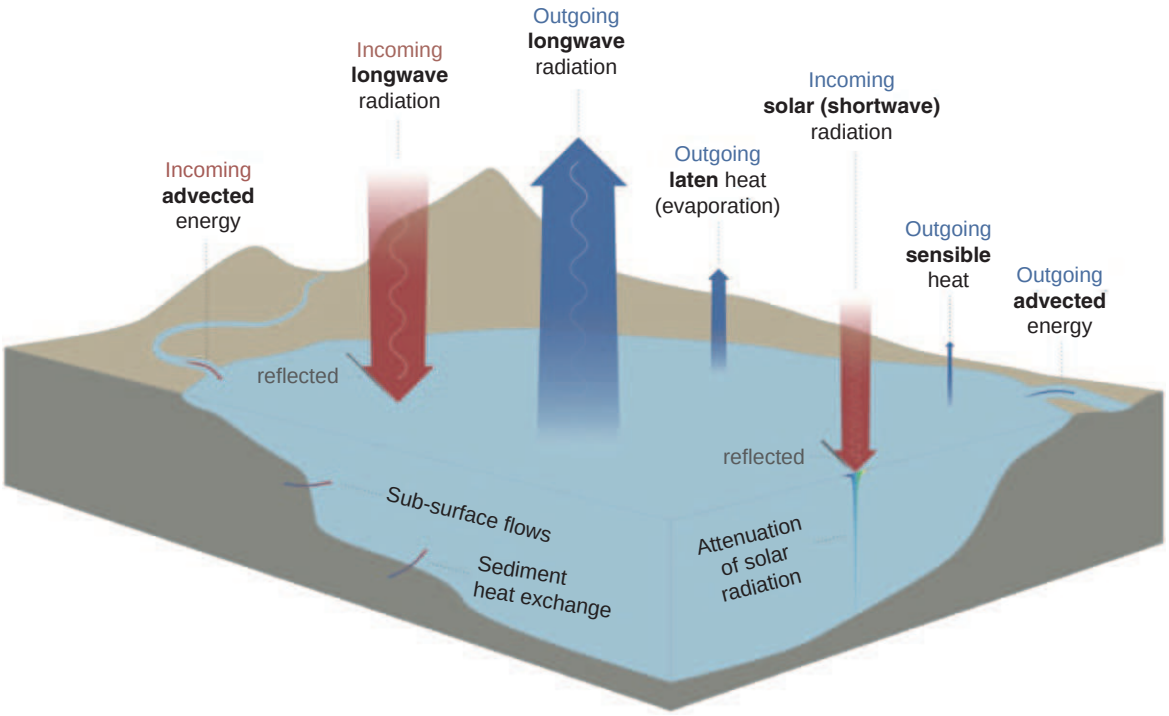

Fig. 1 Components of the heat exchange between a lake and the environment.

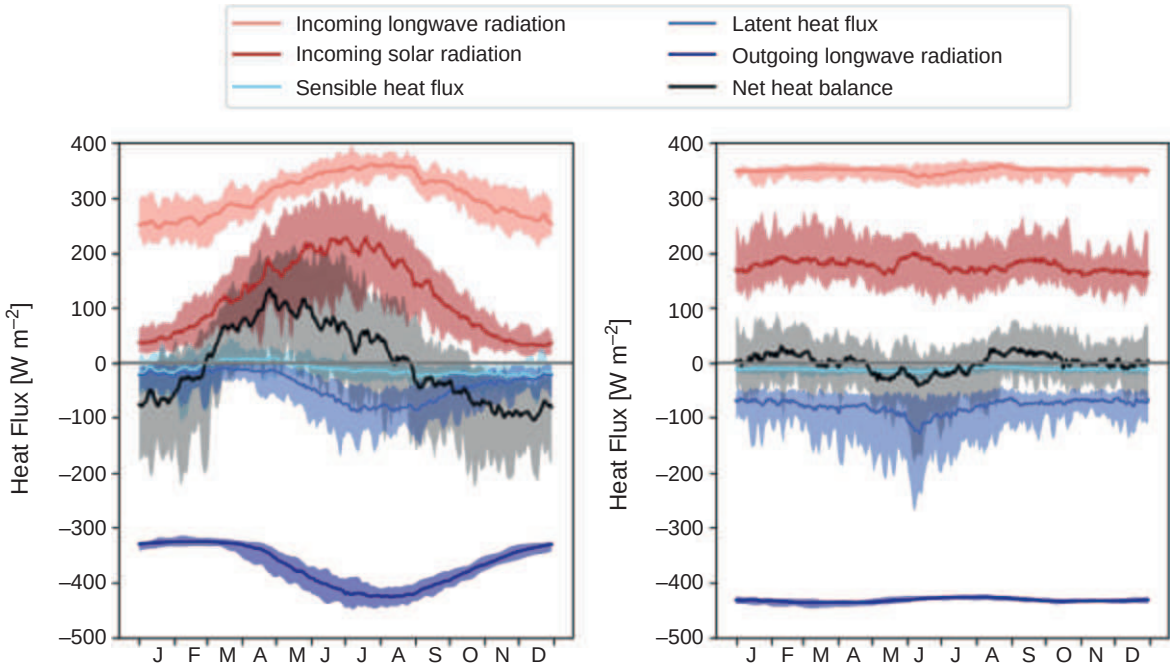

Fig. 2 Components of the surface heat fluxes for temperate Lake Zug (Switzerland) and tropical Lake Kivu (DR Congo, Rwanda). The fluxes were calculated with the lake model Simstrat (Goudsmit et al., 2002; Gaudard et al., 2018) based on meteorological data from MeteoSwiss for Lake Zug, and the MiroC5 control scenario from ISIMIP2a for Lake Kivu (F. Bärenbold, personal communication). The lines show the median values, the ranges the minima and maxima over a period of 30 years. The data were smoothed with a window of 1 week. The effects of inflows and sediment heat exchange were not included in the calculations.

treated as a surface energy flux. Radiation of shorter wavelengths penetrates below the surface to be attenuated within the water column or absorbed by the lakebed (Kirk, 1994). The percentage of non-penetrative shortwave radiative energy has been defined as ranging from 35% (Thiery et al., 2014) to 55% (Hipsey et al., 2019).

Incoming longwave radiation

Downwelling longwave radiation (H_A) is the radiative energy flux from the atmosphere, and the magnitude of this flux depends primarily on the atmospheric temperature and humidity and cloud cover. See Flerchinger et al. (2009) for various methods to estimate longwave radiation. Approximately 3% of downwelling longwave radiation is reflected at the lake's surface (the longwave albedo) and the remaining energy is absorbed by the surface of the lake.

Outgoing longwave radiation

Longwave radiation is emitted from the lake (H_W) as a function of surface water temperature (in Kelvin) to the fourth power. This outgoing energy flux is typically the largest energy loss term in a lake heat budget, more than offsetting the gains of downwelling H_A in most cases (although see Section "Overall seasonal heat budget of lakes in different climate zones"). As such, the net sum of incoming and outgoing longwave radiation is often measured near the surface of a lake with paired upward- and downward-oriented sensors, which capture H_A and the sum of H_W and the portion of H_A reflected upward, respectively. When direct measurements are not available, H_W is often estimated as $\varepsilon\sigma T_0^4$ where ε is the emissivity of water, σ is the Stefan-Boltzmann constant, and T_0 is the absolute temperature of the water surface.

Latent heat flux (evaporation/condensation)

The flux of latent heat (H_E) at the lake surface quantifies the energy lost or gained to the lake via a state change from liquid water to vapor (evaporation) or vapor to liquid water (condensation). These state changes remove or add water to the lake and are therefore also relevant to the closure of the lake's water budget. Most latent heat exchange occurs as evaporation, where the magnitude of the flux depends on the deficit of vapor in the air and the efficiency of removal, which is based on the atmospheric conditions above the lake. Common methods for estimating the latent heat flux include calculating a residual to the energy budget (Winter et al., 2003), eddy covariance (Nordbo et al., 2011), and mass transfer coefficient parameterization (Rasmussen et al., 1995; Woolway et al., 2015); alternative methods including pan evaporation, mass budget, and use of stable isotopes are also applicable to estimating evaporative water loss.

Sensible heat flux

The sensible heat flux (H_C) contrasts with latent heat exchange in that no state change occurs and energy is transferred via conduction between the lake surface and the atmosphere. As with H_E, H_C can remove or add energy to the lake depending on

the prevailing meteorological conditions and the surface temperature of the lake, although most H_C fluxes are losses from the lake. The magnitude of the H_C flux depends on the difference in temperature between air and water and the atmospheric removal. All primary methods listed above for estimating H_E either include a complementary formulation for H_C (see Woolway et al., 2015) or involve partitioning the relative contributions of H_C and H_E as part of the method (in the case of energy budget or eddy covariance methods).

Inflows

The net heat flux H_F (W m^{-2}) caused by an inflow with discharge Q_{in} and temperature T_{in} is given by Livingstone and Imboden (1989):

$$H_F = \frac{c_p \rho}{A} Q_{in}(T_{in} - T_{out})$$

where c_p and ρ are the heat capacity and density of water, respectively; and T_{out} is the outflow temperature, which is close to the lake surface temperature in most lakes. This equation assumes constant lake volume with inflow equal to outflow. For calculating the full heat budget of a lake including volume variations, all individual water fluxes and their temperatures need to be considered (Winter et al., 2003), but in that case care must be taken when comparing components of the heat budget that result from temperature changes with those resulting from volume changes.

If an inflow mixes into the surface mixed layer of a lake, the respective heat flux modifies the lake surface temperature in a similar way as a change in a surface heat flux. As a consequence, the outgoing longwave radiation and the latent and sensitive heat fluxes are modified, partially compensating the heat flux from the inflow. Conversely, if the inflow plunges into the metalimnion, as is typically the case for cold inflows in the warm season, it does not directly affect the lake surface temperature, and the net heat flux from the inflow can accumulate in the lake until the next mixing event. Cool plunging inflows can thus cause a significant cooling of a lake throughout the summer. Similarly, direct groundwater inflows can modify hypolimnion temperatures of a lake (Safaie et al., 2017).

Heat exchange with the sediment

Heat is generally transported from the water column into the sediment by conduction during the warm season and released back to the water during the cold season (Fang and Stefan, 1998), although diurnal heat exchange can also be relevant, especially in shallow lakes or littoral areas where sediments receive direct solar radiation (de la Fuente, 2014). The seasonal heat storage in sediments is relevant mainly for the heat budget of shallow lakes, where the seasonal temperature variation above the sediment is large and the heat capacity of the overlying water is comparably small. However, the amount of heat that can be stored and exchanged is limited by the thermal diffusivity of the lake sediment. Even for lakes with large seasonal temperature variation, the seasonal heat flux between the sediment and the overlying water typically does not exceed a few W m^{-2}. The effects of heat exchange between the sediment and the water are therefore most noticeable in ice-covered lakes where the heat fluxes across the lake surface are limited as well. Heat release from the sediment can be an important driver for both horizontal currents and vertical mixing in ice covered lakes (Kirillin et al., 2012).

Heat fluxes through ice cover

The presence of an ice cover completely modifies the heat fluxes at the lake surface (Leppäranta, 2015). The water temperature at the ice-water interface is fixed to 0 °C. The temperature at the surface of the ice cover reacts to meteorological conditions, resulting in a temperature gradient within the ice and a corresponding molecular heat flux. Shortwave radiation can partially penetrate the ice cover and add heat to the underlying lake water. This is particularly important in spring when the ice cover becomes thinner and incoming shortwave radiation increases. The warming of the near-surface water can then induce convective mixing below the ice cover, as water density increases with temperature at temperatures below 4 °C (Kirillin et al., 2012). The transfer of shortwave radiation through the ice cover strongly depends on the ice properties and is reduced in the presence of snow.

Anthropogenic heat fluxes

Heat can be artificially added to or removed from a lake when water is used for cooling or heating purposes. More than 4 GW of heat is introduced globally to freshwater systems from the cooling of power plants. An estimated 44% of this heat directly enters reservoirs and lakes (Raptis and Pfister, 2016) and in some cases causes considerable warming of these waterbodies. One of the best investigated case studies is Lake Stechlin, which was used for cooling a nuclear power plant from 1960 to 1996, with significant effects on its mixing and stratification regime (Kirillin et al., 2013). The remaining 56% of the heat is introduced into rivers, but can be further transported into downstream lakes (Råman Vinnå et al., 2017). More recently, freshwater systems have been increasingly used for extracting heat for heating purposes, resulting in a cooling of the waterbodies. Heat extraction from deep lakes using heat pumps provides a substantial potential for replacing fossil fuel (Gaudard et al., 2019a, b). Wastewater also typically has different seasonal temperature dynamics than natural surface waters, and its discharge into a lake can therefore modify the heat budget of a lake.

Concept of equilibrium temperature

The equilibrium lake surface temperature is a useful proxy for the responses of lakes to climate variability and climate change (Schmid et al., 2014). A lake surface equilibrium temperature can be calculated as the temperature for which the net heat flux at the

lake surface is zero given a set of meteorological conditions (Edinger et al., 1968). The lake surface temperature tends to exponentially approach this equilibrium temperature if meteorological conditions are held constant. A deviation of the lake surface temperature from the equilibrium temperature of 1 °C results in a heat flux from the lake of ~30 W m^{-2}. This heat flux would be sufficient to cool a water layer of 1 m thickness by 1 °C within 1.6 days. Consequently, for constant meteorological conditions, and assuming that the incoming solar radiation is entirely absorbed within the surface mixed layer, the lake surface temperature would exponentially approach the equilibrium temperature with a time scale of 1–2 days for a 1 m thick mixed layer or 1 month for a 20 m thick mixed layer. In shallow lakes or in stratified lakes with a shallow surface mixed layer, the lake surface temperature is therefore often close to this equilibrium temperature. For a wide range of meteorological conditions, a change in air temperature of 1 °C results in a change in lake surface equilibrium temperature of ~0.8 °C (Schmid et al., 2014). In small and shallow lakes, but also in stratified deeper lakes, a trend in air temperature is therefore expected to result in a corresponding trend in lake surface temperature of ~80% of the air temperature trend.

Overall seasonal heat budget of lakes in different climate zones

The importance and seasonality of the different heat fluxes varies with latitude and in different climate zones (e.g., Fig. 2). This results in different lake thermal regimes, and also a different sensitivity of lakes in different climate zones to climate change (Maberly et al., 2020). Climatic and lake-specific factors (such as morphometry) modulate the seasonal heat budgets in lakes and contribute to global diversity in lake thermal regimes.

In temperate and boreal climate zones, where the majority of lakes are located, the seasonality of the heat budget is mainly driven by the strong seasonality of incoming shortwave and to a lesser extent incoming longwave radiation. As a result, large seasonal amplitudes of lake surface temperatures and dimictic or monomictic mixing regimes are common in these climate zones. The lag between lake temperatures and atmospheric conditions also results in seasonality of outgoing heat fluxes (Livingstone and Imboden, 1989), including latent and sensible heat fluxes, which peak in the summer or late fall. Lakes that become cold enough for surface ice to form experience modified heat fluxes (Section "Heat fluxes through ice cover") and as day length and H_S increase in the spring, have a lagged response to warming until ice melts and surface waters return to tighter coupling with atmospheric heat exchanges.

In the tropical climate zone, incoming shortwave radiation is relatively constant throughout the year. Lake surface temperatures vary seasonally only within a few degrees Celsius, and temperature differences between the surface and bottom waters are typically small, resulting in a more dynamic behavior of the mixed layer depth than in temperate lakes (Lewis, 2000). The lowest lake surface temperatures, and consequently deep mixing events, often occur during the local dry season, when low relative humidity and seasonal winds increase evaporative heat losses and decrease incoming longwave radiation.

Indirect anthropogenic impacts on heat fluxes

Anthropogenic uses of water and land can result in significant changes to lake heat budgets, which in turn modify lake thermal regimes and ecosystem functions. Tanentzap et al. (2008) examined Clearwater Lake in Canada, where forest regrowth and deacidification (along with coincident changes in water clarity) resulted in lower wind speeds and a colder, more strongly stratified lake. Urban heating impacts on lake heat fluxes can be significant, but few studies exist that describe this phenomenon (although see Cosgrove and Berkelhammer, 2018). Using lakes as storage volumes for pumped-storage hydropower can strongly affect their heat budget and thermal properties (Kobler et al., 2018). Other examples of indirect alterations to heat fluxes via anthropogenic change include interventions that modify lake surface area, morphometry, and flowrates via impoundment, channelization, water diversion, and sedimentation. Additionally, agricultural drainage and wastewater effluents have been mostly examined for rivers, but can also affect lake heat budgets (Gaudard et al., 2018). The impact of these anthropogenic alterations on water temperatures depends on their relative magnitude in the overall energy budget of a lake.

Impacts of climate change on heat fluxes and heat budgets

All heat fluxes mentioned in Section "Components of the heat budget" can be modified by climate change. The most direct impact of climate change results from changes in air temperature. Increased air temperature leads to increased incoming longwave radiation and modifies the sensible heat flux between the lake and the atmosphere. For many individual lakes, high correlations between annual or seasonal mean air temperature and lake surface temperature have been observed. At a global scale, for a large number of lakes, the correlation between long-term trends in summer air temperature and lake surface temperature is less consistent (O'Reilly et al., 2015). This observed variability can result from different reactions of different lakes to the forcing, from surface water temperature trends in some lakes being affected by other factors (e.g., trends in clarity), or from the uncertainties in the observed trends of either air or lake surface temperature. Locally, climate change can also lead to modified incoming solar radiation, relative humidity, average wind speeds, and the timing and magnitude of hydrologic fluxes, with corresponding impacts on lake heat fluxes. For example, reduced wind speeds have been proposed to have accelerated warming of lakes in the Northern Hemisphere (Woolway et al., 2019). For boreal and temperate lakes, climate change typically results in a prolongation of the summer stratified period with a significant additional accumulation of heat throughout the summer, which then needs to be removed again in autumn before complete lake mixing can occur.

Conclusions/synthesis

The heat fluxes between lakes and the environment determine the dynamics of their thermal structure, and in consequence, are a control on biogeochemical processes in lakes. The heat budget of an individual lake depends on the local climatic conditions and is modulated by the lake's properties. While incoming shortwave and longwave and outgoing longwave radiation contribute most to the heat budget, other heat fluxes can nevertheless be relevant for driving seasonality, e.g., the latent heat flux in tropical lakes. Modification of the heat fluxes, and in consequence of the thermal structure, is the most direct impact of climate change on lakes. The heat budget of lakes can otherwise be affected by anthropogenic activities, either directly by heat discharge or extraction, or indirectly by changes in a lake's watershed.

Knowledge gaps

- The spatial heterogeneity in lake thermal properties, fluxes, and in-lake responses to forcings (e.g., evaporative cooling, locations of warm water inflows, and complex wind fields) may be relevant but has rarely been investigated.
- Direct measurements of heat fluxes (e.g., eddy covariance for sensible and latent heat) are rare.
- The representation of heat fluxes in numerical lake models is often simplistic and constrained by measurement limitations (e.g., single point weather observations).
- Data for calculating fluxes is biased to temperate regions, and few studies have taken place at high altitude or in tropical lakes.
- Studies quantifying the effects of diffuse anthropogenic heat sources (e.g., urbanization, land use change) on lake temperatures are rare.

Lake Colors: Interpreting Apparent Optical Properties

Daniel Odermatt[a] **and Peter Gege**[b], [a]Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland; [b]German Aerospace Center (DLR), Remote Sensing Technology Institute, Wessling, Germany

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Apparent optical properties Aquatic optical properties that depend, among others, on ambient light and observation conditions, such as attenuation and reflectance.
Inherent optical properties Aquatic optical properties that are irrespective of ambient light and observation conditions, but depend only on water and its optically active components, such as absorption and scattering.
Irradiance Radiant flux received by a surface in units Watt per square meter.
Radiance Radiant flux received by a surface in units Watt per solid angle per projected area.
Reflectance Measure of a surface's effectiveness in reflecting radiant energy, with reference to the illumination and observation geometry.
Attenuation The gradual loss of radiant flux in a given medium, in units per path length.
Remote sensing The process of observing the physical characteristics of an area by measuring its reflected or emitted radiation at a distance.
Spectroradiometry The process of measuring a radiant flux at individual wavelengths of the electromagnetic spectrum.

Introduction

Sensing color is a convenient way to obtain information about the environment. The earliest standardized measures of water color, Secchi depth and the Forel-Ule scale, use the human eye as a sensor. They were defined more than a century ago, but recently experienced a revival in citizen science. Meanwhile, the emerge of opto-electronic sensors enabled an increasing level of automation in environmental monitoring using a variety of submerged to orbiting measurement platforms. This section covers the interpretation of apparent optical properties of natural waters, which are those that depend on ambient light and observation conditions.

The transparent spectral window of pure water, human light perception and absorption by photosynthetic pigments are all ranging from 400 to 700 nm wavelength of the electromagnetic spectrum (Mobley, 1994). This may seem coincidental, or less so given that both photosynthesis and vision evolved in water-borne organisms. It was even hypothesized that eyesight sparked the evolutionary arms race referred to as *Cambrian Explosion* (Parker, 2004), emphasizing the huge practical value of eyesight. Solar illumination in the visible spectral domain is the primary energy source for human vision as well as for spectroradiometers. Observations are thus subject to different illumination conditions, namely the brightness and spectral composition of down-welling irradiance. Compensating for these conditions is key to accessing color in a reproducible manner.

 https://doi.org/10.1016/B978-0-12-819166-8.00041-4

The hues of most natural surface waters range from blue and green to brown (Giardino et al., 2019; Lehmann et al., 2018), and their brightness spans across two orders of magnitudes (IOCCG, 2018). The Forel-Ule scale is a traditional, self-contained method to classify this range according to 21 color standards (Novoa et al., 2013). In water quality remote sensing, up to 22 optical water types from statistical clustering of spectral reflectance are used to support the retrieval of color producing agents such as inorganic and organic particles, phytoplankton pigments, and dissolved organic matter from spectral reflectance (Eleveld et al., 2017; Spyrakos et al., 2018). Absorption and scattering of these agents determine also Secchi disk visibility, which is related to turbidity and the underwater light availability (Lee et al., 2015).

Earth observation satellites are used for water quality remote sensing since the launch of the ERTS-1 mission, later known as Landsat-1, in 1972 (Strong, 1974). The spectral sampling of the first multispectral scanners was coined by human light perception. Image acquisition in a red, green and blue spectral channel enabled true-color imagery that is comparable to color photographs. This scheme is still present in many Earth observation sensors. But the number of application-specific satellite missions has increased steadily over the past decades, enabling a wide range of applications related to surface water quality (IOCCG, 2018). Currently, several hyperspectral satellite sensors are emerging that sample hundreds of adjacent spectral channels and resolve an unprecedented level of color detail.

Color appearance

Sensitivity of the human eye

In the eye of people with normal vision three types of light sensitive cells (cones) allow for color vision, while another cell type (rods) enables vision during low-light conditions. Lacking cone types lead to color-blindness. Fig. 1 shows the typical distribution of cones in the central part of the retina (Zhang et al., 2019).

The different cone types allow for a bulk wavelength selection similar to a broadband multispectral sensor with overlapping bands. Their spectral response to light is given by the cone fundamentals. These are the products of spectral absorption of the cones' photo pigments multiplied by the spectral transmittances of the ocular media through which light passes to reach the retina (Judd, 1966). Each person has a slightly different color vision that varies furthermore with the viewing field and with age. Fig. 2 shows the average cone fundamentals derived from 49 persons for a field of view of 10 degrees (Stiles and Burch, 1959).

Color space

Long before cone fundamentals were known, it was demonstrated that all color perception can be evoked with three primary colors (von Helmholtz, 1852). Wright (1929) and Guild (1931) performed experiments where a target spectral radiance was matched by additive mixing of monochromatic blue (436 nm), green (546 nm) and red (700 nm) light, with the addition of a virtually negative red contribution. From these experiments three wavelength dependent functions were derived, called color matching functions (CMF), which form the basis of modern colorimetry (CIE, 2006). The CMFs relate mathematically the physical

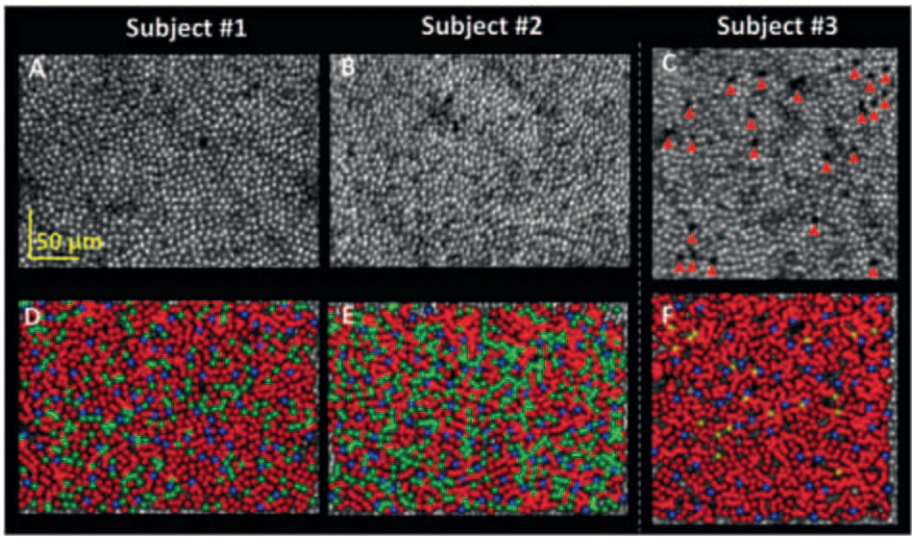

Fig. 1 Distribution of cones sensitive to shortwave (S cones, blue), midwave (M, green) and longwave (L, red) light in the central part of the retina. En face intensity images of cone mosaics (A–C) are color coded on the basis of cone classification (D–F). Subjects #1 and #2 have normal vision. Subject #3 is a deuteranope, whose missing cone outer segments, indicated by red arrows, impair green and brightness perception. Reproduced with permission from Zhang F, Kurokawa K, Lassoued A, Crowell JA and Miller DT (2019) Cone photoreceptor classification in the living human eye from photostimulation-induced phase dynamics. *Proceedings of the National Academy of Sciences* **116**: 7951–7956. doi: 10.1073/pnas.1816360116.

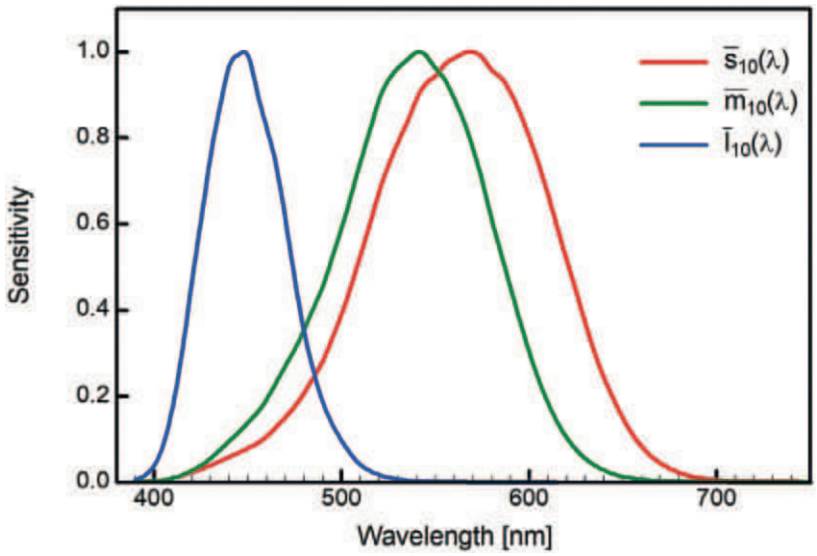

Fig. 2 Cone fundamentals for observation at 10 degrees field of view. Data from Stiles WS and Burch JM (1959) N.P.L. Colour-matching investigation: Final report (1958). *Optica Acta: International Journal of Optics* **6**: 1–26. doi: 10.1080/713826267.

quantity of radiance with the physiological perception of color. For details of this transformation refer to the "Supplementary Material" in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00041-4.

Based on the CMFs, the International Commission on Illumination (CIE) published in 1931 the so-called chromaticity diagram which allows visualizing all colors in a two-dimensional plot (Fig. 3). Its curved boundary represents monochromatic light, while its straight edge from 380 to 700 nm has no physical counterpart and is called the line of purples. CIE 1931 is still the most widely used color space despite several updates and physiology-based approaches to color specification. For printing and projecting colors or displaying them on a monitor, the CIE 1931 color space has to be transformed to a technical color space like sRGB (IEC 61966-2-1, 1999).

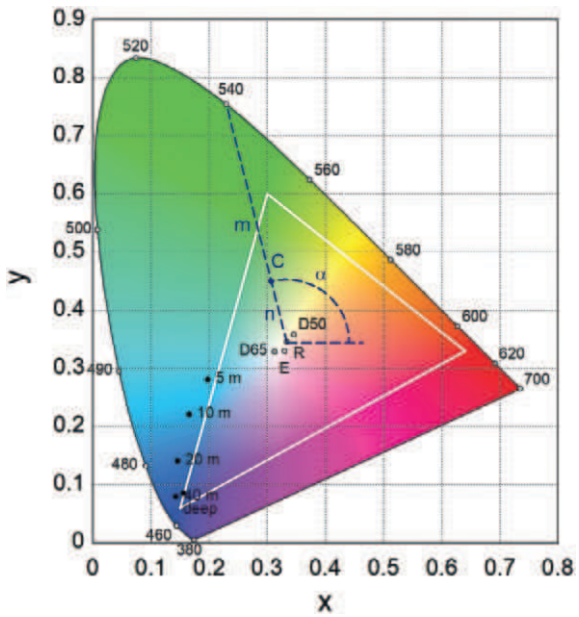

Fig. 3 The CIE 1931 chromaticity diagram. The triangle indicates the technical sRGB space for displaying colors. Equal energy point E and daylight spectra D50 and D65 are common references for white light, and R represents white for reflectance-based colorimetry. The angle α of a color C is termed hue, and the ratio n/(n + m) is called saturation; both depend on the chosen white reference. Black points: Perceived colors for a white object seen at different depths in clear, blue water.

Spectral radiance and irradiance

Spectroradiometers sample emitted, transmitted or reflected light with reference to the spectral domain. They typically comprise a monochromator that diffracts or disperses panchromatic light into distinct spectral wavelengths, and a photodetector or array of detectors that converts the monochromatic light into current. The most widely used radiometric measures are radiance and plane irradiance (Mobley, 1994). Spectral radiance L in a given direction is the fundamental radiometric quantity, from which all other radiometric quantities can be derived. It is defined with reference to position $\vec{x}$, time t, pointing direction $\hat{\xi}$ and wavelength λ as:

$$L\left(\vec{x}, t, \hat{\xi}, \lambda\right) \equiv \frac{\Delta Q\left(\vec{x}, t, \hat{\xi}, \lambda\right)}{\Delta t\, \Delta A\, \Delta\Omega\, \Delta\lambda}$$

Where ΔQ is the sampled energy, Δt is the sampling time, ΔA the detector area, $\Delta\Omega$ the solid angle of the field of view, and $\Delta\lambda$ the spectral sampling interval. The plane irradiance E is the hemispherical integral of L weighted by the cosine of each photon's incidence angle, as sensed by a plane collector. Down-welling plane irradiance represents the light incident on a flat surface, for example as down-welling irradiance E_d at top of atmosphere or ground level (Fig. 4).

In aquatic remote sensing, the parameter of interest is the water-leaving radiance L_w, a virtual quantity that corresponds to the upwelling radiance above a water surface L_u, minus the surface reflected radiance L_{surf} (Fig. 5, left). The upwelling radiance observed by spaceborne sensors at top-of-atmosphere L^{TOA} consists of L_w after atmospheric transmission t_A, and path radiance L_{path} from atmospheric scattering (Fig. 5, right). The sum of L_{surf} and L_{path} is typically one to two orders of magnitude higher than L_w, particularly in the blue, and must thus be accounted for when interpreting the color of surface waters.

Multispectral satellite sensors for land remote sensing (e.g., Landsat-8 OLI, Sentinel-2 MSI) provide high spatial resolution but a limited number of spectral bands that sample relatively large wavelength intervals, similar to the human eye (see Sections "Sensitivity of the human eye" and "Spectral reflectance"). Multispectral sensors for ocean color remote sensing (Aqua/Terra MODIS, Sentinel-3 OLCI) feature narrower spectral bands and higher radiometric accuracy at the expense of spatial resolution. Hyperspectral sensors acquire images in hundreds of contiguous, registered, spectral bands such that for each pixel a radiance spectrum can be derived (Goetz et al., 1985).

Spectral reflectance

Spectral reflectance is the ratio of upwelling to down-welling radiant fluxes for given surface, illumination and observation properties, including the sensor's spectral sampling properties. Similar to the human eye's brightness and chromatic adaptation, such normalization by a down-welling flux helps the interpretability of reflectance as opposed to the radiance reflected by a given target (Mobley, 1994). Reflectance is directionally variable and defined using conical and hemispherical incidence and exitance integrals (Schaepman-Strub et al., 2006). Aquatic reflectances in particular are defined with reference to the air-water interface. Remote sensing reflectance R_{rs} is most frequently used:

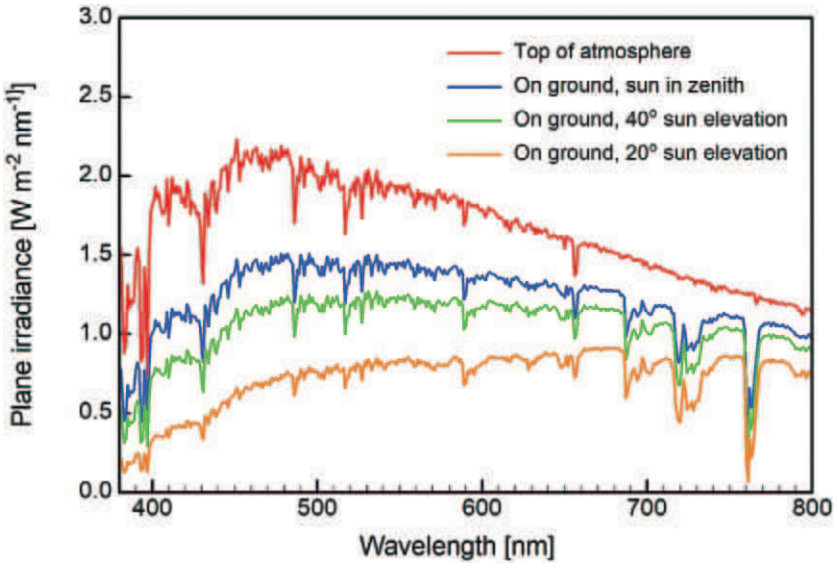

Fig. 4 Spectral plane irradiances at mean earth-sun distance. The resolution is 1 nm. The irradiances on ground were calculated for Sea level, a horizontal visibility of 15 km, an ozone concentration of 300 Dobson units and a scale height of precipitable water of 2.5 cm.

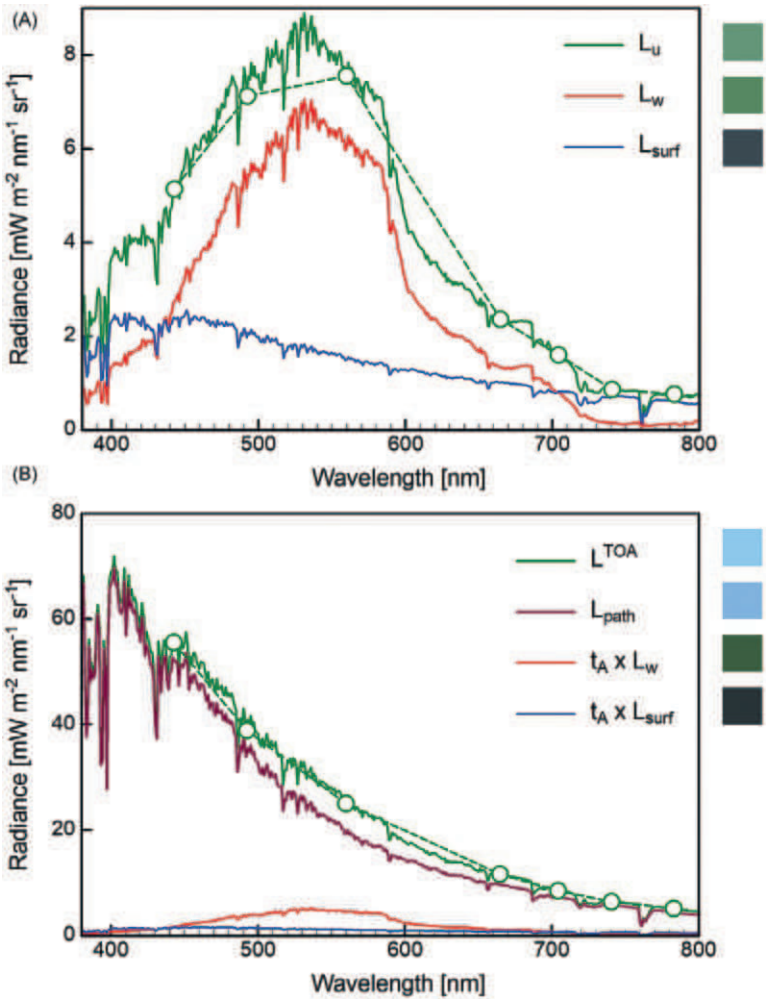

Fig. 5 MODTRAN simulated aquatic radiance spectra at bottom (A) and top of atmosphere (B). Solid lines are hyperspectral, dashed lines are resampled with Sentinel-2 band response. Plain squares indicate the human color perception for each spectral radiance.

$$R_{rs}(\lambda) = \frac{L_w(\lambda, \theta, \phi)}{E_d^{0+}(\lambda)}$$

Where L_w is water-leaving radiance in units W m^{-2} nm^{-1} sr^{-1}, i.e., the fraction of upwelling radiance passing the air-water interface in zenith direction θ and azimuth direction ϕ. E_d^{0+} is the plane down-welling irradiance just above the same interface. L_w cannot be measured but needs estimation from radiance measurements acquired just above or below the water surface.

Reflectance is a common parameter in remote sensing. It is accessible from satellite observations after compensation of atmospheric and air-water interface effects (Fig. 6), as well as from radiative transfer modeling using the constituents' absorption and scattering properties together with the light distribution of the incident light (Mobley, 1994). As reflectance is an illumination-corrected color property, it is much better suited to visualize changes of environmental parameters than radiance. For this reason, reflectance-based colorimetry has been introduced in remote sensing, which uses $R_{rs}(\lambda)$ instead of $L(\lambda)$ in the equations defining the CIE tristimulus values X, Y, Z. This corresponds to a spectrally constant illumination. Fig. 3 shows that the chromaticity coordinates of this fictive light source (x = 0.334, y = 0.346) lie between the daylight spectra D50 and D65, hence reflectance-derived colors approximate well the colors perceived by the human eye. For many multispectral satellite sensors, the hue angle (definition see Fig. 3) has been implemented as a measure of water color (Van der Woerd and Wernand, 2018). It correlates in a nonlinear way with the concentrations of colored dissolved organic matter (CDOM) and chlorophyll-a (Van der Woerd and Wernand, 2018).

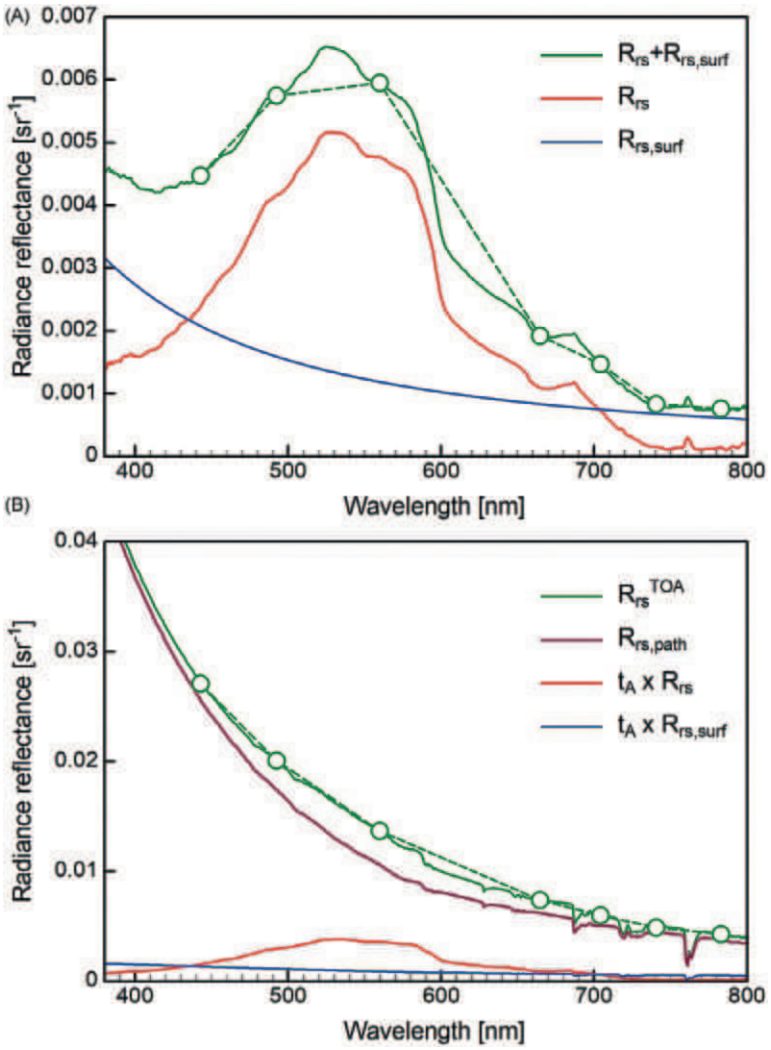

Fig. 6 Remote sensing reflectance spectra at bottom (A) and top of atmosphere (B). Solid lines are hyperspectral, dashed lines are resampled with Sentinel-2 band response.

Bio-optical modeling

Inherent and apparent optical properties

Equations relating the concentrations of water constituents to the optical properties of a water body are called bio-optical models to acknowledge the omnipresence of biological components (Morel, 2001). Two types of optical properties can be distinguished according to Preisendorfer (1961), Inherent Optical Properties (IOP) and Apparent Optical Properties (AOP).

IOP are distinct properties of water and its optically active components, such as absorption (a) and backscattering (b_b). Fig. 7 shows a and b_b for pure water and three common components: the colored fraction of dissolved organic matter (CDOM), phytoplankton and non-algal particles (NAP). The individual components' IOPs add up to the bulk IOP of natural water. All components absorb and scatter light across the entire visible spectral range, which complicates their individual estimation from optical measurements.

AOP depend additionally on the ambient light field and the viewing geometry, and they are related to the bulk processes of light transmission, reflection and extinction. Depending on illumination and viewing geometry, different definitions are used for the same process to account for the geometric conditions of the actual measurement setup. For example, nine definitions exist for the reflection at solid surfaces (Schaepman-Strub et al., 2006). When the human eye or a radiance sensor observe a horizontally extended object under natural outdoor illumination conditions, the most appropriate definition for reflection is the ratio of upwelling radiance (L_u) to plane down-welling irradiance (E_d). This ratio is known in the land community as hemispherical–conical reflectance factor (HCRF), and in the water community as remote sensing reflectance excluding reflections at the water surface. The ratio is different for measurements above the water surface (R_{rs}) and below (r_{rs}).

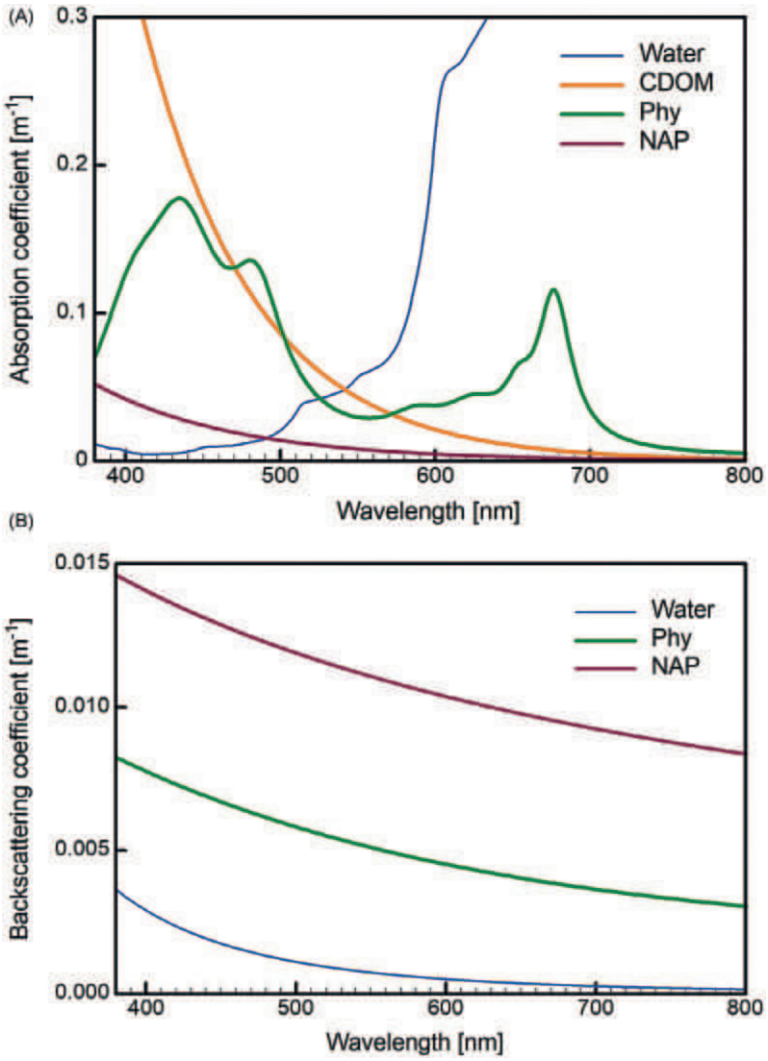

Fig. 7 Absorption (A) and backscattering coefficients (B) for oligo- to mesotrophic water, with 0.2 m^{-1} CDOM at 440 nm, 5 mg m^{-3} phytoplankton (phy) and 1 g m^{-3} non-algal particles (NAP).

Radiative transfer modeling

The radiance reflected by an object in the natural environment cannot be calculated exactly because the underlying radiative transfer equation (RTE) has no analytical solution for all practical situations. In hydrologic optics, L_u depends on the details of atmospheric conditions, the water surface geometry and the spatial distribution of a variety of molecules and particles in the water. The RTE can be solved approximately using coupled models of the atmosphere, the water surface, the water body, and in case of shallow waters, additionally of the bottom. Zhai et al. (2009) provide an overview of methods to solve the RTE and radiative transfer codes available for a coupled atmosphere-ocean system.

Several schemes are available for numerically solving the RTE in hydrologic optics, but the commercial software Hydrolight (Mobley, 1994) is most widely used. It is computationally too expensive for many applications in remote sensing, and the achievable accuracy is often limited by the variability in IOP rather than by numeric accuracy. RTE solvers are therefore often used to create a database of reference spectra for different combinations of the relevant environmental parameters. These pre-calculated spectra are then used as look-up tables and training data to derive analytical equations in the application case. Analytical equations obtained in this way are called semi-analytical models (Sokoletsky and Shen, 2014).

An example how R_{rs} of optically deep water depends on water constituents is given in Fig. 8 (Giardino et al., 2018). The plots were created using the publicly available software WASI (Gege, 2004) and its implementation of the semi-analytical R_{rs} model of Albert and Mobley (2003). The simulations are based on the IOPs of Fig. 7. Simulating r_{rs} or R_{rs} from known concentrations and IOP is called forward modeling, while obtaining IOP or concentrations from measured R_{rs} spectra is called inverse modeling. The inverse problem has often no unique mathematical solution (IOCCG, 2006) because different water compositions can produce very similar R_{rs} spectra.

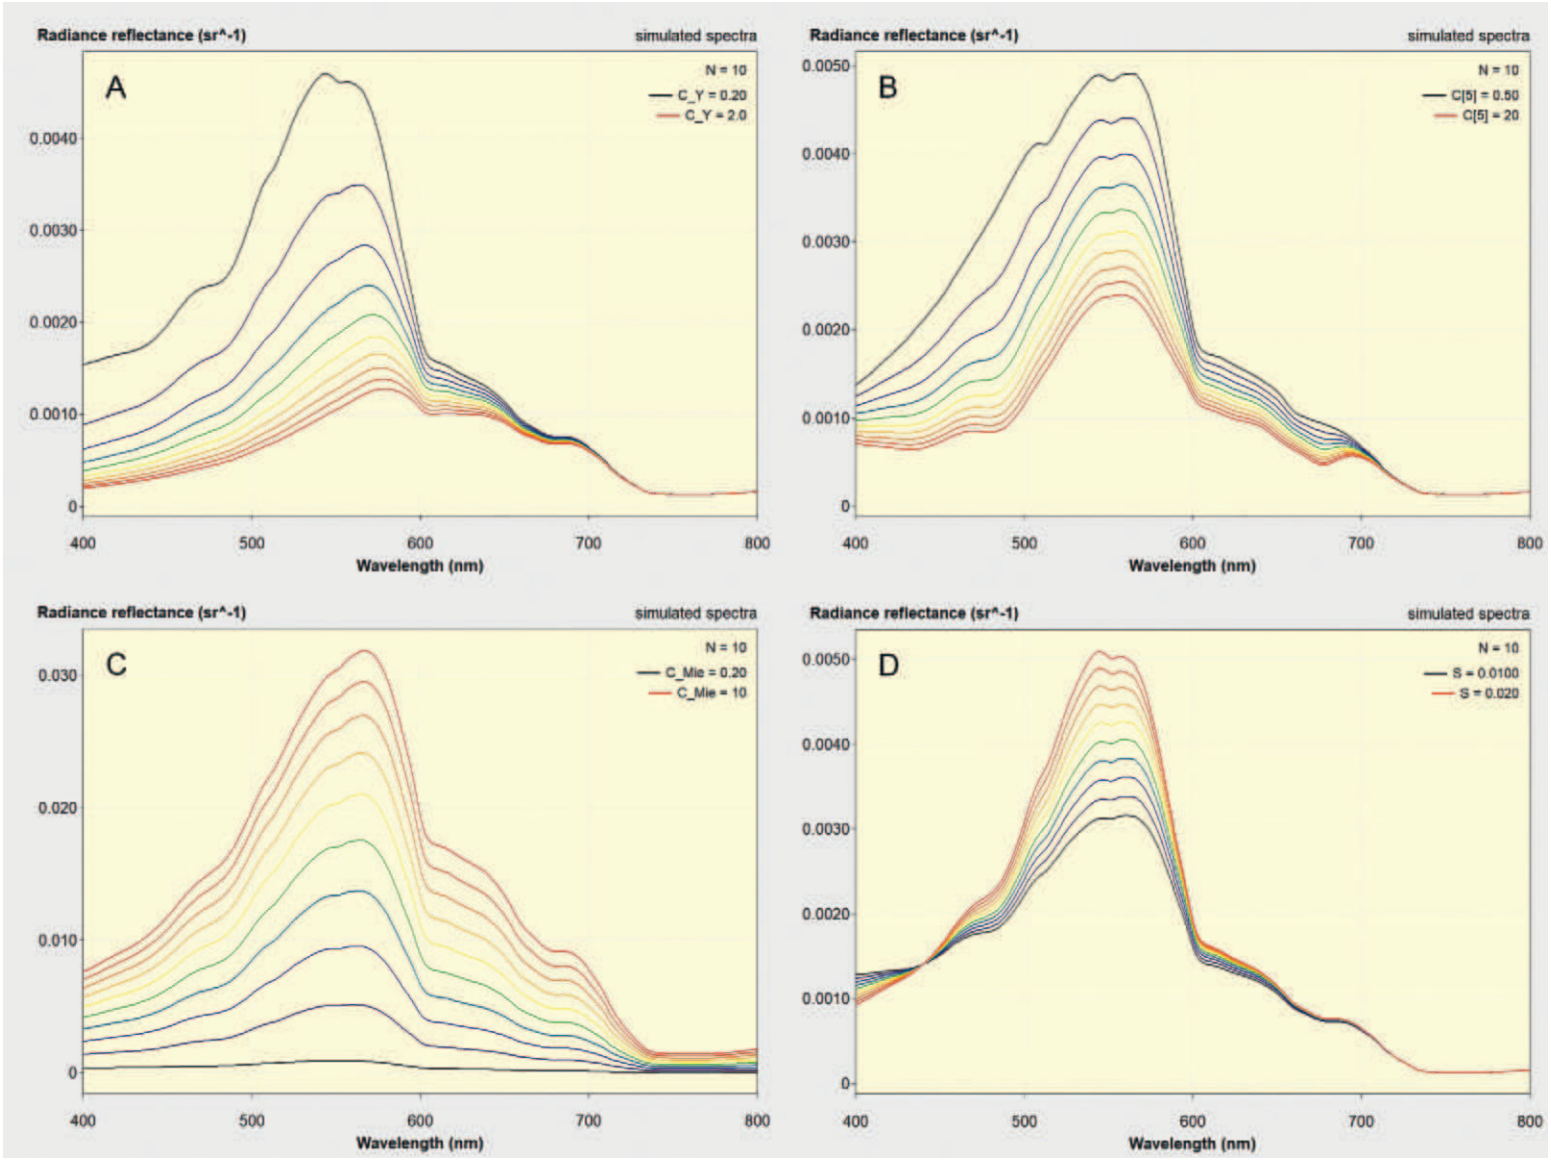

Fig. 8 Simulated remote sensing reflectance of optically deep water, using the IOP of Fig. 7 with alterations in one parameter per panel. (A) CDOM absorption at 440 nm, range 0.2–2 m^{-1}; (B) chlorophyll-a, range 0.5–20 mg m^{-3}; (C) NAP, range 0.2–10 g m^{-3}; (D) spectral slope of CDOM absorption, range 0.01–0.02 nm^{-1}. Bulk optical properties in aquatic research

Secchi depth

Since the 17th century, sailors and naturalists have lowered objects such as plates, tins, kitchen gear, painted thermometers or copper balls in the ocean, and recorded the depth at which they disappear (Wernand, 2010). Pietro Angelo Secchi (1864) advanced this measurement practice to a scientific standard. Secchi depth is usually measured with a white Secchi disk of 30 cm diameter in oceans, or a black and white Secchi disk of 20 cm size in lakes (Fig. 9).

Secchi disk measurements are relatively robust under different observation conditions, because the human eye adapts well to brightness variations of the ambient light. Secchi indicated that observation must be done at nadir over a water surface that is shaded by a ship or the observer. His suggestion to prevent surface reflectance by using an aquascope was however discarded in practical usage (Pitarch, 2020). The use of Secchi depth as a measure for water transparency recently experienced a revival in citizen science, for example in the scope of the Secchi disk study by the Secchi Disk Foundation, or the Secchi dip-in by the North American Lakes Management Society (see Supplementary Material in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00041-4).

According to classical visibility theory, the Secchi depth was hypothesized to be inversely proportional to the sum of the encompassed water's diffuse and beam attenuation coefficients. It was shown recently that the corresponding assumptions for visibility in air are inappropriate in water, and therefore the inverse of the average diffuse attenuation coefficient of radiance reflected by the target should be used to model Secchi depth (Lee et al., 2015). Secchi depth estimates are also available from satellite remote sensing, since both diffuse attenuation and R_{rs} can be expressed in terms of bulk absorption and scattering (Lee et al., 2016).

Forel-Ule scale

When lowering objects into surface waters, they not only disappear but also change their color due to the selective transmissivity at different spectral wavelengths. In the late 19th century, F. A. Forel and W. Ule proposed mixed chemical compounds to frame a comparator scale for the color of natural waters (Fig. 10). The resulting Forel-Ule color scale comprises of eleven standards with blue to green hues (FU 1–11) and ten standards with blue-green to brown hues (FU 12–21). The scale is used to match the color of a Secchi disk at half the Secchi depth, and is similarly popular in citizen science.

The preparation protocol for the reference compounds of the Forel-Ule color scale was recently revised, and transmission measurements allow transferring the standards to the CIE chromaticity diagram (Fig. 11) by means of hue angles and dominant

Fig. 9 Secchi disk being lowered into the water of Greifensee (Switzerland).

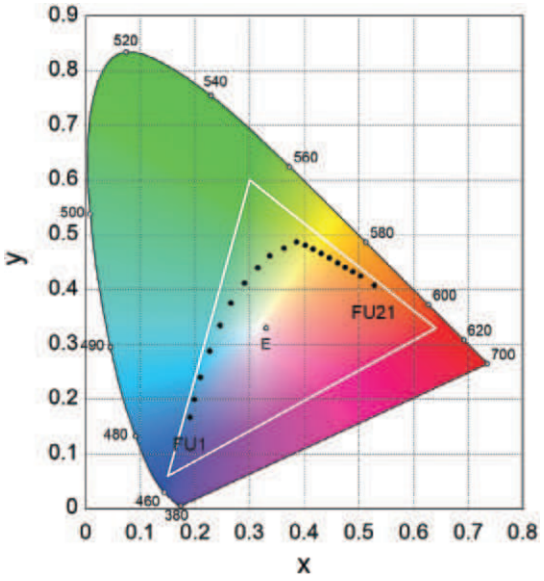

Fig. 11 Chromaticity diagram of the 21 FU standards. Based on Novoa S, Wernand MR and van der Woerd HJ (2013) The Forel-Ule scale revisited spectrally: Preparation protocol, transmission measurements and chromaticity. *Journal of the European Optical Society* **8**: 13057.

wavelengths (Novoa et al., 2013). Hue angles and dominant wavelengths can also be derived for remotely sensed R_{rs} (Van der Woerd and Wernand, 2018). By giving each hue angle a membership for its two radially adjacent Forel-Ule classes, reflectance can effectively be related to the Forel-Ule scale, which inspired the mapping of Forel-Ule classes from global Earth observation satellite data despite the scale's limited sensitivity to oligotrophic oceans (Pitarch et al., 2019).

Optical water types

Estimating water constituents from spectral reflectance is complicated by the diverse composition of natural surface waters, the diversity of their constituents, and the information content available in a limited number of spectral bands. Statistical clustering of reflectance spectra is an efficient means to improve the accuracy for an ensemble of retrieval algorithms against the background of missing universal solutions (Moore et al., 2014).

The optical water types obtained in such manner can be described in terms of their mean reflectance and typical bio-physical properties, such as the range of phytoplankton pigment concentrations or Secchi depths occurring for each of them. But the use of optical water typologies from reflectance clustering is currently limited to remote sensing signal interpretation. Most notably, the Copernicus Land Service provides trophic state estimates for more than 4000 lakes worldwide based on an ensemble approach for Optical Water Types (Neil et al., 2019; Spyrakos et al., 2018).

Remote sensing applications

Field spectrometry

Measuring reference reflectance with field spectrometers at ground level is a fundamental principle for remote sensing of all types of land cover. Such measurements, often referred to as ground truth, are used to validate satellite-observed, atmospherically corrected reflectance. Moreover, they serve as input for radiative transfer models that allow the calculation of expected upwelling radiance at the top of atmosphere, which can then be used to adjust the radiance measurements by satellites. This technique is referred to as vicarious calibration. More recently, advances in field spectrometer design promote ground measured reflectance and derived bio-physical parameters as a user-friendly water quality monitoring tool.

Vicarious calibration is essential for ocean color satellite missions, and a number of internationally coordinated programs aim to establish networks of operational ground-based facilities to acquire high-quality measurements of reference reflectance. The AERosol RObotic NETwork comprises of ground-based sun photometers for aerosol monitoring and part of the NOAA Observing System Architecture. It comprises of an Ocean Color component, AERONET-OC, whose observatories measure also water-leaving radiance in marine and lacustrine sites (Zibordi et al., 2010). RadCALNet by CEOS (https://www.radcalnet.org) and WATER-HYPERNET by ESA and BELSPO (https://waterhypernet.org/) federate similar networks of above-surface radiometers with multi- and hyperspectral resolution, respectively. The experimental Thetis profiler in Lake Geneva (Switzerland, Fig. 12) performs comparable measurements below the water surface while simultaneously acquiring IOP measurements.

Field spectrometer measurements are subject to lower uncertainty than atmospherically corrected satellite observations, and their spectral resolution is about one order of magnitude higher than most satellite sensors'. Therefore, water quality estimation from ground measured reflectance is a viable option for monitoring smaller water bodies, where the spatial resolution provided by satellites is dispensable. Various spectroradiometers can be used for this purpose, including those designed for satellite vicarious calibration measurements, as well as less precise but more user-friendly handheld devices (Hommersom et al., 2012). A main limitation of this approach, sometimes referred to as close-range remote sensing, is the compliance of methodologies and the water quality parameters they yield with monitoring requirements and sampling protocols (Bowling et al., 2017).

Satellite Earth observation

Color represented by reflectance is perhaps the most pivotal parameter in satellite remote sensing. For decades it has been input to most methods for the retrieval of water quality parameters in deep, or benthic substrates in shallow waters. The Steering Committee of the Global Climate Observing System (GCOS) is evaluating lake color in terms of spectral water-leaving reflectance as an Essential Climate Variable (ECV; WMO, 2016). In fully normalized form, water-leaving reflectance is independent of Earth-Sun distance, illumination angle and atmospheric attenuation and hence comparable (Gordon and Wang, 1994).

Satellite sensor measurements are affected by distinctive atmospheric effects, viewing angle and sun elevation dependence (see also Fig. 5). Backscattering by gas molecules and aerosols can easily exceed the signal reflected on the ground, especially over dark targets such as water bodies, and in short wavelengths. In consequence, surface waters appear brighter and their hue is usually blue when seen from space (Fig. 13, top). These effects can be rectified using image-based estimates of atmospheric optical density, which yields a water body's outer sight (Fig. 13, bottom). The water's true color is revealed when also reflection and refraction at the air-water interface are accounted for, which shifts the hue further towards long wavelengths, and yields often green to brown colors (Fig. 5, right and Fig. 13, bottom).

Colorimetry provides a framework for color calculations with reference to the light spectrum as resolved by cone fundamentals. This allows a representation of spectral reflectance vectors as scalars such as hue angle or dominant wavelength (Fig. 14, left), and ultimately as Forel-Ule classes (Fig. 14, right). Based on this approach, lake color inventories from satellite remote sensing are

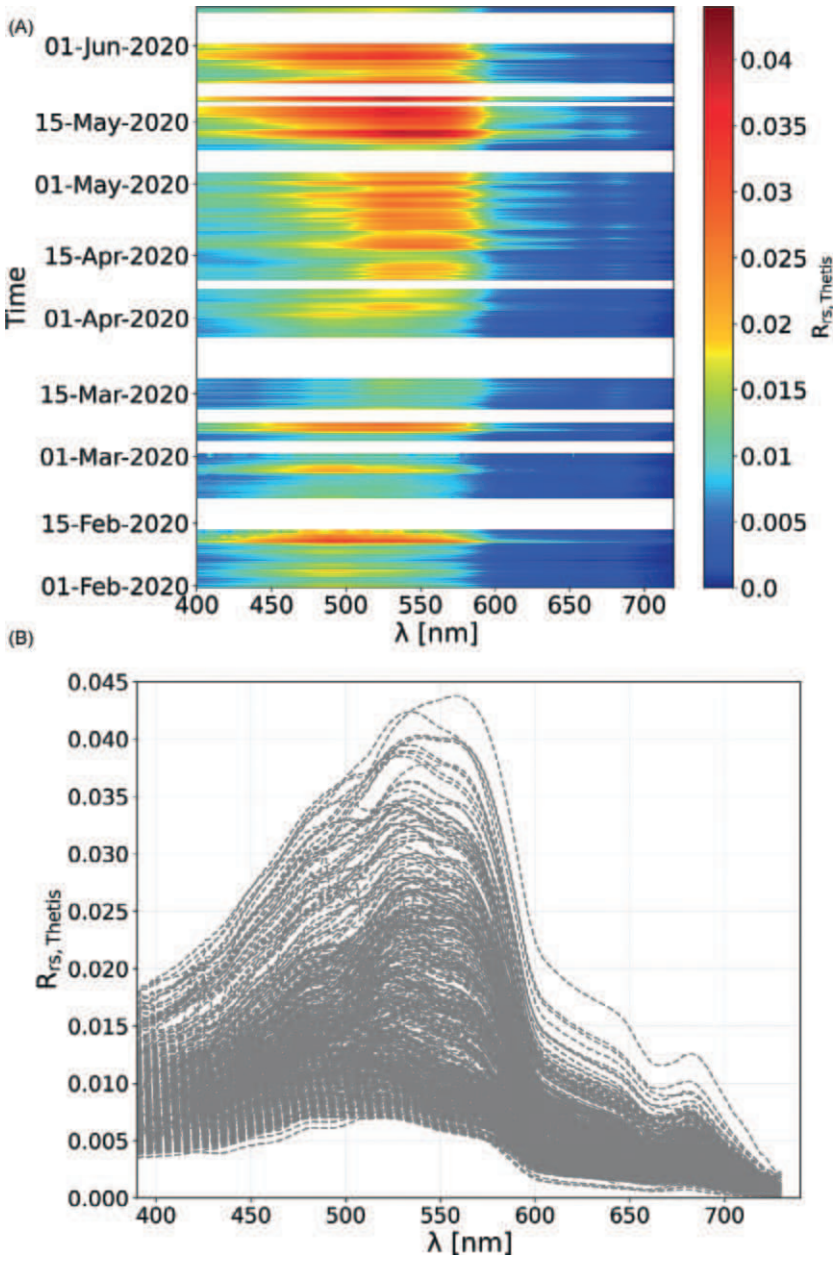

Fig. 12 Spectral remote sensing reflectance measured by the Thetis profiler in Lake Geneva (Switzerland). (A) Reflectance magnitudes increase with phytoplankton growth both seasonally and incidentally. (B) Due to higher chorophyll-a content, higher reflectances feature lower blue-to-green ratios and more prominent absorption and fluorescence emission features at 650–700 nm. Courtesy A. Irani Rahaghi and C. Minaudo.

available for lakes in New Zealand (Lehmann et al., 2018), as well as for lakes (Topp et al., 2021) and rivers (Gardner et al., 2021) in the United States. They convey visible, large-scale changes in lake water quality in the most impressive manner. It should be noted that the definition of colorimetric products is not as rigorous as for water-leaving reflectance and other spectro-radiometric parameters. They imply that the reflectance acquired by opto-electronic sensors corresponds to the radiance perceived by human eyes and cognition. Nonetheless, the emerging, indicative use of colorimetry algorithms in remote sensing might revive color assessments despite the fading use of the Forel-Ule scale in monitoring practice.

Secchi depth is a widely-used indicator for transparency monitoring, for example with regards to the Sustainable Development Goals (Shen et al., 2020). It is also used in the forcing of hydrodynamic models (Baracchini et al., 2019). Remote sensing algorithms based on the revised optical theory for Secchi depth retrieval (Lee et al., 2016) are accordingly popular, and their use was demonstrated in dozens of lake-specific studies. Latest advances in algorithm development should also enable larger scale application through a revised parameterization of attenuation anisotropy (Jiang et al., 2019).

Synthesis

Measuring and interpreting water color under natural illumination comes with challenges that can be addressed both empirically and analytically. Robust, empirical techniques based on the human perception of color, namely Secchi depth and the Forel-Ule scale, provide low-threshold water quality monitoring techniques for a large audience. Remote sensing techniques, on the other hand, comprise measurements and retrieval methods that are based on a rigorous framework of radiant definitions and radiative transfer equations, which are predominantly used by Earth observation specialists. They allow for the retrieval of bio-physical parameters such as water-leaving reflectance or chlorophyll-*a* concentration, which feed directly into recent global environmental monitoring initiatives such as GCOS or the UN Agenda for Sustainable Development. The further development of such techniques is thus the main priority. Remote sensing and measures based on human color perception are however theoretically linked by the colorimetry framework, and practically complementary in many use cases.

Knowledge gaps

- How are the Forel-Ule classes, the Optical Water Types and the bio-physical properties of ambient waters related to each other?

Currents in Well-Mixed Layers

Marco Toffolon, Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie-Elodie Perga and Damien Bouffard.

Glossary

Anisotropy Property of being directionally dependent, as opposed to isotropy; for instance, turbulent fluxes are typically dependent on the direction (in particular, vertical vs. horizontal).
Barotropic flow A flow that it is driven by the horizontal gradient of the free-surface elevation.
Circulation Large-scale description of the currents occurring in a lake.
Coriolis acceleration/force Fictitious acceleration of particles moving in a rotating frame of reference. Earth rotation tends to deviate the flow to the right (left) in the northern (southern) hemisphere.
Eddy viscosity Space- and time-dependent coefficients that relate the average shear stress within a turbulent flow to the velocity gradient (first proposed by Boussinesq in 1877), formally analogous to the kinematic viscosity in laminar flows for Newtonian fluids.
Gyre A circular pattern of currents at the surface of or within a water body.
Momentum Product of mass and velocity of a particle, its time derivative is a force; in fluid dynamics, momentum equations formulated for the continuum mechanics are the equivalent to the Newton's second law of motion for particles.
Newtonian fluid A fluid in which the shear stresses are linearly related to the local shear rate, so that viscosity is constant and independent of the stress.
Secondary circulation A component of the flow field that develops as a result of the interaction between the dominant velocity (e.g., directly driven by the wind) and other physical processes (e.g., Coriolis acceleration).
Stratification Vertical structure of the water column with layers of different density; in a stable stratification, water density increases downwards (in the direction of gravity acceleration).
Turbulence Fluid motion characterized by instability that results in chaotic changes in pressure and flow velocity, which strongly enhance momentum exchange (a process modelled using eddy viscosity, depending on the flow field); different from the laminar flow occurring in parallel layers, where momentum is transferred only by means of dynamic viscosity (a property of the fluid).

Introduction

Understanding lake circulation

Water movements in lakes are generated and controlled by forces acting both on the boundaries of the water body (free surface, lake bottom) and within its volume. The wind stress on the lake surface is often the most important force producing a direct circulation, but other processes can interact with it or even predominate in specific conditions. An emblematic example is the effect of the heat exchanged with the atmosphere (or with the bottom sediments) which, by altering the water density locally, can produce convective motions (buoyancy-driven flows) leading to complete lake overturn in some cases. Another important contribution may come from inflowing waters, which introduce fluxes of mass, momentum and heat into the lake: especially during floods, the effect on the lake's movements can be substantial. Factors such as the spatial variation of the atmospheric pressure or the presence of tides are usually considered unimportant unless the lake is extremely large. In addition, water movements can be affected by the Coriolis effects due to Earth rotation.

From this introductory description, it appears that the prediction of currents in lakes is a difficult task, which depends on many physical factors and on the atmospheric forces exerted at the air-water interface. Nowadays, numerical models are routinely used to simulate the transport within lakes, but a proper exploitation of their capabilities requires both experience about the model and in-depth understanding of the physical processes. Fig. 1 shows a beautiful example of a large gyre in Lake Geneva retrieved from

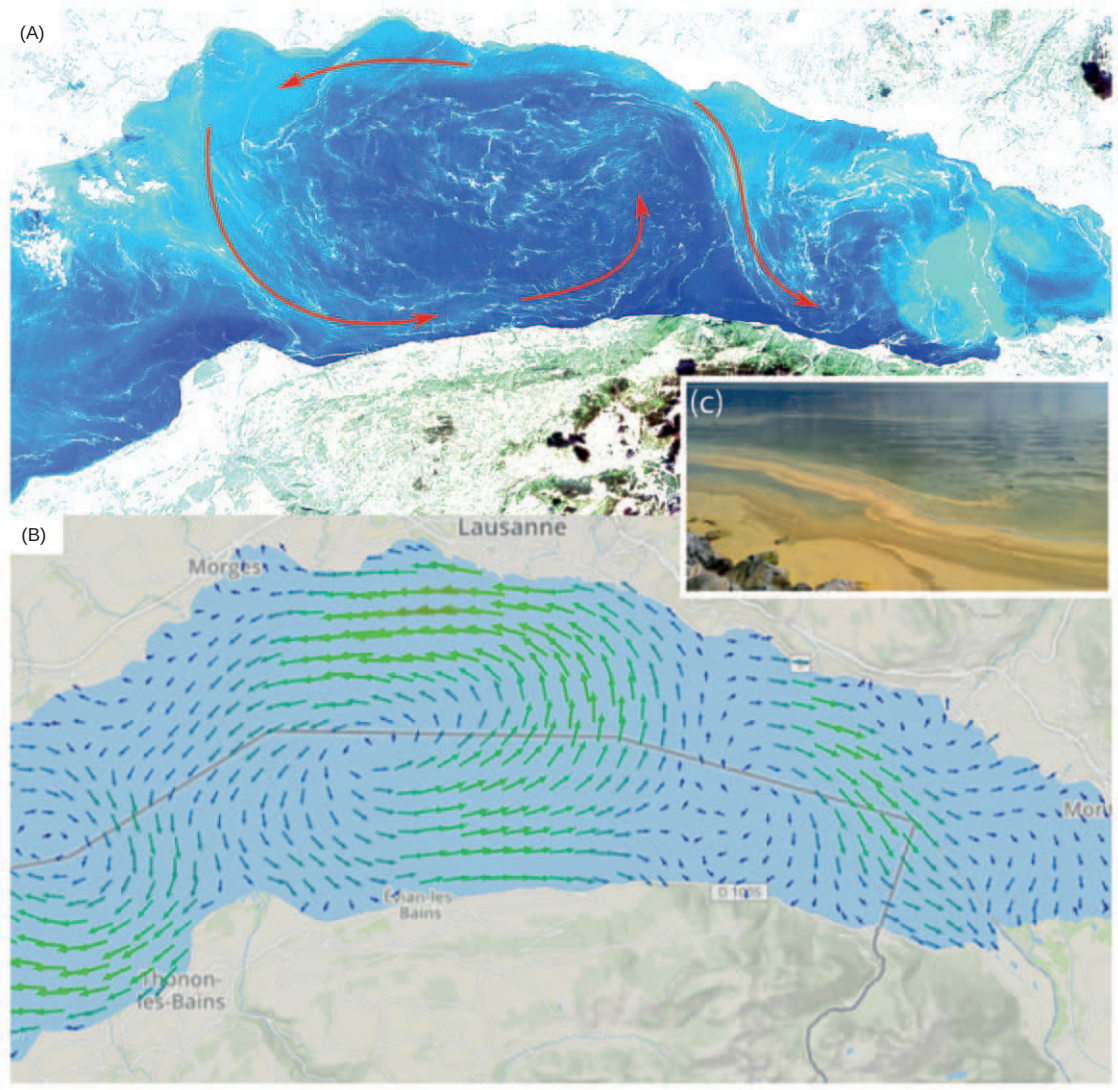

Fig. 1 An example of a large gyre in the central region of Lake Geneva (Switzerland-France) highlighted by the presence of pollen at the surface. (A) Satellite imagery from Sentinel 2, where colours have been altered to show the regions with higher concentration of pollen (lighter blue); red arrows represent a qualitative reconstruction of the main horizontal circulation. (B) Numerical simulation of the flow field obtained by Meteolakes (http://meteolakes.ch/); arrows represent the reconstructed velocity field, with colours tending to green indicating faster movements. (C) Source of pollen at the lake's northern shore (Photo: Hannah Chmiel, EPFL). Source: https://www.eawag.ch/en/news-agenda/newsportal/news-detail/pollen-reveals-huge-gyre-in-lake-geneva/, modified by altering the colours and adding the red arrows in panel A.

satellite imagery thanks to the presence of a large quantity of pollen, transported at the surface from the shores to the interior of the lake. Numerical simulations are able to reconstruct the main dynamics, even though some details cannot be captured exactly (Fig. 1B): at the current state of knowledge, a blind faith in numerical simulations is not recommended. Hence, it is essential to have a physical intuition of causes and effects, which is possible only by knowing the physics of the system and the limitations intrinsic in any model of the real world.

In this article, we aim at helping the inexpert reader to approach the physics behind water motion and the language in which it can be effectively described, i.e., the mathematics of partial differential equations (PDEs). As an introduction to such a challenging topic, we will refer to some simple cases that allow for analytical solutions. Due to lack of space, the derivation of these solutions is provided as Supplementary Material in Data 1 in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00012-8.

We will focus our attention on the case of spatially constant water density ρ (homogeneous water body, also indicated as well-mixed). However, it is essential to be reminded that water movements are strongly affected by the presence of density stratification, which in natural lakes is mostly associated with water temperature gradients, although dissolved substances can also alter the density significantly. In this context, the assumption of constant density can be limited to a single well-mixed layer, where—as a first approximation—the velocity field can be described by neglecting baroclinic effects, that is, those processes where gravity interacts with density gradients.

We will proceed even further with the simplifications and consider only the water motion that is induced by the action of wind at the lake surface. For this purpose, atmospheric models are increasingly used to provide proper boundary conditions to lake models. Although considering the spatial and temporal distribution of the wind is extremely important, here we examine only cases where the wind field is simplified. The simplest case is when the wind forcing is steady or can be approximated by analytical functions. Analytical solutions derived in this case serve as conceptual tools to understand the dynamics of more complex cases.

The transmission of forces in fluids

Wind-driven flows receive an input of momentum flux at the lake surface, which diffuses into the water body entraining the water below until possibly reaching a steady state (Fig. 2). In Newtonian fluids, when the flow is laminar (i.e., for sufficiently low values of the Reynolds number) this process is due to the viscous stress between adjacent water volumes moving with different velocity. For a unidirectional flow with velocity u varying only with z (please refer to Table 1 for the notation), the shear stress can be expressed as

$$\tau = \mu \frac{\partial u}{\partial z} \tag{1}$$

where the dynamic viscosity μ, or equivalently the kinematic viscosity $\nu = \mu/\rho$, is a property of the fluid at a given temperature.

Velocities in lakes are typically low. Nevertheless, the flow tends to be turbulent in most cases, especially where density stratification does not inhibit the vertical movements. The traditional procedure of averaging high-frequency turbulent oscillations leads to the appearance of additional stresses enhancing the exchange of momentum in the averaged flow field: they have been termed Reynolds stresses. In the so-called Boussinesq model, a Fickian closure (i.e., the same as in Eq. (1) for the viscous stress in laminar flows) is adopted for Reynolds stresses, introducing the concept of eddy viscosity in analogy with the kinematic viscosity. Then, the total shear stress is computed as

$$\tau = \rho(\nu + K)\, \frac{\partial \bar{u}}{\partial z} \tag{2}$$

where $\bar{u}$ is the turbulence-averaged velocity (hereafter, we will skip the overbar and use u in the general case to simplify the notation) and ν is negligible with respect to K in well-developed turbulent flows.

Different from the laminar case, the eddy viscosity K is not a property of the fluid, but of the flow itself, making it intrinsically variable in space and time. Turbulence models of various complexity have been developed since Reynolds' pioneering contribution in 1895 (e.g., Pope, 2000; Wilcox, 2006). Among them, algebraic relations for the eddy viscosity have been proposed to describe simplified conditions. We will rely on these approximations, and eventually adopt constant and uniform values, to derive analytical solutions.

Some questions

With all these simplifications in mind, we consider some idealized geometries to detect which processes primarily affect the development of the flow field. Having said that wind-driven flows are locally forced at the air-water interface, what modulates the global response of the water body? Which are the effects of a given morphology (i.e., bathymetry) of the lake? How important is the spatial distribution of the wind field? How does it interact with the turbulent exchanges and in particular their anisotropic behaviour? Does Earth's rotation affect the flow field, and in which cases can it be neglected? These are some of the questions we want to tackle in this article.

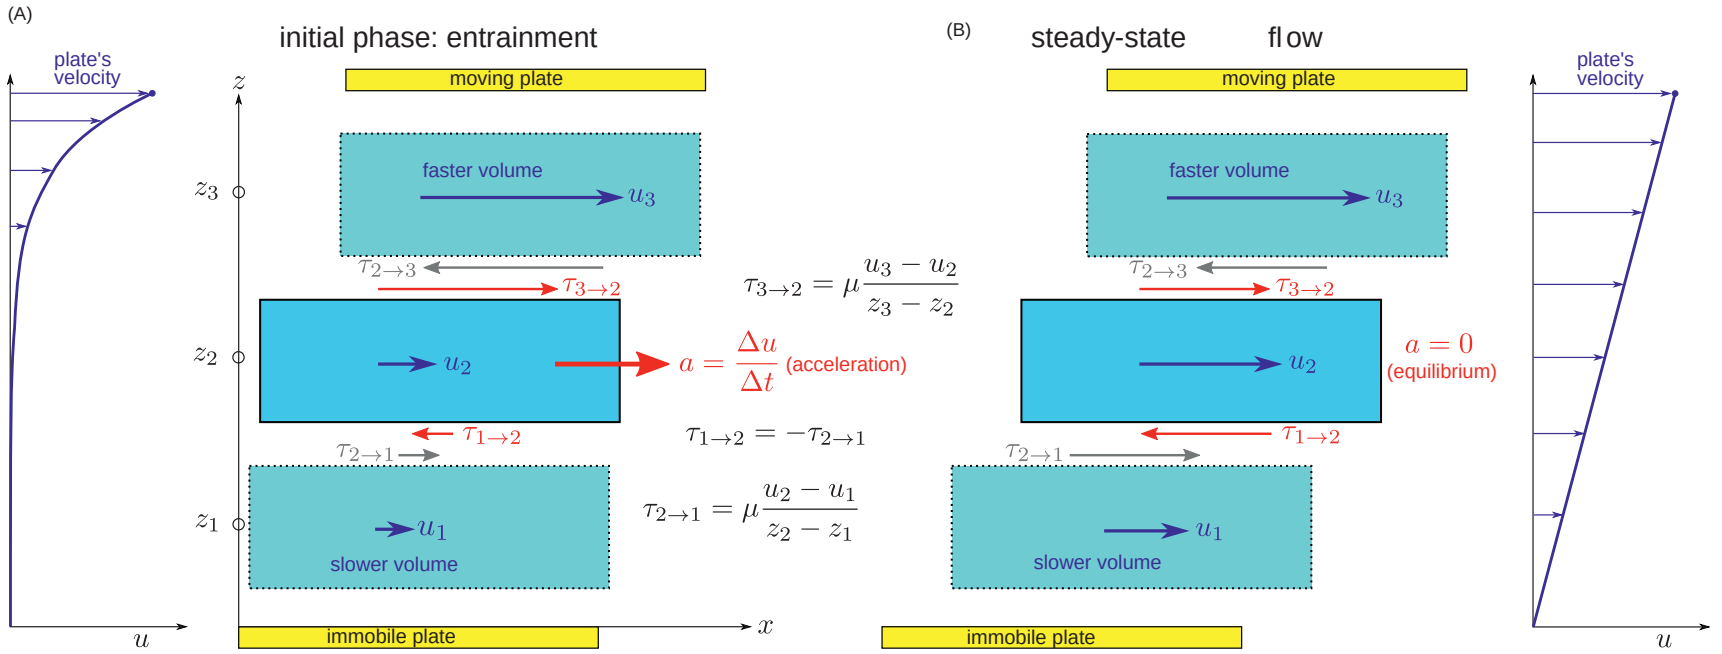

Fig. 2 Conceptual scheme illustrating the vertical transfer of momentum in a Couette laminar flow starting from still water in a Newtonian fluid. The figure considers only three layers, but the process is continuous along the vertical. (A) During the initial phase, the plate moving at the top entrains the upper volume (level z_3). The velocity difference with the central layer (level z_2) produces a shear stress that tends to accelerate it, while the slower volume at the bottom (level z_1) exerts a drag force that slows it down. The net force (for the central element having dimensions Δx and Δz, with $\Delta y = 1$) is $\rho \Delta x \Delta z\, a_2 = \tau_{3\to2}\Delta x - \tau_{2\to1}\Delta x$, which gives the acceleration $a = \rho^{-1}\, d\tau/dz$ in a continuous description. (B) A steady-state flow is reached when the central volume moves with a velocity for which the shear stresses at the top and at the bottom are balanced, and the same occurs for the lower layer, so that none of the layers is accelerated. Note that in a Newtonian fluid the shear stress depends on the difference between velocities and not on the relative displacement of the layers (different from a solid). The qualitative sketch is also valid for turbulent flows, where the momentum transfer is mostly due to eddy viscosity.

Table 1 List of symbols used in the article and their dimensional units (L: length, T: time, M: mass).

t	time	T	g	gravitational acceleration	LT^{-2}
x, y	horizontal coordinates	L	f	Coriolis parameter	T^{-1}
z	vertical coordinate (pointing upwards)	L	p	pressure	$ML^{-1}T^{-2}$
u, v	horizontal components of the velocity vector	LT^{-1}	ρ	water density	ML^{-3}
w	vertical component of the velocity (positive upwards)	LT^{-1}	ν	kinematic viscosity	L^2T^{-1}
U, V	depth-averaged velocities	LT^{-1}	A	horizontal (eddy) viscosity	L^2T^{-1}
h	depth of the layer	L	K	vertical (eddy) viscosity	L^2T^{-1}
η	free surface elevation	L	τ	shear stress	$ML^{-1}T^{-2}$
B	width (in the direction orthogonal to the main flow)	L	τ_w	wind stress at the free surface	$ML^{-1}T^{-2}$
W	wind speed	LT^{-1}	τ_b	shear stress at the bottom	$ML^{-1}T^{-2}$
ζ	depth-averaged vorticity	T^{-1}			

Governing equations

Shallow water approximation

Different approximations can be used to describe the flow field in natural water bodies such as lakes. The most general formulation for Newtonian fluids, like water, is given by the three-dimensional (3D) Navier-Stokes equations, which express the Newton's second law (i.e., acceleration is proportional to the net force, and inversely proportional to the mass) for the continuum. Unfortunately, these equations are not solvable in real cases because flow instabilities, known as turbulence (e.g., Pope, 2000), modify the internal forces. The Reynolds-Averaged Navier-Stokes (RANS) equations describe the average dynamics of turbulent flows by adopting closure relationships, as in Eq. (2), for the transfer of momentum, mass and energy due to turbulent fluctuations. The choice of the turbulence model for the eddy viscosity is a key issue for modern fluid dynamics.

In the so-called geophysical flows, the vertical scale of variation is typically much shorter than the horizontal scale (thence, the names "shallow water" or "long wave" approximations). Dimensional arguments suggest that the pressure p is hydrostatically distributed along the vertical direction. Hence, pressure is not explicitly present in the equations and can be obtained directly from the elevation η of the free surface (Fig. 3). For a homogeneous fluid (i.e., with constant density):

$$p(z) = p_0 + \rho\, g\, (\eta - z) \tag{3}$$

where the atmospheric pressure p_0 will be assumed uniform (and hence neglected) in the following considerations.

The governing equations for a homogeneous layer in direct contact with the atmosphere are reported in Table 2 (see equations of set *a*). As turbulence is typically anisotropic (the eddies' size is statistically smaller in the vertical direction, coherently with the

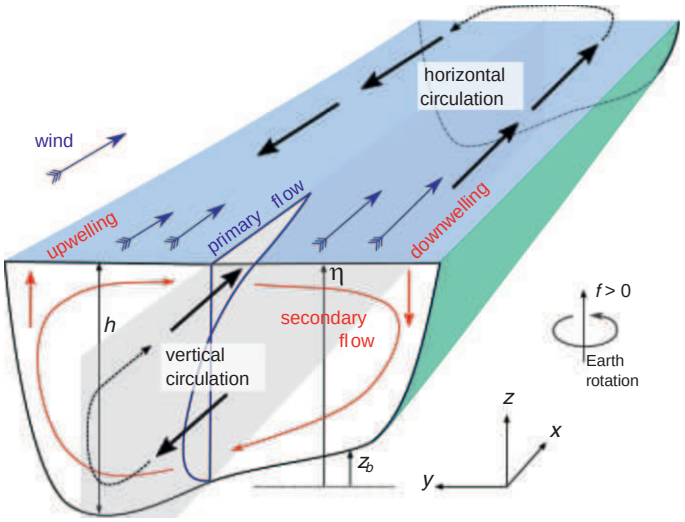

Fig. 3 Simplified geometry for the "trunk region" of an elongated lake, indicating the main notation used in the text. The primary flow can be divided into vertical (also identified as "conveyor belt" circulation, producing downwelling leeward and upwelling windward, see the grey-shaded region) and horizontal circulation (due to lateral variations of wind stress and depth). The secondary flow, due to the interaction of the primary flow with other forces (e.g., Coriolis), can produce upwelling and downwelling at the opposite shores.

Table 2 Governing equations mentioned in the text.

(*b*.2)	*y*-momentum	$\frac{\partial V}{\partial t} + U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} - fU = -g\frac{\partial \eta}{\partial x} + \frac{\partial}{\partial x}\left(A\frac{\partial V}{\partial x}\right) + \frac{\partial}{\partial y}\left(A\frac{\partial V}{\partial y}\right) + \frac{\tau_{wy}}{\rho h} - \frac{\tau_{by}}{\rho h}$
(*b*.3)	continuity	$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(Uh) + \frac{\partial}{\partial y}(Vh) = 0$
steady state, plane flow, longitudinally uniform, no Coriolis → uniform flow in the "trunk" region		
(*c*)	*x*-momentum	$0 = -g\frac{\partial \eta}{\partial x} + \frac{\partial}{\partial z}\left(K\frac{\partial u}{\partial z}\right)$
steady state, horizontally uniform, uniform eddy viscosity → Ekman spiral		
(*d*.1)	*x*-momentum	$-fv = -g\frac{\partial \eta}{\partial x} + K_0\frac{\partial^2 u}{\partial z^2}$
(*d*.2)	*y*-momentum	$-fu = -g\frac{\partial \eta}{\partial y} + K_0\frac{\partial^2 v}{\partial z^2}$
depth-averaged, steady state, longitudinally uniform, no Coriolis, → uniform flow in the "trunk" region		
(*e*)	*x*-momentum	$0 = -g\frac{\partial h}{\partial x}h + \frac{\tau_{wx}}{\rho} - \frac{\tau_{bx}}{\rho}$
unsteady, horizontally uniform, uniform eddy viscosity, no Coriolis → alternate wind		
(*f*)	*x*-momentum	$\frac{\partial u}{\partial t} = K_0\frac{\partial^2 u}{\partial z^2}$
unsteady, horizontally uniform → inertial currents		
(*g*.1)	*x*-momentum	$\frac{\partial u}{\partial t} - fv = -g\frac{\partial \eta}{\partial x}$
(*g*.2)	*y*-momentum	$\frac{\partial v}{\partial t} + fu = -g\frac{\partial \eta}{\partial y}$

[a]This approximation is not valid for flows in the equatorial region where f tends to vanish and the vertical velocity plays a role in equation (a.1).

shallow water approximation), the values of eddy viscosity along the vertical, K, and the horizontal, A, are different. In the shallow water approximation, only the x- and y-momentum equations are solved, while the z-momentum reduces to the pressure distribution (3). Then, the vertical velocity is retrieved from the continuity equation (*a*.3). The free surface η is unknown, and is usually obtained by the continuity equation integrated along the whole thickness $h = \eta - z_b$ of the homogeneous layer, with z_b the bottom elevation. This equation, labelled as (*b*.3) in the table, is expressed in terms of the depth-averaged two-dimensional (2D) velocity components $\{U, V\} = h^{-1}\int_{z_b}^{\eta}\{u, v\}\, dz$.

Steady-state approximation in a closed water body

Although the shallow water RANS equations are already a simplified version of the exact ones, they cannot be solved in general. One exceptional approximation that allows for obtaining analytical solutions is the assumption of a steady flow in a closed domain: in this idealized case, all variations in time are neglected. By dividing the domain into two parts with a surface S_γ having constant γ (but the derivation is valid for any cross-section, independent of the orientation), it directly follows from the integration of the continuity equation that the net exchange flow must be null (see Fig. 3 for the notation):

$$\int_{S_\gamma} u\, dA = \int_B U\, h\, d\gamma = 0 \tag{4}$$

Another way to interpret this condition is that the net flow must vanish as none of the two sub-domains changes its volume in time.

As a powerful conceptual tool, we will also refer to an idealized geometry used to derive analytical solutions in the past (e.g., Csanady, 1973): an elongated water body with a central prismatic "trunk region" where uniform conditions may be assumed along the main axis (x in Fig. 3) aligned with the wind. In order to help the reader understand the underlying physical processes, in the following sections we isolate the individual factors. We anticipate that all of them in general play a role in real water bodies.

Lake circulation: Unit processes

The purely vertical circulation

There is an idealized case that allows to obtain a simple analytical solution for a wind-driven flow. Let us assume a steady flow that develops exclusively in the x-z plane in an elongated lake, without any variability in the lateral direction y, neither in the geometry

nor in the forcing. Such assumption implies that we cannot consider the effect of Earth rotation, as it would couple the problem for u and v through the Coriolis acceleration. Let us further assume that, in the central trunk of this plane flow, uniform conditions are achieved, so that the continuity equation ($a.3$ in Table 2) implies that the vertical velocity is null. Hence, the x-momentum equation ($a.1$) reduces to

$$\frac{\partial}{\partial z}\left(K\frac{\partial u}{\partial z}\right) = g\frac{\partial \eta}{\partial x} \tag{5}$$

The first term describes the local imbalance between the shear stresses acting on the top and on the bottom of an infinitesimal water volume, due to velocity variations along the vertical (Fig. 2). The second term is the force resulting from the horizontal imbalance of the pressure (which is hydrostatically distributed, see Eq. 3), due to the free-surface slope. Two boundary conditions are to be specified to solve this second-order differential equation: (i) the wind stress at the free surface, τ_w; and (ii) a suitable representation of the flow resistance at the bottom, τ_b.

Fig. 4 illustrates the steady-state flow (please refer to the black lines initially; closure relations are reported in Table 3). Reconstructing the dynamics in time, we can think that the wind initially moves a thin layer of water at the surface (as in Fig. 2A). Then, the momentum is progressively transferred, by means of viscous or turbulent forces, downwards to the bottom, producing a velocity profile (Fig. 4C). The movement of the water determines a tilt of the free surface $\partial\eta/\partial x > 0$ (Fig. 4A). Integrating Eq. (5) along the vertical, we can see that three forces act on the water column:

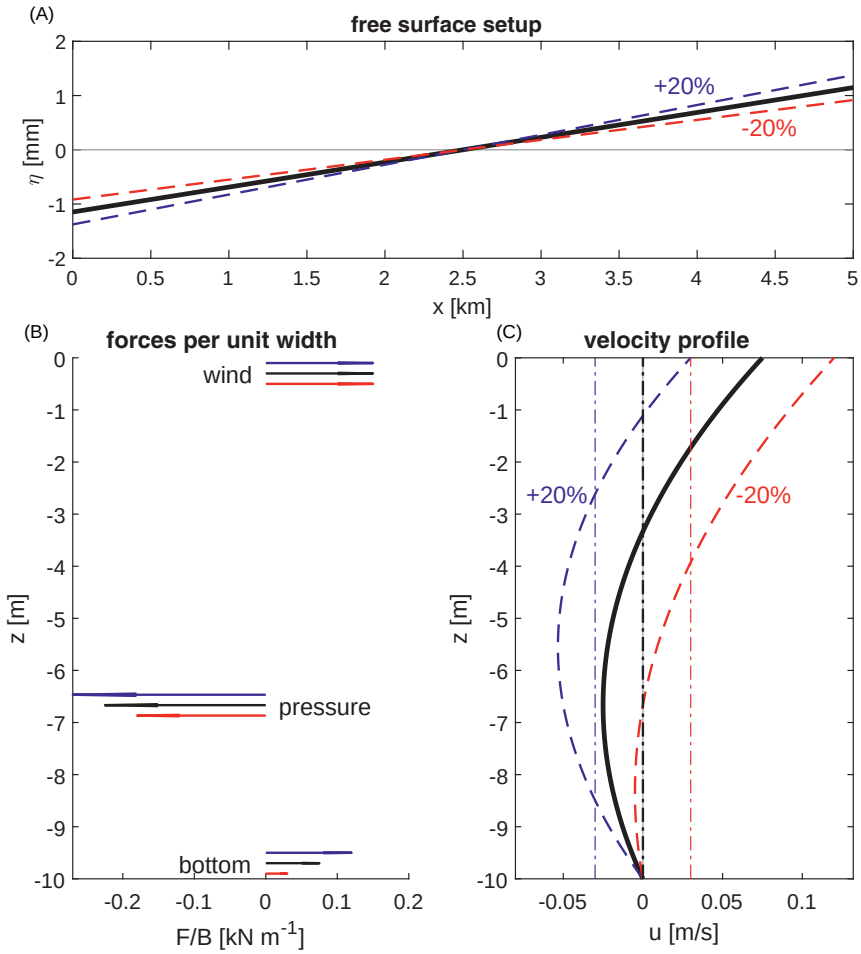

Fig. 4 Wind-driven, purely vertical, circulation for a plane flow in a closed basin, assuming steady-state conditions, uniform viscosity K_0, and no-slip ($u = 0$) at the bottom (thick black lines), compared with the results obtained altering the free surface setup by +20% (blue lines) and −20% (red lines), but for the same wind. (A) Free surface elevation along the basin respecting the steady-state condition (solid line) and modified (broken lines); note that the units are mm and km for the z- and x-axis, respectively, as the slope is very mild. (B) Force balance in the three conditions (total force F per unit width B; colours indicate the case), showing: wind force, pressure difference resulting from the free-surface slope, bottom drag (direction of the force as acting on the water). (C) Velocity profiles in steady-state balance (thick black line) and for modified setups (coloured broken lines); the corresponding depth-averaged velocity are plotted with dash-dot lines (note that only the steady-state balance respects the no-flux integral condition). [Main data: wind speed 5 m/s; depth 10 m; length 5 km; $K_0 = 10^{-3}$ m^2/s].

Table 3 Typical values and formulas for the physical parameters used in the text.

Variable	*Description/notes*	*Range of variation*
g	(approximately) constant	9.81 m/s
f	$=2\,\Omega \sin\varphi$, where:	$O(10^{-4})$ s^{-1} [a]
Ω	Earth rotation rate	7.2921×10^{-5} rad/s
φ	latitude	$-\pi/2$ to $\pi/2$
ρ	varying with temperature, pressure, dissolved substances	$\sim$1000 kg m^{-3}
A	dependent on (turbulent) flow field	$O(10^{-2}-10^{1})$ m^2/s [b]
K	dependent on (turbulent) flow field and stratification	$O(10^{-6}$–$10^{-1})$ m^2/s [b]
ν	depending on temperature	$\sim 10^{-6}$ m^2 s^{-1}
τ_w	$=\rho_a C_D W^2$, where:	$O(10^{-3}-10^{-1})$ N m^{-2} [b]
ρ_a	air density	$\sim$1.2 kg m^{-3}
C_D	drag coefficient, dependent on wind speed W	$O(10^{-3})$

[a]The symbol $O(.)$ refers to the order of magnitude of the quantity between brackets.
[b]The values are to be taken only as examples, as they depend on other variables.

$$\tau_w - \tau_b = \rho g \frac{\partial \eta}{\partial x} h \tag{6}$$

The three terms are represented in Fig. 4B as forces per unit width over the whole lake length. It is worth noting that the stress at the bottom is in the same direction of the wind stress and opposed to the horizontal component of the pressure force, as it represents the action of the boundary on the return flow in the lower part of the water column.

Assuming a null velocity at the bottom (no-slip condition) and a uniform $K \cong K_0$, Eq. (4) can be integrated twice to obtain the velocity profile

$$u(z) = \frac{z}{K_0}\left[\frac{\tau_w}{\rho} - g\frac{\partial \eta}{\partial x}\left(h - \frac{z}{2}\right)\right] \tag{7}$$

where, without loss of generality, we set $z_b = 0$ and $\eta = h$. Different profiles are possible depending on $\partial\eta/\partial x$, but only one is compatible with the requirement that $U = \int_0^h u\, dz = 0$ for a plane steady flow in a closed water body. This additional condition imposes that

$$\frac{\partial \eta}{\partial x} = \frac{3}{2}\frac{\tau_w}{\rho g h} \tag{8}$$

As a result, the downwind flow at the top is balanced by a return flow at the bottom, closing the vertical circulation exactly (the solution is reported in Table 4). The proportionality coefficient in Eq. (8) varies depending on the bottom boundary condition, being 3/2 only for the case of no-slip condition.

Fig. 4 also shows the effect of changing the free-surface setup $\eta(x)$ on the velocity profile: by increasing it (blue lines), the pressure force contrasting the flow becomes stronger and the flow is pushed back (see the negative depth-averaged velocity U in Fig. 4C). In the opposite case, flattening the free surface determines a net downwind flux, shifting a mass of water that will eventually rise the free surface downwind, thus tending to restore the equilibrium. By adding the water mass inertia to this process, periodic oscillations of the free surface can be described: they are known as *seiches* (see the last section of this article).

Despite being highly idealized, the steady-state plane flow solution helps understanding the physical driver of the return flow at the bottom and the forces acting in the system. The use of an algebraic closure for the eddy viscosity $K(z)$ does not modify the result that the shear stress varies linearly, but both the velocity profile and the setup change. The model can also be adapted to more than one layer (e.g., Heaps and Ramsbottom, 1966; Simons, 1980).

Table 4 Analytical solutions for the idealized steady-state flows in the "trunk" region.

Case	*Velocity*	*Shear stress*	*Free-surface setup*
General, with no-slip bottom boundary condition	$u = \frac{z}{K_0}\left[\frac{\tau_w}{\rho} - g\frac{\partial\eta}{\partial x}\left(h - \frac{z}{2}\right)\right]$	$\tau = \tau_w - \rho g \frac{\partial\eta}{\partial x}(\eta - z)$	$\frac{\partial\eta}{\partial x} = \frac{\tau_w - \tau_b}{\rho g h}$
Purely vertical plane flow	$u(z) = \frac{\tau_w}{\rho K_0}\frac{z}{4}\left(3\frac{z}{h} - 2\right)$	$\tau(z) = \frac{\tau_w}{2}\left(3\frac{z}{h} - 1\right)$	$\frac{\partial\eta}{\partial x} = \frac{3}{2}\frac{\tau_w}{\rho g h}$
Lateral variation of depth (with $A \cong 0$)	$u(z, y)$ as from the general solution with local $h(y)$	$\tau(z, y)$ as from the general solution with local $h(y)$	$\frac{\partial\eta}{\partial x}\int_0^B h^3(y)dy = \frac{3}{2}\frac{\tau_w}{\rho g}\int_0^B h^2(y)dy$
Lateral variation of wind stress (with $A \cong 0$)	$u(z, y)$ as from the general solution with local $\tau_w(y)$	$\tau(z, y)$ as from the general solution with local $\tau_w(y)$	$\frac{\partial\eta}{\partial x} = \frac{3}{2\rho g h B}\int_0^B \tau_w(y)dy$

Lateral vs. vertical circulation

The steady-state plane flow solution without lateral variations, derived in the previous section, can exist only in specific conditions of symmetry, which are violated in almost all real cases. In fact, four main factors may affect the velocity field: the morphology of the lake (i.e., bathymetric variations), the spatial variability of the wind forcing, the effect of Earth rotation, and the anisotropy of turbulent fluxes. All these factors induce a spatial variability of the flow field, both in the vertical direction (as in the previous case) and in the horizontal direction. While quite elaborated models have been proposed to analyse them (e.g., Simons, 1980; Winant, 2004), here we rely on the extension of the simple arguments introduced above.

Effect of variable depth

We start by showing the effect of a variable bathymetry in a real lake (Fig. 5), which has a round shape with a deeper region in the middle. The circulation that develops, represented in terms of depth-averaged velocity, is structured into two gyres, with the downwind flow at the shores and a return upwind current in the middle. How is it possible that the flow in the deeper region is against the wind? Although this case can be hardly described using a "trunk" approximation, we can exploit the idealized case to understand the underlying dynamics.

We focus on the effect of a lateral variation of the depth, neglecting Earth rotation and assuming a uniform wind over the lake. Moreover, we neglect the lateral exchange of momentum that a variable velocity would be subjected to (i.e., $A \cong 0$), which means isolating individual water columns (the effect of this assumption will be discussed later). Thus, in the trunk region, Eq. (5) continues to be valid locally, as well as the procedure to obtain the velocity profile (7). What is different is the variability of the depth $h(y)$, while the values of τ_w and $\partial\eta/\partial x$ do not vary along y (the former by assumption, the latter because a different slope would produce a lateral slope at different x). Therefore, $\partial\eta/\partial x$ can be determined as a function of τ_w by means of the integral condition (4) over the cross-section, yielding a balance similar to that in Eq. (7) but including the lateral variation of h (see Table 4). Hence, it is possible to determine the distribution of the shear stress and the flow field in the whole cross-section (Fig. 6).

Velocity with an opposite sign with respect to the wind occurs at the bottom in the deeper region (qualitatively similar to the vertical circulation in the plane flow), while the sign is aligned with the wind in the shallower region (Fig. 6B). Hence, a horizontal circulation should exist to balance the downwind flow in the shallow region (typically, close to the shore) with a return flow in the deep water (the lake's centre). This is immediately clear when looking at the depth-averaged velocity (Fig. 6D), which is negative (i.e., upwind) in the deep part.

Thus, even if the wind is spatially uniform, an overlap of horizontal and vertical circulations develops in water bodies with variable bathymetry. The horizontal circulation can be represented in a two-dimensional plane by means of the depth-averaged velocity, which is obtained by integrating Eq. (7) along the depth,

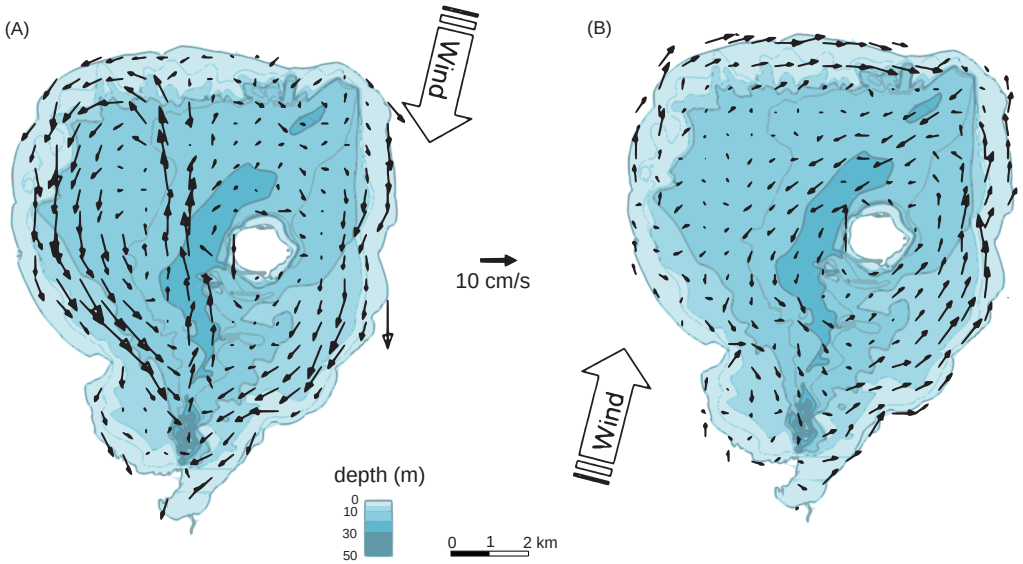

Fig. 5 An example of the two-gyre structure of wind-driven circulation depending on the variable bathymetry in Lake Rotorua, New Zealand. Arrows within the lake outline denote depth-averaged current speed and direction obtained from a 2D numerical model. The deeper region at the centre accommodates the return up-wind current, while currents are directed as the wind in the shallower coastal regions, both for northerly (A) and southerly (B) winds. Note that two different wind directions were considered, but the wind was assumed spatially uniform. The mechanism is the same as for the idealized model in Fig. 6. Modified from Gibbs M, Abell J and Hamilton D (2016) Wind forced circulation and sediment disturbance in a temperate lake. *New Zealand Journal of Marine and Freshwater Research*, 50 (2): 209–227. DOI: 10.1080/00288330.2015.1116998, combining two different figures.

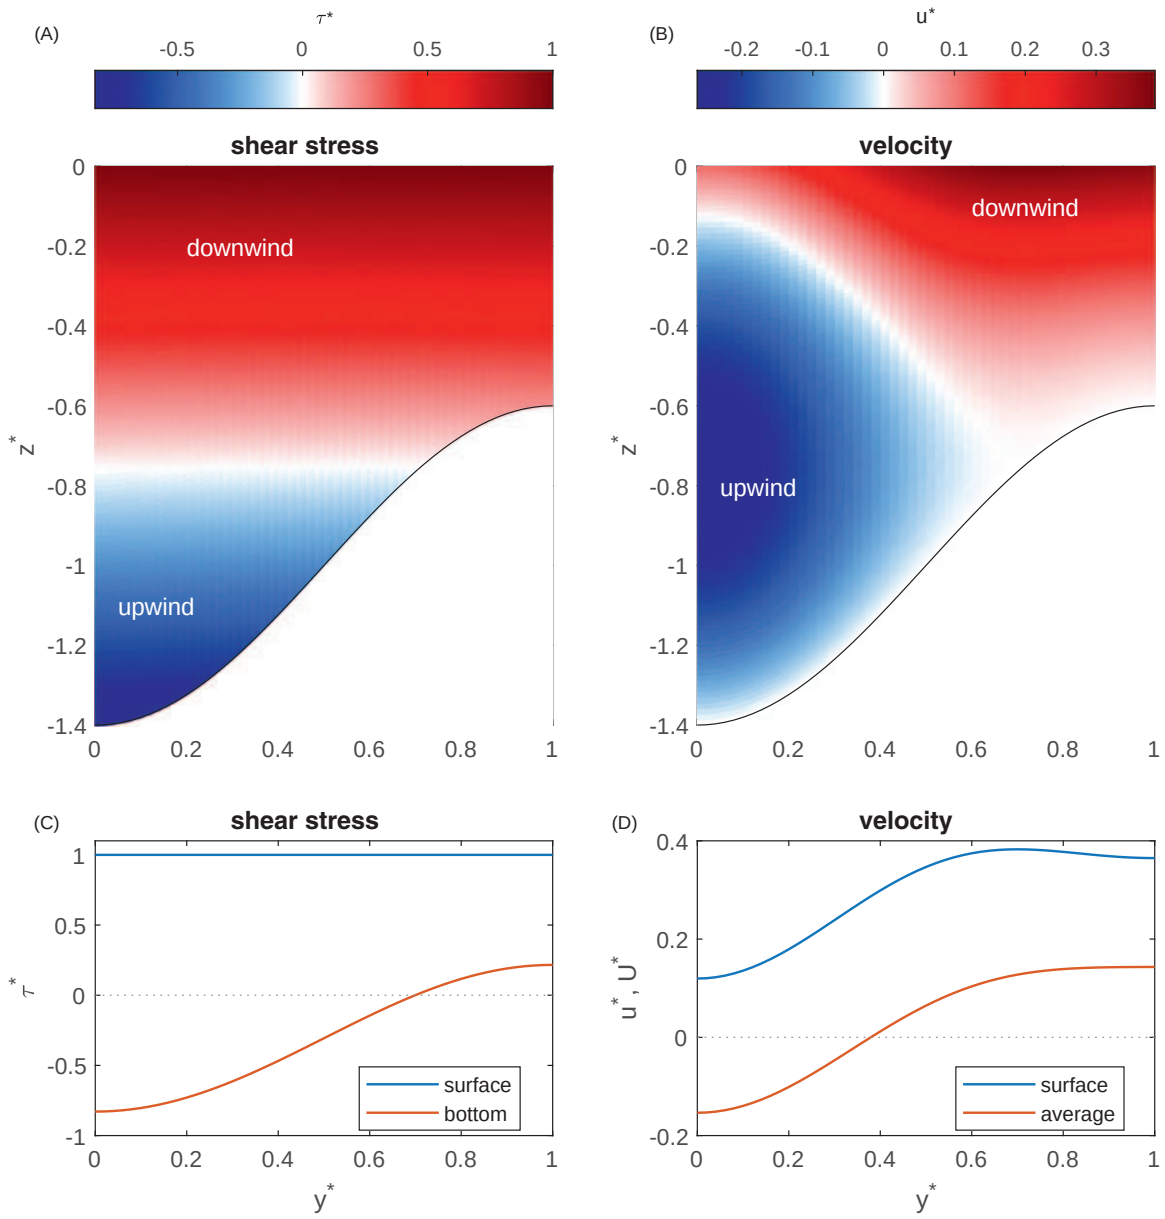

Fig. 6 Effect of depth variations. Steady-state flow field in an idealized cross-section of an elongated trunk region, for a uniform wind stress τ_{w0} but laterally variable depth $h = h_0[1 + 0.4\ cos(\pi y/B)]$, uniform eddy viscosity K_0, and no-slip conditions at the bottom. The plots refer to the dimensionless variables $z^* = (z - h)/h_0$, $y^* = y/B$, $\tau^* = \tau/\tau_{w0}$, $u^* = u\,\rho K_0/(\tau_{w0} h_0)$.

$$U = \frac{h}{K_0}\left[\frac{1}{2}\frac{\tau_w}{\rho} - \frac{1}{3} g \frac{\partial \eta}{\partial x} h\right] \tag{9}$$

and closing it with the proper value of the free-surface slope. The structure of Eq. (9) allows for recognizing that increasing h contributes to making U negative through the last term (remember that $\partial \eta/\partial x > 0$): indeed, the pressure force opposing the flow becomes stronger as the depth becomes larger.

Effect of inhomogeneous wind

A similar effect is produced by an inhomogeneous wind in a water body characterized by uniform depth. Using the same assumptions, we find the same local solution as above in each water column (which are independent from each other because the horizontal viscosity is neglected), and the integral condition (4) provides the free-surface slope $\partial \eta/\partial x = (3/2)\overline{\tau_w}/(\rho g h)$, which is the same result as in Eq. (8) but for the laterally averaged wind shear stress $\overline{\tau_w}$.

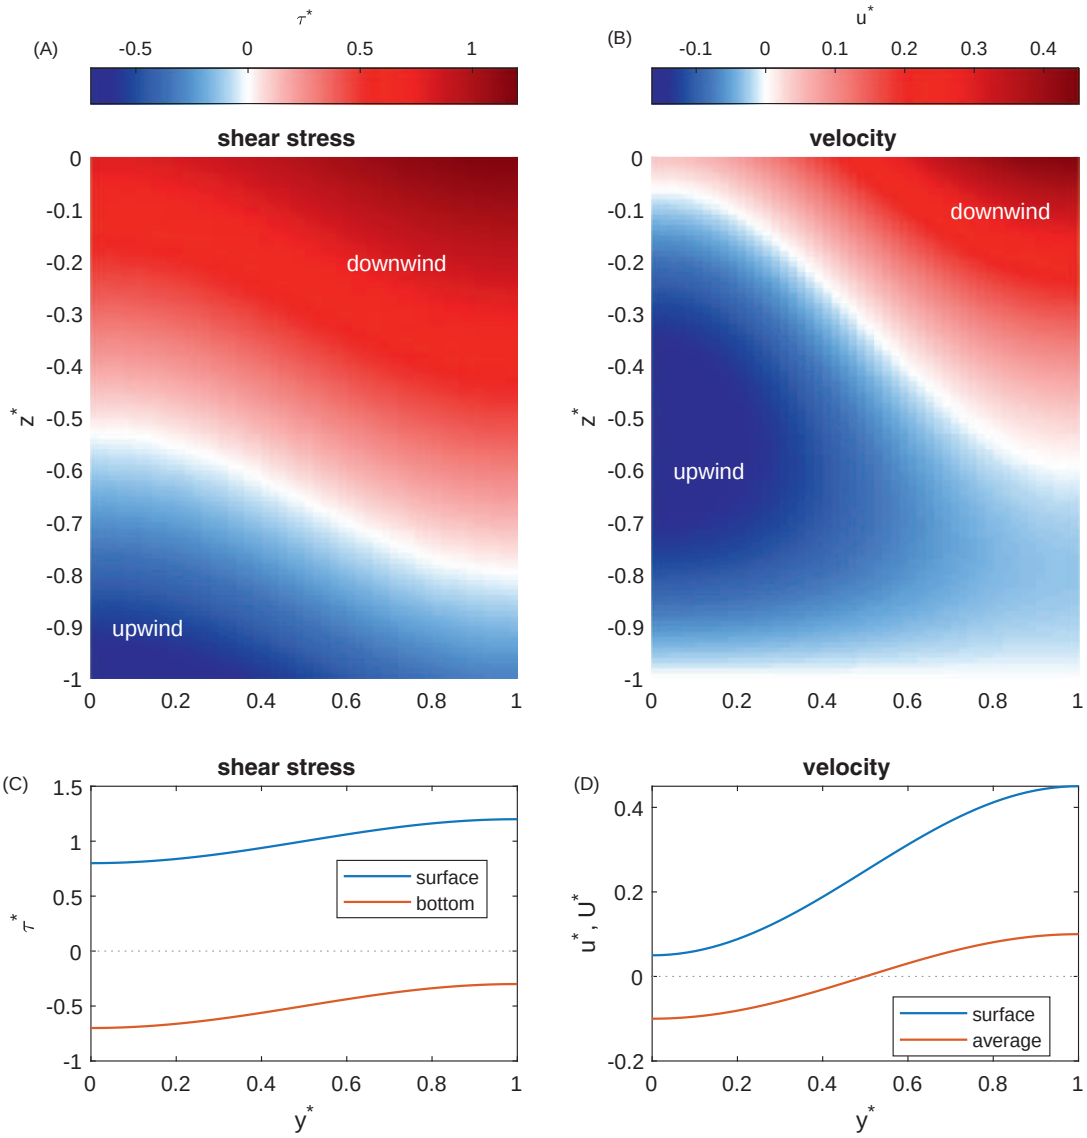

Fig. 7 Effect of wind variations. Steady-state flow field in an idealized cross-section of an elongated trunk region, for uniform depth h_0 but laterally variable wind stress $\tau_w = \tau_{w0}[1–0.2\ cos(\pi y/B)]$, uniform eddy viscosity K_0, and no-slip conditions at the bottom. Dimensionless variables are defined as in Fig. 6.

All the considerations done previously for the variable depth can be repeated in this case, which shows a depth-averaged return flow in the region where the wind is weaker (an example is shown in Fig. 7). The interpretation of the process in terms of the wind stress curl generating 2D vorticity is proposed at the end of the chapter.

The interaction of variable bathymetry and wind can alter the large-scale circulation significantly, with the return flow located in the region where the wind is sheltered (typically close to a shore) even if the depth is shallower (Podsetchine and Schernewski, 1999; Rueda et al., 2005).

Effect of Earth rotation

Considering the effect of Coriolis acceleration makes the description intrinsically more complex, since the two horizontal components of the velocity are intertwined. There is no possibility to describe the flow as occurring in parallel planes in the trunk region because the x–velocity u produces an acceleration in the y–direction, and vice versa. The simplest model considers an infinite domain, which allows for neglecting all the non-linear advective terms (similar to what happens in the uniform trunk region). Then, the two steady-state momentum equations (set *d* in Table 2) describe the balance among Coriolis acceleration, free surface slope (barotropic terms), and vertical diffusion of momentum by the eddy viscosity, for which it is assumed a constant value K_0.

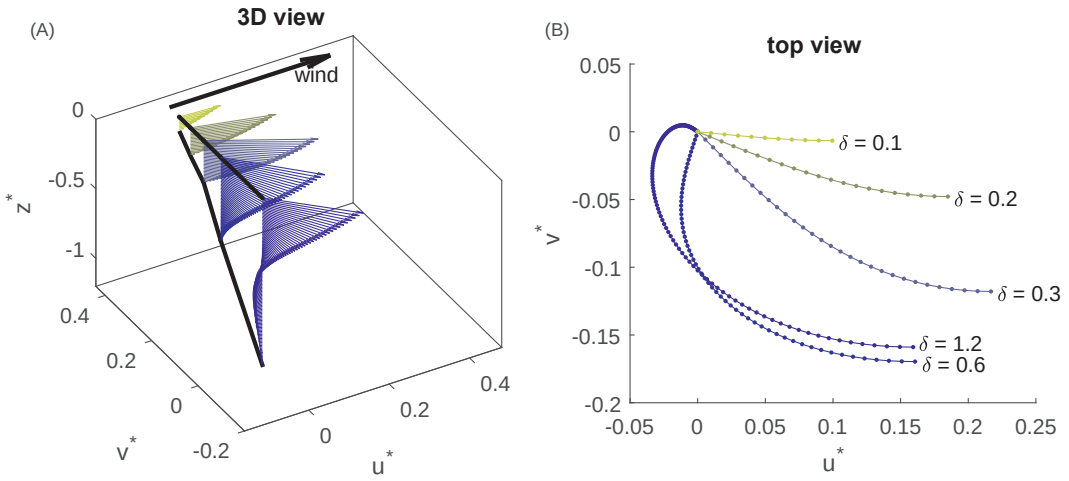

Fig. 8 Ekman spiral developing in a horizontally unbounded domain for a wind aligned with the *x*-axis (in the northern hemisphere, see the deviation of the surface velocity to the right of the wind), considering the effect of the finite depth with a no-slip condition at the bottom. (A) Five different cases depending on the local depth (note that they are independent of each other and are represented together only for drawing purposes). (B) Hodograph showing the horizontal components of the velocity at different depths. The number at the end of the curves (velocity at the surface) denotes the dimensionless depth ratio, $\delta = h/D_E$, with $D_E = \pi\sqrt{2K_0/f}$ the Ekman depth. The following dimensionless variables are used in the plot: $z^* = z/D_E$, $\{u^*, v^*\} = \{u, v\}/U_0$, with $U_0 = \tau_{w0}D_E/(\rho K_0)$; note that the length scale D_E is used instead of h to compare the results for different depths. As an example of the values in dimensional terms, we assume $\tau_{w0} = 0.03$ N/m^2 (for a wind speed of approximately 5 m/s) and $f = 10^{-4}$ s^{-1} (mid latitude): for $K_0 = 10^{-3}$–10^{-2} m^2/s, it follows that $D_E = 14$–44 m and the velocity scale is $U_0 = 0.4$–0.13 m/s (note that the actual velocity at the surface is about one order of magnitude smaller).

Ekman (1905) originally proposed a solution for these equations forced by a uniform wind in an infinite domain, neglecting the barotropic terms. For a depth much larger than the Ekman depth $D_E \sim \sqrt{K_0/f}$ (definitions proposed in literature may differ by a multiplicative factor), the flow in the surface layer does not 'feel' the effect of the bottom boundary, and the solution is represented by the well-known Ekman spiral (e.g., Hutter et al., 2011). The term "spiral" refers to the tendency of the velocity vector to rotate to the right (left) in the northern (southern) hemisphere, starting from a direction of 45 degrees with respect to the wind (Fig. 8). Where the depth is shallower, the flow tends to be aligned with the wind. It is worth noting that the definition of D_E includes the Coriolis parameter (f, depending only on the latitude) and the vertical eddy viscosity, which typically changes spatially and temporally, making the identification of a meaningful reference value K_0 difficult. Moreover, the Ekman spiral is rarely observed, as different factors can affect the flow field, among which barotropic flow (which can be dominant), the variability of the eddy viscosity, and the lack of spatial uniformity associated with the presence of boundaries (as discussed below).

There is another well-known theoretical result concerning the Ekman spiral in infinite depth: the vertically integrated transport is orthogonal to the wind (i.e., 90 degrees to the right/left in the northern/southern hemisphere). For instance, for a wind blowing along x, the y–component is quantified as $\int_{-\infty}^{0} v\, dz = \mp\, \tau_{wx}/\rho f$ (the sign depending on the hemisphere). As a result, persistent alongshore winds produce coastal downwelling or upwelling phenomena.

The assumption of infinite domain is a limitation of the traditional approach. What happens in relatively small (the meaning of "relative" is discussed later) closed water bodies? *We* have seen that lateral boundaries impose additional integral conditions to steady-state flows, as in Eq. (4), in order to respect the absence of mass exchange across any cross-section separating the water body into two regions. Referring again, for simplicity, to an elongated prismatic trunk region with the wind aligned along the main axis, two integral conditions (e.g., applied on cross-sections with fixed x and fixed y) can be used to determine the values of the free surface slope in the two directions (e.g., Kasai et al., 2000).

The process is such that, in a closed lake, a secondary circulation develops due to the effect of the Coriolis acceleration, in addition to the more intuitive "conveyor belt" circulation aligned with the wind (e.g., Ambrosetti et al., 2010; see also Fig. 3). The effects of this secondary circulation have recently been observed in Lake Garda, Italy, whose northern deep basin can be approximated using the prismatic trunk assumption (Piccolroaz et al., 2019). By artificially switching off the effect of the Coriolis force in numerical simulations (Fig. 9), it is possible to see how this process acts in elongated lakes: it affects momentum, mass and heat transport, and modifies the mechanism of deep ventilation. An interesting effect is the lateral shift of high-momentum surface flow towards the right shore (in the northern hemisphere), whereas the left shore is affected by an upward movement of low-momentum flow (Toffolon, 2013): the overall effect is an acceleration of the flow on the right shore and a reduction on the left (the opposite in the southern hemisphere).

The effect of Earth rotation on lake hydrodynamics can produce noticeable deviations of the surface velocity with respect to the wind direction (e.g., Koçyigit and Falconer, 2004) also in small lakes if they are deep enough. Actually, the intensity of the steady-state secondary circulation depends on the depth ratio, $\delta = h/D_E$, and should not be assessed using the widely used criterion

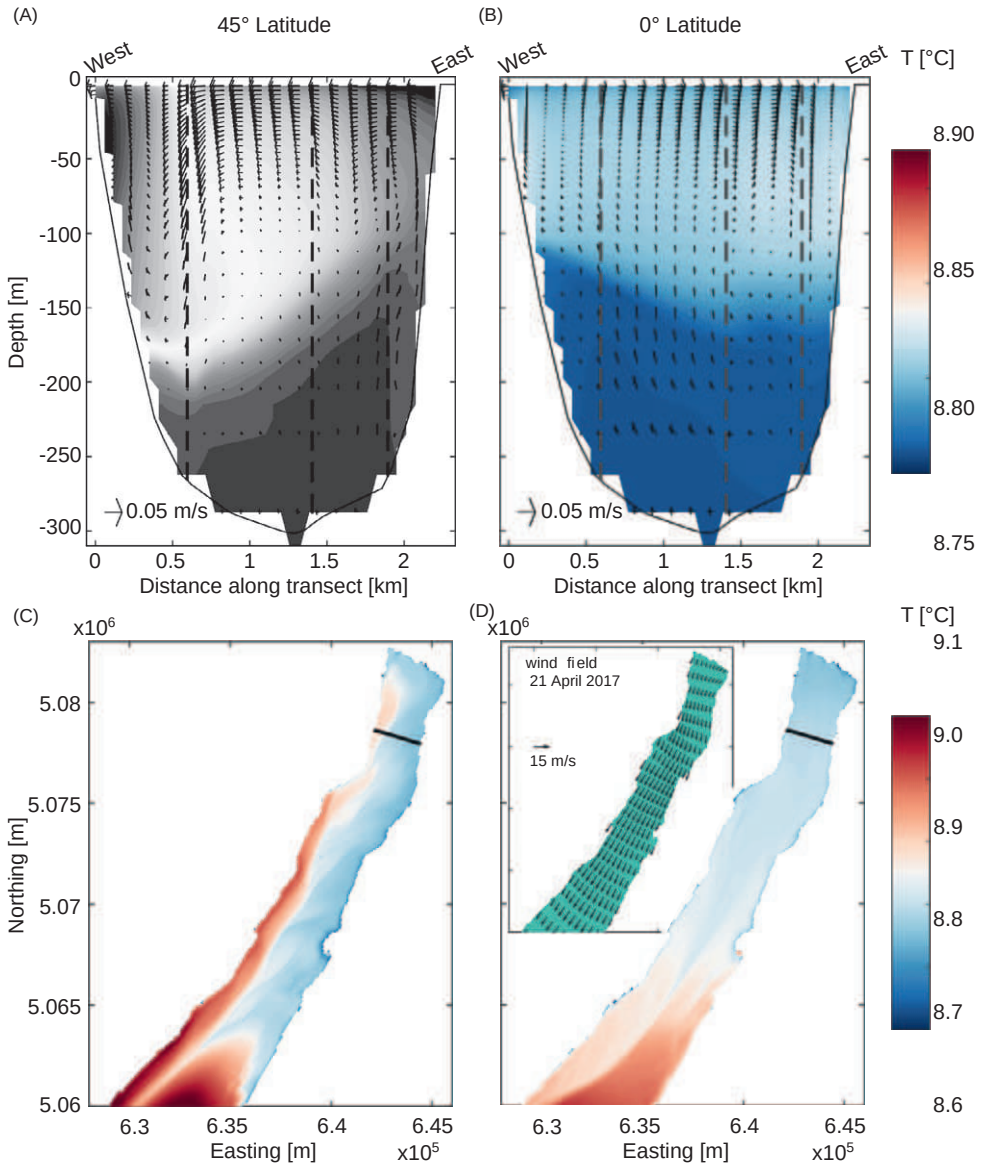

Fig. 9 The effect of Earth rotation producing a secondary flow in a wind-driven circulation, analysed by means of numerical simulations in Lake Garda, Italy, accounting for (A and C) and excluding (B and D) the Coriolis force. Upper panels: water temperature and flow field (arrows) in the transect indicated with a black line in the lower panels. Lower panels: map of surface water temperature. The inset in panel (D) shows the strong and uniform wind field blowing from north-east and aligned with the lake main axis. Modified from Piccolroaz S, Amadori M, Toffolon M and Dijkstra HA (2019) Importance of planetary rotation for ventilation processes in deep elongated lakes: Evidence from Lake Garda (Italy). *Scientific Reports*, 9: 8290. DOI: 10.1038/s41598-019-44730-1, by adding the inset in panel D.

based on the Rossby number $Ro = U_0/(fB)$ (Amadori et al., 2020). Comparing the horizontal size of a lake with the Rossby radius U_0/f is correct for waves and inertial currents, but not for this kind of secondary circulation, where the mixed layer's depth should be compared with the thickness of the Ekman layer (Hutter et al., 2014).

Effect of horizontal turbulence

When examining the previous effects, we always relied on the possibility of neglecting the horizontal viscosity. This common assumption, usually based on dimensional considerations, recognizes that in shallow flows the vertical variations are stronger than the horizontal gradient. However, this is not always true. The size of the lake, and in particular the across-wind width, enters into play for sufficiently narrow cross-sections where the extension of the boundary layers at the shore becomes comparable with the width itself, and the horizontal viscosity dampens the lateral velocity gradients.

In order to understand the dynamics, we develop a simple dimensional argument. The lateral gradient is imposed by the geometrical constraint and the only degree of freedom is the intensity of the velocity at the two sides. This means that the

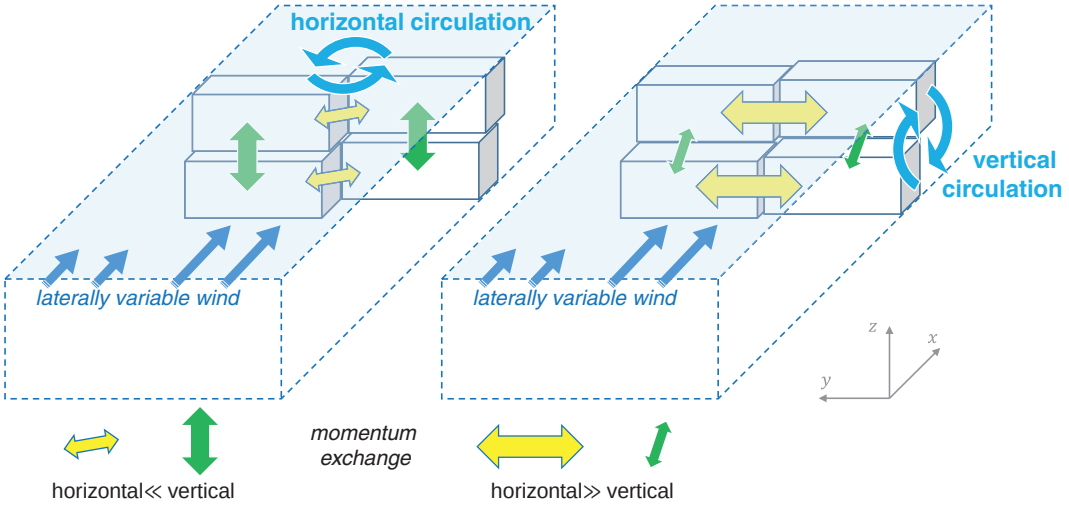

Fig. 10 Conceptual scheme of the effect of turbulence anisotropy and geometry on the development of lake circulation induced by a laterally variable wind stress with uniform depth. (Left) Horizontal circulation prevails for isotropic turbulence and shallow/wide geometry. The vertical exchange of momentum is dominant due to the large width-to-depth ratio that reduces the lateral ($\partial u/\partial y$) and enhances the vertical ($\partial u/\partial z$) velocity gradient. Hence, the lower layers tend to follow the inhomogeneous movement of the upper layers driven by the variable wind. (Right) Vertical circulation prevails for the strongly anisotropic and deep/narrow geometry. The vertical exchange of momentum is limited due to the small width-to-depth ratio and the reduced vertical eddy viscosity. Here, the whole surface layer tends to move in the same direction, as the region subjected to stronger wind effectively drags the region where wind is milder, and the lower layers are affected by the return current to compensate the mass balance (in steady-state conditions). Analogous descriptions can be done for the other factors that tend to produce a horizontal circulation (e.g., variable bathymetry, Coriolis acceleration, etc.).

acceleration resulting from the lateral flux of momentum can be quantified as $(1/\rho)\partial\tau_{xy}/\partial y = \partial(A\partial u/\partial y)/\partial y \sim A_0U_0/B^2$, with U_0 and A_0 suitable scales of the velocity and horizontal eddy viscosity, respectively. Analogously, the vertical momentum flux is $(1/\rho)\partial\tau_{xz}/\partial z = \partial(K\partial u/\partial z)/\partial z \sim K_0U_0/h^2$. The ratio between these two terms, $\alpha = (h/B)\sqrt{A_0/K_0}$, combines the aspect ratio of the cross-section and the turbulence anisotropy (Toffolon and Rizzi, 2009), whereby typically $K_0 \ll A_0$. Fig. 10 shows a conceptual scheme of the narrow/anisotropic vs. the wide/isotropic condition for the simple case of a lateral variability of the wind.

The overall effect is that, in narrow sections, the lateral gradient of the velocity is damped by the turbulent exchange of momentum. The same reasoning can be done for the vertical velocity associated with downwelling and upwelling phenomena at the two opposite shores of a narrow lake.

The world described by a depth-averaged model

Nothing more than horizontal circulation

The simultaneous presence of vertical and horizontal circulations, which can be due to different factors, all of them generally acting in real cases, poses an interesting question about the possibility to describe the flow field by means of a depth-averaged model. By averaging the RANS equations along the depth, it is possible to obtain the approximate 2D equations in primitive form (set *b* in Table 2).

The shear stress at the bottom, $\vec{\tau}_b$, needs to be closed in terms of the resolved variables, in particular the depth-averaged velocity $\vec{U}$. A common choice is to use the dimensionless Chézy coefficient, C, in the quadratic relation $\vec{\tau}_b = \rho|\vec{U}|\,\vec{U}/C^2$ (note that $C = {C_D}^{-1/2}$, with C_D a drag coefficient). Using this closure relation, the system of partial differential equations (set *b* in Table 2) can be solved in terms of U, V and η.

An obvious limitation of 2D models is the impossibility to describe the vertical circulation. We discuss this issue referring again to the simplified case of a steady-state flow in the trunk region with variable h. Neglecting horizontal viscosity, the x-momentum equation can be cast in the following form (corresponding to equation *e* in Table 2):

$$\frac{|U|U}{C^2} = -g\frac{\partial\eta}{\partial x}h + \frac{\tau_{wx}}{\rho} \tag{10}$$

This equation can be used to compute U directly, and then apply the integral condition (4) to obtain $\partial\eta/\partial x$: however, the result would be different from that obtained through Eq. (9). Moreover, for a plane flow with uniform wind and depth, the integral

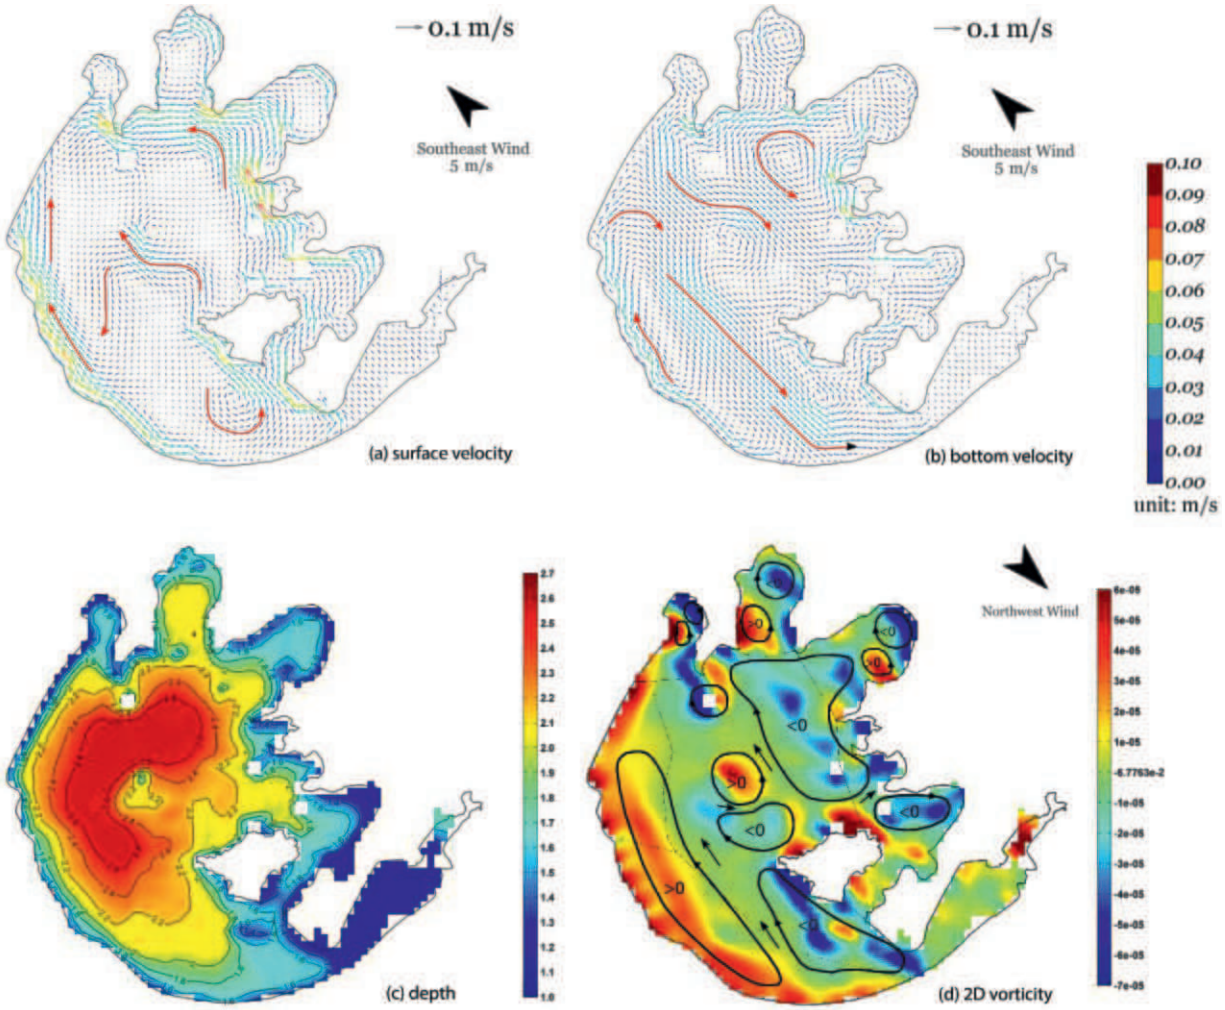

Fig. 11 A complex flow field combining horizontal and vertical circulation can develop also in shallow lakes. Taihu Lake, China, is a large (2250 km^2) but very shallow lake (mean depth 2 m; see bathymetry in panel C). Numerical simulations show that the flow field is markedly 3D, with velocity at the bottom (B) opposite to surface velocity (A) in deeper areas (for the interpretation, see the analysis of the idealize case in Fig. 6). In terms of depth-averaged circulation, the 2D vorticity field (colours in panel D) allows to recognize multiple-gyre structures (black lines approximately indicate streamlines); note that the wind direction in panel d is opposite to that in panels A and B. Modified from Liu S, Ye Q, Wu S and Stive MJF (2018) Horizontal circulation patterns in a large shallow Lake: Taihu lake, China. *Water* 10: 792. DOI: 10.3390/w10060792, combining different figures; streamlines drawn with red lines in panels a-b have been added.

condition (4) in the 2D approach imposes $U = 0$, i.e., no flow can be produced, which is of course incorrect, and only a still-water balance would be possible between the wind drag and the gravitational setup.

It is important to stress that, although very common, the assumption that the flow can be well represented by the depth-averaged velocity is often not satisfied. Even in very shallow lakes, water velocity at the bottom can be reversed with respect to that at the surface (an example is shown in Fig. 11). Only in those cases where the variability of depth or wind stress is strong enough, the development of a well-defined horizontal circulation makes the depth-averaged description reasonable (e.g., Fenocchi et al., 2016).

The 2D vorticity equation

The analyses in the previous sections were based on assumptions used to isolate the different processes. Here, we briefly examine how the 2D vorticity equation can describe the generation of horizontal circulation in more complex situations (e.g., Schwab and Beletsky, 2003). The vorticity is a measure of the rotational character of the flow. Referring to the depth-averaged velocity, the component of the vorticity vector in the z direction,

$$\zeta = \nabla \times \vec{U}_z = \frac{\partial V}{\partial x} - \frac{\partial U}{\partial y} \tag{11}$$

is a scalar quantity for a 2D x-y flow (to simplify the notation, it is implicitly assumed that only the z-component of the cross product is considered in the following equation). Hence, the vorticity equation is a single equation

$$\underset{\text{(i)}}{h^2 \frac{d}{dt}\left(\frac{\zeta + f}{h}\right)} \; \underset{\text{(ii)}}{- h\bar{A}\,\nabla^2\zeta} = \underset{\text{(iii)}}{\nabla \times \left(\frac{\vec{\tau}_w}{\rho}\right)} + \underset{\text{(iv)}}{\frac{1}{h}\frac{\vec{\tau}_w}{\rho} \times \nabla h} \; \underset{\text{(v)}}{- \nabla \times \left(\frac{\vec{\tau}_b}{\rho}\right)} \; \underset{\text{(vi)}}{- \frac{1}{h}\frac{\vec{\tau}_b}{\rho} \times \nabla h} \tag{12}$$

where the terms can be interpreted as follows. Term (i) contains the material derivative of the so-called potential vorticity; considering only this term, the vorticity increases moving to larger depths because of the need to conserve mass and angular momentum simultaneously (hence, squeezing of the water column and faster rotation). Term (ii) describes the diffusion of vorticity due to horizontal viscosity (assumed uniform for simplicity). Term (iii) is the source of vorticity due to variable wind stress (as for the idealized examples in Fig. 7). Term (iv) is the source due to variation of depth not aligned with the wind (as for the case in Fig. 6). Term (v) is a sink, as can be seen by using a simplified linear closure for the bottom shear stress, $\vec{\tau}_b \cong \rho k \vec{U}$ with $k > 0$, which allows for rewriting the term as $-\nabla \times \left(k \vec{U}\right) \cong -k\zeta$, i.e., always suppressing the existing vorticity. Term (vi) depends on the interaction of the flow field with bathymetrical variations.

Two idealized conditions can be considered to show the analogy with the cases discussed previously. The first is where depth variations are small with respect to wind stress variation, i.e., $O(\Delta h/h) \ll O(\Delta \tau_w/\tau_w)$. By neglecting the advective and diffusive terms, the vorticity equation (12) can be approximated as $h\partial\zeta/\partial t \cong \rho^{-1}\nabla \times \vec{\tau}_w - k\zeta$, which suggests that the evolution of vorticity is driven by the curl of the wind stress. Under steady forcing, vorticity tends to approach it ($\zeta \cong \nabla \times \vec{\tau}_w/\rho k$) for a sufficiently long time scale. The second is the opposite case (mostly uniform wind but strongly variable bathymetry): under the same additional assumptions, the vorticity dynamics described by Eq. (12) is dominated by the term $\vec{\tau}_w \times \nabla h$, which is responsible for the two-gyre structure in a basin with a deeper region in the middle (see the examples in Figs. 5 and 11D).

Unsteady flows

Response to variable forcing

After a detailed analysis of steady-state currents, we briefly discuss how the flow reacts to variations in the forcing due to the inertia of the water mass. Let us recall the effect of an impulse of wind stress at the surface of an infinite water body initially at rest (Fig. 2): the force transferred from the air moves the water through a downward flux of momentum along the water column. The mechanism is complex for turbulent flows because K is not constant. Assuming a reference value K_0, the length scale of the vertical region affected by the transfer of momentum grows in time as for any diffusive process, $L_D \propto \sqrt{K_0\, t}$ (e.g., Fischer et al., 1979). Hence, a well-established flow requires a time scale $T_0 \sim h^2/K_0$ to develop over a depth h. This is not a precise estimate, as different factors can affect it: the presence of a multiplicative coefficient that is larger than 1 for the actual value of L_D (e.g., see the case in Fig. 12 discussed later), or the fact that a return flow may occur at the bottom to respect mass conservation.

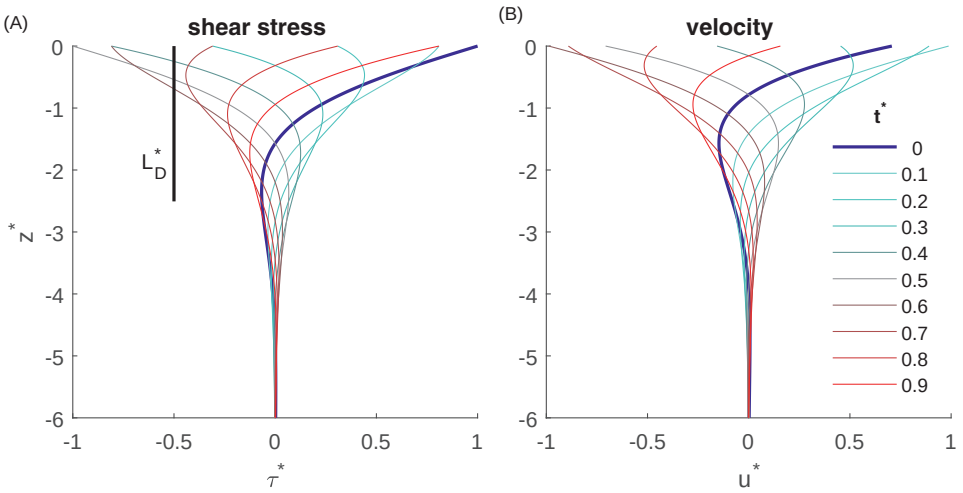

Fig. 12 The response of (A) shear stress and (B) velocity to a periodically variable wind forcing $\tau_w = \tau_{w0}\cos(\omega t)$, for a unidirectional flow in an infinite domain, neglecting Coriolis acceleration and assuming uniform and constant viscosity K_0. The length $L_D = \sqrt{2K_0T_0}\left(L_D^* = L_D/H_0 = \sqrt{2\pi}\right.$, with $H_0 = \sqrt{2K_0/\omega}$ and $T_0 = 2\pi/\omega)$ is the scale of the diffusion process and provides an indication about the depth at which momentum can penetrate. Note that it does not depend explicitly on wind speed, but in turbulent flows K_0 does, thus introducing an indirect dependence. The following dimensionless variables are used in the plot: $t^* = t/T_0$, $z^* = z/H_0$, $\tau^* = \tau_w/\tau_{w0}$, $u^* = u/U_0$ with $U_0 = \sqrt{2}\tau_{w0}/\rho\omega H_0$. As an example of the dimensional quantities, we assume $\tau_{w0} = 0.03$ N/m^2 (for a wind speed of approximately 5 m/s), $T_0 = 86{,}400$ s (daily periodicity): for $K_0 = 10^{-3}$–10^{-2} m^2/s, it follows that $U_0 = 11$–3.5 cm/s, $H_0 = 5.2$–17 m, and $L_D = 13$–42 m. It is worth noting that the larger is K_0, the smaller is U_0 because the inertia of the mass affected by the wind ($\propto L_D$) is larger.

There is a case where an analytical solution can be easily obtained and is illustrative of some general properties. For a unidirectional flow (neglecting Coriolis effects) in an infinite domain, and for constant and uniform K_0, the x-momentum equation becomes

$$\frac{\partial u}{\partial t} = K_0 \frac{\partial^2 u}{\partial z^2} \tag{13}$$

which is formally equivalent to the standard diffusion equation. If we consider a wind stress periodically alternating its direction (e.g., the daily sequence of anabatic and katabatic winds in mountain regions), the maximum depth at which momentum penetrates can be determined as a function of K_0 and of the time scale of the wind (Fig. 12).

However, the assumption that the vertical eddy viscosity is uniform and constant is incorrect. In fact, the vertical eddy viscosity is variable along the water column even in steady-state conditions. In the so-called "law of the wall" approximation (e.g., Wilcox, 2006), K grows with the distance from the bottom or the free surface, and follows an approximately parabolic profile. Moreover, the eddy viscosity is not constant in time, as turbulence is generated at the boundaries and tends to diffuse inside the water body, taking time to reach an equilibrium state. For instance, a wind pulse generates turbulent kinetic energy (TKE) at the surface, which is then advected and diffused into the water body, but it takes a relatively long time to be effective everywhere. More often, in the case of intermittent winds, TKE penetrates only down to a certain depth, even in the well-mixed surface layer. Hence, the wind-generated momentum can diffuse effectively only in a limited region of the water column close to the surface, producing velocity profiles that are quite different from the ones examined above for steady-state conditions, which only represent the asymptotic tendency of the flow.

Inertial currents and seiches

The unsteadiness of the forcing is crucial to understand the dynamics of the flow field in real conditions, but the effect is not limited to the period when the forcing is active. Two examples can illustrate how unsteady flows can persist after the original cause of the motion has stopped.

Inertial currents are ideal frictionless movements that are primarily affected by Earth rotation. They can last for some time after a strong wind event, and are the result of the balance between the inertia of the water and the Coriolis acceleration, with the possible effect of the barotropic terms (see set g in Table 2). The peculiarity of this flow is that it follows circular trajectories with constant velocity magnitude $\left|\vec{u}\right|$ and radius $R = \left|\vec{u}\right|/f$. The geostrophic flow determined by the barotropic terms, $u = g/f\,\partial\eta/\partial y$ and $v = -g/f\,\partial\eta/\partial x$, produces a shift that is orthogonal to the direction of the pressure (free-surface) gradient. A beautiful example of inertial trajectories is shown in Fig. 13.

Seiches are standing waves that occur in closed water bodies as a reaction to the instability produced by, e.g., wind setup. Knowing the celerity of propagation of gravity waves, $c = \sqrt{gh}$, and neglecting the effect of Earth rotation, the period $T_0 = 2L/(n\,c)$ of the free-surface oscillations (external seiches) can be determined given the length L of the water body and the number n of nodes of the wave. Interfacial waves, i.e., those occurring at the interface between two well-mixed layers, travel with a much slower speed, depending on the reduced gravity $g' = g\,\triangle\,\rho/\rho_0$ (with $\triangle\,\rho$ being the density difference between the two layers). Adding the Coriolis acceleration, external and internal waves earn a rotational character, leading to more complex types of motion (e.g., Kelvin and Poincaré waves).

Numerical modelling

In the last two decades, numerical models have become easily available, potentially removing the limitations that are necessary to obtain analytical solutions. However, three main issues should be considered for successful hydrodynamic simulations.

The first is the need to develop affordable and reliable turbulence models: on the one hand, the use of k-ε models is already the state of the art, but limitations are known especially in stratified conditions; on the other hand, the use of Large Eddy Simulations (LES) is becoming more common (e.g., Santo et al., 2017), but requires some specific expertise.

The second issue that strongly affects the results of hydrodynamic models is the external forcing. The one-way coupling with atmospheric models is already seen as necessary, as the only way to reconstruct a reasonable wind field on the lake surface. A further effort is needed to reconstruct reliable heat fluxes at the lake surface (a topic not discussed in this article). For instance, latent and sensible heat fluxes are affected by the atmospheric stability: testing two-way coupling options, possibly supported by comparison with field measurements, is the next step towards a physically sound description of the interface processes.

The third issue is the coupling with the ecology of the lake. Apart from the obvious effect of the currents on the transport of biological components, there is at least one process that is essential for the development of thermal stratification and, hence, for the thickness of the surface well-mixed layer: light extinction. The Secchi disk depth is routinely used as a parameter in thermo-hydrodynamic models, but its estimation in prognostic models is still challenging.

It seems that the futures challenges are tightly related with the use of increasingly complex numerical models, often developed by experts of different disciplines. Thus, why should we care about simplified analytical solutions? The answer to this question is simple: while numerical simulations can be considered analogous to (virtual) laboratory experiments, the interpretation of

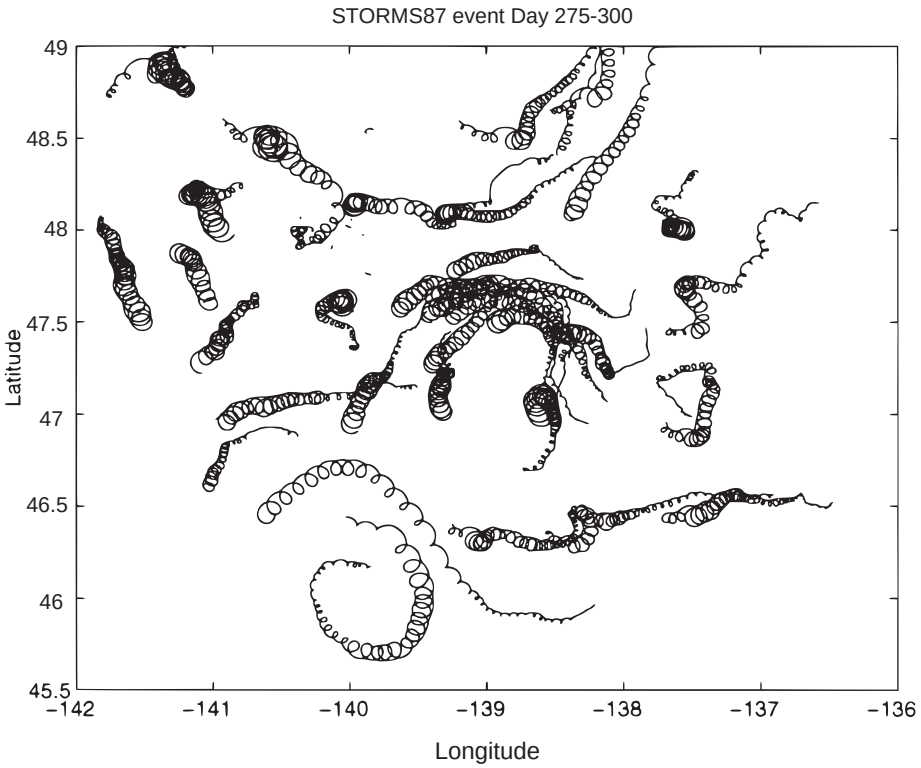

Fig. 13 Inertial currents: drifter tracks recorded during the Ocean Storms Experiment in a region off the coast of Washington. Note that a larger breadth of the trajectory corresponds to higher velocity, as $U_0 = R\,f$ with R the radius of an equivalent circle fitting the envelope. For a latitude of 47°N (whereby $f = 1.07 \times 10^{-4}$ s^{-1}), 1 degree longitude is approximately 76 km, thus the size of the large patterns in the figure is approximately 5 km, from which it is possible to estimate a maximum velocity 0.5–0.6 m/s after the storm event. Reproduced from van Meurs P (1998) Interactions between near-inertial mixed layer currents and the mesoscale: The importance of spatial variabilities in the vorticity field. *Journal of Physical Oceanography* 28 (7): 1363–1388. DOI: 10.1175/1520-0485(1998)028<1363:IBNIML>2.0.CO;2.

fundamental dynamics becomes more obscure as the complexity of the models increases (and, possibly, introduces spurious numerical artefacts). Therefore, simplified analytical models are often the best way to obtain a direct intuition of the physical processes under investigation.

Conclusions

The article presented an overview on the influence of some factors (variability of wind forcing and bathymetry, turbulence anisotropy, Earth rotation) on the basin-scale circulation in lakes. The main focus was on analytical solutions that can be derived for steady-state conditions, as a way to understand the physics governing the transport processes. Indeed, the analytical approach is effective in isolating the physical processes and in providing conceptual tools to grasp the underlying dynamics. The analytical approach is not alternative to numerical modelling; more correctly, it should be a complement of all numerical experiments. In fact, numerical models simulate the flow field and the resulting transport (e.g., of mass and heat) in realistic conditions, as they allow to include temporally and spatially varying forcing, and virtually all the processes that occur in the interior of the lake. However, the interpretation of the numerical results is not simple, and analytical solutions can provide powerful glasses to recognize and explain the observed behaviour. Moreover, the choice of the proper numerical model requires care. For instance, circulation in lakes is inherently a three-dimensional phenomenon, and two-dimensional depth-averaged models should be used only being aware of their limitations.

Knowing the trajectories of the transport in lakes is essential for all processes that involve nutrients, oxygen, temperature, and contaminants. Water quality and food webs are strongly affected by the transport patterns, and cannot be properly studied without simulating the hydrodynamics correctly. This is not an easy task and this article did not aim at being exhaustive. Here, the goal was to give a first introduction on the mathematical tools that can be useful to the scholars of all the limnological disciplines to delineate the conceptual framework for understanding how the large-scale physical processes influence the bio-geo-chemistry and the ecology of lakes.

Knowledge gaps

- Monitoring velocity in lakes is still a challenging task. In most cases, only point measurements of velocity are available, or velocity profiles along water columns collected with ADCP. The reconstruction of time-varying velocity fields, for instance at the lake surface, would be extremely important to understand the actual circulation patterns.
- Complex turbulence models are available, but the parameterization of the spatial and temporal variability of the eddy viscosity (and especially the effect of density stratification) did not improve significantly in the last decades.
- Very large uncertainties affect the estimate and the modelling of the horizontal viscosity and the understanding of its effect on the flow field.
- The interaction of the wind shear stress and the atmospheric stability with the roughness of the water surface, and hence the accurate quantification of the drag force, has not been completely clarified.
- The "golden age" of the analytical approach ended with the increasingly widespread use of numerical models. Nowadays, several studies simply present the results of numerical simulations, sometimes with a poor interpretation. Retrieving the knowledge that was developed in the second half of the 20th century might give more value to the results of the most advanced modelling efforts.

Glossary

Baroclinic wave A wave in flow where the fluid density is a function of temperature, salinity and pressure. For example, waves on the thermocline of a lake.
Barotropic wave A wave in flow where the fluid density is a function of pressure only. For example, waves on the free surface of a lake.
Burger number Ratio of the Rossby Radius R to the lake width W; for $S = R/W < 1$ the Coriolis force will modify internal seiches into Kelvin and Poincaré waves.
Diurnal thermocline Strong vertical gradient that sets-up within the epilimnion during calm and warm conditions.
Epilimnion Warm well mixed (often turbulent) surface layer (~10 m thick) where momentum, heat, light and biogeochemical parameters are exchanged with the atmosphere.
Hypolimnion Cold, quiescent and nutrient rich bottom layer that is isolated from the atmosphere by the thermocline.
Inertial frequency The frequency $f = 2\pi/T_i$ of oscillations at the inertial period T_i.
Inertial period The time for a fluid parcel deflected by the Coriolis force to complete a full circle (inertial circle) at a particular latitude.
Internal Kelvin wave Sub-inertial (period $> T_i$) internal seiche that is modified by the Coriolis force to propagate cyclonically (clockwise/counter-clockwise in the northern/southern hemisphere) around the basin perimeter.
Internal Poincaré wave Super-inertial (period $< T_i$) internal seiche that is modified by the Coriolis force to propagate anticyclonically (counter-clockwise/clockwise in the northern/southern hemisphere) energizing strong mid-basin currents.
Metalimnion Layer between the warm epilimnion and cold hypolimnion that exhibits a strong temperature gradient, which inhibits vertical mixing of momentum, heat and biogeochemical parameters (nutrients, oxygen, etc.).
Rossby Radius $R = c_o/f$ is the length-scale (lake size) at which the Coriolis force becomes important, at a particular latitude or inertial frequency f, for fluid motion characterized by a velocity scale c_o.
Seasonal thermocline Region of the metalimnion where the vertical density gradient is strongest.
Seiche Basin-scale standing wave acting on the lake surface, thermocline or other density stratifying layers.

☆*Change History:* October 2021. L Boegman prepared the update with assistance from the section editors. Fig. 1 has been simplified, Table 2 has been added, Fig. 4 has been added, Fig. 5 has been added, text has been added on Internal Seiches under the effect of Earth Rotation.

Turbulent bottom boundary layer (TBBL) Layer of turbulent fluid above the sediments at the lake perimeter (~1 to ~10 m thick) where oscillatory seiche-induced currents drive turbulence and mixing, both in the watercolumn and across the sediment water interface, as they dissipate energy through frictional drag.

Introduction

The surface layer of a lake contains oxygen and light, which are required for growth of plankton and other aquatic life. However, the essential nutrients (e.g., phosphorus, nitrogen and carbon) are found above the sediments, where oxygen may be depleted. The watercolumn density stratification, arising from a vertical temperature gradient between the surface and lakebed, suppresses vertical mixing of nutrients and oxygen, thereby effectively isolating the oxygenated surface layer from the nutrients below.

The density stratification is an ideal environment for the generation of internal waves (i.e., interfacial waves on the thermocline). Forced by surface winds, internal waves drive oscillatory currents that energize a quasi-steady turbulent bottom boundary layer (TBBL) above the sediment bed. This turbulence provides transport through the thermocline, mixing oxygen toward the sediments and nutrients toward the surface (Imboden and Wüest, 1995; Imberger and Patterson, 1989).

Wave motions, in lakes, are initiated by the surface wind stress (Mortimer, 1974; Fischer et al., 1979). Waves occur on both the free surface (e.g., barotropic or surface seiche) and internal stratifying layers (e.g., baroclinic or internal seiche on the thermocline). The waves are categorized according to their length scale. Basin-scale waves have wavelengths that are of the same order as the lake diameter and occur as standing wave modes—or *seiches* (Fischer et al., 1979; Mortimer, 1974). Sub-basin-scale waves have wavelengths ~10–1000 m (Boegman et al., 2003). These waves are progressive and break where they shoal on sloping topography at the depth of the thermocline (Wüest and Lorke, 2003; Boegman et al., 2003, 2005b). However, wave shoaling and wave breaking is not addressed in this article.

Characteristic geometry and water-column stratification

We limit the present analysis to several characteristic types of density stratification that are commonly observed in lakes. Consider a lake basin of length L, width W and depth H. During the summer months, solar heating causes the lake to become stratified with a layered temperature structure consisting of an *epilimnion*, *metalimnion*, and *hypolimnion*; the *seasonal thermocline* being where the vertical density gradient is strongest within the metalimnion (see The Surface Mixed Layer in Lakes and Reservoirs). If the thermocline is abrupt, the lake may be approximated as a simple two-layer system of thickness h_1 and density ρ_1 over thickness h_2 and density ρ_2, where $H = h_1 + h_2$ is the total depth (Fig. 1B) (Horn et al., 2001). In lakes where a strong *diurnal thermocline* is present or the metalimnion is thick, the vertical density structure may be approximated with three contiguous fluid layers of density ρ_1, ρ_2 and ρ_3 with thicknesses h_1, h_2 and h_3 (Fig. 1C and D). The layered model for the stratification is inappropriate for polymictic lakes (e.g., shallow lakes $H < \sim 15$ m), which are often well mixed, but may also be weakly stratified (e.g., Fig. 1A); in these lakes an ephemeral diurnal thermocline may form in the epilimnion (e.g., Imberger, 1985).

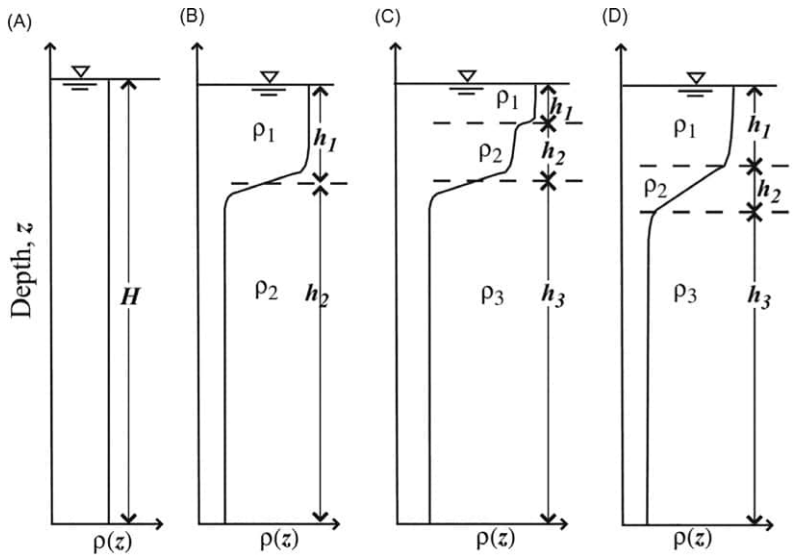

Fig. 1 Characteristic continuous water-column stratifications as found in lakes and typical layer approximations. (A) Homogeneous water-column of constant density. (B) Two-layer approximation of the continuous stratification, where the layer separation occurs at the thermocline. (C) Three-layer approximation of the continuous stratification, where the layer separation occurs at the diurnal and seasonal thermoclines. (D) Three-layer approximation of the continuous stratification, where the layer separation occurs at the upper and lower surfaces of the metalimnion.

Surface momentum transfer and wind set-up (phase 1, wind blows)

The internal waves described in this section are in lakes that are not affected by the Coriolis force due to the Earth's rotation. The wave modes that are supported depend upon the nature of the water column stratification and the wind forcing.

Wind set-up of the free surface

The action of the wind across the lake surface results in frictional momentum transfer from the wind to the water (see The Surface Mixed Layer in Lakes and Reservoirs). This transfer occurs in the form of a stress (N m^{-2}) applied at the free surface. The stress τ may be parameterized as (Fischer et al., 1979; Imboden and Wüest, 1995)

$$\tau = C_D \rho_a U_{10}^2 = \rho_o u_*^2$$

where C_D is the drag coefficient, $\rho_a = 1.2$ kg m^{-3} is the air density, $\rho_o = 1000$ kg m^{-3} is a reference (or mean) water density, $U_{10}$the wind speed measured at 10-m above the water surface and $u_* = \sqrt{\tau/\rho_o}$ is the surface shear velocity. Typically, $C_D = 1.3 \times 10^{-3}$, but this value may vary by ±40% depending upon the wind speed, water depth, and the relative temperature difference between the water surface and the atmosphere (Fischer et al., 1979; Wüest and Lorke, 2003).

The momentum transfer associated with steady winds will push the surface water to the leeward shore causing an upward displacement of the free surface, due to the presence of the solid boundary (Fig. 2A), and a simultaneous downward displacement of the thermocline. For long and shallow lakes the free surface displacement may be as large as several meters (e.g., ~2 m in Lake Erie; Hamblin, 1987).

This displacement is called wind set-up. If the wind stress is applied for sufficient time, a steady-state tilt of the free surface will occur where there is a balance between the applied wind force ($\tau \times$ surface area) and the hydrostatic pressure force due, to the desire of the free surface to return to gravitational equilibrium. Balancing these forces, at steady state, gives the interfacial (surface) displacement from the equilibrium position $\eta_s(x,t)$, where x is the longitudinal coordinate and t is time.

Wind set-up of the internal stratification

In a manner analogous to the set-up at the free surface, wind induced displacements can also occur along the thermocline. Consider a simple two-layered lake where the water piled-up at the leeward shore, by windward drift, simultaneously pushes down the thermocline while pushing up the free surface (Fig. 2B and D) (Mortimer, 1974; Monismith, 1986). The free surface remains comparatively horizontal owing to a return flow that develops in the hypolimnion, leading to vertical velocity shear through the metalimnion. A corresponding upwelling occurs at the windward shore (Fig. 2D). The steady-state slope of the thermocline surface $\eta_i(x,t)$ is given by a balance between the baroclinic gravitational pressure force from the tilted thermocline and the force due to the wind-stress acting through the epilimnion.

$$\frac{\partial \eta_i}{\partial x} = \frac{u_*^2}{g' h_1}$$

Here, $g' = g(\rho_2 - \rho_1)/\rho_o$ is the reduced gravity across the interface (thermocline), where g is the gravitational constant. The equation for the thermocline slope may be obtained through integration of η_i over the basin length (Boegman et al., 2005a).

$$\eta_i = \pm \frac{u_*^2}{g' h_1} \frac{L}{2}$$

The effect of buoyancy is evident by decreasing the density difference between the two layers, resulting in a decrease in g' and corresponding increase in η_i. A simple comparison $\eta_s/\eta_i = ((\rho_2 - \rho_1)/\rho_o)(h_1/H)$ shows that for weakly stratified deep systems, internal displacements (~1–100 m) may be more than an order of magnitude greater than their surface counterparts (~0.01–1 m); for example in Lake Baikal $\eta_s/\eta_i \sim 0.1$ m/75 m $\sim 10^{-3}$.

After the thermocline tilt has reached steady state, work done by continued winds is either dissipated internally as heat or acts to mix the water column by further deepening the surface layer (Imberger, 1985). Surface layer deepening has been characterized into four distinct regimes based on the strength of the stratification and winds (Fig. 3A) (Spigel and Imberger, 1980; MacIntyre, 2008). For strong stratification and weak winds (Regime A) the thermocline set-up is small, internal seiches persist for long times, mixing is weak, and the thermocline remains sharp. If the stratification is weaker or the winds stronger (Regimes B and C), seiche amplitudes increase and become a predominant feature, shear instabilities (e.g., Kelvin–Helmholtz billows) form leading to entrainment of the metalimnion into the epilimnion, enhanced mixing and rapid damping of the internal seiches (Saggio and Imberger, 1998, Horn et al., 2001). For weak stratification and strong winds (Regime D), shear instabilities are strong; the thermocline becomes diffuse with a steep slope and rapidly deepens toward the lakebed. This creates a sharp downwind interface and a broad upwelling at the upwind shore. The upwelled fluid forms a longitudinal temperature gradient, which completely mixes the lake horizontally. The colder upwelled water is nutrient rich and as it mixes, rapid fluctuations in temperature and biogeochemistry result.

Complete mixing will only occur near spring and fall turnover events in temperate lakes, when convection has sufficiently weakened the density stratification, or in shallow polymictic or weakly stratified arctic lakes (Boegman, 2020). In deeper lakes, seasonal stratification during summer will prevent complete mixing and upwelling of metalimnetic (partial upwelling) or hypolimnetic (full upwelling) water will occur (Imberger and Patterson, 1989).

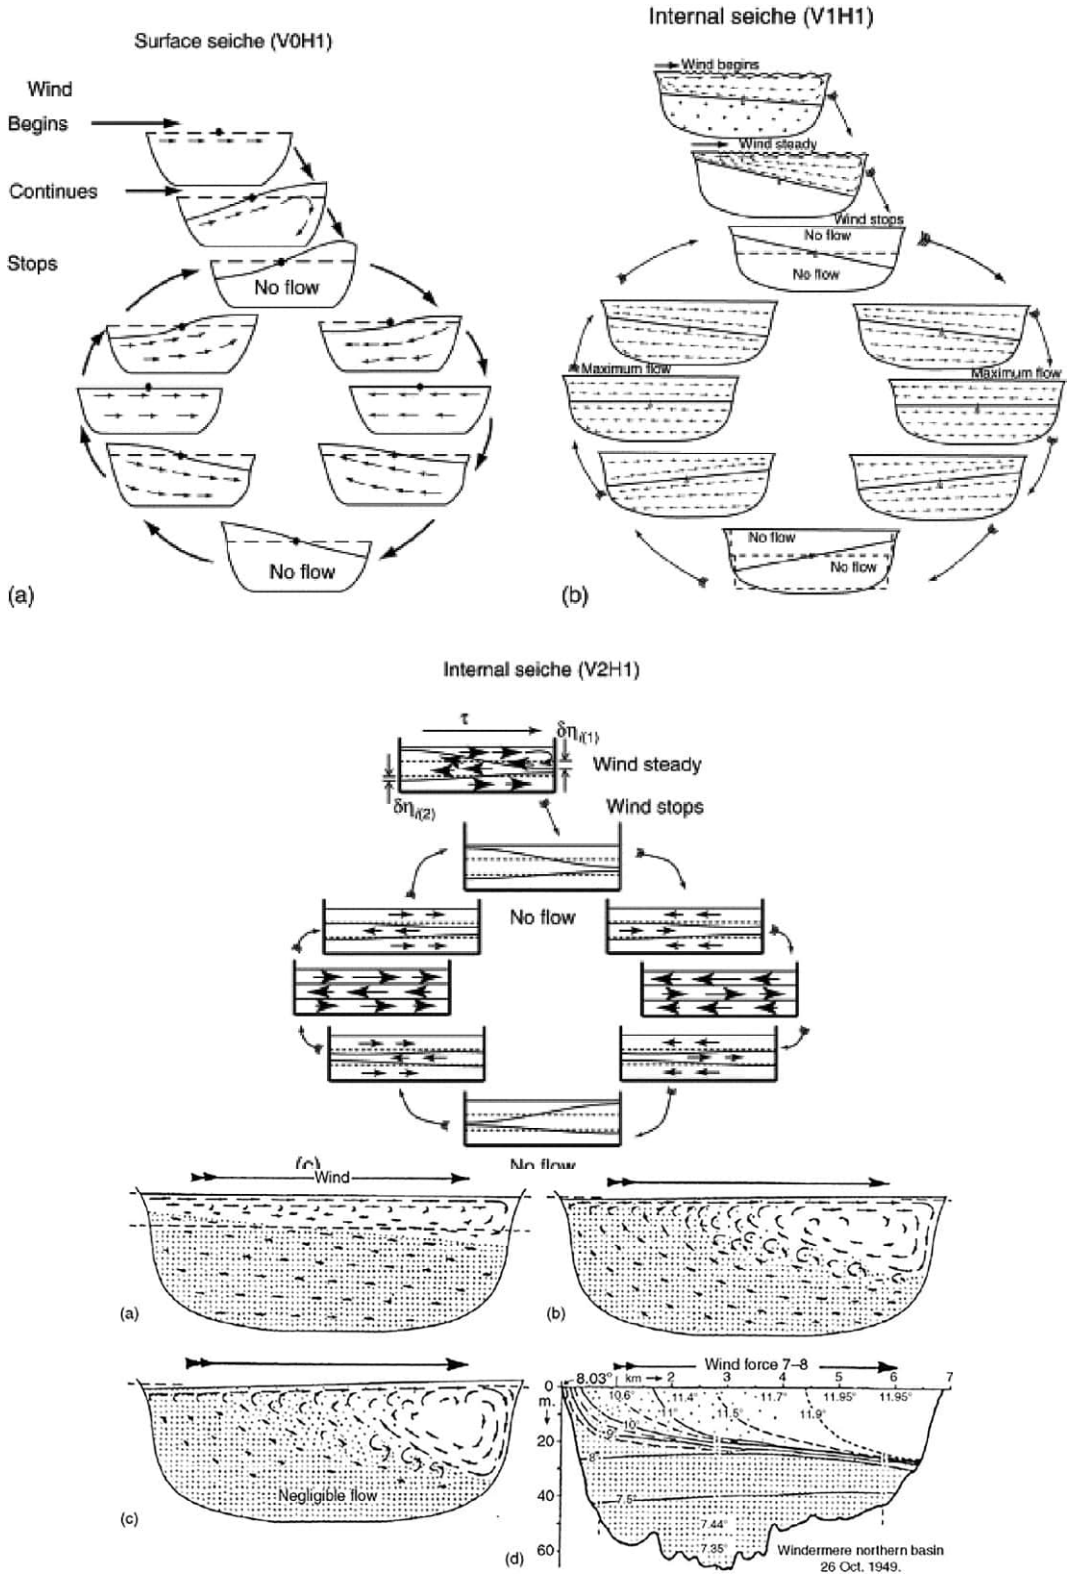

Fig. 2 Movement caused by wind stress on a hypothetical layered lake and subsequent internal seiche motion neglecting damping. (A) Horizontal mode one surface seiche in a homogeneous one-layered system. (B) Horizontal mode one vertical mode on internal seiche in a two-layered system, and (C) horizontal mode one vertical mode two internal seiche in a three-layered system. Arrows denote distribution and magnitude of water particle velocities. At $t = 0$, $(1/2)T_1$, T_1, $(3/2)T_1$, etc. the wave energy is purely in the potential form, isotherms are at their maximum tilt and there is no seiche induced flow, while at $t = (1/4)T_1$, $(3/4)T_1$, $(5/4)T_1$, etc. the energy is purely kinetic, giving rise to strong horizontal currents within the lake-basin and horizontal isotherms. (D) The response of a stratified lake to a surface wind stress. (i–iii) show the stages of development of a steady state thermocline tilt. The hypolimnion is shaded and the arrows show the relative speed and direction of the flow. (iv) Isotherm distribution and temperatures in Lake Windermere, northern basin, after a steady wind for 12 h. (E) The first three horizontal interfacial seiche modes: horizontal mode-one ($n = 1$), mode-two ($n = 2$) and mode-three ($n = 3$). Arrows denote direction of water particle velocities. Solid and dashed lines denote the interfacial displacement at one-half period intervals. Upper layer velocities for the baroclinic case are not shown and can be inferred from symmetry.

Basin-scale internal waves (phase 2, wind stops)

Internal seiches in a layered stratification

Horizontal modes

When steady winds drop and the surface stress condition is relaxed, the gravitational restoring force associated with the tilted interface (water surface or thermocline) becomes unbalanced. The available potential energy embodied in the tilt is released and converted to kinetic energy by gravity. The interface then oscillates in the form of a sinusoidal standing wave or seiche (Fischer et al., 1979; Boegman et al., 2005a). Antinodes are at the basin end walls and nodal points in the basin interior (Fig. 2A and E). Seiches are commonly called linear waves because the evolving wave-field is well described in space and time by the linear wave equation where c_o *is* the linear shallow water phase speed at which the crests/troughs propagate. This equation is equally applicable to interfacial waves traveling on the free-surface or thermocline using an appropriate form of $c_o = \sqrt{gH}$ or $c_o = \sqrt{g'h_1h_2/H}$, respectively. Due to the reduced effect of gravity across the thermocline, relative to the free surface ($g' \ll g$), surface waves travel at ~50 times the speed of internal waves.

The familiar standing wave patterns associated with seiches form as a result of symmetric progressive waves of equal amplitude and wavelength, but opposite sign, propagating from the upwelled and downwelled fluid volumes at the opposite ends of the basin (Fig. 2) (Boegman et al., 2005a; Fischer et al., 1979; Mortimer, 1974). These waves can by represented with cosine functions (Fig. 2E), which have nodes at the mid-basin and antinodes at the basin walls. Summing cosine equations for waves propagating in opposite directions, gives the equation for the horizontal mode one (H1) standing wave pattern (Fig. 2E(i)). For an enclosed basin, there is ½ wavelength of an H1 seiche in a lake, giving an overall wavelength $\lambda = 2L$ and a period according to the Merian formula

$$T_n = \frac{2L}{nc_o}$$

Here, $n = 1$ for an H1 seiche and is the number of nodal points or ½ wavelengths in the horizontal direction. The layer-averaged horizontal velocities associated with the H1 seiche are maximum the center of the basin (Horn et al., 2001). These velocities are zero

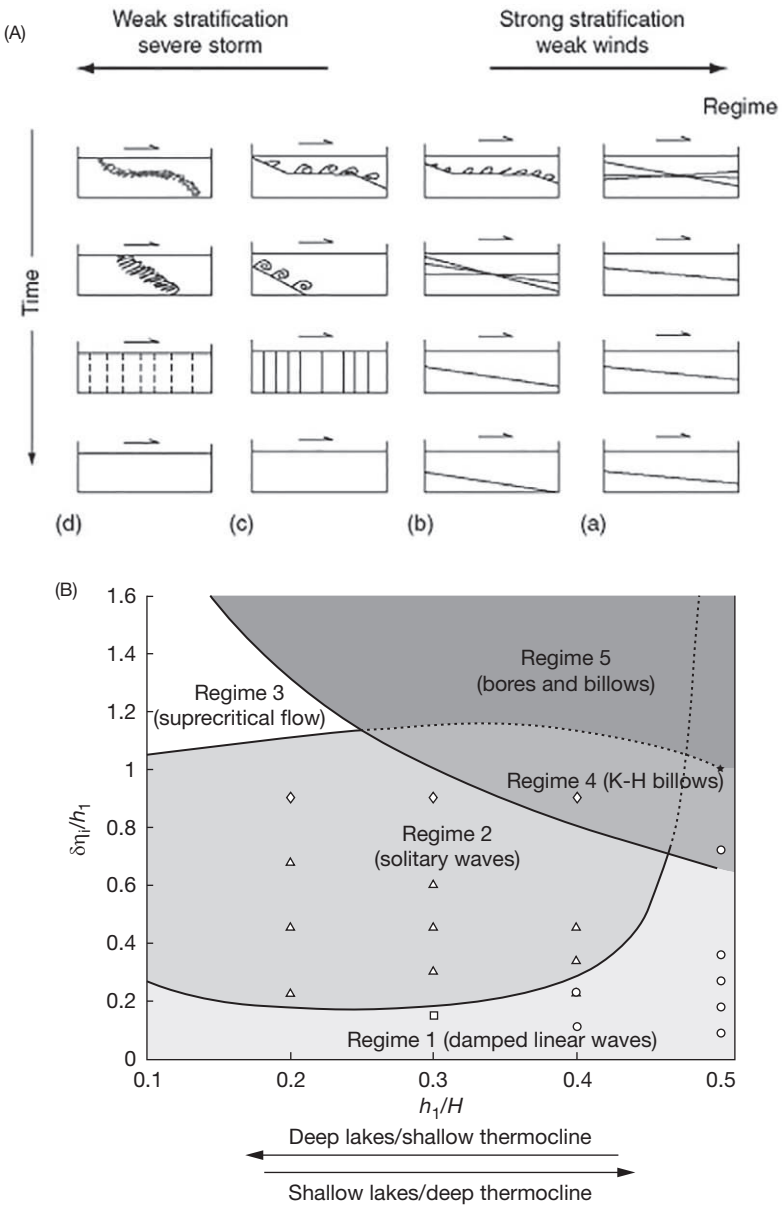

Fig. 3 (A) Schematic showing the mixed layer deepening response of a lake to wind stress. at the vertical boundaries, where the motion is purely vertical (Fig. 2E). The oscillatory seiche currents are low-period and quasi-steady. Observations from a variety of lakes and reservoirs show the surface and internal seiche currents to have a typical range of 0.02–0.20 m s^{-1}, with a maximum ~0.2 m s^{-1}during storms and to approach zero at the no-slip sediment boundary where the flow is impeded by friction (Valipour et al., 2015a).

Higher horizontal mode seiches ($n > 1$) have been observed in lakes. These are described by a more general solution of the linear wave equation, where the initial condition is a uniformly tilted interface, made up of the superposition of all higher horizontal modes (Spigel and Imberger, 1980; Boegman et al., 2005a; Horn et al., 2001). These solutions are composed only of odd modes

(i.e., $\eta_i(x,t) = 0$ when n is even). This intuitively expected because only odd modes have a nodal point at the mid-basin location, where there is zero displacement associated with a uniform tilt of the interface along the basin from the initial condition (Fig. 2A–C, and E) (Boegman et al., 2005a). By calculating the available potential energy associated with each mode, it can be shown that that more than 98% of the wave energy is contained in the H1 mode, but the energy distribution between modes may be significantly altered by resonant forcing or basin shape (Boegman and Ivey, 2012; Fricker and Nepf, 2000; Imam et al., 2020).

Examples of surface and internal seiche periods for various horizontal modes are given in Table 1. Energy will pass between potential and kinetic forms as the wave periodically oscillates with time (Fig. 2A–C, and E). At $t = 0$, $(1/2)T_1$, T_1, $(3/2)T_1$, etc. the wave energy is purely in the potential form, while at $t = (1/4)T_1$, $(3/4)T_1$, $(5/4)T_1$, etc. the energy is purely kinetic, giving rise to horizontal currents within the lake basin (Fig. 2A–C, and E). For a non-dissipative system, the modal energy distributions represent the sum of kinetic and potential energy and are independent of time. Dissipative processes will lead to a decrease in wave amplitude, but not period, with time (Table 1); unless there is sufficient mixing across the thermocline to cause a change in the stratification and hence c_o. For surface seiches the decay in amplitude with each successive period can range from 3% (Lake Geneva) to 32% (Lake Erie).

The governing equations of motion can be solved to determine modal response of a lake or reservoir to an arbitrary wind stress (Monismith, 1985), including the effects of rotation (Antenucci et al., 2000) and irregular bathymetry (Shimizu et al., 2007).

Vertical modes

Basin-scale (barotropic) wave modes that occur on the free surface have no nodes in the vertical direction and are, therefore, vertical mode zero (V0). These are the only vertical modes in a lake of constant density (e.g., Fig. 1A; V0H1 in Fig. 2A). When a single thermocline is present (Fig. 1B), V1 seiches may also occur (e.g., V1H1 in Fig. 2B). A vertical density structure approximated with three or more fluid layers (e.g., Fig. 1C and D) will support higher vertical modes (e.g., V2H1 in Fig. 2C).

Vertical mode-two seiches require a comparatively thick metalimnion (Vidal et al., 2013). They can be generated when there is an asymmetry in the tilting of the upper and lower interfaces of the stratifying layers (the diurnal and seasonal thermoclines or the upper and lower boundaries of the metalimnion (MacIntyre et al., 1999)). Laboratory and limited field data show that such asymmetries are introduced from the compression and expansion of the metalimnion along the downwind and upwind shores, respectively, under upwelling conditions (e.g., Fig. 2D(iv)). This can create strong shear across the base of the surface layer and a relatively undisturbed lower interface; whereas a V1 response occurs for comparable tilts of both interfaces and generates stronger currents in the hypolimnion (Table 2).

Higher vertical mode basin-scale internal waves have also been observed in several lakes after a sudden wind pulse has excited an initial V1H1 response, which then evolves into a V2 seiche (e.g., Wood Lake, Wiegand and Chamberlain (1987)). Resonance with

the wind forcing (e.g., Lake Alpnach, Münnich et al. (1992)), sloping basin topography (Upper Mystic Lake, Fricker and Nepf (2000)) and unequal density differences between stratifying layers (Monismith, 1985) can cause this preferential excitation of higher vertical modes.

Internal seiches under the effect of Earth rotation

The effect of the Coriolis force acting on internal waves, can be quantified according to the Burger number $S = R/W$. Here, $T_E = 86{,}400$ s is the period of rotation of the Earth and $R = c_o/f$is the *Rossby radius* of deformation, which varies with latitude θ according to the *inertial frequency* $f = (4\pi/T_E) \sin \theta$ (Antenucci et al., 2000). The *inertial period*, which may be defined as $T_i = 2\pi/f$, is infinite at the equator, ~18 h in the Laurentian Great Lakes, and minimum (12 h) at the poles.

We can interpret R as the length scale over which an internal wave traveling at c_o will be influenced by rotation for a particular latitude-dependent f: for rotational effects to be significant $W > R$, or equivalently $S < 1$. For example, using a typical $c_o = 0.5$ m s^{-1} rotational effects will be significant for small lakes in the arctic ($W > \sim 3$ km), mid-sized lakes in temperate latitudes (i.e., $W > \sim 5$ km) and larger lakes near the equator (i.e., $W > \sim 100$ km). The effect of rotation is gradual and continuous; there is not a sudden transition at $S = 1$. For surface seiches, the fast phase speeds lead to $R \rightarrow$ 300 km and, correspondingly, there are few lakes that are sufficiently large for the surface seiche to be influenced by rotation (Antenucci, 2009).

Surface momentum transfer and wind set-up with Coriolis force

For lakes where $S < 1$, steady winds will generate surface currents that are deflected 45 degrees by the Coriolis force fu, acting on a fluid parcel with velocity u. The deflection is to the right/left in the northern/southern hemisphere and continues to spiral, with depth, for each contiguous fluid layer decreasing logarithmically in magnitude. The overall depth of the *Ekman layer* $D \sim 2v_T/f$, where v_T is an eddy viscosity, varies according to the strength of the wind stress and the latitude. For example, in Lake Ontario, Csanady (1982) observed a steady 7 m s^{-1} wind to generate a 10-m deep Ekman layer with an average current of 0.1 m s^{-1}.

Integrated over D, the total *Ekman drift* is oriented 90 degrees to the wind, inducing a down-welling of the thermocline along the shore to the right/left of the wind in the northern/southern hemisphere and a corresponding upwelling along the left/right shore. This situation is similar to the wind induced up- and down-welling shown in Fig. 3, but in a direction perpendicular to the wind stress. The Coriolis force is in geostrophic balance with the gravitationally induced pressure force acting on the tilted thermocline. The density gradient creates a cyclonic pressure-driven current, constrained to run shore-parallel in a counter-clockwise/clockwise direction in the northern/southern hemisphere. Conversely, an anti-cyclonic motion would be clockwise in the northern hemisphere, and counter-clockwise in the southern hemisphere.

Internal Kelvin and Poincaré waves

For the rotational case, as in the non-rotating case, when the wind stress drops the pressure gradient becomes unbalanced. The subsequent relaxation of the wind-induced thermocline tilt generates two classes of rotational basin-scale internal waves along the thermocline: (i) anticyclonic Poincaré waves (Poincaré, 1910) that extend over the width of the lake and energize currents in the interior at super-inertial frequencies (periods $< T_i$); and (ii) cyclonic Kelvin waves (Thomson, 1879) that are trapped along the boundary and propagate at sub-inertial frequencies (periods $> T_i$) around the lake perimeter (Antenucci et al., 2000, Antenucci, 2009). Various vertical and horizontal modes are possible, depending on the characteristics of the basin shape, wind stress and density stratification (Saggio and Imberger, 1998; Lemmin et al., 2005; Antenucci et al., 2000). The Kelvin and Poincaré wave solutions, to the governing equations of motion in a rotating reference frame, were developed from the analysis of wave motions in channel flows; the Kelvin wave corresponding to the wave mode propagating along the channel and the Poincaré wave corresponding to the cross-channel mode (Antenucci et al., 2000; Mortimer, 2004).

Internal Kelvin waves travel parallel to the boundary with a maximum amplitude at the shore; the wave crest is to the right/left in the northern/southern hemisphere when looking along the direction of wave propagation (Fig. 4A). The seiche pattern (Fig. 2B) is modified such that the transverse nodal line has become a central amphidromic nodal, around which the Kelvin wave propagates with an exponential decrease in amplitude in the radial cross-shore direction over an e-folding distance $\sim R$ (Fig. 4B). The phase speed c_o and wave period T_n are the same as for waves in a nonrotating reference frame. Kelvin-wave induced currents generate an along-shore coastal jet (Fig. 4B) (Csanady, 1982), which is indistinguishable from the jet that forms due to the initial wind-induced geostrophic adjustment (Csanady, 1982). The exponential slope in the cross-shore direction balances the Coriolis force and consequently there is no cross-shore flow. The Kelvin wave will interact with local topography as it propagates, generating eddies and exchange into coastal embayments (Flood et al., 2020; Wake et al., 2005).

The internal Poincaré waveform (Fig. 5A) (Antenucci, 2009, Mortimer, 2004) energizes strong mid-basin seiche currents that are deflected by Coriolis such that the orbital wave velocities form *inertial circles* with diameter $\sim R$ once per wave cycle (Fig. 5B). Two transverse progressive Poincaré waves can combine to form a cellular standing wave pattern (Fig. 5A). At very long wavelengths, Poincaré waves have a near-inertial period $\rightarrow T_i$ and the wave energy increasingly becomes kinetic (currents) as opposed to potential (amplitude), with the overall motion becoming indistinguishable from an inertial circle.

To satisfy the wave boundary conditions at the lake perimeter, it is necessary to sum the solutions from a progressive Kelvin wave and a transverse standing Poincaré wave (Fig. 5B). As the Poincaré wave impinges upon the coastline, the inertial circles become ellipses and eventually shore parallel oscillations (Troy et al., 2012; Mortimer, 2004). The degree of interaction between the Kelvin and Poincaré waves depends on S (Mortimer, 2004). For medium sized lakes ($W \sim (1 - 10)R$ or $S \sim 0.1 - 1$), both Kelvin and Poincaré waves manifest their signals throughout the basin (Fig. 5B) (Antenucci and Imberger, 2001) (e.g., Lake Simcoe, Bouffard and Boegman (2011); Lake Geneva, Lemmin et al. (2005); Lake Kinneret, Hodges et al. (2000); however, for large lakes ($W \sim 20R$ or $S \ll 1$) rotational effects predominate and the basin-scale internal wave modes become independent of one-another (e.g., Lake Erie, Valipour et al., 2015b; Lake Michigan, Choi et al., 2012); Lake Superior, Austin, 2013). Kelvin waves propagate within $\sim R$ of where the thermocline intersects the coast and Poincaré waves propagate in the basin interior (Mortimer, 2004; Antenucci et al., 2000).

Degeneration of basin-scale internal waves in lakes (phase 3)

Understanding the factors leading to wave degeneration has been a major goal of limnologists. This is because internal waves ultimately lose their energy (degenerate) to dissipation (viscous frictional heating of the fluid at mm scales) and diapycnal mixing

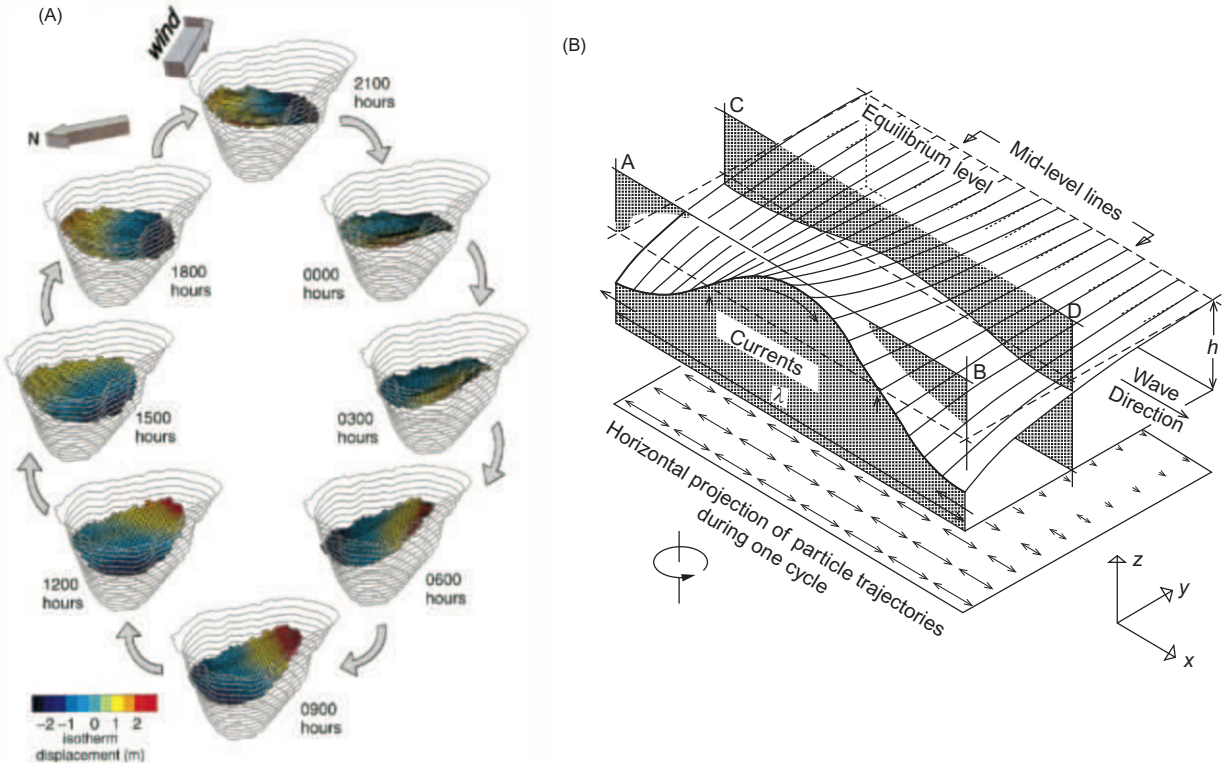

Fig. 4 (A) Computer simulated cyclonic propagation of a vertical mode-one horizontal mode-one internal Kelvin wave in Lake Kinneret starting at 21:00 h. (mixing of fluid perpendicular to isopycnals or surfaces of constant density) in regions where the flow is turbulent. In turn, mixing drives biogeochemical fluxes. Turbulence is produced directly from the seiche induced currents by fluid straining in the lake interior (Bouffard et al., 2012) and TBBL (Jabbari et al., 2020; Cannon and Troy, 2018), and from processes that are uncoupled from seiche generation, such as surface wave breaking and inflows (Hamblin, 1977), which may act to disrupt the seiche motion. Seiche-induced mixing in the lake interior (Pernica et al., 2013) and TBBL (MacIntyre and Jellison, 2001) as well as internal wave shoaling and breaking (Boegman and Stastna, 2019) all impact lake biogeochemistry.

As a general rule, for deep lakes, the period of internal seiche decay is about 1 day per 40 m of water-column depth (Wüest and Farmer, 2003). For very deep lakes, e.g., Lake Baikal where $H = 1637$ m, this equates to a decay period of more than 1 month. The time scale associated with viscous damping of a basin-scale seiche T_D can be estimated from the ratio of the seiche energy to the rate of energy dissipation in the benthic boundary layer ε_{TBBL}

$T_D \sim \frac{\text{Seiche energy}}{\varepsilon_{TBBL}} \times \frac{\text{Lake volume}}{\text{TBBL volume}} \sim 1$ to 10 d for moderately sized lakes (Imberger, 1998)

The energy dissipation in the lake interior $\varepsilon_{interior}$ is neglected because observational studies show that $\varepsilon_{TBBL} > 10\varepsilon_{interior}$ (Wüest et al., 1996). As a result, degeneration of basin scale internal waves occurs primarily due to turbulence production in the TBBL rather than the interior. The degeneration can occur through four possible mechanisms that depend on the degree of wind-induced thermocline tilt (η_i/h_1) and thermocline depth (h_1/H) (Horn et al., 2001); Fig. 3B): (1) viscous damping of seiche currents in the TBBL (Imam et al., 2013; Spigel and Imberger, 1980); (2) the formation of shear instabilities in the interior (Gomez-Giraldo et al., 2008; Boegman et al., 2003); (3) the production of high-frequency nonlinear internal waves that will break on sloping topography (Boegman et al., 2005b; Preusse and Peeters, 2014); and (4) the formation of internal hydraulic jumps (Dorostkar and Boegman, 2013; Thorpe et al., 1996). By calculating the timescales over which each mechanism will occur, regimes have been delineated in which a particular mechanism will predominate (Horn et al., 2001) (Fig. 3B).

Internal wave degeneration processes are different in large lakes ($S < \sim 1$), where Coriolis impacts the thermocline setup and energy flux paths to the internal wave field (Valipour et al., 2015b; Bouffard et al., 2012; Lin et al., 2021). The internal Kelvin wave leaks energy to transverse Poincaré waves as it propagates (de la Fuente et al., 2008; Mortimer, 2004) and to high-frequency internal waves through nonlinear steepening (Boegman et al., 2005a). The internal Poincaré wave may degenerate through the formation of Kelvin-Helmholtz billows at the wave crests and troughs (Bouffard et al., 2012).

Resonant and forced internal waves

The periodicity inherent in weather patterns creates over-lake wind fields at regular frequencies. For example, the winds over Lake Erie have periodicities of 10 d and 24 h, associated with frontal weather systems and diurnal land/sea breeze phenomena, respectively (Hamblin, 1987). When the forcing frequency matches one of the natural frequencies of the basin-scale wave modes, resonant amplification will occur. Seasonal heating and deepening of the thermocline will adjust the natural frequencies relative to the forcing frequencies, thus tuning the system into and out of resonance (Antenucci and Imberger, 2003).

Laboratory experiments show that the relative frequencies of the wind forcing f_w and H1 internal seiche f_{H1}can be used to model internal wave response to periodic forcing conditions (Boegman and Ivey, 2012). When the forcing frequency of the wind stress is less than the natural frequency of the H1 internal seiche ($f_w < (2/3)f_{H1}$), the phase of the basin-scale oscillations are reset with each wind event and a forced internal seiche is generated at the same frequency as the wind forcing (Gómez-Giraldo et al., 2006). A resonant H1 seiche will occur when the frequency of the wind forcing is near the frequency of the H1 seiche ($(2/3)f_{H1} < f_w < 2f_{H1}$; Antenucci and Imberger (2003)) and when the forcing frequency is greater than the natural frequency of the H1 seiche ($f_w > 2f_{H1}$)), higher-mode horizontal seiches are generated. Resonance appears to be particularly effective in amplifying the response of the second vertical mode (e.g., Lake Alpnach (Münnich et al., 1992)) and the even horizontal modes that are not naturally energized by a wind-induced interfacial setup.

Resonance between the wind and the H1 internal mode leads to increased seiche amplitudes under relatively weak wind forcing conditions. For example, the formation of a steepened internal wave front in Loch Ness (Thorpe, 1974).

Analysis of timeseries data

The various wave, instability and turbulence processes described in this chapter are shown schematically in Fig. 7. These processes occur beneath the lake surface and so practicing limnologists do not have the luxury of being able to directly observe them in the field. Some insight regarding their spatial structure is gained from idealized laboratory and computational models but for the most part, limnologists must resort to deciphering timeseries data from thermistor chains, which are the most useful tools in their arsenal. Fig. 6 shows many of the processes from Fig. 7 as they would appear on thermistor data, which has been contoured to show isotherm displacement timeseries with depth.

During the strong wind event, shear instabilities form at the base of the surface layer (Fig. 6D). Shortly thereafter, a thermocline jet occurs within a compressed region of the metalimnion and causes a rapid expansion of the strata and localized mixing (Fig. 6E). The basin-scale internal wave energized by the wind has steepened into an internal surge supporting large amplitude nonlinear internal waves of depression and series of step like features resembling internal hydraulic jumps (Fig. 6C). The surge wave interacts with the lakebed leading to significant mixing over the bottom 20 m of the water column.

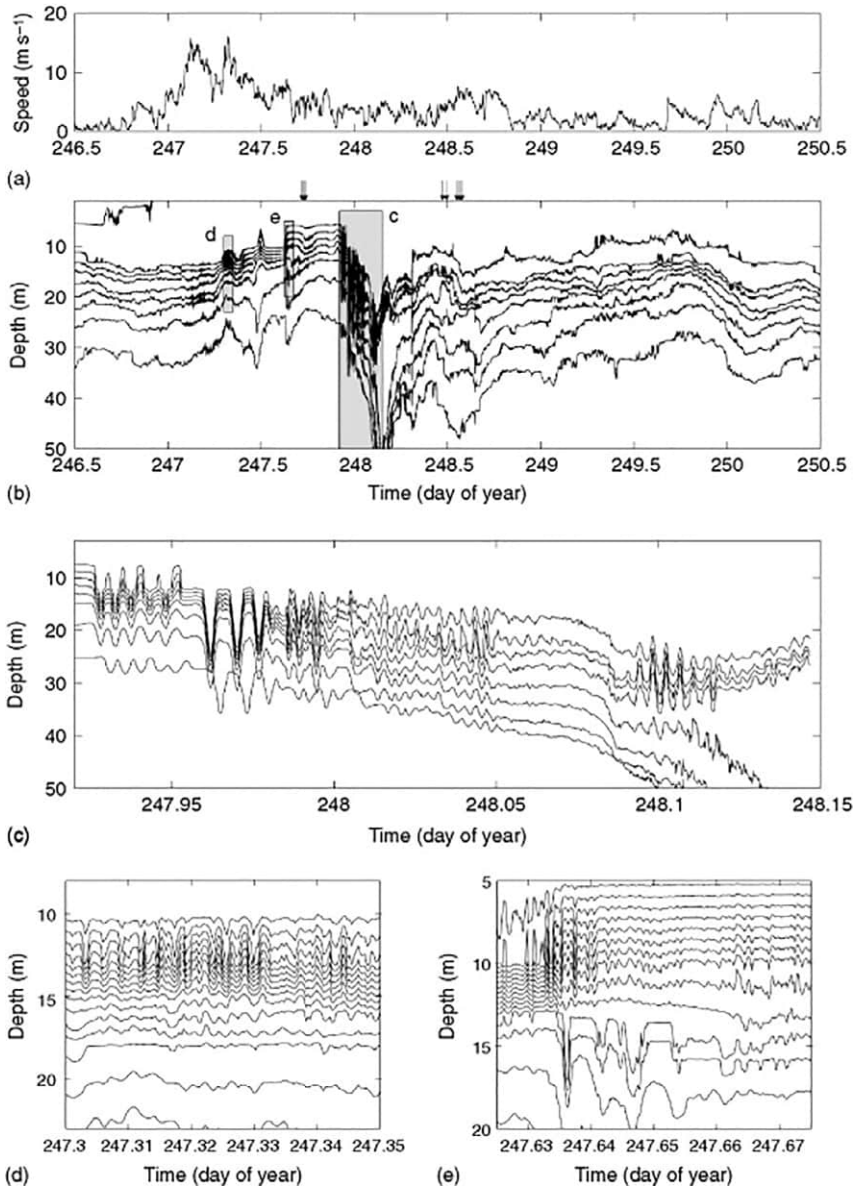

Fig. 6 Observations from Lake Biwa (Japan) in 1993 showing steepened nonlinear basin-scale internal wave front and associated nonlinear internal waves. (A) Wind speed collected at 10-min intervals showing the passage of a storm event; (B) nonlinear response of basin-scale internal wave field showing steepened wave front (2 °C isotherms); (C) magnified view of shaded region in panel b showing details of NLIWs (2 °C isotherms). The motions described above all result from a single intense wind event. Considering the periodic nature of surface winds, it is not surprising that periodic wave motions occur in lakes over a range of length scales and frequencies. Spectral frequency analysis is used to conveniently analyze timeseries data and determine the relative amount of energy found at each frequency.

Relevant case studies

See Table 2.

Summary

The dynamic interplay between stratification, waves, and wind is best summed up in using the conceptual model proposed by (Imberger and Patterson, 1989); Fig. 7) and supported by more recent measurements (Wüest et al., 1996, 2000; Imberger, 1998; Nakhaei et al., 2016; Lin et al., 2021). A lake behaves like an engine that is powered by the wind and does work against the potential energy embodied in the stratification. Approximately 2% of the wind energy enters the lake; of this ~80% is dissipated in the surface layer and ~20% is transferred to the basin-scale internal wave field. The basin-scale seiches energized by the wind are frictionally damped as they swash along the lakebed and by degeneration into progressive high-frequency internal waves, shear instabilities, and eventually turbulence. Approximately 90% of the seiche energy is lost energizing turbulent dissipation and mixing in the TBBL; <1/4 of which first passes through the nonlinear internal wave field prior to wave breaking and >3/4 of which is lost to frictional swashing in the TBBL. The remaining ~10% of the seiche energy results in intermittent shear instability in the basin interior. The overall mixing efficiency of the turbulence is ~15% leading to an upwards buoyancy flux that works to weaken the stratification and raise the center of gravity of the lake. The lake engine is extremely inefficient with only ~0.06% of the wind work acting to irreversibly mix the stratification; the bulk of the wind work is lost to frictional viscous dissipation, which due to the large heat capacity of water has no significant effect on the lake temperature. From this model, it is clear that while internal waves influence biogeochemical mixing and transport within a stratified waterbody, they are unable to significantly influence the stratification upon which they propagate. Wind-induced vertical mixing at basin-scales is, therefore, greatly reduced by diurnal/seasonal/meromictic stratification and only occurs in polymictic systems (Loewen et al., 2007; Boegman et al., 2008) or when convection has eroded the seasonal stratification (Bouffard and Wüest, 2019; Boegman, 2020; Ghane and Boegman, 2021).

Knowledge gaps

- How energy is transferred from basin-scale internal Kelvin and Poincaré waves to ultimate dissipation and mixing in rotational systems
- The relative importance of internal wave-induced mixing versus convection, in regulating vertical biogeochemical fluxes
- The coupling between wind-driven surface waves and internal waves in lakes
- How internal waves resuspend sediments and form nepheloid layers

Currents in Stratified Water Bodies 1: Density-Driven Flows

F Peeters, Universität Konstanz, Mainaustrasse, Konstanz, Germany
R Kipfer, Swiss Federal Institute of Environmental Science and Technology (Eawag), Swiss Federal Institute of Technology (ETH), Ueberlandstr, Duebendorf, Switzerland

This is a reprint of F. Peeters, R. Kipfer, Currents in Stratified Water Bodies 1: Density-Driven Flows, In Encyclopedia of Inland Waters, Edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00080-6.

Introduction

Vertical transport of dissolved substances and heat in lakes mainly results from two different mechanisms: (a) mixing by turbulence that is usually described as a diffusive transport and (b) density-driven exchange that can be considered as an advective transport. A typical example of the latter is convection owing to surface cooling in fall, which often leads to isothermal conditions in shallow lakes of the temperate zone. Because entrainment of ambient water limits the depth of convective plumes, density-driven transport to large depth in deep lakes usually occurs along the lake boundaries and is often the result of specific and localized processes, which are discussed later.

The important role of density-driven transport for vertical exchange in lakes becomes evident if one considers that temperature stratification typical for most lakes is characterized by a decrease in water temperature with increasing water depth. Turbulent diffusion causes heat to flow from high to low temperatures and hence typically leads to a gradual continuous warming of cold deep-water regions. Thus, on a long-term average, advective processes transporting cold surface water downwards must be sufficient to compensate for the heat flux due to turbulent diffusion. The low temperatures in the deep water are usually either the remnant of isothermal conditions generated by buoyancy-driven overturn during the cold season or originate from cold density currents propagating to largest depth. Because vertical transport due to density currents plays an important role in overall deep-water renewal and heat exchange, density driven exchange processes are central to the understanding of oxygenation and nutrient transport especially in deep lakes.

In the world's largest and deepest water bodies several processes have been identified that lead to advective deep-water renewal by density currents: river inflow, e.g., in Lake Constance, Lake Geneva, and Lake Baikal; inter-basin exchange, e.g., in Lake Lucerne, Lake Baikal, or even in the Caspian Sea; differential cooling, e.g., in Lake Geneva, Lake Constance, Lake Issyk-Kul, and Lake Malawi; thermal-bar mixing, e.g., in the Lake Ontario, Lake Ladoga, Lake Michigan, and Lake Baikal; and transport due to thermobaric instabilities, e.g., in Lake Baikal and possibly in Crater Lake. All these processes have been shown to significantly contribute to deep-water renewal in lakes, although advective transport to the lake bottom was not conclusively demonstrated in all cases. More details on the different processes are given below.

In the following, we first describe the principal characteristics of density currents and the associated signals of intrusions in vertical profiles of water constituents and temperature. Then, we present several mechanisms that lead to the generation of density plumes in deep freshwater lakes and discuss which of these processes can also be responsible for deep-water renewal in tropical and saline lakes. Finally, we discuss the potential impact of changes in the catchments of lakes and in the meteorological conditions on deep-water renewal by density currents.

Characteristics of Density Currents

Density currents are driven by differences in water density, which can result from gradients in water temperature, salinity, dissolved uncharged substances, or suspended particles and are also affected by pressure. If a water mass with higher density is situated above

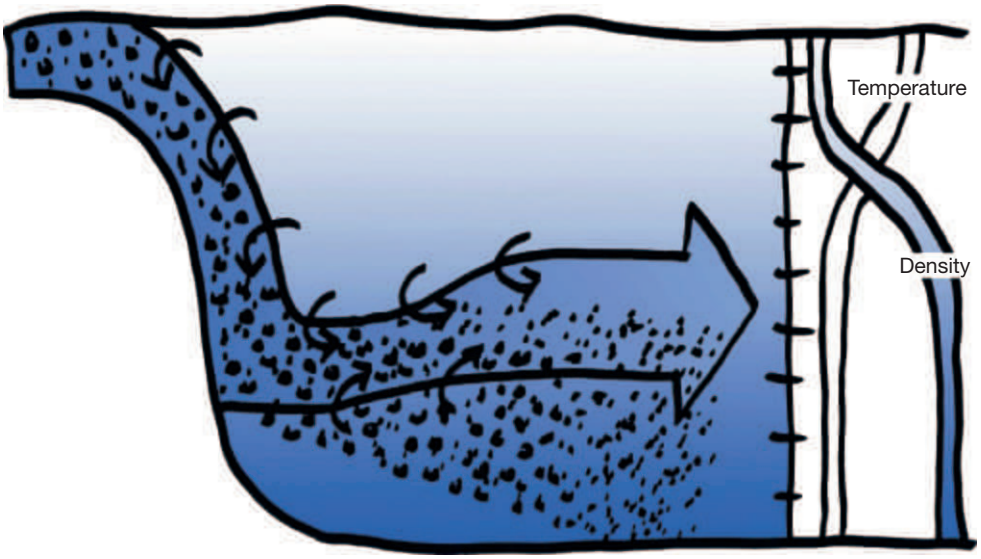

Figure 1 Schematic illustration of density currents. The shading on the left-hand side of the figure indicates an increase in density with increasing depth.

a water mass with lower density, the stratification is unstable and buoyancy causes the upper water mass to sink. In the sinking process ambient water is mixed into the sinking water mass and thus alters its density (Figure 1), thereby reducing the density difference between the density plume and the ambient water.

Furthermore, the properties of the ambient water change along the path of the sinking water mass. Hence the buoyancy of the sinking plume changes continuously as it sinks into deeper depth. Eventually, a depth is reached where the density of the density plume and the density of the surrounding water become equal. At this depth the sinking process ceases and the plume water spreads out laterally into the ambient water forming an intrusion (Figure 1). In many cases the sinking plume meets the lake boundary and then continues to sink along the lake boundary (Figure 1). In this case, entrainment of ambient water is limited to the upper side of the density plume and less ambient water is entrained per unit sinking depth. Hence the characteristic properties of the water within the density plume (e.g., temperature, salinity, suspended particles, dissolved oxygen) change more slowly and the density plumes typically can propagate to larger depths than would be possible in the open water.

The occurrence of density plumes propagating from shallow to deep water are indicated by intrusions that can be identified in CTD -profiles (conductivity as measure of salinity, temperature, and depth) and in pro files of dissolved substances and suspended particles. Figure 2 presents an ex ample from Lake Issyk-Kul (Kyrghystan), where intrusions are characterized by a higher dissolved oxygen con centration and a lower light transmission than is observe d in the ambient water.

High oxygen levels in the intrusions indicate oxygen -rich surface water that must have been transported recently because oxy gen levels have not yet been significantly reduce d by degradation processes. The low light transmission in the intrusions indicates water with a high load of suspended particles suggesting either, that the water that generated the density current was enriched in suspended particles and thus may have originated from river inflow, or, that the density plume responsible for the intrusions has propagated along the lake boundary and caused resuspension of sediments during the sinking process. Temperature is usually not a good indicator of intrusions because it is a key parameter deter mining plume density. Thus, at the depth of the intrusion, plume water and surrounding water often have about the same temperature. However, in cases where the density plume propagates down to the largest depths, as it is some times the case e.g., in Lake Baikal, temperature anomalies at the lake bottom can be used to identify density plumes.

Density Plumes Generated by External Inputs

River Inflows

The density differences required to drive density plumes originate from processes that generate horizontal or vertical gradients in water properties. An obvious example is river inflow (Figure 3).

River water usually contains an increased load of suspended particles and has a different temperature and salinity than the lake water. Hence, river inflow is commonly associated with density plumes propagating from the river mouth to larger depths. The kinetic energy associated with the inflow of the river water is usually rapidly dissipated and the horizontal density gradients resulting from the different densities of river water and lake water are the main cause of river induced transport of water masses in lakes. During summer, the density plumes induced by river inflow typically intrude at some depth within the thermocline of freshwater lakes. Because of the large temperature gradients in the thermocline, water densities change significantly within a rather narrow depth range in the lake. Hence, the probability that the density of the plume water agrees with the density in the water column of the

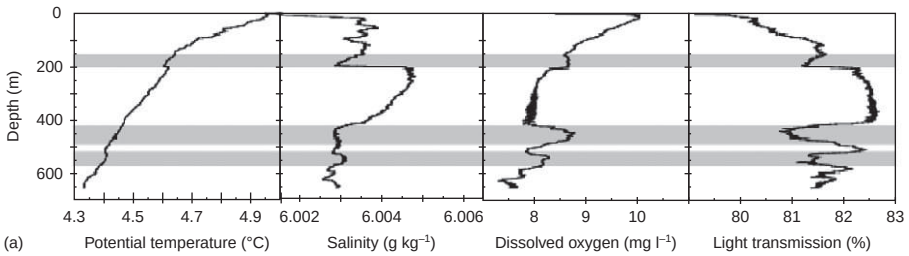

Figure 2 Intrusions as indicators of density currents. Vertical profiles of temperature, salinity, dissolved oxygen, and light transmission measured in Lake Issyk-Kul. The distinct features in these profiles suggest intrusions from density currents. Grey bars mark depth regions with high concentrations of dissolved oxygen and low light transmission, suggesting water originating from shallower depth regions. Redrawn from **Figure 2** in Peeters FD, Finger M, Hofer M, Brennwald DM, and Livingstone R Kipfer (2003). Deep-water renewal in Lake Issyk-Kul driven by differential cooling. *Limnology & Oceanography* 48(4): 1419–1431.

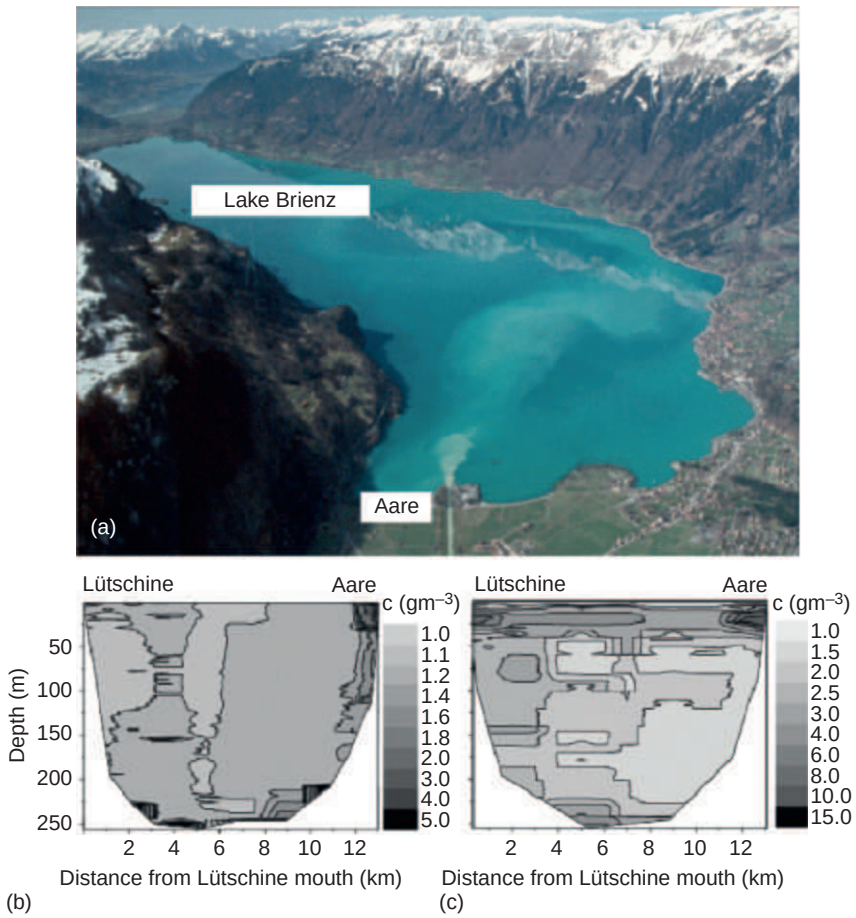

Figure 3 Density currents generated by river inflow. (a) Water of river Aare indicated by high turbidity intruding near the surface of Lake Brienz. The sharp boundaries of this surface plume indicate plunging of river water to larger depth. (b, c) Suspended particle distribution inferred from light transmission measurements in a longitudinal cross-section of Lake Brienz measured in February (b) and October (c). The particle distributions suggest that, in February water introduced by the river Aare (inflow on the right-hand side) sinks as density plume along the lake bottom towards largest depth (b). In October river Aare and river Lütchine both intrude at intermediate depth (c). (Figure 3(a) was provided by Ueli Ochsenbein; **Figure 3(b)** and **(c)** are redrawn from **Figure 7(a)** and **7(d)** in Finger D, Schmid M, and Wüest A (2006). Effects of upstream hydropower operation on riverine particle transport and turbidity in downstream lakes. *Water Resources Research* 42, W08429, doi:10.1029/2005WR004751. Reproduced/modified by permission of American Geophysical Union.

lake is especially large within the thermocline. This fact explains that river water typically intrudes in this depth range. The depth reached by the density plumes varies during the course of the year since water properties and hence the density of lake and river water changes seasonally (Figure 3). Density currents containing a high load of suspended particles are often called turbidity currents. Sedimentation of particles out of intrusions resulting from turbidity currents can reduce the density of the intruding water sufficiently that the depth of the intrusions becomes shallower over time. Density currents induced by river inflows usually

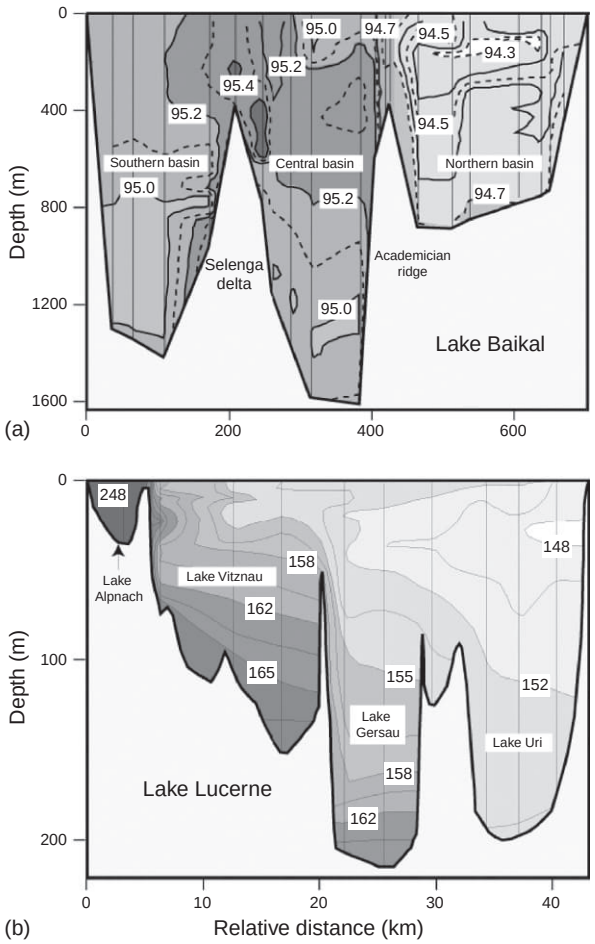

Figure 4 Density currents generated at sills between sub-basins. Vertical transects of salinity in Lake Baikal (a) and in Lake Lucerne (b). In both lakes the horizontal gradients in salinity are generated by river inflows introducing water with different ion concentration. The salinity distributions suggest that density currents are not only generated directly by river inflow as is the case in Lake Baikal at the Selenga delta (see panel a) but that density currents also occur in both lakes at the sills between sub-basins most likely driven by horizontal transport across the sill. Contours depict salinity in mg kg^{-1}. **Figure 4(a)**: redrawn from Kipfer R and Peeters F (2000). Speculation on consequences of changes in the deep water renewal in Lake Baikal, in K Minoura (ed.) *Lake Baikal a mirror in time and space for understanding global change processes*, pp. 273–280. Amsterdam, Netherlands: Elsevier. **Figure 4(b):** drawn using data from Aeschbach-Hertig W, Kipfer R, Hofer M, Imboden DM, and Baur H (1996) Density-driven exchange between the basins of Lake Lucerne (Switzerland) traced with the ^{3}H-^{3}He method. *Limnology and Oceanography* 41: 707–721.

propagate along the sloping bottom boundary before the water intrudes laterally. If the concentrations of solutes and particles are very different between the river and the lake water, the plumes can propagate down to the deepest parts of the lake. In cases where the sinking water is confined to underwater channels, e.g., density plumes propagating down the Kukui Canyon of the Selenga delta in Lake Baikal, entrainment of ambient water is reduced, and the density plume can propagate over a depth range of more than 1000m down to 1640m (see also **Figure 4(a)**).

Interbasin Exchange

River inflows not only result in localized density plumes propagating from the river mouth to larger depths but also can generate subtle large scale gradients in water properties that affect the horizontal density distribution on a basin scale. These small density gradients on a large spatial scale may contribute to the generation of density currents far from the river inflow that occur especially in the vicinity of sills separating sub-basins of the lake. This mechanism is exemplified in **Figure 4** for two lakes of different size, Lake Baikal and Lake Lucerne, that both are structured into several sub-basins separated by sills.

In both lakes large scale horizontal salinity gradients are generated by river inflows introducing water with different ion concentrations into the different sub-basins. In the case of Lake Baikal, the River Selenga introduces more saline water into the Central Basin than the Upper Angara River introduces into the Northern Basin. In case of Lake Lucerne, the River Sarner Aa introduces more saline water into the sub-basin Lake Alpnach than the River Reuss introduces into the sub-basin Lake Uri. Because

of the salinity gradients, the density of the water in the different sub-basins differs if temperature is the same. In Lake Lucerne the densest water can be found in sub-basin Lake Alpnach when winter cooling reduces surface water temperature to ~4 °C. Horizontal transport of the dense water from Lake Alpnach to the subbasin Lake Vitznau across the sill separating the two sub-basins induces a density current renewing the deep-water of sub-basin Lake Vitznau (**Figure 4(b)**). The density plume causes upwelling of cold dense water within Lake Vitznau. Horizontal transport of water across the sills between sub-basin results into a cascading of density driven transport within all sub-basins (**Figure 4(b)**). A similar process is operating in the different basins of Lake Baikal (**Figure 4(a)**). Prerequisite of these density currents generated at sills between sub-basins is (1) the structuring of the lake basin into sub-basin that prevents homogenization of water properties by horizontalmixing and (2) a heterogeneous input of water properties, as e.g., the salinity by the river inflows in **Figure 4**.

Subsurface Inflows

Besides the input from rivers, external water sources derived from groundwater inflows and from hydrothermal vents can generate density currents depending on the depths at which the inflows are located. Groundwater and hydrothermal water is usually highly enriched in ions and thus can cause salinity driven density plumes. Groundwater inflows into lakes are common in artificial lakes such as mining lakes or gravel-pit lakes or occur in karstic environments. Density currents due to hydrothermal vents have been reported for instance in Lake Baikal, where hydrothermal water is introduced in Frohliha Bay at a depth of 200–400m and propagates as a bottom following density current down to 1400m depth. In this specific case the salinity of the hydrothermal water is sufficiently large to compensate the decrease in density due to the increased water temperatures in the hydrothermal water.

Density Plumes Generated by Internal Processes

Differential Cooling

A key parameter affecting water density is temperature. However, for density currents to be induced on the basis of the temperature of water, horizontal gradients in temperature are required. Horizontal temperature gradients are generated by external surface and subsurface inflows (see earlier text) but also by internal processes. In most lakes the heat flux at the lake surface (expressed per unit area) can be considered as horizontally homogeneous because meteorological parameters and radiation do not vary significantly at the length scale of the lake basin. Nevertheless, differential cooling can generate significant temperature differences within lakes and thus generate density currents (e.g., Wellington Reservoir, Lake Geneva, Lake Constance, Lake Banyoles). Heat loss at the lake surface causes vertical convection and thus mixing of surface water with water from layers below. This process continuously mixes the cooled surface water with water from deeper layers containing heat stored during the warm season. In shallow-water regions, the reservoir of warmer deep water is exhausted earlier than in regions with large water depth. Hence, in shallow-water regions heat loss at the lake surface leads to a faster cooling of the water column than in deep-water regions. Because the cold water in the shallow-water regions has a larger density than the warmer water in the pelagic, deep-water regions, the cold water propagates downwards as a density current. Such density plumes often occur only sporadically. They are typically generated during night-time cooling in fall as has been demonstrated in e.g., Lake Constance and Lake Geneva (**Figure 5**) or during events that also induce cooling such as cold fronts or monsoons.

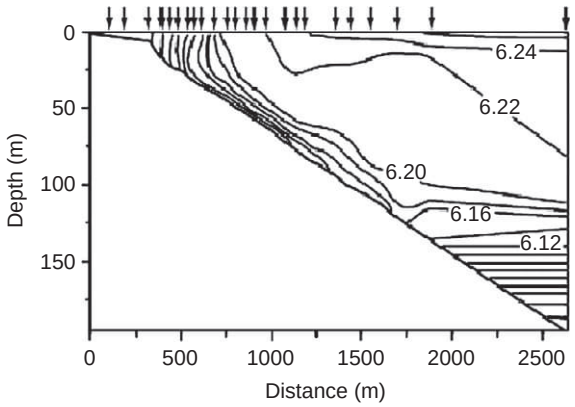

Figure 5 Density current generated by differential cooling. Contour lines represent isotherms in °C indicating a density plume generated by differential cooling in Lake Geneva. Note that the temperatures are well above 4 °C. The isotherms are constructed from CTD-data collected at the locations indicated by the arrows. Redrawn from **Figure 2(b)** in Fer I and Lemmin U. Winter cascading of cold water in Lake Geneva. *Journal of Geophysical Research* 107, NO. C6, 10.1029/2001JC000828, 2002. Reproduced/modified by permission of American Geophysical Union.

Differential cooling can result in density driven currents from any shallow region in a lake basin. Therefore it may affect a large volume of water and thus may significantly contribute to overall vertical transport. The process is particularly effective if large shelf regions are located around a deep basin. The density currents induced by differential cooling propagate along the lake bottom and can reach large depths especially if channels exist along which the density current can propagate without significant entrainment of ambient water, as is the case e.g., in Lake Issyk-Kul. Note, that in freshwater lakes differential cooling can only generate density plumes if water temperatures are above the temperature of maximum density (T_{md}) which is about 4 °C at the lake surface. Cooling below T_{md} implies a decrease in water density and thus prohibits density plume development by differential cooling. Hence, in freshwater lakes the temperature of density plumes associated with differential cooling is at least 4 °C or higher.

Thermal Bar

Temperature-driven density currents can also result from horizontal mixing of two adjacent surface water masses, one having a temperatures above and the other below T_{md}. Because of the non-linear temperature dependence of the equation of state, mixing of water masses with different temperatures always results in an increase in the mean density of the water. This process is called cabbeling. If the temperature of the mixed water is closer to the T_{md} than the water below, it sinks as a density plume. A so-called thermal bar develops which is characterized by a vertically isotherm water column with a temperature close to T_{md} separating an open water region with temperatures below T_{md} from a warmer shore region with temperatures above T_{md} (**Figure 6**).

The downward flow of dense surface water at the thermal bar can cause significant renewal and oxygenation of deep water. As time progresses the thermal bar moves further away from the shore to the open water. The dynamics of this process depends on the morphometry of the lake and on the atmospheric forcing. Mixing associated with the thermal bar has been reported for Lake Ontario, Lake Ladoga, Lake Michigan, and Lake Baikal. Because the thermal bar requires open-water temperatures below T_{md}, it occurrs mainly in lakes which become ice covered in winter.

The horizontal temperature gradients required for thermal bar development are generated by differential heating during spring warming, a process similar to differential cooling. Initially in spring, when surface-water temperatures are below T_{md}, an increase of water temperature during spring warming leads to an increase in the density of the surface waters and thus to convection. Because convection mixes the warmer surface water with colder water from below and the reservoir of the cold water from below is smaller in shallow near-shore than in deeper open-water regions the temperature in the shallow-water regions increases faster than in the deep off-shore regions. When the temperature in the shallow regions exceeds 4 °C the water column is stratified and further influx of heat is not connected to convection, but leads to an even faster increase in the water temperature. Thus, a horizontal temperature gradient typical for a thermal bar situation develops with temperatures below T_{md} at the surface of the open-water region and temperatures above T_{md} at the surface in the shallow near-shore regions. A reverse thermal bar situation with temperatures below T_{md} in the shallow-shore region and temperatures above T_{md} in the open-water region could develop in fall as a consequence of differential cooling if cooling in the shore region progresses to temperatures below T_{md}. However, in the case of the reverse thermal bar exchange processes will be dominated by horizontal density gradients below the surface (see the section on 'Differential cooling').

Thermal Baricity

Another process that can generate density plumes as a consequence of the nonlinearity of the equation of state of freshwater is the thermobaric effect. The thermobaric effect results from the fact that T_{md} decreases with increasing pressure. The generation of density currents by the thermobaric effect requires a very specific temperature stratification that occurs only in few stably stratified deep freshwater-lakes, e.g., Lake Baikal or Crater Lake. To generate density currents by the thermobaric effect, water temperatures must be below 4 °C throughout the water column. The temperature in the surface layer must increase with increasing depth, whereas the temperature in the deep-water must decrease with increasing depth. Then, the temperature profile has a maximum at intermediate depth, the so-called mesothermal maximum (**Figure 7**).

A water column with such a temperature profile is stably stratified because of the effect of pressure on fresh water density. If the water column is displaced downwards or pressure is increased, the temperature at the mesothermal maximum is higher than the local T_{md} and the water column becomes unstable. Cold water from above the mesothermal maximum can sink downwards as a density plume (**Figure 7**). Similarly, a water mass from the cold upper layer can be pushed downwards below the mesothermal maximum to a depth where its temperature is closer to T_{md} than the temperature of the ambient water. Then, it will continue to sink driven by its buoyancy until the surrounding water has the same temperature as the sinking water mass. Besides the specific temperature profile in the water column the exchange due to the thermobaric effect also requires a mechanism by which the water pressure is altered substantially and/or the water is locally pushed downwards across the depth of the mesothermal maximum. Hence density plume generation by the thermobaric effect is not very common. Several investigations have claimed that the thermobaric effect may be important for deep-water oxygenation in Lake Baikal. However, the mechanism that could cause the required downward displacement in the open water column remained unclear. Recently, wind-driven Ekman transport near the coast of the Southern Basin of Lake Baikal has been suggested to cause thermobaric instabilities.

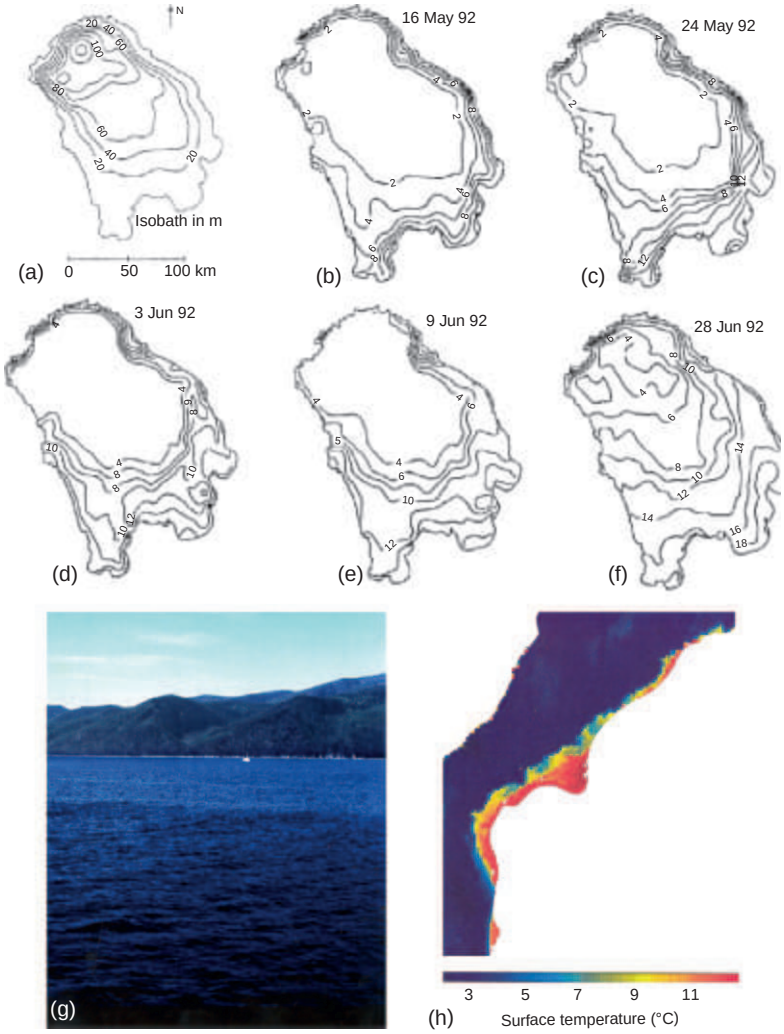

Figure 6 The thermal bar. The development of a thermal-bar in Lake Ladoga indicated by surface temperatures measured with satellites (a–f) and the observation of a thermal bar near Selenga delta in Lake Baikal (g and h). Panel (a) provides the morphometry of Lake Ladoga with depth contours given in m. Panels (b–f) depict surface temperatures with isotherms in °C. Panels (b–f) show how the thermal bar, which is located at the 4 °C isotherm, moves towards deeper water as the season progresses. The position of the thermal bar changes more rapidly in the gently sloping shallower south-eastern part of the lake than in the steep and deep northern part. In (g), the sharp boundary between near shore water and open water indicates the position of the themal bar located near the Selenga delta in Lake Baikal. The color differences result from differences in the load of suspended particles. The water trapped near shore by the thermal bar has an increased load of suspended particles owing to the nearby inflow of the Selenga River. Panel (h) shows an image of the surface temperatures near Selenga delta derived from satellite data. Density currents are generated at the sharp transition between warm shore water and cold open water characterized by a temperature close to 4 °C. White areas are land. **Figure 6(a–f)** are redrawn from **Figures 1** and **3** in Malm J, Mironov D, Terzhevikl A, and Jiinsson L (1994) Investigation of the spring thermal regime in Lake Ladoga using field and satellite data. *Limnology and Oceanography* 39(6): 1333–1348. Copyright 2000 by the American Society of Limnology and Oceanography, Inc.

Turbidity Currents Generated by Waves

Internal processes not only can generate temperature gradients but also can cause gradients in suspended particles that are sufficient to drive density currents. Shear stress at the lake bottom associated with surface waves and high-frequency internal waves can induce sediment resuspension and thus increase the load of suspended particles in the water column. If the density increase induced by the change in particle load is sufficiently large to compensate vertical density stratification, turbidity currents are generated. Because the turbidity gradient is generated by the interaction of waves with the sediment, the resulting turbidity currents usually originate either near the shore at the lake surface (surface waves) or at the depth of the thermocline (high-frequency internal waves). The turbidity currents usually propagate along the lake bottom to larger depth until they intrude into the open water.

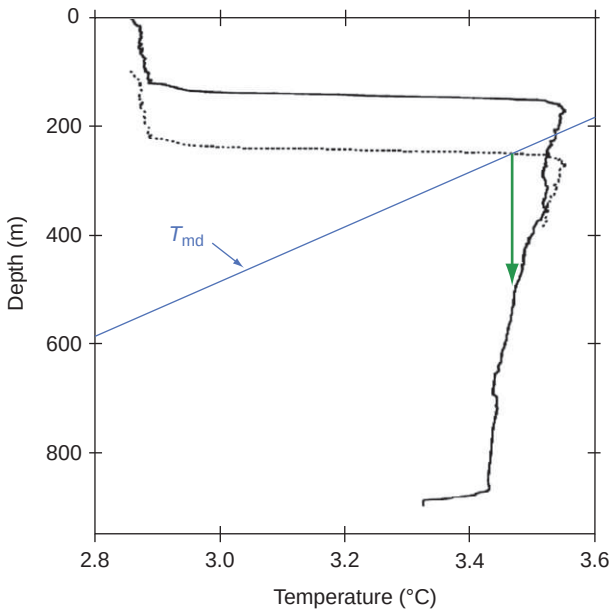

Figure 7 Schematic on the generation of density currents by the thermobaric effect. The temperature profile presented has been measured in the northern basin of Lake Baikal. The temperature of maximum density as function of depth shown for comparison is labelled with T_{md}. Vertical displacement of the temperature profile (indicated by the dashed line) leads to a density driven vertical transport that is self supporting over the depth range indicated by the arrow.

Horizontal Density Currents Generated under Ice Cover

Temperature-driven density currents can also occur under ice cover due to differential heating by solar radiation. This process is invoked if the optical properties of the ice and snow cover vary horizontally either due to a variation in the ice structure (e.g., white ice and black ice) or in the thickness of snow cover. Then, penetration of solar radiation through the ice and snow cover varies horizontally and thus induces differential heating in the surface water below the ice. This process causes convection below the ice and results in horizontal density gradients that can drive horizontal density currents. Such under-ice currents are believed to be essential for the development of algal blooms in early spring in Lake Baikal.

Density Currents in Tropical and Saline Lakes

In tropical lakes and also in saline lakes several of the processes mentioned above do not occur. Because the development of a therma bar requires a lateral transition of water temperature from above to below T_{md} at the lake surface, a thermal bar never occurs in tropical lakes where water temperatures are above 4 °C all year round and thus always exceed T_{md}. Because T_{md} decreases with increasing salinity reaching freezing temperature at about 25 g kg $^{-1}$, thermal bar development and the associated density currents also do not play an important role for the vertical exchange in saline lakes. The same arguments exclude the thermobaric effect as a significant cause of density currents in tropical and saline lakes.

In tropical lakes temperature gradients play the dominant role in the generation of density currents because at high water temperatures, slight temperature gradients imply large differences in density. Therefore, salinity gradients play a smaller role for density plume generation in tropical lakes than for lakes of temperate regions during the cold season. Convection due to night-time cooling and density currents due to differential cooling and river inflows can be expected to be the most important processes for advective deep-water renewal in tropical lakes.

In saline lakes, however, river inflows usually cannot drive density currents because rivers typically introduce freshwater that in most cases has a much lower density than the saline lake water, even if the inflow has a low temperature. For example water with a salinity of 4 g kg^{-1} and a temperature of 24 °C has a greater density than freshwater with 4 °C. Hence, river inflows can only directly drive density currents in saline lakes, if the riverine water carries a substantial load of suspended particles. Nevertheless, in saline lakes river inflows can generate large scale differences in salinity and thus may indirectly lead to density currents at sills induced by inter basin exchange as is probably the case in the Caspian Sea. Another process that is likely to cause density currents in saline lakes is differential cooling. In contrast to freshwater lakes this process can trigger density currents with temperatures well below 4 °C and even down to freezing temperature, because T_{md} can be substantially reduced or even does not exist depending on the salinity of the water.

Impact of Changes in the Environmental Conditions on Density Currents and Deep-Water Renewal

Changes in climatic conditions and human activities in catchments may affect density currents and thus vertical mixing in lakes. An increase in precipitation and in the percentage of the land made impervious by human development typically leads to a higher discharge of rivers. Enhanced river discharge is usually associated with increased erosion and a higher load of suspended particles in the river water such that density currents will propagate to larger depth. Enhanced deep-water renewal is thus anticipated in freshwater lakes. In saline lakes, however, the increase in freshwater input associated with increased precipitation reduces the density of the surface waters and thus can significantly limit the generation of density currents. Consequently, deep-water renewal may be reduced or suppressed. Deep-water exchange decreased drastically as a consequence of increased riverine discharge in the Caspian Sea and in Mono Lake, CA.

Water storage dams in the catchments of lakes have the opposite effect on density currents than soil sealing. Retention by water storage dams reduces peak discharge and the load of suspended particles in downstream rivers. This results in a decrease in the intensity of density currents and in the depth of intrusions in lakes located downstream of dams.

Climate warming can lead to a reduction of deep-water renewal in lakes because additional input of heat at the lake surface may result in an increase in density stratification of the water column and in an extension of the stratified period. Persistence of the increased stratification over many years likely depends on the lake's latitude and depth and whether warming is intensified in winter or summer or, for tropical lakes, during the monsoon period or during less windy periods.

In a warmer climate, however, mixing in freshwater lakes due to density currents associated with the thermal bar and/or the thermobaric effect may cease, if climate warming leads to an increase in surface water temperature to values above 4 °C all year round, i.e., to values above T_{md}. Because density is a nonlinear function of temperature, warming of surface water may also shift the relative importance of turbidity and salinity gradients towards temperature gradients as agent to drive density plumes.

The potential consequences of environmental change on density currents are exemplified for Lake Baikal, the deepest lake on earth. Because of the peculiar temperature profile with the mesothermal temperature maximum (see **Figure 7**), deep-water renewal in Lake Baikal is predominantly driven by salinity differences between river and lake water and between the basins of the lake. The salinity differences result in density plumes associated with riverine inflows and inter-basin exchange. Hence, changes in the catchments leading to an increase in the concentration of dissolved ions and suspended particles in river inflow will intensify deep-water mixing by density plumes. Climate warming on the other hand will not severely affect density plumes and thus deep-water renewal in Lake Baikal, as long as the lake has an annual ice cover. Higher air temperatures most likely result in a shift of ice break-up to earlier times in the year, but will not have an affect on the thermal conditions immediately after ice break-up. Hence, the conditions required to generate density plumes will not change, but may occur earlier in the season.

In summary, density currents significantly contribute to deep renewal, especially in deep and very deep lakes. The density currents can result from a variety of processes. Which of these processes are relevant in a specific lake depends on the temperature regime of the lake, its salinity and also its morphometry. The environmental conditions, e.g., precipitation in the catchments and heat flux at the lake surface affect the occurrence of density currents and the depth reached by the density plumes. Hence, changes in the environmental conditions will have consequences for deep-water renewal and oxygenation of deep lakes not only because of a change in turbulence levels, but also by their effect on the intensity of density currents.

Glossary

Congelation ice (Also called black ice) Transparent ice with large crystals and low amount of impurities growing at the base of existing ice cover.
Snow-ice (Also called white ice) Ice with low transparency, small crystals with random orientation and significant amount of bubbles, forming typically on top of the black ice from slush.
Frazil ice Loose ice crystals formed in highly turbulent open water slightly supercooled below the freezing point.
Slush A mixture of water and snow formed by flooding of lake water on the ice surface, by liquid precipitation over snow surface, or by melt–freeze cycles.
Rotten ice Melting porous ice with water pockets between the crystals and irregular structure due to thaw-refreeze processes. At later stages, the vertical crystals of former congelation ice get disintegrated by internal melting, creating "candled ice."
Freezing-degree-days A cumulative sum of mean daily air temperatures (in degrees Celsius) for a period with temperatures lower than the freezing point. The measure is often used as an estimate of the cooling fluxes at the lake surface and of the ice growth, in particular in the Stefan's equation.
Inverse stratification Increase of water temperature with depth, typical for ice-covered freshwaters and conditioned by the increase of freshwater density with temperature in the temperature interval from 0 °C to 3.98 °C.

Introduction: Lake ice in the earth system

Freezing of lakes, physical properties of ice

The zone of freezing lakes covers most of Eurasia and North America down to around 40°N latitude at sea level (see Hutchinson and Löffler, 1956). In the Southern Hemisphere, there are only minor land areas with freezing inland water basins, in addition to Antarctica with seasonal and specific perennial frozen lakes. Most lakes contain fresh water, and their ice cover consists of congelation ice formed of the lake water and an eventual snow-ice layer on top, formed by freezing of slush on the ice (Michel and Ramseier, 1971). River ice is different from lake ice in that ice formation takes place in turbulent flow with a large fraction of

frazil ice as the result. When the salinity of the lake water is more than around 1 g kg^{-1}, the ice is significantly different from freshwater ice. The freezing point and the temperature of maximum density are depressed, and liquid brine pockets are captured between ice crystals during ice growth.

Importance of lake ice cover for climate and air-land interaction. Human use of lake ice: Transportation, food industry, recreation

The lake ice cover comprises only a small part of the cryosphere. However, it plays an important role in regional weather and climate. Ice cover is an insulating layer for heat transfer and possesses a high albedo, especially when covered with snow. Therefore, once formed, the ice cover stays stable even at significant downward heat flow in the lower atmosphere. The ice cover isolates the lake water body from the atmosphere, influencing weather conditions in lake-rich regions. Under thin ice, the warm water makes the ice surface warmer than the surrounding land with strong impact on stability and turbulent fluxes (Yang et al., 2013), and as long as there is ice in spring, the lake surface temperature is at the melting point that can be much lower than in the surrounding land (Leppäranta et al., 2019). The land–lake surface temperature difference can be more than 10 °C. Since lake ice formation and breakup are closely coupled with the local and regional climate, ice phenology is an excellent indicator of regional and local climate change.

A large fraction of freezing lakes is located in the neighborhood of major settlements, where the ice cover played an important practical role in the human life. The main issue in history has been on-ice traffic (Fig. 1B), expressed in science as the problem of the bearing capacity of ice. Later on, ice loads on man-made structures became another ice mechanics problem, but ship traffic in ice conditions has been limited to large lakes. In cold regions, people have learned to live with and utilize frozen lakes. In the past, lake ice was used to store perishable products; ice was removed during the winter and stored for use in the summer (Fig. 1A). Also, ice cover has been used for recreational purposes such as tourism and sport events.

Perennial, seasonal and "ephemeral" ice cover. Seasonal ice cover duration, its dependence on climatic conditions

The global lake ice zone can be sub-classified into three sub-zones: (1) *Perennial ice zone*, (2) Stable or *seasonal ice zone*, where ice occurs annually and ice-on and ice-off take place every year, and (3) Unstable or *ephemeral ice zone*, where ice forms but not every year (Leppäranta, 2014). The exact boundaries between the three zones are provisional because ice formation depends strongly on the continuously changing climate conditions as well as the local geography. Apart from latitude, altitude and the lake depth are the two major factors determining the ice regime of lakes. A relatively simple but insightful regionalization is offered by the mean climatic values of the near-land air temperatures in form of *negative-degree-days* (see Section "Stefan's law and simple models of the ice cover") as a proxy for the maximum ice cover thickness. The resulting picture reveals the major factors forming the global ice distribution and explains the observed seasonal ice features (Fig. 2), among them:

- perennial lake ice cover in the Northern Hemisphere is rather small, restricted to the Greenland ice cap and the northernmost parts of high Arctic (Mark 6 in Fig. 2). The factors preventing the development of a persistent ice cover are the absence of land at the high latitudes, poleward advection of warm air (in contrast to Antarctica which is isolated from warm latitudes by the westerly winds and Antarctic circumpolar current with the polar front), and the large amount of solar radiation during the polar day.
- The alpine regions of Rocky Mountains, Central Europe, Caucasus and Tibetan plateau are clearly distinguished by the southward advance of the seasonal ice zone.
- The Great Lakes (Mark 1 in Fig. 2), the Caspian Sea and the Aral Sea (Mark 4 in Fig. 2), as well as Lakes Issyk-Kul and Balkhash (Mark 3 in Fig. 2) reside at the boundary between seasonal and ephemeral ice cover, indicating the backward effect of large lakes on climatic air temperatures. The ice cover on these lakes is never purely seasonal; moreover, these large lakes directly affect the

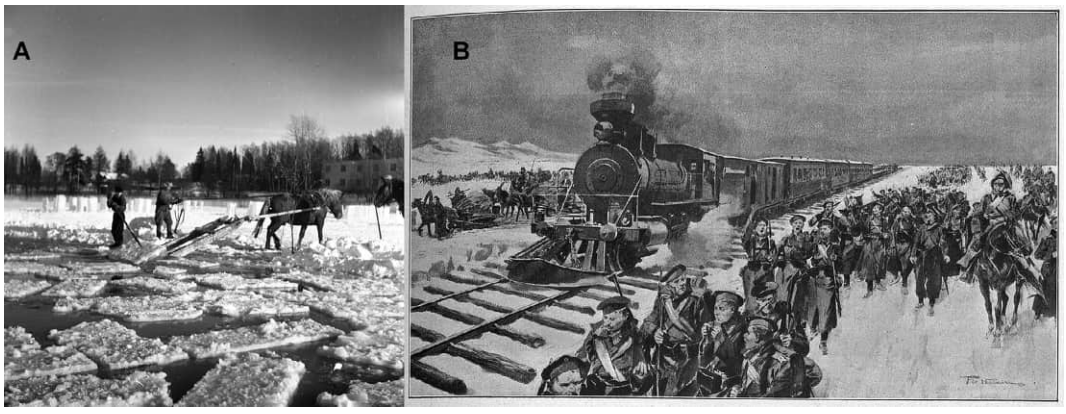

Fig. 1 (A) Ice harvesting in Lake Tuusulanjärvi in the 1960s.(B) Russian troops with a military train crossing Lake Baikal, 1904. Illustration by Frédéric de Haenen. (A) Photograph by Eino Nikkilä. Fig. 2 Distribution of the lake ice cover over the Northern Hemisphere derived from the NCEP/NCAR global reanalysis data on near-surface air temperature for 1990–2010. The following values for the maximum seasonal ice thickness were used as lower boundaries based on observational ice data and results of lake ice modeling: 10 negative degree-days for the ephemeral ice zone; 250 negative degree-days for the seasonal ice zone; 2500 negative degree-days for the perennial ice zone.

surrounding air temperature, maintaining by this warm winters and preventing ice cover formation. A remarkable feature of the large lakes in winter is the production of heavy snow-storms due to strong cooling and evaporation from the ice-free surface (Vavrus et al., 2013). Lake Baikal (Mark 2 in Fig. 2), despite its exceptionally large water volume, has persistent seasonal ice cover, being the most remote large lake from the ocean, and located in the center of the Siberian High-Pressure Area.

The picture for the Southern Hemisphere is not provided. The amount of ice-covered lakes in the Southern Hemisphere is much lower and is basically concentrated in three areas: seasonally ice-covered alpine lakes of Andes and the Antarctic coast, and perennially ice-covered lakes of the Antarctic continent.

Physics of ice cover formation and melt. Types of lake ice

Ice cover formation

The low-flow conditions and freshness of water in most lakes of the "*seasonal ice zone*" make the process of lake ice cover formation different from that in seawater and rivers. At temperatures above the maximum density value T_{md} ($T_{md} \approx 3.98$ °C for freshwater; it decreases with increasing pressure at the rate of $\beta_P \approx 0.020$ °C per 1 bar and with increasing salinity at $\alpha_S \approx 0.22$ °C per 1 ppt), the surface cooling produces sinking of cold waters towards the lake bottom. The resulting convective mixing homogenizes the water column and removes the heat stored in deeper layers. By this, the surface temperature cannot drop below T_{md} before the whole lake body gets uniformly mixed and cooled to this temperature (exceptions are very deep or saline lakes, where T_{md} changes with depth due to thermobaric effects β_P or mineralization α_S). Once the lake temperature achieves T_{md}, any further loss of heat from the surface creates a stable vertical density gradient in the upper water column preventing heat supply from deeper waters and accelerating surface cooling. This "*inverse density stratification*" (in contrast to "direct" density stratification with temperature decrease with depth, prevailing in natural water bodies) develops in a relatively thin surface layer and is easily destroyed by external forcing. In rivers, such a mixing is produced by the persistent flow; the main mixing source in lakes is wind.

The lake ice cover is usually formed during calm conditions, typically at cold nights. Isolated by the inverse stratification from warmer deep waters, lake surface may quickly, within hours, cool down to the freezing point and by further supercooling to at most −1 °C. The primary millimeter-thin ice grows horizontally with vertical optical axes (c-axes) of crystals. The newly formed ice prevents later destruction of stratification by winds, allowing further rapid growth parallel to the temperature gradient down at the base of the ice. In some years, ice formation may start during snowfall or in the presence of surface waves resulting in frazil ice, akin permanently mixed rivers. In lakes, frazil consolidates into a solid layer after turbulence in water has damped. Crystals of frazil are fine, millimeter-scale and bear random c-axis orientation.

The uniform growth of ice at the ice base ensures regular vertical orientation of ice crystals—the reason for the high transparency and bearing capacity of young *congelation* ice, often called therefore "black ice" (see Fig. 3). If the ice formation begins with a frazil layer, congelation crystals grow below the solid ice cover but deeper their c-axes turn horizontal. In some cases, surface freeze-over can take several days to weeks, starting in shallow and wind-sheltered near-shore areas and possibly including several cycles of melt-refreeze, especially in large lakes and/or in the *ephemeral ice zone*.

Congelation ice thickness increases proportionally to the heat conducted through the ice to the atmosphere. In very dry climate—e.g. Antarctic, Andes, Tibet and Lake Baikal—the ice cover consists completely from the crystal-clear *congelation ice*.

Snow cover formation. Slush and white ice

In most lakes, snow accumulation alters the lake ice development. Due to the low heat conductivity and low transparency of snow, even a centimeter-thin snow cover effectively isolates the lake surface from the surface cooling and drastically decelerates the ice cover growth. If the snow thickness increases, flooding becomes possible when the snow weight forces the ice sheet below the level of the water surface. Therefore, the snow cover is never more than about one-third of the ice thickness. In addition, temperature at the snow-ice boundary may reach the freezing point due to the limited heat release to the atmosphere and continuous heat supply from under-ice water. As a result, a layer of *slush* (mixture of snow and liquid water) forms above the primary ice layer. *Slush* can easily freeze by release of the latent heat of its liquid part giving rise to the superimposed ice layer, also called *snow-ice* or *white ice*. Snow-ice grows from the topmost slush down, and then pockets of slush can be captured inside the ice sheet and persist for several weeks. Liquid precipitation or meltwater may also contribute to superimposed ice formation. *White ice* has incoherent structure with small size and random orientation of ice crystals, high porosity, and a lower density compared to *congelation ice* (Fig. 3). Thickness of white ice varies strongly from year to year depending on weather conditions. The relative contribution of white ice to the total ice cover generally grows towards the end of the ice-covered period. Snow-ice has low strength; a congelation ice cover is much safer for walking or driving on than an ice cover of the same thickness with a significant snow-ice fraction.

Ice melt and break-up. Surface, bottom and internal melt. Candled ice

Ice melting period begins in spring when the heat balance turns positive. Ice becomes nearly isothermal, and conduction of heat ceases. If there is a thick snow cover, the high albedo of snow delays the start-up of melting. Once the snowmelt started, the albedo

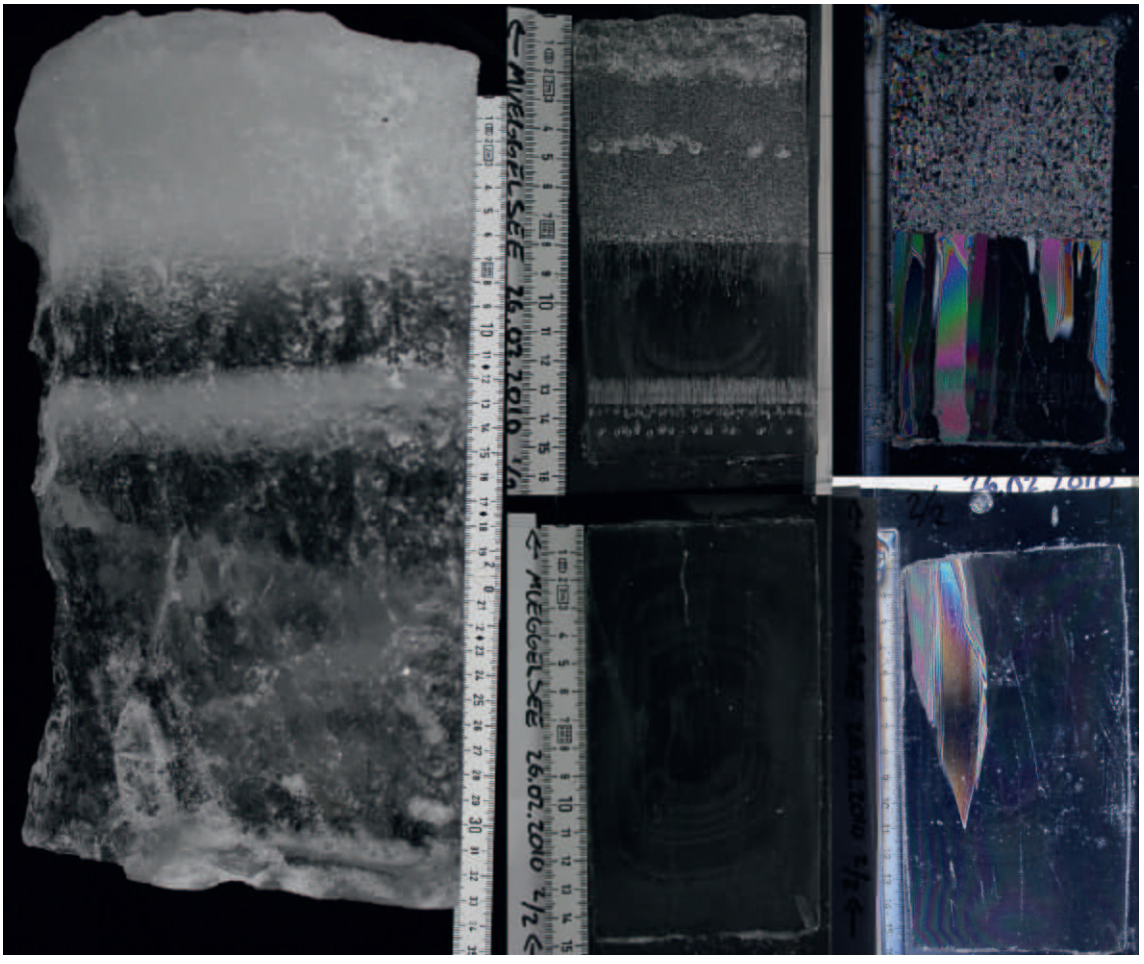

Fig. 3 Structure of the ice sample from German Lake Müggelsee in winter 2010. Clockwise from the left: the original ice sample in normal light, the thick section of the top part in normal and polarized light, and the bottom part in the polarized light and in the normal light.

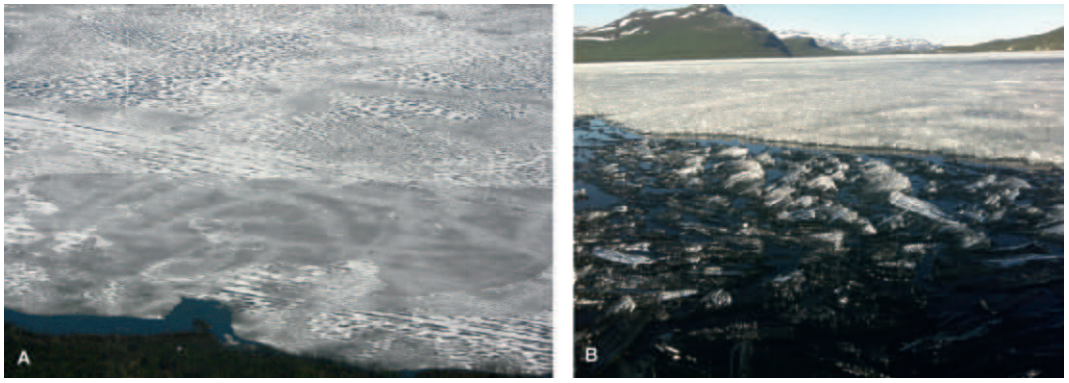

Fig. 4 (A) Photograph of the ice surface on Lake Kilpisjärvi (Finland) taken on May 29, 2013 from the nearby Saana mountain; (B) a close picture taken 2 days later, on May 31, 2013 of the ice cover edge destroyed by internal melting with floating candled ice. Photographer: Alexander F. Forrest.

decreases accelerating the melt. Due to this albedo-melting feedback, the surface of melting lake ice is patchy, with areas of snow, bare and rotten ice (Fig. 4A).

Ice melting takes place due to heat fluxes at the boundaries and by absorption of solar radiation in the ice interior. Surface melting is favored by warm air advection over the ice cover, and basal melting is forced by heat flux from the water beneath the ice. In turn, solar radiation absorption is distributed between the surface, the ice interior and the upper water column. While the boundary melting decreases ice thickness, the internal melting increases ice porosity. The relative contributions of the three melting mechanisms vary depending on the weather and under-ice flow conditions. During clear-sky calm weather, solar radiation can be the governing melting factor, and the porosity increase leads eventually to the break-up by formation of *candled ice*: loose ice crystals with meltwater between (Fig. 4B).

Heat budget of ice. Models of ice cover

Heat budget components, fluxes at the ice surface and the ice base

Ice growth/melting at the ice base results from the balance between the conductive heat flux into ice and the heat flux from the water:

$$\frac{dh}{dt} = \frac{k}{\rho_{ice} L_f} \cdot \frac{\partial T}{\partial z} - \frac{1}{\rho_{ice} L_f} Q_w, T = T_f \tag{1}$$

where h is ice thickness, k is thermal conductivity of ice, ρ_{ice} is ice density, L_f is latent heat of freezing, Q_w is heat flux from water, and T_f is the freezing point temperature (see Table 1 for numerical values).

The heat balance at the ice surface is written as

$$Q_0 = \gamma(1 - \alpha)Q_s + Q_{LW} + Q_H + Q_E + Q_P \tag{2}$$

where Q_s is the incident solar radiation, α is albedo, $\gamma \approx 0.5$ is the fraction absorbed in the near-surface layer, Q_{LW} is the net longwave radiation balance between the ice and the atmosphere, Q_H and Q_E are the turbulent sensible and latent heat fluxes, respectively, and Q_P is the heat transfer from precipitation. Heat transfer from precipitation is often neglected but can be an important short-term flux for rainfall on ice or snowfall on open water.

Radiation fluxes, the role of albedo

The first two terms in Eq. (2) sum up to the radiation balance and make the major contribution to the surface heat flux. Albedo α of bare ice is around 0.5, but over a frozen lake it varies from 0.2 to 0.9 due the strong scattering, largely depending on the liquid water and gas contents of snow and ice. Albedo of snow is above 0.5, up to 0.9 for fine-grained dry snow, 10 times higher than that of ice-free water (0.05–0.1). By this, snow drastically reduces the heating by solar radiation. The snow-albedo feedback plays a crucial role during melting phase, when snowmelt lowers the albedo and the variability of albedo becomes large due to a positive feedback mechanism in the system, which produces the typical patchy lake ice cover in spring (Fig. 4A). The longwave radiation of lake surface is close to that of black body with emissivity 0.96 – 0.98. The longwave radiation of the atmosphere is more complicated, coming from different altitudes with different emissivity. For standard weather data, a gray body analogical model is used with air temperature as the reference temperature.

Table 1 Thermal properties of freshwater lake ice and liquid water.

Property	*Ice 0 °C*	*Ice –20 °C*	*Liquid water 0 °C*
Density (kg m^{-3})	916.7	920.3	999.8
Latent heat of melting (kJ kg^{-1})	333.5	–	–
Specific heat (kJ kg^{-1} $°C^{-1}$)	2.11	1.96	4.22
Thermal conductivity (W m^{-1} $°C^{-1}$)	2.14	1.88	0.561

Thermodynamic properties of ice and snow: Heat capacity, conductivity and transparency

The thermal properties of freshwater lake ice (Table 1) depend primarily on the temperature, crystal structure and gas content. Gas bubbles with a typical size of millimeters occupy about 1% of congelation ice with small influence on the thermal properties. In snow-ice, bubbles occupy about 5%, causing notably lower density and conductivity. Other impurities have mostly minor impacts since their concentrations are small.

Snow and ice covers act as diffusive filters to the solar radiation transfer. The light attenuation coefficient is 0.1 – 5 m^{-1} for lake water, around 1 m^{-1} for congelation ice, ~5 m^{-1} for snow-ice and ~10 m^{-1} for snow (e.g., Lei et al., 2011). Gas content is the most important impurity for light transfer. Gas bubbles cause strong scattering, which is almost independent of the wavelength. Bubble-free congelation ice is normally more transparent than the liquid water of the same lake. Snow-ice possesses large amount of air from the parent snow cover and is opaque. In the melting season, the presence of liquid water has a major impact on the light transfer. Liquid water layers absorb light on long wavelengths. Dissolved substances and suspended particles are mostly rejected from the congelation ice crystal lattice growth back to lake water, but a fraction remains between crystal platelets. In snow-ice, more impurities are captured into the ice. In very humic lakes, liquid humus inclusions have been found from congelation ice resulting in stronger absorption on short wavelengths.

Stefan's law and simple models of the ice cover

The classical problem of modeling lake ice thermodynamics is the growth of congelation ice. The first ice growth model was presented by J. Stefan back in 1891. The model was based on the quasi-steady balance between the latent heat released in freezing and heat conduction through the ice (Eqs. (1)–(2)).

Later the heat flux from the ice surface to atmosphere was added:

$$\rho L_f \frac{dh}{dt} = k\frac{T_f - T_0}{h} = K_a(T_0 - T_a) \tag{3}$$

where T_0 and T_a are the ice surface and air temperatures, respectively, and K_a is air–ice heat transfer coefficient. Eliminating the surface temperature from the latter equation, the solution is

$$h(t) = \sqrt{[h(0) + b]^2 + a^2 S(t)} - b$$

$$a = \sqrt{\frac{2k}{\rho L_f}}, S = \int_0^t \left(T_f - \min\left[T_f, T_a(\tau)\right]\right)d\tau, b = \frac{k}{K_a} \tag{4}$$

where $a = 3.48$ cm $(°C \cdot d)^{-1/2}$ and $b \approx 10$ cm are the model parameters. In semi-empirical modifications, a has been replaced with a reduced coefficient $\frac{1}{2}\, a \le a^* \le a$. The case $a^* \approx 0.5\, a$ corresponds to effective snow insulation, while $a^* \approx 7\, a$ corresponds to snow-ice-only growth. The formula ignores the heat flux from water that is generally acceptable in small lakes, but does bias the simulation upward. Assuming $T_0 \approx T_a$ gives a simple rule-of-thumb formula.

$$h^2 \approx {h_0}^2 + 10\ \text{cm}^2\ (\text{d°C})^{-1}\ S \tag{5}$$

Eq. (5) is directly related to the *negative-degree-days* concept used in Section "Perennial, seasonal and "ephemeral" ice cover. Seasonal ice cover duration, its dependence on climatic conditions": when using 24-h time step of integration, the ice thickness grows as the square root of the sum of the negative-degree-days. Herewith, the formula is insightful for rough estimation of ice growth: So, e.g., at initial ice thickness $h_0 = 9$ cm, the ice grows during 1 day with the mean air temperature of –4 °C to $h = 11$ cm (note that Eq. (5) overestimates the growth rate, especially at small h_0).

Modeling the decay of lake ice is straightforward since the ice loss is due to the net gain of energy from the external fluxes (in particular, radiation) and heat conduction is less significant. The radiation balance is, however very variable because of the space–time variability of the albedo and the light attenuation coefficient. Analytic melting models are simplified energy balance models, where changes in the optical properties are parameterized. The first-order ice growth and melting models can be used to obtain the scale of ice thickness for different lakes and environmental conditions, and they are convenient tools for sensitivity analysis and evaluation of the climate change impact. The main source of uncertainties is in the treatment of the snow cover.

Advanced ice models, unresolved problems

More advanced numerical lake ice models are of two basic types: (1) Quasi-steady models, where the ice sheet is divided into layers with a quasi-steady heat flow through the system, and (2) Time-dependent models, where the vertical equation of heat conduction is directly integrated. Depending on model complexity, variation of the ice thermal properties and snow metamorphosis can be included with corresponding changes in snow thickness, density and thermal conductivity. A typical model simulates the development of four distinct layers: snow, slush, snow-ice and congelation ice. These layers interact: snow accumulation creates slush and snow-ice depending on the total thickness of ice, while the growth and decay of congelation ice depend on the snow and slush conditions. An example of simulation results is shown in Fig. 5. The modeled ice cover grew by 0.5 cm day^{-1} in December–March and ablated at 2 cm day^{-1} during April. The tuned heat flux from the water to ice was 0.5 W m^{-2}. The ice growth was highly sensitive to snow conditions and the diurnal weather cycle significantly affected the ice melt in spring.

Internal melting (Section "Ice melt and break-up. Surface, bottom and internal melt. Candled ice") is an important process in the melting season. It changes the physical properties of the ice sheet, strongly decreasing the strength of the ice, and forming liquid water pockets serving as habitats for biota (Leppäranta et al., 2019). A proper modeling of the internal melting requires inclusion of the ice porosity as a dependent model variable, which changes after the temperature reaches the freezing point, due to radiation absorption. A realistic structural profile can be obtained with locations of liquid water containing layers.

Circulation and mixing under ice

Ice-covered lakes are isolated from the wind mixing. Moreover, water temperature at the ice-water boundary is fixed at the melting point. Two factors—the ice-water interface is at the freezing point and the under-ice water is typically colder than the T_{md}—cause sinking of warmer waters to the bottom and thus determine the major characteristic of the ice-covered water bodies—*inverse thermal stratification*. The resulting circulation is close to "natural laboratory" conditions, rarely met in other natural fluids, where the drivers of under-ice circulation and mixing include (Kirillin et al., 2012):- Heat flow from sediments;

- Solar radiation penetrating the ice;
- Surface and groundwater inflows beneath the ice;
- Seiching (lakewide water body oscillations) induced by the oscillation of a floating ice sheet;

and- the Coriolis force, which does not supply any energy to water motions but rather alters the circulation pattern under the ice and affects thereby stratification and mixing.

The relative contributions of the two former energy supplying mechanisms—heat flow from sediments and solar heating—depend strongly on snow conditions, because even a thin snow cover effectively isolates the surface from solar radiation. In most regions, the ice-covered period is accompanied by snowfalls, and the snow cover disappears first during the early ice melt. It makes convenient to separate the under-ice circulation in two stages (Kirillin et al., 2012): "Winter I" (Fig. 6A) is characterized by insulation of the lake by snow cover from the solar radiation and release of summer-accumulated heat from the sediment, which serves as the main driver for circulation and mixing. "Winter II" replaces Winter I when the snow cover melts, allowing radiation to penetrate through the ice cover. The heating of the upper water column and the subsequent sinking of warmer and heavier waters produce convection, which takes place in the background of stable density stratification, such that the convectively mixed layer of

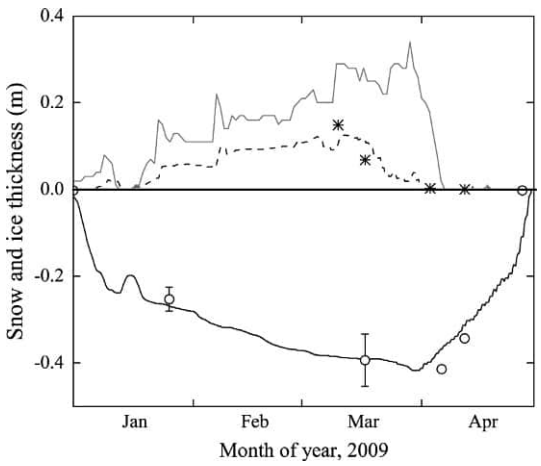

Fig. 5 Time series of observed and modeled snow and ice thickness in Lake Vanajavesi, southern Finland. The black dashed and solid lines are modeled snow and ice thickness, respectively. The dark gray line and the asterisks are the observed snow thickness on land and on the lake, respectively. The circles are the observed average ice thickness and the spatial standard deviation is indicated by the vertical bar (Yang et al., 2012).

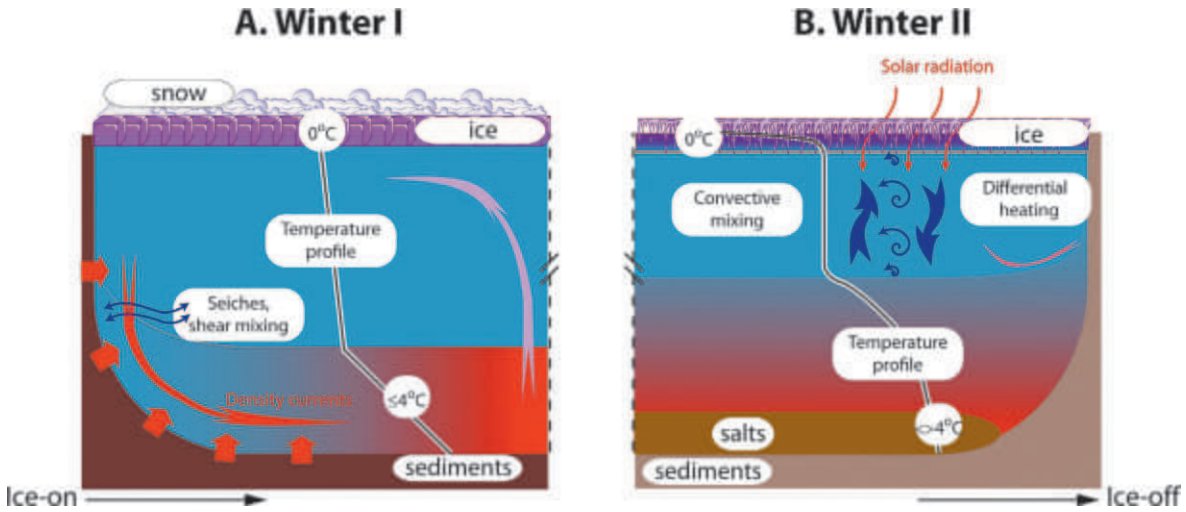

Fig. 6 A schematic of major circulation pathways in ice-covered lakes.

uniform temperature/density thickens with time and penetrates the stably stratified fluid below. Convective mixing due to solar heating dominates the circulation during the Winter II (Fig. 6B).

In dry arid climate zones (e.g. in Antarctic, East Siberia and Central Asia), mode II persists in lakes through all winter. In Antarctic Dry Valleys, it facilitates a perennial solid, thick ice layer over a liquid lake body.

Winter I: "Quiet" circulation conditions in snow-isolated lakes

Immediately after the ice-on, the release of the sediment-stored heat creates horizontal density gradients between the shallow regions and the pelagic zones and gives rise to the organized circulation pattern with the flow of the warm dense water along the bottom slopes and the upward compensating flow in the lake interior (Mortimer and Mackereth, 1958). The warm waters accumulate in the deepest parts of the lake. In shallow lakes, where sediments can accumulate significant amount of heat during summer, temperatures at the water-sediment interface are often close to T_{md}. Since the temperature effect on density decreases in the vicinity of T_{md}, even the small vertical salinity gradients due to the release of solutes from the sediment may slow down the near-bottom mixing and create a < 1 m thin layer with high concentrations of dissolved matter (Malm, 1998; Petrov et al., 2006). The rest of the water column asymptotically approaches a steady state with a quasi-linear downward density increase. Large-scale circulation patterns during Winter I are characterized by slow (≤ 1 cm s^{-1}) water motions driven by density gradients between shallow littoral and deep pelagic parts of the lake. Major mechanisms enhancing the interior mixing are the shear instabilities produced by the density currents and breaking of the internal waves.

Winter II: Convective phase of the ice-covered period

In Winter II (Fig. 6B), solar radiation penetrates through the snow-free transparent ice cover and heats up the upper water layers giving rise to the most energetic mixing process in freshwater ice-covered lakes—radiation-driven free penetrative convection. The warmer and heavier water sinks across the stratified water column and creates a horizontal mixed layer of nearly constant temperature (see the temperature profile in Fig. 6B), advancing downward at the rates of up to several meters per day (Kirillin et al., 2012). The radiatively-driven convection in ice-covered lakes is a crucial process affecting chemical and biological processes in lakes (Matthews and Heaney, 1987; Mironov et al., 2002). Besides, being a rare natural example of free convection driven by volumetric absorption of radiation in the absence of mean shear, the phenomenon has been actively investigated in a number of observational and modeling studies (Farmer, 1975; Ulloa et al., 2018; Volkov et al., 2019). Finally, the convection is a major factor controlling heat supply from the water column to the ice cover and subsequent melt at the ice base. Characteristic features of convective mixing without the mean shear include relatively slow (mm s^{-1}) vertical motions organized in coherent convective structures (cells). At later stages of ice melt, the convective pattern can be observed on the ice surface (Fig. 7A and B), attracting attention of researches by its similarity to convective cloud patterns in the atmosphere (Katsaros, 1981).

During Winter II, the shallow near-shore areas warm faster than the deep interior. The *differential heating* produces radial temperature gradients and secondary circulation (Cortés and MacIntyre, 2020) with density currents converging towards the lake center, similar to that driven by the sediment heat release in Winter I (Fig. 6). Depending on the strength of the lateral temperature gradient, the converging flow may follow the bottom of the convectively mixed layer (Ulloa et al., 2019, Fig. 6B), or plunge to the maximum lake depth (Kirillin et al., 2015, Fig. 6A). In both situations, the secondary circulation intensifies the lake-wide mixing, accelerates ice melt and ventilates the deep waters.

The role of inflows, earth rotation, and under-ice waves

Inflows alter the under-ice circulation if their temperature and/or mineralization differ from that of the lakes. Apart from the local effects near inlets and outlets, like reduced ice thickness or altered vertical thermal stratification, inflows may drive large-scale mixing by producing *thermobaric instability* or inducing *cabbeling* (contraction by mixing). Both effects are related to the non-linearity of the water equation of state (the dependency of the water density on pressure and salt content, respectively), and are therefore the strongest at water temperatures close to T_{md}, where the temperature effects on density are minor. Herewith, inflows entering deep lakes may produce renewal of the otherwise mixing-free near-bottom waters, playing a crucial role in *deep water renewal* (Weiss et al., 1991; Schmid et al., 2008; Tsimitri et al., 2015).

Due to the low magnitudes of the under-ice current speeds, the earth rotation affects water flow even in lakes with horizontal size of $\leq$1 km: The *Coriolis force* transforms the radial density-driven water motions to rotational currents, which can occupy the whole lake (Rizk et al., 2014; Kirillin et al., 2015), or take form of localized gyres with a size from several hundred meters to tens of kilometers (Forrest et al., 2013; Kouraev et al., 2016; Granin et al., 2018). On one hand, these rotational motions effectively promote water homogenization in the horizontal plane, on the other hand, they capture the kinetic energy of density currents reducing their transformation into vertical mixing. A prominent manifestation of the Coriolis-balanced gyres is the development of ring-shaped patterns on large ice-covered lakes, first observed on Lake Baikal (Kouraev et al., 2016; Granin et al., 2018). The "Baikal rings" (Fig. 7C) with the diameter of several kilometers are formed over warm-core gyres similar to the mesoscale oceanic eddies. Ascending heat in the eddy cores accelerates ice melt and makes the gyres visible from space as areas of dark "rotten" ice turning later in open water areas (polynyas).

Ice cover prevents the formation of surface waves by the direct wind forcing. However, *standing waves* (*seiches*) contribute essentially to the under-ice circulation. The relatively thin ice cover does not cancel lake-wide oscillations of the entire water body produced by air pressure variations or wind gusts over the lake surface. These oscillations persist in the form of barotropic seiches, slowly dissipating at the solid boundaries. Seiches destroy stable thermal stratification in the thin water layer adjacent to the ice base, hence accelerating the ice melt (Kirillin et al., 2018). At the concluding stage of the ice-covered period, seiches may play a decisive role in the final mechanical destruction of the ice sheet. The second major type of waves under ice are internal or *baroclinic* basin-scale waves developing in the thermally stratified lake water bodies (Kirillin et al., 2009; Bouffard et al., 2016). Affected by rotation, these oscillations take the form of inertial gravity waves traveling around the lake—analogs of Kelvin and Poincare waves (Gill, 1982) for enclosed basins. In contrast to planar seiches, Kelvin waves reach their maximum amplitudes and current speeds near the lake shores, thereby intensifying the water-sediment mass exchange in the littoral zone (Kirillin et al., 2009).

Physical-biogeochemical interactions in ice-covered waters

Dissolved oxygen as the major indicator of biochemical processes under ice

Dissolved oxygen (DO) in ice-covered lakes is both a crucial ecological parameter and a sensitive indicator of physical transport processes. Under ice, without an oxygen supply by water aeration and reduced photosynthesis, respiration causes oxygen depletion, potentially resulting in fully anoxic conditions with negative ecological consequences, such as winter fish kill and the loss of benthic organisms. Driven by microbiological processes, oxygen consumption rates differ between lakes of various trophic levels and are the highest at the water-sediment boundary. Therefore, the risk for DO depletion under ice is greatly controlled by the ratio between lake volume and area of exposed sediment (Bengtsson and Ali-Maher, 2020). The small shallow lakes with prolonged isolation from photosynthetically active radiation by the snow cover are particularly prone to fast anoxia development (Terzhevik et al., 2009). The respiration rates of winter microbiological communities are shown to be highly temperature-sensitive, so that even a

several degrees increase of water temperatures drastically accelerates anoxia development (Golosov et al., 2007). In Central Asian lakes, photosynthesis contributes significantly to the oxygen storage under the bare ice but falls small in the presence of even a thin snow layer (Song et al., 2019).

Other dissolved gases: CO_2, HS_4, CH_4

In anoxic conditions, the hypolimnetic mineralization involves other reduced substances such as S(-II), CH_4, NH_{4+} (Matzinger et al., 2010). Among them, the under-ice production of methane (CH_4) attracts close attention of researchers because of the high greenhouse potential of CH_4. Methane is produced anaerobically by archaea via methanogenesis and is consumed by microbial methanotrophs. Accumulation of CH_4 during winter can lead to a massive CH_4 release to the atmosphere upon ice-off (Phelps et al., 1998). Unless a lake gets completely oxygen free under ice, the large part of methane is oxidized, thereby, reducing it potential contribution to the atmospheric CH_4 (Schmid et al., 2007). Apart from diffusion, the methane is transported to the surface by ebullition, which often causes accumulation of gas bubbles frozen in the ice cover. An exotic way of the methane interaction with the ice cover was reported in Lake Baikal, the only lake where methane was found in the form of solid methane hydrates forming under high pressure. Occasionally, the hydrates emerge from the depths of their formation and may reach the lake surface, being frozen into the ice cover (Granin et al., 2019).

Plankton dynamics under ice

Phytoplankton blooms are often observed under ice, as long as enough solar radiation penetrates the ice (Bižić-Ionescu et al., 2014; Song et al., 2019). Low water temperatures appear to be a secondary limiting factor for plankton growth compared with light availability, the latter largely controlled by the snow thickness. The *vertical mixing intensity*, which is directly connected to light availability by radiation-driven convection, is another crucial factor determining the phytoplankton composition and growth. At low levels of radiation and mixing, blooms of small species develop in the close vicinity of the ice base (Bižić-Ionescu et al., 2014). Also, motile species have preference because of their ability to position themselves in optimal light and nutrient environments (Hawes, 1983). Higher radiation rates produce stronger convective mixing, which can inhibit plankton growth. However, in lakes with long periods of Winter II, endemic diatom species are adapted to benefit from convective motions as a supporting mechanism and source of nutrients (Kelley, 1997; Jewson et al., 2010).

Outlook

Physics of ice-covered lakes is a relatively young but rapidly developing branch of environmental sciences. There are still many unresolved processes and interactions requiring their quantification, such as deterioration and mechanics of ice in the melting period, albedo and light transmittance of snow and ice cover, water circulation under ice-covered lakes, and biogeochemical interactions under ice. The global changes in the cryosphere are clearly pronounced in the lake ice and provide a strong impetus to intensive research on the ice season. Lake ice phenology is a good climatic indicator due to its sensitivity to the climate conditions and existence of long records (e.g. Magnuson et al., 2000; Duguay et al., 2006; Karetnikov et al., 2017). A large amount of data has been collected on lake ice phenology. Still, these phenomenological observations are insufficient for quantifying the ice season in lakes. Ice thickness is more related to the severity of the ice season but long time series for that are rare and for more complete understanding would also require information on snow accumulation.

Heat transport in the air-ice-water system has to be resolved in order to adequately describe seasonal and climatic variability in ice-covered lakes. The time scales of the physical processes under ice are slower than those typical for open water, but result in significant redistribution of heat and mass during the several months of the ice-covered period. Hence, the widespread concept of "quietness" of ice-covered lakes is not valid. Quantification of heat and mass transport in ice-covered lakes, ice melting process, and the atmospheric boundary layer over the ice is a prerequisite for solution of the key problem in global-scale lake modeling—correct prediction of the seasonal ice cover duration.

Glossary

Buoyancy flux Quantifies the change of potential energy in a water body caused by a vertical density flux. Turbulent mixing in a stratified water body produces a downward buoyancy flux (or upward mass flux), which increases the potential energy of the system.

Buoyancy Upward directed force per unit mass experienced by a water parcel that has lower density than surrounding water.

Cold monomictic lake Ice-covered most of the year, mixing once a year during ice-free period in the warm season, but not warming above 4 °C.

Continuous cold polymictic lake Ice-covered part of the year, ice-free above 4 °C during the warm season, and stratified at most on a daily basis during the warm season.

Continuous warm polymictic lake No seasonal ice cover, stratifying at most for a few hours at a time.

Dimitic lake Ice-covered part of the year and stably stratified part of the year with mixing at the transitions between these two states.

Discontinuous cold polymictic lake Ice-covered part of the year, ice-free above 4 °C and stratified during the warm season for periods of several days to weeks, but with irregular interruption by mixing.

Discontinuous warm polymictic lake No seasonal ice cover, stratifying for days or weeks at a time, but mixing more than once per year.

Epilimnion Surface layer of a lake that is in contact with atmosphere and has highest levels of light. In lakes that are stratified, this layer is usually mixed and sits above the metalimnion.

Fetch The distance over which the wind can blow over a lake. The fetch depends on lake geometry and will vary with wind direction.

Hypolimnion Deep, cooler waters of a stratified lake, lying below the metalimnion. Usually this region has lower turbulence, and insufficient light for photosynthesis.

Internal seiches Basin-scale internal waves with periodic sloshing motions of the lake thermocline across the lake basin. In large lakes, the earth's rotation affects these motions.

Metalimnion Transition layer of water between the epilimnion and hypolimnion in which temperature declines with depth.

Richardson number A dimensionless ratio that compares the stabilizing effect of thermal stratification to the destabilizing effect of velocity shear. Stratified flows with high Richardson number are stable to turbulent mixing, whereas flows with low Richardson number have increased turbulence.

Stratification The vertical structure of temperature (and therefore density) in a lake. It is quantified with the Brunt-Väisälä or buoyancy frequency (N, s^{-1}), defined as $N^2 = -(g/\rho)\,(\partial\rho/\partial z)$, where ρ is the water density and z is the vertical coordinate. Waters that are stably stratified have $N^2 > 0$, whereas waters that are unstably stratified have $N^2 < 0$.

Thermocline The region in a stratified water body where the temperature drops significantly with depth, corresponding to the region of maximal stability (maximum N^2). Usually this depth is defined as the region of maximum thermal gradient (maximum dT/dz).

 https://doi.org/10.1016/B978-0-12-819166-8.00126-2

Warm monomictic lakes Lakes with no seasonal ice cover, stably stratified part of the year, and mixing once each year.
Wedderburn number A dimensionless parameter that quantifies stabilizing effect of stratification relative to destabilizing wind-induced shear. It is conceptually related to a Richardson number multiplied by the aspect ratio of the lake.

Introduction

The dynamics of the surface mixed layer of a lake are central to understanding the distribution and productivity of plankton, the dispersion of buoyant material and the exchange of gases. A key feature of freshwater lakes is that they exhibit stable thermal stratification, with lighter warmer waters at the surface and denser colder waters at depth. The presence of such thermal stratification means that mixing of the surface layer is often confined to a thin layer only several meters in depth, and is located above the thermocline (the region where temperatures drop most rapidly). Light levels in lakes usually drop exponentially with depth, so it is important to know if the surface layer is shallower or deeper than the euphotic zone in order to estimate average light levels experienced by phytoplankton (MacIntyre, 1993). The surface mixed layer is dynamic and can change depth rapidly compared to the slower changes in depth of the seasonal thermocline. Depending upon the relative strengths of wind and surface heating or cooling, the active mixed layer can extend down to a seasonal thermocline, or occasionally to the lake bed during periods of lake overturn and/or in shallow waters. In contrast, during calm periods with daily surface heating, a strong diurnal thermocline can form, limiting mixing and trapping buoyant plankton near the surface.

A starting point for the discussion of mixing in the surface layers of lakes is the classification of lakes of Lewis (1983) that is based on the seasonal thermal mixing regimes. We need to distinguish between two fundamental lake types: those lakes that are thermally stratified during a large portion of the year (mono- and dimictic) and those where winds can regularly mix waters to the lake bottom (polymictic). The surface mixed layer is constrained by depth of the thermocline in dimictic and monomictic lakes, whereas the whole water column mixes regularly in polymictic lakes and effectively the entire depth is the surface mixed layer.

In regions that experience warm summers, and very cold winters, the most common form of lakes are dimictic lakes, so called as they experience two periods of full water column mixing in spring and fall (Fig. 1). In summer there is a strong thermal stratification splitting the lake into three distinct regions, a surface epilimnion, a metalimnion where temperatures drop rapidly, and a deep cold hypolimnion in contact with the lake bed. The surface mixed layer is contained within the epilimnion during summer. In fall, the air temperatures drop, winds generally increase, and the surface layer cools and deepens until the whole water column is actively mixing. This period of fall overturn can often last for weeks or months. Cooling of the lake continues into winter, until waters drop below the temperature of maximum density, roughly 4 °C, and an inverse thermal stratification can form. The depth of the winter thermocline is in part set by mixing due to the wind fetch, so is a function of lake size (Yang et al., 2021). This period of inverse stratification can last for months in many northern lakes. In spring, there is a brief period of full water column mixing as the lake warms through 4 °C (the temperature of maximum density) after which a weak surface stratification starts to develop and confines mixing to a shallow surface layer.

In regions that experience warm summers and mild winters, the most common form of lakes are warm monomictic lakes, so called as they experience one period of full water column mixing when air temperatures are coldest during the winter. The stratification cycle in these lakes essentially looks like Summer-Fall-Spring in Fig. 1, with the key point that water temperatures never drop below 4 °C, so an inverse stratification never forms. In contrast, at very high latitudes such as the many lakes in the Canadian sub-arctic, cold monomictic lakes are common. The temperature of these lakes is below 4 °C all year, and most of the time they have an inverse stratification as in the Winter panel in Fig. 1. In the brief arctic summer, their waters warm up to near 4 °C and the lake experiences overturning.

Many shallow lakes never experience the strong thermal stratification typical of dimictic or monomictic lakes, but rather their whole water column mixes every time the wind blows or there is a significant change in air temperature. These lakes are called polymictic, and as there is no seasonal thermocline, the entire lake depth is essentially the surface mixed layer. Lewis (1983) defines four sub-types of polymictic lakes based upon latitude and whether mixing is continuous or episodic. A key feature of these lakes is that weak episodic stratification can develop, similar to the diurnal thermoclines seen in the epilimnion of dimictic and monomictic lakes. If there is a high sediment oxygen demand (typical of eutrophic lakes), hypoxia can even develop in some polymictic lakes. For instance, in a study of large eutrophic polymictic lake (Clear Lake, CA, United States), Cortés et al. (2021) observed an inverse relationship between DO saturation next to the sediments and the mean buoyancy frequency in the water column when the buoyancy frequency exceeds a threshold of $N > 0.015\ s^{-1}$. This threshold corresponded to a weak temperature gradient of less than $0.2\ °C\ m^{-1}$.

In all lake types the depth to which the surface mixed layer is actively mixing is critical for the depth distribution of buoyant plankton (Fig. 2). Often it is implicitly assumed the full epilimnion is homogenous and actively mixing (Fig. 2A), whereas usually only the upper part of a water column is actually turbulent (Fig. 2B). The difference in temperature profiles between the two cases is subtle, but as light decays exponentially with depth there is a big difference in average light levels experienced by plankton between the two cases (MacIntyre, 1993). Hence the productive layer in lakes depends upon both the depth of the surface mixed layer and the euphotic depth (Minaudo et al., 2021). In some cases, the water currents generated by wind-induced turbulence can become greater than the swimming capabilities of organisms, leading to changes in distribution of motile plankton (Pernica et al., 2013).

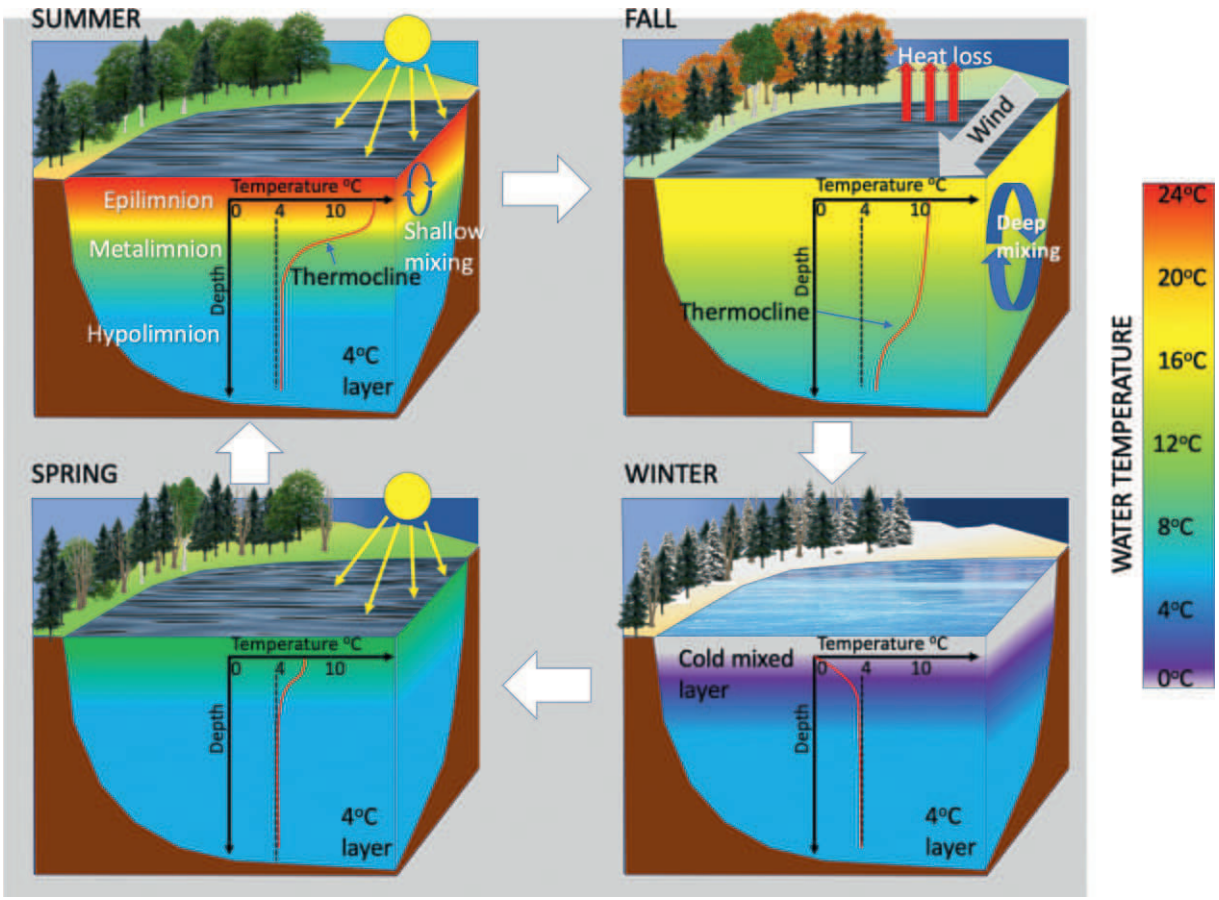

Fig. 1 A schematic of mixing and stratification in a dimictic lake, typical of temperate latitudes in Northern Eurasia or North America that experience very cold winters. The thermal stratification and mixing dynamics are sketched for Summer, Fall, Winter and Spring.

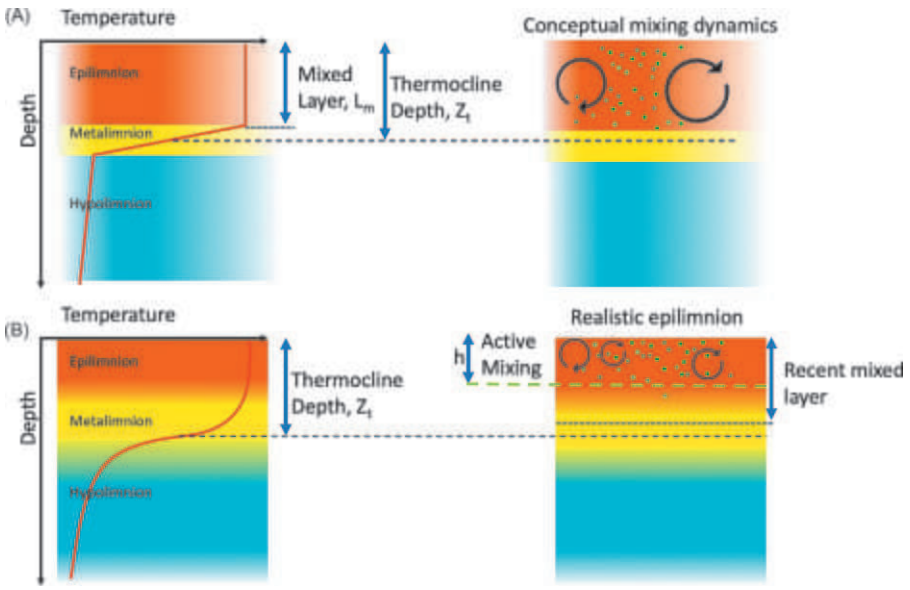

Fig. 2 (A) Often the epilimnion of lakes is assumed to have uniform properties, so that planktonic material is uniformly mixed in the epilimnion. (B) In reality, the depth of active mixing is much less than the depth of the thermocline or the depth of the recently mixed layer. The differences in mixing dynamics result in a shallower distribution of buoyant phytoplankton (illustrated as green spheres).

The depth distribution of buoyant plankton is very sensitive to diurnal variations in turbulence and stratification in the surface mixed layer. This can result in thin phytoplankton layers readily forming under low mixing conditions (Serra et al., 2007) or the formation of "scums" of harmful algal blooms (Wu et al., 2019). In a similar way, the depth distribution of buoyant microplastics is controlled by a balance between the speed at which they rise, compared to turbulent mixing rates (Kukulka et al., 2012).

Example of stratification in a dimitic lake

An example of the seasonal cycle of thermal stratification in the dimictic Harp Lake is shown in (Fig. 3; Supplemental File 1 in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00126-2). This well-studied lake is located at 45.38° N, 79.13° W in Ontario, Canada. The lake has a maximum depth of 34 m but is only 500 m wide. It is sheltered by hills and forest so wind driven mixing is less important than buoyancy fluxes (Read et al., 2012). Forty high precision temperature loggers were deployed every 25 cm starting at 10 cm below a floating platform, down to 9.85 m depth, hence in Fig. 3 we only show the top 10 m where active changes take place. These PME T-Chain loggers (Precision Measurement Engineering, Vista, CA, United States) record every 10 min, and most significantly have a very high accuracy (±0.005 °C) that allows for the detection of subtle changes in thermal stratification associated with mixing. At this mid-latitude location in Canada, winters are severe with 3–5 months of ice cover. During winter, the lake has an inverse stratification (Yang et al., 2021), then after ice melts around day 109, there is a brief spring overturn, followed by a lengthy summer stratification (Yao et al., 2014). The surface waters of the lake can reach 25 °C, while the deep waters remain near 4 °C year-round (Fig. 3A). As the mixed layer is shallow, the thermocline is very strong, and the temperature drops by over 15 °C in just a few meters, so that maximum temperature gradients reach 8 °C m^{-1}, which is a very high gradient. The thermocline can be seen to deepen as summer progresses (Fig. 3B). There is a two-week period of full water overturn before ice forms on the lake on day 348.

Definition of the thermocline depth

The depth of the thermocline is most often defined as the depth where the vertical temperature gradient is greatest. In the example shown in Fig. 4, there is a very strong stratification in the metalimnion so it is unambiguous where the thermocline is located. In spring and fall in dimitic lakes, thermal profiles can be more diffuse so the classic three layers of epilimnion, metalimnion and hypolimnion are not as obvious. Similarly, warm monomictic lakes also have diffuse thermal profiles. Thus, many authors also have a minimum threshold for dT/dz in order to say a thermocline is present. For example, in Fig. 3B, the backline represents the location of maximum dT/dz, where dT/dz exceeds 1 °C m^{-1}. There are weak density gradients in fall and winter, but such a threshold is useful for defining start and end of summer stratification in dimitic lakes.

The depth of the thermocline at the end of summer in dimictic lakes has been found empirically to increase with fetch and mean wind speeds (Gorham and Boyce, 1989). For instance, Gorham and Boyce (1989) used a two-dimensional argument based on the Wedderburn number to show that the depth of the late summer thermocline was related to the magnitude of wind-driven mixing and the lake's geometry as

$$Z_T \approx \overline{u^*}\sqrt{Fetch/g'} \tag{1}$$

where u^* is the water-side wind friction velocity averaged over the summer stratified period (typically about 1/1000 of wind speed, see Read et al., 2012), the fetch is the distance the wind blows over the lake, and g′ is the reduced gravity across the thermocline, defined as $g' = g\frac{\Delta\rho}{\rho_o}$, where g is the gravitational acceleration, Δρ is the density difference across the thermocline, and ρ_o is the average density of the water column. The density of fresh water can be calculated from high resolution temperature measurements using equations in Chen and Millero (1977). Gorham and Boyce found a good agreement with their prediction when looking at end-of-summer thermocline depths Z_T in 150 lakes. A related empirical survey by Fee et al. (1996) found that Z_T during midsummer had a positive correlation with $A^{1/4}$, where A is the surface area of the lake. This observational result generally agrees with the Gorham and Boyce semi-empirical result since if the lake is circular, then $Fetch \sim A^{1/2}$. As an example of the fetch dependence, the thermocline depth in Harp Lake is less than 5 m and the fetch is less than 500 m, whereas in nearby Lake Simcoe, the later summer thermocline is 15–20 m and the fetch is closer to 50 km (Cossu et al., 2017).

The distinctions between stratified monomictic, dimictic, and polymictic lakes also depend upon whether or not the depth is shallower than that of a stable thermocline. For instance, Lewis (1983) argues that the aspect ratio of fetch to depth largely determines if lakes are polymictic, and hence have a surface mixed layer that extends to the lake bed. He quotes an empirical relationship from Ragotskie (1978) that the fetch effect can approximated according to the empirical relationship $Z_{mixed} = 4\sqrt{Fetch}$, where Z_{mixed} is the mixed layer thickness in m and $Fetch$ is in km. If the lake is shallower than this depth, it is likely to be polymictic. For instance, Lake Taihu in China is a large, shallow and almost circular lake, with area = 2250 km^2. The mean fetch is 47 km, and the predicted $Z_{mixed} = 27.5$ m. As the mean depth of Lake Taihu is 2 m, it is not surprising it is a polymictic lake with only weak ephemeral stratification (Wu et al., 2018).

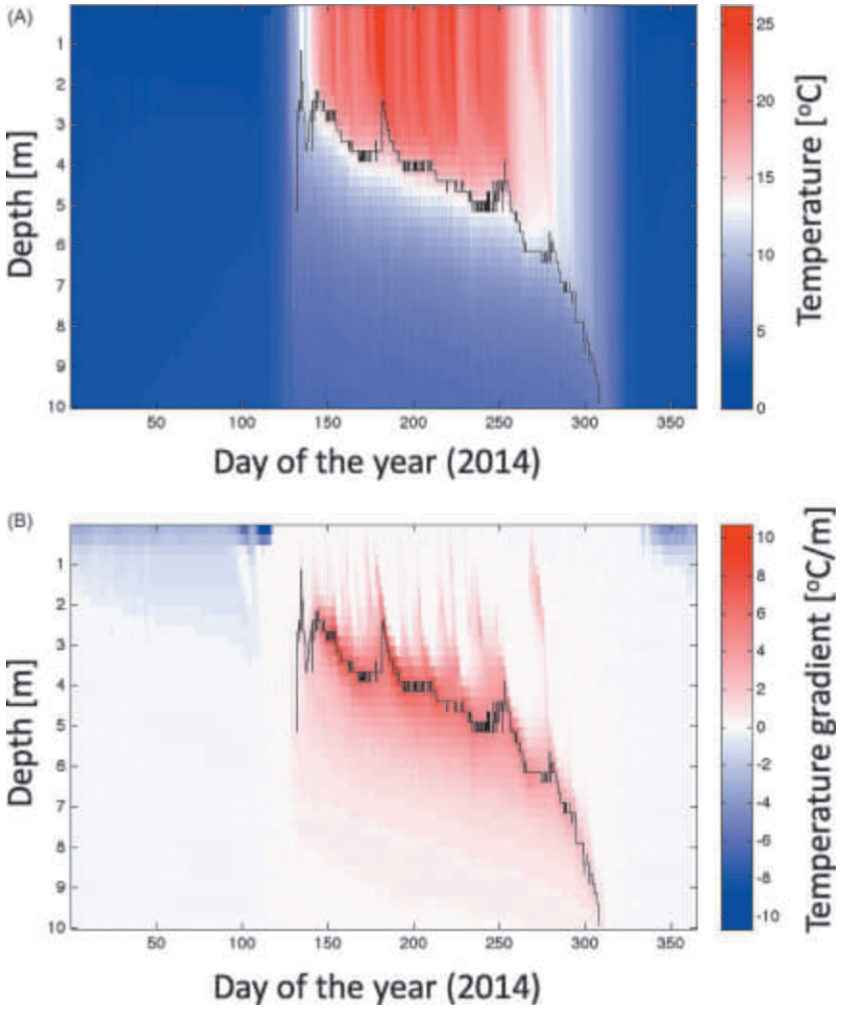

Fig. 3 A timeseries of temperature stratification in dimictic Harp Lake is shown in (A), and the very strong thermal stratification is visible during summer. The vertical temperature gradient is shown in (B). There is a very strong thermal gradient in summer and an inverse temperature gradient in winter. In early spring and fall there are periods of overturn, and hence lack of thermal gradients. The depth of maximum thermal gradient (the thermocline) is shown with a black line (Data from Dr. James Rusak, included as Supplemental File 1).

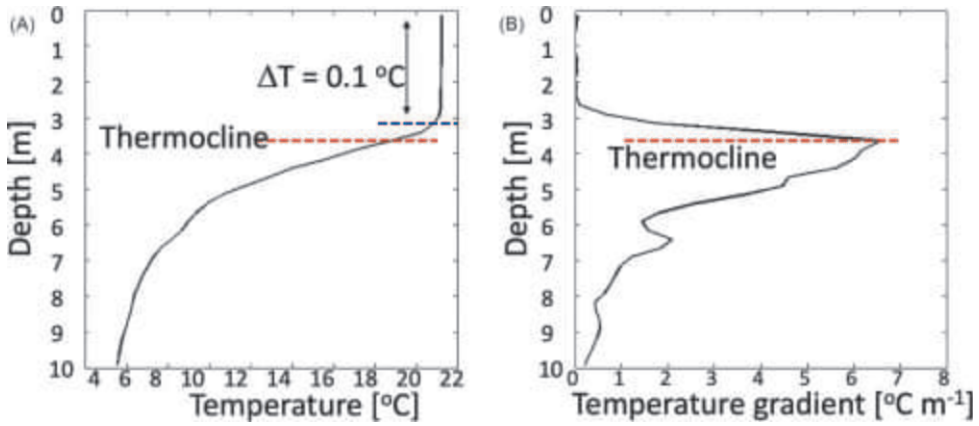

Fig. 4 (A) A thermal profile from Harp Lake on Day of Year 203.3 in 2014. The surface layer is here defined as the zone where there is less than 0.1 °C difference from the surface. (B) The vertical temperature gradient. The depth of maximum temperature gradient can be used to define the thermocline. Note, these are very strong temperature gradients, and most dimitic lakes have lower values (Data from Dr. James Rusak).

Other definitions of thermocline depth

In addition to the common definition of the thermocline being the depth of maximum temperature gradient, there are a number of other possible definitions for thermocline depth that are often used. If the temperature profile was as two layers idealized two layer, with a warm homogenous epilimnion, a very thin metalimnion and a cold homogenous hypolimnion, all the following definitions would be the same, but due to the typically diffuse thermal profiles in lakes, the following definitions can result in differences of 10–20% between definitions of thermocline depth. These differences can sometimes confound comparisons between different lakes.

One somewhat common definition of thermocline used in calculating the Wedderburn number (Robertson and Imberger, 1994; Coman and Wells, 2012) is an integral definition by calculating first moment of density as

$$Z = \int_{bottom}^{surface} \rho(z) z \, dz \Big/ \int_{bottom}^{surface} \rho(z) \, dz \tag{2}$$

This gives a weighted center of mass of density distribution, which is used to define Z, the depth of the thermocline.

In some cases, it is important to define the thermocline depth in terms of velocity gradients, instead of temperature gradients, if internal waves or "internal seiches" are the focus of ones' studies. Internal seiches are periodic sloshing motions of the thermocline across the lake basin, and seiches can induce strong currents in lakes that affect transport and mixing of pollutants, biota, and nutrients. For internal seiches, water velocities are oppositely directed above and below the thermocline, and the point of zero velocity or maximum velocity gradient are useful ways for identifying the thermocline location (see, for example, Woolway and Simpson (2017)).

There is also the concept of a biologically important thermocline, as fish habitat is often vertically portioned by thermal guilds (Plumb and Blanchfield, 2009). For instance, in many temperate dimictic lakes, cold water fish stay at temperatures below 12 °C, which often coincides with other definitions of the thermocline. Warm water fish in these stratified temperate lakes are then found only above the thermocline in summer (Brooks et al., 2022) while cold water fish sit below this thermocline (Flood et al., 2021a). In these lakes internal seiches move the thermocline up and down and hence influence fish habitat usage (Flood et al., 2021b).

Definition of the surface mixed layer depth

The surface mixed layer depth is bounded below by the depth of thermocline, but can change dynamically in response to wind and buoyancy forcing. During the summer stratification season, short periods of cool, windy weather can increase the thickness of the mixed layer temporarily without completely disrupting the deeper seasonal stratification. When warm, calm weather returns, a secondary thermocline develops in the former mixed layer, again restricting mixing to a much thinner layer (Pernica and Wells, 2012). This secondary layering may persist for a period of days or weeks, after which it is typically disrupted again by cool or windy weather. Thus, the definitions of the surface mixed layer depth often depend on small gradients of temperature or turbulence within the surface layer. Often the permanent thermocline is used as a short-hand definition as the bottom of surface mixed layer, i.e. the depth below which diurnal surface mixed layers no longer influence temperature. However, it is usually the case that the surface mixed layer is significantly shallower than this depth. Furthermore, it is crucial to distinguish between a recent "*mixed*" layer, and an actively "*mixing*" layer (Brainerd and Gregg, 1995; Pernica et al., 2014). While it is possible to use turbulent microstructure profilers to rigorously define an active surface mixed layer (Tedford et al., 2014), it is more common practice in limnology to rely on temperature profiles that often are controlled by past mixing events.

Various definitions of the surface mixed layer have been proposed, as illustrated in Fig. 5. In general, these lead to similar estimates of mixed layer depth but as they emphasize different processes, they will differ in the exact values (Wilson et al., 2020).

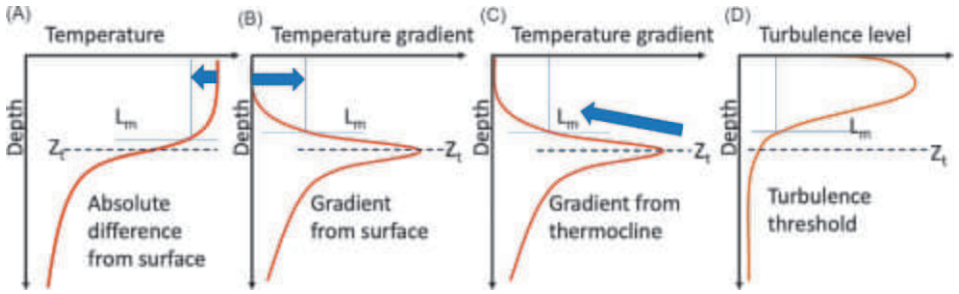

Fig. 5 There are numerous definitions commonly used for the depth of mixed layer (L_m) relative to depth of thermocline (Z_t). (A) The mixed layer can be defined in terms of a drop of temperature (or density) from the surface, (B) or a threshold gradient first encountered from above the thermocline. (C) Another definition is to fix the mixed layer depth relative to a threshold stratification that is proportional to stratification at the thermocline. (D) If turbulence can be measured or modelled then the mixed layer can be defined when turbulence drops below a threshold. (Figure modified after Wilson HL, Ayala AI, Jones ID, Rolston A, Pierson D, de Eyto E, Grossart HP, Perga ME, Woolway RI and Jennings E (2020) Variability in epilimnion depth estimations in lakes. *Hydrology and Earth System Sciences* **24**(11): 5559–5577.

In a review of different definitions, Gray et al. (2020) were most in favor of the mixed layer being defined in terms of Fig. 5A, where the depth of mixed layer is defined in terms of a drop of density of $\Delta\rho = 0.1$ kg m^{-3}, which corresponds to a change of density due to a moderate and measurable temperature change of 0.5 °C between 20.5 °C at top of mixed layer to 20 °C at the base. This is a simple pragmatic number which is easy to measure with most field equipment; however it may overestimate active mixing layer depths in some cases. Related work on mixing in the ocean surface layer has used smaller density steps of $\Delta\rho = 0.03$ kg m^{-3} (Somavilla et al., 2017) or even $\Delta\rho = 0.005$ and 0.01 kg m^{-3} (Brainerd and Gregg, 1995). These thresholds would require higher resolution temperature loggers to be determined in lakes. Detailed turbulence measurements by Pernica et al. (2014) showed that a weak thermal gradient of as little as 0.1 °C m^{-1} could suppress active turbulence, and they defined the mixed layer in terms of the depth at which a minimum buoyancy gradient threshold first occurs, as in Fig. 5B. A widely used toolbox called "LakeAnalyzer" was developed by Read et al. (2011). In their code they search up from the thermocline to find a user-specified threshold buoyancy gradient in order to define the top of metalimnion, which is assumed to be the bottom of the mixed layer (Fig. 5C). The ideal way to measure the depth of the surface mixed layer would be to directly measure the turbulence in the layer using either a microstructure profiler (Pernica et al., 2014; Lin et al., 2021; Piccolroaz et al., 2021), an underwater drone (Kaminski et al., 2021) or by using a moored acoustic doppler current profiler (Jonas et al., 2003; Tedford et al., 2014). Then with a profile of turbulence intensity, the bottom of the mixed layer could be defined in terms of a minimum turbulence threshold (Fig. 5D). In practice this is expensive, and has rarely been done for any significant timescale over which the thermocline depth changes.

Processes that control mixing in surface layer

A key parameter than determines the local stability of the surface mixed layer is the Richardson number. It is defined, at a particular point, as the ratio of the stabilizing buoyancy gradient ($N^2 = -g/\rho\ (\partial\rho/\partial z)$) to the velocity shear (dU/dz) which can cause turbulent mixing. Specifically, when $N^2 >> (dU/dz)^2$ a density stratified flow has little turbulence, whereas when $(dU/dz)^2 >> N^2$ turbulence can be strong (Ivey et al., 2008). The Richardson number is defined as

$$Ri_g(z) = -\frac{g}{\rho_o}\frac{\frac{\partial\rho(z)}{\partial z}}{\left(\frac{\partial U(z)}{\partial z}\right)^2} \tag{3}$$

where g is gravity, $U(z)$ the horizontal velocity as a function of depth z, $\rho(z)$ the density as a function of depth and ρ_o a representative mean density. It is now routine to measure velocity in the surface layer with an ADCP (acoustic doppler current profiler), and density can be calculated by using moorings chains with high resolution temperature loggers that can measure at least to 0.01 °C accuracy. Numerous studies in atmosphere, ocean and laboratory have all shown that $\mathrm{Ri_g} = ¼$ is the boundary between stable and unstable shear flows, i.e., flows with $\mathrm{Ri_g} > ¼$ are stable, whereas flows with $\mathrm{Ri_g} < ¼$ are very turbulent (Miles, 1961; Howard, 1961; Ivey et al., 2008). However, the free surface zone of the water column is problematic for ADCP measurements due to reflections, and additionally, coarse spacing of ADCP bins and thermistor locations can preclude a highly accurate estimate of the gradient Richardson number in the mixed layer, at least very close to the lake surface.

If high-precision, finely spaced measurements are not available to estimate Ri_g, a bulk version of the Richardson number can be defined in terms of bulk values across the layer depth L as

$$Ri_{bulk} = -\frac{g}{\rho_o}\frac{\Delta\rho\, L}{\Delta U^2} \tag{4}$$

where $\Delta\rho$ is the density difference, and ΔU the velocity difference across the surface mixed layer. The interpretation of Ri_{bulk} is similar to that of Ri_g, except that it is a single "bulk" stability metric for the entire mixed layer. Similar to Ri_g, when Ri_{bulk} is small, the mixed layer is expected to be turbulent, and when Ri_{bulk} is large, the mixed layer is expected to be stable. The bulk Richardson number does not have a clear-cut critical value, in contrast to the well-defined $Ri_g = \frac{1}{4}$ cutoff for Ri_g.

As an example, a density difference of $\Delta\rho = -0.1$ kg m^{-3} corresponds to a change of density due to a moderate and measurable temperature change of 0.5 °C between 20.5 °C at top of mixed layer to 20 °C at the base. If this was a 5 m deep mixed layer it would have a weak temperature gradient of $dT/dz = 0.1$ °C m^{-1}. We can re-arrange the equation of the bulk Richardson number to estimate what the maximum velocity gradient is before this temperature gradient becomes unstable, as $\Delta U = 2\sqrt{g\frac{-\Delta\rho}{\rho_o}L}$. Taking $\rho_o = 1000$ kg m^{-3} and $g = 9.81$ m s^{-2} with $L = 5$ m and $\Delta\rho = -0.1$ kg m^{-1}, then gives $\Delta U = 0.14$ m s^{-1}. Surface water currents are usually 2–3% of wind speeds, so this velocity difference across mixed layer could be generated by winds blowing at 5–7 m s^{-1}. Winds slower than this speed would not generate enough shear to mix a weakly stratified surface layer, whereas faster winds would produce enough turbulence to quickly homogenize surface layer. Thus, the bulk Richardson number can be used as a predictive tool to estimate the relative resistance of thermal gradients to various shear flows.

The depth of the surface mixed layer can also be related to the competition between the surface buoyancy flux and shear-driven turbulent mixing (Fig. 6). This idea was first advanced by Monin and Obukhov (1954) to understand the stability of the atmospheric boundary layer due to competition between wind stress and surface heat fluxes. The idea has also since been widely used to help understand mixing in oceanic and lake surface mixed layers (Farmer and Carmack, 1981; Tedford et al., 2014). The so-called Monin-Obukhov length scale is defined as $L_{MO} = -u^{*3}/kB$, where k is the von Kármán constant ($k = 0.4$), B the surface

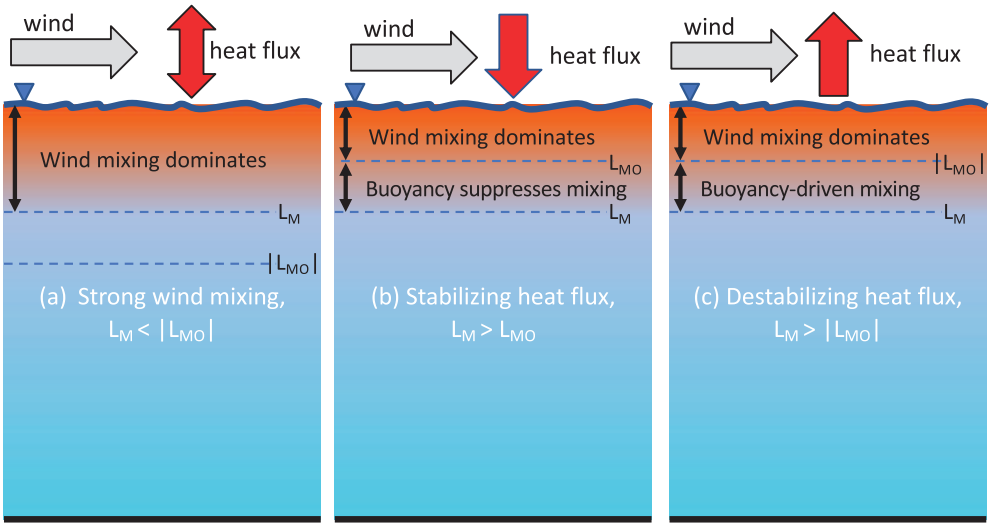

Fig. 6 A graphical interpretation of the Monin-Obukhov length scale L_{MO} compared to the surface mixed layer scale L_M. (A) When wind driven mixing is strong, the predicted Monin-Obukhov length scale L_{MO} is greater than the surface mixed layer depth, and hence stratification limits the depth over which wind driven mixing is strong. (B) When there is a stabilizing heat flux and weak winds, the wind driven mixing is only strong in the top of the surface mixed layer. (C) With a strong destabilizing heat flux, buoyancy fluxes can drive mixing to the base of the surface mixed layer.

buoyancy flux and the shear velocity is defined as $u^* = \sqrt{\tau_{wind}/\rho}$ where τ_{wind} is the surface wind-stress. The buoyancy flux can be either positive or negative depending on the relative contributions of various heat flux terms. This length scale represents the depth above which the production of turbulent kinetic energy is expected to be dominated by wind driven mixing. At depths greater than $|L_{MO}|$, turbulence would be suppressed by a stabilizing buoyancy flux and would be enhanced by an unstable buoyancy flux (convection). The length-scale L_{MO} is essentially a benchmark length scale against which to compare the depth of the mixed layer thickness to determine what process limits the boundary layer. Within this turbulent boundary layer, the levels of shear driven turbulence can be predicted by Monin-Obukhov similarity theory (Tedford et al., 2014), hence this relationship is often assumed in models of surface layer dynamics.

The surface layers of lakes are dynamic and the degree of mixing depends upon the relative importance of wind stresses and buoyancy fluxes (Fig. 7). As discussed above, the magnitude of wind stress is one key factor in determining if mixing can occur (Bouffard and Wüest, 2019). Weak mixing in a stratified epilimnion of depth L_M is shown in Fig. 7A. Here weak mixing occurs during periods when $Ri_g > 1$. The time-scale for vertical mixing is set by $T_{Mix} = L_M^2/4K_z$ and as the vertical turbulence diffusivity K_z is generally low for $Ri_g > 1$, it can take days to homogenize such a layer. For example, many studies (Pernica et al., 2013; Lin et al., 2021) find values of vertical diffusivity K_z in the range 10^{-5} m^2 s^{-1} to 10^{-3} m^2 s^{-1}, implying timescales of $T_{mix} = 8$ h to 1 month in a 10 m deep surface layer. Stronger mixing in a weakly stratified or unstratified epilimnion of depth L_M is shown in Fig. 7B. Complete mixing of the epilimnion occurs whenever stratification is weak, i.e., when there is any cooling or wind and $Ri_g \ll 1$. Other estimates for the timescale for mixing are $T_{Mix} = L_M/u^*$ or L_M/w^*. The shear velocity in water can be estimated as $u^* \sim (\varepsilon L)^{1/3}$ where ε is dissipation of turbulent kinetic energy, and the convective velocity estimated from negative buoyancy fluxes as $w^* \sim (BL)^{1/3}$

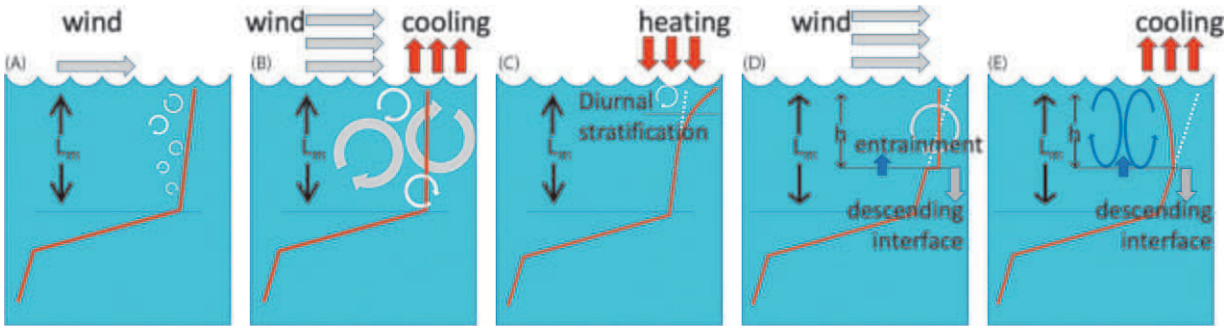

Fig. 7 A number of processes control mixing in the surface layer of lakes. The cases include (A) Weak mixing in a stratified epilimnion, (B) Mixing in an unstratified epilimnion of depth L_M, where B is the buoyancy flux (see chapter by Schmid and Read) and u^* and w^* are the shear velocity and convection velocity respectively computed as in Read et al. (2012), (C) formation of a diurnal thermocline due to surface heating (Woolway et al., 2016), (D) Wind-driven entrainment of a stratified epilimnion to a depth h (Kaminski et al. 2021), and (E) Erosion of a stratified epilimnion by entrainment to a depth h by convective cooling (Tedford et al., 2014). Figure modified from Pernica P, Wells MG and MacIntyre S (2014) Persistent weak thermal stratification inhibits mixing in the epilimnion of North-Temperate Lake Opeongo, *Canada Aquatic Sciences* 76 (2): 187–201.

(Read et al., 2012). Here the negative buoyancy flux B is related to the surface heat flux H as $B = g\alpha H/\rho C_\rho$ where α ισ the co-efficient of expansion of water, ρ the density of water and C_p the specific heat of water. Due to the non-linearity of equation of state of water, α is a strong function of temperature, and changes sign below 4 °C, such that a positive heat flux becomes a negative, destabilizing buoyancy flux.

Many lakes experience strong diurnal thermal stratification, as shown in Fig. 7C. Field observations by Woolway et al. (2016) of the magnitude of diurnal stratification in lakes have found a strong lake size dependence. During summer, they measured the near surface layer (<1 m) and found that small ponds had diurnal thermal changes of as much as 8 °C. They found that small lakes (between 10^4 and 10^6 m^2) had diurnal temperature changes of 1–4 °C, and larger lakes less than 0.5 °C diurnal changes. All of these are substantial changes, which can cause strong thermal stratification in surface layers and the inhibition of mixing (Xenopoulos and Schindler, 2001; Pernica et al., 2013).

After a period of warming, a diurnal stratification can erode quickly due to wind driven entrainment of a stratified epilimnion (Fig. 7D) or erosion of a stratified epilimnion by convective entrainment (Fig. 7E). Rapid wind driven deepening of a previously stratified epilimnion during strong winds depends upon the stability of the stratified layer, so is a function of the Richardson number. The speed at which the layer of depth h deepens, has been shown to scale as $dh/dt \approx u^*/Ri_g$ (Monismith and MacIntyre, 2009). Convective deepening of a stratified epilimnion occurs frequently, especially during cold fronts and on cold nights (Tedford et al., 2014). For this process, the speed of the descending front depends upon the buoyancy flux B, and the buoyancy frequency N as $dh/dt \approx B/hN^2$ (Turner, 1973). Recent observations in the ocean surface mixed layer have documented the overturns at the upper thermocline due to scouring motions caused by wind driven turbulence (Kaminski et al. 2021). It is thought that the large-scale wind-driven Langmuir circulations in the surface layer play an important role in advecting the turbulent motions from the air-water interface down to the top of the thermocline, where entrainment of denser waters can occur (Kaminski et al. 2021).

Example of mixed layer dynamics from Harp Lake

The use of high-resolution temperature loggers can reveal the dynamic nature of the surface mixed layer (Fig. 8). In this figure the same data is plotted as in Fig. 3, but the scales are changed to emphasize the subtle but rapid changes in stratification. Fifty days of data are shown, and the mixed layer depth is estimated by superimposing a line that depicts the depth that is 0.1 °C cooler than the surface in Fig. 8A. There is a clear diurnal signal in the depth of this contour, shallower during the day, then deeper at night. In addition, two cooling events can be seen on day of year 210 and 226, where the surface mixed layer almost reaches the depth of

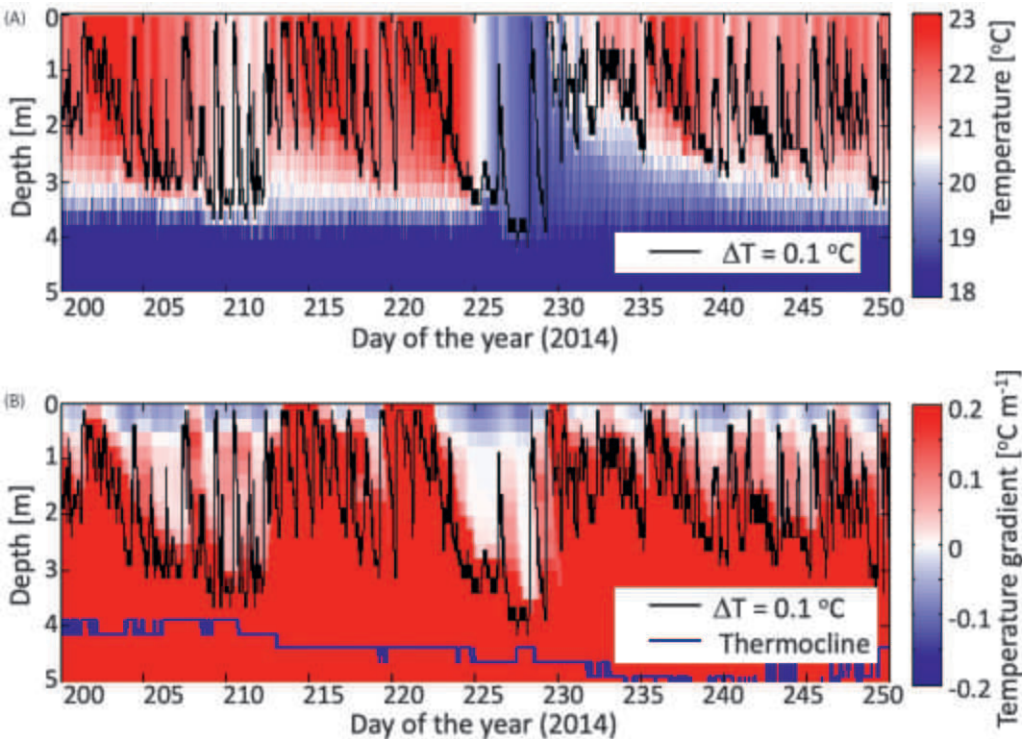

Fig. 8 Variation in depth of the mixed layer in Harp Lake during summer 2014. The temperature in the top 5 m is plotted in (A) with the black line indicating the depth where there is a 0.1 °C drop from surface water temperatures. The vertical temperature gradient is plotted in (B). Unstable negative gradients are plotted in blue, while stable gradients are plotted in red. Here the range is limited to −0.2 to +0.2 °C $m^{-1}$to emphasize the subtle changes in stratification in the upper layers.

thermocline. The subtle temperature gradients are shown in Fig. 8B, where the range has been limited to $-0.02\ ^{\circ}C\ m^{-1} < dT/dz < +0.02\ ^{\circ}C\ m^{-1}$. In contrast, data in Fig. 3B was plotted between $-10\ ^{\circ}C\ m^{-1} < dT/dz < +10\ ^{\circ}C\ m^{-1}$so that none of these subtle gradients were visible. Another key feature to note in Fig. 7B is the small negative temperature gradients in the top 50 cm of the water column. They are gravitationally unstable and so would indicate active convective mixing. All the times the surface mixed layer deepens are associated with these unstable profiles. Also compare the difference between the dynamic changes in mixed layer depth (black curve in Fig. 8B) with the very slow and steady changes in the thermocline depth (blue curve in Fig. 8B). As noted by Serra et al. (2007), such diurnal mixing can influence the vertical distribution of buoyant plankton layers.

Horizontal wind driven currents

Winds over the surface of a lake drive lateral currents in addition to vertical mixing. These surface layer currents then transport plankton, buoyant larvae, fish eggs, microplastics or oil spills downwind. A simple description of this advection is to use a wind factor (defined as the ratio $U_{surface}/V_{wind}$) to estimate the magnitude of these surface currents. The wind factor theory was originally developed for very large lakes and the ocean, for which the earth's rotation becomes important. In this case the surface currents driven by steady winds after a day can be described using the classic theory of Ekman (1905), whose famous result can be expressed using a wind factor that relates the wind velocity to the water surface velocity: $U_{surface}/V_{wind} = 0.0127/\sqrt{\sin\theta,}$ where $U_{surface}$ equals the surface water current velocity, V_{wind} is the wind velocity, and θ is the latitude (Haines and Bryson, 1961). The formula gives a constant wind factor for a specific latitude, and gives a wind factor of 2.5% at 15° N, and 1.4% at 60 ° N. More importantly, Ekman found that due to Coriolis forces the surface water current was directed at 45 degrees to right of wind in northern hemisphere, and 45 degrees to left of wind in southern hemisphere. Only at the equator does the Coriolis force vanish and currents directly follow wind direction. The classic theory of Ekman (1905) did not consider the additional influences of wave driven currents, which tend to make surface currents slightly faster and reduce influence of Coriolis deflection to less than 45 degrees, typically in range of 15–35 degrees (Krauss, 1993).

For small to medium lakes where the earth's rotation is not important, studies consistently find currents with wind factors of $U_{surface}/V_{wind} \sim 1.5$–3% (Henderson-Sellers, 1988). The steering influence of the coastlines on current direction is more pronounced in smaller lakes, as is the sheltering influence of trees (Markfort et al., 2010) so it is less common to apply Ekman theory directly. As an example, Fig. 9; Supplemental File 2 in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00126-2 shows drifter data collected in June 2011 in the large shallow Lake St Clair, located on the Canada/United States border. The three drifters recorded their position via GPS every hour, from which we estimated the speeds over a three-day period. Wind speeds are taken from the Environment and Climate Change Canada meteorological station 45,147 (located at 42°25′48" N 82°40′48″ W). There is some scatter in the raw data, but the bin-averaged data is consistent with a wind factor of 2–3%. For comparison we also plot in Fig. 10 a relationship derived from 356 observations from Lake Mendota, Wisconsin, United States by Haines and Bryson (1961) where the wind factor is

$$U_{surface}/V_{wind} = 0.053/V_{wind} + 0.013 \tag{5}$$

where $U_{surface}$ and V_{wind} are in m s^{-1}.

In the pelagic regions of very large lakes, surface currents can be largely decoupled from the wind and strongly periodic during the stratified period due to the dominance of near-inertial internal Poincaré waves (Choi et al., 2012, 2015). These waves occur in large, stratified lakes for which the earth's rotation is dynamically important, and can control mixed layer transport, shear, and lateral dispersion. Internal Poincaré waves are seiches of the thermocline that are modified by the earth's rotation (Csanady, 1966; Antenucci and Imberger, 2001). For these waves, the thermocline rotates anti-cyclonically around the basin like a spinning coin, with a period approaching the local inertial period for very large lakes such as the Laurentian Great Lakes. The surface currents associated with these waves can be very large in the center of the lake, with nearly perfectly periodic currents. These currents transport material in telltale clockwise-spiraling paths (in the northern hemisphere) termed "inertial waltzes" (Mortimer, 2004; Choi et al., 2020).

Examples of near-inertial surface currents measured in Lake Michigan (United States) are shown in Fig. 10 and as an animation in a Supplemental File 3 in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00126-2. The eastward and northward currents measured in the mixed layer can be seen to show strong periodicity with periods of 17.5 h. Six satellite-tracked drifters released at the center of the basin exhibit the clockwise-spiraling particle pathlines while in the lake's interior. While these currents lead to a strong absolute dispersion of drifters from their initial position, it is striking that the relative dispersion between the eight drifters is quite slow, as they move as a cluster until they reach the coastal boundary currents in Lake Michigan (see Choi et al., 2015, 2020, for additional details).

Horizontal dispersion at the lake surface

The presence of turbulence in the surface layer of lakes acts to disperse material horizontally as well as vertically. There is a rich history of measuring lateral dispersion in lakes and ocean, starting with measurements of the separation rates of disks made of sliced

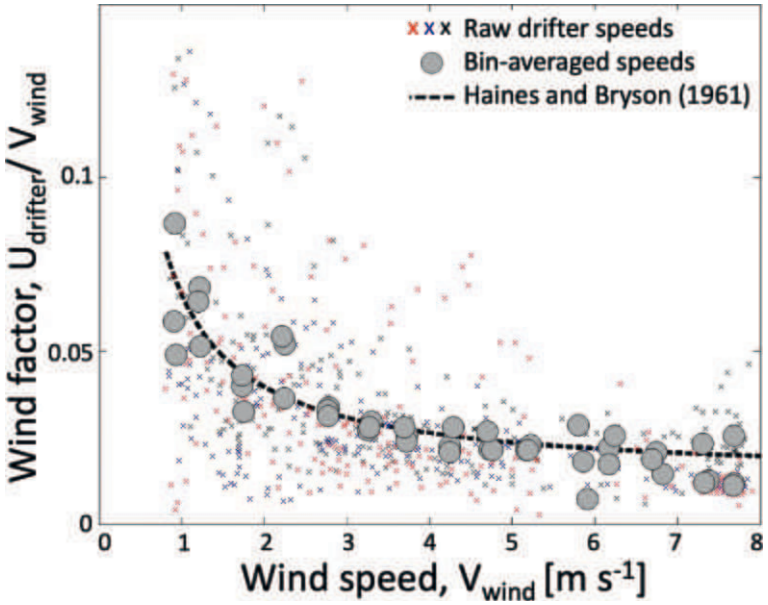

Fig. 9 Wind factor as a function of wind speed. The results from Lake St Clair show that the magnitude of the total surface current is around 3% of the wind speed at 10 m height. An animation of all drifter tracks is included in Supplemental File 2.

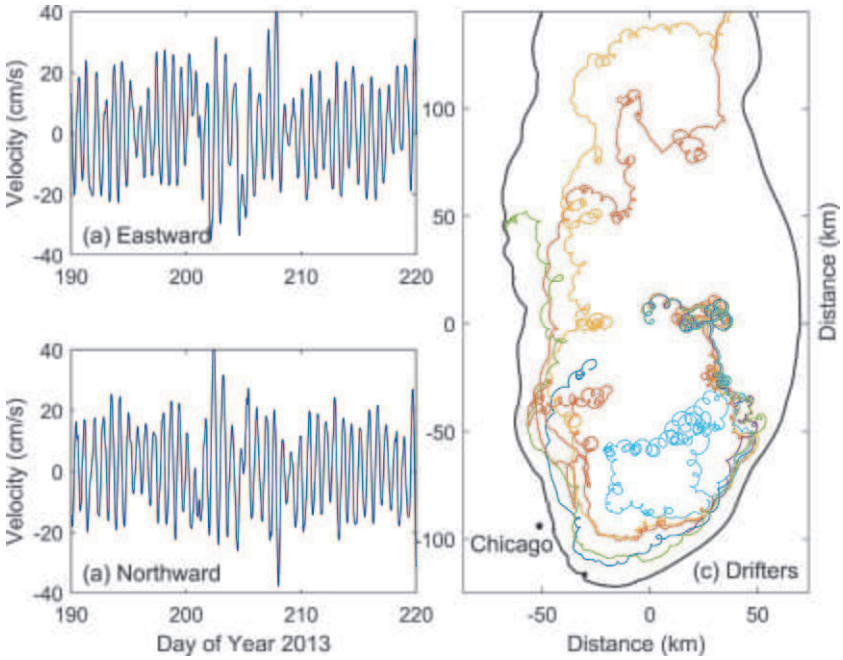

Fig. 10 Currents and drifter paths measured in Lake Michigan. Shown are the eastward and northward currents measured by an ADCP at 5 m depth over a 30 day period (A and B) and the paths of six satellite-tracked drifters followed over 115 days. Details can be found in Choi et al. (2015, 2020). The drifter track in (C) is provided as a supplementary animation.

parsnips (Richardson and Stommel, 1948), through to much more sophisticated studies using close to 1000 biodegradable GPS tracked drifters in the Gulf of Mexico (Novelli et al., 2017). The rate of lateral spreading in lakes is related to variance in horizontal velocities, and as these velocities are orders of magnitude larger than vertical velocities in mixed layer, the horizontal diffusivity is also ordering of magnitude larger. For instance, Choi et al. (2020) report horizontal dispersion coefficients of order 1 $m^2\ s^{-1}$, while the vertical diffusivity in mixed layer is much less, and of order $K_z = 10^{-5}\ m^2\ s^{-1}$ to $10^{-3}\ m^2\ s^{-1}$. The timescale for diffusion scales as $T \sim H^2/D$, where H is a length-scale and D the diffusivity. Thus, for a given time period the ratio of horizontal to vertical scales of dispersion are roughly $H_{horizontal}/H_{vertical} \approx \sqrt{D_{horizontal}/K_z}$. As the ratio $D_{horizontal}/K_z$ could be in the range 10^2 to 10^6, this implies a

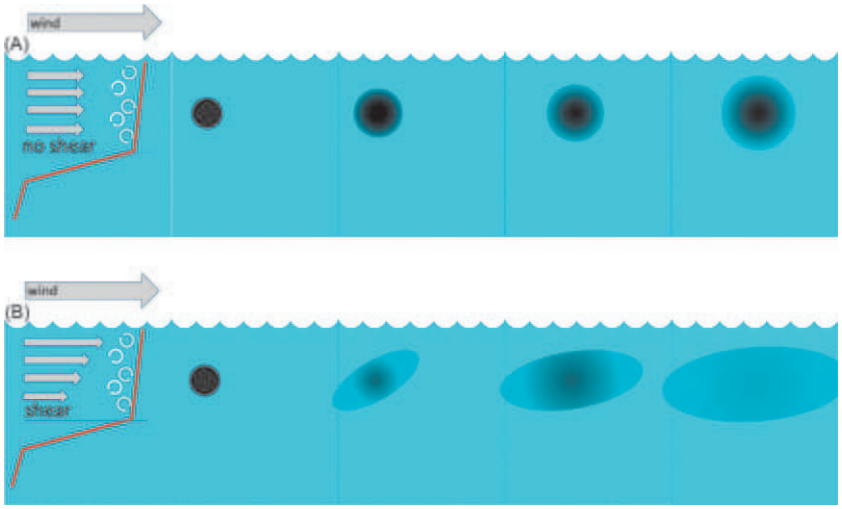

Fig. 11 Lateral dispersion in a mixed layer due to advection + turbulence (A), versus advection + vertical shear + turbulence (B). The shear is a natural result of wind driven currents. The addition of shear leads to much faster dilution rates in the second case, illustrating importance of shear driven dispersion in the surface layers of large water bodies.

ratio of dispersion scales between 10 and 1000. While this ratio is large, it is worth remembering this is also a typical aspect ratio of the width of a lake to the fetch in a lake, i.e., dispersion across a lakes' mixed layer can happen on comparable timescales to vertical mixing through the depth of a mixed layer.

An important caveat about the use of a diffusive model for dispersion is that they implicitly assume the turbulence is divergence free across the surface of a lake or ocean. This is a reasonable assumption for how dye might mix laterally in the surface layer of a lake, but the presence of converging flows in surface layers can be problematic for applying these ideas to dispersion of surface drifters. In particular, many large lakes and coastal ocean regions have converging flows in the surface layers at fronts in the waterbodies, where drifters will accumulate. A classic example in large dimictic lakes are the near-shore convergence zones during spring overturn associated with so-called "thermal bars" (Rao et al., 2004). In large scale ocean flows, fronts and other mesoscale flow features are also seen to accumulate GPS tracked drifters (Novelli et al., 2017).

The presence of shear within the surface mixed layer adds an additional mechanism that can greatly increase lateral dispersion rates (Fig. 11). Winds drive the production of both turbulence and currents, and the combination of these two processes leads to so-called "Taylor shear dispersion" whereby the effective lateral dispersion rate is much greater than the small-scale turbulence mixing rate (Taylor, 1954; Csanady, 1966). For instance, Taylor dispersion was found to be very important in a numerical study of the surface layer in Lake Michigan by Choi et al. (2015). Shear was dominated by Poincaré waves, and they found that the dominant shear structure was observed to mirror the thermal structure, with the location of maximum shear located across the thermocline. In their numerical experiments, Choi et al. (2015) found this oscillating internal wave shear greatly enhanced lateral dispersion. The estimated depth-averaged surface layer vertical turbulent diffusivity grew as shear became stronger from 10^{-5} m^2 s^{-1} to 10^{-3} m^2 s^{-1} over the stratified period, and the associated lateral dispersion coefficients are estimated as 0.1–40 m^2 s^{-1}. These predictions were largely verified in the field study of Choi et al. (2020). Significantly, Choi et al. (2020) found that the horizontal dispersion rates of the GPS tracked surface drifters were far less than for the lateral mixing rates of the dye release, emphasizing the importance of shear dispersion in mixing the dye within the surface layer. This difference in dispersion rates also implies that care must be taken in comparing dye studies to drifter studies as they measure slightly different processes of dispersion in the surface mixed layer.

Wind driven horizontal dispersion of algae within lake surface

Plankton and other floating material in lakes are not uniformly distributed in space but are patchy at multiple scales as a result of interactions between their directed motion and both large- and small-scale water currents (Pernica et al., 2013). For instance, light winds can set up circulation patterns and vertical shear that influence the distribution of phytoplankton and small zooplankton (George and Edwards, 1976) as sketched in (Fig. 12A). Stronger winds can even lead to upwelling of the hypolimnion. In a field study in Lake Opeongo, Cyr (2017) found that on windy days, phytoplankton biomass was higher along the downwind shorelines. However, she found that this was mostly due to dilution from upwellings, not just algae accumulating downwind. She noted that buoyancy and motility affect the distribution of individual taxa. Hence in this medium sized lake, with a 7 km fetch, both processes sketched in Fig. 12A and B were important. Further studies in Lake Opeongo suggested that planktivorous fish actively respond to the higher downwind concentrations of plankton (de Kerckhove et al., 2015).

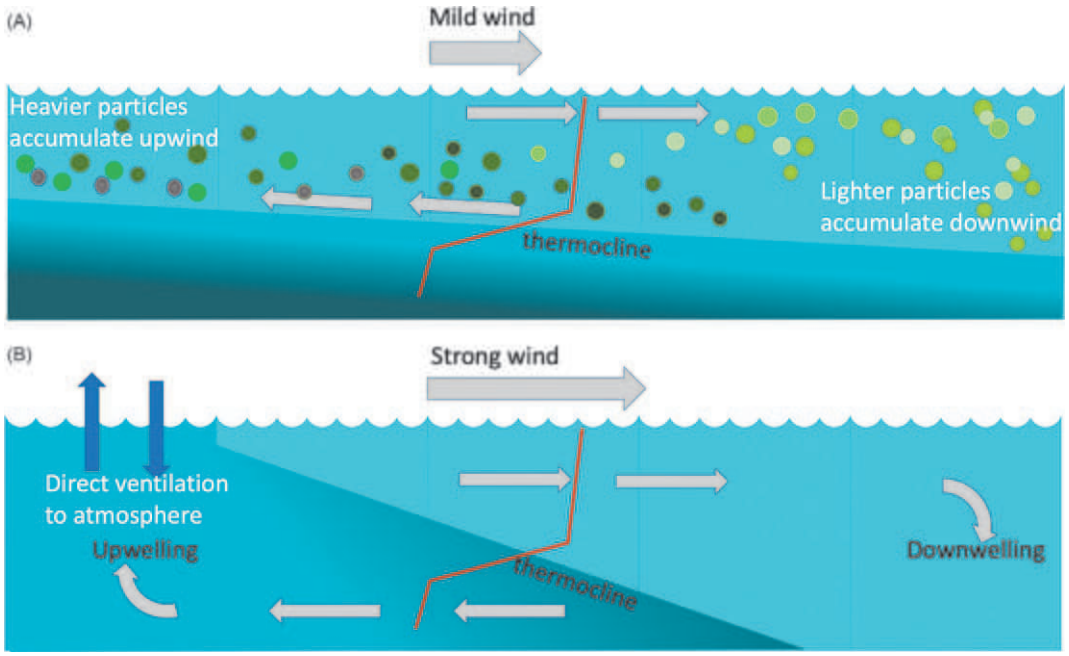

Fig. 12 (A) Under light winds a return flow can be set up in the surface layer of a stratified lake. This can form a so-called "conveyor belt" circulation in small lakes (George and Edwards, 1976) leading to basin-scale phytoplankton aggregation. (B) Strong winds can result in dramatic tilts of thermocline, so the hypolimnion can upwell at the upwind end of lake, allowing ventilation of deep waters.

Upwelling and Wedderburn number

Under strong winds, deep hypolimnetic waters can upwell to the surface of lakes (Fig. 12B). This allows deep waters to ventilate directly to atmosphere, so that briefly the surface layer is in contact with deepest regions of lakes. In eutrophic lakes with low DO at depth, this can have positive and negative impacts—positive in that deep waters can increase their oxygen levels (Reiss et al., 2020), while negative effects include fish kills due to drops in dissolved oxygen in surface waters at edges of lakes (Rao et al., 2014). Upwelling of cold water can also influence temperatures in shallow regions of large lakes (Hlevca et al., 2015; Flood et al., 2021b). Regions with persistent downwelling will generally have stable surface water temperatures.

The fundamental physics of upwelling magnitude are explained by the Wedderburn number (Stevens and Lawrence, 1997). The Wedderburn number, W, is defined as the ratio of the baroclinic restoring force to wind stress:

$$W = -\frac{g}{\rho_o}\frac{\Delta\rho\, L}{u^{*2}}\frac{L}{Fetch} \tag{6}$$

where $\Delta\rho$ is the density difference between the upper and lower layers (kg m^{-3}); L is the thickness of the upper mixed layer (thermocline depth in m); *Fetch* is the basin length-scale (m); and u* is the water-side wind friction velocity (m s^{-1}) defined as $u^* = \sqrt{(\rho_{air}/\rho_{water})C_D U_{10}^2}$ where ρ_{air} is the density of air (1.225 kg m^{-3}) and ρ_{water} that of water ($\sim$1000 kg m^{-3}); C_D is the drag coefficient between air and the water surface ($\sim 1.3 \times 10^{-3}$); and U_{10} is the wind speed measured 10 m above the water surface in m s^{-1} (Flood et al., 2021a,b).

The way Eq. (6) is written, the Wedderburn number can be seen to be related to a bulk Richardson number multiplied by the aspect ratio of the surface mixed layer.

A smaller W corresponds to a greater influence on the waterbody from wind stress, and hence a more severe thermocline tilt. When wind forcing is strong enough and long enough (greater than one-fourth of the fundamental mode period), complete upwelling can occur where the thermocline breaches the surface. The degree of upwelling due to wind driven forcing is inversely related to W as

$$\Delta L/L = 2/W \tag{7}$$

where ΔL is the degree of upwelling measured at one end of the basin (Stevens and Lawrence, 1997; Coman and Wells, 2012). An upwelling of ΔL at the upwind end results in a downwelling of ΔL at the downwind end, resulting in a cross-basin thermocline deflection of $2\Delta L$. Thus, full upwelling is expected when $W = 0.5$. However, experiments in rectangular basins show that the thermocline becomes nonlinear and curves up near the edges, leading to full upwelling at $W \approx 1$ (Shintani et al., 2010).

Wind driven upwelling events can strongly influence surface water quality and fish habitat in the surface waters of large lakes. For instance, persistent diurnal winds, mean that the upwind end of the 7 km long Hamilton Harbour basin experience frequent hypoxia as cooler hypolimnetic water are driven to the surface (Flood et al., 2021a,b). This upwelling in turn influences the depth distribution of fish located in surface mixed layer (Brooks et al., 2022). In larger lakes, upwelling is also influenced by the Coriolis force, and similar thermal and DO variability occurs in near shore regions of Lake Michigan (Troy et al., 2012), in Lake Erie (Jabbari et al., 2021) and in Lake Geneva (Reiss et al., 2020). Such upwelling is often associated with pulses of nutrients from the hypolimnion to epilimnion that can fuel algal blooms.

Conclusions/synthesis

The mixed layer of lakes is dynamic, and active mixing can often be confined to a layer much shallower than the depth of the thermocline. The vertical distribution of mixing in turn determines the vertical distribution of plankton within the surface layer, as well as other buoyant material such as microplastics. In order to capture the mixed layer dynamics, it is important that high resolution and high frequency temperature measurements be made in the surface of lakes. With modern thermistors this is now feasible. Historically the thermal profile in lakes may have only been measured weekly or even monthly, which was adequate to track evolution of seasonal thermocline, but made it hard to appreciate the rich dynamics at play in this critical region of lakes.

Knowledge gaps

- There is a need for more high-frequency and high-resolution measurements of physical properties in the mixed layer to better interpret distribution of plankton and gases. Standard measurements with 0.1 °C accuracy for temperature will miss much of the dynamics.
- The whole water column of a polymictic lake is essentially the surface layer. Mixing will also be highly episodic, with many periods where water column has weak stratification. The frequency of active mixing in such lakes needs to be better understood.
- The role of surface layer mixing in blue-green algae aggregation and potential to lead to harmful algal blooms is a key area to study.
- Due to challenges of working from boats, there is a bias towards field work in calm conditions, and there are far fewer measurements of mixed layer conditions during energetic conditions. Moored systems of autonomous underwater vehicles should be used in future studies to fill these gaps.
- The process of wind and waves driving Langmuir circulations has not been systematically studied in lakes. While there is some research in the ocean, a key difference is the smaller scale of lakes, which are likely fetch limited.
- The energy transfer between the wind and various surface mixed layer processes such as wind waves, near-surface currents, and turbulence is still not well-understood. This has important implications for the ability of models to estimate surface layer gas exchange, transport, and dispersion.

Case studies

Glossary

Buoyancy frequency A measure of the strength of stratification, which is proportional to the vertical gradient in water density. In the simplest cases, if a parcel of fluid is displaced vertically through stable stratification and then released, it will bob up and down with the buoyancy frequency (neglecting added mass and friction). Frequencies of free internal waves never exceed the buoyancy frequency.

Diffusion Molecular diffusion is the mixing resulting from random thermal motions of molecules, leading to chemical fluxes from high concentration to low. Turbulent diffusion, by analogy, is the mixing resulting from random turbulent motions of fluid parcels, usually leading to chemical fluxes from high concentration to low. The magnitude of the turbulent flux depends in a complex manner on the properties of the turbulent flow.

Diffusive Boundary Layer (DBL) Thin (order 1-mm-thick) bed-adjacent layer, within which molecular diffusion dominates chemical fluxes (in contrast, turbulence dominates chemical fluxes above the diffusive boundary layer).

Inner turbulent boundary layer Lower region of the turbulent boundary layer, where stratification, time-dependence of flows, Coriolis, boundary-normal variations in stress, and any possible effects of the water surface can be neglected. Within this layer, dimensional analysis yields many simple and useful theories for flows and mixing.

Isotherm A contour of constant temperature. In some lakes density is determined primarily by temperature, so that isotherms also correspond to contours of constant density.

Laminar flow Non-turbulent flow. Laminar flow can often be visualized as thin layers of fluid flowing over one another in an orderly manner.

Outer boundary layer The upper region of the boundary layer, where mixing and the frictional effects of the bed remain significant, but where the simplifying assumptions applicable to the inner boundary layer do not hold. Stratification, time-dependence, Coriolis, and boundary-normal variations in stress are often important in the outer boundary layer.

Richardson number A dimensionless number useful for estimating the effect of stratification on turbulence. Very low values (nominally, magnitude <0.05) indicate minimal local effect of stratification, whereas much larger values indicate significant

effect. The gradient Richardson number, which is one of several forms of Richardson number often used, is defined as the squared ratio of the buoyancy frequency to the velocity shear (velocity shear is the vertical gradient of velocity).

Reynolds number A dimensionless number, often useful for evaluating the damping of turbulence by molecular viscosity. For sufficiently low values of Reynolds number flows are laminar, whereas for higher values flows are turbulent. The Reynolds number equals fluid velocity multiplied by a length scale and divided by the kinematic molecular viscosity. A variety of length scales are chosen for application to various flows, and the minimum Reynolds number required for turbulence varies depending on this choice.

Stratification In a stratified fluid, density varies in the vertical (strictly, after accounting for adiabatic compression). In "freshwater," density gradients often result from temperature gradients, although salinity and suspended sediments can also play a role. Stratification can be stable (dense fluid under light), in which case turbulence is inhibited, or unstable (light fluid under dense), in which case turbulence is often enhanced by free convection.

Turbulence Fluctuations in fluid flows, which appear random, taking the form of swirling eddies and gusts. Unless inhibited by viscosity or stratification, turbulent eddies often become energetic as they draw energy from more deterministic background flows (such as waves or steady currents). Above thin viscous and diffusive layers, turbulence is responsible for most boundary layer mixing.

Viscous sublayer A thin (order 1-cm-thick) bed-adjacent layer within which molecular viscosity dominates the vertical mixing of momentum (in contrast, turbulence dominates momentum fluxes in overlying layers).

Introduction

The bottom boundary layer and its sublayers

The bottom boundary layer (BBL) is a region of relative rapid mixing overlying lakebeds, riverbeds, and seabeds. A surface boundary layer, also characterized by rapid mixing, often extends downward from the water surface. Between these two boundary layers, vertical mixing is sometimes relatively inhibited in a stratified interior (Fig. 1, left). This article introduces the flows and mixing processes found in BBLs.

BBLs may extend only a small distance from the bed, and occupy only a small fraction of the total basin volume. Nevertheless, BBLs play a vital role in lakes and many other aquatic systems. For example, oxygen consumption, denitrification, and methane production are often intense within lakebed sediments, and BBL mixing is responsible for associated chemical fluxes between sediments and overlying waters. BBLs also influence the habitats of benthic organisms, and are the location of much sediment transport. BBL mixing may influence currents, even currents above the BBL. Finally, BBLs (together with surface boundary layers) are often the regions where most dissipation of mechanical energy occurs.

A variety of BBL flow regimes is found in natural lakes and rivers, depending on stratification and water velocity. We first consider conditions common in temperate lakes during summer, for which BBLs can sometimes be divided into four layers (Fig. 1, right). First is a thin "Diffusive Boundary Layer" (DBL), which extends just a millimeter or so above the bed. Within this layer chemical gradients are particularly intense, because chemical transport is limited to the very weak process of molecular diffusion. Next is a "viscous sublayer," extending about a centimeter upwards from the bed. Within this layer, turbulence is dissipated by molecular viscosity, so flow is almost laminar. Above the viscous sublayer is an inner turbulent boundary layer, extending tens of centimeters from the bed, within which swirling turbulent eddies rapidly mix chemicals, heat, and sediments. In this inner turbulent layer,

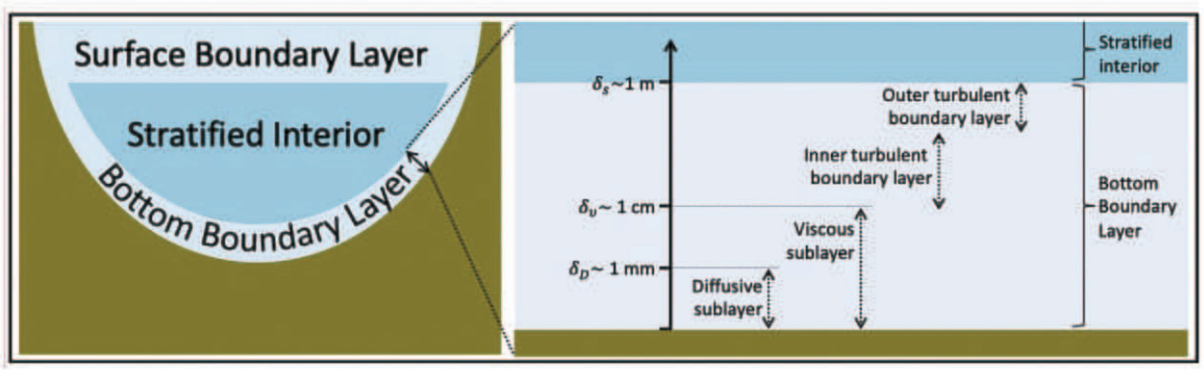

Fig. 1 Left: The bottom boundary layer is a near-bed region of rapid mixing found in many inland waters, often bounded above by a stratified interior where vertical mixing is greatly inhibited. Right: The bottom boundary layer can be divided into several layers, each characterized by different mixing processes. The layers shown, and the order-of-magnitude layer thicknesses, are observed under cm s^{-1} currents in some small stratified lakes. However, across a range of environments, the thickness of layers can vary greatly (note logarithmic vertical scale), and in some environments some layers can be absent.

stratification is too weak to directly inhibit the relatively intense turbulence. In contrast, in the overlying outer turbulent boundary layer, turbulence is progressively more inhibited by stratification with increasing elevation, until finally the stratified interior is reached a meter or more above the bed. The layers described above often lack sharp boundaries and their thickness varies greatly with flow speed, stratification, bed slope and flow direction. Additional layers can be introduced to account for factors such as Coriolis and benthic vegetation, and some layers vanish entirely in certain flow regimes.

After briefly introducing BBL mixing processes (Section "Overview of mixing processes"), we describe the inner turbulent boundary layer (Section "The inner turbulent layer"). We then consider the viscous and diffusive layers underlying the inner turbulent layer (Section "Viscous and diffusive sublayers"), before describing the overlying outer boundary layer (Section "The outer turbulent layer"). We end by examining interactions between BBLs and overlying waters, as well as a range of factors that can cause departures from the simple four-layer description (Section "Additional considerations"). Such departures are particularly common in high- and low-energy environments, and may also result from unsteady flows, Coriolis, or the presence of aquatic vegetation.

Overview of mixing processes

Within the BBL, the various layers outlined above are each defined by a dominant mixing process. Therefore, we first introduce the most important mixing processes, which include molecular diffusion and turbulent stirring.

Random thermal motions lead to molecular diffusion. For example, a chemical diffuses downward if its concentration C increases with increasing elevation above the bed z. Such downward diffusion is common for chemicals such as Oxygen and Nitrate, which are consumed in the sediments (gradients and fluxes reverse for chemicals such as methane, which are produced in the sediments). Similarly, momentum diffuses downward if the water velocity u increases with increasing elevation above the bed. Such downward diffusion of momentum is common in BBLs, because the water velocity often declines as the bed is approached, owing to bottom friction. Downward momentum diffusion can also be viewed as the frictional force exerted on underlying waters by overlying waters, and is usually expressed as horizontal force per unit horizontal area (units: Pa). The downward flux of chemical F_m and momentum τ_m resulting from molecular diffusion obey

$$F_m = D_m \frac{\partial C}{\partial z} \tag{1a}$$

$$\tau_m = \rho \nu_m \frac{\partial u}{\partial z} \tag{1b}$$

where ρ is the water density, while the effectiveness of molecular mixing is quantified by the molecular diffusivity D_m and viscosity ν_m ($m^2 s^{-1}$). Molecular mixing transports momentum much more effectively than chemicals ($\nu_m \approx 0.8 - 1.7 \times 10^{-6}$ m^2 s^{-1}, whereas for many chemicals $D_m \sim 10^{-9}$ m^2 s^{-1}, where '$\sim$' indicates order-of-magnitude). This result is summarized by the molecular Schmidt number, defined by $S_{cm} = \nu_m / D_m$, which is often $\sim 10^3$.

Random motions associated with turbulent eddies are responsible for additional mixing. Turbulence is often distinguished from more deterministic currents by a process of "Reynolds averaging"—that is, quantities such as water velocity are averaged across a series of turbulent eddies, and turbulence is defined as the departure from the averaged flow. Similarly, other quantities such as chemical concentration and water density can also be separated into a Reynolds-averaged part and a turbulent fluctuation. Reynolds-averaging is represented by an overbar, so the Reynolds-averaged concentration and velocity are $\bar{C}$ and $\bar{u}$. Turbulent mixing is more complex than molecular mixing. Nevertheless (given $\partial \bar{C}/\partial z \neq 0$ and $\partial \bar{u}/\partial z \neq 0$), it is always possible to define a turbulent diffusivity D_T and a turbulent viscosity ν_T by

$$F_T = D_T \frac{\partial \bar{C}}{\partial z}, \tag{2a}$$

$$\tau_T = \rho \nu_T \frac{\partial \bar{u}}{\partial z}, \tag{2b}$$

where F_T is the mean downward turbulent chemical flux, and τ_T (called the "Reynolds stress") is the mean downward turbulent momentum flux. Unlike D_m and υ_m, which are properties of the fluid, D_T and ν_T (also called the "eddy diffusivity" and "eddy viscosity") are properties of the turbulent flow, and vary greatly with time and location. The relative effectiveness of momentum and chemical mixing is measured by the turbulent Schmidt number $S_{cT} = \nu_T / D_T$.

The total chemical flux F is the sum of molecular and turbulent components, i.e., $F_m + F_T$. Similarly, the total momentum flux τ is $\tau_m + \tau_T$. The total downward momentum flux is transferred to successively lower layers, and ultimately transferred to the bed. The resulting bed-parallel force, expressed per unit area of bed, is called the "bed stress" and denoted τ_b.

Turbulent mixing dominates over molecular mixing (i.e., $D_T \gg D_m$ and $\upsilon_T \gg \upsilon_M$) in the inner and outer turbulent layers (Sections "The inner turbulent layer" and "The outer turbulent layer"). Conversely, molecular mixing of chemicals dominates over turbulence ($D_m \gg D_T$) in the diffusive layer, while molecular mixing of momentum dominates over turbulence ($\upsilon_M \gg \upsilon_T$) in the viscous sublayer (Section "Viscous and diffusive sublayers").

Turbulent mixing is often affected by stratification, i.e., by vertical gradients in water density. Specifically, turbulence is inhibited in the case of "stable stratification," when denser waters underly lighter waters, whereas turbulence becomes more energetic in the 'unstable' case, when lighter waters underly denser waters. The effect of stratification on turbulence is often large in the outer

boundary layer, but small in the inner layer. The turbulent Schmidt number is likely about 0.7 in unstratified flows, but substantially exceeds 1 in stably stratified flows (Smyth et al., 2005). In many lakes, density stratification is controlled by temperature. However, sediment suspension and salinity also affect density, and sometimes play a major role.

The fluxes τ and F have great practical importance. For example, the stress τ_b exerted on the bed by the overlying water flow is responsible for mobilizing sediments, and therefore is fundamental to the study of sediment transport. Furthermore, the equal and opposite force exerted by the bed on the overlying flow is a primary mechanism for dissipating currents, of importance to physical limnology. In addition, chemical fluxes F often play vital roles in biogeochemical cycles. Therefore, a recurring theme of this article will be the examination of relationships between the fluxes τ and F and more easily measured quantities such as $\bar{u}$ and $\bar{C}$. Such relationships aid the understanding of BBL dynamics, while providing useful tools for flux estimation from measurements.

The inner turbulent layer

Bed stress and the logarithmic velocity profile

Stress varies continuously with elevation, so the Reynolds stress τ_T must approach the bed stress τ_b at elevations sufficiently near the bed (but above the viscous sublayer). This section describes the turbulent "constant stress layer," which is the lower part of the turbulent BBL within which $\tau_T \approx \tau_b$ (so τ_T and τ_b can be used interchangeably throughout this section). It will be convenient to re-express stress in units of m s^{-1} by defining the "friction velocity" u_* as

$$u_* = (\tau_b/\rho)^{1/2}, \tag{3}$$

where ρ is water density.

To analyze the vertical variability of mean velocity, note that $d\bar{u}/dz$ may depend on τ, ρ and z. In the simplest cases, other variables can be neglected and the only dimensionally consistent possibility is for $d\bar{u}/dz$ to be proportional to u_*/z. This is usually written

$$\frac{d\bar{u}}{dz} = \frac{u_*}{\kappa z}, \tag{4}$$

where the empirical "von-Karman constant" $\kappa \approx 0.4$. Vertical integration yields the well-known "law-of-the-wall" logarithmic velocity profile (Fig. 2, left)

$$\bar{u} = \frac{u_*}{\kappa} \log\left(\frac{z}{z_0}\right), \tag{5}$$

where *log* denotes the natural logarithm, and the constant of integration is incorporated into the "roughness length" z_0, which is discussed in Section "Viscous and diffusive sublayers". Manipulating (3) and (5) yields

$$\tau_b = \rho u_*^2 = C_D \rho \bar{u}^2, \tag{6}$$

where the bottom drag coefficient $C_D = [\kappa/\log(z/z_0)]^2$. The bottom drag coefficient depends on flow speed or bed roughness, and on elevation above the bed, but in many practical cases with velocity measured tens of centimeters above the bed, C_D ranges between 1×10^{-3} and 4×10^{-3}.

Further dimensional analysis yields useful scalings for mixing rates. Multiplying (4) by $\rho\kappa u_* z$, and using (2b) and (3) yields

$$\nu_T = \kappa u_* z. \tag{7}$$

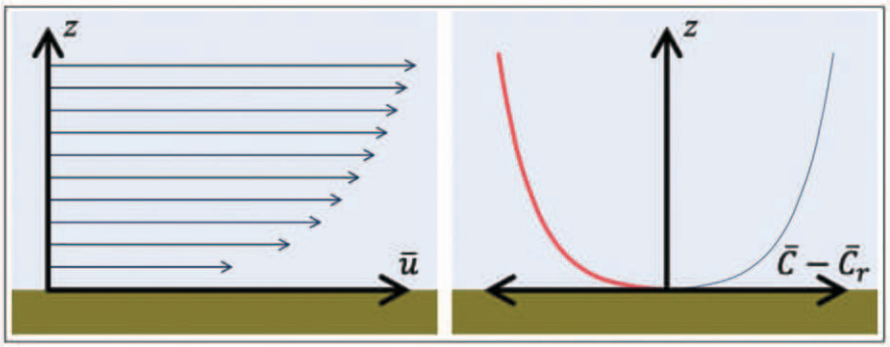

Fig. 2 Logarithmic profiles of mean velocity (left) and chemical concentration (right, with arbitrary near-bed reference concentration $\bar{C}_r$ subtracted), as predicted by inner turbulent layer theory. For chemicals that are consumed in the bed (e.g., O_2), the turbulent flux F_T is directed towards the bed, and concentration increases with elevation (thin blue curve, right panel). Conversely, for chemicals that are produced within the bed (e.g., CH_4), the turbulent flux F_T is directed away from the bed, and concentration decreases with elevation (thick red curve, right panel).

Therefore, the effectiveness of turbulent mixing, as measured by eddy viscosity, increases with flow speed (from 5 and 7) and with elevation above the bed. Furthermore, since $S_{cT} \approx 0.7$ in unstratified regions (Section "Overview of mixing processes"), similar scaling is expected for the eddy diffusivity ($D_T \approx 0.6 u_* z$, where we have used $\kappa/0.7 \approx 0.6$). Assuming a constant chemical flux F, as is expected in steady state without chemical sources or sinks, and vertically integrating (2a) then yields a logarithmic profile for chemical concentration (right panel, Fig. 2).

Additional useful scalings can be found for inner boundary layer turbulence. The turbulent kinetic energy scales with u_*^2, and velocity fluctuations with u_*. The rate of dissipation of turbulent energy is $\varepsilon = u_*^3/\kappa z$ (W kg^{-1}). This dissipation is balanced at all elevations by turbulent production, which is the energy turbulence extracts from the mean flow. We refer to the results of this section collectively as inner turbulent layer (ITL) theory.

Applications of inner turbulent layer theory

To illustrate the applications of ITL theory, consider fast and slow flows of 20 cm s^{-1} and 2 cm s^{-1}, measured at $z = 1$ m above the bed with a bottom roughness $z_0 = 0.5$ mm. In fast and slow cases, $u_* = 1$ cm s^{-1} and 1 mm s^{-1} respectively (from 5), with corresponding $\tau = 10^{-1}$ Pa and 10^{-3} Pa (from 3). Analysis based on the "Shields parameter" (which compares bed stress with the gravitational force resisting sediment motion, Fredsoe and Deigaard, 1992) suggests that the larger stress is sufficient to mobilize fine sand, whereas the smaller stress is insufficient to mobilize even fine silt (although conclusions for fine sediments may be modified by cohesive forces between grains, or by the very high porosity of some unconsolidated silty bottom layers). Further useful results can be derived concerning sediment suspension. Suspension cannot be maintained if a sediment's settling velocity w_s greatly exceeds the turbulent velocity fluctuations. Since velocity fluctuations scale with u_* (Section "Bed stress and the logarithmic velocity profile"), it follows that suspension cannot be maintained if the 'Rouse parameter' $w_s/\kappa u_*$ greatly exceeds 1. Therefore, given typical settling speeds of 6 mm s^{-1} and 0.3 mm s^{-1} for fine sand and silt respectively, only the faster flow can suspend much fine sand, whereas both flows can suspend silt for considerable time. From (7), eddy viscosities 1 m above the bed are $\upsilon_T = 5 \times 10^{-3}$ and 5×10^{-4} m^2 s^{-1}. Even the lower of these eddy viscosities exceeds molecular viscosity by a factor of hundreds, while turbulent diffusivity D_T exceeds molecular diffusivity by hundreds of thousands, highlighting the dominance of turbulent mixing over molecular diffusion.

An advantage of ITL theory is that stresses and mixing rates can be inferred from measured mean-flow profiles alone, without the need to resolve rapid turbulent fluctuations in velocity. From (5), plotting $\bar{u}/u_*$ against $log(z/z_0)$ yields a straight line (dark grey, Fig. 3A). Consequently, linear regression of measured $\bar{u}$ against $log(z)$ can be combined with (5) to yield estimates of u_* and bed stress. Numerous current meters can measure mean-velocity profiles, including Acoustic Doppler Current Profilers (ADCPs), as well as mobile impellor current meters or vertical arrays of Acoustic Doppler Velocimeters (ADVs).

In principle, just as measured and theoretical profiles of mean velocity can be compared to estimate Reynolds stress, measured and theoretical profiles of mean concentration can be compared to estimate chemical fluxes. Since only mean profiles are required, this approach would not require the high temporal resolution that is needed for alternative eddy covariance estimates (-Section "Applications, and general measurement of turbulent mixing"). Errors might result from the weakness of the chemical gradient in the turbulent layer (the most intense gradients are concentrated in the DBL, Section "Diffusive boundary layer"), although limited observations of boundary layer chemical gradients are encouraging (Deemer et al., 2015; Holtappels et al., 2011). To our knowledge this approach has not been applied to freshwater systems, but plausible fluxes have been obtained for marine (Takeshita et al., 2016) and atmospheric boundary layers.

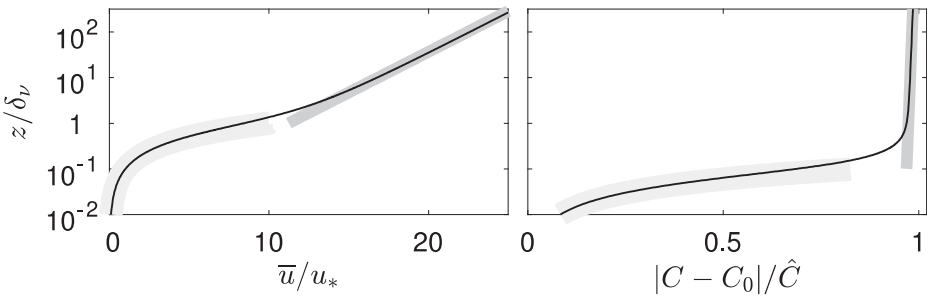

Fig. 3 Normalized vertical profiles of mean velocity (left) and chemical concentration (right). The normalized departure of chemical concentration from the value C_0 at the sediment-water interface is plotted in the right panel for a typical molecular Schmidt number $S_{cm} = 10^3$, neglecting chemical sources and sinks. Elevation normalized by viscous sublayer thickness δ_υ, velocity normalized by u_* (3), and chemical concentration normalized by typical change $\widehat{C} = 12 S_{cm}^{1/3} |F|/u_*$, appropriate for high S_{cm}, where F is the total chemical flux. Black curves are empirical profiles calculated following Deacon (1977). Thick light grey curves are viscous and diffusive models [from (8) and vertical integral of (1a)], whereas dark grey curves are logarithmic models applicable in the inner turbulent layer. Although viscous and diffusive sublayer profiles are linear, light grey lines appear curved owing to logarithmic vertical scale.

Limits to theory

Numerous factors cause departures from the attractively simple ITL theory. One complicating factor is time-dependence, which becomes particularly important for oscillating flows under surface waves with periods less than 10 s (Section "Time-dependent flows and wave bottom boundary layers"). However, ITL behavior can often be found sufficiently near the bed under long-period motions such as seiches. Stratification and Coriolis can influence outer-BBL motions (Sections "The outer turbulent layer" and "Coriolis"), but again ITL theory may apply sufficiently near the bed, especially if stratification is not too strong (although see section on Low Energy Environments). Even in unstratified flows, ITL theory applies over only a small fraction of the total water depth, partly owing to the constant-stress assumption. Finally, ITL analysis neglects molecular mixing, and consequently is inapplicable in viscous and diffusive sublayers.

Viscous and diffusive sublayers

Viscous sublayer

Turbulent mixing becomes weaker as the bed is approached (from 7). Sufficiently near the bed, turbulent mixing becomes so weak that molecular mixing dominates. Consequently, the analysis of Section "The inner turbulent layer", which neglected molecular viscosity, fails near the bed. For a smooth bed (i.e., without bottom roughness), more complete analysis shows that molecular viscosity becomes dominant at elevations much less than the viscous sublayer thickness (δ_v) with $\delta_v = 10\nu_m/u_*$. From (1b) and (3),

$$\bar{u} = \frac{10u_* z}{\delta_v} \tag{8}$$

in the viscous sublayer. Observations show a gradual transition between the linear profile (8) for $z \ll \delta_v$ and the logarithmic profile (5) for $z \gg \delta_v$ (Fig. 3A; observations also indicate $z_0 \approx 0.013\delta_v$). Natural beds are not perfectly smooth, owing to the presence of sediment grains, bedforms or benthic vegetation. However, if the height of roughness elements is substantially less than δ_v then smooth-bed results still apply. Larger roughness leads to complex, often-turbulent flows around roughness elements. Even for rough beds, ITL theory (Section "The inner turbulent layer") may apply far above the roughness elements. In such cases z_0 is proportional to the size of roughness elements, with the exact scaling depending on the element geometry.

Diffusive boundary layer

Molecular diffusivities are much smaller than molecular viscosity (i.e., molecular Schmidt numbers are very large, Section "Overview of mixing processes"). Consequently, although turbulent mixing is too weak to greatly affect momentum transport in the outer viscous sublayer (where z is only slightly less than δ_v), turbulent mixing remains significant compared with the very slow rates of molecular chemical diffusion except in the lower part of the viscous sublayer (where $z \ll \delta_v$). As a result, the most intense chemical concentration gradients are confined to a diffusive boundary layer whose thickness δ_D is much less than δ_v (Fig. 3B). Since chemical mixing is much slower in the underlying viscous and diffusive sublayers than in overlying turbulent layers, concentration gradients in overlying layers are relatively small. For smooth beds, $\delta_D \approx S_{cm}^{-\alpha}\delta_v$ where $0.25 < \alpha < 0.5$ (Deacon, 1977; Lorke et al., 2003; Lorke and Peeters, 2006).

Fig. 3B may appear to imply an increase in concentration with elevation, as expected for a downward chemical flux. However, if the flux reverses, the concentration gradient reverses (from 1a and 2a; note also the symmetry of red and blue curves in Fig. 2B). In Fig. 3B, upward- and downward-flux cases are combined in a single curve by plotting the absolute value $|C - C_0|$ on the horizontal axis.

Within the DBL the concentration profile is linear with slope determined from (1a), i.e., $C - C_0 = F_m z/D_m$, where C_0 is concentration at the sediment-water interface. Extrapolating this profile to the elevation δ_D at the top of the DBL yields the widely-used expression

$$F_m = (D_m/\delta_D)(C_u - C_0), \tag{9}$$

where C_u is concentration just above the DBL. Fast flows and energetic turbulence reduce DBL thickness (δ_D), leading to higher fluxes and higher within-layer gradients for a given $C_u - C_0$ (Lorke et al., 2003, Bryant et al., 2010, although C_0 may also vary with δ_D, e.g., Glud, 2008).

Several factors complicate analysis in some realistic cases. In addition to the diffusive flux, advection by groundwater flow can be significant in coarse sediments. Furthermore, bubbles emerging from sediments sometimes carry substantial fluxes of chemicals such as methane. Finally, filter feeders, burrowing benthic organisms and vegetation can all significantly enhance fluxes. Partly for these reasons, fluxes across the DBL often display substantial spatial variability (Glud, 2008).

Applications of viscous and diffusive boundary layer theories

To evaluate typical boundary layer thickness, consider $\nu_m = 1.1 \times 10^{-6}\text{m}^2\,\text{s}^{-1}$ and $D_m = 1.7 \times 10^{-9}\text{m}^2\,\text{s}^{-1}$, appropriate for dissolved oxygen and 15 °C. For $C_D = 2.25 \times 10^{-3}$, 2 cm s^{-1} flow gives $\delta_v = 1.3$ cm and $\delta_D = 1.5$ mm, whereas 20 cm s^{-1} flow gives $\delta_v = 1.3$ mm and $\delta_D = 0.15$ mm (using $\alpha = 0.33$).

Instruments have been developed that can resolve the thin viscous sublayer, and even the diffusive layer. For low-energy flows, specialized profiling Acoustic Doppler Velocimeters, which can resolve vertical profiles with mm vertical resolution, could provide estimates of bed stress using (8), although such measurement of velocity in the viscous sublayer is rare. Microprofilers can resolve profiles of chemical concentration with 0.1 mm vertical resolution, from which chemical fluxes can be estimated using (9). Such direct estimates of chemical fluxes are particularly valuable, although the spatial variability noted at the end of Section "Diffusive boundary layer" can be problematic.

The outer turbulent layer

Scaling stratified layer thickness

Above the inner boundary layer, stratification often inhibits turbulence. Consequently, although a logarithmic profile often fits measured mean velocity fairly well, direct measurements of Reynolds stresses and turbulent dissipation are sometimes found to be smaller than predicted by ITL theory (Holtappels and Lorke, 2011; Henderson, 2016). The influence of stratification on turbulence increases with increasing gradient Richardson number

$$Ri_g = N^2 / \left(\frac{d\bar{u}}{dz}\right)^2, \tag{10}$$

where the squared "buoyancy frequency" $N^2 = -(g/\rho)d\rho/dz$ measures the strength of stratification (N is also called the Brunt-Vaisala frequency). Where $|Ri_g| < 0.05$, stratification may have minimal effect on turbulence. In contrast, where Ri_g exceeds about 0.25–1, stratification inhibits turbulence so strongly that mixing becomes weak and intermittent.

A plausible scaling for BBL thickness δ_S (Fig. 1B) can be obtained using a "bulk Richardson number" $Ri_b = (\bar{N}\delta_S/\bar{u}_\infty)^2$, where $\bar{N}$ is vertically averaged across the BBL and $\bar{u}_\infty$ is above-BBL velocity [from (10), $Ri_b \sim Ri_g$ if $d\bar{u}/dz \sim \bar{u}_\infty/\delta_S$]. To understand the relevance of Ri_b, consider a thin BBL with $Ri_b \ll 1$, as may be created when flow suddenly accelerates. At such low Ri_b mixing is not inhibited by stratification, so the BBL will rapidly grow thicker, entraining waters from the overlying stratified interior. Initially, this thickening of the BBL rapidly increases Ri_b (because $Ri_b \propto \delta_S^2$; detailed analysis shows that mixing also often increases $\bar{N}$, further increasing Ri_b). However, the rate of BBL thickening slows dramatically when Ri_b reaches an order-one value, because stratification greatly inhibits further mixing. Therefore, in many natural cases, BBL thickness may adjust quickly towards order-one Ri_b (Trowbridge and Lentz, 1991). Requiring order-one Ri_b yields a very approximate scaling

$$\delta_S \sim \bar{u}_\infty / \bar{N}. \tag{11}$$

The ITL is limited to elevations far below δ_S. Given an upper velocity of 2 cm s^{-1} and a 10–10.5 °C temperature range, (11) suggests $\delta_S = 1$ m. Therefore, given the slow flows and significant stratification found in many small lakes, the outer BBL may reach only 1 m above the bed, and the applicability of the ITL theory is limited to elevations much less than 1 m. However, BBL thickness increases with increasing flow speed, and δ_S of several meters is common for more energetic flows, particularly in larger lakes. As expected from (11), the BBL is often relatively thick in the relatively weakly stratified hypolimnion (where $\bar{N}$ is small), and becomes thinner where the thermocline meets the sloping lakebed (Wüest and Gloor, 1998).

Modification of stratification by advection and mixing

The scaling (11) for BBL thickness is descriptive, but its predictive value is limited by the fact that $\bar{N}$ itself depends on BBL flows. For example, sheared BBL flows can modify stratification by tilting isotherms (Fig. 4). Consequently, above the sloping beds of many lakes, the oscillating flows of internal seiches alternately create and destroy BBL density stratification during downslope and upslope flows, a process called Strain-Induced Periodic Stratification (SIPS, Lorke et al., 2005). Similar oscillations are observed in chemical stratification, with implications for biogeochemical fluxes (Deemer et al., 2015). Upslope flows can even tip isotherms beyond vertical, creating overturns and free convection.

The net effect of SIPS on mixing is complex (Umlauf and Burchard, 2011). On the one hand, turbulence is enhanced by weak or unstable stratification during upslope flow, and suppressed by intensified stable stratification on downslope flow. On the other hand, mixing requires a gradient on which to act, and gradients are reduced during upslope flow, but increased during downslope flow. A further complication is that gravitational forces oppose the tilting of density contours, and these forces modify the sheared velocity profile that first tilted the contours. Other than the descriptive model (11), theoretical scalings for outer-BBL mixing and BBL thickness under SIPS are limited (although, see Brink and Lentz, 2010), and field validation is lacking.

Despite the complexity described above, some consistent patterns are observed. Specifically, mixing is relatively rapid and Ri_g is low near the bed, whereas mixing is weaker and Ri_g increases at higher elevations. Correspondingly, BBL isotherms often curve, from relatively bed-normal, indicating well-mixed conditions near the bed, towards more horizontal or bed-parallel in the outer BBL, indicating increasingly strong stratification (Fig. 4B). Intense concentration of stratification can create a step-like density jump, or "cap," at the top of the BBL (Wüest and Gloor, 1998). Despite these simple trends, detailed BBL observations in low-energy, stratified systems sometimes reveal complex behavior unrepresented by simple models (Fig. 5), highlighting a need for further research.

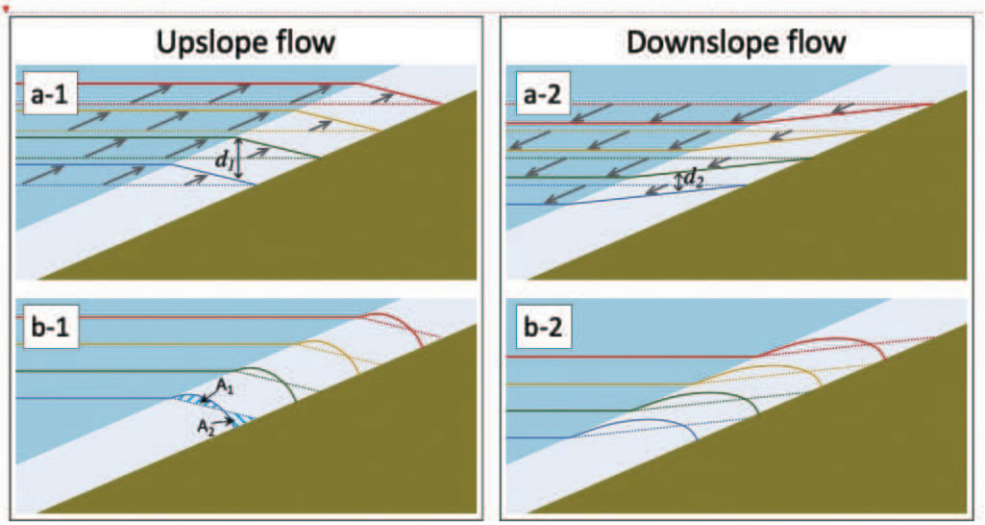

Fig. 4 Control of BBL stratification by advection and mixing above a sloping bed (in brown). For simplicity, development of stratification is illustrated as sequential stages of (A) advection and (B) mixing, although in reality these processes act simultaneously. Dotted and solid curves represent isotherms before and after each of the two stages, with warmer colored isotherms corresponding to higher temperatures. Panels a-1 and a-2: Bed-parallel flow displaces isotherms (grey arrows). Displacement, which is assumed uniform in the stratified interior (dark blue region), is reduced in the BBL (light blue region) where flows are slowed by bottom friction. This variable displacement tilts isotherms. Upslope flow reduces BBL stratification (large isotherm spacing d_1, panel a-1), whereas downslope flow increases BBL stratification (small isotherm spacing d_2, panel a-2). Panels b-1 and b-2: Mixing exchanges heat across the BBL, respectively warming and cooling the lower and upper regions of the BBL. Mixing is neglected in the stratified interior. Negligible heat transfer through the bed ensures that isotherms intersect the bed at right angles (also, since no heat is added to the BBL, areas A_1 and A_2 in panel b-1 must equal). Acting together, the combined processes of advection and mixing ensure that the final state (solid isotherms in panels b-1 and b-2) is more stratified after downslope-flow (b-2) than after upslope-flow (b-1).

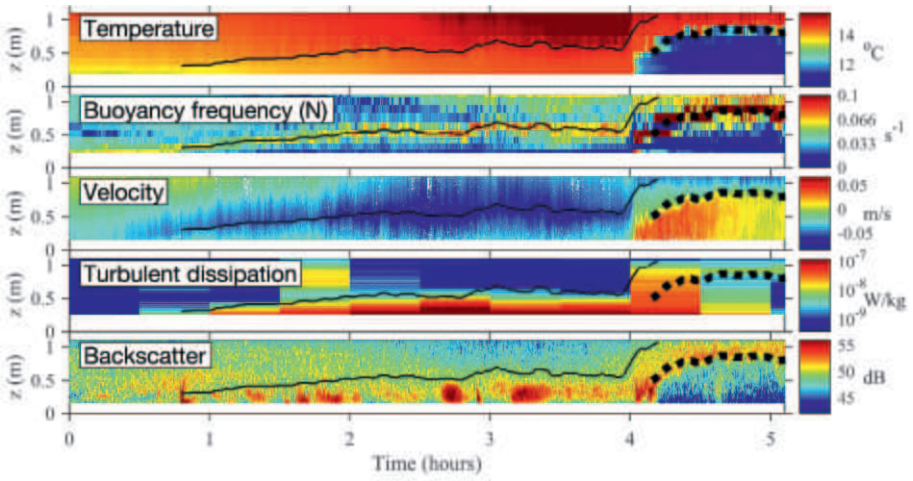

Fig. 5 Complex stratified BBL dynamics measured in small lake, where the thermocline base intersects the sloping lakebed (from Nielson and Henderson, 2021). In this lake, an internal seiche causes roughly two flow reversals each day. A 5.2-h interval around a reversal from downslope to upslope flow ($t = 4$ h) is shown. During downslope flow ($t < 4$ h), a warming bottom mixed layer (BML) develops, capped by a layer of high buoyancy frequency indicating intense stratification (solid black curve). The warming BML is a region of intense turbulence and sediment suspension (high acoustic backscatter), whereas stratification suppresses turbulence and suspension in overlying waters. At t = 4 h, the warming BML separates from the bed, owing to sudden arrival of an upslope-propagating dense cold BML (black dotted line marks the intensely stratified boundary between cold and warm layers). These observations, with BBL thickness often much less than 1 m, highlight the major stratification-induced departures from simple inner-BBL theory that can occur, even very near the bed, in low-energy stratified lakes.

Applications, and general measurement of turbulent mixing

Although ITL theories are inaccurate in the outer BBL, several instruments have been developed that can measure turbulence and associated fluxes across both inner and outer BBL regions. If turbulent fluctuations in bed-normal velocity w' and chemical concentration C' can be measured at the same location, then the turbulent chemical flux can be estimated as the mean of $C'w'$ (this approach is called "eddy covariance"). Similarly, the Reynolds stress is the mean of $\rho u'w'$, which can be measured at a point by ADVs (Holtappels and Lorke, 2011). Alternatively, some ADCPs can provide Reynolds stress profiles, particularly if "pulse coherent"

processing is used to provide low-noise velocity estimates (e.g., Henderson, 2016). However, estimating chemical fluxes is more challenging, because measuring rapid turbulent fluctuations in C' very near the velocity-measurement location, without disturbing the flow, requires streamlined fast-response probes, which are currently available for only a few chemicals (e.g., Oxygen). Nevertheless, eddy covariance has several advantages. Relative to DBL micro-profiles, eddy covariance estimates are less affected by small-scale spatial variability. Furthermore, relative to benthic flux chambers, eddy covariance is less likely to modify fluxes by disturbing mixing processes (e.g., Berg et al., 2013). Even where eddy covariance is unavailable, it may be possible to infer the flux of one chemical from the known flux of another (Holtappels et al., 2011). As turbulence becomes more intermittent in highly stratified (high Ri_g) cases, eddy covariance estimates often become noisy.

Quantification of turbulent dissipation provides useful information about mixing, and is feasible when eddy covariance estimates are unavailable. Even in strongly stratified (high Ri_g) environments, the dissipation of turbulent energy ε can be estimated from the small-scale variability in velocity or temperature (Klymak and Nash, 2010; Holtappels and Lorke, 2011; Simpson et al., 2015). When combined with models for stratified mixing, these measurements can be used to estimate turbulent diffusivity D_T (Klymak and Nash, 2010). Using estimated D_T, chemical fluxes could be estimated from relatively easily measured gradients of Reynolds-averaged chemical concentration, using (2b). In principle, this could generalize the chemical flux estimation method noted in Section "Applications of inner turbulent layer theory" to account for stratification, as may be valuable in inland waters where stratification often limits mixing, although to-date freshwater BBL applications are lacking.

Additional considerations

Time-dependent flows and wave bottom boundary layers

Time-dependence is most easily analyzed by considering an oscillating flow with velocity amplitude $\widehat{u}$ and period T, as might be observed under waves. The effects of friction on the oscillating flow are confined to a thin "wave bottom boundary layer" (WBBL), above which flow is depth-uniform. Above a smooth bed, turbulence is intensified in an unstratified WBBL if the Reynolds number $\widehat{u}^2 T/(2\pi\nu)$ exceeds about 1.6×10^5, whereas for substantially lower Reynolds numbers the WBBL is laminar. For example, oscillations with amplitudes of 0.05, 0.2 and 0.8 m s^{-1} transition to turbulence as wave period exceeds about 500, 30, and 2 s respectively. Therefore, the short-period, low-amplitude surface waves common in sheltered inland waterways often induce a laminar WBBL (boat wakes and rough beds can be important exceptions), whereas boundary layers induced by longer-period seiches and steady currents are often turbulent. The maximum WBBL bed stress is related to velocity by $\tau_{max} = \rho(f_w/2)\widehat{u}^2$, where the "friction factor" f_w plays a role similar to a drag coefficient. Friction factors depend on velocity, wave period, and bottom roughness, but often $0.02 < f_w < 0.2$ for wave periods of a few seconds, whereas lower values are common for longer periods (e.g., Fredsoe and Deigaard 1992, p. 23). In turbulent cases, unstratified WBBL thickness $\delta_T \approx \beta u_{* max} T$, where $\beta = \kappa/(2^{1/2}\pi) = 0.09$ and $u_{* max}$ is the maximum of u_* through the wave cycle. In laminar cases, WBBL thickness $\delta_T = (\upsilon_m T/\pi)^{1/2}$. Far inside turbulent wave boundary layers (when $z \ll \delta_T$, but above the viscous sublayer), time-dependence can be neglected and steady ITL theory provides a good approximation, except during brief intervals around flow reversals (although the inner BBL flow leads the outer BBL, e.g., Henderson, 2016). For long-period motions, stratification often causes large departures from the above scalings for δ_T (Section "The outer turbulent layer").

Coriolis

The earth's rotation can become significant when flows persist for more than a small fraction of a day. For steady flow over a planar bed, Coriolis leads to a limited BBL thickness δ_f, above which $d\bar{u}/dz$ and Reynolds stress approach zero. The resulting BBL is often referred to as a "bottom Ekman layer," and in the northern hemisphere flow spirals to the left as the bed is approached. Sufficiently near the bed ($z \ll \delta_f$), flow is nearly unidirectional (directed to the left of overlying velocity in the northern hemisphere) and ITL scaling applies. Above the ITL, flow is often affected by finite basin width or strain-induced stratification.

Accounting for Coriolis and strain-induced stratification over a sloping bed leads to "arrested Ekman layer" models. In such models, above-BBL currents flow parallel to bathymetric contours, so that Coriolis deflection induces sheared up- or down-slope BBL flows. These flows steadily tilt isotherms, resulting in a growing difference between the density of BBL and overlying waters. Gravity acts on this density difference, eventually bringing vertically integrated across-slope transport to a halt (Brink and Lentz, 2010). Departures from such simple planar-bed theories may result from lateral variability. Observations are lacking, although small leftward deflection of near-bed flows is often observed (e.g., Henderson, 2016).

High-energy environments

BBL thickness increases with increasing velocity and decreasing stratification (11). For sufficiently energetic cases the stratified interior can be eliminated, as the BBL overlaps with the surface boundary layer. Even in lakes with a stratified interior, the BBL can be unstratified in shallow regions, where total water depths are less than the surface mixed-layer depth.

Low-energy environments

Flows may be reduced to a few millimeters per second in small stratified lakes and ponds, and under ice. As speeds decrease, the viscous sublayer grows thicker (8), while the upper edge of the turbulent BBL approaches the bed (11). The resulting decline of δ_S/δ_v suggests a condition for the total elimination of the turbulent layers of the BBL, although field confirmation is lacking. In other physical settings, high-resolution numerical simulations show that BBL turbulence becomes very weak and intermittent in sufficiently slow stratified flows (e.g., Ruan et al., 2019). Furthermore, observations show a dramatic increase in DBL thickness, and associated near-shutdown of sediment-water chemical fluxes, when flows are very weak (Bryant et al., 2010). Such shutdown of BBL turbulence could significantly influence the biogeochemistry of low-energy regions.

In very slow flows, even weak stratification can have a major effect (11), and the stratification resulting from very low concentrations of salt or other chemicals often becomes important. Even small biogenic salinity fluxes from the sediments may shut down BBL turbulence in deep lakes (Wüest and Gloor, 1998).

Vegetated beds

In many natural waterways, aquatic vegetation greatly modifies near-bed flows. Key parameters describing vegetation geometry are n = number of stems per square meter of bed, d = mean stem diameter, and h = stem height. Given stem Reynolds number $\mathrm{Re} = \bar{u}d/\nu$ less than a few hundred, stem wakes are laminar, in which case vegetation shelters the bed and reduces mixing (although the vegetation itself can carry significant chemical fluxes). Conversely, given higher Reynolds numbers, stem wakes are turbulent and the influence of vegetation is more complex. For turbulent flows through sufficiently sparse canopies (water occupying >90% of total volume) of near-bed vegetation ($h \ll$ water depth), the reduction of steady currents within the canopy is governed by the parameter $\lambda = ndh$. Near-bed velocity is reduced only slightly when $\lambda < 0.1$, but is reduced greatly when $\lambda > 1$ (Nepf, 2012). Dependence of total near-bed turbulence on λ is therefore non-monotonic: stem wakes enhance near-bed turbulence as λ increases from zero to 0.2–0.3, but for much larger λ near-bed turbulence is reduced as the near-bed flow is reduced. Consequently, the relationship between turbulent energy and bed stress within vegetation canopies can depart from the standard ITL scaling. Sediment transport may scale with turbulent energy, rather than bed stress (e.g., Yang and Nepf, 2019). Similarly, vegetation-induced turbulence could cause departures from inner-layer relationships between stress and sediment-water chemical fluxes, although observations are lacking.

Interactions with above-BBL flows

The BBL can interact strongly with above-BBL motions. An example is provided by internal waves, which propagate throughout the stratified interior. Internal waves result from the action of gravity on tilted density contours, just as more familiar surface waves result from the action of gravity on a tilted water surface. Internal waves substantially displace isotherms while only slightly disturbing the water surface. Basin-wide internal waves ("internal seiches") are often particularly energetic, although a spectrum of higher-frequency internal waves is also often present. Internal waves may transport energy towards certain regions within lakes, causing hotspots of intensified dissipation (Thorpe, 1998). Particularly high BBL dissipation may occur where the bed slope approaches a 'critical slope' along which internal wave energy is propagated (Umlauf and Burchard, 2011). Intense mixing can also occur when internal waves break as they propagate into shallow depths (Thorpe, 1998).

Basin-wide flow patterns may further influence BBLs where dense inflowing river waters plunge down sloping lakebeds, creating bottom gravity currents. Dense bottom currents are also generated and when surface heat fluxes create particularly dense water in shallow regions, and after ice-on when sediments warm overlying bottom waters.

Through boundary-dominated mixing, BBL dynamics may modify above-BBL flows. Although the thin BBL often occupies only a small fraction of total basin volume, mixing may sometimes be so much more intense in the BBL than in the stratified interior that the BBL may be the location of most vertical mixing (Goudsmit et al., 1997). Theory suggests that remarkable, non-intuitive patterns of mean lateral advection could result, although observations are lacking (McDougall, 1989). The mechanisms for associated BBL-interior lateral exchanges are complex. Exchanges require boundary-parallel variability, because mass conservation ensures that water cannot flow out of the BBL everywhere. Several processes may generate such variability. Random small-scale mixing events, or other small-scale instability processes, may create well-mixed layers of water that slump into the interior under the influence of gravity (Thorpe, 1998). Larger-scale baroclinic instabilities can also generate BBL-interior exchanges (Wenegrat et al., 2018). More persistent exchange flows may be generated by variations in bed slope or background stratification (McDougall, 1989). Finally, the finite wavelengths of internal waves result in convergent boundary-parallel flows, which can periodically force boundary layer waters to separate from the bed (Thorpe, 1998, and Fig. 5). The relative importance of these various mechanisms is unclear.

Summary

In bottom boundary layers, chemicals and momentum are exchanged between sediments and overlying waters, with important implications for aquatic ecosystems. This exchange occurs through complex interactions between molecular diffusion, turbulent mixing, stratification, and advection. Simple theories successfully represent some of these processes, especially for energetic flows near planar beds. However, BBL dynamics are less well understood at higher elevations, in slow stratified flows, and in cases with strong lateral variability.

In the inner turbulent layer, the viscous sublayer and the DBL, simple models predict profiles of velocity and concentration, together with related fluxes. Using these models, fluxes can be estimated from measured profiles. For example, momentum fluxes are estimated by fitting logarithmic velocity profiles in the inner turbulent layer, and chemical fluxes are estimated by fitting linear concentration profiles in the DBL. Chemical fluxes could in principle be estimated by from profiles or gradients in concentration above the DBL, but to-date such applications appear to be limited to marine systems. Established techniques for non-invasive chemical flux estimation require instruments with exceptionally high resolution (sub-mm resolution for DBL studies, and sub-second resolution for eddy covariance). This restricts the set of chemicals for which fluxes that can be directly estimated.

In contrast to the lower regions of the BBL, simple models for stratified outer regions of the BBL are lacking. Important upper-BBL processes have been identified and described, but quantitative scalings have yet to be developed. Extensive research on SIPS in estuaries (e.g., Stacey and Ralston, 2005) and on the outer boundary layer in the atmosphere (Sections 4–6 of LeMone et al., 2018) may be relevant.

This article has focused on simple laterally-uniform cases, with minimal boundary-parallel variability. However, this simple description is sometimes complicated by boundary-parallel variability created by filter feeders, burrowing organisms, bottom roughness, vegetation or non-planar bathymetry.

Knowledge gaps

- Techniques such as flux chambers, diffusive boundary layer profiling, and eddy covariance have provided much useful information about chemical fluxes between sediments and overlying waters. However, for many chemicals, available techniques for flux estimation either disturb boundary layer mixing processes, or are affected by small-scale variability. Therefore, development of non-invasive flux estimation techniques for application to a broader range of chemicals may be valuable.
- In many low-energy flows, the inner boundary layer becomes very thin, while the outer boundary layer is strongly affected by stratification. Therefore, improved understanding of outer boundary layer dynamics, and development of corresponding simple models, may be valuable.
- Since mixing is so intensified in boundary layers, exchange of waters between boundary layers and the interior may influence the transport of heat and chemicals throughout stratified lakes. However, uncertainty remains concerning the relative importance of various proposed exchange mechanisms.

Glossary

Buoyancy flux, J_B Quantifies the change of potential energy in a water body caused by a vertical density flux and, by definition, it is opposed to the density flux. Therefore, a downward density flux is equivalent to an upward buoyancy flux which, in a stratified water column, makes surface waters lighter thereby reducing the potential energy. Turbulent mixing in a stratified water body produces a downward buoyancy flux (or upward mass flux), which increases the potential energy of the system.
Buoyancy Upward directed force per unit mass experienced by a water parcel having lower density than surrounding water.
Dissipation rate of temperature variance, χ_θ Rate at which small-scale fluctuations of temperature/heat created by turbulent eddies are extinguished by the smoothing effect of molecular diffusion. An equivalent concept applies to other properties and water constituents like dissolved solids (or salinity).
Dissipation rate of turbulent kinetic energy, ε The rate at which turbulent kinetic energy is dissipated to heat by internal friction caused by molecular viscosity (ν).
Gradient Richardson number, $\mathrm{Ri_g}$ Non-dimensional ratio between the stability, N^2, and the squared vertical shear of the horizontal flow velocity, $(\partial u/\partial z)^2$. It characterizes the tendency for the development of turbulence in a stably stratified water column, which is subject to vertical gradients of the horizontal currents u. A necessary condition for turbulence to occur is $\mathrm{Ri_g} < 1/4$.
Internal waves Oscillations of the internal layers of a stratified water body after a disturbance, e.g., driven by a wind event, due to the gravitational restoring force inherent to density stratification.
Mixing efficiency Non-dimensional ratio $\gamma_{mix} = J_b/\varepsilon$ expressing the rate of change of potential energy stored in the water column stratification (see buoyancy flux, J_b) relative to the rate of energy dissipation (ε).
Stratification Refers to the vertical gradient of density ρ in a water body, which confers stability by limiting vertical motions. It is quantified with the Brunt-Väisälä or buoyancy frequency (N, $\mathrm{s^{-1}}$), defined as $N^2 = -(g/\rho)\,(\partial\rho/\partial z)$, where g is the gravitational acceleration.
Thermocline The region in a stratified water body where the temperature changes significantly with depth, corresponding to the region of maximal stability (maximum N^2).
Turbulent diffusivity Proportionality factor relating the spatial gradients of a property, C, to its turbulent flux. The (vertical) turbulent diffusivity (K_z, $\mathrm{m^2\,s^{-1}}$) is defined in analogy to molecular diffusivity by using the First Fick's Law, $F_C = -K_z\,\partial C/\partial z$. Usually, turbulent diffusivity is much larger than molecular diffusivity, except in calm and extremely strongly stratified environments.
Turbulent flux Flux of a property C caused by the action of turbulent eddies within a fluid. Turbulent fluxes are directed from regions with high C values to regions with low C values, i.e., directed downgradient. This allows their expression in terms of a turbulent diffusivity, in analogy to the First Fick Law of molecular diffusion.
Vertical shear Vertical gradient of horizontal flow velocities, $\partial u/\partial z$.
Viscosity (kinematic), ν Internal friction arising between adjacent layers of fluid that are in relative motion.

☆*Change History*: August 2021. B Fernández Castro updated the abstract, text body, references, Figure 3 and added the glossary and Figures 4 and 5. Contributions from A Wüest and A Lorke.

Introduction

Nearly all lakes, reservoirs and ponds deeper than a few meters exhibit density stratification during at least part of the seasonal cycle due principally to the temperature-dependence of water density. During spring/summer—or the wet season in the tropics, when the air is warmer, particularly at nighttime—the water is heated from above and a surface layer (SL: typically a few m thick) with warmer and hence lighter water develops on top of the cooler and heavier water below (Fig. 1; Imberger, 1998). In addition, biological and hydrological processes may strengthen the density stratification by generating a vertical gradient of dissolved solids (salinity). The resulting stratification is usually depicted by a strong density gradient (also called pycnocline or metalimnion), separating the SL from the deeper part of the water column, which is more weakly stratified and referred to as hypolimnion (Fig. 1). Density stratification, as a consequence of heavier water laying below lighter water, causes a lowering of the center of mass of the water body below the center of volume by a vertical distance Δh_M. This lowering entails a reduction of the potential energy of the water body that can be approximated as $\Delta E_{pot} = H\rho g \Delta h_M$ (J m^{-2}) by considering a rectangular basin, where H is the average depth of the water body, g is the gravitational acceleration, and ρ is the density (Δh_M is negative because the center of mass is displaced downwards, and ΔE_{pot} is also negative).

Mixing of heavier water from greater depth with lighter water from the SL, implies movement of water parcels against the density gradient. A source of mechanical energy is required for this work. The amount of work needed to mix the entire water column is determined by $-\Delta E_{pot}$. Density stratification thus imposes stability on the water column and reduces—or even suppresses—vertical exchange restricting motions to occur along surfaces of equal density, i.e., mainly along the horizontal. The only exception to this constriction are small-scale turbulent eddies, which maintain a weak and continuous vertical mixing. In the absence of turbulent motions, the vertical exchange of properties would be driven exclusively by molecular diffusion operating on their mean vertical gradients, which is a very slow process. Small-scale turbulent eddies stir the water parcels, putting them in close contact with each other and enhancing the small-scale gradients, which are then eroded faster by molecular diffusivity (Fig. 2). In this way, turbulent fluxes are typically several orders of magnitude larger than expected from molecular diffusion alone.

Besides convective mixing in the SL, caused by seasonal or nocturnal surface cooling, the major source of energy for vertical mixing in lakes and reservoirs is wind, whereas river inflows usually play a minor role (Fig. 1; Imboden and Wüest, 1995). Wind-driven mixing within the stratified water body below the SL occurs indirectly through the excitation and dissipation of basin-scale currents. By blowing at the lake's surface, wind drives basin-scale surface currents that cause the stratified water body to pivot with warm water piling up at the downwind end (causing downwelling) and deep-water accumulating at the upwind end (causing upwelling). After the wind ceases, the water displacement relaxes and various types of internal motions and waves develop—including basin-scale seiches and gyres—inducing motion in the deepest layers. These large-scale currents eventually degenerate into turbulence and decay as a series of eddies that transfer the energy towards small scales, where it is dissipated as heat by viscosity. However, not all the turbulent kinetic energy is lost as heat, since turbulent eddies cause mixing of denser with lighter water, which effectively results in an upward mass flux raising the center of mass of the water body (Fig. 2).

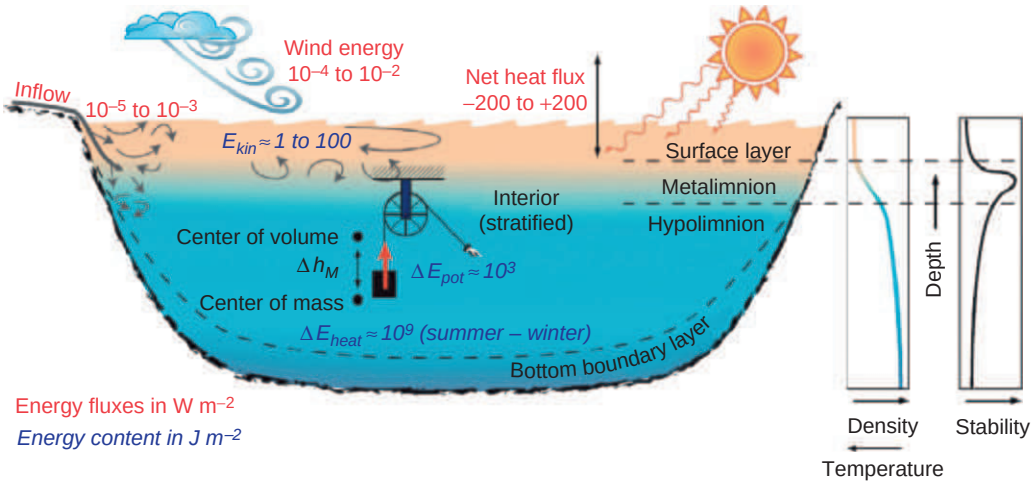

Fig. 1 Energy input (heat, wind, and river inflow; in red) to the water, expressed as fluxes (W m^{-2}) and energy content (heat, kinetic energy, potential energy; in blue) stored in the lake water body (J m^{-2}). Note that the energy fluxes and contents related to heat are many orders of magnitude larger than those of kinetic and potential energy. The effect of mixing by the river is only local and less effective than wind. The stratified part of the lake (below surface layer) has historically been divided into the metalimnion (large stability, right) and the deep hypolimnion (weak stratification) below. The lower water column can also be differentiated into the interior region (away from the boundaries), which is mostly quiescent except during storms, and the bottom boundary layer where turbulence is enhanced. Adapted from Imboden DM and Wüest A (1995) Mixing mechanisms in lakes. In Lerman A, Imboden D and Gat JR (eds.) *Physics and Chemistry of Lakes*, pp. 83–138, Springer-Verlag: Berlin.

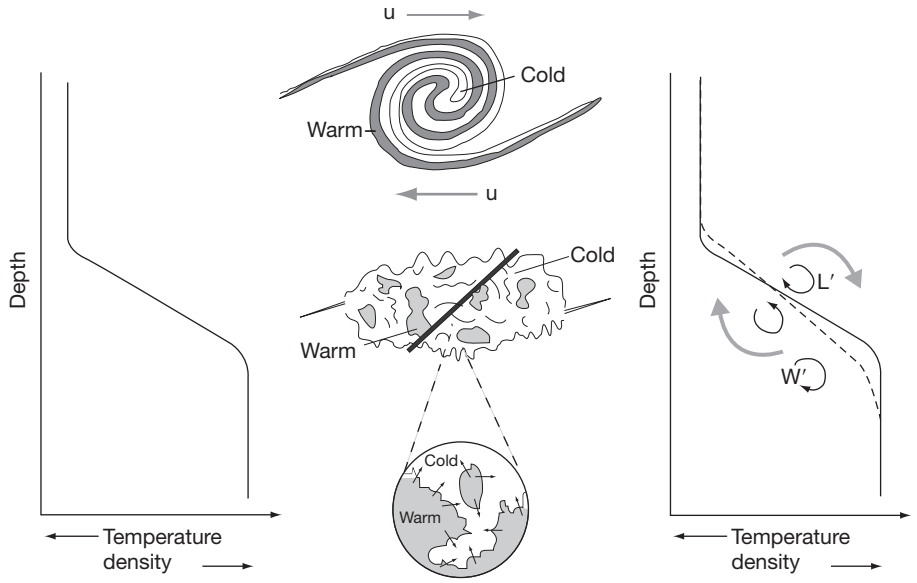

Fig. 2 The effect of turbulent mixing in a stable stratification: if the vertical gradient of horizontal currents (current shear $\partial u/\partial z$) is stronger than the stability of the water column (Eq. 2), Kelvin Helmholtz instabilities can develop (top of middle panel) bringing warmer (lighter) and cooler (heavier) water in close proximity (bottom of middle panel). Finally, heat (or any other water constituent) is mixed by molecular diffusion across the manifold small-scale interfaces, which are generated by turbulence. The turbulent exchange of small water parcels leads to a fluctuating vertical heat flux (Fig. 3) which averages to a net down-gradient (here downward) heat flux. As a result, the original temperature profile (left) is modified (right): the gradient is weakened and expanded vertically with heat transported from top to bottom, and density vice versa. This net upward mass transport results in rising the center of mass of the water body and requires energy supply. The energy needed for mixing is extracted from the kinetic energy of turbulent motions. Figure after the idea of Winters et al. (1995). Experiments were first performed by Thorpe (1973). The phenomenon of sheared stratification in lakes was reported by Mortimer (1952); and by Thorpe (1977).

In this article, we follow the energy pathways from wind stress at the air-water interface to the generation of mixing and vertical turbulent fluxes in the stratified interior of lakes. In the following sections, we address the dynamics of turbulence and mixing in terms of their energetics at the basin-scale and the key concepts describing their functioning at small scales. We focus particularly on the concept of turbulent diffusivity, which provides a quantitative measure of the intensity of turbulent fluxes, and we outline how to measure or estimate such fluxes. Next, we describe in more detail the different mixing mechanisms that operate in the surface and bottom boundaries, as well as in the interior of the water body. We end the chapter with a summary of the main points and open questions for future research.

Energetics and significance of mixing at basin-scale

Following the previous reasoning, vertical mixing in stratified lakes can be understood as a conversion of wind kinetic energy into potential energy stored in the density profile of the water body. Therefore, quantifying the pathways of energy inside lakes (i.e., performing an energy budget) is a useful, integrative approach to estimate the magnitude of turbulent fluxes in these systems. This approach has been adopted in a number of field studies (Wüest et al., 2000) and used to describe turbulent fluxes in one-dimensional lake models (Goudsmit et al., 1997). Field observations have shown that the energy pathways are rather indirect and leaky, diverting large amounts of energy towards heat by viscous dissipation at different steps. The first step of the energy transfer occurs at the air-water interface. Since water is 800 times denser than air and since momentum (and not energy) is conserved across the air-water interface, the SL receives only about 3.5% (or $1/\sqrt{800}$) of the wind energy from the atmosphere (30–300 mW m^{-2}), the remainder 96.5% being dissipated as heat in the atmospheric boundary layer. The majority of the flux transferred into the water body is either dissipated as heat in the surface boundary layer or transiently stored in surface waves, which get dissipated mostly in littoral regions, and their energy does not reach the stratified part of the water body (Wüest and Lorke, 2003). The remaining energy causes large-scale surface currents, with surface water flows with speeds of 5–30 cm s^{-1}, smaller compared to the wind velocity (2–20 m s^{-1}) (Wu, 2006), which trigger oscillatory displacements of the internal density interfaces, i.e., basin-scale internal motions. The mechanical energy reaching these deep-water currents is usually a small fraction (<1%, typically ~0.3% or <1 mW m^{-3}) of the wind energy flux from the atmosphere (Wüest et al., 2000; Fernández Castro et al., 2021). The velocities of deep-water currents are usually of a few cm s^{-1} (or ~1 J m^{-3}), one order of magnitude less energetic than those in the SL.

The internal flows decay by various processes (including friction at the lake bed, degeneration of internal waves by non-linear steepening or interaction with the slope, and shear instabilities in the interior of the water body), and their energy is dissipated by

viscous friction at rates of less than 1 mW m^{-2}. Direct turbulence measurements and indirect estimates of its effect (e.g., temporal changes in the density profiles, see "Quantification of Turbulent transport: Eddy diffusivity") show that the fraction of the turbulent kinetic energy spent in mixing against the stratification is ~10–15%, resulting in an increase of potential energy of the water body by 0.01–0.05 mW m^{-2} (Wüest et al., 2000, Fernández Castro et al., 2021). Therefore, about 0.03% of the wind energy flux is stored as potential energy. Compared to the energy required to fully overcome stratification (order of 1000 J m^{-2}; Fig. 1), it would take much longer than one season to entirely mix a moderately deep lake. This implies that wind energy input can impact the vertical density structure at times of weak stratification (beginning of the season), whereas the wind is not able to substantially change the vertical structure once the strong seasonal stratification is established. Therefore, in most regions on Earth, only very shallow waters, less than a few meters deep (such as Lake Balaton, Hungary) are found to be entirely non-stratified during the warm/wet season. The majority of lakes and reservoirs, deeper than a few meters, are thus only "partially" mixed to a limited depth, which defines the SL thickness. For those lakes that show a well-mixed SL, its maintenance is mostly supported by nighttime cooling. In this article, we focus on the "limited" mixing below the SL, which occurs in the metalimnion and hypolimnion (Fig. 1). This mixing is vital for the functioning of the ecosystem as it plays an important role in a number biogeochemical processes affecting the water quality: resuspension of sediment particles, the exchange of substances between the sediment and water, the supply of oxygen towards anoxic or suboxic regions, and the uplift of nutrients towards the photic zone, among others.

Small-scale turbulent mixing

The same concepts of stability and mixing—described in the preceding sections for the entire water body—also apply locally within the water column for small-scale vertical mixing of stratified layers. Local stability of the density stratification is quantified by the Brunt-Väisälä frequency (also buoyancy frequency) N (s^{-1}), defined (in its squared form) by:

$$N^2 = -\frac{g}{\rho}\frac{\partial \rho}{\partial z} \tag{1}$$

where g is gravity (≈9.81 m^2 s^{-1}), ρ is water density, and z is depth (positive upward). When the water body is set in motion by the wind, horizontal flow velocities (noted as u) develop within the fluid. Because of wind-forced motions, a vertical gradient of the horizontal current u (shear, $\partial u/\partial z$) is superimposed on the vertical density gradient $\partial \rho/\partial z$. Depending on the relative strength of N compared to $\partial u/\partial z$, stratified shear flows may eventually become unstable and develop into turbulence (Fig. 2). The tendency of a stratified flow towards instability (i.e., transition from a horizontal current to turbulence) is described by the gradient Richardson number,

$$Ri_g = N^2/(\partial u/\partial z)^2 \tag{2}$$

and the transition to turbulence is expected for low Ri_g values <1/4. Once established, turbulence transfers kinetic energy from basin-scale motions (~km) towards progressively smaller eddies until it is dissipated by viscous friction at the smallest possible scales (~cm). Turbulent eddies stir the water parcels, enhancing the small-scale gradients of density and other properties (Fig. 2). These small-scale gradients are smoothed by molecular diffusion. The effect of turbulence is thus to homogenize (i.e., mix) the water properties.

Although the large-scale (advective) motions are mainly horizontal, the turbulent eddies are associated with random velocity fluctuations in all three dimensions (u', v', w'). Turbulent kinetic energy (TKE; J kg^{-1}) is defined as the energy per unit mass of water that is contained in these velocity fluctuations:

$$\mathrm{TKE} = \frac{1}{2}\left\langle u'^2 + v'^2 + w'^2 \right\rangle \tag{3}$$

The intensity of turbulent motions and the energy transferred towards small-scales are described by the rate at which TKE is dissipated by viscosity and represented as ε (m^2 s^{-3} = W kg^{-1}). The intensity of turbulent mixing of scalar properties (such as temperature or density) is quantified by the rate of dissipation of small-scale gradients (or variance) by molecular diffusion, and represented by χ. This rate of variance smoothing is proportional the molecular diffusivity of the considered property (D_C, where C represents the property) and the small-scale variance of the gradients induced by turbulent stirring, $\chi \sim D_C\ (\partial C'/\partial z)^2$. It thus depends on the molecular characteristics of the property, through the value of D_C, and on the intensity of turbulence, through the generation of small-scale gradients ($\partial C'/\partial z$). Therefore, χ is usually represented with a subscript indicating this property, such as χ_θ for temperature (units: K^2 s^{-1}).

Turbulence can also be characterized in terms of size distribution of the turbulent eddies (Thorpe, 2007). The size of the largest possible turbulent eddies in stratified flows is described by the Ozmidov length scale, $L_O = (\varepsilon/N^3)^{1/2}$, since eddies larger than L_O (typically 0.1–10 m) are damped by stratification. On the other hand, the size of the smallest possible turbulent eddies (1–10 mm), able to resist the effects of molecular viscosity, is defined by the Kolmogorov length scale ($L_K = (\nu^3/\varepsilon)^{1/4}$, where ν is the kinematic water viscosity). For most properties, such as temperature and dissolved solids or gases, the molecular diffusivity is much smaller than the kinematic water viscosity ν. Subsequently, fluctuations of those quantities are observed at scales smaller than L_K. The L_K-equivalent for scalar properties is the Batchelor length ($L_B = (\nu D^2/\varepsilon)^{1/4}$), which ranges 0.4–4 mm for temperature and 0.04–0.4 mm for dissolved matter and gases.

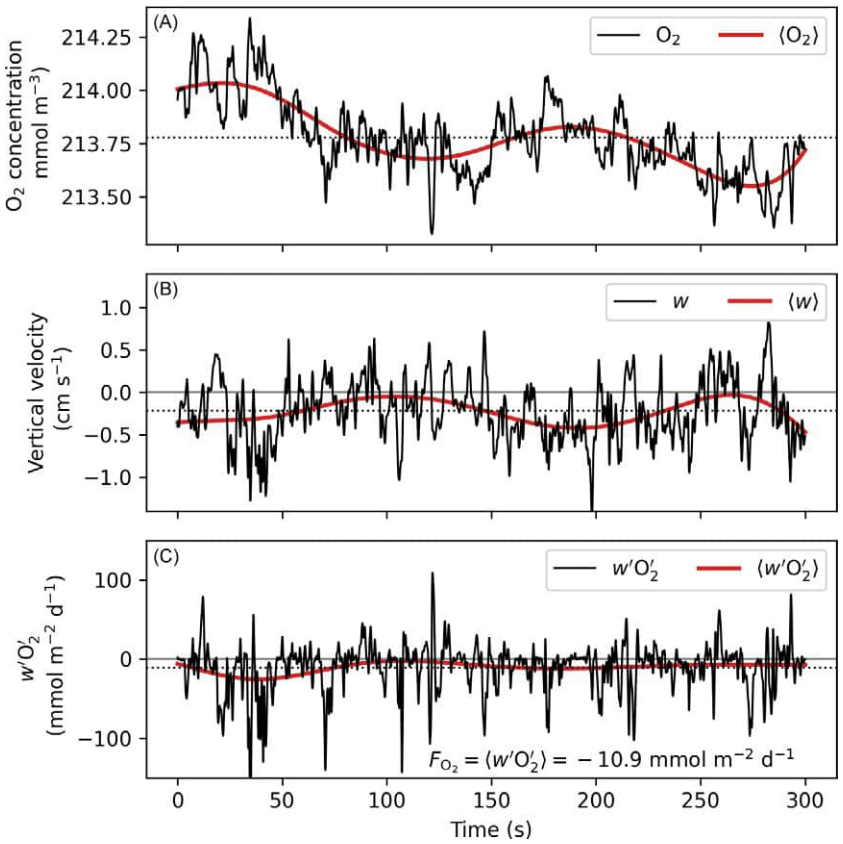

Fig. 3 Time series of O_2 concentration (black line, A) and vertical velocity w' (black line, B; positive = upward), as measured 10 cm above the sediment in the Wohlensee Reservoir (Switzerland) at a frequency of 64 Hz. Red lines indicate the temporally varying averages, determined as running means, whereas the horizontal dotted lines indicate the segment mean. Panel (C) shows the instantaneous eddy flux—covariance of w' and O_2'—and its running average. The average downward O_2 flux over the 300 s (~19,200 data pairs) is –10.9 mmol m^{-2} day^{-1} as indicated by the dotted line. Data source: Lorrai C, McGinnis DF, Berg P, Brand A and Wüest A (2010) Application of oxygen eddy correlation in aquatic systems. *Journal of Atmospheric and Oceanic Technology* **27**: 1533–1546.

Turbulent fluctuations of the vertical velocity w' transport water parcels and their constituents against the stabilizing force of density stratification (Fig. 3). The product of the vertical velocity fluctuations w' and the associated density fluctuations ρ' describes an instantaneous vertical flux of density ($w'\ \rho'$; kg m^{-2} s^{-1}). The instantaneous turbulent flux is composed of irregular fluctuations (Fig. 3). However, due to the dissipation of small-scale gradients by molecular diffusion and to the presence of a background vertical density gradient, the average flux is not zero. The non-zero component appears when averaging $w'\rho'$ over sufficiently long time as a net downgradient (i.e. upward) mass flux $<w'\ \rho'>$, which is usually expressed as a buoyancy flux J_b (W kg^{-1}).

$$J_b = -g\rho^{-1}\langle w'\rho' \rangle \tag{4}$$

Therefore, we can interpret vertical mixing as an upward flux of mass, which causes a change of the potential energy of the stratification (Figs. 1 and 2), expressed as a buoyancy flux (Eq. 4). The required energy originates from TKE, which stems from horizontal flow. Approximately 90% of the TKE, however, does not contribute to the buoyancy flux (and hence to vertical mixing) but is instead dissipated into heat by viscous friction. By defining local rates of production P (W kg^{-1}) and viscous dissipation ε (W kg^{-1}) of TKE, the simplest form of TKE balance reads as:

$$\frac{\partial}{\partial t}\mathrm{TKE} = P - \varepsilon - J_b \tag{5}$$

As mentioned above, the dissipation rate is usually much larger than the buoyancy flux, and hence the mixing efficiency γ_{mix}, which is defined as the ratio.

$$\gamma_{mix} = \frac{J_b}{\varepsilon} = \frac{-g\rho^{-1}\langle w'\rho' \rangle}{\varepsilon} \tag{6}$$

is well smaller than unity. A number of studies in stratified lakes and reservoirs revealed typical mixing efficiencies in the range of 10–15% (Ivey and Imberger, 1991; Imberger and Ivey, 1991). Nonetheless, γ_{mix} can be highly variable along the development of a turbulent event and among turbulent events, depending on the intensity of turbulence relative to stratification (Ivey et al., 2008,

Mashayek et al., 2017). Maximum γ_{mix} values of ~20%, averaged over a turbulent event, are expected when inertial forces of turbulence are comparable to buoyancy forces of stratification. However, γ_{mix} can be severely curbed by especially strong or especially weak stratification. Such situations are common in strong thermoclines and in deep bottom boundaries, respectively, where γ_{mix} can be significantly lower than 10–20%. For this reason, at least in medium-sized lakes, most of the mixing occurs within the bottom boundary layer at locations where the thermocline intersects the lake slope.

Quantification of turbulent transport: Eddy diffusivity

Turbulent eddies act on any water property or constituent as they do on density, enhancing small-scale gradients and driving turbulent fluxes. Therefore the local turbulent vertical fluxes of water constituents, such as oxygen (O_2), nutrients or organic matter are similarly described by the covariance of vertical velocity fluctuations and concentration fluctuations, $<w'\ O_2'>$ (Fig. 3; Lorrai et al., 2010). Although the instantaneous fluxes are almost of equal magnitude in the upward and downward directions, the averaging $<w'\ O_2'>$ reveals slightly larger fluxes towards the sediment, where O_2 is consumed. The turbulent fluxes are always from high to low concentrations, and replenish water constituents in locations where they are consumed by biogeochemical processes, such as O_2 in the sediments or nutrients in the photic zone.

The quantification of turbulent fluxes is therefore relevant for ecological processes and of key interest for research and management of aquatic systems. Direct measurements of turbulent fluxes can be achieved with the eddy covariance technique (Fig. 3). This technique is based on simultaneous, precise, well-resolved measurements of the turbulent fluctuations of the vertical water velocity and the property of interest (such as temperature, O_2) in a small control volume (Fig. 3). High-precision velocity measurements can be obtained with acoustic velocimeters and the method has proven useful to measure turbulent fluxes of heat and oxygen at the water-sediment interface as well as in the water column. The method has some important drawbacks as it is based on rigorous assumptions (steady-state conditions, horizontal homogeneity and negligible production or consumption of the constituent within the water column above the sediment). In addition, the method is technically challenging and costly and the observations have limited spatial representativeness. Moreover, sensors with sufficiently high resolution and sampling frequency are only available for a small number of properties.

Alternatively, turbulent fluxes in stratified waters are usually expressed using the eddy diffusivity concept. Applied to the mass flux $<w'\ \rho'>$, it implies assuming that (i) a well-defined local density gradient $\partial\rho/\partial z$ exists (due to the stratification) and (ii) the flux—in analogy to molecular diffusion—can be expressed by the eddy (or turbulent) diffusivity K_z ($m^2\ s^{-1}$) multiplied by this local gradient:

$$\langle w'\rho'\rangle = -K_z\frac{\partial\rho}{\partial z} \tag{7}$$

In this formulation, K_z describes the net vertical transport of density caused by turbulent velocity fluctuations. Therefore, in contrast to the molecular diffusion process and to the rate of variance smoothing (χ), eddy diffusivity is neither a function of the medium (water) nor of the water constituents, but rather a property of the stratified turbulent flow. In particular, K_z reflects the extent of the velocity fluctuations w' and the eddy sizes L': K_z can be interpreted as the statistical average $<w'\ L'>$ over a large number of eddies (Fig. 2 and Fig. 3).

All water properties—such as temperature or dissolved substances—are transported and mixed in the same way via the turbulent exchange by small eddies (Fig. 3). The eddy diffusivity concept can be applied to any dissolved or particulate substance and the associated vertical fluxes F can be estimated in analogy to Eq. (7) by.

$$F = -K_z\frac{\partial C}{\partial z} \tag{8}$$

where C is the considered concentration. In the last decades, two fundamentally different approaches have been used for the estimation of K_z: (i) the microstructure method and (ii) the tracer method.

The microstructure method (i) is based on the TKE balance of Eq. (5). Assuming steady-state conditions, by neglecting the left-hand side of Eq. (5), and by combining Eqs. (1), (5) and (6) yields:

$$K_z = \gamma_{\text{mix}}\frac{\varepsilon}{N^2} \tag{9}$$

This equation provides an expression to estimate K_z from field measurements of ε and N^2 and an assumed or parameterized value of the mixing efficiency. Moreover, it demonstrates the direct proportionality between K_z and the level of turbulence (ε) and the inverse proportionality on the strength of stratification (N^2), meaning that the vertical fluxes depend on an interplay between a driving force (turbulence) and a suppressing force (stratification).

An alternative microstructure method relies on the equation for temperature variance ($<\theta'^2>$) conservation, analogously to the TKE equation (Eq. 5),

$$\frac{\partial\left\langle\theta'^2\right\rangle}{\partial t} + 2\left\langle w'\theta'\right\rangle\frac{\partial\overline{\theta}}{\partial z} = \chi_\theta \tag{10}$$

where the second term on the left hand side is the variance production by turbulent motions acting on the mean vertical temperature gradient, $\frac{\partial \bar{\theta}}{\partial z}$, and χ_θ is the dissipation rate of temperature variance by molecular diffusion. By writing $\langle w'\theta' \rangle = -K_z \frac{\partial \bar{\theta}}{\partial z}$ and assuming steady state, K_z can be estimated as a function of χ_θ and the vertical temperature gradient:

$$K_z = \frac{\chi_\theta}{2\left(\frac{\partial \bar{\theta}}{\partial z}\right)^2} \tag{11}$$

This method has the advantage that it is a more direct measure of mixing and it is not contingent to any assumption regarding the efficiency of mixing γ_{mix}.

The dissipation rates of TKE and of thermal variance can be derived from observations with microstructure profilers (Kocsis et al., 1999). These instruments include high-resolution velocity and temperature sensors that allow measuring turbulent fluctuations at small scales close to the Kolmogorov and Batchelor scales (1 mm – 10 cm). The dissipation rates (ε and χ_θ) are proportional to the small-scale variance of the velocity and temperature gradients, which are normally derived by spectral analysis of the microstructure signal. This type of measurements offers a detailed vertical mapping of turbulence and mixing rates in the water column, but is often limited in temporal resolution, since it usually requires manned operation. Conversely, highly temporally resolved estimates of ε and χ_θ, and therefore K_z, in localized regions of the water column can be derived from continuous velocity and temperature measurements with high-resolution acoustic Doppler current profilers (ADCP) and temperature sensors mounted on moorings, using the so-called inertial subrange (Bluteau et al., 2017) or structure functions method (Wiles et al., 2006) (see Figs. 4 and 5 for examples).

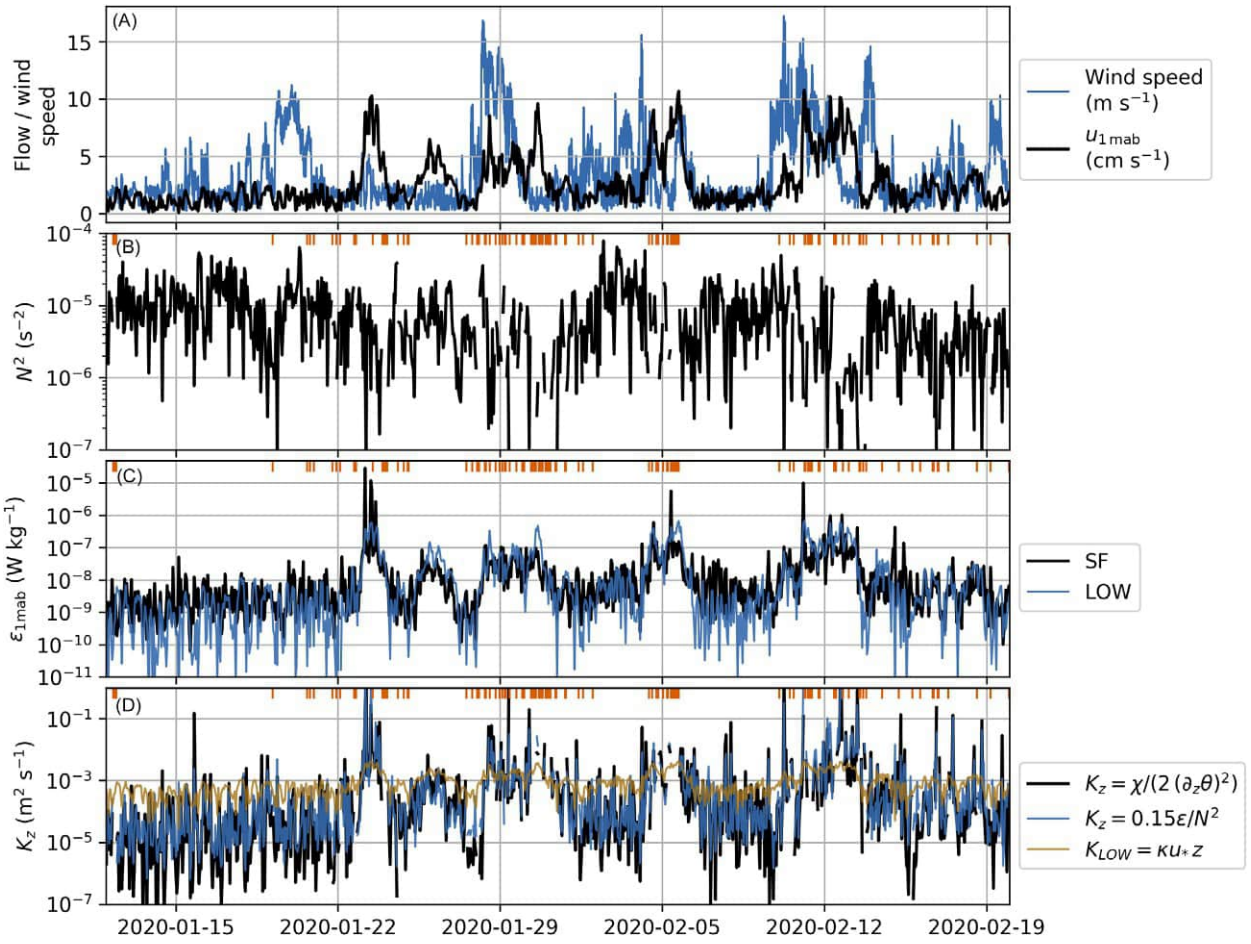

Fig. 4 Bottom boundary layer flow, stratification, dissipation and diffusivity in a slope region of Lake Geneva during a windy winter period measured with moored instruments (high resolution ADCP and thermistors). (A) Flow speed at 1 m above the lake bed ($u_{1\ mab}$, black) and wind speed at 10 m above the lake surface; (B) mean stratification (N^2) in the bottom 3 m; (C) TKE dissipation at 1 mab ($\varepsilon_{1\ mab}$) derived from high-resolution velocity measurements with the structure function method (SF) and from mean flow velocities ($u_{1\ mab}$) following the Law-of-the-Wall (LOW, Eq. 12) with an adjusted drag coefficient $C_D = 0.00368$; (D) vertical turbulent diffusivity (K_z) derived with the temperature variance method (black, Eq. 11), the dissipation method assuming $\gamma_{mix} = 0.15$ (blue, Eq. 9), and estimated from the LOW as $K_{LOW} = \kappa\, u_* z$, with $z = 1$ m and $\kappa = 0.41$ is the von Kármán constant (brown). Periods of unstable stratification ($N^2 < 0$) are indicated with orange markers on top of the axes. This figure illustrates important aspects of the BBL turbulence dynamics: (1) the indirect delayed response of the BBL currents to wind forcing (panel a), (2) the variability of TKE dissipation rates in the range 10^{-9}–10^{-6} W kg^{-1} as a response to varying near-bed velocities consistent with the Law-of-the-Wall (LOW, panel c), (3) the persistence of stratification ($N^2 \approx 10^{-5}$ s^{-2}) in sloping boundaries despite strong mixing events likely due to secondary circulations (panel b), (4) diffusivity values ranging between 10^{-5} and 10^{-4} m^2 s^{-1} during calm conditions, and 10^{-3} and 10^{-1} m^2 s^{-1} during energetic episodes (panel d), (5) the consistency between Eqs. (9) and (11) indicating an almost constant mixing efficiency of $\gamma_{mix} \approx 0.15$ (panel d), (6) the suppression of mixing by stratification, as Eqs. (9) and (11) give lower K_z values than the LOW approximation ($K_z \approx \kappa\, u_*\, z \approx 10^{-3}$ m^2 s^{-1}) during calm periods (panel d). Fig. 5 Time-series of 24-h of turbulence profiles in Lake Geneva on 13–14 June 2019. Profiles of TKE dissipation (A) and diffusivity (B), collected every 3 h, are shown as bars. The magnitude of log-transformed ε and K_z are represented by the length of the bars and their color (lighter color meaning higher values). The background colored contours represent the zonal water velocity (positive eastward) measured with an ADCP. The black contours represent isotherms with a resolution of 1 °C. These observations illustrate the rapid changes in metalimnetic turbulent mixing as a response to changes in ambient stratification and shear due to the presence of basin-scale motions. The strong (~15 cm s^{-1}) westward flow centered at 15 m depth at the beginning of the period was associated with large displacements of the isotherms, causing a thermocline expansion and a reduction of stratification. Therefore, dissipation rates and vertical diffusivity were initially high at $\varepsilon \approx 10^{-8}-10^{-7}$ W kg^{-1} and $K_z \approx 10^{-5}-10^{-3}$ m^2 s^{-1}. As the currents relaxed, ε decayed to minimal values of $\sim 10^{-9}$ W kg^{-1} at 6:00 am, and the isotherms came closer together creating a highly stratified layer between 5 and 20 m depth, where K_z dropped to molecular values ($\sim 10^{-7}$ m^2 s^{-1}). Data source: Fernández Castro B, Bouffard D, Troy C, Ulloa HN, Piccolroaz S, Sepúlveda Steiner O, Chmiel HE, Serra Moncadas L, Lavanchy S and Wüest A (2021). Seasonality modulates wind-driven mixing pathways in a large lake. *Communications Earth & Environment*, **2**(1): 215. https://doi.org/10.1038/s43247-021-00288-3.

At larger spatio-temporal scales, turbulent diffusivities can be estimated from observations of the three-dimensional spreading of artificial or natural tracers. The diffusivities derived from the tracer method (ii) have the advantage of integrating all the mixing processes affecting the tracer spread over the considered period and thus are representative of mixing at the basin-scale (Fig. 6), as opposed to microstructure diffusivities, which account only for mixing events encountered by the vertical path of the profiling instruments. However, the estimation of K_z by releasing artificial tracers is time and resource consuming and thus restricted to specific studies. A more suitable alternative is offered by the heat budget method, which uses heat as a natural tracer and allows estimating K_z from a series of temperature profiles (Powell and Jassby, 1974). Below the photic zone, where the penetration of solar radiation is small, the accumulation of heat can be described as the result of the turbulent heat flux crossing a certain depth level. Because of the small magnitude of K_z, the heat budget method requires repeated temperature profiles over a sufficiently extended period (>weeks). In addition, the vertical dislocation of the isotherms by internal waves can have a first-order disturbance to heat budget, and the observations must be averaged over sufficiently long time-scales. Typical diffusivity values in stratified natural waters are listed in Table 1 and Figs. 4–7.

Turbulence and mixing in the surface boundary layer

There are fundamentally two mechanisms generating turbulence in the SL: (i) the action of wind causing wave breaking and current shear in the top few meters of the water column and (ii) cooling causing heavier water parcels to sink from the surface.

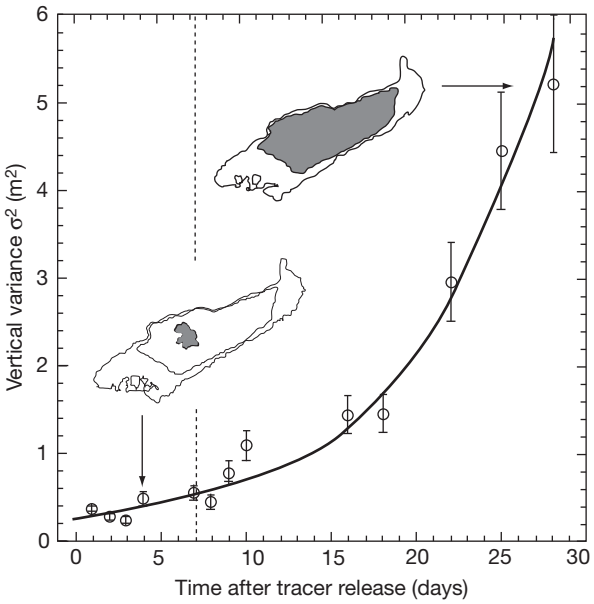

Fig. 6 Vertical spreading of the tracer Uranine after injection at 25 m depth in Lake Alpnach (Switzerland). The vertical line demarcates the initial period of 7 days, during which Uranine resided in the interior of the stratified deep water. The two insets show the lake area at the surface and at the depth of the Uranine injection, as well as the horizontal distribution of the Uranine cloud (shaded in grey) after 4 and 28 days. The slow growth of the spreading in the first 7 days illustrates the quietness in the interior. The fast growth of the vertical spreading after day 7 is due to the increasing contribution of BBL mixing after the tracer has reached the sediment at 25 m depth. Reproduced from Goudsmit GH, Peeters F, Gloor M and Wüest A (1997) Boundary versus internal diapycnal mixing in stratified natural waters. *Journal of Geophysical Research* **102**: 27903–27914, with permission from American Geophysical Union.

Table 1 Typical values of dissipation, stability and vertical diffusivity in stratified waters.

	Dissipation[a] ε *(W kg^{-1})*	*Stability* N^2 *(s^{-2})*	*Diffusivity* K_z *(m^2 s^{-1})*
Ocean thermocline	$10^{-10}-10^{-8}$	$\sim10^{-4}$	$(0.3-3)\times10^{-5}$
Surface layer	$10^{-9}-10^{-6}$	$0-10^{-5}$	$10^{-5}-10^{-2}$
Lake interior only (without BBL)	$10^{-12}-10^{-10}$	$10^{-8}-10^{-3}$	$10^{-7}-10^{-5}$
Metalimnion (basin-scale)		$\sim10^{-3}$	$(0.5-50)\times10^{-7}$
Near-shore metalimnion	$10^{-10}-10^{-6}$	$\sim10^{-3}$	$(0.3-3)\times10^{-4}$
Deep hypolimnion (basin-scale)	$10^{-12}-10^{-10}$	$10^{-8}-10^{-5}$	$(0.03-3)\times10^{-4}$

[a]During storm events values are larger by orders of magnitudes.

Cooling-driven mixing (ii) leads to homogenization of the SL and therefore to non-stratified conditions—at least for a few hours or days—before heat fluxes from/to the atmosphere or the gravitational collapse of lateral density gradients restratify the SL. Only in shallow ponds or basins with high throughflow, turbulence can have other site-specific sources.

For wind-driven mixing (i), the parameter governing the dynamics of turbulence in the SL is the surface shear stress τ (N m^{-2}), the force per unit area exerted on the water by the wind. This stress is equal to the downward eddy-transport of horizontal momentum from the atmosphere. Part of τ is consumed by the acceleration of surface waves (τ_{wave}), whereas the remaining momentum flux τ_{SL} generates currents and turbulence in the SL. By assuming a constant stress across the air-water interface, the momentum fluxes at the waterside are equal the total wind stress ($\tau = \tau_{SL} + \tau_{wave}$).

Immediately below the waves, the momentum flux, τ_{SL}, drives the vertical profiles of horizontal velocity $u(z)$. If the wind remains relatively constant for hours, steady-state conditions may develop in the SL: $u(z)$ then depicts the Law-of-the-Wall (LOW), $\partial u/\partial z = u_*(\kappa z)^{-1} = (\tau_{SL}/\rho)^{1/2}(\kappa z)^{-1}$, where $u_* = (\tau_{SL}/\rho)^{1/2}$ is the frictional velocity and κ (=0.41) is the von Kármán constant. Because the buoyancy flux in the SL (defined in Eq. 4) is not a large contribution in Eq. (5), we can assume a balance between the production and the rate of viscous dissipation (ε) of TKE. This local balance between production and dissipation of TKE determines the turbulence intensity as a function of depth throughout the SL. Under those assumptions, the dissipation,

$$\varepsilon = (\tau_{SL}/\rho)\partial u/\partial z = {u_*}^3(\kappa z)^{-1} \qquad (12)$$

is only a function of the wind-induced stress τ_{SL} (here expressed as the friction velocity u_*) and of depth z. Several experiments have demonstrated that dissipation is indeed inversely proportional to depth (Eq. 12), if averaged for long enough. However, one has to

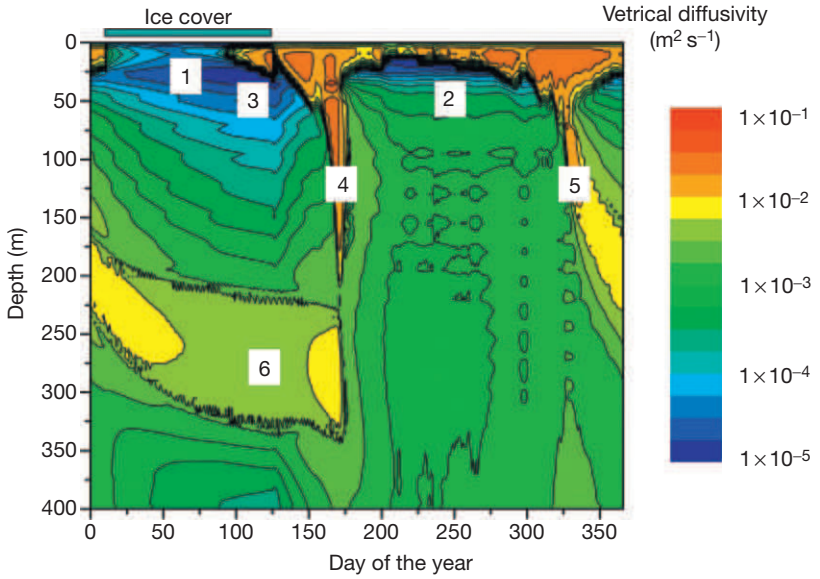

Fig. 7 Vertical diffusivities in Lake Baikal simulated with a k-epsilon model. The numbers (1–6) on the contour plot indicate the main features of the seasonal stratification and changes in diffusivity: the formation of thermal stratification with weak mixing (1) during winter under the ice and (2) during summer; (3) the formation of a radiatively-driven convectively mixed layer in spring under the ice; the deep convective mixing in (4) June and (5) November; and (6) the formation of a mixed layer near the temperature of maximum density. Here the emphasis is on the temporal and vertical structure of the turbulent diffusivity and not on the absolute accuracy, which may be difficult to achieve with turbulence modelling better than a factor of 2–3. Reproduced from Schmid M, De Batist M, Granin NG, Kapitanov VA, McGinnis DF, Mizandrontsev IB, Obzhirov AI and Wüest A (2007) Sources and sinks of methane in Lake Baikal: A synthesis of measurements and modeling. *Limnology and Oceanography* **52**: 1824–1837, with permission from American Society of Limnology and Oceanography.

be critical about the validity of Eq. (12) for two reasons: First, at the very top of the water column, breaking waves, in addition to shear stress, produce a significant part of the turbulence in the SL. This additional TKE generation at the surface can be interpreted as an injection of TKE from above. Therefore, in the uppermost layer, the turbulence exceeds the level described by Eq. (12), depending on the intensity of the wave breaking. Second, Eq. (12) relies on quasi-steady-state conditions, which may hold applicable for only limited episodes, due to the variable forcing. Third, the presence of some stratification within the SL, particularly due to solar heating during the mid-day hours, can hamper the development of the LOW logarithmic velocity layer.

Despite these restrictions, Eq. (12) gives a reasonable idea of the magnitude of energy dissipation rates and diffusivity in the stratified SL. Because ε is several orders of magnitude larger in the SL than in the interior layers and N^2 is usually small, Eq. (9) reveals that the rate of mixing is large within the SL (Table 1). Therefore, gradients of temperature, nutrients, and suspended particles are usually smallest at the surface and increase with depth. Mixing in the SL undergoes large temporal variations due to changes in wind stress and heating (day) and cooling (night) cycles. During sunny days, near-surface diurnal thermoclines are formed, where stratification ($N^2 \approx 10^{-5}$ s^{-2}) can limit the development of overturns. Under light winds ($\sim$2 m s^{-1}, $\varepsilon \approx 10^{-8}$ W kg^{-1}), turbulent eddies are constrained by the Ozmidov scale ($L_O \approx 1$ m) and mixing can be relatively weak ($K_z \approx 10^{-4}$ m^2 s^{-1}). On cloudy, windy days, the SL may mix fully and may even deepen depending upon the surface forcing. Under strong winds or intense cooling, SL stratification is eroded and the size of turbulent eddies is no longer limited by L_O but by the vertical extension of the SL. In this case, Eq. (9) is not a good estimate of K_z, because $N^2 \approx 0$. Instead, K_z can be estimated as the product of the turbulent velocity (u_*) and the SL depth (h_{SL}), $K_z = \kappa\, u_*\, h_{SL}$. For strong winds (>10 m s^{-1}) and deep SL (>10 m), $K_z \approx \kappa\, u_*\, h_{SL}$ can be as large as $\sim$0.05 m^2 s^{-1}.

Turbulence and mixing in the bottom boundary layer

Turbulence generation and mixing along the bottom boundaries of water bodies can be described in analogy to the SL. The energetics of the bottom boundary layer (BBL) are governed by the bed-shear stress due to the flow friction with the sediment, $\tau_{BBL} = \rho\ C_D\ u^2$, where C_D ($\sim 1\text{–}5 \times 10^{-3}$) is the bottom drag coefficient and u a near-bed flow velocity. Under steady-state conditions, the resulting BBL follows a vertical structure of (i) current shear (see above), (ii) rate of TKE dissipation (Eq. 12) and (iii) rate of vertical mixing similar to those described for the SL. Although the ultimate energy source for turbulence in the BBL is also wind, its action on the BBL is indirect and mediated by large-scale wind-driven currents and basin-scale internal waves, which loose energy by friction against the sediment. Moreover, along sloping boundaries in particular, the breaking of propagating internal waves and convective processes—a secondary effect of bottom friction—can produce additional TKE, leading to dissipation and mixing in excess of that predicted by Eq. (12) (Lorke et al., 2008).

As with the SL, the BBL is also often weakly stratified. Again, turbulence (Eq. 9) increases substantially when approaching the sediment and often a completely homogenized layer, a few m thick, can develop above the sediment. As a result, the contribution of the BBL to basin-scale mixing is particularly strong in sloping regions, where the BBL is adjacent to interior stratified meta- or hypolimnetic waters. This difference in stratification generates a pressure gradient driving secondary exchange flows that continuously restratify the BBL, allowing mixing to continue (Gloor et al., 2000). The BBL dynamics described here are illustrated with a time-series of flow velocities, stratification, dissipation rates and diffusivity at 1 m above the bed in a slope region of Lake Geneva during a winter period alternating strong winds and calmer conditions (Fig. 4).

Turbulence and mixing in the stratified interior

In the lake interior, away from surface and bottom boundaries (Fig. 1), the water body is largely stratified and mostly quiescent, since it is not exposed to the direct effects of the turbulent boundary layers. When sampling a property at fixed depth (such as with moored instruments), internal waves often dominate the variability over time-scales comparable to their periods (a few minutes to a few days). This is due to the transient and reversible dislocation of vertical gradients across the observation depth, whereas turbulent mixing acts as a continuous, slow process that tends to reduce those gradients. Mixing is generated by local shear instabilities related to currents and waves (Fig. 2, Eq. 2), which occur mostly where the usually weak background shear is enhanced by non-linear steepening of internal waves or wave-wave interactions. The mechanical energy needed for mixing in the interior derives mostly from basin-scale internal currents and waves. Smaller waves with higher frequencies, although generated at specific locations, can also contribute to the basin-scale energy budget (Preusse et al., 2010). At the transition between small- and large-scale waves are the near-inertial currents, which can carry—especially in large lakes—a significant portion of the mechanical energy. The response of dissipation and mixing to changes in ambient shear and stratification due to internal motions is illustrated in Fig. 5 for a summer period in Lake Geneva.

The difference in stratification between the meta- and hypolimnetic realms gives rise to distinctly different turbulence properties. High stratification ($N^2 \approx 10^{-3}$ s^{-2}) in the metalimnion can favor wave-wave interactions and dissipation rates may vary from low to moderate ($\varepsilon \approx 10^{-10} - 10^{-7}$ W kg^{-1}; Table 1, Figs. 5 and 7). However, strong stratification limits the development of turbulent eddies, with L_O ranging from <1 cm to ~10 cm. In order to drive vertical mixing, L_O must significantly exceed L_K, such that there is a well-developed range of eddies not damped by viscosity or stratification. In particular, vertical mixing gets strongly suppressed when the ratio $(L_O/L_K)^{4/3} = \varepsilon/(\nu N^2)$ falls below ~10 to 30. In the metalimnion, the onset of vertical fluxes is thus only possible at the upper range of the typically observed dissipation rates, $\varepsilon > 10^{-8}$ W kg^{-1}. The resulting vertical diffusivities range from molecular values (~10^{-7} m^2 s^{-1}, for heat) to $10^{-6} - 10^{-5}$ m^2 s^{-1}. In the hypolimnion, quiescent conditions are prevalent ($\varepsilon \approx 10^{-12} - 10^{-10}$ W kg^{-1}) but stratification is also weaker ($N^2 \approx 10^{-8} - 10^{-5}$ s^{-2}), such that large turbulent eddies ($L_O \approx 0.1 - 10$ m) can potentially develop. In deep and weakly stratified lakes, such as Lake Baikal, diffusivity can range from molecular to ~10^{-3} m^2 s^{-1} (Fig. 7; Schmid et al., 2007).

Overall, the rate of mixing in the interior away from the boundaries of lakes is usually lower than in the SL or BBL because (i) currents and shear are weak and the resulting turbulence production is reduced and (ii) stratification suppresses turbulent mixing. Direct observations of turbulence and mixing, using microstructure and tracer techniques, generally endorse this concept. In many lakes, only a few percent of the water column in the pelagic zone is found to be actively mixing (Etemad-Shahidi and Imberger, 2001). The occurrence of such turbulent patches is highly intermittent in space and time. During periods when the fluid is non-turbulent, we can expect laminar and molecular transport conditions. The observable average basin-scale diffusivity can be considered as representing the superposition of the rare turbulent events separated by molecular diffusion for most of the time. Tracer experiments and microstructure profiling conducted in small and medium-sized lakes confirmed these quiet conditions in the interior and enhanced turbulence in the boundaries. In Fig. 6, the vertical spreading of a tracer, injected into the hypolimnion, is shown for the interior (first few days) and for a basin-wide lake volume including the BBL (after a few days). From Fig. 6 it is evident that turbulent diffusivity in the interior is at least one order of magnitude lower than in the basin-wide body, including the BBL. Recent field observations have shown that this picture may be slightly different for large lakes with more intense basin-scale motions in form of Poincaré and Kelvin waves. Those seem to frequently give rise to internal instabilities and enhanced mixing at basin-scale (Bouffard et al., 2012). This was also the case in the water-column microstructure observations in Lake Geneva shown in Fig. 5. For this summer period, depth-integrated interior dissipation derived from microstructure profiles was ~0.20 mW m^{-2}. Near-bed flows were weak (<2 cm s^{-1}) and the contribution of the BBL to energy dissipation (~0.03 mW m^{-2}) was comparatively small.

In addition to these spatial differences, one has to be aware of the temporal variability. During storms, turbulent dissipation and mixing rates can be enhanced by several orders of magnitude during short episodes. The transition from quiescent to actively-mixing flows occurs rapidly once winds increase above a certain threshold relative to the stratification. The internal wave field becomes energized and turbulence can develop. However, the greatest increases occur in the BBL. It is during such storms, when most of the vertical flux takes place. This is clearly illustrated by comparing the winter (Fig. 4) and summer (Fig. 5) observations in Lake Geneva. During this winter period, the wind energy flux was five times larger than during summer (300 vs. 70 mW m^{-2}) but, in both cases, interior dissipation derived from microstructure profiles was similar ~0.2 mW m^{-2}. In contrast, BBL dissipation increased massively from ~0.03 mW m^{-2} in summer to ~0.7 mW m^{-2} in winter (see also Fernández Castro et al., 2021). In spite of these large differences, the sum of BBL and interior dissipation (~0.2 and ~0.9 mW m^{-2}, respectively) represented ~0.3% of the wind energy flux during both seasons, while the remainder 99.7% was dissipated in the atmospheric and surface boundary layers and as surface waves (Fernández Castro et al., 2021).

Synthesis and knowledge gaps

From the discussion above, we can draw the following overall scheme of the energy flux through stratified lake waters. The origin of the energy for turbulent mixing in the interior of stratified lakes is usually wind, which imposes momentum onto the water surface. Approximately 3% of the wind energy reaches the epilimnion in the form of horizontal currents and about 10% thereof (i.e., 0.3% of the wind energy) is finally transferred to the stratified water body underneath. The major part of the energy is dissipated by bottom interaction, and the minor part is dissipated in the interior by shear instabilities and breaking of internal waves. However, recent findings indicate that the partition between the bottom boundary and the interior depends on the forcing and stratification, at least in large lakes, where interior dissipation can also represent a major sink of energy. Of the dissipated energy, only ~10% contributes to a change in potential energy of stratification (mixing efficiency γ_{mix}, Eq. 6). Compared to the wind energy flux from the atmosphere, only a small fraction (~0.03%) actually causes the mixing against the stratification in the deep water, whereas the largest fraction (~99.97%) is dissipated somewhere along the flux path. Although this partitioning depends on many factors, the overall scheme likely holds within a factor of 2–3 for different lakes.

The small amount of energy available for mixing—compared to the potential energy stored in the stratification—explains why lakes deeper than a few m remain permanently stratified during the warm season. Consistent with this conclusion, the enhanced turbulence in the surface and bottom boundaries cannot erode the stable—and partly strong—stratification in the interior. Turbulent patches are intermittent and turbulent eddies are too small compared to the lake depth. As an example, the timescales to transport heat, solutes or suspended particles over a distance of 10 m would be $(10\,\mathrm{m})^2\ K_z^{-1}$; i.e., several years for $K_z = 10^{-6}\ \mathrm{m^2\ s^{-1}}$ in the metalimnion (Table 1). Therefore, two-dimensional processes, such as upwelling, contribute importantly to vertical exchanges. Despite recent progress, the spatial and temporal dynamics of mixing challenges not only experimental estimation, but also numerical simulation. Local measurements of K_z following Eq. (9) often neither resolve its spatial variability, nor its temporal dynamics and the coarse grid sizes used in numerical simulations do not capture the small scales relevant for mixing processes in the interior. Future research should target, on one side, at improving the sampling capacities through the development of autonomous turbulence-measuring devices allowing to resolve episodic and extreme mixing events, and, on the other side, at coupling of small-scale turbulence simulations with basin-scale hydrodynamic models. Fundamental knowledge on the spatio-temporal distribution of stratified turbulent fluxes in lakes is essential to anticipate the evolution of these systems in a context where climate change is profoundly altering their stratification dynamics.

Prokaryotic Viruses: Intriguing Players in the Aquatic Realm

Johannes Sergej Schweichhart[a,b], [a]Department of Functional Ecology and Evolution, Unit Limnology, University of Vienna, Vienna, Austria; [b]Biology Centre CAS, SOWA, České Budějovice, Czechia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie_Elodie Perga and Damien Bouffard.

Glossary

Auxiliary metabolic genes (AMGs) Genes within phage genomes which encode enzymatic functions that optimize the metabolism of the host cell for viral reproduction during infection.
Chronic infection Stable establishment of a virus in the host cell (lysogeny). In contrast to lytic infections viral progeny is released continuously and usually *without* rupture of the host cell.
Lysis The bursting of a prokaryotic cell during the release of viral progeny.
Lysogenic/temperate infection Viral infection which leads to the stable integration of the phage genome (prophage) in the host cell. Depending on the phage, a lysogenic infection may turn out to be chronic or lead to a delayed lytic reproductive cycle.
Lytic infection Viral infection directly leading to viral reproduction and subsequent destructive release of viral progeny (lysis).
Metagenomics The isolation and sequencing of DNA from biologically complex samples; followed by the bioinformatic analysis and interpretation of the gained sequence information.
Phages Here used to refer to viruses infecting prokaryotes (i.e., bacteria and archaea). Often also used to refer to viruses of bacteria only.
Prokaryote Unicellular microorganism without cell nucleus of the domains Bacteria or Archaea.
Prophage Functional phage genome which is integrated in the host cell either within the host genome or as plasmid.
Virioplankton Viral particles dispersed in the water column of aquatic environments.

Introduction

Viruses are the most abundant and diverse biological entities in the biosphere (Dion et al., 2020). Although they are commonly known for causing disease in multicellular organisms, most viruses found in aquatic environments infect prokaryotes (Jacquet et al., 2010). This chapter therefore focuses on the activities and ecological consequences of infections caused by prokaryotic viruses, here referred to as phages. Phages in aquatic ecosystems impact their hosts not only as infectious particles killing an estimated 20% of the prokaryotic standing stock per day but also as mobile genetic elements inside host cells which can alter their hosts' metabolism and

acquire and transfer genetic information (Cordero and Polz, 2014; Zimmerman et al., 2020). Whereas phages affecting model organisms have been studied by microbiologists and molecular biologists since the early 20th century, they have been ignored in aquatic ecology till the late 1980s. Since then, phage ecology has developed into a multidisciplinary and dynamic field of research which is constantly fed by new findings from various disciplines (Ofir and Sorek, 2018). While microbiological, genetic and molecular biological studies steadily unravel new variants of phage-host interplay, the integration of these findings into coherent ecological concepts is challenging. Currently aquatic viral ecology is heavily based on data and concepts developed in marine systems. Despite genetic differences of virioplankton from marine and freshwater systems, so far, no systematic differences between the controls of the activities and the diversity of phages in marine and freshwater systems have been identified (Wilhelm and Matteson, 2008). The aim of this chapter is to give a condensed overview on the activities and ecological consequences of phage-infections in lake ecosystems based on general concepts for virus-host relationships. Specifics of lake ecosystems will be pointed out throughout the chapter and will be illustrated by two case studies in which phages exhibited (1) a remarkable impact on top-consumers in lake ecosystems and (2) played an important role in the epidemic dynamics of a (fresh)waterborne disease.

Viral taxonomy and phage morphology

Viruses are genetically unprecedentedly diverse and in contrast to cellular organisms have no single conserved gene which can be used for phylogenetic analysis and taxonomic classification. Therefore, criteria specified by the International Committee on Taxonomy of Viruses (ICTV) are mainly based on phenotypic traits like virus morphology and the type of nucleic acid constituting viral genomes, i.e., single-stranded (ss) or double-stranded (ds) deoxyribonucleic acid (DNA) or ribonucleic acid (RNA). However, the extended use of high-throughput sequencing in the past decade has led to the endorsement of the formal classification of viruses based on genetic data by the ICTV. This resulted in a major overhaul of virus taxonomy and the recent revision of the 5-rank structure to a 15-rank structure by the ICTV which, for large parts, resembles the Linnaean taxonomic scheme used for cellular organisms. Phage morphologies are important for taxonomic classification and are informative regarding the biomechanics of infection. It is yet important to note that phage morphologies are not congruent with the (much higher) genetic diversity of phages and allow little inference about potential hosts. Since most phages are significantly smaller than the wavelength of visible light, phage morphology is commonly investigated using transmission electron microscopy (TEM). Fig. 1 shows an overview of phage morphologies. In aquatic environments, tailed phages (*Caudovirales*) and icosahedral phages like *Microviridae* make up the largest fractions of morphotypes (Brum et al., 2013).

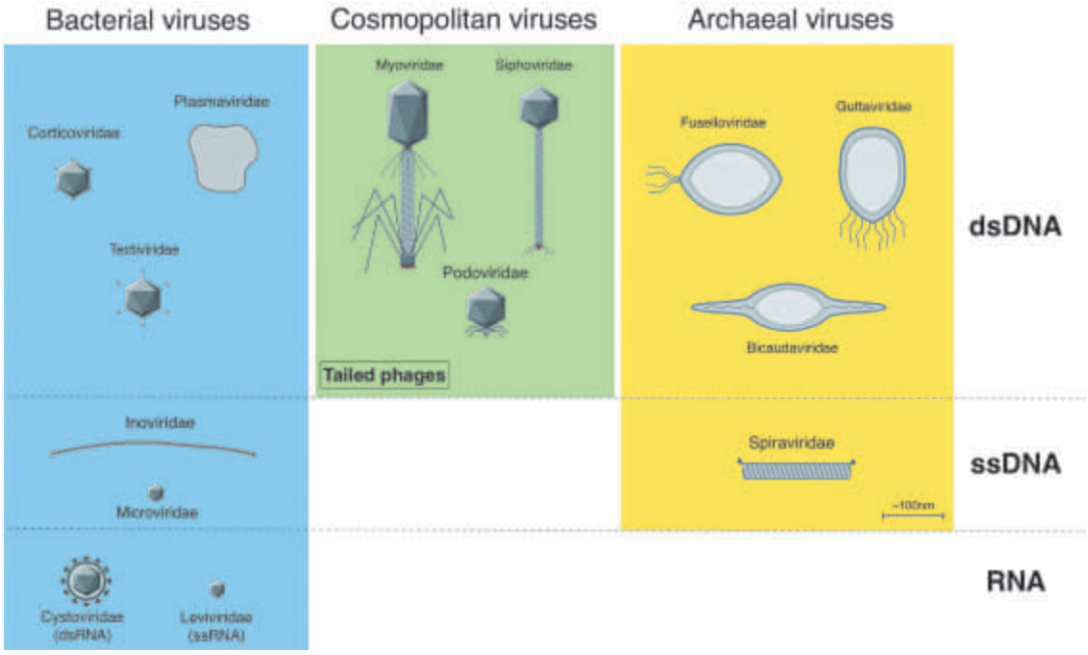

Fig. 1 Overview of phage morphologies. In most aquatic environments, phages infecting bacteria represent the largest fraction of viruses which include representatives containing each type of nucleic acid. *Myo-*, *Sipho-* and *Podoviridae* constitute the tailed phages (*Caudovirales*) members of which have dsDNA-genomes and have been found among archaeal and bacterial viruses (therefore here referred to as 'cosmopolitan'). Archaeal viruses represent only a small percentage of characterized phages. Examples found in hot springs like *Guttaviridae* and *Ampullaviridae* frequently have less regular shapes than bacterial phages. Thus far no archaeal phage containing a RNA-genome has been found.

Principles of phage-host relationships

Types of phage-infections

Phages can cause at least three different types of infections which are central to the outcome of phage-host interactions. In all cases, the phage first attaches to the surface of the host cell by specific binding to a 'phage receptor' followed by the injection of the phage genome into the host cell. What happens next differs between the types of infections. During lytic infections the phage genome serves as a template for the metabolic reprogramming of the host cell, the construction of new viral particles (i.e., virions) and the replication of the phage genome. Concomitantly, host resources become exploited and the host DNA becomes degraded. Following a latent period (in the range of hours), a variable number of phage progeny (i.e., burst size) is released during the lysis of the host cell. In lysogenic (or synonymously temperate) infections, the phage genome can either support a lytic infection or become quietly integrated into the host genome as so-called prophage. The basis on which this lysis-lysogeny decision is made is currently little understood but factors like cell size and the multiplicity of infection (i.e., ratio of phages to hosts) have been implicated. When lysogeny prevails, the prokaryotic cell is referred to as 'lysogen' or 'lysogenic cell.' In this phase most of the phage genome is inactive but potentially beneficial traits can be conferred to the host cell in a process called 'lysogenic conversion.' After a time period of variable length, prophages can spontaneously turn into a lytic cycle. Known triggers for this 'prophage induction' include DNA-damage e.g., through hydrogen peroxide, UV-C radiation and anthropogenic chemicals (Weinbauer, 2004) but also coordinated mechanisms like the recently discovered 'arbitrium' system (Erez et al., 2017). This system allows phages infecting bacteria of the genus *Bacillus* to coordinate their lysis-lysogeny decisions based on the density of the host population via virus-mediated signaling. The third infection type is referred to as chronic and is caused by members of the bacterial *Inoviridae* and the archaeal *Fuselloviridae* family. During chronic infections, the phage genome becomes integrated in the host cell as prophage (as for lysogeny) while viral progeny is produced and released without lysis of the host cell. Little is known about *Inoviridae* in natural environments but laboratory experiments using model organisms suggest a comparatively low burden for the host cell. In certain settings *Inoviridae* infections even developed mutualistic characteristics and increased the growth speed of the host (Shapiro and Turner, 2018). Most of the research about this type of infection has been carried out using phages of enterobacteria, but recent findings indicate that *Inoviridae* also play a role in a broad spectrum of aquatic bacteria (Roux et al., 2019). Fig. 2 shows an overview of the mentioned infection types.

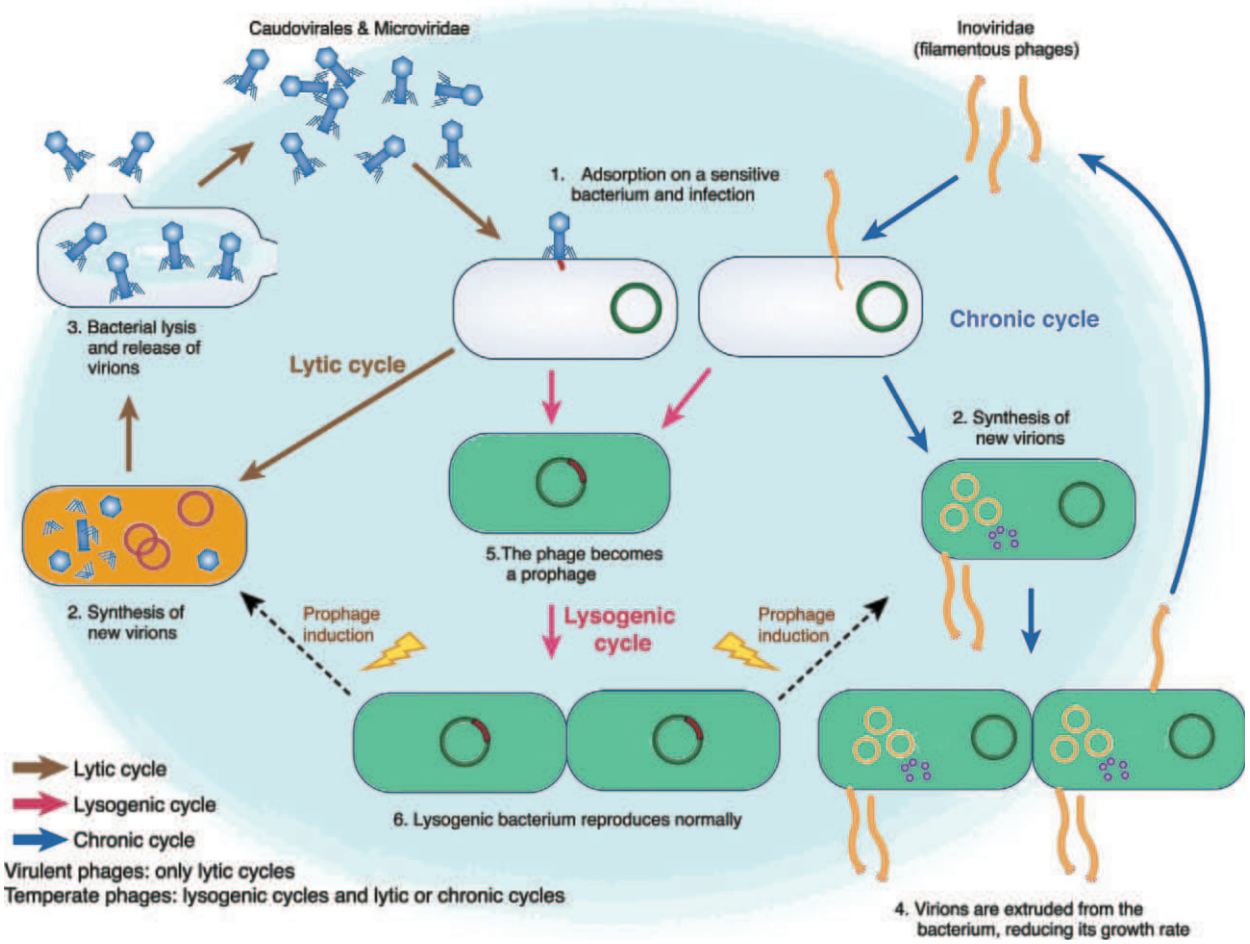

Fig. 2 Types of phage infections. Lytic infections lead to the reproduction of the phage genome, the synthesis of new virions, and the subsequent lytic release of viral progeny. Until the lysis of the host cell occurs, the metabolism of the host becomes altered by the phage (orange cell). Lysogenic infections result in the integration of the phage genome into the host cell. This can confer potentially beneficial traits to the infected cell through lysogenic conversion (green cells). *Inoviridae* cause chronic infections which combine lysogeny with the non-lytical release of virions. Modified from Sausset R et al. (2020) New insights into intestinal phages. *Mucosal Immunology* pp. 205–215. doi: 10.1038/s41385-019-0250-5.

Host-resistance and the arms race between phages and hosts

In aquatic environments a single host cell can be challenged by several distinct phages at the same time but not all phage-host encounters result in successful infection. One reason for this is the broad set of defense strategies employed by prokaryotes against phages. Phages on the other hand evolve mechanisms to bypass these defenses in a coevolutionary arms race which is a substantial driver of prokaryotic and phage-diversity (Koskella and Brockhurst, 2014). Basically, prokaryotes can either prevent, neutralize or abort infections by phages. Prevention frequently occurs through surface modifications e.g., the masking or mutating of phage receptors on the hosts surface (Hampton et al., 2020). Especially in highly streamlined genomes with comparatively fewer other resistance mechanisms, this might be the primary mode of resistance. The downside of this type of resistance is that, as phage receptors are often prominent proteins involved in nutrient uptake, altering them comes at a fitness cost for the host (van Houte et al., 2016). Phages overcome surface modifications either through the mutation of their own receptor-binding proteins, the enzymatic removal of sugars that mask docking sites on phage receptors or by using an alternative receptor for attachment. If a phage successfully overcomes this first line of defense and injects its genome into the host cell, the infection can still be neutralized by the host. Two mechanisms functioning as widespread prokaryotic 'immune system' are restriction modification- (R-M) and Clustered Regularly Spaced Short Palindromic Repeat- (CRISPR-) systems. Whereas R-M systems allow the host to assess whether DNA inside the cell is 'self' or 'non-self', CRISPR-systems respond adaptively and specifically by 'remembering and recalling' genomic bits of previously infecting phages. Phages counter R-M- and CRISPR-mediated defense e.g., by mutating parts of their genome to avoid recognition, by deactivating nucleases or even through mechanisms normally employed by the host. If a phage infection can neither be prevented nor neutralized, abortive infection (Abi) mechanisms can still limit the damage to the host population by triggering a programmed cell death in infected cells which lowers the number of released phage-progeny (Hampton et al., 2020). In addition to the systems mentioned above a series of novel defense and counter-defense mechanisms have been discovered in recent years. But not only phages and their hosts interact, also phages compete or cooperate with each other in order to overcome the host's defenses (Díaz-Muñoz et al., 2017; Dedrick et al., 2017; Landsberger et al., 2018). Competition among phages is frequently carried out through prophage-conferred 'superinfection exclusion' which either blocks the entry or replication of competing phages. This leads to a very complex interplay between phages and prokaryotes in natural systems which is difficult to disentangle.

Phage ecology in lakes

Enumeration of phages

Phages are incapable of active locomotion and are mainly transported by advection and Brownian motion (i.e., random motion of suspended particles) in the water column. Prokaryotes, if motile, sense and move along gradients of dissolved chemicals which carry no information about the location of phages. Therefore, contacts between phage and host are stochastic and mainly depend on the abundances of both partners. A series of methods for the quantification of viruses are in use today—each with their individual strengths and weaknesses. 'Plaque assays' rely on the counting of the visual signs ('plaques') phages leave when they lyse host cells growing on a culture plate. This method works well for lytic phages and when only a single type of host is investigated. However, environmental samples contain a multitude of prokaryotes of which only a tiny fraction can be cultured. It was the dominant application of such culture-based approaches that led to a significant underestimation of the number of active prokaryotes and viruses in the environment ('great plate count anomaly'). Although the necessary methodology had been developed 40 years earlier, actual abundances of dispersed viruses in aquatic environments were first attained in the late 1980s through the counting of virus-like particles (VLPs) sedimented on TEM-slides (Bergh et al., 1989). In the following years viruses have been started to be quantified using fluorescent dyes which sensitively stain nucleic acids in viral capsids in combination with epifluorescence microscopy (EFM), flow cytometry (FCM) and nanoparticle tracking analysis (NTA). If detailed genetic knowledge of the targeted phages is available, specific genotypes can also be quantified using quantitative PCR (qPCR) and the 'polony' (PCR colony) method. Notably, a recent comparative study indicated that sample preparation is delicate and that the various methods available for virus quantification might lead to significantly different results (Kaletta et al., 2020). Relative abundances of (metagenome-assembled) phage genomes can also be attained in the course of metagenomic analyses (i.e., the isolation and sequencing of viral DNA from environmental samples; Coutinho et al., 2018). An overview of methods including advantages and disadvantages is given in Table 1.

Abundances of viruses in lakes

In the water column of most lakes viral abundances fall in the range of 10^9–10^{11} VLP L^{-1}. Abundances have frequently been related to the trophic state of the waterbody (Jacquet et al., 2010). Consequently, the lowest values have been found in alpine and arctic lakes e.g., with 2×10^7 VLP L^{-1} in the Gossenköllesee (Austria) and the highest in hypereutrophic East African Soda Lakes (EASL) reaching $>10^{12}$ VLP L^{-1} (Peduzzi and Luef, 2009). Temporal (seasonal) and spatial (depth) variability within one lake may fluctuate by one order of magnitude with peak values occurring in more shallow waters or close to the surface during warmer and more productive periods (Jacquet et al., 2010). These fluctuations also occur on short temporal scales and some groups of phages like cyanophages exhibit diurnal infection patterns. Like total viral abundances, the average number of virions released per infected

Table 1 Methods for the enumeration of phages.

	Method	*Advantage*	*Disadvantage*	*Quantification*
Culture-based	Plaque assay	Simple Can also be used for phage-isolation	Requires cultivation of host	Only active and lytic phages of cultivated host
Particle-based	TEM	Information on phage morphology	Extensive manual counting	All phages
	EFM	Simple	Extensive manual counting	Low sensitivity for ssDNA and RNA viruses
	FCM	Fast	High initial cost for equipment	Low sensitivity for ssDNA and RNA viruses
	NTA	Gives also size distribution of VLPs	High initial cost for equipment	All phages
Sequence based	qPCR	Sensitive detection of specific genotype	Requires sequence information	Only specific genotype
	Polony method	Can capture diversity of gene	Requires sequence information	Group of phages sharing homologous gene
	Metagenomics	Acquisition of sequence information	Time consuming and comparatively costly	Only relative abundances of either DNA or RNA phages

TEM, transmission electron microscopy; EFM, epifluorescence microscopy; FCM, flow cytometry; NTA, nanoparticle tracking analysis; qPCR, quantitative polymerase chain reaction.

cell ('burst size') also relates to the trophic state of the water column. In oligotrophic freshwaters burst sizes of ~30 virions per infected cell and ~40 in eutrophic environments have been reported (Parada et al., 2006). Extremely low burst sizes but a high frequency of visibly infected cells (FVIC, i.e., the fraction of cells in which virion-formation is visible using TEM) have been reported from ultraoligotrophic lakes in the Arctic and Antarctic. This has been explained by 'pseudolysogeny' which might correspond to stalled infections under severe growth-limitation of the host (Anesio and Bellas, 2011). In comparison to marine environments, the total abundances of pelagic VLPs in lakes tend to be slightly higher and to vary stronger with seasons (Wilhelm and Matteson, 2008). A correlation-based study also indicated that bacterial, cyanobacterial and chlorophyll *a* concentrations might have different relative importance as drivers of viral abundance in marine and in freshwater systems. One possible explanation for these differences might be higher decay rates of viruses in lakes e.g., caused by higher concentrations of clays and particulate matter. In lake sediments VLP densities range between 10^7–10^{10} per gram dry weight in the upper layers, decreasing rapidly with depth (Jacquet et al., 2010). Sediments can also be an important reservoir for phages which can stay infectious for decades (Danovaro et al., 2008; Hargreaves et al., 2013). For an extensive review of viral abundances in a diverse set of aquatic environments readers are referred to the chapter on viruses in the previous issue of the Encyclopedia of Inland Waters (Peduzzi and Luef, 2009).

Virus-to-prokaryote ratios (VPRs) and the piggyback-the-winner (PtW) model

Even though an important first step, viral abundances alone cannot be used to directly measure their ecological impact. An attempt to define a more functional ecological parameter is the 'virus-to-prokaryote ratio' (VPR) or often synonymously named the 'virus-to-microbial cell ratio' (VMR). An extensive meta-study compiled VPRs from 210 publications and various environments (Parikka et al., 2017): In freshwater the mean VPR is 17.2 (from 0.01 to 267, $n = 229$) whereas in marine environments VPRs tend to be higher (mean 26.5, $n = 233$). The authors confirmed previous findings of a significantly positive correlation of VPR with the concentration of chlorophyll *a*, the frequency of lysogenic cells (FLC) and the frequency of visible infected cells (FVIC). A significantly negative correlation was found between VPR and temperature (hot springs tend to have very low viral abundances) and salinity (salines have both, high viral and prokaryotic abundances). However, Parikka et al. (2017) also advised 'extreme caution' when attempting to infer phage-host relationships from VPRs. A recent example for this notion is the Piggyback-the-Winner (PtW) model. PtW has been based on two findings: (1) a systematic decline of VPRs with higher microbial densities and (2) a concomitant increase in viral genes indicative of a lysogenic lifestyle (Knowles et al., 2016). PtW proposes that at higher microbial densities the frequency of lysogeny increases which in turn would suppress lytic infections (e.g., through 'superinfection exclusion'). Although this would explain the observed lowered VPRs at higher microbial densities the authors could not corroborate a positive correlation of prokaryotic densities and the frequency of chemically inducible lysogenic cells in an extensive follow-up survey (Knowles et al., 2017). Subsequently the PtW model was contended based on the current lack of 'robust empirical and theoretical support' (Weitz et al., 2017). This high-profile discourse highlights both the conceptual and technical difficulties associated with the identification of a central parameter capable of gauging viral activity in aquatic systems and the apparent need to integrate lysogenic phages into the current theoretical framework of viral ecology.

Lysogenic phages in aquatic ecosystems

One reason why the role of lysogenic phages in aquatic ecosystems is little understood is their elusive nature. They lead a double life as prophages in prokaryotic genomes which are not trivial to detect and virions which are indistinguishable from the particles of lytic phages. This makes it difficult to dissect and quantify their impact in natural systems. Previously the significance of lysogeny in prokaryotic communities has been assessed through the induction of prophages by the mutagen mitomycin C (Weinbauer, 2004; Knowles et al., 2017). Notably, not all prophages can be induced this way which can lead to significant underestimates (Köstner et al., 2019). Nonetheless, several studies in marine environments found that the frequency of lysogenic cells is high in winter and decreases rapidly during the increase of productivity in spring (McDaniel et al., 2002; Brum et al., 2016). A similar pattern has also been observed in lakes (Fig. 3; Thomas et al., 2011).

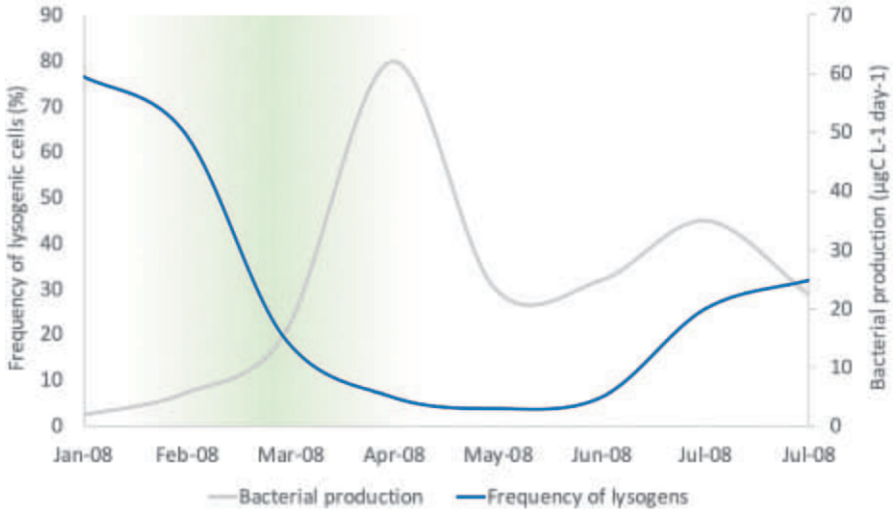

Fig. 3 Schematic representation of the seasonal trend of lysogeny in lake Bourget (France, 2008). During the winter-spring transition (green shading) the frequency of lysogenic cells, as assessed by mitomycin C induction, is inversely related to bacterial production (Thomas et al., 2011).

Experimental studies with water from Lake Pavin indicate that this switching from lysogeny to lysis might be triggered by the increase in nutrient concentrations (Pradeep Ram and Sime-Ngando, 2010). This is consistent with physiological studies showing that (1) shifts to higher nutrient concentrations can lead to quick changes in the cell size of prokaryotes and that (2) phage Lambda, the model organism for lysogenic phages, frequently opts for a lytic cycle when infecting larger cells. The recent interest in the ecological role of temperate phages has been spurred by experimental studies implicating lysogenic phages with a multitude of functionalities. Examples are the prophage-mediated defense against other phages (Dedrick et al., 2017), prophage-mediated cell-to-cell signaling (Erez et al., 2017), the scavenging and transfer of beneficial genes to host-populations, the invasion of lysogens into non-lysogenic host populations and new habitats (Brown et al., 2006) and the potentially prophage-mediated establishment of a symbiotic relationship of bacteria with aquatic metazoa (Jahn et al., 2019). Since prophages persist as genetic elements, their investigation has been significantly progressed through (meta)genomic and bioinformatic studies. Among others this led to the identification of prophages in almost half of all sequenced bacterial genomes (Touchon et al., 2016) and specifically extended our prospective knowledge about prophages of the *Inoviridae* family, suggesting that these phages are far more widespread than previously thought (Roux et al., 2019).

Metagenomic investigation of phage communities in lakes

In the past two decades, genomic and metagenomic studies of phages and their hosts revealed astonishing aspects of prokaryote-phage interplay in aquatic ecosystems. Examples are the discovery of novel phage-defense mechanisms (Hampton et al., 2020), previously overlooked prophages in prokaryotic genomes (Roux et al., 2019), the widespread occurrence of phage-encoded auxiliary metabolic genes (AMGs) in phage-genomes (Zimmerman et al., 2020), the reconstruction of genomes of non-isolated phages (e.g., Kavagutti et al., 2019), and the prediction of previously uncharacterized phage-host pairs (Coutinho et al., 2018). One major hindrance in the current metagenomic investigation of phages in lakes is their incredible genetic diversity which is not represented in existing sequencing databases and therefore has been dubbed 'the great viral unknown.' This is aggravated by biases of sequence databases towards certain well-sampled environments like the human gut and the ocean. Consequently, in metagenomic studies of viruses in freshwater environments as little as 3% and at most 30% of the sequences display reasonable sequence homology to known viral sequences (Bruder et al., 2016). The metagenomic characterization of the composition of phage communities in lakes is therefore based on conserved genomic features and sets of genes found in different groups of phages. Notably, this characterization of viral communities is not always congruent with the morphological characterization of virions in aquatic samples using TEM (Brum et al., 2013). This has also been attributed to several biases in sample preparation identified during the investigation of a large group of previously overlooked phages (Kauffman et al., 2018). Although in most investigated perennial ponds and lakes *Caudovirales* seem to dominate the viral community (e.g., Skvortsov et al., 2016), notable exceptions of lakes with a majority of ssDNA-viruses are known (e.g., Roux et al., 2012). Recent advancements in sequencing technology and bioinformatics allowed the temporal and spatial monitoring of the relative abundance of single metagenome-assembled phage genomes (i.e., phage genomes reconstructed from acquired sequencing data) in lakes. Among others this revealed that (1) in lakes individual phages have distinct dynamics of relative abundance over the course of a year, reaching from single appearances in certain months to recurrent patterns of appearance (Arkhipova et al., 2018) and that (2) the hypolimnion is constituted of different sets of phages which behave less dynamic than those in the epilimnion (Fig. 4; Kavagutti et al., 2019).

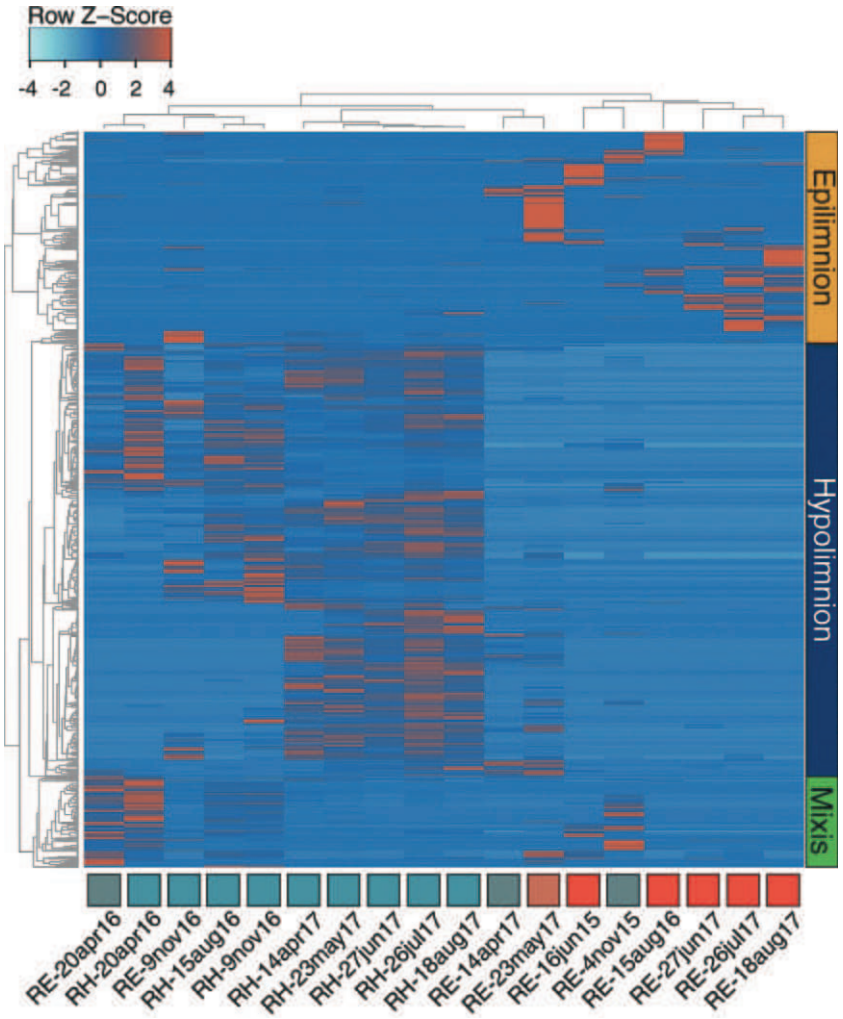

Fig. 4 Composition of the pelagic viral community of Rimov reservoir (Czech Republic, 2016–2017). Each column corresponds to a single metagenome; each line of the y-axis corresponds to the genome of one of 1398 metagenome-assembled phage genomes. Red indicates relative presence of the phage genome in the water column, light blue represents relative absence. Epilimnion (RE) and hypolimnion samples (RH) were taken at 0.5 m respectively 30 m depth during summer stratification whereas mixis samples were taken during winter/spring mixing. From Kavagutti VS et al. (2019) Phage-centric ecological interactions in aquatic ecosystems revealed through ultra-deep metagenomics. *Microbiome* **7**(1). doi: 10.1186/s40168-019-0752-0.

Ecological consequences of phage-infections in lake ecosystems

The viral shunt

One of the first ecological consequences of phage infection explored in aquatic ecosystems was the potential impact of lytic phages on carbon-cycling in the ocean. A model named 'viral shunt' assumes that lytic infections release dissolved and particulate organic matter (DOM and POM) from lysed hosts which in turn can stimulate the growth of surrounding prokaryotes and can hamper the transport of organic matter to higher trophic levels (Fig. 5). In surface waters of the ocean an estimated 6–26% of photosynthetically fixed carbon is channeled this way (Wilhelm and Suttle, 1999). For lakes such estimates are missing. However, the amount of organic carbon flowing through the viral shunt might be related to prokaryotic abundances and the current lytic activity of phages, which can vary significantly across lakes and over the year (Keshri et al., 2017; Bettarel et al., 2004; Ram et al., 2010; Meunier and Jacquet, 2015). The stimulatory effect of the viral shunt on surrounding prokaryotes on the other hand might depend on the trophic status of the water column (Wilhelm and Matteson, 2008; Jacquet et al., 2010).

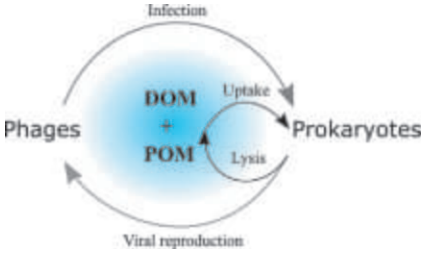

Fig. 5 The viral shunt. Virus-mediated lysis leads to the release of dissolved organic matter (DOM) and particulate organic matter (POM) which serves as an additional nutrient pool for surrounding prokaryotes.

Cyanophage-mediated inhibition of CO_2-fixation

Another ecological consequence of lytic phage-infections originates from the alteration of the host metabolism by phages during lytic infections. This has been studied in detail for cyanobacteria and cyanophages. Cyanophages often encode AMGs implicated in phosphorus acquisition and intracellular nitrogen recycling (Zimmerman et al., 2020). In addition, these phages frequently cause a significant inhibition or even complete cessation of CO_2-fixation in infected host cells during the latent phase (Puxty et al., 2016). This effect is widespread in marine *Synechococcus* and *Prochlorococcus* which are responsible for an estimated 10% of global primary production. Combined with the finding that about half of marine *Synechococcus* are infected by cyanophages at the same time, cyanophage-mediated inhibition of CO_2-fixation might affect global carbon budgets (Sieradzki et al., 2019). Originally this effect was discovered in freshwater cyanobacteria (Ginzburg et al., 1968). Although calculated estimates are missing it seems likely that this process also significantly affects primary production in lakes. Contrasting the effect of cyanophage-infections a recent metagenomic study in Lake Baikal identified AMGs that might enhance light-independent CO_2-fixation in nitrifying bacteria. Additional examples of phage-mediated metabolic tinkering in aquatic ecosystems can be found in a recent review by Zimmerman et al. (2020).

Impact of lytic phages on prokaryotic community composition

Phages have been proposed to 'maintain microbial diversity at many levels and across ecosystems' (Koskella and Brockhurst, 2014). At the level of prokaryotic communities, ambient phages have been experimentally shown to impact their composition (e.g., Weinbauer et al., 2007; Bouvier and Del Giorgio, 2007) and frequently also their species richness (Weinbauer et al., 2007; Meunier and Jacquet, 2015). Although the exact mechanisms *in situ* remain unknown this was attributed to the differential control of various members of the community by lytic phages (Fig. 6A; Schwalbach et al., 2004; Bouvier and Del Giorgio, 2007). While these experiments were carried out with marine samples, Meunier and Jacquet (2015) found that the effect of ambient phages on community richness in Lake Bourget is concentration-dependent (Fig. 6B).

However, this density-dependent relationship of VLP-concentration and species richness was not found in experiments one month earlier and one month later. Explanations for these mixed results can be derived from two concepts of classic predator-prey relationships: (1) negative-frequency dependent selection (NDS; i.e., more abundant members of the community are preferentially targeted by phages) and (2) the competitive advantage conferred to rare prokaryotic groups by the diminution of dominant ones by predators. While NDS derives from concentration-dependent phage-host contact rates in the water column, the latter might be mediated by the redistribution of nutrients from more abundant prokaryotic groups to more rare ones via the viral shunt (Meunier and Jacquet, 2015). The observed phage-mediated increase in species richness could therefore reflect an increase of previously rare community members to levels above detection, whereas in the absence of phages certain phage-controlled prokaryotic groups might become dominant (Fig. 6). The fact that not only the most abundant prokaryotic groups react in phage-treatments can be explained by the finding that the groups of prokaryotes sustaining the most phages in the water column are not necessarily the most abundant ones but can also be the most active (Bouvier and Del Giorgio, 2007). The findings that phage-treatments did not increase species richness in all experiments (Meunier and Jacquet, 2015) might be explained by the significant fluctuation of the lytic activity over the course of the year (Bettarel et al., 2004; Ram et al., 2010) and the possible insufficient resolution of the method used to discriminate different prokaryotic groups (Johnson et al., 2019). In a survey of 25 mostly shallow temperate lakes, Keshri et al. (2017) found that phage-mediated lysis could explain 33% of the variation in bacterial diversity in temperate lakes during summer (Fig. 7). However an earlier study found that bottom-up factors (nutrients and organic matter) controlled bacterial diversity more significantly than phages, ciliates and flagellates together (Berdjeb et al., 2011).

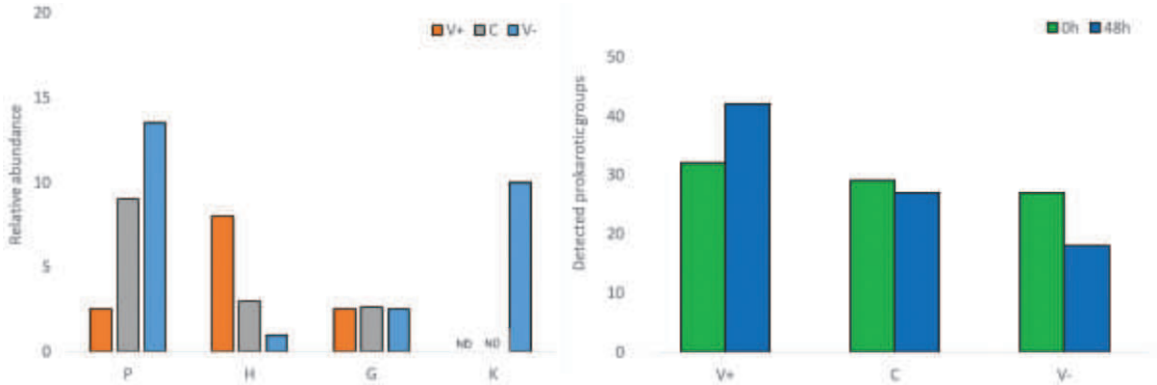

Fig. 6 (A) Schematic representation of prokaryotic groups (here arbitrary named 'P', 'H', 'G', 'K') which are differentially controlled by ambient lytic phages. P: strongly phage-controlled, abundance decreases at elevated concentrations of viruses (V+) and increases at lowered concentrations of viruses (V-); H: not phage-controlled but profits from viral predation on other groups; G: not impacted by phages; K: strongly phage-controlled, not detected (ND) in presence of ambient phages. Control (C, after Schwalbach MS, Hewson I and Fuhrman JA (2004) Viral effects on bacterial community composition in marine plankton microcosms. *Aquatic Microbial Ecology* **34**(2): 117–127. doi: https://doi.org/10.3354/ame034117; Bouvier T and Del Giorgio PA (2007) Key role of selective viral-induced mortality in determining marine bacterial community composition. *Environmental Microbiology* **9**(2): 287–297. doi: https://doi.org/10.1111/j.1462-2920.2006.01137.x). (B) Effects of the increase and decrease of the concentration of ambient viruses on the richness of prokaryotic communities after 0 h and 48 h (France, March 2013). V+: increase of the VLP-concentration to ~1.5 ×; V: control with 1 × VLP-concentration; V-: virus-reduced samples with ~0.15 × VLP-concentration. Control (C, after Meunier A and Jacquet S (2015) Do phages impact microbial dynamics, prokaryotic community structure and nutrient dynamics in Lake Bourget? *Biology Open* **4**(11): 1528–1537. doi: https://doi.org/10.1242/bio.013003).

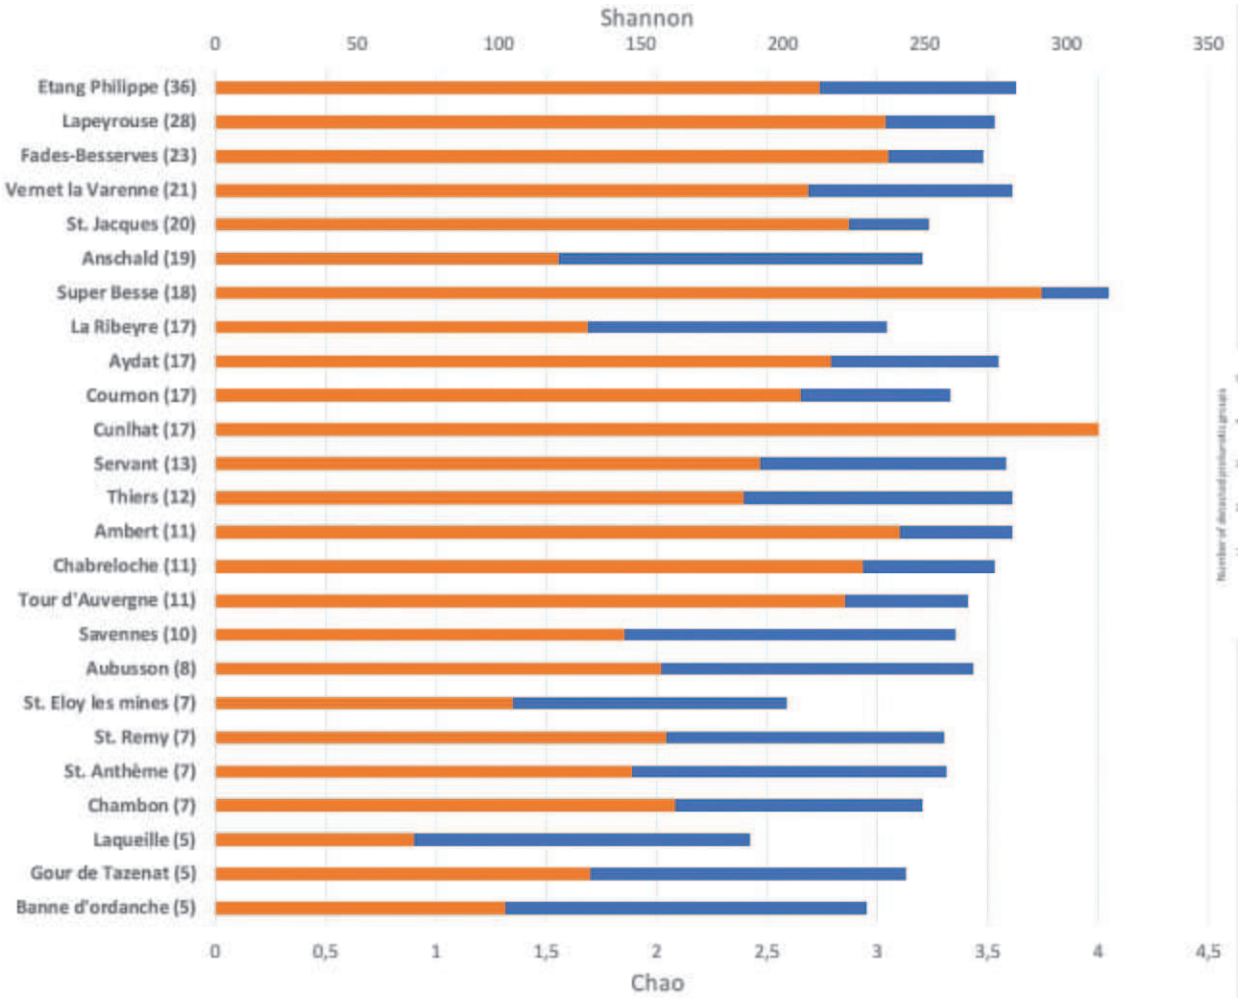

Fig. 7 Shannon- (diversity) and Chao1- (richness) values for prokaryotic communities in 25 temperate lakes as assessed by 16S rRNA (V3-V4) sequencing (July 2015). The frequency of infected cells (%) found in each lake is given in brackets next to the name of the lake. After Keshri J et al. (2017) Differential impact of lytic viruses on the taxonomical resolution of freshwater bacterioplankton community structure. *Water Research* **124**: 129–138. doi: 10.1016/j.watres.2017.07.053.

A model that integrates both phage-mediated top-down and nutrient-mediated bottom-up control is the Kill-the-Winner model (KtW; Thingstad and Lignell, 1997). KtW hypothesizes that the 'winner' in the competition for nutrients (i.e., the most abundant or most active hosts) are held in check by lytic phages through NDS. In addition, KtW emphasizes that prokaryotes have to economize between resource acquisition and investment into phage resistance which is tied to fitness trade-offs (Winter et al., 2010). These trade-offs on the other hand are thought to be a major mechanism contributing to prokaryotic diversity under changing environmental conditions. In order to assess these hypothetical explanations, a more detailed exploration of the impact of phages on prokaryotic communities in natural ecosystems is needed.

Phages as drivers of prokaryotic evolution and diversity

Prokaryotes and phages in natural ecosystems are extremely diverse. To simplify the investigation of the diversity of prokaryotic communities in the environment, operational taxonomic units (OTUs) commonly based on amplicon sequencing of a variable segment of the 16S rRNA are used. A single lake sample can host hundreds of prokaryotic OTUs (Keshri et al., 2017), each representing something in between a prokaryotic genus and a species (Johnson et al., 2019). Despite their extensive use OTUs stayed controversial in the assessment of prokaryotic diversity since extensive horizontal gene transfer (i.e., the transfer of genetic information among distinct cells) in prokaryotes (and phages) occurs even at lower taxonomic ranks (Cordero and Polz, 2014; Gregory et al., 2016). As an illustration, among >2000 strains of *E. coli* with an average genome size of 5000 genes, only around 3000 genes occur in all of them, whereas the additional genes contained in at least one *E. coli* strain cover almost 90,000 gene families (Booth et al., 2016). One prokaryotic species in any given environment disaggregates into numerous sequence-discrete populations consisting of individuals having an average nucleotide identity (ANI) of 94–100% within a single population and 80–85% between populations (Rodriguez-R and Konstantinidis, 2014). Since prokaryotes have genomes in the range of millions of base pairs, already single populations can contain a broad genetic diversity which is technically difficult to assess (Kashtan et al., 2014). Also, phages differentiate into discrete genotypic populations (Gregory et al., 2016). However, it is currently not known at which taxonomic host-rank individual phage genotypes preferentially operate in natural ecosystems. Although phages with a

broader host range have been described, most isolated phages infect hosts of the same strain or species. For these reasons the most comprehensive studies identifying phages as drivers of prokaryotic diversity are coevolutionary studies of isolated phage-host pairs in the laboratory (Koskella and Brockhurst, 2014). For example, co-cultivation of *Pseudomonas fluorescens SBW25* with the lytic phage phi2 increased the mutation rates in both partners, especially in genes relevant for phage-host interaction. This led to the rapid diversification of phage and host and constrained the acquisition of mutations beneficial for intraspecific competition (Scanlan et al., 2015). These findings reflect an arms race dynamic, i.e., the antagonistic coevolution of both partners consisting of adaptation of the host to the parasite (evolution of resistance) and counter-adaptation by the phage (restoration of infectivity). This arms race between *P. fluorescens SBW25* and phi2 decelerates after about 250 bacterial generations likely due to the increasing cumulative trade-off of resistance- respectively infectivity- mutations and gives way to sustained oscillations of individual bacterial- and phage populations which emerged from this arms race (Koskella and Brockhurst, 2014). This appears to be similar to the overall behavior of natural viral communities in the sunlit ocean (Ignacio-Espinoza et al., 2020). However, individual phage genotypes in lakes, especially those in the epilimnion, appear to be less stable than those in the open ocean which might support a different overall behavior of viral communities in lakes (Arkhipova et al., 2018; Kavagutti et al., 2019; Ignacio-Espinoza et al., 2020). While most studies and models focus on the activities of lytic bacteriophages, lysogenic (and chronically infecting) phages lack comparable experimental and theoretical frameworks. Lysogenic phages potentially have similar effects on prokaryotic communities and populations when reproducing lytically. However, the same effects might be mitigated e.g., through superinfection exclusion during the lysogenic phase (Knowles et al., 2016). How lysis-lysogeny decisions are controlled in natural ecosystems and if all lysogenic phages have a similar intrinsic tendency for the lytic respectively the lysogenic cycle remains little understood. Little is also known about the quantitative effect of phage-mediated horizontal gene transfer ('transduction') for the diversification of ambient prokaryotic populations. While numerous observations document the importance of phage-mediated horizontal gene transfer for evolutionary innovations in prokaryotes and eukaryotes (Shutt and Gray, 2006), its role in ecological processes needs further investigation.

Potential functioning of prophages in grazing-defense

Besides by lytic phages, prokaryotic mortality in lakes is often strongly controlled by protist grazers. In the case of lysogens, prophage and host share a common fate when ingested by a grazer. Under strong grazing pressure this might select for prophages conferring traits protecting their hosts against grazing. Support for this mechanism comes from two lines of evidence. First, experimental studies showing that prophage-encoded toxins kill grazers and increase the abundance of the respective lysogens (Arnold and Koudelka, 2014) and second, findings that substantiate the 'coincidental evolution hypothesis.' This hypothesis is based on the similarity of the cellular processes mediating phagocytosis in immune cells and in protist grazers and proposes that virulence factors (i.e., factors promoting the pathogenicity of bacteria) frequently evolved in bacteria in response to grazing pressure (Adiba et al., 2010). Support for this comes from the finding that various protist grazers select for virulence-related traits in waterborne pathogens like *Legionella* (Amaro et al., 2015) and from studies reporting a dual function of virulence factors in virulence as well as in grazing protection (Erken et al., 2013). Prophages are known to confer virulence factors e.g., during the pathogenesis of diphtheria, botulism and cholera and therefore can be assumed to play a role in this process. Besides prophage-encoded toxins this is supported by the widespread occurrence of prophage-encoded virulence factors in non-pathogenic environmental *Vibrio* (Castillo et al., 2018). Recently Kavagutti et al. (2019) proposed that the presence of genes implicated with the inactivation of reactive oxygen species (ROS) in 10% of phage genomes recovered from freshwater might stem from protective measures against grazers (Fig. 8). It remains to be tested how relevant the proposed role of prophages in the defense against protist grazers is in lakes and other aquatic ecosystems.

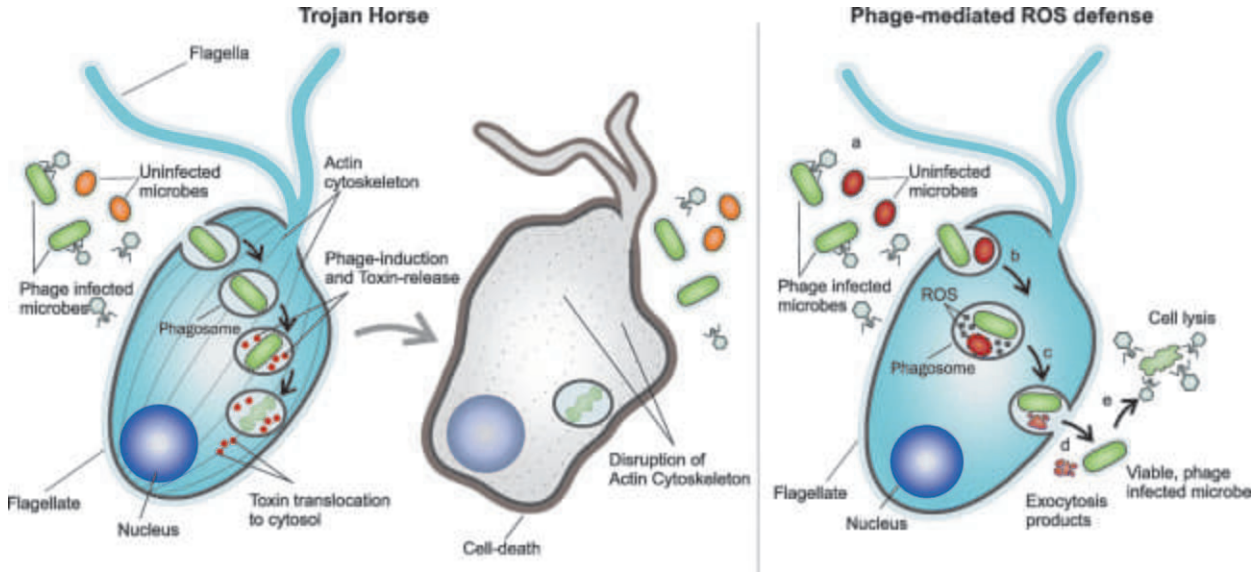

Fig. 8 Phage-mediated defense mechanisms against grazers. Left: 'Trojan horse' mechanism: A lysogen becomes ingested by a protist grazer. Digestion induces the production a phage-encoded toxin which disrupts the actin-cytoskeleton of eukaryotic cells. The toxin kills the grazer and thereby negatively selects against it. Right: A bacterium escapes the digestion by a grazer through a phage-encoded ROS-defusing mechanism. From Kavagutti VS et al. (2019) Phage-centric ecological interactions in aquatic ecosystems revealed through ultra-deep metagenomics. *Microbiome* **7**(1). doi: 10.1186/s40168-019-0752-0.

Knowledge gaps

- Roles of lysogenic phages in aquatic environments.
- Ecological factors directing lysis-lysogeny decisions.
- Archaeal phages in aquatic ecosystems.
- *Inoviridae* in aquatic ecosystems.
- Quantification of cyanophage-mediated inhibition of CO_2-fixation in lakes.

Case studies

Phage-mediated trophic cascade in east African Soda Lake

Site	*Country*	*Concept covered*	*Reference*
Lake Nakuru	Kenya	Phage-mediated trophic cascade	Peduzzi et al. (2014)

East African Soda Lakes (EASL) host large flocks of *Phoeniconaias minor* (Lesser Flamingos). These birds are considered Near Threatened by the International Union for Conservation of Nature and Natural Resources (IUCN) and conservation efforts have been hampered by a lack of understanding of their migration patterns. The preferred food source of *P. minor* is the filamentous cyanobacterium *Limnospira fusiformis* (formerly designated *Arthrospira fusiformis)* which can form extensive blooms in EASL (Schagerl, 2016). These blooms have been found to crash unpredictably due to previously unknown reasons. After ruling out other potential causes, Peduzzi et al. (2014) found that thus far uncharacterized phages caused a massive lysis of *L. fusiformis* in Lake Nakuru (Kenya). Among others, this has been assessed by the determination of the frequency of visibly infected *L. fusiformis* cells using TEM. Since phage particles become visible only during part of the infection cycle the actual number of infected cells can be assumed to be several times higher. During periods of steep declines in *L. fusiformis* biomass in lake Nakuru, up to 24% of *L. fusiformis* cells showed visible signs of infection indicating that the large majority of *L. fusiformis* cells had been infected at that time. These bloom crashes coincided with the migration of *P. minor* flocks from the affected lake and might be an important factor directing their migration behavior. Although *L. fusiformis* phages require further characterization, this study demonstrates that phages can trigger trophic cascades affecting even top consumers within lake ecosystems. It also links phage ecology to the waxing and waning of cyanobacterial blooms which impose serious risks to human health and drinking water quality in lakes worldwide.

Role of phages in cholera epidemics in Dhaka

Site	*Country*	*Concepts covered*	*References*
Dhaka	Bangladesh	Lysogenic conversion Lytic control of bacterial populations	Faruque et al. (2005a, 2005b)

Cholera still ravages in developing countries and according to WHO-numbers leads to 21,000 to 143,000 deaths per year. The transmission of the disease has been linked with the ingestion of water containing the aquatic bacterium *Vibrio cholerae* by Robert Koch as early as 1884. Today it is known that the occurrence of cholera epidemics coincides with the increased prevalence of often antibiotic resistant *V. cholerae* strains belonging to the O1 and 0139 serotypes in surface waters. A hallmark of these strains is that they have been infected by the lysogenic CTX-phage (*Inoviridae* family) which encodes the cholera toxin. Faruque et al. (2005a) revealed that during the seasonal cholera epidemic in Dhaka (Bangladesh) over a 3-year period, the incidence of *V. cholerae* O1 and 0139 in surrounding surface waters was negatively correlated with the incidence of phages lytic to these serotypes. This was further detailed in a follow-up paper (Faruque et al., 2005b) in which the abundance of one of those lytic phages (JSF4/ICP1, Seed et al., 2011) in surface waters and patient stools was found to be negatively correlated with the number of cholera patients in the 2004-epidemic. This was true for both the onset of the epidemic as well as its decline. The important role of JSF4/ICP1 and related phages was later substantiated by the genetic and molecular characterization of *V. cholerae* phages in the same region over a 10-year period (Seed et al., 2011) as well as experiments in which these phages were tested as potential therapeutic agent against cholera (Yen et al., 2017). This example illustrates that lytic phages as well as lysogenic phages play an important role in cholera epidemics and likely also for other waterborne pathogens (Feichtmayer et al., 2017). What remains to be answered is how exactly these phages interact with *V. cholerae* within aquatic environments and how this integrates with the known interplay of *V. cholerae* with other biota.

Conclusion

This chapter set out to outline general principles governing phage-host interactions. These should provide a comprehensible and well-founded basis for the understanding of potential consequences of phage infections in lake ecosystems. However, since the body of literature on phages is extensive this can only cover some aspects in phage ecology. Care was taken to choose topics which are of both ecological relevance and due to the close connection of lakes with human activities of relevance to human health.

Diversity and Dynamics of Bacterial Communities in Freshwater Lakes

Stefan Bertilsson and Maliheh Mehrshad, Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

16S rRNA amplicon sequencing Denotes a method to describe the taxonomic composition of bacterial and archaeal communities. A diagnostic region of the 16S rRNA gene is PCR amplified from an environmental DNA sample for high throughput sequencing and subsequent annotation by comparing with previously classified 16S rRNA sequences.

Anaplerotic reaction Anaplerotic reactions are reactions that replenish intermediate compounds of a metabolic pathway in the cell.

Auxotrophy Auxotrophy is an obligate metabolic dependency typically linked to genome streamlining. Auxotrophic bacteria require exogenous source of essential biomolecules that must be provided by other members of the community who are capable of producing this biomolecule (prototroph).

Axenic cultures In microbiology, axenic culture refers to a culture that contains only a single population of microbes with no other contaminating organisms present.

Catalyzed reporter deposition-Fluorescence in situ Hybridization (CARD-FISH) CARD-FISH is an improved and more sensitive version of the Fluorescence in situ Hybridization (FISH) method that use horseradish peroxidase signal amplification. It enables detection of small, slow growing, or starving bacteria in oligotrophic environments (such as lakewater).
Copiotroph Copiotrophy is a physiological trait. Copiotrophs respond to abrupt availability of resources by rapidly assimilating them for growth.
Genomic island A genomic island is a part of genome that has evidence of horizontal transfer between different lineages. Genes present in genomic islands often provide the microbe with adaptive advantages.
Metagenomics Metagenomics refer to direct (non-selective) sequencing of DNA extracted from environmental samples. Bioinformatic analyzes of metagenomes can also enable genome reconstruction. This can provide insights about diversity and metabolism of microbial groups in the environment.
Oligotrophic microbes Oligotrophy is a physiological trait. Oligotrophs are characterized by their competitive ability in low nutrient environments and typically exhibit slow growth.
Single cell amplified genomes Genomic information obtained from single cells. Cells from complex samples are first partitioned, then lysed and subjected to whole genome amplification before sequencing and bioinformatic processing.
Streamlining theory This theory suggests that minimizing the cell size and genome complexity benefit Bacteria and Archaea specifically in low-nutrient environments. From a genomic perspective streamlining leads to smaller genome sizes with less non-coding DNA and few non-essential genes.

Introduction

Invisible to the naked eye, our freshwaters are teeming with bacterial life. Each drop of lakewater typically hosts a staggering million bacterial cells that engage in elemental cycles by assimilating, transforming, or degrading biomolecules and other bioactive elements. While their combined biomass might not be immediately impressive, their large surface area interfacing with the surrounding water, fast reproduction and functional diversity makes bacteria the true ecosystem engineers of our inland waters, analogous to the situation in most other biomes and ecosystems. As such they deserve our respect and attention. So, what have we learned about the identity and function of these invisibles since they were first seen by van Leeuwenhoek in the late 1600s?

In this chapter we first outline the history of freshwater microbiome studies and the role of methodological advances in shaping our understanding of lake bacteria. Then we review in more detail the charismatic lake bacteria and their genomic characteristics and microdiversity. We move on to the role of "metabolic landscapes" and discuss the role of bottom-up controls on the diversity and dynamics of lake bacteria. In this section we also highlight the role of lake bacteria in biogeochemical cycles. We also review the role of food web interactions in shaping communities characterized by metabolic dependencies and top-down controls and the consequences for their ecology and evolution. In the next section we discuss bacterioplankton dynamics in the context of both spatial heterogeneity, temporal change and biogeography and touch upon how different lake types affect bacterial diversity and dynamic. Finally, we present an overview and suggest an outlook on the future direction of lake bacterioplankton research.

The freshwater microbiome as we know it

There have been several technological milestones in the field of microbiology, but arguably the advances that enabled us to isolate and culture clonal populations of microorganisms on defined media was a seminal step towards a better understanding of microbial diversity and function. This capability also had a strong impact on how freshwater bacteria were perceived, with most early studies focusing on the culturable, most often copiotrophic representatives which could be brought into isolation for enumeration and characterization. This led to many groundbreaking discoveries with regards to drinking water quality and microbial physiology, but at the same time created a narrative where bacteria were marginalized and mainly seen as indicators of poor water quality with little influence on ecosystems and biogeochemical processes.

In reaching the next few technological milestones, where an array of cultivation-independent methods was being put to use for describing and studying lake microorganisms, it became clear that the scientific community had grossly underestimated both the significance and diversity of freshwater microorganisms. Direct staining and microscopic enumeration of bacterial cells gave at hand that cultivation approaches underestimate the bacterial abundances by several orders of magnitude, leading up to Staley and Konopka (1985) coining the expression "the great plate count anomaly." In the following years, the growing use of cultivation independent methods based on RNA and DNA characterization have revealed that conventional cultivation techniques typically only scratch the surface in terms of uncovering the microbial diversity of natural ecosystems and this also applies to lakes (Newton et al., 2011; Buck et al., 2021). Nevertheless, as we will describe in this chapter, significant advances have been made in this regard and cultivation-based microbiology is gradually catching up, with more and more charismatic groups of lake bacteria isolated and maintained in pure culture or stable co-culture with other organisms, changing the playfield for learning about the intricate nature of their metabolism and other traits central for their biology and functioning in the ecosystem.

A turning point for the field was no doubt the invention of PCR in the mid-1980s and subsequent use of this method to broadly amplify, clone and Sanger sequence taxonomic markers such as the 16S rRNA gene from mixed communities, an approach developed and successfully promoted by Norman Pace and colleagues. Beyond characterizing communities by sequencing such marker genes, the typically high number of rRNA molecules in individual cells also enable coupled visualization and quantification of taxonomically defined groups of organisms with fluorescence in situ hybridization (FISH). By hybridizing specific oligonucleotide probes carrying different fluorescent markers to perfectly matching rRNA targets, the spatial organization of uncultured populations could now be visualized and studied (Glöckner et al., 2000). Following these methodological milestones, a wealth of studies has described the composition of local or regional microbial communities across a broad range of ecosystems. With the accumulation of data there have also been synoptic and global community inventories for different biomes and groups of organisms, including lake bacterioplankton (Glöckner et al., 2000; Zwart et al., 2002; Newton et al., 2011). For lake studies specifically, these all point to a globally dispersed and largely shared freshwater microbiome distinct from that of adjacent terrestrial and marine ecosystems.

We are now experiencing yet another methodological revolution. The development and application of more powerful high throughput sequencing methods beyond the Sanger method have for the past 10 years flooded the scientific literature with amplicon-based microbial community data collected across both spatial and temporal scales (e.g., Peura et al., 2012; Linz et al., 2017; Ruiz-Gonzalez et al., 2017). The sequencing capacity and associated bioinformatic tools have now even developed to the point where PCR is becoming redundant and where microbial communities in larger sets of samples can be broadly described by direct shotgun metagenome sequencing at the community level (Eiler et al., 2014; Peura et al., 2015) or at the level of individual metagenome assembled genomes (He et al., 2017; Garcia et al., 2018; Mehrshad et al., 2018; Linz et al., 2018) or for individual microbial cells (Ghylin et al., 2014; Eiler et al., 2016). This paves the way for more quantitative and complete assessments of microbial communities without PCR bias and can also be combined with parallel analyzes of metatranscriptomes to assess what potential functions are being expressed under given experimental or natural conditions (Linz et al., 2020). These are exciting times to be a microbial ecologist and we can only guess what the future may bring in terms of new approaches and groundbreaking insights. One exciting prospect is to integrate microbial communities and their intricate metabolic processes in ecosystem-scale and global biogeochemical models. Some first steps have been taken in this direction (Arora-Williams et al., 2018) with exciting prospects for a new level of ecosystem understanding that look beyond the black box of microbes.

Key groups and charismatic lake bacteria

Freshwater lakes across the globe might present some differences in bacterial community composition. However, certain bacterial lineages seem to have ubiquitously occupied niches across almost all freshwater lakes. These charismatic bacterial lineages account for the majority of the freshwater bacterial census. While their quantitative contribution, prevalence and distribution patterns in lakes have been demonstrated with FISH analyses and/or 16S rRNA data as illustrated in Fig. 1, our first glimpses of their metabolic potential and genomic structure have primarily been enabled by analyzing the reconstructed genomes of cultures and more recently also single cell amplified genomes (SAGs) and/or metagenome assembled genomes (MAGs) of their representatives (Fig. 2). These metabolic insights have helped us understand their evolution, ecology and multifaceted biogeochemical roles in the ecosystem. This knowledge has also guided refined cultivation that have recently brought many of these fastidious microbes into culture, enabling more detailed studies of their physiology. In the following section we briefly summarize the state of our knowledge for representatives of some of the most abundant and charismatic freshwater bacteria. Needless to say, this inventory will not be exhaustive, but should give an overview of the functional, genomic and ecological traits in some of the abundant bacterioplankton groups retrieved in pelagic communities.

Cyanobacteria

Cyanobacteria which are quite often grouped and studied together with eukaryotic phytoplankton, are the main bacterial phototrophic primary producers in the photic layer of lakes. Important from an ecosystem perspective, freshwater Cyanobacteria that are capable of fixing nitrogen have the capacity to shape the elemental stoichiometry of the ecosystem towards the Redfield ratio (C:N:P 106:16:1) defined by the average elemental composition of living cells. Under favorable conditions (sufficient nutrient supply, stagnant/stratified waters creating niches with high light availability), many Cyanobacteria can grow excessively and produce toxic secondary metabolites leading to formation of harmful blooms. With the increasing rate of lake eutrophication due to anthropogenic pressures and climate change, cyanobacterial blooms are becoming more common particularly in lakes that are situated in populated or intensively farmed areas. Cyanobacteria with toxin producing capacity and bloom-forming potential such as *Microcystis* or filamentous *Cylindrospermopsis*, *Anabaena* and *Planktothrix* can in this way decrease the quality of water and limit the lake's services as a drinking water resource as well as its recreational value. However, not all cyanobacterial lineages have this concerning lifestyle. Many of the unicellular representatives such as the broad range of representatives from e.g., *Synechococcus* persist in the background and can still be major contributors to primary production in the lake ecosystem (Callieri, 2008). Also, within *Microcystis* and other known bloom-forming genera there seems to be high functional diversity among strains where only some strains have the capacity to form harmful secondary metabolites (e.g., microcystin) and where variable genomic traits for nutrient acquisition and dealing with oxidative stress creates phenotypic diversity (Dick et al., 2021).

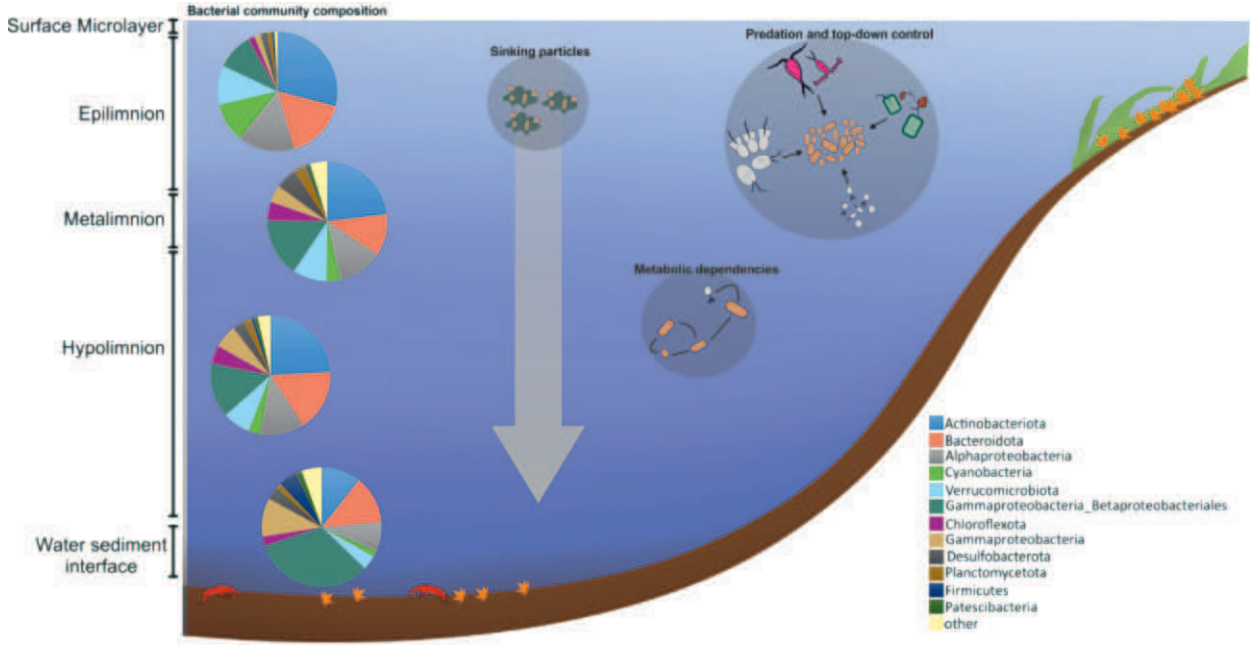

Fig. 1 Schematic illustration of a stratified lake with the composition of the bacterial community shown as pie charts in different water layers (Epilimnion, metalimnion, hypolimnion, and sediment/water interface). Bacterial community composition represented as pie charts along the depth profile is based on 16S rRNA reads extracted from metagenomic datasets of lake Erken with methods as described in (Mehrshad et al., 2018). Metagenomes are retrieved from (Buck et al., 2021).

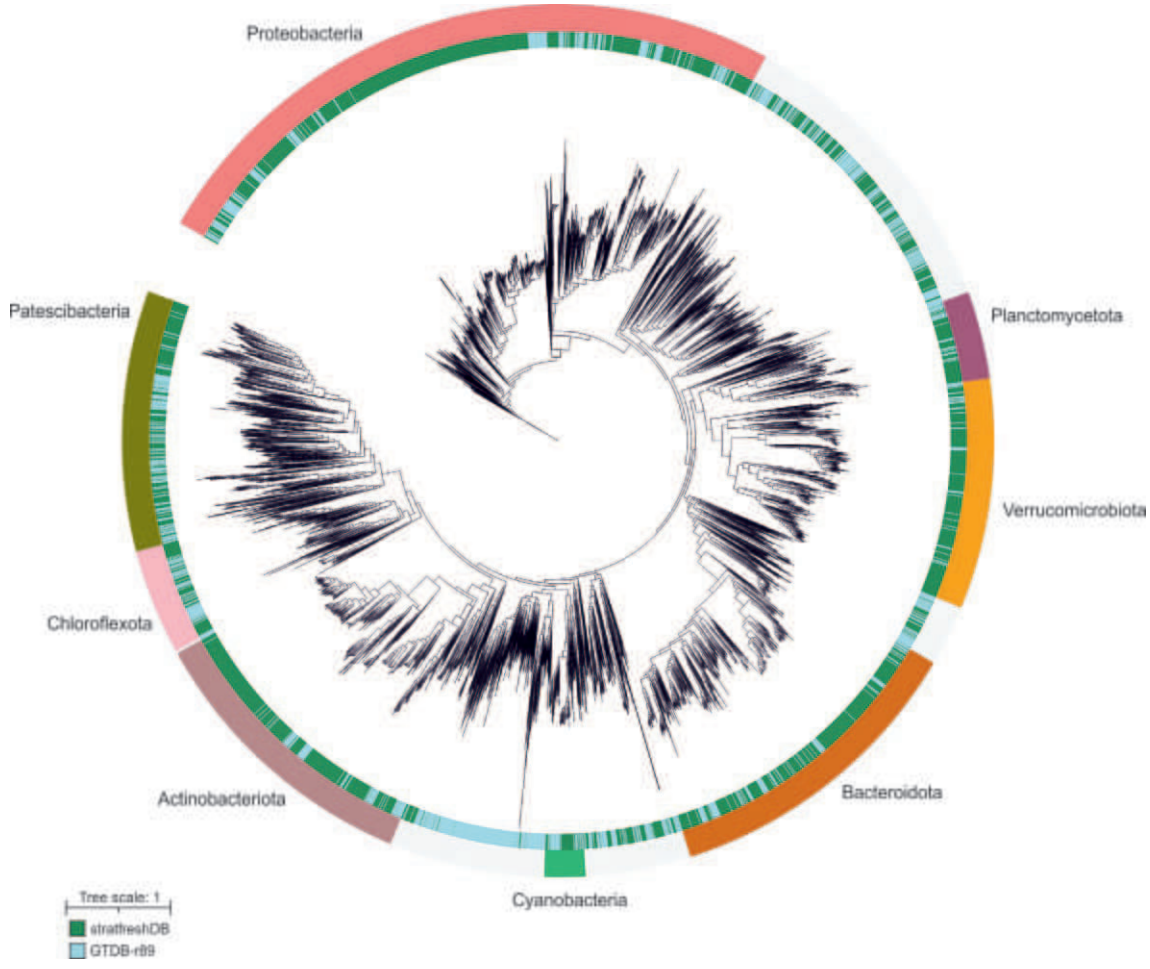

Fig. 2 Phylogenetic diversity of microbial genomes reconstructed via a comprehensive metagenomic study of freshwater lakes including 267 shotgun metagenomes from 41 stratified lakes and ponds (This dataset is called stratfreshDB). The inner circle shows the origin of genomes either from stratfreshDB or the genome taxonomy database (GTDB, https://gtdb.ecogenomic.org/) release 89. GTDB release 89 is a comprehensive database comprising of isolate genomes, metagenome-assembled genomes (MAGs), and single-amplified genomes (SAGs) (statistics of release 89 database can be found at https://gtdb.ecogenomic.org/stats/r89). GTDB offers a phylogenetically consistent and genome-based taxonomy for these genomes we have used this taxonomy throughout the text. The outer circle highlights the taxonomy of charismatic microbial phyla discussed in this chapter. Modified from Buck M, Garcia SL, Fernandez L, Martin G, Martinez-Rodriguez GA, Saarenheimo J, Zopfi J, Bertilsson S and Peura S (2021) Comprehensive dataset of shotgun metagenomes from oxygen stratified freshwater lakes and ponds. *Scientific Data* 8: 1–10. doi: 10.1038/s41597-021-00910-1.

Actinobacteriota

Actinobacteriota comprise the majority of the bacterial community in most lakes where lineage acI of Actinobacteriota are the most abundant freshwater bacteria. Members of this diverse lineage (Fig. 2) have streamlined genomes with low guanine + cytosine content in the DNA (G + C%) and small genome sizes ranging from 1.2 to 1.4 megabases (Mbp). Metabolic capabilities of the acI bacteria inferred from genomes generated from dilution to extinction cultures and single cell genomes confirm that these cells are oligotrophic chemoheterotrophs with diverse metabolic dependencies (Garcia et al., 2015; Ghylin et al., 2014). These metabolic dependencies with surrounding microbes are hindering the isolation and cultivation process of acI representatives. Looking a bit closer at this phenomenon, genome reduction or streamlining in the acI bacteria had led to auxotrophy for some amino acids and vitamins, as well as reduced sulfur compounds. Phylogenomic studies of 16 closed genomes sequenced from transiently axenic cultures further shows that they belong to nine novel species in two novel genera named "*Candidatus* Nanopelagicus" and "*Candidatus* Planktophila" (Neuenschwander et al., 2018). Comparative analyzes of these genomes suggest a high level of diversity in the genomic content, specifically in relation to carbohydrate metabolism and transport. Many genes related to these functions are encoded in genomic islands that show considerable abundances in the environmental metagenomes. This suggests high levels of microdiversity among representatives of the acI lineage. Further studies on this lineage, showed that the way to achieve sustainable cultures of acI Actinobacteriota was to add catalase to the culture media (Kim et al., 2019), with the stimulatory effect later attributed to heme supplementation (Kim et al., 2021). These cultures suggest distinct but variable preferences for reduced sulfur compounds and carbohydrates in different acI isolates. Recent progress in obtaining sustainable cultures for representatives of this lineage is now paving the way for studies that will provide a better understanding of their physiology, adaptations, and ecological role.

Apart from acI, other relatively abundant Actinobacteriota lineages in freshwater lakes include acIV and acIII. Compared to acI, the acIV lineage represents a wider biome distribution, with representatives being present in freshwaters but also in marine sediments, and soil (Newton et al., 2011; Warnecke et al., 2004). Several metagenomic-assembled genomes have been reconstructed for representative lineages within the order Acidimicrobiales that includes acIV, and 3 novel species of the genus *Ilumatobacter* from this lineage have also been isolated and taxonomically described (Ghai et al., 2014; Hugerth et al., 2015; Mehrshad et al., 2016). However, a thorough study of this specific lineage and characteristic metabolic and ecological capabilities in freshwater ecosystems is still missing. As for the acIII lineage, it belongs to order Actinomycetales and shows a notable abundance in hypersaline soda lakes and estuaries (Newton et al., 2011; Warnecke et al., 2004).

Proteobacteria

Fonsibacter

Freshwater lakes are ubiquitously dominated by subclades of SAR11 Alphaproteobacteria, a group known to be the most abundant bacterial lineage in oceanic waters. While most freshwater representatives of SAR11 belong to subclade IIIb which is more widely known as LD12, a recent study on metagenomes of Lake Baikal report a freshwater representative genome that phylogenetically forms a sister clade to subcluster I. Phylogenomic analysis suggests that LD12 bacteria have evolved from their streamlined marine counterparts and similarly have reduced genomes which are among the smallest reported for free-living bacteria (1.1–1.4 Mbp) and low G+C content (29–32%) (Eiler et al., 2016) They are adapted to freshwater oligotrophic habitats and represent an aerobic chemo-organoheterotrophic lifestyle and similar to the Actinobacteriota acI they feature auxotrophies for some amino acids and vitamins (Salcher et al., 2011). Existing genomes and a recently obtained isolate (Henson et al., 2018), suggest that they depend on reduced organosulfur compounds and ammonium as sulfur and nitrogen sources, respectively. *Fonsibacter ubiquis* LSUCC0530T is the sole cultured LD12 representative and initial physiological tests suggests that cells can double roughly every 2 days (average growth rate of 0.52 day^{-1}) with optimum growth at around 1.45 PSU salinity while they show growth up to 8 PSU.

"*Ca.* Methylopumilus"

Methylotrophs capable of using reduced one-carbon compounds such as methanol and methylamine are among the abundant freshwater bacteria. One of these prevalent freshwater methylotrophs is "*Ca*. Methylopumilus" (Salcher et al., 2019). The C1 compounds that they feed on are supposedly to a large extent produced by phytoplankton primary producers, forming the basis for strong ecological associations. Accordingly, the temporal abundance patterns of "*Ca*. Methylopumilus" are synchronous with diatom and/or cyanobacterial blooms. Representatives of this genus seem to be psychrophilic and reach their maximum abundance (ca. 4% of total prokaryotes) after such phytoplankton blooms where they thrive on released exudates (Salcher et al., 2015). Three species within "*Ca*. Methylopumilus" genus could be identified based on genome analyses of 39 isolates. Genomes from representatives of this genus seem to have small size (1.26–1.36 Mbp), low G+C content (36.7–37.4%) and streamlining attributes.

Polynucleobacter

Genus *Polynucleobacter* was first recognized and studied as a type species with obligate endosymbiotic lifestyle. This representative (*Polynucleobacter necessarius*) thrives in the cytoplasm of the ciliate species *Euplotes aediculatus*, but pelagic and free living *Polynucleobacter* representatives were also later reported to be prevalent in lake ecosystems. Pelagic *Polynucleobacter* seem to be inhabiting a wide range of niches but also feature strong seasonal dynamics in abundance and diversity patterns and also vary spatially across e.g., depth. Environmental factors such as pH, conductivity and productivity are known to impact the prevalence of different

Polynucleobacter subclusters A, B and C (Nuy et al., 2020). *Polynucleobacter* members have relatively small genome sizes (1.5–2.5 Mbp) with intermediate G+C content (40–50 mol%). Most members of this genus are organoheterotrophs whereas some contain genes for aerobic anoxygenic phototrophy and carry rhodopsins (a light-sensitive receptor protein) that may confer phototrophic potential (Hoetzinger et al., 2017).

Limnohabitans

Genus *Limnohabitans* is ubiquitous freshwater Proteobacteria and was first taxonomically classified in 2010 with *Limnohabitans curvus* as the type species. (CARD)-FISH, 16S rRNA amplicon, and metagenomic analyzes have shown ubiquitous presence of the morphologically diverse *Limnohabitans* members also known as the "R-BT cluster" in nearly all freshwater lakes worldwide, where they represent on average 12% of freshwater bacterioplankton communities (Kasalický et al., 2013; Props and Denef, 2020). Despite their fastidious nature, cultivation efforts have succeeded to bring representatives from 4 out of 5 existing *Limnohabitans* lineages (Lim A-E) into culture (more than 50 isolates). Their high cellular productivity combined with relatively larger mean cell volume compared to other prevalent epilimnetic ultramicrobacteria (i.e., microbes with cell volume $<0.1\ \mu m^3$) and susceptibility to protist predation makes *Limnohabitans* an important link in the flow of carbon to higher trophic levels in freshwater lakes. *Limnohabitans* is primarily heterotrophic bacteria that encode traits for versatile metabolic capabilities that also include the genetic elements for aerobic anoxygenic phototrophy metabolism (pufLM and bchY). They typically have large genomes (3.3–4.8 Mbp) with G+C content ranging from 56% to 60% (Kasalický et al., 2018), (though more recent genomes show a wider range for genome size and G+C content).

Chloroflexota

Chloroflexota has historically been represented by lineages capable of aerobic anoxygenic phototrophy (belonging to class Chloroflexia) in shallow freshwaters. In 2001, a 16S rRNA gene cloning-sequencing study of deeper strata (500 m) in Crater Lake (United States) reported on a novel lineage of Chloroflexota named CL500-11, that dominated the hypolimnetic bacterial community (Urbach et al., 2001). Later, studies based on 16S rRNA and (CARD)-FISH showed the ubiquitous abundance of this lineage in oxygenated hypolimnia of deep lakes, accounting for up to 26% of the total prokaryotic community. Cell volume calculations show that they are among the largest prokaryotic cells in the water column (median cell volume $0.06\ \mu m^3$). Their large population size and cell volume emphasize the large contribution of CL500-11 to the lake's bacterial biomass. The first CL500-11 MAG was reconstructed from metagenomes of the ultraoligotrophic Lake Michigan, and functional annotations suggested that CL500-11 representatives have the metabolic capability for oxidation of C1 compounds and mineralization of proteinaceous compounds and other nitrogen-rich dissolved organic matter (Denef et al., 2016). Further metagenomic analysis of the lake water column revealed a bigger phylogenetic diversity of Chloroflexota in freshwater compared to marine ecosystems (Mehrshad et al., 2018). Other freshwater Chloroflexota lineages include lineages SL56, TK10, JG30-KF-CM66, and Chloroflexia.

Planctomycetota

Planctomycetota have been recognized for their unique cell structure that is comparable yet distinct to other Gram-negative bacteria. They show variable abundances in different ecosystems ranging from <1% to 20% of the community. The known Freshwater Planctomycetota are chemoorganotrophs belonging to classes Phycisphaerae (clade CL500-3) and Planctomycetes. Inspecting the genomic potential of metagenome assembled genomes affiliated to freshwater Planctomycetota show that they contain a variety of carbohydrate-active enzymes that suggests high glycolytic potential. Additionally, some Phycisphaerae MAGs seem to encode for a cellulosome-like machinery that is hypothesized to be involved in polypeptide degradation. CARD-FISH analysis suggests that freshwater planctomycetota could be associated with sedimenting organic particles along the lake's water column (Andrei et al., 2019).

Verrucomicrobiota

While not among the most abundant bacterial phyla, Verrucomicrobiota are present in almost all freshwater lakes and contribute from 1% to 6% of the total community. For some humic lakes, higher abundances have been reported with Verrucomicrobiota contributing up to 20% of the total community. Freshwater representatives are suggested to participate in carbon cycling by degradation of glycolate and (poly)saccharides and this has also been confirmed by functional annotation of metagenome assembled genomes where functional tuning of populations to the local organic substrate pool (allochthonous vs. autochthonous) was also hypothesized (He et al., 2017). Higher nutrient availability, labile dissolved organic carbon, cyanobacterial blooms, low pH, higher temperature, and longer retention time are shown to favor the abundance of freshwater Verrucomicrobiota representatives in lakes. Estimated genome size seems to vary extensively from ca. 2 to >7 Mbp and the same applies to G+C content which range from 42% to 68% (He et al., 2017).

Patescibacteria

Ultramicrobacteria that can pass the 0.2 μm membrane filters typically used to collect bacteria from water samples, can comprise a notable proportion of the lake's microbiome. Within this operationally defined group, members of the Candidate Phyla Radiation (CPR) also referred to as Patescibacteria with representatives in the Parcubacteria (previously known as candidate division OD1) and Microgenomates (previously known as candidate division OP11), are abundantly present in hypolimnetic waters and are also found at the water-sediment interface of lakes (e.g., Peura et al., 2012). The diverse reconstructed MAGs of Patescibacteria from different freshwater ecosystems (Fig. 2) have features that imply a symbiotic lifestyle and they generally have small genome sizes and a reduced genomic repertoire that in most groups is lacking the capacity to synthesize amino acids, nucleotides, and lipids while having the capacity for fermentation. The ecological role of these microbes in lakes and their symbiotic interactions with potential hosts in freshwater ecosystems is still a hot topic that needs further study.

The enigmatic freshwater Bacteroidota

The final group that we will highlight here is certainly abundant and diverse in freshwaters (Fig. 2), but also functionally elusive, dynamic and devoid of charismatic representatives with known genomic features. While this phylum is both diverse and abundant in lakes (often >10% of 16S rRNA reads), remarkably little details are available about their ecology and biogeochemical function in the system beyond a consistent organotroph metabolism with more patchy phototrophic potential (Newton et al., 2011). The phylum seems to be overrepresented on particles and occur in high abundances associated with phytoplankton blooms where they also feature high growth and turnover (Neuenschwander et al., 2015; Newton et al., 2011). With the recent availability of a large number of Metagenome assembled genomes from freshwater Bacteroidota representatives (Buck et al., 2021), the time is now ripe for a more systematic treatise on their ecological and metabolic niches.

Microdiversity and pangenomes

Lakes are dynamic and heterogeneous ecosystems. Over time and between locations they receive variable inputs of allochthonous and autochthonous dissolved organic carbon. Most lake, at least within the temperate and boreal zone undergo seasonal stratification and complete or partial mixing across their annual cycle while as a result of this featuring dynamic niches linked to chemical and physical gradients. This spatial and temporal heterogeneity can foster microdiversification of microbial populations and lead to spatiotemporal distribution patterns for different "ecotypes" of the same or closely related species. Importantly, such microdiversification enable coexistence of closely related populations that differ in one or more eco-evolutionary traits. Such sympatric coexistence of ecotypes can confer advantages for the survival of the microbial lineage as a whole over a broader range of environmental conditions as compared to a homogeneous population and also influence their competitive ability and susceptibility to predation.

Recent studies have demonstrated that environmental factors such as temperature, oxygen concentration and redox, pH, light preference, and nutrients can cause population microdiversification and structure the distribution pattern of ecotypes (García-García et al., 2019; Hoetzinger et al., 2017; Neuenschwander et al., 2018; Props and Denef, 2020). Microdiversification has been reported for several charismatic and ubiquitous freshwater bacteria such as actinobacteriota acI, *Polynucleobacter*, and *Limnohabitans*. The growing microdiversity uncovered for these lineages is also manifested as a steady increase in the known intra-specific gene pool also defined as the pangenome. Such pangenomes represent an expanded and flexible genetic toolbox of the respective lineage.

One pertinent example is the Actinobacteriota acI which shows a high level of genomic microdiversification. Different populations encode variable genes for cross-membrane transport and carbohydrate metabolism-related genes, genomic traits which are mainly found on genomic islands prone to horizontal gene transfer. Genomic islands containing cell wall biosynthesis and modification genes as well as pili assembly genes are detected in closely related genomes of the acI lineage. These functions could be involved in defense against phage infection by modifying glycotypes in the cell surface (Neuenschwander et al., 2018). As an additional example, *Limnohabitans* genomes recovered from a lake Michigan transect showed that temperature and nutrient levels are important factors structuring microdiversity within the genus *Limnohabitans* (Props and Denef, 2020). *Polynucleobacter* genomes also contain various genes involved in nutrient assimilation and cell surface modification on the genomic islands (Hoetzinger et al., 2017). These functions are expected to bring competitive ecological advantages to the ecotypes that harbor them.

The metabolic landscape and competition for resources

Cellular stoichiometry and nutritional needs

Regardless of taxonomic affiliation, bacterial cells have certain biomolecular features in common that constrain their macromolecular composition and cellular elemental ratios. All cells have carbon as a major element and with a major contribution from amino acids and other nitrogen-rich biopolymers alongside phosphorus-rich nucleic acids and membrane lipids. It therefore comes as no surprise that these three macronutrients, either alone or in combination, often limit bacterial growth and that the success in competitively scavenging the environment for nutrients will have a strong influence on dynamics, composition and biogeochemical

function of bacterial communities in lakes (Muscarella et al., 2019; Pernthaler, 2017; Salcher et al. 2013). Accordingly, bacterial populations feature various high and low affinity transporters to import compounds that consist of such elements into the cell and/or enzymes to condition more complex nutrient-containing macromolecules in order to render them more readily assimilable or mineralize them all the way to inorganic forms that can then feed biosynthetic processes (Hamilton et al., 2017). Such traits are not evenly distributed across microbial taxa, but lineages specializing in nutrient scavenging in high-and low-substrate environments can be found, while others host efficient hydrolytic or combustive enzymes that enable them to specialize in recycling nutrients bound in detrital biomass and other types of complex organic matter.

Exploiting inorganic nutrients

There are also alternative strategies to satisfy the need for nutrients and diazotrophy (a.k.a nitrogen fixation) is one such special adaptation where cyanobacteria along with representatives from a number of other bacterial linages (and also some archaea) can reduce the abundantly available atmospheric nitrogen gas to ammonia in an energetically expensive reaction catalyzed by nitrogenases, with the potential to relieve not only the diazotroph population but by extension entire microbial food webs from nitrogen limitation (Fernandez et al., 2020). For bacterial carbon demand there are similar mechanisms where autotrophic or anaplerotic fixation of inorganic carbon can release bacterial populations or communities from being critically depending on availability of organic substrates for their nutritional demands (Peura et al., 2015). For phosphorus there is no such untapped nutrient source and beyond recycling of biomass, the processes controlling phosphorus availability in lakes relate mostly to catchment processes (including anthropogenic processes) and internal phosphorus loading from the large nutrient pools stored in sediments. Under certain circumstances (ultraoligotrophic lakes), also other elements, such as iron, may act as limiting nutrients for bacterioplankton growth, but normally most other elements for assembling bacterial cells are available in excess.

Competing for energy in organic matter

Beyond the nutritional needs to acquire essential elements, microbial growth relies on access to energy that can be used to drive molecular conversion and assembly in the cell. There is often fierce competition between microbial populations and diverse metabolic groups of organisms for such energy sources. In this context, reduced organic matter holds a pivotal role as an abundant source of chemically bound energy that can fuel fermentative and respiratory metabolic processes. The term "heterotrophic bacteria" or "organotrophs" is sometimes collectively used for the bacteria that rely on such substrates to fuel oxidative catabolic metabolism, but it is important to understand that these do not represent an ecologically or functionally coherent group (Salcher et al., 2013). Many different traits and functions have evolved that enable bacteria to exploit and use nearly every imaginable organic substrate found in nature, but for many organic substrates the occurrence of such genome-encoded traits are patchy across the bacterial domain and this forms the basis for the competitive ability of populations (Muscarella et al., 2019; Pernthaler, 2017). To complicate things further, the catabolic use of organic substrates for cellular energy mobilization is coupled to either fermentative or respiratory processes where different terminal electron acceptors are used to recover the chemically bound energy in a form that can be used to fuel cellular processes. The repertoire of such available electron acceptors has given rise to classification of organotroph populations as being either aerobes/oxytrophs, denitrifiers, sulfate reducers, iron reducers, etc. Such information carries ecological meaning, both in a sense that the metabolic mode exerts strong influence on where and when the bacterial population can grow and persist, but also with regards to how they influence the biosphere via their metabolic processes that generate products such as nitrogen gas, nitrous oxide and not least sulfide and ferrous iron with major implications for phosphorus speciation.

Alternative energy sources

Such coupled oxidation/reduction processes do not always involve reduced organic substrates as energy source. Also reduced inorganic compounds such as ammonium, reduced sulfur compounds and ferric iron can be coupled to thermodynamically feasible electron acceptors and yield energy to fuel cellular processes. Functional guilds such as nitrifiers and iron- as well as sulfur-oxidizing bacteria can be dominant community members when oxygen is in short supply and exert a strong influence on the characteristics and biogeochemical functioning of lakes (Peura et al., 2015; Arora-Williams et al., 2018). Last but not least, many organisms can also to variable extent harvest energy from solar radiation. Bacterial phototrophy, with oxygenic cyanobacteria as the primary example, played a key role in the evolution of oxygenated earth and the evolution of plants and still maintain a central role as globally significant primary producers in marine, freshwater and terrestrial environments. However, there are many more groups of phototrophic bacteria, including those that couple light harvesting systems with anoxygenic processes such as sulfide or thiosulfate oxidation (purple and green sulfur bacteria) and those that seem to use light energy more as an alternative energy subsidy that they can tap into for enhanced survival in times of starvation, including Proteorhodopsin featured in various abundant freshwater lineages as well as aerobic anoxygenic phototrophy present in groups such as Gemmatimonadota and *Limnohabitans* (Kasalický et al., 2018).

Heterogeneous resource distribution

Lakes may at a first glance be perceived as rather well-mixed and homogenous ecosystems. However, this is far from the real situation where spatial heterogeneity within lakes is manifested in many ways: (i) as a result of thermally controlled vertical stratification of the water column where solar exposed epilimnetic waters present very different conditions as compared to dark and oxygen-depleted hypolimnetic waters (ii) along steep chemical gradients at the water-sediment interface (iii) at the microscopic scale associated with living or detrital particles that present both surfaces for colonization and locally enhanced nutrient availability in the water column (iv) in response to local inputs of nutrients or pollutants from the watershed (Kraemer et al., 2020). These and other features and processes that create spatial heterogeneity in the resource landscape can have strong effects on bacterial communities and also contribute to maintaining diversity because of the multitude of niches presented (Pernthaler, 2017; Linz et al., 2017). Strongly stratified lakes do for example feature very different communities in epilimnetic and hypolimnetic water masses with typically higher diversity in the deeper water masses that are in contact with sediments and dominant populations tuned to the available substrates and light regime (Peura et al., 2012, 2015). Analogously, particle attached bacteria differ from their associated counterparts both in composition, functional attributes and seasonal dynamics (reviewed in Pernthaler, 2017). Considering that particle-association may confer predation resistance while also offering opportunities to exploit nutrients bound in the particle, this should come as no surprise.

Linking bacterioplankton to biogeochemical processes

Considering the complex and diverse composition of microbial communities and the patchy distribution of all these different genetically encoded modes of nutrient and energy acquisition, it may seem like a daunting task to ever link features seen in bacterial communities with manifested processes and characteristics at the ecosystem scale. There is however some structure to the madness and basic thermodynamic principles can usually inform about conducive metabolic modes in different lake habitats: With a steadily growing database of functional metabolic traits of the dominant bacterial groups, we are now in the process of building a foundation for a more in-depth and mechanistic understanding of the causes for the dynamic behavior of lake bacterioplankton (see further section "Key groups and charismatic lake bacteria"; Salcher et al., 2013; Muscarella et al., 2019). Additionally, there has been a recent increase in broad metagenomic and metatranscriptomic sequencing approaches to characterize the functional potential and activated metabolic processes of large collections of spatially and temporally separated samples while concomitantly mapping biogeochemical process rates and chemical change (Linz et al., 2018; Peura et al., 2015; Buck et al., 2021). This greatly increases our prospects of succeeding to link bacterioplankton to ecosystem features and in the long run improves ecosystem-level understanding and biogeochemical models using genomic data. Some first steps to move beyond the "bacterioplankton black box" and account for the dynamic nature and metabolic features of these complex communities have already been taken, mainly for marine ecosystems, but more recently also for some intensively studied lakes (Arora-Williams et al., 2018; Linz et al., 2020).

Food-web interactions

Metabolic dependencies

Many freshwater bacteria profit from (or depend) on metabolites produced by other macro- or microorganisms (Hamilton et al., 2017; Garcia et al., 2015) and consequently participate in functional consortia or metabolic networks. Some of these interactions are loosely defined and constitute non-essential interactions based on leveraging leaky metabolites produced by other community members or benefitting from "leaky processes" such as hydrolysis products generated from extracellular hydrolytic enzymes, trace-element scavenging siderophores or enzymes that degrade toxins or quench reactive oxygen species (Kim et al., 2019). However, many of the most abundant groups of freshwater bacteria have more obligate metabolic dependencies that are typically linked to genome reduction and where auxotrophic populations require exogenous source of essential biomolecules. This requirement leads to an obligate interaction between the auxotroph and at least one member of the community that can produce the required organic molecule (prototroph). The most numerically dominant freshwater lineages such as Actinobacteriota acI and *Fonsibacter* have streamlined genomes and represent auxotrophies for several amino acids, vitamins, and reduced sulfur sources (Eiler et al., 2016; Henson et al., 2018; Neuenschwander et al., 2018). This has inspired network analysis of the freshwater community leading to the conclusion that these microbes thrive in functional cohorts where their metabolic needs are supplied via their interactions (Mondav et al., 2020). While most experimental analyses explore auxotrophies for amino acids and B vitamins and some recent studies on heme auxotrophy (Kim et al., 2021), there potentially could be many other forms of auxotrophies that are still unrecognized. These unknown interactions can hinder cultivation efforts to bring environmentally relevant microbes to culture.

Predation and top down control

Lake bacterioplankton are typically under strong top-down control, largely through trophic interactions with microeukaryote predators and viruses, but also from zooplankton, predatory bacteria, and other parasites. Such mortality will broadly select for traits that confer resistance and accordingly influence bacterioplankton community composition, diversity and activity (Pernthaler,

2017). Examples of such traits to develop resistance against bacterivory can be the ability to form filaments or colonies through oversizing (e.g., Bacteroidota representatives), miniaturization (the case of highly abundant streamlined Actinobacteriota acI and *Fonsibacter*), biofilm formation, allelopathy or other inducible defense mechanisms (Pernthaler and Posch, 2009), while resistance to viral infection may be attributed to surface masking or various intracellular defense mechanisms such as CRISPR/cas systems or carrying genomic islands with genes that encode phage recognition sites (seen in "*Ca*. Nanopelagicales") (Neuenschwander et al., 2018). This defense mechanism can justify the large populations size of the streamlined Actinobacteriota despite the intense top-down control imposed by viruses.

The non-selective top-down control mainly enforced by heterotrophic nanoflagellates, protists, and zooplankton, transfers nutrients and energy directly to higher trophic level in the aquatic food web. This control has a potential stabilizing effect on bacterioplankton communities by keeping the growth of rapidly dividing population in check. Similarly, the host specific top-down controls are mainly mediated by viral infection, which finely tune the dynamics, abundance and microdiversity of their host in the lake ecosystem (Pernthaler and Posch, 2009). Phages influence the bacterial community composition either directly by infecting them or indirectly via influencing the flow of carbon in the food web. At the same time, phages can influence the entire food web either by producing dissolved organic carbon (DOC) that could be remineralized by other prokaryotes (viral shunt) or by producing sticky lysates that aggregate DOC and promote sinking, effectively shuttling organic carbon from the surface to sediments (viral shuttle). Phage-mediated microbial lysis potentially influences the community interactions by making public goods accessible to the host's neighboring cells. While the diversity and dynamics of viral genomes have been explored via metagenomic approaches (Arkhipova et al., 2017), their impact on the microbial community is less explored specifically in freshwater ecosystems.

Bacterioplankton dynamics

Selection vs. dispersal

What are the processes that create biogeographical patterns in lake bacterioplankton? Principally we can differentiate between on the one hand dispersal processes that bring in bacteria from outside the environment under scrutiny and on the other hand the perpetual process of selection which act on communities and populations and by means of population growth and mortality can shift the composition and diversity of resident microbiome (Pernthaler, 2017). To some extent, both of these mechanisms are always active, but their relative importance will vary across both ecosystems and different populations in the community. The consensus seem to be that selection (a.k.a. "species sorting") is for most lakes the dominant process shaping bacterioplankton communities (Lindström and Langenheder, 2012), but there are of course exceptions to this: lakes with short hydrological turnover that receive large inputs of water from other water bodies in the catchment, and mass effects (import of cells) associated with specific episodic events such as spring floods and heavy precipitation with intense surface runoff, biological invasions and storms causing sediment resuspension. To understand and correctly interpret changes in bacterioplankton one needs to know the conditions for the specific lake being studied and the mechanisms at play, not only at the time of sampling, but in the weeks to months preceding the observations made.

Differences between lakes

First and foremost, while many of the most abundant freshwater bacterial lineages are widely present in most freshwaters, there are marked differences in bacterioplankton communities between lakes. This has been known for decades (Zwart et al., 2002; Glöckner et al., 2000; Newton et al. 2011) and while these early syntheses were based on rather limited and scattered information, this view has recently been validated in a flood of studies that have used next generation sequencing or shotgun metagenomics for a more complete inventory of the identity and representation of bacterial taxa in these communities. The more obvious differences relate both to shifts in the relative abundances of shared classes or entire phyla (Eiler et al., 2012; Kraemer et al., 2020) as well as the distribution of more highly resolved lineages or ecotypes that may even be altogether absent in some systems (Ruiz-Gonzalez et al., 2017; Linz et al., 2017; Props and Denef, 2020). The specific factors underscoring such differences are hard to elucidate, but ecosystem productivity (Eiler et al., 2012), watershed land use (Kraemer et al., 2020) and variable geochemical conditions that define and constrain fundamental niches (Ruiz-Gonzalez et al., 2017) have been implicated as strong influencing factors. Most likely these ecosystem or landscape features will influence bacterioplankton communities via a combination of all the bottom-up and top-down structuring factors discussed in previous sections, with variable weight of the different factors in the different lakes and for the different bacterial groups.

Vertical stratification of bacterial populations

Thermal stratification is a fundamental concept in limnology with far reaching consequences for both biotic and abiotic processes. By solar heating at the lake surface combined with mixing of the uppermost water layers by wind action, distinct water masses emerge, resulting in a density-driven physical partitioning of the water column that hinders vertical transport of dissolved chemicals and planktonic organisms. This has major implications for resource availability and conducive metabolisms (see Section "Food-web interactions") and will accordingly also lead to vertical differences in bacterioplankton community composition (Fig. 1) and their realized or potential biogeochemical functions (Arora-Williams et al., 2018; Linz et al., 2018).

Such vertical structuring of bacterial populations is perhaps most notable in lakes that never or very seldom mix, or productive lakes with extended periods of stratification where the deeper layers will become oxygen-depleted. In such episodic or permanent anoxia, the hypolimnetic waters will present novel metabolic niches along chemical gradients, contrasting redox zones and in moving from low light to complete darkness. Among the more abundant groups in such deep anoxic waters we tend to find representatives from the quite widely distributed Patescibacteria (CPR) and Bacteroidota (Peura et al., 2012), but there are also local hotspots for lineages that are rare or absent in the surface waters, such as Chlorobia, Chloroflexota and members of the ε-proteobacteria (Peura et al., 2015; Mehrshad et al., 2018). Additionally, oxygen depleted hypolimnetic waters seem to host a higher bacterioplankton diversity as compared to surface waters, with an array of more rare groups that are not usually considered to be "typical lake bacteria" contributing significantly to the community (Peura et al. 2012; Linz et al., 2017).

Vertical shifts in population structure are also seen for some of the more abundant lineages that are shared between water masses. Here certain populations of *Polynucleobacter* clearly prefer the dark and oxygen scarce hypolimnion to the solar exposed and oxygen saturated surface waters while other appear to have the opposite preference (Linz et al., 2017) and the same can be seen in for example closely related populations of "*Ca*. Methylopumilus" (Salcher et al., 2015). In contrast, some of the ubiquitous lake bacterioplankton lineages such as *Fonsibacter* (LD12) and abundant members of the Actinobacteriota (acI) are overall clearly more abundant in surface waters and more highly resolved lineages seem to have only weak preference for either of the two different water masses while other factors such as lake type and season seem to matter more (Neuenschwander et al., 2018).

Changes over days, seasons and years

Resources and top down pressures that shape bacterial communities do not only vary spatially, but also change over time. This is not unique for lakes as few if any environments stay constant, but in many ways the temporal change seen in lakes can be more dramatic and harder to predict as compared to other aquatic biomes (oceanic waters, groundwaters). Such drivers act over both shorter and longer timescales with variable impacts on bacterial communities while concomitant hydrological influences may also change local communities via mass effects and homogenization.

Studies of temporal change in lake bacterioplankton has mainly focused on seasonal change and for good reasons: in many of the more lake-intensive parts of the world, the different seasons feature very different environmental conditions and host distinct and differentially composed bacterial communities (Eiler et al., 2012; Linz et al. 2017; Mondav et al., 2020). While e.g., phytoplankton seasonal dynamics have been recognized for quite some time, it has only recently been recognized that bacterioplankton also feature similar strong seasonal dynamics where populations "bloom" and collapse. Interestingly such seasonality patterns in community composition do not seem to be annually reoccurring (Linz et al., 2017), implying more complex and cryptic regulation of bacterioplankton as compared to oxygenic phototrophs. The same inter-annual variation can be seen for individual dominant lake bacterial groups such as *Fonsibacter* (Salcher et al., 2011), and "*Ca*. Methylopumilus" (Salcher et al., 2015).

As one example of such seasonality, the bacterioplankton in dimictic lake Erken (Sweden) experience dramatic change as the seasonal ice cover breaks up in April with subsequent holomixis until the water column stratifies in mid-May (Fig. 3). In this period, the abundant *Fonsibacter* (Pelagibacteraceae) and Bacteroidota populations decline dramatically and are replaced by a transient abundant Verrucomicrobiota population concomitant to a predictable spring diatom bloom which likely feed these bacteria via organic exudates. At the same time, some groups (e.g., Actinobacteriota) seem to be remarkably persistent throughout the year, at least at the broader taxonomic level. However, this may just be because of methods based on 16S rRNA sequencing with insufficient resolution. Metagenome enabled population tracking did for example uncover cryptic ecotypes with seasonal preferences hidden behind such apparent constancy for abundant lake bacterial groups such as *Limnohabitans* (Props and Denef., 2020), Actinobacteriota acI and *Fonsibacter* (Garcia et al., 2018; Neuenschwander et al., 2018). Another elusive aspect of temporal bacterioplankton community change is biotic interactions and dependencies which cause entire functionally interactive cohorts of bacteria to change in synchrony with one another (Eiler et al., 2012; Mondav et al., 2020).

Multiple lines of evidence suggest that bacterioplankton communities may also change in composition over shorter than seasonal timescales. This can for example be seen in the dynamic spring period of lake Erken (Fig. 3) and also happen during rainstorms or other extreme weather events that mix water columns or bring in large amounts of bacteria or easily exploitable substrates to the system. But what about the dramatic changes that happen over diurnal timescales? There is limited information and likely not enough time for bottom-up structuring mechanisms to cause measurable community change. Nevertheless, a recent study of bacterioplankton community change that take place over diurnal timescales clearly show that while composition do not change, there are quite prominent diel cycles in community function sensu expressed genes and also temporal partitioning of active populations (Linz et al., 2020). This type of studies will be further facilitated by the growing database of freshwater bacterial genomes with promises of further mapping of how individual bacterial populations and consortia respond functionally to various environmental drivers.

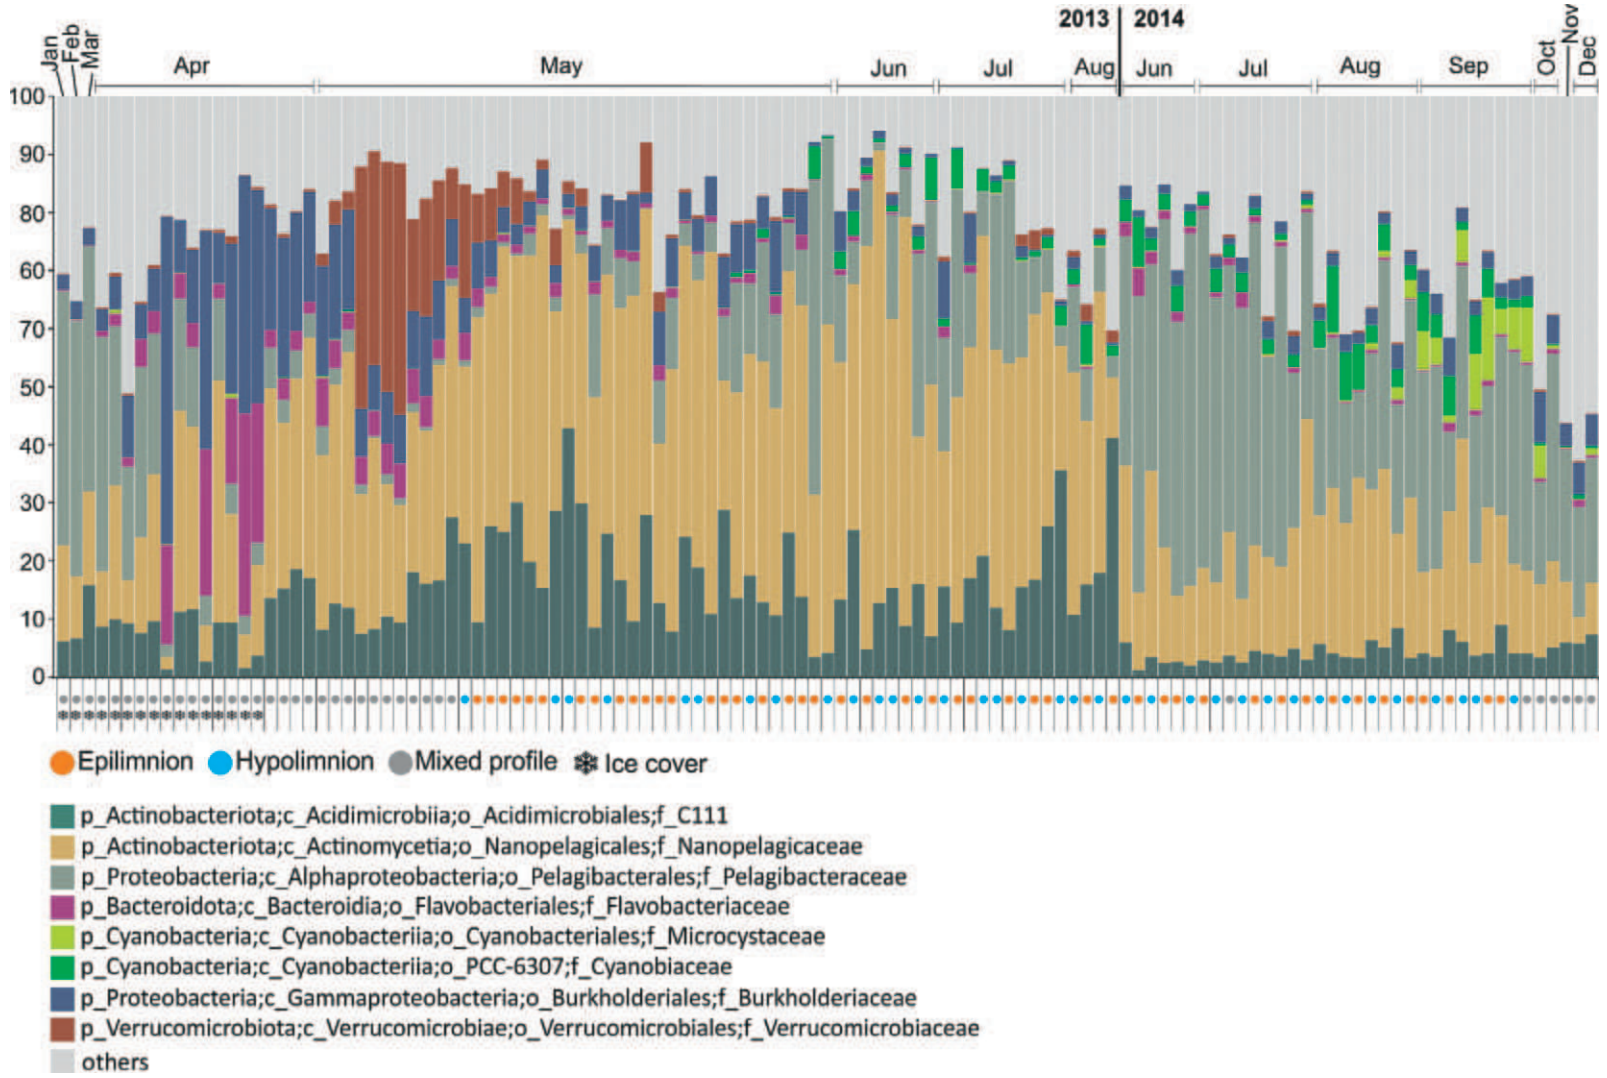

Fig. 3 Seasonal dynamics of the charismatic lake bacteria based on 16S rRNA amplicon analyzes of the Lake Erken time-series collected during 2013 and 2014. Samples are ordered based on date and the sampling month in shown on top. Based on data from (Mondav et al., 2020).

Summary and outlook

Freshwater bacterial communities are diverse and phylogenetically distinct from their counterparts in other biomes. At the core of such communities are a set of globally dispersed and abundant bacterial lineages whose biology we are now starting to uncover with genome sequencing and refined cultivation methods. While you can find these charismatic bacterial groups in nearly all freshwater lakes, their activity, abundances, population structure and microdiversity vary a lot both between and within lakes and over weekly to seasonal timescales. Why is that? While it is hard to generalize for all lakes (after all they are quite diverse in their functioning and features) we feel confident in concluding that lake bacterial communities are dynamically structured and constrained by a combination of bottom-up (resource availability) and top down (predation and mortality) mechanisms that create opportunities and challenges for the resident microbiota. Recent studies also suggest that there are surprisingly widespread and strong metabolic dependencies between different groups of lake bacteria, and this also shed new light on their dynamics and biogeography. A research challenge for the forthcoming years would be to more directly couple functional traits of these bacterial groups (and their ecotypes) to apparent distribution patterns in ecosystems and unravel the implications of their trophic interactions with the ultimate goal of using such combined information to enable the development of mechanistic, informative and robust models of "ecosystem metabolism".

Important knowledge gaps

- Physiological characteristics of the charismatic and as of yet uncultured freshwater bacteria
- Comprehensive mapping of functional traits in freshwater bacteria
- Implications of metabolic dependencies and trophic interactions in the food web for the dynamics and functioning of freshwater bacteria
- Finding the causal drivers behind biogeographical patterns and expressed functions in bacterioplankton (metatranscriptome surveys could be one idea)
- Genome-informed models for improved understanding of biogeochemical processes and cycles.

Further reading

For further reading we refer the reader to the quite extensive reference list which nevertheless is not complete. Over the years there have been a few broader reviews of the diversity and ecology of lake bacterioplankton, illustrating the increasing amount of data and development of the field. We especially recommend the early synoptic studies by Glöckner et al. (2000) and Zwart et al. (2002) which were some first attempt to describe the global freshwater microbiome. With an increasing number of studies, this was followed by an in-depth review by Newton et al. (2011) which provided a guide to the "natural history of lake bacteria." Another recent and very comprehensive review by Pernthaler (2017) followed up on this with a focus that was more on the ecology and metabolic functioning. We are still lacking an in depth "genome guide" of freshwater bacteria, but predict that this will come in the near future when such data from metagenome assembled genomes, single cell genomes and new isolates is becoming increasingly available.

Funding that gave us time to engage in the book project was kindly provided by the Swedish University of Agricultural Sciences and the Swedish Research Council. Bioinformatics analyzes were carried out utilizing the Uppsala Multidisciplinary Center for Advanced Computational Science (UPPMAX) at Uppsala Universitet (projects SNIC 2020/5-19 and SNIC 2021/5-53).

We thank Rhiannon Mondav for saving us time by sharing the OTU tables for the Lake Erken 16S rRNA dataset and the section editors and publisher for being patient with our delays.

Glossary

Benthic shortcut A trophic pathway where aquatic fungi channel terrestrial-derived organic matter to higher trophic levels in the aquatic food web.
Chytridiomycosis Originally used for describing the emerging fungal disease in amphibians caused by the chytrid *Batrachochytrium dendrobatidis*. The term has been extended to the more general context of chytrid parasitism.
Cryptic species Species that are difficult to distinguish by morphology but have pronounced genetic divergence.
Hyphae Long, branching filamentous structures. In most fungi, hyphae are the main mode of vegetative growth, and are collectively called a mycelium.
Morphospecies A group of organisms regarded as a taxonomic species solely based on the sharing of distinctive morphological traits.
Mycoflux A pathway of organic matter transformation in the pelagic which involves fungal interactions leading to aggregation or disintegration of organic matter.
Mycoloop A trophic pathway where the biomass of inedible phytoplankton or pollen is transferred to higher trophic levels via edible fungal zoospores.
Osmotrophy Nutritional mode based on absorption of dissolved organic compounds from the surrounding environment. Organisms that use osmotrophy include bacteria, many species of protists and most fungi. Fungi break down enzymatically organic compounds in the external environment, before absorbing the smaller molecules resulting from external digestion.
PEG-model A model, formulated by the Plankton Ecology Group that describes the seasonal succession of plankton in lakes, an annually repeated process of community assembly during which most major external factors and internal interactions shaping communities are considered. The first model was published in 1986 and has since been under continuous development.
Pseudofungi Organisms that resemble fungi in their morphology and mode of nutrition but are phylogenetically more related to plants. Characteristics that make pseudofungi distinct from other true fungi are their cell wall composition which is mainly composed of cellulose, non-septate hyphae and multi-flagellated zoospores.
Rhizoid Small branching hyphae that anchor the chytrid fungus to the substrate, and release digestive enzymes to absorb organic material.
True fungi Organisms that belong to the kingdom Fungi. They are either single celled or have septate hyphae with cell walls primarily consisting of chitin.
Zoospore Asexual spore that lacks a cell wall and uses one or more flagella for locomotion.
Zoosporic fungi Chytrids and other early diverging fungi that have a zoosporic stage during their life cycle.

 https://doi.org/10.1016/B978-0-12-819166-8.00005-0

Introduction

Among aquatic micro-organisms such as algae, protozoans or bacteria, fungi have received so far only little attention in aquatic ecology research and are mentioned at most very briefly in biology courses, generally falling between the fields of botany and microbiology. Although fungi have been more intensively studied in terrestrial ecosystems, evidence is accumulating that they are as ubiquitous and highly diverse in aquatic ecosystems and play an important role in aquatic biogeochemical cycling. This article provides an overview on the diversity and functions of fungi in freshwater habitats, with particular emphasis on zoosporic fungi (e.g., chytrids), which are an abundant and diverse group of fungi in the pelagic zone of lakes. We will highlight recent progress regarding the high diversity of early diverging fungi, including Chytridiomycota, discovered by environmental sequencing approaches, their role in lake plankton succession, aquatic food webs and nutrient cycling, i.e., Mycoloop. Finally, we also discuss the impact of anthropogenic stressors on emerging fungal disease in freshwaters caused by parasitic chytrids.

What are aquatic fungi?—Functional and taxonomic classification

One of the first records of aquatic "true fungi" dates back to the mid-19th century when Braun discovered parasitic fungi on green algae (Braun 1856). He named these fungi "chytridien" (e.g., chytrids) which later became the phylum Chytridiomycota (Hibbett et al., 2007). Collectively, aquatic fungi were called Phycomycetes (algal-fungi) (Sparrow, 1960) (Table 1). As many Phycomycetes

Table 1 Functional and taxonomic classification of aquatic fungi.

	Previous classification	*Morpho-functional classification*	*DNA based classification Phyla containing aquatic lineages*	*Representative genera*	*Trophic interactions*
True Fungi	Ascomycota	• Aquatic Hyphomycetes/ Filamentous fungi	Ascomycota	*Tetracladium*	Saprophytic on decaying
				Clavariopsis	leaves and submerged wood
		• Aero-aquatic Hyphomycetes/ Filamentous fungi		*Crucella*	Parasitic on other fungi
				Debaryomyces (Y)	Saprophytic and symbiotic?
				Metschnikowia (Y)	Parasitic on zooplankton
	Basidiomycota	• Yeast (Y)	Basidiomycota	*Rhodotorula (Y)*	Saprotrophic
				Cryptococcus (Y)	gut endosymbionts?
					Mutualistic interaction with algae/opportunistic human pathogen
	Zygomycota	Trichomycetes/Filamentous fungi	Kickxellomycota	*Harpella*	Endosymbionts freshwater arthropods
			Zoopagomycota	*Acaulopage*	Predators of amoeba
				Zoophagus	Predators of rotifers
		Filamentous fungi	Basidiobolomycota	*Basidiobolus*	Saprotrophic and parasitic on amphibians
	Phycomycetes	Zoosporic fungi	Olpidiomycota	*Olpidium*	Parasitic on plants, animals, protists, and fungi
			Chytridiomycota	*Zygophlyctis*	Parasitic on diatoms
				Rhizophydium	Parasitic on algae Saprotrophic on pollen/
				Rhizoclosmatium	Saprotrophic on chitinous substrates
				Batrachochytrium	Parasitic on invertebrates
			Monoblepharomycota	*Monoblepharis*	Saprotrophic on water-logged twigs
			Neocallimastigomycota	*Piromyces*	Anaerobic symbiont
			Blastocladiomycota	*Blastocladiella*	Saprotrophic on plant debris
				Paraphysoderma	Parasitic on algae
			Aphelidiomycota	*Amoeboaphelidium*	Parasitic on algae
			Rozellomycota	*Rozella*	Parasitic on chytrids and oomycetes
Pseudo-Fungi			Oomycota	*Phytium*	Saprotrophic on pollen
				Olpidiopsis	Parasitic on diatoms
				Saprolegnia	Parasitic on fish/fish eggs
			Hyphochytriomycota	*Hyphochytrium*	Saprotrophic on pollen
					Parasitic on algae and resting spores of oomycetes
			Labyrinthulomycota	*Labyrinthula*	Saprophytic and opportunistic pathogens of algae

DNA based classification based on Tedersoo et al., 2018 and Wijayawardene et al., 2018.

share the morphological trait of flagellated zoospores which are the primary agents of dispersal and infection/colonization of substrates in water, they have also been classified under the term "zoosporic fungi." Since Braun's first observations of parasitic chytrids on algae, many more species have been discovered which interact with a large variety of living organisms and organic substrates (Sparrow, 1960). Chytrids have been found to display a continuum of consumer strategies ranging from obligate parasites to saprophytes (Frenken et al., 2017; Sparrow, 1960). There are even zoosporic fungi (e.g., Rozellomycota) that parasitize other parasitic chytrids of phytoplankton (Canter, 1969). With the advent of DNA-based taxonomy, it is now well established that zoosporic fungi are a polyphyletic group including true zoosporic fungal lineages (Kingdom Fungi) and pseudofungal lineages (Kingdom Chromista). This indicates that shared functional characteristics such as osmotrophy and certain growth habits arose through convergent evolution. Chytrids, which currently encompass phyla Chytridiomycota, Blastocladiomycota and Neocallimastigomycota, represent the largest group of true zoosporic fungi in freshwater lakes.

A second important ecological group of aquatic fungi was discovered by Ingold in the mid-20th century, who observed characteristic fungal spores associated with decaying leaves in streams, and which he defined as aquatic hyphomycetes (Ingold, 1942). These are filamentous fungi that reproduce mainly asexually and in addition to leaves in streams, are found on decaying macrophytes or driftwood in running river systems, wetlands or littoral of lakes. The majority of them belong to Ascomycota and few to Basidiomycota.

The Ascomycota and Basidiomycota also contain unicellular yeasts which are often found in the pelagic zone of lakes as free-floating cells, attached to substrates, or within animal hosts (Buzzini et al., 2017). Trichomycetes are another diverse ecological group of aquatic fungi that are obligate endosymbionts in the gut of many aquatic insects. They used to be a member of the phylum Zygomycota; however, molecular identification methods have shown that some Trichomycete species are more related to Protozoa than to true fungi.

There is not always a clear distinction between aquatic and terrestrial fungi. Whereas some aquatic fungi have an obligate aquatic lifestyle and complete their whole life cycle in water (residents), others have both an aquatic and terrestrial life cycle and are so called aero-aquatic fungi (Chauvet et al., 2016). Finally, terrestrial fungi may occur in water, merely by being washed or blown in, without showing any activity in water (transients). It remains a challenge to precisely characterize where species fall along this gradient of adaptation to aquatic habitats (Shearer et al., 2007).

Fungal adaptations to an aquatic lifestyle

Aquatic fungi have evolved increasing size, complexity, and metabolic functioning from small intracellular fungal parasites up to larger mycelian networks of filamentous fungi capable of decomposing large refractory organic material. Fig. 1 displays a variety of dispersal and vegetative structures of aquatic fungi with their respective size ranges. Macroscopic fungal structures, i.e., large fruit bodies, are nearly completely absent in aquatic habitats (but see *Psathyrella aquatica*, the first fungi discovered fruiting underwater, (Frank et al., 2010)).

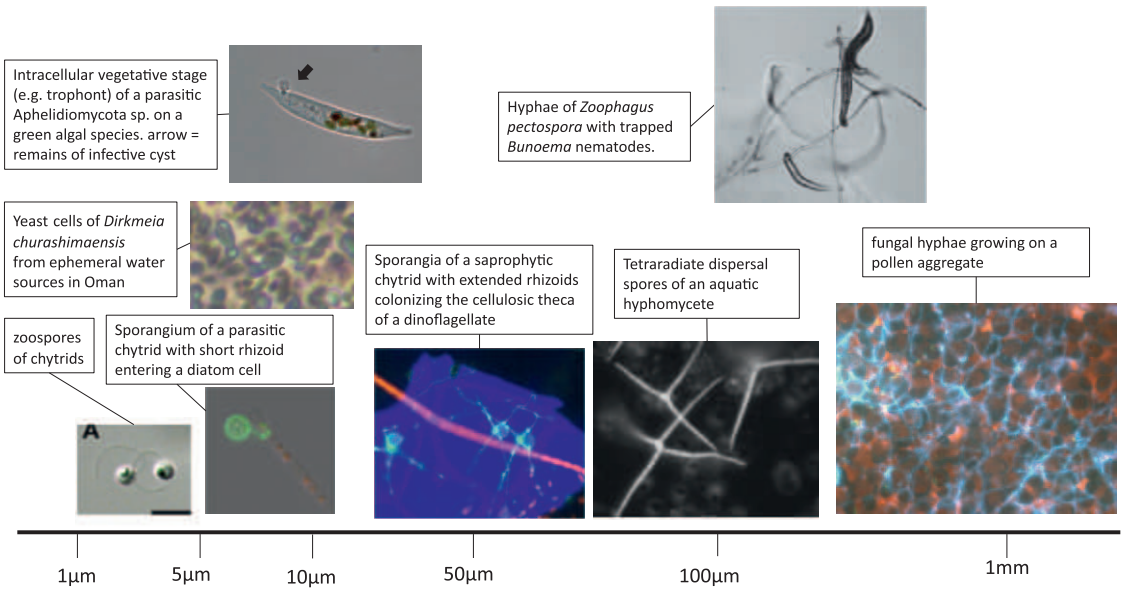

Fig. 1 Relative sizes of various dispersal and vegetative structures of aquatic fungi. Images for chytrid zoospores and Aphelidiomycota courtesy of K. Seto, University of Michigan, US. Davies, United States Department of Agriculture, US. Image of dispersal spore of aquatic hyphomycete courtesy of C. Wurzbacher, Technical University of Munich, Germany.

Zoosporic true fungi which are ancient in term of evolution, since they diverged from the other fungal lineages ca. 750 million years ago (Medina and Buchler, 2020), have most likely an aquatic origin. Their dispersal stages show primary adaptations to an aquatic lifestyle in the form of flagellated motile zoospores. Contrary to heterotrophic nanoflagellates, fungal zoospores have unique characteristics, such as a single posterior whiplash flagellum and a large refractive lipid globule that serves as an energy reserve for fueling active zoospore movement.

The recently discovered Aphelidiomycota, endoparasites of unicellular algae, have both amoeboid and flagellated dispersal stages (Karpov et al., 2014a). In contrast to other fungi that absorb dissolved nutrients from the environment (osmotrophy), endoparasitic lineages Aphelidiomycota and Rozellomycota engulf the content of their host, like amoebae, and digest it in special vacuoles (phagocytosis). The vegetative structures of chytrids are called rhizoids, which are tiny root-like hyphae. Rhizoids anchor the chytrid to the substrate (or host) and excrete enzymes to break it down (Powell, 2017). Chytrids can modify their rhizoidal structure in response to nutrient availability in a similar way as filamentous fungi (Laundon et al., 2020).

Aquatic hyphomycetes most probably evolved from terrestrial fungi and secondary morphological adaptations to colonize aquatic environments have evolved independently in multiple lineages (Baschien et al., 2013). The asexual dispersal stages of aquatic hyphomycetes are typically tetraradiate or sigmoidal shaped and have sticky sheaths that facilitate their attachment under turbulent conditions to submerged substrates.

The size difference between the rhizoidal structures of chytrids and hyphal structures of aquatic hyphomycetes implies ecological niche differences between both fungal groups. Wurzbacher et al. (2016) formulated this as the "morphotype hypothesis," i.e., zoosporic fungi become increasingly more important on fine particulate organic matter (FPOM) such as pollen grains or algae, whereas aquatic hyphomycetes tend to colonize proportionally more the larger coarse particulate organic matter (CPOM).

Some members of Ascomycota, Basidiomycota and Zygomycota have developed trapping structures, such as adhesive spores, hyphae or rings to capture water-inhabiting micro invertebrates, like nematodes, rotifers or amoeba (Corsaro et al., 2018; Davis et al., 2019; Karling, 1936). After they have captured their prey, hyphae penetrate and digest the prey tissues. Most single celled yeasts represent fungal lineages where the ancestral hyphal growth form was abandoned. However, some yeast species still produce pseudo-hyphae or are dimorphic, i.e., they grow as single celled yeast or form true hyphae depending on environmental conditions (Harris, 2011). The diverse ecological role of yeast in aquatic ecosystems is still poorly understood (Wurzbacher et al., 2010). Yeast have been identified as members of the gut microbiota and parasites in aquatic invertebrates and animals. As saprophytes, consuming dissolved organic matter (DOM), they potentially share ecological niches with heterotrophic bacteria and compete for nutrients. Mutualistic relationships have been documented between the alga *Euglena mutabilis* and yeast of the genus *Cryptococcus*, which allow both species to colonize together extreme acidic and heavy metal polluted habitats (Nakatsu and Hutchinson, 1988). Yeast display a wide variety of extracellular enzymatic activities that can promote algae and plant growth by increasing nutrient availability and absorption (Gomes et al., 2015).

Freshwater fungal diversity in the next generation sequencing era

Although fungal diversity in terrestrial ecosystems is considered to be higher than in aquatic ecosystems, the extent of fungal biodiversity in general may need to be revisited in the light of recent molecular high-throughput sequencing approaches, which have greatly increased the discovery of uncultured taxa, or so-called "dark matter fungi" (Grossart et al. 2016). The number of fungal species is estimated to be between 2.2 and 3.8 millions, of which only around 120,000 are currently accepted and named (Hawksworth and Lücking, 2017).

Where are all the missing fungi? Aquatic habitats have certainly been overlooked and undersampled in the context of diversity (Grossart et al., 2019). The majority of fungal sequences retrieved from freshwaters are represented by Ascomycota, Basidiomycota and early diverging fungal lineages, i.e., Chytridiomycota and Rozellomycota (Lepère et al., 2019; Panzer et al., 2015; Wurzbacher et al., 2016). The active fraction of the community, identified by RNA analysis, shows the same dominant groups (Lepère et al., 2019). These proportions are also more or less in agreement with diversity estimates based on described species isolated from freshwater (Shearer et al., 2007).

In a time when biodiversity screening by high-throughput sequencing methods is becoming routine, knowledge gaps in terms of both taxonomy and marker coverage in the reference sequence databases are posing severe limitations for the ecological interpretation of environmental DNA surveys. Especially the early diverging zoosporic fungal lineages are highly underrepresented in sequence databases (Table 2). The coupling of cultivation and single-cell isolation methods with long-read sequencing technologies

Table 2 Different marker and taxonomic coverage of fungal lineages in the GenBank-NCBI sequence database.

Marker	*Fungi*	*Ascomycota*	*Basidiomycota*	*Chytridiomycota*	*Rozellomycota*	*Aphelidiomycota*
SSU	563,096 (258153)	237,592 (18751)	92,939 (21932)	2087 (1113)	130 (117)	13 (0)
ITS	844,401 (216006)	438,236 (21410)	194,133 (32618)	4273 (2810)	40 (32)	37 (31)
LSU	494,647 (107783)	276,115 (16657)	117,999 (26628)	1935 (657)	46 (31)	36 (31)

Early diverging zoosporic fungal lineages (Chytridiomycota > Rozellomycota > Aphelidiomycota) only represent < 0.5% of total fungal sequences and have a high percentage of sequences related to uncultured species (>50%) compared to Dikarya. GenBank search 01/04/2020: search example: Basidiomycota AND 18S OR SSU/(Basidiomycota AND 18S OR SSU) AND "uncultured" filter—sequence length range 300–10,000; () = number of sequences from uncultured species from the total number of sequences.

(e.g., PacBio and Nanopore sequencing) generating high-quality de novo reference data for the full ribosomal operon, is a promising approach to fill the gaps in reference sequence databases (Wurzbacher et al., 2019). This approach will facilitate access to more than a century of taxonomic and ecological knowledge on aquatic fungi.

Hidden chytrid diversity

A neglected but significant source of unrecognized fungal diversity is the restudy of known taxa, applying species recognition techniques to molecular data (Rad-Menéndez et al., 2018; Seto et al., 2020; Van den Wyngaert et al., 2017). In the beginning of this article we highlighted that chytrids have been studied for more than a century using microscopy. However, from the >400 chytrid morphospecies known to be associated as parasites or saprophytes on phytoplankton, only a few species have ribosomal DNA sequences deposited in sequence databases (see summary table in Frenken et al., 2017). Recent efforts using targeted isolation approaches in lakes have highlighted that many "dark matter fungi" and novel lineages within the early diverging fungi represent parasitic zoosporic fungi of phytoplankton (Karpov et al., 2014b; Seto et al., 2020; Van den Wyngaert et al., 2018). Some of these fungi are indeed rediscoveries of known morphospecies (Van den Wyngaert et al. 2018), whereas others represent genuinely new species (Seto and Degawa, 2018; Van den Wyngaert et al., 2017).

Until now most of our knowledge on phytoplankton-chytrid interactions is derived from in situ morphology-based identification of phytoplankton-chytrid species pairs (Sparrow, 1960). Morphological features of chytrids are, however, scarce and host identity is often used as the main guide for identification of parasitic fungi. Consequently, morphology-based identification may mask cryptic host-fungal associations (Van den Wyngaert et al., 2018). Moreover, a high degree of morphological plasticity is frequently reported among chytrids (Barr, 1973), which poses another challenge for morphological distinction among species. Whereas the presence of (semi)cryptic species causes underestimation of diversity, phenotypic plasticity overestimates this diversity (Fig. 2). An extra layer of complexity is added to phytoplankton-chytrid species interactions as phytoplankton host species are themselves prone to cryptic diversity (Van den Wyngaert et al., 2015, 2018). The use of molecular markers for species identification can overcome certain limitations of traditional morphology-based approaches to infer species diversity and host/substrate interactions of chytrids. Resolving cryptic host-fungi associations is important for interpreting biodiversity, biogeographical patterns, seasonal dynamics and population dynamics of phytoplankton-fungi interactions.

Ongoing development of molecular tools have enabled ecologists to discover novel aquatic fungi and interactions in situ. Direct isolation and sequencing of single phytoplankton-chytrid pairs from the environment have been applied to assess diversity and uncover the relationship between various fungal lineages and their specific host species. This approach has revealed that fungi attached to large diatoms include not only members of Chytridiomycota, but also Aphelidiomycota, Rozellomycota and even Ascomycete yeast (Ishida et al., 2015). Another promising approach to reveal and quantify fungal interactions in the field is catalyzed reporter deposition fluorescence in situ hybridization (CARD-FISH). Using this method, Chambouvet et al. (2019) recently discovered a novel chytrid-like-clade-1 (NCLC1) of intracellular fungal parasites of diatoms.

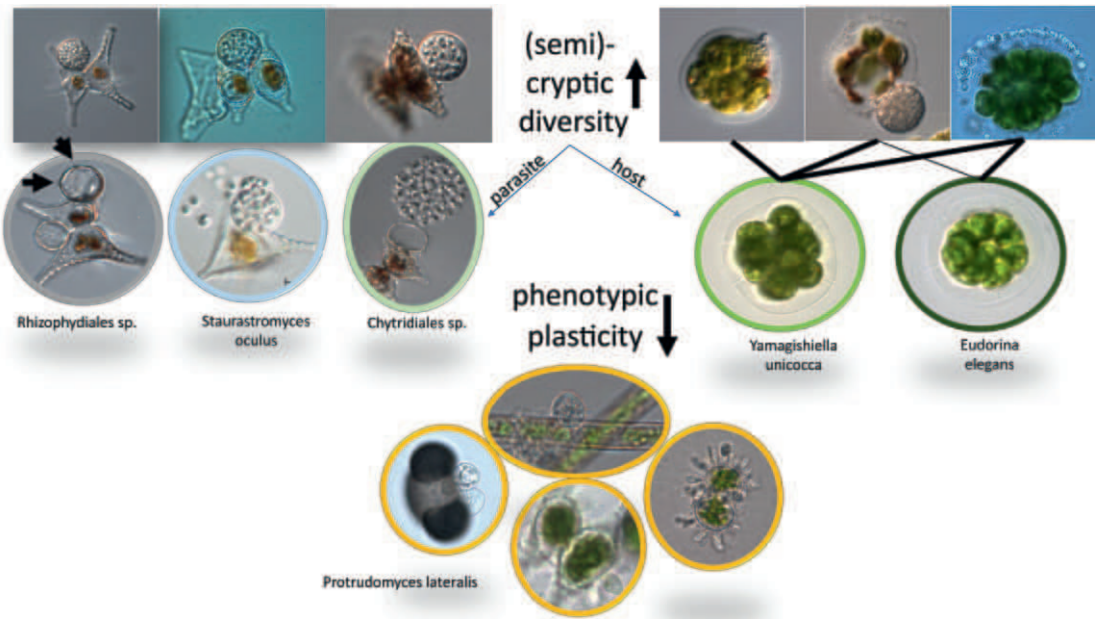

Fig. 2 Examples of cryptic diversity and phenotypic plasticity in phytoplankton-chytrid pairs. The top left shows the morphologically similar sporangia of three chytrids isolated from different lakes and infecting the same host species *Staurastrum* sp. After cultivation, subtle morphological differences in zoospore discharge can be observed and molecular analysis identifies three distantly related chytrid species. The top right shows an example of cryptic diversity in the phytoplankton host and their different susceptibility to three chytrid species. Below is shown the same chytrid species with a high degree of sporangium morphological plasticity on different phytoplankton host species and pollen substrate.

Lake fungal communities in space and time

A recent meta-analysis found that freshwater biomes have the highest fungal diversity at the phylum level (Panzer et al., 2015). This is likely attributed to the large amount of habitat/substrate diversity and temporal dynamics of environmental parameters in freshwater systems, allowing for a multitude of available niches and fungal lifestyles. The composition and relative abundance of fungi differs significantly between the type of freshwater ecosystem (e.g., streams, wetlands, lakes) and between habitats within the ecosystem (Wurzbacher et al., 2010, 2016). As is the case with most microbes, environmental selection seems to play a more important role than dispersal limitation for fungal distribution (Tian et al., 2018).

Lake morphology (i.e., size and depth) and physical and chemical properties of water (i.e., trophic status, concentrations and composition of organic matters) influence fungal colonization and thus community structure. In large, deep lakes, where organic matter is mainly supplied internally by photosynthesis of algae, zoosporic fungi, especially chytrids, dominate by parasitizing/utilizing phyto- and zooplankton (Wurzbacher et al., 2010). In contrast, in small ponds or shallow lakes where the relative importance of allochthonous organic matter from terrestrial riparian vegetation is usually higher and where submerged and emergent macrophytes are abundant, filamentous fungi such as Ascomycota dominate. The fungal community pattern throughout a longitudinal transect across southern Scandinavia was partly explained by the concentrations/composition of total organic carbon (TOC) and total phosphorus (TP) (Khomich et al., 2017). Yet, it is not clear how fungal communities change along a latitudinal gradient and how strong temperature may affect this pattern.

Within lakes, spatial variation of fungal community structure is explained by habitat and type of organic matter (CPOM or FPOM) (Wurzbacher et al., 2016). In general, fungi dominate the eukaryotic community in the benthic area of lakes and their abundance decreases in the pelagic zone. Following the "morphotype hypothesis," aquatic hyphomycetes dominate benthic and reed habitats where CPOM is the dominant organic energy source, whereas chytrids become the dominant fungi in open water where FPOM is the main type of organic matter (Fig. 4). Lake sediments mainly serve as fungal spore banks. Besides resting spores of chytrids and other resident fungi, dispersal spores of terrestrial species that are blown in by wind or washed in by rain, are frequently found in sediments (Voronin, 2014; Wurzbacher et al., 2016). Whether aquatic sediments are a dead end for these terrestrial fungi or if they represent an alternative viable habitat remains poorly studied. More complex habitats, containing a mix of CPOM and FPOM, such as periphyton biofilms are characterized by high fungal species richness and a mixed community of both filamentous and zoosporic fungi (Wurzbacher et al., 2016). Overall, these observations confirm a positive relation between habitat heterogeneity and fungal species diversity at different spatial scales.

Besides the type of organic matter, oxygen is an important environmental factor which strongly influences the presence and activity of aquatic fungi. Aquatic hyphomycetes in general need well oxygenated environments and become negatively affected by sub- or anoxic conditions. Other fungi, especially Neocallimastigomycota, are adapted to anoxic conditions (Hackstein et al., 1999). Yeast become relatively more abundant in eutrophic systems. Their increase in the pelagic zone of lakes has been reported to coincide with the crash of the annual phytoplankton spring bloom, as possible response to an autochthonous nutrient pulse (Quinn, 1984).

Temporal succession of fungi in lakes—Chytrid fungi in the PEG model

Canter and Lund (1951) were the first to show that parasitic chytrids may cause a delay in the timing of the diatom peak or may decrease the height of the peak, depending on the environmental conditions affecting growth. Moreover, as many chytrids are host specific, chytrid parasitism of one species can favor the development of others, thereby affecting seasonal succession of phytoplankton species (Canter and Lund, 1951; Van Donk and Ringelberg, 1983), as well as intraspecific diversity (Gsell et al., 2013c). Parasitic chytrids of phytoplankton have only recently been considered in the updated PEG model as an important "novel" interaction driving seasonal succession of plankton in lakes, in addition to the role of physical factors, grazing and nutrient limitation (Fig. 3, (Rasconi et al., 2012; Sommer et al., 2012)). However, as studies on chytrids in plankton assemblages are often limited to the investigation of the phytoplankton spring bloom, or focus on a single or few host-chytrid interactions, the seasonal dynamics of chytrids at the community level remains understudied in most water bodies. The few existing seasonal studies, performed in temperate lakes undergoing thermal stratification, have shown that temporal dynamics of planktonic chytrid species are closely coupled to the seasonal population dynamics of their phytoplankton hosts (Holfeld, 1998; Rasconi et al., 2012). In winter, phytoplankton activity is in general low and consequently the abundance of parasitic chytrids is likewise at a low level. Increasing nutrient availability by vernal holomixis, together with increasing light availability and rising temperatures, initiate the development of the diatom spring bloom. Chytrid infections increase due to increased host-chytrid contact rate and high prevalence of infection may be established on the dominant diatom species. The principle of "killing the winner" causes succession of species during the bloom. Lakes in forested areas experience massive pollen rains, often after the spring bloom decline in May/June, thus coinciding with the clear water phase. During this period, the abundance of parasitic chytrids sharply declines, whereas pollen grains are rapidly colonized by saprophytic chytrids. Summer and autumn months are characterized by a diverse phytoplankton assemblage leading to the association of different parasitic chytrid species of chlorophytes, diatoms and cyanobacteria, but in general with lower prevalence of infection. Favorable environmental conditions occasionally allow for short peaks of diatom species to occur in this period which may result in subsequent short but severe chytrid epidemics (Canter and Lund, 1951; Holfeld, 1998).

Whereas parasitic chytrids are mostly associated with large inedible phytoplankton species, they can also occur on smaller-sized chlorophytes and diatoms (Sparrow, 1960); however, prevalence of infection has been reported to be generally low compared to larger hosts (Canter-Lund and Lund, 1995; Rasconi et al., 2012). Nevertheless, when a small-sized (<10 μm) *Cyclotella* species made up the dominant biomass during a diatom spring bloom in the oligo-*meso*trophic Lake Stechlin (Germany), a chytrid species was

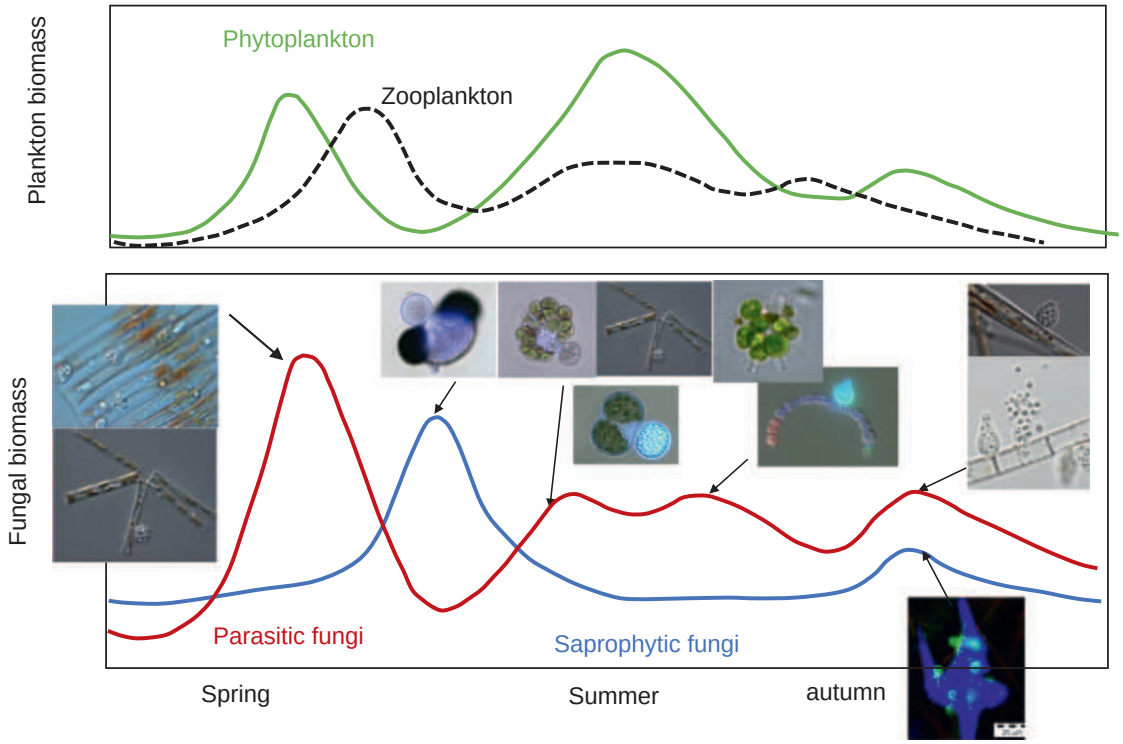

Fig. 3 PEG model of the seasonal biomass patterns of plankton and hypothetical seasonal succession of parasitic and saprophytic fungi. (Top) Seasonal biomass patterns of plankton in meso-eutrophic water bodies based on PEG model. (Bottom) Hypothetical seasonal succession of parasitic and saprophytic fungi. Parasitic fungi of diatoms increase in spring and autumn corresponding to the diatom bloom. During clear water phase when pollen deposition is significant, saprophytic fungi dominate. In summer, diverse parasitic fungi appear corresponding to the phytoplankton community with diverse green algae and cyanobacteria. In autumn, a slight increase of parasitic chytrids infecting diatoms and saprophytic chytrids on cellulosic theca of dead dinoflagellates may occur. Image of parasitic chytrid on diatom *Aulacoseira* sp. courtesy of K. Seto, University of Michigan, US.

able to infect up to 40% of the *Cyclotella* population. Diatoms are well known as preferential hosts for chytrid epidemics. Cyanobacteria which can make up a large proportion of autotrophic biomass in meso -and eutrophic lakes are also infected by chytrids, but epidemics on cyanobacterial blooms have only rarely been reported (Holfeld, 1998; Canter and Lund, 1951). The study by Rohrlack et al. (2013) suggests that oligopeptide production in the toxic cyanobacteria *Planktothrix* is part of a defensive mechanism against chytrid parasitism. In contrast, a case study in the eutrophic Lake Aydat (France) has shown that high prevalence of chytrid infection (almost 100%) can also be reached during an autumnal bloom of the potentially toxic filamentous cyanobacteria *Dolichospermum macrosporum* (Rasconi et al., 2012). In general, strong inter-annual variations in chytrid infections occur due to the complex interplay of several factors, i.e., host density, biotic and abiotic environment and co-evolutionary processes (Gerphagnon et al., 2017; Gsell et al., 2013c; Ibelings et al., 2011). No clear seasonal succession pattern could be observed in the eutrophic shallow Lake Inba (Japan), where diverse fungi infected two dominant diatoms with low prevalence of infection (<10%) (Kagami et al., 2012). These studies highlight that seasonal dynamics of chytrids may not be generalizable to all types of water bodies. Furthermore, they show the importance of long-term monitoring of chytrid-phytoplankton dynamics to understand the implications for plankton communities and food web dynamics.

Fungi in aquatic food webs

Fungi occupy multiple trophic levels in aquatic food webs, functioning as decomposers, consumers (e.g., parasites) or prey. As major decomposers of terrestrial derived organic matter, they hold a key position in coupling aquatic and terrestrial food webs. In the following section, we will introduce different trophic pathways that involve fungi in aquatic habitats with a focus on the "Mycoloop" concept (Fig. 4). Evaluating the trophic contribution of fungi in aquatic food webs and nutrient cycling remains a key challenge, besides identifying their presence, quantifying their abundance/biomass and activity.

Chytrid fungi in pelagic food web—Mycoloop

During epidemic events, when parasitic chytrids infect and kill a large proportion of the dominant phytoplankton species, the consumption by chytrids can account up to 25% of primary production in Lake Biwa (Japan) (Kagami et al., 2006). Similar

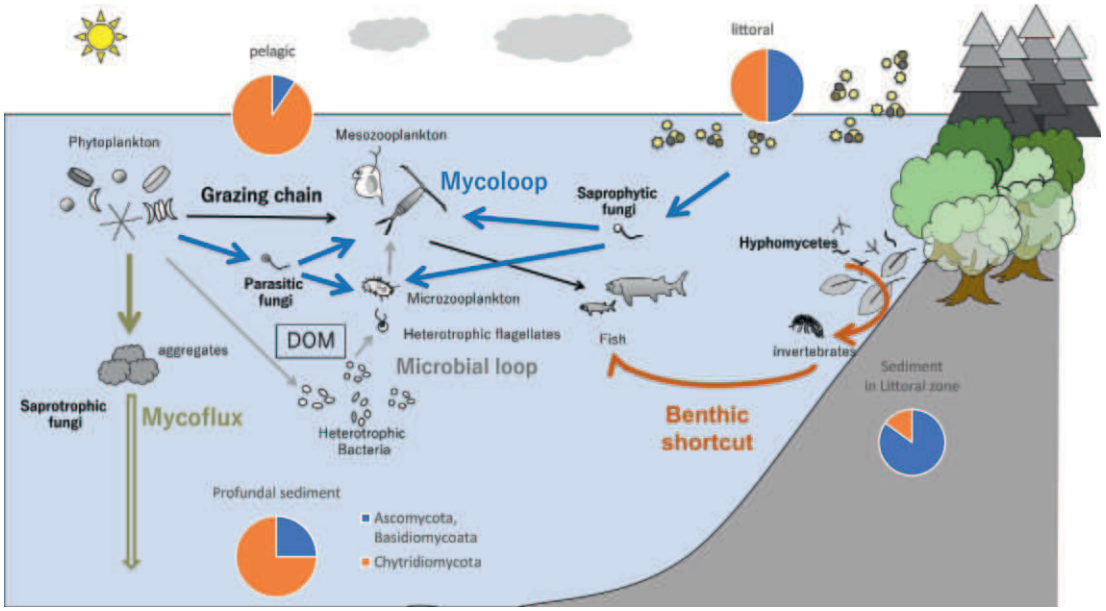

Fig. 4 Roles of fungi in aquatic food webs with community composition. Three major processes by which aquatic fungi transform and incorporate allochthonous and autochthonous organic matter into the food web are highlighted: mycoloop, mycoflux and benthic shortcut. The mycoloop refers to both parasitic and saprophytic fungi rendering inedible phytoplankton/pollens edible to zooplankton grazers either by producing zoospores or by fragmentation of the phytoplankton. The benthic shortcut/shunt refers to fungal colonization of organic litter rendering it palatable for macrozoobenthos on the sediment, which are in turn consumed by fish. The mycoflux describes fungal mediated flux through aggregation or disintegration of organic matter. The consequences are still largely unknown, but it is likely that they greatly affect aquatic carbon pump and sinking fluxes. DOM, dissolved organic matter. Pie charts indicate the general proportions of higher fungi (Ascomycota, Basidiomycota) and Chytridiomycota in each habitat.

percentages have been calculated for the oligo-mesotrophic Lake Pavin (France) (Grami et al., 2011) and eutrophic Lake Aydat (France) (Rasconi et al., 2014). Spring blooms and summer/autumn blooms dominated by large diatoms and toxic filamentous cyanobacteria respectively, are not considered as efficient links in the classical grazer chain. In contrast, chytrid zoospores, which are released after having consumed their phytoplankton host, are high-quality food for zooplankton both in terms of size (2–5 μm in diameter) and nutritional value (rich in polyunsaturated fatty acids PUFAs and cholesterols). This trophic pathway where the biomass of inedible phytoplankton is channeled to higher trophic levels via edible fungal zoospores has been conceptualized in the mycoloop (Kagami et al., 2007, 2014).

Quantifying the mycoloop in the field is challenging because of difficulties in quantifying the abundance and biomass of different chytrid life stages. Chytrids lack ergosterol, and therefore the traditional methods using this biomarker to estimate fungal biomass are not applicable (Gessner et al., 1991). The chitin stain Calcofluor white (CFW) is a fast and easily implemented staining method used to identify attached sporangia stages of chytrids (Rasconi et al., 2009). The density of parasitic chytrid sporangia during epidemics can reach 10^1–10^8 sporangia L^{-1} (Kagami et al., 2014). Limitations of CFW, however, are that it also stains cellulose by binding unspecifically to ß-1-3 and ß-1-4 polysaccharides. More specific chitin stains are based on chitinases or lectins conjugated with fluorochromes (Ota and Kawano, 2015; Wurzbacher and Grossart, 2012). Detection of chytrid infections can be improved by a CFW-WGA (wheat germ agglutinin) dual staining protocol (Klawonn et al. 2021). Recently, the use of phospholipid-derived fatty acid (PLFA) profiles have been evaluated for quantifying fungal groups in mixed communities. Although the method is promising for filamentous fungi, it currently has limitations for the detection of low chytrid biomass (Taube et al., 2019).

It is even more challenging to quantify the biomass of the free living zoosporic stage of chytrids, as the majority of chytrid zoospores lack a cell wall, making the use of chitin cell wall stains not possible. Molecular methods such as real-time qPCR (Lefevre et al., 2010; Maier and Peterson, 2016), and CARD-FISH (Hassett et al., 2019; Jobard et al., 2010) have been applied to quantify zoospores in the field and have detected zoospore abundances in lakes up to more than 600 spores mL^{-1} (Jobard et al., 2010; Kagami et al., 2014). Using CARD-FISH, Jobard et al. (2010) revealed that chytrid zoospores have often been miscounted as HNF (heterotrophic nanoflagellates), with up to 60% of HNF turning out to be chytrid zoospores.

In addition to zoospores as a food source, chytrids can fragment large filamentous cyanobacteria which may become more edible to zooplankton and strengthen the flow of the mycoloop (Frenken et al., 2020; Gerphagnon et al., 2013). Moreover, by synthesizing sterols de novo they upgrade the quality of cyanobacteria-derived organic matter for zooplankton (Gerphagnon et al., 2019). The "mycoloop" may thus substantially support zooplankton growth, especially in eutrophic systems where large inedible algae or toxic cyanobacteria dominate (Haraldsson et al., 2018; Kagami et al., 2014; Miki et al., 2011). Furthermore, in oligo-mesotrophic lakes, the mycoloop has been shown to be important. Using a linear inverse modeling approach, combining field data and parameter values derived from experimental studies, the impacts of parasitic chytrids on the pelagic food web were

quantified (Grami et al., 2011; Niquil et al., 2011; Rasconi et al., 2014). Chytrid epidemics during the diatom spring bloom channeled up to 20% of primary production via chytrid zoospores to the higher trophic levels. Zoospore consumption made up 38% of the microzooplankton diet. This resulted in a higher global trophic efficiency coupled to a higher efficiency of carbon transfer through each trophic level of the grazing chain. Chytrids reduced the sedimentation loss of large inedible algae and their contribution to the detritus pool, therefore less carbon is lost from the pelagic zone. On the other hand, chytrid infection may induce phytoplankton aggregation and enhance phytoplankton sedimentation (Kagami et al., 2005). Quantification of these processes in the field is needed in order to obtain a full understanding of the role of parasitic chytrids play in the aquatic carbon cycle.

Pollen is an important input of allochthonous organic matter to lakes located in forested areas. Unlike leaf litter, pollen grains are rich in phosphorus, and pollen deposition can contribute from 2% to 35% of a lakes total phosphorus loading (Banks and Nighswander, 2000). For the oligo-mesotrophic Lake Stechlin (Germany), situated in a highly forested area, an annual P load of 82.9 kg via pollen has been calculated, accounting for nearly half of the yearly atmospheric P input into the lake (Rösel et al., 2012). Pollen grains are hardly ingested by zooplankton nor are they well degradable by bacteria due to their extracellular wall (exine). Although chemical leaching of macro nutrients from pollen can indirectly stimulate the microbial loop (Rösel et al., 2012), chytrids are among the few microorganisms which are able to directly utilize pollen with high (30–60%) P utilization efficiency (Kagami et al., 2017). Similar to the "mycoloop" pathway described for parasitic chytrids, nutrients from inedible allochthonous pollen are incorporated into aquatic food webs by saprophytic chytrids, and transferred to higher trophic levels via zoospores (Kagami et al. 2014, 2017). When pollen rains coincide with the period of lowest phytoplankton productivity, the presence of highly nutritious fungal zoospores may continue to sustain zooplankton populations for a longer time in lakes (Fig. 3). In those cases, food limitation as a factor controlling zooplankton biomass during the clear water phase may be overestimated compared to losses by predation (Sommer et al., 1986).

The mycoloop can theoretically be further extended to encompass all pathways where saprophytic chytrids channel inedible or less degradable organic matter via zoospores to higher trophic levels. For example, planktonic aggregates or insect and crustacean exuviae, containing large amounts of refractory materials such as cellulose and chitin, can be heavily colonized by chytrids (Karling, 1945; Wurzbacher et al., 2010).

More or less unexplored is the impact of chytrids on the microbial loop. Chytrids can change the quality and quantity of organic matter, which feeds back not only to higher trophic levels but also to the microbial loop (Klawonn et al. 2021b). Chytrids enter with their rhizoids into particulate organic matter (POM) and degrade it with enzymes, which often increase the leakage of dissolved organic matter (DOM) and stimulate the growth of heterotrophic bacteria (Kagami et al., 2007, 2017). As a result, the composition of DOM is changed (Senga et al., 2018). A negative feedback on the microbial loop may also occur due to the competition between chytrids and bacteria for substrates. By quantifying cell-to-cell carbon transfer rates between phytoplankton, parasitic chytrids, and bacteria, Klawonn et al. demonstrate that a substantial part of photosynthetic C is diverted from the microbial loop to parasitic chytrids (e.g. fungal shunt). The "fungal shunt" together with the mycoloop promotes zooplankton-mediated over microbe-mediated remineralization. Fungi:bacteria ratios on pollen have also been shown to vary between lake types with fungi being most prominent in acidic dystrophic water (Wurzbacher et al., 2014).

Many knowledge gaps remain with regards to organic matter transformation pathways mediated by aquatic fungi. The term "Mycoflux" has been recently introduced and refers to currently unknown pelagic fungal interactions leading to aggregation or disintegration of organic matter (Grossart et al., 2019). Fungi actively colonize organic aggregates which may lead to the release of DOM and nutrients into the water, in turn affecting the aquatic carbon pump and sinking fluxes. Besides chytrids, yeast may play a particularly important role in nutrient recycling on plankton detritus aggregates, as peak abundances of yeast in the pelagic have been recorded to coincide with the crash of the annual phytoplankton spring bloom (Quinn, 1984).

Fungi in benthic food webs

In lakes, allochthonous leaf litter inputs can be significant; sometimes contributing up to 10% of primary production in lakes (Gasith and Hosier, 1976). Hyphomycetes are the first colonizers of leaf litter and act as primary degraders of terrigenous carbon which is further conditioned together with bacteria, then mechanically disintegrated by macroinvertebrates (Bärlocher, 1985). Fungi, particularly hyphomycetes, render leaf litter palatable and upgrade its nutritional value by lowering the carbon:nitrogen:phosphorus (C:N:P) ratio (Krauss et al., 2011). This specific pathway is termed the "benthic shortcut", which efficiently channels refractory organic matter up to higher trophic levels (Attermeyer et al., 2013). The contribution of energy from fungal mycelia to the growth of various shredders typically varies between 1% and 59% (Suberkropp, 1992). Filamentous fungi can account for more than 90% of total microbial biomass in emergent macrophytes and leaf litter (Gulis et al., 2009). Fungal biomass largely surpasses bacterial biomass especially during early stages of leaf decay (Findlay and Arsuffi, 1989), whereas at later stages of decay and on smaller organic particles, fungal biomass declines while bacterial biomass remains relatively constant (Findlay et al., 2002; Mille-Lindblom et al., 2006). However, the presence of labile algal POM greatly affects the dominance of bacteria over fungi within the degrader communities, and stimulates the overall decomposition of leaf litter (Danger et al., 2013; Fabian et al., 2017). Fungi primarily contribute to terrigenous C turnover by providing litter C for the microbial loop, whereas bacteria determine whether the supplied C substrate is assimilated into biomass and transported to higher trophic levels or is recycled back into the atmosphere. Environmental conditions such as phosphate availability may have a strong effect on these processes (Fabian et al., 2017).

Emerging fungal diseases (chytridiomycosis) in freshwater

The key drivers of aquatic ecosystem shift (i.e., eutrophication, climate warming with increasing water temperature and UV radiation, brownification, habitat alteration, invasive species and pollution) may impact fungi and their interactions with other species, and alter food web dynamics and biogeochemical cycles. Artificial aquatic ecosystems, such as sewage systems, street gutters, aquaculture and algal farms, may enhance the colonization of fungi including pathogens and parasites (Letcher et al., 2013). In general, the role of aquatic fungi in water quality management and biotechnological applications deserves more attention.

Warmer temperatures

Climate change and other anthropogenically induced stressors are expected to increase the impact of disease on host populations (Daszak et al., 2001). However, interactions between physiological stress and disease are likely to be much more complex. In the Northern Hemisphere, winters are warming at about twice the rate of summers. A consequence of warmer and shorter winters is an earlier onset of phytoplankton spring blooms in temperate lakes. Climate warming may enhance the importance of phytoplankton chytridiomycosis, as under experimental warming conditions a parasitic chytrid infecting the diatom *Synedra* accelerated the termination of the spring bloom, which was dominated by this diatom species (Frenken et al., 2016). The unique long-term study in Lake Maarsseveen (The Netherlands) has shown that cold winters with ice cover inhibit the activity of chytrids that infect the diatom *Asterionella formosa* (Ibelings et al., 2011). Temperatures below 3 °C offer a "cold" thermal refuge for the host (Bruning, 1991a; Gsell et al., 2013b). This provides a disease-free window of opportunity for *A. formosa* to grow before increasing temperatures allow the chytrid to kick in and utilize the large amount of buildup host resources. In contrast, warmer winters without ice coverage allow the chytrid to infect *Asterionella* earlier, at the start of the growing season, resulting in a lower peak of host and parasite abundance, and lower peak of infection prevalence (Ibelings et al., 2011; Van Donk and Ringelberg, 1983). Thus, although infection levels in mild winters are lower than in colder years, chytrid infections act as a species-specific loss factor, reducing the size of *Asterionella* inoculum and weakening its competitiveness (Ibelings et al., 2011). The incidence of ice-free winters is likely to increase in the future and changes in chytrid infection rates of diatoms are expected to have cascading effects on phytoplankton community structure and the entire food web. A shift from large diatoms to a mixed community in years with mild winters may benefit food webs due to the poor edibility of larger diatoms, unless the chytrid zoospores produced during epidemics significantly contribute to zooplankton nutrition (Ibelings et al., 2011; Frenken et al., 2016). Beside a "cold" thermal refuge, *Asterionella* has also a "warm" thermal refuge, with temperatures above 21 °C having a negative effect on the growth of its chytrid parasite (Gsell et al., 2013b). Global warming may therefore reduce the impact of phytoplankton chytridiomycosis during the summer, and facilitate the occurrence of high-density summer/autumn blooms of *Asterionella* due to the chytrid's lower thermal maximum (Gsell et al., 2013a). Negative effects of elevated temperature have also been found for *Batrachochytrium dendrobatidis* (Bd), the chytrid causing disease and worldwide decline in amphibians; amphibians having been reported to clear chytrid infections by seeking high temperature environments (Woodhams et al., 2003). In amphibians, the skin microbiota plays an important role in host defense and temperature dependent antifungal properties of the skin microbiota may provide an alternative mechanistic explanation for patterns of disease susceptibility related to climate change (Woodhams et al., 2014). Additional support for chytrids preferring colder temperatures comes from a long-term seasonal study in Devil's Lake (US), where highest infection levels of the chytrid *Polycaryum laeve* on *Daphnia* occurred between January and March when the lake's surface was frozen, whereas very low prevalence of infection occurred in summer (Johnson et al., 2009). However, the impact of global warming on chytridiomycosis is likely to be species-specific as the location of refugia on the temperature scale may vary from host to host. The study by Rohrlack et al. (2016) identified a large "cold" thermal refuge below 8 °C, inside which the cyanobacteria host *Planktothrix* can grow without becoming infected. In contrast to the *Asterionella*-chytrid systems, temperatures above 21 °C provided no "warm" refuge for this host. *Planktothrix* is well adapted to low light and temperatures and is capable of vertical migration, allowing it to form dense metalimnetic blooms in stratified lakes. The steep temperature gradient in the metalimnetic zone may thus provide a spatial "cold" thermal refuge, protecting a large part of the *Planktothrix* population from chytrid infection and allowing it to form blooms even under suboptimal conditions (Rohrlack, 2018). In both systems intraspecific variability in chytrid susceptibility has been demonstrated which additionally varies with temperature (e.g., host genotype × temperature interactions) (Agha et al., 2018; Gsell et al., 2013b). The effect of global warming on chytridiomycosis is thus more likely to result in species and/or genotype shifts, due to altering temperature-dependent susceptibility of the host and through enabling or disabling thermal host refugia.

Pesticides

Pesticides and other chemical contaminants are a widespread problem in freshwaters because rivers and lakes act as conduits or sinks that transport, accumulate and concentrate chemical pollutants (Relyea, 2009). Environmentally relevant concentrations of several agriculture fungicides significantly reduce chytrid infection, while not affecting the growth of cyanobacteria *Planktothrix* (Ortiz-Cañavate et al., 2019). The application of fungicides has been explored as an approach to control chytridiomycosis in amphibians. However, fungicides paradoxically increased infection and *B. dendrobatidis* induced mortality rates by suppressing the immune response of the amphibian host (Rohr et al., 2017). Pesticides that directly target host physiology, such as herbicides, have been shown to modify infection dynamics and the impact of chytridiomycosis in the *Asterionella*-chytrid system (Van den Wyngaert et al., 2013). Photosynthesis inhibiting herbicides may interfere with host-finding mechanisms of chytrids (chemotaxis) and in this

way can reduce parasite transmission under low host densities (Van den Wyngaert et al., 2014). Similar to herbicides, light limitation also causes a reduction in host photosynthesis and has likewise been shown to reduce chytrid infection on diatoms (Bruning, 1991b; Canter and Jaworski, 1981). Both findings hint towards a general mechanism of chytrid zoospores using photosynthesis-dependent chemical cues to locate their host. If this hypothesis holds true, then any environmental condition impacting host photosynthesis may lead to similar outcomes of reduced chytrid transmission potential. Considering climate change-related increases in humic matter concentration in lakes (e.g., lake brownification) causing reduced light availability, there is an urgent need to increase our knowledge on the general relationship between light and phytoplankton parasite interactions. The free-living zoospore stage of chytrids, which lacks a cell wall, is presumably the most vulnerable stage to adverse external environmental factors. When considering control strategies for chytridiomycosis, the zoosporic stage may thus be the preferred target (Frenken et al., 2019).

Conclusion

Advances in next generation sequencing technologies have given a new boost to aquatic mycology, unveiling a high diversity of molecularly uncharacterized fungal diversity in a variety of aquatic habitats. In particular, early diverging zoosporic fungal lineages, including chytrids, Aphelidiomycota and Rozellomycota, show a great potential for filling current research gaps concerning aquatic biodiversity and ecology in freshwater lakes. Chytrids are the dominant fungi in the pelagic zone of lakes, interacting with phytoplankton and other microbes as parasites or saprophytes. As they are partly being re-discovered, the integration of morphological and molecular tools has also identified novel species and interactions, refining chytrid host/substrate utilization and specificity. This is important as chytrids have, in addition to the role of physical factors, grazing and nutrient limitation, a substantial role in driving seasonal succession of plankton in lakes. Advances have been made in estimating the impact of chytrids in pelagic food webs and nutrient cycling via the Mycoloop, which still needs to be further evaluated. In general, assessing the ecological relevance of fungi in overall biogeochemical cycling still faces methodological challenges to reliably quantify biomass and activity of different fungal groups in mixed microbial communities. Species-specific variation and non-linear dynamics of host-chytrid interactions impede clear-cut predictions about the impact of anthropogenic change on chytridiomycosis.

Knowledge gaps

- Functional diversity (e.g., substrate specificity) of aquatic fungi across broader taxonomic groups
- Quantifying fungal biomass and activities within microbial communities to assess their relative contribution to biogeochemical processes
- Other organic matter transformation pathways and nutrient recycling mediated by aquatic fungi, such as Mycoflux
- Symbiotic relationships between fungi and plankton
- Life form and roles of yeasts in food web and biogeochemical cycling
- Degradation and detoxification of pesticides, pharmaceuticals and microplastics by fungi
- Anthropogenic impacts on fungal mediated interactions and its consequences
- Lack of studies on quantification of chytrid-phytoplankton dynamics in different types of freshwater ecosystems to understand relevance for plankton communities and food web dynamics.
- What are the factors driving spatial and temporal variation in phytoplankton susceptibility to chytrid infection?

Protists: Flagellates and Amoebae[☆]

Robert W Sanders, Department of Biology, Temple University, Philadelphia, PA, United States

This article is an update of R.W. Sanders, Protists, in Encyclopedia of Inland Waters, edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00131-9.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Benthic/benthos Associated with the sediment or bottom of a body of water.
Cyst A cell state within a continuous enclosure by an extracellular matrix during which the cell exhibits little activity; often used to increase survival during unfavorable environmental conditions.
Detritus Dead organic matter.
Flagellum In eukaryotes, a filamentous membrane covered structure with a skeletal component of microtubules used for movement and feeding.
Heterokont A flagellate that possesses two different types of flagella, one usually with flagellar hairs (mastigonemes); typical of many Stramenopiles.
Lorica An organic or inorganic casing or shell that incompletely surrounds a cell, sometimes called a test.
Mixotrophy The use of energy from the sun to take up nutrients and grow combined with the ability to ingest and digest prey. Some consider the symbiotic relationship between heterotrophic protists and phototrophic protists to be a form of mixotrophy.
Nanoflagellate A general description of flagellates between 3 and 20 μm in size, used mostly in ecological studies where their small size and preservation techniques preclude more precise identification.
Osmotrophic A form of nutrition in which soluble compounds are taken up by the organism.
Periphyton Photosynthetic microorganisms living attached to rocks or other surfaces; sometimes used to describe the whole community of prokaryotes and microbial eukaryotes associated with this layer.
Phagocytosis To ingest food particles by enclosing them in a membrane to internalize and form a food vacuole.
Plankton Organisms living suspended in the water column; many can swim, but are incapable of resisting currents.
Pseudopodia Transient extensions of the cell surface used for locomotion and feed in amoeba and some flagellates includes subtypes filopodia (thread-like) and lobopodia (broad), as well as the internally supported axopoda.

[☆]*Change History:* October 2021. RW Sanders prepared the update. All sections, tables and figures were revamped. Antonio Guillén provided all of the photomicrographs, but Sanders combined them into the final two figures. Original article included ciliates, but that was assigned to another author as a stand-alone chapter.

What are protists?

The protists are a diverse group of distantly related eukaryotes that includes most of what have been historically called protozoa (ciliates, amoeba, and heterotrophic flagellates) plus, in aquatic systems, phytoplankton and periphyton. The term is one of convenience used to describe an assemblage of eukaryotic organisms that falls outside of the multicellular groups of animals, land plants and fungi. Being thus defined by exclusion, the term protist is not phylogenetically useful. However, most of the high-level diversity in the eukaryotic Tree of Life (eToL) results from the organisms grouped as protists and identified, to a large degree, using molecular phylogenetics (Burki et al., 2020).

Like other eukaryotes, protist cells possess at least one membrane-bound nucleus plus endoplasmic reticulum and other organelles that can include mitochondria, chloroplasts and flagella or cilia. Some protists are colonial or related to multicellular groups, but none develop tissue. The different ecological roles filled by protists within morphologically recognized phyla led to some subgroups historically being described by both zoological and botanical nomenclature. Many monophyletic lineages (clades) include a mixture of taxa from both of the "International Codes" ("Nomenclature for algae, fungi, and plants" and "Zoological Nomenclature") (Adl, et al., 2019). For example, many dinoflagellate genera contain both phototrophic (most now recognized to be mixotrophic) and heterotrophic species; some euglenids can even switch from phototrophy to heterotrophy when photosynthetic species are induced to lose their chloroplasts and survive using dissolved organic matter for energy and carbon.

The protists do have lineages that are properly organized to represent evolutionary relationships. Some clades, which are groups of ancestral species and all their known descendants, include only protists. Alveolata (ciliates, dinoflagellates and apicomplexa), Rhizaria (amoeba and amoeba-flagellates with fine pseudopods or filopodia), and Euglenozoa (euglenids, kinetoplastids, and diplonemids) typify purely protistan clades. Other clades, however, indicate a shared ancestry between some protists and plants or animals that is closer than their evolutionary relationship to other protistan groups. For example, the choanoflagellates group with true fungi, chytrids and animals as Opisthokonts, and the green algae, including common freshwater species like *Chlamydomonas* and *Volvox*, group with the Viridiplantae. The Stramenopile clade also contains protist (e.g., diatoms) and multicellular organisms (e.g., kelps and other brown macroalgae).

As one might expect from such an evolutionarily and ecologically diverse group, making generalizations about the protists must be a cautionary exercise. Yet, for the practicing field biologist or ecologist, the small size and functional similarities of many of the protists makes grouping them together a rational practice. Subdivisions based on movement are usually easily distinguishable with light microscopy and are retained here, not because they reflect current understanding of phylogeny, but rather because they often reflect niches and form the basis of much of the study of community ecology in freshwater protists to date. The classification of these protists is represented here in Tables 1 and 2, in which some common members of freshwater flagellates and amoebae are arranged at the higher taxonomic ranking following the "nameless-rank" classification system of Adl et al. (2019). This classification scheme considers the taxonomic endings to be accidents of history without the traditional hierarchical meaning of past classification codes. Higher rankings found in both tables, indicating the taxonomic overlap of the flagellates and amoebae, include Opisthokonta, Stramenopiles, Rhizaria and Discoba.

Morphological groups

Flagellates

Flagellates have one-to-many flagella that function in motility, attachment to a substrate, and also for feeding. They are diverse (Table 1 and Fig. 1) and are the most numerous of the freshwater protists, reaching abundances in eutrophic systems that can approach 10^5 cells mL^{-1} and 10^6 cells cm^{-3} in the plankton and sediments, respectively. Purely heterotrophic free-living flagellates include choanoflagellates and bicosoecids. Choanoflagellates, with a distinctive "collar" of microvilli/pseudopodia used to trap bacteria and a single flagellum to create water currents, can have a lorica that is sometimes difficult to see with light microscopy. In fresh waters they are most often attached and/or colonial. Bicosoecids are heterokonts—possessing two different types of flagella—and often are attached by one of the flagella to a lorica or to the substrate. Cercozoans have two flagella but are amoeba-flagellates that use pseudopodia for feeding. Some species traditionally considered as amoeba also are now classified as Cercozoa (see below).

Among the several taxa of photosynthetic flagellates most groups have members that are wholly heterotrophic or that combine photosynthetic and heterotrophic nutrition (mixotrophy). Dinoflagellates, chrysomonads, euglenids, and cryptomonads have numerous phagotrophic or osmotrophic species that lack chloroplasts (Patterson, 2000). Phagotrophy of bacteria or protists by chloroplast-containing species also has been reported for dinoflagellates, chrysomonads and cryptomonads, and is discussed further below and elsewhere in this volume.

Many recent ecological field studies separate flagellates into different groups based primarily on size. This is most common in examinations of the microbial food web, where assemblages of heterotrophic nanoflagellates are enumerated collectively due to their high abundance, importance as bacterivores, and the difficulty of separating taxa in preserved samples (e.g., Šimek et al., 2018). This size-based assemblage originally described nanoplankton as $\leq$20 μm in diameter, but flagellates $\leq$5 μm often numerically dominate nanoplankton. It is difficult to separate individuals this small into different taxonomic groups by light microscopy; even division into functional groups of photosynthetic versus heterotrophic flagellates is problematic without proper

Table 1 Some common genera of heterotrophic flagellates.

Group	*Genera*	*Comments*
Opisthokonta		
Choanoflagellata		
Salpingoecidae	*Monosiga*	Phagotrophic flagellates with a single flagellum surrounded by cytoplasmic "fingers" used in feeding on bacteria; mostly sessile/attached; *Salpingoeca* with an organic theca (sheath)
	Salpingoeca	
Stramenopiles		Motile cells typically biflagellate and heterokont with tubular hairs (mastigonemes) on anterior flagella
Bigyra		
Opalozoa	*Bicosoeca*	Predominantly sedentary in a lorica, filter feed on bacteria
Ochrophyta	*Actinomonas, Ciliophrys*	Pedinellids, single flagellum, often radiating filopodia, usually stalked, feed on bacteria
	Paraphysomonas	One short and one long flagella; silica spines on cell body used to identify species requires electron microscopy
	Pedinella[a]	Apple-shaped with a posterior stalk and a single apical flagellum
	Pseudopedinella[a]	Most common in oligotrophic systems
	Spumella (Monas)	Colorless, nearly identical to *Paraphysomonas* using light microscopy
	Ochromonas[a]	Typically with chloroplast, which may be reduced in mixotrophic populations using osmotrophy or phagotrophy
	Uroglena[a]	Colonial, all photosynthetic, mixotrophic
Rhizaria		
Cercozoa	*Cercomonas*	Bacterivorous with pseudopods; glide on surfaces using long posterior flagellum
Haptista		
Haptophyta		
Prymnesiophyceae	*Chrysochromulina*[a]	Autotrophic, mixotrophic or heterotrophic. Mostly single cells; some in colonies; motile cells mostly possessing a haptonema, a filiform appendage situated between a pair of flagella
Cryptista		
Cryptophyceae	*Goniomonas, Chilomonas*	Bacterivorous; primarily photosynthetic species, some of these with low rates of phagotrophy reported (mixotrophy); *Chilomonas* species were recently reassigned, with freshwater members assigned as heterotrophic *Cryptomonas*
	Cryptomonas[a]	
Alveolata		
Dinoflagellata	*Gymnodinium*[a]	Two flagella, one horizontal around cell that gives slow spinning motion when swimming; photosynthetic, predatory and mixotrophic species
Discoba		
Euglenozoa	*Peranema, Entosiphon, Astasia*	Most euglenids have two flagella emerging from an anterior pocket, with one trailing and usually in contact with the substrate. Colorless species ingest detritus, bacteria and/ or are osmotrophic.
Euglenida		
Kinetoplastea	*Bodo, Rhynchomonas*	Only two common genera of free-living kinetoplastids; generally glide on substrates and ingest attached bacteria.

Some rankings are tentative. Most of the higher groups include photosynthetic flagellates, many of which combine phototrophic nutrition with phagocytosis (i.e., are mixotrophic).
[a]Genera with known mixotrophic species.

fixation and slide preparation methods (Sherr et al., 1993). Consequently, care must be taken to determine if literature reports combined all small protistan cells into one trophic category or functionally divided groups into autotrophic and heterotrophic forms (usually based on the presence or absence of chloroplasts). Differentiation of these forms is commonly based on epifluorescence microscopy with stains that highlight the cells' cytoplasm and filter sets that identify chloroplasts by their red autofluorescence. Flow cytometry is another useful tool that can separate autotrophs from heterotrophs based on fluorescence and size from light-scatter signals. Heterotrophic flagellates larger than 20 μm are typically much less abundant than nanoflagellates and include many, but not all, of the dinoflagellates and euglenids. These species often are more easily identified by light microscopy, either live or in preserved samples, because of their larger size; epifluorescence microscopy is also an appropriate method for enumeration.

Amoeboid protists

Amoebae are plastic cells that generally lack a fixed external morphology, although some inhabit capsules or lorica and are less plastic. They move primarily using pseudopodia with shapes that vary in different taxa from finely pointed and branching filose extensions to blunt lobopodia. Several amoeboid groups become flagellated during temporary swimming stages for dispersal, and some of these, including the stalked heliozoans ("sun animicules"), have affiliations with Stramenopiles (Table 2).

Amoebae are common on surfaces and in the sediments of freshwaters (mostly in the top cm), reaching abundances greater than 10^3 cm^{-3} in eutrophic lakes (Fig. 2). Amoebae are usually less numerous in the plankton compared to the sediment but may also be concentrated in a microlayer associated with the air-water interface. Testate amoebae have vase-shaped or spherical coverings from which the pseudopods extend, and some of these species form oil droplets or gas vacuoles that reduce their density and allow them to rise from the sediment into the plankton. Non-testate planktonic amoebae may take on stellate floating forms, a flagellated

Table 2 Some common genera of amoeboid protists with comments on habitat and food.

Group	*Genera*	*Comments*
Tubulinea		
Elardia		
Euamoebida	*Amoeba, Chaos*[a], *Hartmannella*	Food is bacteria and/or small protists (cytotrophic)
Arcellinida	*Arcella, Difflugia*[a]	Testate/shelled, benthic and planktonic stages; omnivores, algae, *Difflugia* is a diatom specialist
Discosea		
Flabellinia		
Dermamoebida	*Mayorella*[a]	Omnivorous, predators of protists, detritus
Vannellida	*Vannella, Platyamoeba*	Benthic and planktonic; food primarily bacteria
Centramoebia		
Acanthopodida	*Acanthamoeba*	Some species are facultative human pathogens, infecting eye and CNS; normally food is bacteria
Opisthokonta		
Rotosphaerida	*Nuclearia*	Food is bacteria, cyanobacteria
Stramenopiles		
Gyrista		
Actinophryidae	*Actinosphaerium*[b], *Actinophrys*[b]	Planktonic or mobile benthic; food includes other protists, rotifers
Centroplasthelida		Planktonic or mobile benthic; food is other protists/phytoplankton
Panacanthocystida		
Pterocystida	*Acanthocystis*[b], *Heterophrys*[b], *Chlamydaster*[b], *Raphidiophrys*[b]	
Rhizaria		
Cercozoa		
Granofilosea	*Clathrulina, Hedriocystis*	Benthic, sessile, often stalked, sometimes colonial; food is fine particulate matter, including bacteria
Discoba		
Heterolobosea		
Tetramitia	*Naegleria, Tetramitus, Vahlkampfia*	Food is bacteria/cyanobacteria; some *Naegleria* strains are facultative human pathogens (amoebic encephalitis)

Many amoebae have flagellated stages, and flagellated forms dominate the life stages of some groups (e.g., Stramenopiles, Cercozoa; see Table 1).
[a]Some species with zoochlorellae or photosynthetic symbionts; which can fall into the definition of mixotrophy.
[b]Heliozoans have some general similarities, which include axopodia (radiating pseudopodia stiffened by microtubule arrays), but the group is not monophyletic. With an extracellular capsule or lorica attached to substrate or free-floating cell, sometimes with a mucous sheath around cell. With biflagellate and amoeboid stages; can be colonial.

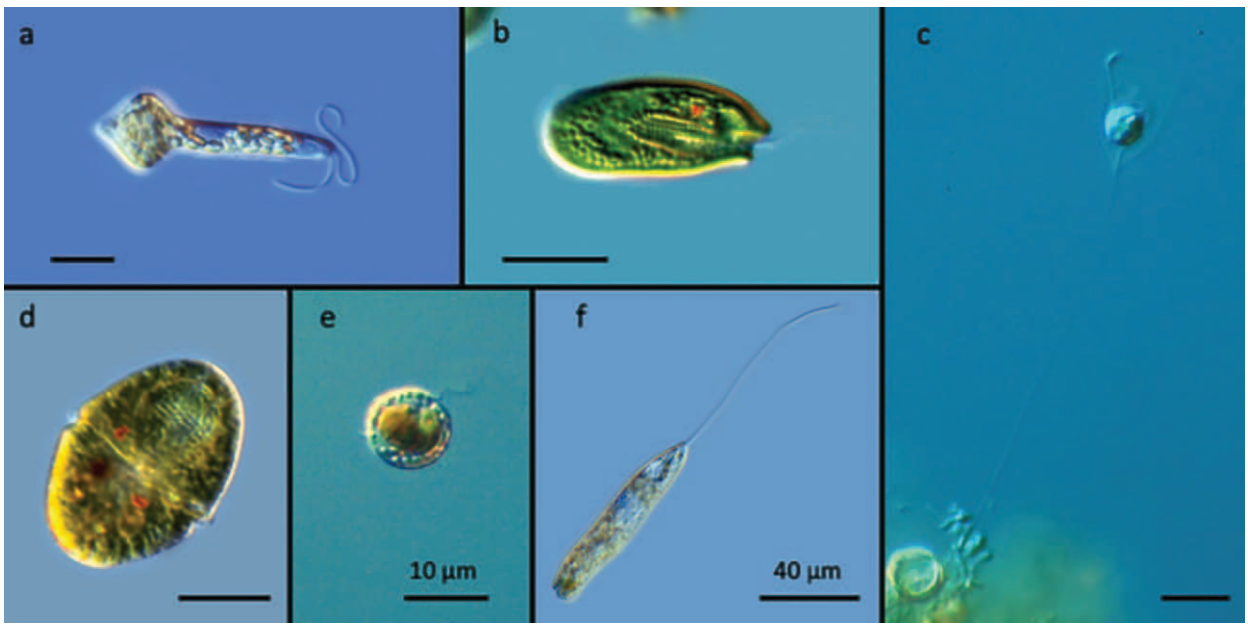

Fig. 1 Photomicrographs of representative flagellates. (A) *Astasia*, a colorless euglenid that can actively distort cell shape; biflagellate, but typically only one flagella emerges from anterior pocket; (B) *Cryptomonas*, with numerous polysaccharide storage bodies; only one of the two flagella is visible here; (C) *Bicosoeca*, immotile cell in a lorica with a long stalk and typically attached to a surface; (D) *Gymnodinium*, one flagella is in an equatorial groove, the second trailing flagella is not visible here; (E) *Ochromonas*, biflagellate with chloroplast and phagocytic capabilities, i.e., mixotrophic; (F) *Peranema*, another colorless euglenid that captures live prey via a unique mechanism using two ingestion rods near the tapering anterior pole. Scale bar 20 µm unless otherwise noted. Photo credit: Antonio Guillén.

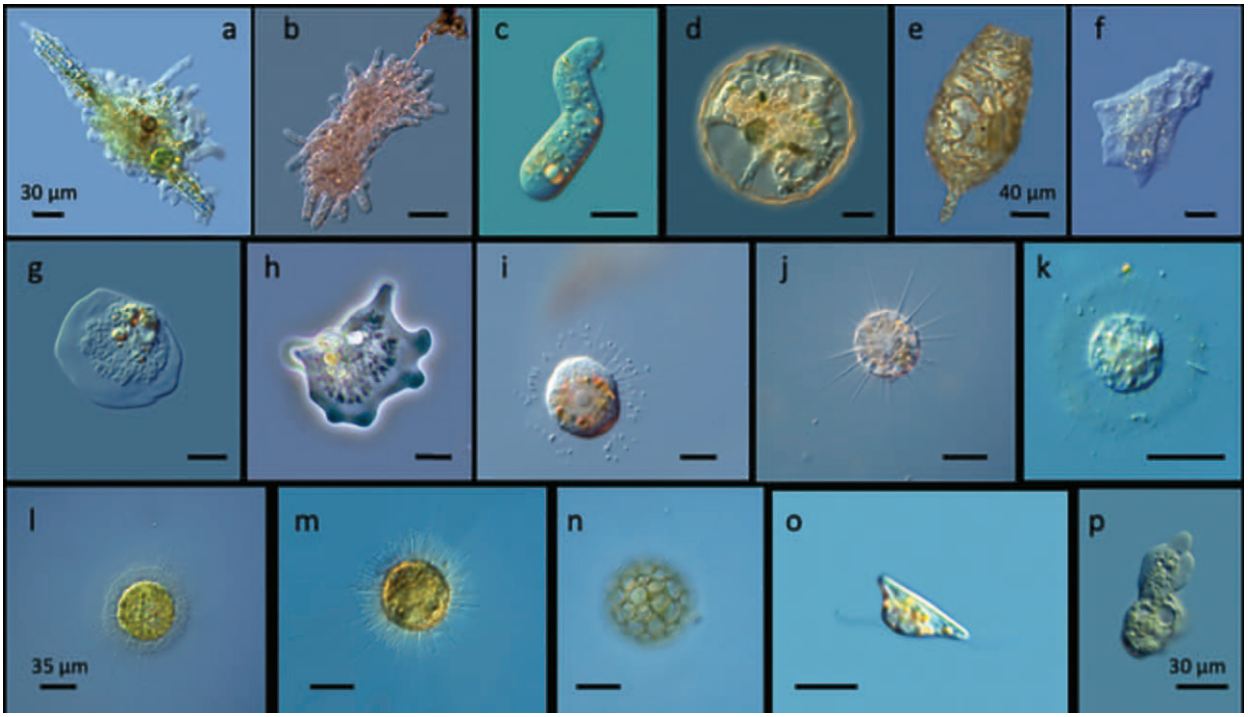

Fig. 2 Photomicrographs of representative amoebae. (A) *Amoeba*, with ingested diatom; (B) *Chaos*, similar morphology to *Amoeba* but with many nuclei; (C) *Hartmannella* moves by steady advance of the usually single pseudopod rather than the erratic, eruptive progress; (D) *Arcella*, viewed through circular test which has a hole where finger-like pseudopods emerge; (E) *Difflugia*, with tubular test; (F) *Mayorella*; (G) *Vannella*, locomotive form commonly fan-shaped, often semi-circular with broad hyaline margin; (H) *Platyamoeba;* (I) *Nuclearia*; (J) *Actinophrys*, pseudopodia extending from all parts of the body with axial filaments arising from the membrane of the single nucleus; (K) *Chlamydaster*, cell body surrounded by a mucus envelope through which axopods extend; (L) *Heterophrys*, mucous coat that often seems grainy with many radial organic spicules; (M) *Acanthocystis*, (N) *Clathrulina*, extracellular capsule attached to substrate with axopodia (not visible here) that emerge from perforations; (O) *Naegleria*, (P) *Vahlkampfia*. Scale bar 20 µm unless otherwise noted. Photo credit: Antonio Guillén.

morphology, or associate with floating detrital aggregates, none of which are taxa specific. Heliozoans are a polyphyletic group (Cavalier-Smith et al., 2015) that have some amoeboid characteristics in that they form specialized pseudopods strengthened with a microtubular array (axopods). Heliozoans are not unusual in the plankton, but they are primarily benthic predators that use the axopods to capture mobile prey such as ciliates from the water. Some species are attached to the substrate by stalks and others tumble across the sediment by changing the lengths of the axopods.

Beyond motility, most amoebae also use pseudopods to capture and/or engulf small prey including bacteria, algae and detritus. Some amoebae, including *Nuclearia delicatula* and some *Mayorella* and *Naegleria* species are specialized predators of larger particles such as filamentous cyanobacteria, and can rapidly reduce prey abundances in lakes. Photosynthetic endosymbionts are associated with several amoebae, including a heliozoan (*Acanthocystis turfacea*). This relationship is even reflected in the species names of some amoebae—both naked (*Chaos zoochlorellae, Mayorella viridis*) and testate (*Paulinella chromatophora*). Despite the widespread occurrence of some of these freshwater amoebae-algal symbioses, the degree to which the algae contribute to the nutrition of amoebae has not been well studied.

Some amoebae, including *Naegleria fowleri* and one or more *Acanthamoeba* species are facultative pathogens of humans and are the causative agents of amebic meningoencephalitis. These amoebae invade via mucus membranes of the eye or nasal passage of human swimmers, typically immunosuppressed individuals, in warm fresh waters, including unchlorinated swimming pools (Maciver et al., 2020).

Reproduction and population growth

Flagellates and amoebae reproduce asexually by binary fission, which can lead to rapid population growth. For heterotrophic protists, population growth rates are generally positively related to food concentration and temperature up to some critical level, and negatively related to species cell size. However, generation times are highly variable and maximum population growth rates of some species with relatively large size can approach those of much smaller protists. Populations of many protists can double several times per day in laboratory situations, although cell division rates of one to several days are probably more realistic for natural populations where food may limit growth. Protistan productivity in natural systems, particularly in the benthos, is not well documented and is likely higher than is generally recognized. Population growth can also be limited via predation by zooplankton,

benthic invertebrates and often other protists such as dinoflagellates and ciliates. However, the high potential growth rates enable heterotrophic protists to persist even during periods of high predation, and to respond rapidly to increases in fast-growing prey such as bacteria and photosynthetic protists.

Sexual reproduction is known for many protists but some are considered asexual, although it is difficult to determine if a protist species is entirely asexual and "absence of evidence does not constitute evidence of absence" (Maciver, 2019). When observed, sexual reproduction takes varied forms in protists, but some of the essential features are formation of gametic cells or nuclei, fusing of the nuclei and halving of the chromosome number at some point in the life cycle. Sex in protists is rarely associated with increases in population size; its occurrence interrupts asexual reproduction and the rapid population growth associated with binary fission. Sex appears to be essential for preventing senescence and extinction of clones for several protists, but is still unknown in many amoebae, in particular. Autogamy, in which the meiotic products fuse in the same cell is the normal pattern in the heliozoan *Actinophrys*. When sexual reproduction does occur, it is usually linked to environmental change, and in many cases to formation of cysts.

However, cyst formation is not always associated with sex in protists. Some protists undergo binary division in cysts, while others do not increase in number during encystment. Whether or not encystment is associated with reproduction, it is frequently a response to environmental stress. For example, *Acanthamoeba*, common in temporary bodies of water and soil, will encyst due to a variety of signals that are linked to drying out. Food shortage, increased salt concentrations, high temperature, and low oxygen all can initiate formation of desiccation-resistant cysts. For species associated with temporary aquatic habitats, this can be an important means of survival as well as dispersal.

Distribution

In the pelagic zone (water column)

Protists are able to position themselves in the water column through several mechanisms including production of gas or lipid vacuoles noted previously for the testate amoebae *Difflugia*. However, swimming with flagella is the most common way that motile algae and heterotrophic flagellates position themselves in response to a variety of gradients in a stratified water column. Light requirements compel phototrophs to maintain themselves in the euphotic zone where there is enough light to support photosynthesis at least some of the time, but many phototrophs will swim deeper to avoid bright light. Motile photosynthetic organisms with algal symbionts, such as some dinoflagellates (and ciliates), are known to migrate toward the surface in the morning and into deeper, potentially nutrient-richer layers, later in the day.

Most heterotrophic protists tend to respond to other environmental parameters such as food abundance or oxygen. The greatest numbers of bacterivorous protists are associated with areas of higher bacterial production. In contrast, algivorous protists will tend to accumulate in layers where light and nutrient levels are best for their photosynthetic prey. Some free-living heterotrophs, including the flagellates *Hexamita* and *Trepomonas*, are common in areas of sediments (see below) and the hypolimnetic layers of eutrophic waters where high organic enrichment leads to low oxygen or anoxia. The amoeba-flagellate *Mastigamoeba* lacks mitochondria and so its distribution is limited to anoxic water.

Aggregates of detritus occur in the water column (as well as the benthos) and these will often have higher abundances of bacteria. As noted above, increases in bacterial prey lead to higher abundances of heterotrophic protists on these microhabitats relative to the surrounding water—especially in oligotrophic systems (Caron, 1991). Occurrence of "benthic" protists, such as the flagellate *Bodo*, in the water column may be due to association with these aggregates. Another distinct habitat, the air-water interface, also can be enriched with protists that use the surface as a substrate. Both naked and testate amoebae, such as *Arcella*, and some flagellates (e.g., *Codonosiga*) can hang below or move atop the water's surface feeding on bacteria or phototrophs growing there.

There tends to be strong seasonal changes in the abundance and species composition of aquatic protists. Phototrophic species often decline in winter and increase again with the longer days and greater light intensity in the spring. Bacterial activity increases with autotroph activity since the photosynthetic organisms release dissolved organic matter that supplies substrate for bacteria. Heterotrophic protist populations then will increase in response to abundance of algal and bacterial prey. Temperature also tends to be positively related to protistan population growth rates, so the low photosynthesis and low growth rates of winter lead to minimum abundances of flagellates and amoebae, while their productivity tends to increase in warmer seasons.

Sediments and hard substrates

The benthic habitat in both lake and stream systems tends to accumulate organic matter and detritus, which offers both a food source and a habitat for benthic protists. Attached and motile protists can occur in high numbers on and in the sediments. Attached heterotrophic organisms typically create a current to bring suspended food from the water (e.g., *Bicosoeca*, Fig. 1), or allow material to fall or swim into specialized feeding appendages (e.g., heliozoan axopodia). Phototrophic species can form mats or biofilms, especially on hard substrates that often have high abundances of cyanobacteria with or without protistan phototrophs. Motile protists move on and through these biofilms, and also at the surface and within the sediment. In sediments with relatively high organic matter content, gradients set up with sediment depth including change in oxygen, redox potential, pH and other chemicals. As noted for the plankton above, species that prefer oxic, microaerophylic, or anoxic environments will move to appropriate depths in the sediment or will even leave the sediment and move into the water column. The sediments are a source of the anaerobic protists that appear in the water column when anoxic hypolimnia develop, typically during summer, in stratified lakes.

Ecological roles and the dynamics of protists in freshwater systems

Primary production

Although the influx of terrestrial carbon and its utilization in aquatic systems suggest that many lake and stream systems may tend toward net heterotrophy where ecosystem respiration exceeds primary production (e.g., Tranvik et al., 2009), photosynthesis still contributes significantly to the food webs of freshwater systems. Protists, including periphyton and phytoplankton, are major contributors to total aquatic primary production and respond prolifically to eutrophication in lakes and marine systems. Globally, phytoplankton account for about half of the photosynthesis on the planet. However, lakes and rivers make up only a small proportion of the surface water of the earth with a total contribution from freshwater phytoplankton of only about 1% of net global photosynthetic carbon fixation from aquatic and terrestrial ecosystems (Dokulil and Qian, 2021).

Photosynthetic species dominate the protistan biomass in the euphotic zones of lakes, but size, depth and nutrient concentration of a lake contribute to whether phytoplankton are the major primary producers. The deeper the lake and the less nearshore shallows (littoral zone), the more pronounced the phytoplankton contribution to primary production because less of the benthic area is within the euphotic zone. In addition, lakes are not uniformly distributed around the earth, so regional freshwater primary production also depends on climatic zone, latitude and altitude.

If dissolved nutrient levels are sufficient, phytoplankton also can reduce the light reaching sediments, and consequently shade the communities of periphytic algae (including photosynthetic protists) and submerged macrophytes. In shallow lakes, eutrophication may thus lead to a switch from a benthic to a pelagic dominance of primary production. In oligotrophic systems, benthic protists can contribute more to whole lake primary production; light attenuation does not so strongly limit photosynthesis in deeper water and nutrients are available from the sediment. In streams and rivers, water depth and sediment load similarly affect the relative importance of the periphyton and phytoplankton, with periphyton contributing relatively more in low to middle order streams where more light reaches the benthos.

Mixotrophy in protists

There is a range of mechanisms by which mixotrophs combine photosynthesis with heterotrophy in a single organism (Mitra et al., 2016). Consequently, we see considerable variability in the physiological abilities and relative importance of phototrophy versus phagotrophy and/or osmotrophy in mixotrophs. Light and nutrient levels affect the grazing of many mixotrophs, some seeming to increase phagotrophy when these resources are limiting (Princiotta et al., 2016; Lie et al., 2018). Mixotrophic dinoflagellates (e.g., species of *Peridinium* and *Gymnodinium*) may be the dominant bacterivores (Hitchman and Jones, 2000), though this is probably rare. However, the combined mixotrophs, primarily chrysophyte (e.g., *Dinobryon*, *Ochromonas*), prymnesiophyte (*Chrysochromulina*) and sometimes cryptophyte flagellates, can sometimes have a greater grazing impact on planktonic bacteria than all the heterotrophs (Sanders et al., 1989).

Food webs and protists

The microbial loop concept, as developed for planktonic marine systems nearly 40 years ago (Azam et al., 1983), recognized that bacterioplankton incorporate dissolved organic matter into biomass and that bacteria are subsequently ingested by heterotrophic protists. Thus, fixed organic carbon that was once considered unavailable to most pelagic organisms could be recovered and funneled into the rest of the pelagic food web via a protistan link. In freshwater systems, heterotrophic protists tend to be the major consumers of bacteria, and heterotrophic flagellates alone can sometimes remove more than 100% of the daily planktonic bacterial production. The usual dominance of bacterivory by heterotrophic flagellates reflects their high abundances, but ciliates and mixotrophic protists also can strongly reduce the abundance and alter the species composition of bacterioplankton—as can rotifers and cladocerans (Sanders et al., 1989). These multiple trophic pathways moving microbial biomass into the higher trophic levels suggest that the "microbial loop" should be considered a highly dynamic and persistent component of aquatic food webs rather than an independent entity that is distinct from the primary production-herbivore trophic pathway.

The impact of heterotrophic protists feeding on phototrophic protists in the freshwater plankton has received less attention than the trophic interactions of protists and bacteria. Many species of ciliates, amoebae and dinoflagellates ingest phytoplankton, but rotifers and crustacean zooplankton tend to cause more phytoplankton grazing mortality. Still, amoebae and ciliates can reduce populations of larger phototrophs. For example, the amoeba *Nuclearia* has been investigated as a potential biocontrol agent due to its high ingestion rates when feeding on filamentous algae and cyanobacteria (Sigee et al., 1999). In sediments, protistan herbivory accounts for $<5\%$ of periphyton production. Likewise, studies to date suggest that protists ingest only about 5% of the daily bacterial production in sediments despite having feeding rates similar to those measured in the plankton. Under long-term anaerobic conditions bacterivory by benthic protists may be relatively more important as metazoan diversity decreases, but comparative studies are lacking.

Higher trophic levels (metazoa) utilize autotrophic and heterotrophic protists in planktonic and benthic environments in freshwater and marine systems (Sanders and Wickham, 1993; Stoecker and Pierson, 2019). As noted above, autotrophic protists have long been recognized as the base of most aquatic food webs. Zooplankton and suspension feeding benthic organisms capture phytoplankton, and browsers/scrapers such as snails and various aquatic insects ingest periphyton. Heterotrophic protists, which can be as abundant as autotrophs and overlap in size, are ingested incidentally by these "herbivorous" metazoans that feed by either size- or non-selective methods.

Predation by metazoans and other protists impacts populations of heterotrophic protists. Ciliates can be important predators of flagellates in the plankton and benthos; most heliozoans (and suctorian ciliates) also feed on other protists. Predator removal (or addition) experiments in lakes demonstrated that moderate grazing by crustacean zooplankton can balance or exceed protistan population growth, and that selective feeding can alter protistan community structure. And though summer "clearwater" phases observed in many lakes generally refer to a reduction in phytoplankton, predation by zooplankton also substantially reduces heterotrophic protist populations during these phases as well. In aquatic systems, it is likely that heterotrophic protists contribute to the diet of at least some life stages of most zooplankton, many fish, mollusks, and aquatic insects that also feed on photosynthetic protists.

Nutrient cycling

The transfer of nutrients through different chemical states and ecological compartments (biotic and abiotic), biogeochemical cycling, is tightly linked to microorganisms—especially in aquatic systems where protists dominate primary production. Availability of dissolved phosphorus and/or nitrogen limits primary production, and recycling is most important where allochthonous input of N and P is low. Heterotrophic protists can be efficient nutrient remineralizers, depending on the nutrient content of their prey, and contribute to phytoplankton nutrient demand in the epilimnion of stratified lakes when measurable dissolved nutrients are low. Recycling often leads to high nutrient retention in benthic systems within the photic zone of lakes and streams. In the benthos, phototrophic and heterotrophic microorganisms, both prokaryotic and eukaryotic, tend to live in close proximity and often within boundary layers that can lead to localized nutrient limitation and a subsequent importance of recycling.

Conclusion-synthesis

Flagellates and amoebae are ubiquitous in freshwater systems. They exhibit an unequaled taxonomic diversity and a huge range of ultrastructure, physiology and ecology. These protists play important roles in aquatic food webs as primary producers, as conduits of bacterial production to higher trophic levels, as algivores and as predators of other heterotrophs; some ingest a broad range of particles, while others feed more selectively. Many of these protists are difficult to identify because of their small size or because specialized handling in preservation, staining or cultivation is needed to distinguish them. These restrictions have started to be overcome in recent decades as the use of DNA/RNA-based tools and high-throughput sequencing has increased. These molecular tools have boosted the discovery of rare and new species and allowed wide-ranging comparative studies of diversity and distribution that complement the traditional methods of observation. With the high impact of climate change on freshwater ecosystems (e.g., Williamson et al., 2019) and the central roles of microbial eukaryotes to these systems, it is important to understand not just the biodiversity, but to continue to experimentally address the ecological roles of protists in the laboratory and directly in the environments where they are found.

Knowledge gaps

- long-term community dynamics
- genetic analyzes—gene number, gene function
- cultures—most species are uncultured with little experimental data at the species level
- roles of mixotrophy at the levels of individual species to ecosystems
- effects of climate change on protist communities
- impact of parasitic protists
- interactions with aquatic fungi

Protists: Ciliates

Thomas Posch[a], Gianna Pitsch[a], and Estelle P Bruni[b], [a]Limnological Station, Department of Plant and Microbial Biology, University of Zurich, Zurich, Switzerland; [b]Laboratory of Soil Biodiversity, Institute of Biology, University of Neuchâtel, Neuchâtel, Switzerland

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie_Elodie Perga and Damien Bouffard.

Glossary

Benthic Living on/in the sediment (bottom) of running and standing waters.
Ciliates Protistan cells which are covered with cilia; the phylum Ciliophora (i.e., ciliates) belongs taxonomically to the Alveolata.
Ciliature All somatic and oral cilia of a ciliate cell.
Cytostome Part of a ciliate cell specialized for uptake of particulate food (from *cyto-*, cell and *stome-*, mouth).
Metabarcoding A method for identifying species using a short section of DNA from a specific gene (or multiple genes).
Nuclear dualism Ciliates have two kinds of nuclei (sometimes in multiple numbers), a diploid micronucleus and a polyploid macronucleus.
Planktonic Living in the free water body (pelagial) of standing and running waters, partly passively floating but many planktonic (micro)organisms are indeed motile.
Quantitative protargol staining (QPS) Albumose-silver staining of fixed planktonic ciliates on filters resulting in permanent microscopic slides for identification and quantification.
Sessile Organisms are attached to an abiotic or biotic surface.

Introduction—What are ciliates?

Book chapters about ciliates often start with the sentence: 'Ciliates (Ciliophora) are a highly developed and diversified monophyletic phylum of unicellular eukaryotes belonging to the Alveolata.' This sentence is correct, but a bit boring. The good news is that nearly all ciliate genera can already be recognized and determined by microscopy owing to their clear morphological characteristics

(Foissner et al., 1999). Thus, even beginners or non-experts in the field can enter the fascinating and esthetic world of ciliates. The bad news: they move. Here, benthic ciliates are easier to observe, as many species crawl slowly over substrates or are even attached (sessile). Already small pieces of biofilm or a few drops of sediment contain a huge variety of specimens. In contrast, planktonic ciliates and especially very tiny taxa (<30 μm) are very motile with quite complex species-specific swimming trails and some appear as real sprinters (with an incredible acceleration). Hence, a direct examination of a drop of water from a pond or lake can be very frustrating at the beginning. Already the use of a simple plankton-net or later on, of specific filtration and staining procedures (see Section "Methods to investigate the diversity of planktonic ciliates") will help to discover the world of planktonic ciliates (Foissner, 2014). This chapter aims in bringing background knowledge about ciliates in standing waters, highlighting ecological, and few taxonomic aspects, giving hints how to study them, and ending up with ideas and suggestions for fascinating aspects which may be studied in future.

Diversity of ciliates in lakes

General morphological features of a ciliate cell

There are obvious morphological characteristics (Fig. 1) which, at precise microscopic observation, often allow for an assignment to a specific group or even to a genus/species (Lynn, 2008). First, ciliates display various ciliature forms: they can (i) be completely covered with cilia in longitudinal rows, (ii) have un-ciliated (naked) cell areas, (iii) show concentrations of cilia towards the cell mouth (cytostome), or (iv) have a dense accumulation of cilia at the apical end, working as filtration apparatus and for locomotion. Only the 'adult' sessile individuals of the group Suctoria (also present in the plankton) are completely naked, whereas their free swimming swarmers still show a clear ciliature. Cell shapes of some species are very rigid and static, whereas other species are highly flexible and motile (Hausmann et al., 2003; Lynn, 2008).

Another peculiar character of ciliates is the dualism of nuclei (Fig. 1). Ciliates have a small, mostly circular micronucleus (diploid) and a large polyploid macronucleus which appears in various species-specific forms. Both types of nuclei can be found also as multiple copies within distinct taxa. Conjugation is the third striking feature, a sexual process allowing for the exchange of genetic material between individuals of the same species (or of congruent mating types within a species). Two cells partly fuse in order to exchange meiotic products previously generated from their micronuclei. Although conjugation is a strong character for this protistan group, it can be seldom observed for planktonic ciliates in situ. However, asexual reproduction by simple division of a mother in two daughter cells can often be observed in living specimens.

Some species show numerous (up to thousands) organelles below the cell surface called extrusomes (Fig. 1). Depending on the type, they act as defense system like little harpoons against predators (trichocysts), or help to catch and immobilize prey organisms (toxicysts, and haptocysts in the group Suctoria). Other types may be involved in the formation of a mucous layer around the ciliate cell (mucocysts). Contractile vacuoles (one or more per cell) are obvious cellular organelles for osmoregulation filling and emptying in regular intervals (Fig. 1). The wide variety of cell-mouth structures (cytostome) reflects the broad spectrum of feeding strategies.

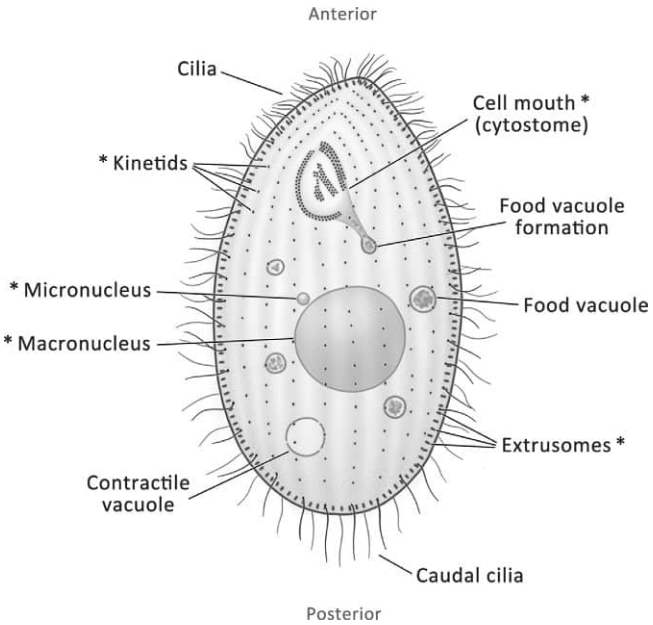

Fig. 1 Drawing of an idealized, typical ciliate cell. Most cellular characteristics are best observed on living specimens. Structures which are clearly recognizable after quantitative protargol staining (QPS), a method used for quantification of fixed planktonic ciliates, are marked with an asterisk. Drawing by Gianna Pitsch.

The formation of resting cysts would be an important trait for planktonic ciliates to overcome harsh environmental conditions; however, cysts of most representatives are unknown and only few studies were dealing with this aspect (e.g., Müller et al., 2002).

Special adaptations to planktonic life

The pelagic layer (free water body of aquatic systems) is not a stable and homogenous habitat as usually expected. In fact, it offers ciliates multiple niches for adaptation. Epilimnetic ciliate species living in the productive upper parts of lakes are confronted with continuous turbulent conditions and protists are to a certain degree trapped in this zone. Sinking into the deep, usually less productive hypolimnion has to be avoided. In this respect, planktonic ciliates developed multiple morphological adaptations (Fig. 2). First, it seems that the specific weight of many species is close to that of freshwater, reducing losses of individuals by sedimentation. Many planktonic species have a small size (<30 µm; e.g., *Balanion planctonicum*, *Cinetochilum margaritaceum*, *Urotricha* spp.), consequently they have a small mass which reduces sinking rates (Fig. 2). Larger sized species seem to be morphologically adapted to hydrodynamics by having conical (e.g., *Rimostrombidium*) or drop-like shapes (e.g., the giant genera *Pelagodileptus* and *Paradileptus*; Figs. 2 and 3).

Secondly, some genera have special bristles (e.g., *Askenasia*, *Halteria*), tentacles (e.g., *Actinobolina*), spines (e.g., *Hastatella*), and elongated cilia (e.g., *Histiobalantium*) to reduce sinking (Figs. 2 and 3). The existence of cytoplasmatic gas vesicles in planktonic ciliates to guarantee buoyancy has still to be proven. An indirect solution to avoid sinking is chosen by epiphytic and epizoic ciliates (various peritrichous genera; e.g., *Epistylis*, *Pseudohaplocaulus*, *Vorticella*), which are sessile on cyanobacterial colonies (Figs. 2 and 3), diatoms or metazooplankton. During some periods of the year, body surfaces of daphnids and especially copepods are densely covered by peritrichs and even suctorians.

However, most planktonic ciliates are free swimming in a very active way with species-specific patterns composed of forward movements, tumbles and jumps, which may be interrupted by 'resting phases' (Fig. 2). Large adoral membranelles (e.g., of *Halteria* and *Rimostrombidium*) do not only serve as filtration apparatus but are also responsible for locomotion. In the case of *Halteria*, the jumping behavior is obviously a grazing defense mechanism against predatory copepods and rotifers (Šimek et al., 2000).

All described morphological adaptations are also known for marine counterparts, but there is a major difference in the total assemblage composition between freshwaters and oceans. In contrast to marine systems, where we find a high diversity of house- (lorica) producing tintinnid ciliates (Dolan et al., 2013), in freshwater ecosystems most planktonic species are 'naked'. There are only a few species in freshwater (mostly within the genera *Codonella* (Fig. 3), *Membranicola*, *Tintinnidium* and *Tintinnopsis*) forming sticky buildings around cells in which organic and mostly inorganic particles agglutinate (Foissner et al., 1999). It might be that the

additional weight of loricae is a drawback for freshwater cells, though there may be other additional reasons for their lower frequencies in lakes and ponds.

Ecology of planktonic ciliates

Planktonic ciliates in the microbial food web

Feeding types and functional groups

From an anthropocentric point of view, many ciliate species show an incredible ratio between ingested prey volume and their own cell volume. Especially algivorous and predatory species are densely packed with food organisms—sometimes filling even the entire cell. Growth efficiencies range between 30% and 40% and are often based on volumetric data, i.e., how much prey volume had to be ingested before cell division took place. However, the feeding modes of planktonic ciliates are manifold and the selective prey uptakes too. Thus, ciliates should not be assigned to a single trophic level in the microbial food web, but represent several functional guilds acting as complex self-standing connections between various lower and higher trophic levels (Fig. 4).

Bacterivorous ciliates

Voracious bacterivores are often very tiny (e.g., *Cyclidium*-like genera) and usually dominate during the cold season or in deep cold water strata. Their feeding rates vary between 100 and 1000 bacteria ciliate^{-1} h^{-1}, depending on prey availability (i.e., functional response). Larger, especially planktonic peritrichous genera (e.g., *Pelagovorticella*, *Vorticella*), can be real 'bacterial vacuum cleaners' with uptake rates up to 15,000 bacteria ciliate^{-1} h^{-1} (Šimek et al., 2019). Consequently, besides grazing by heterotrophic nanoflagellates (HNF), also ciliates may strongly affect the fate of bacterial production and standing stock (Šimek et al., 2000). With the increasing trophic status of a pond/lake, ciliates' contribution to total grazing rates on bacteria is rising and can even be higher than rates of HNF (Šimek et al., 2019). Ciliates feeding on the size range of picoplankton (0.2–2 μm) may not only be efficient consumers of heterotrophic bacteria (Fig. 4), but also of autotrophic organisms, i.e., of coccoid cyanobacteria.

Algivorous ciliates

Strictly algivorous species exist, however only few show this unimodal feeding behavior. Indeed, the determination of in situ feeding rates of algivores is still tricky and asks for new research initiatives. Up to now, we have to come back to lab-based grazing rates for the interpretation of in situ data and even for the calculation of energy fluxes within food webs. However, most cultivated

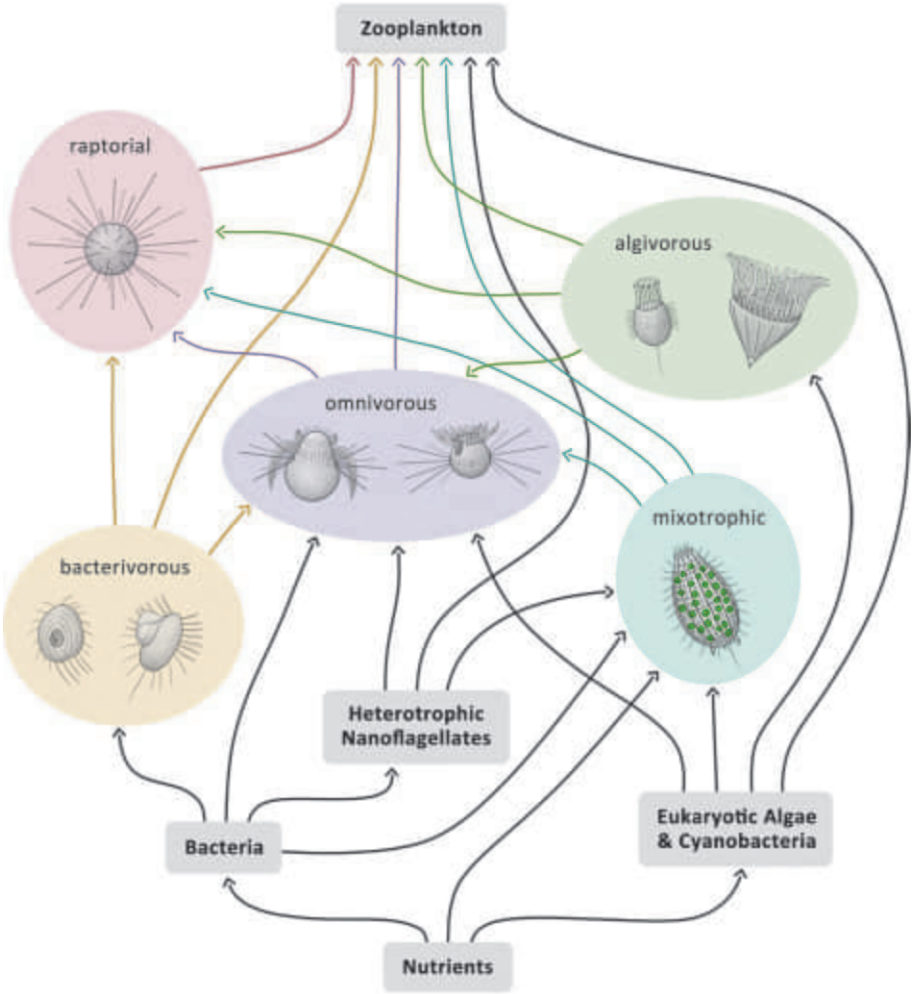

Fig. 4 Schematic representation of the complex interactions of ciliate functional guilds within the microbial food web, emphasizing the role of ciliates at different trophic levels according to their feeding modes. Drawing by Gianna Pitsch.

ciliates are kept on a single diet organism, i.e., on *Cryptomonas*. The best studied representative for algivorous ciliates is *Balanion planctonicum*. This species can radically decimate population peaks of cryptomonads, especially during their spring bloom development (Müller et al., 1991a,b).

Omnivorous ciliates

Omnivory guarantees high ecological versatility for survival throughout the year at even harsh environmental conditions. For ciliatologists, this strategy literally causes troubles to characterize the grazing impact of ciliates in a qualitative and quantitative way (Weisse, 2017).

First, it is still unknown if typical omnivorous ciliates are indeed unselective feeders, choosing prey only according to size. Actually, it seems that in addition to prey size preferences, some omnivores are more inclined to certain types of food items (i.e., rather hetero- or phototrophic organisms), still accepting both food sources in case of shortage. On the other hand, some omnivorous species, e.g., the filter feeding *Stentor roeselii*, show an immense size range and variety of ingested prey particles. Starting from hetero- and autotrophic picoplankton (0.2–2 μm), this species can phagocytize objects having nearly its own cell length. Another example concerns species of the genera *Halteria* and *Pelagohalteria*, which may have a strong impact on heterotrophic bacterial production (Šimek et al., 2000) and on picocyanobacteria, but also on algal cells with a size up to 5 μm.

These observations highlight that a quantification of in situ grazing rates is extremely challenging for omnivorous species (Šimek et al., 2019). The simultaneous use of multiple food sources (being labeled by, e.g., fluorescent dyes) definitely remains a methodological challenge (or even a nightmare). Additionally, owing to their versatile feeding modes and direct impacts on several trophic levels (Fig. 4), the categorization of omnivorous ciliates for energy fluxes within microbial food webs is still a challenge.

Mixotrophic ciliates

The real gardeners in the world of planktonic ciliates are mixotrophic representatives. During defined periods of the year (see Section "Seasonality"), they may reach high abundances profiting from their dual strategy to accept particulate food, while having at the same time algal endosymbionts and thus becoming 'phototrophic organisms'. Several species 'cultivate' indeed living algae inside their cytoplasm (e.g., *Vorticella chlorellata*, *Stokesia vernalis*), mostly belonging to the chlorophyte genera *Micractinium* and *Chlorella* (Pröschold et al., 2011). Other mixotrophic species (e.g., *Pelagostrombidium mirabile*, *Limnostrombidium viride*) are 'robber gardeners', as they keep only the plastids of ingested algae (kleptoplastids) for some time.

Other feeding types

Spectacular feeding modes are realized by predatory and histiophagous (tissue feeding) ciliates. Ciliates of the omnivorous genus *Coleps* have armored calcium carbonate plates, sometimes even with spines at both body ends. When feeding on living or dead tissue (e.g., daphnids or copepods), ciliates quickly rotate and invade their prey organisms like a 'driller' (Hausmann et al., 2003). After the first successful attack by a single ciliate, more individuals quickly join the feeding process, ending up in a crowd of 'microbial hyena' (Foissner et al., 1999). Whereas some predatory ciliates are actively moving (e.g., *Didinium*), others are rather passively waiting for prey. The unciliated life stages of the group Suctoria have multiple contractile tentacles with knobbed ends and effective extrusomes (haptocysts). When other ciliates get in contact with such haptocysts, they are rapidly immobilized and sucked out via tentacles. Beside these two examples, there is a huge behavioral variety of predatory ciliates (see Foissner et al., 1999; Hausmann et al., 2003). Nevertheless, the determination of their in situ grazing rates and impacts on energy fluxes in food webs is still understudied.

Quantitative and qualitative aspects of planktonic ciliate assemblages

Abundance and biomass

Ciliate numbers per volume water (abundance) and the assemblage composition itself are strikingly dependent on the quantity and kind of available food sources. The amount of prey organisms, in turn, depends on the trophic status of a lake/pond and on the climatic zone in which the freshwater body is located. Ciliate abundance varies from less than 1 cell mL^{-1} in surface layers of ultraoligotrophic systems and rises up to 1000 cells mL^{-1} in hypertrophic waters (Šimek et al., 2019). However, even in one ecosystem, numbers may change over the season by up to 2 orders of magnitude. Depending on the size and depth of a standing water and its mixing and stratification regime, clear vertical gradients in terms of ciliate abundances can be observed (Müller et al., 1991a; Sonntag et al., 2006). Highest abundances are expected in the epilimnion, irregular accumulations can be found also in the metalimnion and very low numbers are characteristic for deep hypolimnetic zones of large lakes. Thus, most studies focused on the productive surface layers of standing waters, resulting in schematic frameworks of typical annual successions (see Section "Seasonality"). Nevertheless, even the barren hypolimnetic environment offers a habitat for ciliates throughout the year (Müller et al., 1991a; Sonntag et al., 2006). In this habitat, ciliate assemblages are often dominated by tiny bacterivorous genera (e.g., *Cyclidium*, *Uronema*). It is still poorly understood how they survive with a rather minimalistic diet, i.e., low bacterial abundances ($\sim 10^5$ bacteria mL^{-1} in the hypolimnion versus 10^6–10^7 bacteria mL^{-1} in the epilimnion, respectively). A special community can be found at the water/sediment contact zone, i.e., especially microaerobic and anaerobic species (depending on redox conditions).

To assess the quantitative role of ciliates for energy and carbon fluxes in food webs, the determination of their total biovolume ($mm^3\ L^{-1}$) or biomass (mg fresh weight L^{-1} or μg Carbon L^{-1}) is recommended. In theory, cell dimensions should be measured from living organisms, although the task is tricky to fulfill for many agile and tiny planktonic forms. Hence, measurements are often done on fixed material, however keeping in mind fixation artifacts that seem to be species- or even growth-phase dependent (Pfister et al., 1999). A good collection of species-specific biomass values for freshwater ciliates can be found in Foissner et al. (1999). Cellvolume (μm^3) is often converted to biomass (fresh weight) assuming a specific mass of 1 ($1\ \mu m^3 = 1$ pg fresh weight). The conversion in cellular carbon is based on empirical conversion factors (Menden-Deuer and Lessard, 2000), although the published range is wide: cell volume (μm^3) is multiplied by a factor of 88 up to 323 (a value of ~200 being often used) to obtain the cellular carbon content (in fg Carbon $cell^{-1}$).

Growth rates of planktonic ciliates

Numerical response curves, i.e., the dependence of growth rates upon available food quantities, have been determined for several planktonic species. However, most studies were made in the lab on isolated strains and focused on temperature-dependent growth success of cultivated species, or even of clonal cultures (Weisse, 2017). In contrast, our knowledge on in situ growth rates is still very limited (Carrias et al., 2001). Changes in cell abundance over time can be easily converted to growth rates assuming a logarithmic rise, although resulting only in net values. For the determination of gross growth rates, information on population losses by predators and natural mortality values are needed. It is still a methodological challenge to determine these rates as, e.g., a direct evaluation of grazing rates by copepods or rotifers on ciliates is difficult to achieve. An indirect approach to judge gross growth rates is based on population dynamics in size-fractionated samples (e.g., <100 or < 150 μm fraction) to exclude metazooplankton versus unfiltered raw water. However, this technique does not work for larger ciliates which are in the same size range as small metazoan predators (nauplius larvae and juveniles of copepods, rotifers). The few reports on in situ growth rates (μ) speak for rather

fast cell divisions of <1 day ($\mu \geq 0.69$ d^{-1}) to 2 days ($\mu = 0.35$ d^{-1}) during productive periods (Carrias et al., 2001). Very high rates have been found for typical pioneer species which seem to colonize any standing water within a few days. Species belonging to the genera *Halteria* and *Pelagohalteria* represent such effective colonizers, with reported growth rates of up to 1.9 d^{-1} (Šimek et al., 2000).

Diversity aspects

According to the 'encyclopedia' of planktonic freshwater ciliates written by Foissner and co-workers, there are over 180 described real planktonic (euplanktonic) morphospecies (Foissner et al., 1999). This number is not a mantra and will definitely increase if scientists apply integrative approaches (see Section "Combining morphological and molecular approaches: Need for integrative studies"). Nevertheless, one should not expect to find the entire described diversity in a single studied lake or pond. Detailed studies based on high temporal and spatial sampling resolution report about 50 to 100 pelagic morphospecies (as a proxy) found in one ecosystem (e.g., Sonntag et al., 2006). Again, species diversity seems to be linked to the trophic status and the geographical location (climate region) of the studied system. In temperate lakes, there are a few, mostly tiny (<30 μm) genera which may numerically dominate the ciliate assemblage throughout the year (Müller et al., 1991b). However, their contribution to total ciliate biomass strikingly fluctuates over time. Typical 'omnipresent' and frequent representatives are: the genera *Balanion* (*B. planctonicum*), various species of the genera *Urotricha*, *Rimostrombidium* (*R. humile*, *R. brachykinetum/hyalinum*), *Halteria* and *Pelagohalteria*, *Mesodinium*, and diverse genera of scuticociliates (e.g., *Cyclidium*-like ciliates). A second part of diversity is formed by 'omnipresent' but less abundant taxa, e.g. species of the genus *Vorticella* or lorica-forming ciliates (tintinnids or the genus *Codonella*). The full spectrum of ciliates' diversity in the plankton is made up by rare and even ephemeral species. Nevertheless, their contribution to total ciliate biomass is often high during presence. The majority of them have fancy morphological and feeding characteristics; some can reach immense sizes with up to 1 mm length (e.g., *Pelagodileptus*). One has to inspect at least 100–300 mL of raw water (depending on the trophic status) to find these rare species (see Section "Sample collection"). Finally, many species have been reported to be ephemeral, i.e., just found at a few sampling occasions, which does not mean that they do not inhabit the ecosystem during other times. It just reflects the limits of detection of standard routines, and the problematic issue to recognize and quantify resting stages. Sequencing analyses of larger water samples showed that some of these presumably ephemeral species have indeed clear seasonal succession patterns as known for frequent representatives (Pitsch et al., 2019).

In sum, there are two golden rules when studying ciliates of standing waters. First, sampling intervals should be kept as short as possible. Population peaks of many species are reoccurring but may last for only a few days (Müller et al., 1991b). Thus, a weekly monitoring of ciliates guarantees good results. Second, be aware that average abundances of distinct species may differ by 2–3 orders of magnitude. Consequently, to study also rare and ephemeral species several methodological approaches are needed to screen also large water volumes.

Seasonality

There is a manageable number of publications on the seasonal succession of ciliate morphotype assemblages in ponds and lakes (see references in Sonntag et al., 2006; Pitsch et al., 2019). For general information on annual successions of planktonic organisms, see Sommer et al. (2012). In terms of biogeography, studies focused clearly on (i) the northern hemisphere, (ii) on ecosystems within the temperate zone, and (iii) on lakes with moderate to low trophic status (i.e., oligo-mesotrophic). A worldwide survey linking seasonal aspects in various types of lakes with typical succession patterns of ciliate assemblages is therefore still missing. Thus, the herein idealized scheme of ciliate morphospecies' seasonality is based primarily on studies originating from Central Europe with a strong focus on temperate lakes.

Depending on the trophic status of the investigated lake, one may expect two to three major peaks in total ciliates' abundance (Fig. 5). The functional guilds within the ciliate assemblage may in turn show very different seasonal developments. Any seasonality of planktonic organisms has to be seen in the context of annual changes in physico-chemical parameters (Fig. 5). Major triggers are irradiance, water temperature, thermal stratification patterns, water turbulence, and concentrations of limiting nutrients for primary producers (i.e., phosphorus, nitrogen, silica, iron). The right symphony of these parameters in spring leads to mass developments of small-sized, grazing-vulnerable algae, often dominated by cryptophytes and centric diatoms (Sommer et al., 2012; Posch et al., 2015). Increased algal production goes in parallel with a rise of extracellular products (mainly carbon compounds) which are suitable sources for heterotrophic bacteria (Šimek et al., 2014). A vernal bloom of algae and bacteria thus offers a rich food supply for ciliates (Fig. 5), but also for heterotrophic nanoflagellates (HNF). Mainly algivorous ciliates are among the first consumers of primary producers, responding much faster to the altered conditions than larger metazoan herbivores (Šimek et al., 2014; Posch et al., 2015). Thus, apparent break-downs of vernal algal blooms can be often attributed to grazing by ciliates, and partly by rotifers. The start of the growing seasons is reflected by all components of the microbial food web, with increasing numbers of algae, bacteria and HNF. This opulent menu favors omnivorous ciliates, which together with larger metazoan consumers (mainly daphnids and copepods) can lead to high clearance rates of the water column. This ends up in the clear water phase in early summer (Sommer et al., 2012), where the high water transparency reflects a period of low primary production and smaller numbers of bacteria and HNF. During the period of low food supply, mixotrophic ciliates (see Section "Mixotrophic ciliates") profit from their versatile lifestyle and can even dominate the ciliate assemblage (Fig. 5).

During summer the algal community is often dominated by larger and colonial forms (chrysophytes and diatoms), several of them also being mixotrophic (e.g., chrysophytes and dinoflagellates). Within the ciliate assemblage, representatives of all functional guilds form a highly diverse community (Müller et al., 1991b). It is also the time for many rare and ephemeral species (see Section "Diversity aspects"), and (semi-) sessile forms which use algal colonies as suitable habitat to show up. Towards autumn and

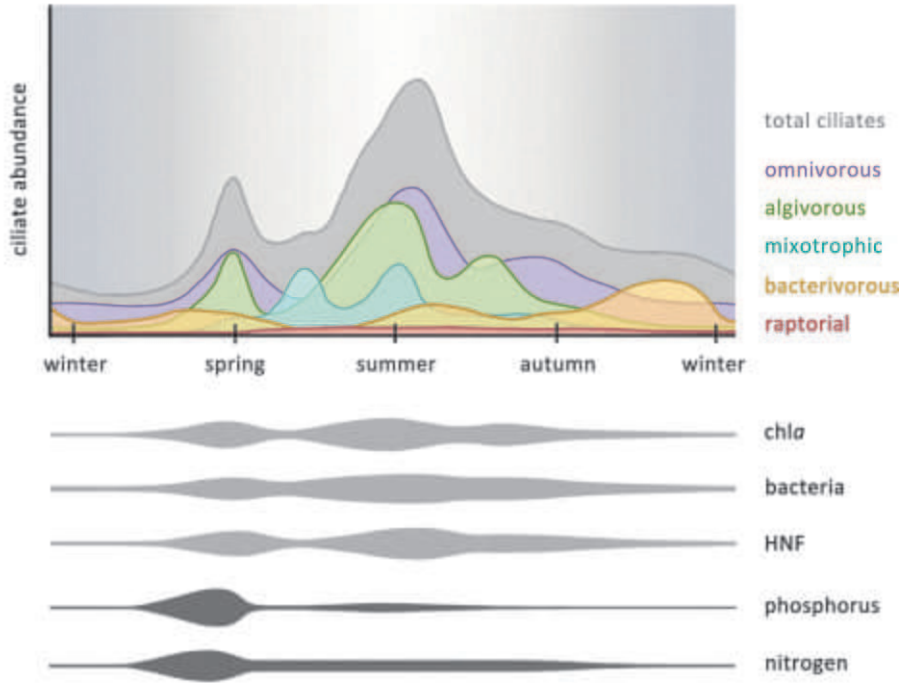

Fig. 5 Seasonal succession of total planktonic ciliates and functional guilds within the assemblage during the year. A vernal increase of nutrients (phosphorus and nitrogen) favors the growth of algae (here symbolized by chlorophyll *a* concentrations), bacteria and heterotrophic nanoflagellates (HNF). This rich 'menu of food organisms' supports the first peak in ciliate abundance. Further maxima of potential prey during summer often result in a second rise of ciliates. Note that functional guilds can show strikingly different seasonal successions. Drawing by Gianna Pitsch.

during winter, when primary production gets limited by environmental factors, omnivorous and increasingly bacterivorous taxa represent the major part of total ciliates.

The described annual succession shown in Fig. 5 is definitely an idealized scheme. In reality, the succession of ciliate assemblages is strongly affected by external drivers, such as allochthonous nutrients and pollutant loads, effects of climate warming, and any anthropogenically induced change of the ecosystem (water usage, restoration, etc.). However, it offers by its simplicity a rough framework for engaged ciliatologists and should motivate to study a lake/pond throughout the year at a high sampling frequency.

Methods to investigate the diversity of planktonic ciliates

Sample collection

One of the most common methods used for qualitative studies is plankton hauling. Nylon plankton nets with 10 μm pore size (the smaller the better) are used to simultaneously capture ciliates from large water volumes and concentrate them in a rather small volume for subsequent analyses (isolation, cultivation, characterization). In routine monitoring programs, samples are usually collected in 5 to 10 L volumes with the help of water samplers (e.g., Ruttner sampler or Niskin bottle). This strategy is preferred for quantitative analyses since the precise sampled volume is measured.

For both types of analyses, qualitative and quantitative, samples should be transported at low temperature (<15 °C) in order to minimize cell losses and shifts in the assemblage composition. Sample processing should happen without delay especially for microscopic observations of living cells. Also, the addition of fixatives (see Section "Fixation and staining techniques") and the preparation for DNA metabarcoding (see Section "DNA-based approaches: Environmental metabarcoding") should be carried out as soon as possible.

Live-cell observation, isolation and cultivation

Living ciliates can already be observed with a binocular by pouring raw water samples (preferentially from net hauls) in small Petri dishes. Be aware (and not disappointed) that only very conspicuous and large specimens can be recognized, although the bulk of ciliates diversity will elude identification by this workflow.

Accurate taxonomic identification of living ciliates usually requires phase-contrast and differential interference contrast (DIC) microscopy. To mount a microscope slide, a droplet of untreated water sample or a drop with isolated ciliates is placed on a clean glass slide. Then a coverslip with four small spots of petroleum jelly (Vaseline) in the corners is put carefully on the slide (Foissner,

2014). This method allows for gentle squeezing and slowing down specimen, thus facilitating the observation of some key morphological features. Be aware that swimming patterns are sometimes also important for species identification and should be observed on ciliates without the pressure caused by a coverslip. The use of chemicals enhancing the viscosity of water to slow down ciliates is not recommended, as these substances may alter the natural shape of observed specimens. Nevertheless, most planktonic species are tiny, usually transparent, move rapidly and have morphological characteristics which are not visible at magnifications lower than 600×. Here, samples have to be fixed and stained prior to precise taxonomic identification and quantification (see Section "Fixation and staining techniques").

The isolation of ciliates (picking) can be done with glass-micropipettes of various diameters, which are adapted to the size of the organisms of interest. Picked cells are subjected to serial washing steps using small droplets of filtrated sample or mineral water (e.g., Volvic ©), in order to reduce or even remove accompanying organisms prior to cultivation (Foissner et al., 1999). This procedure is not 'appreciated' by all species and requires some experience.

It is recommended to initialize the cultivation of planktonic ciliates by using 24-wells plates filled with pre-filtrated mineral water. Usually one to several individuals of the same species are sufficient to establish a new culture. The food source is added periodically according to the expected feeding mode. Bacterivorous filter feeders, such as *Vorticella* or *Cyclidium*, require sufficient bacterial prey provided by adding a low amount (~50 μL) of a bacterial suspension into the wells. Our in-house suspension is made by adding 5–7 wheat grains in 100 mL Volvic mineral water. After sterilization, the suspension is inoculated with a defined or mixed bacterial community. Omnivorous and algivorous ciliate species are commonly cultivated with the alga *Cryptomonas* as prey item. One can, however, not neglect that the preferred food source of many planktonic species is still unknown. After successful initiation, culture volumes should be increased. In this way, planktonic ciliates can be maintained for several weeks up to months or even years. Prerequisites for a fruitful cultivation are periodic feeding with suitable food sources, temperatures adapted to in situ conditions, light regimes with regular day-night cycles and, last but not least, a lot of patience.

Fixation and staining techniques

The fixation of water samples or cultures should preserve, in theory, the specimens' cells and their shape. Common fixatives used in microbiology such as formaldehyde, glutaraldehyde and Lugol's solution are not suited for the fixation of many species, and lead to specific artifacts (Pfister et al., 1999). Bouin's solution, which contains picric acid, formaldehyde and acetic acid, proved as best chemical for routine methods (Montagnes and Lynn, 1987).

The quantitative protargol staining (QPS) is a widely used silver-proteinate impregnation method for planktonic ciliates (Montagnes and Lynn, 1987; Pfister et al., 1999). After staining, the cell's shape and key morphological characteristics (i.e., nuclei, ciliature, cytostome structures) get visible on the resulting permanent microscopic slides. The QPS approach allows for the identification and quantification of ciliates at the same time, making it a great tool for morphology-based monitoring of planktonic assemblages.

Other techniques for more detailed investigations of ciliates using optical or scanning electron microscopy (SEM) exist. Foissner (2014) improved and reviewed a wide range of staining methods, which reveal very precise and detailed cellular features. These methods are qualitative and typically used for fine taxonomic identifications, e.g., describing a new morphospecies or the ultrastructure of specimens (Foissner, 2014; Abraham et al., 2019).

Taxonomic identification

The determination of ciliate morphospecies is still based on classical identification keys. Major references in the field are the 'blue books' published in the 1990s by Foissner and colleagues (see Foissner and Berger, 1996, and references therein; Foissner et al., 1999). These publications form a brilliant collection of taxonomic and ecological records for both, benthic and planktonic morphospecies. Despite the lack of updated versions, the data provided by identification keys proved to be in most cases accurate at species and genus levels. However, for higher taxonomic levels (beyond genera), classical phylogenies based on morphological data are often obsolete. Therefore, taxonomists rely on sequencing data and molecular-based phylogenies in order to accurately assign ciliate species to taxonomic ranks (Lynn, 2008; Gao et al., 2016) in light of the entire eukaryotic tree of life (Archibald et al., 2017). Gao et al. (2016) offer a comprehensive tree depicting the evolutionary relationships between different groups of the phylum Ciliophora.

DNA-based approaches: Environmental metabarcoding

During the last decades, the development of DNA-based tools reshaped our understanding of ciliates' diversity, taxonomy, evolutionary history, and ecology in marine and freshwater environments (e.g., Stoeck et al., 2010; Gao et al., 2016; Pitsch et al., 2019). These techniques paved the way for the analysis of large amounts of samples at high frequencies of both, spatio- and temporal scales. Furthermore, molecular analyses can surpass the sensitivity of morphological descriptions in delineating cryptic species and detecting rare ones of known and unknown lineages.

DNA metabarcoding is currently the method of choice for assessing ciliate assemblages in environmental studies. Briefly, DNA from a given sample is collected and the specific DNA, including the desired genetic barcode marker, is amplified by polymerase chain reactions (PCR). The routinely used genetic barcode markers for planktonic ciliates are the hypervariable V4 and V9 regions of

the 18S rRNA genes (Stoeck et al., 2010; Abraham et al., 2019). Using next-generation sequencing (e.g., Illumina ©), genetic material is sequenced, resulting in hundreds of thousands of amplicons. The amplicons are routinely clustered based on sequence similarity into Operational Taxonomic Units (OTUs), each OTU representing, in theory, a single taxon. Fine-tuning of laboratory and bioinformatics procedures are needed. Santoferrara (2019) provides a review on optimizing and error handling procedures for plankton metabarcoding studies. Finally, taxonomic assignments of OTUs are based on reference databases which should allow for the description and estimation of ciliates' diversity. Unfortunately, sequences of many freshwater morphospecies of ciliates are still not known, which asks for more research initiatives to expand reference databases.

Currently, one drawback of DNA metabarcoding approaches is the lack of truly and directly quantifiable data due to multiple copies (and intraspecies variations of this number) of single genes within individual cells (Gong et al., 2013). Therefore, combining molecular and morphological methods should be favored when monitoring planktonic freshwater ciliates (Pitsch et al., 2019). Abraham et al. (2019) provide an updated synthesis of classical (morphology-based), molecular (DNA-based), and statistical tools that can be used synergistically. Besides 18S rRNA genes, several other genetic barcodes are used but not further covered in this chapter (see Abraham et al., 2019; Zhao et al., 2016).

Knowledge gaps

Ecology of ciliate species: Let's open the black box

Although many species are described and known for several decades, knowledge about their ecology and ecological functions within freshwater systems is often limited. Laboratory experiments with isolated strains may help to document their species-specific feeding strategies, food preferences, and elucidate ciliates' roles within microbial food web and abundance patterns. Nevertheless, in situ techniques should be stronger emphasized on e.g., (i) using fluorescently labeled bacteria (FLBs) as food surrogates for assessing bacterivory (Šimek et al., 2019), (ii) the application of in situ hybridization techniques (FISH and CARD-FISH) for the quantification of ciliates but also the determination of their food vacuole contents, and (iii) using size-fractionation methods in combination with mesocosms to study energy fluxes within trophic levels.

Combining morphological and molecular approaches: Need for integrative studies

The development of sequencing and molecular barcoding techniques downplayed the usage of classical taxonomic identification. However, discrepancies appear frequently between morphological and molecular-based methods, and they seldom generate homogenous results. Especially, the non-quantitative character of sequencing methods for the analysis of planktonic ciliates is a central issue. However, studies combining both methods have the potential to extend our current view on ciliates' diversity and functions (Zhao et al., 2016; Pitsch et al., 2019). In this regard, classical taxonomy and the use of integrative approaches should be encouraged and promoted, especially among young researchers. Additionally, the documentation of ciliate diversity must ensure information homogeneity and accuracy of taxonomic descriptions in publications and databases (Warren et al., 2017).

Ciliates and global warming: Time to act!

Climate-induced changes within microbial food webs have striking effects on functionalities and ecosystem services of lakes and ponds. Quantitative and qualitative losses of organisms at one trophic level are cascading to lower and higher trophic levels. Therefore, in times of lake warming, monitoring of planktonic ciliates using integrative approaches is a major concern. Future research may elucidate how resilient ciliate assemblages are to sustain their ecological functions, especially as they are definitely essential key players in microbial food webs.

Klement Tockner is director general of the Senckenberg Society for Nature Research and professor for ecosystem sciences at Goethe University, Frankfurt am Main. He was president of the Austrian Science Fund—FWF (2016–20), full professor for aquatic ecology at the Free University Berlin (2007–20), and director of the Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin (2007–16). He received a Ph.D. from the University of Vienna (1993) and a Titulary Professorship at ETH Zürich (2005).

Klement Tockner is an internationally leading freshwater scientist, in particular in the research domains biodiversity, ecosystem science, and environmental management. He has published about 250 scientific papers including 180 ISI papers. He was editor-in-chief of the journal *Aquatic Sciences* (2005–2014) and is subject editor of the journal *Ecosystems*. He has published about 250 scientific papers including 180 ISI papers. In 2009, he edited a comprehensive book on European Rivers (Rivers of Europe, Elsevier; 2nd Edition in 2021). He is elected member of the Austrian Academy of Sciences and the German Academy of Sciences, Leopoldina.

Thomas Mehner is vice director and senior researcher at the Leibniz Institute of Freshwater Ecology and Inland Fisheries in Berlin, Germany. He is limnologist and fisheries biologist by training, and has got his Diploma and Ph.D. at the University of Rostock (formerly East Germany) in 1992. In 1999, he had received his habilitation and venia legendi in limnology, which allowed him to start teaching as Privatdozent at universities. Since 1997, he has been working at IGB in several positions. He has published about 170 ISI papers, with primary focus on fish communities, lake food webs, and species interactions. However, his topical interests are broader, and he has authored and co-authored several publications on freshwater fisheries management, fish population genetics and evolutionary and behavioral ecology of aquatic organisms. He has been Handling Editor of the journals "*Aquatic Ecology*" and "*Freshwater Biology*" for several years, and he is currently member of the Editorial Boards of "Global Change Biology" and "Limnologica." Since spring 2018, he has been the president of the International Society of Limnology (SIL), the oldest and most international scientific society devoted to the study of inland waters. Thomas Mehner has taught M.Sc. courses at universities on limnology, fish ecology, fisheries management, and behavior and evolution. His one-week course on "Scientific Writing" for Ph.D. students has been run at 3 universities and in total 18 times, with >120 international students participating. He has trained many M.Sc. and Ph.D. students and supervised their theses, and he is actively mentoring undergraduates, graduates, and post-doc researchers.

EDITORIAL BOARD

Editorial Board Names and affiliations

SECTION EDITORS

Damien Bouffard is leader of the aquatic physics lab at Eawag (Switzerland). He holds a Ph.D. from EPFL (with Ulrich Lemmin). After his Ph.D. he worked in Canada with Leon Boegman (Queen's U.), Ram Yerubandi (Environment Canada), and Joe Ackerman (Guelph U.) before returning to Switzerland as first assistant at EPFL with Alfred (Johny) Wüest. He has published over 70 peer-reviewed papers in aquatic physics and serves as associate editor for JGLR, AS, and HESS. His program research is focused on two axes: (i) linking the small-scale turbulence to the large-scale forcing with today a special interest in convective processes in lakes and (ii) aquatic physics as a tool to understand lake ecosystems. The later includes the use of 1D and 3D operational hydrodynamic models such as simstrat.eawag.ch or meteolakes.ch. Bouffard is also involved in promoting multidisciplinary and high-tech research on lakes, notably as member of the steering committee of the LéXPLORE floating research platform in Lake Geneva and in promoting open science in limnology with the web platform Datalakes-eawag.ch.

Debbie Chapman as a graduate of the University of London, Deborah Chapman started her research career as limnologist at the Freshwater Biological Association in the English Lake District. She subsequently became interested in monitoring the impacts of disposal of sewage sludge on aquatic organism and the potential for human health impacts from aquatic pollution. In 1986 she joined the United Nations Environment Programme's (UNEP) Monitoring and Assessment Research Centre (MARC) in London, participating in the international monitoring and assessment activities of UNEP and the World Health Organization (WHO), and assisting in global environment assessment programs. In 1988 she became the deputy director of MARC and took responsibility for the developing country workshops and training program, and global environment data review and compilation. After moving to Ireland in 1990, she worked as a freelance Environmental Consultant engaged mostly on international and developing country projects for WHO, UNEP, and other international organizations. She has assisted with the compilation of State of the Environment reports and has contributed to, edited, and produced more than 20 books on water resources and environmental management, including the internationally successful *Water Quality Assessments: A guide to the use of biota, sediments and water in environmental monitoring.*

In 1998 she joined UCC becoming the first lecturer in Environmental Science and then Head of Environmental Science in 2013. In recent decades her research interests have focused on water resources management, especially recreational and amenity lakes and reservoirs, developments and current practice in design and implementation of water quality monitoring programs, and human health risk assessment in relation to the use of freshwater resources and wastewater disposal. Drawing on 30 years of international experience, in 2015 she established the UNEP Global Environment Monitoring System for Water (GEMS/Water) Capacity Development Centre at UCC. This center delivers capacity development activities in water quality monitoring and

assessment worldwide for UNEP, including support for the Sustainable Development Goal indicator for good ambient water quality. She retired as director of the center in June 2021 and now acts in an advisory role and as an independent consultant.

Kendra Spence Cheruvelil is professor of limnology and co-director of the Data-intensive Landscape Limnology Laboratory at Michigan State University (MSU) in the Department of Fisheries and Wildlife (https://www.canr.msu.edu/fw/). She is also serving as Interim Dean of the Lyman Briggs College, which is MSU's residential college for studying the sciences and maths within their societal and global contexts (www.lbc.msu.edu). Kendra co-established the discipline of landscape limnology (https://bigdatalimno.org/research-themes/landscape-limnology/) and co-leads the LAGOS research program that is creating the research infrastructure to conduct big-data research on U.S. lakes (https://lagoslakes.org/). This large, collaborative, and interdisciplinary research program has been funded by the U.S. National Science Foundation and seeks to understand how global changes such as climate change and land use intensification affect lakes across regions and continents and through time. Dr. Cheruvelil also pushes the boundaries of how to conduct limnology research by using data-intensive science, science of team science, and open science approaches, tools, and perspectives to answer complex scientific questions. She also has an active research program to advance diversity and inclusion in the sciences (https://ee-stem.weebly.com/) and serves as an associate editor for the journals *Limnology & Oceanography Letters* and *Frontiers in Ecology & the Environment*. Prior to joining MSU, Dr. Cheruvelil was a faculty member in the Purdue University system. She has a dual Ph.D. from MSU in Fisheries & Wildlife and Ecology, Evolution, & Behavior (2004).

Catherine Febria is a Tier 2 Canada Research Chair in Freshwater Restoration Ecology and assistant professor at the Great Lakes Institute for Environmental Research (GLIER) & Dept. of Integrative Biology at the University of Windsor. Her research focuses on the ecology and restoration of small streams and wetlands in human-impacted landscapes, and the role of small waterways in supporting good ecosystem health in the Laurentian Great Lakes. She launched her lab—the Healthy Headwaters Lab—in 2019 and also wears multiple hats as co-director of the GLIER Organic Analysis & Nutrients Laboratory (a central research facility), associate director of FishCAST (an NSERC CREATE graduate student training program in Canada), co-chair of the International Science Advisory Panel for New Zealand's Biological Heritage National Science Challenge, coordinating editor with the journal *Restoration Ecology* and alumni fellow and contributing author with the Intergovernmental science-policy Platform on Biodiversity and Ecosystem Services (IPBES). She previously held a postdoctoral role at the University of Maryland's Chesapeake Biological Laboratory (USA), the University of Canterbury (Aotearoa New Zealand). Her research has been published in the *Science*, *Nature Geoscience*, *Canadian Journal of Fisheries and Aquatic Sciences*, *Environmental Science & Technology*, and *Frontiers in Microbiology*, *Restoration Ecology*, *Proceedings of the Royal Society*, to name a few. She is co-founder of the Kindness in Science global initiative, and contributes actively to actions, scholarship and mentorship to advance justice, equity, diversity, and inclusion in academia.

Christian Griebler is full professor and head of the Limnology unit at the University of Vienna, Austria. He is a dedicated groundwater ecologist with core expertise in microbial ecology and biogeochemistry.

Kenneth Irvine has a broad range of multidisciplinary experience working on aquatic ecology, ecological assessment of surface waters, especially lakes and wetlands, and policy and related policies and management. After gaining a Ph. D. in 1987 at the University of East Anglia (U.K.) for a study on trophic ecology of shallow lakes, he worked for the U.K. Nature Conservancy Council, before moving to study ecosystem structure of Lake Malawi in Africa. He moved to Trinity College Dublin in 1994 Ireland. There, he continued work on the African Great Lakes, as well as building a research group working on ecological assessment in support of the EU Water Framework Directive. In 2011 he moved to IHE Delft Institute of Water Education, the Netherlands, as chair of Aquatic Ecosystems. Current work focusses on wetlands and capacity development in Sub-Sahara Africa. Recent work also includes a review of hydromorphology and links to policy. He currently sits on the Board of the Board of the *African Center for Aquatic Research and Education* (ACARE) and on the Scientific Advisory Board of the *Leibniz Institute of Freshwater Ecology and Inland Fisheries* (IGB), Berlin.

Wolfgang Junk was scientist of the Max-Planck-Institute for Limnology, Dep. Tropical Ecology, Plön during 1970–75.He was scientist of National Amazonian Research Institute, leader of the Dep. of Hydrobiology and Inland Fishery at Manaus, Brazil during 1976–79. and leader of the Working Group "Tropical Ecology" at the Max Planck Institute for Limnology in Ploen, Germany during 1980–2007.He is expertise in ecology and sustainable management of floodplains, land-water interactions, wetland classification. His main research areas arestudies on biomass, primary production, and decomposition of wetland plant communities; nutrient fluxes between land and water; adaptations of plant and animals to periodical drought and flooding; ecology of aquatic macrophytes and fish communities; biodiversity; conceptional considerations on river-floodplain systems, sustainable management of wetland resources and wetland protection with emphasis on the Amazon River floodplain and the Pantanal of Mato Grosso, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 300 peer-reviewed publications, including several books and book chapters on Amazonian wetlands and the Pantanal of Mato Grosso. He received many honors, among them the Award of the Grande Cruz (the highest distinction of Brazil) for exceptional scientific performance, and the Cross of Merit First Class of the Federal Republic of Germany. He is corresponding member of the Academy of Sciences of Brazil.

Krantzberg is professor and lead for the engineering and public policy in the School of Engineering Practice and Technology at McMaster University offering Canada's first master's degree in engineering and public policy. Gail completed her M.Sc. and Ph.D. at the University of Toronto in environmental science and freshwaters. She worked for the Ontario Ministry of Environment from 1988 to 2001, as coordinator of Great Lakes Programs, and senior policy advisor on Great Lakes. Dr. Krantzberg was the director of the Great Lakes Regional Office of the International Joint Commission from 2001 to 2005. In 2007 she was appointed as an adjunct faculty member of the United Nations University Institute for Water and Environmental Health and participated in the twinning of the Laurentian and African Great Lakes (principally Lake Victoria). She has co-authored and edited 9 books and more than 200 scientific and policy articles on issues pertaining to ecosystem quality and sustainability and is a frequent speaker to media and the public. Her research interests include investigating Great Lakes governance capacity, analyzing interjurisdictional co-management arrangements internationally for application to the Great Lakes regime, and methods to better integrate science and engineering in policy formulation and decision-making.

Marie-Elodie Perga is associate professor of limnology at the University of Lausanne in Switzerland. Since receiving her Ph.D. from the University of Savoie-Mont Blanc (France), she has worked at the University of Victoria in Canada, and the French National Institute for Agronomy and Environment (France), before moving UNIL.

Because she is a Lindeman's groupie, her research lies at the interface of community ecology and biogeochemistry, through lake food webs and carbon processes. More recently, she added a pint of hydrodynamics with the intent to bridge physical and biogeochemical mechanisms, especially in alpine and high-altitude lakes. Her work covers centennial up to minute timescales through the combination of high-resolution paleo-records and high-frequency data from autonomous sensors.

She is also involved in promoting high-tech research on lakes, notably as a member of the steering committee of the LéXPLORE floating research platform in Lake Geneva, and in connecting science and management through a transdisciplinary network involving National Parks in France. She has published over 75 peer-reviewed papers and serves as associate editor for WIRES Water.

N. LeRoy Poff is professor of biology at Colorado State University and holds a partial appointment as distinguished professor at the University of Canberra, Australia. Since receiving his Ph.D. in 1989, his research has focused on understanding how natural and human-caused hydrologic variability regulates the interactions among species and the structure and function of riverine ecosystems. By developing techniques to quantify streamflow variability in ecologically meaningful terms and using species (functional) traits as generalized, mechanistic response variables, he has been a leader in advancing the field of hydroecology. Through his interdisciplinary and collaborative work, he has contributed fundamentally to the development of the field of "environmental flows," which aims to support sustainable management of streams and rivers at local to regional to global scales in the face of growing human water demands. His current interests are on developing better conceptual frameworks and decision support tools for science-based management of streams and rivers in our current period of rapid climate and ecological change.

Lars Rudstam is professor of fisheries and aquatic sciences in the Department of Natural Resources and the Environment, Cornell University (USA) and the director of the Cornell Biological Field Station. He has a master's degree from the Center for Limnology, University of Wisconsin-Madison and a Ph.D. from Stockholm University, Sweden. Rudstam has published over 250 papers ranging from lake physics to phytoplankton, zooplankton, mussels, mysids, fish, birds, and anglers, mostly about processes associated with food web interactions and ecosystem dynamics. He has worked in lakes in North America, Europe, and Asia as well as the Baltic Sea.

Stuart Warner works with the United Nations Environment Programme with a focus on helping countries to monitor and assess their freshwaters. He was born in England, he moved to Ireland in 2001 to work at University College Cork. Stuart has published in the areas of water quality monitoring and assessment and citizen science approaches to data collection. He has written reports on the capacity of countries to understand their freshwaters which highlight the challenges faced in different world regions. Recent efforts have focused on the development and implementation of a global water quality indicator, and the delivery of capacity development targeted at improving freshwater management. His professional interests include using both traditional and innovative approaches to understand and protect freshwater ecosystems.

Florian Wittmann is professor for physical geography and head of the Department of Wetland Ecology at the Karlsruhe Institute for Technology, Germany. He studied geography, geology, and botany at the Universities of Mannheim and Heidelberg, got his Ph.D. in physical geography at the University of Mannheim, and his lecturer qualification at the University of Bayreuth, Germany. He held post-doc positions at the Max Planck Institutes for Limnology and Chemistry, Germany, where he was working at the bilateral project between the Max Planck Society and the National Institute for Amazonian Research in Manaus, Brazil, for more than 15 years.

His research focuses on neotropical wetlands, with special interest in biogeography, plant species distribution, species diversity, forestry and sustainable management, remote sensing, biomass and primary productivity, and botany and vegetation ecology. Actually, he teaches at the Institute for Geography and Geoecology of the Karlsruhe Institute for Technology, Germany, and in the post-graduate program of Tropical Ecology—Botany at the National Institute for Amazon Research—INPA, Manaus, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 150 peer-reviewed publications, including several books and book chapters on Amazonian wetlands.

A Diversity of Primary Producers in Lakes

Francesco Pomati[a], Marta Reyes[a], Anita Narwani[a], Robert Fischer[b], and Robert Ptacnik[b], [a]Eawag, Department of Aquatic Ecology, Zurich, Switzerland; [b]WasserCluster Lunz, Lunz am See, Austria

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie_Elodie Perga and Damien Bouffard.

Glossary

Alpha diversity Local (in space and time) diversity in organisms.
Beta diversity Dissimilarity among local communities in terms of composition.
Biodiversity The diversity of life forms, including variation among species, genes and functional traits.
Community assembly The processes determining the composition and abundance of local communities starting from a pool of organisms.
DNA-barcoding Method of taxonomic identification using a short section of DNA from a specific gene or genes.
Eco-evolutionary dynamics How ecological dynamics interact with evolutionary change, with reciprocal feed-backs.
Evenness Equivalence of the abundances of individual units (e.g., taxa, genes, traits) in a community.
Flow-cytometry Technique for rapid detection, characterization and enumeration of microbial cells based on their light scatter and fluorescence properties.
Gamma diversity Regional (large scale) diversity in organisms.
Mixotrophy Refers to the ability of organisms to combine different trophic strategies, i.e., (phago-) heterotrophy and photoautotrophy, to acquire energy, carbon, nutrients or other factors for growth.
Richness Number of different units (e.g., taxa, genes, traits) represented in a community.
Trait Morphological, physiological, phenological or behavioral features of an organism—normally measured at the individual level, but sometimes measured as an average of individuals for a population, species or whole community.

Introduction

Within the variety of species we can see in lake ecosystems, we find a vast diversity of plankton species. Plankton is a collective term for all organisms inhabiting the open water space and cannot control their horizontal position in the water, thus are rather drifting than swimming. Hence plankton has no phylogenetic basis, and comprises viruses, prokaryotes and eukaryotes. Phytoplankton—literally translated from the ancient greek, "plant wanderer/drifter"—are planktonic photosynthetic autotrophs and the primary producers of the pelagic (open water) ecosystem. In fact, the collective term phytoplankton pools an incredible diversity of organisms (Fig. 1). These organisms are all microscopic, however they span four orders of magnitude in size, from roughly 1 μm to 1 mm, which corresponds to the size range of a football to the island Manhattan (Finkel et al., 2009).

Though being easily comprehensible, research in the past 20 years has rendered the above definition of phytoplankton difficult. Most of the clades comprising phytoplankton contain mixotrophic taxa which combine photosynthesis with phagotrophic uptake of prey (usually bacteria or small protists) (Flynn et al., 2012). Mixotrophy is regarded as a common life strategy in phytoplankton. The developing knowledge regarding the nutritional capabilities (and flexibility) of planktonic microorganisms challenges a

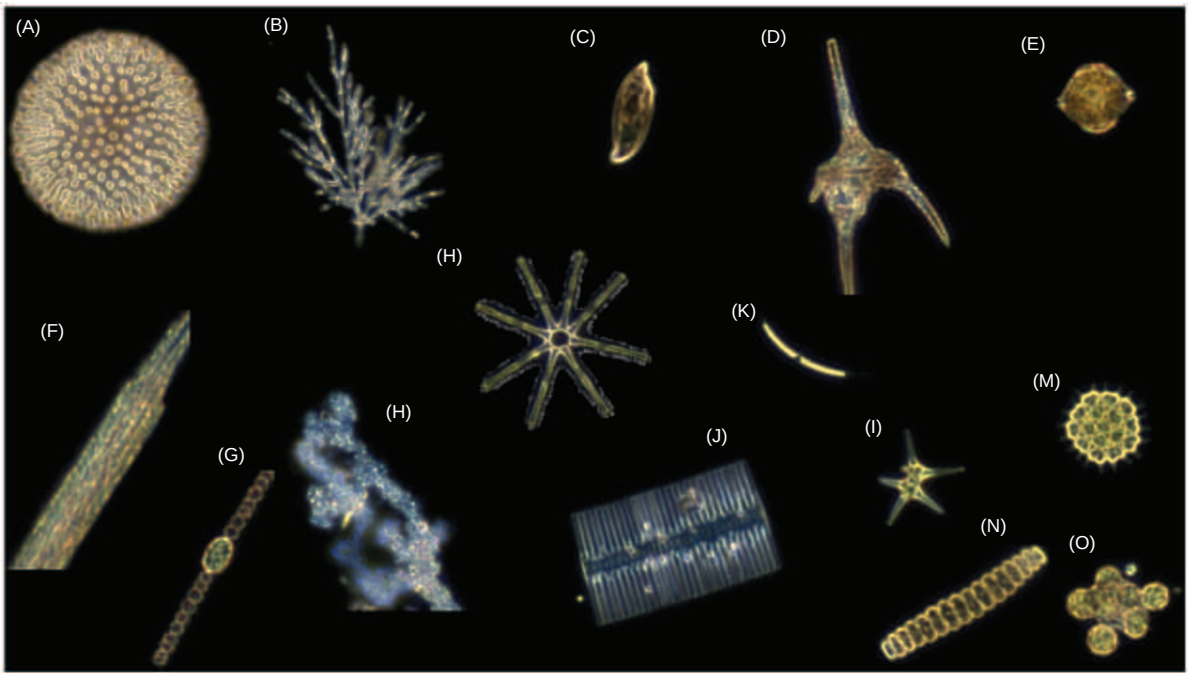

Fig. 1 A selection of phytoplankton species (objects not to scale; c-e, k and l depict individual cells, all other objectives depict colonies of the respective species). historical dichotomy that divides them into phytoplankton (algae) and protozoa (or zooplankton), according to their respective mode of nutrition (i.e., photoautotrophs vs. heterotrophs). Our considerations in this chapter, therefore, have to be understood to include unicellular and colonial plankton irrespective of their nutritional/trophic mode, spanning a gradient of strategies between strict photoautotrophs and strict heterotrophs.

Due to their variety of species, large population numbers, and their importance as base of the food-web, phytoplankton have an essential role in aquatic ecosystems, regulating e.g., the carbon and nitrogen cycles at local water bodies, as well as at regional and global scales. It has been hypothesized that phytoplankton regulate about half of the carbon cycle at the global scale (Falkowski, 2012). They actively contribute to ecosystem services, i.e., benefits stemming from properly-functioning natural environments, such as provision of clean drinking water, decomposition of wastes and pollutants, recreation, and fisheries. As phytoplankton have short generation times (1–2 days in nature), their populations respond very sensitively to environmental changes, including human impacts at different scales (e.g., extreme weather events and pollution as well as eutrophication and climate change). To note, phytoplankton blooms (events of algal or cyanobacterial overgrowth) can occur as a consequence of anthropogenic pollution and climate warming (Huisman et al., 2018). Blooms by cyanobacteria in lakes can be dominated by species that produce toxins and injure animals, humans, food-webs and the whole ecosystem (a.k.a. harmful algal bloom). These can lead to fish die-offs, cities cutting off water to residents, or fish farms having to close down.

Here we present an essential review of the current state of knowledge with regards to the biodiversity of phytoplankton in lakes. We present the most important aspects of diversity that are pertinent to understand the importance of phytoplankton in lake ecosystems, and review the mechanisms regulating phytoplankton diversity at local and regional scales. We finally present case studies for further reading, which summarize the current state of knowledge of how environmental changes such as eutrophication and climate warming are affecting the diversity of phytoplankton in lakes, at different scales of space and time, and their consequences for lake ecosystems and the services that they provide to human society (like the case of cyanobacterial blooms).

What is biodiversity in phytoplankton

We identify biodiversity as the diversity of life forms, including variation among species, genes and functional traits (Cardinale et al., 2012). Traditionally, biodiversity has been mostly recorded at the level of taxonomic richness and evenness. For phytoplankton, microscopic identification and analysis have been the state of the art until very recently. Meanwhile, molecular methods have become critical for assessing diversity in unicellular organisms, and help overcoming obvious limitations in microscopic identification. As opposed to taxonomic information, there is an increasing interest to identify and quantify diversity in terms of ecological functions. A new focus on estimating trait diversity (both genetic and phenotypic) reflects an attempt to attain mechanistic understanding of the functional diversity of ecological communities (Litchman and Klausmeier, 2008).

Phytoplankton covers an enormous variety of shapes and sizes (Fig. 1). This enormous morphological diversity stems from an extreme phylogenetic diversity. Consider that all terrestrial plants, including mosses, ferns and trees, emerged from one major phylogenetic group, chlorophytes. Chlorophytes are but one out of many phylogenetic groups making up phytoplankton. The large phylogenetic diversity corresponds to an evolutionary diversity that encompasses multiple steps of endosymbiosis, which in turn has resulted in an enormous array of photosynthetic pigments and light harvesting systems. As a result, phytoplankton comprise manifold nutritional strategies, nutrient requirements and utilization strategies, metabolic pathways and secondary metabolites (among which are the infamous toxins produced by cyanobacteria), all acquired over nearly 1 billion years of macroevolution. Besides being the main photoautotrophic group driving the carbon cycle in pelagic ecosystems, some members of the phytoplankton, namely cyanobacteria of the family Nostocales, are the main nitrogen fixers in oligotrophic environments. Moreover, only cyanobacteria and diatoms are strictly photosynthetic, corresponding to the nutrition of typical "plants." The majority of clades making up the phytoplankton include members with diverse nutritional strategies, often combining photosynthesis with phagotrophic nutrition. Several groups like chrysophytes, dinoflagellates and cryptophytes comprise taxa that cover the full range from photoautotrophic to heterotrophic growth.

It is not easy to quantify phytoplankton diversity for a number of reasons. First, the species concept as such is problematic in organisms that may reproduce as clones. While alteration of sexual and clonal reproduction is known for many taxa, we do not know if clonal reproduction is the only way of reproduction in those where sexual reproduction has not been observed. Moreover, molecular methods reveal a high level of cryptic diversity, which again makes it difficult to assign distinct species, especially for groups that are not cultivated or cultivable. Finally, due to their short reproductive cycles (in the range of several hours to few days), phytoplankton communities exhibit enormous temporal turnover. While a single phytoplankton sample in a lake may consist of several 10 to maybe 100 morphologically distinct taxa, the annual species inventory of a lake sampled over multiple seasons may comprise hundreds of taxa.

Regional species pools at the sub-continental level usually comprise several hundred taxa (e.g., 850 taxa are found in the lakes of Fennoscandia, and 1100 species in lakes of the peri-Alpine area) (Moe et al., 2008; Pomati et al., 2019). This regional species richness is known as gamma diversity, while local richness (i.e., in each lake at each time), is called alpha diversity, and accounts for nearly a hundred species per sample. The dissimilarity, or differences, among local (i.e., lake) communities in terms of species composition is called beta diversity. Diversity in species is called taxonomic, since it's based on a classification of individual specimens based on identification keys. Individual organisms can however be classified also based on other expressed phenotypic characteristics (not necessarily taxonomic characters), for example morphological, physiological or genetic features (also known as traits).

Grouping of organisms based on morphological and/or physiological traits leads to functional classification of phytoplankton into so called functional groups. One example of morpho-functional group classification is the one proposed by Kruk et al., where taxa are assigned to classes based mostly on morphological characters (Kruk et al., 2010). In other cases, morphology and physiology can be combined with phenology and co-occurrence patterns in the environment to form sociological associations, such as Reynolds categories (Reynolds et al., 2002). Functional associations of species reflect both similar traits, and similar ecological requirements or behavior of species. Species or individual level traits (i.e., morphology of the taxon or single specimen) can be used to characterize communities in terms of overall trait diversity (the diversity of "trait values" covered by the whole community), which have the same component of taxonomic diversity: richness, evenness and dissimilarity (Fontana et al., 2016).

Similarly to the use of phenotypic (morphological and physiological) traits, also genetic traits can be used to characterize the biodiversity of phytoplankton, both within populations (i.e., individual level variation) and between species in terms of phylogenetic (evolutionary) markers and functional genes. Indeed, the classification of phytoplankton taxa has been influenced significantly by the rearrangements of groups due to phylogenetic studies that have guided periodic revisions of their taxonomy. Some expressed morphological and physiological traits are also used to guide phytoplankton classification, because they vary in correlation with phylogenetic relationships, while others do not (Narwani et al., 2015). One example of periodic re-arrangements in taxonomic classification is the clade of cyanobacteria, where morphological characters are poor descriptors of phylogenetic (evolutionary) relationships.

Trait-based approaches have been used in phytoplankton to both group organisms and to link their responses to environmental gradients, with good evidence for explanatory and predictive power. In particular, population level traits (e.g., parameters of environmental response functions) have shown high prediction of species dynamics over seasonal or long-term gradients, understanding of mechanisms leading to species coexistence and re-arrangements of phytoplankton communities due to climate change (Edwards et al., 2013; Litchman and Klausmeier, 2008; Thomas et al., 2012). Additionally, individual level variation in phytoplankton traits, which has become possible to measure only recently due to new automated technology (see further in the text—Methods to study phytoplankton diversity), has revealed high variation between individuals of the same species, fine-scale dynamics in the interaction of individual microbes, and showed high power in predicting phytoplankton community processes like productivity and resource use, compared to taxonomic diversity (Fontana et al., 2018; Krismer et al., 2017).

The application of genotyping and phenotyping tools, over the last decade, has shown how phytoplankton is characterized by a very large genetic and functional diversity. A high proportion (>80%) of unique genotypes has been reported in many phytoplankton taxa studied in marine environments, with certain populations comprising thousands of different genetic lineages (Collins et al., 2014). These high levels of genetic diversity are expected to result in variation in functional traits and fitness, and in the presence of potential cryptic species (recognizable only by genetic markers, and not by morphology), though some portion of it may also be functionally neutral. Little is known about the genetic diversity of populations of lake phytoplankton (Lebret et al., 2012). Few studies focusing on adaptation to abiotic and biotic environmental conditions across lakes have shown that, for example, populations of the diatom *Asterionella formosa* show high differentiation within lakes, even stronger than among lakes

(Van den Wyngaert et al., 2015). This may be caused in part by local selection due to host-parasite interactions. Similarly, filamentous cyanobacterial populations of *Planktothrix rubescens* have shown high genetic diversity between lakes, with strong selection for lake-specific variants that have gas vesicles (used to regulate colony buoyancy) better adapted to each lake depth and turbulence conditions (high pressure at depth can collapse gas vesicles causing sinking and death of the organism) (D'Alelio et al., 2013).

The processes shaping phytoplankton biodiversity

Community assembly

In extreme synthesis, biodiversity of natural communities is controlled by selection, speciation, dispersal and stochastic drift (Vellend, 2010). The interplay of these mechanisms over a landscape is called community assembly. Organisms from a regional pool of species, genes and traits, colonize a local environment and interact with abiotic and biotic factors to form a local community (Fig. 2). While different processes operate at diverse spatiotemporal scales (Figs. 2 and 3), spatial processes involving dispersal and relevant vectors, and historic contingencies (the past history of the regional species pool—constrained by evolution), generate large-scale biogeographic patterns in diversity. On the other hand, biotic and abiotic interactions, and priority effects (the advantage of who gets there first), occurring at small spatiotemporal scales, contribute to local co-occurrence and diversity (HilleRisLambers et al., 2012) (Fig. 2).

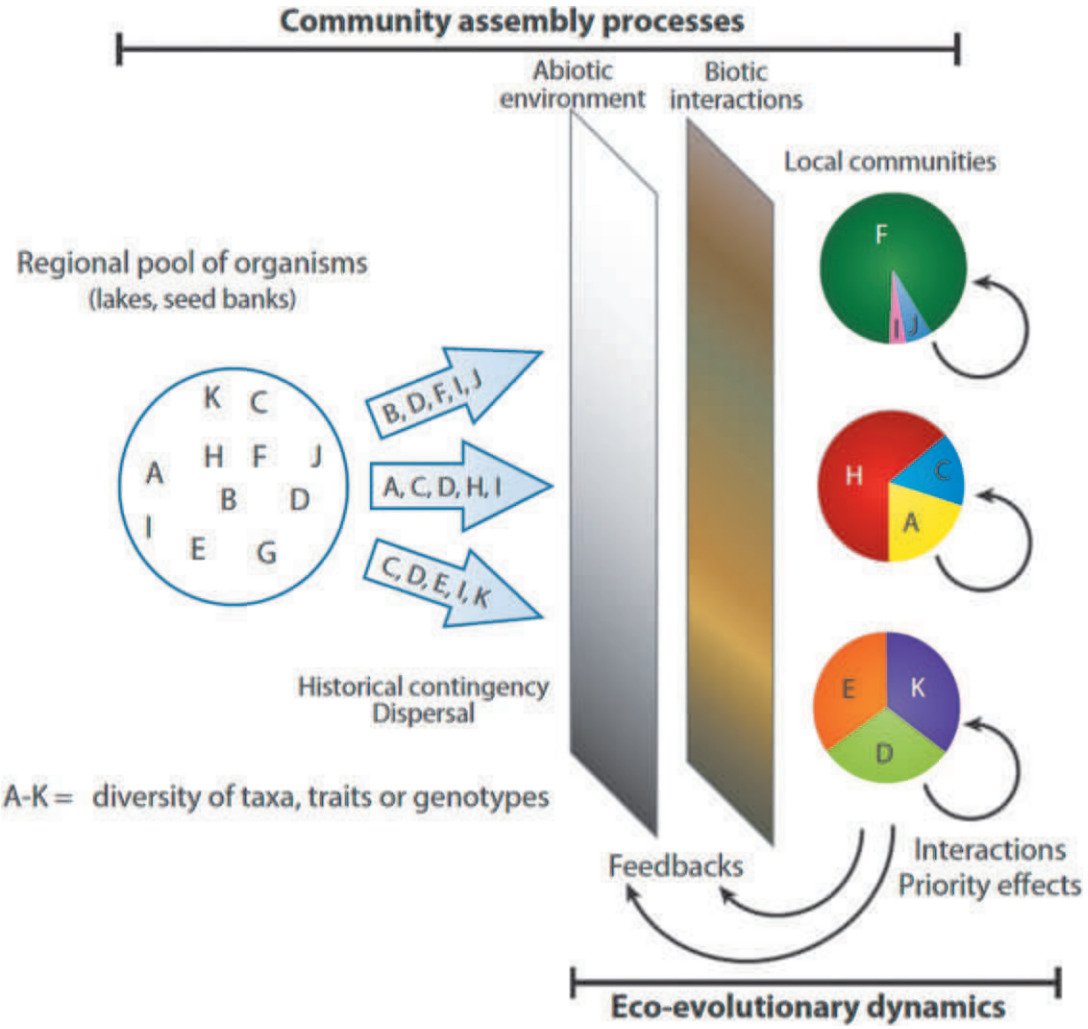

Fig. 2 The assembly of lake phytoplankton communities is influenced by ecological and evolutionary processes operating at different spatial scales. Organisms belong to a regional pool of organisms that is constrained by historical processes (including evolution). A subset of this pool (influenced by chance and dispersal limitation) is available for growth at a particular moment in time. The realized community can be seen as the result of priority effects (who gets there first has an advantage), and selection by environmental (abiotic) filters and biotic interactions (competition, facilitation, predator-prey and host-parasite dynamics). Adapted from HilleRisLambers J, Adler PB, Harpole WS, Levine JM and Mayfield MM (2012) Rethinking community assembly through the lens of coexistence theory. *Annual Review of Ecology, Evolution, and Systematics* 43: 227–248. doi: 10.1146/annurev-ecolsys-110411-160411.

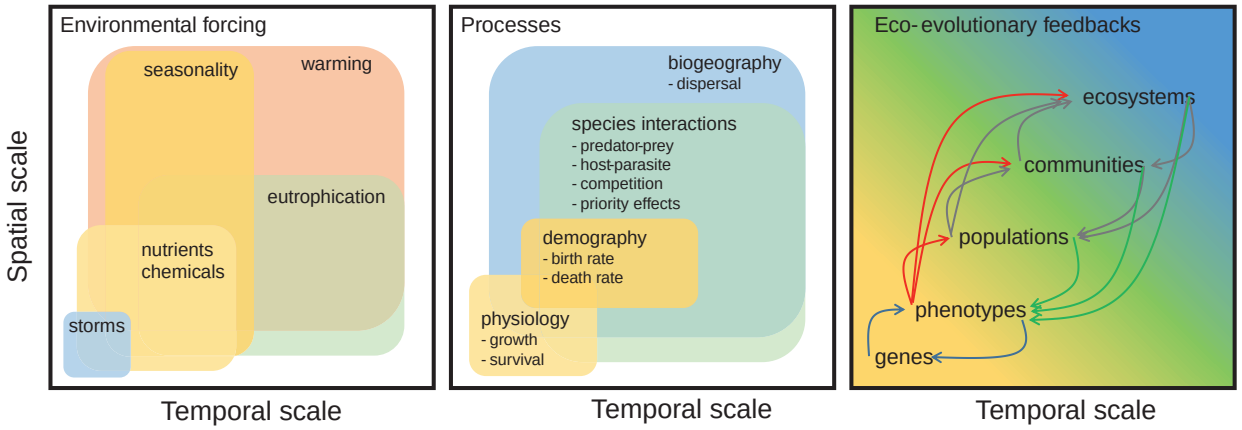

Fig. 3 The diversity of phytoplankton communities is maintained by the interaction of a spatially and temporally variable environment (both by natural and anthropogenic forcing) (A), acting on a complex set of nested processes (engaged at different spatial and temporal scales) (B), themselves influenced by eco-evolutionary feedbacks (C) (blue arrows = evolution; grey arrows = ecology; red arrows = evolution influences ecology; green arrows = ecology influences evolution; adapted from "What are eco-evolutionary dynamics?,"http://ecoevoevoeco.blogspot.com/2010/03/what-are-eco-evolutionary-dynamics.html).

Following this conceptual model, the mechanisms influencing biodiversity include both local and short-term mechanisms as well as regional processes occurring over longer timescales, and not all of the mechanisms involved are deterministic. Local communities are influenced by dispersal and also by demographic stochasticity (random death processes and disturbances). In many cases, therefore, random drift may be an important mechanism shaping the composition and relative abundances of local communities, in particular if species are very similar or equivalent in their competitive abilities (i.e., are neutral) (Rosindell et al., 2011), or have small population sizes. At the local scale, deterministic mechanisms might be more prevalent: abiotic factors like climate or nutrient levels, and biotic factors like interactions with natural enemies, can be seen as selective environmental filters, favoring organisms with only certain specific genetic, morphological or physiological traits. Local mechanisms represent the most dynamic core of the community assembly process, with responses and feed-backs between the interacting organisms and their biotic and abiotic environment (e.g., populations grow, respond to, and impact on, limiting resources or natural enemies). This local set of interactions belongs to the so-called eco-evolutionary dynamics. Interactions of co-occurring organisms with competitors, predators, mutualists, or parasites, in fact, not only depend on the abiotic environment, but can feed back to influence both abiotic factors and the interactions themselves.

Phytoplankton, in particular, is a well-known example in which eco-evolutionary dynamics occur: between consumers and resources, predators and preys, and hosts and parasites. This is due in part to their short generation time, therefore effectively coupling ecology and evolution at the same time scale, and to their potential for rapid, local and ecologically relevant adaptation given their large population sizes (Hairston et al., 2005; Thibodeau et al., 2015). Additionally, as mentioned earlier, phytoplankton are characterized by a large amount of genetic, metabolic and functional diversity, which offers many opportunities to respond to selective environmental filters.

Diversity as an emergent property of the ecosystem

The large diversity of phytoplankton species and forms that can be found at the local community scale has been puzzling aquatic ecologists for more than half a century. Hutchinson (1961) was the first scientist to highlight how phytoplankton is a particularly inspiring example of a natural community comprising a large number of different species from the same trophic level, therefore similar in terms of broad functions, which co-occur over many generations in the same (sometimes very small) water body. Hutchinson introduced the term "paradox of the plankton" to refer to this surprising diversity: "how it is possible for a number of species to coexist in a relatively isotropic or unstructured environment all competing for the same sorts of materials?" The paradox, which is one of the most classical problems in ecology, stems from the prediction, by the principle of competitive exclusion, that in homogeneous environments species that compete for the same resources cannot coexist for long, since the best competitor should eventually prevail when a final equilibrium is reached. This paradox of high diversity is not even restricted to the species level only, since species comprise multiple genotypes that appear to fit different environmental conditions, but yet co-occur in nature.

To explain the paradox of the plankton, many solutions have been proposed by numerous scientists over the years. The principal mechanisms invoked suggest that phytoplankton communities never reach a stable equilibrium, due to both external forcing (e.g., environmental fluctuations in essential resources, disturbances), and internal species interactions generating chaotic dynamics (Fig. 3) (Roy and Chattopadhyay, 2007). Out-of-equilibrium dynamics set temporal limits for single species to become dominant, minimizing competitive exclusion. Similarly, resources (nitrogen, phosphorus, light) are not homogeneously distributed, but vary spatially and temporally. Likewise, for organisms exhibiting a high diversity in photopigments, light is not one but an array of resources (Roy and Chattopadhyay, 2007). Additionally, phytoplankton taxa can coexist if they are similar enough to be

competitively neutral (Scheffer and van Nes, 2006). All of these mechanisms are plausible and have found evidence in field or laboratory investigations. The main process allowing such a large diversity of species in lake phytoplankton communities remains however a mystery. The relative importance of the above mechanisms likely changes over space and time.

The diversity of phytoplankton, in terms of genetic, phenotypic and consequently taxonomic characters, is a property of the community that emerges from the interaction of ecological and evolutionary processes in a fluctuating environment (Fig. 3). Individuals respond to their immediate environment by regulating their gene expression, therefore adapting their phenotypes (morphology, physiology) to the environment. Such changes at the individual level influence the diversity and demography of populations, which interact with one another therefore determining the structure (richness, evenness, composition) and dynamics of communities and food-webs (Fig. 3) (Norberg, 2004). This rich and complex set of nested responses and feed-backs might explain the stunning diversity of planktonic ecosystems, and the reason why understanding such systems is still a hot research topic.

The issues above make phytoplankton communities fascinating from many different points of view: from the variety of species and forms, which highlight how explosive biodiversity can be even in small ecosystems, to the puzzling ecological and evolutionary questions of how this diversity is achieved and maintained over the long term. The processes invoked imply both deterministic (fundamentally predictable) and stochastic (fundamentally unpredictable) mechanisms, with implications for both fundamental research and applied science and management of lakes and their biodiversity. Not all the changes in an essential functional component of the biosphere like phytoplankton might in fact be predictable. This consideration is particularly relevant for lake ecosystems, which provide important resources to human societies like fisheries and drinking water, and require careful and adaptive management especially as a consequence of a general increasing prevalence of phytoplankton blooms due to climate change and eutrophication (Ho et al., 2019).

Algal blooms, i.e., mass occurrences of phytoplankton, have long been observed, and are usually associated with systems impacted by eutrophication (they may have been depicted already in the bible—"... and all the waters that were in the river were turned to blood" [Exodus 7:20]). They represent a response to anthropogenic pollution and a threat for aquatic ecosystem services (water quality, fishery, farming, recreation) worldwide, with annual societal costs in the billions of Euros (Note that the spring bloom in a lake is a seasonal, recursive natural phenomenon, not associated with eutrophication (Sommer et al., 2012).). In lakes, cyanobacteria are known to form dense blooms (Fig. 4) and produce a wide array of neurotoxins, liver toxins, cell toxins and skin irritants. Blooms can cause significant operational issues to intakes in drinking water plants, and consumption of toxins by animals or humans can result in multiple minor and major health issues (Huisman et al., 2018). Forecasting of algal blooms is a central concern in ecosystem management. The ability to anticipate blooms even just a week in advance would allow stakeholders to respond to human health or ecosystem service concerns.

Methods to study phytoplankton biodiversity

Traditional methods

The diversity of plankton communities is most commonly revealed by microscopy (Fig. 1). Only the development of optical microscopes, starting in the 17th century, enabled the first detailed characterizations of phytoplankton and their diversity by direct observation of their morphology. Early microscopic work revealed specifically the diversity of larger phytoplankton cells with distinct and rigid structures, such as diatoms (Fig. 1i–j). Further, and ongoing, advancements in optical microscopy render this method still one of the most commonly used techniques in characterizing phytoplankton biodiversity.

The maximal resolution of most light microscopes does not allow for useful magnifications above 2000x, which may not be sufficient to identify distinct morphological traits of small phytoplankton (<2 μm), but also of larger species that lack evident morphological features. The development of the electron microscope in the early 20th century enabled the investigation of cellular ultrastructures (e.g., the silica frustules of diatoms), which in turn helped to further resolve phytoplankton biodiversity. Novel developments in optical microscopy led to new techniques (e.g., confocal laser scanning microscopy or structured illumination microscopy), which allow for resolutions higher than those imposed by the diffraction limit of light microscopy. Combined with the use of specific fluorescent dyes, these techniques enable to achieve higher resolutions and directly resolve processes at the

Fig. 4 Blooms of cyanobacteria in Swiss lakes. From FAQ – Cyanobacteria / blue-green algae. https://www.eawag.ch/en/research/water-for-ecosystem/pollutants/faq-cyanobacteria-blue-green-algae/.

cellular level, which in turn may allow to characterize and distinguish phytoplankton beyond morphology and taxonomy, namely on the physiological functional level.

Lake water samples for microscopy are typically taken from a boat using niskin bottles (bottles that close at discrete depths) or Schroeder bottles (which intake water based on a pressure valve, for depth-integrated sampling), with a monthly frequency (as suggested by many water quality directives). The Utermöhl method is the most widely used to examine phytoplankton: the protocol presumes the use of a preservative solution (either formaldehyde or Lugol's iodine), which blocks biological activities but can damage cellular structures and shrink cell size. Samples are then sedimented, cells recovered in a counting chamber, and counted manually under an optical inverted microscope. Traditional sampling and Utermöhl-based microscopy have been applied to lake phytoplankton diversity monitoring for more than a century worldwide, and have provided historical time series (generally decades long) of species counts and biodiversity estimates that have been instrumental for understanding lake processes (Table 1).

The counting and classification of phytoplankton is however a very tedious process, and often taxonomists miss items, count some objects more than once and misclassify others (MacLeod et al., 2010). This is exacerbated by continuous taxonomic rearrangements in the classification of phytoplankton and by methodological changes over time. As a consequence of the above processes, water sampling and microscopy are very time consuming, costly, and therefore low throughput and expensive, making it challenging to measure and track phytoplankton diversity with high resolution across time and space. An additional problem of traditional monitoring data is that they often have a strong association with the person (e.g., taxonomist) collecting them. Harmonization of methods and procedures is of big concern in microscopic analysis of phytoplankton, and arguably also a source for biased data analyses in cases where data from multiple authors is merged (Moe et al., 2008). Manual microscopical identification also does not allow to consistently extract quantitative plankton morphological features, such as size, shape, or pigment information. These features are key plankton traits that determine individual, population and community responses to a changing environment, and in turn affect ecological processes (e.g., energy transfer, algal blooms), and services (e.g., fisheries, water quality). These limitations of traditional monitoring, together with the general demand for time-efficient analysis, have stimulated the development of a multitude of alternative and automated plankton monitoring tools (Johnson and Martiny, 2015; Lombard et al., 2019). New approaches can afford high-throughput and lower costs of plankton community analysis, in the laboratory and in the field, each with their own advantages and limitations. The taxonomic resolution of microscopy can be achieved and surpassed by DNA-based methods, traits can be measured by flow-cytometry and imaging, and in situ sensors can provide high-frequency real-time data on bulk community properties.

New and alternative methods

Phytoplankton contain pigments for harvesting light. Eukaryotic phytoplankton contain chlorophyll a as their core pigment, however, many accessory pigments (e.g., other types of chlorophyll, carotenoids or phycobiliproteins) are taxon-specific. Therefore many lineages have specific optical spectra; however, these accessory pigments and their abundance relative to the universal chlorophyll a are not necessarily unique to specific groups, hence precise distinctions at fine taxonomic scale are challenging (Johnson and Martiny, 2015). Nonetheless, chromatographic approaches such as high-performance liquid chromatography (HPLC) are used to obtain a broad taxonomic characterization of a given phytoplankton sample based on its pigment composition, also because they are usually economic and relatively high throughput. An advantage of pigment ratios is that they may provide information on the physiological/functional diversity of phytoplankton, because they are influenced by light (spectrum and intensity), nutrient availability and other environmental factors. Phytoplankton pigments (e.g., Chl-a, phycocyanin) can also be used to estimate abundance and diversity, in terms of broad functional groups, using remote sensing from satellites, airplanes or drones over varying areas of a water body or region. Remote sensed data can provide information about horizontal distribution of phytoplankton, or across many lakes (Ho et al., 2019), which is not possible to achieve with traditional monitoring. Remote sensed data (i.e., from satellites) are available worldwide and daily at low cost. Unfortunately remote sensing has no vertical (depth) resolution and, being based solely on main pigment type, provides little information about the taxonomic diversity of phytoplankton.

DNA amplification and sequencing, and other techniques derived by DNA-based hybridization, have become an increasingly common and cost-effective approach to estimate phylogenetic and functional diversity in phytoplankton (Johnson and Martiny, 2015). Here we will concentrate only on the most common and effective approaches. Based on highly conserved DNA regions, which are however different among taxa, such as the 18S ribosomal DNA (rDNA) for eukaryotes or 16S rDNA for prokaryotes, the so-called DNA-barcoding aims to amplify and sequence such targets. As mentioned earlier, sequencing of phylogenetic marker genes such as the 18S and 16S has helped discovering cryptic species, i.e., two or more morphologically indistinguishable species, and supported the rearrangement of taxonomic classifications. Meta-barcoding, which is referred to the amplification and sequencing of marker genes across an entire community, allows the identification and classification of organisms as Operational Taxonomic Units (OTUs), by assigning different sequences to taxa through matching of such sequences to reference databases (in which reference sequences are obtained from certified taxonomic classifications). Meta-barcoding, which can be achieved directly using environmental samples (e.g., environmental DNA or eDNA), has become common practice in biodiversity estimation in aquatic environments (Deiner et al., 2017), principally due to next generation sequencing (NGS) that is high throughput and cost-effective, and the availability of well-curated database and efficient pipelines for data analysis.

To date, meta-barcoding probably represents the state of the art to estimate the diversity of small prokaryotes and eukaryotes in phytoplankton, for which morphological characters cannot be distinguished (nevertheless, standard metabarcoding is less accurate for quantitative analysis of those taxa that are accessible to microscopic analysis). Metagenomics, i.e., the sequencing of all DNA present in an environmental sample, allows the reconstruction of genomes in uncultivated phytoplankton organisms, including their functional genes. Metatranscriptomics, which targets all RNA present in a water sample, can be used to study and quantify the diversity of expressed phytoplankton genes in the environment. In this way, metagenomics and transcriptomics provide information about the different functions of a community and these changes under different environmental conditions (Johnson and Martiny, 2015). While metatranscriptomics can provide quantitative data about expressed functions, barcoding and genomics mostly provide qualitative (presence/absence) information, and all these approaches can be severely limited by coverage in the reference databases used to annotate the sequences obtained.

Many quantitative methods have been proposed for the estimation of taxonomic and functional diversity in phytoplankton (Johnson and Martiny, 2015; Lombard et al., 2019). Here we will focus, again, on the most common and effective approaches with a particular emphasis on methods that can be automated. Flow cytometry measures fluorescence and scattering signals from single microbial cells or colonies (from viruses to eukaryotes) contained in a water sample: particles are separated using one or more stages of injection of the sample into an internal fluid system, and are oriented along their main axis through a flow-cell where they are beamed sequentially by one or multiple lasers (wavelengths are generally chosen to excite different algal pigments). The scattering (forward and side scattering) and fluorescence (from many different filters, associated with different pigment emissions) signals are parameterized and recorded for each individual particle. Depending on how many and which lasers, and fluorescence filters, flow cytometry is able to resolve several phytoplankton features including size, shape, granularity and pigment quantity and composition (Fontana et al., 2014). These measures of phytoplankton morphology and color represent important functional traits: flow-cytometry can be considered a high throughput phenotyping technique, and can provide highly valuable estimates of community diversity based on individual level phenotypic data, similar to genetic data (Johnson and Pomati, 2020). Additionally, flow-cytometry can be applied in situ under automated use, which has allowed to pioneer the study of natural phytoplankton dynamics at scales of space and time that were not possible with traditional methods (Table 1).

Imaging techniques are emerging as those that have the highest potential to yield standardized and reproducible quantification of abundance, biomass, diversity and morphology of plankton (Lombard et al., 2019). Boosted by the recent developments in the miniaturization of optics and electronics, plus continuous advances in image processing and artificial intelligence (AI) for object recognition and classification, automated imaging microscopy offers the best prospects to substitute traditional methods in the monitoring of phytoplankton biodiversity. Imaging allows us to harness the knowledge of taxonomists to train automated AI classifiers (MacLeod et al., 2010). Some of these instruments can be deployed in the field, therefore allowing high-frequency automated monitoring. Among those is worth mentioning imaging flow-cytometers, which combine the resolution of flow-cytometry laser detection and scanning with imaging of selected particles (Lombard et al., 2019). Underwater microscopes and cameras are more recent advances allowing rapid and cost-effective monitoring of phytoplankton (and zooplankton) in situ by imaging, without disrupting natural spatial aggregates, behaviors, shape, and co-localization of organisms (including symbionts and parasites). Some basic information about phytoplankton such as in situ physical morphology, natural heterospecific aggregates, or individual level interactions, have rarely been studied at the right scale due to biases introduced by sampling (Fig. 5). Underwater cameras are cheaper and more robust than previous in situ tools, and allow complete automation in functioning and data analysis (by exploiting the constantly advancing fields of image processing, whose tools are also generally open-source). New developments in underwater cameras allow to automatically image with multiple magnifications (two distinct objectives) phytoplankton and zooplankton at unprecedented spatial (10 μm to 8 mm) and temporal (seconds) resolution. Aided by automated image processing pipelines and classification by AI, this approach allows to track plankton taxa diversity (including morphological traits) at the food-web level in real-time (Figs. 1 and 5).

Case studies

Table 1 Here we provide a non-exhaustive overview of case studies analyzing phytoplankton diversity in lakes. We distinguish studies where (1) diversity itself is the dependent variable from those where (2) diversity is explaining processes, and (3) technical studies about the quantification of phytoplankton diversity. We keep the focus on inland water bodies, so references to marine studies are not reported.

Synthesis

Phytoplankton biodiversity is as fascinating today as it was a century ago, being still partially unexplored, in part due to the paucity of methods to study microbial communities with large dispersion and population sizes. Exciting times are coming ahead in terms of new technology developments, which will allow us to study the dynamic world of these mighty microbes at scales that were unimaginable only a couple of decades ago. We emphasized several aspects about the diversity of plankton, in terms of both conceptual and practical knowledge and current limitations. The need for more data, particularly at the genetic and functional level, and across scales of space and time, is motivated by questions regarding the relative importance of different mechanisms driving

phytoplankton biodiversity change. Conclusive results rely on careful investigations from the field and ecological models, which need to be informed by experiments and observational data analysis. Results so far testify for very sensitive responses of phytoplankton communities to environmental change, with potential implications for the resilience of lake ecosystem processes and the conservation of freshwater habitats and the biodiversity that they harbor. These issues are particularly important in our current times, characterized by local and global human impacts, like climate change. Our ability to predict and manage lake ecosystem services strongly depends on our understanding of the mechanisms regulating diversity in an essential functional component of the biosphere like phytoplankton communities.

Knowledge gaps

1. Measuring or inferring ecologically relevant traits (e.g., physiological responses), particularly for morphologically indistinguishable species, in the smaller nano size range (i.e., <5 μm).

2. Incomplete understanding of the carbon metabolism in majority of clades (use of inorganic vs. organic C-sources).
3. Methods to study local processes at the temporal scale that matters to understand eco-evolutionary dynamics, including methods to study single cell genomes and phenotypes.
4. Understand and quantify the relevance of colonization-extinction events as opposed to "dispersal in time" (colonization from the egg-bank).
5. Extent of genetic diversity and importance of sexual reproduction versus clonal proliferation in freshwater phytoplankton, and how this contributes to functional diversity.
6. Approaches to mitigate human impact on phytoplankton diversity and conservation strategies specifically targeting phytoplankton.
7. Incomplete understanding of the effects of environmental change on phytoplankton communities, e.g., globally reduced primary production due to warming (shift toward net heterotrophy).
8. The relative importance of physiological responses, ecological interactions and evolutionary adaptation in phytoplankton community change over long-term environmental gradients and under extreme events.
9. Globally, poor coverage of monitoring programs leads to a lack of data on phytoplankton diversity (and how it changes with time) at different spatial scales.
10. Factors selecting for toxins in phytoplankton, leading to toxic algal blooms.
11. Consequences of changes in phytoplankton diversity in the food web context (other trophic levels).

Glossary

Alternative stable states Ecosystems may exist in several, alternative, steady states each with its self-enforcing negative feedbacks. This paradigm has been adopted from theoretical ecology and has become widely accepted and applied in shallow lake research and management.

Belt transect Band of defined width oriented at right angles to the shoreline or bank, which starts at the water line including the wash and inundation zones starting at the highest seasonal waterline and in lakes extends to the lowermost limit of the aquatic macrophyte vegetation.

Benthivory Effects of the feeding on benthic animals by benthivorous fish. This includes direct impact on macrophytes and sediment and indirect impact on other biotic and abiotic compartments.

Clonal growth Many macrophyte species groups display a clonally branching growth form, i.e., the branched plant architecture consists of repeated vegetative modules that each can survive and establish as an independent plant, and continue further clonal growth and generative reproduction. Clonal branching and subsequent fragmentation and spread may lead to the distribution of genetically identical individuals over larger distances.

Dispersal Spread over shorter or longer distances of more or less specialized vegetative plant fragments or organs, as well as generative units such as seeds and spores. The dispersed units can establish new stands of macrophytes.

Dissolved Inorganic carbon (DIC) Dissolved inorganic carbon is present in equilibrium as three species, carbonate, bicarbonate (HCO_3^-) and carbon dioxide (CO_2). The distribution over these three is governed by pH, as is steady state total concentration.

Eutrophication Increased nutrient (mainly phosphorus and/or nitrogen) availability in a water body leading to increased productivity of primary producers.

Growth form A phenotypically recognizable similarity in the functional organization of the stem, leaf, root and reproductive organs across different plant species, which is interpreted as an adaptive response of the whole plant form to its environment.

Herbivory One of many food-web interactions. The consumption of plants or plant parts by animals, loosely similar alternatives are grazing and browsing.

Maximum colonization depth Lowermost limit of the aquatic macrophytes which are adherent to or rooted in the sediment.

 https://doi.org/10.1016/B978-0-12-819166-8.00043-8

Overyielding A mixture of species performs an ecosystem function better than monocultures.
Percent volume infested/inhabited (PVI) Volume of lake inhabited by macrophytes in percent.
Periphyton Periphyton is the community of microorganisms (microalgae, micro-, meio- and mesofauna, fungi, bacteria), the surrounding matrix of co-precipitated carbonates and excreted polycarbohydrates and detritus developing on submerged surfaces. Vertical depth of periphyton communities ranges in the order of micrometers to a few centimeters.
Regime shift See alternative stable states.

Introduction

Macrophytes are "aquatic photosynthetic organisms, large enough to see with the naked eye, that actively grow permanently or periodically submerged below, floating on, or up through the water surface" (Chambers et al., 2008). They have adapted to living in aquatic environments and grow in or near water in emergent, submerged or floating forms. This definition includes vascular plants, charophytes and aquatic bryophytes. The global number of macrophyte species is not known. Aquatic vascular macrophytes (*Tracheophyta*) alone include about 3500 species (without hybrids) that occur in permanent, temporary or ephemeral inland freshwater and brackish waterbodies worldwide (Murphy et al., 2019).

Most macrophyte species have narrow global distributions. About 80% of vascular aquatic macrophytes reportedly have ranges that individually occupy <10% of the world area present within the six global ecozones which provide habitat for macrophytes. Macrophyte diversity is highest in subtropical to low tropical latitudes and at ecozone scale, macrophyte species endemism is pronounced (Murphy et al., 2019).

Based on growth forms, several major macrophyte groups can be distinguished (Den Hartog and Segal, 1964, Fig. 1A–F):

Charophytes (Fig. 1A) are a class of macroscopic green algae exhibiting a complex whorl-shaped thallus and bottom-dwelling growth forms. They mainly occur in lakes with low nutrient concentrations and can grow down to deep (40–60 m) water. In eutrophic, turbid lakes, they are restricted to shallow water.

Aquatic bryophytes (Fig. 1B) can occur at great depths (down to 140 m). Efficient, low metabolism underlies tolerance of low light levels and low year-round temperatures in the hypolimnion of deep, cold lakes, and benefit from higher nutrient and CO_2 levels. The high accumulation capacity of bryophytes for contaminants has led to their use for monitoring regional and local patterns of deposition, particularly of metals and radionuclides.

Submerged rooted macrophytes (Fig. 1C) are angiosperms and pteridophytes that can complete their life cycle fully submerged, with some species displaying amphibian plasticity. A modal depth limit is 10 m. Root uptake is the primary pathway for nitrogen, phosphorus and micronutrients of these species.

Floating-leaved macrophytes are angiosperms, rooted in submerged sediments from about 0.5 to 3 m water depth with both submerged and floating leaves. The most familiar floating-leaved plants are the water-lilies (Nymphaeaceae; Fig. 1D).

Free-floating macrophytes are aquatic plants that are found suspended on the water surface or in the water. If present, their roots are not attached to the sediment. Abundant representatives are floating species like water hyacinth (*Eichhornia crassipes*) and duckweed (*Lemna* spp., Fig. 1E). There also submerged free floating species like bladderwort (*Utricularia* spp.) and hornwort (*Ceratophyllum* spp.).

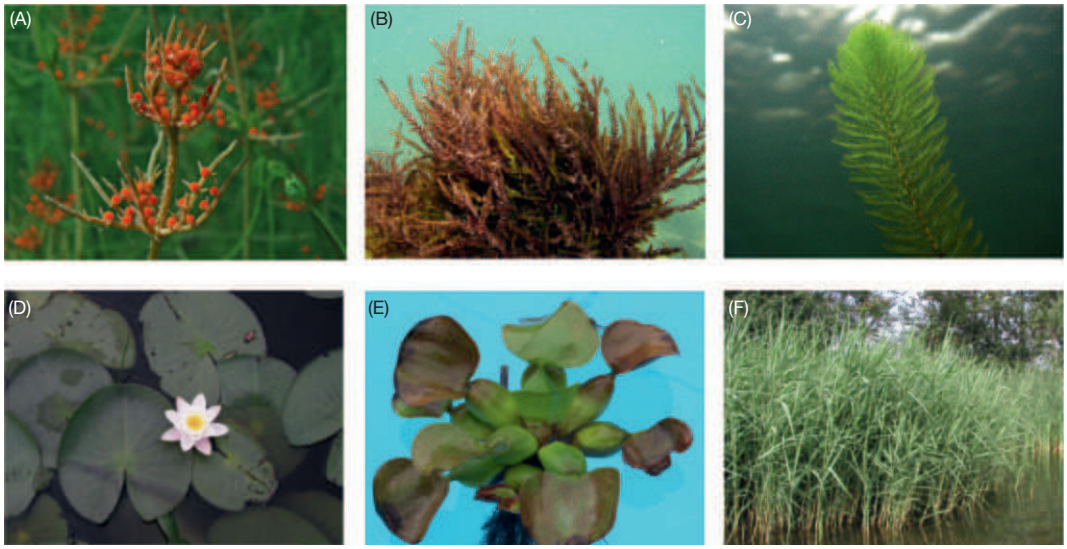

Fig. 1 Typical aquatic macrophyte species representing the different groups of growth forms in lakes (A: *Chara tomentosa*, B: *Fontinalis antipyretica*, C: *Myriophyllum heterophyllum*, D: *Nymphaea alba*, E: *Eichhornia crassipes*, F: *Phragmites australis*). Fotos: Klaus van de Weyer.

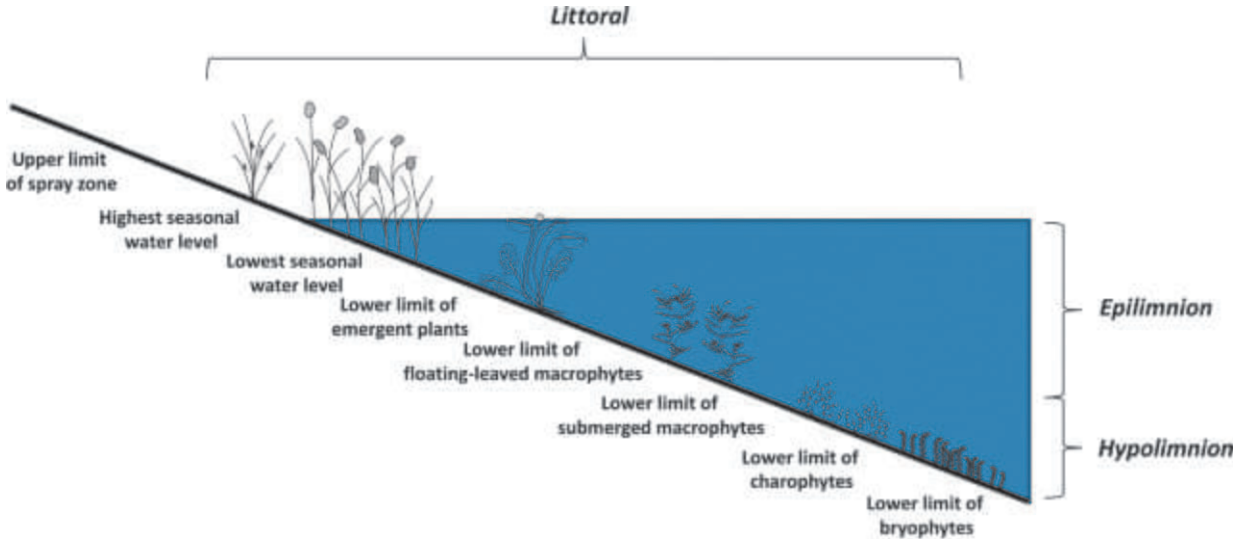

Fig. 2 Macrophyte zonation along depth gradients in the lake littoral.

Emergent macrophyte species (Fig. 1F) grow in waterlogged soils of the land-water interface, which is generally defined to be 0.5 m above the water table to about 2 m water depth. Their shoots are above the water surface and they often have rhizomes or corms. Many have developed an extensive root aeration system to cope with low oxygen levels in the sediment.

Amphiphytes can grow submerged in the water up to completely above the water, typically under fluctuating water level conditions.

Macrophytes tend to form recognizable assemblages composed of several species belonging to different growth forms. These assemblages are commonly organized along depth gradients and often form easily-distinguishable zones in relation to water depth. In general, emergent species dominate in shallow areas while the submerged ones colonize deeper sites and floating-leaved species are intermediate (Fig. 2).

A variety of macrophyte sampling and survey methodologies has been developed to measure the composition and abundance of macrophytes in lakes for specific applications including conservation, drainage impact, management, or habitat. Lake macrophyte surveys can be undertaken at different levels of intensity, but the most widely used method is based on belt transects surveyed by diving (most accurate and reproducible) or by boat. This relatively cost-effective approach allows mapping of the distribution of individual species and their abundance and provides robust data sets that can be used to generate indices and metrics (CEN, 2007). Hydroacoustics and remote sensing techniques are also increasingly used to monitor macrophyte distribution and abundance (Stocks et al., 2019).

Composition and abundance of macrophyte communities in lakes are regulated by a complex array of chemical, physical and biological factors exerting bottom-up and top-down control. In turn, macrophytes affect physical, chemical and biological conditions and processes in lakes therewith determining their state, ecosystem functions and services (Fig. 3).

Here, we review how lakes are a habitat for aquatic plants, but also how the plants affect their habitat and are habitat for other organisms. Whilst we try to cover macrophytes in lakes worldwide, we recognize that there is a bias. Only 6% of the world macrophytes species have by now been investigated in dedicated single species studies (Dalla Vecchia et al., 2020).

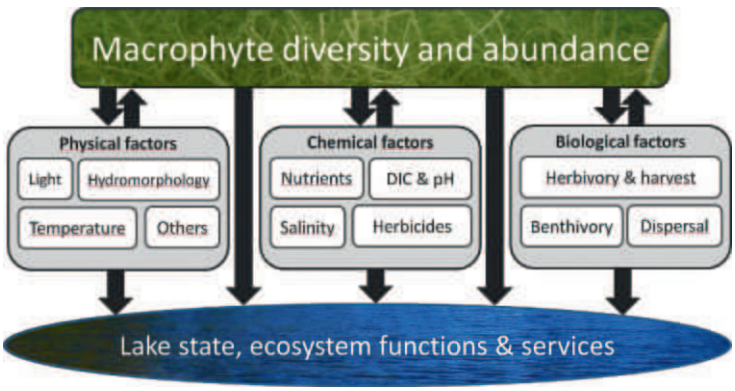

Fig. 3 Interactions between macrophyte diversity and abundance in lakes and important physical, chemical (DIC: dissolved inorganic carbon) and biological factors together affecting lake state, ecosystem functions and services.

Factors affecting macrophyte diversity and abundance in lakes

Physical factors

Light availability

Usually, light availability is the most important factor for the development of submerged macrophytes, and it determines the maximum colonization depth. Light for submerged macrophytes is attenuated by shoreline or floating vegetation, particulate suspended matter, colored dissolved organic matter, phytoplankton and periphyton, and also by self-shading in dense stands. Maximum colonization depth of charophytes is higher than that of angiosperms in clear lakes (Fig. 2). In turbid lakes, however, angiosperms can have a higher maximum colonization depth due to adaptations to poor light availability such as shoot elongation, canopy formation and rapid growth during spring. The colonization depth of macrophytes was found to decrease at latitudes above approximately N 60 degrees (Duarte and Kalff, 1987) and Middelboe and Markager (1997) estimated an average decrease in maximum depth for charophytes of 0.12 m per degree increase in latitude (ranging from N 37 degrees to 74 degrees).

Different percentages of surface light at maximum colonization depth have been reported ranging from 2% to 4% for characeans (Schwarz et al., 2000), 8–10% for *Isoëtes lacustris* (Rørslett and Johansen, 1995), 10–21% for vascular plants (Sheldon and Boylen, 1977; Chambers and Kalff, 1985). Søndergaard et al. (2013) analyzed about 750 European lakes and found maximum colonization depths relatively closely related to Secchi depths.

Light attenuation by phytoplankton and periphyton plays a key role for macrophyte abundance and species composition during changing nutrient loading to lakes (Phillips et al., 2016; Hilt et al., 2018). The dynamics of periphyton cover are only partly linked to that of phytoplankton, but a similar seasonality with spring and autumn blooms is reported (Van Dijk, 1993). Accumulation of periphyton to a densely shading cover takes time (in the order of a few weeks), and rapid expansion to the water surface is a macrophyte strategy to overcome this.

Temperature

Temperature is of high importance in determining the distribution, growth rates, timing of life history events and metabolism of macrophytes in lakes at larger spatial scales, such as latitudinal or altitudinal gradients. Macrophyte growth is affected by temperature because all enzymatic-catalyzed reactions and membrane processes in plant metabolism are temperature dependent (Brown et al., 2004). Most aquatic vascular plant species exhibit optimal rates of photosynthesis at relatively high temperatures (between 20 °C and 35 °C, Santamaría and Van Vierssen, 1997, Fig. 4). Some cold-water adapted charophytes (e.g., *Nitella hookeri*) reportedly have lower temperature ranges (Starling et al., 1974). For macrophyte species growing in both temperate and low arctic regions, the optimum temperature for growth is therefore often well above the ambient water temperature, although acclimation capacity in macrophytes is likely substantial (Pilon and Santamaría, 2002, Fig. 4) and shallow waters may warm up more rapidly than limnological data would suggest. In principle, global warming is expected to stimulate macrophyte growth in temperate (Zhang et al., 2019) and arctic lakes (Lauridsen et al., 2020). Species-specific responses to climate change among submerged macrophytes can significantly influence their species composition (Li et al., 2017). Macrophyte cover is expected to decrease under the current nutrient levels in regions where climate warming would lead to fewer frost days (Kosten et al., 2009).

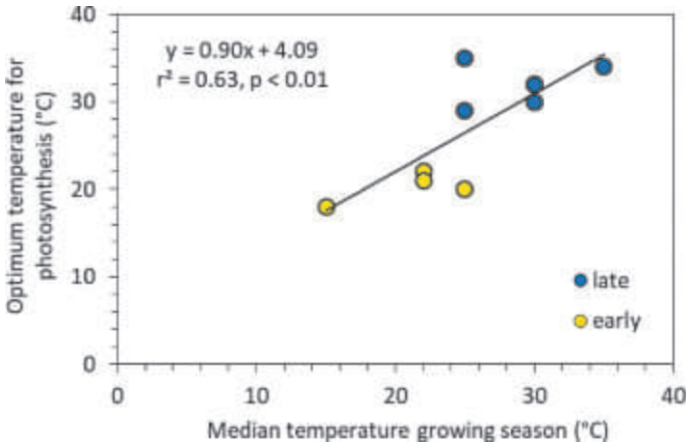

Fig. 4 Temperature effects on macrophyte growth: the optimum temperature for photosynthesis appeared correlated with the median temperature in the growing season, across a range of species, some having their growth optimum early in the season, others late, suggesting both variation among species as well as acclimation potential. Data extracted from Santamaría L and Van Vierssen W (1997) Photosynthetic temperature responses of fresh- and brackish-water macrophytes: A review. *Aquatic Botany* **58**: 135–150.

Hydromorphology

Several lake morphological characteristics interact to set the potential maximum spatial extent and depth distribution of macrophyte in lakes. First and foremost, littoral slope is critical (Duarte and Kalff, 1990). A steep slope usually only allows for narrow bands of macrophytes, whereas shallow, gradual banks can be inhabited by wide stretches of aquatic vegetation. In addition, the response strategies of macrophytes to low light conditions affect their distribution: canopy-forming species were found to prevail at sites with lower slopes because they responded to low light conditions by stem elongation and were more susceptible to drag forces. In contrast, rosette-type species tolerated shading by increased shoot chlorophyll content and thus could survive at sites with steeper slopes (He et al., 2019).

A second prime factor is wave exposure driven by fetch. A highly wave-exposed littoral will have coarse grained sediments with little fine particles and organic matter deposition—this turbulent environment sets limits to growth forms that successfully colonize it and nutrient availability is often low. Larger lakes have longer fetches and greater wave energy than smaller ones. Variation in wave action also directly influences macrophyte distribution within lakes. In wave-exposed sites rooted species with fine or dissected leaves are at an advantage over those with larger and floating leaves (Gasith and Hoyer, 1998). Wave-exposed sites generally have a lower macrophyte biomass (Madsen et al., 2001). Sediment grain size distribution covaries with sediment quality, such as organic matter and nutrient content (Chambers and Kalff, 1985). The strong variation in nutrient availability and sediment particle size also leads to variation in selection for different growth forms (Duarte and Kalff, 1990).

Shoreline development and the shading cover of trees on the banks may have a strong impact on the littoral as habitat for macrophytes. Increased shore harnessing with riffraff, boulders and concrete embankments reduces the availability of suitable habitat along relatively sheltered shorelines for littoral reed stands reaching from land into the water, and hence for a gradual transition into deeper water with changing predominance of growth forms (Radomski and Goeman, 2001). Large seasonal fluctuations in water level would compress the habitat available for submerged macrophytes (e.g., Rørslett, 1984, 1990) and, depending on the coarseness of the substrata, create a littoral zone mainly colonized by short-lived annuals or specialized emergent species that can cope with both submergence and drought. Annual winter drawdowns can decrease taxonomic richness of macrophytes (Carmignani and Roy, 2017). Amphiphytic, annual macrophyte species and helophytes reportedly can benefit from drawdown (Bornette and Puijalon, 2011). In tropical regions with strong seasonality of rainfall, submerged plant communities can be greatly reduced during periods of increasing water level and/or turbidity. Induced bank filtration can contribute to water level fluctuations and additionally negatively affect submerged macrophyte growth by interrupting seepage of CO_2 rich groundwater (Gillefalk et al., 2019).

Ice cover, also in combination with snow influences the survival of macrophytes. Some submerged macrophytes can maintain high population densities and productivity throughout the winter. For example, Boylen and Sheldon (1976) reported maximum winter photosynthetic activity to be 10–20% of summer rates. Ice scouring during spring-melt can remove large quantities of aquatic vegetation in the upper littoral (Rørslett, 1990).

Chemical factors

Nutrient availability and uptake

Nutrient availability is a key factor determining macrophyte diversity and abundance in lakes. Nutrient limitation is of particular importance for restricting biomass production in high-latitude lakes (Lauridsen et al., 2020), although accumulated biomass can still be high (Moe et al., 2013). Rule-of-thumb critical nutrient levels for maximum growth of freshwater angiosperms are suggested to be 0.13% and 1.3% dry weight for phosphorus (P) and nitrogen (N), respectively (Gerloff and Krombholz, 1966). Strong linear relationships between concentrations of N and P reflect a common biochemical basis among different aquatic plant groups (Duarte, 1992).

For most submerged macrophytes, root (or rhizoid-node complexes in charophytes) uptake is the primary pathway for the major nutrients N and P as well as micronutrients, whereas foliage uptake is the primary pathway for calcium, magnesium, sodium, potassium and sulfate (Barko and Smart, 1981). In nutrient-rich water, some species satisfy their demand for mineral nutrients by leaf nutrient uptake alone (Madsen and Cedergreen, 2002). In nutrient-poor environments, a symbiosis with arbuscular mycorrhizal fungi facilitates uptake of P and N from sediments (Søndergaard and Laegaard, 1977). This mechanism has been shown to be important for nutrient uptake by isoetids in oligotrophic lakes (Smolders et al., 2002).

Nutrient enrichment was found to increase macrophyte nutrient content and decrease the C:nutrient ratios (Velthuis et al., 2017). Up to certain thresholds (see below), nutrient enrichment to lakes may thus result in an increased macrophyte biomass with a potential for mass developments (Moe et al., 2019). Species richness of macrophytes in lakes, however, decreases with increasing nutrient loading (Jeppesen et al., 2000) or shows unimodal relationships (Vestergaard and Sand-Jensen, 2000) and eutrophication homogenized shallow lake macrophyte assemblages over space and time (Salgado et al., 2018), because isoetids are replaced by elodeids, and among elodeids small slow-growing species are replaced by large fast-growing species (Vestergaard and Sand-Jensen, 2000). Macrophyte cover also decreased above certain thresholds due to shading by periphyton and phytoplankton (see Section "Light availability"). In Danish lakes, macrophyte cover decreased at increasing total N concentrations when total P concentrations were between 0.1 and 0.4 mg P L^{-1} (Søndergaard et al., 2017). Based on an analysis of data from about 800 lake years in different climate zones in North America, South America, and Europe, Kosten et al. (2009) reported that the proportion of lakes with substantial submerged macrophyte coverage (>30% of the lake area) decreased in a sigmoidal way with increasing total P concentration, falling most steeply between 0.05 and 0.2 mg P L^{-1}.

Many temperate shallow lakes are found to show typical patterns of macrophyte loss with nutrient enrichment, developing from diverse communities via intermediate states characterized by the occurrence of only a few macrophyte species to a turbid state lacking macrophytes (Hilt et al., 2018). Paleolimnological studies of lake sediment cores and long-term data-sets revealed that lake eutrophication over the past 100–200 years has dramatically reduced macrophyte diversity and left a large proportion of species as regionally extinct and nationally red-listed (Sand-Jensen et al., 2000). Recent reductions of external nutrient input have led to macrophyte re-establishment in some lakes, but often not with the same areal cover and species richness as before eutrophication commenced (Hilt et al., 2018).

Carbon availability and uptake

CO_2 availability is a factor that can control the abundance and species composition of submerged macrophytes in lakes. All aquatic plants can use CO_2 as a carbon source, and the CO_2 concentration needed to half-saturate the photosynthesis of aquatic plants is approximately 6–13 times atmospheric levels (Demars and Tremolieres, 2009). The 10^4-fold lower diffusion coefficient of gases in water compared to air presents a major challenge to submerged macrophytes and inorganic carbon limitation of photosynthesis is a common feature (Pedersen et al., 2013). To maintain net photosynthesis, macrophytes have evolved different strategies. Some submerged species develop aerial leaves that can take up atmospheric CO_2, while others can take up CO_2 from the sediments. About 50% of the submerged macrophyte species (but not aquatic bryophytes and pteridophytes) can use HCO_3^- as a carbon source in addition to free CO_2 (Sand-Jensen and Gordon, 1986). The ratio of obligate CO_2 users to HCO_3^- users is significantly related to the HCO_3^- concentration which is generally determined by catchment properties. Increased HCO_3^- concentrations as a consequence of deforestation, cultivation of land, application of nitrate fertilizers, and reduced atmospheric acid deposition were proposed as drivers of changes in species composition in originally HCO_3^--poor lakes by allowing tall, fast growing HCO_3^- users to suppress smaller species adapted to the use of CO_2 alone (Iversen et al., 2019).

Some specialist macrophyte species display C_4 or CAM (Crassulacean Acid Metabolism) metabolism which can occur simultaneously with HCO_3^- use (Pedersen et al., 2013). Productive lakes are often depleted of free CO_2 in summer and macrophytes depending on free CO_2 availability may be restricted to areas with high organic carbon content in the sediment such as shallow protected bays or upwelling groundwater. In contrast, aquatic vegetation of lakes with low pH, low alkalinity, and thus low HCO_3^- availability, is often dominated by isoetids and bryophytes rather than HCO_3^--using elodeids (Vestergaard and Sand-Jensen, 2000). The global increase in atmospheric CO_2 may induce changes in plant productivity and species dominance. Indeed, macrophytes using CO_2 and HCO_3^- were projected to double their growth rate due to atmospheric CO_2 elevation, while the growth of macrophytes restricted to CO_2 assimilation may increase with a factor three (Schippers et al., 2004). However, because CO_2 supersaturation is widespread in lakes, increasing atmospheric CO_2 may not necessarily lead to corresponding increases in lake water free CO_2.

Salinity

Most macrophyte species are intolerant of high salinity concentrations and therefore are largely confined to freshwater lakes. Consequently, macrophyte species richness decreases with increasing salinity. Few species of submerged macrophytes (*Chara canescens*, *Lamprothamnium* spp., *Lepilaena* spp., *Ruppia* spp., *Tolypella* spp.) are restricted to brackish water and are found even in polyhaline waters (according to the Venice system, >18 psu, James et al., 2003, Schubert and Blindow, 2003). Usually, species tolerant of moderate to medium salinities (*Lemna* spp., *Myriophyllum spicatum*, *Najas* spp., *Stuckenia pectinata*, *Zannichellia* spp.), are found over the entire salinity spectrum into mesohaline waters (<10 psu) and thrive there (Hammer and Heseltine, 1988).

Herbicides

Native macrophyte communities can also be affected by herbicides that enter lakes unintentionally from e.g., agricultural run-off or antifouling paints, or intentionally as a management tool against invasions of alien macrophytes. Herbicides can be persistent in aquatic environments, with low abiotic and biotic degradation and high phytotoxicity. The effect of herbicide treatment on native macrophytes is variable and can be significant. Mikulyuk et al. (2020) reported that lake-wide herbicide treatments aimed at controlling invasive *Myriophyllum spicatum* had larger effects on native macrophytes than on the target species. A review by Vonk and Kraak (2021) concluded that an extensive catch-up must be made for macrophytes to achieve a reliable herbicide hazard and risk assessment.

Biological factors

Herbivory and harvest

In contrast to earlier views prevailing until the 1990s, top-down control by herbivores significantly affects macrophyte abundance and species composition by grazing and bioturbation (Bakker et al., 2016). Macrophyte herbivory can alter the functioning of lakes, including biogeochemical cycling, carbon stocks and primary production, transport of nutrients and propagules across ecosystem boundaries, habitat for other organisms and the level of shoreline protection by macrophyte beds (Bakker et al., 2016). Herbivores were estimated to remove a 5–10 times greater macrophyte biomass from aquatic than from terrestrial ecosystems. This may be explained by the lower C:N stoichiometry found in submerged macrophytes. Global environmental change is projected to increase herbivore impacts (Bakker et al., 2016 and references therein). The outcomes of macrophyte-herbivore interactions appear to be highly variable across aquatic ecosystems. Herbivorous taxa differ in their impact, with insects associated with smaller effects than

all other taxa (birds, mammals, crustaceans, molluscs, fish, echinoderms; Wood et al., 2017). Herbivory alone may often not be sufficient to cause macrophyte collapse, but other stressors such as shading from periphyton were found to enhance the effect of herbivores. Significant herbivore impact may thus indicate a reduced resilience of vegetation to eutrophication, making it an early warning signal for an imminent macrophyte collapse (Hidding et al., 2016).

The presence of extensive macrophyte stands can have negative effects on some forms of human use (see below) and harvesting is a common management measure applied. However, shallow lakes can have alternative stable states (see below). When a critical, in practice unknown, proportion of submerged vegetation is removed, the system can be propelled to the turbid state with a much lower macrophyte diversity and abundance due to the stabilizing effect of macrophyte cover on the clear water state (Kuiper et al., 2017).

Benthivory

The effect of benthivorous fish such as common carp (*Cyprinus carpio*) or bream (*A. brama*) on macrophytes has been documented since the 1920's Cahn (1929). Benthivorous fish can reduce the biomass and diversity of macrophytes by direct destruction. They disturb sediments while searching for food and pull rooted macrophytes out of the sediment. Breukelaar et al. (1994) showed in experimental studies, that the effects of benthivorous fish on macrophytes are related to fish biomass. Benthivory can also increase the amount of suspended sediment, enhance remobilization of nutrients from the sediment and thus contribute to reduced water transparency (Miller and Crowl, 2006; Zambrano et al., 2001). Also Vilizzi et al. (2015) found a very high impact of common carp on aquatic macrophytes.

Dispersal

Aquatic plants can be dispersed by seeds and spores as well as by vegetative fragments. The latter can be simply broken off pieces as well as specialized forms such as turions (winter buds). Dispersal takes place by water flow (hydrochory), by animals (zoochory), by wind (anemochory), or by human-mediated dispersal (hemerochory or anthropochory) (Fig. 5). Hydrochory is limited by the extent of the hydrological network that forms the habitat (Sun et al., 2019). Successful dispersal events among river networks and lake districts thus have a low probability, although the life span of clonal macrophytes may be long enough for such rare events to occur. Water birds however have the potential to transport a wide variety of aquatic plants over several hundreds of kilometers, and this is likely a common process. Both endozoochory (internal transport) and ectozoochory (external transport) are important (Figuerola and Green, 2002; Van Leeuwen et al., 2012). Water bird migratory flyway patterns are reflected in the genetic similarity among macrophyte subpopulations in the lakes that are functioning as bird stepping stones (Hidding et al., 2014). On the other hand, when new habitat becomes available, for example after lake restoration, the time window open for successful colonization may be limited (Beltman et al., 2011). Recreational boat traffic can also contribute to macrophyte dispersal, which is of particular relevance for invasive species (Johnstone et al., 1985). Alahuhta et al. (2018) investigated global patterns and found that macrophyte communities in lakes were typically not dispersal-limited within metacommunities, but spatial barriers may have hindered movements of macrophytes in some regions.

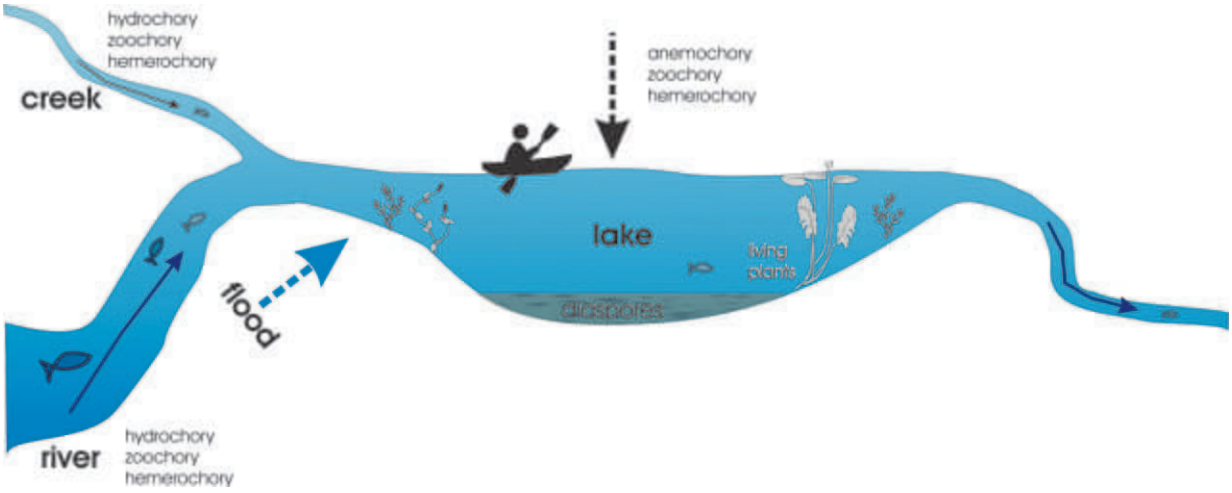

Fig. 5 Pathways of macrophyte dispersal in lakes.

Macrophyte effects on lakes

Effects on biotic components in lakes

Macrophytes in lakes can be a major food resource for invertebrates, fish, waterfowl and mammals (see above, Bakker et al., 2016). Usually, a positive relationship can be found between submerged macrophyte presence and the diversity of waterfowl, fish, benthic invertebrates, and zooplankton, while the situation was less clear for the diversity of phytoplankton, bacteria, parasites, viruses, and pathogens (Hilt et al., 2017). Enhanced recycling of P from the sediments and a positive effect of macrophytes on fish abundance, resulting in increased predation on both littoral grazers and zooplankton, are supposed to result in a high secondary productivity of lakes with abundant submerged macrophytes. However, yearly primary productivity of submerged macrophytes compared to that of phytoplankton in a lake can be minor, because macrophyte primary production depends on lake size and morphology, as well as littoral slope of the lake (Hilt et al., 2017). Submerged and emergent macrophytes also provide surface for periphyton, which plays a particularly important role in supporting fish production and in linking aquatic and terrestrial habitats through phenomena such as aquatic insect emergences, with implications for terrestrial plants, consumers, and ecosystems (Vander Zanden and Vadeboncoeur, 2020).

Macrophytes also provide refuge against planktivorous fish for zooplankton and suppress phytoplankton growth by competition for nutrients and excretion of allelochemicals that inhibit phytoplankton (Scheffer et al., 1993). Along with the effects of macrophyte on sediment resuspension, and particle sedimentation, these biotic interactions can stabilize clear-water conditions in lakes (see below). A global meta-analysis by Song et al. (2019) using 47 studies suggested that the positive effects of macrophytes on water quality were similar to or greater at lower than at higher latitudes. These findings challenged the prevailing paradigm (e.g., Meerhoff et al., 2007) of macrophytes being less effective at enhancing lake-water quality in the (sub)tropics. Macrophyte effects varied by growth forms, and Song et al. (2019) suggested that the growth forms that positively affect water quality differ between (sub)tropical and temperate areas. Submerged macrophytes were found to be more effective in reducing phytoplankton biomass than emergent and floating leaved species, particularly in the (sub)tropical area.

While an increasing species number caused overyielding and species complementarity in terrestrial plant communities, the few existing studies for aquatic plants are inconclusive, potentially due to the low species number tested (Riis et al., 2018).

Effects on abiotic parameters in lakes

Macrophytes can significantly reduce resuspension of bottom material (James et al., 2004) and increase sedimentation (Vermaat et al., 2000) inside dense stands by physically reducing water movement. Increased sedimentation also increases the removal of particulate P from the overlying water (Kufel and Kufel, 2002). Particularly dense stands may strongly affect biogeochemical processes at the sediment-water interface: in the root environment steep redox gradients are maintained by radial root oxygen loss affecting P solubility and nitrification/denitrification. Also the annual assimilation of N and P into new plant material is a net removal of nutrients from the water (Vermaat et al., 2000). In dense macrophyte stands, also the dynamics of oxygen and dissolved inorganic carbon (DIC) are strongly affected (Caraco et al., 2006). High photosynthetic activity during the daytime may raise oxygen concentrations above saturation levels and remove CO_2 and HCO_3^- (Trolle et al., 2012). Emissions of other greenhouse gases such as methane can also be affected by macrophytes in several ways (Hilt et al., 2017).

Macrophyte state shifts, decline and recovery

Submerged macrophytes were probably widespread with high cover in lakes throughout Europe and potentially many other parts of the world until cultural eutrophication from about 1950 onwards led to their decline or local eradication (Blindow, 1992). At present, an increasing number of lakes is losing submerged vegetation worldwide and loss rates are increasing (Zhang et al., 2017). Lake restoration efforts by reducing external nutrient loading or applying internal measures (Hupfer and Hilt, 2008) show variable results. In some lakes, abundance, coverage, plant volume inhabited or depth distribution of submerged macrophytes increase during reduced nutrient loading, while others show little change despite greater water clarity (Jeppesen et al., 2005).

Analyzing the long-term dynamics of submerged macrophytes in lakes with changing nutrient loading has led to the description of several patterns. In large, deep, naturally oligotrophic lake ecosystems, changes in submerged vegetation dynamics appeared to be closely related to changes in transparency coupled to phytoplankton and TP concentrations in the water (Murphy et al., 2018). In shallow lakes, submerged macrophytes can have a clearing effect on lake water due to several negative effects on phytoplankton and particle resuspension. Different feedback mechanisms prevail depending on whether charophytes or angiosperms are the dominant macrophyte group (Blindow et al., 2014). Such feedbacks have been suggested to underly the observed alternative stable states in shallow lakes—a clear, macrophyte-dominated state and a turbid, phytoplankton-dominated state (Scheffer et al., 1993). These states may appear stable for periods extending from years to decades (Scheffer and Van Nes, 2007). The occurrence of such a bistability has important implications for the possibilities of restoring eutrophied shallow lakes. Nutrient load reduction alone may not be sufficient, but an ecosystem disturbance like food web manipulation can bring the lake back to a stable clear state (Scheffer et al., 1993, Fig. 6). In deeper lakes, macrophytes may also contribute to stabilizing clearer water, but hysteresis is less likely to occur. Collapse and recovery of macrophytes in response to gradual changes in nutrient loading should thus be more predictable in deep than in shallow lakes (Sachse et al., 2014). In many north-temperate shallow lakes nutrient enrichment was associated with a

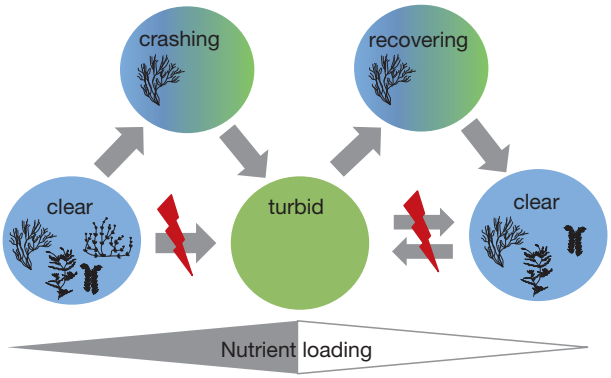

Fig. 6 Response patterns of north temperate shallow lakes to changes in external nutrient loading or strong disturbance (red flash).

reduction in the seasonal duration of macrophyte dominance and cyanobacteria blooms in summer (Hilt et al., 2018). With increased nutrient loading, lakes may thus shift from a stable clear-water state featuring a diverse plant community to a "crashing" state with fewer macrophyte species and turbid summers before the collapse to almost continuously turbid conditions lacking macrophytes (Fig. 6). Reduction of external nutrient loading can lead to an intermediate recovery state with clear-water conditions in spring and turbid water in summer and specific macrophyte communities with short growth seasons and eventually stable clear conditions with a diverse macrophyte flora if nutrient loading is reduced sufficiently or additional internal measures are applied. Lake-internal measures such as biomanipulation or sediment suction dredging can lead to unstable clear-water conditions with specific macrophyte communities that may collapse resulting in a shift back to turbid conditions unless nutrient loading is reduced. The final clear state may still differ in its macrophyte species composition from the initial state before anthropogenic nutrient loading started (Fig. 6; Hilt et al., 2018).

Macrophytes as indicators for the ecological state of lakes

Macrophyte species are long-lived compared to other aquatic organisms and likely can integrate long-term changes in environmental conditions. Their community composition can thus provide a long-term indication of overall lake condition, due to a limited response at weekly or daily time scales to changes in water clarity and chemistry. Lakes in "good ecological state" generally have a littoral zone with a high number and diversity of native aquatic macrophytes, and few or no invasive species (Poikane et al., 2018). Certain species groups are indicators for specific standing water types and are adversely affected by anthropogenic impact. Consequently, macrophytes can be used for ecological quality assessments of lakes. Mikulyuk et al. (2017) developed and tested a lake bioassessment method using aquatic macrophytes and defined an anthropogenic disturbance index for north temperate lakes. In Europe, macrophytes are one of the key metrics used to measure the ecological status of lakes under the Water Framework Directive (European Commission, 2000) and some macrophytes also serve as indicators for the European Habitats Directive (European Commission, 1992), one of the most powerful conservation policy tools in the world (Lockwood, 2006). Indeed, macrophyte communities of "good" status lakes are diverse with many charophytes and several *Potamogeton* species (Poikane et al., 2018). In New Zealand, the LakeSPI index (submerged plant indicators) was developed (Clayton and Edwards, 2006) and applied to 195 New Zealand lakes to examine how component metrics responded over gradients of anthropogenic pressures. Metrics measuring depth and diversity of native vegetation negatively correlated with independent measures of lake trophic state and were also well explained by multiple regression with lake and catchment attributes that included proxies for anthropogenic pressure (De Winton et al., 2012).

Ecosystem services of macrophyte-dominated lakes

Dense and diverse macrophyte beds can potentially contribute to several final services by their profound effects on a wide range of ecosystem functions. In their biomass, macrophytes may retain nutrients that would otherwise contribute to eutrophication reducing the lake value for the provisioning service "drinking water" and the cultural service "recreation." The same biomass may form a longer-term sink for carbon if it is sequestered in the sediment and hence contribute to greenhouse gas mitigation. Macrophyte beds form feeding and nursery grounds for fish and birds and thus contribute to the rich biodiversity that society finds sufficiently important to be legally protected, which can be considered a cultural service. Some of these fish species are important for recreational angling (a cultural service) or commercial exploitation (a provisioning service). Submerged macrophytes can be harvested as green manure, contributing to food production (a provisioning service), whilst emergent macrophytes are used for a wide variety of products (roof thatching, baskets), and are considered a potential source of biofuel (Janssen et al., 2021).

The collapse of dense macrophyte beds will have a range of cascading effects throughout the lake ecosystem and thus likely affect several final services at the same time. Due to the complexity of the functional network, changes in less apparent functions and feed-backs could lead to unexpected effects. Very dense macrophyte beds are often considered as nuisance aquatic weeds (Pieterse and Murphy, 1990) because they hamper navigation and angling, reduce the efficiency of irrigation schemes, and are considered "unaesthetic". Worldwide, mechanical, chemical and biological control programs have focused on removal of these nuisance plants without much acknowledgment of the possible benefits. It would be worth to include trade-offs between such "disbenefits" and benefits more comprehensively in the scientific and societal debate leading to informed management decisions covering all ecosystem services and all beneficiary sectors in society (Janssen et al., 2021 and references therein).

Synthesis

Lakes are an important habitat for macrophytes, particularly the littoral where sediments allow colonization and sufficient light is available. The study of the disappearance of macrophytes in many culturally eutrophicated lakes worldwide as well as their recovery has spawned an understanding of how feedbacks prevent regime shifts and maintain clear-water or turbid states. This review also shows the potential manifold of functions of macrophytes in the littoral of lakes and their great diversity. Some of these functions are of clear and direct benefit to human society whereas others are less apparent; these may include feedbacks that strengthen the macrophyte-dominated state.

Benthic Algae in Lake Littoral Habitats[☆]

Yvonne Vadeboncoeur and Leon Katona, Department of Biological Sciences, Wright State University, Dayton, OH, United States

This is an update of Y. Vadeboncoeur, Aquatic Plants and Attached Algae, in Encyclopedia of Inland Waters, edited by Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00217-9.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Autotrophic structure The relative contribution of attached algae, phytoplankton, and macrophytes to total whole lake primary production.
Benthic Associated with the bottom of aquatic ecosystems.
Biofilm A growth form in which a mixed assemblage of microbial organisms grows on a surface. Often, bacteria and algae exude extracellular polymers that form an extracellular matrix (ECM) that holds the biofilm together.
Eutrophic A lake with high concentrations of inorganic nutrients (N, P) in the water column and high phytoplankton biomass, which often reduces light availability for benthic algae.
Fatty acids Macromolecules used in the synthesis of fat and lipids consisting of hydrocarbon chains with a terminal carboxyl group. Algae (especially diatoms) produce essential fatty acids (EFAs) that are required in the diet by metazoans for growth and development.
Filamentous algal blooms (FABs) Refers to an atypical macroscopic proliferation of filamentous benthic algae, especially green algae or cyanobacteria. FABs have been increasingly reported in lakes with high water quality and high light penetration.
Food web A group of organisms relying upon the same basal resources and linked by feeding relationships.
Grazer An animal that consumes primary producers such as algae or macrophytes.
Lake metabolism The sum of all photosynthetic and respiratory processes within the lake.
Macrophyte Literally "large plant". An aquatic vascular plant. Also, macroscopic green algae that have a growth form that resembles a vascular plant (Characeae).
Oligotrophic A lake with low concentration of water column nutrients (N, P) and consequently low phytoplankton biomass. These lakes often have very clear water which facilitates the growth of benthic algae.
Periphyton The consortium of benthic algae, bacteria, archaea, fungi, and animals that form biofilms and structured turfs on and around submerged surfaces in lakes, rivers, and wetlands.
Photic zone The part of the lake bottom or water column where there is sufficient light for photosynthetic organisms to grow. Typically, this is thought to extend to a depth of 1% light penetration. However, living benthic photosynthetic organisms have been observed at depths where $<0.1\%$ surface light is available.
Top-down control The influence of consumption on the biomass of the trophic level immediately below the consumer.

Overview

Photosynthetic organisms, including cyanobacteria, eukaryotic algae and vascular plants (macrophytes) flourish in the well-lit surface waters of lakes. Benthic, or bottom-dwelling, algae and cyanobacteria are not simply settled phytoplankton, but grow in

[☆]*Change History*: October 2021. Y Vadeboncoeur and L Katona updated the chapter.

structured biofilms and complex turfs made up of photosynthetic (autotrophic, or "self-feeding") and heterotrophic organisms. The stratified growth form of biofilms creates complex resource gradients that make it inappropriate to apply paradigms developed for phytoplankton to benthic algae. In this chapter, we describe the taxonomic diversity of benthic algae in lakes and review the abiotic and biotic factors that affect their growth and abundance. We briefly summarize monitoring techniques and speculate on the effects of climate change (temperature, lake level, and circulation patterns) on littoral algal assemblages.

Taxonomic composition of benthic algae

Illuminated lake bottoms are coated with a dynamic living slime composed of cyanobacteria, algae, heterotrophic bacteria, fungi, and small animals. This complex association of living, largely microscopic, organisms is called periphyton. This chapter focuses on the autotrophic components of periphyton, and we use the inclusive term "algae" to refer to non-vascular photosynthetic organisms, including cyanobacteria. Benthic algal assemblages are overwhelmingly dominated by three groups of algae: prokaryotic cyanobacteria, diatoms (Bacillariophyceae) and green algae (Chlorophyta) (Fig. 1).

Cyanobacteria occur on surfaces throughout the littoral zone. Many coccoid cyanobacterial taxa (e.g. *Aphanocapsa*, *Chroococcus*) commonly occur in benthic habitats, but filamentous cyanobacteria often dominate biomass. Motile filamentous cyanobacteria in the Oscillatoriales, including *Oscillatoria* and *Phormidium*, form tissue-like mats over soft (unconsolidated sediments) and hard (rock) substrate (Fig. 1A). These motile taxa readily move in response to changing light conditions, and many are adapted to low light conditions in the deep transitional habitats between the photic and aphotic zones. Some (e.g., *Leptolyngbya* sp., *Microcoleus paludosus*, *Phormidium murrayi*) form toxins that can poison or kill birds and mammals (Wood et al., 2020). Nitrogen-fixing (N-fixing) filamentous cyanobacteria with basal heterocysts (e.g., *Calothrix*, *Tolypothrix*, and *Rivularia*) are commonly attached to rocks in high light littoral habitats of oligotrophic lakes (Fig. 1B).

Diatoms are a ubiquitous component of periphyton (Fig. 1C and D), and have a characteristic silica cell wall. Unicellular taxa include motile, non-motile, and stalked single-celled forms, and some taxa are filamentous. Adnate taxa that grow closely appressed to the substrate are among the first photosynthetic taxa to establish a biofilm on clean rocks. In waved-washed rocky shores, these low-profile taxa may be the only algae that persist. In quiescent habitats, adnate species will be overgrown by taxa that produce a mucilaginous stalk (e.g., *Gomphonema*) that allows them to protrude above the understory taxa and take advantage of higher light conditions at the mat surface (Fig. 1D). Highly mobile, raphid taxa (e.g., *Navicula*) thrive at low light intensities and in sediments because they can glide up and down in pursuit of optimum light conditions (Lowe, 1996). Some taxa in the Rhopalodiacaeae have symbiotic N-fixing cyanobacteria (Lowe, 2003) and are prevalent in the well-lit upper littoral habitats of very nutrient poor lakes. Unlike in the phytoplankton, diatoms are abundant throughout the year in benthic habitats, presumably because silica is readily available at the sediment water interface.

Filamentous and single-cell green algae (Fig. 1E and F) are common in lake littoral zones, but their presence is strongly affected by grazing and disturbance. Unicellular species in the order Desmidiales (Fig. 1F) are common in undisturbed shallow sediment habitats and macrophyte beds. Unattached filamentous taxa in the order Zygnematales, including *Zygnema*, *Spirogyra* and *Mougeotia*, can form dense clouds growing up from the lake bottom in protected bays, wetlands, and other low energy habitats. In high energy wave zones, green algae that can attach firmly to rocky substrates such as *Ulothrix zonata*, *Cladophora glomerata*, and *Stigeoclonium* can form dense turfs many centimeters thick with fronds elongating into the water column. These filamentous green algae require high light and the densest growths sometimes occur at the very upper limit of wave action forming a green "bathtub ring" of algae in large lakes (Fig. 1E).

Most algae have unique morphologies and are large enough to be seen using light microscopy. However, identification of algae is time-consuming and requires expertise. DNA metabarcoding using next-generation sequencing techniques enables the rapid identification of microbes from environmental samples with unprecedented resolution. Metabarcoding uses short sequences of extracted DNA to identify taxa, making it more sensitive than microscopy at detecting rare species and distinguishing species that have similar morphologies. In general, there is good agreement between metabarcoding and morphological identification for eukaryotic algae and cyanobacteria (Groendahl et al., 2017). Using primers that target prokaryotic (16S rRNA gene) and eukaryotic (18S rRNA gene) organisms allows for the exploration of algal-bacterial interactions within periphyton.

Littoral habitats

Benthic algae form biofilms on submerged unconsolidated organic sediments (epipelon) (Fig. 1A), sand (epipsammon) (Fig. 1C), rocks (epilithon) (Fig. 1E), wood (epixylon), animals (epizoon) and plants and macroalgae (epiphyton) (Fig. 1D). The distribution of these substrata within littoral zones is non-random. Portions of lakeshores can either be exposed to wave action (high energy, erosional habitats) or protected from waves by land masses that intercept wind (depositional habitats). Organic sediments, downed trees, and macrophyte beds are more common in depositional habitats along shorelines, while erosional shorelines are dominated by boulders, cobbles, and sand. With distance from shore, the lake bottom becomes increasingly dominated by soft sediments. Whether sediments are composed of inorganic sand or organic muds depends upon the lake's landscape position (high or low in the watershed), the geologic parent material, and the topography of the landscape. High slope areas of the lake bottom may have areas of exposed rock, whereas flat areas will be dominated by organic sediments accumulated from the lake and the surrounding landscape. The structural heterogeneity of the littoral zone and the distribution of substrates relative to light are strong determinants of the structure and function of benthic algal assemblages (Lowe, 1996; Cantonati and Lowe, 2014).

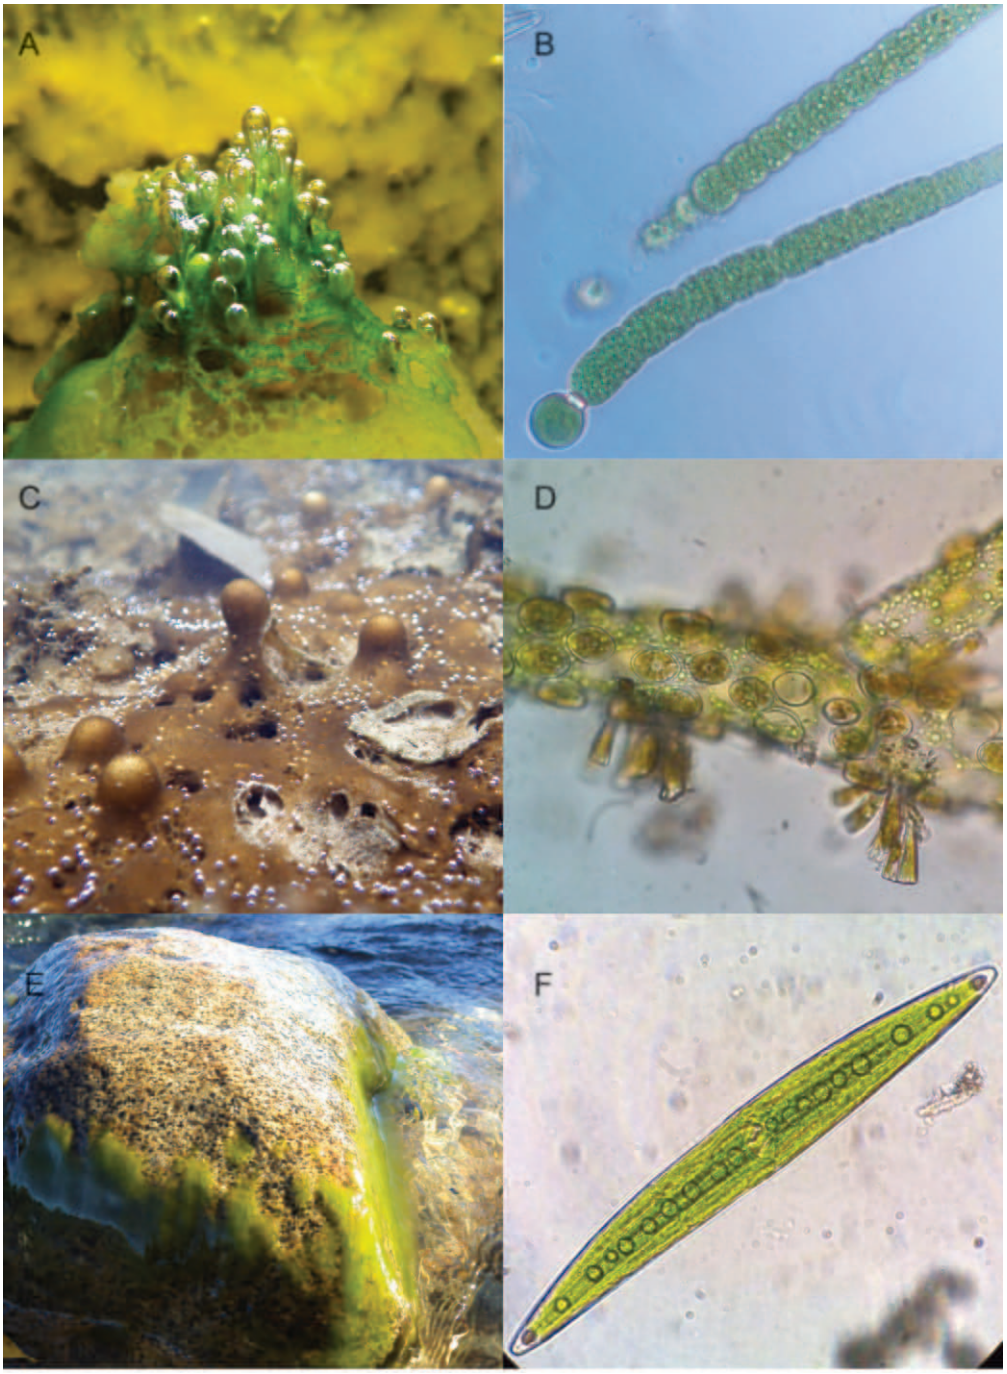

Fig. 1 Cyanobacteria (A, B), diatoms (C, D) and green algae (E, F) dominate benthic algal assemblages in lakes. High photosynthesis rates trap oxygen bubbles in the biofilms of A and C. (A) A biofilm dominated by the cyanobacterium *Oscillatoria* in an experimental aquarium. (B) The cyanobacterium *Calothrix* (Rivulareaceae) has a basal heterocyst where N-fixation occurs. (C) A biofilm dominated by diatoms gives sandy sediments a golden hue. (D) A filamentous green alga (*Cladophora*) is overgrown with epiphytic diatoms including closely appressed ovoid *Cocconeis* and stalked *Rhoicosphenia*. (E) A rock along the shoreline of Lake Tahoe (USA) is coated with a thick turf of *Spirogyra*. (F) The desmid green alga *Closterium* can be found in shallow benthic habitats in lakes, and epiphytically on submerged vegetation. Photos credits: A, C–F by Leon Katona; B by Rex Lowe.

Growth-regulating resources: Light, nutrients, and temperature

Light is necessary to fuel photosynthesis and attached algae only grow in the photic zone where the substrate intercepts enough light for photosynthetic rates to exceed basic metabolic requirements. Benthic algal composition changes markedly with depth in response to changes in light because taxa are adapted to different wavelengths and light intensities (Lowe, 1996). Filamentous

green algae require high light, and are abundant in shallow, rocky habitats of clear lakes. Attached cyanobacteria in the Rivulariaceae and diatoms in the Rhopalodiales are common in high light rocky habitats because high photosynthesis rates are necessary to support energy demanding N-fixation (Higgins et al., 2003). Many raphid diatoms efficiently use light energy and photosynthesize at very low irradiances. Cyanobacteria in the Oscillatoriales form thin mats in deep, low light environments and can use long-wavelength energy because they have auxiliary pigments. We know that the lower depth limit for benthic algae is well below the photic zone (defined by 1% surface light). Viable, healthy benthic algal assemblages have been retrieved or observed from habitats that receive less than 0.1% surface light, but comprehensive sampling of deep habitats is still necessary to determine the extent of benthic algal distribution in lakes.

The water column is just the first matrix that controls light availability to periphytic algae. As biofilms accrue vertically, rapidly growing cells on the surface shade cells at the base of the biofilm, inducing senescence. This self-shading impairs the integrity of biofilms on hard substrates and induces sloughing. Similarly, epiphytic diatoms and cyanobacteria growing on the much larger thalli of filamentous green algae will shade and compromise the health of their host (Fig. 1D; Furey et al., 2012). Rapid light attenuation on epipelic biofilms creates vertically structured laminated communities with marked changes in pigments and photosynthesis over the scale of millimeters (Hawes et al., 2014).

Algal growth is limited by the availability of nutrients, especially nitrogen (N) and phosphorus (P) (Borchardt, 1996; Elser et al., 2007; Harpole et al., 2011). Although nutrient concentrations in the water and sediments tend to increase with depth, it is not clear that this has a strong influence on algal distribution because of the overwhelming negative effect of decreasing light availability with depth. Benthic algae living on sediments, macrophytes, or animals (such as snails or mussels) rely on nutrients leaked or excreted from the substratum for growth. Unconsolidated sediments (the most abundant surface for algal growth) accumulate N and P, and epipelic algal biomass and production are often decoupled from water column nutrients (Figs. 2–5; Vadeboncoeur et al., 2003). Furthermore, boundary layers on all types of surfaces decrease the diffusion rate of inorganic nutrients into the biofilm, and as biomass accrues, microbial nutrient recycling within the biofilm becomes increasingly important to new algal growth. High nutrient concentrations in groundwater and at the sediment water interface can cause excessive benthic algal growth (Figs. 2 and 4; Higgins

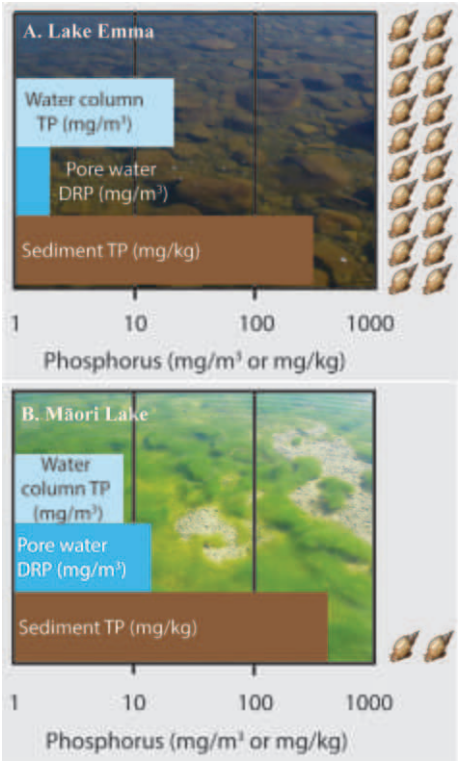

Fig. 2 The visibility of benthic algae depends upon the availability of resources that help algae grow and the abundance of animals that eat algae. In two adjacent subalpine New Zealand lakes, Lake Emma (A) has thin biofilms of diatoms and cyanobacteria, while Māori Lake (B) has dense growths of the green alga, *Spirogyra*. Water column nutrient concentrations in Lake Emma (A) are higher than in the filamentous algal bloom (FAB) afflicted Māori Lake (B). However, sediment-associated nutrients (which benthic algae can access) are higher in Maori Lake than in Lake Emma. Comparatively low densities of the New Zealand mud snail (*Potamopyrgus antipodarum*) in Māori Lake (each snail represents 1 grazer/m2) may allow *Spirogyra* to flourish. From Waters S, Verburg P, Schallenberg M, and Kelly D (2021) Sedimentary phosphorus in contrasting, shallow New Zealand lakes and its effect on water quality. *New Zealand Journal of Marine and Freshwater Research* 55: 592–611; Stewart SD, Kelly D, Laroche O, Biessy L, and Wood SA (2021) Individual diet specialization drives population trophic niche responses to environmental change in a predator fish population. *Food Webs* 27: e00193; and Vadeboncoeur Y, Moore MV, Steward SD, Chandra S. et al. (2021) Blue waters green bottoms: Benthic filamentous algal blooms (FABs) are an emerging threat to clear lakes worldwide. *BioScience* 71: 1011–1027.

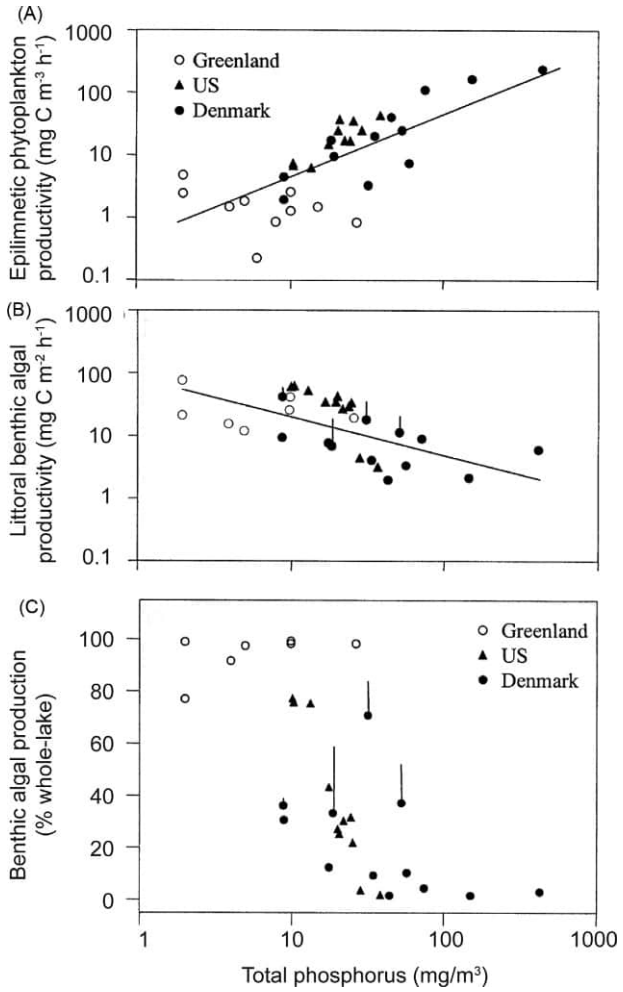

Fig. 3 Benthic and planktonic productivity in small northern lakes. Although phytoplankton productivity increases with increasing nutrient load (A), the increased phytoplankton biomass shades littoral algae, causing a decrease in benthic algal productivity (B). Therefore, as nutrient loading to surface water increases, autotrophic structure shifts from dominance by benthic algae to dominance by planktonic algae. Each point represents average productivity in a single lake. From Vadeboncoeur Y, Jeppesen E, Vander Zanden MJ, Schierup H-H, Christoffersen K, and Lodge DM (2003) From Greenland to green lakes: Cultural eutrophication and the loss of benthic energy pathways in lakes. *Limnology and Oceanography* 48:1408–1418.

et al., 2008, Timoshkin et al., 2018; Waters et al., 2021). However, high nutrient concentrations in the water column also stimulate phytoplankton that shade benthic algae, retarding their growth (Figs. 3 and 5). Thus, maximum benthic algal biomass and production usually occurs in lakes with low to moderate water column nutrient concentrations.

Algal growth rates increase with increasing temperature through much of the temperature range experienced in most lakes (0–30 °C). The temperature optima for diatom growth tend to be lower than for green algae, and cyanobacteria are the most tolerant of high temperatures (>30 °C), but there are many exceptions to these broad patterns. For example, cyanobacteria are very tolerant of temperature extremes and dominate benthic mats in both polar lakes and hot pools (Vincent and Quesada, 2012). Temperature determines maximum specific growth rates and succession in community composition throughout the year. Seasonal cycles of benthic algal biomass, with a winter minimum and spring maximum, and taxonomic turnover in oligotrophic lakes have been documented (Wetzel, 2001). However, winter sampling of littoral habitats is extremely rare, and more research is needed to ascertain how littoral algal biomass varies over time. In a turbid, eutrophic Danish lake, maximum epipelic algal production occurred in spring when light penetration to the sediments was highest (Fig. 5; Liboriussen and Jeppesen, 2003). Climate warming is likely to warm littoral zones faster than offshore waters and this may promote more profuse growth of filamentous green algae and cyanobacteria (Wood et al., 2020).

Interactions with heterotrophic microbes

Many algae and bacteria have characteristic external extracellular coatings (sheaths) that affect transport of metabolites into the cell. In aggregate, these structures produce an extensive extracellular matrix (ECM) composed of extracellular polysaccharides (EPS),

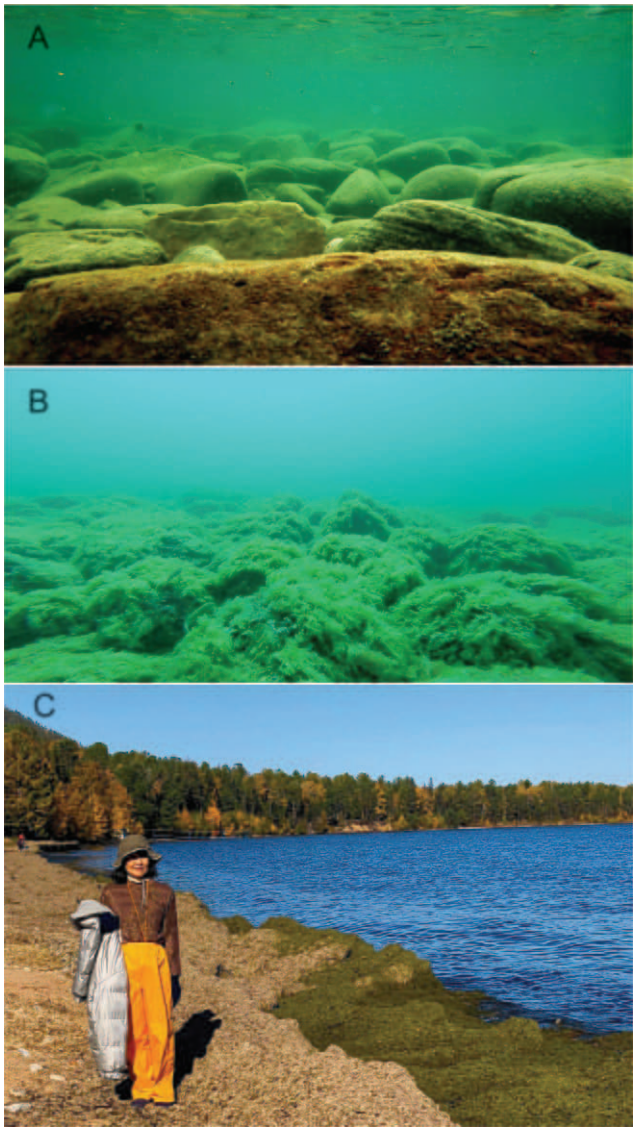

Fig. 4 Filamentous algal blooms (FABs) are an emerging threat to clear lakes. (A) The wave-washed littoral zones of large, oligotrophic lakes, like Lake Superior (USA/CA), typically support thin skins of diatoms and cyanobacteria along the rocky shore. (B) Lake Michigan (USA) is also a large, oligotrophic lake, but an invasive mussel transports nutrients to the benthos, promoting dense growths of the filamentous green alga, *Cladophora*. (C) Lake Baikal (RU) has extraordinarily low nutrient concentrations in the water, limiting phytoplankton growth. However, nutrient pollution of the ground water causes dense growths of filamentous green algae that wash up on shore. The green area of shore is wash up from the current growing season, while the brown material that researcher Masumi Yamamuro is standing upon is from the previous year (see Vadeboncoeur et al., 2021). Photo credits: (A) Leon Katona; (B) Harvey Bootsma; (C) Marianne Moore.

proteins, and DNA fragments that give the biofilm cohesion. This external scaffold slows the exchange of metabolites and nutrients with the environment beyond the biofilm, and provides a matrix within which extracellular enzymes can be used to exploit nearby organic resources. The ECM also stabilizes soft, organic sediments, reducing resuspension. New molecular techniques are providing a fascinating window on the function and composition of ECM associated with periphyton, and this is a rich, relatively unexplored, area of research (Scott et al., 2014).

Biofilms blanket unconsolidated sediments on the lake bottom, and algal constituents often dominate biomass in the euphotic zone. Epipelic algae influence carbon, nitrogen and phosphorus fluxes across sediment-water interfaces. For instance, oxygen produced during algal photosynthesis reduces the daytime exchange of phosphorus across the sediment-water interface, affecting redox gradients (Carlton and Wetzel, 1988; Wood et al., 2015). Within the biofilm itself, the steep oxygen gradients caused by diminishing photosynthesis with depth can generate a gradient in heterotrophic microbial metabolism (Hawes et al., 2014), with oxidation of labile algal exudates on the biofilm surface to fermentation of refractory detritus deeper in the sediments. These vertical oxygen gradients also cause layering of microbial taxa in biofilms. For example, the photoheterotrophs (purple sulfur bacteria) require very low oxygen environments and occur in deep layers of microbial biofilms (Martínez-Alonso et al., 2005).

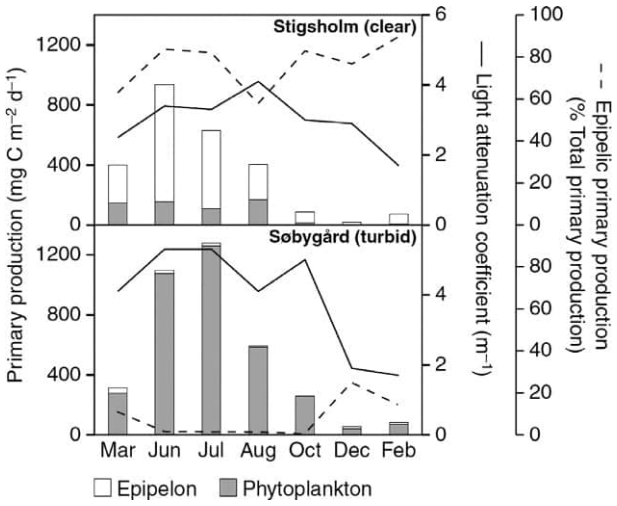

Fig. 5 Seasonal variation in productivity of benthic epipelic algae and phytoplankton in two Danish lakes. Lake Stigsholm has lower phosphorus concentrations (96 μg P L^{-1}) and is relatively clear, while lake Søbygård is eutrophic (275 μg P L-1) and turbid from high phytoplankton biomass. Epipelic productivity is much higher in the clear lake relative to the turbid lake because more light hits the lake bottom. Both epipelic and phytoplankton productivity tends to peak during the warm summer months. This is not true of epipelic productivity in the turbid lake which remains low during the summer months because epipelic algae are shaded by phytoplankton. In the clear lake, epipelon dominates autotrophic structure, while in the turbid lake, phytoplankton productivity dominates. From Liboriussen L and Jeppesen E (2003) Temporal dynamics in epipelic, pelagic and epiphytic algal production in a clear and a turbid shallow lake. *Freshwater Biology* 44:418–431.

Algae and heterotrophic bacteria both need inorganic N and P to grow, and algae benefit when bacteria mineralize nutrients from dead cells. Algae use light to produce labile organic carbon that provides an energy source for heterotrophic bacteria. When there is abundant non-algal organic carbon available (e.g., when terrestrial dissolved organic carbon creates tea-colored lakes) bacteria can outcompete algae for nutrients (Halvorson et al., 2020). However, in high light environments interactions between autotrophic and heterotrophic constituents of biofilms may be more mutualistic. Living and dead algae are a source of labile, easily exploited organic carbon for heterotrophic bacteria, which in turn, recycle the inorganic nutrients necessary for algal growth (Halvorson et al., 2020).

Top-down effects on benthic algae

Benthic algae are nutritious, easily digestible, rapidly renewing food resources for grazing animals (Vadeboncoeur and Power, 2017). An examination of periphyton under the microscope reveals an abundance of protozoans, rotifers, copepods, nematodes, and larval chironomids moving among the algal and bacterial cells ingesting diatoms, ECM, and detritus. Many larger invertebrates such as snails and some larval insects have specialized scraping mouthparts that efficiently remove algal biofilms at their base, leaving noticeable, bare grazing "scars" on hard surfaces. Others, including mayflies, chironomids, stoneflies, and caddisflies have mouthparts adapted to sweep benthic algae and detritus from soft and hard surfaces. Algivorous fish are a dominant trophic guild in tropical lakes, accounting for up to 40% of fish species in some lakes (Vadeboncoeur et al., 2011). Grazers in lakes can exert top-down control on benthic algae affecting the amount of algae that accumulates on a surface (Fig. 6), the rate of productivity, and the types of algae that dominate the assemblage.

Grazers reduce the amount of benthic algae that accumulate on surfaces in littoral zones. When grazers are prevented from consuming benthic algae in grazing exclusion experiments, algal biomass rapidly increases (Steinman et al., 1987; Steinman, 1996). A compilation of results from experiments in freshwater and marine habitats suggest that grazers, on average, reduce algal biomass by 56% (Hillebrand, 2009) and reduce spatial variability in algal biomass (Hillebrand, 2008). The effect of grazing on algal biomass depends upon how effectively grazers can remove biofilms from surfaces and upon grazer density. Efficient grazers with scraping mouthparts (e.g., the radulas of snails) can scrape to the bottom of a biofilm on rocks, but more selective grazers will consume surface epiphytic algae off larger algae and plants (Furey et al., 2012), which may affect algal composition more than algal biomass. The diversity of grazer sizes, densities, and efficiencies creates variability in their effect (Hillebrand, 2008).

Grazers often have the strongest effect on algal biomass in the early successional stages of a biofilm (Steinman, 1996). Any bare substrate, such as a newly scoured rock or an emerging macrophyte, is first colonized by bacteria and low growing diatoms. With time, the periphyton becomes more structurally complex and larger filamentous algae become established. Grazers can keep algal assemblages at early successional stages, dominated by prostrate and low-profile taxa that persist in the face of continuous nipping and scraping. Filamentous green algae can be too large and awkward for some insect grazers to handle and ingest. Larger grazers can prevent the establishment of attached filamentous green algae, but once established, these taxa form dense turfs or foliose aggregations that escape grazer control (Fig. 6; Power, 1990, Harrison and Hildrew, 2001). Many filamentous chlorophytes, such

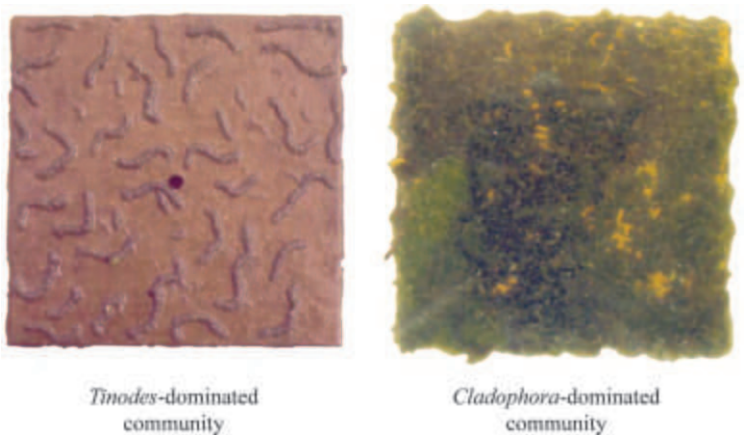

Fig. 6 The distribution of an invertebrate grazer, *Tinodes waeneri*, controls the distribution of benthic algal biomass in a eutrophic English lake. (A) The caddisfly lays its eggs in the vicinity of riparian trees, leading to patches of the nearshore littoral zone with high densities of *Tinodes* and low benthic algal biomass. (B) At similar depths, but distant from oviposition sites, *Tinodes* is rare and a luxuriant growth of the green alga, *Cladophora glomerata*, covers the lake bottom. From Harrison SSC and Hildrew AG (2001) Epilithic communities and habitat heterogeneity in a lake littoral. *Journal of Animal Ecology* 70: 692–707.

as *Cladophora*, become colonized by epiphytic diatoms and cyanobacteria. Micrograzers, such as chironomids, live in the filamentous algal assemblage, consuming epiphytes and indirectly benefiting the algal host (Furey et al., 2012).

Although it is tempting to think of grazing as inherently negative because algal cells are eaten and (perhaps) digested, grazing usually benefits algae left uneaten. Benthic algal growth is limited by light and the rate of nutrient acquisition. When animals consume cells from the surface of biofilms or from the surface of macroalgae, the cells deeper in the assemblage experience an increase in light. Additionally, grazers excrete N and P in their waste that, by meeting nutrient demand, increases algal growth rate. Thus, removal of biomass by grazers tends to increase biomass-specific productivity of benthic algae (Steinman, 1996).

The role of benthic algae in food webs

Primary producers are the energetic foundation of any food web because these autotrophic organisms transform inorganic carbon into organic carbon that is subsequently used as food by heterotrophic microbes and animals. Three sources of primary production in lake food webs are littoral macrophytes, benthic algae, and phytoplankton. Additionally, imported particulate terrestrial detritus (e.g., leaves and wood) is a food source for benthic invertebrates, while dissolved substances leached from terrestrial plants are used by bacteria (Mehner et al., 2016). These internally and externally derived basal resources are not equally nutritious. Macrophytes and terrestrial detritus are largely derived from vascular plants that are structurally complex, difficult to digest, and have high concentrations of carbon relative to nitrogen (C:N). High C:N is an index of low food quality. Algae, whether benthic or planktonic, have fewer structural compounds than vascular plants, and have a relatively low C:N. Thus, algae are a higher quality food than macrophytes and terrestrial leaves. High quality basal resources such as algae are often more efficiently entrained into food webs because they are selectively sought after by animals but also because growth efficiency (growth per gram consumed) is higher than for foods that are difficult to digest or contain low concentrations of the N necessary for protein synthesis.

Not all algae are equally nutritious and accessible. Filamentous green algae contain difficult to digest cellulose, have a low N content relative to other algae, and often pass through invertebrate guts undigested (Moore, 1977). Cyanobacteria are relatively high in protein (N), lack cellulose, and may be more digestible than filamentous green algae. Diatoms are lipid-rich and produce the essential fatty acid EPA that is required for the normal development of many animals (Guo et al., 2016). The abundance, seasonal persistence and high food quality of diatoms make them a critical component of lake food webs. Diatoms are readily digested, and can thrive under high grazing pressure. This algal super-food often dominates benthic algal biomass, and is efficiently consumed and assimilated by primary consumers. Additionally, the biofilm growth form presents consumers with algal carbon in a much more concentrated form than the planktonic algae dispersed in the water column (Vadeboncoeur and Power, 2017). Thus, the benthic caddisflies, mayflies, and snails that consume benthic algae are many orders of magnitude larger than zooplanktonic primary consumers in the water column. The large size of benthic primary consumers makes them an important resource for fish (Fig. 7).

The widespread use of natural tracers, including stable isotopes of C, N, and H, and fatty acids, has revealed that benthic algae are an integral basal resource for primary consumers and fish in lakes. Compilations of stable isotope data from lakes throughout the world demonstrate that fish species, regardless of trophic level, rely on benthic algal sources of carbon for about 50% of their growth (Vander Zanden et al., 2011). This does not mean that 50% of fish production in lakes is ultimately derived from attached algal carbon because this metric is not adjusted for the relative abundance of different types of fishes within individual lakes. However,

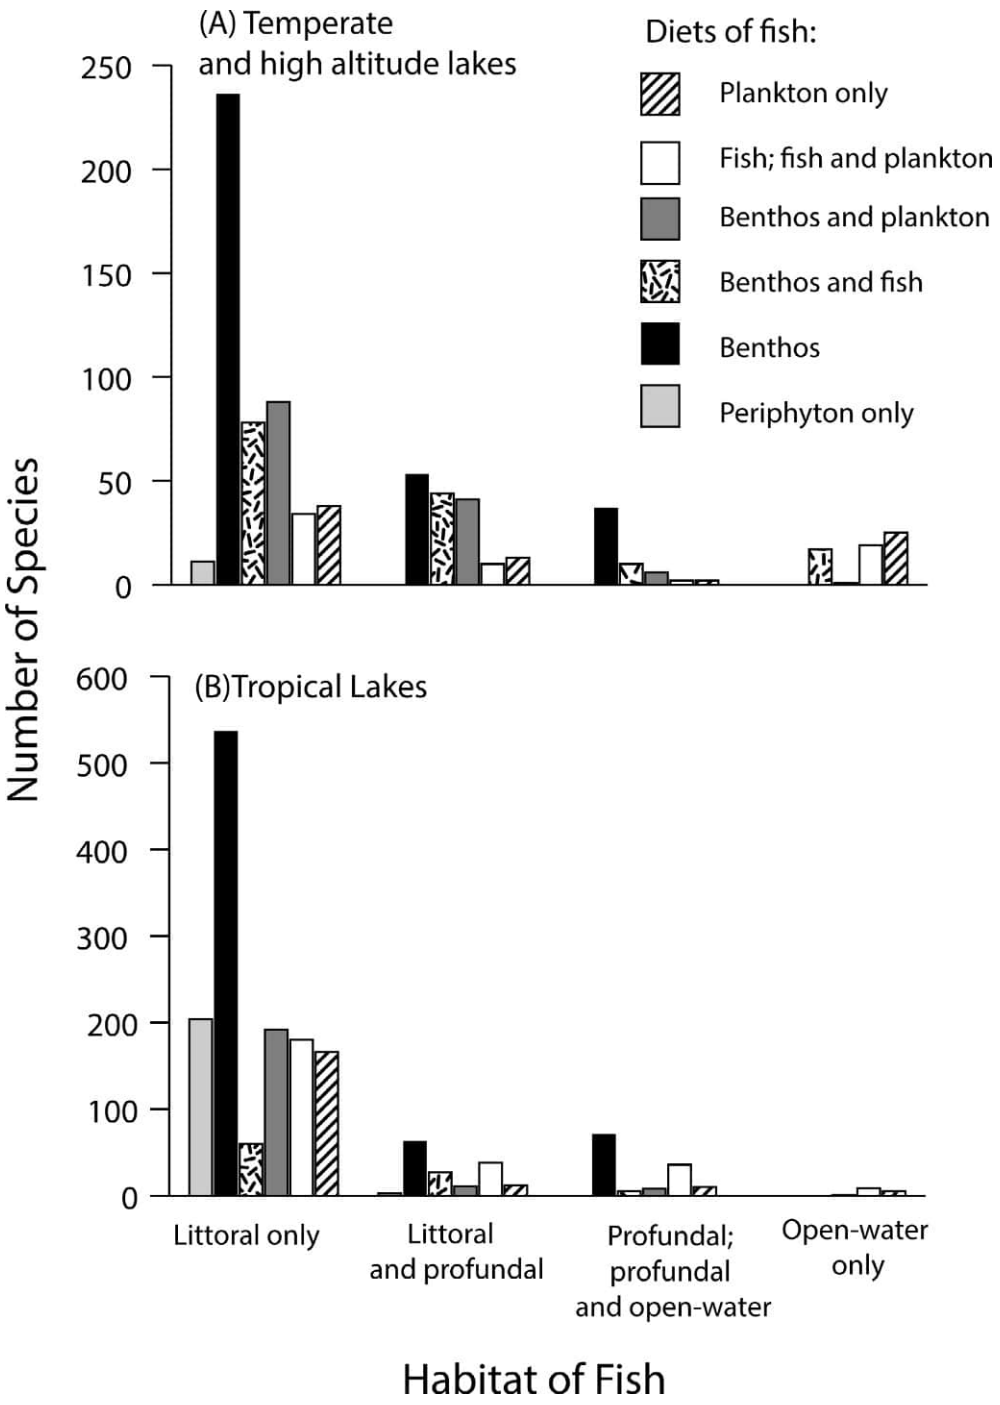

Fig. 7 Littoral zones, and the carbon fixed by benthic algae, support the majority of fish diversity in the largest lakes in the world. Few species live exclusively in the vast open water (limnetic) habitats of these lakes or in the deep profundal waters below the zone of light penetration. Rather, most fish species are concentrated in the thin rind of littoral habitat at the edge of these huge lakes. (A) In temperate latitudes, few littoral fish directly consume benthic algae, but the fish eat the zoobenthic invertebrates that consume benthic algae. (B) In tropical lakes many fish are themselves grazers, directly consuming benthic algae. From Vadeboncoeur Y, McIntyre PB, and Vander Zanden MJ (2011) Borders of biodiversity: Life at the edge of the world's large lakes. *BioScience* 61:526–537.

most fish species rely on the algal base of the littoral food web either by directly consuming benthic algae (e.g., grazing fishes in tropical lakes) or indirectly by consuming invertebrates that grazed on benthic algae (Fig. 7; Vadeboncoeur et al., 2011). Although it is widely accepted that benthic algae are an integral and dominant part of lake food webs, littoral basal resources are still understudied and under-monitored relative to planktonic elements of the food web (Vander Zanden and Vadeboncoeur, 2020).

Benthic algae and whole-lake metabolism

Littoral zones and benthic algae contribute substantially to the total amount of gross primary production (GPP) in lake metabolism (Vadeboncoeur et al., 2003; Van de Bogert et al., 2007; Ask et al., 2009). Relative contributions of benthic algae to ecosystem GPP are highest in small, shallow, clear lakes and lowest in large, clear lakes and eutrophic lakes (Fig. 3). This variability reflects the influence of surface water nutrients, which usually have a larger effect on phytoplankton than on periphyton, and the effect of lake morphometry, which influences how much of the lake bottom is exposed to light (Vadeboncoeur et al., 2008).

Light is critical for both benthic and planktonic algal production and many lakes have high concentrations of colored dissolved organic carbon (DOC) that limit algal productivity. In humic lakes, DOC reduces productivity of both benthic and planktonic algae (Vadeboncoeur et al., 2008; Ask et al., 2009; Karlsson et al., 2009) and in some lakes, algae on the fringing bog vegetation may dominate ecosystem GPP and contribute substantially to secondary production of zooplankton and zoobenthos (Vesterinen et al., 2017).

Primary production in small, shallow (average depth < mixing depth) lakes can be overwhelmingly dominated by benthic algae or dominated by phytoplankton depending upon surface water nutrient concentrations (Figs. 3 and 5). Shallow, clear lakes in high latitudes (arctic and boreal lakes) as well as clear shallow mountain lakes are usually unaffected by anthropogenic nutrient inputs and are dominated by benthic algal production (Rautio et al., 2011). Eutrophication driven by surface water N and P pollution increases shallow lake productivity and shifts the autotrophic structure toward increasing dominance by phytoplankton. As water column concentrations of total phosphorus (TP) and total nitrogen (TN) increase, phytoplankton increasingly shade benthic algae and consequently phytoplankton dominate whole-lake metabolism. In shallow lakes, internal loading of nutrients from the lake sediments exacerbates eutrophication and dominance of phytoplankton (Fig. 3C).

The contributions of benthic algae to whole ecosystem GPP declines as lake area and depth increase. Littoral zone area is a small fraction of total lake area in small steep-sided mountain lakes or large tectonic lakes like Lakes Baikal, Malawi, and Tanganyika. However, such lakes are usually oligotrophic and the littoral habitat that does exist can support complex autotrophic communities that are highly productive, leading to area-specific production of benthic algae that can be many times that of phytoplankton (O'Reilly, 2006; Malkin et al., 2010). In the largest lakes in the world, low surface area to volume ratios mean that the amount of carbon fixed by the vast open water pelagic habitat dwarfs that of benthic algae (O'Reilly, 2006). However, the littoral zones of these lakes can extend to over 60 m deep, form the most extensive continuous freshwater habitat in the world, and support the majority of biodiversity in these lakes (Fig. 7; Vadeboncoeur et al., 2011). Thus, it is a mistake to overlook the functional importance of littoral habitats in large lakes based on the small contribution to whole ecosystem GPP. Unfortunately, many clear lakes are suffering from nearshore benthic filamentous algal blooms (FABs), and limnologists are ill-equipped to respond to this threat because nearshore habitats of large lakes are overlooked in lake monitoring programs (Fig. 4; Vadeboncoeur et al., 2021).

Monitoring benthic algae

Benthic algae are not routinely monitored in lakes (DeNicola and Kelly, 2014), but they ought to be, and the methods developed for rivers and wetlands (e.g., Biggs and Kilroy, 2000; Steinman et al., 2006) are readily applied to littoral zones. Biomass is assessed as AFDM, chlorophyll, or comprehensive pigment analysis using HPLC (Steinman et al., 2006). Chlorophyll must be measured using an acidification step that corrects for degraded chlorophyll (phaeophytin) because periphyton often contains a large proportion of dead cells that will inflate biomass estimates if unaccounted for. Comparison of chlorophyll data within and among lakes needs to be interpreted with care because algal taxonomic composition changes markedly with depth and cellular chlorophyll concentrations increase with decreasing ambient light (depth). It is best to combine biomass measurements with analyses of taxonomic composition. These can include simple microscopic examinations to document dominant taxa or detailed quantifications of taxonomic composition and biovolume (Biggs and Kilroy, 2000). Fatty acid analysis is a synthetic approach that provides qualitative information on dominant algal phyla, microbial components and food quality for consumers (Guo et al., 2016). Quantifying C, N, and P content of algae can be used to further assess food quality.

The rate of carbon fixation by benthic algae can be measured in chambers in situ or in the lab with either bulk oxygen exchange or ^{14}C methods (Vadeboncoeur et al., 2003; Devlin et al., 2016), but in most cases benthic productivity is high enough to make oxygen measurements a much simpler and preferable approach. Chamber measurements from different depths and substrates are integrated with morphometry, light, and substratum distribution to model whole lake benthic algal primary production. Pulse Amplitude Modulated (PAM) fluorometry is a useful tool for assessing photosynthetic capacity of biofilms in situ and for describing variation in photosynthesis with depth (Devlin et al., 2016; Hawes et al., 2014). Diel oxygen curves monitored by oxygen sondes deployed in the littoral zone can be used to monitor littoral contributions to whole lake metabolism but deployment position, and wind and mixing patterns affect data interpretation (Van de Bogert et al., 2007; Brothers and Vadeboncoeur, 2021).

Most metrics of benthic algal biomass and production are expressed per square meter of lake bottom (soft sediments, boulder) or substratum (e.g., macrophyte or cobble). Thus, sampling designs of naturally occurring algal assemblages must incorporate approaches that isolate algae in a known area. Biofilms growing on soft sediments or very gelatinous colonies on rocks can be collected with core samples. Corers can be constructed from Perspex tubes or cut-off syringes. A 20 mL syringe (inner diameter ~1 cm) will collect sufficient material for biomass or species composition measurements. Once the core is collected the syringe is inverted and the upper 0.5–1.0 cm is retained based on visual inspection of the depth of algal colonization. Perspex corers are

excellent for collecting intact sediment cores for measuring primary productivity. Clear and dark chambers of a known area can be deployed over sediments or rocks and equipped with oxygen loggers to measure photosynthetic rates in situ.

Relatively uniform artificial substrata, such as clay tiles (Fig. 6) and glass microscope slides, are used to grow benthic algae in situ or in the laboratory with an inoculum. Deployment of nutrient diffusing substrata (NDS) is useful for determining which nutrients (e.g., N, P, Si) limit benthic algal growth and can be useful in diagnosing the driver of nuisance benthic algal proliferations in lakes. NDS samples can be used for taxonomic, biomass, or productivity assessments, allowing for exploration of the structure and function of periphyton under different nutrient conditions (Steinman et al., 2006). DeNicola and Kelly (2014) and Poikane et al. (2019) provide excellent reviews of how different monitoring designs capture (or fail to capture) patterns and processes relevant to littoral zone degradation.

Benthic algae and global change

Increases in air and water temperature alter physical dynamics in lakes in ways that both reduce and enhance benthic algal growth. Increases in water temperature stimulate benthic algal growth and may alter the types of algae that are present in lake littoral zones (Wood et al., 2020; Vadeboncoeur et al., 2021). Filamentous cyanobacteria and green algae are generally more tolerant of increases in temperature compared to diatom-dominated assemblages. Greater warming of nearshore water and substrate than of offshore waters creates thermal bars that trap water and material flowing off the landscape in the littoral zone. Increases in air temperature can stimulate wind waves that may reduce benthic algal biomass accumulation on substrata in nearshore areas. Conversely, strong wave action may increase lake turnover events, moving nutrient-rich hypolimnetic water into the littoral zone to stimulate benthic algae. Climate-driven fluctuations in lake levels can scour benthic algae, but also enhance the flow of nutrient-rich groundwater and advect nutrients from the landscape into nearshore areas for use by benthic algae. Increased atmospheric transport of nutrients is leading to a widespread loss of oligotrophic lakes in North America (Stoddard et al., 2016), and benthic algae may be early responders to the widespread change in nutrient availability.

The benthic algae that grow on illuminated surfaces in lakes (Fig. 1) are a fascinating, taxonomically diverse group of organisms that are often overlooked in lake research. Although benthic algae are less well-studied than phytoplankton, periphyton contribute substantially to aquatic food webs and to whole-lake metabolism. Anthropogenic stressors including climate change, nutrient pollution, extensive use of herbicides and pesticides, and increased human access to remote lakes are contributing to changes in littoral zone function (Stewart et al., 2021). Many of these stressors may be shifting benthic algae from a cryptic, low growing resource that ultimately provides energy for fish, to a prolific, unsightly green scum along the shoreline of clear lakes. The public, managers, and scientists can work together to document and mitigate this growing threat to pristine lakes.

Knowledge gaps

- Interactions between heterotrophic microbes and algae in the periphytic phycosphere
- Phenology, growth, and taxonomic shifts in benthic algae in response to a warming world
- Non-nutrient drivers of Filamentous Algal Blooms
- Effects of benthic toxic cyanobacteria on food webs and humans

Benthic Invertebrate Fauna, Lakes and Reservoirs

DL Strayer, Cary Institute of Ecosystem Studies, Millbrook, NY, USA

This is a reprint of D.L. Strayer, Benthic Invertebrate Fauna, Lakes and Reservoirs, In Encyclopedia of Inland Waters, Edited by: Gene E. Likens, Elsevier Inc., 2009, https://doi.org/10.1016/B978-012370626-3.00161-7.

Glossary

Benthos – The community of organisms living around surfaces (e.g., sediments, plants) in aquatic ecosystems.
Bioturbation – Sediment mixing caused by the activities of organisms.
Macrobenthos – Benthic animals large enough to be retained on a coarse (usually ~0.5-mm mesh) sieve.
Meiobenthos – Benthic animals too small to be retained on a coarse (usually ~0.5-mm mesh) sieve, but large enough to be retained on a fine (usually ~0.05-mm mesh) sieve.
Zoobenthos – The community of animals living around surfaces (e.g., sediments, plants) in aquatic ecosystems.

Introduction

Benthos includes all animals that live in association with surfaces in lakes and reservoirs. This includes animals that live in and on sediments of all kinds (mud, sand, stones), as well as animals that live in, on, or around aquatic plants or debris. Animals large enough to be retained on a coarse sieve (usually 0.5- mm mesh) are called macrobenthos, those that pass through a coarse sieve but are retained on a fine sieve (usually ~0.05mm) are called meiobenthos, and those that pass through even fine sieves sometimes have been called microbenthos, although this last term is rarely used. It is customary to ignore the small benthic animals, but studies have shown that animals too small to be caught on a 0.5-mm mesh may constitute >95% of the individuals, ~25% of the biomass, ~50% of the metabolic activity, and >50% of the species in a zoobenthic community.

Composition and Biological Traits of the Lacustrine Zoobenthos

The density of zoobenthos depends strongly on the mesh size of the sieve used for the study (Figure 1). Densities of macrobenthos (i.e., animals large enough to be caught on a 0.5-mm mesh) in lakes typically are 1000–10 000m^{-2}, while the total density of all benthic metazoans probably usually is ~1 000 000 m^{-2}. There is a great deal of variation in densities within and among lakes, so that densities reported for a given mesh size range over ~100-fold within and among lakes.

Estimates of zoobenthic biomass usually include only the macrobenthos and exclude large bivalves. Because small benthic animals usually constitute a small part of zoobenthic biomass, estimates of the biomass of the macrobenthos probably are nearly equivalent to the entire zoobenthos. However, it appears that the meiobenthos may be especially important in unproductive habitats (Figure 2). Macrobenthic biomass without large bivalves ranges from ~0.2 to 100 g dry mass m^{-2}, and dense populations of large bivalves can increase these values by >10 g DM m^{-2}. Zoobenthic biomass rises up to a point with increasing phytoplankton production, then asymptotes or even declines with further increase in phytoplankton production. Zoobenthic biomass also tends to be highest in shallow lakes, where rooted plants are abundant, where the lake bottom is flat or gently sloping, in warm lakes or in the epilimnion of stratified lakes, and in lakes of low color.

There are relatively few data on the production rates of entire macrobenthic assemblages and almost no estimates that include the small benthic animals. One would expect to see as much variation in rates of production as in biomass, and based on the expected ratio of annual production to biomass of ~5 for animals of macrobenthic size, production of the lacustrine macrobenthos might range from ~1 to 500 g DM m^{-2} $year^{-1}$. Production of smaller benthic animals in lakes might be about the same order of

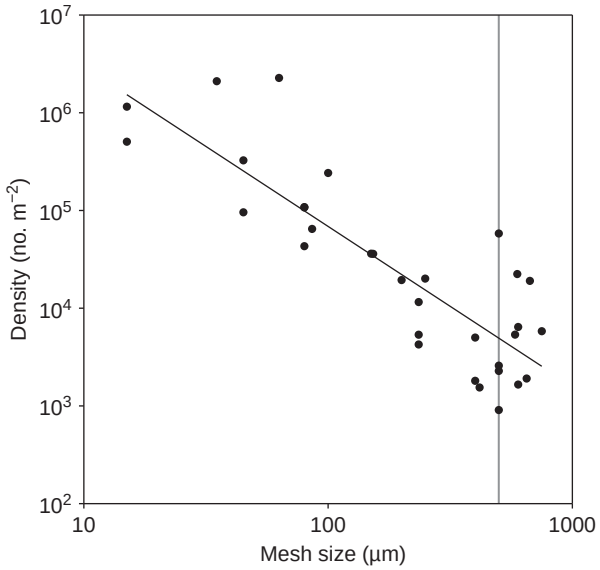

Figure 1 Reported density of zoobenthos as a function of sieve mesh size in a series of lakes from the northern temperate zone ($r^2 = 0.72$, $p < 0.000001$). The vertical gray line marks the 500-μm mesh commonly used for macrobenthos.

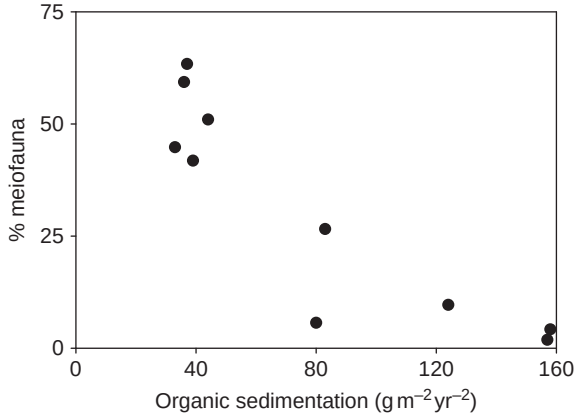

Figure 2 Percentage of zoobenthic biomass belonging to the meiofauna, as a function of organic sedimentation at various sites in the profundal zone of Lake Paijanne, Finland ($r^2 = 0.79$, $p = 0.0006$). Adapted from Hakenkamp *et al.* (2002), after data of Särkkä (1995).

magnitude, based on the sparse data now available. Production of the macrobenthos increases with increasing primary production (Figure 3), with no hint of an asymptote or downturn at very high primary production, as has been seen for macrobenthic biomass.

The lacustrine zoobenthos is enormously diverse; a typical lake contains hundreds of species from 12 to 15 animal phyla (Table 1, Figure 4). The macrobenthos often is numerically dominated by oligochaetes and chironomid and chaoborid midges, although large-bodied mollusks may dominate the biomass of the community. Aquatic insects other than dipterans (such as mayflies) may be abundant, especially in shallow lakes. Nematodes usually are by far the most numerous of the meiobenthos (and of the zoobenthos as a whole), although gastrotrichs, rotifers, and microcrustaceans often are abundant as well. Many important families are ecologically important in lakes around most parts of the world, including the Chironomidae and Chaoboridae in the Diptera; the Ephemeridae in the Ephemeroptera; the Tubificidae (including the 'Naididae') in the Oligochaeta; the Unionidae and Sphaeriidae in the Bivalvia; the Lymnaeidae and Planorbidae in the Gastropoda; the Chydoridae, Canthocamptidae, and Cyclopidae among the microcrustaceans; and the Chaetonotidae in the Gastrotricha. In contrast, several important groups are restricted to particular biogeographic regions (mysid shrimps and gammarid amphipods chiefly in the Northern Hemisphere, hyriid bivalves in the Southern Hemisphere) or habitats (ephydrid flies or brine shrimp in fishless or saline inland waters). Human introductions have vastly increased the ranges of several ecologically important species of the lacustrine zoobenthos that once had small geographic ranges, most notably *Dreissena* spp. (zebra mussels, Bivalvia), *Mysis* (opossum shrimp, Crustacea), and several crayfish species.

Because the lacustrine zoobenthos is so diverse, it is difficult to generalize about the biological traits of its members. The largest animals in the community (bivalves and decapods, $>10^1$ g dry mass) are more than 10 billion times larger than the smallest (rotifers and gastrotrichs, $\sim 10^{-9}$ g DM), so this community spans an enormous range of body sizes. Life spans of zoobenthic

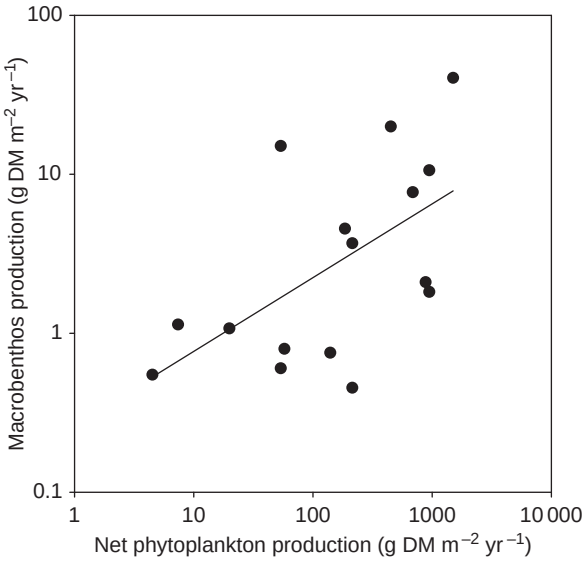

Figure 3 Relationship between production of macrobenthos and production of phytoplankton in a series of lakes ($r^2 = 0.34$, $p = 0.02$). Adapted from data of Kajak *et al.* (1980).

Table 1 Estimates of species richness of the zoobenthos (excluding parasitic forms) in Mirror Lake, a small, unproductive lake in New Hampshire (USA), and typical densities of major phyla in lakes

Phylum	*Estimated number of species in Mirror Lake*	*Typical density in lakes (no. m^{-2})*
Porifera (sponges)	4	NA
Cnidaria (hydras and jellyfish)	2	100–1000
Platyhelminthes (flatworms)	40	1000–50 000
Nemertea (ribbon worms)	1	<100
Gastrotricha	30	100 000–1 000 000
Rotifera	210	10 000–250 000
Nematoda (roundworms)	35	100 000–1 000 000
Annelida (earthworms, leeches)	30	5000–50 000
Mollusca (snails, clams)	6	100–1000
Ectoprocta (moss animicules)	2	<100
Crustacea (water-fleas, seed shrimp, copepods, and relatives)	70	20 000–200 000
Chelicerata (mites)	50	1000–10 000
Tardigrada (water-bears)	5	1000–50 000
Uniramia (insects)	120	1000–50 000

Many lakes around the world contain the same phyla and a comparable numbers of species as Mirror Lake, but have not been so well studied.

animals range from less than a week (rotifers, gastrotrichs) to decades (bivalves). Some species have tough long-lived resting stages (sponge gemmules, ectoproct statoblasts, cladoceran ephippia) that allow populations to reestablish themselves after long unfavorable periods, and assist in passive dispersal between lakes. Various species burrow into the sediments (bivalves, tubificid oligochaetes, *Chaoborus*), glide at the sediment–water interface (gastrotrichs, ploimate rotifers, flatworms), attach (sessile rotifers) or mine (some chironomids in the genus *Cricotopus*) in aquatic plants, or crawl on or attach to solid object such as stones (*Dreissena*, many gastropods).

The zoobenthos includes species that suspension-feed on phytoplankton (many bivalves and some chironomids) or interstitial bacteria (*Pisidium*), graze on benthic algae (gastropods and many rotifers), deposit-feed on sedimented detritus and bacteria (tubificid oligochaetes), are predators on other benthic animals (odonates, tanypodine chironomids, dicranophorid rotifers) or zooplankton (*Chaoborus*), feed on either the leaves (crayfish, chrysomelid beetles) or roots (dorylaimid nematodes, larvae of the beetle *Donacia*) of rooted plants, or shred leaves of terrestrial plants that fall into the water (isopods, caddisflies). Not surprisingly, passive suspension-feeders such as hydropsychid caddisflies and black flies are much rarer in lakes than in flowing waters, presumably because currents in lakes are too slow or undependable to provide them with food.

Benthic animals have several adaptations for dealing with low oxygen concentrations that occur in many benthic environments. Some burrowing animals (chironomids and mayflies) produce currents to bring oxygenated water into the otherwise anoxic sediments in which they burrow. Species in several taxonomic groups (e.g., cladocerans, chironomids, gastropods) produce hemoglobin, which improves oxygen transport under hypoxic conditions. A few species of nematodes, bdelloid rotifers,

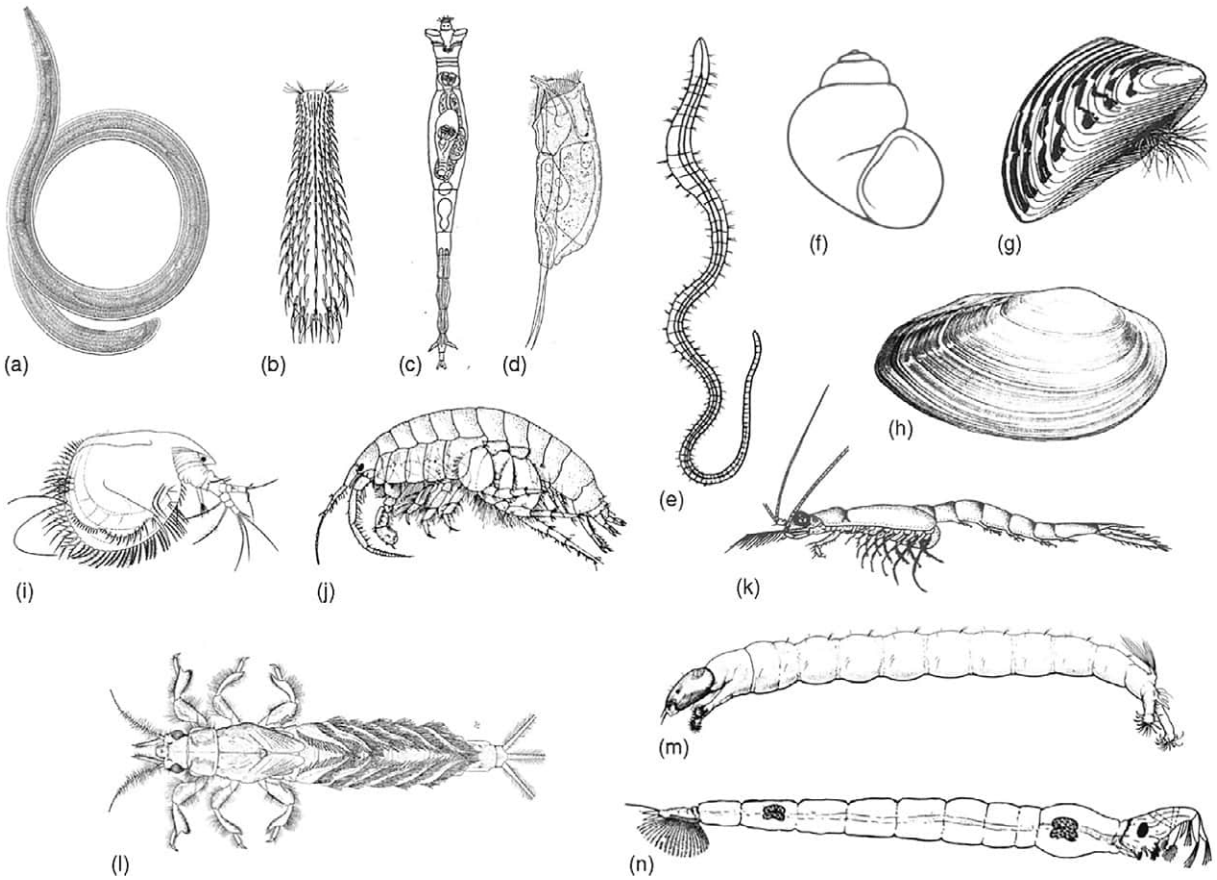

Figure 4 Some important members of the lacustrine zoobenthos. Typical adult body lengths are given in parentheses. (a) a nematode (2mm); (b) a gastrotrich (0.2mm); (c) a bdelloid rotifer (0.5mm); (d) a ploimate rotifer (0.1mm); (e) a tubificid oligochaete (50mm); (f) a hydrobiid snail (3mm); (g) the bivalve *Dreissena* (20mm); (h) a unionid bivalve (75mm); (i) a cladoceran (1mm); (j) an amphipod (10mm); (k) a mysid shrimp (20mm); (l) an ephemerid mayfly (20mm); (m) a chironomid (10mm); (n) the phantom midge *Chaoborus* (10mm).

gastrotrichs, tubificid oligochaetes, copepods, ostracods, and chironomid and chaoborid midges are commonly found in the anoxic profundal sediments of productive lakes. These animals apparently survive extended anoxia either by using anaerobic metabolism of substances like glycogen or by going into extended diapause. Finally, many of the benthic animals (e.g., many insects and pulmonate snails) avoid the problem of low dissolved oxygen altogether by obtaining their oxygen from the air.

Methods of Study

A few members of the lacustrine zoobenthos are large enough to be directly observed in situ (e.g., by SCUBA or mask-and-snorkel), but most species must be collected and brought into the laboratory for study. Scientists have invented a wide range of gear to collect benthic animals (Figure 5). Most often, scientists use grabs, corers, sweep nets, closing bags or boxes, or traps to collect animals or sediments. Often, animals need to be separated from the sediments or plants in which they live. This is usually accomplished by washing the sample through a sieve, most often of 0.1–1-mm mesh, sometimes followed by staining the sample with a dye such as Rose Bengal or examining the sample under a low-power microscope to aid in finding the animals. More or less experimental methods such as density-gradient centrifugation using silica sols (e.g., Ludox®) or application of ice or gentle heat are sometimes used as well.

Variation in the Lacustrine Zoobenthos

One of the chief characteristics of the zoobenthos is its extreme patchiness. The abundance and species composition of the zoobenthos varies within lakes, at scales ranging from centimeters (replicate samples at a single site) to kilometers, as well as among lakes. A number of factors are known to affect the abundance and species composition of the zoobenthos.

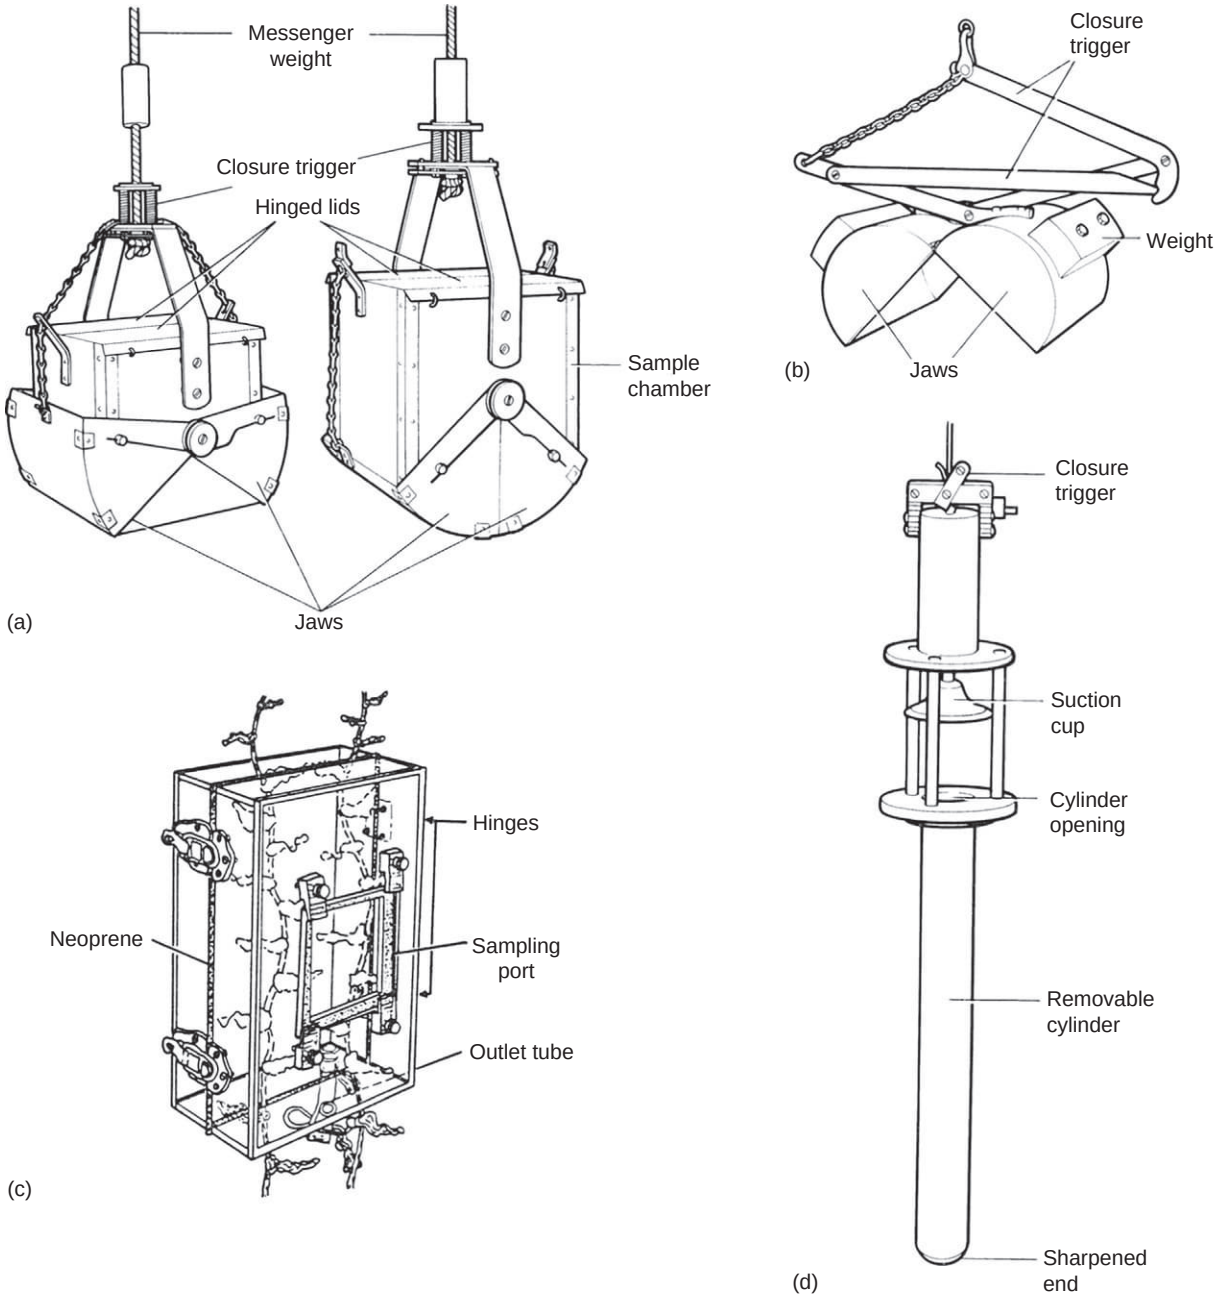

Figure 5 Four samplers commonly used for quantitative studies of the lacustrine zoobenthos. (a) Ekman grab; (b) PONAR grab; (c) Downing box sampler for vegetation-dwelling invertebrates; (d) Kajak-Brinkhurst corer. Adapted from Downing (1984, 1986).

Variation within Lakes

The composition of the zoobenthos almost always varies greatly with water depth within a lake. The abundance of nearly every species in the zoobenthos varies with water depth (Figure 6), and species richness often is much lower in the deep waters of a lake than near the shore (Figure 7). Many studies have also reported variation in the total numbers or biomass of benthic animals with water depth in individual lakes. No single pattern of variation of abundance or biomass with water depth applies to all lakes, because the many mechanisms that link water depth to the zoobenthic community vary in strength across lakes and produce a wide range of patterns in different lakes.

The most important factors that cause zoobenthic composition and abundance to vary with water depth include dissolved oxygen, quantity and quality of organic matter inputs, temperature, sediment grain size and compaction, disturbance, and depth-dependent biotic interactions. The relative contributions of each of these factors and their interactions in driving zoobenthic community structure

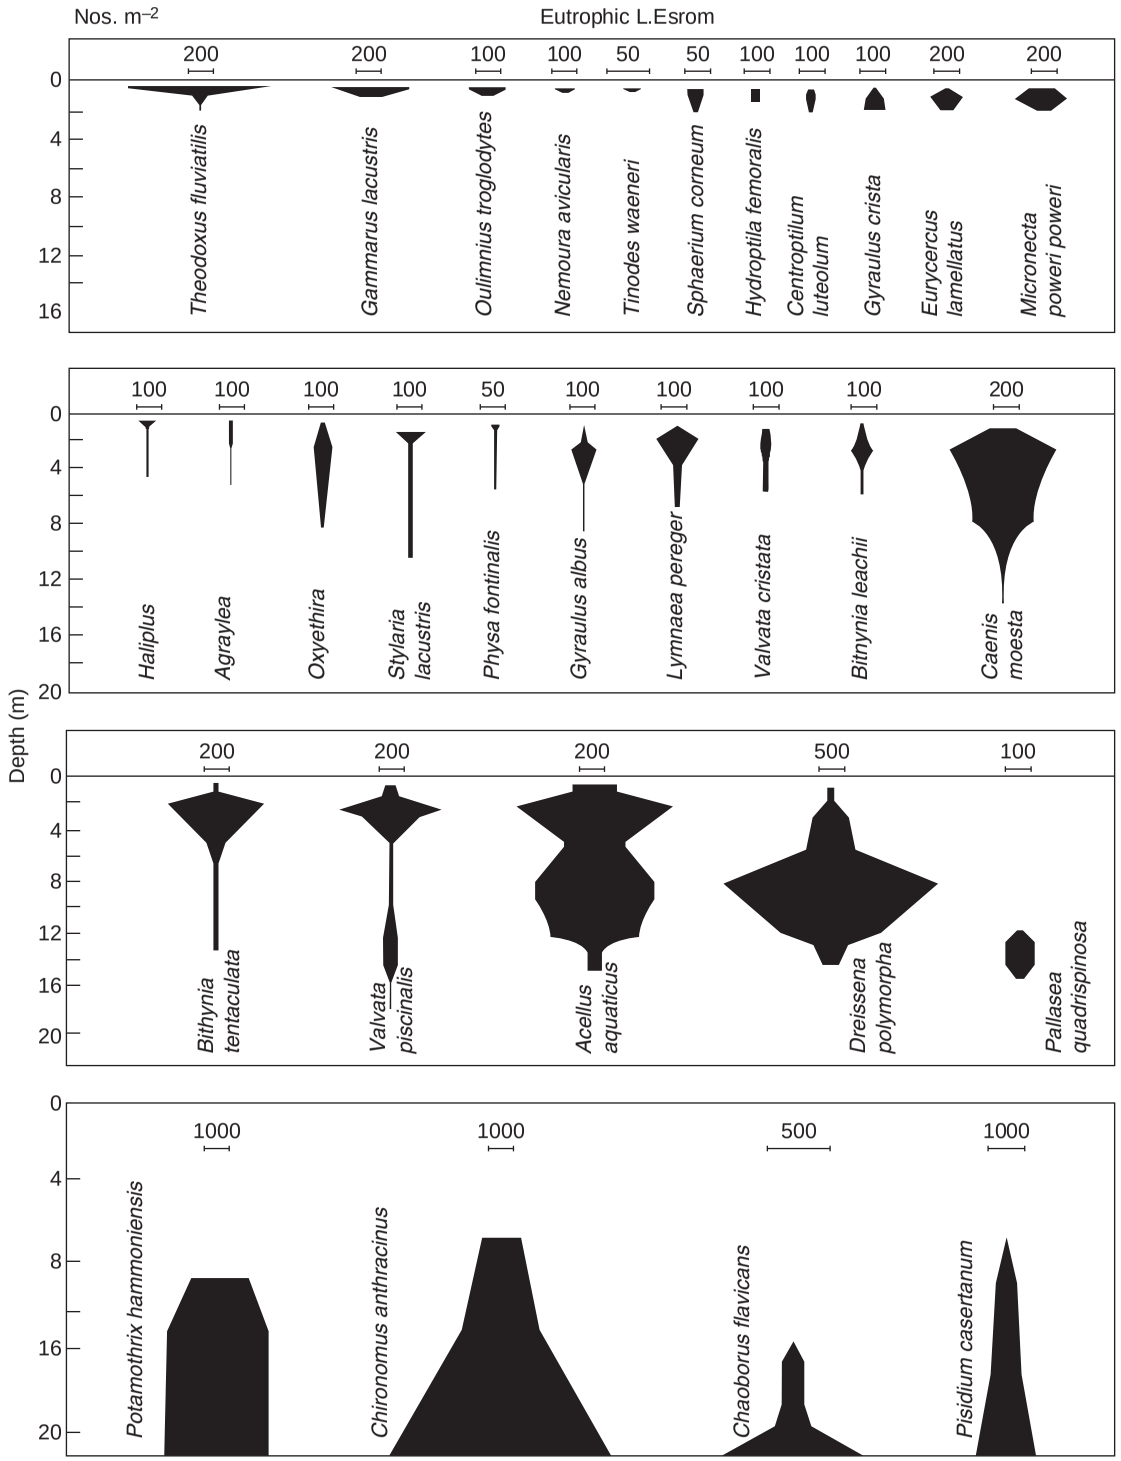

Figure 6 Distribution of benthic animals with water depth in eutrophic Lake Esrom, Denmark. Adapted from Jonasson (2004).

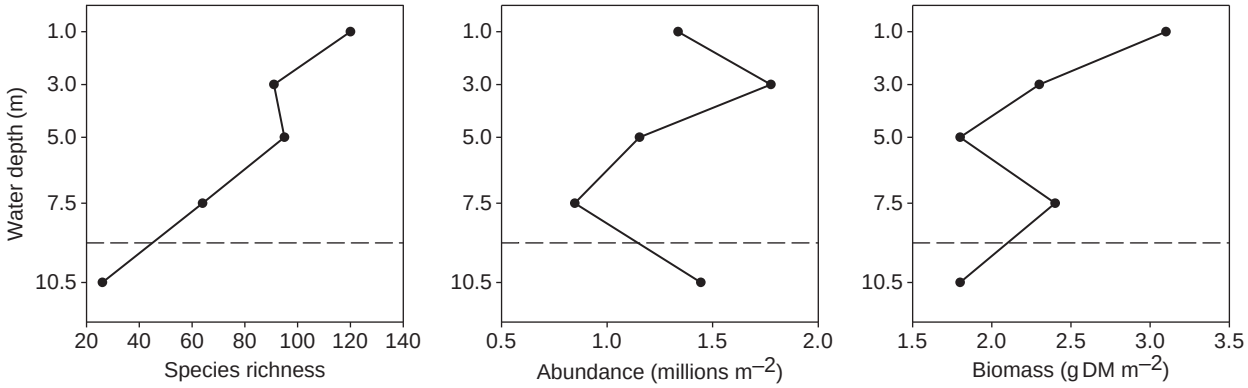

Figure 7 Species richness, abundance, and biomass of benthic animals (including all metazoans) as a function of water depth in Mirror Lake, a small unproductive lake in New Hampshire. The dashed horizontal line shows the depth at which oxygen at the sediment surface falls below 1mg l^{-1} by late summer. Adapted from Strayer (1985).

have not yet been disentangled. In stratified lakes, concentrations of hypolimnetic dissolved oxygen fall through the stratified period, and often reach zero at the sediment surface by the end of the summer. Only a few species of animals can tolerate hypoxic ($<2 mg l^{-1}$) or anoxic conditions for any period of time. The hydrogen sulfide that often accompanies anoxia also is toxic to most animals. Thus, inadequate dissolved oxygen at the sediment surface probably is a major cause of the vertical zonation of the zoobenthos and low species richness in profundal sediments. Nevertheless, declines in richness often occur well above the depth of oxygen depletion (Figure 7), so factors other than oxygen must be important as well. Although few zoobenthic species can tolerate anoxia, these species may be abundant, so low dissolved oxygen does not necessarily reduce zoobenthic density or biomass. Even in unstratified lakes, periods of warm, windless weather may reduce mixing enough to cause short-termdepletion of oxygen at the sediment surface and catastrophic losses of benthic animals. Such ephemeral stratification and oxygen depletion killed nearly the entire population of ~2500 metric tons (dry mass) of the mayfly *Hexagenia* in the shallow western basin of Lake Erie in late summer 1953.

Temperatures in the hypolimnion of a stratified lake are much lower and steadier than in the epilimnion. These low temperatures slow metabolic rates of benthic animals, may not meet thresholds for growth and reproduction of many species, and presumably exclude many species from profundal sediments.

The food base for the zoobenthos changes from the shoreline to the profundal zone. Aquatic plants and attached algae grow only in relatively shallow or clear water. In deep water, freshly settled phytoplankton supplements older detritus washed in from the watershed and littoral zone, and the amount and quality of organic matter reaching the profundal sediments of deep lakes probably declines with increasing water depth. The deposition of this sinking organic matter on the lake bed is highly uneven, depending on wave energy and the slope of the bottom. It seems reasonable to suppose that the quantity and quality of food is usually highest in the littoral zone and in depositional areas, and leads to variation in zoobenthic biomass (Figure 8).

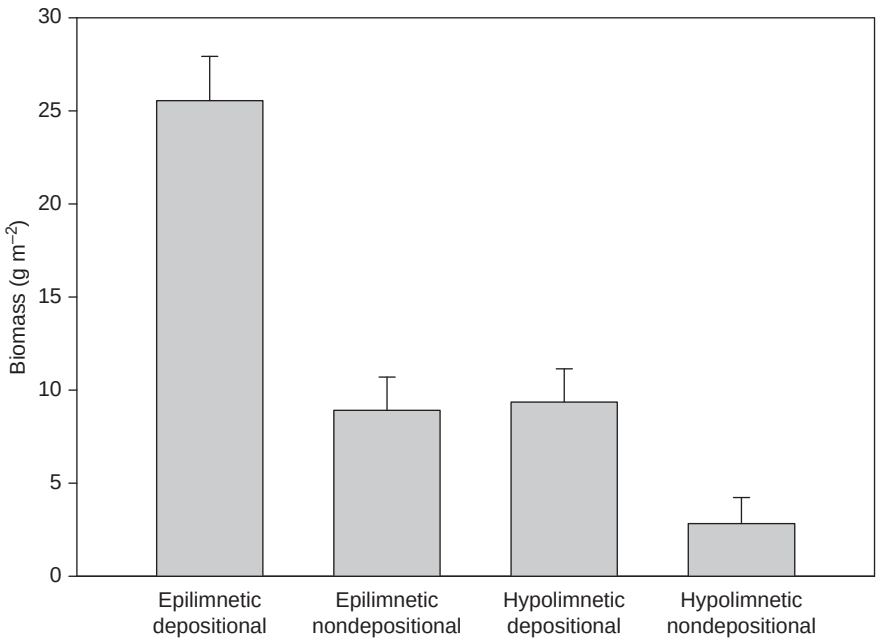

Figure 8 Mean (±1SE) biomass (wet mass) of macrobenthic animals at various sites in Lake Memphremagog, Quebec, as a function of thermal and depositional regime. Adapted from Rasmussen and Rowan (1997).

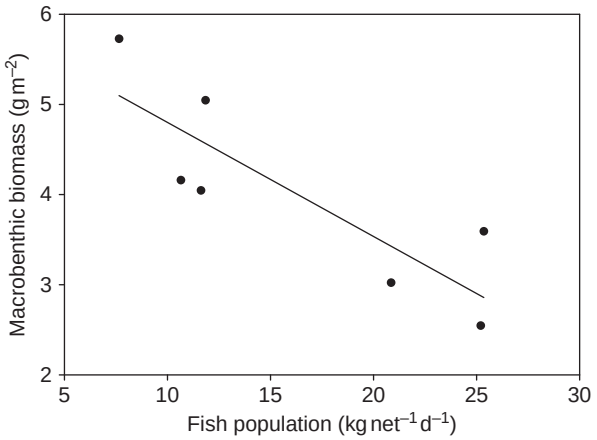

Figure 9 Dependence of macrobenthic biomass (wet mass) on fish predation in the Finnish Lake Pohjalampi. Each point is one year during a long-term experimental manipulation of fish populations. Adapted from Leppä *et al.* (2003).

Sediment grain size and heterogeneity also vary with water depth, typically changing from a highly patchy mosaic of coarse sediments in shallow water to a monotonous plain of fine-grained sediments in the profundal zone. Because of the many mechanisms that link benthic animals to their sediments, this variation in sediments must have a large effect on the kinds of benthic animals that can live at different depths in a lake. High heterogeneity in shallow-water sediments probably is a major cause for the high species richness in the littoral zoobenthos.

Disturbance from wave-wash, ice-push, or fluctuating water levels often causes a zone of markedly reduced zoobenthic density and diversity near the water's edge, particularly in large lakes and reservoirs.

Finally, many of the biotic interactions that affect the zoobenthos are depth-dependent. Fish predation can have very large effects on the number, size, and species composition of benthic animals (**Figure 9**). The numbers and kinds of fish change from the littoral to the profundal zone; indeed, anoxic profundal sediments may be free from fish predation. Likewise, the density and kind of macrophytes, which are important in providing surfaces for attachment, shelter from predation, and food for benthic animals, change markedly with water depth, and can drive major changes in the zoobenthos. Thus, biotic interactions underlie much of the within-lake variation in the zoobenthos.

Most benthic animals are found near the sediment surface (**Figure 10**), presumably because food (benthic algae and sinking phytoplankton) and oxygen are most available there. Nevertheless, animals can be found deeper in lake sediments, sometimes

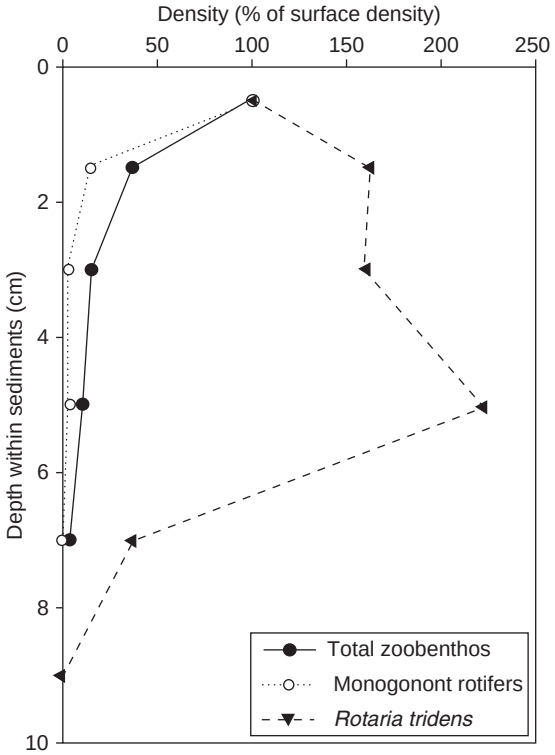

Figure 10 Vertical distribution of benthic animals within the sediments of Mirror Lake, New Hampshire. The three lines show the distributions of all benthic animals, a surface-dwelling taxon (monogonont rotifers), and a taxon that lives deeper in the sediments (the bdelloid rotifer *Rotaria tridens*). Modified from Strayer (1985).

reaching depths of more than 50 cm. Tubificid oligochaetes feed head down in the sediments, so it is easy to understand why they reach deep below the sediment–water interface, but the activities of other benthic animals that live deep within-lake sediments (e.g., some candonid ostracods, midges and bdelloid rotifers) are less well understood.

Variation across Lakes

Organic matter inputs, especially phytoplankton production, affect the numbers and kinds of benthic animals in lakes (**Figure 11**). Typically, lakes with higher organic matter inputs support more benthic animals (**Figures 3** and **11**), although there is some evidence that very high inputs of organic matter may actually reduce numbers of benthic animals, possibly by increasing the area of anoxic sediments. The kinds of benthic animals change with lake productivity as well. Indeed, one of the earliest systems for classifying the productivity of lakes was based on the composition of the profundal zoobenthos.

Lake morphometry has a strong influence on zoobenthic communities. Small, shallow lakes tend to support higher densities of benthic animals than do large, deep lakes. This pattern probably has at least three causes: (1) macrophytes, which support dense and diverse zoobenthic communities, are most abundant in small, shallow lakes; (2) shallow lakes are less likely to stratify than deep lakes, resulting in higher concentrations of dissolved oxygen at the sediment surface; (3) sinking phytoplankton (and other food particles) are less likely to be degraded before reaching the sediment surface in shallow lakes than in deep lakes.

Temperature affects both the number and kinds of benthic animals in lakes. Tropical lakes support different species than do temperate lakes (or arctic lakes), although groups such as chironomids, *Chaoborus*, and oligochaetes are abundant over wide latitudinal ranges. Warm lakes tend to support higher zoobenthic densities than do cold lakes.

Several aspects of water chemistry have strong effects on the zoobenthos. Saline lakes contain distinctive communities of benthic animals. Very salty lakes may contain just a few species of benthic animals, even though overall abundance or biomass of the zoobenthos may not be reduced. Soft water lakes of low pH and low calcium typically contain different species than do hard water lakes, and often are poor in shell-bearing animals (mollusks, ostracods) that need calcium to build their shells. Consequently, the recent acidification from atmospheric deposition has had important effects on the zoobenthos. High concentration of dissolved organic matter in lake water may reduce abundance of benthic animals.

Finally, differences across lakes in biotic interactions can have strong effects on the number and kinds of benthic animals. Only a few examples are well known. Fishless lakes usually contain large, active invertebrates (e.g., swimming or crawling insects) that are

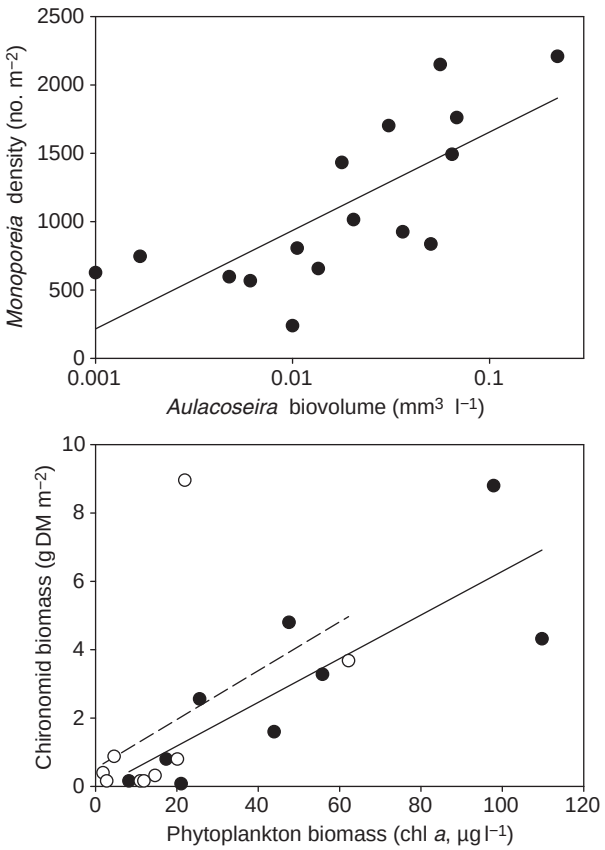

Figure 11 Examples showing the dependence of the zoobenthos on phytoplankton. The upper panel shows the numbers of the amphipod *Monoporeia affinis* in Lake Erken, Sweden, as a function of the amount of the important planktonic diatom *Aulacoseira* in the previous year ($r^2 = 0.54$, $p = 0.0008$). The lower panel shows the biomass of chironomids in April–May at two sites in Lake Balaton, Hungary, as a function of phytoplankton biomass in the previous summer (for black circles, $r^2 = 0.66$, $p = 0.008$; for white circles, $r^2 = 0.20$, $p = 0.23$). Adapted from Johnson and Wiederholm (1992) and Specziár and Vörös (2001).

quickly eliminated if fish are introduced. Crayfish and large bivalves can have strong effects on other benthic animals, as has been shown when invasions of lakes by alien crayfish and *Dreissena* have caused very large changes in benthic animal communities. It seems likely that other unstudied biotic interactions are responsible for variation in the zoobenthos across lakes.

Roles of the Lacustrine Zoobenthos

Secondary production by the zoobenthos in most lakes is modest (Table 2), and energy flow through the zoobenthos certainly is much smaller than that passing through microbial communities. Nevertheless, benthic animals play important roles in lake ecosystems, and even in human affairs. Broadly speaking, the ecological roles of the zoobenthos can be defined as food web or nontrophic roles.

As participants in lacustrine food webs, benthic animals consume phytoplankton, aquatic plants, animals, bacteria, and detritus. Consumption rates can be high enough to control the amount and composition of these food resources. The best-known examples involve the consumption of plankton by benthic animals. Suspension-feeders such as *Dreissena*, sponges, and cladocerans may be abundant enough to reduce phytoplankton biomass, or change its composition (Figure 12). Likewise, benthic animals that eat zooplankton (*Chaoborus*, mysids) can exert strong control on zooplankton communities, with effects that ramify through the ecosystem (Figure 16). Although relatively few benthic animals (crayfish, plant–parasitic nematodes, and some aquatic insects) eat or destroy aquatic plants, they can strongly affect macrophyte biomass and species composition; indeed, benthic animals have been used for biological control of nuisance weeds such as milfoil. Much less is known about the influence of the zoobenthos on attached algae, bacteria, and detritus, although these are the primary foods of most benthic animals. Further, some benthic animals have highly specialized diets and might therefore have selective effects on food resources. Benthic animals probably often control the

Most benthic data exclude the meiofauna, and are therefore underestimates. Because of methodological differences among studies, data are only approximately comparable. Compiled from many sources.

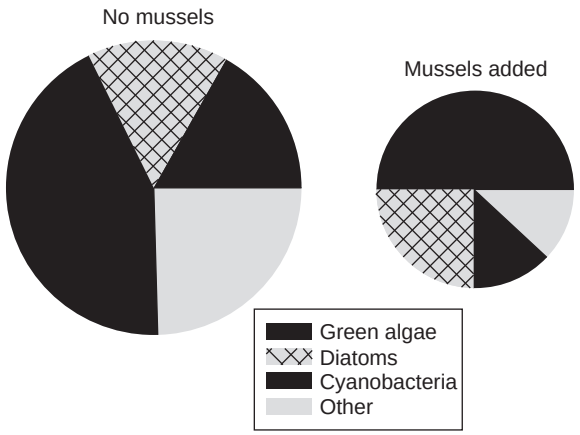

Figure 12 Changes in the amount and composition of phytoplankton in two small Dutch lakes following the experimental addition of *Dreissena polymorpha* to one of the lakes. The area of each circle is proportional to the biovolume of the phytoplankton in each lake. Adapted from data of Reeder *et al.* (1993).

amount and kind of attached algae in lakes, and it seems likely that most particles of detritus pass through at least one benthic animal before being buried in the lake bottom. Thus, there is ample evidence that benthic animals can control the amount and character of food resources in lakes, although we do not yet know how often and under what conditions such strong control occurs.

Benthic animals release nutrients such as inorganic nitrogen and phosphorus when they consume food. Such nutrient regeneration may be important to phytoplankton and attached periphyton in nutrient-limited lakes.

The predominant fate of zoobenthic production is to be eaten, whether by other members of the zoobenthos, fish, or terrestrial predators (**Table 3**). Consequently, the zoobenthos serves as an important link to higher trophic levels. Almost all lake-dwelling fish depend to some extent on zoobenthos, and benthic animals are the primary food of many fish species (**Figure 13**). Large populations of birds, bats, spiders, and other predators may be drawn to lakes or lakeshores to feed on benthic animals, including emerging insects.

Although it has been customary to treat the plankton and the benthos as belonging to separate food webs, many species of the zoobenthos depend either directly or indirectly on the plankton for food, and there are strong reciprocal links between the plankton and the zoobenthos. The pelagic and benthic zones of lake are linked by many strong connections (**Figure 14**), and function as an integrated system.

The major nontrophic role of the zoobenthos is sediment mixing (bioturbation). Three activities are important: (1) feeding, especially by conveyor-belt feeders such as tubificid oligochaetes, which feed in deep layers of the sediments and leave fecal pellets at the sediment surface; (2) burrow construction and ventilation, which are done by ephemerid mayflies and some chironomids; (3) ordinary locomotion by large, active animals such as *Chaoborus* and unionid bivalves. Bioturbation mixes sediments and

increases exchange of dissolved substances (e.g., oxygen, ammonium) between the overlying water and the sediment pore-water. These activities can have large effects on nutrient regeneration and cycling and burial of toxins. In addition, shell-building benthic animals (chiefly large bivalves) can alter the character of benthic habitats through accumulations of their living and dead shells. Such shell accumulations, which can probably reach masses $>1 kg\ m^{-2}$, serve as habitat or spawning sites for other animals, as well as altering biogeochemical transformations at the sediment–water interface.

Applied Issues

Some of the most important diseases of humans and wildlife are carried by benthic animals. Chief among these are diseases caused by trematodes (or flukes), in which freshwater snails, and occasionally decapods, serve as intermediate hosts. In a typical life cycle (**Figure 15**), eggs shed from the definitive host hatch into swimming larvae (miracidia) that seek out and penetrate an aquatic snail. Many species of fresh-water snails serve as hosts for the various trematodes that affect humans, livestock, and wildlife. After undergoing development in the snail, a second free-swimming larval stage (the cercaria) may either enter the definitive host directly when the host is in the water, enter a second intermediate host (a fish or decapod), or encyst on an aquatic plant. The trematode passes from the second intermediate host or aquatic plant into the definitive host when uncooked fish, decapods, or aquatic plants are eaten. Adult trematodes may live in the intestines, liver, blood vessels, or lungs of humans or other vertebrates, and often cause chronic, debilitating diseases. The most important of the snail-borne diseases is schistosomiasis, a debilitating disease caused by the genus *Schistosoma*, which affects ~200 million humans throughout the tropical world. Other significant snail-borne diseases include liver flukes (especially *Fasciola hepatica* and *Opisthorchis sinensis*), which cause large damage to sheep and cattle, as well as affecting millions of people, and various intestinal or lung flukes, which affect many people around the world. Trematodes using freshwater snails as intermediate hosts also affect many vertebrate species other than humans. In fact, cercaria of trematode species that use birds as definitive hosts sometimes burrow into humans. Although such cercariae do not develop normally in humans, they can cause a skin irritation known as 'swimmer's itch' and thereby limit recreational use of lakes. The acanthocephalans are another important group of parasites carried by freshwater benthic animals. Adult acanthocephalans are intestinal parasites of many fishes and other aquatic vertebrates, and benthic crustaceans usually serve as their intermediate hosts.

Human-caused changes to natural habitats sometimes increase disease problems (e.g., impoundments have increased prevalence of schistosomiasis), and ecological interventions (e.g., habitat management, introductions of predators or other biological controls) may be implemented as part of integrated programs of disease control.

Other benthic species are pests. Fouling species such as *Dreissena*, *Corbicula*, and occasionally sponges and ectoprocts block water intakes and may force plant operators to use mechanical cleaning, biocidal chemicals, or pipe coatings to keep water flowing. It appears that large emergences of chironomid midges may be a major cause of 'hay fever' and asthma in some parts of the world. Mass emergences of lake-dwelling insects (chiefly ephemerid mayflies or chironomid and chaoborid midges) may be so large that they cause traffic hazards, produce windrows of dead insects that need to be cleaned up with heavy equipment, and even short-circuit power plants.

Although there has been some interest in biomanipulation to increase the positive impacts of benthic animals, or reduce their negative impacts, such efforts have not proceeded as far as in the pelagic zone, where biomanipulation is now widely practiced. At least three types of biomanipulation have been considered involving benthic animals. Because benthic

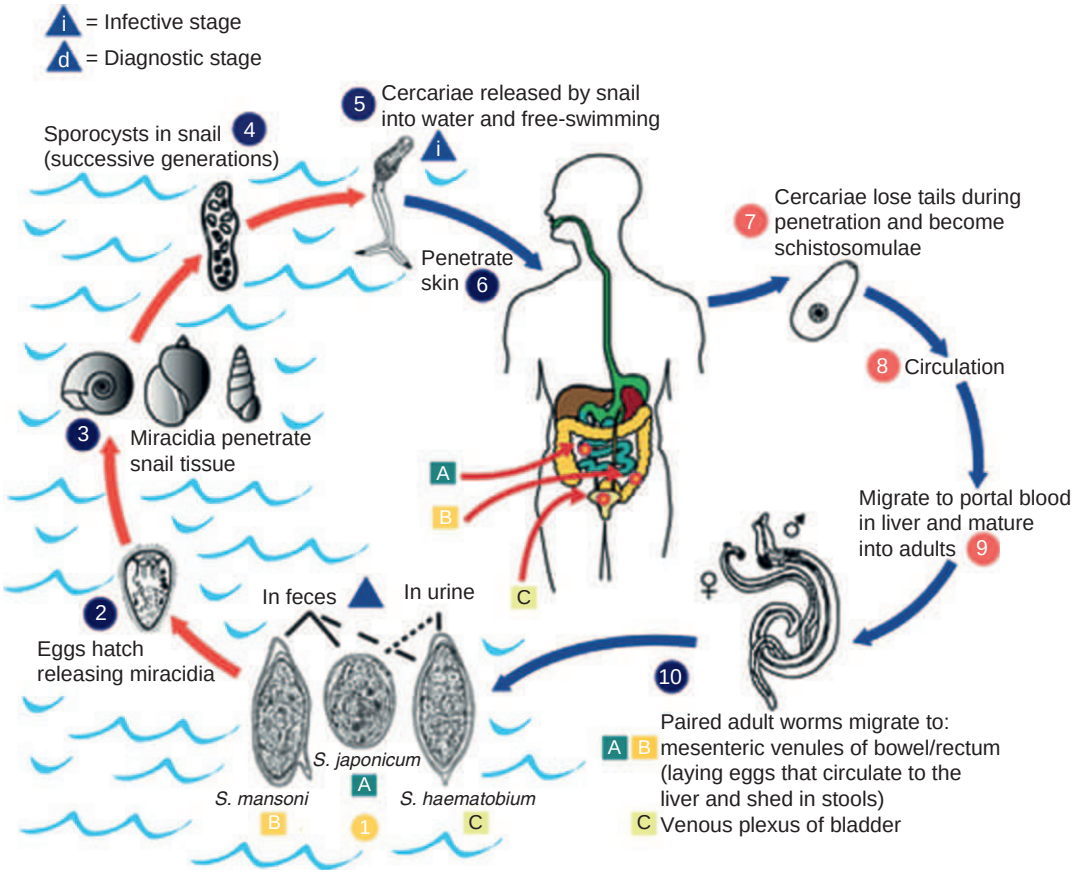

Figure 15 Life cycles of three species of the blood fluke *Schistosoma*. From the Centers for Disease Control.

suspension-feeders may control phytoplankton biomass and composition, some studies have sought to manage nuisance phytoplankton by increasing populations of benthic suspension-feeders (Figure 12). Benthic animals are valuable food for fish, so fisheries managers often have introduced large benthic animals (crayfish and the opossum shrimp *Mysis*) to lakes to increase growth rates or biomass of fish populations. Such introductions rarely have been supported by a careful analysis of likely impacts, and introductions of forage invertebrates sometimes have led to undesirable and unforeseen impacts (Figure 16). Finally, there have been a few attempts to increase populations of benthic animals to control populations of animals that carry diseases. Probably, the most prominent examples have been the additions of predators or competitors of the snails that carry schistosomiasis. Clearly, biomanipulation of lakes using benthic animals is still in its infancy.

Like other freshwater plants and animals, human activities have harmed some species of the lacustrine zoobenthos, which are now extinct or imperiled. Several activities have been especially harmful. Large water diversions have caused some lakes to become excessively salty or even dry up altogether, endangering or eliminating the benthic animals that formerly lived there. Many lakes have been badly polluted by toxins from industry and other sources or sediment from poor land-use practices. Nutrient loading from fertilizers or domestic wastes has increased the productivity of many lakes, leading to anoxic sediments, with obvious consequences for benthic animals. Many of the alien species (sport fish, aquatic plants, and invertebrates) that have been introduced into lakes around the world have had strong effects on benthic animals. An accounting of the summed effects of these harmful activities on benthic animals does not exist, but surely many populations in individual lakes have been imperiled or eliminated. In the case of ancient lakes that support endemic species of benthic animals, local extirpations would translate into global extinctions for the species. Extinctions among the endemic fish species of ancient lakes are well known, and presumably, such extinctions have occurred among the zoobenthos as well.

A few species of benthic animals are harvested from lakes or reservoirs for human use. Important fisheries for wild or cultured populations of various freshwater decapods (crayfishes, prawns, crabs) are scattered in lakes, ponds, and wetlands around the world. Several of the large bivalves have been harvested for millennia for food, pearls, and mother-of-pearl, although the largest fisheries for these animals are in rivers rather than in lakes. Particularly in the nineteenth century, large numbers (>10 million animals/year) of the medicinal leech (*Hirudo medicinalis*) were taken from the wild. Other members of the lacustrine zoobenthos (adult chaoborid midges, eggs and adults of corixid bugs, snails) are harvested in large numbers for human food locally.

Zooplankton Diversity and Variation Among Lakes

Stephen J Thackeray, Lake Ecosystems Group, UK Centre for Ecology & Hydrology, Lancaster, United Kingdom

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie-Elodie Perga and Damien Bouffard.

Glossary

Heterotroph An organism that cannot produce its own organic matter (e.g., by photosynthesis), but instead gains nutrition by consuming preexisting organic carbon sources.
Metabarcoding A method that allows the simultaneous identification of multiple species within environmental samples, using variations in the structure of short sections of DNA.
Metacommunity A set of local communities separated in space but that are linked by the dispersal of organisms among them.
Molecular Operational Taxonomic Units (mOTUs) Clusters of DNA sequences that are highly (often 97%) similar to each other, and can therefore be pragmatically considered as belonging to the same species.
Next generation sequencing High-throughput methods for determining the sequence of nucleotides present within sections of DNA.
Parthenogenesis A form of asexual reproduction, where embryos develop without the need for eggs to be fertilized by sperm.
Species richness The number of unique species found in a biological survey. This can be calculated at a single point in space and time, or cumulated.

Introduction

The zooplankton are a diverse grouping of small heterotrophic organisms that live in the open waters of aquatic habitats. They are of great importance for the functioning of aquatic ecosystems, consuming phytoplankton, bacteria and each other, while themselves being consumed by a range of invertebrate and vertebrate predators. As such, the zooplankton are important conduits for the transfer of energy through food webs, they influence water quality, and they sustain life at other trophic levels. Here, as a grounding for later chapters, I introduce some of the major taxonomic groupings of freshwater zooplankton, their traits, and their life cycles. I then address how the diversity and community composition of selected zooplankton groups varies among lakes, as a function of landscape and local lake habitat features. The focus is explicitly spatial (among-lake differences), though there are clearly temporal changes in zooplankton community structure as well.

Taxonomic diversity

Rather than a single, coherent taxonomic group, the zooplankton comprise a variety of multicellular animal taxa in addition to single-celled protists, such as ciliates and flagellates. Here, the focus is on multicellular members of the zooplankton community: the rotifers and planktonic crustacea.

Rotifers

The Rotifera (once known as "wheel animalcules") are a Phylum of small (50–2000 μm), primarily freshwater zooplankton, dominated by two major groupings; the Monogononta and Bdelloidea. Collectively, these groups include an estimated >1900 species capable of inhabiting fresh water, though this may be an underestimate, given incomplete taxonomic knowledge and the likely presence of cryptic species. Many species are very widely distributed at a global scale, though there are some cases of regional endemism. Rotifers can be found across a wide variety of freshwater habitats, from large lakes and reservoirs, to small ponds, temporary puddles, birdbaths, and even the interstitial waters within sediment layers and films of water on mosses and liverworts. Within a specific freshwater ecosystem, rotifers will be found not just in the open water (true zooplankton), but also in littoral and benthic zones. A number of species crawl or attach to substrates, or are sessile: indeed, a relative minority of the total known number of rotifer species are truly planktonic.

Rotifers are highly variable in morphology (Fig. 1), but consistently possess an anterior region of hair-like cilia (called a corona) which is used for food collection and locomotion, a defined pharynx (the mastax), and hardened jaws (trophi) adapted for grasping, piercing, or grinding prey. Most rotifer species exist as single individuals, though colony formation occurs in some cases (e.g., *Conochilus unicornis*).

Cladocera

The Cladocera are a group of microcrustaceans (Phylum Arthropoda), comprising four known Orders: the Anomopoda, Ctenopoda, Haplopoda and Onychopoda. Most species occupy a body size range of 0.2–6 mm. However, the highly-transparent predator *Leptodora kindtii* is considerably larger, approaching 2 cm in length. At a global scale, the number of species has been estimated at 400–500, or even around 620, with a number of regional endemics. However, this is likely to be an underestimate since, as for rotifers, many cryptic species may exist. Cladocerans may be found in a wide range of water body types, including large and small lakes, ponds, and slow-flowing rivers. Some species are truly planktonic, while others live in association with littoral and benthic habitats. For example, *Sida crystallina* (Ctenopoda) may attach to submerged plants while filter feeding, and members of the Chydoridae (Anomopoda) may be observed crawling along strands of filamentous algae as they scrape for food.

A large compound eye (sometimes accompanied by a light-sensitive ocellus) is a conspicuous feature of cladoceran species (Fig. 2). In addition, cladocerans have large second antennae, which are used for swimming or crawling, for pelagic and benthic species, respectively. For many species (those in Orders Anomopoda and Ctenopoda), the body is enclosed in a bivalve carapace. In members of the Onychopoda and Haplopoda, such as *Bythotrephes longimanus*, *Polyphemus pediculus* and *Leptodora kindtii*, this carapace is much reduced to a brood pouch positioned on the thorax.

Copepods

The Copepoda are a Subclass of small crustaceans (Phylum Arthropoda). Although over 2800 known species of copepod inhabit freshwaters, a great many more species are found in marine environments. Freshwater species are found within five Orders, namely the Calanoida, Cyclopoida, Harpacticoida, Gelyelloida, and Siphonostomatoida. Collectively, these species inhabit a very wide range of freshwater habitats, from large lakes to small ponds, groundwater and small pools of water trapped within terrestrial plants (called phytotelmata). Within lake environments, copepod species differ in their habitat use, with some adopting a planktonic, open water existence, while others live in association with submerged plants and surface sediments. Others still are parasitic, particularly on fish and molluscs. Although some species are widely-distributed at a global scale, the overwhelming majority appear to be endemic to single zoogeographic regions, or indeed single (often ancient) lakes.

Many freshwater copepod species are of the order of 1–2 mm in size, though some species exceed this. They have jointed appendages and highly-segmented bodies (Fig. 3), which comprise an anterior section (the prosome) and posterior section (the urosome). Thoracic appendages, used for feeding and locomotion, are attached to the prosome. The first antennae of copepods are armed with an array of chemo- and mechanoreceptors that are used to detect potential food items, mates, and predators.

Other members of the zooplankton

Though much research on the environmental drivers of zooplankton diversity has focused on rotifer, cladoceran and copepod communities, it is important to recognize that, in some water bodies, other taxa can contribute to the zooplankton assemblage. These may include other crustaceans, such as freshwater members of the Mysidae (e.g., the opossum shrimp, *Mysis relicta*) and ostracods. Numerous insect species may also join the zooplankton assemblage during their larval and pupal stages (e.g., chironomids). A notable insect addition to the plankton of many lakes is the larval stage of the "phantom midge" (*Chaoborus* spp.); insects that can be voracious and influential predators of other members of the zooplankton community.

Life cycle diversity

Different species within freshwater zooplankton communities adopt widely-varying life cycle strategies. These life cycle attributes play an important role in determining the way in which zooplankton respond to environmental conditions, and the time scales over which these responses will manifest.

Cyclic parthenogenesis

Asexual reproduction, without fertilization (parthenogenesis) is commonplace within the rotifers and cladocerans, and may alternate with bouts of sexual reproduction (a pattern known as cyclic parthenogenesis). During the parthenogenetic phase of the life cycle, and under favorable environmental conditions, female individuals produce eggs that develop, without fertilization, into a new generation of adult females. However, certain triggers (e.g., food shortage, overcrowding, change in temperature or day length) can initiate the production of males and sexual reproduction, the result of which is fertilized resting eggs. Resting eggs, often more thick-walled than their unfertilized counterparts, lay dormant (a state known as diapause) until development and hatching are triggered by environmental conditions.

In the case of the rotifers, diploid, amictic females produce diploid eggs by mitosis. Often, a single egg is produced, and is carried by the female, though in some cases these are attached to plants or released freely into the water. In monogononta rotifers, the switch to sexual reproduction is marked by the meiotic production of haploid, mictic eggs that hatch, if unfertilized, into male rotifers. The males, often smaller and much simplified compared to the females, fertilize other haploid eggs, to produce diploid resting eggs.

In many ways, the cladoceran life cycle is similar, with amictic females producing amictic eggs under favorable conditions. However, for cladocerans, the switch to sexual reproduction involves the production of diploid, not haploid, males, which fertilize haploid eggs. As in the case of rotifers, though, the result is the production of toughened resting eggs. These resting eggs are deposited in a hardened pouch, called an ephippium. In the parthenogenetic phase of the cladoceran life cycle, offspring develop from the egg inside the adult female brood pouch, and are released as free-swimming individuals.

Obligate sexual reproduction

Sexual reproduction is commonplace in copepods with both male and female individuals comprising the total population, although a minority of harpacticoids reproduce asexually. There is sexual dimorphism, in that the sexes may differ in body size, as well as in appendage structure. An especially notable feature is that male copepods have major points of articulation on their antennae that allow them to grasp females during copulation. In male cyclopoids, both antennae are modified in this way, whereas in calanoids only the right antennae is typically modified. In the case of calanoids, the right-hand 5th thoracic limb also bears spines that allow the female to be grasped, and sperm transferred, during mating. Fertilized eggs are, for many species, carried in sacs at the rear of the body; typically a single sac for calanoids, and two sacs for cyclopoids. However, some species release their eggs directly into the water, rather than retaining them in sacs. Though eggs frequently develop without delay, some harpacticoid and calanoid copepods can produce resting eggs, which enter a state of diapause. For cyclopoid copepods, diapause typically occurs in sub-adult or adult stages, rather than in the egg stage. In comparison with rotifers and cladocerans the copepod life cycle is complex, comprising six naupliar stages, and five copepodite stages, before adulthood.

Diversity of feeding modes/ecology

All zooplankton face the challenge of obtaining their food from a highly dynamic fluid medium. Approaches to food acquisition vary among species, affecting which prey resources are consumed, how they are located and handled, and the extent to which consumers can actively select for specific prey items. Even species demonstrating the same broad feeding mechanism may feed on different size ranges of particles, or demonstrate a degree of food selectivity based upon factors other than food particle size. These feeding behaviors therefore underpin the way in which zooplankton interact within freshwater food webs, and we can expect that differences in zooplankton diversity and composition will determine the cumulative "grazing" effect that these consumers have upon phytoplankton communities.

Filter feeding

Many cladoceran species filter feed, generating water currents by beating thoracic appendages enclosed within their bivalve carapace. This motion carries particles into a "food groove" between these limbs. The limbs themselves are armed with hair-like setae and setules, and these filters are scraped by other limbs in order to pass food towards the mouth. Filter feeding is considered to be non-selective, though the rejection of non-preferred food items is possible. Cladocerans may reject such items by "kicking" them away from the feeding groove using their post-abdominal claw.

Suspension feeding

Suspension feeding generally involves the generation of water currents that carry small food particles (such as bacteria, protists, microalgae) towards the mouth. In the case of rotifers, these currents are generated by rhythmically beating the anterior cilia. Food items may be ejected by the oral canal or cilia, rather than ingested. Calanoid copepods may also suspension-feed on small particles by vibrating appendages on the prosome in order to create a current that draws food items close enough to the mouthparts that they can be ingested.

Selective and raptorial feeding

Many predatory zooplankton adopt a raptorial feeding mode. This is commonplace within the cyclopoid copepods for which individuals have been observed attacking large prey, such as the larvae of chironomid midges. Raptorial feeding is known for some rotifers, such as the large predatory species *Asplanchna priodonta* which can grasp and ingest smaller rotifers. A number of predatory cladocerans also feed raptorially, such as *Leptodora kindtii*, *Bythotrephes longimanus*, *Polyphemus pediculus* and *Cercopagis pengoi*. This mode of feeding is highly selective, in that individual prey are targeted and consumed, and is generally associated with the consumption of larger prey items than is the case for filter or suspension feeding. Interestingly, calanoid copepods and *Bosmina* can also selectively grasp individual prey items in addition to suspension and filter feeding, respectively.

Scraping

While pelagic species typically employ the feeding mechanisms introduced above, it is noteworthy that many littoral species also scrape the biofilm of underwater surfaces in order to gather food. As an example, such an approach is adopted by certain bdelloidea rotifers (e.g., *Adineta*) and cladocerans (e.g., *Alona* spp.).

Quantifying zooplankton diversity

Before examining the ecological drivers of zooplankton diversity among water bodies, it is worth noting that there are in fact a great number of ways of quantifying diversity itself.

What is diversity, anyway?

In a large number of studies, diversity is expressed in terms of taxonomic (often species) richness; the number of unique taxa found in a defined set of samples. The species complement does indeed appear to vary among water bodies, and in ways that can be at least partially explained by measured ecological factors. However, this measure alone provides no information on the relative abundances of the species involved, and so would be insensitive to situations in which the dominance patterns of species changes, but the species richness does not. To address this issue, some studies have used measures of diversity that account for relative abundance (e.g., Shannon's H). As a single number summary of a community, these measures do not explicitly reveal changes in the identity of the species involved; which particular species are present, and dominate in different communities. Of course, there are analytical approaches that can account for such variation. However, the key point here is that it is important to consider which diversity measurements are most relevant to any given ecological hypothesis or question.

Sampling considerations

When examining patterns in zooplankton diversity, it is also important to recognize that estimates of zooplankton diversity are sensitive to variations in survey design, sampling effort, sample collection, and sampling processing procedures. A diversity of sampling gear and methods are used to collect zooplankton in the field. Net tows are commonly used, though net designs vary among studies. Aspects of net design can fundamentally affect diversity estimates. Nets with coarse mesh sizes will fail to capture small species and life stages, producing samples that give a biased estimate of overall diversity. While finer mesh sizes will, in principle, allow the collection of smaller species, and produce less biased data, they are more prone to clogging by algae and other suspended matter. This will, in turn, reduce net filtration efficiency. Net mouth diameter also has implications for diversity estimates, since larger nets are more likely to capture rare species and minimize net avoidance. Means of deployment also vary; samples may be collected by vertical tows from all or part of the water column, or by horizontal tows. Given the spatial heterogeneity of zooplankton populations, such deployment decisions will also influence diversity estimates.

Other sampling gears are often used. For example, transparent Schindler-Patalas plankton traps are also commonly deployed in place of net tows. In addition, some investigators use pumps to draw samples from different depths, for subsequent filtration. Tube samplers are also used, especially in littoral areas where net sweeps may underrepresent plant-associated species. Among-lake estimates of zooplankton diversity are therefore very likely to be affected by variations in key aspects of the sampling process, for example differences in net mesh size, in the volume of water collected or filtered for a single sample, and in the likelihood that sediment- or plant-associated species are collected alongside true planktonic forms.

Furthermore, one would expect to find more species if searching a large number of samples collected at different locations and depths throughout a water body, and over time, than if analyzing only a single zooplankton sample. This is simply because spatial and temporal sample replication will capture community variation among habitat types within a water body, and as part of seasonal succession. Even within a specific habitat type, such as the pelagic zone, zooplankton communities are patchily distributed due to the effects of water movements, swarming and migratory behaviors, and variability in food concentrations. In addition to this dependence of diversity estimates on sample replication, the number of species "discovered" within any specific sample will vary according to whether the whole sample is searched, or only a sub-sample of it. When comparing diversity among water bodies, methodological inconsistencies are likely to add additional among-water body variation in zooplankton diversity which is not likely to be correlated with environmental drivers, and might partially obscure correlations between diversity and its drivers.

Advances in monitoring zooplankton diversity

Much of our knowledge of the structuring of zooplankton communities is derived from the analysis of samples by light microscopy. However, the toolbox available to freshwater ecologists is ever expanding, and recent methodological innovations promise to deliver high volumes of new, complementary data that will further shed light on zooplankton community dynamics.

It is now becoming possible to use imaging technologies to analyze zooplankton community samples (Fig. 4A). By circulating collected samples through instruments equipped with high speed cameras, it is possible to rapidly gather images of individual organisms, count their abundance, and calculate measures of size and shape. In principle, statistical analysis of the recorded size and

Phylogenetic distribution of assignable components of zooplankton CO1 diversity. (a) A tree diagram of the representative sequence of each taxon. Distance was measured by the number of base substitutions per site, based on the Kimura two-parameter (K2P) method. One thousand bootstrap trials were run using the neighbor-joining algorithm of the Mega 6.0 program. (b) Number of reads of each taxon. (c) Number of OTUs of each taxon. (d) Number of reads per OTU. (e) Occurrences of each taxon in all samples. (f) Proportions of OTUs in the same taxon. Different color represents different OTU, and stacked bar means relative abundance of each OTU. (g) Distribution of each taxon in all samples. The color weighted by relative reads abundance (e.g., 0.01 means the number of reads for this taxon accounts for 1% of total number of reads). (B) Reproduced from Yang J, Zhang X, Xie Y, Song C, Zhang Y, Yu H and Burton GH (2017) Zooplankton community profiling in a eutrophic freshwater ecosystem-lake Tai Basin by DNA metabarcoding. *Scientific Reports* 7: 1773. https://doi.org/10.1038/s41598-017-01808-y.

shape data may allow the automatic identification of taxa in samples based upon their morphological distinctiveness. However, much methodological development is needed to realize this potential. While this continues, images from these instruments can be manually inspected by experienced taxonomists, to allow identification. Interestingly, success in finding rare species by these means is strongly dependent on the abundance of those species and the level of counting effort (the total number of individuals examined), as is the case for traditional light microscopy (Stanislawczyk et al., 2017).

It has been suggested that DNA-based approaches to diversity assessment may overcome some of the uncertainties that can confound traditional, microscopically-derived data, such as inconsistencies in taxonomic identification among analysts, hybridization, and high within-species morphological variability. Furthermore, these approaches potentially allow the rapid quantification of diversity in large numbers of samples, a process that would be time consuming via traditional means. Such methods are based upon metabarcoding of particular gene regions (e.g., the cytochrome *c* oxidase I, COI, region of mitochondrial DNA), following DNA extraction from collected zooplankton samples (Fig. 4B). Using Next Generation Sequencing (NGS) of the extracted DNA, it is possible to identify molecular Operational Taxonomic Units (mOTUs) that are present within that sample, and to subsequently assign these to known zooplankton species using reference databases such as GenBank® and the Barcode of Life Data System (BOLD). This method of diversity assessment shows great promise, delivering data that are consistent with that from more traditional microscopic approaches, and allowing the identification of differences in zooplankton community composition among water bodies (Yang et al., 2017). However, to be effective, DNA-based approaches require careful methodological optimization and, crucially, the inclusion of a wide diversity of zooplankton species sequences in reference libraries. Furthermore, there is active debate regarding the ability of DNA-based approaches to deliver data on species (relative) abundances, in addition to species presence/absence, and thus richness.

Within-species diversity

To date, most research on zooplankton communities has focused on interspecific diversity. However, thanks to DNA-based methods, we now know that, even "within" a species there can exist considerable variation. Populations of the same zooplankton species, but in different water bodies, may be genetically distinct from each other. Such within-species diversity has been demonstrated for a number of species, for example *Daphnia longispina* in the Pyrenees (Ventura et al., 2014) and *Sinocalanus tenellus* in China (Wang et al., 2018). Numerous mechanisms could account for such patterns, including colonization history, dispersal limitation, and local adaptation to environmental conditions. Genetically-distinct lineages of a given species may appear morphologically identical and are sometimes referred to as cryptic taxa. Therefore, without molecular approaches, this aspect of diversity would be invisible to us.

Traits, as well as taxonomy

The majority of existing research into patterns and drivers of zooplankton diversity has adopted a taxonomic approach, where diversity is expressed in terms of the numbers and relative abundances of species, or genera. However, an alternative approach is to consider diversity from a more functional perspective; in terms of the ecological roles that organisms play, and the traits that determine the way in which they respond to, and affect, the wider ecosystem. Functional traits characterize key features of the life-history, population dynamics, and food web interactions of zooplankton taxa, and then permit the delineation of functional groups; sets of species that share similar traits. The excellent paper by Barnett et al. (2007) demonstrates this approach, synthesizing information on body size, habitat use, trophic group and feeding type for 36 North American crustacean zooplankton species, and grouping them into five distinct functional groups. These groupings were not simply a reflection of taxonomy, since the predatory cladoceran *Polyphemus pediculus* was included in the same functional group as a number of omnivorous and carnivorous copepods, while small herbivorous Cladocera were grouped together with herbivorous-omnivorous calanoid and cyclopoid copepods.

Functional approaches to investigating the ecological significance of zooplankton diversity show great potential to clarify links between diversity, ecosystem structure and function. However, important decisions must be made regarding the application of such an approach. For example, investigators will need to consider how many, and which traits are needed to capture the most important aspects of species' ecological roles, and whether these trait data are already available for many species. Furthermore it is important to recognize, and incorporate where possible within-species variation in traits that may arise through growth and development (e.g., juveniles vs. adults), and due to differences in the experimental and field conditions under which they are measured.

Drivers of zooplankton diversity

Zooplankton diversity and community composition vary greatly among water bodies, and these patterns are determined by a range of local and regional scale processes (Fig. 5). While the natural or human-aided dispersal of zooplankton allows species to reach new habitats, the successful establishment of newly arriving species is mediated by physical, chemical and biological features of the recipient water body (Lukaszewski et al., 1999; Shurin, 2000). We must therefore consider zooplankton diversity from a meta-community perspective; as the product of both dispersal among water bodies, and the influence of habitat features that determine which species can survive and reproduce. Here I introduce some of the key habitat features and processes that have been implicated in determining zooplankton diversity though, in reality, there is a great deal of complexity in the way that these factors interact to affect community composition.

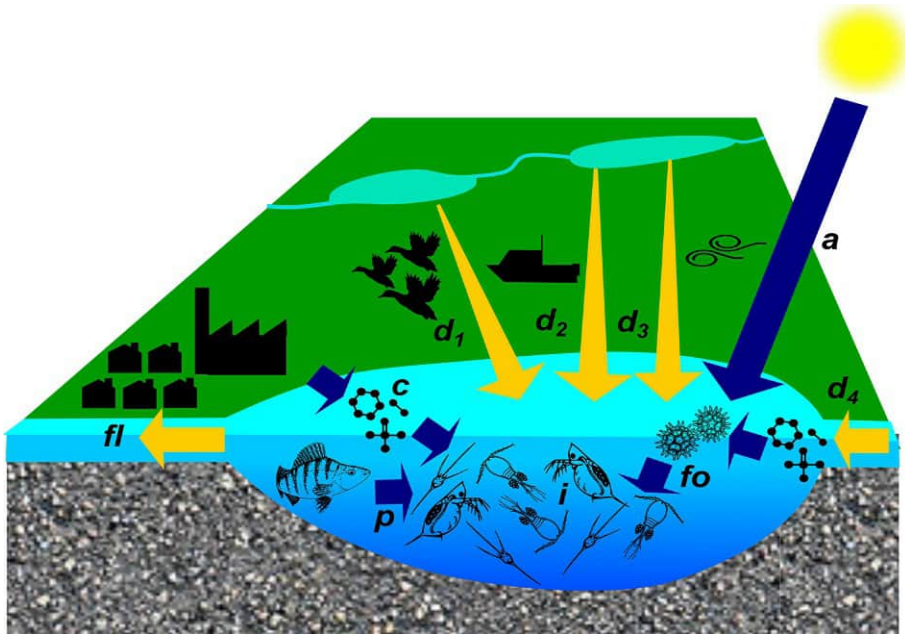

Fig. 5 Example drivers of zooplankton diversity. Local diversity arises as a result of the combined influence of both water body and landscape-scale factors. New species may reach a specific water body through dispersal via other organisms (d_1), human movement among water bodies (d_2), aeolian transport of propagules (d_3), or connections to upstream water bodies (d_4). Local features of the water body environment influence the species that establish; predation (*p*), food quality and quantity (*fo*), interspecific interactions within the zooplankton (*i*), inputs of contaminants (*c*), and flushing (*fl*). Climatic and atmospheric factors (*a*) can also influence diversity through inputs of energy, UV, and acid deposition.

Water body morphometry

Lake morphometry has long been recognized as a correlate of zooplankton community richness. Species richness has often been observed to increase with lake surface area and, sometimes, depth (Dodson, 1992; Merrix-Jones et al., 2013). It has been suggested that this correlation arises because zooplankton immigration rates and lake habitat complexity (the diversity of available niches) increase, while extinction rates decrease, with lake size (Dodson, 1992). However, these patterns are not universally observed (Hessen et al., 2006), possibly because of overriding effects of intrinsic ecosystem properties, and sampling issues. Indeed, it has been suggested that small water bodies might support comparatively high species diversity, if they lack fish (Scheffer and van Geest, 2006). Correlations between lake morphometry and diversity could be mediated by food web structure. Given that deeper, larger lakes tend to have longer food chains (Post et al., 2000), the presence of piscivores reducing planktivore fish feeding pressure could also drive zooplankton communities toward dominance by larger Cladocerans (Carpenter et al., 2001), potentially influencing richness.

Climatic considerations

Zooplankton species richness and composition have been shown to vary with elevation and latitude; patterns that suggest a role for climatic factors in determining diversity. For example, maximal richness values decline at high latitude and elevation across Norway (Hessen et al., 2006), cladoceran species richness declines from south-to-north throughout Canada (Henriques-Silva et al., 2016), and zooplankton compositional change occurs among fishless North American lakes spanning an elevation gradient (Symons and Shurin, 2016). Changes in zooplankton community composition have also been more directly correlated with large-scale temperature and precipitation gradients (Loewen et al., 2019). Lower local or regional-scale species richness in locations with lower temperatures and incoming solar radiation suggest that zooplankton communities may follow the predictions of the species-energy hypothesis, which posits that higher energy inputs support a greater number of species, by stimulating ecosystem productivity, and thereby reducing the chances of species' populations declining to extinction (Pinel-Alloul et al., 2013; Lyons and Vinebrooke, 2016).

It has also been suggested that temperature and diversity may be linked through overlaps in species distributions. This would result in a hump-shaped relationship between species richness and temperature, with maximum species richness at intermediate temperatures, and declines in cooler or warmer systems (Patalas, 1990). The proposed mechanism is that, over the intermediate temperature range, southern warm-water and northern cool-water species would potentially coexist, resulting in a comparatively high diversity. Interestingly, it may not be just average temperature that is correlated with zooplankton species richness, but also temporal variability in water temperature (Shurin et al., 2010). It is thought that lakes that demonstrate strong temperature variation over time allow larger numbers of species to coexist, since those species can occupy niches that occur at different points in time, during periods of either water column mixing or stable thermal stratification.

Additional physical factors

Water flow and availability have clear effects on zooplankton diversity. It has been suggested that differences in water residence time, especially, may act as a potential determinant of the composition of large-bodied crustacean zooplankton communities in reservoirs (Doubek et al., 2019), because taxa with longer generation times (e.g., calanoid copepods) are more likely to be flushed from short residence time systems before completing their life cycles than are short generation time taxa (e.g., cladocerans). This mechanism may underpin observations that zooplankton community composition differs between natural lakes and reservoirs (Merrix-Jones et al., 2013; Doubek et al., 2019).

For temporary ponds, the seasonal timing of flooding or drainage also appears to influence zooplankton communities. In experiments simulating Mediterranean ponds, both the richness and composition of rotifer and crustacean zooplankton varied according to when in the year pond-filling occurred, presumably due to the different environmental conditions that ensue in temporary water bodies that fill at different times of year (Florencio et al., 2020). In an urban setting, winter drainage as part of pond management can also influence community composition (Mimouni et al., 2015).

Research has also addressed the potential role of ultraviolet (UV) radiation in affecting zooplankton diversity and community structure. UV exposure causes DNA damage and mortality in zooplankton, but there are various mechanisms that may allow these organisms to survive under such conditions, including photoenzymatic repair, accumulation of protective pigments and migration away from surface waters. Crucially, species differ greatly in the extent to which they use these strategies, such that high UV can alter the structure of communities. The result is that species richness and diversity can be lower for lakes typified by high UV penetration and exposure, in which only the most tolerant species are likely to survive (Marinone et al., 2006).

Chemical constraints

Many aspects of lake water chemistry may impact upon the diversity of zooplankton communities. Considering the many different potential chemical drivers, the role of pH has received particular attention. Among-lake variability in pH is known to be correlated with crustacean zooplankton species richness, with a decline in species number in more acidic ecosystems (often $<$ approximately pH 6). As well as this effect of average pH, lakes with higher interannual and seasonal variability in pH also support fewer zooplankton species, presumably as a result of higher extinction risks brought about by chemical instability (Shurin et al., 2010). Concentrations of calcium are also known to impact upon zooplankton communities, with relatively Ca-rich *Daphnia* species being less abundant in the communities of lakes with lower Ca concentrations (DeSellas et al., 2011).

Many zooplankton communities are exposed to complex mixtures of environmental contaminants, including pesticides, road salt, detergents, and heavy metals. While diverse communities of rotifers and crustaceans can be supported even in heavily polluted systems, such as wastewater contaminated municipal ponds (Adhikari et al., 2017), contaminants undoubtedly shape community structure. For example, metal (Cu, Ni) contamination of the Sudbury lakes in Canada appears to affect zooplankton community composition, with many *Daphnia* species being particularly sensitive (Valois et al., 2010). However, interactions between contaminant effects and other factors may result in great variability in zooplankton responses. Due to the complexity of ecosystem processes, community-level responses to contamination may be surprising. For example, it is conceivable that diversity would increase in response to pesticide exposure, when competitively superior zooplankton species are selectively eliminated by contamination.

Salinity is a key chemical attribute that influences freshwater zooplankton communities. Studies of South American water bodies undergoing salinization, as a result of climate change, show marked variations in zooplankton composition among lakes of different salinity. While many species struggle to survive under highly saline conditions some are highly tolerant of elevated salt concentrations (e.g., the copepod *Boeckella poopoensis*). Elsewhere, such as in North America, elevated chloride contamination due to road salt application can bring about changes in crustacean zooplankton composition, but the magnitude and nature of the effect varies with exposure history, and might be partially offset by dispersal of species into the contaminated system (Sinclair and Arnott, 2018).

Food quantity and quality

Both the overall availability of food resources, and their nutritional quality, impact greatly upon the growth and reproduction of freshwater zooplankton. This has implications for zooplankton consumer-resource interactions. Here, however, the focus is on relationships between among-lake variations in food availability, and zooplankton community structure.

Previous studies, principally in Europe and North America, have suggested that among-lake variations in crustacean zooplankton species richness are correlated with the availability of food resources, measured as primary production or chlorophyll-*a* concentration. Studies vary with regard to whether this relationship appears to be linear (Hessen et al., 2006) or hump-shaped, with maximum richness at intermediate productivity (Dodson et al., 2000). Such discrepancies may arise as a result of among-study variation in productivity gradient length. In other words, unimodal relationships only become apparent when comparing lakes spanning a very wide productivity range. It has been suggested that the apparent hump-shaped relationship emerges as a result of the balance between more production energetically supporting more species on the one hand, and deteriorating food quality and abiotic conditions, and increasing predation on the other. However, some have challenged this view, suggesting that the pattern may also emerge because intensifying human pressures, that are likely correlated with nutrient loading and productivity (e.g., from contaminant loading),

reduce species richness in highly productive systems (Hoffman and Dodson, 2005). Moreover, it appears that a typical curvilinear relationship between diversity and productivity (using total phosphorus concentration as a proxy) can shift to a linear negative relationship when considering functional, rather than taxonomic, diversity (Barnett and Beisner, 2007). This negative functional trait-based change correlated with a loss of spatial heterogeneity in phytoplankton resources, and a decline in relative food quality. These factors apparently influenced the degree to which functional differentiation could occur in the zooplankton community.

Predation

Zooplankton play an important role in freshwater food webs, and thus ecosystem structure. Here, rather than unpicking these complex dynamics, I present a brief introduction to observed relationships between zooplankton community structure and among-lake variations in predation pressure.

Zooplankton species composition does indeed vary among lakes with and without plankton-feeding fish (Knapp et al., 2001; MacLennan et al., 2015), and species richness may vary with fish community structure (Hessen et al., 2006). For example, Jeppesen et al. (2000) observed that the contribution of *Daphnia* and calanoid copepods to total crustacean zooplankton biomass was lower, while that of small cladocerans and cyclopoid copepods was higher, in Danish lakes with higher planktivorous fish biomass. Studies contrasting the zooplankton communities of lakes that are fishless, and that have been stocked with fish, suggest larger-bodied zooplankton are especially vulnerable to predation by visually-feeding fish (Knapp et al., 2001; MacLennan et al., 2015).

In fishless lakes, invertebrate predators can play an important role in structuring zooplankton communities by suppressing populations of small species. For example, studies into the plankton of Wisconsin bog lakes showed that the insect *Chaoborus* and the copepod *Diaptomus leptopus* can reduce cladoceran, copepod and rotifer populations in the absence of fish (Arnott and Vanni, 1993).

However, discerning the unique effects of predation and other environmental factors on zooplankton community structure can be challenging. In a study of lakes in the Sierra Nevada mountains, Symons and Shurin (2016) demonstrate that zooplankton communities are potentially structured by interactions between these factors. Specifically, the presence of fish suppressed elevational gradients in zooplankton composition, but the strength of the trophic cascade varied with other aspects of the lake environment, such as water temperature and concentrations of dissolved organic matter.

Habitat affinities

Compared to the pelagic zone, the aquatic plants and sediments of littoral zone habitats are structurally complex, and thus are likely to provide a wider range of niches. Numerous studies have shown that these complex habitats can support more diverse, and different assemblages than adjacent open waters. Indeed, researchers have often made a distinction between the "true" zooplankton of the pelagic zone, and purely littoral species, inhabiting only the surfaces of aquatic plants and sediments. However, some have challenged the view that species can be neatly categorized in this way. In a major survey of Norwegian lakes, Walseng et al. (2006) showed that very few crustacean species were found only in open water samples. Many more species were found primarily in littoral zones but, crucially, a great number of cladoceran and copepod species were found in both of these major habitat types. Some microcrustacea can be considered facultatively, or semi-planktonic, and it is possible for littoral zone species to be carried offshore by water movements. As a result, zooplankton diversity estimates, even if based on pelagic samples, will likely be influenced by among-lake variations in the structure and extent of littoral zone habitats.

Dispersal

Zooplankton life cycles typically include stages that permit ready dispersal among water bodies. Rotifers can produce hardened cysts (Monogononta) or desiccation-tolerant forms (Bdelloidea), while cladocera and calanoid copepods produce tough resting eggs, that are readily dispersed by water flow, winds, larger organisms and human activity.

Despite this relative ease of dispersal, many species have restricted geographic distributions. In addition, zooplankton richness is sometimes observed to be greatest for lakes that are less isolated from other water bodies (Dodson, 1992; Merrix-Jones et al., 2013; Lyons and Vinebrooke, 2016), and zooplankton composition may be more similar in water bodies that are close together (Santos et al., 2016) or hydrologically-connected. This apparent influence of other water bodies on local diversity suggests the dispersal of zooplankton among fresh waters. Indeed, such spatial structuring in community composition has been used to infer that dispersal is a limiting factor for local community diversity. This limitation may be especially important for some zooplankton (e.g., copepods), compared to others (e.g., cladocerans), such that typical geographical range sizes differ among major zooplankton groups (Henriques-Silva et al., 2016).

However, zooplankton community structure in any given water body will be a function of both dispersal and local habitat conditions. Although new species may be able to reach a specific standing water body, this alone does not ensure their successful colonization. Shurin (2000) found, through experimentation, that colonization success of new rotifer and crustacean zooplankton can be very low; potentially because interactions with native zooplankton species exclude them. Dispersal effects can also be affected by the previous establishment of non-native species (Sinclair et al., 2015).

Given the importance of recipient ecosystem characteristics in governing colonization success and community structure, it has been suggested that the diversity of local lake communities is only likely to be limited by dispersal when this is occurring over very

large distances (Shurin et al., 2000). Furthermore, the relative importance of dispersal and local species sorting by habitat features may change over time. For newly-formed water bodies, community composition may initially be governed by the dispersal of potential colonist species and then, after this colonization phase, by the influence of local habitat features (Allen et al., 2011).

While human-mediated and natural dispersal may act to increase the richness of local communities, through the introduction of new species, this might not always be the case. In fact, the effects of dispersal depend upon the nature of immigrating species and water body conditions in complex ways. For example, if dispersal introduces new predators or strong competitors to a water body, the local zooplankton diversity might actually decline due to the loss of native species through negative interactions with the newly-established species. The invasion of North American lakes by the predatory cladoceran *Bythotrephes longimanus*, and subsequent declines in the diversity of resident taxa, are case in point. Furthermore, high rates of dispersal could act to homogenize communities across the landscape (i.e., similar community compositions in all water bodies), such that dispersal can no longer increase local water body diversity through the introduction of new species from elsewhere.

Knowledge gaps

- *Resolving both inter- and intraspecific variation in functional traits*. Trait-based approaches to zooplankton community studies promise new insights into the relationship between diversity, ecosystem structure, and ecosystem function. To fully capitalize on this potential at a global scale there is a need to expand the number of taxa for which we have trait-based information, integrate these data, and make them openly accessible. However, in doing so, we need to incorporate and quantify intraspecific trait variation, recognizing that populations and individuals "within" a species are not necessarily functionally-equivalent. We can then begin to ask questions about the relative importance of intra- and interspecific trait variation for zooplankton community structure, and wider ecosystem behaviors.
- *Direct measurement of zooplankton dispersal*. Among water body dispersal is a key process within the metacommunity approach to investigating zooplankton diversity. However, the importance of dispersal is often inferred only indirectly based upon spatial patterns in community similarity among ecosystems. This approach is not ideal, as such patterns could potentially reflect spatial gradients in unmeasured environmental conditions as well. Advances in methods for estimating dispersal via different mechanisms (e.g., through hydrological connectivity, aeolian transport, or by waterfowl) would greatly enhance our understanding of the processes underpinning community assembly.
- *Developing the capabilities of new methods*. We must investigate the capabilities of new methods for measuring zooplankton diversity (e.g., image analysis and DNA-based monitoring), in relation to those of more traditional methods. In doing so we will be able to identify potential complementarities among methods, both novel and established, that allow us to address new questions about the patterns, drivers, and consequences of zooplankton diversity.
- *Zooplankton as indicators of ecosystem state*. The diversity of zooplankton communities is demonstrably sensitive to a wide range of environmental pressures, including contaminants, nutrient enrichment, climate change, and species introduction. As such, these communities are potentially powerful indicators of biodiversity change and ecosystem state change. To operationalize the widespread use of zooplankton as biological indicators, there is a need for research to develop candidate indicators that are sensitive to known pressures, and that can be incorporated into biodiversity monitoring programs.
- *Global tests of theory*. Much of our current understanding of the drivers of freshwater zooplankton communities originates from observations in Europe and North America. We need to understand how scalable and transferable such theory is to other regions and biogeographic provinces, if we are to arrive at a globally-relevant theory of zooplankton community assembly.
- *Diversity and food webs*. Though much valuable work has been done on the diversity of freshwater zooplankton, it would be valuable to expand our understanding of the relationships between zooplankton diversity and food web interactions. Interactions between communities of both fish and invertebrate predators and zooplankton diversity, are worthy of further study, accounting for the different temporal and spatial scales at which these organisms operate and are sampled. A particularly interesting area is the role that diversity and community structure elsewhere in the food web (e.g., phytoplankton, macroinvertebrates, fish) play in affecting zooplankton diversity.

Glossary

CPUE Catch-Per-Unit-Effort (CPUE) is the absolute catch of a species standardized with respect to the amount of sampling effort that produced that catch. Units vary greatly, but are frequently some form of numbers (or weight) per time period.
Keystone species Species which have a functional impact on their ecosystem which is disproportionately high in relation to their abundance.
Recruitment/stock/stock-recruitment curves The graphical relationship between the abundance of reproducing adults and the subsequent abundance of resulting young, usually defined with respect to a particular life cycle stage such as end-of-summer juveniles.
R-species Species exhibiting a particular life history strategy involving the production of large numbers of young which subsequently show relatively high mortality. Such species are frequently small, short-lived and can show rapid population growth under appropriate circumstances.
Year-class strength The relative strength of a species' reproduction in a given calendar year.

Introduction

Fish species found in inland waters are extremely diverse, both biologically and taxonomically (Nelson et al., 2016), and are relatively long-lived. Individual longevities of years may be contrasted with the months or even weeks of many other inhabitants of inland waters. Furthermore, fish commonly attain relatively large individual sizes of several kilograms in weight and are usually by far the most abundant vertebrates present in such ecosystems, features which often combine to lead them to act as keystone species with impacts at several trophic levels. The relatively large individual sizes attained by many species have also attracted the attention of humans for millennia (Hart and Reynolds, 2002), initially as a food source in capture fisheries and latterly also as a source of enjoyment in recreational fisheries or even just "fish watching" in ornamental water bodies (Fig. 1).

This historical interest in the fish of inland waters has acted as a major global driver for studies of their populations, particularly in terms of changes in population abundance and individual growth rates. While the underlying science of such studies has much in

☆*Change History:* December 2020. This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie-Elodie Perga and Damien Bouffard.

Photograph by DT Creations.

common with corresponding research on other taxonomic groups, components of it are more specific to the demands of the quantitative study of fish populations. In particular, the diversity of habitats occupied (from fast-flowing upland streams to the bottoms of large lakes), the diversity of individual sizes (from eggs of less than 1 mm in diameter to adults in excess of 1 m in length), the substantial locomotory abilities (with which individuals may undertake migrations in excess of hundreds of kilometers, including temporary or permanent departures from inland waters) and the diverse sensory systems (commonly based not just on vision but also olfaction and mechano-reception) mean that the scientific sampling of the fish populations of inland waters is not a simple matter. To this difficulty must be added the challenges posed to population dynamics theory and understanding by the diversity of life cycle strategies shown by such fish, sometimes even within a single species. With further complications arising from the great longevities of many species, which significantly complicate reproduction dynamics and which may result in a population going through only a handful of complete life cycles during the lifetime of a researcher, the study of fish population dynamics is arguably one of the greatest challenges encountered in the scientific study of inland waters.

This review of the fish populations of inland waters will firstly address in some detail the issue of sampling problems, which as indicated above remain considerable despite the immense collective experience of the world's freshwater fisheries. It will then consider fish population ecology itself using as a framework the equation

$$N_{t+1} = N_t + I - E + R - M$$

where N_{t+1} is future population abundance, N_t is present population abundance, I is immigration, E is emigration, R is reproduction and M is mortality. It will thus take account of the impacts of fish movements through immigration and emigration, both of which are exhibited to a much greater extent than in any other biota of inland waters, before moving to the core features of population ecology, i.e. reproduction and mortality. The combined effects of these diverse factors will then be considered in terms of overall population dynamics. The review will finish with brief conclusions and a personal consideration of persisting knowledge gaps.

Sampling

Almost all readers will have at some time in their life caught a fish. Many will have done this as a young child using a hand-net, quite likely netting a common shiner (*Luxilus cornutus*), a European minnow (*Phoxinus phoxinus*) or some similarly widely distributed species depending on their geographical location. Others may have used rod-and-line with a baited hook or an artificial fly to catch one of many species of fisheries interest such as a bluegill sunfish (*Lepomis macrochirus*) or a brown trout (*Salmo trutta*). However, although it is a simple matter to catch an individual fish, their evasive capabilities, great growth, high longevity and other factors combine to make robust scientific sampling very difficult. On top of this practical challenge, additional complexities are rightly prompted by ethical issues and, paradoxically, by fisheries issues as the owners of local fishing rights are often reluctant to allow others to take "their" fish for scientific study.

As a result of these difficulties, practically every fisheries capture technique has also been used to produce scientific data of varying qualities. Indeed, fishery data themselves are frequently used to give information on relative fish abundance by standardizing catch (e.g. number or weight of fish) with respect to effort (e.g. number of hours fished with a rod or the area of netting used). Although often only approximate and usually relating only to species of specific interest to the fishery (which may be a small fraction of the total species actually present), such so-called catch-per-unit-effort data have the advantages of being relatively readily available for many inland waters and have often been so for many years. However, extensive runs of such data stretching back over several decades are less common. Individual fish samples may also be taken from fisheries catches and, like the products of scientific sampling described below, be examined for a range of biological parameters including the determination of individual age through the detailed examination of their scales or other hard parts such as otoliths.

However, sampling of fish populations is best based on activities undertaken independently of fisheries interests and such scientific effort for monitoring and research is carried out extensively in inland waters (Zale et al., 2013). The methods involved may be broadly categorized into three major groups: passive techniques, active techniques and remote techniques (Fig. 2).

Passive techniques are essentially various forms of traps that rely completely on fish movement. One such method is entrapment, in which fish accidentally find their way into water abstraction systems such as those of reservoirs or power stations. Fish, and other unwanted objects, are removed from the water intake of such operations by meshes before being killed and discarded. If appropriate arrangements can be made with the plant operator, these unwanted fish can be counted and otherwise examined in order to gather basic population data. Although usually biased in various ways which must be taken into account in analysis, entrapment has the great advantages of being typically of long duration and in continuous operation around the clock and throughout the year. True trapping using mesh or netting traps, the latter known as fyke nets, is also frequently undertaken in studies of fish population dynamics, usually with traps set overnight before being lifted. Whether made of mesh or net, the operation of the trap is similar in principle with fish entering through a valve-shaped opening back through which exit is more difficult. A final and by far the most extensively used passive technique is the gill net which comprises a curtain of netting hanging vertically in the water column and which, like traps, is typically set overnight. If the relative sizes of the mesh of the gill net and the cross-section of the fish are appropriate, then only the head of the fish can pass through the mesh and its gill covers prevent it from reversing out. In scientific use, gill nets typically contain several different mesh sizes which allow a range of sizes of fish to be captured by a single net. A significant disadvantage of the gill net is that most captured fish are killed or injured by the operation.

Active techniques are independent of fish movement and, with one notable exception, are essentially scaled-up variations on the hand-net theme. The seine net is a curtain of fine-meshed netting running from the top to the bottom of the water column which is set in a semi-circle from the shore, thus enclosing a known area or volume of water. The two ends of the net are then carefully pulled in, resulting in fish being brought to the shore where they can be transferred to water-filled containers for examination and ultimate release. A second major active technique is the trawl net which is effectively a giant hand-net, typically several meters across, which is pulled horizontally by a powered vessel. Fish are caught in the trawl just as they are in a hand net and, under appropriate conditions, can be brought onboard, examined and released alive. The final active technique considered here is electrofishing (or electric fishing), in which a carefully controlled electrical current is passed into the water to stun temporarily any fish within a radius of typically 1 or 2 m. Stunned fish are caught using an electrically insulated hand net and placed in a water-filled container, from which

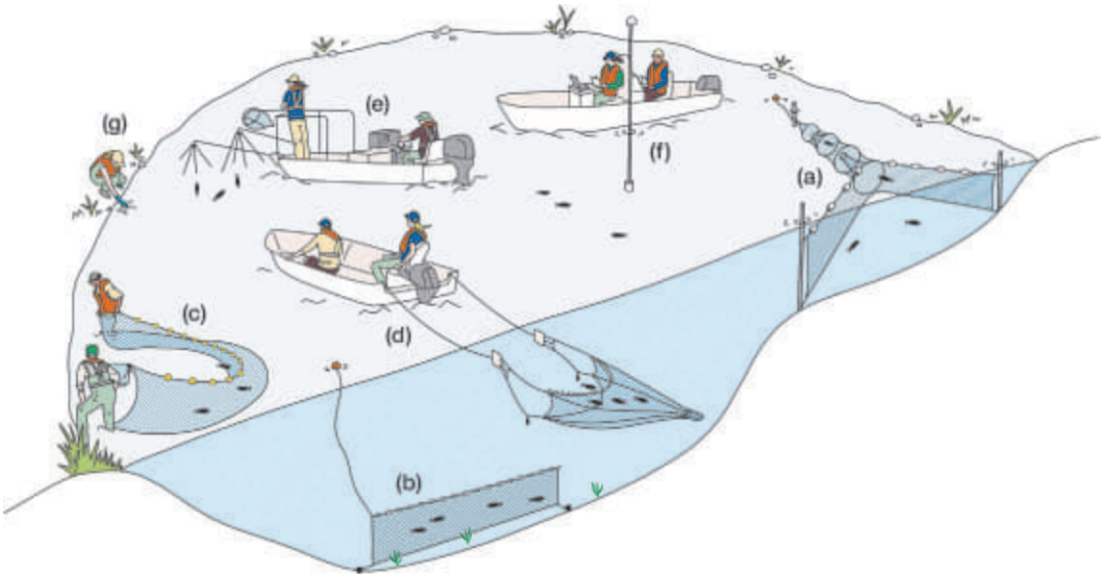

Fig. 2 Scientific sampling techniques commonly used for fish in inland waters include the passive techniques of (a) fyke netting and (b) gill netting, the active techniques of (c) seine netting, (d) trawling and (e) electrofishing, and the remote techniques of (f) hydroacoustics and (g) environmental DNA. Artwork by Rosie C. Winfield.

they can be subsequently examined and released. The major limitation of electrofishing is that its spatial influence is very limited and so it can only be used effectively in small, shallow inland waters or in the shallow littoral zone of larger water bodies.

Remote techniques do not result in the actual capture of fish but instead gather information on them. The most obvious example is visual observation by either diver or by underwater camera, but this approach is usually limited in inland waters by their low water clarities. Alternatively, fish can be counted and their individual size estimated by measuring the disturbances their bodies make to the detectable resistance of the natural electrical environment. Unfortunately, the need to minimize the distance between the fish and the detecting apparatus means that such so-called resistivity counters can only be deployed in shallow habitats and their practical use is largely restricted to detecting the passage of fish along river systems. In contrast, the use of transmitted high frequency (typically 70–400 kHz) sound by an echo sounder to count and to some extent to measure the size of individual fish is a remote technique feasible in all types of inland waters. A relatively recently developed form of such hydroacoustics involves the use of extremely high frequency sound (0.7 or 1.8 MHz) to produce a moving image, much like a monochrome low-resolution video camera but with the benefit of being independent of light and turbidity conditions. Even more recently, there is currently great research interest in the rapidly developing field of environmental DNA (or eDNA) sampling in which DNA is sampled not directly from an organism but from its environment (Rees et al., 2014). This eDNA which has been "shed by an organism or organisms is collected, amplified and then identified through bioinformatics techniques involving extensive species DNA libraries. In addition to the rapid production of fish species lists for inland waters by sampling nothing but water, such use of eDNA can also provide information on the relative abundance of different species (Hänfling et al., 2016). However, the present utility of eDNA in studies of population dynamics is limited because of its inability to estimate age or size distributions.

Immigration and emigration

The substantial locomotory abilities of fish, which result from their relatively large body sizes combined with their sophisticated sensory systems and behavioral repertoires, lead to all species exhibiting directed movements over a range of timescales (from minutes to years) and to many individuals undertaking migrations in excess of hundreds of kilometers, including temporary (e.g. some brown trout known as sea trout) or permanent (e.g. European freshwater eel (*Anguilla anguilla*)) departures from inland waters. Such movements are typically species- and age-specific and may be undertaken along any of the three dimensions of the aquatic environment for a variety of purposes including feeding, predator avoidance and reproduction.

Movements for reproductive purposes, typically referred to as spawning migrations, are often the most dramatic in terms of distance travelled and spectacle. Species which leave inland waters to spawn in the marine environment (termed catadromous) are relatively few in number and are typified by the European freshwater eel, which leaves inland waters to cross the Atlantic Ocean and spawn in the Sargasso Sea. Relatively more species make the converse move, i.e. enter inland waters to spawn having matured at sea (termed anadromous). The best known and arguably most spectacular such species is the Atlantic salmon (*Salmo salar*), which must often overcome substantial waterfalls (Fig. 3) as it migrates up rivers from the coast to headwaters before spawning.

Although such movements may be considered to be on the periphery of population ecology, their resulting immigrations and emigrations have far-reaching consequences for the understanding of local changes in population dynamics. The critical point to

Fig. 3 An Atlantic salmon (*Salmo salar*) leaping a waterfall during its upstream spawning migration. Photograph by Matthew G. Hull.

appreciate is that the local population dynamics of fish in inland waters may be significantly influenced by factors operating distantly. Such distances may vary from just a few tens of meters (e.g. the abundance of young vendace (*Coregonus albula*) in the pelagic zone of a lake may be influenced by oxygen conditions experienced by the previous generation's adults at the bottom of the water column) to thousands of meters (e.g. the abundance of young coho salmon (*Oncorhynchus kisutch*) in the headwaters of a river may be influenced by barriers impeding progress of the previous generation's adults in the estuary).

Reproduction

The reproduction of fish in inland waters has already been referred to in the context of spawning migrations, which are themselves necessary because the habitat requirements of free-swimming fish (whether young or adult) and incubating eggs are usually very different.

Almost all fish species in inland waters are dioecious (i.e. have male and female sex organs in different individuals (Fig. 4)) and the vast majority of them have external fertilization, with only a relatively few species such as the well-known guppy (*Poecilia reticulata*) displaying internal fertilization and development. Outside the tropics, spawning is almost always restricted to a marked seasonal window resulting in the temporally-pulsed production of eggs. Such seasonality follows a general pattern with members of the Order Salmoniformes spawning in winter, those of the Order Perciformes in spring and those of the Order Cypriniformes in summer. The number of eggs produced by females usually numbers in the several hundreds if not thousands and is strongly influenced by individual condition and thus recent feeding history, with important implications for overall population dynamics through the mechanisms of intra- and inter-specific competition for food. Courtship may be elaborate, in some species involving the development of vivid spawning colorations or the construction of a nest of varying complexity, although the act of spawning itself may last only a few minutes. Subsequent parental care ranges between none at all, with many species in captivity readily consuming their own eggs although such cannibalism may be less frequent in nature, through to active nest maintenance and guarding of young. Some species even undertake mouth-brooding in which eggs and young are held within the buccal cavity for up to several weeks. An individual fish may reproduce just once and then die (termed semelparity), or survive to reproduce on at least one further occasion (termed iteroparity).

The relationship between the number of spawning adults and the number of subsequent young produced is of obvious interest to fisheries managers and so has been the subject of considerable research for many decades, at least for those species of commercial importance (Quinn II and Deriso, 1999). Such relationships, which may involve intra-specific competition and predation in the form of cannibalism, are evidently rarely linear but are notoriously difficult to quantify further because of the protracted life cycles and sampling problems reviewed above. In fisheries research these relationships are usually termed stock-recruitment curves, with recruitment essentially being a fisheries term for the production of young fish. This is one of the most important biological relationships requiring statistical description in order to facilitate robust predictions about future population abundance under alternative fisheries management regimes.

To add to this complexity, the stock-recruitment curve is only one contributor to the overall degree of reproductive success shown by any given fish population in any given year. This overall degree of success (commonly referred to as year-class strength) may also be a function of a host of biotic factors including food availability, inter-specific competition and predation (the degree of

Fig. 4 A pair of oscars (*Astronotus ocellatus*), a South American cichlid species which shows elaborate courting behavior and parental care. Photograph by K. C. Blanchett.

each of which may be completely unrelated to the abundance of the population in question), together with abiotic factors including water temperature (including subtle aspects thereof), water flow and water level.

Mortality

Given the highly fecund nature of most fish species, it is not surprising that mortality rates are also relatively high and in life strategy terms they can generally be considered to be classic r-selected species. Survivorship curves for fish of inland waters thus arguably bear more similarities with those of larger macroinvertebrates than they do with those of fellow vertebrates such as birds, mammals and reptiles, although they do share more features with those of amphibians.

The detailed quantification of mortality in fish is notoriously difficult for at least three reasons. Firstly, the determination of mortality rates requires estimates of population abundance over at least two points in time. As noted above, the quantitative sampling of fish populations in all but the smallest of habitats is extremely difficult. Furthermore, in order to assemble a picture of overall population mortality such data have to be collected for each significant life stage transition, for example from egg to larva, from larva to juvenile, and from juvenile to adult. Secondly, apparent individual gains to or losses from a population are often complicated by any immigration or emigration from the study site. As discussed above, such movements are commonplace in the fish populations of inland waters and so require the additional study of migratory behavior before robust mortality measurements can be derived. Thirdly, the relatively great longevities of most fish species mean that the collection of such data usually takes a considerable number of years. Unsurprisingly, density-dependent mechanisms present major and often controversial challenges to our understanding of fish population dynamics (Rose et al., 2001). High quality mortality data exist only for a few populations of a few species, with a stream-based, long-term study of brown trout by Elliott (1994) providing an excellent example of such investigations.

The potential for differing mortality rates to impact fish population age structure is illustrated in Fig. 5 for three modelled (with constant reproduction) populations and one actual population. In the simplest case, Fig. 5a shows the age structure of a population in which each age class suffers an annual mortality rate of 50%. Fish in their first year of life (age 0 years) comprise *c.* 50% of the population and relatively few individuals live longer than 5 years. Such fixed mortality rates are in fact unknown in nature and so Fig. 5b depicts a more common situation in which mortality is 90% during the first year of life, reducing to 20% thereafter. Underyearling (age 0 years) fish now make up *c.* 67% of the population, but more individuals survive to greater ages (in fact to the maximum of 15 years shown in this figure). In Fig. 5c, the mortality scheme is identical with the exception of it returning to 90% after age 5 years to simulate an intense fishery for older fish. As a result, the contribution of underyearling fish to the population increases slightly to *c.* 75% and once again individuals become much rarer after age 5 years. It is important to appreciate that all of these populations are modelled assuming a constant level of recruitment, which is extremely unlikely to occur in nature for reasons discussed above. Finally, Fig. 5d presents the observed age structure of an unfished population of European whitefish (*Coregonus lavaretus*) surveyed using scientific gill nets in Loch Eck, Scotland, United Kingdom. The apparent absence of fish aged 0 and 1 years is probably an artefact of sampling limitations, although it cannot be discounted that recent reproduction has failed. One notable feature is that the abundance of successive age classes clearly does not follow the smooth declines of any of the modelled populations, with the most probable explanation being significant variations in the level of recruitment over the previous decade or so.

A complete explanation of the above observed age structure of European whitefish requires a detailed study of local population dynamics, itself requiring the synthesis of information on immigration and emigration, reproduction, mortality and other factors into quantitative and predictive models of varying degrees of complexity. This challenging area of fish population ecology is considered below.

Population dynamics

The study of population dynamics can be defined as the analysis of the factors that affect the increase, stability and decrease of populations over time. As explained above, in the context of fish populations in inland waters it thus integrates investigations of immigration and emigration, reproduction, mortality and other factors. Such studies are increasingly performed within a framework of quantitative and predictive models of varying degrees of complexity.

As a consequence of their high fecundities and high mortality rates, population abundance in fish generally varies more than in any other vertebrate taxa of inland waters. This variation includes seasonal and long-term components as shown in Fig. 6 for the fish community of a lake monitored by monthly night hydroacoustics surveys over 28 years from 1990 to 2018. Within each year, abundance clearly peaks at the end of the summer as that year's reproduction is completed and results in a several-fold increase in overall fish abundance. Superimposed on this short-term variability is a marked overall increase in abundance from *c.* 2000 onwards.

A brief consideration of this time series, actually recorded from the north basin of the two-basin lake of Windermere, England, United Kingdom, illustrates the potential complexities of fish population dynamics in inland waters, even in the absence of any significant impacts from fisheries. The fish community of this temperate, mesotrophic lake is dominated by the salmonid Arctic charr (*Salvelinus alpinus*), the percid perch (*Perca fluviatilis*), the esocid pike (*Esox lucius*) and, in recent years, the cyprinid roach

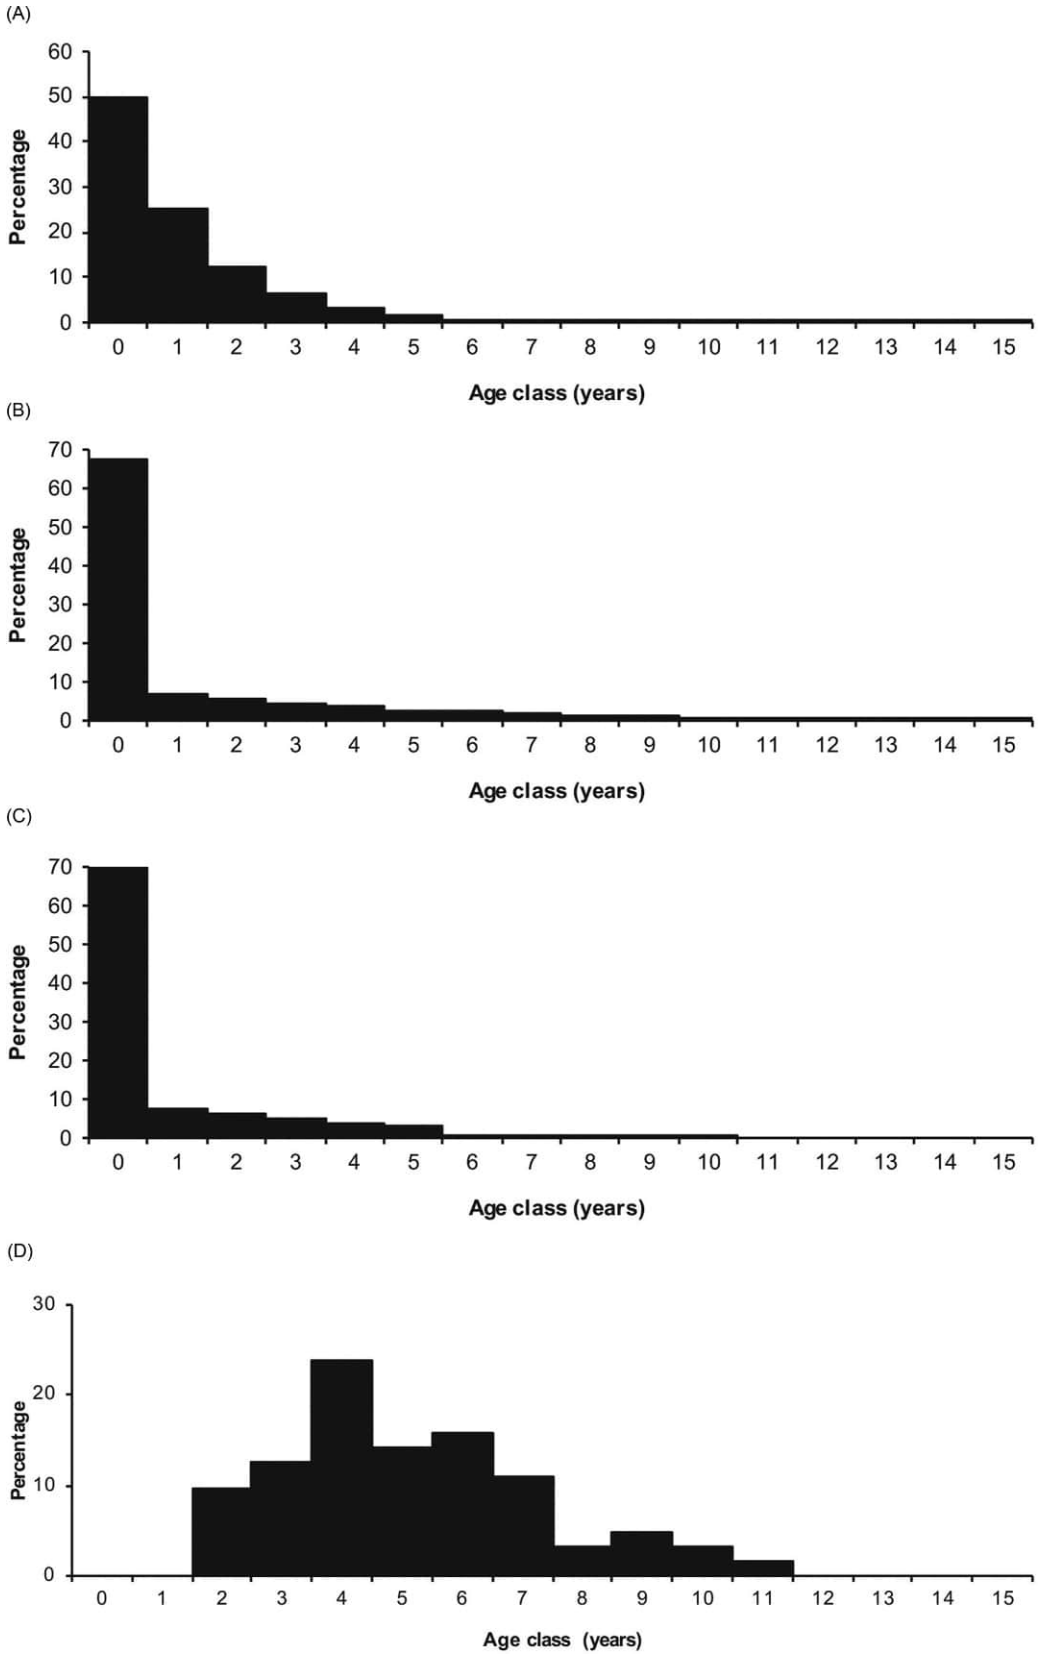

Fig. 5 The impact of differing mortality rates on the age structure of three modelled (with constant reproduction) fish populations and one actual fish population: (a) Modelled population experiencing a fixed annual mortality rate of 50%, (b) Modelled population experiencing a mortality rate of 90% during the first year of life reducing to 20% thereafter, (c) Modelled population experiencing a mortality rate of 90% during the first year of life before reducing to 20% and then returning to 90% after age 5 years to simulate an intense fishery for older fish, (d) Observed age structure of an unfished population of European whitefish (*Coregonus lavaretus*) in Loch Eck, Scotland, United Kingdom. Fig. 6 Seasonal and longer-term variability of the abundance of fish populations exemplified by monthly (January 1990 to December 2018) night-time hydroacoustic surveys of the north basin of Windermere, England, United Kingdom. Author's unpublished data.

(*Rutilus rutilus*). Historical netting studies have shown that the open water of the lake, i.e. the habitat surveyed by the hydroacoustics system, was previously dominated by Arctic charr. Consequently, the changes in fish abundance of the first few years of the present data series have been interpreted in terms of this species and its movements between the two basins of the lake in response to poor oxygen conditions in the hypolimnion of the south basin (Elliott et al., 1996). However, the dramatic increase in fish abundance observed since *c.* 2000 coincides with the spread into the open water of a rapidly-expanding littoral roach population (Winfield et al., 2008). Perch also undoubtedly constitute some fraction of the fish detected during the hydroacoustics surveys, but trapping shows that this species has not shown any marked inter-basin differences in abundance over this time. Pike, in contrast, have shown diverging population biology in the two basins and have made directed movements between them (Haugen et al., 2006), but they are so rare in the open water that their contribution to the hydroacoustic record is negligible.

Using the trapping data referred to above over a longer timescale going back to the 1940s, modelling of the perch populations of both basins of Windermere has been able to explain *c.* 60% of observed variation in recruitment, which was itself strongly synchronous between the two basins (Paxton et al., 2004). Stock-recruitment curves explained a significant component of the annual production of young perch, while the presence of widespread disease and a positive relationship with late summer water temperature were also important factors. Interestingly, water temperature has been consistently higher than the long-term average in recent years and is thought to be a major contributor to the recently increased abundance of roach.

Conclusions

Alongside the provision of potable water and the disposal of selected waste products, the hosting of fish populations is one of the most important ecosystem services provided by inland waters. The importance of abundant and healthy fish populations for commercial and recreational fisheries is self-evident, but these vertebrates are also of great importance to the considerable sector of human society which is not immediately concerned with their capture (Winfield et al., 2018). Whether manifested in the full glory of a spawning run of sockeye salmon (*Oncorhynchus nerka*) or the cosmopolitan distribution of the humble three-spined stickleback (*Gasterosteus aculeatus*), fish populations are often the *de facto* sentinels of the quality of our inland waters. In this context it is reassuring that so much is now known about their populations, while at the same time our currently changing climate challenges us to redouble our research efforts in this complex field.

Knowledge gaps

Sampling young fish

As considered above, fish populations are usually dominated numerically (and often also gravimetrically) by their young stages. Unfortunately, quantitative sampling is particularly difficult for such individuals because their evasive capabilities allow them to

escape samplers designed for invertebrates while their small body size allows them to escape net meshes commonly used for older and larger fish. Limited advances have been made recently in the application of hydroacoustics for the sampling of such individuals, but the need for quantitative biological sampling methods remains.

Sub-population genetic structure

Another issue largely neglected in this review has been the sub-population genetic structure of fish populations. The existence of such diversity has been empirically demonstrated for the vast majority of studied populations, although its implications for overall population dynamics remain poorly understood.

Parasites and diseases

The effects of parasites and diseases on fish populations have been almost completely neglected in the present review, an omission which reflects the scientific literature on which it is based. Although the impacts of parasites and diseases are occasionally obvious even to the casual observer during spectacular outbreaks, their more routine contribution to fish population dynamics in inland waters remains little explored.

Interactions with lower trophic levels

In many lakes, fish populations have been found to exert clear impacts on their zooplanktonic prey, which may in turn have consequent effects for phytoplankton populations. In contrast, in other lakes no such top-down effects are apparent and instead local fish populations appear to be limited primarily by bottom-up effects of prey availability. Such interactions are frequently exploited in the science of biomanipulation in attempts to improve local water conditions, but much remains to be discovered about how the prevailing net directions of such effects are determined.

Endocrine disruptors

In many rivers in the developed world, anthropogenically-generated endocrine disruptors have been found to have demonstrable effects on the reproductive physiology of a variety of fish species. However, the implications for fish population dynamics of endocrine disruptors, and indeed those of many other pharmaceuticals, remain poorly understood.

Microplastics

The use of plastics is near ubiquitous in the modern world, but following their post-use disposal the accumulation of this diverse group of materials in the natural environment is causing increasing concern. Moreover, although plastics typically persist for many years they may be relatively quickly broken down in size (to 5 mm and smaller) by various processes to form microplastics which are themselves small enough to be taken up by a wide range of organisms including fish of all life stages. Little is currently known about the ecological consequences of such processes and this is a very active field of research.

Climate change

In addition to the obvious impact of an increase in water temperature, climate change will also result in fundamental changes to the inland waters inhabited by fish populations through changes in stratification patterns, level fluctuations, flow patterns (including both droughts and floods), period of ice cover, and numerous other features of the abiotic and biotic environments (including deep hypoxia). Considering such impacts within our present understanding of fish population dynamics and becoming able to make meaningful predictions about their effects continues to be a major challenge.

Glossary

Abundance Is the relative representation of a species in a particular community.
Biomass Is the mass of living organisms of a population or a community in a given area at a given time.
Community An ecological community is a group of populations of different species occurring at the same geographical location at the same time.
Evenness An index of numerical equality of species within a community.
Functional diversity A measure of the number of functionally different species within a community.
Functional redundancy Refers to the pattern that multiple species from several taxonomic groups can share similar roles in ecosystem functionality.
Richness Is the number of different species represented in an ecological community.
Size structure The distribution of organismal size (length, mass) within a population or a community.
Taxonomic diversity A measure of the number of taxonomically different species within a community, can also be quantified as the probability that the two randomly taken individuals represent different species.
Trophic cascade Reciprocal effects of predators on prey or of prey on predators that alter the biomass of a trophic level across more than one link in the food chain.

Introduction

To determine factors and processes that generate the structure of local communities is one of the central topics of community ecology. The unified neutral theory of biodiversity and biogeography (Hubbell, 2001) discusses that biodiversity arises at random. In contrast, the niche theory assumes that there are abiotic and biotic determinants that would predict local communities in a deterministic way. Subsequently, we follow the hypothesis of a non-random structure of communities, and elucidate concepts and empirical evidence for abiotic and biotic determinants of fish community structure in lakes.

The structure of fish communities in lakes is a suitable study object for community ecologists because many lakes are spatially isolated and form aquatic islands in the terrestrial landscape. Therefore, first concepts on studying fish community structure referred to the concept of island biogeography (McArthur and Wilson, 1967). In one of the most influential and comprehensive earlier studies, Tonn et al. (1990) developed the concept of hierarchical filters to explain the fish community structure in northern

Wisconsin lakes. These filters ultimately generate local fish species pools from processes operating on different spatial and temporal scales. These authors distinguish between historical and contemporary determinants of species diversity and community composition. Furthermore, they classify the spatial dimension into regional, lake-type and local processes (Tonn et al., 1990).

In this article, we follow the concept of hierarchical filters by covering the main processes and determinants of fish community structure in lakes at varying temporal and spatial scales. At the beginning of the chapter, we include a coarse overview on the global and continental biogeography of freshwater fishes. However, in the subsequent parts we focus in more detail on the contemporary processes determining the composition of fish communities, which operate on lake-type and local scales. Whereas the majority of the studies we refer to have been conducted in the temperate regions of the Palearctic and Nearctic realms, we summarize separately the results of a few studies on lake fish communities in sub-tropical, tropical and Arctic regions. We close the chapter by a list of topics, which are unresolved, and where we expect that future studies will contribute fundamentally new insight to the community ecology of freshwater fishes in lakes.

Methods and key terminology

The exploration of fish community composition in lakes is inherently difficult because fishes cannot be observed visually, except for situations with extremely clear water where visual surveys conducted by divers may inform about species occurrences and numbers. In the majority of cases, however, fishing surveys are used, which shall catch representative parts of the entire fish community to obtain data on community composition and population abundances. Survey fishing gears can be distinguished into active gears (e.g., pelagic or bottom trawls), which are actively moved to catch fish, and passive gears, which rely on the movement of the fish to be caught (e.g., gillnets). A comprehensive overview on fishing gears applied in freshwater ecosystems is provided by Bonar et al. (2009). All survey fishing gears are made of net material with certain mesh sizes, selecting only species and fish sizes that are big enough to be retained by the dimension of the mesh. Accordingly, fishing nets are inherently size- and species-selective. The active fishing by electricity can be applied in particular in shallow water areas, often along the shoreline, but the method is likewise biased towards certain species and size classes of fish that are most efficiently attracted by the electric field. Alternative methods include hydroacoustic devices (echosounders), which are suitable to accurately count fishes and estimate their sizes, but which have severe limits to distinguish species (Simmonds and MacLennan, 2005). More recent developments include the application of environmental DNA (eDNA), which seems to be a reliable tool to obtain qualitative and quantitative information about the fish community composition in lakes (Hänfling et al., 2016; Spear et al., 2020).

To obtain standardized fish catches for evaluating the water quality and ecological integrity according to the European Water Framework Directive, fishing surveys by multi-mesh gillnets in lakes have to follow the European standard (CEN, 2015). This standard defines the number of nets, their distribution to depth zones, the application of benthic and pelagic nets, the duration of net exposure, and the time period during which fishing is recommended. Furthermore, the dimension of the nets and the mesh size and yarn diameter of the panels are exactly described. The application of hydroacoustics (CEN, 2014) and electrofishing (CEN, 2003) for fish community surveys are similarly standardized.

Obtaining accurate coverage of species occurrences and reliable size distributions of fish in lakes is possible only by combining various fishing gears. There are several studies comparing the species or size compositions of fishes in lakes across differing fishing gears (Emmrich et al., 2012; Alexander et al., 2015). A ground-truthing by comparing fish catches from several fishing gears with an accurate census of fish abundance and community composition has been performed only once in a large pond, which could be drained after fishing, enabling to count all fish in this ecosystem (Ravn et al., 2019).

Fishing surveys can deliver several key metrics, which are informative for the fish community composition (see Glossary). First, taxonomic diversity can be expressed as species richness, species diversity and species evenness. Second, species-specific abundances and biomasses can be calculated. For passive gears, relative abundances or biomasses can be derived if a standardisable unit effort (e.g., number of nets, size of nets, number of catching days) can be defined (catch per unit effort). The unit effort is hardly comparable across fishing gears, preventing that relative abundances from different gears (for example, from gill nets and electrofishing) can be combined. For active gears and hydroacoustics, a reference to the fished area or volume is usually possible, and hence true densities (number of fish per area or volume) can be calculated. A third informative metric that can be derived from fishing surveys is the size (length or mass) distribution of fishes, either expressed as size spectrum ignoring taxonomic units, or as species-specific size distributions, reflecting the size- and age composition of populations.

Diversity indices and fish abundance and biomass can be accumulated beyond the taxonomic categories of species or genera. Typical groupings refer to feeding guilds (e.g., planktivores, piscivores, benthivores), temperature preference (cold-water, cool-water and warm-water species), spawning substrates (e.g., lithophils, psammophils, phytophils) and preferred lake habitat (pelagic, littoral, profundal species). By this approach, taxonomic diversity is converted into functional diversity, by assuming that the function of fishes is more important than the taxonomic identity for determining the occurrence of a species within a local community. Functionally dissimilar species usually have low niche overlap, and hence are less affected by interspecific competition. The exact species within a functional groups is, however, strongly dependent on the colonization from the regional species pool, contingent on the hydraulic connectivity of the lake to other aquatic systems. Few systematic comparisons between taxonomic, functional and size diversity have been conducted for fish communities in lakes (but see e.g., Brucet et al., 2018; Lamothe et al., 2018).

There are two different terms in describing all fish within a lake. The term assemblage refers to the species occurring in a lake, without considering interactions between them. In contrast, we use the term community because we demonstrate that species interactions may contribute substantially to forming local fish communities in lakes. When we elucidate potential determinants of

fish community composition in lakes, we will distinguish between effects on taxonomic diversity, effects on functional diversity and redundancy, effects on fish abundances or biomasses, and effects on the size structure of populations or communities.

Historical processes explaining global, regional and local fish species diversity

There are two major processes operating at differing temporal scales, which influence the regional and local occurrence of fish species. First, speciation is the process by which two or more reproductively isolated gene pools are generated from a previously single gene pool. This process includes spatial and geographical, ecological, and sexual components (Bernardi, 2013). Lakes are well-known hot-spots of fish speciation. For example, the African Great Lakes Tanganyika, Victoria and Malawi are all famous for their extraordinarily rich fish fauna dominated by Cichlidae (Fryer and Iles, 1972). The origin of the numerous species is evolution of species flocks from single ancestors, for example by divergent selection on sensory systems (Seehausen et al., 2008), having occurred independently in all lakes. Similar species flocks are described for sculpins (Cottidae) in the Russian Lake Baikal (Kontula et al., 2003), sailfin silversides (Telmatherinidae) in lakes of Sulawesi (Herder et al., 2006) and Midas cichlids in Nicaraguan crater lakes (Barluenga et al., 2006). Evolution of fish species flocks has been described also for temperate lakes in post-glacial landscapes during more recent geological times. Examples are species groups of whitefishes (*Coregonus*) in North and Central European lakes (Ostbye et al., 2005; Hudson et al., 2011) or *Coregonus* ciscoes in the North American Great Lakes (Turgeon et al., 1999). Furthermore, incipient ecological speciation is considered the process generating sympatric morphs of charrs (genus *Salvelinus*) in European postglacial lakes (Jonsson and Jonsson, 2001).

The second historical process is the balance between colonization and extinction. Geologically, the landmasses on earth have changed their position and connectivity (continental drift). Starting from the supercontinent Pangaea about 230 million years ago, the evolution and movements of freshwater fish lineages were affected by the breakup of Pangaea and the subsequently newly formed connections between landmasses. The currently existing configuration of continents has persisted since the Miocene about 15 million years ago. Therefore, colonization of the continents from connected landmasses by the currently existing fish fauna can date back several million years. The most important geological event with respect to the structure of the current fish fauna of the Palearctic and Nearctic realms was the last glaciation during the Pleistocene about 15,000 years ago. Glaciation and de-glaciation altered drainage patterns by change of flow of river systems, and created thousands of moraine and "kettle" lakes in Central and North Europe and in North America. At the glacial maximum, all fishes were extirpated from areas under glaciers or ice shields. Where possible, fishes could move into non-glaciated refuge areas. Re-colonization from refugia after the retreat of the glaciers is seen as the major process explaining the current regional fauna of the northern Palearctic and Nearctic (Griffiths, 2006). Therefore, the lakes formed during the Pleistocene and their fish faunas are geologically very young and hence species-poor, in comparison with the geologically much older and species-rich systems, for example the African Great Lakes.

The current continental and regional occurrence and distribution of freshwater fishes can be ordered along 426 Major Freshwater Ecoregions (Fig. 1) (Abell et al., 2008). An overview of the fish species richness per major freshwater drainage basin is provided by Tedesco et al. (2017). These regional species pools determine the availability of fish species for forming local fish communities in lakes. Large-scale trends of fish species diversity in North America and Europe follow differences in spatial climatic trends, primarily caused by temperature and rainfall, suggesting a strong effect of physiological constraints on species occurrence (Griffiths et al., 2014; Brucet et al., 2013). Europe contains 546 native species of freshwater fish, and there is a clear trend of declining species diversity and number of endemic species from east to west, and from south to north (Griffiths, 2006).

Contemporary processes predicting local fish community composition

Overview

In contrast to the historical processes summarized before, subsequently we cover contemporary processes that contribute to forming lake fish communities. Colonization and extinction contribute to forming both regional and local fish species lists. We further summarize a number of main studies, in which lake fish communities were analyzed at world-wide or continental levels. In the second part of this sub-chapter, we elucidate in more detail the abiotic and biotic predictors of lake fish communities, as obtained from studies at smaller geographical scales, primarily from temperate regions. Finally, we elucidate results from a few studies on lakes in Arctic and tropical regions.

Dispersal and colonization

In lakes, which are hydraulically connected, fish populations and communities can be regarded as forming meta-populations or meta-communities. Dispersal of individuals from a source to a sink population then becomes an important process contributing to formation of local communities. In very large lakes, a meta-population structure can even be found between separate lake basins (Haugen et al., 2006). There is not much known about fish meta-communities across lakes because lakes have been considered primarily as closed systems. However, single studies suggest that the hydraulic connectivity of lakes with their watersheds modifies the fish community structure through dispersal of migrant species (Griffiths, 2017). Furthermore, the pairwise dissimilarity of fish community composition increases with increasing spatial distance between lakes along waterways, attributable in particular to small littoral fish species with a presumed lower capability of long-distance dispersal (Mehner et al., 2014).

Freshwater Ecoregions of the World. Available at www.feow.org. Figure re-drawn by Vanessa Bremerich. Richness for the following ecoregions are estimates: Aceh, Indian Ocean Slope of Sumatra & Java, Southern Central Sumatra, Southern Sumatra—Western Java, Central & Eastern Java.

Extinction risk

Freshwater fish species and populations have severely been affected by several threats including destruction or modification of their habitat, water pollution, overexploitation, spread of invasive species, spread of alien parasites and pathogens, salinization, acidification and climate change (Gozlan et al., 2019). In Europe, for example, at least 37% of freshwater fish species are threatened, about 17% of populations are declining, and at least 13 European fish species are globally extinct (Freyhof and Brooks, 2011). The highest number of threatened freshwater fish species is found in the south of the Europe. In central Asia, at least 30 of the 120 fish species that inhabit inland waters are on the Red List (Visconti et al., 2018). In the biogeographical region of North America, the freshwater fish fauna had the highest extinction rate worldwide among vertebrates in the 20th century and the number of threatened freshwater fishes has increased by 25% during the last three decades (Burkhead, 2012). Whereas these data refer to entire freshwater drainage basins, there is a lack of specific data for trends of species richness in lakes. In general, monitoring data for freshwater fish species diversity and abundance are urgently needed worldwide to accurately measure population trends and improve the accuracy of future Red List assessments.

Large-scale studies on lake fish communities

An excellent conceptual overview of approaches and determinants of fish community composition has been published about 20 years ago (Jackson et al., 2001). However, there are also a number of recent studies analysing the effects of abiotic filters and biotic interactions on local fish species richness and composition in lakes at continental or world-wide scales. Strong spatial patterns in structure and functional diversity (as based on trophic niche estimates) were found among 159 fish communities from lakes distributed over almost all continents. There was a complex interplay between external and internal filters, but these patterns may be blurred by anthropogenic species introductions (Comte et al., 2016). A comprehensive overview on almost 2000 lakes in Europe, as based on standardized fishing surveys in the context of the European Water Framework Directive, found strong effects of large-scale climatic differences and abiotic filters on local fish communities (Brucet et al., 2013). The contribution of non-native fish species to these European lake fish communities and its predictors has been explored separately (Trochine et al., 2018). Based on data from almost 7000 Ontario lakes, functional diversity and redundancy of lake fish communities were calculated. Fish communities in larger, deeper and warmer lakes were functionally most redundant (Lamothe et al., 2018). In a similar approach including lakes in Western Europe, taxonomic and functional richness of fishes were strongly correlated, and rare species contributed singular

functions only in rivers and estuaries, but not in lakes, suggesting low sensitivity of lake fish communities to single species loss (Teichert et al., 2017). The size structure of European lake fish communities has been compared by Emmrich et al. (2014). Lakes located in colder European regions dominated by cold-water salmonids were characterized by unimodal or bimodal body-size distributions, whereas lakes in the warmer European lowlands dominated by eurythermic cool- and warm-water species were characterized by almost linear negative log-log abundance-size distributions.

Abiotic predictors of community structure in temperate lakes

Lake morphometry

Lake morphometry has an important effect on the composition of lake fish communities, in particular in interaction with large-scale climatic factors (temperature, rainfall) and productivity (Fig. 2) (Brucet et al., 2013). This has similarly been confirmed for functional diversity of boreal lake fish assemblages (Erös et al., 2009). Lake morphometry affects all horizontal and vertical gradients of abiotic factors in lakes (light, temperature, oxygen concentration, nutrient concentration, pH), and hence creates the within-lake habitat diversity. Accordingly, lake morphometry determines the lake type, which essentially groups lakes into either shallow and polymictic, or deep and monomictic or dimictic types. The logarithm of the lake surface area is a good predictor of the (logarithm of) local species richness (species-area relationship) (e.g., (Griffiths, 1997). Accordingly, lakes with a surface area of <0.001 km^2 (equivalent to <1 ha) may host often only one or two fish species, whereas several hundred species can be found in large (>100 km^2) lakes, for example in the Great Lakes of Africa. Functionally, larger lakes have a greater variety of differing habitats, have a lower probability of local species extinctions and a higher colonization rate. These processes explain why fish species richness increases with lake area.

A comparatively strong effect on local fish community composition is attributable to lake depth. Lake depth is a key determinant for the thermal and mixing regimes of lakes. In temperate and warm regions, only deep (maximum depth $> \sim 12$ m) lakes provide permanent cold-water habitats. Lake depth in combination with turbidity also determines whether light can reach the bottom of lakes. Accordingly, the benthic zone of lakes can be divided into the littoral zone (illuminated) and the non-illuminated profundal zone. Therefore, deep stratified lakes can be inhabited by fishes occurring in either littoral, profundal or pelagic habitats, whereas the fish community composition of shallow and clear lakes consisting only of littoral habitats may be confined to littoral species. The three lake habitats may substantially differ with respect to species richness, diversity and dominant species (Diekmann et al., 2005). The deep-water pelagic and profundal layers of stratified lakes, which are usually cold and naturally well oxygenated, are inhabited by cold-water adapted species, mostly from the order Salmoniformes (genera *Salmo*, *Coregonus*, *Salvelinus*). In turn, there are species bound to the structured littoral areas because of small size, their reproduction relying on macrophytes (phytophils or phytolithophils), or fish species requiring benthic biotic hosts (Unionidae mussels) for their eggs (European bitterling, *Rhodeus amarus*). These littoral species often belong to the thermal guild of warm-water species, and hence cannot propagate into the cold deep-water layers of stratified lakes. Accordingly, fish species richness and diversity of entire lakes can reliably be evaluated only by including fishing surveys in all available habitats.

Further morphometric effects on fish community composition can be expected from shoreline length, shoreline development (length of shoreline relative to perimeter length of an ideal circle of the same surface area) and shoreline slope. With increasing shoreline development and shallower shoreline slopes, habitat variability and complexity of littoral areas usually increase, resulting in higher richness and diversity of the littoral fish communities (Lewin et al., 2014). Finally, the hydraulic connectivity of lakes determines whether lakes are accessible or can be left by moving fish, suggesting that all species with non-resident life styles have a

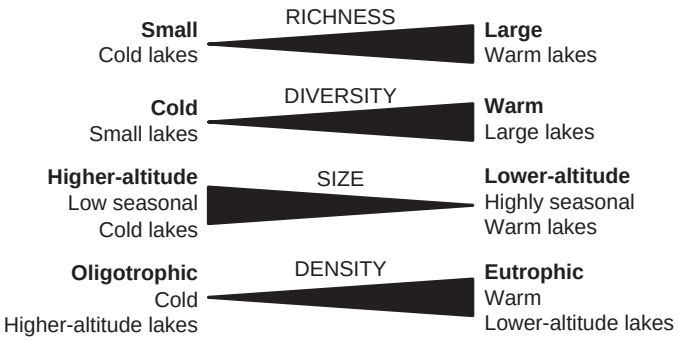

Fig. 2 Scheme showing changes (increase and decrease) for each fish assemblage descriptor in European lakes. Main variables driving changes in each descriptor are given in boldface. Figure reproduced with permission from Brucet S, Pedron S, Mehner T, Lauridsen TL, Argillier C, Winfield IJ, Volta P, Emmrich M, Hesthagen T, Holmgren K, Benejam L, Kelly F, Krause T, Palm A, Rask M and Jeppesen E (2013) Fish diversity in European lakes: Geographical factors dominate over anthropogenic pressures. *Freshwater Biology* 58: 1779–1793.

higher chance to be present in connected lakes. Furthermore, the rates of first colonization and re-colonization are certainly also higher in lakes that are hydraulically connected to other aquatic ecosystems.

There are only few studies demonstrating strong effects of lake morphometry on total fish abundance or biomass and on size distributions. Warm and shallow lakes at lower altitudes usually have higher fish densities than deep lakes with big volumes of cold-water hypolimnetic habitats, and average fish size increases with altitude and declines with temperature and seasonality (Brucet et al., 2013).

Lake productivity

There are several studies showing a strong effect of changing lake productivity on the fish community composition. In the temperate zone of both the Palearctic and the Nearctic, species of the order Salmoniformes (salmon-like species) were replaced by Perciformes (perch-like species), and these have gradually been replaced by species of the order Cypriniformes (carp-like species) with increasing concentrations of phosphorus and nitrogen (lake eutrophication) (Hartmann and Nümann, 1977; Argillier et al., 2013). However, these changes in species dominance are not a direct consequence of the higher nutrient concentrations, but are caused by indirect consequences of the higher lake productivity. Higher nutrient concentrations result in higher phytoplankton densities and biomasses, which make the water more turbid. Lower underwater visibility impairs all fish species, which rely on vision for feeding (e.g., perch *Perca fluviatilis*), whereas species adapted to low illumination (e.g., pikeperch, *Sander lucioperca*) may thrive. Lower illumination of the benthic zones declines the extension of the littoral zone and may ultimately prevent growth of aquatic macrophytes. Hence, all species with a phytophilous spawning mode may become extinct. Furthermore, fine-grain sediment may cover fish eggs deposited at the bottom, hence preventing successful egg development and hatching (Ventlingschwank and Livingstone, 1994).

A second major indirect effect of eutrophication on fish community structure is attributable to the decomposition of the increased amount of organic matter in the deep lake zones, which requires higher oxygen amounts than at the low-productivity situation. If the oxygen deficit cannot be balanced by fresh oxygen from primary production or atmospheric supply, for example in deep-water layers of lakes during the stratification period, layers of low oxygen concentrations may expand and ultimately prevent the occurrence of fish. If the entire deep-water pelagic area of lakes has become inhabitable because of lack of oxygen, also the cold-water habitat is completely lost, and hence species of the cold-water guild can no longer survive in heavily eutrophied lakes. If only the warm-water layer above the thermocline remains habitable, eutrophied stratified lakes resemble shallow lakes, and hence the fish community composition of shallow and stratified lakes becomes more similar with increasing eutrophication (Mehner et al., 2005). Excessive oxygen consumption of lake sediments from decomposition of organic material also impairs successful embryogenesis of bottom-laid fish eggs (Muller and Stadelmann, 2004).

A more direct effect of increasing productivity of lakes is an increase in total fish abundance and/or biomass (Brucet et al., 2013). Primary consumers like pelagic zooplankton and benthic macroinvertebrates respond to higher primary production by increasing biomasses, which then are used by fish consumers to likewise generate higher biomasses. However, the relative increase in fish biomass is often higher than the relative increase in biomass of primary consumers, and hence the per-capita available energy for fishes declines with eutrophication. The consequence is higher competition among the species of the same feeding guild, resulting in slow, so-called stunted growth with a measurable decline of size-at-age in the dominant fish species. These low growth rates are reflected in distorted size spectra, where accumulation of fish in certain size classes becomes obvious as significant residuals from the otherwise log-linear size-abundance relationships (Arranz et al., 2019).

Biotic predictors of community structure in temperate lakes

Predator-prey interactions

Predation by piscivorous (fish-eating) fish on prey fish is considered a strong structuring force for lake fish communities. Time series obtained from small lakes show strong population fluctuations of prey fish in response to drastic declines and subsequent recovery of predator fish, for example after winterkills (Tonn and Paszkowski, 1986). Similarly, the intentional or unintentional stocking or invasion of fish predators (perch; pike, *Esox lucius*) into lakes can induce local extinctions of prey species (Henriksson et al., 2016). The best documented example is the eradication of the native fish fauna composed mainly of small cichlids by introduction of the non-native piscivorous Nile perch (*Lates niloticus*) to the African Lake Victoria (Ogutuohwayo and Hecky, 1991). There are not many studies that report whether certain native predator and prey fish species co-occur less often than by chance, a pattern that would suggest that there is the risk of local extinction of prey in response to the occurrence of the predator. A recent study from more than 700 lakes in Ontario did not find evidence that even large-sized piscivorous species eradicated potential prey fish species from local communities in a systematic and predictive way. Where negative co-occurrences between predator and prey species pairs were found, these were context-dependent and prominent only in a small sub-set of lakes with particular features (MacDougall et al., 2018).

A clearer picture emerges if abundances and biomasses of predator and prey fishes are considered. In response to strong predation by fish predators, substantial declines in prey numbers can be expected. For example, to combat consequences of lake eutrophication, biomanipulation of the fish community was popular to indirectly suppress phytoplankton blooms via a trophic cascade (Mehner et al., 2002). However, the enhancement of piscivorous fish biomass as one of the biomanipulation strategies has often resulted only in a short-term decline of prey fish biomasses in lakes, whereas in the long-term the biomasses of planktivorous and benthivorous fish species recovered despite higher biomasses of piscivores. These results suggest that the piscivorous fish

biomass cannot permanently be enhanced without ongoing maintenance, and the biomass ratios between predators and prey seem to be lake-specific and relatively invariant (Mehner et al., 2002).

To demonstrate the effects of predation by piscivorous fish on prey fish, the structure of fish communities has also been compared among lakes, often from the same regional area. Even by accounting for the effects of differing lake morphometry and productivity on fish communities, the expected negative correlation between predator and prey fish biomasses could not be found (Mehner et al., 2016; Kokkonen et al., 2019). Accordingly, fish-induced trophic cascades by which phytoplankton is suppressed by high predator fish biomasses could not be detected by among-lake comparisons (Mehner, 2010; Bartrons et al., 2020).

Most of fish predators are gape-limited, and hence can swallow prey at once only if the prey fish is smaller than the maximum opening width of the mouth of predators (Hambright, 1994). Typical ratios of predator to prey fish length range between 3:1 and 5:1 (Mittelbach and Persson, 1998), which convert into predator-to-prey mass ratios of about 27–125 (3^3–5^3) (Brose et al., 2006). Accordingly, a strong effect of size-selective predation on the size structure of prey fish communities could be expected. Similarly to the predator effects on prey biomass, time series from single lakes reflected a stronger signal of size-selective predation (Tonn and Paszkowski, 1986) than approaches comparing the size structure of prey fishes among lakes with differing predator size structure (Mehner et al., 2016).

Competition and resource segregation

Interspecific competition has not been a major focus of studies investigating the structure of lake fish communities. We are not aware of a study showing that a certain fish species has become excluded from a local lake community as the consequence of competition with another local fish species, but invasion by non-native species may induce stronger negative effects. In turn, a dominance of positive co-occurrence patterns of species or habitat-specific groups of species among lakes suggests that facilitation and niche similarity structure richness and composition of lake fish communities substantially (Fig. 3) (MacDougall et al., 2018). Mutually negative effects on abundance or biomass of competing fish species are more likely (Eloranta et al., 2016), but systematically negative abundance or biomass correlations between species with similar niches among lakes have not been found (MacDougall et al., 2018). It has to be noted that studies of interspecific competition have to consider the frequent ontogenetic niche shifts in freshwater fishes (Werner and Gilliam, 1984), resulting in a succession of different biotic interactions while fish grow. The effect of competition among species is usually best demonstrated by niche segregation between co-occurring fish species (Genner et al., 1999; McMeans et al., 2020). This process is also considered as a route towards ecological speciation in lake fish communities (Knudsen et al., 2006). However, these young speciation events can be reversed and sympatric species can disappear if anthropogenic influences on lakes destroy the ecological gradients along which niche segregation has been expressed (Vonlanthen et al., 2012).

Stronger effects of competition have been found with respect to size structure of lake fish populations and communities. Interspecific competition modifies the size distribution of lake fish populations, with shifts towards steeper slopes of size spectra where the density of interspecific competitors is high. However, the strongest effect from competition on size spectra is attributable to intraspecific competition (Arranz et al., 2016). The size-at-age declines with increasing density of individuals from the same species, resulting in delayed reproduction and recruitment. Under extreme cases, negative density dependence can induce cyclic population dynamics with alternating strong and weak year classes, e.g., in vendace (*Coregonus albula*) (Hamrin and Persson, 1986) or roach (*Rutilus rutilus*) (Cryer et al., 1986). These results support that biomass and size structure of local fish communities are strongly affected by the available energy provided by autotrophic (phytoplankton, algal biofilms, macrophytes) and heterotrophic (bacteria and fungi) production and the efficiency by which this energy is transferred to the higher trophic levels (Bartrons et al., 2020).

Fish community structure in lakes outside temperate latitudes

Sub-Arctic and Arctic lakes

A few comparative studies have been conducted on the fish communities in Sub-Arctic and Arctic lakes. Lakes in this region respond strongly to the current effects of global warming, and hence comparison of their patterns and dynamics with those from lakes from the temperate zone may shed light on overarching processes and principles of fish community ecology.

The fish assemblages in small Sub-Arctic lakes of northern Alberta (Canada) were structured by species-environment relationships, but also by biotic interactions. Despite a smaller regional species pool, local fish species richness was comparable to similar lakes in the boreal zone (Tonn et al., 2004). Fish species richness in Arctic lakes of Alaska was substantially enhanced by hydraulic connectivity via a permanent channel, primarily caused by higher numbers of restricted species in comparison with non-connected lakes that were dominated by widespread fish species (Laske et al., 2016). The response of fish communities and their trophic interactions to a gradient of productivity and warming was studied in Finnish Sub-Arctic lakes, all located north of the Arctic Circle. In warmer and more productive waters, fish density increased, whereas average fish size declined, most apparent in littoral and benthic habitats (Hayden et al., 2017). The trophic structure of Greenland lakes was strongly determined by the presence of fish and the fish species occurring in the lakes. Fish-induced trophic cascades shifted the zooplankton composition from large taxa towards small-bodied crustaceans, in particular if sticklebacks (*Gasterosteus aculeatus*) were the single fish species present. Invasion of currently fishless lakes by fish will hence substantially modify these lakes (Jeppesen et al., 2017).

Overall, the patterns of fish community structure and the abiotic and biotic correlates in Arctic lakes were very similar to those described for temperate lakes of the Palearctic and Nearctic. Stronger trends of warming and enhanced productivity in Arctic than in

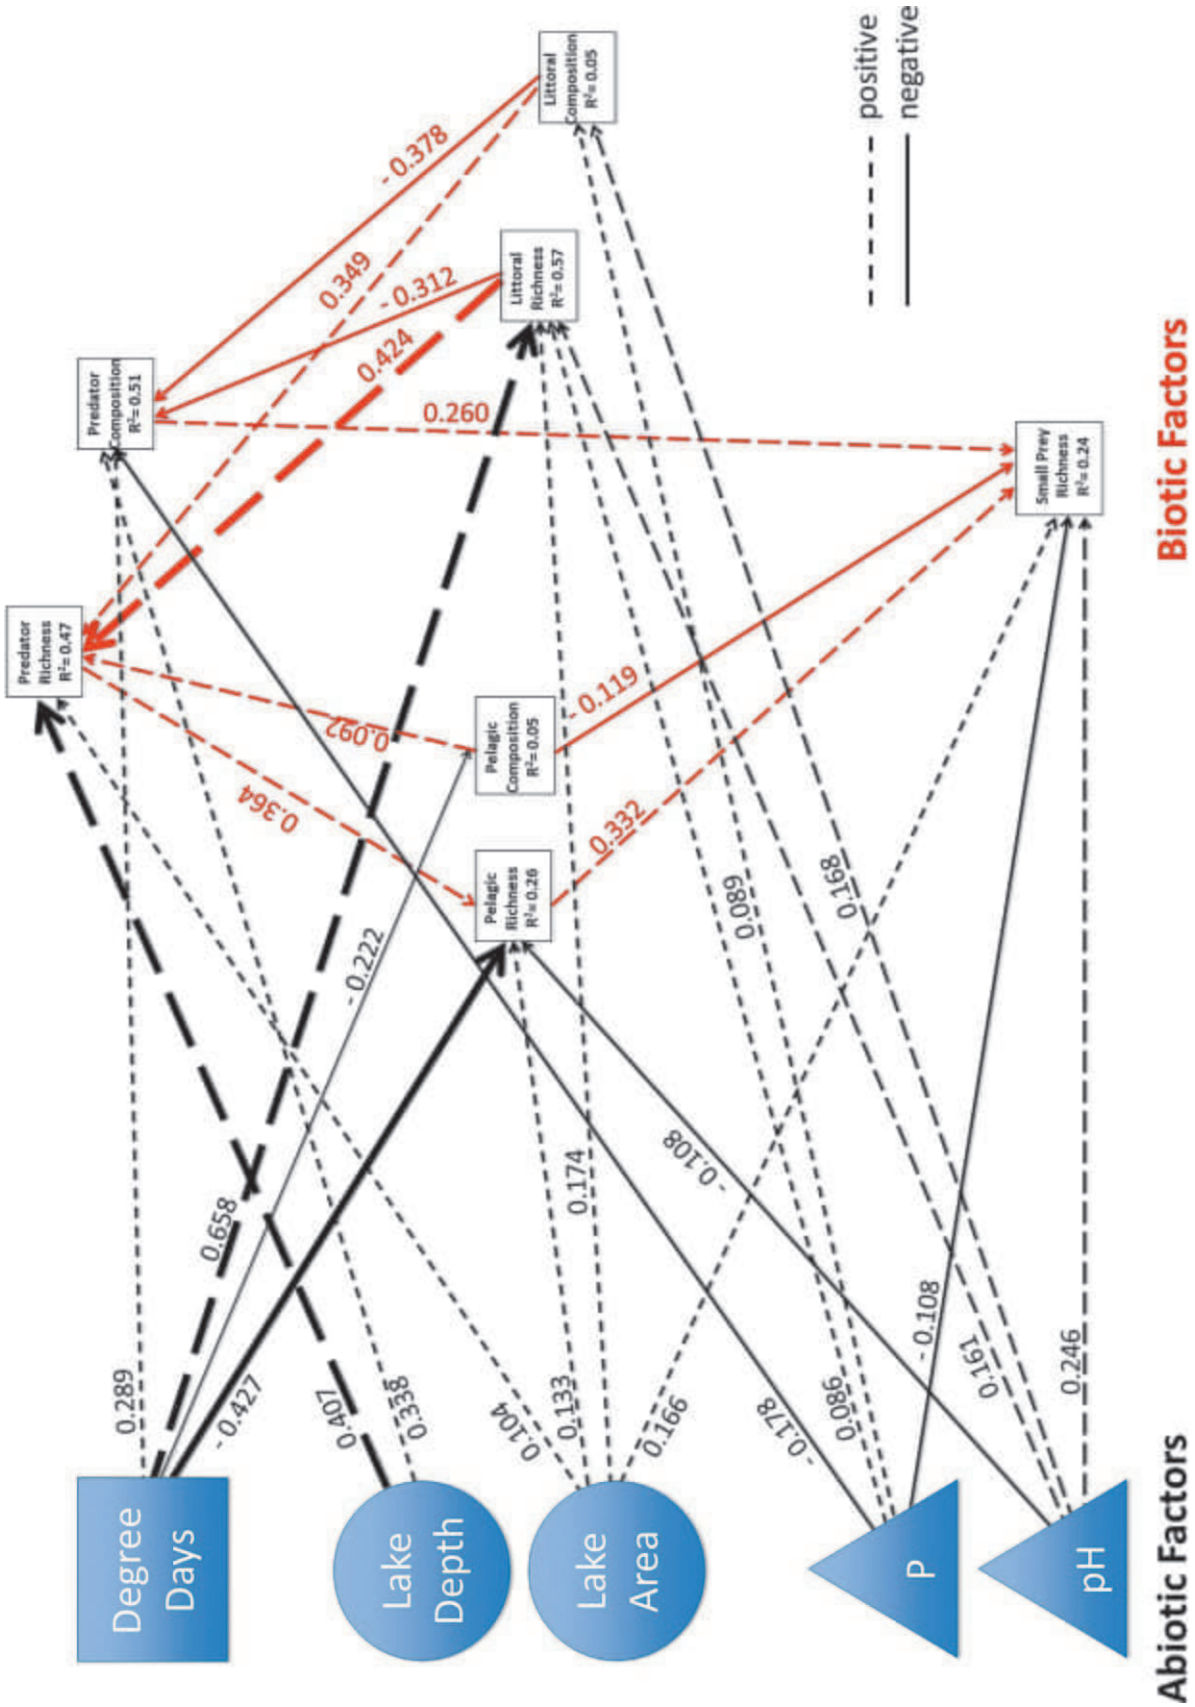

Fig. 3 Direct and indirect drivers of species richness in fish. Structural-equation-model-derived multivariate relationships among integrated abiotic and biotic regulatory factors (blocks = degree days, circles = lake morphometry, triangles = water quality, and biotic factors [red lines]) for the richness and composition of four major fish functional groups in 721 lakes along an 11 degrees latitudinal gradient in Ontario, Canada (SEM integrative model: $n = 648$, MLEST = 4.91, Degree of freedom = 13, $P = .977$). Solid lines indicate negative relationships; dashed lines indicate positive relationships. Arrows indicate the direction of the relationship. Bold lines indicate stronger relationships, arbitrarily assigned as standardized path coefficient values >0.40. Black lines indicate abiotic influences on biotic factors and red lines indicate influences between biotic factors. Functional groups are predator, littoral, pelagic, and small-prey species. Reproduced with permission from MacDougall AS, Harvey E, McCune JL, Nilsson KA, Bennett J, Firn J, Bartley T, Grace JB, Kelly J, Tunney TD, McMeans B, Matsuzaki SIS, Kadoya T, Esch E, Cazelles K, Lester N and McCann KS (2018) Context-dependent interactions and the regulation of species richness in freshwater fish. *Nature Communications* 9: 973.

temperate lakes due to global change will hence increase the similarity in fish community structure between these geographically distant freshwater systems.

Sub-tropical and tropical regions

In contrast to numerous studies from temperate and a few from Arctic and sub-Arctic areas, there is no systematic overview on fish community structures and their predictors in tropical or subtropical lakes. Geologically, most of the lakes in the tropical areas are much older because these areas were not affected by glaciation during the Pleistocene. Freshwater fish diversity in coastal southern Africa lakes and lagoons is a function of historical and present biogeography and salinity, with elements of marine fish communities persisting in lakes which retained a tenuous linkage with the sea. Furthermore, higher fish richness was found in lakes fed by rivers in subtropical than in temperate areas of this region (Whitfield et al., 2017). In tropical and sub-tropical floodplain lakes, the natural flow regime of the river feeding the lakes was most important (Pool et al., 2019). The community structure in floodplain lakes of the Orinoco River in Venezuela was predictably related to transparency, conductance, depth, area and the numerical density of piscivorous fishes (Rodriguez and Lewis, 1997). Fish communities in shallow lakes of the subtropical South America are characterized by higher densities, but smaller average sizes of fish in comparison with lakes at similar productivity in temperate regions (Teixeira-de Mello et al., 2009), and have a higher proportion of omnivorous fish and a lower proportion of piscivorous fish (Gonzalez-Bergonzoni et al., 2012). Therefore, predator fish-induced trophic cascades are less prominent in subtropical and tropical lakes, resulting in higher phytoplankton biomasses than in comparable shallow lakes of the temperature region (Jeppesen et al., 2010). In a large-scale comparison between >1600 temperate Danish and subtropical Florida shallow lakes, a greater control of zooplankton and benthic macroinvertebrates by fish consumers was documented for the subtropical lakes relative to those in Denmark (Jeppesen et al., 2020).

In general, all these results are also important to elucidate potential changes in fish community composition and food-web interactions in temperate lakes in response to global change because the warmer current climate in tropical region may reflect conditions in the temperate regions is a few decades. However, the processes of community formation, predictors of local species diversity and overall fish species richness differ fundamentally between postglacial temperate areas and the geologically older lakes in sub-tropical and tropical regions. Furthermore, the prominent number of floodplain lakes at lower latitudes points to a strong effect of the annual flood regime of the adjacent rivers on the lakes. Patterns and processes of fish community formation in floodplain lakes therefore differ fundamentally from those in the typical moraine lakes of the northern temperate zones. A systematic exploration of fish community composition and their local and regional predictors in tropical and sub-tropical regions in comparison with temperate areas could help identifying general processes at varying temporal and spatial scales that contribute to forming fish communities in lakes.

Future research topics

There are three research areas, in which substantial progress can be expected during the next years. First, the potential of eDNA to generate world-wide fish species inventories is one of the major promises of recent methodological advancements. Although not yet all confounding factors are known, which affect the results of eDNA studies, fish community ecology will massively profit from eDNA sampling because it is substantially less cost- and labour-intensive than the traditional fishing surveys. If (semi)-quantitative analyses as based on eDNA will become possible and will generate reliable results (Spear et al., 2020), even abundance and biomass information for local communities will become available. In combination with remote sensing of lake morphometry and productivity, determination of local predictors for species occurrences and abundances and monitoring of temporal changes in community composition will become possible for thousands of lakes world-wide at less effort than now, revolutionizing the conservation and management of freshwater fish communities in lakes.

Second, community ecology will profit from the finer resolution of empirical trophic networks by new or improved tracer technologies. Stable isotopes, compound-specific stable isotopes, fatty acids, and DNA-based stomach analyses are examples of recently developed or matured approaches. Furthermore, tracking swimming and behaviour of fishes in-situ will facilitate better understanding of contributions from predator-prey and competition interactions to formation of local communities and their temporal dynamics. Host-pathogen interactions and their effects on fish population dynamics and community structure are so far largely ignored, but may likewise change the view on critical processes affecting the presence and persistence of certain species in local communities.

A third important development refers to the statistics of among-lake comparisons of community structure. To evaluate whether interspecific interactions contribute to forming local fish communities in lakes is notoriously difficult. Comparison of patterns among lakes is often hampered by the fact that positive or negative species co-occurrences are caused by similar or dissimilar environmental requirements, respectively, without indicating the effect of interactions. Disentangling between joint occurrences and interaction effects requires recently advanced statistical approaches, for example the hierarchical modelling of species communities (Ovaskainen et al., 2017). These multivariate models allow, by a latent variable approach, to eliminate the effects of spatial configuration of lakes, their environments and phylogeny on species occurrences, making it plausible that the residual variation reflects true interaction effects between species. However, these models have not yet been applied to lake fish communities.

The Carbon Cycle in Lakes: A Biogeochemical Perspective

Yves T Prairie[a] and Jonathan J Cole[b], [a]Department of Biological Sciences, Université du Québec à Montréal, Montreal, QC, Canada; [b]Cary Institute of Ecosystem Studies, State University of New York, Millbrook, NY, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Alkalinity (Acid Neutralizing Capacity, also ANC) A property of water describing its buffering capacity. In most freshwaters, the bulk of the alkalinity results from the bicarbonate and carbonate inputs from the catchment but organic compounds and certain reduction reactions (e.g. sulfate and nitrate reduction) can also contribute.
Carbon burial Process describing the rate of permanent accumulation of carbon in lake sediments. It is larger than the rate of carbon sedimentation because a portion of the deposited can be mineralized (generally to CO_2 or to CH_4) and returned to the water column.
Dissolved and particulate carbon Operationally defined as carbon passing through or retained by a 0.45–0.7 μm porosity filter, respectively.
Gas exchange coefficient (piston velocity, k_{600}) A coefficient linked to the turbulence at the air-water interface describing the exchange rate of gases between the water and the atmosphere.
Inorganic carbon (IC) Consists of the dissolved and particulate phases of the carbonate system. Dissolved inorganic carbon (DIC) refers to the sum of dissolved CO_2 + the bicarbonate anion + the carbonate ion. Particulate inorganic carbon consists only of carbonate in the solid phase in minerals such as calcite, aragonite and vaterite. These minerals can be formed either by chemical precipitation or by the actions of shell-making organisms such as bivalves and snails.
Lake metabolism Refers to the ensemble of processes regulating the balance between primary production and respiration.
Organic carbon (OC) Carbon containing compounds other than inorganic carbon species generally generated or transformed by living organisms. Dissolved organic carbon (DOC) found in lakes typically consists of a mixture of thousands of different organic compounds.
Organic carbon reactivity The rate at which organic compounds are degraded in a sample of lake water, usually expressed as a first-order reaction rate constant. Because lake water typically contains compounds of different reactivities, organic carbon degradation corresponds to a continuum of reactivity.
Primary production The fixation of inorganic C into organic constituents performed by primary producers.
Respiration The conversion of organic matter to inorganic carbon, generally CO_2. Respiration is performed by both autotrophic and heterotrophic organisms.

Introduction

The lake carbon cycle encompasses all the processes that transport, transform, use, exchange or recycle any form of carbon found in lakes. As the common currency of all life, the flow of carbon through lake ecosystems is thus considered a general metric of the intensity of biological activity within, although some carbon transformation also may also occur through abiotic mechanisms. While this biological activity occurs within the lake's shoreline, lake ecosystems are largely a reflection of what they receive and are

inextricably linked with the terrestrial catchment they drain. This paradigm of lakes as receptor funnels and reactors is not unique to carbon and is necessary to account for their observed responses to changes in external loadings, be it of nutrients in the case of eutrophication, or of sulfur or nitrogen oxides for acidification. For carbon, this terrestrial-aquatic linkage is even more pronounced because carbon processing is not only a function of the amount and form lakes receive but also by the input of other substances such as nutrients or, in some cases, of pollutants as well.

At its simplest level, the lacustrine carbon cycle is the study of how lakes react to the external loads of carbon and nutrients they receive from upstream, how the various carbon pools interact with—and are transformed into—one another, and how and in what form they are lost from the lakes, all of which are constrained or augmented by physical, chemical and biological processes. In this chapter, we review the main transformation and transport processes of the largest carbon pools and fluxes and how carbon ultimately leaves the lake at the ecosystem main interfaces: the outflow, the air-water surface and the sediments.

Carbon inputs to lakes: Forms and sources

Carbon in streams, rivers and lakes occurs in a variety of forms that are coarsely distinguished as inorganic (IC) and organic (OC) carbon fractions, each of which can be either dissolved (DIC, DOC) or particulate (PIC, POC). Furthermore, each of these forms is actually the sum of multiple chemical species. In the case of DIC, it comprises three distinct species (dissolved CO_2, bicarbonate and carbonate ions) that are in chemical equilibrium with each other (see details in section below). For DOC, it is composed of thousands of different soluble compounds of varying molecular complexity originating from the leaching and partial degradation or processing of terrestrial organic matter. CH_4 is the simplest dissolved organic compounds but is not normally included in the definition of the DOC pool or inputs, and is nearly always treated separately. Their particulate counterparts, PIC and POC, are generally composed of various carbonate minerals (calcite, aragonite. . .) and small plant or animal organic debris (living or dead), respectively. The four carbon fractions enter lakes mostly via riverine and groundwater inputs but the relative contribution of each of these forms varies enormously between lakes of different regions and even between lakes of the same region (Stets et al., 2009). Nevertheless, some generalities emerge: the dissolved component is generally much larger than the particulate and the riverine load is usually greater than the groundwater load. The partitioning between the organic and inorganic loads is more variable and largely determined by the geological, edaphic and topographic settings of the lake and its catchment. Sedimentary rocks will yield higher inorganic carbon exports than igneous geology while the soil organic content and flat terrains will promote the export of organic carbon. The inputs of inorganic and organic carbon to lakes therefore varies considerably among different regions of the world depending on their topography and local geology (Meybeck, 1987).

Ultimately, both inorganic and organic carbon exports can be viewed as the product of terrestrial primary productivity (Maberly et al., 2013). While this is obvious for the organic fraction, the inorganic carbon export is derived either from the direct transport of soil respiratory CO_2 to the stream channel or by first reacting with various silicate or carbonate minerals to produce bicarbonates through weathering reactions (Viers et al., 2007) such as

$$NaAlSi_3O_8(s) + CO_2(g) + 5\ 1/2\ H_2O \rightarrow Na^+ + HCO_3^- + 2H_4SiO_4 + \text{kaolinite} \quad (1a)$$

and

$$CaCO_3(s) + CO_2(g) + H_2O \rightarrow Ca_{2+} + 2HCO_3^- \quad (1b)$$

In the case of carbonate mineral weathering, only half of the carbon delivered as bicarbonates would be derived from terrestrial primary production and the other half from the mineral itself. Stream surfaces are active sites of gas transfer to the atmosphere and most of the inorganic carbon reaching the lake is in the form of ionic species (HCO_3^- and CO_3^{2-}).

Upon entering the lake, inorganic and organic carbon loads from the catchment constitute an important subsidy to the carbon economy of the lake but not all forms undergo transformation to the same extent. For example, carbonate alkalinity (CO_3^- and HCO_3^{2-} ions) is largely conservative in lakes except in cases where some primary producers (e.g., macrophytes and some algal species) can use bicarbonate ions as inorganic substrates when dissolved CO_2 is scarce (Prins and Elzenga, 1989), or when carbonates precipitate as in marl lakes. Organic carbon inputs however have a much different fate. Most (typically 90%) of the organic carbon enters lakes as dissolved, while the particulate remainder is composed mostly of detrital terrestrial plant and soil material. Although the dissolved organic matter can be quite old and therefore suggestive of a high degree of recalcitrance, the conditions prevailing in aquatic systems are more conducive to its rapid transformation (McCallister and del Giorgio, 2012).

Dissolved inorganic carbon (DIC)

All water, even distilled water, contains some amount of inorganic C in solution. The total dissolved inorganic C content is generally referred to as DIC (total CO_2 by some authors). DIC, however, is made up of several chemical species: the bicarbonate ion (HCO_3^-), the carbonate ion (CO_3^{2-}), and aqueous carbon dioxide, which consists of two pools (dissolved free CO_2 and its hydrated form H_2CO_3, carbonic acid). At equilibrium with each other, H_2CO_3 is about 1/1000th of the concentration of free CO_2. Neither CO_2 nor H_2CO_3 is a charged species; they interchange readily and behave as one pool in chemical reactions. Thus, all of the constants and equations treat $CO_2 + H_2CO_3$ as a single pool and refer to it as either $H_2CO_3^*$ or simply as dissolved or aqueous CO_2.

The concentration of DIC in the oceans is large and within a narrow range (near 2400 μM) and varies with salinity. In inland waters, DIC ranges from <20 μM in acidic soft waters to >5000 μM in alkaline hard waters and even higher in endorheic, saline lakes. In most freshwaters, DIC lies between 100 and 1000 μM in the surface and typically the concentration increases with depth in stratified systems because of the accumulation of respiratory CO_2 (Ducharme-Riel et al., 2015).

Chemical equilibrium of the carbonate complex

When dissolved in water, carbon dioxide ($CO_{2(aq)}$) enters into an equilibrium with the other two carbon species following the bulk simplified reaction

$$CO_{2(aq)} \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons H^+ + CO_3^{2-} \tag{2}$$

with equilibrium constants K_1 and K_2 as:

$$K_1 = \frac{[H^+][HCO_3^-]}{[CO_{2(aq)}]} \tag{3a}$$

and

$$K_2 = \frac{[H^+][CO_3^{2-}]}{[HCO_3^-]} \tag{3b}$$

Neither K_1 nor K_2 are constant; rather their values change slightly with temperature and ionic strength. Values for K_1 and K_2 in dilute waters and equations describing their temperature dependence are given in Table 1. The reaction rates of these protonation/deprotonation between carbonic acid, bicarbonates and carbonates are very fast and can be considered instantaneous. The hydration of CO_2 to carbonic acid (H_2CO_3) is slower but still in the order of a few seconds meaning that for processes that alter any of the three inorganic carbon pools at longer time scales, they can be considered in equilibrium with each other. The partitioning of DIC into its three species is entirely predictable from pH and is expressed by the ionization fractions of each species (α_{sp}), i.e. their fraction of the total DIC pool (thus, the three α's always add up to one):

$$\propto_{CO_2} = \frac{1}{1 + \frac{K_1}{[H^+]} + \frac{K_1K_2}{[H^+]^2}} \qquad \propto_{HCO_3^-} = \frac{1}{1 + \frac{[H^+]}{K_1} + \frac{K_2}{[H^+]}} \qquad \propto_{CO_3^{2-}} = \frac{1}{1 + \frac{[H^+]}{K_2} + \frac{[H^+]^2}{K_1K_2}} \tag{4}$$

Fig. 1 illustrates the relative contribution of the three species to the total DIC pool as a continuous function of pH.

Another important quantity involving DIC is the alkalinity of the water, also known as the acid neutralizing capacity (ANC, expressed in μ- or mequivalents L^{-1}). In older literature alkalinity was often expressed in mg $CaCO_3$ L^{-1} or ppm $CaCO_3$. These units sum up CO_3 and HCO_3 and assume the balancing anion is Ca and then express it as a weight as if it were actually $CaCO_3$. The conversion is 50 mg $CaCO_3$ L^{-1} = 1 mequiv L^{-1} given that carbonate ions are divalent.

Because of the equilibrium described in Eq. (2) the movements between the three species act as the main buffer mechanism in freshwaters, whereby acid additions will displace the equilibrium but with only modest changes in pH, until the ANC is exhausted.

Table 1 Equations describing the temperature dependence of the acid dissociation constants K_1 and K_2 defined in Eqs. (3a), (3b).

$$pK_1 = -126.34048 + \frac{6320.813}{\text{Temp} + 273.15} + 19.568224 \cdot \ln(\text{Temp} + 273.15) \tag{T1a}$$

$$pK_2 = -90.18333 + \frac{5143.692}{\text{Temp} + 273.15} + 14.613358 \cdot \ln(\text{Temp} + 273.15) \tag{T1b}$$

Salinity correction

$$\text{T1c}: \; pK_1' = pK_1 + A_1 + \frac{B_1}{\text{Temp} + 273.15} + C_1 \cdot \ln(\text{Temp} + 273.15) \tag{T1c}$$

where $A_1 = 13.4038 \cdot \sqrt{S} + 0.03206 \cdot S - 5.242 \cdot 10^{-5} \cdot S^2$
$B_1 = -530.659 \cdot \sqrt{S} - 5.8210 \cdot S$
$C_1 = -2.0664 \cdot \sqrt{S}$

$$pK_2' = pK_2 + A_2 + \frac{B_2}{\text{Temp} + 273.15} + C_2 \cdot \ln(\text{Temp} + 273.15) \tag{T1d}$$

where $A_2 = 21.3728 \cdot \sqrt{S} + 0.1218 \cdot S - 3.688 \cdot 10^{-4} \cdot S^2$
$B_2 = -788.289 \cdot \sqrt{S} - 19.189 \cdot S$
$C_2 = -3.374 \cdot \sqrt{S}$

The dissociation constants are usually expressed on a logarithmic scale where $pK_{1\text{ or }2} = -\log_{10}(K_{1\text{ or }2})$. Eqs. (T1a), (T1b) are for dilute freshwaters (Millero, 1979). For estuarine conditions, Eqs. (T1c), (T1d) provide salinity corrections to the freshwater equations (Millero, 2010). Temp is temperature in °C and S is salinity.

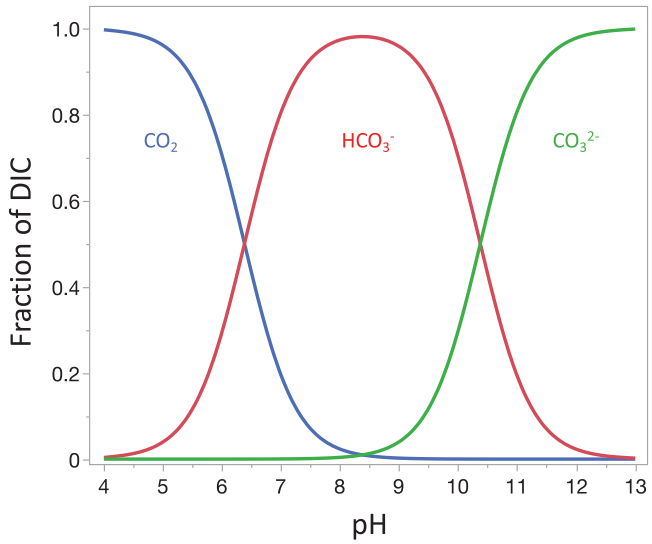

Fig. 1 The fraction of the total DIC pool comprised by CO_2 (blue), HCO_3^- (red) and CO_3^{2-} (green) as a function of pH. This diagram is common in limnology textbooks but has caused some confusion. First, it is actually the proportions of the forms of DIC that regulate the pH rather than vice versa as the diagram might suggest. Second, the *Y* axis is the fraction, not the absolute amount. It is useful to remember that at pH 6.3 the amount of CO_2 and HCO_3^- will be equal and at pH 10.3 the amount of CO_3^{2-} and HCO_3^- will be equal. Values for K_1 and K_2 are not constant but vary with temperature and ionic composition, and are quite different in seawater from the values in dilute freshwater lakes (Table 1).

Carbonate ANC is defined as

$$ANC = \left[HCO_3^-\right] + 2 \cdot \left[CO_3^{2-}\right] + \left[OH^-\right] - \left[H^+\right] \quad (5)$$

While there are other sources of alkalinity in freshwaters (organic acids, sulfate and nitrate reduction, . . .), carbonate alkalinity is by far the most important buffering mechanism. Nevertheless, in very soft waters (<100 μeq L^{-1}), dissolved organic substances can add a non-negligible source of alkalinity (about 1–3 μeq mg C-DOC^{-1}). Since HCO_3^- is generally the main constituent of DIC, it is easy to infer from Eq. (5) that DIC and ANC are generally tightly related. Conversely, Eq. (5) also shows ANC is not altered by the addition or removal of CO_2. This implies that biological processes either producing or consuming CO_2 will not change the alkalinity of the system (unless accompanied by a net change in the base cations). Nevertheless, all of the properties of the DIC complex are intricately related via the equilibrium reactions and the values of ANC, pH and CO_2 concentration form a "triad," whereby knowing any two variables, there can be only one solution for the third. This is very practical because it allows the easy calculation, for example, of CO_2 concentration from pH and Alkalinity (or DIC) measurements (see Stumm and Morgan, 1995). Fig. 2 illustrates the relationship between ANC, pH and pCO_2 at 20 °C, where pCO_2 is the partial pressure of CO_2. Because CO_2 is a gas, it is often expressed as a partial pressure rather than as a concentration. The concentration of CO_2 gas is related to pCO_2 by Henry's law: $[CO_2] = Kh \cdot pCO_2$ (where CO_2 is expressed in μmoles L^{-1}; pCO_2 in μatm and Kh is a constant that varies with temperature). At 20 °C, Kh is about 0.039 μmoles L^{-1} μatm^{-1}. Thus, if the aqueous pCO_2 is 400 μatm (the approximate current value in the overlying atmosphere), CO_2 concentration would be about 16 μM.

The dependence of the ionization fractions (the α's, Eq. 4) on pH alone has sometimes led to the misleading causal inference that it is pH that dictates the concentrations of the constituents. In fact, it is more appropriate to view the CO_2 system as controlling pH. Indeed, even large additions of CO_2 to an aqueous solution of a given alkalinity will induce only a very small shift in the bicarbonate and carbonate concentrations and will instead remain as dissolved CO_2, thereby inducing a substantial lowering of pH. Note that there is a strong asymmetry in this equilibrium process in that removal of CO_2 by photosynthesis or other process can draw a significant amount of CO_2 from the bicarbonate + carbonate pool. Such movements can be important to consider when CO_2 is measured by headspace equilibration (Koschorreck et al., 2021). It is also true that if one adds an acid or a base to lake water, both the pH and the species of DIC will be altered.

Dissolved organic carbon (DOC)

Unlike DIC, dissolved organic carbon is a very heterogeneous mixture of thousands of different organic compounds, the concentrations of which are generally not subject to a chemical equilibrium although some may be. Recent analytical capabilities have revealed that the general order of abundance is highly unsaturated and phenolic compounds > polyphenolic compounds > condensed aromatics > aliphatic compounds, although this order can change upon degradation (Kellerman et al., 2018). The carbon concentration of the bulk DOC pool varies broadly from less than 1 mg to over 300 mg C L^{-1} although the vast majority of lakes fall below 30 mg C L^{-1} (Sobek et al., 2007). In the newer literature, DOC is often expressed in molar units of C, thus the range would be from <80 to >2500 μM. In many freshwater ecosystems, DOC constitutes by far the largest pool of

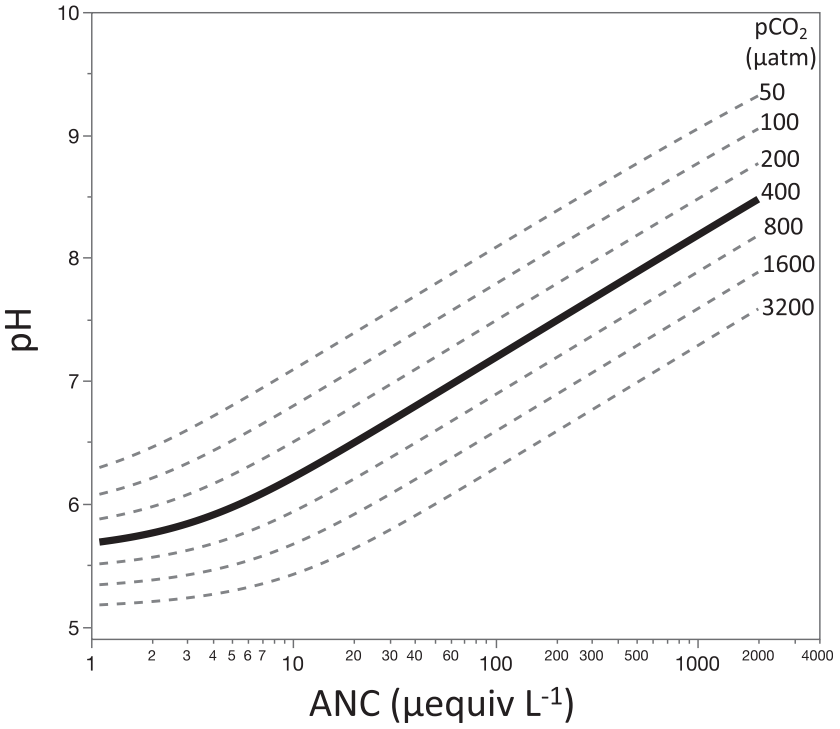

Fig. 2 The triadic relationship between pH, ANC and pCO_2 at 20 °C. Solid line represents atmospheric equilibrium at approximate current levels of 400 µatm (2020).

organic carbon in the water column, exceeding that of phytoplankton except in very eutrophic systems. The nature of the DOC can be characterized in several ways using optical properties, size exclusion chromatography, and more recently, the molecular formula of individual compounds (Stubbins et al., 2014). The colored fraction of the DOC (known as CDOM, m^{-1}) is often a useful metric of its reactivity, particularly with regards to the absorption of light energy. DOC can also be characterized by stable isotopes and both ^{13}C and ^{2}H have been useful. Based on both of these isotopes, DOC in lakes appears to be largely to entirely of terrestrial origin, at least in the small lakes that have been studied (Bade et al., 2007).

Particulate carbon in the water column

In the water column, particles of both organic C (particulate organic C or POC) and particulate inorganic C (PIC) can occur. PIC is a rare and short-lived phenomenon in most lake and generally happens only in those lakes that are both eutrophic and have large amounts of DIC and ANC. During a phytoplankton bloom, CO_2 can be reduced to very low levels thus raising the pH to the point where the solubility of calcium carbonate is exceeded. In Lake Michigan, for example, these "whiting events" occur every few years. In lakes with low DIC, even if there is CO_2 draw down from the atmosphere, there is insufficient carbonate to form a precipitate.

Particulate organic C is defined operationally as those organic particles that are caught on a GF/F filter (about 0.7 µm pore size) but pass through a 63 µm plankton net. Thus, POC in the water column includes living phytoplankton, bacterioplankton, protozoa, and some of the very smallest rotifers as well as detritus. This organic detritus can be the remains of planktonic organisms or detritus of terrestrial origin. The inputs of POC to lakes include phytoplankton primary production, resuspension from the sediments, and inputs of terrestrial particles in streamflow or from the air. The concentrations of POC tend to be much lower than that of DOC, typically about 10-fold lower. Isotopic approaches have shown that POC is a mixture of terrestrial and within-lake sources and this mixture varies along gradients over which these two sources vary.

Carbon transformation processes and lake metabolism

At the broadest level, carbon transformation processes in lakes are the conversion of inorganic carbon to organic forms, and its reverse process, the mineralization of organic compounds to inorganic C, mostly CO_2. These two processes are not regulated by the same drivers and are therefore only loosely coupled. The balance between them is commonly known as the "net lake metabolism" and can be summarized by the general bulk stoichiometric reaction.

$$106\,CO_2 + 106\,H_2O + 16\,NH_3 + H_3PO_4 \underset{\text{Respiration}}{\overset{\text{Primary production}}{\rightleftharpoons}} (CH_2O)_{106}\,(NH_3)_{16}(H_3PO_4) + 106\,O_2 \quad (6)$$

While the fixation of inorganic C in lakes (forward reaction) is essentially performed by primary producers through photosynthesis (micro-algae and macrophytes), the mineralization of organic carbon (backward reaction) can be autotrophic, microbial (heterotrophic respiration) and photo-chemical. In general, microbial respiration accounts for the majority of the mineralization of organic matter in lakes. While this bulk equation (Eq. 6) conforms to the average stoichiometric composition of aquatic biomass (C:N:P = 106:16:1, the Redfield ratio), heterotrophic respiration of organic matter can have different elemental ratios (Berggren et al., 2012). In the broad sense, all biological carbon transformations are either a production or a respiration process, both of which are apportioned among autotrophs and heterotrophs, and can be quantified at any scale: from individual cells to entire ecosystems, or for broad single compartments such as bacteria, phytoplankton, benthic plants, zooplankton, benthos, or fish.

Primary production

Carbon fixation by aquatic primary producers primarily uses dissolved carbon dioxide (CO_2) as the main substrate although many species can use also HCO_3^- ions when ambient dissolved CO_2 is depleted or through various carbon concentrating mechanisms (CCM) (Maberly and Gontero, 2017). At the cellular level, photosynthesis in algae is often described as Monod kinetics whereby rates are limited by the concentration of the main limiting substrate, CO_2. When at equilibrium with the atmosphere, CO_2 concentration in water is around 16 μmole L^{-1} (at 20 °C) which is well below the half-saturation constants of many freshwater algal and macrophyte species (>50 μmole L^{-1}). As a result, rates of aquatic photosynthesis can be enhanced in higher CO_2 concentrations (Jansson et al., 2012). While rates of primary production can therefore be considered limited by inorganic carbon, algal biomass at the ecosystem level is generally limited by a combination of light and nutrients, most notably phosphorus. Inorganic carbon is not considered biomass limiting at this scale because it can be replenished by CO_2 exchange with the atmosphere. It can however strongly affect the composition of the phytoplankton assemblage responsible for pelagic photosynthesis (Low-Décarie et al., 2015).

At the ecosystem scale, primary production occurs in two spatially distinct compartments: benthic and pelagic. Their magnitude is often inversely related and their relative contribution to total lake photosynthesis is usually determined by factors regulating light penetration and by the areal coverage of the littoral zone. Benthic primary production is generally low when phytoplankton abundance is high because of the reduced light penetration to the surface of the sediments. Thus, the contribution of benthic primary producers to the overall production of the lake ecosystem declines with increasing lake trophic status (Vadeboncoeur et al., 2003). Conversely, it can represent most of the lake's productivity, particularly in shallow oligotrophic systems. Among lakes, pelagic primary production spans a very large range, from a few mg C m^{-3} d^{-1} in oligotrophic lakes to >2000 mg C m^{-3} d^{-1} in hyper-eutrophic conditions. Among lakes, differences in both primary production and biomass are thus largely explained by variation in phosphorus concentration although nitrogen is often considered co-limiting. The relationship between algal biomass (expressed as the concentration chlorophyll-*a* in the water column) and phosphorus concentration has served as the basis for the management of eutrophication worldwide (Schindler, 2006). Primary production reaches a plateau in hyper-eutrophic condition when light becomes the limiting factor.

The diurnal cycle in photosynthetic activity induces corresponding variations in the CO_2 concentration of the photic zone of lakes, variations that are used to estimate the magnitude of photosynthesis. The daily amplitude of the CO_2 signal can be quite large and depends on the rates of photosynthesis (Gross Primary Production, GPP) and respiration (R, heterotrophic + autotrophic) as well as on the rate of exchange with the atmosphere (Eq. 7):

$$\frac{d[CO_2]}{dt} = GPP - R \pm Atm.exch. \quad (7)$$

Assuming that R is constant throughout the day and night, estimates of GPP and R can be extracted from time-series of CO_2 (Fig. 3) provided an accurate CO_2 air-water exchange can be obtained (see section CO_2 flux at the air-water interface below). This simple model assumes that, at such short time scales, changes in external inputs and outputs can be neglected. A significant advantage of this approach to quantify aquatic primary production is that it integrates all photosynthetic compartments (algae and macrophytes, pelagic and benthic).

The carbon fixed by photosynthesis has multiple fates. First, it is an important food source for heterotrophic organisms (zooplankton, some rotifers) and thereby sustains a large portion of the whole aquatic foodweb of lakes. As the energy is transferred with various efficiencies to higher components of the trophic chain, organic matter will be lost to respiration in form of the CO_2. Second, upon senescence organic matter (whether of plant or animals) will settle to the sediment floor of lakes where it will undergo either further degradation or be permanently buried (see "Carbon sedimentation" section). Third, all forms of primary production (pelagic and benthic algae and macrophytes) are associated with some release of organic compounds back to the water column (Cole et al., 1982; Demarty and Prairie, 2009; Wyatt et al., 2014). The importance of such autochthonous DOC varies widely among lakes and will fuel further microbial metabolism. In shallow lakes with high coverage of aquatic plants, the release of DOC by macrophytes can exceed allochthonous organic inputs.

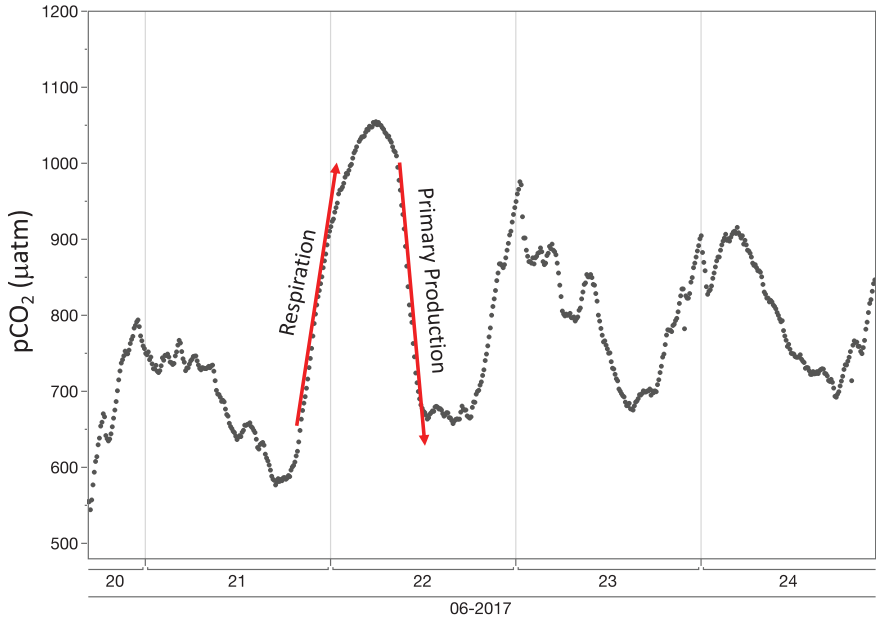

Fig. 3 Diurnal cycle in pCO_2 in L. Croche (Québec) over a period of a few days. Rates of respiration and primary production can be inferred by the pCO_2 oscillations (red arrows) once gas exchange at the air-water interface is taken into account. Irregularities in the diurnal cycles generally originate from intermittent clouds and/or wind-induced changes in gas exchange.

Microbial degradation of DOC

The rate of degradation of DOC by microbes depends on the nature of the organic material as well as on the microbial communities involved. In general, the rate of DOC consumption increases with the concentration and lability of the DOC. While the DOC exuded from autochthonous production (algae and macrophytes) can be consumed rapidly, lake DOC of allochthonous origin has a slower degradation. Further, short-term lake water incubations have shown that the decomposition is not linear in time and is therefore better approximated as a first-order reaction, with decay constants generally in the range of 0.005–0.10 d^{-1}. Decay rates vary according to chemical groups. For example, aromatic compounds tend to have slower decays while simpler molecules such amino acids, proteins and sugars are much more labile. Recent methodological advances using FT-ICRMS have permitted to follow the degradation of the individual organic compounds (or elemental formulas) comprising the DOC and have shown that different compounds decay at very different rates and that some organic molecules are actually generated as a product of microbial metabolism (Mostovaya et al., 2017). This has led to the confirmation of the so-called "reactivity continuum concept" whereby lake DOC cannot be viewed as a single carbon pool of homogenous reactivity but instead as a complex mixture comprising a continuum of reactivities. A popular model (originally developed by Boudreau and Ruddick (1991) for sediment processes) describing the time course of mineralization of a DOC mixture that account for the spectrum of biological reactivities is

$$[DOC]_t = [DOC]_0 \left[\frac{\alpha}{\alpha + t}\right]^{\upsilon} \tag{8}$$

where $[DOC]_0$ and $[DOC]_t$ are respectively the DOC concentrations initially and at time t (in days), and α and ν are parameters describing the probability (gamma) distribution of reactivities within the DOC pool. The α describes the average half-life of the more reactive compounds and ν is a dimensionless shape parameter related to the reactivity of the most abundant species. This model (Eq. 8) is extremely flexible and can accommodate a large range of initial distribution of reactivities of the compounds. Fig. 4 illustrates how the relative distribution of the reactivities will change in time as degradation progresses, with the more reactive compounds disappearing at a faster rate. Accordingly, the same model can be used to illustrate how the apparent decay rate (k_{DOC}, d^{-1}) of the whole DOC pool (the weighted average of the reactivities, dash lines in Fig. 4) will also decrease in time as the more labile material becomes progressively exhausted.

The instantaneous degradation constant at any given time ($k_{DOC\ t}$, in d^{-1}) is given by

$$k_{DOC\ t} = \left[\frac{\upsilon}{\alpha + t}\right] \tag{9}$$

Beyond its simple description of a complex biogeochemical process, the reactivity continuum concept described above has important consequences on our understanding of DOC dynamics of lakes in their landscape. The water residence time of lakes (τ_w), the average time a water molecule spends in the lake before being lost to the outflow, is typically in the order of a few months to a few years, much longer than the degradation time scale of the more labile organic compounds (a few days). Thus, the molecular profile and the biological reactivity of the lake DOC can be quite different from that of the allochthonous DOC fueling the lake

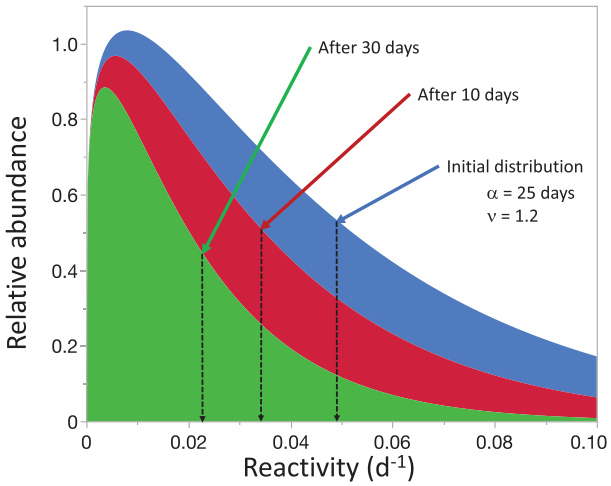

Fig. 4 Illustration of the reactivity continuum concept whereby the abundance of the most reactive compounds (right side of the abscissa) is more rapidly lost, leading to a shift in the distribution of the reactivities (colored surfaces, expressed here as probability density) as time of degradation progresses. Dashed arrows correspond to the average reactivity of the DOC pool ($k_{DOC\ t}$) at different times (initial, 10 days, 30 days) given by Eq. (9).

because the bulk of the easily degradable DOC forms has already been mineralized. Consequently, lake DOC will in general exhibit a much lower apparent decay rate that its main source material (riverine input) and the extent of the decoupling will vary inversely with the water residence time of lake. This implies that even within a region where the nature of the terrestrial DOC is expected to be relatively uniform, lakes with different hydrological regimes will exhibit very different DOC degradation rates.

The effect of hydrology on DOC degradation can be quantified by accounting simultaneously for the continuum of reactivity (α and ν) and for the distribution of water ages within a lake. Assuming for simplicity that fluvial inflows are instantaneously and completely mixed once in the lake, the distribution of water ages about the average water residence time is expected to follow an exponential distribution. Combined with the reactivity continuum parameters, the inverse relationship between organic matter decay constant (k) and lake hydrology can be well approximated by $k = \frac{0.85\ \nu}{\tau_w} \ln\left[1 + \frac{\tau_w}{\alpha}\right]$ (Fig. 5). Nevertheless, lakes with long water residence times will process a larger fraction of the organic carbon load they receive from their catchments even if their overall decay rate is slower. The exact form of the relationship will depend on the reactivity parameters of the source material (insets of Fig. 5) and also of the autochthonous DOC produced (Vachon et al., 2017).

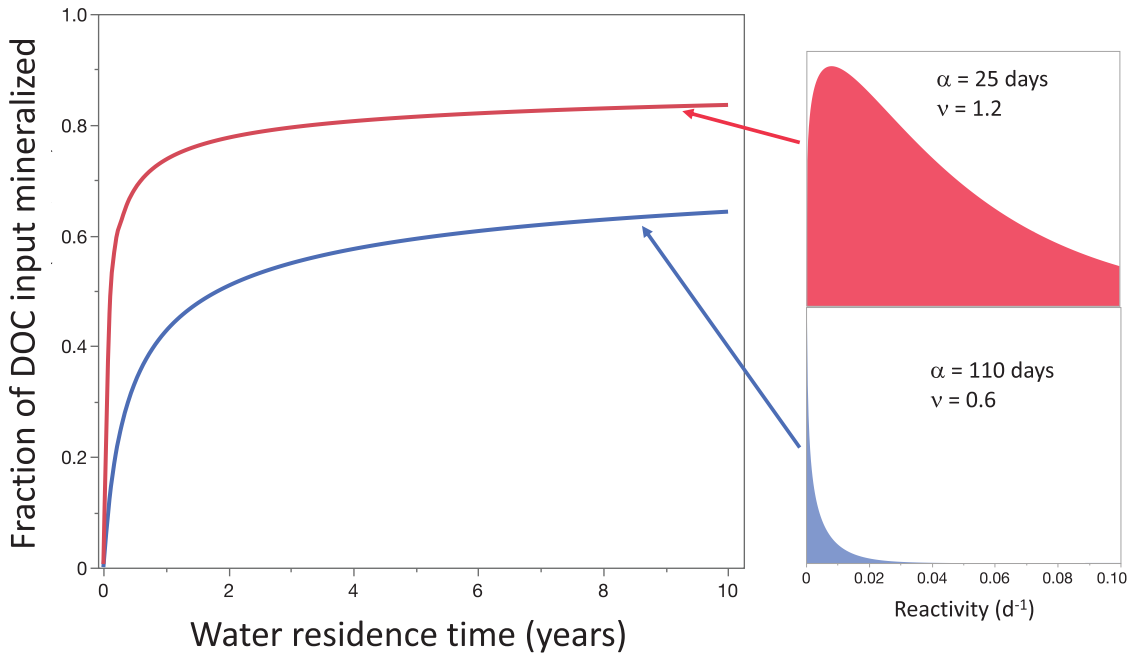

Fig. 5 The influence of water residence time (τ_w, in years) on the fraction of the incoming DOC loads lost annually to mineralization. Depending on the reactivity of the organic material (reactivity distributions on right), the influence of water residence time can be markedly different.

Fate of the organic carbon inputs processed by microbes

For lakes with water residence times greater than 6 months, Fig. 5 shows that a substantial portion of the allochthonous DOC inputs will be processed by microbes. Aquatic microbes are fairly efficient at converting their substrate (DOC) into microbial biomass. In many systems, a bacterial growth efficiency between 10% and 30% is observed but can reach up to 50% in eutrophic systems where a larger fraction of the ambient DOC pool is derived from algal production and associated release of more labile organic carbon. The microbial biomass produced will eventually make its way to higher components of the food web through flagellates and ciliates or through mixotrophic algae. In small DOC-rich lakes, even fish can be construed as being partially composed (up to about 30%) of organic carbon of terrestrial origin and microbes play a central role in this transfer (Pace et al., 2007). In eutrophic lakes, this pathway of energy transfer is less prevalent and mostly consists of algal or macrophyte derived primary production. Thus, most of the organic carbon processed by microbes will be respired to CO_2. In lakes where allochthonous DOC sources constitute a substantial portion of the organic carbon budget, heterotrophic microbial respiration will release CO_2 in excess relative to what is assimilated by primary producers, raising the CO_2 partial pressure above that of the atmosphere and therefore act as a source of CO_2. These lakes have been termed "net heterotrophic" because R > GPP (Eq. 7). As a rule of thumb, lakes with DOC concentrations below and above the threshold value of about 5 mg C L^{-1} are, in general, net autotrophic and net heterotrophic, respectively.

Given that lakes often have DOC concentrations exceeding this threshold (Sobek et al., 2007), net heterotrophy is much more prevalent than net autotrophy. Nevertheless, eutrophic systems routinely exhibit, at least temporarily, CO_2 concentrations well below atmospheric equilibrium and therefore exacerbate the physiological CO_2 requirements of primary producers to function at sub-optimal photosynthetic rates. Reviews of the published literature suggest that the vast majority of lakes (>90%) are oversaturated in CO_2 and are therefore net emitters to the atmosphere (Cole et al., 1994). CO_2 partial pressures in the surface waters of lakes are generally within the 400–2000 μatm (or ppmv) range. If the pCO_2 in the surface water is higher than that in the air (currently about 400 μatm), the net flux of CO_2 will be from the water to the air. We call this condition supersaturation. The converse is called undersaturation. In hypolimnetic waters, pCO_2 can reach much higher values because of isolation from atmospheric exchange but rarely exceeds 10,000 μatm, roughly corresponding to the complete depletion of O_2 from aerobic respiration (Eq. 7, backward reaction). A caveat is that CO_2 excess is not always the result of in situ metabolism but can also originate from other sources, such as inputs of CO_2-rich groundwaters or other geologic processes (Vachon et al., 2016).

Carbon loss processes

At the ecosystem level, there are only three possible fates for carbon: fluvial outflow, outgassing of CO_2 and sedimentation. The relative importance of the loss pathways is very variable among lakes and is still not fully understood. While lakes with very short water residence times will naturally lose most of their carbon through the outflow, the partitioning between evasion and sedimentation is an active area of research and will generally depend on the source and nature of the organic material. In oligotrophic lakes, CO_2 diffusion at the air-water interface will dominate while sedimentation and burial are more important is eutrophic lakes. In this section, we review the processes modulating the magnitude of each of the main loss processes.

CO_2 flux at the air-water interface

Although many carbon-containing gases can exchange, most notably CO_2 and CH_4 but also some volatile organic compounds (VOCs), this section will pertain mostly to CO_2 because CH_4 is treated in other chapters. Carbon dioxide, like all gases, obey basic principles of gas equilibrium (ideal gas law), which states that gases contained in a system with both a gas and a liquid phase are driven to an equilibrium in which their partial pressures in the two phases become equal ($pCO_{2(air)} = pCO_{2(water)}$). In air, the partial pressure of a gas is equivalent to its mole fraction at standard barometric pressure (1 atm). This is because a mole of any gas occupies the same volume at any given temperature and pressure. Thus, partial pressure and concentration in air follows the same relationship for all "ideal" gases. In water however, the relationship between partial pressure and concentration varies between gases because of their different solubilities. For example, if CO_2 and CH_4 are present in lakes at the same concentration of say 200 μmole L^{-1}, the partial pressures exerted by the two gases would be about 5100 and 133,333 μatm at 20 °C, respectively, because CO_2 is much more soluble than CH_4. The relationship between partial pressure and aqueous concentration is given by Henry's law.

$$[Gas] = k_H \cdot pGas \tag{10}$$

where the square bracket represents concentration, p the partial pressure and k_H is Henry's constant for the particular gas at hand. Some gases deviate from this "ideal gas" relationship with partial pressure. For such gases, partial pressure is replaced by fugacity, which corresponds to the effective partial pressure and differs from the mechanical pressure the gas exerts at a given concentration. For CO_2, fugacity and partial pressure are nearly equal in the range of temperature and hydrostatic pressure normally found in lakes and therefore are often used interchangeably. Despite the name, Henry's constants k_H for gases are not constant but are instead dependent on temperature. For CO_2, k_H is about 0.039 at 20 °C but can be estimated for any lake temperatures (0–40 °C) using.

$$\ln k_{H(CO_2)} = -60.2409 + \frac{9345.17}{T + 273.15} + 23.3585 \cdot \ln\left(\frac{T + 273.15}{100}\right) \tag{11}$$

where T is temperature (in °C).

If all lakes were in equilibrium with the atmosphere ($pCO_{2(air)}=pCO_{2(water)}$), they would all exhibit the same concentration of CO_2, except for the temperature effect shown in Eq. (11). However, the mineralization of organic carbon to CO_2 or the consumption of CO_2 by photosynthesis pushes the lake water away from this equilibrium and the water therefore becomes either under or over-saturated with CO_2 with respect to the atmosphere. The ensuing air-water gradient in pCO_2 will initiate a net diffusive transport at the air-water interface of lakes following Fick's first law of diffusion:

$$Flux_{air\text{-}water} = k \cdot k_{H(CO_2)} \cdot \left(pCO_{2(water)} - pCO_{2(air)}\right) \tag{12}$$

which states that the flux (positive is outflux, mmol m^{-2} d^{-1}) is, for a given set of environmental conditions, directly proportional to the air-water concentration gradient $k_{H(CO_2)} \cdot (pCO_{2(w)} - pCO_{2(air)})$ (in mmoles m^{-3}) by a factor k, known variously in the literature as the gas exchange coefficient, exchange velocity or piston velocity (m d^{-1}). To compare the gas exchange coefficients of different gases or of a given gas at different temperatures, k is often standardized to a fixed Schmidt number (Sc). The Schmidt number is the dimensionless ratio of the turbulent transport of momentum to that of mass and therefore depends on the diffusivity of a particular gas and how it varies with temperature. In freshwaters, gas exchange velocities are usually standardized to Sc = 600, which corresponds approximately to the Sc of carbon dioxide at 20 °C and are referred to as k_{600}.

The magnitude of k_{600} depends primarily on the turbulence regime occurring at the air-water interface and is therefore largely driven by wind shear. However, convection whereby cooled surface waters sink to deeper layers also creates turbulence and can significantly contribute to k_{600}, particularly in calm conditions (MacIntyre et al., 2010; Tedford et al., 2014). It is therefore temporally and spatially quite variable and its magnitude generally varies between ≈0.5 m d^{-1} in very calm conditions to >10 m d^{-1} in highly turbulent environments (high winds over large lakes). In average conditions, k_{600} values between 1 and 3 m d^{-1} are often encountered. Several models with different input data requirements exist but a simple empirical formula to estimate k_{600} is given by

$$k_{600} = 0.602 + 0.355\ U_{10} + 0.094\ U_{10} \cdot \log_{10} Area \tag{13}$$

where U_{10} is wind speed (m s^{-1}) at a height of 10 m and Area is the lake' surface area (in km^2) (Vachon et al., 2013). The intercept term of Eq. (13) (0.602 m d^{-1}) is often considered the result of convection-induced turbulence. Since k_{600} is a velocity term that describes the exchange between epilimnetic waters and the overlying atmosphere, values of k_{600} (in m d^{-1}) can be loosely interpreted as the thickness of the epilimnion that can be re-equilibrated with the atmosphere in 1 day. This is informative because it can be compared to the actual depth of the mixed layer to infer the average time a random molecule of CO_2 (or of any gas) stays in the epilimnion before being lost to the atmosphere. This average gas residence time ($\tau_{gas} = \frac{mixed\ layer\ thickness}{k_{600}}$) in the epilimnion of lakes is typically in the order of a few days.

The formulation of the gas flux at the air-water interface in Eq. (12) can accommodate various physical representations of the actual exchange process taking place at the interface. While k is often viewed simply as the empirical exchange coefficient of Fick's diffusion law, it can be also construed as a laminar surface boundary layer of thickness (Z_{BL}) through which CO_2 diffuses strictly by molecular diffusion (D_{CO_2}, about 1.9×10^{-5} cm^2 s^{-1} at 25 °C). In this case,

$$k = \frac{D_{CO_2}}{Z_{BL}} \tag{14}$$

and Z_{BL} is a few hundred microns thick in calm conditions and considerably thinner in highly turbulent periods. Alternatively, k can also be interpreted as resulting from the exchange of small water parcels or elements of various sizes randomly reaching the surface and equilibrating with the atmosphere (Asher and Pankow, 1991). In this so-called *surface renewal model*, k is proportional to $\sqrt{\frac{D_{CO_2}}{\tau}}$ where τ is the average residence time of fluid elements at the water surface and assumed to be the same for all water elements (note that this is τ is distinct and unrelated to τ_{gas} i.e. the average gas residence time in the mixed layer discussed earlier). Further refinements of the surface renewal model have led to more detailed representation of the residence time distribution of the fluid elements at the surface.

For most gases, the choice of physical description of the gas exchange is not particularly important because they ultimately all collapse to the same general expression of gas exchange (Eq. 12). However, in certain situations, the fluxes of CO_2 at the air-water interface need to account for chemical reactions between CO_2 and other ionic species that occur at time scales that are similar to the diffusion process and thereby compete with one another. The physical representation of the exchange process then becomes relevant. While the main CO_2 hydration pathway is with water $CO_{2\ (aq)} + H_2O \rightleftarrows H_2CO_3$, CO_2 also reacts directly with OH^- ions to form bicarbonates and the CO_2 exchange with the atmosphere then becomes a diffusion-reaction system. If CO_2 is able to react chemically during its transport, it will enhance the flux and therefore result in an apparent exchange coefficient (k or k_{600}) that is higher than what would be expected from diffusion alone. The magnitude of this chemical enhancement factor (α) can be expressed as the ratio of the gas exchange coefficient with and without reaction

$$\alpha = \frac{k_{600\ (diff\ +\ reac)}}{k_{600\ (diff)}} \tag{15}$$

and will depend on the time scale of the chemical reaction relative to the time scale of the diffusion process. The faster is the reaction relative to the diffusion, the higher is the chemical enhancement factor. Consequently, chemical enhancement will be highest when the reaction is fastest (high $[OH^-]$, high pH) and diffusion slowest (thicker boundary layer, i.e. calm conditions). Various mathematical expressions have been developed to estimate α depending on the particular physical description of the exchange

process (laminar boundary layer or surface renewal model) but are beyond the scope of this chapter. In most conditions encountered in lakes however, the magnitude of α is close to 1 (no enhancement) but chemical enhancement needs to be accounted for in systems with high pH (generally associated with CO_2 depletion in eutrophic systems) and very calm conditions.

Given the physical and chemical constraints on gas exchange between lakes and the atmosphere described above, research of the past 15 years has shown that the vast majority of lakes are net emitters of CO_2. While some (mostly eutrophic) lakes are net sinks for CO_2 on an annual basis, most are sources. This can only be sustained by allochthonous organic matter that is mineralized in the lake and/or by the direct injection of CO_2-rich groundwater in the water body. The relative contribution of the groundwater source is currently poorly constrained but can very significant. Regardless of the exact source of the lake CO_2 excess relative to the atmosphere, the magnitude of the CO_2 outgassing rate is, while widely variable among lakes, surprisingly large even for the average lake. As a comparison, the amount of CO_2 emitted by a single 1 km^2 lake in 1 day is equivalent to two return trips by car per day between the residences of the two authors of this chapter (a total distance of about 5600 km)! While this natural footprint of lakes cannot be rightfully compared to anthropogenic sources, it serves well to illustrate the intensity of the carbon processing occurring in inland waters. At the larger regional or even global scales, the flux of CO_2 from lakes to the atmosphere is an important but often neglected component of the regional carbon balance (incompletely accounted for by forest carbon models) and is comparable in magnitude to the global CO_2 fluxes absorbed by the combined oceans, despite the huge disparity in areal coverage.

Carbon sedimentation and burial

The loss of carbon from the active pool via sedimentation processes is by far the least well understood part of the lacustrine carbon cycle. Even the source and nature of the sediments is, to a certain extent, only loosely known. While the remains of aquatic organisms (both plants and animals) are an obvious component of sediments, the isotopic signature of sediment carbon often suggests that it is of terrestrial origin. Sediments contain both inorganic and organic forms of carbon and their relative importance is largely determined by the geology of the catchments they drain. Lakes in the boreal regions often harbor very soft waters with little carbonate minerals in the landscapes and sediment carbon will be mostly organic. Although carbon sedimentation often represents a relatively small flux on annual basis, the high preservation of sedimentary organic carbon can lead to large accumulations over millenia (Kortelainen et al., 2004). On the other hand, lakes draining carbonaceous landscapes, such as marl lakes, will be susceptible to calcite precipitation particularly in eutrophic warm waters. The concentration of organic C in sediments is relatively low (3% by weight) in some lakes but can be as high as 30% especially in small lakes with anoxic hypolimnia.

In general, the sedimentary flux of carbon is a function of the amount of particulate material either transported from the catchment or generated within the lake. A significant component of the sedimenting material can also be dissolved organic carbon of allochthonous origin that coalesce into colloidal material to ultimately flocculate and sink down (von Wachenfeldt and Tranvik, 2008). Once sedimented, the material will undergo early diagenetic processes. However, in the time scales relevant to lake functioning, the most important one is the post-depositional mineralization of organic carbon, a process that will decrease through time. The few studies that have examined this directly suggest that after 15–25 years, most of the degradable organic carbon will be lost to mineralization (Gälman et al., 2008) while the remaining mostly terrestrial carbon is permanently buried (Guillemette et al., 2017). This is one of the most striking differences between terrestrial soils and lake sediments. The organic carbon fraction of soils is rarely more than a few hundred years old whereas sediment organic carbon remains for thousands of years and its continued accumulation makes lake sediments a significant stock of carbon even at the landscape level. In the boreal biome, organic carbon buried in soils and lake sediments are of similar magnitude even if lakes occupy a few percent of the terrestrial landscape. An enlightening manifestation of this phenomenon is the realization that the sediments of exceptionally old and deep lakes such as L. Tanganyika in Africa contain more organic carbon than the entire living biosphere! Admittedly this organic carbon can no longer be considered part of the active pool of carbon in these lakes.

The distinction between the carbon flux reaching the sediments (*carbon sedimentation*) and what remains permanently buried (*carbon burial*) is important and is highly variable between lakes. The burial efficiency, i.e. the fraction of the sedimentary influx of carbon that will be permanently buried, ranges from a low of a few percent in lakes when the source of the organic material is largely autochthonous and the sedimented material is exposed to dissolved oxygen, to nearly 100% in lakes receiving mostly allochthonous organic carbon with little oxygen exposure time. Since the oxygen penetration depth in sediments is rarely more than a few millimeters, burial efficiency generally increases with the magnitude of the sedimentation flux because the sediments are rapidly buried by newly sedimented material and therefore does not remain in contact with oxygen very long (Sobek et al., 2009). This process leads to a synergistic effect whereby lakes with higher sedimentary influx will exhibit an even faster carbon burial rate because of the associated increase in burial efficiency.

At the ecosystem scale, the process described above leads to an enormous range in sediment carbon accumulation rates, from a few g C m^{-2} $year^{-1}$ in large oligotrophic lakes to >10 kg C m^{-2} $year^{-1}$ in small agricultural ponds (Downing et al., 2008). In both artificial ponds and natural lakes, the size (surface area) of the ecosystem is one of the prime determinants of burial rate. All else being constant, carbon burial rate generally decreases with increasing ecosystem size. However, the bathymetric shape of the particular system also modulates the rate at which carbon can accumulate. Lakes with high dynamic ratios ($DR = \frac{\sqrt{Area}}{Z}$), i.e. flat lakes, tend to accumulate much less carbon than deeper lakes of the same size because a larger fraction of their surface area is in the littoral zone where degradation proceeds faster (Ferland et al., 2012).

Conclusion

The C cycle has fascinated biogeochemists working on every imaginable ecosystem or biome on Earth and particularly so for the global Terrestrial-Atmosphere-Ocean linkage. At the global scale, CO_2 is a major regulator of climate and the measured rise of atmospheric CO_2 stimulated a great deal of research into the C cycle. Limnologists have been attracted to the C cycle almost since the inception of limnology because of the central role of C in metabolism and the role of the dissolved inorganic C system in regulating both pH and alkalinity. The study of C in lakes is almost a subfield in its own right and has been called "carbocentric limnology" (Prairie, 2008). Lakes had not been thought of in the context of the global C cycle until relatively recently, but they do play a role. The sediments of lakes contain more organic C than the entire rest of the terrestrial part of the biosphere. However, the accumulation rate is slow, so the annual net flux into lake sediments is not particularly large. Further, lakes, taken together, are a modest global source of CO_2 into the atmosphere as a result of both inputs of ground water rich in CO_2 and the catabolism of terrestrial inputs of organic C into lakes.

Lakes, of course, are intimately connected to their terrestrial watersheds and receive terrestrial inputs in stream and groundwater and from the atmosphere. Further, lakes discharge water and C downstream in ground and surface water. At a broader scale each lakes is a node in a terrestrial and stream nexus. So, a chapter like this on the C cycle of lakes tends to underplay these connections. Further, it should be also obvious that there is no such thing as "the carbon cycle" in isolation. The C cycle is closely connected to the cycle of many other elements, notably oxygen, nitrogen, phosphorus, sulfur and hydrogen and calcium as well. While it is possible to focus on the C cycle, biogeochemists usually are studying C and many other elements simultaneously.

Lacustrine Phosphorus Cycling

Grace M Wilkinson and Ellen A Albright, Center for Limnology, University of Wisconsin-Madison, Madison, WI, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Bioavailable phosphorus Bioavailable phosphorus is a form that is readily available to be used by organisms to synthesize organic phosphorus molecules.
Dissolved phosphorus Dissolved phosphorus is phosphorus that is in an inorganic aqueous form (e.g., orthophosphate) or part of dissolved organic matter.
External loading External loading is the delivery of phosphorus from the watershed to the lacustrine environment.
Internal loading Internal loading is the release of phosphorus from lacustrine sediments.
Particulate phosphorus Particulate phosphorus is phosphorus associated with particles including incorporated in minerals, sorbed to particle surfaces, and bound in particulate organic matter.
Redox conditions Redox conditions describe the abundance of oxidative or reductant substances in the environment, mainly oxygen, that drive biogeochemical processes.
Sediment-water interface Sediment-water interface is the boundary between the surface of sediments and the overlying water.
Sorption/desorption Sorption/desorption is the process by which phosphate attaches or detaches from the surface of other substances such as clays and mineral oxides.

Introduction

Phosphorus is one of the elemental building blocks of life. It is a component of DNA (deoxyribonucleic acid), the cellular energy molecules ATP and APD (adenosine tri- or diphosphate), the phospholipid bilayer of cell membranes, and the material that forms bones, to name a few examples. Given the importance of phosphorus for so many biological processes, the availability of this element in the environment helps to shape ecological interactions in lacustrine ecosystems. Phosphorus concentrations in the surface waters of lakes can range from undetectable to hundreds of micrograms per liter and are tightly coupled to algal biomass (Dillon and Rigler, 1974), defining the trophic state of the lake (Carlson, 1977). Due to human activities in the watershed, many lakes are becoming enriched in phosphorus making them increasingly likely to suffer from poor water quality, deep water oxygen depletion, and a loss of ecosystem services. Phosphorus's role as a building block of life makes its elemental cycle in lakes a delicate balance between limiting ecosystem functioning when there is too little and a water quality problem when there is too much. The aim of this article is to provide an overview of phosphorus cycling in lacustrine environments including the forms, sources, pools, fluxes, and management of phosphorus in these aquatic ecosystems.

Forms of phosphorus in lakes

Elemental phosphorus is rare in nature. Instead, phosphorus in inland waters usually occurs bound to oxygen in the phosphate molecule (PO_4), which may occur as orthophosphate (PO_4^{3-}) or protonated anions ($H_2PO_4^-$ and HPO_4^{2-}). Phosphate is incorporated into many other molecules that are cycled through the biotic and abiotic components of lacustrine ecosystems. These molecules can be in an inorganic form or as a component of organic matter (Fig. 1). The inorganic form is either particulate—found in minerals or adsorbed to the surface of sediment particles—or dissolved in an aqueous solution. Orthophosphate, a form of dissolved inorganic phosphorus, is the form that is taken up by plants and algae. Organic phosphorus—a term that

 https://doi.org/10.1016/B978-0-12-819166-8.00048-7

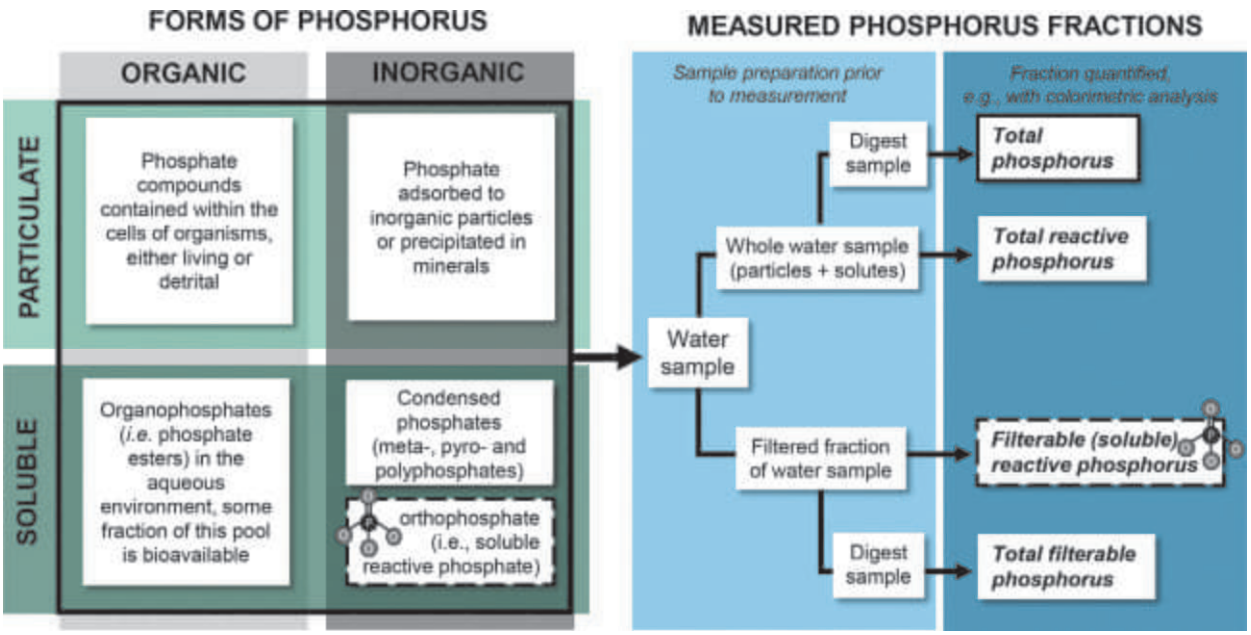

Fig. 1 There are many forms of phosphorus in aquatic environments that can be functionally separated based on whether the phosphorus is in a particulate or soluble form (*green rows*, *left panel*) and if it is part of an organic or inorganic molecule (*gray columns*, *left panel*). A water sample from the environment can contain one, some, or all of these functional forms of phosphorus (*arrow from left to right panel*). The measurement of phosphorus concentration is made from either the whole water (particles + solutes) or filtered fraction (solutes + particles smaller than the filter pore size), on either digested or non-digested samples, yielding the phosphorus fractions and concentrations measured with colorimetric analysis (*right panel*). Total phosphorus (TP; solid outline), which can contain any number of the functional forms of phosphorus, and soluble reactive phosphorus (SRP; dashed outline) are noted with boxes in both panels as they are two of the most frequently reported concentrations from lacustrine ecosystems.

encompasses a complex set of molecules—can also be dissolved in water or particulate, being contained in the living tissues or necromass of microbes, plants, and animals. In addition to the dynamics of phosphate concentrations, bioavailability, and cycling in the water column, sediments are another large pool of phosphorus that can be available for biological uptake (see "Internal Loading" section below). In the sediment, phosphorus also occurs in the particulate, dissolved (in pore water), organic, and inorganic forms (Fig. 1).

One of the most commonly reported measurements of phosphorus in inland waters is the concentration of total phosphorus, which is a measure of all the particulate, dissolved, organic, and inorganic phosphorus contained within a sample (Fig. 1). To measure total phosphorus, unfiltered water samples are digested to convert all phosphorus forms, including the phosphorus bound in organic molecules, into dissolved orthophosphate. Persulfate oxidation is a common digestion technique for samples from the water column, for which a strong acid is used to hydrolyze condensed phosphates and persulfate (an oxidant) is used to separate orthophosphate from organic compounds. The orthophosphate is then measured from the digested sample, often using a molybdenum blue colorimetric method (Murphy and Riley, 1962; APHA, 1988). While the total phosphorus concentration is a measure of all the phosphorus present in a sample, the measurement does not necessarily provide information on the forms or bioavailability of phosphorus present in the ecosystem. Instead, water samples that are filtered to remove particles can be analyzed for dissolved phosphorus fractions, such as the commonly-reported soluble reactive phosphorus. Whether the water sample is filtered prior to analysis and how it is digested determine the fraction that is quantified (Fig. 1). Measurements of dissolved phosphorus reveal more about the abundance and form of potentially bioavailable phosphorus in the environment. By definition, the concentration of dissolved phosphorus cannot be higher than total phosphorus, as it is a fraction of the whole phosphorus pool in the sample.

Soluble reactive phosphorus concentrations are usually low in the epilimnion of lakes and reservoirs even as total phosphorus concentrations are high. This can be caused by the phosphorus present in the epilimnion being bound in algal and microbial biomass or sorbed to inorganic sediment particles suspended in the water column. Repeated measurements of phosphorus concentrations and forms in lacustrine environments can provide insight into the source and dynamic cycling of this element. Ultimately, the source of phosphorus in the water column of a lake is from the watershed, including groundwater (external loading), or from the sediments of the ecosystem (internal loading). As it is the magnitude and timing of phosphorus loading that helps to shape aquatic ecosystem dynamics, particularly algal biomass, understanding the sources of phosphorus in a lake can be key to managing water quality in that ecosystem.

External phosphorus loading

Unlike nitrogen, which can enter ecosystems through fixation of gaseous N_2 into a bioavailable form by cyanobacteria, phosphorus enters aquatic ecosystems through physical transport from the watershed. Phosphate is originally derived from the weathering of

rocks, which forms terrestrial soils. Both climate and surficial geology, interacting with human land use, control the rate of weathering and abundance of phosphate from this process. The inorganic phosphate in soils can then be taken up by plants or microbes, be transported through groundwater or surface water, or sorb to soil particles and be transported through erosive processes. During snowmelt or precipitation events, eroded soil is transported through surface runoff and can enter nearby waters. The magnitude of external loading from soil erosion is mediated by the magnitude of the precipitation event and soil conditions prior to and during the event. Bed and bank erosion in streams during high energy flows will also transport substantial amounts of phosphorus downstream. In addition to runoff-driven soil erosion, wind-driven erosion can mobilize fine particles and deposit them in lakes. Eolian deposition of phosphorus-containing particles can contribute substantially to the phosphorus budgets in distant waterbodies, particularly alpine lakes with few other external inputs.

Phosphorus can also enter aquatic ecosystems as part of an organic molecule. Similar to inorganic forms, detrital particles containing phosphorus can be transported through runoff and deposition from the atmosphere. However, phosphorus contained in dissolved organic matter produced in the watershed is likely a larger source of organic phosphorus in the water column of many lakes. Dissolved organic matter in lakes is often derived from the surrounding terrestrial environment. In undisturbed catchments, exogenous dissolved organic phosphorus can have a large effect on the total phosphorus concentration within a lake. However, in disturbed catchments, high phosphorus concentrations are more commonly the result of human activity.

Global phosphorus and nitrogen cycles have been greatly disrupted by anthropogenic land use and resource extraction, leading to widespread eutrophication of inland and coastal waters. Mining of phosphorus-rich minerals for use in fertilizers has led to phosphorus accumulation in soils globally, particularly agricultural soils, which has increased phosphorus loading to lacustrine environments through surface runoff and groundwater infiltration (Bennett et al., 2001). Agricultural practices like tilling also lead to higher rates of soil erosion, further exacerbating the magnitude of phosphorus loading from the catchment. Practices such as conservation tillage reduce soil erosion, and therefore the flux of particulate phosphorus to receiving waters. Livestock operations are another potential source of agricultural phosphorus pollution. While nonpoint sources of phosphorus from agriculture, urbanization, and other land-use change are pervasive (Carpenter et al., 1998), municipal and industrial effluent can also be substantial point sources of nutrient pollution. A consequence of all these human activities is an increasing amount of phosphorus stored in the watershed that is susceptible to erosion and leaching into surface waters (Kusmer et al., 2019). This pollution threat is further aggravated by changes in precipitation frequency and intensity due to climate change. Once phosphorus has entered a lake from the surrounding watershed, it can be taken up into biomass and cycle through the food web, be transported further downstream, or be stored in the bottom sediments with the potential to be either buried or released back into the overlying water.

Internal phosphorus loading

Internal loading is the release of phosphorus from lakebed sediments to the overlying water column where it is available for uptake by planktonic organisms or export further downstream (Orihel et al., 2017). The sediment phosphorus pool is composed of both organic and inorganic phosphorus, deposited through external loading from the watershed or as detrital particles from internal production. In some lakes, the retention of phosphorus in the sediments through immobilization and burial can be greater than the amount released into the water column, causing the sediments to be a net sink of phosphorus in the ecosystem. Yet in many nutrient-rich lakes, the release of phosphate from the sediments contributes substantially to the bioavailable phosphorus pool in the water column. When sediment-released phosphate reaches the photic zone, it supports phytoplankton blooms that can reach nuisance or even harmful levels. Even with substantial reductions in external phosphorus loading, internal loading of legacy phosphorus from the sediments can continue to fuel algal production, delaying improvements in water quality. As such, being able to predict the timing, location, and magnitude of internal phosphorus loading is key for managing water quality in many lakes. However, the physical, chemical, and biological mechanisms that lead to internal loading vary in both space and time, complicating the prediction of this influential phosphorus flux.

One of the main pathways for internal loading is the movement of phosphate from sediment pore water into the overlying water through diffusion. The phosphate concentration gradient between the pore water and the overlying water column drives the rate of diffusive internal loading (Fig. 2, bottom panel). Numerous processes control the concentration of phosphate in pore water including sorption to and desorption from mineral oxide and clay surfaces, complexing with and dissociation from dissolved organic matter, the formation and dissolution of phosphate-containing minerals, and biological uptake and release through organic matter decomposition and subsequent phosphorus mineralization (Goldberg and Sposito, 1985; Reitzel et al., 2007). Sorption, complexing, precipitation, and uptake processes remove phosphate from the pore water, which decreases diffusive internal loading. Conversely, desorption, dissociation, dissolution, and mineralization release phosphate into the pore water. For example, when conditions at the sediment-water interface or deeper in the sediment profile become anoxic (no oxygen available), iron and manganese oxides will undergo reductive dissolution, which will release any sorbed phosphate. As a result, pore water phosphate concentrations will increase as will the diffusive phosphate flux from the sediments. Phosphorus release due to reductive dissolution under favorable sediment redox conditions was demonstrated early on by Mortimer (1941) studying the sediments of Lake Windermere (United Kingdom). Mortimer's research was foundational to understanding diffusive phosphorus flux from sediments and coupled iron-phosphorus cycles. However, many mechanisms besides redox conditions control sediment phosphate sorption capacity and thus diffusive internal phosphorus loading. These mechanisms include temperature, pH, microbial activity, aqueous phosphate concentrations, sorption site competition, concentrations of alternative electron acceptors, and the geochemical characteristics of the sorbent (Jensen and Andersen, 1992; Caraco et al., 1993; Hupfer and Lewandowski, 2008).

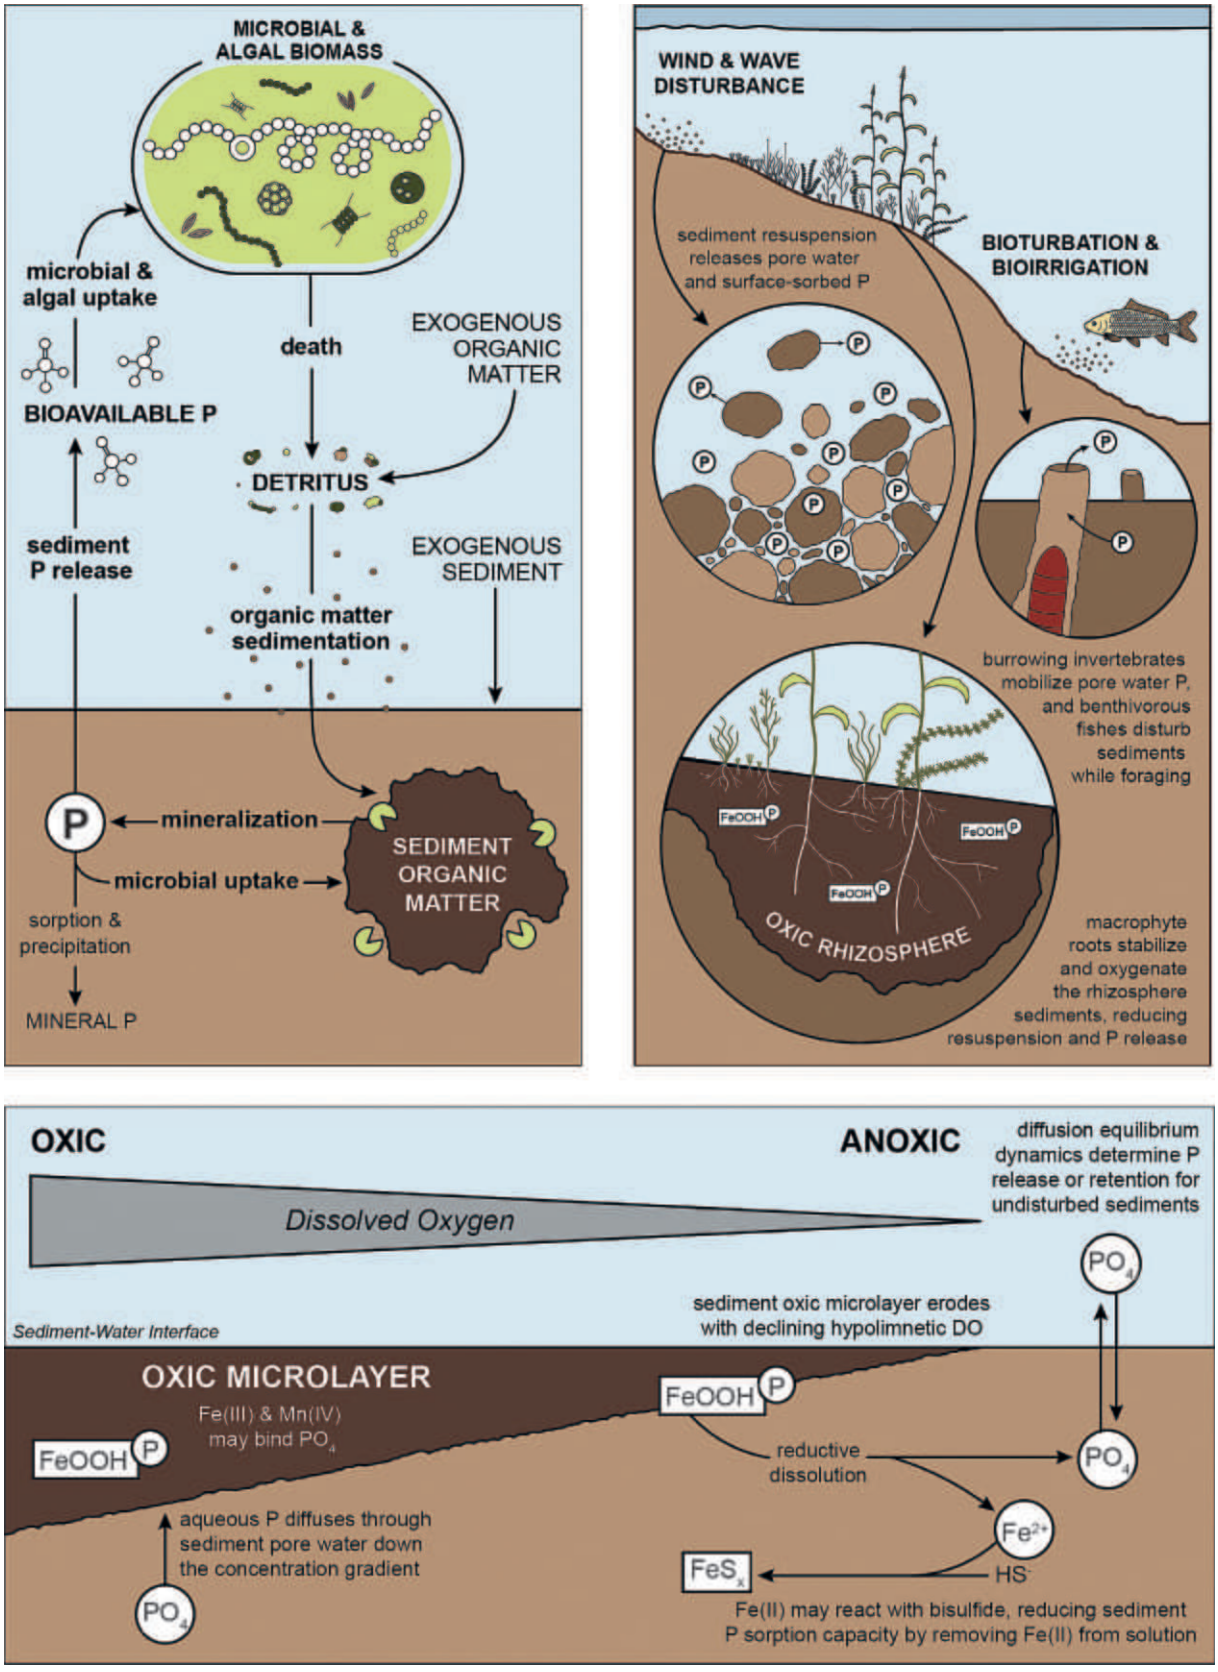

Fig. 2 Phosphorus cycling at the sediment-water interface. Panels focus on the importance of sediment organic matter in biologically-mediated internal phosphorus loading (top left), the role of sediment disturbance and stabilization in internal phosphorus loading (top right), and some of the physical and chemical processes that drive sediment phosphorus dynamics under variable oxygen availability (bottom).

The phosphorus incorporated in organic matter is another active pool of sediment phosphorus. The sedimentation of detritus from the water column, which is a combination of production from within the lake (endogenous) and organic matter from the watershed (exogenous), adds to benthic detritus from biofilms and rooted macrophytes, forming the sediment organic matter pool (Fig. 2, top left panel). Sedimentation of endogenous organic matter is particularly high in nutrient-rich lakes due to the large amount of algal production that escapes consumption. Respiration by heterotrophic microbes leads to the release of the phosphorus bound in sediment organic matter, often leading to increased concentration of soluble phosphorus in pore water (Orihel et al., 2017). Microbes exude phosphatase enzymes that convert less bioavailable forms of phosphorus into the more labile form, orthophosphate (PO_4^{3-}). This biologically-mediated conversion of phosphate can result in high rates of internal loading under aerobic conditions at the sediment-water interface.

Phosphate released into the water column from diffusive flux from sediment pore water will build up in the hypolimnion of stratified lakes. In deeper waters, the hypolimnion is largely aphotic, preventing biological uptake of internally recycled phosphate from the sediments. However, entrainment of deeper water during storm events, internal seiches, or seasonal mixing can make substantial amounts of internally-recycled phosphorus available for uptake by organisms in the photic zone. For example, in Lake Mendota (Wisconsin, United States), internally-recycled phosphorus can become entrained from deeper waters when the thermocline is deepened in the summer following storm events. During a typical year of runoff, entrainment was estimated to be 10 times greater than the external loading of phosphorus to the epilimnion of the lake, whereas it was equivalent to external loading during a year with higher-than-average runoff (Soranno et al., 1997).

In addition to the diffusive flux of phosphorus from undisturbed sediments, internal loading can also occur through advection from physical disturbances. The resuspension of sediment from wind, wave, and gas bubble disturbance leads to the release of pore water phosphorus and potentially the release of loosely bound phosphorus from sediment particles (Fig. 2, top right panel). In general, wind-driven sediment disturbances are episodic, and their spatial distribution in the lake is dictated by both bathymetry and fetch. As such, the contribution of wind-driven disturbances to internal loading is dynamic, likely creating hot spots and hot moments of sediment phosphorus release from shallow sediments. Bioirrigation and bioturbation from organisms such as burrowing invertebrates and benthivorous fishes cause physical sediment disturbance similar to wind. In addition to physical disturbance, burrowing organisms can also modify the redox conditions in the sediment profile, altering the rate of the chemical processes controlling internal loading.

In shallow lakes, aquatic macrophytes play an influential role in internal phosphorus loading dynamics. Macrophyte beds promote the retention of particulate phosphorus in lakebed sediments by limiting resuspension events. Specifically, macrophyte root systems stabilize rhizosphere sediments while the macrophyte canopy reduces turbulent flow above the sediments. However, by reducing turbulent flow, macrophyte beds can also increase local sedimentation rates and organic matter inputs to the sediments. Heightened organic matter accumulation in macrophyte beds may mobilize phosphorus through mineralization or the dissolution of redox-sensitive phosphate minerals if organic matter decomposition consumes all available oxygen at the sediment-water interface. Local, nighttime anoxia has been observed in dense macrophyte beds due to reduced water column mixing and decomposition (Vilas et al., 2017). Few quantitative studies have addressed reduced resuspension versus increased organic matter accumulation in macrophyte beds, so the net effect on internal phosphorus loading remains unclear. The balance of these processes likely varies among different lakes and across seasons in temperature waterbodies.

Macrophytes additionally mediate sediment phosphorus dynamics through radial oxygen loss and root exudates within the rhizosphere. Dissolved oxygen can leak from root tissue into the surrounding sediments, yielding an oxygenated rhizosphere. Radial oxygen loss is associated with phosphorus retention in rhizosphere sediments because oxidizing conditions protect iron and manganese oxides from dissolution, increasing sediment phosphorus sorption capacity (Han et al., 2018). The root exudates of some macrophyte species contain chelating agents that facilitate the dissolution of iron- and aluminum-phosphate minerals, mobilizing any sorbed phosphorus. However, this phosphorus release is tightly coupled with plant uptake and is unlike to release phosphorus directly into the water column (Xing et al., 2018). Although macrophytes are associated with processes that may either enhance or limit internal phosphorus loading, available evidence suggests that macrophytes tend to constrain sediment phosphorus release.

The relative importance of the physical, chemical, and biological mechanisms that control internal phosphorus loading in lacustrine environments is highly dependent on the characteristics of the individual ecosystems and the timescale under consideration. For example, the chemical speciation of iron and phosphorus in the sediments and relative abundance of iron to phosphorus (Fe:P ratio) is a control point for internal loading through the adsorption pathway. Similarly, the abundance of ions that compete with phosphate for sorption sites will also alter internal loading rates (Caraco et al., 1993). Physical characteristics will additionally dictate the spatial and temporal dynamics of internal loading. Shallower lakes may experience frequent episodes of sediment resuspension or brief periods of stratification and mixing which could lead to short pulses of phosphate release. The relative importance of these mechanisms can also change depending on the timescale of interest; physical disturbance may be overwhelmingly important for phosphorus flux on the order of hours or days but less important on an annual basis when compared to other processes such as remineralization or desorption from iron. Timescale is also important when considering the method for quantifying internal phosphorus loading rates in a lacustrine ecosystem.

Measuring internal loading rates

Internal phosphorus loading rates vary considerably among waterbodies. Meta-analyzes of internal loading rates in over 100 lakes and reservoirs around the globe revealed that rates may range anywhere from −27 to 54 mg TP m^{-2} day^{-1} (Nürnberg, 1988; Orihel et al., 2017). Negative rates indicate that sediments retain phosphorus while positive rates signify sediment phosphorus release into

the water column. The relative importance of internal phosphorus loading compared to external phosphorus sources also varies across systems. In some waterbodies the annual internal phosphorus load is masked by large external phosphorus loads; however, in other waterbodies, internal phosphorus loading drives the phosphorus dynamics in the water column (Nürnberg, 1984). Internal phosphorus loading rates are controlled by site-specific mechanisms and basin characteristics and may change dramatically across seasons in temperate waterbodies. As such, it is difficult to predict precise internal loading rates without direct measurements or modeling approaches. However, it is generally assumed that recycling of phosphorus from the sediments is more likely if the hypolimnion is anoxic, although this paradigm is challenged by observations of high release rates from oxic sediments and oligotrophic lakes that experience anoxia with minimal phosphate release (Prairie et al., 2001).

Sediment core incubations, benthic flux chambers, or mass balance approaches are often used to quantify internal loading rates. The appropriate measurement technique should be selected based on research objectives, data availability, and the timescale of interest. Core incubations are performed by removing an intact sediment core with overlying water from the ecosystem and incubating it under ambient or experimental environmental conditions. The rate of change in phosphorus concentration in the overlying water, usually measured every few hours or days, is used to calculate an aerial rate of internal loading. Similarly, deploying benthic flux chambers and measuring the increase of phosphorus concentrations in the overlying water provides a short-term aerial estimate of phosphorus flux. Core and chamber methods have the advantage of allowing investigators to study the variation in rates among sub-habitats, among seasons, or to experiment with environmental conditions to learn more about the mechanisms controlling internal loading rates. However, these methods are also subject to so-called "bottle effects" that can be induced by sealing off the area of measurement from the inputs and dynamics of the surrounding environment.

Mass balance approaches for quantifying internal loading rates do not suffer from bottle effects as these approaches estimate internal loading at the ecosystem scale. In its simplest form, a lake phosphorus mass balance model accounts for the mass of phosphorus in the water column and assumes this mass to be constant. As such, all inputs and outputs of phosphorus from the system must be balanced. Internal phosphorus loading can be estimated from a mass balance model if all other major inputs (e.g., surface and ground water inflows, atmospheric deposition) and outputs (e.g., surface and groundwater outflows) of phosphorus are measured (Mitchell, 1984). Advances in this modeling approach include partitioning lakes into multiple water and sediment compartments and allowing the water column phosphorus mass to be dynamic over time.

Mass balance approaches quantify the net phosphorus exchange between sediments and the water column for an entire lake ecosystem, generally over the course of a year. At this timescale, net loading represents the balance between sediment phosphorus release and retention via sedimentation (Orihel et al., 2017). Although this ecosystem-scale perspective is valuable, estimation of internal phosphorus loading via mass balance cannot reveal when or where sediment phosphorus release is likely to occur or illuminate the underlying mechanisms. Additionally, direct measurements of internal loading rates via core incubations or benthic flux chambers are unlikely to match estimates from mass balance models. This discrepancy arises because it is difficult to scale incubation and chamber measurements to the whole ecosystem and over longer time periods. A better understanding of spatio-temporal variation in internal phosphorus loading is needed to scale direct measurements of loading rates accurately.

Phosphorus use by aquatic organisms

All organisms require phosphorus to support their growth and reproduction. As such, phosphorus availability in the environment, whether from internal or external sources, drives ecosystem dynamics. In particular, primary production in many lacustrine environments is limited by the availability of phosphorus. As a result, phosphorus is mainly bound in the biomass of phytoplankton, heterotrophic microbes, and other organisms when present in the water column of many lakes. The exception to this is most common in hypereutrophic (nutrient-rich) waterbodies where other nutrients such as nitrogen may also limit primary production. However, in most inland waters, when new phosphate is introduced to the ecosystem from external or internal loading in the water column, the uptake rate by phytoplankton and bacteria is rapid. In strongly phosphorus-limited waters, the uptake rates of orthophosphate can be on the order of seconds to minutes (Currie and Kalff, 1984). The strong correlation between phosphorus availability and algal biomass underpins the trophic state classification scheme of lakes and reservoirs (Carlson, 1977).

Trophic state is defined as the total mass of biological material in an ecosystem. Lakes with low biomass are classified as oligotrophic (from the Greek *oligos*, meaning few) and have low concentrations of phosphorus in the water column, limiting productivity. Conversely, those waterbodies with high biomass are classified as eutrophic (from the Greek *eu*, meaning good or well) and have higher concentrations of phosphorus supporting higher rates of productivity (Table 1). In 1977, Carlson proposed a trophic state index that classified lacustrine ecosystems based on either Secchi depth (a measure of water clarity), chlorophyll *a* concentration (an index of algal biomass), or total phosphorus concentrations, due to the strong correlation between these variables (Fig. 3). The trophic state index has been widely adopted by lake managers and policymakers as a tool for classifying waterbodies and predicting the consequences of eutrophication or restoration on aquatic ecosystems (see "Managing The Consequences Of Excess Phosphorus" section below). While the correlation between phosphorus availability and phytoplankton biomass is clear, phytoplankton growth is also dictated by the availability of other essential elements including nitrogen.

Table 1 Trophic state index values from Carlson (1977).

Trophic category	*Trophic state index*	*Phosphorus ($\mu g\ L^{-1}$)*	*Chlorophyll-a ($\mu g\ L^{-1}$)*	*Secchi depth (m)*
Oligotrophic	<1–40	<1–12	<1–2.6	>8–4
Mesotrophic	40–50	12–24	2.6–7.3	4–2
Eutrophic	50–70	24–96	7.3–56	2–0.5
Hypereutrophic	>70	>96	>56	<0.5

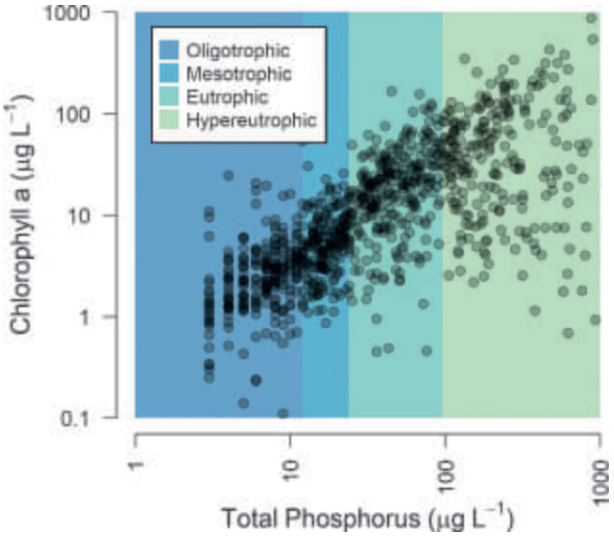

Fig. 3 The relationship between total phosphorus and chlorophyll-a concentrations for 968 lakes in the United States and the trophic state classification for each lake based on the total phosphorus concentration. Data are from the United States Environmental Protection Agency's 2012 National Lake Assessment.

There is considerable variation in phosphorus acquisition strategies and use efficiencies across different macrophyte growth forms. Emergent (e.g., cattails, *Typha* spp.) and floating-leaf (e.g., water lilies, *Nymphaea* spp.) macrophytes primarily obtain phosphorus from sediments and have extensive root and rhizome systems for perennial phosphorus storage. In contrast, submersed macrophytes (e.g., pondweeds, *Potamogeton* spp.) may take up phosphorus from either sediments or the water column, although the importance of foliar uptake varies across species (Granéli and Solander, 1988). Phosphorus use efficiency also differs between emergent or floating-leaf macrophytes and submersed species, especially in temperate lakes. Complex root and rhizome systems allow emergent and floating-leaf species to efficiently use and recycle phosphorus across seasons. Specifically, these macrophytes can translocate phosphorus and other nutrients from their shoots into the rhizomes prior to vegetative senescence in autumn. Unlike emergent and floating-leaf macrophytes, submersed species generally experience continual sloughing of leaves and shoot fragments throughout the growing season. These biomass losses remove a substantial amount of phosphorus from submersed macrophyte beds (Adams and Prenkti, 1982). Although perennial submersed species can translocate phosphorus from shoots to overwintering structures, reduced root systems limit perennial phosphorus storage and thus use efficiency.

While much of the phosphorus contained in the biomass of primary producers in the water column can succumb to sedimentation, a portion of it is lost to consumption by other organisms. Aquatic consumers acquire the phosphorus they need through their diet. The need for essential nutrients such as phosphorus drives ecological interactions among consumers and can shape ecosystem dynamics. For example, the crustaceous zooplankton *Daphnia* are a keystone grazer of phytoplankton in many lacustrine ecosystems. As phosphorus-rich organisms, *Daphnia* need to consume a large amount of phosphorus in their diets which leads to their high grazing rates.

When there is too much phosphorus in a consumer's diet compared to their nutritional needs, they will excrete the excess phosphorus either in a dissolved form readily available for phytoplankton or heterotrophic bacteria uptake or in fecal pellets. The phosphorus in fecal pellets may be lost to the water column through sedimentation or can be dissolved and taken up by primary producers and microbes. The phosphorus that is incorporated into consumers' tissues turns over at a slower rate than the phosphorus in phytoplankton or heterotrophic bacteria due to consumer's longer life span. In general, the longer-lived an organism is in the environment, the slower the turnover of the reservoir of phosphorus in their biomass. When consumers die, the

phosphorus in their necromass is stored in the sediments or recycled back into the water column through mineralization. In some phosphorus-poor lakes, the accumulation of phosphate in the bones and scales of long-lived fishes is an appreciable reservoir of phosphorus in the water column that is not available for uptake by other organisms and turns over slowly.

Managing the consequences of excess phosphorus

Eutrophication is the condition of excessive algal production in waterbodies due to over enrichment of nutrients. Algal blooms can range from an unsightly nuisance to impairing ecosystem services and threatening human health. For example, severe algal blooms can lead to fish kills through the drawdown of dissolved oxygen during senescence. Blooms that are dominated by cyanobacteria can produce dangerous levels of toxins that can harm humans if ingested through drinking water or during recreation. As the production of algae in lakes and reservoirs generally depends on the availability of phosphorus (although some inland waters can experience periods of nitrogen limitation as well), preventing or managing excess phosphorus loads to inland waters is critical for protecting ecosystem services (Schindler et al., 2016).

In 1968, Vollenweider produced a technical report for Organization for Economic Cooperation and Development (OECD) that contained a model describing the relationship between mean phosphorus availability and chlorophyll-a in lakes. He found that the annual index of phosphorus availability in the water column—calculated as a function of external phosphorus inputs, outflows, and the rate of phosphorus loss to sedimentation—was strongly correlated with the mean annual chlorophyll-a concentration among lakes. Simply put, the greater the magnitude of external phosphorus loading to lakes, the greater the algal biomass. The Vollenweider model, along with the seminal whole-lake nutrient enrichment experiments of Schindler (1974) and recovery of Lake Washington after effluent diversion in the 1960s, launched widespread efforts to reduce external phosphorus loading to lacustrine environments in order to mitigate eutrophication. However, eutrophic waterbodies often exhibit a delayed and nonlinear response to declining phosphorus loads. Long-term reductions in external phosphorus loads are not effective at limiting algal biomass and the prevalence of cyanobacteria until in-lake phosphorus concentrations fall below a certain threshold. Similarly, hypolimnetic oxygen depletion due to decomposition of deposited organic matter remains a concern until there are substantial reductions in surface water phosphorus availability (Müller et al., 2019). These hysteretic responses often result from internal phosphorus loading, which can delay or prevent recovery of some lakes even after substantial reductions in external loading. Depending on the size and form of the sediment phosphorus pool and water residence time, it could take decades for the water column to reach equilibrium with surface sediments. The hysteretic response of lakes to reductions in external loading means that management of internal loading may also be necessary to achieve water quality targets in a shorter time frame.

The effective management of phosphorus availability in an individual lake or reservoir is dependent upon an accurate assessment of the mechanisms controlling phosphorus loading in the ecosystem (see table below for examples of phosphorus management case studies). For example, aerating the sediment-water interface to prevent the release of iron-bound phosphate may not have a substantial effect on water column concentrations if there is large pool of labile organic phosphorus that can be mineralized. In fact, the presence of oxygen could have the unintended effect of stimulating aerobic respiration, accelerating the conversion of organic phosphorus to more bioavailable forms. Similarly, phosphate inactivation agents such as alum (aluminum sulfate; $Al_2(SO_4)_3$) that are primarily targeted at improving the phosphorus binding capacity of the surface sediments may be less effective in shallow lakes that experience substantial sediment resuspension, which disturbs the alum "cap" on the sediment surface. The effect of biological communities cannot also be discounted in some ecosystems as excretion of translocated phosphorus by mobile fish can exceed external phosphorus loading for portions of the year. As these scenarios illustrate, predictive models of phosphorus concentrations in lakes that do not provide insight into the mechanisms controlling phosphorus loading are less likely to lead to measurable reductions in eutrophication due to management.

Conclusions

Phosphorus is an essential element, the availability of which shapes the structure and function of lacustrine ecosystems. The form of phosphorus in the water column, whether inorganic or organic, particulate or dissolved, were either transported from the watershed or recycled internally from the sediments. A complex suite of interacting chemical, physical, and biological mechanisms controls sediment phosphorus release including sediment redox chemistry, sediment resuspension via wind mixing or bioturbation, and the structure of macrophyte communities. Internal phosphorus loading mechanisms vary not only between different lakes but also within individual systems. This variability makes internal loading difficult to measure and often challenging to predict. The consequences of widespread eutrophication have created the need to manage phosphorus availability in many lakes to protect ecosystem services. However, effective management hinges on a mechanistic understanding of internal phosphorus cycling in addition to the sources outside of the ecosystem. While substantial gains have been made in our understanding of the pools and fluxes of phosphorus in lakes, better predictive models are needed for more effective lake management, especially as eutrophication is exacerbated by the changing climate in many regions.

Knowledge gaps

- Reliable identification of the magnitude, timing, and mechanisms controlling internal phosphorus loading in individual lakes to guide eutrophication management.
- Phosphorus availability, cycling, and internal loading rates during the winter in lacustrine ecosystems at higher latitudes.
- The bioavailability and cycling of lacustrine dissolved organic phosphorus.
- The importance and role of macrophytes in phosphorus cycling in the sediments.
- Resolving the temporal and spatial complexity of internal versus external phosphorus loading, particularly as it initiates and sustains algal blooms.
- The effect of climate change on the physical, chemical, and biological processes that control phosphorus availability and cycling in lakes.

Case studies of phosphorus management in lakes

Waterbody	*Location*	*Citation*	*Phosphorus Management Strategy*	*Description and Outcome*
Lake Washington	United States	Edmundson (1970)	Sewage delivery to the lake began in 1941 and peaked in 1962. *Diversion* began in 1963. Phosphate concentrations declined 72% but nitrate concentrations only declined by less than 20% by 1969	The mean summertime chlorophyll-a concentrations declined and were closely correlated to mean winter phosphate concentrations from the previous year, indicating that phosphorus was the most important limiting element in the lake
Lake 226	Canada	Schindler (1974)	*Experimental addition* of nitrogen and carbon to one basin of the lake and nitrogen, carbon, and phosphorus to another	An ecosystem experiment was performed by dividing Lake 226 with an impermeable curtain and adding nitrogen and carbon to one half of the lake and nitrogen, carbon, and phosphorus to the other. An algal bloom did not occur in the half with only nitrogen and carbon, but a bloom did occur on the half with phosphorus added. This experiment demonstrated that phosphorus was the key limiting nutrient for algal growth
Lake Dianchi	China	Yan et al. (2019) and Liu et al. (2015)	Enhanced *wastewater treatment* capacity and *sediment dredging* (over 51 million m^3 sediment and 14,800 t phosphorus removed)	Algal blooms in Lake Dianchi are linked to phosphorus availability. Advances in wastewater treatment have reduced external phosphorus loads and sediment dredging has reduced in-lake phosphorus pools. However, internal phosphorus loading remains high due to decomposition of algal detritus and phosphorus mineralization
Lake Tuusulanjärvi	Finland	Horppila et al. (2017)	*Sewage diversion* (reduced mean external phosphorus load by 50.4%, from 1533 to 761 mg P m^{-2} $year^{-1}$) and *aeration* (prevented hypoxia but increased total internal phosphorus load from 432 to 659 mg P m^{-2} $year^{-1}$)	Sewage effluent was diverted from the lake in 1979; however, internal loading delayed water quality improvements. Aeration was used consistently from 1998 to 2010, which prevented summer thermal stratification. The artificial destratification caused total internal phosphorus loading to increase due to warmer bottom water temperatures, enhanced phosphorus mineralization, and sediment resuspension from aeration
Lake Trummen	Sweden	Cronberg (1982) and Bengtsson et al. (1975)	*Sewage diversion* and *sediment dredging* (the top 0.5 m of sediment removed, 50,000 kg phosphorus)	Diverting sewage effluent from the lake in 1959 was not sufficient to reduce algal blooms due to persistent internal phosphorus loading. In 1970–1971 precision, suction dredging was used to remove phosphorus-rich sediments. Coupled management of external and internal loads reduced total algal biomass and the prevalence of cyanobacteria by the mid-1970s
Minneapolis Chain of Lakes	United States	Huser et al. (2016)	*Alum additions* to control phosphorus release from sediments and catchment management to *reduce external loading* (achieved between 1% and 49% across the 4 lakes)	In-lake alum treatments resulted in 4–20 years of water quality improvements in the lakes whereas efforts to manage external loads had a minimal effect on water quality during the same period
Lake Susan	United States	Bajer and Sorensen (2015)	Experimental *removal of common carp* (*Cyprinus carpio*), decreasing biomass from 307.1 kg ha^{-1} to 40.8–64.5 kg ha^{-1}	Carp were removed to reduce bioturbation of sediments resulting in a large increase in aquatic vegetation (+40% in coverage) and early summer water water clarity due to a decline in suspended solids. However, total phosphorus concentrations did not decrease as internal loading not associated with the carp combined with periodic entrainment of hypolimnetic water in this shallow lake maintained high phosphorus concentrations in the water column after carp removal

pH of Inland Waters

Kerri Finlay[a] **and Matthew J Bogard**[b], [a]Department of Biology, University of Regina, Regina, SK, Canada; [b]Department of Biological Sciences, University of Lethbridge, Lethbridge, AB, Canada

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Acid deposition Any form of precipitation that contains acidic components. Carbonic, sulfuric and nitric acid are common acids present in acid precipitation.
Acidity A measurement of the strength of an acid, or the ability of a compound to lose a proton.
Acidification Process by which inland waters become more acidic.
Alkalinization Process by which inland waters become more alkaline.
Acid neutralizing capacity (ANC) The capacity of a water body to buffer against acidification.
Alkalinity The ability of a water body to neutralize acids. Alkalinity is the stoichiometric sum of bases in solution, measured in μeq L^{-1}. *Total alkalinity* refers to the sum of all bases in the solution. *Carbonate alkalinity* is the sum of the number of moles of HCO_3^- + CO_3^{2-} in solution, where 1 mol of HCO_3^- represents 1 M equivalent, and 1 mol of CO_3^{2-} is 2 M equivalents, due to charge differences. Since bicarbonate and carbonate are the most abundant ions in aquatic ecosystems, alkalinity is often estimated through the measurement of carbonate alkalinity alone.
Basicity A measurement of the strength of a base, or a compound's ability to accept protons.
Buffering capacity Measurement of a water body's ability to resist changes in pH. Defined as the number of moles of acid or base required to change the pH of the water by 1 unit. A lake with a high buffering capacity would require more acid or base to shift its pH.
Cation exchange Refers to the process by which one cation is replaced by another. This can occur on soil particles, or across biological membranes, and usually refers to the replacement of specific biologically-important cations (e.g., Ca^{2+}) with protons from an acid source.
pH The negative of the base 10 logarithm of the concentration of free hydrogen ions.
Salinization syndrome The observation of increasing salinity in inland waters through the landscape loading of salts, acceleration of weathering, and the increased use of concrete and lime. Often associated with increasing lake pH.

Introduction

The dissociation of water molecules to H^+ and OH^- ions determines the pH of water, which is defined as the negative (or inverse) of the base 10 logarithm of the concentration of free hydrogen ions ($-\log_{10}[H^+]$).

pH is a fundamental property of inland waters that is well understood chemically, and has profound and complex ecological implications. Measuring pH is relatively straightforward and as a result has been assessed in inland waters since the inception of limnology. This ease of measurement has led to a great abundance of pH measurements, revealing that surface freshwaters typically range between pH 6 to 9, with values of 2 to 12 observed in more extreme environments. The pH of the aquatic environment is an important driver of physical, chemical, and biological properties, which both regulates, and responds to ecosystem functioning. Human activities have dramatically shifted the pH of many inland waters, from a trend of acidification beginning in the late 1960s,

 https://doi.org/10.1016/B978-0-12-819166-8.00045-1

to a more recent trend of widespread alkalinization. The magnitude and direction of these pH shifts vary regionally, as they are dependent on many interacting factors, including underlying geology, land use, and climate. To anticipate and mitigate further impacts of anthropogenic pH change on inland waters, we require a comprehensive understanding of the biogeochemical and physical drivers of pH change, and ecological impacts on freshwater ecosystems.

This chapter outlines an understanding of the drivers underlying the natural range of pH of inland waters, provides an overview of the natural and anthropogenic factors that cause deviations from baseline values, and describes the implications of these perturbations for ecological community structure and functioning.

Measurement of pH of inland waters

Comprehensive overviews of methodologies underlying pH measurement in aquatic environments for both the field and the laboratory are available from the US Geological Survey (Ritz and Collins, 2008) and the US Environmental Protection Agency (USEPA, 2017), and many other authorities. Briefly, standard measurement requires a probe consisting of ion selective reference- and measurement electrodes connected to a digital visualization interface (Ritz and Collins, 2008). Most pH meters include an internal temperature sensor that automatically adjusts pH measurements based on ambient conditions. Where ambient temperature is not directly measured, direct temperature measurements must be made, and pH values adjusted accordingly. Current potentials generated between measurement and reference electrodes are converted to pH with the ideal Nernstian response, which links the electrical response to activity of H ions (59.16 mV per unit pH), and if present, the built-in temperature correction factor (Ritz and Collins, 2008).

Controls of pH

Natural pH range

The pH of pure water is given to be neutral (7.0). Most inland waters lie within a pH range of 6–9, because of buffering with the carbonic acid system, described below. Many systems deviate dramatically from this range, and can have pH values as low as 2 to as high as 12 in extreme environments (Langmuir, 1997; Wetzel, 2001). The pH of inland waters can be altered when water interacts with basic or acidic substances originating in the atmosphere, the terrestrial environment, within ground- and surface waters, and aquatic sediments.

Buffering capacity

The ability of inland waters to resist changes in pH (**Buffering capacity**) is primarily accounted for by the equilibrium of the carbonate system (Eq. 1, Fig. 1).

$$CO_{2(g)} + H_2O \rightarrow H_2CO_{3(aq)} \leftrightharpoons H^+_{(aq)} + HCO_3^-{}_{(aq)} \leftrightharpoons 2H^+_{(aq)} + CO_3^{2-}{}_{(aq)} \quad (1)$$

Here, CO_2 dissolves in water and forms carbonic acid (H_2CO_3). This carbonic acid equilibrates with bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}). Increases or decreases of any of the compounds from this equation (Eq. 1) can cause shifts to the left or right. Together, the sum of $CO_{2(g)}$, $H_2CO_{3(aq)}$, $HCO_3^-{}_{(aq)}$ and CO_3^{2-} is known as dissolved inorganic carbon, or DIC.

The buffering capacity of inland waters is typically measured through estimates of alkalinity, which is estimated by adding acid to a sample and measuring the resulting changes in pH. Alkalinity is a functional measurement that encompasses the sum of all acids and bases in the sample. In natural waters, it is often assumed that alkalinity arises entirely from carbonate alkalinity, which is

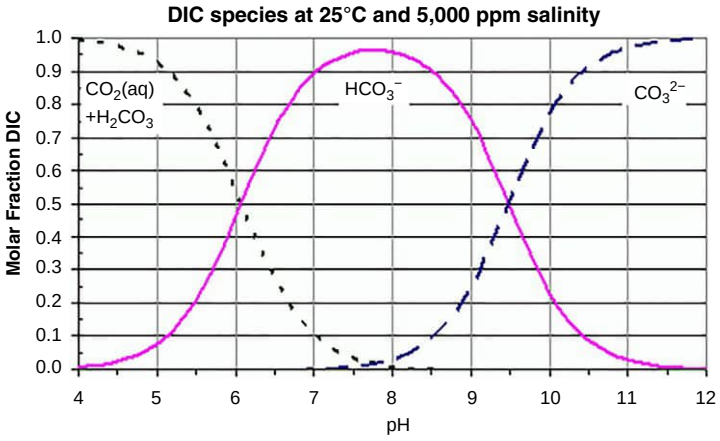

Fig. 1 Carbonate equilibrium showing the relative proportion of carbon species ($CO_2 + H_2CO_3$, HCO_3^-, and CO_3^{2-}) in relation to the pH of water. This diagram demonstrates that at high pH values, most inorganic carbon is in the form of CO_3^{2-}, while most inorganic carbon is present as CO_2 at low pH.

the sum of bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}), as these are the most common ions in aquatic ecosystems. Carbonate alkalinity is calculated by summing the molar quantity of bases, where 1 mol of HCO_3^- is 1 M equivalent, and 1 mol of CO_3^{2-} is 2 M equivalents, so carbonate alkalinity in molar equivalents = (moles HCO_3^-) + 2 × (moles CO_3^{2-}). The different molar equivalents of HCO_3^- and CO_3^{2-} refer to the moles of protons that are produced in the equilibrium as seen in Eq. (1). Thus, for example, a system with more carbonate will be better able to withstand inputs of protons, as Eq. (1) will shift to the left. The carbonate equilibrium is also often represented graphically (Fig. 1), which shows the relative proportion of inorganic carbon species at varying pH.

New inputs of CO_3^{2-} or other sources of alkalinity via precipitation, runoff, and groundwater delivery increase the acid buffering capacity of aquatic ecosystems. Internal production of solutes can also alter the balance of acids and bases in a system, and thus the alkalinity (Schindler et al., 1985). Evapoconcentration can lead to increased concentrations of all acids and bases and thus increase pH of basic systems, or lower the pH of acidic systems. The bulk of the alkalinity linked to inorganic C ultimately comes from chemical weathering processes in terrestrial landscapes that mobilize bicarbonate and carbonate, and thus is strongly influenced by underlying geology. However, microbial reduction of oxidized compounds of C, N, S, Fe, and other elements also generates alkalinity through both assimilatory and dissimilatory pathways (Kelly et al., 1995). In extremely dilute, soft-water lakes, the internal biological generation of alkalinity through processes such as sulfur oxidation and nitrification can actually account for the largest sources of alkalinity to the system (Schindler et al., 1985).

Biological controls of pH

pH can vary significantly over multiple timescales. On shorter timescales (hourly to seasonal), temporal fluctuations are directly related to the consumption and production of CO_2 from photosynthesis and respiration, which can increase and decrease ecosystem pH, respectively, through associated shifts in the balance of the inorganic carbon system (see Eq. 1). Changes in the balance of the rates of photosynthesis and respiration can therefore generate both spatial and temporal variability in pH within a water body. Temporally, pH varies over both diel and seasonal scales to match patterns in primary production, where pH is often lower at night than it is during the daytime (Maberly, 1996), and can match seasonal trends in algal production with mid-summer peaks when algal concentrations are also peaking (Kratz et al., 1987). pH also tends to be dramatically lower during winter in ice covered lakes as respired CO_2 accumulates under ice (Kratz et al., 1987; Finlay et al., 2015). Interannual and decadal-scale variability in pH for a given system can range widely, from 0.8 to 1.3 units (Maberly, 1996; Finlay et al., 2015), owing to shifts in factors affecting the balance of primary productivity and respiration such as nutrient loading and temperature. Spatially, one of the most obvious pH gradients in productive lakes occurs where pH values are high in the photic zone due to the predominance of primary production and lower in the hypolimnion due to intense heterotrophic respiration (Wetzel, 2001), a pattern which inversely tracks variations in dissolved inorganic carbon concentrations (Wetzel, 2001). These differences in productivity can also explain cross-ecosystem patterns of pH, as lakes with higher productivity often have higher pH than do those with lower productivity.

Chemical controls of pH

In general, the pH of aquatic systems is a result of the "dynamic interplay between natural acids and bases, with extreme pHs found when either dominates" (Langmuir, 1997) (Fig. 2). As summarized by Langmuir (1997) and shown in Fig. 2, systems with low pH ($< \sim 3$) are often dominated by inputs of acid rain or weathering products of pyrite (FeS_2). Therefore, extremely low pH can be found in regions of volcanic activity and watersheds composed of pyrite rocks and clay soils, which export sulfuric acid to surface waters. Ecosystems with intermediate pH of ~4.5–10 often reflect respiration-derived carbonic acids or organic acids (dominant in

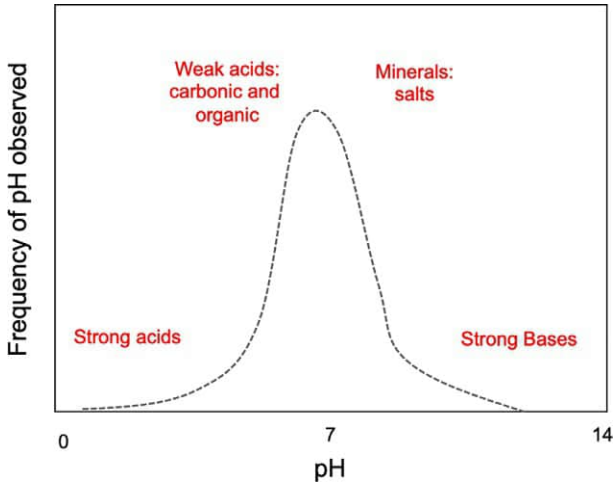

Fig. 2 The general distribution of pH values observed in natural aquatic ecosystems, and the corresponding acids and bases that often dominate in the general range of corresponding pH. Figure adapted from Langmuir D (1997) *Aqueous Environmental Geochemistry*. Englewood Cliffs: Prentice-Hall, Inc., 601.

systems with pH < 7), or mineral byproducts of bedrock (silicate, alumino-silicate, and carbonate) weathering (in systems with pH > 7) (Langmuir, 1997; Fig. 2). Moderately alkaline systems typically have elevated carbonate and are well buffered above pH of 8 (Wetzel, 2001). Accordingly, surface water pH has been shown to increase in response to enhanced catchment weathering and export of base cations, and following decreases in the delivery of organic acids from land (e.g., Tibby et al., 2003). Aquatic systems with extreme pH > ~10 are often dominated by the dissolution and evapoconcentration of minerals rich in HCO_3^- and CO_3^{2-} such as calcite (Langmuir, 1997; Fig. 2). With a lack of outflow, lakes in the continental interior in endorheic basins experience evapoconcentration of salts delivered from the watershed, and are accordingly also typically saline. The pH of lakes is therefore often high in endorheic regions where the watershed contains high levels of alkali salts, such as $NaCO_3$ and $CaCO_3$.

Calcite ($CaCO_3$) precipitation and dissolution is a common process in hardwater lakes that has profound impacts on lake pH, owing to the following equilibrium:

$$CaCO_{3(s)} + CO_{2(aq)} + H_2O \leftrightharpoons Ca^{2+}{}_{(aq)} + 2HCO_3^-{}_{(aq)} \quad (2)$$

Whiting events can be observed when calcite precipitates out of solution, seen as a milky turquoise cloud forming surface water (Fig. 3). When calcite becomes oversaturated, it can precipitate out of solution, generating CO_2 and reducing pH following Eq. (1) above. Specifically, these triggers include warming temperatures in spring and summer which lead to reduced $CaCO_3$ solubility, the removal of CO_2 and elevation of pH due to increasing rates of photosynthesis, causing a shift in Eq. (2) to the left, and an increased presence of nucleation sites (algal cells or other small particles) that provide a substrate for the formation of calcite crystals (Wetzel, 2001).

Physical controls on pH

Climate-driven hydrologic shifts over multiple timescales are often an important driver of aquatic pH. Precipitation typically has a pH between 5 and 5.6, due to dissolution of CO_2 and other N, S, and C trace gases that are oxidized in the atmosphere (Schlesinger and Bernhardt, 2020). Owing to the low pH of snow and rain (Baas Becking et al., 1960), precipitation patterns can drive temporal variations in pH. In response to acidic rainfall and snowmelt inputs, changes in surface water pH can range from 0.4 to 3.2 units (Maberly, 1996). Snowmelt and runoff flowing via surface or subsurface paths can pick up CO_2 and organic acids from soils, causing a further decrease in pH (Buffam et al., 2008).

Surface water pH is often very low (~3) in bog systems, where inputs of weathering products from the catchment are minimal, rain and snowfall are quantitatively important (Baas Becking et al., 1960), or where *Sphagnum* moss in the watershed actively exchanges cations, releasing H^+ into the water (Wetzel, 2001). Therefore, landscapes dominated by bogs tend to have bog-fed headwater streams with low pH.

Acidification can also occur through changes in climate. For example, drought conditions can reduce delivery of alkaline groundwater with high acid neutralizing capacity (ANC), reduce lake ANC, and lead to a decline in surface water pH (Webster et al., 1990). Warmer winters can lead to alkalinization through shorter ice cover, causing reduced accumulation of respiratory-derived CO_2 under ice in winter and elevated pH in spring (Finlay et al., 2015).

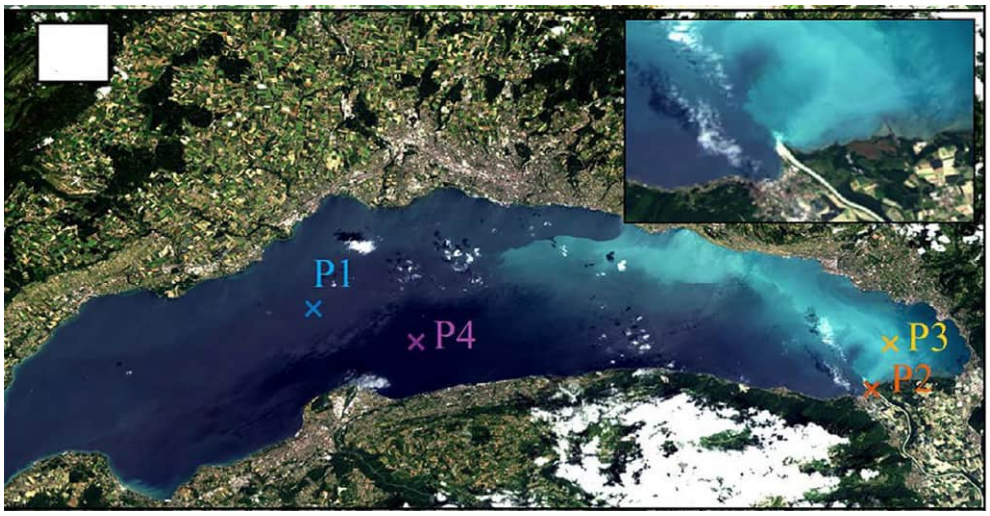

Fig. 3 Remote sensing photograph of a whiting event in Lake Geneva. Whiting events occur when calcium carbonate precipitates out of solution From Nouchi V, Kutser T, Wuest A, Muller B, Odermatt D, Baracchini T, Bouffard D (2019) Resolving biogeochemical processes in lakes using remote sensing. *Aquatic Sciences* 81: 27. https://doi.org/10.1007/s00027-019-0626-3.

Human impacts on pH: Acidification and alkalinization

Around the globe, distinct shifts in human activities have resulted in dramatic and non-linear changes in surface water pH over decadal- to millennial timescales. Therefore, we emphasize a need for caution when attempting to define natural, baseline pH of most aquatic systems. For example, Renberg et al. (1993) show that Swedish lakes have undergone four periods of pH change since the last glaciation (Fig. 4). First, a long-term acidification period from 12,000–2300 BP demonstrated decreasing pH from ~7.0 to 5.5 resulting from a decline in base cation concentrations in catchments (region I, Fig. 4). This period was followed by an anthropogenically induced alkalinization period (2300 BP–1900 AD) when land use changes resulted in increased nutrient (causing increased primary productivity) and base cation loading to lakes, thereby increasing pH to above 6.0 (region II, Fig. 4). Next, the more recent acidification period, from 1900 AD to present, corresponded to the period of widespread industrialization and combustion of fossil fuels (region III, Fig. 4, described below). The fourth period started in the 1970s and corresponds to the liming activities initiated by the Swedish government (region IV, Fig. 3, Renberg et al., 1993). This localized case study highlights two critical concepts relevant to any watershed: First, that "background" pH in aquatic networks varies through time, and second, that sequential shifts in dominant human stressors can lead to unique temporal trajectories of pH.

Acidification

A dramatic acidification of inland waters across North America and Europe started in the late 1960s and early 1970s as a result of widespread fossil fuel combustion and smelting of sulfide ores. Sulfide ore smelting and gasoline and coal burning release sulfur dioxide (SO_2) into the atmosphere where chemical reactions produce sulfuric acid. Nitrogen oxides (NO_x) are also produced through smelting and gasoline and coal burning and similarly react in the atmosphere to produce nitric acid. These acids are removed from the atmosphere through acid rain and acidify inland waters, most notably in regions of hard bedrock in the north-eastern United States, south-eastern Canada, and Scandinavian countries. The extent of this acidification was significant: between 25% and 35% of the lakes in the Adirondack region (New York, United States) were found to have acidified, and those with low alkalinity and ANC were much more strongly affected than were those with higher ANC (Cumming et al., 1992). Similarly, over 50% of lakes in southern and central Sweden experienced pH levels below 6.0, and 22–36% were lower than 5.0, with dramatic impacts on diatoms and other phytoplankton, zooplankton, and fish (Almer et al., 1974). Similar multidecadal observations of declining pH have been recorded in other industrialized regions (Tibby et al., 2003). The impacts of acidification on aquatic ecosystems are widespread, and are discussed in detail below.

Pollution generated from diverse mining activities has caused acidification of many streams and rivers worldwide (Dold, 2008). The phenomenon of acid mine drainage (AMD) arises largely due to the unearthing of previously buried minerals, which are oxidized by microbes after atmospheric exposure. This mechanism generates sulfuric acid during the oxidation of sulfide minerals, the dominant form of which is pyrite (FeS_2) (Herlihy et al., 1990). AMD is exported from mine sites through groundwater and overland flow (Dold, 2008), and in some cases during catastrophic events such as breaching of the walls of tailings ponds. AMD export can cause pH declines in weakly buffered streams to values <4 (Herlihy et al., 1990; Dold, 2008). By using a survey of acid-sensitive streams throughout the eastern United States, Herlihy et al. (1990) demonstrated that up to 2% of streams had been impacted by AMD, with AMD acidifying up to 10% of streams in sub-regions that were intensely impacted by coal mining. Yet where mine tailings consist of alkalic materials that are low in S and rich in calcite (Kennedy et al., 2016), mine drainage can remain neutral to alkaline, and can have little long-term effect on aquatic ecosystem pH in well buffered catchments (Herlihy et al., 1990; Kennedy et al., 2016), or even increase the pH in sediment layers receiving settled tailings materials. Therefore, mining activities do not exert a uniform effect on the pH of downstream ecosystems, but depend on underlying geology of the region.

Surface water acidification may be further exacerbated by land use change (Renberg et al., 1993; Erlandsson et al., 2011). The recovery of previously deforested lands in Europe and North America may have contributed to lake acidification, where soil

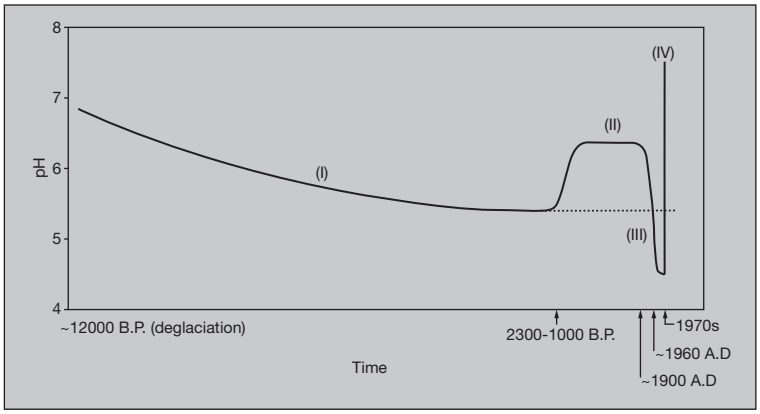

Fig. 4 Schematic diagram of the pH development in acidic lakes in southern Sweden during the postglacial period, with the four periods discussed in the text (I = the natural long-term acidification period, II = the anthropogenic alkalinization period, III = the recent acidification period, IV = the liming period). From Renberg I, Korsan T, and Anderson NJ (1993) A temporal persepective of lake acidification in Sweden. *Ambio* 22(5): 264–271.

development allowed for accumulation of organic matter on the terrestrial landscape, enhanced soil microbial activity, and therefore export of organic acids and CO_2 to downstream water bodies. Because reforestation and sulfate deposition were both occurring at the same time in the early- mid- 20th century, and both primarily affect hard-bedrock and thin-soiled regions, it is often difficult to differentiate between the two drivers.

In general, the impacts of acid rain on inland waters have been dramatically reduced since the 1990s, when regulations were implemented to scrub sulfur and nitrogen oxides from smelters and coal burning plants, and vehicle exhausts were regulated in North America and Europe (Driscoll et al., 2001). Additional efforts to mitigate acidification have been enacted in western Europe (e.g., Sandøy and Langaker, 2001 and references therein). In Sweden, the National Swedish Board of Fisheries has limed lakes through the addition of limestone, or dolomite, directly to the lakes. These additions began in 1976, have been applied to >7500 lakes, and continue to this day, with costs exceeding 360 million Euro. This liming has been effective in increasing "the pH of lakes" in Sweden by an average of ~0.8 units, has resulted in increased biodiversity, and has prevented the loss of endangered flora and fauna (Svenson et al., 1995).

Ecosystem recovery from acidification depends on many factors beyond chemical restoration of water bodies to pre-impacted levels. Other important processes include other vectors of water quality, the presence of a regional pool of colonizing species, and a consideration of other community-level ecological interactions, which are highly complex and often difficult to predict (Yan et al., 2003). As a result, biological recovery of lakes is often slower than chemical recovery (Arnott et al., 2006).

While the release of N and S oxides have been greatly reduced in the past decades, and acid rain is much less of a concern than it once was, there are some current trends in acidification, particularly through the process of brownification, the increased loading of colored organic matter from the catchment (Erlandsson et al., 2010). Here, increasing mobilization of terrestrially-derived organic acids to inland waters can lower pH directly, and has caused an increase in respiration of allochthonous organic matter, causing elevated CO_2 and thus depression of pH (Erlandsson et al., 2010). Further, increasing atmospheric pCO_2 linked to human emissions may increase the concentration gradient and enhance the rate of ingassing of CO_2 into inland waters, thus lowering pH. Yet the vast majority of inland waters remain supersaturated with pCO_2 at levels well above atmospheric content.

Alkalinization

Interestingly, recent exploration of decadal water quality trends in many regions show an increase in alkalinity, salinity and often the pH of many inland waters, termed the "salinization syndrome" (Kaushal et al., 2018). Alkalinization results from increased inputs of basic molecules such as base cations or bicarbonate which can result from a number of processes. These include changes to the hydrologic cycle of river basins, changing land use patterns, or the addition of weatherable material like lime and concrete. Alkalinization is not always associated with increasing pH, but, broadly speaking, the rate of change of pH tends to be inversely proportional to the initial conductivity of the river (Kaushal et al., 2013).

Alkalinization and pH increase are widely reported for inland waters. While alkalinization in some regions is the direct result of recovery from acidification, other regions that did not experience acidification are now becoming more alkaline. Recent studies have shown that >60% of streams in the United States have seen increases in pH, with stronger trends observed in more heavily populated areas (Kaushal et al., 2013, 2018). Carbonate lithology was the primary cause of increasing alkalinity in rivers of the eastern United States (Kaushal et al., 2013), and recovery from acidification combined with increasing agricultural lime usage to alkalize soils caused alkalinization in rivers of the conterminous United States (Stets et al., 2014). Following European settlement and watershed development, a centuries-long increase in pH has occurred in an Australian Floodplain lake (Tibby et al., 2003). Significant alkalinization of 134–185% has also been demonstrated in large Russian Arctic rivers between ~1980 and 2020, attributed to factors including higher temperatures and precipitation, anthropogenic activity, thaw of permafrost (perenially frozen) soils, changes in hydrology, vegetation shifts and decreased acid deposition (Drake et al., 2018). Another example of alkalinization has been demonstrated in mountain streams in northeastern China, which have demonstrated, on average, an increase of nearly 1.5 pH units (from 7.08 to 8.49) between the 1970s and the 2010s, linked to mining activities and agricultural fertilization (Zhao et al., 2019). Collectively, these studies point to the widespread alkalinization and pH increase linked to human impacts in watersheds worldwide.

The impacts of pH change on ecosystem properties

The effects of pH change on aquatic ecosystems are varied and often can be difficult to tease apart from other drivers of environmental change, namely climate change and watershed development. Moreover, pH change is often the response to, not the cause of different environmental changes, such as changing CO_2 concentrations linked to metabolic shifts. Often, acidification or alkalinization of inland waters occur in concert with other sources of perturbation, so changes to pH are seldom the sole driver of variation in ecosystem structure and functioning. Here, we establish how pH drives variability in ecosystem functioning and note specifically where other factors may contribute to ecosystem change. As such, we summarize the influence of pH on ecosystems broadly, while emphasizing the myriad additional factors that interact with water chemistry to affect ecosystem change.

Physical properties of inland waters, pH, and ecosystem change

Changes in pH of inland waters impact UV penetration and lake stratification depth. In the Experimental Lakes Area of Ontario, Canada, a 20-year experimental acidification study demonstrated that acidification increased rates of dissolved organic carbon DOC photo decomposition processes, and in combination with climate change (notably increasing temperatures and reduced

precipitation) contributed to reduced DOC concentrations (Schindler et al., 1996). This reduced DOC concentration caused increased UV penetration with cascading effects on lake biota (see below, Schindler et al., 1996).

Biogeochemistry

Variability in pH is an important regulator of biogeochemical functioning in aquatic environments, with shifts in either direction reflecting *responses* to both aerobic and anaerobic biogeochemical processes (Wetzel, 2001). Wetzel (2001) notes that a change of 1 pH unit under standardized conditions induces a far greater change in the oxidation-reduction (redox) potential (58 mV increase per increase in pH unit) than do modest and environmentally-relevant changes in dissolved oxygen concentrations or water temperature. Therefore, patterns of chemical speciation in aqueous environments are summarized as a function of both the gradient of proton- (pH) and electron availability (pE, or electrical potential). A detailed exploration of these relationships for individual elements is beyond the scope of this chapter, but can be found in many geochemical and biogeochemical textbooks (e.g., Stumm and Morgan, 1995; Langmuir, 1997; Schlesinger and Bernhardt, 2020).

Organic matter and nutrient cycling

Organic matter (OM) cycling in aquatic ecosystems is complex and depends on a multitude of factors that regulate its concentration and chemical composition. Changes in pH thus have a variable, and typically secondary influence on dissolved aquatic OM (DOM) properties, relative to other environmental changes such as land use, hydrology, and other factors (Spencer et al., 2007). In a controlled lab setting, in vitro modification of pH from 2 to 10 demonstrated modest changes in OM light absorbance and fluorescence at intermediate pH adjustment, and more pronounced changes at both pH extremes (Spencer et al., 2007). Changes to pH can also impact how OM interacts with nutrients and bioreactive metals. The capacity for the dissolved fraction of organic matter to bind bioreactive elements such as Fe decreases dramatically as pH increases from ~4.5 to 7 (Neubauer et al., 2013). Pace et al. (2013) showed that increases in pH from 7 to >10, alongside increased base cation availability, may cause polymers and colloids in the dissolved OM pool to expand in size, exposing chromophoric OM to sunlight that transforms and photo-bleaches the OM pool. This mechanism may alter the light climate of alkaline surface waters, where light-attenuation by the OM pool is reduced.

Changes in pH can also impact aquatic nutrient cycling. Where photosynthetic CO_2 uptake leads to pH increases to ~8 to 9.2, sediment P absorption can be slowed, and eventually reversed to cause sediment P desorption and release (Fisher and Wood, 2004). Such moderate increases in pH may have less impact on ecosystem P recycling than do other drivers such as biological organic P recycling or wind-driven mixing (Fisher and Wood, 2004). In systems with extreme autotrophic growth or large inputs of alkaline solutes, pH increases to >10 can generate much higher rates of sediment P desorption and release, where hydroxide and other ions may replace phosphate at binding sites on oxidized iron precipitates (Fisher and Wood, 2004 and references therein). Aquatic nitrogen cycling is also importantly mediated by environmental pH. Sediment nitrification rates in temperate US streams showed a unimodal response to pH changes, and were highest at pH ~7 to 7.5 (Strauss et al., 2002).

Carbon cycling

In many systems, the tight coupling between pH and inorganic carbon speciation (Eq. 1 and Fig. 1) yields a direct correlation between pH and the concentration of CO_2, an important greenhouse gas. Lake acidification has been demonstrated to increase aqueous CO_2 in several studies. For example, acidification of two shallow tropical lakes resulted in large emissions of CO_2 (Marotta et al., 2010). In contrast, alkaline lakes can often act as CO_2 sinks due to CO_2 undersaturation relative to atmospheric concentrations (Finlay et al., 2015). Yet, this undersaturation is dependent on dissolved inorganic carbon concentration in the water, where highly saline lakes, with elevated DIC can still act as CO_2 sources, despite pH levels above 9.0 (Duarte et al., 2008). This pattern can be explained by the equilibria between carbonate species with pH (Fig. 1). Elevated pH can additionally impact CO_2 flux and alter exchange with the atmosphere through chemical enhancement of CO_2 flux, whereby flux rates are accelerated at higher pH levels than would be seen without enhancement (Wanninkhof and Knox, 1996).

As is often the case when describing the chemical environment of lakes, it can be difficult to determine causal pathways: do changes in pH impact CO_2, or do changes in CO_2 impact pH? The answer is usually "both." Metabolic CO_2 cycling directly controls pH on shorter timescales (hourly, to daily and weekly) (e.g., Maberly, 1996); intermediate timescales of pH change (e.g., seasonal) can be shaped by inputs of external water masses with distinct pH due to different content of CO_2, organic acids, bases, and nutrients (Buffam et al., 2008); over years to centuries, natural and human driven changes can regulate the influx of acids and bases to aquatic networks via catchment weathering, atmospheric deposition, direct loading of nutrients, acids, and bases from point sources, and climatic shifts that restructure ecosystems and drive solute evapoconcentration and alkalinization (e.g., Tibby et al., 2003; Finlay et al., 2015; Kaushal et al., 2018).

Metals and metal toxicity

The pH of aquatic ecosystems exerts an important influence over metal exposure and toxicity. Whether natural or linked to human activities such as mining and AMD (reviewed by Gray, 1997; Dold, 2008), acidified water interacts with the surrounding geology to liberate metals and other elements, and induce potentially toxic effects on aquatic food webs. Metal toxicity effects are exerted on organisms both directly, and indirectly through biomagnification or bio accumulation (Gray, 1997). Metals typically become more toxic to biota at low pH because of cation exchange in biological membranes, where H^+ competes with metal cations for exchange sites, and because pH affects metal speciation (Peterson et al., 1984). Conversely, as pH increases above 4.5 iron speciation shifts

from predominantly organic-bound, to the formation of iron (oxy)hydroxide precipitates that increase in size, and are thus more prone to deposition, as a function of pH and redox conditions (Neubauer et al., 2013). At low pH, Cd and Cu inhibit P uptake by algae, which causes increased metal toxicity in acidic conditions (Peterson et al., 1984). The increasing bioavailability of metals in low pH waters results in increasing bioaccumulation of methylmercury, Cd, and Pb in fish. At elevated levels, these heavy metals become increasingly toxic when Ca^{2+} concentrations are low, which increases the permeability of biological membranes to the metals (Spry and Wiener, 1991).

Community ecology

The pH of inland waters has considerable impacts on community ecology, through all levels of the food web. Species have optimal pH ranges and these biological tolerances are one factor that can initially structure the aquatic community, a fact that has led to the recreation of lake pH over time using paleolimnological analyses of diatom valves in sediment cores (e.g., Cumming et al., 1992). Many additional environmental factors frequently interact and contribute to the effect of pH on organisms and ecosystem functioning (Schindler et al., 1996). The following section provides illustrative examples of the responses of biological communities to changing pH, but is not intended to be an exhaustive evaluation of the extensive research which has been conducted on this topic.

Plankton

Limited studies on the impact of lake water pH on bacterial community structure and function have demonstrated a few interesting trends. Like other biota, bacterioplankton exhibit maximal growth at taxa-specific optimal pH (Bååth and Kritzberg, 2015). In lakes of the Mackenzie Delta in northern Canada, bacterial community respiration and production declined during rapid (hourly to daily) increases in pH arising from an macrophyte growth. These reductions in bacterial community metabolism recovered after a few days when the bacterial community composition shifted to adjust to the new lake pH (Tank et al., 2009).

The impact of changing pH on the phytoplankton community is complex and involves many interacting factors including not only pH, but also DOC, DIC and other components of the food web (Fig. 5, Leavitt et al., 1999), and algal communities have consequently experienced dramatic changes through lake acidification and recovery. In one study conducted at the Experimental Lakes Area, total algal biomass increased 200–400% under mild acidification (from pH 6.6 to 5.0), but then declined to near-baseline levels under severe acidification (pH 4.5, Leavitt et al., 1999).

Zooplankton species richness, diversity, and abundance all were reduced by acidification. Calcium-rich zooplankton species, including *Daphnia* are often dramatically affected by acidification and reductions of calcium to <1.5 mg L^{-1} can reduce population growth rates through inhibition of reproduction and clutch sizes (Jeziorski et al., 2008).

Zooplankton recovery after lake pH recovery from acidification has been demonstrated to be slow, owing to the varying recovery rates of predators in the system causing a top-down trophic cascade. The slow return of catchment derived Ca^{2+} can also delay the recovery of *Daphnia* species and other calcium-rich biota (Jeziorski et al., 2008). The slow recovery of fish populations (see "Fish" section below), resulted in elevated invertebrate predator populations (the beetle *Graphoderus liberus*) which maintained low calanoid and cladoceran zooplankton population sizes through predation (Arnott et al., 2006).

Macroinvertebrates

Acidification and associated reductions in Ca^{2+} were found to reduce populations of oligochaetes, mayflies and some chironomids, but increased odonata, trichoptera, other chironomids and *Crangonyx* (amphipod) (Stephenson et al., 1994). *Chaoborus punctipennis* populations doubled in an experimental acidification study in Little Rock, Wisconsin, United States. This increase in *Chaoborus* numbers was attributed to a decline in an invertebrate predator (*Mesocyclops edax*) on early stages of *Chaoborus*, rather than an increase in food availability or reduction in fish predation (Fischer and Frost, 1997). The impact of acidification on macroinvertebrates has also been attributed to varying metal toxicity, where cadmium toxicity decreased, but aluminum toxicity was much higher when pH was reduced (Wren and Stephenson, 1991).

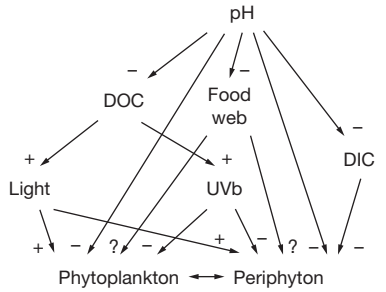

Fig. 5 Main potential direct and indirect effects of lake acidification on algal abundance. Effects of acidification either inhibit (–) or stimulate (+) response variables. Effects of food-web changes on algae depend on complex food-web interactions and are not predictable (?). From Leavitt PR, Findlay DL, Hall RI and Smol JP (1999) Algal responses to dissolved organic carbon loss and pH decline during whole-lake acidification: Evidence from paleolimnology. *Limnology and Oceanography* 44: 757–773.

Fish

Lake acidification has had dramatic impacts on fish populations and communities, reducing fish diversity at low pH (Driscoll et al., 2001). Scandinavian lakes lost entire fish populations, and acidification was determined to be the cause of the most devastating fish losses recorded in Scandinavian history (Muniz et al., 1984). After a few years of fluctuating population sizes of fish in Lake 223 of the ELA, lake trout (*Salvelinus namaycush*), white sucker (*Catostomus commersonii*), fathead minnow (*Pimephales promelas*) and slimy sculpin (*Cottus cognatus*) all showed a reduction in survival to adulthood (Mills et al., 1987). At low pH (<5 or 6) reproductive failure and extirpation of populations can occur (Magnuson et al., 1984). The reduction in DOC concentrations with acidification can cause increased UV-B penetration and changes to epilimnetic depth (see "The impacts of pH change on ecosystem properties" section), with consequences to the fish community. An increased epilimnion depth and increased exposure to UV-B penetration might cause a reduction in habitat, limiting fish to a narrow vertical layer where UV-B limits their survival above, and low oxygen limits them below (Schindler et al., 1996).

Conclusions

The pH of inland waters can range widely (2–12), but is typically well buffered, such that most systems naturally lie within the circumneutral range (6–9). Surface water pH is not static, but can change on hourly to much longer (multidecadal, centennial) timescales as a result of both abiotic and biotic processes operating both within and outside a waterbody's physical boundaries (e.g., in watershed soils, or in distant landscapes that are connected by atmospheric transport of materials).

Aquatic ecosystems have undergone changes (in many cases, extreme) in pH due to human activities that have dramatically intensified since the onset of the industrial revolution. The consequences of these activities are complex, and vary from system to system and process to process, such that both acidification and alkalinization of aquatic systems are observed in different environments. These large, directional changes in pH (both natural and human-induced) have dramatic impacts on the structure and functioning of aquatic ecosystems, which can restructure communities from bacteria up to fish and other vertebrates.

Lotic and lentic aquatic systems can recover from human disturbances to their baseline pH. Case studies show how intensive government-led initiatives can mitigate negative impacts of acidification and allow for the recovery of biota in impacted systems. These examples highlight the important role that science-guided policies can have in remediating pH levels in aquatic ecosystems, but also note the importance of a comprehensive understanding of the long-term (centennial- to millennial-scale) patterns in pH if the goal is to reach "baseline" values. Moreover, despite these accomplishments, we have not entirely curtailed anthropogenic pH change in aquatic ecosystems, and in many cases it is now the non-point influences that are driving acidification and alkalinization of watersheds worldwide.

Knowledge gaps

- Alkalinization is much less studied than acidification, and remains less well understood.
  - In many cases, we can learn from lessons related to recovery from acidification, but new challenges are expected with alkalinization
- Differentiating between underlying causes of acidification and alkalinization will be important for mitigation efforts
- Determining baseline pH of lakes in a historical context is crucial for determining whether mitigation is required

Ecological Zonation in Lakes

WM Lewis, University of Colorado, Boulder, CO, United States

This is a reprint of W.M. Lewis, Ecological Zonation in Lakes, Editor(s): Gene E. Likens, Encyclopedia of Inland Waters, Academic Press, 2009, Pages 416-422, ISBN 9780123706263, https://doi.org/10.1016/B978-012370626-3.00209-X.

Glossary

Aphotic – **Without light, generally interpreted limno-logically as receiving less than 1% of solar irradiance reaching a lake surface.** Epilimnion – **The uppermost and warmest layer (also called the mixed layer) of a lake that experiences density stratification induced by seasonal warming at the lake surface.** Euphotic – **That portion of a lake receiving sufficient solar irradiance to support photosynthesis (typically more than 1% of full solar irradiance).** Hypolimnion – **The most dense, deepest, and coolest layer of a thermally stratified lake. The hypolimnion does not support photosynthesis, because it lacks solar irradiance, and in many cases shows partial or complete depletion of dissolved oxygen.** Littoral – **Near the shore of a waterbody, where irradiance reaching the bottom is above 1% of solar irradiance at the water surface.** Metalimnion – **A layer of transitional density and temperature that connects the epilimnion to the hypolimnion.** Pelagic – **Beyond the littoral zone of a lake.** Benthic – **The zone of a lake extending a few centimeters above and below the bottom of the lake.**

Introduction

Lakes show many kinds of spatial variation in both vertical and horizontal dimensions. Variation can be chemical, physical, or biotic, and is important to the understanding of ecosystem functions. Although some types of variation are unique to specific classes of lakes, others are common to most lakes, and correspond to an obvious spatial organization of the biota in lakes. The existence of certain common types of spatial organization in lakes has led to the naming of specific zones that have distinctive ecological characteristics.

A complete list of all zones that have been named by limnologists would be lengthy and complex (Wetzel, 2001). Complex nomenclatures have been abandoned by modern limnologists, however. Modern limnology focuses on simple zonation systems that are easily applied by limnologists and others interested in lakes. Table 1 gives a summary of zonation systems that are currently in broad use.

Horizontal Zonation: Littoral and Pelagic

The nearshore area of a lake (littoral zone) differs from the offshore shore area (pelagic zone). The only group of autotrophs in the pelagic zone is the phytoplankton, which consists of very small algae that are suspended in the water column. The littoral zone also has phytoplankton (which move freely between littoral zone and pelagic zone), but also has two other categories of autotrophs (Figure 1): aquatic vascular plants (aquatic macrophytes), and films of attached algae (periphyton). Periphyton grow on the leaves of macrophytes and on other solid surfaces such as mud, sand, rocks, or wood.

The outer margin of the littoral zone, beyond which is the pelagic zone, is the point at which significant growth of macrophytes and periphyton becomes impossible because of darkness. This boundary corresponds approximately to the location at which the amount of solar irradiance reaching the bottom of the lake is $<1\%$ of surface irradiance. At bottom irradiances $<1\%$, there is little or no net photosynthesis, which prevents growth of the attached autotrophs (macrophytes and periphyton) that are typical of the littoral zone.

For a lake of a given size and shape, the width of the littoral zone depends on transparency of the water as well as shoreline slope (Figure 2). In oligotrophic lakes, which have low nutrient concentrations and therefore develop very small amounts of the phytoplankton biomass that could shade the lower water column of lakes, the littoral zone extends to depths of 4–20m or even

Table 1 Summary of the four major zonation systems for lakes.

Zonation	*Temporal variability*	*Description*
Horizontal	Stable	
Pelagic zone		Offshore (bottom irradiance $<1\%$)
Littoral zone		Nearshore (bottom irradiance $\geq 1\%$)
Vertical	Stable	
Water column		Water extending from lake surface to bottom
Lacustrine sediments		Lake-generated solids below the water column
Benthic zone		Interface of water column and lake bottom
Vertical	Seasonal	
Epilimnion	(mixed layer)	Uppermost density layer (warm)
Metalimnion		Middle density layer (transition)
Hypolimnion		Bottom density layer (cool)
Vertical	Dynamic	
Euphotic zone		Portions of a lake with $\geq 1\%$ light (photosynthesis)
Aphotic zone		Portions of a lake with $<1\%$ light (no photosynthesis)

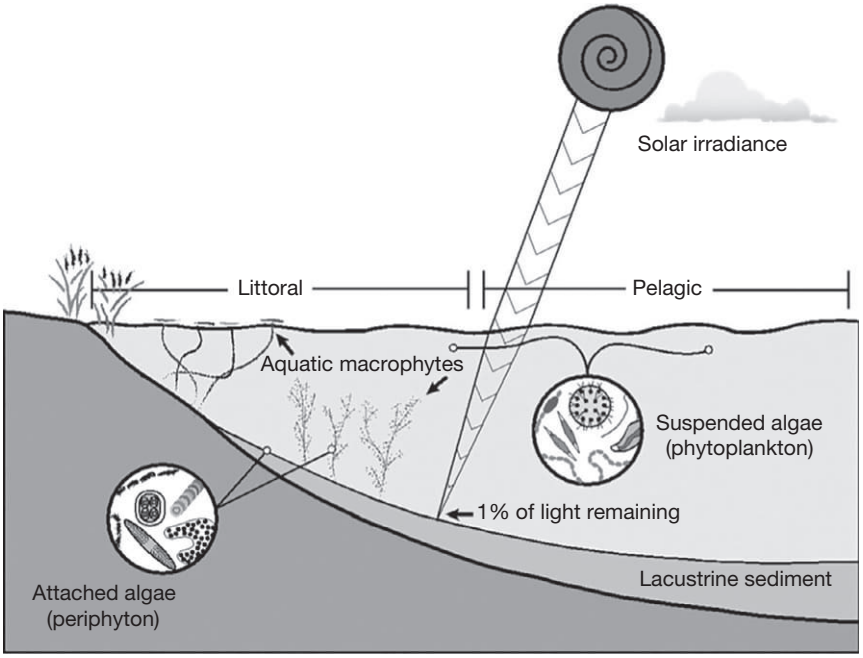

Figure 1 Depiction of the littoral and pelagic zones of a lake. The littoral zone extends outward from the shoreline to approximately the location at which the solar irradiance at the bottom of the lake corresponds to about 1% of the solar irradiance at the top of the water column. Within the littoral zone, growth of aquatic macrophytes and attached algae (periphyton) is possible. The pelagic zone begins at the outer margin of the littoral zone. Phytoplankton are exchanged freely between the littoral and pelagic zones as well.

more, depending on transparency of the water. In the eutrophic category, the depth of 1% irradiance ranges between 0.1 and about 2 m, and the mesotrophic category spans ~2–4 m. In the most extreme cases of eutrophication (lakes highly enriched with nutrients), where the depth of 1% light corresponds to only a few centimeters, the littoral zone as defined by light is virtually absent, and the littoral zone may be defined instead by the zone of influence for traveling waves and corresponding disturbance of the bottom (0.5–1.5 m). In general, small lakes have a higher percentage of surface area in the littoral zone than do large lakes (**Figure 2**), although some large, shallow lakes have large littoral zones (e.g., Lake Okeechobee, Florida).

Although littoral zones are most easily defined on the basis of macrophytes and attached algae, a littoral zone can also be distinguished from a pelagic zone by its distinctive heterotrophic communities and by its food-web structure. Because littoral zones provide shelter, whereas pelagic zones do not, littoral zones often support dense populations of organisms that thrive when protected from predation. Larval and juvenile fish, for example, seek shelter within the littoral zone from predation by larger fish. Large invertebrates, such as dragonfly larvae or crayfish, typically are most abundant in littoral zones, where they are least likely to be consumed by fish. The littoral zone also has invertebrate communities that specialize in the consumption of attached algae by nipping or scraping the algal coatings on macrophytes or other solid surfaces. In the pelagic zone, there is no food source comparable to the periphyton of a littoral zone. In general, the communities of a littoral zone are more diverse than those of the pelagic zone, and the key species of the two zones differ.

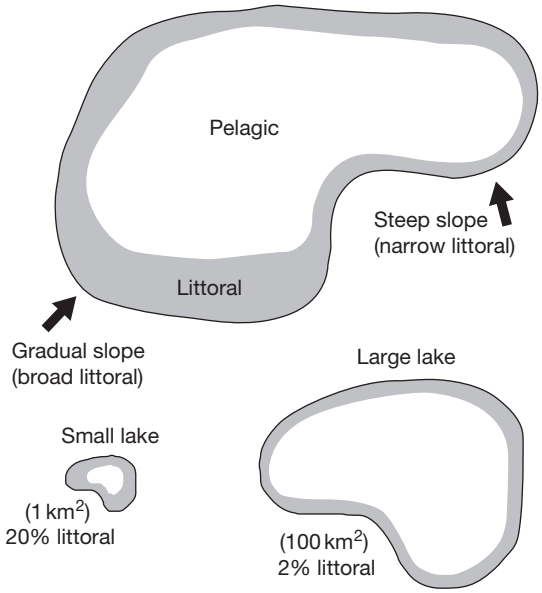

Figure 2 A plan view of the littoral and pelagic zones of lakes, illustrating variation in the width of the littoral zone associated with changes in slope along the margin of any given lake, and the tendency of smaller lakes to have a higher percent areal coverage of littoral zone for the total lake area.

In the pelagic zone of a lake, the autotroph community is composed of phytoplankton (**Figure 1**), which are adapted for life in an environment that is free of solid surfaces. Consumers, such as zooplankton, living and reproducing in the pelagic zone must escape predators by avoiding the upper, illuminated part of the water column during the day, or must be agile or so small as to be impractical as a food for many predators.

Vertical Zonation: Water Column, Sediments, and the Benthic Interface

Lakes have a vertical zonation consisting of the water column, underlying lacustrine sediments (lake sediments), and the benthic zone, which occupies a few centimeters above and below the sediment–water interface (**Figure 3**). The water column extends across both the pelagic and littoral zones. The water column of the pelagic zone is driven by wind-generated currents into the littoral zone

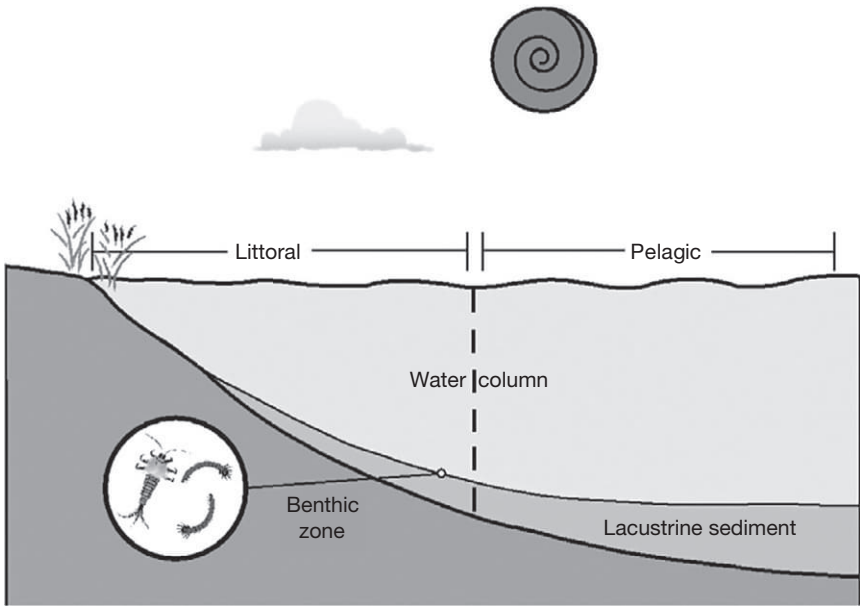

Figure 3 Illustration of the division of a lake into three vertical components: water column, lacustrine sediments, and the boundary between the water column and sediments (benthic zone).

where water is displaced from the littoral zone into the pelagic zone. Thus, water-column constituents such as dissolved gases, dissolved solids, suspended solids, and suspended organisms are constantly exchanged between the pelagic zone and the littoral zone whenever there are currents in the top few meters of a lake. Chemical differences between the top few meters of the pelagic zone and the littoral zone may develop under the influence of biological processes, however, when currents are weak.

Although the water column is shared by the pelagic zone and the littoral zone, lacustrine sediments always underlie the pelagic zone but may or may not cover all of the littoral zone. Sediments are produced by the settling of mineral and organic matter that is derived from the watershed of a lake, and from organic matter consisting of fecal pellets, organic debris (detritus), and skeletal fragments of organisms derived from the lake itself. A constant sedimentation of this fine mixed solid material occurs over the entire lake. Disturbance of sediments by moving water occurs primarily in shallow water, where most of the energy of wind-generated currents and traveling waves are expended against the bottom of the littoral zone. Thus, energy near the shore may cause fine sediments, such as those that are characteristic of lakes, to be swept to deeper water. For this reason, lacustrine sediments may not accumulate in all parts of a littoral zone. Alternatively, in lakes that are small or strongly sheltered from wind, and thus not subjected to extremes of wind-generated disturbance, lacustrine sediments may occupy most or all of the littoral zone.

Lacustrine sediments are capable of supporting eukaryotic organisms (algae, protozoans, invertebrates, vertebrates) only when they are oxic. When the hypolimnion is oxic, the top few millimeters of sediment often (but not always) will be oxic. Below the top few millimeters, there typically is a decline in oxygen because microbial respiration supported by organic matter in the sediments leads to the depletion of oxygen, but some oxygen (e.g., 50%) may persist because invertebrates in the sediment pump oxygen through small tunnels into the sediment to as much as 10–20 cm within the sediments. Almost all of the deeper sediments (>10–20 cm) in lakes, which may be many meters thick, are anoxic and can support only microbes that are capable of anaerobic metabolism. When the water of the hypolimnion is anoxic, the entire sediment profile is anoxic, and can support only anaerobic microbes. There are many such microbes, and anoxic sediments show strong evidence of their metabolism, including accumulation of reduced substances such as ferrous iron, sulfide, and methane. At progressively greater depths in sediments, however, the metabolism of microbial anaerobes slows because the easily used portions of organic matter are exhausted or because oxidizing agents such as sulfate or nitrate may be depleted. Thus, there is a decline in microbial metabolic rate from the upper sediments to the deepest sediments, which are almost inert biologically.

The interface between the water column and the lacustrine sediments carries its own name ('benthic zone') because it is exceptionally important from the ecosystem perspective, despite its narrow dimensions. Organisms that live on the sediment surface or just below it (down to about 20 cm) carry the name 'benthos'. In sediments below the pelagic zone, the benthos does not include autotrophs because there is no light reaching these sediments. The benthic zone is rich in invertebrates, provided that it is oxic at the surface, which is not always the case. Oxic benthic zones often support a number of important invertebrates, most of which are embedded within the sediment, as necessary to avoid predation. Examples include midge larvae and the larvae of other insects (**Figure 3**). Certain fish species (e.g., catfish) may be associated closely with the benthic zone, in that they are adapted to find and consume the embedded invertebrates by chemosensory means, without using vision. Oxic benthic zones also support protozoans and bacteria conducting oxic metabolism, including especially the oxic breakdown of organic matter. Anoxic benthic zones only support anaerobic bacteria and a few specialized protozoans.

The benthic zone extends not only across the bottom of the pelagic zone but also across the bottom of the littoral zone (**Figure 3**). The benthic component of the littoral zone includes not only the interface between lacustrine sediments and the water column but also between the water column and any parts of the littoral zone that happen to be swept free of lacustrine sediments. Thus, the entire solid surface at the bottom of a lake lies within the benthic zone.

Seasonal Zonation: Vertical Layering Based on Density

Because the temperature of water affects its density, it is common for lakes to develop layers of different density corresponding to temperature differences across the layers. At temperate latitudes, all but the shallowest lakes develop a density stratification during spring that typically persists until late fall. Similar seasonal stratification is also common in subtropical and tropical lakes, but the duration of stratification is longer and the nonstratified period (mixing period) does not contain an interval of ice cover, as it often does at temperate latitudes.

Density stratification causes an ecologically important vertical zonation of lakes (**Figure 4**). An upper layer, which contains the air–water interface, is the epilimnion of a stratified lake; it may also be referred to as the 'mixed layer'. The epilimnion is the warmest and least dense of the three layers. Its thickness is strongly influenced by the size of the lake, in that larger lakes show a higher transfer of wind energy to water currents, which thickens the mixed layer during its period of formation. In sheltered water bodies, mixed layers may be as thin as two meters, but in larger (>10km^2), windswept water bodies, they may be as thick as 15–20m. In addition, the thickness of a mixed layer in a given lake increases over the fall cooling period, during which the bottom of the mixed layer erodes the layer below.

The mixed layer often shows sufficient irradiance throughout its full thickness to support photosynthesis. Even in lakes that have very low transparency, the uppermost portion of the mixed layer is well illuminated.

The mixed layer extends continuously across the pelagic zone and littoral zone. Only in highly transparent lakes does the littoral zone extend below the mixed layer. Within the pelagic portion of the mixed layer, zooplankton herbivores feed vigorously on phytoplankton, but may move downward out of the mixed layer during the day in order to avoid predation. Other small

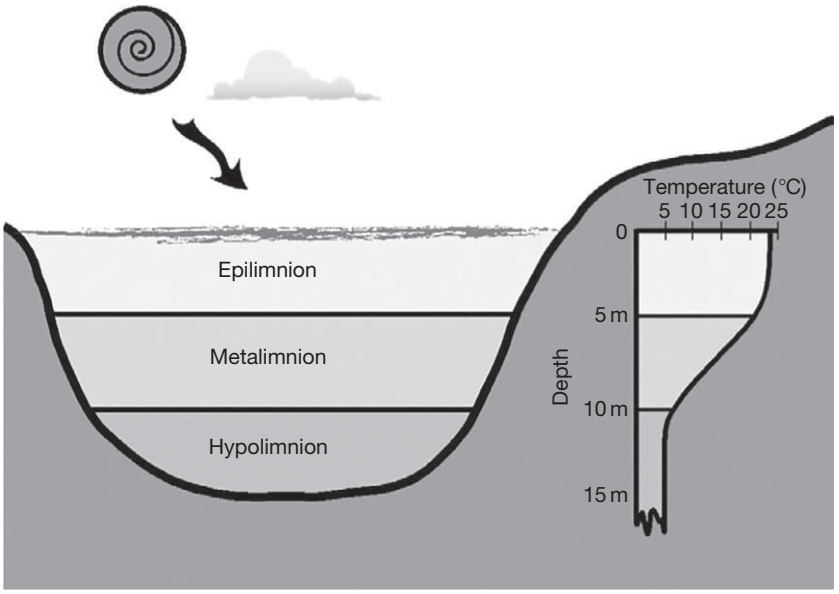

Figure 4 Illustration of the three density (temperature) layers determined by seasonal stratification of a water column.

invertebrates often migrate out of the mixed layer during daylight hours as well. Most of the energy of wind transferred to water is dissipated within the mixed layer; this energy contributes to the high degree of uniformity in the mixed layer at small to intermediate distance scales (up to 10km or more), except during extended calm weather.

Below the mixed layer of a stratified lake is a thermal gradient, corresponding to a density gradient. The gradient makes a transition in temperature and density between the mixed layer and the coolest layer, which lies in contact with the bottom of the lake. The thermal transition is referred to as the thermocline, but the layer within which the thermocline lies is best referred to as the metalimnion (Figure 4). The metalimnion may or may not receive sufficient irradiance to support photosynthesis. In lakes that are quite transparent, phytoplankton often grows in the metalimnion, whereas lakes of low transparency seldom show growth of autotrophs in the metalimnion. In the pelagic zone, phytoplankton growing in the metalimnion of a transparent lake may be of different species composition than phytoplankton growing in the mixed layer. Some mass transfer occurs between the epilimnion and the metalimnion, the amount of which is dependent on the amount of turbulence at the interface of the two layers. The thickness of the metalimnion varies a great deal among lakes. It is seldom thinner than 2 m, and may be as thick as the mixed layer or even thicker.

The deepest seasonal layer in lakes is the hypolimnion. The temperature and density of the hypolimnion typically reflect conditions that occur when seasonal stratification becomes established. It is common for stratified lakes at temperate latitudes to have hypolimnetic waters that are near 4 °C, the temperature at which water is most dense, or slightly above 4 °C, reflecting the prevailing water temperature at the time of spring stratification. At lower latitudes, the minimum temperature increases, until it reaches approximately 24 °C within 10° latitude of the equator. Thus, a stratified lake might have a hypolimnion of 4 °C in Wisconsin and 24 °C in Venezuela.

The hypolimnion, in contrast to the mixed layer, has a very low degree of turbulence, is too dark for photosynthesis, and is isolated from the surface. Also, except at low latitudes, it is much cooler than the mixed layer (Figure 4).

Because of its physical isolation from photosynthesis and from atmospheric oxygen, the hypolimnion typically loses oxygen during the period of stratification. The loss of oxygen depends on the size of the hypolimnion, its temperature, the duration of stratification, and the amount of organic matter coming down to it from above, which is a byproduct of the trophic status of the lake. In lakes that are just deep enough to support stable stratification (e.g., 10–20 m), the hypolimnion may be absent, as the metalimnion reaches the bottom of the lake. In deeper lakes, the hypolimnion may equal the volume of the epilimnion, and in very deep lakes (e.g., >100 m), the hypolimnion may be much larger than the epilimnion. Lakes with a very large hypolimnion often maintain hypolimnetic oxygen throughout the stratification season, especially at temperate latitudes where the hypolimnion is cool. Lakes with a very small hypolimnion typically lose most or all of their oxygen, even if they have low productivity, because the sediments of a lake contain enough organic matter to demand most or all the oxygen from a small hypolimnion. Oxygen concentration in lakes with a hypolimnion of intermediate size is quite sensitive to trophic state. Eutrophic lakes typically lose most or all of their hypolimnetic oxygen, thus producing an anoxic benthic zone, whereas lakes of lower productivity may retain an oxic hypolimnion overlying a benthic zone that has an oxidized surface.

Loss of oxygen is of great importance to the metabolism of a lake because eukaryotes (most protozoa, invertebrates, fish, algae) cannot live in anoxic waters. Thus, loss of hypolimnetic oxygen excludes nonmicrobial components of the biota from the deep waters of a lake.

Zones with Dynamic Dimensions: Euphotic and Aphotic

Photosynthesis in the water column of lake is dependent on the availability of photosynthetically available radiation (PAR, wavelengths 350–700 nm). PAR, which corresponds closely to the spectrum of human vision, is removed exponentially as it travels through a water column. The availability of PAR is high during daylight hours at or near the surface of the water column. If nutrients are present, rates of photosynthesis are likely to be high near the surface. A progressive decline in PAR with depth is paraleled by a decline in rates of photosynthesis with depth. At a depth corresponding to ~1% of the surface irradiance, net photosynthesis reaches zero, which is a threshold beyond which accumulation of plant biomass is not possible. At depths below the 1% level, photosynthetic organisms (e.g., phytoplankton) lose mass and either die or become dormant unless they are returned to the surface by water currents, which commonly occurs in the mixed layer but not in the metalimnion or hypolimnion.

The depth between the water surface and the depth of 1% irradiance is referred to as the euphotic zone (Figure 5). Below the depth of 1% irradiance is the aphotic zone. The euphotic zone may not occupy the entire epilimnion of a lake, or may extend to the full thickness of the epilimnion. In some cases, the euphotic zone may extend into the metalimnion, but its extension into the hypolimnion of a lake is unlikely.

The thickness of the euphotic zone is dependent on transparency of the water, which in turn is influenced by dissolved color (colored organic acids from soils), inorganic suspended matter (silt and clay), and living organisms, and especially those that contain chlorophyll, an efficient absorber of light. Because the concentrations of each of these constituents can vary on relatively short time scales (e.g., weekly), the thickness of the euphotic and aphotic zones is dynamic; it is subject to both seasonal and irregular change over time.

The thickness of the euphotic zone may be small at times of high runoff, when suspended inorganic material and colored organic compounds enter lakes in the largest quantities. Other times when the euphotic zone may be thin it coincides with algal blooms, which can produce sufficient chlorophyll to reduce the transparency of the water column substantially. Conversely, the euphotic zone may thicken substantially when nutrients are exhausted because phytoplankton biomass is likely to decline, thus increasing transparency of the water. Also, strong grazing by zooplankton may thicken the euphotic zone by removing phytoplankton biomass.

The euphotic zone extends across an entire lake, including both pelagic and littoral zones. In fact, the mean thickness of the euphotic zone determines the outer boundary of the littoral zone because of its effect on the attached vegetation that is characteristic of littoral zones.

Overview

The four sets of zones shown in Table 1 define distinctive habitats within lakes that are associated with specific categories of organisms and biogeochemical or metabolic processes. The zones reflect some of the most important physical and chemical factors

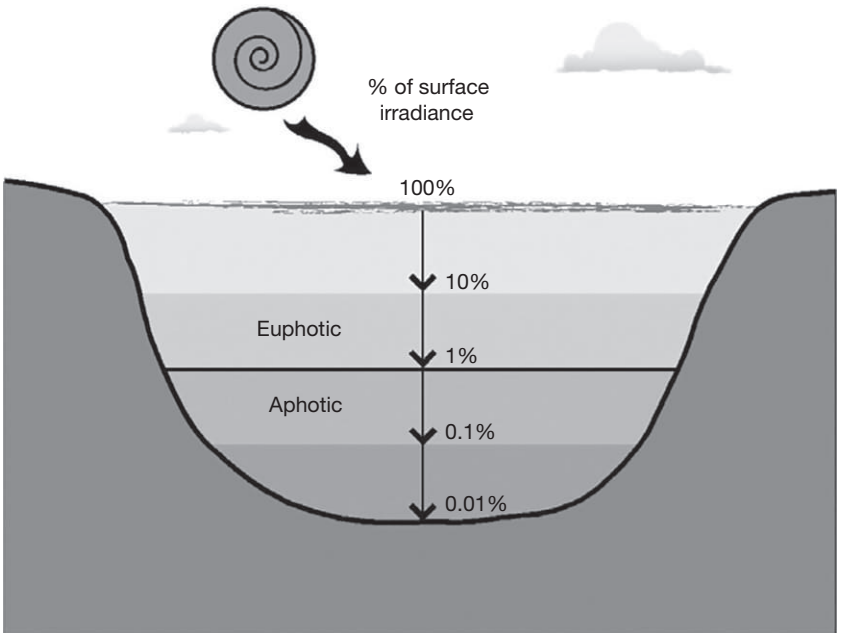

Figure 5 Illustration of the division of a lake into euphotic and aphotic zones. The euphotic zone, which is the lake volume within which positive net photosynthesis can occur, corresponds approximately to the depth at which ≥1% of incoming irradiance is found. Portions of the lake below this boundary have negative net photosynthesis or negligible total photosynthesis.

that control biotically driven processes and biotic community structure. Zonation, although generally a qualitative rather a quantitative concept, reflects accumulation of experience and measurements across lakes of many kinds. Therefore, knowledge of zonal boundaries in a lake allows some general predictions to be made about the kinds of organisms and rates of biogeochemical processes that will occur in a given lake, and the spatial distribution of these organisms and processes.

Glossary

Catchment The land and water area that drains into a given inland water. It is defined at its perimeter by the watershed, and is synonymous with the drainage basin.
Cell quota The amount of a particular element in a cell.
Eutrophication The process, often driven by human activities, that increases productivity usually as a result of increased nutrient load and causes a series of consequent changes to the ecosystem.
Michaelis-Menten/Monod kinetics A kinetic response curve with the form of a rectangular hyperbola characterized by a large increase in rates of activity (Michaelis-Menten) or growth (Monod) at low substrate concentrations and no further increase in rate at high, saturating, substrate concentrations.
Mixotrophy The ability to use a combination of both inorganic and organic sources of nutrients and energy.
Osmo-organotrophy The ability to use dissolved organic compounds as sources of nutrients and energy.
Phago-organotrophy The ability to ingest living or dead organic particles as sources of nutrients and energy.
Photoautotrophy (=photolithotrophy) involves the photoproduction of ATP, and NAD(P)H with an inorganic electron source, and the consumption of ATP and NAD(*P*)H to convert CO_2 to reduced organic C using an autotrophic CO_2 fixation pathway.
Stoichiometry The relative amounts of different elements, usually expressed on an atomic basis.

Introduction

Phytoplankton form the base of the pelagic food web in inland waters. Unlike rooted plants with access to nutrients in the sediment, phytoplankton depend on the open water as their sole direct source of minerals. Phytoplankton comprise cyanobacteria and phylogenetically diverse eukaryotic algae that convert light energy and mineral nutrients into organic matter. Many species also exploit the elements and energy within dissolved organic compounds and particles produced in the catchment or within the water. Here, we describe the nutrient requirements of phytoplankton, their different modes of nutrition, the mechanisms they employ to acquire nutrients and the ecological consequences of their varying ability to exploit an often scarce and spatially and temporally variable resource. When nutrients are abundant, often as a result of human disruption of nutrient cycles, phytoplankton productivity, and often biomass, increases to the point that it causes a range of ecological consequences that reduce the value of the water resource for mankind.

☆*Change History:* October 2021. SC Maberly, DB Van de Waal, JA Raven are involved in preparing this update. The chapter has been completely rewritten with no common figures/ tables, etc.

Nutrient requirements and cellular composition

Phytoplankton take up and assimilate nutrients with the use of light as an energy source. Although carbon is not always thought of as a nutrient, we include it here since it is a major element in most phytoplankton cells, typically comprising around 50% of ash-free dry weight. Nutrients are assimilated into a range of biochemicals, including carbohydrates, lipids, amino acids and nucleotides. These serve as structural compounds, are involved in energy and nutrient capture and storage, and the transfer of genetic information. A large range of elements are required including, in (approximate) order of atomic abundance: H, C, O, N, P, K, S, Mg, Ca, Cl, Fe, Mn, Cu, Zn, Ni, Co and for some heterokonts such as diatoms, Si.

In the 1930s, the American oceanographer, Alfred Redfield, analyzed depth profiles in the ocean and showed that nutrients and phytoplankton had an average atomic ratio of 106C: 16 N: 1P (Redfield, 1934). Subsequent refinements to the ratio have been produced (Geider and La Roche, 2002), but it is widely used to represent the approximate stoichiometric requirements of exponentially growing, nutrient replete marine and freshwater phytoplankton for these three important elements. Trace elements are required, in smaller amounts, and are involved in many processes. For example: sulfur is contained in some amino acids and redox-signaling compounds, the oxygen-evolving complex of Photosystem II requires Mn, the electron transport chain between photosystems II and I involves Fe and sometimes Cu, the nitrogenase enzyme in cyanobacteria able to fix N_2 requires Fe and usually Mo (rarely V), different aspects of nitrogen assimilation involve Mo and Ni, the extracellular hydrolysis of organophosphates involves Zn or Co, and while carbonic anhydrase normally requires Zn, other elements including Co, Cd or Mn are present depending on the sub-type of the enzyme or as replacements when Zn is unavailable (Morel et al., 2020). Using algal cultures of marine and freshwater phytoplankton, (Quigg et al., 2011) showed that the average trace element atomic stoichiometry was 18 Fe: 2.8 Mn: 1.34 Zn: 0.50 Cu: 0.11 Co: 0.11 Cd to 1000 mol P. However, there were consistent differences among evolutionary groups. For example, the green plastid lineage had higher Fe, Cu and Cd to P ratios and lower Mn to P ratios than the red plastid lineage. Growth limitation or yield limitation by P, N and C has been demonstrated in freshwater phytoplankton populations, and Si can limit diatom at certain times of the year. There is also evidence for limitation by trace elements including K, Co, Cu, Fe, and Mo in some lakes.

The nutrient content of phytoplankton cells will vary, between bounds, depending on nutrient availability. The minimum cell quota (Q_{min}) occurs where the growth rate is zero and increases with cell volume in a similar way for marine and freshwater phytoplankton (Edwards et al., 2012). Many phytoplankton indulge in "luxury consumption," storing nutrients in excess of the cell quota to permit growth when external nutrients are depleted. For example, the commonly limiting nutrient phosphorus can be stored as polyphosphate granules and used as a reserve of P and energy (Sanz-Luque et al., 2020).

Modes of resource acquisition

The typical mode of nutrition in phytoplankton is photoautotrophy, with inorganic carbon (CO_2 or HCO_3^-) as the C source. For photosynthesis, inorganic carbon (as CO_2) is fixed, where H_2O acts as the reductant source, and photons in the wavelength range 400–700 nm as the energy source, and O_2 as the by-product (Eq. 1):

$$CO_2 + 2H_2O^* + \geq 9 \text{ photons } 400 - 700 \text{ nm} \rightarrow CH_2O + H_2O + O_2^* \quad (1)$$

where the * on the oxygen of H_2O is to emphasize that the oxygen in O_2 comes from H_2O. The minimal photon requirement for photosynthesis with diffusive CO_2 uptake saturating the carboxylating enzyme ribulose-1.5-bisphosphate carboxylase-oxygenase is 9 photons per CO_2 molecule. This mode of nutrition relies on the flux of photons and inorganic carbon to the cells being adequate to permit net photosynthesis to exceed losses caused by processes such as phytoplankton respiration, loss of dissolved organic carbon, sinking, grazing, parasitism and hydraulic removal.

Oxygenic photoautotrophy only occurs in cyanobacteria among extant prokaryotes, and was transferred to eukaryotes through endosymbiosis with genetic integration in the ancestor of the Archaeplastida around 1600 million years ago, and independently around 60–140 million years ago in the ancestor of the phototrophic rhizarian *Paulinella*. In inland waters, phytoplankton of the dominant members of the Archaeplastida are the chlorophyte and streptophyte green algae, although some red algae phytoplankton also exist. Secondary endosymbiosis of an excavate with a chlorophyte alga yielded photosynthetic Euglenophyceae, while secondary endosymbiosis involving one or more phagotrophic eukaryotes and (a) red algal endosymbiont(s) produced the basal photosynthetic Dinophyta, the Cryptophyta and the Ochrophyta, including the important inland water Bacillariophyceae and Chrysophyceae and Synurophyceae. These endosymbioses, with some horizontal gene transfer, yielded organisms with Form IB and Form ID ribulose bisphosphate carboxylase-oxygenase (Rubisco) and light-harvesting pigments. In inland water Dinophyta there have been losses of photoautotrophy, in some cases regained by tertiary endosymbiosis of cyanobacteria or eukaryotic algae.

Osmo-organotrophy involves the uptake of dissolved organic matter as a source of energy, carbon and other essential nutrients, and occurs in some inland water planktonic Chlorophyta, Dinophyta and Euglenophyta. Phylogenetic analysis, and the presence of variously reduced, non-photosynthetic, plastids, shows that this trophic mode is a derived condition among these algae. Osmo-organotrophs can grow in the dark or very low light and so can occur where obligately photoautotrophic algae cannot grow.

The phago-organotrophic mode of nutrition involves the ingestion and digestion of dead or living organic particles. It is very likely that a particle ingestion mechanism is ancestral in eukaryotic algae, having been involved in the endosymbiosis of a

cyanobacterium that became chloroplasts of the Archaeplastida and, by secondary and tertiary endosymbiosis, other algae. Phago-organotrophic nutrition occurs in freshwater Cryptophyta, Dinophyta and Euglenophyta.

Another organotrophic mode of nutrition in freshwater microalgae is parasitism; a freshwater dinoflagellate infecting fish is an ichthyoparasite. Whether the parasite can be considered as planktonic could be debated, but it at least has a planktonic dinospore phase in its life-cycle.

The first three trophic modes of freshwater plankton are not mutually exclusive: there are planktonic mixotrophs (mixoplankton) that combine two, or all three, trophic modes (Jones, 2000). In marine phytoplankton, mixotrophy is widespread (Flynn et al., 2019) and this is likely also to be the case for freshwater phytoplankton. Osmo-mixotrophs combine photoautotrophy with osmo-organotrophy. The mere capacity to take up and metabolize dissolved organic compounds does not necessarily mean that the cells can grow exclusively on dissolved organic carbon. Phago-mixotrophy combines photoautotrophy with phago-organotrophy. Constitutive phago-mixotrophy, i.e., with both the photoautotrophy and phago-organotrophy components encoded in the nuclear genome and, in part for photoautotrophy, the plastid genome occurs in the Chrysophyceae, Cryptophyta, Dinophyta and Euglenophyta. There are large variations in the fraction of the maximum possible growth rate that can be achieved relying on organic carbon, with Cryptophyta toward the photoautotrophic end of the spectrum and *Dinobryon* (Chrysophyceae) requiring light to perform phagotrophy, and many members of the Chrysophyceae at the phago-organotrophic end. An alternative mode of phago-mixotrophy involves kleptoplasty, i.e., retention of plastids from food items ingested by a phago-organotroph in a form that allows continued photosynthesis. Kleptoplasty is known from some freshwater dinoflagellates. Since most of the genes needed for plastid repair are encoded in the nucleus of the ingested phototroph, the longevity of the ingested plastid will be limited unless appropriate genes have been incorporated into the host genome from previous ingestion events, or retained from the current food item. This second alternative verges on a photosynthetic symbiosis, a form of constitutive phago-mixotrophy, e.g., in "dinotoms."

Mechanisms of inorganic and organic nutrient acquisition

Nutrients include the chemicals supplying essential elements and, for mixotrophs, energy, and also, in many cases, compounds such as vitamins that are mainly enzyme cofactors that the alga is unable to synthesize. Emphasis is placed here on the nutrients that contribute most to limitation of phytoplankton photosynthetic productivity and those that contribute to eutrophication and harmful algal or cyanobacterial blooms, with some consideration of chemo-organotrophy.

From a global biogeochemistry perspective, the ultimate growth rate-limiting element for photoautotrophic growth is phosphorus, however in the short term in particular locations other elements such as (combined) nitrogen, carbon, sulfur and trace elements may be limiting. Uptake involves nutrients crossing the lipoprotein plasma membrane. Ions, and neutral solutes with a molecular weight >50–100 kDa, have very limited permeability. Permeability is defined at the uncatalysed rate at which a solute crosses a unit area of membrane for a given driving force. The driving force is the concentration difference for neutral solutes, and, for ions such as many nutrients, the electrochemical potential difference involving both concentration difference and electrical potential difference that is inside-negative except in acidophiles. Catalysis involves transmembrane proteins that allow solute-specific energetically downhill flux of nutrients through channels or transporters, and energy-coupled flux of the solute. The energy for this process comes from energetically downhill flux of some other solute, or exergonic biochemical reactions. Maintaining the electrical potential difference across the plasma membrane involves active efflux of electrogenic H^+ and Na^+ by ATPases.

The concentration of the nutrient solutes containing carbon, nitrogen and phosphorus is low relative to the half-saturation value for the assimilating enzyme in the cell in many (relatively) anthropogenically uninfluenced inland water bodies or during blooms in more impacted waters as a result of high nutrient demands. For CO_2, where there is the possibility of diffusive entry through the lipid component of lipoprotein membranes, lack of saturation of the enzyme could be offset by increased content of the assimilatory enzyme Rubisco, although at a large cost in protein synthesis, given the low specific reaction rate of the enzyme. This is exacerbated by restriction on transport by aqueous diffusion boundary layers and, in eukaryotes, plastid chloroplast membranes. Some inland waters are naturally enriched in CO_2 relative to atmospheric equilibrium as a result of runoff from the catchment containing CO_2 from root respiration (Maberly et al., 2013) or in situ mineralization of organic carbon from terrestrial productivity. However, many eukaryotic phytoplankton organisms, and all cyanobacteria, have CO_2 concentrating mechanisms (CCMs). These catalyze the energized accumulation of CO_2 at the active site of Rubisco relative to the concentration in the medium. These generally involve active influx of HCO_3^- at one of the membranes between the medium and Rubisco in eukaryotes and at the plasma membrane of cyanobacteria, or CO_2 influx followed by energized conversion of CO_2 to HCO_3^- in cyanobacteria. In all these cases, carbonic anhydrase activity is essential to interconvert CO_2 and HCO_3^- rapidly at particular locations within the cell. Since CO_2 is the C species assimilated by Rubisco, there is a requirement for H^+ influx/OH^- efflux for internal acid-base regulation when HCO_3^- enters the cell.

Other inorganic solutes containing major nutrient elements bearing a negative charge are NO_3^-, $H_2PO_4^-/HPO_4^{2-}$ and SO_4^{2-}. The assimilation of NO_3^- and SO_4^{2-}, with carbohydrate from photosynthesis, produces an array of organic compounds that bearing a much smaller negative charge per element than do the nutrient anions plus OH^-, and charge balance and acid-base regulation requires influx of H^+ or efflux of OH^-. As well as their electrical charge, the low affinity for their anionic substrate of the assimilatory enzymes, and the low external concentrations in many inland waters, especially for NO_3^- and $H_2PO_4^-/HPO_4^{2-}$, mean that active influx is needed (Raven et al., 2008). Environment concentrations of NH_4^+ are often also low; as a cation the inside-negative electrical

potential difference across the plasma membrane favors entry. However, again based on the affinity of the assimilatory enzyme for its substrate, and the magnitude of the electrical potential difference across the plasmalemma, NH_4^+ entry frequently needs active transport. Since the products of final organic products of NH_4^+ assimilation have a slight negative charge per N, H^+ efflux/OH^- influx is needed for acid-base and charge balance. At high pH and NH_4^+ concentration there is sufficient external NH_3 to allow its unregulated diffusive entry, and toxicity.

The important signaling ion Ca^{2+} enters cells by specific channels, and active efflux involves a Ca^{2+} ATPase. Trace element transport in freshwater phytoplankton has been best investigated in the unicellular green alga *Chlamydomonas* for Cu^{2+}, Fe^{2+}, Mn^{2+} and Zn^{2+} (Blaby-Haas and Merchant, 2012). The inside-negative electrical potential difference across the plasma membrane provides a greater driving force for entry of doubly charged than singly charged cations. The cytosol concentration of these free ions is believed to be very low, for example because free Fe^{2+} and Mn^{2+} generate the very damaging hydroxyl radical by the Fenton reaction. An external Fe^{3+} reductase allows external Fe^{3+}, the dominant species of iron in oxic environments, to be acquired by cells.

For the entry of osmo-organotrophs and osmo-mixotrophs, organic solutes generally require active transport, e.g., H^+-glucose cotransport has been characterized in *Chlorella*. However, acetate entry seems to involve entry of undissociated acetic acid. There is growing evidence that organic forms of nitrogen and phosphorus are bioavailable to riverine phytoplankton (Mackay et al., 2020). This is an overlooked but potentially important source of nutrients since in some inland waters, concentrations of organic nutrients exceed that or inorganic nutrients. These nutrients may be taken up directly, e.g., active influx of amino acids in *Chlorella*, while others depend on the facultative production of exoenzymes such as acid or alkaline phosphatases allowing influx of phosphate derived for organic phosphate precursors, or rely on external metabolism by microbial consortia to produce inorganic ions. Some freshwater algae require exogenously supplied vitamins. In some cases the supply depends on close association of the algae with bacteria that produce the vitamin(s) while phago-mixotrophy can supply such vitamins directly.

Competition for nutrients

Phytoplankton growth is often constraint by nutrients, in oligotrophic systems with low nutrient loads as well as in eutrophic systems when phytoplankton biomass build-up is high and has stripped nutrients from the water (e.g., during blooms). In the latter case, light can also become a limiting resource due to self-shading. The outcome of resource competition depends on the balance between rates of growth and loss, and on resource acquisition traits. For nutrients, the concentration where growth rate equals the loss rate is referred to as Tilman's R^* (Fig. 1; Tilman, 1982), and reflects the overall competitive strength of a species for a given resource based on a number of physiological processes (Fig. 1A; Eq. (2); Litchman et al., 2015). Specifically, higher maximum growth and acquisition rates (μ_{max} and V_{max}), lower half-saturation concentrations ($K_{1/2}$), lower minimal cellular quota (Q_{min}), and lower loss rates (L) will lead to a stronger decrease in resource concentrations and thereby a lower R^*. The species with a lower R^* will be the better competitor for a particular resource as compared to species with a higher R^*, because under these resource levels growth rates of the weaker competitor becomes lower than the loss rates (Fig. 1B).

$$R^* = \frac{K_{1/2}\,\mu_{max}\,Q_{min}\,L}{V_{max}\,(\mu_{max} - L) - \mu_{max}\,Q_{min}\,L} \tag{2}$$

While R^* originally described competition for nutrients such as nitrogen, phosphorus and silicon, similar relationships have been produced for inorganic carbon and light (Ji et al., 2017). For some elements, including inorganic carbon and nitrogen,

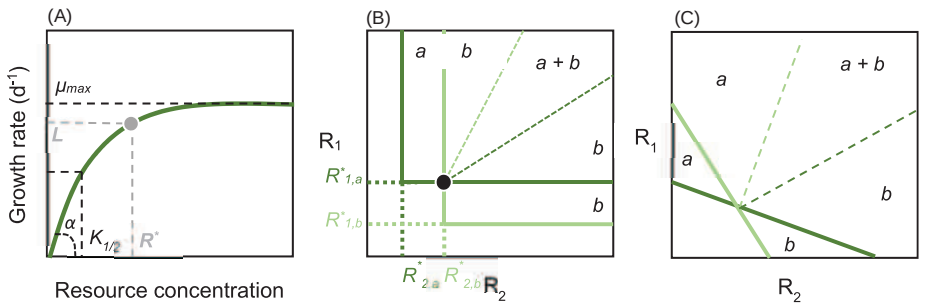

Fig. 1 Schematic overview on the coupling of physiological processes to resource competition. Growth (μ) depends on resources following a Monod function (sensu Michaelis-Menten enzyme kinetics), with maximum growth rates μ_{max} achieved under highest resource concentrations, and the half-saturation concentration $K_{1/2}$ of the limiting resource at half the maximum growth rate (A), and the affinity α as indicated by the initial slope (i.e., $\mu_{max}/K_{1/2}$). When inducing a fixed loss rate (*L*, gray dashed line), for example representing the dilution rate in a chemostat, the species will deplete resources until reaching a stable equilibrium (gray circle), where μ equals *L* at its respective R^* value. The R^* thus represents the concentration of a resource (i.e., R_1 or R_2) that allows zero net growth. When species *a* (dark green lines) and *b* (light green lines) exhibit different R^* values for different resources (B), their zero-net growth isoclines (i.e., lines where μ equals *L*) intersect. This can lead to a stable equilibrium when the better competitor for R_1 (species *b*) more rapidly takes up R_2, and vice versa, and is reflected by the ratio at which R_1 and R_2 are taken up (dashed vertical lines). For substitutable resources (C), the zero net growth isoclines intersect with the axes. In these cases, the outcome of competition depends on the slopes of the zero net growth isoclines in combination with the ratio at which R_1 and R_2 are taken up.

phytoplankton can compete for different chemical forms (i.e., CO_2 and HCO_3^-, or NO_3^-, NO_2^- and NH_4^+). While competition for these substitutable resources will also depend on the various physiological processes, including the ratio at which resources are taken up, there is no single R^* for each resource (Fig. 1C). Rather, competition depends on the ability of species to compete for either substitutable resource in the absence of the other (i.e., the points where the zero net growth isoclines cross the axes in Fig. 1C). The acquisition of one resource may also depend on the availability of other resources, which will change the trajectory of the zero net growth isoclines (i.e., to a non-linear relationship), with consequent shifts in the competitive outcomes. Moreover, the acquisition of nutrients such as N and P may be influenced by other factors, such as light, CO_2 concentrations and temperature, and thus also alter competitive outcomes (Van de Waal and Litchman, 2020).

Trade-offs are typically involved in nutrient acquisition by phytoplankton. For instance, fundamental catalytic constraints restrict processes with a high maximum rate from having a high affinity and vice versa. Small cells have a high surface area to volume ratio that maximizes uptake rate but limits the capacity to process and store nutrients. Limited space on the plasma membrane for transporters will produce trade-offs in the nutrients taken-up. Trade-offs within and among resource acquisition traits prevent dominance of a limited number of species, and can thereby mechanistically explain coexistence of multiple species under a limited set of resources. Moreover, species with differences in specific resource acquisition traits may exhibit comparable R^* values, and thus not be able to outcompete each other, thus following the neutral theory of biodiversity (Hubbell, 2001).

Alternative resource acquisition strategies such as N_2 fixation and mixotrophy increase the competitive ability of species for resources. The facultative ability of diazotrophic cyanobacteria to fix N_2 allows them to grow under combined nitrogen-deprived conditions, while phagotrophy and osmotrophy by mixoplankton allows growth under general resource deprived conditions (Flynn et al., 2019). When competing for inorganic resources, species with alternative resource acquisition strategies can maintain growth when the original resources are absent. They will thus be superior competitors under these conditions, provided that organic resources are available. Competition for inorganic resources is furthermore affected by direct species interactions, referred to as interference competition, such as the synthesis of allelochemicals that inhibit growth or cause increased mortality of competing species, as well as intraguild predation shown by some mixoplankton.

Nutrient acquisition traits (V_{max}, $K_{1/2}$, α), as well as nutrient demands (Q_{min}), depend on cell size, and competitive ability for resources therefore also will change with cell size. Due to their smaller surface area to volume ratio, larger phytoplankton can have a lower overall affinity for a resource and thereby decrease their competitive ability (i.e., increasing R^*; see also Eq. 1). At the same time, their larger cell volumes lead to higher minimum cellular quota, which will also reduce their competitive ability (i.e., increasing R^*; see also Eq. 1). Larger cells can contain more cellular machinery to acquire nutrients, such as pigments or food vacuoles, yet they are also hampered by stronger self-shading (i.e., package effect). Generally, smaller phytoplankton are found to be better competitors for inorganic resources, while larger phytoplankton have beneficial traits to acquire organic resources, experience lower grazing losses, and show higher plasticity toward changing environmental conditions (Van de Waal and Litchman, 2020).

Stoichiometric considerations

The overall elemental composition of phytoplankton is linked to the biochemicals within the cells and in the cell walls. For example, lipids are rich in carbon, proteins in nitrogen, and nucleotides contain relatively high amounts of nitrogen and, particularly, phosphorus while silicon is essential for diatom cell walls. The phytoplankton elemental composition thus reflects their biochemical make-up, and the relative balance of these elements (e.g., C:N, C:P, N:P and C:Si) can potentially be linked to dedicated functions (Geider and La Roche, 2002; Sterner and Elser, 2002).

The elemental stoichiometry of phytoplankton varies as phytoplankton acquire their nutrients through separate pathways, and because elements can be effectively stored in molecules such as carbohydrates, polypeptides, and polyphosphates. Such plasticity supports phytoplankton growth under resource deficient conditions as it reduces the minimum quota (Q_{min}; see section "Competition for nutrients"), while effective storage provides an extended supply of elements when a resource is temporarily limiting. Because phytoplankton species differ in their biochemical make-up, they can also exhibit a distinct elemental stoichiometry. The optimal N:P stoichiometry of phytoplankton has been defined as the ratio between minimum quota for N and P (i.e., $Q_{min,N}$: $Q_{min,P}$), reflecting the ratio where cells shift from N to P limitation (Klausmeier et al., 2004). Alternatively, the optimal ratio can be considered as the N:P ratio at μ_{max} under prevailing environmental conditions (Hillebrand et al., 2013). Following this latter approach, differences have been observed across phytoplankton phyla, with generally consistent lower optimal N:P ratios in diatoms and a tendency to higher N:P ratios in cyanobacteria and chlorophytes (Hillebrand et al., 2013).

Taxonomic differences in optimal N:P ratios are difficult to couple directly to distinct cellular structures of the phytoplankton phyla, except for higher N:P ratios in cyanobacteria which may reflect the ability of various species to fix N_2. When considering other elements, clear functional differences can be expected. Among the clearest examples are diatoms that require large amounts of Si for their silica frustules, and calcareous phytoplankton, mainly found in the ocean, that have higher demands for Ca to produce their calcite liths or plates that are involved in their cell wall structure. Moreover, phytoplankton superfamilies have distinct differences in their composition of various trace metals (see section "Mechanisms of inorganic and organic nutrient acquisition"). Regulation of trace metal composition also closely interacts with shifts in the composition of macroelements such as C, N and P (Twining and Baines, 2013). The whole suite of elemental changes is reflected by the ionome (i.e., the elemental composition of an organism), which reveals physiological shifts that are linked to overall cellular metabolism including the acquisition and assimilation of limiting and non-limiting resources (Jeyasingh et al., 2017).

Role of nutrients in controlling ecosystem structure and function

Nutrient concentrations in inland waters are a function of diffuse or point source inputs from the catchment, hydrological losses and exchange with the atmosphere, the sediment and the biota. Lakes can be divided into different trophic types based on their productivity, assessed primarily by the amount of phytoplankton, but also sometimes supported by secondary effects such as on light or oxygen concentrations (see below). Lakes are categorized into oligotrophic (or ultra-oligotrophic) for the least productive through mesotrophic and eutrophic to hypertrophic for the most productive. A widely-used classification uses a numerical "trophic state index" based on phytoplankton biomass (chlorophyll *a* concentration), Secchi disk depth and total phosphorus concentration as surrogates of productivity and stresses that productivity is a continuous gradient (Carlson, 1977). The natural gradient in lake trophic state from oligotrophic to eutrophic is controlled largely by the transfer of nutrients from the catchment to water. In addition, anthropogenic nutrient addition, caused primarily by diffuse leaching of fertilizers added to the catchment to boost production, and release of domestic, agricultural, and industrial waste often as point-sources, cause nutrient enrichment of inland waters. In contrast to lakes, there is not a widely-used trophic-state scheme for streams and rivers.

The dilute concentrations of major nutrients in many inland waters, especially in areas with low anthropogenic impact, results in widespread nutrient limitation of phytoplankton primary productivity and growth. Large-scale relationships between the availability of P and N and phytoplankton biomass, as the concentration of chlorophyll-*a*, were first established by Vollenweider (1968). This, along with pioneering work by David Schindler and his group on lakes in the Experimental Lakes Area of the Canadian Shield, where addition of phosphate to whole lakes, or parts of a lake, stimulated large phytoplankton populations (Schindler, 1977) helped to establish the importance of P as a potentially limiting nutrient. More recently, N has been more fully recognized as a co-limiting or solely limiting nutrient in inland waters and other environments (Elser et al., 2007). An analysis of a dataset of over 1000 European lakes showed the effects of both P and N in supporting phytoplankton populations, partly because they tend to co-vary and also because the phytoplankton themselves contribute to the total nutrient concentrations (Fig. 2; Phillips et al., 2008).

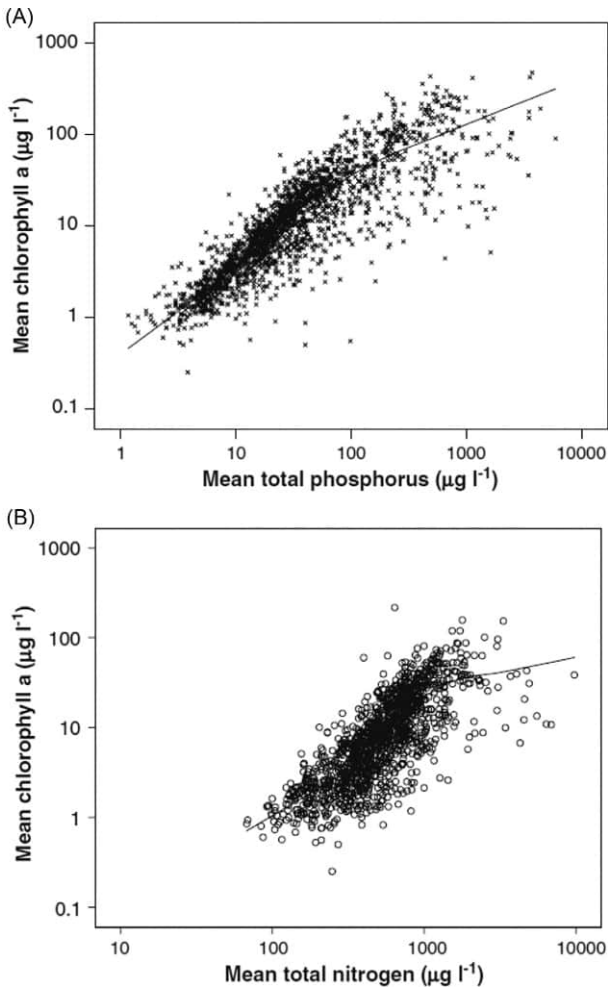

Fig. 2 Relationship between growing season chlorophyll-a concentration and (A) total phosphorus concentration and (B) total nitrogen concentration. The solid line is the LOESS fitted curve (Phillips et al. 2008).

They also showed that at high nutrient concentrations, increases in nutrient no longer increased phytoplankton populations, presumably because the nutrient is no longer limiting, and that deep lakes generate less phytoplankton chlorophyll-*a* per unit nutrient than other lakes which is likely to be caused by greater light limitation. Interestingly, there is evidence that anthropogenically-driven atmospheric deposition of N has pushed phytoplankton away from native N limitation toward P limitation (Bergstrom and Jansson, 2006).

The ecology of naturally eutrophic or anthropogenically eutrophic (cultural eutrophication) lakes is very different from oligotrophic lakes. Decomposition of the larger amount of organic material that is produced can often lead to oxygen-depletion at depth during seasonal stratification (Foley et al., 2012). This has important consequences for re-release of P (and N) from the sediment to the overlying water with the obvious risk of causing further eutrophication. At the same time, oxygen-depletion may promote denitrification, causing dissolved N concentrations to decrease by loss of N_2 to the atmosphere, and which may lead to seasonal N limitation. Oxygen depletion also restricts the distribution of other forms of life and can limit depth-refuges from warming surface water and can cause fish-kills. The higher phytoplankton biomass intercepts more light in the surface water, increasing surface warming and strengthening stratification and reducing the penetration of light to depth and consequently reducing the maximum depth of rooted higher plants. More widely, the competitive balance between the two main types of photoautotrophs, phytoplankton and higher plants, is pushed toward phytoplankton as nutrient availability increases with the potential to switch from a clear water, plant-dominated state to a turbid, phytoplankton-, dominated state (Janssen et al., 2021; Scheffer et al., 1993).

The species composition of the phytoplankton community is affected by nutrient availability (Reynolds et al., 2002). A common symptom of nutrient enrichment is the summer-dominance by cyanobacteria (also referred to as blue-green algae), many of which have the facultative ability to produce a range of toxins, primarily neurotoxins and hepatotoxins (Svirčev et al., 2019) and can form "scums" at the water surface (Fig. 3). Green algae (chlorophytes) also often benefit from nutrient enrichment while cryptophytes and chrysophytes are often reduced.

Cultural eutrophication is widespread and is probably the greatest cause of anthropogenic change to inland waters worldwide (Carpenter et al., 2011). Many mitigation measures have been implemented, although often with relatively modest success (Søndergaard et al., 2007) and have focussed more on P than N. These include reducing nutrient loads to the inland waters from point sources, use of buffer strips adjacent to water to reduce diffusive nutrient input from fields, and reducing fertilizer application to fields. A second approach applies agents to the water to bind P chemically, reduce its release from anoxic sediments and to kill phytoplankton directly. A third approach, more applicable in reservoirs than natural lakes, alternately de-stratifies the water and

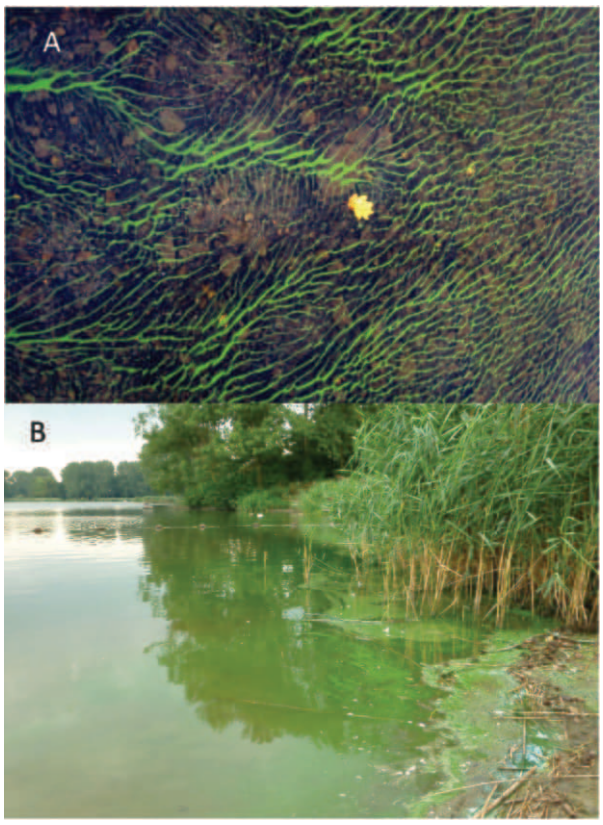

Fig. 3 Cyanobacterial blooms. (A) Cyanobacteria blooming under ice in Loweswater, UK. (B) Cyanobacterial bloom at "De Grote Plas," The Netherland. (A) Photo courtesy of Prof John Macfarlane. (B) Photo courtesy of Dedmar van de Waal.

allows stratification to form so that neither species that favor stratified nor unstratified conditions can produce large populations. A fourth approach promotes the density of zooplankton by manipulating the food-web to reduce the population of planktivorous fish (Søndergaard et al., 2007). Nevertheless, there is some evidence for reduction in nutrient loads as a result of mitigation actions and reversal of eutrophication effects at some lakes (Jeppesen et al., 2005).

Problems caused by nutrient enrichment are exacerbated by multiple stressors, particularly climate change (Moss et al., 2011). Since climate change is a global problem that cannot be solved locally, reduced nutrient loading to inland waters will need to be increased even further to mitigate the adverse effects of cultural eutrophication. This exposes a potential tension between water and food security that is yet to be resolved. A largely unknown aspect is the extent to which dissolved organic forms of P and N can substitute for inorganic nutrients and support phytoplankton populations in natural conditions.

Conclusion/Synthesis

Freshwater phytoplankton extract a large range of essential elements from often low concentrations in water. The stoichiometric requirements for different elements are broadly similar but vary among different phylogenetic groups. Phytoplankton exploit inorganic chemicals, dissolved organic compounds and organic particles to satisfy their nutrient and energy requirements, often involving mechanisms that require energy. Nutrient availability often limits the productivity and biomass of phytoplankton in inland waters. Species with superior kinetic uptake characteristics, diverse sources of supply, high storage capacity and low rates of loss will tend to outcompete other species. Human activity has caused a widespread increase in the supply of nutrients to inland waters. This "cultural eutrophication" has increased productivity and phytoplankton biomass, with a consequent cascade of secondary effects that frequently reduce the value and availability of water resources to mankind.

Knowledge gaps

1. The availability and ecological role of organic forms of nutrients.
2. Mechanisms of acquisition and assimilation of nutrients in a wider range of phytoplankton taxa.
3. Studies of uptake and assimilation of nutrients at the transcriptomic and proteomic level.
4. How interaction among environmental factors affect nutrient uptake and competition.
5. The role of mixotrophy in affecting competitive interactions
6. The role of trace elements in controlling phytoplankton productivity and diversity.

Phytoplankton Productivity

Martin T Dokulil, Research Department for Limnology, University of Innsbruck, Innsbruck, Austria

This is an update of M.T. Dokulil, C. Kaiblinger, Phytoplankton Productivity, In Encyclopedia of Inland Waters, Edited by: Gene E. Likens, Academic Press, 2009, https://doi.org/10.1016/B978-012370626-3.00140-X.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie-Elodie Perga and Damien Bouffard.

Nomenclature

E_k	Light-saturation parameter ($E_k = P_m/\alpha$)
F_0	Fluorescence at a baseline value
F_m	Maximum fluorescence when all traps are closed
F_V	Variable fluorescence
GPP	Gross primary productivity (production)
NPP	Net primary productivity (production)
NPQ	Nonphotochemical quenching. Defined as a mechanism to protect from the adverse effects of high light intensity
optical depth	One-unit O.D. is equal to a halving of light intensity
P/E	Photosynthesis (production) versus energy (light) curve
PAR	Photosynthetic active radiation (typically 400–700 nm)
PET	Photosynthetic electron transfer
P_G	Gross photosynthesis
P_m	Production at light saturation level at which photon absorption exceeds steady state electron transport
P_N	Net photosynthesis
PQ	Photosynthetic quotient (volume O_2 released in photosynthesis as a proportion of the volume of CO_2 used in that process)
PSI	Photosynthetic unit I
PSII	Photosynthetic unit II
PSU	Photosynthetic unit
qP	Photochemical quenching (decrease of fluorescence reflecting photosynthetic activities)
R_C	Community respiration
R_P	Respiratory loss
z_c	Compensation depth (the depth where daily GPP = R_P per day)

z_{cr}	Critical depth (depth where daily integral NPP = integral R_P per day)
z_{eu}	Euphotic zone (equal to the depth of 1% light intensity)
z_{mix}	Mixing depth (water column which is mixed by wind)
α^*	Chlorophyll-a specific light absorption (production per unit chlorophyll-a)
$\sigma_{(\lambda)}$	Optical absorption cross section calculated from $\frac{2.3 - \left(Ln\frac{E_\lambda}{E_{0\lambda}}\right)}{Chl-a}$ and σ^* integrated over PAR, with E_λ is transmitted irradiance for wavelength, $E_{0\lambda}$ is incident irradiance and Chl-a is the chlorophyll-a concentration, all per unit area
σPSII	Functional absorption cross section (Dimension: area per unit of compound), Defined as the in vivo cross section of the light harvesting system absorbing photons by wavelength dependent probability
Φ_m	Maximum quantum yield (maximum of an event per photon absorbed by the system)

Introduction

This chapter intends to provide a theoretical and practical introductory fundament for the understanding of phytoplankton primary production in freshwater by students, novices in the field, practitioners and any interested person. Text and associated graphs highlight concepts, measurements techniques, models and physiology of plankton photosynthesis. Additional information on the production ecology of other autotrophic producers in freshwaters can be gained from "Comparative primary production."

Concepts related to production

Production of new organic matter from inorganic nutrients using sunlight as energy source, known as photosynthesis, is an essential prerequisite for life on earth. The organsims carrying out photosynthetic processes to build cellular material are therefore called autotrophs. Marine and freshwater algae contribute about half of annual primary productivity on the planet. Clarifying the processes contributing to the drawdown of inorganic carbon (CO_2) is crucial for understanding carbon cycling and functioning of global ecosystems.

In its early phase, studies on the energy flow through aquatic systems revealed by estimates of primary productivity largely rested on the ecosystem concept (Goldman, 1968). The 50 year aniversary of invention of the radioactive carbon-14 method triggered a new interest in productivity measurements (Williams et al., 2002), boosting techniques (Fahey and Knapp, 2007) and concepts (e.g. Falkowski, 2012). New concepts were developed such as the "active pipe" concept for the global quantification (Tranvik et al., 2018), nutrient stoichiometry (Maranger et al., 2018) and integrative understanding (Hotchkiss et al., 2018; Seekell et al., 2018) of carbon metabolism. Advancements in carbon acquisition and concentrating mechanisms have been reviewed by Griffiths et al. (2017). Dokulil and Qian (2020) provide an article reviewing the history of photosynthesis, carbon acquisition and primary productivity.

Photosynthesis in algae

All autotrophic oxygenic organisms carrying the pigment chlorophyll-a, both prokaryotes and eukaryotes, share the same fundamental reaction equation of photosynthesis using light as energy source:

$$2H_2O + CO_2 + \text{Light} \overset{\text{Chl-a}}{\rightarrow} (CH_2O) + H_2O + O_2 \quad (1)$$

In this equation, chlorophyll-a catalyzes a reaction, or a series of reactions whereby light energy is used to oxidize water producing molecular oxygen:

$$2H_2O + \text{Light} \overset{\text{Chl-a}}{\rightarrow} 4H^+ + 4e + O_2 \quad (2)$$

This partial reaction starting with light absorption is one of the two core reactions in oxygenic photosynthesis. The second reaction is the reduction of CO_2 which can proceed in darkness as well as in light and can be described as

$$CO_2 + 4H^+ + 4e^- \rightarrow CH_2O + H_2O \quad (3)$$

These two reactions require an intermediate reducing compound (not shown here) because free electrons normally do not occur in biological systems (Falkowski and Raven, 2007).

Impinging light is processed in two photosynthetic reaction centers (RCs) by two electron acceptors: a quinone, in type II, and an Iron-Sulphur cluster in type I. These two RC-types called Photosystem II (PSII) and Photosystem I (PSI), work in tandem, produce oxygen and lead to linear electron transport, delivering electrons to carbon dioxide fixation and other mechanisms. The common

basic photosynthetic equation (1) shown above has gained complexity during algal evolution in terms of photosynthetic structures, pigments, and metabolic differences to cope with a multitude of light climates and ecological niches (Falkowski et al., 2004).

While photosynthetic structures in cyanobacteria are internal membranes called thylakoids, all algal phyla have specialized organelles, called plastids or chloroplasts which themselves contain thylakoids. Primary plastids were most likely acquired from primary cyanobacterial endosymbiosis by the Glaucophyta (glaucophyte algae), the Rhodophyta (red algae), and the green algae. These linages share a two-membrane bound photosynthetic plastid organelle (Table 1; Bellinger and Sigee, 2010). After primary plastids were established in ancestors, they disseminated into other phyla such as Bacillariophyta (diatoms), dinoflagellates, cryptophytes, haptophytes and euglenophytes through multiple secondary and tertiary endosymbiosis. These divisions have plastids surrounded by 3–4 membranes and have 1–2 flagella, at least in reproductive cells (Table 1).

Photosynthetic organisms are frequently exposed to changes in light quality and quantity to which they have to acclimate or even adapt. They need to collect light energy efficiently particularly when light is limiting. Consequently, different algal divisions have distinctive accessory pigmentation in terms of chlorophyll and carotenoid species (Table 1). In case the capability of the photosynthetic apparatus is exceeded, organisms must also be able to dissipate light energy absorbed in excess.

Light harvesting

Photosynthesis begins with photo-absorption by pigments located in the thylakoid membranes. The only pigment present in all oxygen producing phytoplankton is chlorophyll-a and it is the essential pigment required for photosynthesis. Most light absorption, however, is due to accessory pigments such as other chlorophyll species and carotenoids as well as phycobilinproteins which are found in Cyanobacteria, Glaucophyta, red algae and Cryptophyta. Major differences in pigment composition among higher taxonomic groups can significantly affect the ability of phytoplankton to absorb light (Table 1). Chlorophyll-a specific light absorption is not only affected by the pigment complement, but also by cell size and intracellular pigment concentration.

Photosynthetic electron transfer (PET), located in large membrane complexes harboring Photosystem I (PSI) and Photosystem II (PSII), allows considerable versatility in electron flow to match varying requirements of nutrient transport, photo- and biosynthesis. The ratio of the two photosystems remains ambiguous because of the variability among algal divisions and environmental conditions. In Heterokontophyta the ratio can exceed 2, whereas in Cyanobacteria it is typically 0.25–0.5. The ratio can also change with growth, irradiance, or nitrogen starvation (Larkum, 2016).

Carbon reduction

Net carbon fixation in photosynthesis involves a cycle of reductions, referred to as the Calvin-cycle, in the plastids of algal cells or in the cytoplasm of Cyanobacteria. At the heart of this cycle is the carboxylation of ribulose 1,5-biphosphate (RuBP) catalyzed by the enzyme RUBISCO, a monophyletic enzyme existing in two forms. The Form I enzyme is found in cyanobacteria and all eukaryotes, except for some peridinin-containing Dinophyta which contain the Form II enzyme. The activity of the enzyme is low compared to other carboxylases. RUBISCO accounts for a sizeable fraction of the cell (1–10% of cell carbon or about 2–10% of total protein), with the amount dependent on ambient light conditions. Under high irradiance, RUBISCO can account for up to five times as much cell mass as chlorophyll-a (Raven et al., 2012; Bracher et al., 2017).

Table 1 Algal divisions (phyla): Pigmentation, origin of chloroplasts by endosymbiosis, fine structure of chloroplasts and flagella in vegetative cells and gametes (reproductive cells = rep. cells). Isokont—equal length, heterokont—unequal length.

Phylum	*Pigmentation*		*Endosymbiont*	*Chloroplast fine structure*		*Flagella*
	Chlorophylls	*Carotenoids*		*Membrans*	*Thylakoids*	
Cyanobacteria	a	β	–	0	0	0
Rhodophyta	a, d	α, β	Cyano 1°	2	0	0
Glaucophyta	a		Cyano 1°	2	0	0
Chlorophyta	a, b	α, β, γ	Cyano 1°	2	2–6	0-many isokont

Modified and combined from Bellinger, E.G., Sigee, D.C., 2010. Freshwater algae: identification and use as bioindicators. John Wiley & Sons, Chichester. ISBN 978-0-470-05814-5 (Table 3.1) and Larkum, A.W.D., Grossmann, A.R., Raven, J.A. (Eds.), 2020. Photosynthesis in Algae: Biochemical and physiological mechanisms. Advances in Photosynthesis and Respiration including Bioenergy and Related Processes 45, Springer Nature Switzerland AG, Cham. https://doi.org/10.1007/978-3-030-33397-3.

Understanding the role of RUBISCO in phytoplankton ecophysiology is essential to determine whether RUBISCO or PET limit light-saturated photosynthesis and to estimate the concentration of CO_2 needed to support a specific photosynthetic rate. This has implications for assessing the inhibition of carbon fixation by oxygen and the role of a CO_2-concentrating mechanism. Activity of the enzyme is regulated in vivo by a multitude of mechanisms and external factors best studied in chlorophytes and Cyanobacteria. Under low light and/or low CO_2, RuBP is saturating and the rate of CO_2 fixation is limited by RUBISCO activity. However, under conditions of high light and/or high CO_2, carbon fixation is limited by the regeneration of RuBP, a process known as sink limitation.

Photorespiration

Photorespiration is the oxygenation of RuBP by RUBISCO followed by photorespiratory glycolate metabolism. Competition between O_2 and CO_2 reduces the rate of carbon assimilation, energetic efficiency of photosynthesis, and may reduce the photosynthetic quotient (PQ = O_2 produced/CO_2 assimilated). Values of PQ of 1.2–1.8 are representative for protein and lipid synthesis. Values of PQ as low as 0.75 can be obtained from photorespiration and glycolate excretion at the CO_2 compensation point where CO_2.uptake equals CO_2 evolution. PQ values below 0.75 can only be explained if unbalanced growth conditions where respiration contributes to net gas exchange are considered.

Evidence that photorespiration influences net photosynthesis and is linked to photoinhibition stems from the effect of oxygen concentration on the rate of ^{14}C assimilation. The observed reduction in particulate ^{14}C is accompanied by an increase of excreted dissolved organic carbon (Hagemann and Bauwe, 2016).

Carbon-concentrating mechanisms (CCM)

Most of the understanding of the biophysical CCM is based on studies of Cyanobacteria and chlorophytes. Bacillariophyceae and peridinin-containing dinophytes have less efficient CCM. Direct evidence for a CCM comes from intracellular CO_2 levels exceeding those in the suspending medium. The CCM is associated with the carboxysomes, microcompartments in Cyanobacteria; in chlorophytes and other eukaryotes it is associated with pyrenoids containing highly varying amounts of RUBISCO.

Estimation of what fraction of the global net primary production is mediated by pyrenoid-possessing algae and what fraction derives from pyrenoid-less eukaryotic algae and cyanobacteria requires knowledge of species abundance. The figure of one quarter to one third of global carbon fixation being mediated by pyrenoid-possessing families has been proposed but there are still unsolved questions (Mackinder et al., 2016; Meyer et al., 2017).

An alternative to biophysical CCM is C_4 photosynthesis, still a controversial issue in algae. The confusion over C_4 metabolism arises because the enzymes present in C_4 photosynthesis are present in algae as well. These enzymes are present in different algal groups in different amounts and are not sensitive to oxygen like the Calvin cycle enzyme RuBP. The best cases so far have been reported for two marine organisms.

Other pathways for C-acquisition

Besides the Calvin cycle, carbon may also be gained via two other pathways, β-carboxylation and mixotrophy. Carboxylation occurs in the dark and does not generally result in a net increase in carbon fixation. Alternatively, carbon can be acquired through mixotrophy. Several algal groups have been shown to be facultatively mixotrophic, heterotrophic, or may utilize dissolved organic compounds osmotrophically. The substitution of autotrophy and the regulation of mixotrophy are not well understood (Beardall and Raven, 2016). See chapter by Raven/Maberly.

More detailed insights into recent advances in the complex photosynthesis of Cyanobacteria and eukaryotic algae, recent discoveries in pigmentation, and the differentiations among algal divisions provide Borowitzka et al. (2016), Pessarakli (2016) and Larkum et al. (2020).

Response of phytoplankton productivity to environmental variability

Instantaneous rates of photosynthesis are controlled by external factors. Understanding how the environment influences chlorophyll-a specific light absorption (α^*), the ratio Chl-a:C and the parameters of the P/E curve are essential to evaluate, model, and predict primary productivity. The rate of photosynthesis is controlled by the efficiency of light utilization to drive the ensemble of photosynthetic reactions. As a first approach, the light dependency can be described as:

$$P_E = E_a \, \Phi_E \tag{4}$$

where P_E is the photosynthetic rate at incident irradiance E, E_a is the light absorbed by the organism (in quanta m^{-2} $time^{-1}$), and Φ_E is the quantum yield at irradiance E (moles O_2 produced or C fixed per moles photons absorbed). The absorbed light is calculated from incident spectral irradiance $E_{0(\lambda)}$ and averaged optical absorption cross section σ^*:

$$E_a = E_{0(\lambda)}\ \sigma^* \tag{5}$$

(for description and units of σ^* refer to the section on abbreviations and definitions above).

The *photosynthesis-irradiance response* (P/*E*-curves) is commonly obtained from oxygen or carbon based rates per hour normalized to chlorophyll-a (α^*), versus irradiance E. Typically three distinct regions, namely a light-limited region, a light saturated region, and a region of photoinhibition can be distinguished (Fig. 3). Photosynthetic rates are linearly proportional to irradiance at low light levels because the rate of photon absorption determines the rate of steady-state electron transport from water to CO_2. The initial slope of this light limited region is commonly denoted by the symbol α or α^B when normalized to chlorophyll-a. This initial slope of the P/E curve is not a photosynthetic rate; rather it is a time independent measure of efficiency indirectly related to the maximum quantum yield Φ_m.

As irradiance further rises, photosynthetic rates become increasingly nonlinear and approach a saturation level P_m at which photon absorption exceeds the steady state electron transport. Light saturated photosynthesis is explicitly time dependent with dimensions of O_2 production or CO_2 fixed per unit chlorophyll per unit time. The curvature can be described by the light-saturation parameter E_k which is never actually directly measured; rather it is derived from the intersection of α and P_m (Fig. 3):

$$E_k = P_m/\alpha \tag{6}$$

At supra-optimal irradiance beyond light saturation a reduction in photosynthetic rate may occur. This reduction is dependent on intensity of the light and the duration of exposure and is called photoinhibition. This modification of P_m is brought about by either a reduction in the number of photosynthetic units or by an increase in the maximum turnover time. The degree of inhibition can be estimated from the parameter β which is derived similarly to α from the P/E curve (Fig. 3). Corresponding to E_K, a light intensity E_I can be inferred describing the onset of inhibition. Several further light intensities can be deduced from P/E curves as indicated in the caption to Fig. 3. Most notable is the compensation irradiance (E_C) when net gas exchange becomes zero because respiration equals gross primary productivity (GPP). The compensation irradiance can be related to α^{Chl} and chlorophyll normalized respiration:

$$E_C = R^{Chl}/\alpha^{Chl} \tag{7}$$

The irradiance at the compensation point is not fixed but varies primarily with respiration and to a lesser extent with α^{Chl}, both of which depend on environmental conditions.

Physiological acclimation of the P/E curve α^{Chl} appears to follow several simple rules under conditions of balanced growth. As a first approximation α^{Chl} can be considered constant, with changes to the carbon-specific light saturated rate (P_m^C) inducing changes in the ratio Chl-a:C. At constant temperature and when cells are nutrient-replete, maximum carbon specific rate is largely independent of irradiance, but is highly correlated with maximum specific growth rate μ_m and temperature because temperature affects enzymatic reactions. The light saturated rate often is also determined by CO_2 availability.

Several empirical mathematical descriptions of the photosynthesis—light response curve P/E exist. The various formulations mainly differ in the abruptness of the transition from light-limited to light saturated photosynthesis. Some models include photoinhibition.

One simple mechanistic interpretation using the terms and notations mentioned above is the exponential function:

$$P^{Chl} = {P_m}^{Chl}\left[1 - \exp\left(-\alpha^{Chl}\, E/{P_m}^{Chl}\right)\right] \tag{8}$$

Defining productivity

Ecologists favor the term phytoplankton productivity although what is usually measured are photosynthetic rates. Moreover, the term productivity is frequently confused with production. It has therefore been argued to abandon one of the two terms or to replace it by activity. Strictly speaking, there is a clear difference. *Productivity* is a time dependent process; it is a rate with dimensions of mass per unit area or volume per time. *Production* is a quantity, with dimensions of mass.

Biological processes perceive and adjust to changes in the external environment. Many regulatory processes occur rapidly to allow photosynthesis to track instantaneously changes in the surrounding medium (Fig. 1). In nature, photosynthetic processes are therefore constantly modified. Regulation describes adjustments of catalytic or energetic efficiency which involve slight structural modifications. Physical, biochemical or physiological response on a short time scale, within the life span of individual organisms or assemblages, are collectively called acclimations which are nonlinearly related to temporal variations in irradiance, temperature and nutrients. Ecological or evolutionary adaptations by assemblages through selection of phenotypic traits occur on a longer time scale. Associated changes in community structure affect photosynthetic rates.

Terminology

Conceptually, photosynthesis or productivity is defined as an instantaneous rate of biomass change over time (dB/dt) over infinite time intervals which cannot be measured. Typically, integral rates over time are obtained. Estimation by fluorescence techniques however comes closest to instantaneous rates.

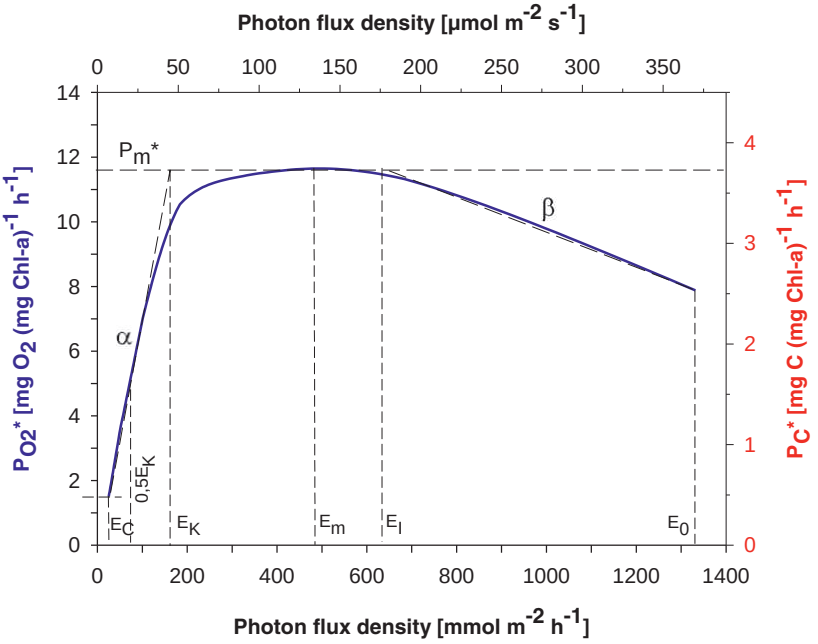

Fig. 1 Example of a photosynthesis-irradiance response curve (P/E) expressed both as chlorophyll specific oxygen evolution (P^*_{02}, left Y-axis) and carbon uptake (P^*_C, right Y-axis) versus photon flux density. The two axes are shifted by PQ = 1.16. P^*_m = Maximum chlorophyll-specific rate of photosynthesis; α = slope of the light limited region; β = slope of the region of photoinhibition; E_0 = subsurface photosynthetic active radiation (PAR); E_I = photon flux density at onset of inhibition; E_m = photon flux at P^*_m, E_K = photon flux density at the onset of saturation; $0.5E_K$ = 50% of E_K used in certain types of column integration calculation; E_C = Photon flux density at the compensation point.

Gross photosynthesis (P_G) is defined as the light dependent rate of electron flow from water to the terminal electron acceptors (e.g. CO_2) in the absence of any respiration losses. This process is directly proportional to linear photosynthetic electron transport and hence, gross oxygen evolution. Therefore, gross photosynthesis should be defined based on oxygen production rather than carbon fixation. This distinction is essential, especially when photorespiration is high. *Respiratory losses* (R_P) in photosynthetic organisms are rates of electron flow from organic carbon to O_2 with the concomitant production of CO_2, including photorespiration. The difference of these two processes is called *Net Photosynthesis* (P_N):

$$P_N = P_G - R_P. \tag{9}$$

Gross primary production is identical to gross photosynthesis. Net primary production, however, denotes organic carbon produced by photosynthetic processes within a specified time period available to other trophic levels.

In natural aquatic environments, direct measurements of primary production are virtually impossible to obtain because it is difficult to determine the contribution of algal respiration to total respiratory losses. Measurements of respiration include the metabolic contribution of heterotrophs, and therefore reflect *Community Respiration* (R_c). In fact, net primary production values, when reported, are usually confused with net photosynthesis.

Estimating photosynthesis in aquatic ecosystems

According to Eq. (2), measurements of photosynthetic rates for autotrophic plankton organisms in aquatic ecosystems are usually based on rates of either *oxygen production* or *inorganic carbon uptake*. Various modifications and alternatives of the basic techniques exist. In addition, fluorescence and remote sensing techniques became increasingly important. Measurements are performed either as in situ incubation or as simulations in the laboratory. A variety of mathematical models describe photosynthetic rates in space and time and their acclimation to environmental conditions.

The O_2-technique (Gaarder and Gran, 1927)

The rate of oxygen evolution is usually quantified from chemical, electro-chemical or opto-chemical methods. Because absolute changes in oxygen concentration are usually small and the background concentration of the gas in most situations is very large, precise data are relatively difficult to obtain. Moreover, even if done precisely, evolution of oxygen in the light represents net community photosynthesis, and fluxes of oxygen in the light and dark include total community respiration. Adding dark respiratory

losses to light dependent oxygen evolution gives a measure of gross photosynthesis. Estimates of net photosynthesis in natural aquatic ecosystems based on measurements of oxygen fluxes are more uncertain than measurements of gross photosynthesis.

Recent advances in sensor techniques allow high frequency estimation of oxygen profiles. The acquired data can be used to estimate metabolism (net ecosystem production) from free water oxygen changes (Staehr et al., 2010, 2016; Obrador et al., 2014). This method is based on the seminal paper by Odum (1956) estimating dissolved oxygen changes in free water basically from.

$$\Delta O_2/\Delta t = GPP - R - F - A \tag{10}$$

with $\Delta O_2/\Delta t$ the change in dissolved oxygen concentration, GPP gross primary production, R ecosystem respiration, F exchange of O_2 with the atmosphere, and A all other processes leading to changes in oxygen.

The technique can equally well be used for both lakes and streams (Izagirre et al., 2007; Demars et al., 2015) and may be combined with estimates from a similar diel CO_2 technique (Peeters et al., 2016). Hoellein et al. (2013) provide a synthesis of metabolic results from various ecosystems. The complex calculations necessary to obtain reasonable results can be facilitated using Lake Metabolizer in R (Winslow et al., 2016).

The ^{14}C-method (Steemann Nielsen, 1952)

For more than half a century, the method most commonly used was based on the rate of incorporation of radioactive ^{14}C in the form of inorganic carbon into acid-stable (usually particulate) organic carbon. Assuming that over some finite time period, the change in concentration of total dissolved inorganic carbon in the bulk water is small relative to the photosynthetic rate of the cells, and the addition of a small amount of radioactively labeled inorganic carbon does not perturb the concentration of the dissolved inorganic carbon, then the rate of incorporation of radioactivity into organic material obeys the rules of tracer analysis. These conditions are met in many environments, but care must be taken in freshwaters having low total concentrations of inorganic carbon.

The rational for the ^{14}C-based tracer method is that the light-dependent rate of incorporation of the radioactively labeled carbon into organic material is quantitatively proportional to the rate of incorporation of nonradioactive inorganic carbon

$$^{12}C_{uptake} : {}^{12}C_{available} = {}^{14}C_{uptake} : {}^{14}C_{available} \tag{11}$$

From Eq. (12) follows that carbon uptake is

$$^{12}C_{uptake} = \left({}^{14}C_{uptake}/{}^{14}C_{available}\right) x\, {}^{12}C_{available} \tag{12}$$

Because ^{14}C is heavier than the stable natural isotope ^{12}C, there is an isotopic discrimination of about 5% against the radioactive isotope during carbon fixation which is accounted for by a factor of 1.05. More recently, tracer-based techniques substituted the use of the radioactive isotope (which incorporation was measured by liquid scintillation counting) by a stable isotope tracer (^{13}C), which incorporation is measured by isotope-ratio mass spectrometry. The basics of the techniques however remain similar.

Over short periods of time, before a significant fraction of organic carbon becomes labeled, the method gives a reasonable estimate of gross photosynthetic rates. As the exposure time continues, the organic carbon pool becomes increasingly labeled, ultimately reaching equilibrium with the isotope in the bulk water. A fraction of the labeled carbon is then respired, and the incorporation of the tracer begins to approximate the rate of net photosynthesis.

The rate at which equilibrium labeling is approached is dependent on the growth rate of the organism(s). The faster the growth rate is, the faster the equilibrium will occur. Thus, the interpretation of radioactive carbon incorporation as gross or net photosynthesis is generally somewhat ambiguous and is complicated by the duration of the experiment in relation to the growth rate. In nature, the latter parameter is usually unknown and numerous discussions have emerged concerning the validity, accuracy and interpretation of the method.

Fluorescence techniques

One of the major problems of the methods mentioned above is the timescale. Photosynthetic rates obtained by in situ incubation techniques are average values over a given time period. To overcome these problems, bio-optical models have been developed in oceanography to extrapolate photosynthesis vs. irradiance curves (P/E). In bio-optical models, it is assumed that the P/*E*--relationship does not depend on the incubation time, which is not true. Most of the short-term physiological adjustments of plankton species are expressed in changes of the functional absorption cross section (σPSII). To keep the timescale short, rapid measurement techniques based on in vivo fluorescence have been developed. Recent active fluorescence techniques opened the possibility to quantify small-scale, rapid changes in physiology and hence provide estimates of primary productivity with a temporal resolution of seconds (review in Hughes et al., 2018).

Fluorescence is a phenomenon which is based on the absorption of light by photosynthetic pigments and its re-emittance at a longer wavelength. When light energy (photons) reaches the light trapping antenna-pigments of a photosynthetic unit (PSU), the Chl-a molecule is excited. In order to return to the ground state, the Chl-a molecule needs to release energy, most of which is lost as heat. What is left is used to "close" the reaction center or is re-emitted as fluorescence. Chlorophyll-fluorescence is very much dependent on the wavelength and intensity of the incoming light. Either photosynthesis or thermal dissipation influence

fluorescence resulting in photochemical quenching (qP) or nonphotochemical quenching (NPQ), respectively. While high light conditions can cause nonphotochemical quenching, weak light which is continuously applied is correlated to in vivo chlorophyll. When phytoplankton is in a dark-adapted state (e.g. during night or when the light is very weak), all reaction centers are in an active, open state and the fluorescence yield is minimal. In this state, fluorescence is at a baseline value F_0. When all the traps are closed the maximum fluorescence level (F_m) is reached. Variable fluorescence is obtained by subtracting F_0 from F_m ($F_v = F_m$-F_0). The potential yield of the photochemical reaction is therefore given by F_v/fm, which is quantitatively related to the photochemical efficiency of PSII. Based on these parameters a wide variety of modifications of fluorometric methods have been developed.

Delayed Fluorescence, DF (Goltsev et al., 2009) most commonly records the decay of fluorescence in the dark after a single turnover flash or after continuous light excitation.

Pump-and-Probe (P&P)-Fluorometry (Falkowski and Kolber, 1990) uses an intense "pump"-flash to close the reaction centers of natural phytoplankton assemblages to reach F_m. After a decay of 80-100 μs, a weak "probe"-flash is induced to re-open the traps to yield F_0. By controlling the intensity of the pump flash and the time delay between the pump- and probe flashes, more physiological information can be retrieved.

Pulse-Amplitude-Modulation (PAM)-*Fluorometry* is a variant of the Pump-and-Probe technique and was introduced to distinguish between photochemical and nonphotochemical quenching. Repeated intense flashes are used against a background of low light to obtain F_m and F_0. PAM as well as P&P-fluorometry are methods which are based on multiple turnover rates. However, both methods have limitations. PAM-fluorometry provides variable fluorescence only and some features of the PSU such as the functional absorption cross section (σPSII) cannot be described, while P&P-fluorometry is too slow to follow the dynamic changes in PSII.

Fast Repetition Rate Fluorometry (FRRF) has been developed to overcome the deficiencies of its predecessors (Kolber and Falkowski, 1992). The instrument is based on high frequency emission of blue light flashes at sub-saturating energy which gradually saturates the PSII reaction centers within a single turnover. The rate required to saturate the PSII reaction center is proportional to the functional absorption cross-section of PSII (σPSII). After reaching the saturation level (F_m), relaxation flashes with longer inter-flash delay are emitted to re-open the reaction center. The rate of relaxation is related to the turnover rate of PSII (τ). FRRF instrumentation has recently been expanded to more than one wavelength to improve the detection of cyanobacteria (Houliez et al., 2017).

Primary productivity estimates can be derived from variable fluorescence. Introducing the photosynthetic quotient (PQ) in the equation, the rate of carbon fixation can be obtained to qualitatively predict photosynthetic rates from changes in the quantum yield of fluorescence.

Remote sensing

Measures of primary production have always been complemented by calculations such as depth, time or wavelength integrated models (Behrenfeld et al., 2002). Similar algorithms became increasingly important as remote sensing, particularly from satellites developed and sensor technologies improved. Initially measurements from space were designed for global marine productivity estimations but can as well be used for larger aquatic systems (Bresciani et al., 2011; Hestir et al., 2015; Boucher et al., 2018). Present

day algorithm estimate chlorophyll which is then used to calculate primary productivity using a variety of models (Fig. 2; Raven and Geider, 2003). Recently, image data derived from remotely piloted aircraft systems (or drones) are under investigation (Joyce et al., 2017) (Fig. 3; Soomets et al., 2019).

Productivity in the "real" world

Let us now consider photosynthesis in a planktonic system in a water column, a planar representation of surface area projected to a depth z. Light (E) incident on the water surface is attenuated with depth, approximately following an exponential function (Fig. 4). We define a depth z_{eu} equal to the 1% light intensity as the base of the euphotic zone. This is the portion of the water column supporting primary production in most instances. In some cases, extremely light adapted assemblages can survive at much lower photon flux densities. The euphotic depth is often confused with the compensation depth (z_c), defined as the depth where daily gross productivity balances respiratory losses over a day. Above z_c, net photosynthesis is possible, below the result of oxygen production and consumption is negative. The average compensation depth is dependent on the surface light intensity E_0 and can be highly variable; it may, however, frequently correspond to the euphotic depth. If the portion of the water column which is mixed by

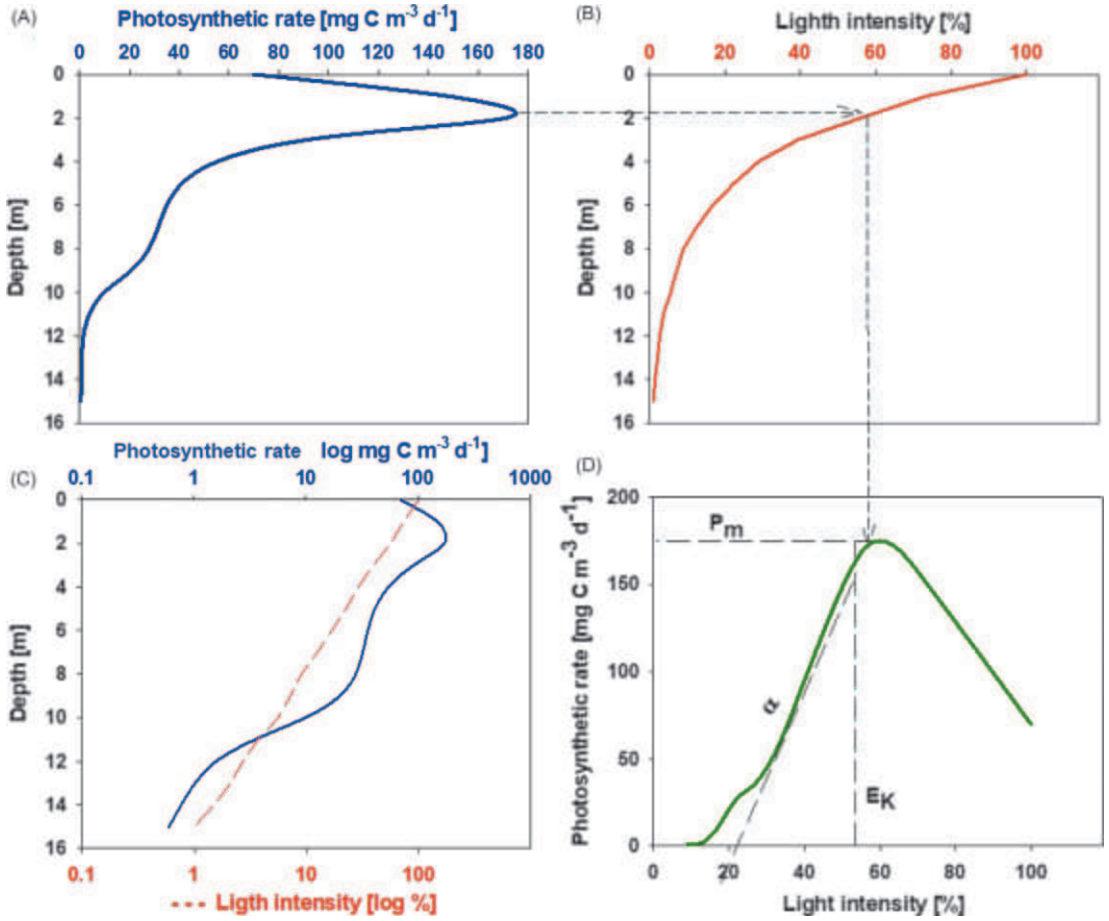

Fig. 4 Example how to convert a measured profile of photosynthetic rates (A) and vertical light attenuation (B) into a P/E curve (D). In addition, the profiles in (A) and (B) are combined into a semi-log plot (C) to indicate the similar decay of both variables with depth.

wind (z_{mix}) extends beyond the euphotic zone, a critical depth (z_{cr}) can be defined where integral net photosynthesis balances integral respiratory losses (Fig. 4).

In Fig. 4, an idealized daily integrated profile of photosynthetic rates is presented with algal biomass assumed to be homogeneous over depth, and therefore unimportant to the shape of the curve. At the surface, photosynthetic rates are typically depressed as a manifestation of photoinhibition which, at least partly, is an artifact of in situ methodology. Common methods keep algae constantly at high irradiance over prolonged periods of time which otherwise would float freely through the light gradient. Rates rise to P_m lower in the column and then decline monotonically as light becomes limiting, representing the low irradiance-dependent region of the P/E curve. Respiration losses (R_P) are assumed to be constant throughout the water column which has recently shown to be far from typical (Mantikci et al., 2019). Traditionally, respiration of the photoautotrophs has been assumed to be 10% of the maximum photosynthetic rate, and independent of irradiance. Many freshwater studies indicate that respiratory losses relative to P_m are variable. Additionally, the euphotic zone is influenced by temperature, supra-optimal light levels, nutrient limitations, nonhomogenous distribution of phytoplankton biomass, or even compositional changes of the assemblage within the water column. Plankton respiration on average increases with chlorophyll-a, total phosphorus (TP), and dissolved organic carbon (DOC) concentrations. Accurate measurement of R_P is one of the biggest challenges in estimations of primary production and will also affect the determination of the compensation depth as well as the critical depth.

A real vertical photosynthetic profile and light attenuation is exemplified in Fig. 4A and B, indicating also the approximate corresponding exponential decrease of both (Fig. 5C). Using the data in Fig. 5A and B, Fig. 5D indicates how to construct a P/E curve from real data.

Depending on the composition and vertical distribution of phytoplankton biomass, vertical profiles of phytoplankton productivity can substantially deviate from the schematic profile shown in Fig. 4. Three examples are depicted in Fig. 6. Deep chlorophyll maxima of various types of algae, such as picoplankton, Cyanobacteria etc., can produce secondary peaks of productivity at a greater depth. Turbid shallow lakes often do not show photoinhibition at the surface and have steep, compressed vertical profiles. High-mountain lakes may have profiles reaching P_m near the sediment because motile phytoplankton species dominate which tend to avoid large UV doses associated the high photon flux at such elevations (Fig. 6). Such "irregular" types of vertical profiles cannot be transferred to P/E curves; hence, physiologically meaningful parameters are extremely difficult to deduce. Moreover, these profiles cannot be described in simple mathematical terms, and modeling therefore is complicated if not impossible.

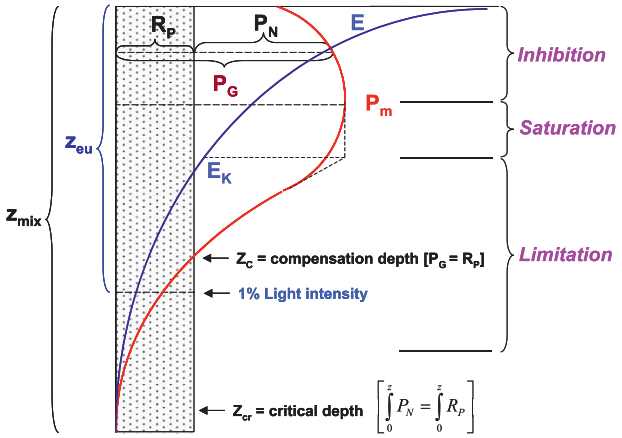

Fig. 5 Conceptual diagram showing a schematic vertical profile of gross photosynthesis (P_G), phytoplankton respiration (R_P), and attenuation of irradiance (E) in a hypothetical lake. Maximum photosynthetic (P_m) and net-photosynthetic rates (P_N) are indicated. The regions of photoinhibition, light saturation and light limitation are indicated on the right-hand side. The depth of the euphotic zone (z_{eu}), equal to 1% light intensity, the compensation depth (z_c) and the critical depth (z_{cr}) as well as the mixing zone (z_{mix}) are given.

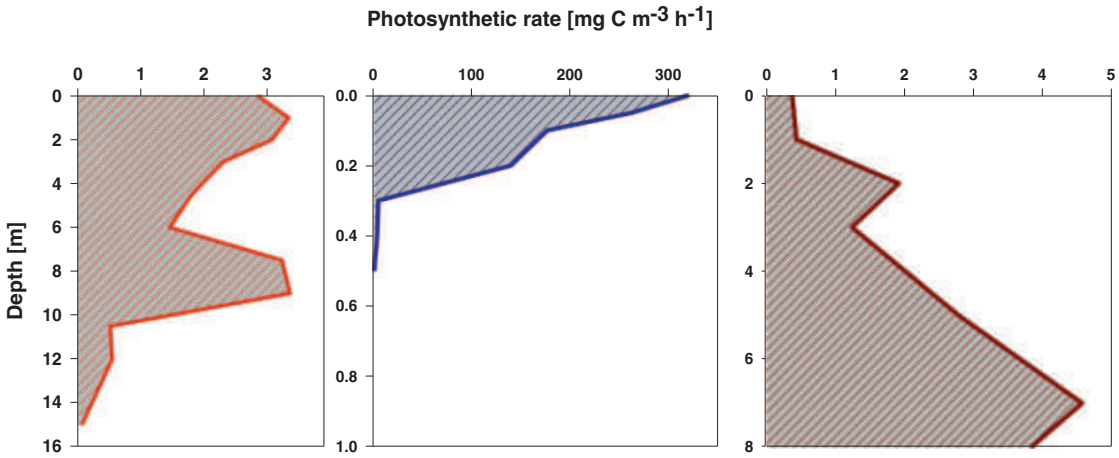

Fig. 6 Examples of nonregular vertical productivity profiles. Left Panel: Profile with a 2nd maximum at depth from a deep living low light acclimated population or assemblage (e.g. *Planktothrix rubescens*). Middle panel: Profile typically for turbid shallow lakes or turbid rivers as well as in highly eutrophic, algal bloom situations- Right panel: Maximum photosynthetic rate occurring at greater depth (often near the bottom). Typically for clear water, high-mountain lakes when UV-light penetrates deeply.

In essence, interpretation of productivity measurements in fresh-waters is often difficult, dependent on the technique used, and further complicated by the complex and variable composition of natural algal assemblages.

Daily, seasonal and inter-annual variability of production

One of the major determinants of variability in photosynthetic response is the daily variation in irradiance. Both the light-saturated and the light-limited chlorophyll specific photosynthetic rates are generally elevated during the photoperiod. The correlation between these two parameters suggests an increase either in the number of active reaction centers or in their turnover rate. The diel irradiance cycle is the natural synchronizing agent for algal populations in the environment constraining growth rates. Algal assemblages must cope with short-term changes in irradiance during a day and acclimate photosynthetic rates to variations from day to day.

Superimposed is the annual cycle of solar radiation which depends on latitude and altitude. Depending on the geographical position, annual variation of irradiance ranges from moderate near the equator to very pronounced at high latitudes. Accordingly, the magnitude of primary production strongly varies with climatic regions (Table 2). It must be emphasized that production continues at exceptionally low light intensities even under ice (Reitner et al., 1997; Dokulil and Herzig, 2009; Dokulil et al., 2014).

Table 2 Ranges of average daily and annual net-productivity in ecosystems of the world. Combined from various authors and sources.

Ecosystem	*Mean daily production (mg C m^{-2} d^{-1})*	*Average annual production (g C m^{-2} yr^{-1})*
Tropical lakes	100–7600	30–2500
Temperate lakes	5–3600	2–950
Arctic lakes	1–170	<1–35
Antarctic lakes	1–35	1–10
Alpine lakes	1–900	<1–250
Temperate rivers	<1–3000	<1–650
Tropical rivers	<1–24.000	1–5000

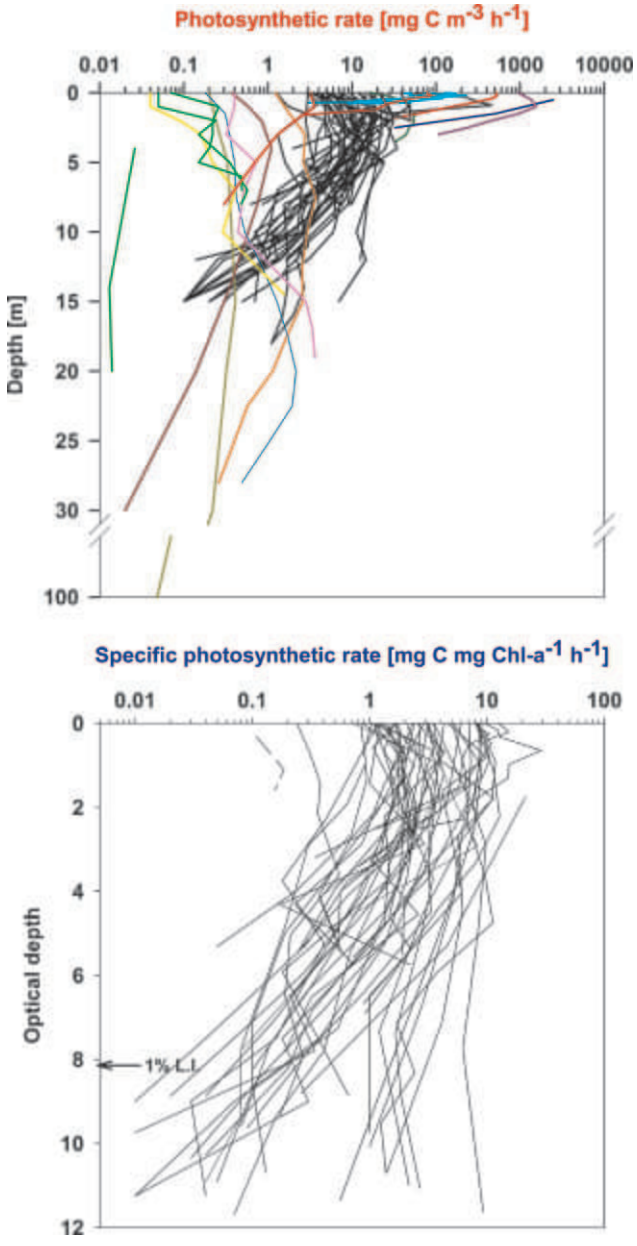

Fig. 7 One hundred vertical profiles of carbon fixation as a function of physical depth (A) and normalized to chlorophyll-a and optical depth (B). One unit of optical depth is equal to a halving of light intensity (Dokulil and Kaiblinger, 2009).

Table 3 Primary production, biomass, chlorophyll-a and dominant algal groups for the trophic categories observed in freshwaters (Dokulil and Kaiblinger, 2009).

Trophic level	*Primary production (mg C m^{-3} d^{-1})*	*Biomass (mg C m^{-3})*	*Chlorophyll-a (mg Chl-a m^{-3})*	*Dominant algal group(s)*
Ultra-oligotrophic	<50	<50	0.01–0.5	Chrysophyceae
Oligotrophic	50–300	10–100	0.3–3.0	Cryptophyceae Bacillariophyceae
Mesotrophic	250–1000	100–300	2–15	Dinophyta
Eutrophic	600–2500	250–600	15–30	Cyanobacteria
Hypertrophic	>2500	>600	> 30	Chlorophyta Euglenophyta
Dystrophic	<50–500	<50–200	0.1–10	

Assessment of primary production at the global scale

Several thousand vertical profiles of daily integrated photosynthetic rates have been obtained world-wide from many different freshwater ecosystems. Vertical profiles of photosynthetic rates from many lakes using different measurement techniques are summarized and expressed as volumetric carbon uptake per day in Fig. 7A. The profiles display a high degree of variability from as low as 0.1 mg C m^{-3} d^{-1} to way over 1000 mg C m^{-3} d^{-1}. The range of photosynthetic rates therefore is at least four orders of magnitude in freshwaters while it is only three in the sea. This is not surprising, considering the wide variety of lake types from extremely nutrient poor (ultra-oligotrophic) to nutrient rich (hypertrophic), from very shallow lakes (<2 m) to deep lakes (>200 m). Similarly, average daily column productivity (ΣΣP) ranges from 50 mg C m^{-2} d^{-1} to greater than 2500 mg C m^{-2} d^{-1} (Table 3).

The major source of variation in photosynthetic rates in aquatic systems is related to the amount and distribution of photoautotrophic biomass. To put it simply, under any irradiance condition photosynthetic energy flow is dependent on population density of the photosynthetic machinery. Since photosynthetic reaction centers are causally related to the concentration of photosynthetic pigments, normalization to chlorophyll-a, which is universally contained in all algal classes should lead to a reduction in variance. When carbon uptake rates from Fig. 7A are normalized to chlorophyll-a and plotted versus optical depth which is independent of physical depth, the magnitude is largely reduced (Fig. 7B). Chlorophyll-specific carbon uptake rates range from less than 1 to over 10 mg C mg Chl-a^{-1} h^{-1}, like observations in the sea (Falkowski and Raven, 2007).

Global gross primary production (GPP) of lakes was assessed as about 54 Tmoles C y^{-1} equivalent to 0.65 Pg C y^{-1} (Pace and Prairie, 2005). The amount of carbon produced in lakes is rather small relative to the 108–128 Pg C y^{-1} produced globally by plants (Walker et al., 2017).

Conclusions

The last 100 years and particularly the 20th century can be entitled as the "century of ecology" (Worthington, 1982) and perhaps equally as the century of productivity investigations. Measurements of photosynthetic rates and primary productivity have been much elaborated in detail on regional, global and temporal or seasonal basis over the last almost hundred years of expertise. A multitude of techniques and methodological refinements were established, and further development is still in progress. The rise in understanding subtle details of photosynthetic metabolism caused essential improvements in models of production, making estimations via remote sensing possible. Several open questions however remain (Hughes et al., 2018).

Knowledge gaps

- Conversion of electron transfer rates to equivalent rates of C-fixation
- Environmental influence of the electron requirement for C- fixation (Φe, C) as well as effects of phytoplankton composition and physiology
- Higher resolution and improved algorithms for remote sensing (Satellite) models
- Improved primary production estimates from high frequency measurements
- Central data repository

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Marie Elodie Perga and Damien Bouffard.

Glossary

Biophysical interactions Examining the interactions of biology and physics to shape the environment.
Convection Movement caused by differences in density between two parcels of water.
Eddy A circular movement of water.
Epilimnion The surface layer of a classically stratified water column, lying above the thermocline; it tends to be the same temperature throughout.
Extinction coefficient A measure of how easily light can penetrate into water.
Hypolimnion The deepest layer of a classically stratified water column, lying below the thermocline; it tends to be the same temperature throughout.
Internal seiching Subsurface movement of water along the thermocline generated by a standing wave oscillating through a waterbody. Frequently caused by the displacement of water upwind during wind forcing, which returns once the forcing is relaxed, setting up the oscillation.
Metalimnion The middle layer of a classically stratified water column, usually coinciding with the region of the thermocline.
Mixed layer The surface layer in a lake, in contact with the atmosphere, it is assumed to be fully mixed.
Phytoplankton A collection of microscopic bacteria, protists and plants which inhabit our open waters, capable of obtaining energy via photosynthesis.
Thermal structure, stratification The vertical temperature variation in a column of water affecting its density. For example, where different water depths have different temperatures, the density difference of these depths results in the water column becoming stratified.
Thermocline The region of rapid temperature change in a stratified water body.
Turbulence Unstable motion characterized by irregular, chaotic movement with rapid changes in velocity.

Introduction

Phytoplankton, the collection of microscopic bacteria, protists and plants which inhabit our open waters, are both shaped by and alter their physical water environment. These interactions occur across a range of spatial and temporal scales from length scales of micrometers and timescales of seconds in turbulent flow to whole lake basins (kilometers) and seasonal patterns reflecting changes in stratification and mixing. Physical interactions at the smallest scales help to shape the form and function of phytoplankton and contributes to shaping the dominant species in the community at any point in time. These biophysical interactions occur through the vertical water column of lakes, where phytoplankton can alter their physical environment through heat absorption and density alteration and the physical environment can structure the extent and intensity of mixing experienced by planktonic organisms and their access to the nutrients essential for survival. Across horizontal gradients in lakes, physical processes of convection, wind mixing and seiching generate gradients in nutrients, patches of surface phytoplankton and subsurface accumulations of phytoplankton which both determine and are determined by the types of phytoplankton present in the community. These accumulations have

 https://doi.org/10.1016/B978-0-12-819166-8.00158-4

implications for understanding patterns in biogeochemical processing and determining spatial patterns in water quality that can impact shoreline recreation or water draw-off. The aim of this chapter is to introduce the main concepts of biophysical interactions in phytoplankton. It provides an overview of different scales of biophysical interactions in phytoplankton over vertical and horizontal dimensions in lakes.

Small-scale interactions

The physical water environment of lakes exerts a fundamental control on the form and function of phytoplankton. At a basic level this is because, according to Stokes' Law, large objects sink faster than small objects of the same density, assuming they have the same shape and drag effects. Reynolds (1998) suggests that this offers an advantage to smaller cell sizes compared to larger ones, as small cells will not sink out of photic layers as quickly and be more likely to remain entrained within moving water, enabling carbon acquisition and cell division to occur. He goes on to hypothesize that the minimum eddy size in a lake places an upper size limit on the phytoplankton form size that can be sustained, which is determined by the balance between the shear or friction velocity of the water (u^*) and the settling velocity of the phytoplankton (ws) (Reynolds, 1998). Where $u^* > ws$, the phytoplankton cell will be entrained within the water motion and where $u^* < ws$ the cell will be dis-entrained resulting in sinking, floating or swimming movements dominating the movement of the organism. In practice, turbulent velocities are usually between one to six orders of magnitude larger than sinking velocities, which results in phytoplankton being continuously redistributed in the turbulent water column (Naselli-Flores et al., 2020). Deeper water columns dissipate energy more slowly than shallower water columns. This is the case where the water may be shallow because of the lake bathymetry or because the lake is stratified and mixing is restricted to the surface mixed later. This difference in water column depth results in larger minimum eddy sizes in a deep lake like Lake Constance, 2.9–1.5 mm, versus a shallow lake like Lough Neagh, 0.7 mm (Reynolds, 1998). In order to stay entrained within the water column and able to access light required for growth, Reynolds suggests that phytoplankton need to be smaller than the eddies likely to be generated in their lifetimes, which is why most planktonic algae are <200 μm in size and colonies <2 mm, the latter being only likely to dominate in very calm or stratified water.

Owing to their small size, phytoplankton experience turbulence as a shear flow, where different fluid volumes flow past each other at different velocities. This difference in velocities generates a torque in the water which results in a constant rotation of organisms (Wheeler et al., 2019). The interaction of turbulence with motility traits has been shown to differ depending on whether species are motile, such as dinoflagellates, or non-motile, such as diatoms, with the result that patchiness may be more pronounced for motile species (Durham et al., 2013). Where the destabilizing effect of torque overcomes stabilizing effects related to cell morphology, such as a pear-shaped morphology with a 'heavy' bottom, cells are deflected from their preferred orientation. This deflection due to turbulence can cause cells to become trapped in high shear regions, resulting in accumulations of cells and patchiness at the mm scale (Durham et al., 2013). These patches can persist for hours to weeks and can often represent ecological hotspots.

The concentration of phytoplankton cells can result in opportunities for enhanced predation but it may also offer some advantages to the organisms, particularly in terms of enhanced encounter rates for phytoplankton with a sexual stage and increasing the concentration of allelopathic compounds which may be used to deter other organisms and reduce predation (Wheeler et al., 2019). Phytoplankton have also been found to exhibit behavioral responses to cues from flow through an ability to change shape and alter swimming behavior. This response is thought to enable motile phytoplankton to escape from physiologically harmful areas of high turbulence, counteracting the destabilizing effects illustrated above (Wheeler et al., 2019).

The physical environment and turbulent mixing play a key role in determining the availability of light energy and nutrient resources to phytoplankton cells (Reynolds, 1998). The ability of individual cells to access the resources required for growth is determined by cell size, where larger surface areas to volumes can confer an advantage in uptake rates. The diffusion boundary layer is the region around a phytoplankton cell which is chemically altered by its presence. In the case of nutrients, this region is depleted due to cell uptake. Turbulence and cell motility both have the action of making this layer thinner, which enhances transport to and from the organism (Wheeler et al., 2019). This passive or active movement around the cell reduces the nutrient uptake advantage of small cell size, because boundary layers around larger cells are more strongly deformed by the movement. This deformation increases the nutrient concentration gradient near the cell and results in more nutrient rich water being brought into the boundary layer enhancing nutrient uptake (Wheeler et al., 2019).

The effect of turbulence on resource acquisition then has implications for the evolutionary adaptation of phytoplankton species and selection for species in different environments. Chain formation in diatoms and dinoflagellates, for example, may in part be explained by the presence of flow and turbulence, since the oscillation of shear flow allows for a greater thinning of boundary layers in chain morphologies than it would for a single cell (Wheeler et al., 2019). At a community level, in nutrient poor environments, pico- and nano-plankton dominance may, in part, be explained by their relatively higher uptake rates than those for larger phytoplankton without exposure to strongly turbulent conditions (Reynolds, 1998). In contrast, nutrient depleted conditions in stratified eutrophic systems, are likely to select for larger cells or colonies, which may be motile and able to dis-entrain from weak turbulence and vertically migrate to access nutrient resources (Reynolds, 1998).

Vertical interactions

Phytoplankton as mediators of their physical environment

Lake thermal structure

A proportion of incoming solar radiation, unlike the other surface heat fluxes, penetrates beneath the surface of a lake. The rapidity of its absorption with depth can vary substantially between lakes and is strongly influenced by phytoplankton concentrations. Thus, these organisms have the potential to influence the thermal structure of lakes.

The relationship between light absorption and depth is parametrized by the light extinction coefficient, k (m^{-1}), in the equation,

$$I_z = I_0 \, e^{-kz},$$

where I_0 is the solar radiation penetrating the surface of the lake and I_z is the solar radiation at a depth z (negative downwards). The higher the extinction coefficient is, the more that light is absorbed nearer the surface (Fig. 1). So, for example, with an extinction coefficient of $k = 2.0$, more than 98% of the light is absorbed in the top 2 m, while for $k = 0.2$ less than 35% of the light is absorbed in the top 2 m. With $k = 0.5$, nearly 2% of the light still reaches 8 m depth, while for $k = 0.2$, the same amount reaches as far down as 20 m (Fig. 1). As the solar radiation is absorbed it heats the water, so for small extinction coefficients the heat from the sun penetrates much deeper into the water column than when the extinction coefficients are large. The profound differences in where the heat is being absorbed in the water column shapes the thermal response. Pure water itself absorbs light, as do a variety of chemical constituents such as humic material, while absorption is further increased by phytoplankton in the water. Extinction coefficients can, therefore, be estimated as a background value, which would depend on the dissolved chemical constituents, and a value proportional to the phytoplankton concentration. For example, for a background extinction coefficient of 0.2 m^{-1}, and an optical cross-section of chlorophyll of 0.015 m^2 mg^{-1} (Kirk, 1994) then extinction coefficients of 0.5 m^{-1} and 2.0 m^{-1} would correspond to chlorophyll *a* concentrations of 20 and 120 mg m^{-3}, respectively.

Lake surface area is a major determinant of the impact of extinction coefficients on thermal structure, with the influence of extinction coefficients being commonly evident in smaller lakes, while being less obvious in larger lakes (Fee et al., 1996). The relationship with lake surface area is, in part, a result of mixed depths typically being deeper in large lakes than in small ones (Fee et al., 1996) and the impact that has on the ratio of mixed depth to photic depth. If the mixed depth is deeper than the photic depth then virtually all the light would be absorbed within the mixed layer and, in theory, the heat would then be distributed throughout that layer, so changes to extinction coefficient would have relatively little impact (Fee et al., 1996; Persson and Jones, 2008). Thus, given the variation in light extinction curves (Fig. 1), a lake with surface area sufficient for a mixed depth of, say 10 m, should be negligibly impacted by a change in extinction coefficient from 2.0 to 0.5 m^{-1}, as for either coefficient nearly all the light is already absorbed by 10 m, but thermal characteristics could be influenced by a change from 0.5 to 0.2 m^{-1}. In comparison, a smaller lake with a mixed depth of only 2 m would be influenced by a change in extinction coefficient from 2.0 to 0.5 m^{-1} as well. Thus, for any lake there would be a sub-range of extinction coefficients which would have an influence on lake thermal characteristics depending on whether all light was being absorbed within the mixed layer or not. Likewise, changes to small extinction coefficients tend to produce bigger effects, while changes to very high values, for example above 2 m^{-1}, tend not to matter too much to thermal structure for all but the shallowest epilimnia (Fig. 1). Hence, small lakes and relatively clear lakes tend to be more susceptible to changes in extinction coefficient than relatively large turbid lakes.

One of the most observed influences of extinction coefficients (Mazumder et al., 1990; Fee et al., 1996; Persson and Jones, 2008) is on thermal length-scale metrics, such as thermocline depth or mixing depth. Typically, these are found to be several meters shallower in lakes with higher extinction coefficients than those with lower extinction coefficients, at least for small to moderately sized lakes. Similarly, long-term changes in extinction coefficient in a lake have been observed to be accompanied by long-term changes in these thermal metrics.

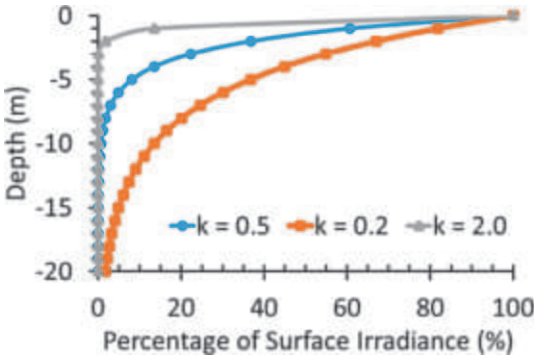

Fig. 1 Percentage of surface solar radiation reaching different depths for three different extinction coefficients, *k*: 2.0 (gray triangles), 0.5 (blue circles), 0.2 (orange squares).

Lake temperatures can also be affected by changes to extinction coefficient, although the most striking impacts are typically observed in the metalimnion and hypolimnion, rather than the epilimnion. In smaller lakes, field and modelling studies of extinction coefficient impacts have consistently shown comparatively cooler deeper water in less transparent lakes, and often by several degrees. For example, Mazumder et al. (1990) studying lakes and enclosures with and without planktivorous fish, the former with fewer zooplankton, more small phytoplankton, and shallower Secchi depths than the latter, showed metalimnetic waters several degrees cooler where the fish were present and the extinction coefficient greater, as the solar radiation was not penetrating to the deeper waters.

Studies are equivocal on the impacts on surface temperature, though. A comparison between two large neighboring enclosures, one with high phytoplankton concentration and one with low, showed the one with the greater concentration to have higher surface temperatures of about 0.5–1.0 °C (Jones et al., 2005). On the other hand, the opposite effect has been observed (e.g. Mazumder et al., 1990) with slightly higher surface temperatures in the clearer lakes, possibly owing to increased backscattering of incoming solar radiation by small phytoplankton. Modelling studies have shown that there is a temporal consideration, with less transparent lakes having comparatively warmer surface temperature at the start of stratification, but then a lower surface temperature later in the summer. The initial comparative rise in surface temperature is moderated by the consequential increase in surface cooling from outgoing longwave and sensible and latent heat fluxes associated with a warmer surface (Jones et al., 2005). Subsequently, the concurrent sizeable decrease in metalimnetic water temperature ultimately leads to cooling from below later in the stratified season when chillier metalimnetic waters gradually entrain into the deepening mixed layer (Persson and Jones, 2008). When the average effect on surface temperature has been studied over the whole stratified period it has been found to be rather small, generally less than 1 °C.

The effect of a marginal increase on surface temperature and a simultaneous significant comparative decrease in temperature of deeper water in less transparent lakes also impacts stratification. Stratification is usually found to be comparatively stronger and comparatively longer in lakes with higher extinction coefficients (Persson and Jones, 2008). Again, the morphology of a lake, and the range of extinction coefficients experienced, will be key to how large the effect could be, but for particular morphologies, the extinction coefficient can make sufficient difference to determine whether a lake is polymictic or dimictic (Shatwell et al., 2016). The temporal consideration of seasonality of phytoplankton growth is also important, with the timing of blooms, when extinction coefficients will be higher, and clearwater phases, when extinction coefficients will be lower, potentially influencing stratification and destratification of polymictic lakes (Shatwell et al., 2016).

Bioconvection

Physical processes generally dominate in controlling the environment experienced by phytoplankton where there is active turbulence. However, there are circumstances, under low turbulent mixing, when microorganisms can induce convective mixing processes, thus altering the physical conditions they experience. This is achieved through alterations to the density of the water due to their presence in high concentrations, and is a phenomenon termed bioconvection. Upward swimming and the aggregation of cells increases the density of the surrounding water above that of the water below it; this results in instability and convective mixing of the cells downwards. The mixing is therefore continued while the organisms continue their active upward swimming behavior. Despite the potential for bioconvection to occur in phytoplankton, particularly actively motile groups, evidenced in laboratory experiments (Bees and Hill, 1997), observations of bioconvection in lakes are currently limited to motile bacteria (Sommer et al., 2017). The relative importance of this process in mixing in lakes is therefore poorly understood at present.

The influence of the physical vertical structure of lakes on phytoplankton communities

Phytoplankton require light and nutrients for growth and each have a heterogenous vertical distribution within the water column (Klausmeier and Litchman, 2001). Light availability reduces with depth with the gradient of attenuation depending on water color and the concentration of suspended solids, including phytoplankton (Kirk, 1994). Photosynthetically active radiation (PAR) is available to phytoplankton until it reaches roughly 1% of its surface value, which is defined as the photic depth; below this depth light levels are generally considered too low for photosynthesis (Kirk, 1994).

The vertical distribution of nutrients and phytoplankton are determined by the depth of surface mixing. During lake stratification, a vertical density gradient inhibits the whole water column from mixing, restricting mixing to surface waters. The depth of surface mixing is important for phytoplankton growth as it determines the light levels and nutrient concentrations that phytoplankton are exposed to. When a lake is stratified, nutrients can be at their highest levels below the mixed layer and scarce within the mixed layer as they are used rapidly by the phytoplankton (Klausmeier and Litchman, 2001).

Phytoplankton resources can therefore have opposing vertical gradients of irradiance and nutrients (Fig. 2). Therefore, vertically, there are narrow bands of space that are suitable for phytoplankton growth which fluctuate depending on the position of the mixed depth (Klausmeier and Litchman, 2001). This led to the development of the "critical depth" hypothesis whereby phytoplankton growth can only be maintained if the surface mixed layer is shallower than some critical depth (Sverdrup, 1953). This theory suggested that if mixing was sufficiently shallow then the light conditions will be favorable for photosynthesis and therefore phytoplankton populations can be maintained (Sverdrup, 1953). This did not explain, however, how phytoplankton blooms can form in the absence of stratification or during times of weak stratification which led to the idea of "critical turbulence" (Huisman et al., 1999). If turbulent mixing was less than a critical value then phytoplankton populations can be maintained as growth exceeds sinking losses (Huisman et al., 1999).

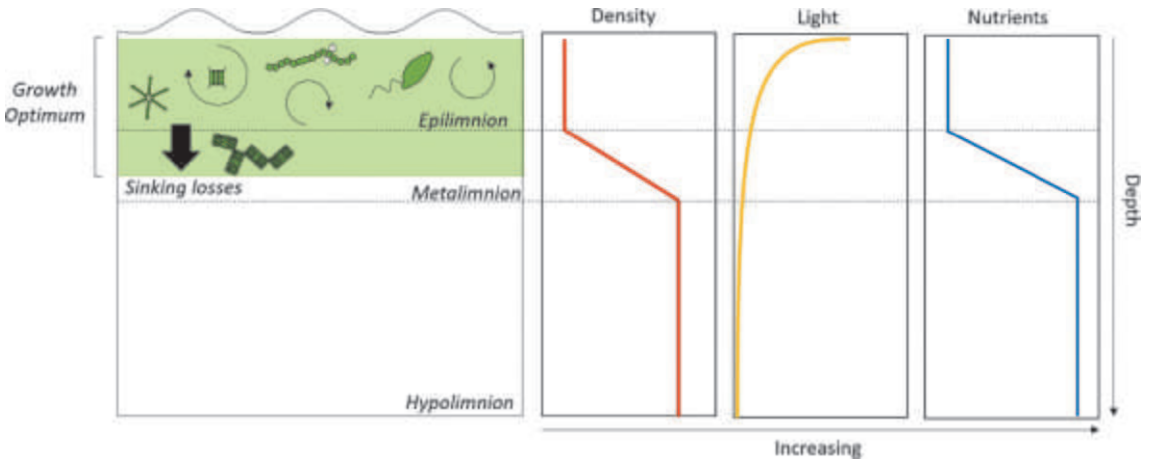

Fig. 2 Vertical gradients in density, light and nutrients create varying optima for phytoplankton growth.

The vertical distribution of phytoplankton in the water column is further complicated by the different resource requirements, sinking rates and levels of motility between phytoplankton taxa (Naselli-Flores et al., 2020). At times of full water column mixing, phytoplankton are mixed throughout the water column and they are roughly exposed to the same light levels and nutrient concentrations (Huisman et al., 1999). Under these conditions, diatoms are often abundant as higher turbulence overcomes the relatively higher sinking velocities of diatoms compared to other taxa, which combined with the low light adaptation of these species, enables them to persist during deep mixing (Reynolds, 2006). These conditions, coupled with the abundance of silica (required for the formation of diatom frustules), mean that diatoms are often the first phytoplankton to bloom in spring in temperate systems (Reynolds, 2006).

As stratification strength increases and vertical mixing becomes weaker, different phytoplankton taxa can occupy different depths according to their specific resource requirements and levels of motility which can lead to vertical niche partitioning (Beisner and Longhi, 2013). Some species of cyanobacteria such as *Dolichospermum* sp. have small air sacs called vesicles which enable them to rise to the surface and form large blooms (Huisman et al., 2018). These blooms have become a major water quality hazard for many lakes and reservoirs globally due to their potential toxicity and other negative ecosystem impacts (Huisman et al., 2018). Mixing induced either by storm events or via an artificial mixing system (Visser et al., 2016) can break up surface blooms as deeper mixing can result in light limitation. In some instances mixing can result in increased pressure deeper in the water column, which can cause the collapse of gas vesicles, preventing buoyancy (Walsby, 1994). Persistent mixing can result in cyanobacteria being replaced by chlorophytes, flagellates or diatom taxa which are adapted to the lower light conditions associated with deeper mixed depths (Visser et al., 2016). The critical role of mixing and mixed depth in determining phytoplankton community composition is illustrated by the rapid community changes induced by short term changes in lake physical structure (Jöhnk et al., 2008). However, these changes can be transitory, with a return to high stratification strength and shallow surface mixing following a mixing event leading to surface blooms of cyanobacteria re-forming.

Phytoplankton biomass can also peak at depths below the surface forming a deep chlorophyll maximum (DCM). This can occur in lakes when the euphotic depth is deeper than the mixed depth (Leach et al., 2018). Phytoplankton occupying this position can access the higher nutrient concentrations in the metalimnion and they can persist due to their adaptation to low light conditions and/or their ability to migrate between areas of favorable nutrient and light levels (Arvola et al., 1991). Taxa associated with deep water biomass peaks include low light adapted cyanobacteria such as *Planktothrix* sp., motile cryptophytes and occasionally diatoms as the cool dense water at deeper depths can slow their sinking rates. Some motile phytoplankton such as the cryptophyte *Cryptomonas* sp. and the dinoflagellate *Ceratium* sp. undergo daily migrations, occupying the upper layers of the water column during the day to access higher light levels and migrating to the metalimnion at night to access nutrients (Arvola et al., 1991).

Horizontal interactions

Spatial patterns in phytoplankton distribution are a common feature of lakes, the drivers of which have been related to physical mixing and water movements, chemical gradients and biological interactions (Pinel-Alloul, 1995). Physical drivers of these patterns are related to convective, advective and seiching processes driving waves and current formation which move phytoplankton around a lake basin. Since physical forcing is rarely constant in time or space, the continual changes in the strength, direction or extent of these drivers and the subsequent relaxation of forcing when the wind drops, for example, result in the formation of phytoplankton patchiness over a range of spatial scales from basin level > 1 km to microscale effects within turbulent eddies.

In lakes, there are a number of convective processes which act on the waterbody that may influence the movement and aggregation of phytoplankton. Differential heating and cooling occurs because water columns of different depths warm and cool

at different rates and to different extents. This affects the spatial development of vertical stratification across areas like the littoral and pelagic zone or in sidearms of lakes and reservoirs. The result is the creation of horizontal density gradients across these areas, setting up a 'thermal siphon' of water movement (Monismith et al., 1990). These convective movements are likely to develop in the absence of other horizontal mixing processes, which would act to equalize the density gradient; therefore they tend to form under low wind speeds and in wind-sheltered locations, frequently at night. Night time horizontal convection has been found to transport nutrients from littoral zones into offshore areas, acting as an internal nutrient source (James and Barko, 1991).

In addition to horizontal patterns established by thermal convective transport, the development of advective movement through wind-derived waves and currents can also act to create horizontal variability in phytoplankton concentrations at a range of spatial scales. At a basin level, wind-induced circulation, wind mixing processes, upwelling and downwelling associated with thermocline tilting and the effect of lake inflows will dominate in determining the spatial distributions of phytoplankton communities (Pinel-Alloul, 1995). Wind field strength and its persistence have been found to be important factors in the accumulation of phytoplankton across scales of greater than one kilometer down to tens of meters (Pinel-Alloul, 1995). The propensity for phytoplankton to form patches or accumulations depends in part on their physical characteristics, with positively buoyant, neutrally buoyant and negatively buoyant species all showing different relationships under different wind forcing (Cyr, 2017). Phytoplankton motility or buoyancy characteristics interact with these physical drivers, with evidence for downwind advective movement of positively buoyant species and upwind movement of negatively buoyant species resulting in high concentrations in areas of upwelling under consistent wind forcing (George and Edwards, 1976). Laboratory studies identified a threshold in wind speed of 2–3 m s^{-1}, for buoyant species, below which surface accumulations may form under low wind speeds and above which more turbulent mixing would result in entrainment into deeper waters (Webster and Hutchinson, 1994). Downwind concentrations have been reported under conditions of higher but steady wind speeds (Cyr, 2017).

Wind exposure and persistence of wind direction can affect how phytoplankton patches form and the extent and duration of phytoplankton patches. Lakeshore morphometry can create sheltered areas of a lake, setting up heterogeneity in wind exposure over the lake surface. This differential wind exposure can set up the development of gyre circulations, with algal patches forming and persisting within them (Schernewski et al., 2005) (Fig. 3). Circulation patterns and the effect on phytoplankton populations will differ over time as a result of changing wind direction. For example, a concentration of algal cells resulting in a surface bloom can occur at times coincident with the prevailing wind direction, as a result of the circulation pattern, compared with times when winds are perpendicular to the main axis of a lake, which results in multiple circulation cells occurring and no bloom (Schernewski et al., 2005). Long-term reductions in wind speed have also been associated with increased extent and duration of cyanobacterial blooms, as cells are not mixed away from the surface or dispersed laterally (Wu et al., 2015).

Fig. 3 Surface phytoplankton bloom following basin scale circulation patterns in Lake Atitlan, Guatemala, 2009. From NASA Earth Observatory image by Jesse Allen, based on data from the NASA/GSFC/METI/ERSDAC/JAROS, and U.S./Japan ASTER Science Team https://earthobservatory.nasa.gov/images/41385/harmful-bloom-in-lake-atitlan-guatemala.

In addition to the surface effect of wind on algal populations, in stratified lakes, internal waves, caused by the oscillation of the thermocline can also drive patch formation in phytoplankton through direct and indirect effects. Internal waves form following thermocline tilting due to wind stress thickening of the upwind epilimnion, which can oscillate once the wind stress is released. These waves interact at the edges of the lake basin where waves can break and result in episodic vertical transport of nutrients from the hypolimnion to epilimnion. Where thermocline tilting is strong, regions of upwelling water at the downwind area of a lake can mix deeper phytoplankton layers to the surface (George and Edwards, 1976). In addition, internal waves can also affect the horizontal distribution of sub-surface accumulations of phytoplankton, such as the cyanobacterium *Planktothrix rubescens*, altering the vertical and horizontal position of the maximum biomass over the course of several days (Cuypers et al., 2011). The accumulation of phytoplankton into patches has implications for the location of biogeochemical cycling in lakes and the potential for hazardous species to impact on ecosystem services provided by the lake. For example, the accumulation of cyanobacteria scums around drinking water draw-off points or along bathing beaches can detrimentally affect the provision of freshwater and amenity use.

Methods for quantifying turbulence and phytoplankton

Technological developments over recent years are enabling improved observations of both the physical properties of water, including turbulence and mixing, and the vertical and horizontal distribution of phytoplankton to be captured at finer scales. As turbulence is so varied over both time and space, fully characterizing turbulence in lakes is very challenging. Measurements of turbulence can be made using highly sensitive instruments such as microstructure profilers, which typically measure temperature, conductivity and shear many times per second as they descend through the water column. These measurements can be used to calculate the dissipation rate of turbulent kinetic energy, which provides a measure of the turbulence of the water. An alternative approach, which is frequently adopted in lake systems, is the use of moored Acoustic Doppler Current Profilers (ADCPs). These instruments can provide measures of water current velocity and the dissipation rate of turbulent kinetic energy and modes of seiching, depending on their configuration (Simpson et al., 2011). Accurate measurements of water temperature over a vertical profile, using for example, thermistor strings, can also provide a means of calculating vertical eddy diffusivity for heat, K_z, which can be used as a measure of vertical water column mixing below the surface layer, where other processes are assumed to be negligible (Jassby and Powell, 1975).

The advent of increasingly sophisticated sensors for measuring biological components of lake systems is leading to an improved resolution of measurement of vertical and horizontal planes in lakes. The deployment of vertical profiler systems with multi-parameter sonde attachments capable of measuring chlorophyll *a* or phycocyanin is providing sub-daily resolution data on the vertical distribution of phytoplankton and even distinguishing broad algal groups based on pigment fluorescence. This high frequency measurement over monthly and longer time periods enables the interactions between physical changes in the water column and interactions of the phytoplankton to be characterized in greater detail. Across horizontal dimensions the increasing use of Earth Observation through satellites and drone technology is enabling the spatial extent and spatial dynamics of algal blooms to be tracked at daily and sub-daily frequency. Linking short term spatial observations of algal movements with two-dimensional and three-dimensional physical models driven by weather predictions is starting to be used to predict bloom movements and enable the forecasting of their potentially hazardous accumulation.

Conclusion/synthesis

This chapter introduces the key features of biophysical interactions in phytoplankton. It considers how interactions occur and manifest themselves at different temporal and spatial scales. Biophysical interactions occur at the microscale as a result of the size and strength of turbulent eddies and swimming or sinking behavior of individual cells. These interactions can have macroscale effects on lake thermal structure, the vertical distribution of phytoplankton cells in response to their resource environment and result in horizontal patch formation at the lake basin scale. Phytoplankton are both structured by and, in some cases, structure their physical environment. These interactions drive community changes, species interactions and the provision of ecosystem services like drinking water and recreation amenity.

Knowledge gaps

- The role of physical mixing in inducing behavioral, physiological and morphological responses in phytoplankton
- Understanding the importance of bioconvection as a mixing process in lake ecosystems
- Process-based links between physical mixing processes and spatial patch formation and dissipation in phytoplankton
- The extent of backscattering of incoming solar radiation by phytoplankton
- The influence of climate on how light attenuation impacts thermal structure
- Detailed high frequency in-situ data on phytoplankton species and morphology

Glossary

Anabolism Metabolic pathways that synthesize complex molecules from smaller molecules.
Attenuation The gradual loss of light intensity through the water column.
Autochthonous Material produced within the lake itself.
Autotrophic Organism producing its own organic matter from inorganic carbon (CO_2), using light or inorganic chemical reactions as an energy source.
Benthic Region of the lake including the sediment surface and shallow sub-surface layers.
Catabolism Metabolic pathways that breakdown complex molecules into smaller units.
Catchment Area of land where precipitation collects and drains towards a lake.
Ecotone The transitional area between two adjacent ecosystems.
Heterotrophic Organism that cannot produce its own organic matter, rather obtains organic materials from living organisms or detrital organic matter.
Hydraulic retention time Average length of time that a water molecule remains in the lake.
Lake metabolism The sum of anabolic and catabolic pathways in a lake.
Littoral Near shore area where light penetrates to the bottom of the lake.
Pelagic Open water area where light does not penetrate to the bottom of the lake.
Photooxidation Oxidative degradation caused by light (this article focuses on photooxidation of dissolved organic matter).
Stoichiometry Relationship between the relative quantities of substances forming a compound or material, typical expressed as a ratio.
Stratification Separation of water into distinct lake layers caused by different water densities.

Lake metabolism

Lake metabolism represents the collective breakdown (catabolism) and synthesis (anabolism) of molecules within a lake. Organismal metabolic rate, from bacteria to fishes, is influenced by organism size and a few key constituents, namely light, nutrients, temperature, and organic matter. The influence of these constituents on organismal metabolism ultimately governs metabolism at the whole-lake scale (i.e., lake metabolism) and can influence whether a lake is a net source or sink of carbon. Estimates of lake metabolism provide insight into energy flow within the lake, measures of trophic status, and how a lake contributes to broad-scale biogeochemical cycling. Variations in constituents that influence lake metabolism result in differences in metabolic rates across lakes and also within lakes both spatially (vertically or horizontally) and over time. The first estimates of

lake metabolism were made several decades ago based on diel measurements of dissolved gasses within freshwater systems (Odum, 1956). With recent advancement in sensor technologies, estimating lake metabolism has become much more accessible, providing unique opportunities for addressing fundamental questions of energy transformation within lakes. In this article, we describe the key drivers of within and across lake variability in lake metabolism including nutrient and light availability, temperature, and organic matter concentration and how these drivers shape lake metabolic patterns across Earth's biomes.

Most metabolic reactions in lakes use oxygen since it is a favorable electron acceptor for organisms. There are several energy pathways utilized by lake organisms that do not involve oxygen, such as iron reduction, acetoclastic methanogenesis, denitrification, and anoxygenic photosynthesis. Although these metabolic processes that utilize electron acceptors other than oxygen are less energy efficient, they can contribute significantly to total lake metabolic rates in some instances. However, much of the focus of lake metabolism studies have been on oxygenic processes, such as aerobic respiration and oxygenic photosynthesis, and this article will cover methods for estimating and constraints on these oxygenic processes. From here on, when we refer to lake metabolism or metabolism in this article, we are referring to oxygenic metabolic processes.

Methods of estimating lake metabolism

Overview

Estimating whole-lake metabolism requires approximating processes that influence the production and consumption of organic carbon by organisms within the lake. Understanding a few key processes and main components of lake metabolism allows researchers to estimate whole-lake metabolism or metabolism at certain locations within a lake. Estimating aerobic metabolism involves measuring molecules produced or consumed in photosynthesis and respiration (Eq. 1). Primary production and respiration are often highly correlated in lakes and span a wide range of metabolic rates (Hoellein et al., 2013; Fig. 1).

$$\begin{aligned} &\text{Photosynthesis}: 6CO_2 + 6H_2O \overset{\text{light}}{\rightarrow} C_6H_{12}O_6 + 6O_2 \\ &\text{Respiration}: C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O \end{aligned} \quad (1)$$

Bottle bioassay method

Photosynthesis only occurs in the presence of light while respiration is a continuous process and occurs in both the presence and absence of light. This key difference between the two processes allows researchers to estimate these fundamental components of lake metabolism by measuring oxygen or carbon dynamics using paired light and dark bottles. With this method, the researcher incubates lake water in two separate bottles, one that is clear and exposed to natural or artificial light regime, the "light" bottle, and another that is sealed off from the light by wrapping the bottle in foil, paint, or another method, thereby shutting off photosynthesis, the "dark" bottle. Changes in carbon fixation or dissolved gasses (O_2 or CO_2) are then measured over a certain time period (e.g., several hours to a day) to estimate the rate of metabolism for specific lake depths, which could be used to estimate metabolic rates for an integrated water column. Carbon fixation can be measured by adding radioactive carbon isotopes, such as ^{14}C, into the bottles, sampling the bottles over time to measure how much carbon has been incorporated into algal cells. Dissolved gas concentrations within the bottles can be measured with dissolved gas probes or the Winkler titration method. The dark bottle gives an estimate of lake respiration (R, table 1), while the light bottle gives an estimate of lake net ecosystem production (NEP, Table 1) since both photosynthesis and respiration occur in the light bottle (Fig. 2). Adding the dark bottle oxygen production rate (should be negative since respiration consumes oxygen) to the light bottle oxygen production rate (could be negative or positive) yields an estimate of gross primary production (GPP, Table 1). Although the light and dark bottles are simple to implement, they

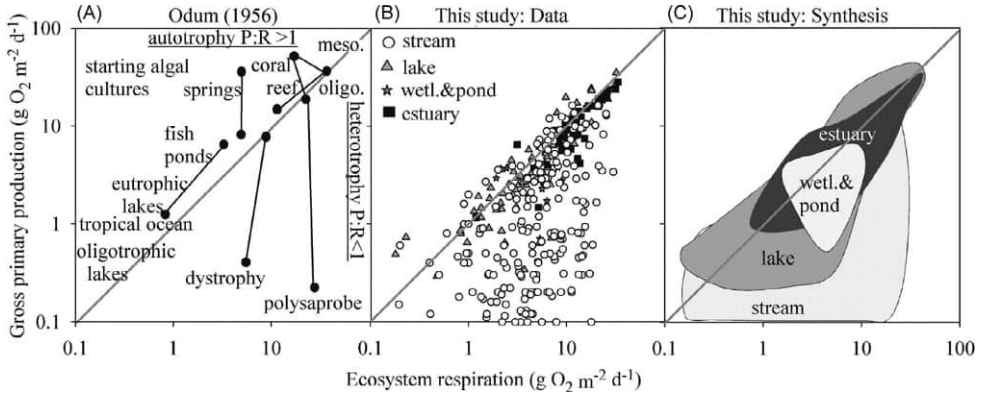

Fig. 1 Rates of gross primary production and ecosystem respiration for several aquatic ecosystems including lakes. Table 1 Lake metabolism terms.

Abbreviation	*Term*	*Explanation*
GPP	Gross Primary Production	Total photosynthesis from all autotrophic organism within the lake
R	Total Respiration	Total respiration from autotrophic and heterotrophic organisms within the lake
R_h	Heterotrophic Respiration	Respiration from heterotrophic organisms
R_a	Autotrophic Respiration	Respiration from autotrophic organisms
NEP	Net Ecosystem Production	Net balance of photosynthesis and respiration in the lake (GPP – R)
NPP	Net Primary Production	Net organic carbon produced from autotrophic organisms (GPP – R_a)

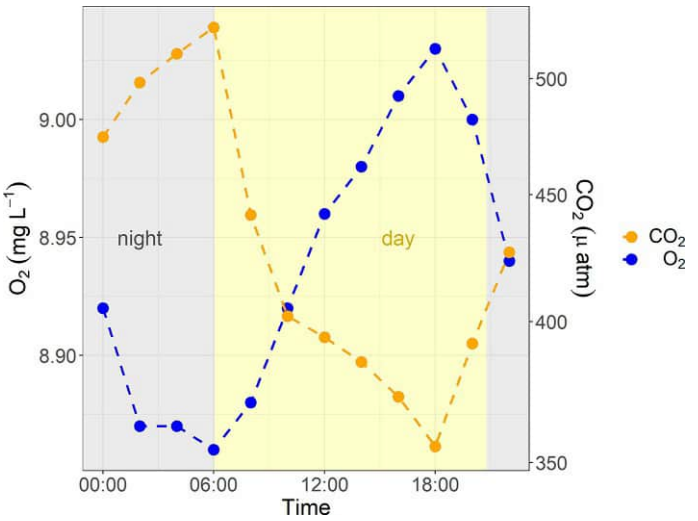

Fig. 2 Example of O_2 and CO_2 cycle within a lake upper mixed layer (epilimnion). During the day, gross primary production outpaces lake respiration resulting in a net production of O_2 and consumption of CO_2. Later in the day when solar radiation is reduced and during the night when there is no light, respiration still occurs in the absence of gross primary production resulting in net consumption of O_2 and production of CO_2. Data for this figure are from Harp Lake on August 1, 2014 (Vachon et al., 2020). By Ludmila S. Brighenti and Jacob A. Zwart—Created and shared by Ludmila S. Brighenti and Jacob A. Zwart to be uploaded to Wikimedia., CC BY-SA 4.0, https://commons.wikimedia.org/w/index.php?curid=97281590.

can be limited in their inference of whole-lake metabolism since estimates of metabolism from the bottle would need to be extrapolated to the entire lake, which often does not capture the spatial heterogeneity of metabolism vertically or horizontally within a lake.

Whole-lake carbon budget method

To better assess metabolism at the whole-lake scale, researchers can measure all the inputs, outputs, and accumulation of either organic or inorganic carbon to a lake over a season or year, also known as a whole-lake carbon budget. Typically, the most important carbon inputs to a lake include surface water and groundwater inflows and litterfall, while the most important outputs include surface water and groundwater outflows and carbon gas emissions. Lakes also accumulate carbon in the water column and lake sediments. This labor-intensive method can be used to estimate NEP. Since NEP is the difference between gross primary production and respiration (NEP = GPP – R), it can be viewed as the net biological conversion of inorganic carbon to organic carbon (and vice versa; Eq. 1) and can thus be determined through whole-lake mass balance of either inorganic or organic carbon (Stets et al., 2009).

Free-water method

Measurement of diel changes in dissolved gasses within the lake, also known as the "free-water" method, has quickly become one of the most common methods of estimating lake metabolism since the wide adoption of autonomous sensors used to measure dissolved oxygen and carbon dioxide in water (Fig. 2). The free-water method is particularly popular since many daily estimates of lake metabolism can be collected relatively inexpensively and can give insights into metabolic regimes during difficult-to-observe time periods, such as during storm events. Measured changes in dissolved oxygen and carbon dioxide within a lake represents the sum of all organismal metabolism from bacteria to fishes, after accounting for abiotic changes in dissolved gasses such as atmospheric gas exchange and advection (Fig. 3). This concept is similar to the light and dark bottle method but at a much larger measurement footprint. Since photosynthesis does not occur without light, changes in O_2 or CO_2 during the night represents lake

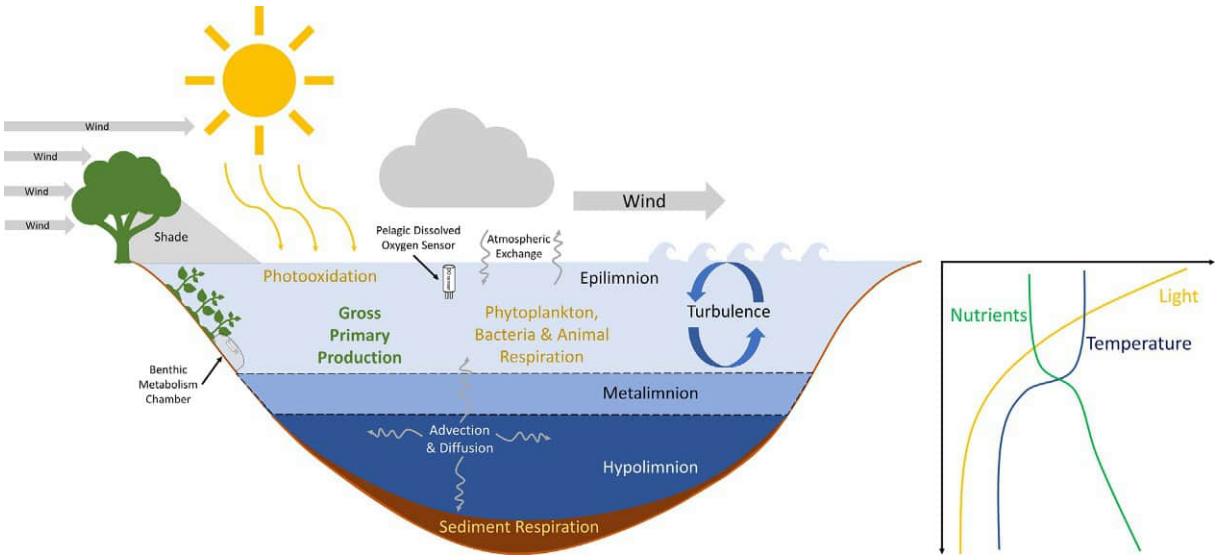

Fig. 3 Lake cross-sectional diagram of the factors influencing lake metabolic rates and concentration of dissolved gasses within lakes. Processes in gold text consume oxygen and produce carbon dioxide while processes in green text produce oxygen and consume carbon dioxide. Physical processes can both increase or decrease dissolved gas concentration, for example atmospheric gas exchange can increase or decrease lake dissolved oxygen depending on whether the lake is undersaturated or oversaturated in dissolved oxygen compared to the atmosphere, respectively. The panel on the right shows how light, temperature, and nutrients tend to change with depth for a stratified lake, which in turn results in variation in metabolic rates vertically within a lake. By Ludmila S. Brighenti and Jacob A. Zwart—Created and shared by Ludmila S. Brighenti and Jacob A. Zwart to be uploaded to Wikimedia., CC BY-SA 4.0, https://commons.wikimedia.org/w/index.php?curid=91461560.

ecosystem respiration (R). Measuring the net change in O_2 or CO_2 over a 24-h period yields an estimate of net ecosystem production (NEP), and adding NEP and R together gives an estimate of GPP. The changes in lake dissolved oxygen concentrations (DO) is represented as:

$$DO_{t+1} = DO_t + GPP_t - R_t + F_{atm,t} + F_{dv,t} \quad (2)$$

where DO_{t+1} and DO_t are the dissolved oxygen concentrations (mg L^{-1}) at times t + 1 and t; $F_{atm,t}$ is the flux of O_2 between the lake and the atmosphere; and $F_{dv,t}$ is the flux of O_2 between water masses driven by advection, turbulent diffusivity, and differences in O_2 concentrations (diffusion). Dissolved oxygen concentrations are usually measured with a oxygen probe, either by a researcher visiting the lake and manually measuring oxygen concentration or via an automated sensor. Gas fluxes between the lake and atmosphere can be measured via floating chambers or eddy covariance methods but are more typically estimated using numerical models relating gas flux to surface water turbulence stemming from wind and changes in lake water temperature. Likewise, diffusive flux of gasses within the lake are typically estimated with numerical models but can be measured with specialized instruments.

Extracting a high signal-to-noise ratio is key to obtaining good estimates of lake metabolism from the free-water technique. Estimates of lake metabolism can be optimized by adequate consideration of the data collection and analysis methods used such as: location of dissolved gas collection (typically in the surface mixed layer); number of sensors vertically and horizontally (Obrador et al., 2014; Van de Bogert et al., 2012); frequency and duration of data collection; and, modeling methods (Staehr et al., 2010a). Extrapolating site or depth specific measurements to the entire lake can be problematic, especially if there is high spatial variability within a given lake. Multiple sensors in the lake, either horizontally or vertically distributed, or targeting different environments (e.g., benthic vs. pelagic metabolism), can help resolve some of the heterogeneity issues when estimating whole-lake metabolism. Correctly accounting for physical processes of dissolved gas dynamics is needed to achieve good estimates of lake metabolism using the free-water method. For example, differing models of gas exchange with the atmosphere can lead to widely varying estimates of lake metabolism (Dugan et al., 2016), and thus, researchers should carefully consider which gas exchange method is most appropriate for their study site. The free-water technique often requires programming skills and knowledge of many equations to convert sensor data to estimates of lake metabolism. Luckily, there are open-source, community-built tools that reduce these analytical barriers, such as the R software package *LakeMetabolizer* (Winslow et al., 2016).

As mentioned above, aerobic processes are most commonly considered in lake metabolism studies in which it's assumed that anaerobic processes contribute negligibly to O_2 and CO_2 dynamics. However, paired O_2 and CO_2 sensors have shown that these dissolved gasses can deviate from the assumed 1 to −1 line (Vachon et al., 2020), meaning that there can be processes not accounted for in lake metabolism studies if only aerobic processes are considered.

Benthic metabolism

In addition to pelagic metabolism, benthic metabolism from periphyton and sediment organisms can sometimes account for a significant portion of whole-lake metabolism. Analogous to the light and dark bottle methods described above ("Bottle bioassay method" section), lake sediment cores can be collected and changes in dissolved oxygen or carbon fixation can be used to estimate rates of primary production and respiration. Recent methods describe isolating the sediment-water interface with transparent domes and measure changes in dissolved oxygen in situ (Godwin et al., 2014), which is a hybrid between the free-water method and light-dark bottle method (Fig. 3).

Constraints on lake metabolism

In the following section, we describe the relationship between constituents that influence organismal and ecosystem-level metabolism, focusing on light, organic matter (OM), nutrients and temperature. Although relationships between organisms and individual constituents are well-established, interacting effects of constituents on metabolic rates from organisms to lake ecosystems makes predicting changes in metabolism across lakes or within lakes through time difficult. Here, we discuss how these basic constraints affect lake metabolism and in "Variable metabolic responses to atmospheric forcings" section we show some examples of how some of these factors and confounding effects can affect lake metabolism at various space and time scales.

Light

Light is one of the primary drivers of primary production since it is essential for the conversion of carbon dioxide and water into organic matter through photosynthesis (Eq. 1). Experimental studies of light dependency of primary production typically show a non-linear relationship. The initial linear increase of primary production with increasing light availability is interpreted as conditions where primary production is mostly light-limited. As light intensity continues to increase, primary production is considered 'light-saturated' when primary production does not increase with light, but rather is limited by other constituents, typically nutrients and temperature. Different species of primary producers have different light utilization efficiencies and different optimum light for growth (Schwaderer et al., 2011). Moreover, the light utilization efficiency of phytoplankton increases with increasing nutrient availability and is higher under low light conditions due to the optimization use of light through physiological and structural adaptations (Girdner et al., 2020). These different responses at the organismal level propagate to influence whole-lake metabolism (Staehr et al., 2016; Zwart et al., 2015). Nevertheless, a linear response of GPP to light remains often a good approximation indicating light-limitation of primary production (Hanson et al., 2008), even in lakes with low nutrient availability (Karlsson et al., 2009). This has typically been explained by self-shading within the algal community and by the vertical distribution of light throughout the water column, where the upper part of the water column may be exposed to light-saturated conditions, whereas deeper depths are light limited.

Light is unevenly distributed vertically through the water column, due to light attenuation (Fig. 3). Thus, GPP rates are also unevenly distributed and restricted to the photic zone of the lakes (i.e., uppermost layers of the water body where light is above 1% of the surface light). In a stratified lake, the vertical distribution of GPP depends highly on the balance between nutrient and light availability throughout the water column. Typically, nutrients increase in concentration from the top to the bottom lake layers while light decreases (Fig. 3). These opposing gradients of nutrient and light availability can lead to a chlorophyll peak in intermediate depths, called the deep chlorophyll maximum. Although more common in oligotrophic lake, in which a peak in dissolved oxygen accompanies the deep chlorophyll maximum, it can also occur in eutrophic and dystrophic lakes (Leach et al., 2018).

Seasonal variations in light levels are important drivers of seasonal variations in lake metabolic rates, especially in high-latitude lakes, where seasonality in light is more pronounced (Fig. 4). For a typical high-latitude lake, high incoming light during summer and spring and longer day length enhance GPP and stimulate R. Respiration rates are increased due to higher autotrophic biomass, but also due to more bioavailable organic matter (OM), coming from increased algal production and photooxidation of recalcitrant OM. Although less pronounced, higher photooxidation of recalcitrant OM during summer and spring also occurs in low-latitude lakes (Amaral et al., 2013). As day length becomes shorter and incoming solar radiation decreases during autumn and through winter, metabolic rates decrease and GPP becomes more light-limited. For many of the world's lakes, ice and snow cover during winter blocks out incoming solar radiation and contributes to light-limitation in the water column (Song et al., 2019). Due to sampling difficulties, under-ice estimations of metabolic rates are scarce and dissolved oxygen depletion is poorly understood (Obertegger et al., 2017). In tropical lakes, seasonality due to differences in light through the four astronomical seasons (spring, summer, autumn, and winter) is less marked than in high-latitude lakes and usually follows annual changes in rainfall and water column stratification and mixing dynamics.

Organic matter

Consumers in lakes require organic matter to maintain organismal function, growth, and reproduction. Often, organic matter in lakes, whether particulate or dissolved, increases rates of respiration as consumers convert the organic matter to cellular growth and organismal maintenance. Indeed, surveys of respiration rates across lakes along an organic matter gradient often exhibit a positive

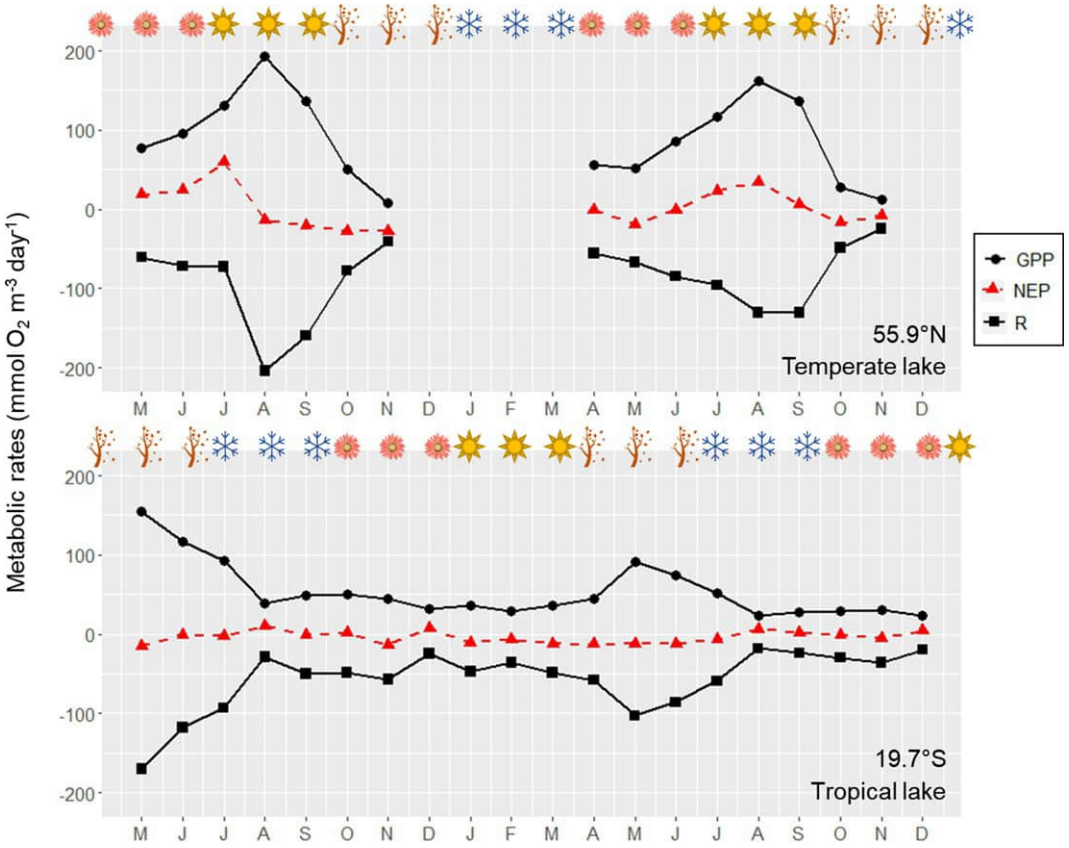

Fig. 4 Seasonal variations in metabolic rates during 20 months (from May to December) in a Danish temperate eutrophic lake (A) and in a Brazilian tropical mesotrophic lake (B). Symbols represent astronomical seasons (autumn—tree, winter—snowflake, spring—flower and summer—sun). Data for the temperate lake was digitized from Fig. 7 in Staehr and Sand-Jensen (2007) and data for the tropical lake is the monthly average of metabolic rates in Brighenti et al. (2015). By Ludmila S. Brighenti and Jacob A. Zwart—Created and shared by Ludmila S. Brighenti and Jacob A. Zwart to be uploaded to Wikimedia., CC BY-SA 4.0, https://commons.wikimedia.org/w/index.php?curid=97325463.

relationship between organic matter concentration and respiration (e.g., Hanson et al., 2003). Often, the excess respiration rate due to high concentration of organic matter exceeds the rates of primary productivity, resulting in a negative NEP. The negative NEP means that more CO_2 is produced than fixed within the lake, indicating that these lakes are likely net emitters of CO_2 to the atmosphere. Highly stained dissolved organic matter can cause an even greater negative NEP due to high attenuation of incoming light, thereby limiting primary production while sustaining ecosystem respiration. Hanson et al. (2003), in a study with 25 high-latitude lakes in the United States, found a positive correlation between R and dissolved organic carbon (DOC), and a negative correlation between NEP and DOC (Fig. 5). However, there is a lack of consensus on the literature regarding the straightforward positive relationship between DOC concentrations and R (Solomon et al., 2013). These varied findings highlight the complexity regarding effects of DOC on lake processes, such as differences in DOC quality and the shading effect of DOC, that can reduce GPP and respiration rates from primary producers (R_a, table 1).

Nutrients

Organisms need different elements to compose biological structures (e.g., enzymes, nucleic acids, cell walls) and maintain biological processes (e.g., photosynthesis, cellular respiration). These elements are called nutrients, and their availability and rate of assimilation control the rate of metabolism from the cellular to the ecosystem level. In lakes, phosphorus (P) and nitrogen (N) are the most common limiting nutrients to primary production and ecosystem respiration. Although P is often referred to as the main limiting nutrient in lakes, lake metabolism can be limited by N or co-limited by P and N (Elser et al., 2007).

Temporal and spatial variation in nutrient availability and its stoichiometry are important drivers of temporal and spatial variations in lake metabolic rates. For example, temporal changes in the catchment (e.g., between seasons and years) affect metabolic rates by altering nutrient and organic matter inputs to the lake, light attenuation and mixing dynamics. Regarding changes in nutrient availability due to changes in the catchment, land use conversions to croplands, pasturelands, and urban areas are associated with increased input of nutrients to the water bodies (Delkash et al., 2018), leading to eutrophication and enhanced GPP and R.

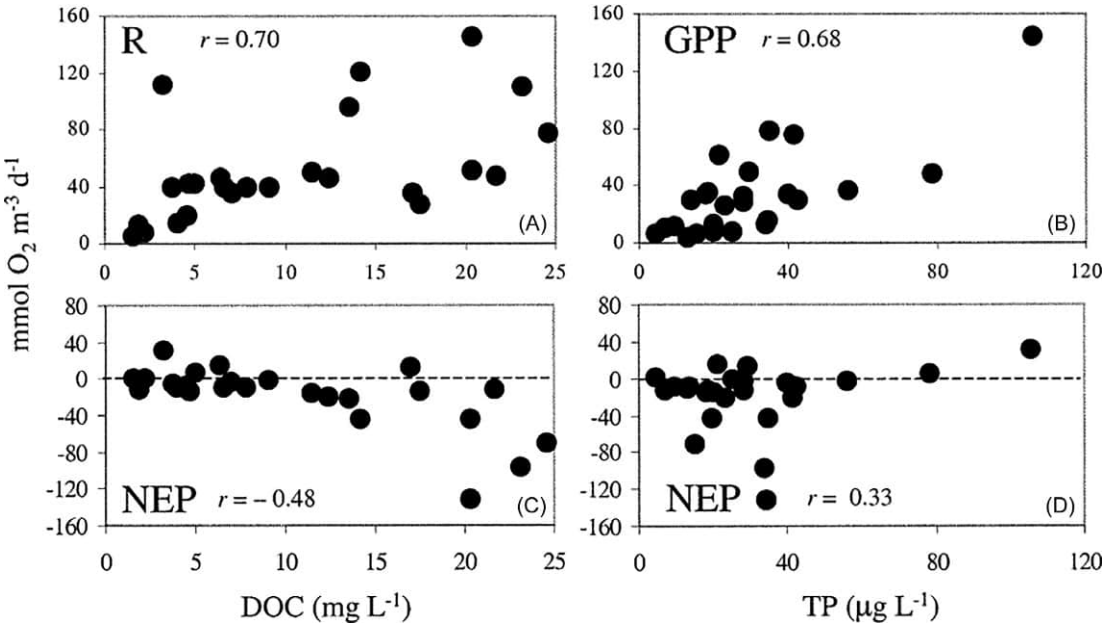

Fig. 5 Relationship of metabolic rates with dissolved organic carbon (DOC) and total phosphorus (TP) concentrations in 25 lakes in Wisconsin and Michigan (USA). From Hanson PC, Bade DL, Carpenter SR and Kratz TK (2003) Lake metabolism: Relationships with dissolved organic carbon and phosphorus. *Limnology and Oceanography* 48: 1112–1119.

Spatially within lakes, nutrients availability can differ laterally from the littoral to the pelagic zone as well as vertically in the water column (Fig. 3). Littoral areas are more prone to receive nutrient inputs from the catchment and also to internal loading from the sediments than pelagic zones. Moreover, littoral areas are more complex and heterogeneous due to high sediment-to-water volume ratio, presence of macrophytes, and due to the water-terrestrial ecotone. Therefore, metabolic rates are usually higher and more variable in the littoral area compared to the open water pelagic zone (e.g., Van de Bogert et al., 2007).

Lakes with different trophic status (i.e., differences in nutrient levels) have different metabolic rates, usually following the gradient from a lower GPP and R in oligotrophic lakes to a higher GPP and R in eutrophic lakes. However, the variation of NEP with trophic status is not so straightforward. Research has shown a weak correlation between NEP and phosphorus concentration (Fig. 5; e.g., Hanson et al., 2003; Solomon et al., 2013), that can be partially explained by the balance between nutrient availability, stimulating primary production, and organic matter availability, stimulating heterotrophic respiration. In a study of 25 globally-distributed lakes, Solomon et al. (2013) reported that although GPP and R increased with increasing total phosphorus (TP), NEP was higher in lakes with higher TP and moderate DOC levels.

Temperature

Temperature influences not only the spatial distribution and the occurrence of organisms, but also the rates of biological activities, physiological processes, and biochemical reactions. Metabolic rates have a hyperbolic relationship with temperature, increasing exponentially, and decreasing at high temperatures outside of organismal optimal ranges. However, thermal stress is not often documented within the temperature ranges experienced by most organisms in their natural sites.

The temperature-dependence of R differs from the temperature-dependence of GPP due to the higher activation energy of aerobic respiration compared to oxygenic photosynthesis (Fig. 6). Thus, R increases more rapidly with increasing temperature than GPP, which influences the metabolic balance of the lakes and can determine whether lakes are net sources or sinks of carbon. Theoretically, with all other factors affecting metabolic rates held constant, warmer lakes are more likely to be net heterotrophic (negative NEP) than similar lakes with colder water. Moreover, temporal variations in temperature drive temporal variations in metabolic rates, especially on respiration rates. On a daily scale, R is largely affected by changes in water temperature due to the day-night cycle (Yvon-Durocher et al., 2012) and affected across days due to changes in weather conditions and inflow of groundwater or surface water masses of different temperatures than the lake. Seasonally, lower temperatures during winter months lead to lower metabolic rates compared to summer months, and this difference is more pronounced in high-latitude and high-altitude lakes that freeze during the winter. Notably, a majority of lakes in the world are at higher latitudes meaning that most lakes' metabolism is significantly influenced by seasonal changes in temperature (Obertegger et al., 2017). However, seasonal dynamics of metabolic rates are complex because seasonal variations encompass multiple factors, including temperature, incident light, and nutrient and organic matter availability.

In addition to temperature, organismal size and community structure can also influence rates of lake metabolism at the ecosystem scale. The Metabolic Theory of Ecology predicts that metabolic rates should vary with body size and temperature

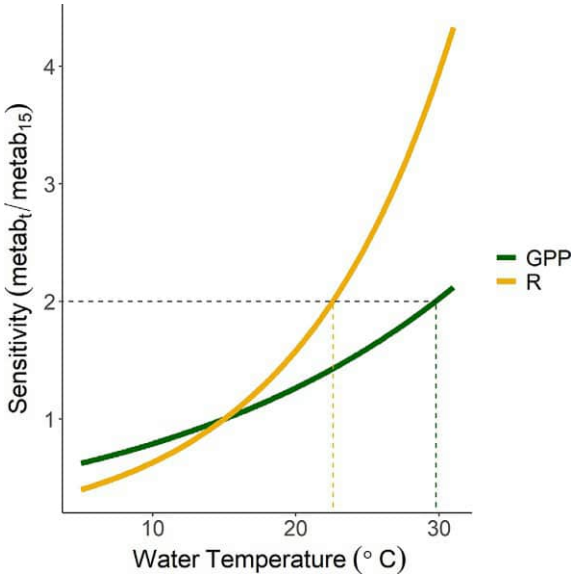

Fig. 6 Temperature sensitivity of gross primary production (GPP) and respiration (R) based on average activation energies reported in Yvon-Durocher et al. (2012). As water temperature increases, R increases more rapidly than GPP due to the higher average activation energy for R. In this figure, GPP and R temperature responses are reported as relative to GPP and R rates at 15 °C. A doubling of metabolic rates compared to metabolic rate at 15 °C (horizontal dashed line) occurs with just a 7.6 °C increase for R but requires a 14.8 °C increase to double GPP. By Ludmila S. Brighenti and Jacob A. Zwart—Created and shared by Ludmila S. Brighenti and Jacob A. Zwart to be uploaded to Wikimedia., CC BY-SA 4.0, https://commons.wikimedia.org/w/index.php?curid=97281589.

(Brown et al., 2004; Enquist et al., 2003), where organisms with smaller body sizes should have a higher metabolic output per unit body mass. This means that if an aquatic community is made up of primarily small organisms, then this community is predicted to have a higher metabolic rate per total biomass at a given temperature compared to a community that is comprised of mostly large organisms. There is some experimental support for these theoretical predictions as well, where aquatic communities with relatively small organisms had a higher temperature-corrected metabolic output (Yvon-Durocher and Allen, 2012).

Variable metabolic responses to atmospheric forcings

Interacting effects of constituents on metabolic rates makes predicting changes in lake metabolism across lakes or within lakes through time a challenging task (e.g., Olson et al., 2020). Understanding these complex interactions on metabolic rates is important given the multiple environmental factors that are expected to change under climate and land use change in the coming decades, including rising water temperatures, changing water column stability, and changing nutrient loading rates. Improving our understanding of how interacting drivers affect lake metabolism will help predict how lakes fit into global biogeochemical cycles and is essential to understand when trying to predict how the world will respond to future perturbations in climate and land use. In the following section, we highlight a couple of scenarios where interacting drivers have complex effects on lake metabolism.

Storm effects on lake metabolism

Storm events that bring strong winds and heavy precipitation affect the balance between light and nutrient availability and in turn affect lake metabolism. However, not all storms affect lake metabolism in the same way for all lakes; for example, some storm events increase net ecosystem production while others decrease. The response of lake metabolism to storm events is related to several interacting factors including the storm characteristics (e.g., duration, intensity, amount of rain), lake morphometric characteristics (e.g., lake depth), and landscape surrounding the lake (e.g., agricultural fields, forests) (Stockwell et al., 2020). Storms that are accompanied by strong winds deepen the mixed layer of lakes which can increase nutrient supply into the upper mixed layer from more nutrient-rich deeper lake layers (Giling et al., 2017). Nutrients can also come into lakes following storm events with heavy rain through increased stream and groundwater inflows to the lake (Zwart et al., 2017). This increase in nutrient supply often leads to increased GPP in the upper mixed layer several days following the storm.

Although storms can relieve primary producers from nutrient limitation, they can also increase light limitation through increased turbidity or loading of colored dissolved organic matter. Storms accompanied with heavy rain flush soil organic matter from the lake's surrounding landscape which increases light attenuation within the lake and can limit GPP despite the increase in nutrients. The increased organic matter load can increase respiration rates within the lake as bacteria and other organisms break down the organic matter and convert it to inorganic carbon (Eq. 1). These complex and interacting effects of storms on GPP and R

can cause some lakes to increase in NEP (GPP > R) while other lakes decrease in NEP (GPP < R) following the storm events. The storm characteristics influence whether lakes increase or decrease in NEP, but lake characteristics can also influence metabolic response. For example, lakes with very long hydraulic retention times show little metabolic response to storm events while lakes with short hydraulic retention times exhibit stronger metabolic responses (Zwart et al., 2017). However, extremely short hydraulic retention times following storms (e.g., 1 day or less) can cause scouring and complete flushing of organisms within the lake or reservoir, which can greatly reduce metabolic activity (Williamson et al., 2021).

Global warming effects on lake metabolism

Temperature is an important regulating factor of lake metabolism, either directly through temperature dependence of physiological rates of respiration and photosynthesis, or indirectly through effects on lake physical processes such as mixing dynamics of the water column.

As described in "Temperature" section, metabolic rates increase exponentially with temperature. Temperature dependence of metabolism is affected by the kinetics of molecules through the activation energy, or the proportion of molecules with enough kinetic energy to start the metabolic reaction. However, this temperature dependence differs between R and GPP due to the higher activation energy of aerobic respiration compared to photosynthesis (Fig. 6). Thus, it is predicted that as temperature increases with global warming, R will increase more rapidly than GPP, in turn leading to a higher heterotrophy of lakes globally. This hypothesis has been corroborated by a manipulative experimental study, which showed that a long-term increase in water temperature causes a shift in experimental ponds from carbon-sink to carbon-sources, reducing carbon sequestration (Yvon-Durocher et al., 2017). These can lead to positive feedback to global warming due to enhanced emissions of greenhouse gasses from lakes, such as carbon dioxide and methane.

Warming temperatures can also influence the size spectrum of the organisms that make up the lake community, which can influence rates of ecosystem metabolism as predicted by the Metabolic Theory of Ecology (Brown et al., 2004; Enquist et al., 2003). Artificial warming experiments have shown that increases in water temperature increase the prevalence of small organisms in the phytoplankton community (Yvon-Durocher et al., 2011). The reduced average size of organisms with increased warming can, in turn, increase the metabolic output per unit biomass independent of direct temperature effects on cellular metabolism (Yvon-Durocher and Allen, 2012).

In regard to the indirect temperature effects on metabolism, some lakes' metabolic rates are strongly influenced by the dynamics between mixing and stratification of the water column. Studies have shown a trend overall the past decades with a warming of surface water and more stable water columns in lakes around the globe, which can potentially affect the mixing and stratification dynamics of lakes (Pilla et al., 2020), thus affecting temporal dynamics of lake metabolism. During mixing events, nutrients, organic matter, and organisms such as bacteria, which were concentrated in the aphotic zone are made available for the euphotic zone of the lake, often stimulating primary production and respiration. However, mixing events and a less stable water column can also cause a decrease in water transparency, which can limit primary production in some environments or at certain times of the year. Whether or not GPP rates increase will depend on a balance between increasing nutrient availability and decreasing light availability (Fig. 7).

In lakes where primary production is mainly limited by light, as in some temperate (e.g., Staehr et al., 2010b) and subtropical lakes (e.g., Tonetta et al., 2016), it is common that, during the mixing season, GPP rates decrease due to less light availability. For example, in a two-year study in a eutrophic temperate lake in Denmark (Staehr and Sand-Jensen, 2007), GPP and NEP increased

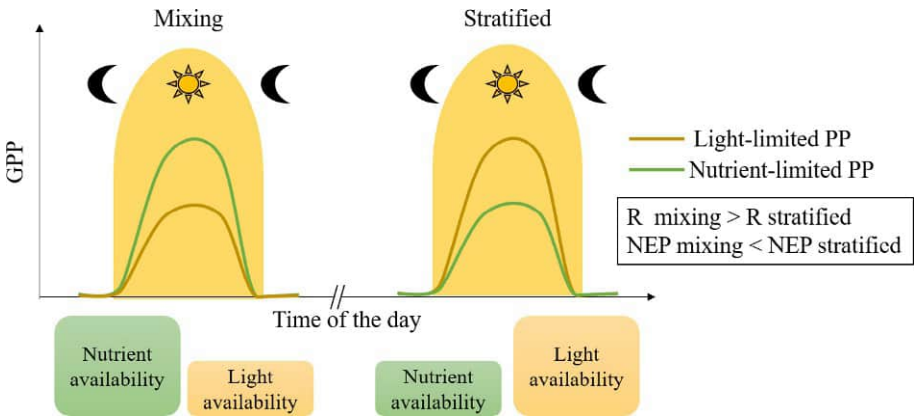

Fig. 7 Conceptual figure of the effects of mixing and stratification dynamics on gross primary production (GPP) in two different situations: one with light-limited primary production (PP) and other with nutrient-limited PP. During the mixing period, nutrient availability is increased, while light availability is decreased. During the stratified period, light availability is increased and nutrient availability is decreased. The scales at the bottom of the figure represent the balance between nutrient and light availability during the mixing and stratified period. R = ecosystem respiration; NEP = net ecosystem productivity. By Ludmila S. Brighenti and Jacob A. Zwart—Created and shared by Ludmila S. Brighenti and Jacob A. Zwart to be upload to Wikimedia commons., CC BY-SA 4.0, https://commons.wikimedia.org/w/index.php?curid=91667821.

during summer stratification (Fig. 4), when temperature, light availability, and chlorophyll-a concentrations were higher and nutrient availability and mixing depth were lower. The increased GPP and NEP rates were highly associated with an increase in light availability. However, periods with relatively high R in comparison with GPP coincided with mixing events of the water column during autumn, due to the greater availability of organic matter, leading to a negative NEP.

In lakes where primary production is mainly limited by the availability of nutrients, mixing events are generally associated with an increase in GPP. For example, in a tropical mesotrophic lake (Brighenti et al., 2015), where light availability was high throughout the year, mixing events that occured in the dry and colder periods (autumn and winter) were associated with an increase in GPP (Fig. 4). In this case, the decrease in light availability was offset by an increase in the availability of nutrients. However, as respiration rates were also increased during the mixing period, NEP tended to remain in balance or slightly heterotrophic ($NEP \leq 0$).

In addition to direct and indirect thermal effects, global warming also influences changes in nutrients and organic matter inputs to lakes, lake water residence time, and lake hydrological balance. Thus, global warming consequences on lake metabolism are not straightforward and strongly interact with land use (Adrian et al., 2009). Differences in lake morphometry (e.g., lake size and shape), catchment properties (e.g., land use and drainage area), and water residence time will affect how metabolic rates differ between lakes and how they may respond to different environmental drivers, such as changes in rainfall regimes and land use. For example, Hayes and others (2015) studied phytoplankton nutrient limitation across 42 lakes in different watersheds. Their study reported a climate and land use interaction, affecting the occurrence and shifts from phosphorus-limitation to nitrogen-limitation in lakes with agricultural-dominated watersheds, whereas phytoplankton in lakes in forest-dominated watersheds were consistently nitrogen-limited.

Knowledge gaps

Recent methods and statistical techniques for estimating lake metabolism are providing insights into the complex relationship between lake metabolic rates and characteristics that control these rates. Often, these new insights are showing that these relationships are more complex and nuanced than previously thought, indicating that a holistic view of the effects on metabolism is the most appropriate approach. Understanding these complex interactions on metabolic rates is important given the multiple environmental factors that are expected to change under climate and land use change in the coming decades, including rising water temperatures, changing water column stability, and changing nutrient loading rates. Improving our understanding of drivers of lake metabolism will help predict how lakes fit into global biogeochemical cycles and is essential to understand when trying to predict how the world will respond to future perturbations in climate and land use. Several outstanding knowledge gaps remain that would help us understand current and future lake metabolism patterns, including:

- Improve accounting for benthic contribution to whole-lake metabolism.
- Test new hypotheses related to interacting effects of light and nutrient limitation on lake metabolism.
- Increase number of estimates of lake metabolism under ice.
- Increase number of estimates of lake metabolism studies for tropical lakes, especially African lakes.
- Improve methods to model physical processes when estimating metabolism using the free-water method.
- Increase number of estimates of horizontal and vertical variability in lake metabolism.

Glossary

Aquatic hypoxia Reduction of the dissolved oxygen concentration in water to the point where it is detrimental for organisms living in that system.
Brunt Väisälä (BV) buoyancy frequency A metric of the stability of water column thermal stratification
Ebullition Bubble formation and loss.
Hypolimnion The lower layer of a stratified lake beneath the thermocline.
Resilience The capacity of a system to prevent a shift to an alternative state.
Schmidt stability The resistance to mechanical mixing due to the potential energy inherent in the stratification of the water column.

General introduction

Weather and longer term climatic cycles are fundamental drivers of change in lake ecosystems. This control is manifested in strong diel and seasonal cycles that are well recognized and described in lake thermal structure, biochemical cycling and biological processes. The climatic cycles that drive in-lake change also include decadal and longer-scale phenomena such as the North Atlantic Oscillation (NAO) and the El Niño/Southern Oscillation (ENSO). All of these cycles will, by definition, have periods of higher and lower values relative to average conditions. Any given lake ecosystem will be adapted to these recurring highs and lows. Recently, however, there has been an increasing research focus on the effect of extremes in both weather and climate on lakes, events which are projected to become even more intense and frequent due to the impacts of global warming. Such extreme events include not only more intense heatwaves and subsequent droughts, but also increases in the frequency and magnitude of, for example, storms. Sudden events like storms are difficult to predict. They result in pressures on lakes that can, in turn, have unexpected and even unprecedented consequences. Understanding how all these weather and climate related pressures subsequently cascade through lake ecosystems will be essential if we are to manage lakes and reservoirs in the future. The aim of this article is to provide an overview of current knowledge on the shorter and longer term effects of extremes in weather and climate on lake ecosystems. We review the definition of extreme weather and climatic events generally and in relation to lakes, describe how such events are propagated through catchments and within lakes, and more specifically how they affect lake physics, lake biogeochemistry and lake biota. We conclude by highlighting gaps in our current knowledge which need to be addressed to ensure that appropriate action can be taken to protect lakes and reservoirs and the services that they provide.

The definition of extreme events: Issues and challenges

While weather describes the atmospheric conditions as a certain location and time, climate refers to how the weather behaves on average over a more prolonged period or over a defined area. Both weather and climate can have extremes. This article will follow the Intergovernmental Panel on Climate Change (IPCC) (Seneviratne et al., 2012) and use the term climate extremes to collectively refer to both extreme weather events and extreme climate events. There is, however, no universally accepted definition of such events, either in relation to weather and climate extremes (Seneviratne et al., 2012) or in relation to the study of ecosystems, including lakes. In fact, the term extreme climatic event (ECE) has become more commonly used in ecological studies recently to include both weather and climate events and their impacts (van de Pol et al., 2017). Extreme events are usually defined (1) statistically, for example, by how frequently they occur or whether they exceed a particular threshold, or (2) based on the impacts they exert (van de Pol et al., 2017). Hydrologists also commonly define extremes in stream discharge using top and bottom percentiles (for example, the Q05 statistic representing the top 5% of stream flow rates), or return periods (for example, a 1-in-200 year flood event).

The IPCC have defined an extreme weather (or climate) event as "the occurrence of a value of a weather (or climate) variable above (or below) a threshold value near the upper (or lower) ends ("tails") of the range of observed values of that variable" (Seneviratne et al., 2012). One issue of note with this type of percentile or threshold approach is that the absolute values will differ depending on location. An assessment of the effects of storm events on a lake on the exposed Atlantic coast of Ireland, for example, used a definition of storms which included those times when mean hourly wind speed was higher than 97.5% of the dataset (the top 2.5%), corresponding to a wind speed threshold of 10.6 m s^{-1} (Andersen et al., 2020). In contrast, a study based in Lake Muzelle in the French Alps used the top 3% of values at that site and had a wind speed threshold of 3.0 m s^{-1} (Perga et al., 2018). In addition to such differences related to location, the temporal span of any dataset that is used to define the percentiles will also affect the magnitude of a change that is considered to be extreme. The use of set value thresholds can also be problematic for defining heatwaves. While there is a general acceptance that heatwaves are periods of extremely high temperatures, again there is no internationally accepted definition (McCarthy et al., 2019). Any defined threshold will again result in different absolute values depending on location, with heatwave thresholds at lower latitudes generally being higher than those at higher latitudes. This can also lead to anomalies even within national borders. For the island of Britain, for example, a heatwave has been defined using a threshold value of 25 °C for most of the island, but with the threshold increasing in increments up to 28 °C in the southeast (McCarthy et al., 2019). In general, studies of lakes have used a heatwave definition based on such locally used climate based thresholds, although more recently, lake heatwaves have been defined using thresholds based on in-lake temperature data, allowing assessment at a global scale (Woolway et al., 2021).

The second approach to defining extreme events in ecological studies, including those on lakes, focuses on the impacts of the events rather than the climatic drivers. Jennings et al. (2012), for example, used the term episodic events (which included extreme in-lake events but also events of a lower magnitude), which they defined as "an increase in magnitude relative to more regular, stable conditions." They presented events where there were clear responses for in-lake variables to a change in climatic conditions without those changes being based on any set percentile or threshold. It could be argued, however, that there are events that regularly recur within the annual cycle in lakes that would be considered as extreme if such a response-based approach were used. These include high inflows in spring following annual snowmelt, and the onset and breakdown of stratification each year, events which can happen rapidly and lead to extreme changes in lakes over days or even hours. If possible, therefore, any comparison of extremes based on in-lake data should place these events in the context of a longer-term record, such as the study of de Eyto et al. (2016) where the effects of an extreme flood that took place over several hours were set in the context of data for the lake over a 5-year window. Given the issues outlined above, and in the absence of universal agreement, studies of extreme events should be careful to at least ensure that any definition used is clearly and comprehensively described.

The propagation of climate extremes through the catchment-lake continuum

Climate extremes have the potential to have large impacts on lake ecosystems, but the extent and nature of any effect will depend on both the timing of the event, and on lake and catchment characteristics. The magnitude of changes in stream discharge, for example, will depend on rainfall or snowmelt, but also on catchment geology, topography, soil type and depth, and on vegetation cover. The increase in discharge for a given quantity of rainfall is dependent on water use by catchment vegetation and therefore will be much higher in winter than in summer, a time when more rainwater will be lost through evapotranspiration. The timing of snowmelt, which results in large springtime flows in some catchments, also depends on both current and prior air temperatures and on the extent of the accumulated snowpack. Climate extremes can also impact processes within a lake by more than one mechanism. The sudden pulse of water flowing into a lake during floods may carry loads of dissolved and particulate material which can lead to changes in the chemical composition of the water column, but may also result in a physical disturbance of the lake. Some high rainfall events may not be accompanied by any extreme in wind speeds, such as the 1-in-250 year rainfall event described for Lough Feeagh, Ireland (de Eyto et al., 2016) (Fig. 1). However, stronger wind speeds do often accompany high rates of precipitation during

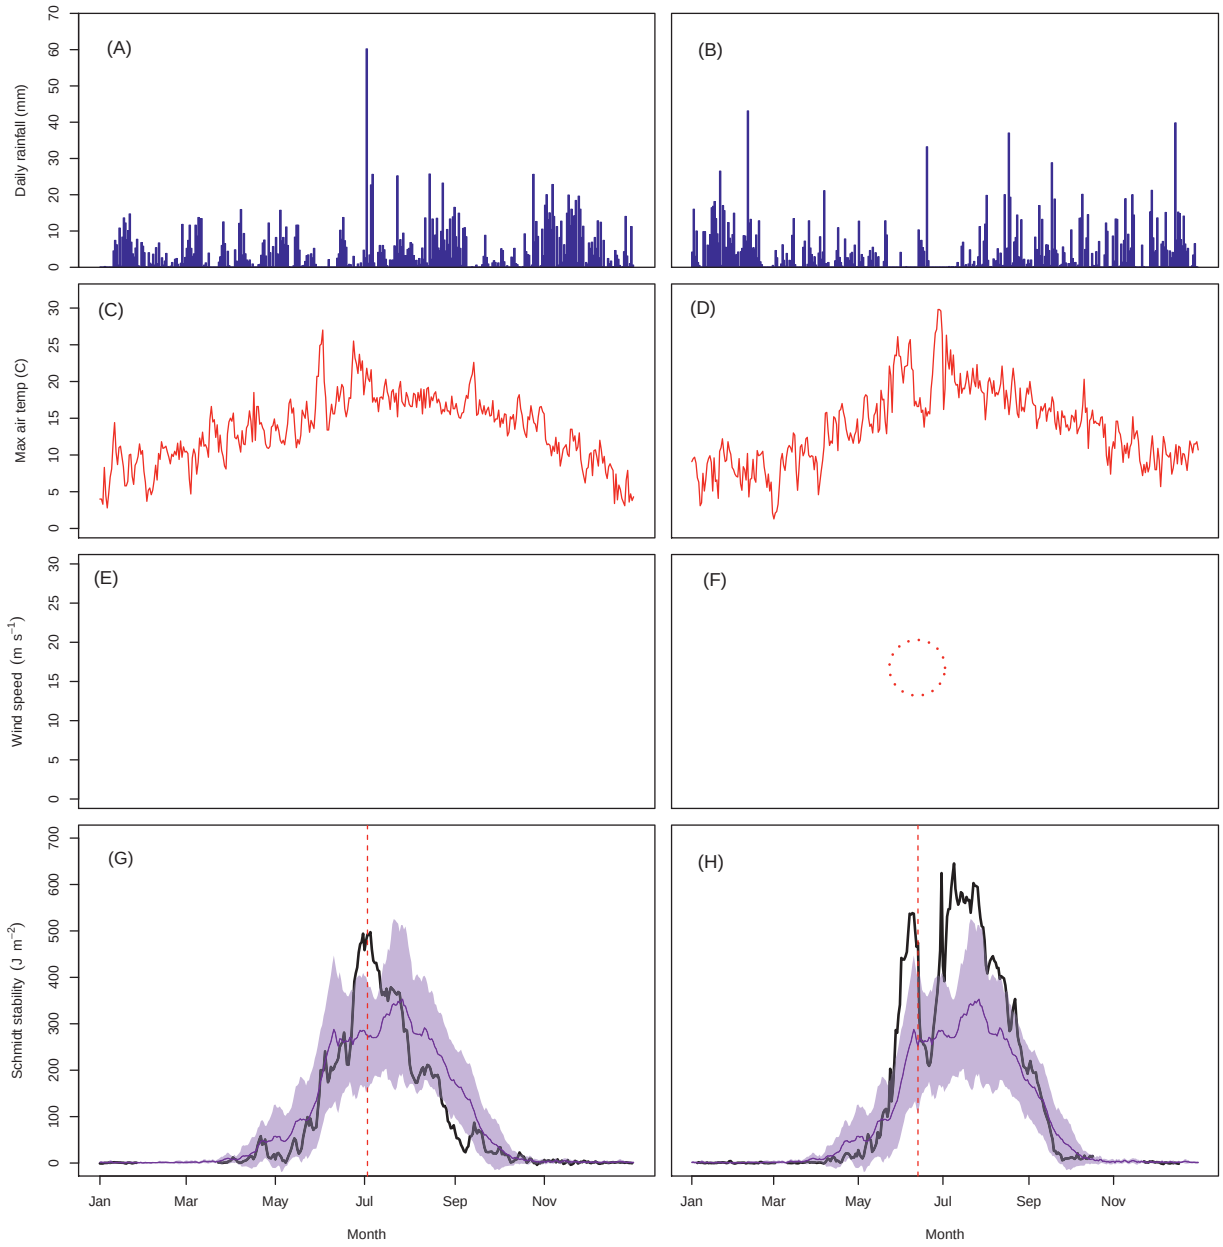

Fig. 1 Data for years with extreme climatic events (left 2009, right 2018) for Lough Feeagh, Ireland: (A and B) daily total rainfall; (C and D) mean daily air temperature; (E and F) highest 10 min mean wind speed (m sec^{-1}); (G and H) lake Schmidt stability. The red dashed lines indicate a 1-in-250 year precipitation event in July 2009 which was accompanied by relatively low wind speeds (de Eyto, et al., 2009) (G), and Storm Hector in 2018 (H), which had a mean daily wind speed of 8.9 m sec^{-1} on June 14th 2008, with gusts of 26 m sec^{-1} (red dashed circle). The purple area and line in (G) and (H) represent the mean and standard deviation for Schmidt stability for the period 2005–18.

storms, and both of these will contribute to mixing and therefore possible resuspension of material from lower waters within the lake. Dissolved substances which are washed out from the catchment may also originate from the atmosphere. Episodic acidification events associated with washout of atmospheric pollutants during high rainfall, for example, have been an important water quality issue in many regions. The impacts of any climate extreme on lake biogeochemistry can also affect other downstream water bodies. Following Storm Ophelia in 2017, there was an upwelling of cold and low-oxygenated waters at the southern-end of Windermere in the United Kingdom lake district which led to a decrease in dissolved oxygen (DO) concentrations by approximately 48% in the main outflow from the lake (Woolway et al., 2018).

Monitoring the effects of climate extremes in lakes

Because of the short timescales of many extreme events, especially high stream discharge events and wind-induced mixing, high frequency monitoring is usually required to discern their effects. This is especially true for storms which are generally short-lived. Few studies have quantified the nature and extent of multiple climate extremes over many years in the context of lakes. A recent detailed analysis of 13 years of storm duration and occurrence for a lake in Ireland found that storm duration based on wind speed was an average of 54.0 h in winter, with a range of 9.0–186 h, and an average of 46.4 h in summer, with a range of 15–94 h (Andersen et al., 2020). Pulses in the export of dissolved and particulate substances from the catchment and in-lake mixing during such storms can, therefore, often take place over relatively short time periods. The deployment of sensors which measure many of the relevant dissolved chemical species, however, have until recently been unreliable and such data are still relatively scarce for many variables. Of the sensors that are commonly used in lakes, those for temperature, conductivity and DO are the most widely deployed, and there are now datasets for these parameters that cover several decades from some sites. Such DO data are also commonly used to calculate estimates of lake metabolism, i.e., the balance between gross primary production and respiration within the lake. Data from in situ monitoring systems can also be used to investigate the impacts of climate extremes on lakes at a regional level, such as the study by Klug et al. (2012) where the effects of Hurricane Irene were tracked across multiple lakes in the eastern United States. However, sensors for many of the parameters that would be needed to comprehensively describe the effects of climate extremes in lakes are still scarce. High frequency data from CO_2 sensors, for example, are only recently becoming available. Such information is increasing knowledge of the processes that drive change in CO_2 cycling and emissions from lakes, information that is critical for quantifying the role of lakes in global greenhouse gas emissions estimates. Both absorbance and fluorescence-based sensors are now commonly used to monitor chlorophyll levels and as proxies for dissolved organic matter (DOM), while sensors for nitrate and ammonium-nitrogen, using UV absorbance, have also become more common. Automated sensors that reliably measure dissolved phosphorus at the low levels required for most lakes are still not available. Similarly, high frequency sensor-based datasets for lake methane (CH_4) concentrations and emissions, another powerful greenhouse gas, are scarce.

Effects of climate extremes within lakes

Effects on lake physics

Climate extremes can have substantial effects on lake physics, and therefore on biogeochemical cycles, however, the magnitude of such effects will also be dependent on the prior thermal conditions. Storms may be associated with extremes in wind, rainfall, or both. Some storms may also induce colder than normal weather conditions promoting additional convective mixing. Overall, storms typically have the effect of decreasing light availability, depressing surface temperatures, increasing mixing, and deepening the thermocline (Stockwell et al., 2020). The extent to which a lake is already warmed or stratified when hit by a storm will mediate the physical impact of the storm on lake dynamics. A recent study of changes in epilimnetic temperatures during storms in the stratified period found, however, smaller changes than had been hypothesized (Doubek et al., 2021). The decreases were on average −0.28 °C across the 18 study lakes during the strongest windstorms, and −0.15 °C after the heaviest rainstorms. Storms with extreme winds will also increase mixing in a lake, thereby weakening stratification and deepening the mixed layer. An increase in cloud cover and decrease in air temperature, often associated with summer storms, would typically also increase cooling fluxes from a lake (Andersen et al., 2020), weakening stratification further and increasing any reduction in surface temperature. The effects of extreme rainfall on lake physics are affected by catchment and lake characteristics, and antecedent weather conditions as described above. Depending on the catchment and its vegetation, extreme rainfall could induce dramatically increased river flow. The extent that this would affect a lake in part depends on the lake residence time, with greater effects happening at shorter residence times. The impact will also depend on the difference in temperature between inflowing water and lake surface water. Often summertime river flow is a cooling flux, so extreme inflows in lakes with a short residence time can reduce lake surface temperature and in-lake stability as well as providing extra energy for mechanical mixing (Strasškraba and Hocking, 2002). Lake water level would also be increased. Furthermore, storms that induce increases in turbidity in rivers can increase light attenuation in a lake. This, in turn, can increase lake surface temperature and lake stability while causing deeper lake waters to cool, as solar heating at depth is reduced (Persson and Jones, 2008). Such impacts on turbidity may mitigate some of the direct effects of increased river flow, but potentially cause longer lasting effects on the lake thermodynamics than the direct impact of the storm (Perga et al., 2018).

Heatwaves can lead to periods of extreme warm surface air temperature, and can have a considerable influence on the physical environment of lakes. The primary physical response of lakes to atmospheric heatwaves is an increase in surface water temperature, with knock-on effects on the vertical temperature profile and on vertical mixing (via buoyancy forces). Air temperature extremes during a heatwave will generally result in a shoaling of the upper mixed layer of the water column, steeper vertical temperature gradients (thus enhanced lake thermal stability), and a cooling of the hypolimnion (Jankowski et al., 2006). The impact of a heatwave on lake physical structure can be more severe when air temperature extremes are accompanied by anomalous conditions in other components of the lake surface energy budget, notably solar radiation and wind speed (Woolway et al., 2020), which influence not only important air-water energy fluxes (i.e., sensible and latent heat in the case of wind speed) but also vertical mixing and heat storage. Specifically, higher than average solar radiation and lower than average wind speed during a heatwave, such as in Europe in 2018, can lead to extraordinary lake surface warming (Fig. 2). These atmospheric variables can even have a greater

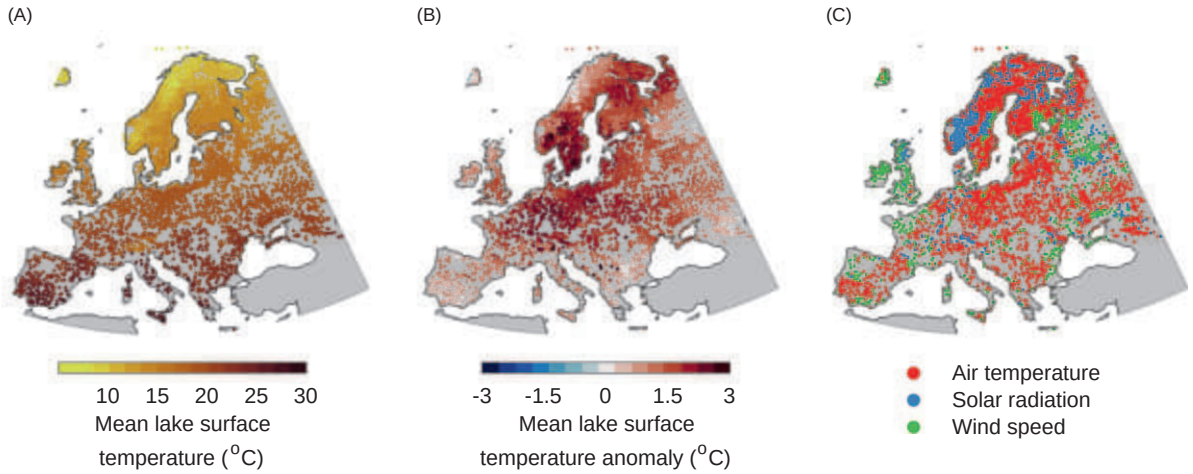

Fig. 2 Simulated surface water temperatures for 46,557 lakes during the 2018 European heatwave. Shown are the variations in May-October (A) mean lake surface water temperature; (B) mean lake surface water temperature anomalies (relative to the 1981–2010 average), and (C) results from an attribution analysis which explored the main drivers of lake surface temperature change. Different colors in panel (C) represent the atmospheric variable (air temperature, solar radiation, wind speed) that had the greatest influence on lake surface temperature anomalies during the 2018 heatwave. Data from Woolway RI, Carrea L and Jennings E (2020) Impact of the 2018 European heatwave on lake surface water temperature. *Inland Waters* 1–11. doi: 10.1080/20442041.2020.1712180.

influence than air temperature on lake surface temperature extremes in some regions (Fig. 2). Periods of extreme lake surface water temperature, recently described as "lake heatwaves," are expected to become more intense and longer lasting during the 21st century (Woolway et al., 2021). Moreover, many lakes worldwide will likely reach a permanent heatwave state, relative to historic conditions, resulting in a substantial departure from the "normal" lake thermal conditions that have shaped lake ecosystems in the past towards a new norm. The occurrence of climate extremes may also be concurrent, or consecutive. Storm Hector, for example, came in from the Atlantic to the west coast of Ireland during the 2018 European heatwave (Fig. 1). Before the storm, the Schmidt stability within the lake was higher than was usual due to lower wind speeds and high temperatures. This stability value decreased dramatically during and following the storm, but then quickly reestablished to pre-storm levels as the heatwave continued.

Effects on lake biogeochemistry

The chemical species in any lake at any given time will include dissolved gases and ions, molecules, and a range of smaller and larger particulate material. The export of substances to lakes, and the processes that lead to their formation within lakes, can be directly influenced by climate extremes. But the effects may also be indirect, with changes related to a cascade of impacts that are propagated through the physical, chemical and biological processes within the lake (Fig. 3) (Jennings et al., 2012). High winds and precipitation associated with Tropical Storm Fay at Lake Annie (United States) resulted in a shallowing of the thermocline and a decline in stability (measured as buoyancy frequency), which in turn resulted in a decline in surface DO levels as deoxygenated water was recirculated from depth (Fig. 3A, D and G). In contrast, a similar storm at Lough Feeagh (Ireland) resulted in only a slight immediate decline in surface water DO (Fig. 3B, E and H). Lake waters can also become supersaturated with oxygen as a result of high levels of photosynthesis during and following algal blooms. The first of two mixing events in Slotssø (Denmark) began during such a bloom (Fig. 3C, F, and I). Dissolved oxygen concentrations did decrease following a first mixing event, but since phytoplankton biomass was still relatively high, they returned to supersaturated levels within 3 days. In contrast, the lake became fully mixed during the second event in October and DO remained low.

Likewise, while increases in lake DOM concentrations often occur following large inflows during storms, they can also have a direct biological cause, such as the decomposition of phytoplankton cells within the lake following periods of high primary production. Where changes in dissolved or particulate substances result from a cascade of linked processes that has been initiated by a climate extreme, they can be considered a consequence of that event. The resultant cascade of impacts can involve many biological, chemical and physical processes. For example, Kasprzak et al. (2017) described a very complex set of events related to a summer storm in Lake Stechlin (Germany). A mean daily wind speed of 7.7 m s^{-1} led to a tilting and deepening of the thermocline, and the release of cyanobacteria that had previously formed a deep chlorophyll maximum into the mixed layer above. The subsequent increase in cyanobacterial photosynthesis raised the pH of the water and induced massive calcite precipitation to levels not previously recorded at the site. As a consequence, the lake then became turbid for several weeks.

Extreme discharge events will only carry a high load of particulate and dissolved substances into a lake or reservoir when those substances are actually available within the catchment hydrological network. The extent of this store of material will itself be governed by antecedent weather. A prior drought in catchment soils, for example, has been shown to affect the magnitude of the export of DOM (Jennings et al., 2012) and sediment (de Eyto et al., 2016; Perga et al., 2018). The load of substances exported will

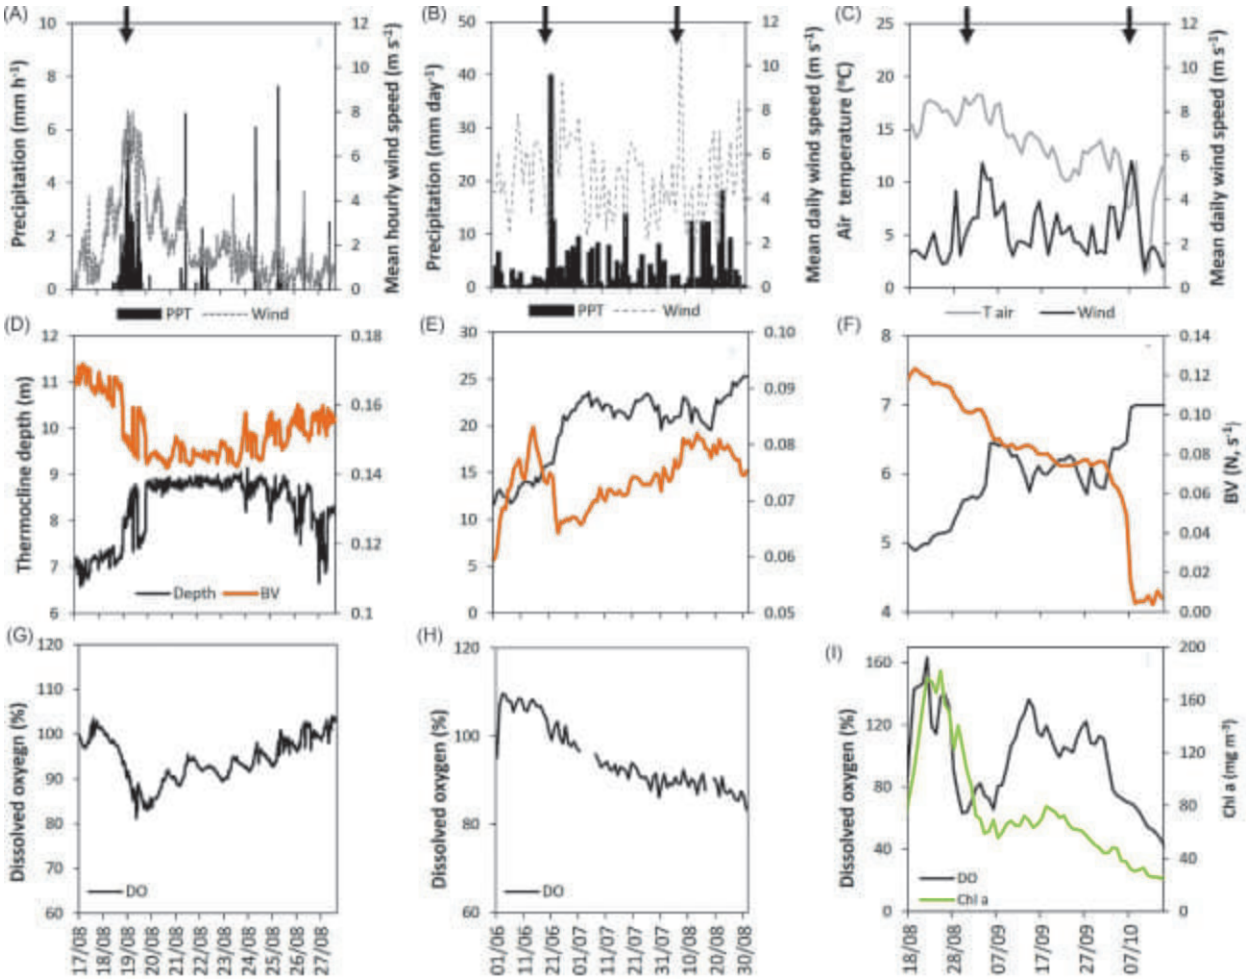

Fig. 3 In-lake responses to extreme changes in wind and precipitation at Lake Annie (United States) (A, D and G), Lough Feeagh (Ireland) (B, E and H), and Slotssø (Denmark) (C, F and I); main meteorological drivers (A–C), Brunt Väisälä (BV) buoyancy frequency and thermocline depth (D–F), dissolved oxygen (DO) levels and chlorophyll *a* concentrations (Slotssø only) (G–I). Black arrows indicate timing of change in meteorological driver. After Jennings E, Jones S, Arvola L, Staehr PA, Gaiser E, Jones ID, Weathers KC, Weyhenmeyer GA, Chiu CY and De Eyto E (2012) Effects of weather-related episodic events in lakes: An analysis based on high-frequency data. *Freshwater Biology* **57**(3): 589–601.

also vary depending on the activation of differing flow pathways through the catchment soils during high precipitation. Gases are lost from the lake surface through ebullition (bubble formation and loss) and diffusion to the atmosphere. Extreme summer rainfall events have been shown to alter CO_2 and CH_4 fluxes in southern Finish lakes, with the systems switching from being a net sink to a net source of CO_2 to the atmosphere (Ojala et al., 2011).

Wind induced mixing of the water column will also result in changes in the concentrations of both dissolved and particulate chemical species. Some of these extreme in-lake mixing events can also be related to long-term extremes in climatic cycles. A major springtime resuspension plume (25-year high) in southern Lake Michigan, for example, was triggered by atmospheric and water column instability in an El Nino year, which temporarily altered the dynamics of autotrophy and heterotrophy in the lake (Cotner et al., 2000). The effects of a sudden in-wash of nutrients or DOM to a lake will also depend on the quality of that material, and whether it is labile and therefore easily decomposed. Farjalla et al. (2006) reported that while flood pulses brought high loads of DOM to the Amazonian Lake Batata, bacterial growth and DOM bioavailability were higher during low-water periods when decomposition of phytoplankton was the main source of organic matter.

Heatwaves can also have dramatic effects on the concentrations and processes controlling chemical species in lakes. It is well recognized that heatwaves, which usually result in stronger and more intense stratification, can promote algal blooms. However, they can also alter the rates of nutrient and gas cycling. The dominant CH_4 emission pathway in a shallow productive lake, for example, shifted from gas ebullition to diffusion following high CH_4 release from sediments that was driven by colder hypolimnetic temperatures during a heatwave, and concurrent high release rate of CH_4 from the lake sediments (Bartosiewicz et al., 2016). Such events will also have longer-term effects and in this case, the release of gases that had accumulated in the hypolimnion during the heatwave resulted in a further high release rate of CH_4 when the lake overturned in the autumn. The impacts of heatwaves and other

climatic extremes can affect the availability of nutrients, for example, lower hypolimnetic oxygen concentrations and higher hypolimnetic nutrient concentrations (Wagner and Adrian, 2011).

The ecological consequences of climate extremes for lake plankton dynamics

While numerous drastic short-term effects have been observed in lake responses to climate extremes, such as exceptionally mild winters, summer heatwaves, extreme storms or heavy rainfall events, the longer term changes in plankton communities and subsequent changes in ecosystem functioning as a result of such events are still unclear (Stockwell et al., 2020). The responses in lakes are complex and inherently variable depending on the severity, frequency, duration and timing of the events and particularly the antecedent conditions, and lake and catchment type (Jennings et al., 2012; Perga et al., 2018; Stockwell et al., 2020). Entrainment from run-off during extreme precipitation events, or entrainment of, for example, hypolimnetic DOM and nutrients, have caused algal biomass and biodiversity to either reduce in some cases or increase in others (Jennings et al., 2012; Kasprzak et al., 2017; Stockwell et al., 2020). The once in 250-year flood event in 2009 in oligotrophic Lough Feeagh (Ireland) caused the water column to destabilize, and was followed by a reduction in primary production (de Eyto et al., 2016). In contrast, an extreme rainy period in 2000 caused a strong increase in external organic carbon loading to Lake Mälaren, a large lake in Sweden, which was followed by a doubling of spring Cryptophyte biomass (Weyhenmeyer et al., 2004). There is also evidence that bacterial communities are more resilient to the effects of storms on the lake environment than the phytoplankton community are. For example, Jones et al. (2008) reported that bacterial communities recovered quickly after typhoons in a small freshwater humic lake in Taiwan, while phytoplankton did not recover in a predictable way.

Heatwaves are likely to promote cyanobacterial blooms as these species exhibit optimal growth at high temperature and profit from stable thermal stratification. However, two extreme hot summers (2003 and 2006), during which water temperatures were above average to the same extent in Müggelsee (Germany), resulted in a cyanobacteria bloom in 2006 but a record low cyanobacteria biomass in 2003. This difference was attributed to the fact that the lake thermal stratification pattern was critically intense only in 2006 (Huber et al., 2012). Heatwaves will also often increase the length of thermal stratification. This effect resulted in a shift towards a higher proportion of buoyant cyanobacteria capable of N-fixation (*Aphanizomenon*, *Anabaena*) and a decline in diatoms because of high temperature, exceeding their upper lethal limit and sedimentation losses (Wagner and Adrian, 2011). Zooplankton species with high thermal tolerances (i.e., *Thermocyclops oithonoides*, *Thermocyclops crassus*) and/or those that grow quickly at high temperatures (i.e., rotifers) became more common (Wagner and Adrian, 2011). Not all climate extremes, however, will have a biological effect. An extreme wind event may have little impact on phytoplankton in a lake that was previously already fully mixed. Conversely, storm effects on phytoplankton communities may be compounded when lakes are not yet recovered from a previous storm, or if periods of drought alternate with periods of intense precipitation, potentially eroding ecosystem resilience (Stockwell et al., 2020).

The ecological consequences of climate extremes for fish populations

Many fish species have low tolerance to high water temperatures because warm water has a low solubility of oxygen. Hence, it is difficult to disentangle the effects of high temperature from the effects of low DO concentrations for fish. Heatwaves, leading to anomalously high water temperatures, and associated aquatic hypoxia, can cause huge problems for lake fish populations, particularly when heatwaves occur over lakes which are already at risk from algal blooms, which, in themselves, can further lower oxygen levels as phytoplankton cells decompose. This chain of events often leads to massive fish kills, as seen in the large shallow Lake Peipsi, on the border of Estonia and Russia. Here, large fish kills of smelt, *Osmerus eperlanus m. spirinchus (Pallas)*, and vendace, *Coregonus albula* (*L.*), have been reported in years when summer water temperatures have exceeded 20 °C for several days in a row (Kangur et al., 2013). As the lake is shallow and well mixed during the summer, these extreme temperature events lead to hypoxia throughout the water column, even impacting the more tolerant bottom dwellers such as ruffe, *Gymnocephalus cernuus (L.)*. This phenomenon has increased in frequency over the last number of decades and has been exacerbated by increasing eutrophication of the lake.

The manifestation of the risk due to the heatwave very much depends on the resident fish species, which will be locally adapted and well suited to their natural habitat. For example, the fish communities of oligotrophic mountain lakes are adapted for life in cold, nutrient poor conditions, while those of shallow eutrophic lakes, such as coarse fish, are probably eurythermal (capable of withstanding a wide range of temperatures) and can thrive even in water with low levels of oxygen. These two differing communities will have varying levels of resistance to sharp increases in temperature and resulting hypoxia. For example, the aforementioned fish community of Lake Peipsi has shifted from a mainly coregonid fish community to one dominated by cyprinids as the frequency of extreme warming events has increased.

Storms bringing high winds can also pose a significant risk to fish populations, particularly those living in highly stratified lakes. High winds can cause sudden overturns of the water column, and the introduction of potentially toxic substances from the sediment water interface into the water column, or the rapid mixing of anoxic waters into the epilimnion. Massive fish kills of tilapia, *Oreochromis mossambicus*, and croaker, *Bairdiella icistia*, have been recorded in the Salton Sea, a coastal lake in California (Marti-Cardona et al., 2008). These fish kills occurred immediately after episodic wind driven upwellings of hypoxic hypolimnetic

water, mixing high concentrations of hydrogen sulfide and ammonium throughout the entire water column, thereby eliminating any refuge for the fish. The severity of this type of impact may be mitigated by the ability of populations to move out of the danger zone quickly. This is often not the case for short lived events that can happen very quickly. In addition, lakes are often used for highly productive aquaculture operations, with fish confined to certain portions of the water body. In these cases, rapid unpredicted overturns can have enormous economic consequences. Cages of Tilapia, *Oreochromis niloticus*, are farmed in Lake Buhi in the Philippines, and fish kills related to extreme climate events including typhoons and hurricanes have been estimated at 322.1 million PhP (~5.6 million euro) between 1998 and 2018 (Nieves et al., 2020). Finally, physical disturbance of habitat resulting from short lived storm events is a considerable risk to fish populations, especially in shallow littoral areas. Massive storms along the coast of Lake Victoria (Africa) caused the death of 2400 t of *Lates niloticus* and *Oreochromis niloticus*, an effect that was attributed to disturbance of the littoral zone causing increases in turbidity and sediment resuspension. The gills of the dead fish were found to be clogged by detritus and algae (Ochumba, 1990).

Longer term effects of climate extremes on lakes

Climate extremes may also have longer-term effects in lakes, although the evidence for this is sparser. Multi-year effects on water chemistry will be more likely in lakes with multi-year retention times (Jennings et al., 2012). In lakes where there is a strong recurring seasonal cycle, biological effects may also be reset during the normal autumn-winter-spring transition (e.g., de Eyto et al., 2016). However, climate extremes may also act as a tipping point and trigger a fundamental shift in the functioning of a lake ecosystem with a transition of one state to another, often referred to as a regime shift. Lake Apopka in Florida (United States) serves as a well-studied example of how long-term stressors and extreme events interact in causing and subsequently maintaining a dysfunctional stable state. Lowe et al. (2001) concluded that hurricanes accelerated a regime shift to a turbid state in that lake, but this was only made possible by a long-term increase in nutrient loading. Before eutrophication, the clear water state was capable of resisting a regime shift and coped well with the damage caused by extreme events.

An additional aspect of the longer-term effects of climate extremes on lakes is the projected increase in their frequency and intensity due to global warming. Quantifying these future impacts requires not only an understanding of historical trends and potentially new theory on the more stochastic impacts within lake ecosystems (Stockwell et al., 2020), but also the use of dynamic models that adequately replicate in-lake responses. Current and projected changes in stratification during heatwaves have been well-captured by lake physical models (Woolway et al., 2021). These physical models have also been shown to capture the effects of short-lived storms on thermal structure (Mesman et al., 2020). As illustrated above, however, the responses for lake biogeochemistry and biota to climate extremes can be complex. Moreover, they can also be strongly affected by processes in the surrounding catchment, interactions between species, and antecedent conditions within a given lake. While there are now many commonly used lake biogeochemical models that can simulate in-lake responses, challenges still remain for adequately quantifying projected changes in climate extremes with the required degree of uncertainty.

Conclusion

Climate extremes, including storms, floods, heatwaves, and droughts, are projected to increase in frequency and magnitude in the coming decades as global warming progresses. Understanding the effects of these extreme events on lakes and reservoirs is crucial if appropriate management is to be planned and implemented. Using high frequency and longer-term monitoring, the effects of storms and heatwaves on lake physics are now relatively well understood. We also now have some detailed examples of how complex the lake ecosystem response to climate extremes can be, involving many trophic levels and feedbacks through linked biogeochemical cycles. Much remains to be learnt, however, in relation to many of the chemical and biological impacts. In particular, we need to increase our understanding of why some lakes seem to have an inherent ecosystem resilience to these extreme climatic events and how this resilience is compromised by otherhuman pressures. Gaining more insights into these effects will inform both lake management and the modelling studies that will be required to assess the impacts of future climate change.

Knowledge gaps

1. More lake studies are needed on the effects of climate extremes on the cycling and emissions of CO_2 and CH_4 and on their role in the global carbon cycle.
2. Whole system studies are required that use high frequency monitoring to explore shifts in nutrient concentrations and plankton communities, during and following climate extremes.
3. New theory and conceptual models which include both trends in climate extremes and in in-lake conditions can be used to predict both linear and more complex whole-system responses and therefore inform dynamic modelling of lake ecosystems.

Important case studies.

Glossary

Cholesterol The predominant sterol in animal tissues.
Co-limitation Simultaneous limitation by multiple nutrients.
Ecological stoichiometry Balance between chemical elements in ecological interactions.
Incipient-limiting level (ILL) Concentration of food or of a food quality constituent above which consumer growth is not anymore limited by food quantity or the specific quality component under consideration.
Long-chain polyunsaturated fatty acids (LC-PUFA) Fatty acids with more than 18 carbon atoms and more than one double bond (unsaturation) that are required as membrane components and as precursors for other bioactive molecules (eicosanoids). Many consumers cannot synthesize LC-PUFA in quantities covering their physiological demands.
Phytosterols Sterols found in plants and algae.
Seston Sum of living and non-living particles suspended in water.
Sterols Lipid-like compounds that are required as membrane components and as precursors for steroid hormones and other bioactive molecules. Arthropods cannot synthesize sterols *de novo* and thus rely on dietary supply.
Threshold elemental/biochemical ratios Ratio between e.g., two elements or between a fatty acid and carbon in the diet at which the element or fatty acid of concern may become limiting.
Trophic upgrading Upgrading of a nutritionally inadequate food by a consumer (e.g., by providing LC-PUFA) for subsequent use by higher trophic levels.

Introduction

Zooplankton is of central importance for material and energy fluxes in aquatic food webs. Nutritional constraints at the phytoplankton-zooplankton interface can thus have severe consequences for ecosystem functioning and services. For example, zooplankton nutritional constraints might limit zooplankton capacity to control algal blooms, as well as fish production. The taxonomic diversity of potential food organisms of zooplankton is analogous to a wide diversity in traits of food organisms, such as size, mineral and biochemical contents, morphological and behavioral defenses, or toxin production, which co-evolved in equally diverse assemblages of zooplankton consumers differing in breadth of resource use, demand for nutrients, and biochemical machinery. Zooplankton may be constrained by the overall quantity of food and/or its quality. The food quantity, i.e., its energy content, is generally equated with the carbon concentration within the size range edible for zooplankton species, whereas the quality of food is usually expressed relative to food quantity, i.e., carbon content. The distinction between quantity and quality limitation is, however, not clear-cut. For example, phytoplankton morphological adaptations reducing edibility are often

considered as quality components, but reduce the food quantity available for the zooplankton (Ger et al., 2016). Likewise, low food quality might be associated with energetic costs due to increased resting metabolism in consumers (Ruiz et al., 2021).

This chapter starts with an overview of controlled laboratory experiments examining various aspects of nutritional constraints, including food quantity and quality limitation, co-limitation by multiple food constituents, as well as the interaction between nutritional constraints and ambient temperatures. We then continue with the complexity of zooplankton nutrition in a food web context, and present evidence about nutritional constraints of zooplankton *in situ*, e.g., during seasonal plankton dynamics in lakes of different trophic status. Finally, the adaptive responses of zooplankton to nutritional constraints will be discussed.

Zooplankton nutrition—Laboratory experiments

In this chapter we will address how laboratory experiments have contributed to our understanding of zooplankton nutritional constraints. We discuss food quantity constraints and several aspects of food quality constraints such as deficiencies of elements, fatty acids, sterols, amino acids and the presence of harmful metabolites in zooplankton diets. Then we examine simultaneous limitation by several diet compounds and how water temperature interacts with both food quantity and food quality to influence zooplankton growth and reproduction.

Food quantity

The dependence of zooplankton growth and reproduction on food quantity can be described using functional responses. Along a food quantity gradient, zooplankton growth rates increase with increasing food availability up to a critical threshold food concentration (Fig. 1A). Below this threshold food concentration, food availability is insufficient to balance metabolic losses, eventually resulting in a decrease in body mass or, on the population level, in a decrease in population density (Lampert, 1987; Sterner and Schulz, 1998). Threshold food concentrations and thus food quantity requirements differ among zooplankton species, but general principles are difficult to extract from the available literature. Threshold food concentrations have been reported to decrease with body size across *Daphnia* species (Gliwicz, 1990), to increase with body size across rotifers (Stemberger and Gilbert, 1985), and to show no relationship with cell size across ciliates (Weisse, 2006). Ciliate threshold food concentrations strongly overlap with those of *Daphnia* and small rotifers (Weisse, 2006). Above the threshold food concentration, growth rates increase further with food quantity until the growth response curve approaches its maximum. The food concentration at which growth is no longer limited by food quantity is often referred to as the incipient limiting level (ILL).

The edible size range, and thus food quantity, can be reduced because of morphological defenses of food organisms interfering with ingestion rates, e.g., formation of filaments, colonies, and spine formation, or assimilation rates, e.g., thickened cell walls and mucous sheets that may allow passing the zooplankton gut unscathed (Lürling, 2021). A well-documented example of morphological properties hampering ingestion is the inducible defense reaction of the green alga *Scenedesmus*. In the presence of a kairomone (i.e., a signaling molecule) released by *Daphnia*, *Scenedesmus* cells form colonies consisting of up to eight cells of which the peripheral cells may express long spines. Inducible morphological defenses can interfere with the filtration process of filter-feeding zooplankton, thus reducing the efficiency with which phytoplankton species are exploited. Another example of morphological properties reducing food uptake is filament formation, which occurs in various phytoplankton groups, especially among cyanobacteria (Lürling, 2021).
