
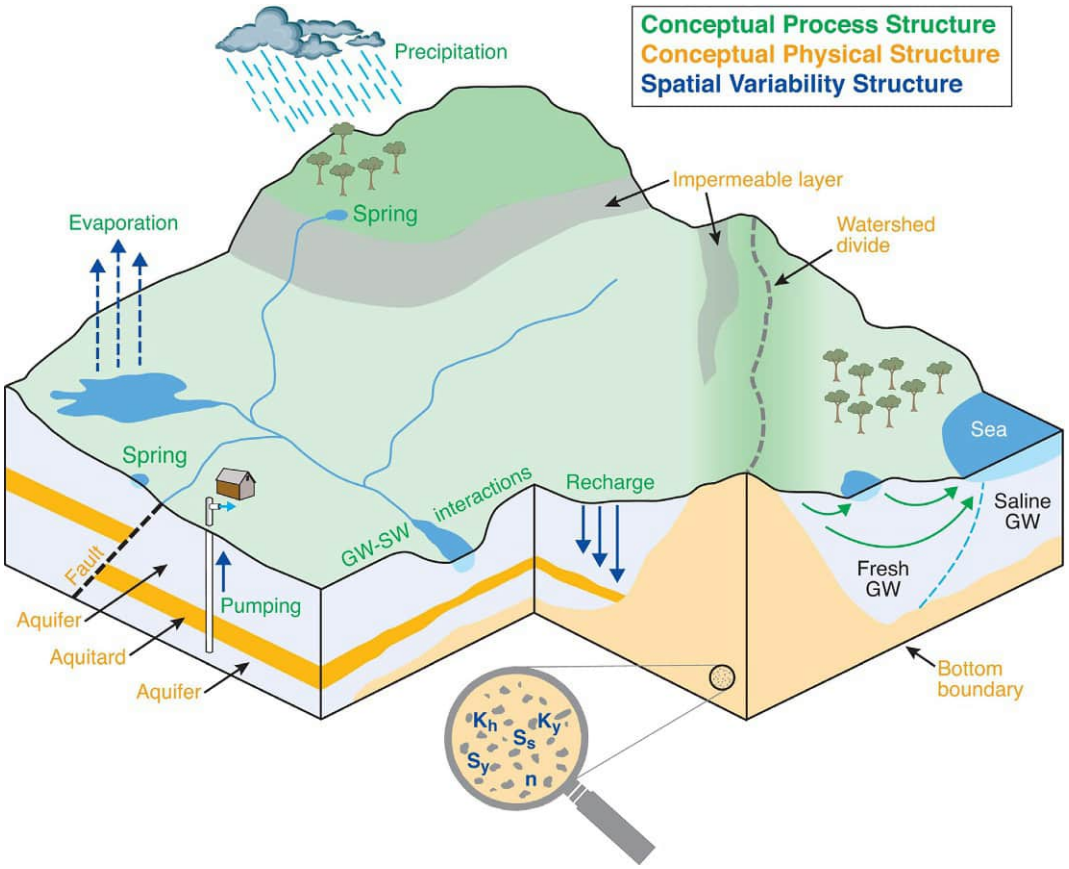

Fig. 6 Example sketch of a conceptual model considering separately the conceptual process structure, the conceptual physical structure, and the spatial variability structure of a groundwater system (Enemark et al., 2019; K_h/K_v: horizontal and vertical hydraulic conductivities, S_s: specific storage, S_y: specific yield, n: effective porosity). From Fig. 2 of Enemark T, Peeters LJM, Mallants D, Batelaan O (2019) Hydrogeological conceptual model building and testing: A review. *Journal of Hydrology* 569: 310–329, doi:10.1016/j.jhydrol.2018.12.007

The availability of data to develop a conceptual model of a chosen groundwater system is case dependent. Usually, existing data, reports or maps with information about topography and lithology exist at varying spatial resolutions to establish a priori knowledge about the conceptual physical structure. Maps and time series of hydrometeorological information, such as precipitation, evapotranspiration, streams and their discharge volumes, springs and their discharge volumes, etc., are often available to get a first understanding of the system. However, information about the spatial heterogeneity of a groundwater system is seldom available at the desired scale and may require additional field work and/or more sophisticated approaches for their definition (de Marsily et al., 2005). Bringing together all this information will allow establishing a visual sketch of the chosen groundwater system that can be regarded as an information-based hypothesis of the system functioning. It can be used for discussion with other hydrologists and be tested using additional observations or modeling (Enemark et al., 2020; Mudarra et al., 2019). With more and more global hydrogeological datasets available (see Table 1 in Gleeson et al., 2020), coarse conceptual models can also be established for regional groundwater systems or large-scale groundwater assessment. They will provide directions for a better representation of groundwater processes in large-scale modeling, e.g. the decrease of groundwater storages due to pumping and climate variability (Scanlon et al., 2018), the impact of focused groundwater recharge on recharge volumes and contamination risk (Hartmann et al., 2017, 2021), or inter-catchment groundwater flow (Fan, 2019; Liu et al., 2020).

Conclusion/synthesis

This chapter provides a brief overview of the hydrology of groundwater systems. The most relevant technical terms are defined and the most relevant processes, from groundwater recharge over groundwater storage to groundwater discharge, are explained. The use of conceptual hydrogeological models is introduced as a valuable tool to summarize and present available information in a combined way to prepare a chosen groundwater system for discussion among colleagues and for the application of groundwater models. The chapter focusses on natural groundwater systems. For an introduction into groundwater systems highly affected by pumping, please refer to Alley (2009) or Alley et al. (2002).

Knowledge gaps (among many others)

- Quantifying groundwater recharge
- Interactions of groundwater systems and surface catchments/rivers
- Behavior of complex pollutants like pharmaceuticals or pesticides in aquifers
- Measurement of spatial variability of hydraulic properties especially in heterogeneous settings like karst
- Understanding the long-term impacts of climate change and land use change on aquifers especially those with long transit times
- Regional or large-scale quantification of groundwater resources

The Vadose Zone—A Semi-Aquatic Ecosystem

Christine Stumpp and Gerhard Kammerer, University of Natural Resources and Life Sciences, Vienna, Department of Water, Atmosphere and Environment, Institute for Soil Physics and Rural Water Management, Vienna, Austria

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Capillary fringe The zone of water above the groundwater table or phreatic zone where water is held by capillary forces and which is saturated, not aerated and under subatmospheric pressure.
Field capacity Soil water content that is supposed to remain in a soil 2 or 3 days after having been wetted with water and after free drainage is negligible.
Hydraulic conductivity The proportionality factor in Darcy's Law, as applied to viscous flow of water in soil, that represents the ability of soil to conduct water and is equivalent to the flux of water per unit gradient of hydraulic potential. Its value combines properties of the porous media and the fluid.
Matric potential Matric potential is attributed to intermolecular cohesive and adhesive forces acting within and between liquid, gaseous and solid phases. These forces lead to surface tensions at the interfaces of adjacent phases and fluid can be hold in the pores against gravity.
Porosity The volume of pores V_p in a known volume—soil sample or drill core sample in solid rock—divided by the bulk control volume V.
Preferential flow Free water and its constituents moving by preferred pathways through a porous medium.
Vadose zone The aerated region of soil or un-/weathered rock above the permanent water table.
Volumetric water content The volume of water V_w in a control volume related to the bulk control volume V.

Introduction, with aim of the chapter

Aim

The vadose zone is the variably saturated zone between the ground surface and the permanent water table of the groundwater. It is an important part of the water cycle and stores at least 8.5 times more water than is held by rivers (Oki and Kanae, 2006). Processes in the vadose zone contribute to food and water security by providing water to plants and contributing to recharge groundwater, which is the main source for drinking water worldwide. The aim of this chapter is to provide an overview of the vadose zone, its function as an ecosystem and how hydraulic properties influence flow processes. We give definitions about the vadose zone and explain the key soil hydraulic properties that influence how water flows through this part of the underground.

Definition of the vadose zone

The vadose zone is the aerated region of soil (SSSA, 2008) or un-/weathered rock above the permanent water table (Fig. 1). An almost synonymous term is the "unsaturated zone." The porous medium of this region is typically soil, but may also be sediments, porous rock, or any other material that occurs near the earth's surface (Nimmo, 2009). Soil might be defined as the

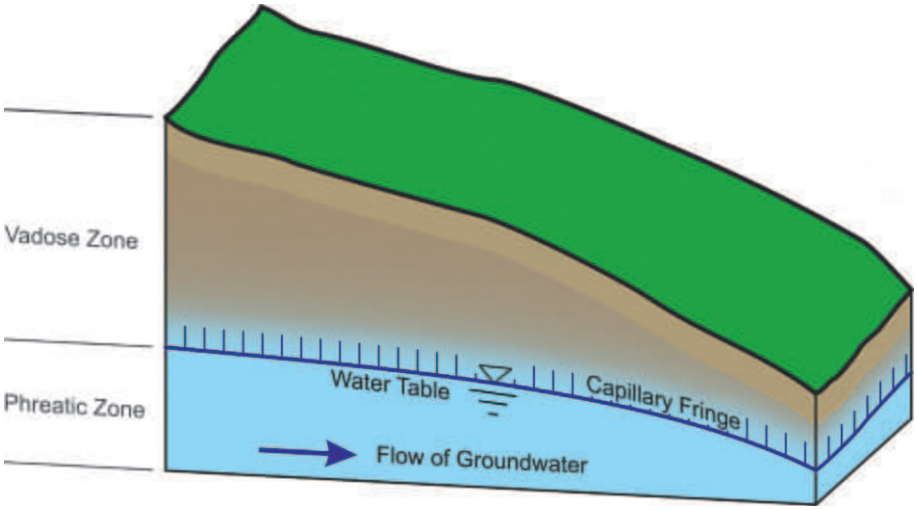

Fig. 1 Scheme of the vadose zone which is the aerated region of soil or un-/weathered rock above the permanent water table.

layer(s) of generally loose mineral and/or organic material that are affected by physical, chemical, and/or biological processes at or near the planetary surface, and usually hold liquids, gases (SSSA, 2008). The vadose zone may also include a capillary fringe which is the zone of water above the groundwater table or phreatic zone where water is held by capillary forces and which is saturated, not aerated and under subatmospheric pressure.

In contrast to surface waters and groundwater, flow and transport processes in the vadose zone are mainly vertical; lateral flow components become important in strongly layered systems with different hydraulic properties or in fractured systems according to the fracture orientation. Processes within the zone are percolation—a gravity driven, relatively fast downward movement—, capillary rise, root water uptake, and wetting and drying as increases and decreases in water storage within the profile of the vadose zone.

It is not only water and air that move through the pores in the vadose zone; the liquid phase may contain nutrients (e.g., carbon, nitrogen, phosphorus), contaminants (e.g., pesticides, fertilizer components, antibiotics), or any other substances dissolved in water or transported in colloidal or fine particulate form. The vadose zone is the living environment for plants and other soil biota comprising microorganisms (bacteria, fungi and archaea), viruses, as well as vertebrates and meso- and macroinvertebrates. Microbial biomass is generally highest in surface soils and declines with depth within the vadose zone (Holden and Fierer, 2005). The total biomass is still similar to groundwater whereas the interface of those two compartments is considered a hotspot for microbial activity (Griebler and Lueders, 2009; Holden and Fierer, 2005). More information about microbial processes in the vadose zone can be found in Holden and Fierer (2005).

Importance of the vadose zone in the hydrological cycle and its role as an ecosystem

The vadose zone is an important part of the water cycle. Generally, water enters the zone from above as infiltration from precipitation, snow and ice melt, as well as irrigation or any other water sources applied on the land surface. Depending on the soil hydraulic properties and topographic features, the soil surface regulates the infiltration process and its accumulation (i.e., ponding) on the surface that can contribute to overland flow. Water can enter the vadose zone also from the bottom due to capillary rise from the permanent water table or through infiltration from surface water bodies. Water leaves the system to the atmosphere as evaporation from bare soil and transpiration by plants. It can also leave at the bottom by recharging groundwater or discharges water to surface water bodies. Water may be held against gravity by capillary forces or flow upwards or downwards according to the hydraulic gradient.

The vadose zone provides several ecosystem services (Robinson et al., 2013). Those include climate regulation through buffering extremes of heat and cold, as well as contributing to greenhouse gas sinks and sources. Buffering floods and consequences of droughts and the storage of water are hydrological regulations. The vadose zone is often the foundation for buildings and infrastructure and a source of sediments and dust. The vadose zone is a habitat for biota and provides a gene pool impacting biodiversity. Geochemical cycling, mineralization of organic matter, natural attenuation processes and the ability to retard or eliminate contaminants define the quality of water which is important for both food and water security. The geochemical and biological processes are fundamental for the provision of clean groundwater as drinking water or the water use for industrial and agricultural purpose.

Porous media

The porous medium of the vadose zone has two components: the solid matrix and the pores in between (Fig. 2). The volume of the solid matrix V_s is composed of particles with distinct size, shape, density, and chemical composition. Inorganic matter e.g., quartz, clay minerals, or limestone dominates, but organic matter and in particular humus are also present. When the vadose zone is comprised of porous rock, the particles are strongly packed to monoliths; those in soils might be structured in aggregates of different types or in a singular granular form with only a few intergrain contacts. Particle size distribution is one of the most important physical properties of the solid phase. The international scale for particle size (in mm) ranges from clay ($\leq$0.002) to silt (0.002–0.063), sand (0.063–2.0), gravel (2.0–63), cobbles (63–200), boulder (200–630), and large boulder (>630). The United States Department of Agriculture classifies the finer soil particles with a diameter $d < 2$ mm into main mass fractions of clay ($\leq$0.002), silt (0.002–0.05), and sand (0.05–2.0). The percentages of these three fractions—independent of the reference scale used—partition soil texture into 12 classes. Soil texture characterizes the soil, and it is also the primary input parameter for pedotransfer functions, which are functions that estimate soil hydraulic properties based on easily measured soil or sediment properties, such as texture.

The pores in between the solid phase can be filled with air or water (Fig. 2), and the ratios of those filled with air or water are variable over time and space. The variation of air and water phases is the basis for the microbiological activity and most of other geochemical, flow and transport processes in the vadose zone. Earthworm holes, fissures, voids, gaps, cracks etc. are some of the many sources or origins of the pore spaces and their many different shapes and configurations. The pores are also the result of soil formation and rock weathering processes, such as shrinking, root growth, frostbites, soil cultivation, and biochemical transformation.

The size and number of pores, described by the pore size distribution, are key determinants of the physical behavior of water in the soil. The pore size distribution can only be indirectly determined with the help of the capillary law. The porosity n of a soil sample or drill core sample in solid rock is determined as volume of pores V_p in in the sample or core divided by its bulk volume V. The porosity of vadose zone matrices is typically larger than in groundwater bodies, ranging from a few percent in slightly weathered rocks to 40% in agricultural soils and up to 80% or more in peat and bog soils. For determining the porosity, the volume V of a sample needs to be analyzed, which is not straightforward in porous media. Either an undisturbed soil or rock sample has to be taken with a cylindrical stainless steel cup or the drill core with given dimensions or a displacement method for soil clods or not bearing material can be used. The pore volume ($V_p = V - V_s$) is calculated after removal of all liquids in the sample from the mass of the solid material m_s and the known particle density ρ_s ($\rho_s = m_s/V_s$).

Whereas porosity of a material is treated as a constant in most physical process descriptions (exceptions are e.g., shrinking and swelling effects or consolidation processes), the amount of water in the vadose zone is highly variable in space and time. An important parameter describing water quantity is the volumetric water content θ, which is the volume of water in a sample V_w related to the bulk volume of the sample V. The reference method for determination of V_w is evaporation of the water with the mass m_w in the sample after drying at 105 °C until constancy of mass. Some soils contain a certain amount of water even after long dry periods without fresh supply. This residual water content is a minimum value for θ, its maximum is approximately equal to the porosity. Another quantity for the amount of water in a soil is the degree of saturation S, defined by the ratio of water volume V_w and the total pore volume V_p; $S = 1$ refers to full saturation.

When the pore space is only partially saturated, the remaining space in the pores is filled with air with the volume V_a, giving a volumetric air content $n_a = V_a/V$. The volumetric portions of water, air and solid material constitute the phase concept in soil physics, together with the assumption that all phases exist in each infinitesimal point of a known volume despite their spatial separation in particles and pores filled with either water or air. Aside of the one gaseous phase in the soil and the aqueous phase liquid, in some cases other non-aqueous phase liquids, such as oils or other organic liquid substances, occur with a density greater or smaller than water.

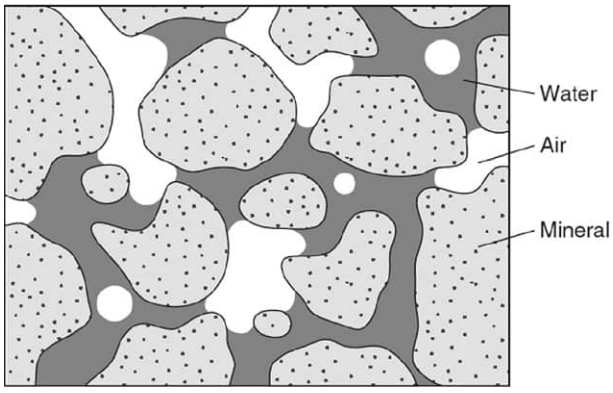

Fig. 2 Pore space of a hypothetical unsaturated medium, illustrating the arrangement of solid, liquid, and air phases. From Nimmo JR (2009) Vadose water. In: Likens GE (ed.) *Encyclopedia of Inland Waters*. Oxford: Elsevier.

Hydraulic properties and water flow

Water content and matric potential

The presence of water in the vadose zone does not necessarily mean that the roots of a plant are able to take it up or that water flows downwards. This illustrates the need for a further measure of quantity, the matric potential ψ_m, which describes how strongly water is bound in the porous medium and is part of the total energy level of soil or sediment water. ψ_m is always negative, as free water in contact with unsaturated soil or sediment will always flow into the soil or sediment, and not the opposite. ψ_m has a dimension of work but can be related either to the volume or the weight of the soil or sediment water and thus is given as a dimension of pressure or length (matric potential head), respectively. Matric potential is attributed to intermolecular cohesive and adhesive forces acting within and between liquid, gaseous and solid phases. These forces lead to surface tensions at the interfaces of adjacent phases and in particular at the liquid-air-interface, e.g., the meniscus in a thin pore. When a soil or sediment sample is submerged in a water bath and then its upper boundary is lifted to the level of the water table, the sample is completely saturated and its matric potential is zero. Reduction of the energy level leads then to a certain decrease in water content. This also means that when lifting the sample above the water level, the matric potential is only equal zero (=atmospheric pressure) at the bottom of the sample and negative above, resulting in water draining from the sample that cannot be held by the matric forces in the pores. This also illustrates that there is a strong relationship between matric potential and water content which is often called soil water characteristics $\theta(\psi_m)$ or soil water retention function.

A physical explanation of matric potential starts with splitting the forces into adsorptive and capillary forces. Capillary forces are responsible for the rise h_c of water in cylindrical tubes (capillaries) with a curved meniscus at the interface with the atmosphere. Under the assumption of full wetting (contact angle between meniscus and solid surface is zero), the pressure difference between the liquid and the gaseous phase or h_c are inversely proportional to the radius of the tube (Jurin's law for capillary rise). If only capillary forces were present and all pores were cylindrical tubes, the pore size distribution would be closely related to the integral of the soil water characteristics $\theta(\psi_m)$. However, soil and sediments also exhibit adsorption, which forms hydration envelopes over the particle surfaces. The presence of water in films is most important in clay which has a large surface area because of the small particle sizes, but relatively insignificant in sand where the capillary effect dominates (Tuller and Or, 2005). Further, real pores are not cylindrical but can have a variety of complex forms making it necessary to measure the soil water characteristics $\theta(\psi_m)$. Soil water characteristics can be determined by simultaneous measurement of matric potential and water content, either in the field or in laboratory experiments by e.g., conducting drainage experiments under known pressure conditions.

Numerous models exist for parametrization of the soil water characteristics $\theta(\psi_m)$; the most commonly used are the models introduced by Brooks and Corey (1966) and van Genuchten (1980). Fig. 3 below shows the water retention curves for a typical sand, clayey loam, and clay parametrized with the van Genuchten approach. There is a steep change in water content of sand at a matric potential head of -10^1 to -10^2 cm, which occurs because the majority of pores in a sand are relatively large and uniform. On the other hand, the pore sizes of a clay are more evenly distributed and mainly smaller, and thus the desaturation, i.e., the slope of the curve in the inflection point, is gentler. Simultaneous measurements of matric potential and water content over long periods often reveal a hysteretic behavior of $\theta(\psi_m)$ and thus the wetting and drying curves are different not having the same unique functional relationship.

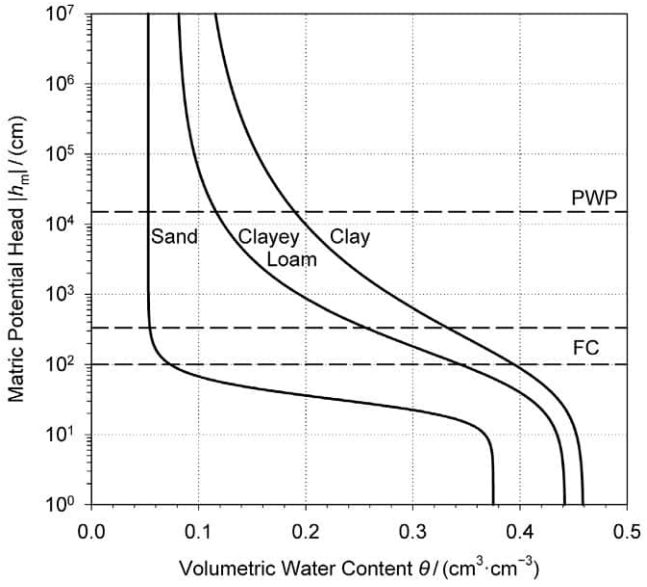

Fig. 3 Soil water characteristics for three typical soil types, modeled with van Genuchten function; PWP, permanent wilting point; FC, field capacity.

The soil water characteristic is not only required when describing flow (see next chapter), it also gives information about the soil water status and whether water is accessible by plants. To avoid the analytical complexities of determining the whole relationship $\theta(\psi_m)$, practitioners tend to focus on two specific measures of soil water. One is field capacity θ_{FC}, a moderately wet condition that gives the water that is expected to remain in the porous medium 2 or 3 days after having been wetted with water and after further drainage is negligible (SSSA, 2008). The other one, a relatively dry status is the permanent wilting point θ_{PWP}. This point represents the largest water content at which indicator plants, growing in that soil, wilt and fail to recover when placed in a humid chamber. Instead of conducting laborious standardized experiments, θ_{FC} and θ_{PWP} are taken from the soil water characteristic. Whereas θ at a matric potential head of -1.5×10^4 cm is considered a good estimation for θ_{PWP} in all soils, field capacity varies from -10^2 cm in sand soils to -3.3×10^2 cm in clays (Fig. 3). The respective pore radii according to the law for capillary rise delimit the range of medium-sized pores. The difference $\theta_{FC} - \theta_{PWP}$ reflects the plant-available water and is an important characteristic of the storage behavior of soils and sediments. The typical number of medium-sized pores is obviously similar in clayey loams and clays ($\theta_{FC} - \theta_{PWP} \approx 0.20$) and much smaller in sands (≈ 0.03). These values from Fig. 3 are consistent with long-term experience in agriculture: poor soils typically have 90 mm of plant available water per meter rooting depth, whereas favorable soils have 250 mm.

Uniform water flow

For describing water flow through porous media, we have to travel back in time to 1856, when Henry Darcy came up with his fundamental empirical relationship of quantifying water flow through a saturated porous filter system (Darcy, 1856) which is still the basis for describing water flow in porous media and was extended by Buckingham (1907) for unsaturated porous media. In an experimental setup (Fig. 4), Darcy calculated that the volumetric water flow Q through a porous filter column is directly proportional to the area A ($A = \pi r^2$; r, radius) of the column and the difference in hydraulic head ΔH and inversely proportional to the length of the column L; the hydraulic potential is the sum of gravitational head and pressure head. The proportionality factor is the hydraulic conductivity K. The water flux q can be calculated by referring the volumetric water flow to the area:

$$q = \frac{Q}{A} = v \cdot n = -K \cdot \frac{\Delta H}{L}$$

The water flux has the same dimension as velocity, but for calculating the average pore water flow velocity v, we must consider that water flow only takes place through the pore space and therefore, we have to additionally consider the porosity n. The hydraulic conductivity combines properties of the porous medium (e.g., pore sizes, pore connectivity) and the fluid (viscosity and density). For porous media with smaller pores, such as in clay, hydraulic conductivities are much smaller compared to media with larger pores, such as in sand.

For unsaturated media, Darcy's law has to be extended as the hydraulic head difference is not only dependent on the gravitational potential, but also on capillary forces and interactions of the liquid and solid phase, which are given by the matric potential. Therefore, the difference in hydraulic potential for unsaturated media equals the difference of the gravitational potential $d\psi_z$ plus the difference of the matric potential $d\psi_m$ over the flow length difference ds. Further, the hydraulic conductivity no longer is

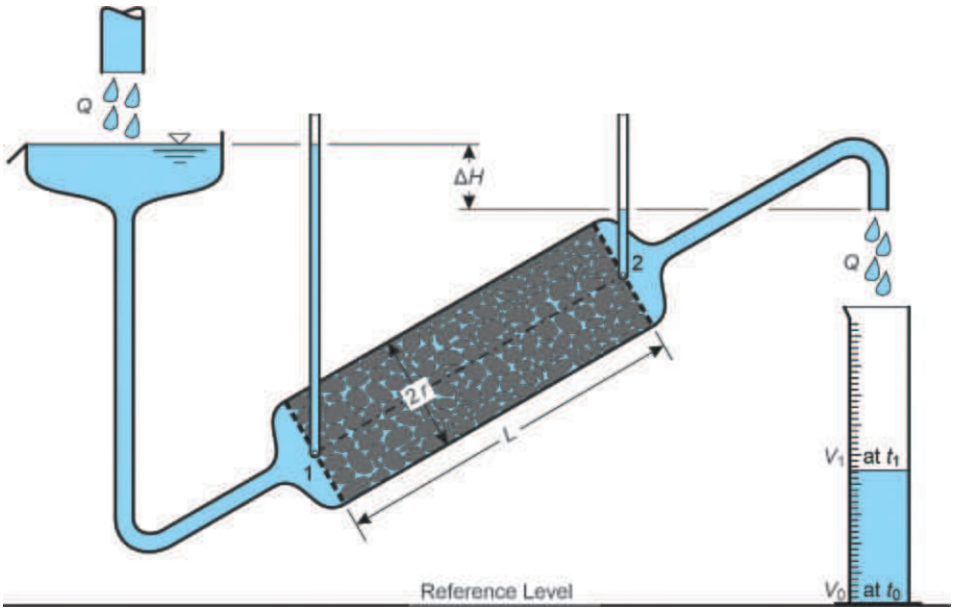

Fig. 4 Setup of a Darcy experiment to quantify water fluxes through porous media. From https://info.bmlrt.gv.at/dam/jcr:8d7b2b61-c5f1-4d54-903a-f02e37b81144/Sammelband_Wasser-im-Boden_BMLRT.pdf.

a constant value, but a function of the matric potential or volumetric water content θ. Both, the pore connectivity and radius of pores filled with water decreases with decreasing matric potential as the larger pores empty first. Thus, fewer and only smaller pores are filled with water being less conductive and increasing the flow paths through the system resulting in lower hydraulic conductivity. The vertical one-dimensional Darcy-Buckingham Law is

$$q = -K(\theta(\psi_m)) \cdot \frac{d(\psi_m + \psi_z)}{dz}$$

This law is all what is needed to describe average water fluxes under steady-state conditions. However, flow processes in the vadose zone are mainly transient and not steady-state. We have to consider that there is water stored and that water fluxes into the vadose zone are not equal to the water fluxes leaving it. Water fluxes—as well as state variables like θ and ψ_m—change over time t and space z ($dq/dz = d\theta/dt$), and therefore, the change in water volume in a specific control volume is no longer equal to zero. Combining this assumption of continuity (mass conservation) with Darcy's law gives the Richards equation (1931) describing transient water fluxes in variably saturated porous media, here given for vertical one-dimensional flow

$$\frac{\partial \theta(\psi_m)}{\partial t} = \frac{\partial}{\partial z} \cdot \left[K(\psi_m) \cdot \left(\frac{\partial \psi_m}{\partial z} + 1 \right) \right]$$

There are different forms of the Richards equation due to the interdependency of θ and ψ_m. For details, more information is available in text books on soil physics (see "Further reading"). The equation can be solved numerically, and in the present form describes uniform, vertical water flow in variably saturated, homogeneous porous media. It can be further expanded by a sink/source term considering plant-soil water interactions or any other sources and sinks of water. There are software programs available for simulating the movement of water (as well as heat and multiple solutes) in variably saturated media, such as HYDRUS-1D (Šimůnek et al., 2009).

Challenges of using the Richards equation have been discussed as numerical solutions are not always straightforward (Farthing and Ogden, 2017). Its applicability at larger scales is also computationally expensive and affects the accuracy of the modelling (Vogel and Ippisch, 2008), and it is complicated by nonlinearity and heterogeneity (Beven, 2001). Further, important processes like preferential flow are not considered in the form introduced above. Still, it is one of the main concepts for describing water flow in porous media, simulations with the Richards equation are consistent with measurements observed at the local scale, and it has also been extended to describe flow in heterogeneous porous media.

Non-uniform water flow

Preferential flow in the vadose zone is the rule rather than an exception. Preferential flow is defined as water and its constituents moving by preferred pathways through a porous medium. This preferential water flow is typically some orders of magnitude faster than flow through the remainder of the porous medium. Preferential flow can thus result in water and matter fluxes bypassing large parts of the vadose zone. Consequently, it influences the water cycle and can impact the quantity and quality of water in and leaving the vadose zone.

Preferential flow can be categorized into three types (i) macropore flow, (ii) funneled flow, and (iii) fingered flow. Macropores are pores that are larger in size, greatly continuous or have other properties enabling fast water flow velocities. Typical structures favoring macropore flow are fractures, root holes, or animal burrows. Funneled flow describes spatially variable water flow as a consequence of heterogeneities in hydraulic properties. It develops, for example, in layered medium or in the presence of differently textured lenses (e.g., clay lenses) compared to the surrounding. The contrasting hydraulic properties of those features cause a concentration of flow in the most conductive, wetter zones. Fingered flow is caused by heterogeneities resulting from different flux distributions or moisture states. A prominent example is the instability of infiltration fronts favoring flow into the wettest, most conductive pathways. Independent of the type of preferential flow, it still remains a challenge to measure, quantify and predict preferential flow due to its complexity, as outlined in detail in Nimmo (2021).

It also remains a challenge to measure other structural heterogeneities that cause non-uniform flow. Here, artificial or environmental tracers have been applied in field and laboratory studies to visualize or quantify flow processes (e.g., Flury and Wai, 2003; Stumpp and Maloszewski, 2010; Weiler and Flühler, 2004). Such use of tracers is limited to the upper part of the vadose zone that is accessible for doing those experiments or installing sensors for measuring volumetric water content or matric potential. For deeper parts of the vadose zone, measurements are even more challenging, and information about flow can be gained, for example, from drilling and water stable isotope analysis (Sprenger et al., 2016; Chesnaux and Stumpp, 2018) or installation of specific vadose zone monitoring systems (Dahan, 2020).

It remains difficult to quantify the importance of structural heterogeneities and their consequences for flow and transport at various scales. Factors such as texture (grain size distribution) and structure (aggregates) can vary vertically and laterally, and so do hydraulic properties. Determining those variable properties in the field is nearly impossible, and including spatial heterogeneity of hydraulic properties in three dimensional flow models based on the Richards equation is computationally only feasible at the plot scale. For simulation of water fluxes in the vadose zone at the catchment scale, homogeneity of hydraulic property often needs to be assumed, the impact of heterogeneities on larger scale remains unknown, and/or hydrological models with less complex flow assumptions for describing flow in the vadose zone are used.

Despite the challenges of quantifying non-uniform flow resulting from structural heterogeneities, there have been several approaches developed. These include the assumption of bimodal soil water and hydraulic conductivity characteristics (Durner, 1994; Priesack and Durner, 2006) and dual-porosity (Šimůnek and van Genuchten, 2008) or dual-permeability approaches (Gerke and van Genuchten, 1993). These approaches each divide the pore system into two or more components with different hydraulic properties. For quantification of macropore flow, kinematic wave approaches have been used (Germann and Beven, 1985) to simulate advective and gravity-driven transport processes.

Synthesis

Here, we provided an overview of the vadose zone, its function as an ecosystem and how hydraulic properties influence flow processes. We showed that hydrological processes are controlled by the ratios of solid, liquid and air phase and the size distribution of grains and pores. Due to adhesion and cohesion forces, water can be held in the porous medium against gravity. Both, gravitational and matric forces constitute the direction of water flow. Porous media have different soil water characteristics and hydraulic conductivities with a clear relationship to texture. Knowing those dependencies, uniform water flow can be quantified through a combined Darcy and mass conservation approach. Water flow in the vadose zone is, however, not always uniform; structural heterogeneities cause preferential or other non-uniform water flow. These processes are difficult to quantify or to even measure in the field. Particularly hydrological processes in the deeper parts of the vadose zone and the scaling of processes from the plot to the catchment scale and vice versa remain challenges in vadose zone research. We further showed that the flow processes in the vadose zone are highly variable and thus, they impact the amount and quality of water fluxes and are essential for food and water security.

Knowledge gaps

- Determination of spatial variabilities of hydraulic properties in the field and its consequences for water flow and transport
- quantification of non-uniform flow including preferential flow
- scaling of soil hydraulic properties and processes (plot vs. catchment scale)
- deep vadose zone processes and missing observations there
- interaction of physical, chemical and microbiological processes
- fate of contaminants in the vadose zone
- groundwater recharge quantification

Groundwater Dependent Aquatic and Terrestrial Ecosystems

Grant C Hose[a], Jodie Dabovic[b], Tess Nelson[a], Loren Pollitt[a], and Kathryn L Korbel[a], [a]Department of Biological Sciences, Macquarie University, Sydney, NSW, Australia; [b]New South Wales Department of Planning, Industry and Environment (DPIE) Water, Parramatta, NSW, Australia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Base-flow The sustained contribution of water from springs and seeps that maintains flow in streams and wetlands in the absence of inputs from rainfall and surface runoff.
GDE Groundwater dependent ecosystem.
Groundwater depth The distance from the surface to the groundwater table.
Groundwater flux The rate of groundwater flow.
Groundwater quality The physical and chemical properties of groundwater that determines its suitability for a specific purpose.
Groundwater pressure The force exerted by the groundwater as a consequence of its depth, the aquifer matrix and presence of over and underlying geological layers.
Groundwater regime A combination of groundwater conditions including pressure, flux, depth and quality of groundwater and the timing of its availability to meet the needs of an ecosystem.
Phreatophytic vegetation Deep-rooted plants that draw water from the saturated zone in the soil profile.
Stygofauna Aquatic subterranean fauna that are adapted to life in caves and aquifers.

Introduction

Groundwater dependent ecosystems (GDEs) are natural systems that require access to groundwater to maintain the diversity of plants and animals, ecological processes and ecosystem services provided by that ecosystem (Richardson et al., 2011). They need access to, and thus have a dependency on groundwater, which can be permanent or intermittent, and required by all or only a few species in the ecosystem, yet remains essential for the long-term persistence of the ecosystem in the landscape (Murray et al., 2003; Richardson et al., 2011).

Groundwater dependent ecosystems have played a critical, yet often unrecognized role in the development of ancient and modern civilizations and folklore. Groundwater springs and desert oases have been the nucleus for major cities that arose along ancient trade routes. For example, many cities along the silk road were established around springs and oases where the stable supply of water sustained populations, provided relief to parched travelers, and supported an ecosystem that provided food, resources for shelter, and enabled agriculture. Early hominids relied on the sustained flows in groundwater-fed wetlands of Tanzania (Ashley et al., 2009). Indigenous cultures of central Australia have had a close association with springs, soaks and groundwater fed swamps that were an integral part of their culture and beliefs (Moggridge, 2020). Today, major cities such as Las Vegas, USA have arisen around desert oases and others such as Bath, UK arose in c. 60 AD around thermal springs (springs chapter; Stevens, 2020). Indeed, more than half of the world's mega cities with >10 mill inhabitants are reliant on groundwater as their primary source of drinking water (Morris et al., 2003), and many major cities globally have significant groundwater issues (Foster, 2020).

Groundwater dependent ecosystems are found in a range of biomes and climate zones, and on all continents of the world, including Antarctica (e.g., Gooseff et al., 2013), and include terrestrial, freshwater and marine ecosystems. Despite their global distribution, they can be classified into three groups based on the ecosystem location (terrestrial/aquatic) and the water resource being used (above ground/below ground) (Box 1). This classification created by Eamus et al. (2006) encompasses all GDEs, including marine and subsurface systems, which are not always included in some regional classifications. In Australia, this

Box 1 Types of groundwater dependent ecosystems (from Eamus et al., 2006).

(I) Aquifer and cave ecosystems, also referred to as subterranean GDEs. Includes ecosystems occurring within karstic, fractured rock and alluvial aquifers (see Humphreys, 2006), as well as hyporheic zones of rivers (see Hancock et al., 2005), which often support a mixture of surface and groundwater organisms.

(II) All ecosystems dependent on the surface expression of groundwater. Also referred to as surface aquatic GDEs or groundwater associated aquatic (GWAA) ecosystems. This includes rivers, streams and wetlands that depend on groundwater for base-flow, springs, coastal lagoons and marine and estuarine areas receiving groundwater discharges.

(III) All ecosystems dependent on the subsurface presence of groundwater. Also referred to as surface terrestrial GDEs or groundwater dependent terrestrial (GWDT) ecosystems. This class includes terrestrial vegetation that accesses deep or shallow groundwater, in either the saturated or vadose zone. No surface expression of groundwater is required in this class of GDE.

classification system has been adopted as part of the National GDE atlas (BOM (Bureau of Meteorology), 2021). This classification is also consistent with the classification of GDEs established by the European Union, which recognizes Groundwater Associated Aquatic (GWAA) and Groundwater Dependent Terrestrial (GWDT) ecosystems (European Commission, 2012, 2015). The aim of this chapter is to provide an overview of the types of groundwater dependent ecosystems, their global extent, their biota, and the current threats to their integrity and existence.

Defining GDEs

In the context of GDEs, groundwater is water that is sourced from subsurface geological layers (aquifers). Groundwater can be utilized or accessed while still underground or used once it emerges at the surface. Groundwater dependent ecosystems rely on (are dependent on) the presence of groundwater to maintain the structure and composition of the ecosystem. Put another way, dependent ecosystems, or species there in would, over time, become locally extinct if the requirements for groundwater were not met. The dependence of an ecosystem on groundwater may vary with seasonal or climatic fluxes (e.g., drought), only requiring infrequent or occasional connectivity. As such, species may only require access to groundwater at specific life stages, or to supplement surface water supplies during drought. In addition, subsurface ecosystems depend entirely on consistent access to groundwater.

Each GDE, or species in it will, have its own set of groundwater "requirements" that must be met for that species or ecosystem to persist. Together, these requirements are referred to as the groundwater regime that is needed. Understanding the thresholds of these attributes for a GDE is critical for setting groundwater management targets and monitoring strategies.

In general, there are four key elements of a groundwater regime that are essential to GDEs (Eamus et al., 2016). These are:

1. Groundwater depth
2. Groundwater pressure
3. Groundwater flux
4. Groundwater quality

The importance of each of these attributes to each GDE type is outlined in Table 1 and is considered further in the following sections as each type of GDE is discussed.

Table 1 Importance of groundwater attributes to different types of GDEs.

GDE type	*Depth*	*Pressure*	*Flux*	*Quality*
Subterranean GDEs	• Provide habitat • Maintain groundwater stratification	• Fauna of deep aquifers may be pressure adapted	• Supply nutrients including organic matter and oxygen	• Maintain physico-chemical conditions to sustain biota and geochemical processes
Surface aquatic GDEs	• Provide open water or water-logged environment • Prevent activation of acid-sulphate soils • Maintain hydraulic gradient for groundwater discharge	• Sustain groundwater discharge to springs and surface waters	• Sustain above ground water levels including base flows • Prevent saltwater intrusion (estuarine/coastal environments) • Flow sufficient to modify conditions in surface environment	• Maintain suitable chemical composition of water for biota
Surface terrestrial GDEs	• Accessible water at root zones • Prevent water-logging		• Sustain water uptake rate (supplement transpiration losses)	• Maintain suitable chemical composition of water for biota

Adapted from Eamus D, Fu B, Springer AE, and Stevens LE (2016) Groundwater dependent ecosystems: Classification, identification techniques and threats. In: Jakeman AJ, Barreteau O, Hunt RJ, Rinaudo JD, and Ross A (eds.) *Integrated Groundwater Management*. Cham: Springer.

GDEs include a range of environments that support highly specialized species and ecosystems and possess unique biotic and abiotic characteristics that make them uniquely different from other ecosystems. GDEs all rely on groundwater for the maintenance of some or all, of their ecological functions (Murray et al., 2003). This dependence on groundwater can range from partial and infrequent dependence, such as seasonal or episodic groundwater use, to total continual access to groundwater and dependence. GDEs can range in area from small springs that may be less than 1 m^2 to forests that may cover hundreds of square kilometres.

Subsurface GDEs

Aquifers, and the groundwater within, account for over 95% of the available global freshwater reserves (Cantonati et al., 2020), making subsurface GDEs the world's largest freshwater biome. Subsurface aquatic GDEs are those that occur in saturated zones below the surface. These include water-filled voids in a variety of geological matrices such as karst (caves), fractured rock and alluvial ecosystems (Fig. 1A and B). They also include hyporheic ecosystems that occur in the sediments of surface waters and form an ecotone between surface and groundwater ecosystems. The hyporheic zones (Fig. 1C), their fauna and processes are discussed in detail in other chapters of this volume and are not discussed further here. Aquatic cave ecosystems (Fig. 1A) are also addressed in other chapters and will be mentioned only briefly below.

Subsurface GDEs may be further categorized based on the geology of the aquifer matrix. The geology strongly determines the size of the voids, which dictates the size of animals able to inhabit the aquifer, and the rate of flow of water. Caves and karst aquifers can have large voids able to support large invertebrates and even vertebrates and have high flows that can deliver large amounts of nutrients and oxygen from the surface. In contrast, aquifers comprised of gravels, sand and silt have smaller void spaces and because of that are constrained to supporting only small-bodied organisms (Dumnicka et al., 2020).

Groundwater environments are void of light, low in nutrients and oxygen, and habitat availability is limited by the size of the pores or fractures in the geological matrix. The groundwater environment is harsh, yet it supports an array of organisms including viruses, Archaea and Bacteria, Protozoa, Fungi and where habitat permits, invertebrates known collectively as "stygofauna" (Humphreys, 2006). It is estimated that 40% of prokaryote biomass on earth is located in the terrestrial subsurface, with microbial density estimates ranging from 10^2 to 10^6 cells per cm^3 in water and 10^4 to 10^8 cells per cm^3 in saturated cave and aquifer sediments (Griebler and Lueders, 2009). The majority of microbes within groundwater environments live in small colonies and biofilms attached to the sediment and rock matrix and provide a food source for larger organisms (stygofauna) to graze upon (Griebler et al., 2014).

Groundwater ecosystems are unique environments. With the lack of photosynthetic organisms in the dark subterranean environment, groundwater ecosystems heavily rely on external sources of carbon, filtering in from the surface. Heterotrophic bacteria, which rely on those allochthonous inputs of organic matter for energy, dominate microbial assemblages, but chemoautotrophic bacteria, which derive energy from inorganic sources, also occur (Gregory et al., 2014).

Stygofauna are essential in groundwater environments as they maintain effective porosity by burrowing, and grazing microbial biofilms and thus, control microbial communities (Griebler et al., 2019). Stygofauna are responsible for bioturbation within groundwater, assisting in biochemical circulation of essential nutrients, including carbon cycling, within aquifers and maintaining groundwater flow (Hose and Stumpp, 2019). Furthermore, stygofauna biodiversity has been linked to ecosystem functioning and services (Stein et al., 2010; Boulton et al., 2008).

Groundwater environments are influenced by a range of factors, all of which contribute to this unique environment. Geological factors including rock type, mineral composition and matrix porosity, combine with hydrological parameters such as hydraulic conductivity to create the physical and chemical habitat conditions that influence the irregular distribution of oxygen and nutrients throughout groundwater ecosystems (Schmidt et al., 2017). Together with the water chemistry (pH, dissolved oxygen concentration, nitrogen and salinity concentrations), these factors influence the distribution of organisms within groundwater (Johns et al., 2015; Korbel and Hose, 2015). However, water chemistry is also influenced by biogeochemical processes undertaken by the microbes living in groundwater (Chapelle, 2000).

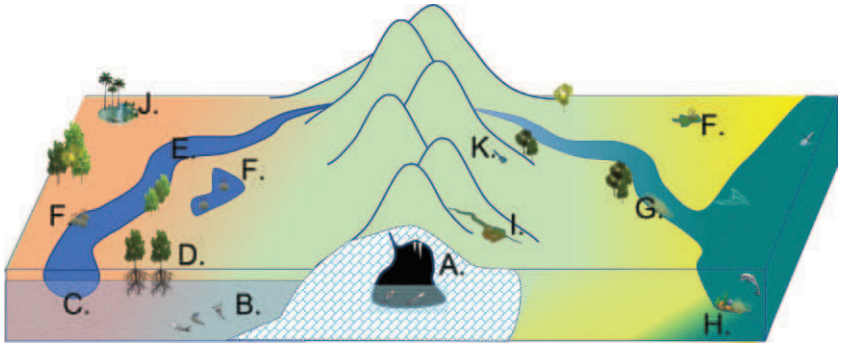

Fig. 1 Example types of groundwater dependent ecosystems in the landscape. A. cave and karst ecosystems, B. aquifer ecosystems, C. hyporheic ecosystems, D. phreatophytic vegetation, E. base flow of rivers and streams, F. wetlands, G. estuarine ecosystems, H. near-shore marine ecosystems, I. swamps and fens, J. springs and oases, K. hypotelminhoreic ecosystems.

Events linked to the hydrological cycle, such as precipitation and flooding, leading to recharge, are important parameters influencing biological assemblages in aquifers. Korbel and Hose (2015) show that the seasonality (during and after drought) accounted for a significant proportion of variation in microbial functional assemblage, while Reiss et al. (2019) showed major shifts in the composition and activity of bacteria, protists and invertebrates following an extreme flooding event. In both cases, aquifer recharge processes were strongly linked to changes in the aquifer ecosystem.

Terrestrial GDEs

For most plants, rainfall is the primary source of water but there are many plant species that routinely make use of groundwater to support their ecological functions and the ecosystem services they provide (Loheide and Booth, 2011; Kath et al., 2014). Vegetation will prioritize drawing water from areas of the soil profile where the least energy is required. This means that vegetation will use shallow soil water first before seeking deeper soil water or groundwater (Eamus and Froend, 2006). Plants will thus become increasingly dependent on groundwater as soil water becomes depleted (Howe et al., 2007).

In terms of water dependence, terrestrial plants span a continuum from vadophytes that rely solely on rainfall and do not access groundwater, to obligate phreatophytes that continually access groundwater and can cope with having some or all roots permanently inundated (Fig. 2). Facultative phreatophytes require groundwater at some stage of their life cycle, and although not requiring continuous access as do obligate phreatophytes, the availability of groundwater at those times may be critical for their survival. Phreatophytes often access groundwater via the capillary fringe or vadose zone (Eamus et al., 2006). Trees mostly take up groundwater from the capillary fringe because the direct uptake from below the water table is difficult due to the saturated and often low oxygen conditions (Eamus et al., 2006). Riparian and aquatic vegetation require continual access to water, which in many cases may be provided by groundwater base flows. Such plants typically have morphological and physiological adaptations to cope with having roots continuously in saturated soils and sediments.

In arid and semi-arid regions, groundwater is a critical resource for the local vegetation, as plants are often exposed to extensive dry periods where surface water is scarce, and transpiration exceeds precipitation (Eamus et al., 2006). Most groundwater-dependent vegetation relies on the availability of the groundwater being within the root zone just below the surface (Eamus et al., 2006). Large trees, for example, can persist for long periods of time without any rainfall, by sending tap roots down to the water table to access the groundwater below (Johansen et al., 2018, Fig. 1D). The *Banksia* woodlands of south-western Australia, and riparian forests of the San Pedro River Arizona, USA, are all examples of GDEs that require a supply of groundwater within rooting depth to maintain their structure and function (Zencich et al., 2002; Stromberg et al., 2006).

Methods for identifying vegetation using groundwater are outlined in O'Grady et al. (2006), Doody and Benyon (2011), Eamus et al. (2016), Doody et al. (2017), European Commission (2014) and others, and range from measurements of water use by individual trees, to remote sensing of canopy cover and "greenness" of large stands of vegetation over climatic cycles (Eamus et al., 2016; Doody et al., 2017; Dabovic et al., 2019). The identification of GDEs is often challenging because of the general limited availability of spatial information or even site-specific data on vegetation types, geology, soil properties and groundwater levels in many areas (Eamus et al., 2015). Information on groundwater levels, particularly in relation to the root depth of the vegetation, are critical for identifying groundwater-dependent vegetation, and this factor, as well as groundwater quality are the most critical attributes of the groundwater regime for this GDE type.

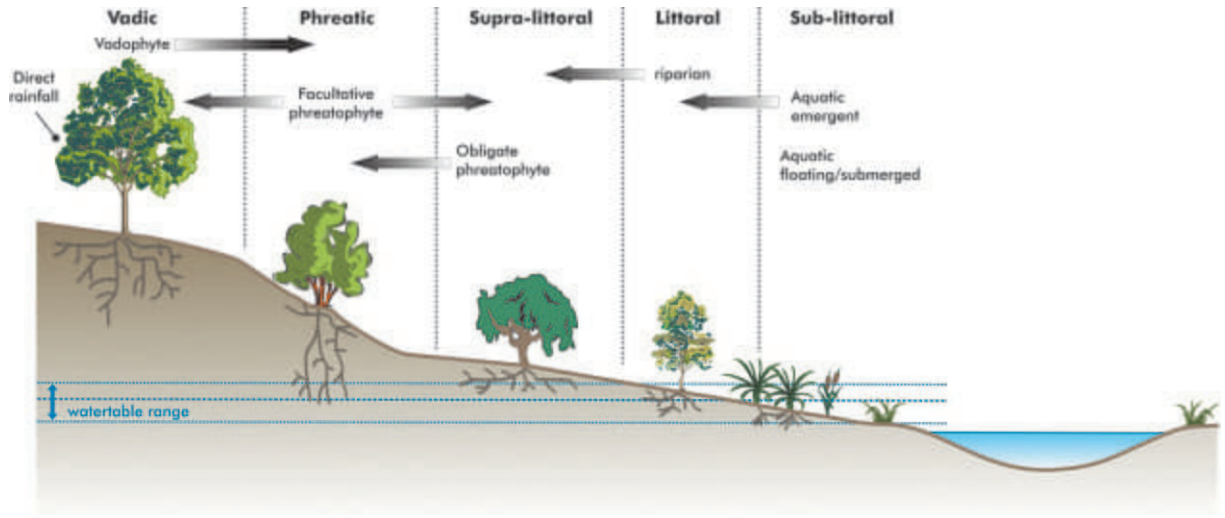

Fig. 2 Example types of groundwater dependent vegetation across a gradient of groundwater depth. From Pettit NE, Edwards T, Boyd TC, and Froend RH (2007) *Ecological Water Requirement (Interim) Framework Development: A Conceptual Framework for the Maintenance of Groundwater Dependent Ecosystems Using State and Transition Modelling.* A Report to the Department of Water. WA, Australia: Centre for Ecosystem Management, Edith Cowan University.

Aquatic GDEs

Aquatic GDEs include rivers and streams (Fig. 1E), wetlands (Fig. 1F), and marine and estuarine systems (Fig. 1G and H) that receive groundwater discharges. The discharge of groundwater to rivers and wetlands most commonly provides continuity of water supply, particularly in dry times when surface flows are limited, and groundwater discharge provides a base level flow. In many cases, the discharge of groundwater is essential for maintaining minimum levels of saturation or keeping river pools topped up so that they may provide a refuge habitat until surface flows return. The discharge of groundwater, often starting as a spring that seeps into surface waters to provide base-flows are critical to the survival of surface water ecosystems and their biota. This is particularly the case in arid and semi-arid environments where surface water flows are unpredictable.

In marine and estuarine environments, the discharge of groundwater often shapes the local physico-chemistry of water in the receiving environment and alters ambient conditions to suit a particular plant or animal species or processes. For example, the discharge of groundwater to nearshore marine systems can lower salinity and provide unique habitat (Leitão et al., 2015) and discharge of warm groundwater to rivers and streams provides habitat for spawning salmon (Saltveit and Brabrand, 2013).

The flow provided by groundwater discharges is essential to maintaining permanently wetted habitat in rivers and streams. Under increasing climate variability and changing rainfall patterns associated with global warming, groundwater discharges are increasingly important for maintaining constant flows in rivers and streams. Under hot and drought conditions, base flows are vital for maintaining refuge habitat. Even in temperate areas, base flows provide sufficient water depth and flow velocity over riffle habitat, and maintain permanent stream pools to support spawning and growth of stream biota (e.g., Hunter and Gillespie, 2011; Larsen and Woelfle-Erskine, 2018). In these cases, the ecosystem is likely dependent on a volume (or rate) of groundwater discharge, which is influenced by the groundwater depth (for unconfined aquifers) and pressure (for confined aquifers) and the flux, which defines the rate of groundwater moving through and out of the aquifer.

Wetlands are highly diverse and are generally characterized into five types (riverine wetlands, lacustrine wetlands, palustrine wetlands, estuarine wetlands and marine wetlands) (Cowardin et al., 1979), which each may be dependent on groundwater (Howe et al., 2007). Wetland vegetation across all wetland types is highly reliant on the degree of soil saturation and as such, wetland species are particularly vulnerable to hydrological changes (Le Maitre et al., 1999; Johansen et al., 2018). Currently the focus of research and management has been on understanding the environmental flow requirements of wetland communities and species (e.g., Powell et al., 2008; Roberts and Marston, 2011; Hernández-Guzmán et al., 2019), and the dependence of wetlands on groundwater is rarely quantified and not well understood (Howe et al., 2007; Johansen et al., 2018).

Some wetlands may be completely dependent on groundwater discharges to maintain water levels or soil saturation, whilst others may have limited dependence, such as at different times of year or stages in the plant life cycle (Thorburn et al., 1994a, b; Mudd, 2000). However, even small amounts of groundwater can be ecologically important, with small seepages supporting unique plant and animal communities, or trickling flows that maintain water levels in river pools. The physico-chemical properties of groundwater are critical to the biochemical processes of the wetland. For example, alkaline groundwater buffers wetland sediments and pore water, prevents acidification (Boomer and Bedford, 2008) and reduces the phosphorus bioavailability (Wassen et al., 2005). Waterlogging limits nutrient and oxygen availability (Almendinger and Leete, 1998) yet can promote high species diversity through the consequent lack of competition (Kotowski et al., 2010). The water table dynamics also influence oxidation-reduction (redox) conditions in the sediments which control the binding and release of carbon and phosphorus in sediments, and its availability to support plant and algal growth and other processes (Pant et al., 2003; Lucassen et al., 2005; Villa and Bernal, 2018; Were et al., 2019).

Included in this category are some peatlands (Fig. 1I) which, although often capturing and retaining rainfall, also require groundwater inputs. Peat swamps in the temperate highlands of eastern Australia (Cowley et al., 2019) maintain a saturated sediment profile with water derived predominantly from local groundwater, however the relative surface water and groundwater inputs to these systems varies across the landscape. For these systems also, the key variables of the groundwater regime are flux and quality. Groundwater depth is often not such a critical concern as it is derived from seeps and springs higher in the catchment (Cowley et al., 2019). However, in fens (peat swamps) in central Oregon, USA, groundwater depth is critical to maintaining plant diversity and peat formation (Aldous and Bach, 2014).

The dominance of shallow-rooted vegetation in wetlands (Fig. 2) means that wetland plants may be more susceptible to water table declines than deep-rooted phreatophytic vegetation (Dillon et al., 2009). A decline in water tables can result in the loss of water tolerant species, which will be gradually replaced by woody terrestrial species and those with broader ecohydrological ranges. In response to water table decline, many wetlands display a proportional response to drawdown, in which the magnitude and rate of water level change is critical in determining the magnitude of impacts (Froend et al., 2004; Dillon et al., 2009).

Along with wetlands, many flowing surface water ecosystems are dependent on groundwater to maintain flow during dry (low rainfall) periods when runoff is insufficient to maintain inundated habitat. In such systems, base flow is maintained by the surface discharge of groundwater. Base flow discharges are critical for maintaining habitat in rivers and streams (Beatty et al., 2010; Choi et al., 2018) and the degree of dependence strongly influences the structure and function of the fish, invertebrate, plant and microbial communities, and the connectivity among habitats within the landscape (Nevill et al., 2010).

Baseflow streams require groundwater depth, pressure and flux that enable sufficient surface discharge. For many streams that gain water from adjoining aquifers (termed “gaining streams”), the groundwater level must be similar to the river or stream water level. Groundwater flux must also be sufficient to maintain a gradient toward the river so that the stream continues to gain water from the aquifer and not lose water to it (termed “a losing stream”). The physico-chemical properties of the groundwater must be

suitable to support life in the stream. For example, the discharge of contaminated groundwater can be problematic to rivers, streams and coastal areas (e.g., Welch et al., 2019), or a change in groundwater temperature may affect the suitability of habitat for fish spawning (e.g., Ficke et al., 2007).

Springs (Fig. 1J), as surface discharge points for groundwater, are widespread globally (Olarinoye et al., 2020). They include desert oases, emergent cave streams and artesian mound springs, and globally are under multiple threats (Cantonati et al., 2020). The ecology of springs is described in detail in other chapters of this volume.

Small groundwater seeps can create permanent, but localized pockets of saturated soil that provide habitat for a unique fauna that often contains species characteristic of subterranean habitats. These small seeps are referred to as hypotelminorheic habitats (Fig. 1K, Culver et al., 2006). Environmental conditions in these systems are rather unique, with a mixture of groundwater and saturated, highly organic soils and leaf material (Culver et al., 2006). They support highly localized, short-range endemic species (occupying a range <5 km (Culver et al., 2006)) and have a species richness that rivals some cave systems. Hypotelminorheic habitats are suggested to be a key pathway for the colonization of subterranean ecosystems by surface fauna (Culver et al., 2006).

The discharge of groundwater to the near-shore marine and estuarine environments (Fig. 1 G.H) is critical to maintaining conditions in sea grass and other habitats that are essential for biota and ecological processes. Although beyond the scope of this chapter, near shore marine GDEs are discussed in more detail in Lecher and Mackey (2018) and Taniguchi et al. (2019).

Threats to GDEs

Groundwater dependent ecosystems are of considerable economic and ecosystem service value (Murray et al., 2006). They provide recreation and tourism opportunities, tangible goods in terms of water, timber and agricultural products, as well as providing valuable ecosystem functions such as maintaining groundwater geochemistry, carbon and nutrient sequestration, stabilizing soil, limiting erosion, maintaining land and water quality, capturing runoff, and preventing dryland salinity (Murray et al., 2006; Kløve et al., 2011; Griebler et al., 2019).

GDEs are under threat the world over because of the growing global demand for groundwater (Kløve et al., 2011). In addition, land clearing and the removal of riparian and terrestrial vegetation, as well as alterations to the hydrology of aquifers, wetland and rivers results in the destruction of GDEs (Kløve et al., 2011). Urbanization, particularly the replacement of natural surfaces with concrete and other impervious surfaces can reduce water infiltration, such that groundwater levels are not readily replenished, and have been linked to the degradation of GDEs (Fryirs et al., 2016; Bugnot et al., 2019).

In addition to habitat loss or change, land use change poses a significant threat to GDEs due to the risk of contamination and change in groundwater quality (Korbel et al., 2013). Groundwater quality is a critical element of the groundwater regime for all GDEs (Table 1, Hose et al., 2004). Heavy metals, pesticides, nutrients and organic chemicals derived from urban development, mining, agriculture and many other activities have the potential to alter subsurface ecosystems impacting their ability to provide necessary functions, such as water purification. There is an established body of ecotoxicological data that are applicable for protecting surface aquatic GDEs but data for terrestrial and subsurface GDEs (e.g., Castaño-Sánchez et al., 2020) remain limited (Hose et al., 2004).

The second threat is primarily associated with the extraction and pumping of groundwater for industrial purposes (Nevill et al., 2010) and occurs when groundwater is extracted at a faster rate than the water is replenished, resulting in a lowering of the water table and reduction of groundwater flow (Nevill et al., 2010). Deep-rooted plant species can become stressed when the water table drops below the rooting depth, which can have a flow on effect to the functioning of the surrounding ecosystem (Cramer et al., 1999).

Groundwater drawdown also has direct effects on subsurface GDEs. Lowering groundwater tables amounts to habitat loss for subsurface GDEs as previously saturated sediments become dry and uninhabitable for groundwater fauna (Stumpp and Hose, 2013). The effect of groundwater extraction can be to lower water tables (increase depth to groundwater), particularly for unconfined aquifers, and a reduction in pressure for confined aquifers. The reduction in aquifer pressure is manifest as decreased flow for example from artesian springs, and lesser volumes discharged to support surface aquatic GDEs (Hayashi and Rosenberry, 2002). Changes in groundwater flow and pressures due to pumping also changes interactions with surface water ecosystems (Sophocleous, 2002). Related impacts include the reduction of nutrients and oxygen inputs as connections with rivers and wetlands are lost, while in coastal areas, ingress of marine water impacts coastal groundwater quality, as reduced flow and pressure of fresh groundwater allows saltwater intrusion. The threat of groundwater abstraction is often unintended and the consequences for all GDE types are poorly understood (Eamus et al., 2016).

Knowledge gaps

1. The global distribution of different GDE types
2. Details and thresholds of change in groundwater attributes that affect GDEs
3. Degree of dependency of ecosystems on groundwater attributes
4. The impact of water quality changes on GDEs
5. Impacts of climate change on groundwater regimes and GDEs

This is an update of H.M. Valett, R.W. Sheibley, Ground Water and Surface Water Interaction, In Encyclopedia of Inland Waters, Edited by Gene E. Likens, Academic Press, 2009, https://doi.org/10.1016/B978-012370626-3.00019-3.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Amphibite Animals (typically invertebrates) with phases of their life cycle adapted to both groundwater and surface environments.
Baseflow Both a temporal distinction of channel flow describing flow that occurs without the influence of recent precipitation and a spatial orientation where groundwater flowpaths are generally perpendicular to the channel.
Damköhler numbers Numbers adopted from chemical engineering that relate alternative fates of solutes (transport or transformation) in a reactor; used to quantitatively describe reactive transport dynamics in environmental systems.
Groundwater Water present beneath the Earth's surface in rock and soil pore spaces and in the fractures of rock formations.
Hydrodynamic driver Relating to pressure gradients on the surface of the streambed primarily resulting from the momentum of channel water molecules interacting with geomorphic features that cause water to flow into the hyporheic zone; hydrodynamic forces strongly influence shallow hyporheic fluxes at fine to moderate spatial scales (e.g., bedforms, pool-riffle sequences).
Hydrostatic driver Relating to the pressure gradients on the streambed surface driven by the depth of the overlying water; hydrostatic forces influence hyporheic fluxes over coarse spatial scales (e.g., reaches or greater).
Hyporheic zone Subsurface volume beneath and lateral to a river or stream characterized by the bidirectional exchanges of water and resources with the stream channel.
Phenomenological models Models that quantify GW-SW exchange or related processes with mathematics that represent the influence of numerous physical drivers without simulating them explicitly.
Physically-based models Mechanistic models that quantify GW-SW exchange or related processes as a function of a suite of physical drivers.

☆*Change History*: November 2021. HM Valett prepared the update. Sections/figure/tables are updated within the article.

Stygobite Obligate groundwater animals (typically invertebrates) with evolutionary history shaped by subsurface environments.
Underflow Groundwater flow that is generally parallel to the longitudinal axis of the stream channel.

Introduction

The hydrologic processes of infiltration, recharge to groundwater, and discharge to channels illustrate the implicit connectivity between groundwater and surface water. Historically, the existence of streams has been argued to be a manifestation of groundwater-surface water (GW-SW) interaction because channel flow typically originates from groundwater discharge. Hence, it is not surprising that hydrologists and ecologists working on streams have led the way in pursuit of understanding GW-SW interactions.

In particular, research addressing GW-SW in streams has focused on the hyporheic zone (Orghidan, 1959), defined here as the subsurface zone beneath and laterally adjacent to a stream channel, characterized by the bidirectional exchange of water between the surface and subsurface (Boulton et al., 1992). Thus, exchange with the hyporheic zone is a type of 'hydrologic exchange flow' (Harvey and Gooseff, 2015), flow that includes lateral and vertical transport of water, materials, and energy between rivers and their surrounding marginal surface and subsurface waters.

This chapter addresses the ecological and hydrologic properties of hyporheic zones, and also reviews GW-SW influences on other inland waters. We first consider how GW-SW exchange has the potential to alter hydrologic, biogeochemical, and biological conditions associated with streams. It then covers flow systems, drivers of GW-SW interaction, and how such exchange flows are measured across scales of assessment. Sections on the modeling of hyporheic flow and reactive transport in the hyporheic zone address an active area of investigation, exploring both theoretical and applied research challenges. Finally, a short overview of GW-SW interactions in the floodplains of larger rivers and in lakes and wetlands is followed by an assessment of knowledge gaps and areas for future research in the context of environmental change.

Implications of hyporheic GW-SW interactions for aquatic ecosystems

Historically, the hyporheic zone has been studied as habitat for unique invertebrate fauna. Classification systems categorizing types of subsurface animals rely on the evolutionary history of the biota and the nature of their affiliation with groundwater habitats (Gibert et al., 1994). Macroinvertebrate assemblages in environments that receive water from and return water to the channel (i.e., hyporheos or stygophiles) are dominated by insects, often similar to benthic forms found on the stream bottom (Boulton and Stanley, 1995). In contrast, groundwater environments that are more isolated from hyporheic systems (i.e., phreatic water) support invertebrates with marine ancestry, predominantly crustaceans with obligate groundwater affinity (i.e., stygobites) frequently lacking eyes and pigment (Dole-Olivier et al., 1993). Other invertebrates that utilize both hyporheic groundwater and benthic environments (i.e., amphibites) share taxonomic affiliation with surface assemblages and emerge from streams as adults, but also display evident evolutionary adaptation to life underground (Stanford and Gaufin, 1974; Stanford and Ward, 1988). These kinds of affiliations underpin why the direction and magnitude of exchange can dictate the taxonomic composition and abundances of animals that live at the GW-SW interface.

Hyporheic exchange also influences habitat for surface biota. Purposefully borrowing terminology from oceanographers, areas of losing (i.e., influent) reaches are 'downwelling zones' and gaining (i.e., effluent) reaches are 'upwelling zones,' emphasizing the potential for nutrient delivery to alter benthic biological conditions (Valett et al., 1994). For instance, in nutrient-poor desert streams, upwelling nutrient-rich water promotes growth of algal forms that flourish among abundant nutrients (Fig. 1A) while downwelling portions of the reach are dominated by nitrogen-fixing cyanobacteria (Fig. 1B). Similarly, patterns of distribution and abundance of aquatic plants have been tied to the direction of exchange (Hendricks and White, 1988; Jones et al., 2008). The distribution of salmonid redds is also strongly related to distinct patterns of hyporheic exchange (Baxter and Hauer, 2000). The spatial configuration of discharge and recharge may organize responses by algae and aquatic plants, benthic macroinvertebrates, as well as fishes and water fowl that occupy surface environments in freshwater systems (Jones and Holmes, 1996).

Hyporheic zones themselves are well recognized as metabolically active systems that support mainly heterotrophic food webs linked to surface inputs of organic matter (Grimm and Fisher, 1984; Jones Jr. et al., 1995a; Fellows et al., 2001) Moreover, they are biogeochemically distinct environments. In many systems, downwelling of water that is rich in organic carbon supports metabolic activity in near-stream groundwater (Findlay et al., 1993) while mineralization of organic material in the subsurface can increase inorganic nutrient pools (Triska et al., 1994). The juxtaposition of electron donors and acceptors that occur at the GW-SW interface supports unique transformations (Dahm et al., 1998). Thus, the direction of exchange is a critical aspect of GW-SW interaction because surface and groundwater environments often differ markedly in their physicochemical composition (e.g., heat, redox potential, pollutants). For instance, surface water systems are generally characterized by turbulent flow and, thus, are typically oxic as compared to subsurface environments where dissolved oxygen content is reduced by chemical and biological demand. Accordingly, the hyporheic zone is often characterized by steep gradients in concentrations of oxidized and reduced compounds (Triska et al., 1989), rendering them biogeochemical hotspots (sensu McClain et al., 2003).

Hyporheic zones support diverse assemblages of microbes (Hendricks, 1993, 1996; Storey et al., 1999) that respond to and alter biogeochemical constituents introduced via GW-SW interaction (Feris et al., 2004, 2009). Because of the microbial and geochemical capacity for hyporheic zones to process a broad array of constituents, hyporheic zones have been referred to as the river's liver

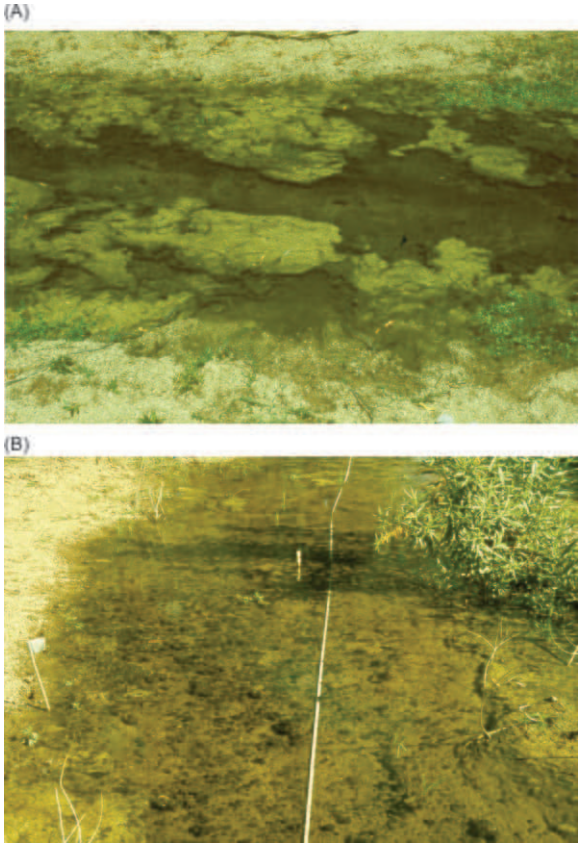

Fig. 1 Benthic algal responses to groundwater-surface water exchange in Sycamore Creek, Arizona, United States. (A) Groundwater discharge in upwelling zones supplies nitrogen from nutrient-rich interstitial environments and supports luxurious blooms of the green alga *Cladophora*. (B) Just 150 m downstream, in a downwelling zone, surface nitrogen concentrations are lower and the benthic flora is dominated by nitrogen-fixing blue green bacteria of the genus *Nostoc*. Photographs by H.M. Valett.

(Fischer et al., 2005). Hyporheic zones have been shown to be instrumental in terms of changing the form and abundance of nutrients that may potentially limit surface water productivity. For instance, studies have documented active hyporheic nitrification and denitrification (Triska et al., 1990; Jones Jr. et al., 1995b; Triska and Duff, 1996; Sheibley et al., 2003). Similarly, nutrient processing in the hyporheic zone of smaller streams (Mulholland et al., 1997; Lapworth et al., 2011) and larger rivers (Vervier et al., 2009) alters phosphorus abundance.

Hyporheic zones also have the capacity to provide critical ecosystem services. For instance, hyporheic zones attenuate transport of mining-derived pollutants (Gandy et al., 2007). Microbial and geochemical processes in the hyporheic zone of contaminated systems influence the concentrations, oxidation states, and mobility of metals, including manganese (Harvey and Fuller, 1998), arsenic (Nagorski and Moore, 1999), chromium (Yang et al., 2018), uranium (Fritz and Arntzen, 2007) and selenium (Arnold et al., 2016) among others. Many organic contaminants are also susceptible to hyporheic transformation and degradation (Lewandowski et al., 2011; Peter et al., 2019). The efficiency with which hyporheic zones process materials results from the catalytic role of microbiota and the balance between material reaction and transport.

The hydrology of hyporheic flow paths is thus a critical organizer of the magnitude and character of chemical loads and associated water residence times (i.e., amount of time spent in flows linking surface and subsurface environments). In this way, the nature of GW-SW exchange sets a physical potential for delivery of water and materials that is acted upon by biological and chemical processes. In combination, these drivers determine conditions experienced by biota that manifest as ecological structure and function within the hyporheic zone with implications for functioning at the whole-system scale (Fig. 2, Valett et al., 1996).

A number of studies have illustrated the potential influences for GW-SW exchange and biogeochemical processing within the hyporheic zone to influence the spiraling of nutrients at the whole-stream scale. Metabolic activity in the hyporheic zone has been tied to shorter spiraling lengths for phosphorous (Mulholland et al., 1997) while greater GW-SW interaction was associated with shorter uptake lengths (i.e., downstream distance required for removal from the water column) for nitrate-nitrogen across streams with different parent lithologies and propensity for hyporheic exchange (Valett et al., 1996). In tropical systems, Gücker and Boëchat (2004) found that stream geomorphology, including measures of hyporheic zone size, determined uptake of ammonium-nitrogen. In fact, Runkel (2007) championed a transport-based assessment of nutrient spiraling that directly linked GW-SW exchange to uptake dynamics, emphasizing the intimate links between them. Conversely, Sheibley et al. (2014) showed that hyporheic exchange is a poor predictor of spiraling in agricultural streams wherein rates of water and nutrient exchange between the surface and subsurface are typically low.

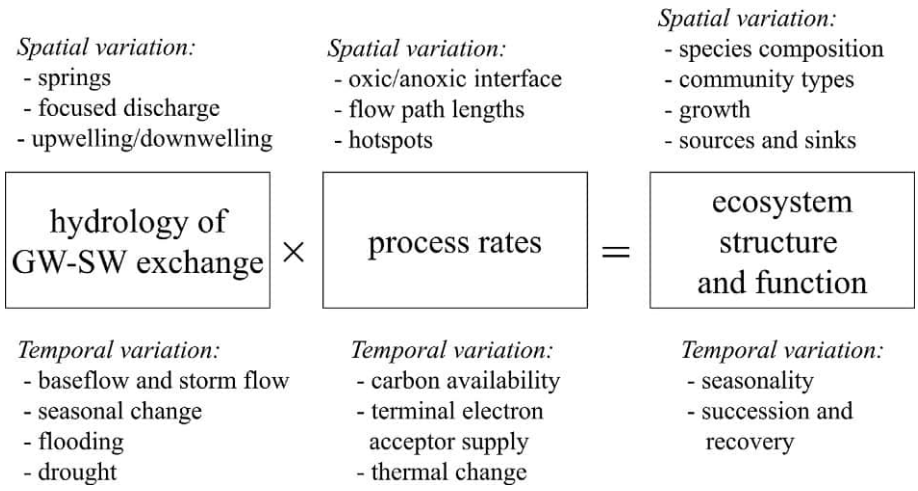

Fig. 2 A general schematic model relating how hydrologic and both geochemical and biological processes dictate the influence of groundwater-surface water exchange on various aspects of inland water environments. Determinants vary with space and time at multiple scales. Hydrologic influences include the magnitude, timing, and locations of interactions between groundwater and surface water. Moreover, hydrologic variance dictates water residence times with implications for how processes influence water availability and composition. Geochemical and biological processes alter water abundance and chemical quality and interact with hydrologic vectors to determine the net influence of exchange on physical, chemical, and biological aspects of inland aquatic ecosystems. Modified from Valett HM, Morrice JA, Dahm CN and Campana ME (1996) Parent lithology, surface-groundwater exchange, and nitrate retention in headwater streams. *Limnology and Oceanography* **41**: 333–345, with permission.

Flow systems, scales, and drivers of GW-SW characterization

Aquifers are linked to above-ground bodies of water at multiple spatial and temporal scales that constrain and characterize the hydrologic character of GW-SW interaction. Early work by Tóth (1963) recognized regional, intermediate, and local 'flow systems' and classified them by the temporal and spatial scales that link precipitation and recharge to groundwater discharge and channel runoff (Table 1). Our addition of a 'proximate' scale emphasizes flow paths of smaller extent that embrace much of the GW-SW interaction associated with hyporheic zones.

In running waters (i.e., lotic systems), water fluxes across the streambed are dictated by the gradient in hydraulic head (i.e., energy per unit weight). At smaller scales, the influences of flow velocity and the pressures created by water interacting with geomorphic features, such as bedforms or point bars, represent 'hydrodynamic' contributions to total head and dictate the magnitude and character of exchange. In contrast, the 'hydrostatic' component of the total head reflects the influences of elevation and the height (i.e., pressure) of overlying water. Water velocity does not contribute to hydrostatic pressure head. Hydrostatic forces are predominant drivers of exchange at larger spatial scales.

Hyporheic exchange flows have a wide range of water velocities and vary widely in terms of subsurface distances travelled. However, flow regimes emerge wherein GW-SW exchange is closely coupled to distinct elements of the stream channel because the mechanisms driving exchange differ in magnitude and etiology across spatial sales (Fig. 3). As emphasized by Boano et al. (2014), this coupling results in predictable patterns between hyporheic residence times and the length or depth of the geomorphic feature associated with the exchange, giving rise to 'characteristic residence times' and 'characteristic flowpath lengths', respectively. Fluid residence times and distances travelled shape how GW-SW exchange influences ecosystem structure and function (see Section "GW-SW interaction, reactive solutes, and the Damköhler number" below).

Table 1 Flow systems linking surface and groundwater at multiple scales.

Flow System	*Connection with Surface Recharge*	*Flow Rates ($m\ d^{-1}$)*	*Oxygen Status*	*Potential for transport form the surface*	*Example*
Regional	Virtually nonexistent	Almost stagnant	Anoxic/Anaerobic	Virtually nonexistent	Deep basin/petroleum reservoirs
Intermediate	Small	Slow	Generally Anoxic/ Anaerobic	Moderate	
Local	Extensive	0.0001–0.001		High	Confined aquifer
Proximate	Extensive	Fast	Often Oxic and Aerobic	Extremely High	Water table aquifer
		0.001–0.01	Fully Anoxic		Hyporheic zones, Seepage lakes
		Extremely Fast	Fully Oxic		
		1–1000	Mixed

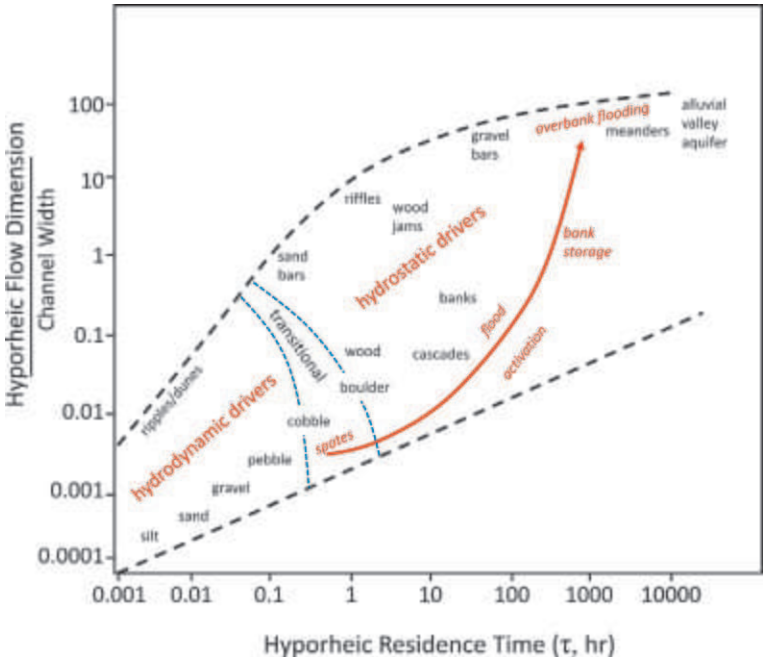

Fig. 3 Schematic representation of the scaling of hyporheic zone size (normalized to river channel width) vs. the time water spends involved in GW-SW exchange. Dashed black lines are boundaries on the spatial and temporal behavior of hyporheic flow. Features of lotic systems that influence exchange are listed within the described functional space at locations commensurate with their characteristic spatial and temporal behavior. Terms in red denote important regimes of hyporheic flow and the role of channel flow in activating them (red arrow). The dashed blue lines illustrate transitional conditions where exchange flows are influenced by both hydrodynamic forces (i.e., velocity and momentum) and hydrostatic drivers (depth, slope). Redrawn from Boano F, Harvey JW, Marion A, Packman AI, Revelli R, Ridolfi L and Wörman A (2014) Hyporheic flow and transport processes: Mechanisms, models, and biogeochemical implications. *Reviews of Geophysics* **52**: 603–679. doi: 10.1002/2012RG000417, Published with permission.

Hydrodynamic drivers are responsible for generating flow through shallow pathways shorter than the stream's depth and are closely associated with streambed substrates. They are highly influential in systems with bedforms composed of silt and sand, typically at the scale of centimeters to tens of centimeters in small streams. However, these types of exchange flows can also occur through mega-bedforms of several meters height and over hundreds of meters in rivers like the Mississippi, Amazon, and Parana (Boano et al., 2014). In contrast, hydrostatically driven exchange reflects changes in stream slope associated with transitions among riffles, runs, and pools, and with gravel bars and meanders. These flowpaths may extend far from the river, up to many hundreds of meters (Stanford and Ward, 1988) with residence times of many hundreds of days (Helton et al., 2014). While these exchange regimes are better described for streams and rivers, similar mechanisms apply to shallow areas of lakes, reservoirs, estuaries, and shoreline oceanic habitat, driven by currents and wave forces.

Biological processes and structures can also influence GW-SW exchange. For example, beaver dams (Lautz et al., 2010) and salmon redds (Gottesfeld et al., 2004) alter exchange as a result of changing instream features. Even small invertebrates such as crayfish (Johnson et al., 2011) and caddisflies (Tumolo and Albertson, 2020) can influence streambed hydraulics; additionally, the biological activity of a wide range of invertebrates can induce flow (i.e., bioirrigation) via activities that alter and organize sediment structure (bioturbation). Finally, aquatic plants and algae can alter stream bed roughness, influencing water residence times and streambed exchange (Hendricks and White, 1988).

Measuring GW-SW interaction: Methods and approaches

Measuring GW-SW exchange

Two general classes of methods for measuring GW-SW interaction can be recognized: physically-based and phenomenological methods. These distinctions apply to direct measures of GW-SW exchange, simulation modeling (see Section "GW-SW interaction, reactive solutes, and the Damköhler number"), or a combination of both. Physically-based methods rely on understanding the physics of the hydrological processes controlling exchange. Approaches in the second class are considered 'phenomenological'. These require observations collected from the system that are interpreted to assist in the quantitative characterization of GW-SW exchange. While data are required for either approach, phenomenological methods are so named because patterns in direct observations are represented with math based on empirical relationships or "phenomena", as opposed to representing mechanisms directly.

Flumes and laboratory studies

Use of flumes and laboratory studies to address GW-SW exchange provides opportunities to experimentally establish forms of roughness elements, to directly control flow, and to alter a single feature, and the physics associated with it, via experimentation. These approaches allow for the development and verification of physically-based simulation models (see Section "Modeling GW-SW exchange") and also facilitate direct measures of the forces and pressures responsible for exchange. Accordingly, they typically address hydrodynamic exchange associated with small-scale bedforms using chemical tracers (e.g., dye or salt).

Field assessment of GW-SW exchange

Measures of GW-SW exchange at field scales include indirect measures via stream flow gauging, hydrometric approaches, and tracer-based methods. The different techniques used involve tradeoffs between specificity and generality related to the spatial scale at which they are employed.

Mass-balance approaches

The magnitude of GW-SW exchange can be determined indirectly through mass-balance approaches that rely on measuring channel flow at designated locations, accounting for tributary inputs, and quantifying exchange by difference. The approach is challenging in complex channels that are shallow and wide, and in larger channels where flow is swift and often associated with unstable streambeds. A combination of dilution gauging (i.e., tracer dilution along a stream reach, see Section "Tracer-based methods" below) and use of acoustic velocimeters has increased the applicability and accuracy of this approach. The same mass-balance approaches apply to lakes and wetlands but require more accurate measures of loss from the water body to the atmosphere via evaporation and evapotranspiration.

Hydrometric approaches

Exchange fluxes can be estimated directly using hydrometric approaches that include measuring hydraulic head gradients vertically and horizontally in the stream bed (Fig. 4A), estimating streambed hydraulic conductivity (K; Chen, 2000), and calculating flux via Darcy's Law. Accurate measures of K are notoriously difficult to obtain, in part due to extensive spatial heterogeneity. Basic estimates

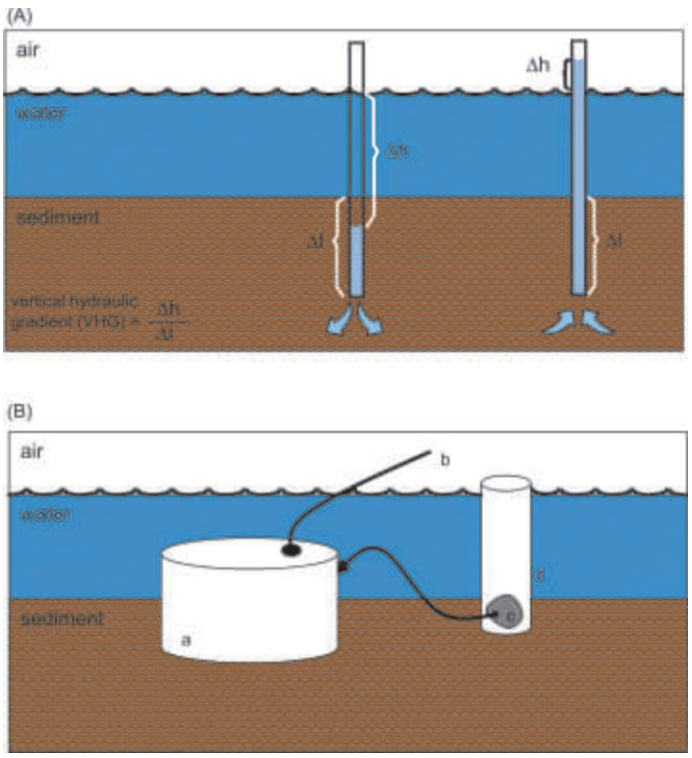

Fig. 4 Schematic representations of the use of (A) mini-piezometers to measure vertical hydraulic head gradients, and (B) seepage meters to quantify volumetric groundwater-surface water exchange in streams. Mini-piezometers allow for comparison of hydraulic heads at depth with surface water potentials. The vertical hydraulic gradient (VHG) is then calculated as the head difference divided by the depth of the piezometer, combined with measures of sediment hydraulic conductivity, and used in Darcy's Law to calculate exchange. Seepage meters measure volumetric flux directly and include an open cylinder (a) inserted into stream sediments and vented to the atmosphere (b). Groundwater discharge is collected in a plastic bladder (c) placed in a stilling well (d).

of K can be derived from laboratory analysis of grain sizes derived from sediment cores. Other methods of assessing K involve pump tests and monitoring wells that provide information on larger scales.

Direct measures of the volumetric flow of water across the surface-subsurface boundary can be provided by seepage meters (Fig. 4B). A seepage meter typically consists of a bottomless cylindrical chamber vented to a plastic bladder. Under conditions of groundwater discharge, flow from the substrate to the water column will collect in the bladder at a measurable rate. Infiltration from the surface to subsurface may be measured as a loss of water purposefully placed into the bladder at the time of chamber deployment. These types of seepage meters have been used extensively in lakes, estuaries, and reservoirs, and less frequently in streams.

Tracer-based methods

Whether direct or indirect, hydrometric methods are effective at relatively small scales ranging from gravel bars to features as large as relatively short (i.e., 10–100 m) reaches. Environmental tracers are often employed when investigators desire information on GW-SW interaction at larger scales. Often, traditional hydrometric approaches (e.g., use of wells and piezometers) are combined with the use of tracers to address spatially distributed measures at larger scales. Below, we provide a brief introduction to the use of tracers; for a recent detailed review of the use of environmental, biological, and anthropogenic tracers, see Abbott et al. (2016).

Environmental tracers are ambient natural or human-derived compounds found widely distributed in the Earth's shallow environments that may be used in hydrologic studies to discern sources, pathways, and timescales of interaction between surface and subsurface waters. To be useful, environmental tracers should naturally occur at different concentrations characteristic of potential sources (e.g., groundwater vs. channel water). The concentration in different water types allows calculation of mixing proportions among proposed sources. Examples of commonly used environmental tracers include specific electrical conductivity, chloride and other major ions, or stable isotopes of water (i.e., ^{18}O, ^{2}H). A range of radioisotopes have also been used to assess GW-SW exchange. More recently, human-derived compounds like caffeine or pharmaceuticals have been employed as environmental tracers with particular focus on materials derived from waste water treatment plants.

Heat in groundwater and surface water can also be used as a tracer to assess GW-SW exchange, an approach that has grown in popularity with the advent of inexpensive, easily-deployable temperature sensors. Most studies of this type employ vertical arrays of sensors to track GW-SW mixing across the streambeds, but also in wetlands and floodplain environments. Quantitative information is also being obtained by applying heat transport equations that account for both conductive and convective transport and heat balance. With this approach stream temperature is the function of groundwater discharge rate, differences in stream and groundwater temperature, stream flow, and heat exchange from the stream surface. Thus, net heat (and water) flux from groundwater is derived by difference.

Efficacy of studies utilizing tracers can be improved by introducing known tracers via solute releases (i.e., solute injections). Injections introduce conservative (i.e., unreactive) tracers—typically inorganic anions like Cl^- or Br^- or fluorescent dyes like rhodamine—that are tracked downstream both in surface and groundwater environments to address mixing between the channel and hyporheic zone. Sampling of the tracers over time generates breakthrough curves (Fig. 5) that can be analyzed to characterize GW-SW exchange. Breakthrough curves from channel water locations can also be used to determine stream flow via dilution gauging (Gordon et al., 1992) where integration of the concentration versus time curve yields flow magnitudes that can be used in mass-balance approaches. Breakthrough curves can also be used in modeling approaches assessing exchange (see Section "Modeling GW-SW exchange" below). Combining tracer methods with hydrometric measures of exchange includes measuring differences in tracer concentrations among wells and piezometers to derive spatial distributions of the extent and rates of exchange. Recently, investigators have combined geophysical imaging techniques that track electrical resistivity with release of electrically conductive salt tracers (e.g., Cl^-) to measure subsurface dynamics.

Modeling GW-SW exchange

Determination of GW-SW exchange and its influences on geochemical and biotic processes remains a major challenge due to variation in catchment lithologies, geomorphologies, land uses, biotic communities, and atmospheric inputs, along with the problems of integrating across scales of investigation (Harvey et al., 2019). Consequently, computer modeling approaches are useful as they allow researchers to isolate and manipulate components of streams systems in ways that are intractable or impossible in empirical studies.

Modeling studies assist researchers in explaining existing patterns through hypothesis generation, refinement, and testing of predictions addressing system behavior. As a method for assessing GW-SW interaction, modeling studies of stream systems also fall into the two broad categories described in Section "Measuring GW-SW exchange": physically-based and phenomenological (Boano et al., 2014). The current section provides a broad overview of these models and their value as tools for understanding GW-SW interaction.

Physically-based models

Physically-based models rely on quantifying key mechanisms driving GW-SW interactions by operationalizing the physical principles of mass and momentum balance as mathematical equations in code (Boano et al., 2014). Such models focus on the

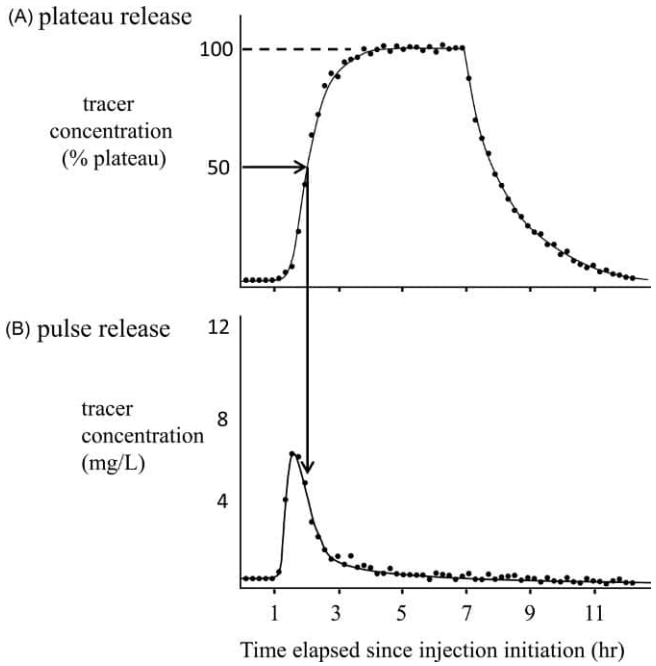

Fig. 5 Simulated tracer response (breakthrough) curves illustrating (A) plateau and (B) slug (or pulse) tracer profiles (black dots) generated by each release design. Plateau releases involve adding tracer upstream at a constant rate for a specified period of time. Once the tracer is well-mixed within the study reach, tracer concentration at the downstream monitoring site are at 'plateau' and will not change with continued tracer addition (panel A). Slug releases entail instantaneous addition of a given volume and mass of tracer that passes the downstream monitoring location and create a pulse profile downstream (panel B). Dashed line denotes plateau concentration. Arrows indicate time after initiation when tracer concentration is 50% of plateau (A) which is the same time at which 50% of tracer mass in a pulse release has arrived at the sampling transect (B). Solid lines are best-fit representations of continuously measured tracer response derived from numerical modeling (see Section "GW-SW interaction, reactive solutes, and the Damköhler number").

factors and forces that control water fluxes between the channel, banks, streambed, and subsurface. Advantages of physically-based models include that they have high mechanistic explanatory power, and help advance scientific understanding of how stream flow and morphology interact to govern GW-SW exchange. However, compared with phenomenological models (see Section "Tracer-based methods" below), physically-based models have a greater number of input parameters that must be determined from empirical study of the hydrosystem (i.e., morphology, sediments, and hydrodynamic drivers therein). Thus, the level of detail required to parameterize physically-based models has resulted in their being focused on spatial scales ranging from small bedforms (Elliott and Brooks, 1997a, 1997b) to sediment bars (Tonina and Buffington, 2007) to river bends (Boano et al., 2006). Physically-based models become more difficult to construct at coarser spatial scales because the number of physical mechanisms and their interactions increases with increasing spatial scale, leading to the widespread application of phenomenological models at the scales of stream reaches to whole catchments.

Phenomenological models

Phenomenological models differ from physical models in that they aim to capture and predict system behavior (i.e., GW-SW exchange) without directly modeling the mechanisms giving rise to them. Thus, phenomenological models do not include equations that physically represent and relate the individual hydrostatic and hydrodynamic forces influencing GW-SW exchange. Instead, they capture the influence of these forces in ways that are consistent with empirical observations and theory.

Phenomenological models rely on signals derived from physically-based models, tracer-release studies, or a combination of both to assist in accurately describing hydraulic behavior. Among the critical components addressed, the residence time distribution for water has received the most attention (Boano et al., 2014). The residence time distribution is among the most important components of many phenomenological GW-SW exchange models because it quantitatively describes the duration that parcels of water will spend in a given spatial domain (e.g., reach, channel, hyporheic zone). Characterization of the residence time distribution is imperative for most phenomenological models of contaminant transport, stream-solute sorption-adsorption dynamics, and coupled biogeochemical-hydrological processing.

Phenomenological modeling has a rich history and remains an active area of research. In a recent review, Boano et al. (2014) described several phenomenological models employed in GW-SW research: the advection dispersion equation (ADE); space and time fractional advection-dispersion equations (S-FADE, T-FADE, and ST-FADE), transient storage model (TSM), multirate mass

transport (MRMT); advective storage paths (ASP); decoupled continuous time random walk (CTRW); and solute transport in rivers (STIR). Details of these models is beyond the scope of this chapter, but we name them here to facilitate further investigation. Of these models, the TSM has been the most influential and widely adopted model of GW-SW exchange in stream ecology (Webster and Valett, 2007).

The TSM model (Bencala and Walters, 1983) predicts how solutes will move through a stream by considering their movement through two compartments: the advection-dominated stream channel and a connected zone which provides temporary (i.e., transient) storage for a volume of water and mass of solute. The TSM approach includes modified advective-dispersion equations that account for two-way hydrological exchange between these compartments. Thus, transient storage describes areas where the stream flow is slowed relative to the bulk advective velocity. Transient storage of stream flow may result from pools, backwaters, eddies, side channels and floodplains, as well as hyporheic exchange. Historically, transient storage was interpreted to represent hyporheic exchange, but surface features (e.g., eddies, pools) contribute to storage under appropriate conditions.

The popularity of the TSM relates to the elegance of the underlying conceptual model, the minimal number of model parameters it requires, and the availability of user-friendly software, which offers a finite difference approximation to the TSM (i.e., OTIS, Runkel, 1998). However, hydroecological modelers have been actively researching ways to overcome some of the simplifications of TSM (e.g., application of exponential residence time distributions and mathematics representing transient storage zones as well-mixed compartments). Many of the phenomenological modeling advances over the last 25 years (i.e., models listed above) have been made to address simulating GW-SW exchange in systems wherein the simplifications in the TSM cannot capture the key drivers and ecosystem patterns of interest, particularly over longer timescales than TSMs can simulate well.

GW-SW interaction, reactive solutes, and the Damköhler number

In a seminal paper, Gerhard Damköhler addressed the efficiency of chemical reactors (Damköhler, 1936) by considering how solutes were influenced by the alternative fates of reaction and transport. The elegance of Damköhler's conceptual approach and mathematical framework has resulted in it being broadly integrated into hydroecological research in a wide range of flow systems. Flow systems, like chemical reactors, have the capacity to transport and process solutes, prompting characterization of groundwater-surface water interactions through use of Damköhler numbers.

Different forms of Damköhler numbers exist (Oldham et al., 2013), but the version applicable to stream systems (Da_I) embraces advective flow and—to date—has employed 1st-order reaction-rate kinetics following Eq. (1):

$$Da_I = \frac{\tau_t}{\tau_r} = \frac{k \cdot l}{u} = k \cdot \tau_t \tag{1}$$

where τ_t is the characteristic transport time (T), τ_r is the characteristic reaction time (T), k is the reaction rate constant (T^{-1}), l is the length of the stream reach (L), and u is the mean water velocity (LT^{-1}). Conceptually, a larger Damköhler number ($Da_I >> 1$) indicates that a system is "reaction dominated" (transformation outpaces reactant delivery) whereas a smaller Damköhler number ($Da_I << 1$) indicates that a system is "transport dominated" (reactant transport through the system outpaces transformation).

Given the assumption of first-order kinetics, the characteristic reaction time (τ_r) occurs when e^{-1} (or 36.8%) of the original reactant remains. With knowledge of transport rates (solute delivery) and reaction rates (solute uptake or transformation), the Da_I quantitatively describes the efficiency of a flowpath, stream reach, or hyporheic zone. The Da_I can also be calculated as function of the initial (C_0) and remaining (C) reactant concentrations as follows:

$$Da_I = \log(C_0) - \log(C) \tag{2}$$

In GW-SW research, Da_I was first used to describe the behaviors of conservative tracers as a tool to improve the design of tracer release studies that quantified hyporheic exchange (Wagner and Harvey, 1997). In more recent studies, focus has shifted to addressing reactive tracers—i.e., nutrients and contaminants—and their behavior in stream systems. Studies describing reactive transport dynamics with Damköhler numbers have expanded greatly since their introduction and have influenced current hydroecological thinking. Quantitative integration of transport and reaction dynamics with Damköhler numbers has led to new ways of characterizing the significance of hyporheic-zone reactions for whole-stream and whole-network biogeochemical budgets. Through calculation of the Reaction Significance Factor (RSF) this approach addresses the tradeoffs between GW-SW fluxes, residence times, and reaction rates for a given exchange zone (Harvey and Fuller, 1998; Harvey et al., 2013). Use of the RSF, and Da_I more generally, has prompted an active and exciting area of research (Oldham et al., 2013; Abbott et al., 2016; Harvey et al., 2019) with implications for understanding controls over water quality.

Expanded use of the Damköhler number reflects the utility of the metric for capturing stream function and its broad applicability. Damköhler numbers are relevant across multiple spatial scales, solute types, and reaction mechanisms. Damköhler numbers have been used to describe the reactive transport dynamics at spatial scales ranging from pores (Briggs et al., 2015) to gravel bars (Zarnetske et al., 2012) and entire river networks (Schmadel et al., 2018; Harvey et al., 2019). Likewise, Damköhler approaches are suitable for characterizing reactive transport for a wide range of solutes and can be used to describe both biotic (e.g., biogeochemical) processing as well as geochemical (e.g., sorption-adsorption) dynamics (Abbott et al., 2016). For these reasons, many hydroecologists have converged on the utility of viewing hydrosystems as reactors whose efficiency can be described using Damköhler numbers.

GW-SW interaction across the inland hydrosphere

Rivers and floodplains

In rivers, the spatial and temporal scale of geomorphic features, flow paths, and fluid residence times associated with GW-SW exchange are increased compared to streams (Fig. 3) including important links to adjacent floodplains, geomorphic entities absent from streams. At the scale of the river basin, two fundamental types of flowpaths exist, (a) underflow, and (b) baseflow (Fig. 6). Underflow occurs when groundwater paths are parallel the river (Fig. 6A), more typical of steeper alluvial river valleys. Baseflow, a term often used to describe flow uninfluenced by recent precipitation, also reflects groundwater flow paths oriented perpendicular to the channel (Fig. 6B). When gradients are low and rivers are highly sinuous, baseflow promotes interaction with the channel through influent or effluent flowpaths. Mesic models of river systems emphasize groundwater inputs along river reaches while river flows in xeric environments typically also include losses to alluvial storage.

Baseflow and underflow can combine to create highly integrated river-aquifer-floodplain systems (Hauer et al., 2021). Complex flow paths generating GW-SW exchange result from changes in the direction of vertical hydraulic gradients responding both to channel constrictions (i.e., nick points) and to snowmelt recharge and baseflow discharge. Evidence for these complex flow paths

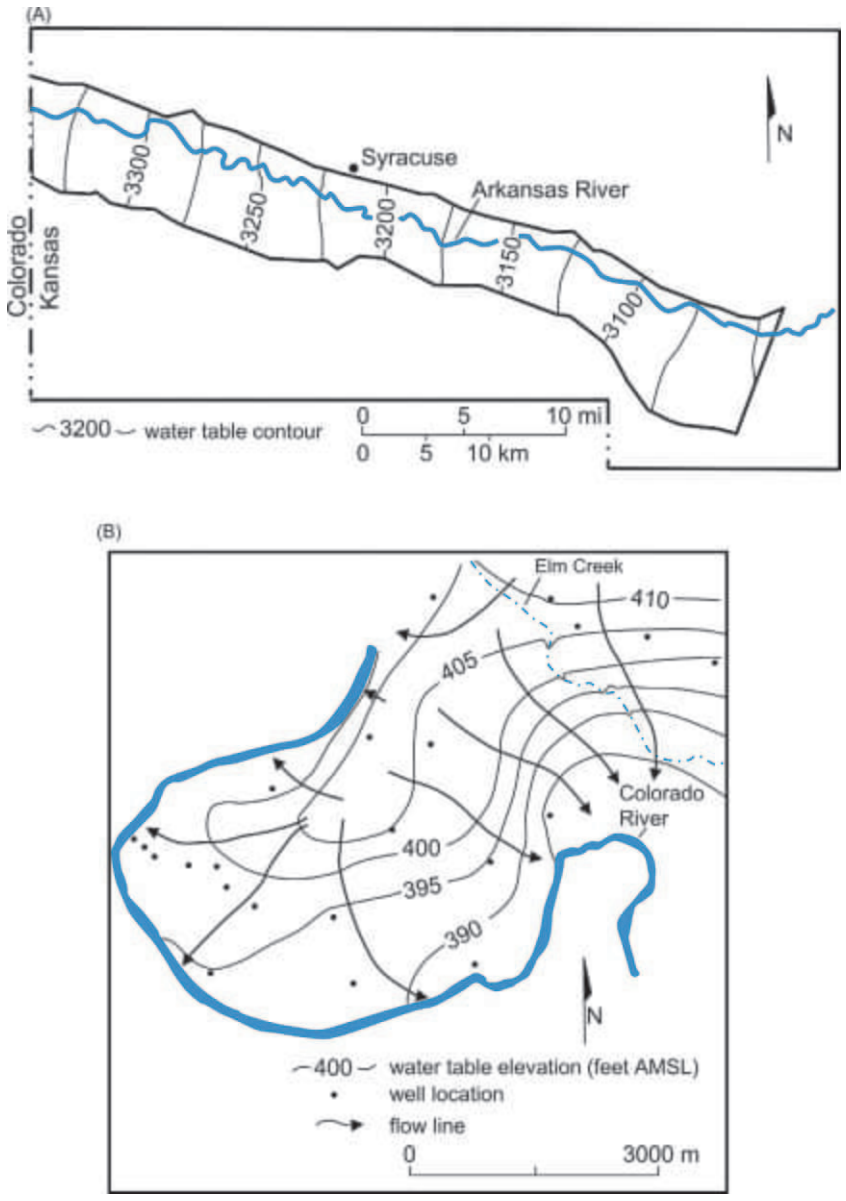

Fig. 6 (A) Groundwater flow parallel to the Arkansas River channel illustrates 'underflow' conditions characteristic of higher valley gradients. (B) Flows paths oriented perpendicular to the Colorado River, Texas generate 'baseflow' exchange between the alluvial aquifer and river channel. Adapted from Larkin RG and Sharp Jr RJM (1992) *Geological Society of America* **104**: 1608–1620.

includes changing groundwater chemistry, but is also apparent in subsurface biological communities. Researchers have documented the emergence of amphibiotic stoneflies from wells and septic fields up to 1 km from the waters of Flathead River, Montana, United States (Stanford and Ward, 1988). These same groundwater denizens have been found in other gravel bed rivers and along saturated beaches of montane lakes suggesting a long history of evolution and dispersal.

River flow can produce floodplain lakes and ponds by both overland flow and groundwater discharge as the water table rises above the land's surface in areas of low elevation. These hydrologic links with groundwater may seasonally connect lakes and ponds of the floodplain to main channel environments. Groundwater that emerges onto the surface of floodplains can also create highly productive 'springbrooks', reflecting groundwater inputs of nutrients and heat. At the same time, changing water table elevations alters metabolism and nutrient cycling in soils and subsurface sediments; inundation may accelerate or retard organic matter processing, and can influence productivity of riparian vegetation. For instance, research on cottonwood growth rates has shown that riparian trees in gaining reaches support larger and longer-lived trees (Harner and Stanford, 2003). Together, these hydrologic exchange flows contribute to the renowned diversity of floodplains worldwide.

Lakes and wetlands

Hydrologic exchange between lake water and groundwater occurs in three basic ways that can be used to categorize GW-SW interaction in lake systems. First, hydrologically mounded lakes receive virtually all of their water from precipitation and have seepage losses to groundwater throughout their beds. Second, terminal groundwater-discharge lakes receive water from adjacent aquifers throughout their beds. Third, pathways for water gain and loss in throughflow lakes is highly variable and dependent on geomorphic context. Because lakes exist in low points on the landscape, they may be influenced by flow systems ranging from local to regional with co-occurring proximate flow paths that influence their functioning as ecosystems.

In the process of GW-SW exchange, physical, chemical, and biological conditions are altered as water enters or leaves lakes. This phenomenon has been well documented for throughflow lakes in glacial and dune terrain where they are underlain by highly permeable deposits and are characterized by groundwater inflow along one shore and outflow along the opposite shore. Biological processes within lakes may provide critical protection from perturbations like acid rain by generating acid neutralizing capacity that is exported through seepage and provided to down-gradient water bodies. Concurrently, groundwater inflow can provide physical and chemical conditions that promote the growth of littoral algae and plants that influence the distribution of invertebrates and water fowl within and among lakes. Under these conditions, throughflow patterns may be relatively stable, but the boundaries of inflow and outflow along the lake bed change with time as the water table rises or lowers. Over varying time periods, precipitation and groundwater inflow may fail to match rates of evaporation, resulting in drastic declines in lake levels, increased concentration of dissolved solutes, and shifts in flow paths that alter GW-SW interaction. Accordingly, drought in the lake districts of Wisconsin and Minnesota, United States, resulted in very different loss of water from lakes that appear identical in most ways other than the character of GW-SW exchange (Webster et al., 1996).

Wetlands exist in climates and landscapes where groundwater discharge overwhelms rates of water loss via drainage or evapotranspiration. Their interaction with groundwater is similar to that of lakes since both wetlands and lakes may be heavily influenced by inflow, outflow, or some combination. However, unlike lakes, wetlands do not always occur at low spots on the landscape and their location influences how they are influenced by GW-SW exchange and how they act as aquatic ecosystems.

Typically, wetlands have been categorized by their hydroperiods (time of annual inundation and saturation). Wetlands such as fens may occur on slopes and act as groundwater donors to down-gradient systems. Bogs typically occur where groundwater flow systems converge or divide; some have no appreciable drainage or throughput (i.e., act as groundwater receivers). Many wetlands have both groundwater inflow and outflow and, thus, act to some degree as groundwater conveyors. Wetlands are highly diverse hydrologically and biologically, occur in both simple and complex flow fields, may be associated with slopes, perched in bottom lands, or integrated via river floodplains. Historic and recent emphasis on geographically isolated wetlands (GIWs, defined as those lacking surface inlets or outlets) has emphasized the importance of GW-SW interaction and the emergence of linkages at the landscape scale that suggest these types of wetlands are far from isolated.

Conclusion and synthesis

Ecological responses to GW-SW exchange are founded on the exchange flows that link water bodies in inherently complex ways. Among the most influential of all legislative accomplishments related to environmental protection, the Clean Water Act (CWA) of the United States regulates discharges of pollutants into the waters of the United States (WoTUS). Generally, WoTUS are defined as navigable waters and the tributaries that supply them. In decisions addressing whether links exist and establish a water body as WoTUS, GW-SW interaction has been identified as potentially representing a 'significant nexus', a condition identified as a legal precedent for inclusion. While much confusion exists around what is needed to establish a significant nexus, there is no doubt that GW-SW interaction influences the physical, chemical, and biological integrity of the waters involved and must be considered in the definition of WoTUS. Accordingly, the US Environmental Protection Agency has embraced issues of connectivity in addressing whether a water body is covered by the CWA. While receiving very different support from successive administrations, court rulings in summer of 2021 have supported expansion of the CWA protections. It is not, therefore, unreasonable to imagine that near-stream environments like hyporheic zones, groundwater flow paths that link lakes and wetlands to adjacent drainage systems, and,

potentially, riparian zones that border these aquatic systems may be regulated by the CWA in the foreseeable future. Beyond the scientific merit of understanding the integration of ecosystems across an array of landscapes, the study of GW-SW interaction plays a pivotal role in regulation, management, and stewardship of aquatic resources.

The realities of climate change, population growth, and energy demands combine to require the convergence of basic and applied research addressing GW-SW interaction across an array of challenging areas. Work remains to address how to build scaling relationships (i.e., mathematical relationships that predict behavior over scales that differ by orders of magnitude) that bridge hydrodynamic and hydrostatic realms of GW-SW exchange. There is an urgent need to understand the coupled spatial and temporal dynamics of GW-SW interaction as climate change alters the quantity, distribution, timing, and magnitude of precipitation. In addition, the propagation and retention of contaminant and wastewater influences in ground and surface waters further emphasize the need for better understanding of GW-SW exchange. Fortunately, the fundamental methods, approaches, and models reviewed here provide a broad and encouraging range of tools that can be applied to better understand GW-SW interaction in both theoretical and applied contexts in the face of rapid environmental change.

Knowledge gaps and environmental change

Human influences are evident at all scales in the natural environment and this is equally true for the processes and effects of GW-SW exchange (Hancock, 2002). Increasing documentation and appreciation of GW-SW exchange has drawn attention to the need to address how it will respond to environmental change, with particular focus on the potential influences of changing climate conditions. Here, we address some of the research needs associated with GW-SW exchange in the Anthropocene.

Water resource depletion and GW-SW linkages

Human activities rely on water availability and use, features that are at odds with one another in the face of climate change (Famiglietti, 2014). Decline in groundwater levels associated with pumping water creates gradients near surface water that may induce infiltration and lead to surface water losses, including streamflow depletion. Streams sourced primarily by shallow groundwater flowpaths are particularly susceptible (Hare et al., 2021). When groundwater depletion and induced recharge attenuates streamflow, water rights associated with groundwater become rights to divert stream waters, linking entities that are initially legally distinct in the United States. More work is needed to address how different approaches to water use and storage will influence key vectors of GW-SW exchange and their influences on water resource allocation.

Hydrosphere modifications

Hydroengineering, including construction of dams and impoundments, gravel extractions, channel straightening, and canalization have resulted in disconnection of rivers from their floodplains with implications for flow regimes and aquifer recharge (Tockner and Stanford, 2002; Nilsson et al., 2005). Changes in the distribution and timing of precipitation associated with climate change will interact with human modifications to the inland hydrosphere with unknown implications for GW-SW interaction and its influences. Increased efforts to address how climate change will interact with the development and operation of engineered water systems has been recognized by the US Army Corps of Engineers as part of their Climate Preparedness and Resilience Community of Practice. Understanding how these diverse drivers will collectively alter GW-SW interaction is a key component of proactive management approaches that will require research focusing on integrating these flows with water policy priorities.

Land use influences—Urbanization and agriculture

Urbanization can dramatically alter GW-SW exchange in streams through increases in impervious surface cover, reducing or eliminating infiltration, and promoting overland routing via flashy storms flows (Walsh et al., 2005). Reduced GW-SW exchange can increase erosion, cause bank failures, and cause urban streams to become dry during low flow periods. Furthermore, urban systems are often built along waterways and urbanization typically involves many of the engineered features described above. These features often eliminate GW-SW interaction, truncate network processes that reduce material transport, and enhance runoff as pulses of contaminants from sewage treatment plants, fluid storage tanks, landfills, industrial lagoons, and storm waters drain. Fundamental research on how urbanization alters GW-SW interaction should be integrated with urban water resource planning as the timing and distribution of water supply changes with climate in urban settings.

Agricultural conversion of land cover influences aquatic systems via erosion and sedimentation, irrigation, and application of agricultural chemicals (Hancock, 2002). These processes may change ecosystem function by altering hydrologic or biogeochemical aspects of GW-SW exchange (see Fig. 2). Erosion and sedimentation introduce fine-grained, often organic-rich, particles that may clog stream-sediment exchange, introduce sediment-bound contaminants, and alter biogeochemical function at the GW-SW interface. Irrigation often includes extensive canals and underground drains (i.e., tiles) that short-circuit flow paths linking surface water to groundwater. In some cases, irrigation returns increase recharge, elevate water tables, and enhance groundwater inputs to surface bodies. Agricultural chemicals, including pesticides and herbicides, may then enter groundwater via these modifications to the hydrologic system. Irrigation from groundwater sources, on the other hand, may result in groundwater decline, stream flow

depletion, and the drying of springs, marshes, and riparian areas, issues of particular concern in semi-arid lands. GW-SW interaction needs to be a central focus of research addressing how to better integrate agricultural practices with water quality and quantity needs, especially as extended drought becomes more challenging to food supplies in a world with changing climate.

Glossary

Benthic zone The area at the bottom of a stream or river including the sediments.
Benthos The community of organisms living in the benthic zone.
Biocenosis An association of different organisms forming a closely integrated community.
Biofilm An assemblage of surface-associated microbial cells that is enclosed in an extra-cellular polymeric substance matrix.
Decomposition rate The rate at which dead organic substances are broken down into simple organic or inorganic compounds.
Ecotone A transitional habitat between two adjacent biological communities.
Hyporheos The community of organisms living in the hyporheic zone.
Macroinvertebrates Invertebrate fauna that can be captured on a 500 μm sieve.
Meiofauna Invertebrate fauna who pass through a 500 μm sieve but are captured on a 45 μm sieve.
Redox potential Tendency of a solution to gain or lose electrons when a new chemical species is introduced. It is used to characterize the oxidation-reduction status of an environment.
Riparian zone The interface between the land and a river or stream.
Stygobites Aquatic organisms that complete their whole life cycle, and are only found, in subterranean environments such as aquifers, springs and hyporheic zones.

Introduction

A significant milestone in freshwater research was the move away from a unidimensional perception of streams and rivers as pipes that move water from the source to the sea. It is now well established that complex multidimensional flow exchanges connect the river channel with the water table and the riparian zones through the bed sediments (Bencala, 1993). The volume of saturated sediments beneath the open channel through which these exchanges occur is known as the hyporheic zone (HZ; from the Greek *hypo* = under and *rheos* = flow or current) (Triska et al., 1989), which in turn is laterally linked to the terrestrial system through the parafluvial zone (the region of the river channel that is dry during low flows (Goldman et al., 2017, Fig. 1). The hyporheic-parafluvial zone (PHZ) is therefore a connected interface which receives aquatic, atmospheric and terrestrial inputs and in which biogeochemical processes occur (Goldman et al., 2017).

This sedimentary interface is an ecotone of enhanced energy and nutrient exchange, supporting diverse communities with taxa unique to the parafluvial and hyporheic zones as well as those from adjacent habitats (e.g., groundwater stygobionts, terrestrial colonizers). Important ecological processes take place within the PHZ, such as nutrient and water storage, cycling of nutrients and organic matter, contaminant detoxification, and fertilization of riparian zones (Boulton, 2007). In addition to their importance in biogeochemical cycling and as biodiversity reservoirs, PHZs are surprisingly large even though they might not be very visible compared to other parts of the riverine ecosystem. Battin et al. (2016) suggest that the bed sediments of streams and rivers have a surface area of between 100 and 1000 m^2 per cubic meter of sediment. Assuming a river bed depth of 1 m and approximating the global surface area of streams and rivers as 662,000 km^2 (from Downing et al., 2012), Battin et al. (2016) estimate a global surface area of beneath stream sediments of up to 662,041,000 km^2 (four times the area of the Pacific Ocean).

In recent years, PHZs have been a research focus for multiple disciplines (hydrology, zoology, microbiology, ecology, environmental engineering), resulting in significant advances in our understanding of their biodiversity, functioning and contribution to

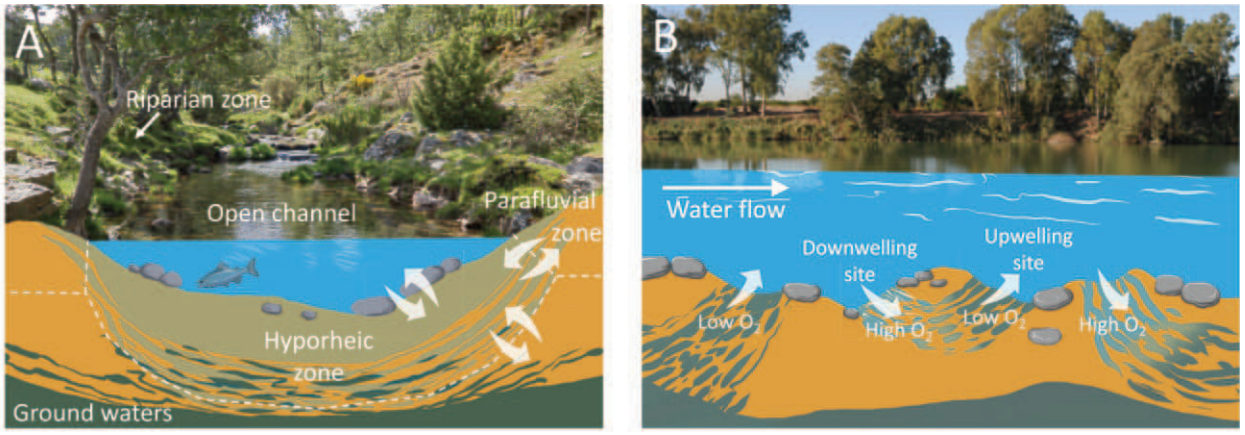

Fig. 1 Transversal (A) and longitudinal (B) representation of a river section. White arrows represent flow paths, which result in the hyporheic interchange.

ecosystem services. These achievements have been facilitated by the development of new analytical methods to capture subsurface hydrodynamics and biochemistry at very fine scales (e.g., Mechelke et al., 2019; Jaeger et al., 2019; Schaper et al., 2019; Martone et al., 2020; Coulson et al., 2021), and supra-disciplinary approaches that have led to the recognition of parafluvial-hyporheic habitats as active bioreactors with an impressive water-purifying capacity (Peralta-Maraver et al., 2018b, 2021).

However, together with their ecotonal nature, the existence of multiple field-specific definitions makes it difficult to delimit hyporheic and parafluvial zones from adjacent habitats, although this is central to quantification of their contribution to riverine ecosystem processes. Additionally, parafluvial habitats have received considerably less attention than hyporheic zones although this is beginning to change, for example a body of emerging research reports the important consequences of dry-rewetting cycles in parafluvial habitats for the biogeochemistry of soil and sediments in the whole river-floodplain landscape (Boye et al., 2017; Goldman et al., 2017; dos Santos Pinto et al., 2020). Furthermore, global knowledge of PHZ functioning is heavily skewed towards temperate zones at the expense of boreal and (sub) tropical regions (Peralta-Maraver et al., 2021). This is an important knowledge gap because temperature varies strongly across latitude and also determines community metabolism, and the ecosystem processes that communities sustain.

The overarching aim of this chapter is to provide a comprehensive framework for understanding the composition, complexity, diversity and functioning of the hyporheic and parafluvial habitats. We first describe how the abiotic habitat, the surface-groundwater hydrodynamics and flood pulses, redox gradient, and geomorphology of the sedimentary matrix define the hyporheic-parafluvial biotope. We then explain how the hyporheic-parafluvial biocenosis is organized through the habitat before moving to the ecological processes and services provided by PHZ. We pay particular attention to biologically driven decomposition processes, specifically organic carbon cycling and pollutants bioremediation. Finally, we propose important knowledge gaps, and suggest fruitful areas for future research.

Hydrodynamics within the sediments is the master variable controlling oxygen availability and parafluvial—Hyporheic zone functioning

Surface water penetrates into the PHZ and travels through the saturated sediments before returning to the open channel. During this journey surface water mixes with groundwater, changing its physicochemical properties due to microbial activity and sediment geology (Jones and Mulholland, 1999). The hyporheic compartment is the interface between oxidized surface waters and reduced groundwater, oxygen levels are typically at their highest in water entering the hyporheic zone from the surface stream and decrease thereafter. Groundwater, upwelling from underlying aquifers has lower levels of oxygen and, as it mixes with surface water entering the PHZ, a complex and spatially and temporally dynamic oxygen landscape comprising patches with differing oxygen concentrations is formed (Fig. 1). The full redox gradient is represented enabling biogeochemical processes such as nitrification and denitrification to occur. These processes are mediated by microbial consortia which in turn are influenced by other groups of the hyporheic zone food web (Krause et al., 2011). Thus the hyporheic zone attenuates nutrients and contaminants although the magnitude of this function varies with local conditions. Water temperature in the PHZ also varies depending on whether water is upwelling from groundwater (when temperature will be lower) or downwelling from the surface stream (when temperature will be higher). In any case temperature fluctuations in the PHZ are dampened compared to the surface stream (Lewandowski et al., 2019). The aquatic-terrestrial interface through the parafluvial compartment has been also recognized as a hot-spot of biochemical activity as a consequence of the drying-rewetting cycles and the resultant sequence of oxic and anoxic conditions. During wet episodes, oxygen is rapidly consumed within the pore space and anaerobic processes, such as denitrification and production of nitrous oxide, increase (Marcé et al., 2019; dos Santos Pinto et al., 2020). However, when desiccation occurs, aerobic pathways are favored again, reducing methane and nitrous oxide emissions, but promoting carbon dioxide emission (Gómez et al., 2012; Reverey et al., 2016).

The surface-groundwater exchange and the flood pulse are variable in space and time and drive the direction and magnitude of flow within the pore-spaces, and consequently, the expansion and compression of the size of the PHZ (Boano et al., 2014; Harvey and Gooseff, 2015). Sediment morphology (e.g., grain size), sediment migration rates, streambed topology (e.g., wavelength of sediment dunes), shape of the river channel, presence of obstacles, and flow regime result in heterogeneous hydrodynamic landscapes within the parafluvial-hyporheic sediments (Magliozzi et al., 2018) that determine the transport of solutes between riverine compartments (Ward et al., 2012) and the chemistry within the pore water (Triska et al., 1990; Bencala, 1993). Importantly, hydrodynamics also regulate the residence time or turnover capacity of pore-water within the PHZ. Short residence times are generally more common in the upper sediment layers, at the surface-hyporheic interface, creating hot spots and moments of enhanced biochemical activity (Briggs et al., 2014; Kaufman et al., 2017). In contrast, deeper sediment layers are generally characterized by longer residence times, low redox potential and slower biochemical reactions (Bardini et al., 2012). As a result, deep subsurface sediments tend to be a sink for recalcitrant compounds (Peralta-Maraver et al., 2019a). Parafluvial habitats and floodplains are also a trap for sediment, water and nutrients since they are exposed to drying-rewetting cycles due to inundation phenomena (Baigún et al., 2008; Walalite et al., 2016; dos Santos Pinto et al., 2020).

Pore-space hydrodynamics can therefore be viewed as the "master variable" of the PHZ functioning (e.g., Dole-Olivier, 2011; Peralta-Maraver et al., 2018b). Thus, quantifying the direction and magnitude of surface-subsurface water exchange, and consequently the size of the parafluvial-hyporheic zones, is of pivotal importance to further study of both the organization of biological diversity within the PHZ and also its role in biogeochemical cycling. A suite of techniques has been developed during the last decade for this purpose (e.g., Kalbus et al., 2006; Brunner et al., 2017). Initially, these approaches were almost exclusively employed in studies of hydrology and engineering (Boulton et al., 2010), but they are increasingly used in ecological sampling protocols (Peralta-Maraver et al., 2018b; Lewandowski et al., 2019).

Thermal sensors are often used to quantify vertical and longitudinal hydrodynamics within the PHZ (Lewandowski et al., 2019) because surface waters and groundwaters differ in temperature. The variation in the recorded temperature gradient is then transformed to vertical flux using well-established 1D heat diffusion-advection equations (Rau et al., 2010). This method is non-destructive, simple and low-cost, and can be easily combined with community and biochemical sampling methods (e.g., Peralta-Maraver et al., 2018b). However, vertical measurements of temperature variation ignore horizontal flow components (Lewandowski et al., 2011; Angermann et al., 2012) that demonstrate the hydrological connectivity with the parafluvial compartment. Recently, hydrologists and environmental engineers have developed active heat pulse sensors to quantify dynamic 3D flows within streambed sediments (Banks et al., 2018) allowing accurate characterization of connectivity and residence times of water across stream compartments. These tools are as yet virtually unused in ecological research on the PHZ.

Hydrological connectivity across PHZs and the natural shift between wet and dry states supports the establishment of diverse aquatic and terrestrial communities within these zones (Fig. 2). It also maintains several ecosystem services on which human well-being depends, such as contaminant attenuation, aquifer recharge and nutrient supply to the alluvial plain. However, traditional flood management techniques such as river clearance, channelization and cementing the river bed have encouraged rapid movement of water through rivers to the sea and global disruption of the vertical and lateral hydrological connectivity between rivers and their PHZs to the detriment of river functioning (Loheide and Gorelick, 2006; Boulton, 2007). Recent river rehabilitation approaches aim to restore connectivity between the surface stream and the PHZ encouraging increased hyporheic exchange flows and biogeochemical processing mediated by the hyporheos (Kasahara and Hill, 2006). Techniques are used that promote hydraulic gradients (e.g., wood debris, step-pools, dam removal) and geomorphological heterogeneity (i.e., bedforms, sediment sorting, meandering, realignment), while reducing sediment load and clogging (e.g., sediment traps) (reviewed in Magliozzi et al., 2019). However, implementation of such restoration strategies is still very recent (Boulton, 2007), and thus,

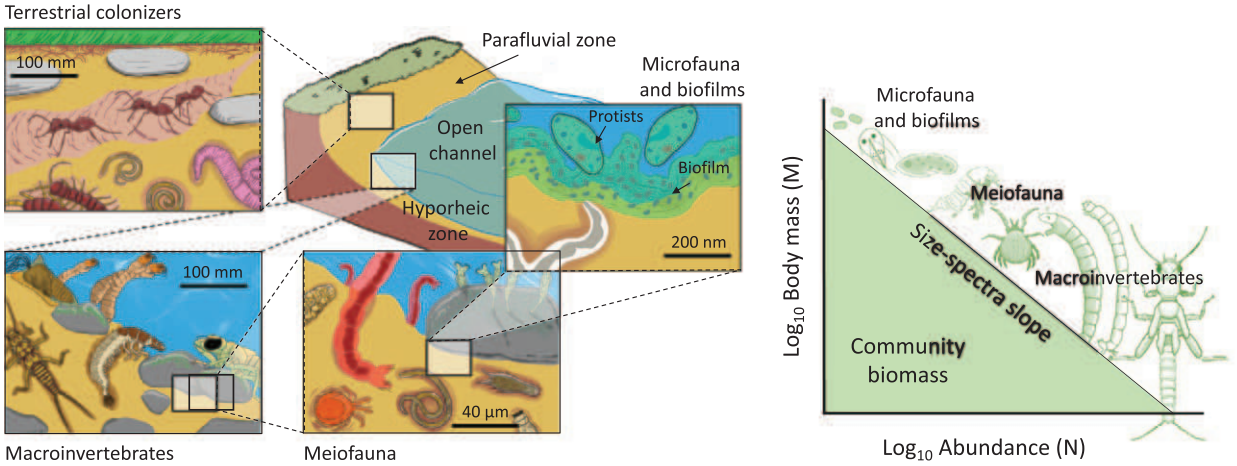

Fig. 2 Conceptual depiction of parafluvial-hyporheic biodiversity across body-size groups, and theoretical body mass (M)/abundance (N)-relationship of the community.

only a very few studies have examined the effect of these measures on the ecology and biochemistry of the PHZ. Robertson et al. (2021) examined the effects of removing an impoundment on the hyporheos and the benthos of an English chalk stream at multiple time points over a 5-year period. They found that both the hyporheic and the parafluvial compartments responded differently to restoration. Morley et al. (2021) found that the density and taxon richness of the hyporheos was significantly higher in reaches where the hyporheic zone had been restored compared to reaches with unrestored hyporheic zones. Given the importance of the hyporheic zone in the provision of ecosystem functions and services, it should undoubtedly be included in future monitoring protocols that aim to assess river restoration success.

An ecotonal interface full of life

The high surface area of the sedimentary matrix in the PHZ can create real hotspots of biodiversity. These habitats are multi-dimensional ecotones across surface-groundwaters and aquatic-terrestrial habitats (Sabater and Vila, 1991). They harbor complex and diverse consortiums that include organisms from across the tree of life (Fig. 2). Permanent inhabitants include biofilms composed of fungi, bacteria and archaea that grow attached to the sediment grains as a microbial skin within the pore space (Battin et al., 2016). Single cell eukaryotes (protists) and metazoa invertebrates also live permanently within these interstitial spaces, swimming in the pore-space or digging into the sediments. Invertebrates include many taxa of crustaceans, worms, rotifers, water mites and insects (reviewed in Rundle et al., 2002), and are characterized as meiofauna or macroinvertebrates. In addition to the permanent communities, surface and subterranean organisms temporarily colonize the parafluvial-hyporheic sediments (Robertson et al., 2000). Furthermore, the lateral transition between aquatic and terrestrial conditions results in cyclic succession of aquatic and terrestrial macroinvertebrates colonizing parafluvial habitats. For example, macroinvertebrates, such as Plecoptera, Trichoptera, isopods and amphipods are replaced by nematodes, annelids and arthropods (e.g., ants) during dry phases, supporting nutrient cycling in the whole river ecosystem (Prather et al., 2013) (Fig. 2).

From the surface, organisms enter the PHZ to find resources, or even refuge (Dole-Olivier, 2011; Stubbington, 2012). Vertical movements are well known in the case of invertebrates. The early larval instars of benthic insects such as stoneflies and mayflies use the small pore spaces of the PHZ as predation refuges (Williams and Hynes, 1974; Stubbington, 2012). Furthermore the HZ is critical in salmonid life histories; salmonids bury their eggs in the HZ of gravel bed streams, and the developing embryos remain there for several months before emerging as free-swimming fish (Malcolm et al., 2004). Vertical migration of multiple taxa from the surface into the PHZ also occurs during surface flow cessation, because the PHZ remains wetted for longer periods (Wood et al., 2010). When flow resumes, these groups rapidly recolonize the surface (Stubbington and Datry, 2013; Datry et al., 2014). Additionally, surface taxa can use the hyporheic zone as a thermal refuge as PHZ temperatures are typically lower than those of the surface sediments (Vander Vorste et al., 2017). Surface taxa may also use the PHZ as a refuge during high flow disturbance (see summary in Robertson and Wood, 2010). The PHZ will be most effective as a refuge from high flow disturbance when it is laterally and vertically extensive with large particle sizes because these provide greater living space. Interstitial architecture in turn influences dissolved oxygen concentrations, the degree of connectivity between the benthic and the hyporheic zone and the ease with which benthic organisms are able to penetrate into the hyporheic zone (Robertson and Wood, 2010). Furthermore, species will differ in their ability to utilize the PHZ depending on the biological traits they possess. Typically, taxa are small and so able to inhabit pore spaces within the PHZ, vermiform enabling movement through the sediments, highly mobile and with no attachment devices so that individuals can move into the HZ during disturbances, and a burrowing habit allowing penetration of the HZ. In fact many permanent residents of the PHZ (e.g., meiofauna such as Copepoda, Nematoda) possess these traits (Robertson and Wood, 2010). In addition to this "top-down" use of the PHZ as a refuge, stygobiotic taxa also colonize the PHZ during adverse conditions in the groundwater environment when extremes of anoxia or pH may occur (Marmonier et al., 2004; Wood et al., 2010). Interestingly, the use of the PHZ as a refuge is not exclusive to invertebrates. Biofilms also use the PHZ as a refuge from desiccation, although they are transported by hydrological pathways through the sediments rather than entering by active migration. During dry conditions at the surface, the PHZ supports prokaryotes associated with the infiltration of water and the maintenance of wet conditions within the sediment; when water exchange is restored during flood events, biofilms recolonize the surface habitats (Febria et al., 2012). Lastly, expansion and contraction of aquatic and terrestrial habitats also occur laterally through the parafluvial interface, even in perennial systems. Parafluvial habitats have different characteristics to those of adjacent riparian, terrestrial and fully aquatic habitats. Thus, PHZ can support unique communities, including inundation-tolerant terrestrial colonists (Tockner and Stanford, 2002; Steward et al., 2011) and desiccation-tolerant aquatic organisms (Stubbington and Datry, 2013; Datry et al., 2017).

Parafluvial–hyporheic communities include therefore a very heterogeneous set of organisms with diverse distribution patterns along the ecotone both in space and time. Dynamic environmental filters at a sediment-scale, driven ultimately by gradients of sediment size, changing hydrodynamics and depth within the streambed, constrain the ability of different taxa to colonize the PHZ (Williams et al., 2010; Robertson and Wood, 2010; Descloux et al., 2014). Consequently, distinguishing between parafluvial–hyporheic communities and those from adjacent habitats, such as benthic or riparian habitats, can be extraordinarily challenging. Traditional approaches define the habitat boundaries operationally, rather than based on the actual distribution of the organisms (e.g., Smock et al., 1992). However, accurately defining natural boundaries is a key aspect of designing ecological studies and for the interpretation of results, and is also central to defining ecosystems (Post et al., 2007). It is only recently that quantitative biocenosis analysis has shown unequivocally that PHZ communities are discrete communities with individual ecological integrity, and that vertical hydrodynamics influences their boundaries (Peralta-Maraver et al., 2018a).

As a rule of thumb, streambed sediments contain assemblages with relatively large invertebrates at the surface that are gradually replaced by a suite of numerous but small-bodied organisms with increasing depth (Schmid-Araya, 1994; Stead et al., 2004; Peralta-Maraver et al., 2018a,b). This is mainly because the reduction of oxygen and nutrients at greater depth and under upwelling conditions limits the colonization capacity of organisms with larger body size and high metabolic requirements (Strayer et al., 1997; Briggs et al., 2012; Descloux et al., 2014). As a result, communities inhabiting the streambed are strongly structured by body size (Schmid et al., 2000), which is inversely proportional to their abundances. When organisms are grouped into body-size classes, irrespective of taxonomic identity, the negative slope of the size-abundance relationship on a logarithmic scale (i.e., size-spectra; White et al., 2007) provides a measure of community size structure. The intercept reflects the carrying capacity, and the area under the slope and intercept gives a measure of total biomass (Fig. 2). Furthermore, the body size of different groups is a relatively good approximation of the trophic level they occupy within the parafluvial-hyporheic food webs (Kerr and Dickie, 2001), although there are some exceptions (e.g., parasites; Leaper and Huxham, 2002).

The size-abundance relationship is therefore an integrative metric of the community structure and the biomass depletion through food chains (White et al., 2007). Thus, size-abundance coefficients can be used to quantify the deviation of a natural community from a reference status due to natural constraints (e.g., oxygen limitation) or anthropic stressors such as organic pollution (Petchey et al., 2002). Size-abundance coefficients from parafluvial–hyporheic communities, including unicellular organisms, meiofauna and macroinvertebrates, are very sensitive to depth, hydrodynamics and anthropogenic stressors. In streambed sediments, the size-abundance intercepts are higher and the size-spectra slopes are flatter under downwelling conditions and in the upper sediment layers, while the opposite occurs under upwelling conditions and at deeper sediment layers (Peralta-Maraver et al., 2019a). Also, there seems to be a strong dependence of the size-abundance coefficients on the presence of emerging organic contaminants in streambeds, to the point of even shielding the effect of important environmental drivers such as temperature, pH, and productivity (Peralta-Maraver et al., 2019b). The size-spectrum coefficients scale with the efficiency of energy transfer across trophic levels (Brown and Gillooly, 2003), and curves typically become steeper as metabolic efficiency decreases. As we discuss in the following section, the variation in the size abundance relationship has therefore important implications for the functioning of the PHZ.

The parafluvial-hyporheic zone is an active interface with an impressive self-purifying capacity

The high surface area of the sedimentary matrix within the PHZ plays the functional role of a bioreactor with the capacity to decompose a wide range of allochthonous organic substrates, and it is sustained by the diverse and active communities that inhabit it (Peralta-Maraver et al., 2018b, 2021). The potential of the PHZ to process dissolved and particulate organic nutrients is well known in temperate streams and rivers (Lewandowski et al., 2011; Follstad Shah et al., 2017). For example, there is a body of literature on the decomposition of leaf litter within the PHZ (e.g., Burrows et al., 2017; Risse-Buhl et al., 2017). Additionally, the formidable bioreactor capacity of the PHZ enables it to decompose a wide range of emerging organic contaminants (EOCs). These include compounds of anthropogenic origin with trace concentrations in natural systems (up to several micrograms per liter), but disproportionately high biological activity (Stamm et al., 2016). Thousands of daily-use synthetic chemicals, such as antibiotics and other medications or pesticides, with hazardous effects on aquatic communities and human health occur among EOCs (Pal et al., 2010). Research in the temperate lowland river Erpe (Germany) provides strong evidence of the capacity of the PHZ to remove EOCs (Schaper et al., 2019; Rutere et al., 2020; Mueller et al., 2021). Unpublished analysis of surface water and pore-water chemistry at a sediment scale shows reductions of diverse EOCs through a depth gradient in the streambed of the River Erpe (Germany, Berlin). EOC concentrations declined strongly with increasing depth, while the artificial sweetener acesulfame increased (Fig. 3). Acesulfame is a good marker of EOC contamination in management and water regulation because it is very persistent and it is hydrophilic enough to penetrate into, and accumulate in, waterbodies (Peralta-Maraver et al., 2019c). Even though reduction of EOCs could be attributed to different processes than biodegradation, these results illustrate that the PHZ acts as a barrier against the contamination of near-surface groundwater aquifers, which are vital to the production of drinking water.

Decomposition of such a wide array of substrates is mainly explained by the fact that prokaryotes embedded in the streambed biofilms have a great enzymatic capacity and develop diverse metabolic pathways; they form consortia to maximize the range of nutrients and contaminants that can be processed and the rate at which their consumption occurs (e.g., Kolvenbach et al., 2014). Furthermore, water flow is strongly reduced within the pore space, resulting in long residence times, allowing time for microbial decomposers to perform these biochemical reactions. Lastly, while biofilms undertake most of the decomposition processes, protists and invertebrates also influence microbial decomposition rates. Life activities of protists and invertebrates inhabiting the PHZ could enhance the hydraulic properties of sediments through burrowing (bioturbation) and maintaining open pore spaces (Hose and Stumpp, 2019). Protozoa grazing on biofilms augment water mixing, increase biofilm surface, and ultimately, promote bacterial activity (Peralta-Maraver et al., 2018b). However, the contribution of protists and invertebrates to organic matter decomposition processes in the PHZ remains poorly characterized (Majdi et al., 2020).

A recent survey across 30 UK streams and rivers has shown that productive communities including flagellates, ciliates and invertebrates promote microbial decomposition within streambed sediments (Peralta-Maraver et al., 2019a). As body size and metabolic requirements constrain the distribution and biomass of organisms within the PHZ, it is reasonable to think that efficiency of the bioreactor will vary with these factors and also with environmental drivers such as depth and hydrodynamics. The size-spectra slope (derived from the size-abundance relationship described above) is a powerful linear predictor of the microbial decomposition

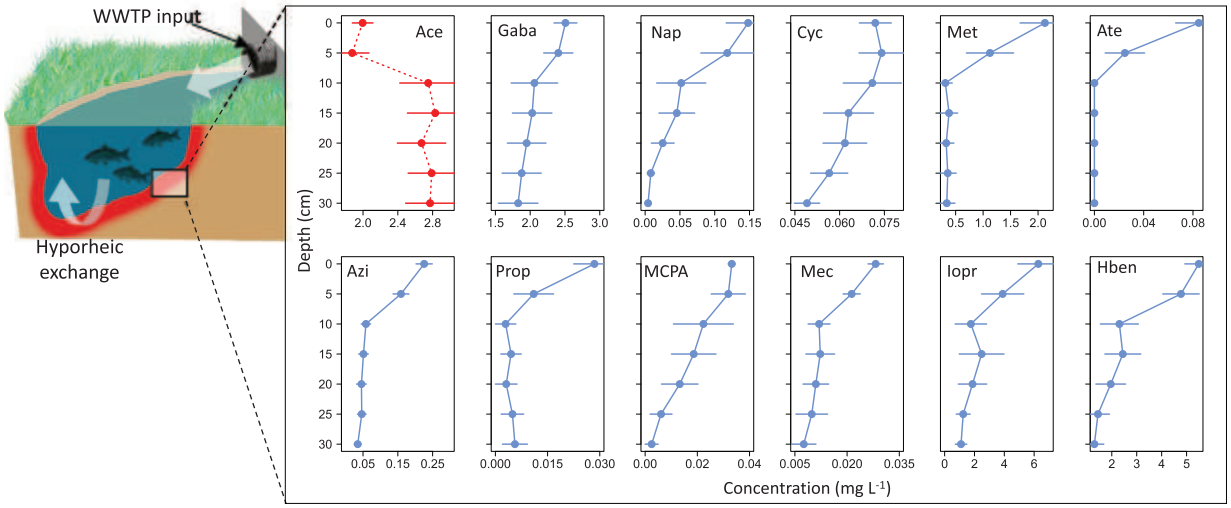

Fig. 3 Depth profiles of emerging organic contaminants (EOCs) measured in the surface and streambed sediments in six reaches of the River Erpe (Berlin, Germany). River Erpe is affected by the water release of a municipal wastewater treatment plant (WWTP). The sampling procedure is described in Peralta-Maraver et al. (2018a). Profiles show mean values and standard error of dissolved compounds measured in the pore-water of the PHZ. The marker acesulfame (*Ace*, in red) accumulates through depth while the other drugs show a strong reduction. Analyzed compounds include: Gabapentin (*Gaba*); naproxen (*Nap*); clofibric acid (*Cyc*); metformin (*Met*); acetaminophen (*Ate*); azithromycin (*Azi*); propanol (*Prop*); MCPA (herbicide); metoprolol (*Mec*); lopromide (*Iopr*); 1H-benzotriazole (*Hben*).

rate within streambed systems (Peralta-Maraver et al., 2021) and may be used to determine the limit of the PHZ bioreactor depurating capacity and the resilience of the system towards anthropic stressors. This metric can integrate information for the whole community, and also allow the effect of environmental factors to be incorporated within the analysis. The decomposition rate can be easily modeled as a response of the interaction between the size-spectra slope and the environmental variable under study (see Peralta-Maraver et al., 2021).

Functional diversity (the range of species' functional traits) is another tentative metric to further study decomposition processes at community level, as it underpins a key mechanistic link between species richness and ecosystem functioning. This approach can also be used to compare potential decomposition processes across biogeographic regions. Evidence from surface freshwaters, where it is well established, suggests that community functional diversity predicts ecosystem functioning better than species based indices (e.g., Gagic et al., 2015; Griffin et al., 2008). However, in the PHZ, the development of functional trait databases and the use of a functional trait approach is in its infancy (but see Robertson et al., 2021; Dunscombe et al., 2018; Claret et al., 1999; Robertson and Wood, 2010; Descloux et al., 2014; Bona et al., 2016; Mathers et al., 2017; Magliozzi et al., 2019). Developing the functional trait approach for the PHZ is a fruitful avenue for future research given the likely role of the hyporheic community in riverine ecosystem functioning. Currently, our knowledge of the capacity of the PHZ to process organic substrates is mostly limited to descriptive field surveys. The complexity of natural systems and the multiple variables interacting during microbial decomposition in these settings limits mechanistic knowledge of the functioning of the PHZ. For example, we do not yet know how protists or invertebrates grazing on biofilms promote microbial activity. This may result from the selective consumption of senescent bacteria, the control of biofilm overgrowth, or the increase of biofilm surface due to moderate grazing (Shapiro et al., 2010; Neury-Ormanni et al., 2016; Peralta-Maraver et al., 2018b). Nevertheless, these explanations remain largely hypothetical. Therefore, experimental approaches such as controlled microcosm experiments, as well as descriptive studies are required to assess the complex mechanisms behind the functioning of the PHZ.

Conclusions

Research on ecotones is challenging because they display aspects of the bordering habitats as well as their own emerging characteristics. A mix of research approaches and theories originally developed for the neighboring habitats is often required, making their study cumbersome; this is definitely the case for the PHZ. Humans prefer to work with clearly delineated systems, unfortunately (or maybe encouragingly), nature rarely works like this. Indeed, ecotonal areas are typically where we find new ecological processes or where those processes occur at a higher rate. The methodological difficulties encountered explain to a large extent why our understanding of PHZ functioning lags far behind those of other inland water habitats, with the notable exception of groundwaters. For the same reason, most of the historical research on the ecological processes driven by the PHZ, such as microbial decomposition, is limited to a local scale. Whilst this is certainly changing, and the latest research on PHZ functioning encompasses larger spatial and temporal scales, we are still unable to scale important processes up to global levels over longer periods of time. For example, benthic habitats in lentic inland waters (e.g., lakes, wetlands, reservoirs) are well established sources of greenhouse gasses

including CO_2, CH_4, and N_2O at a global scale (e.g., Tranvik et al., 2009; Bastviken et al., 2011; Soued et al., 2016). In contrast, the existing estimates of global greenhouse gas emissions from the PHZ are highly uncertain (Schelker et al., 2016; Boodoo et al., 2019), even though we know that the PHZ is a very active interface, because they are based on limited local observations that do not represent the variability that exists in PHZs globally. We began this chapter by stressing the advance in our understanding of riverine ecological processes gained by moving from a unidimensional to a multidimensional perception of rivers. We are convinced that the next great milestone will be to scale the ecological processes occurring within the PHZ in a macroecological context.

Knowledge gaps

- Communities inhabiting the PHZ are strongly influenced by the timing, frequency, duration and magnitude of hydrological connections with the surface and groundwaters. In addition, hydrological exchange conditions and flood pulse varies enormously at different time scales, from a short-term daily basis up to a climatic scale. However, the relative importance of circadian, seasonal and climatic scales on ecological processes of the PHZ have not been explored yet.
- Taxonomic knowledge on organisms inhabiting the PHZ lags far behind that of surface counterparts. These taxonomic impediments become especially severe among small size fractions such as protists and biofilms. The lack of a solid taxonomic knowledge critically limits advances in ecological research and monitoring of the PHZ. The recent surge in molecular-based identification methods is a promising approach to unravel the hidden diversity of PHZ communities in the future.
- Carefully designed microcosm experiments are needed to determine how the predator-prey interactions between biofilms and grazers affect the rate of microbial decomposition of nutrients and contaminants. Combined with knowledge from experimental trials this is a feasible strategy to unravel the inherent complexity of natural ecosystems.
- Parafluvial-hyporheic inhabitants and colonizers must be incorporated into our understanding of the energetic connectivity between terrestrial and aquatic ecosystems. This is especially relevant considering that climate change is expected to alter the frequency, intensity, spatial extent, duration and timing of extreme floods and droughts.
- Our understanding of the impact of novel pollutants such as emerging organic contaminants and microplastics on PHZ food webs and thus the functioning of the bioreactor is limited to non-existent. This knowledge gap should be addressed through field surveys and laboratory experimentation.
- Scientific interest in the production of CO_2, CH_4 or N_2O within PHZ is very recent, and research on this field is still limited to local-scale studies. Therefore, global estimates or even prediction of the role of the PHZ as sources or sinks of greenhouse gasses are largely unknown. This knowledge is however essential to anticipate the rate of global warming.

Important case studies

Site	*Country*	*Main topic*	*Key references*
River Erpe	Germany	This study reports how environmental filtering at a micro-scale determine diversity, productivity and composition of the whole streambed assemblage through depth and with the direction of vertical water exchange	Peralta-Maraver et al. (2018b)
River Erpe	Germany	Authors analyze changes in molecular composition of seven dissolved organic compounds, and the attenuation of 17 emerging organic contaminants within the hyporheic sediments of an urban stream receiving treated wastewater	Mueller et al. (2021)
8 streams from two regions located in humid subtropical east-ern Australia	Australia	Authors analyze particulate organic carbon decomposition, as well as rates of microbial respiration, to quantify rates of organic carbon processing in surface and parafluvial-hyporheic environments of intermittent and perennial streams	Burrows et al. (2017)
2 catchments in each of 3 geologies (chalk, limestone, sandstone). 4 sites per catchment	UK	Authors used a functional trait approach. They found that HZ community structure varied between streams draining different geologies. However, HZ community biomass and functional measures did not vary across geologies, suggesting that the HZ functions equally across geologies	Dunscombe et al. (2018)
Traisen River (Danube tributary)	Austria	Novel study assessing the effects of water fluctuation on the magnitude of greenhouse gasses emissions in the parafluvial zone of a restored river floodplain	dos Santos Pinto et al. (2020)

Glossary

Auxiliary metabolic genes (AMGs) Viral genes frequently encoding enzymatic functions which optimize the metabolism of the host for viral reproduction during infection.
Chronic infection Viral infection which leads to the stable integration of the phage genome (prophage) in the host cell (i.e. lysogeny). In contrast to lytic reproduction, viral progeny is released continuously without rupture of the host cell.
Kill-the-Winner model Describes the hypothetical trade-offs between defense and competition specialists among unicellular planktonic microorganisms. Predicts that more abundant and/or more active prokaryotes become preferentially targeted by lytic phages.
Lysogenic/temperate infection Viral infection which leads to the stable integration of the phage genome (prophage) in the host cell. Depending on the phage, a lysogenic infection may either turn out to be chronic or lead to a (delayed) lytic reproductive cycle.
Lytic infection Viral infection directly leading to the reproduction of viral progeny whose release results in the rupture (lysis) of the host cell.
Metabolic standby Metabolic state in which microorganisms are ready to perform translation (protein synthesis) but are otherwise metabolically inactive.
Phages Viruses infecting prokaryotes (i.e. bacteria and archaea). Often also limited to those infecting bacteria.
Prokaryotes Microorganisms without cell nucleus belonging to the domains bacteria and archaea.
Viral ecology Research field investigating the ecological role of viruses in the environment.
Viral shunt The lysis-mediated release of dissolved and particulate organic matter which can stimulate the activity of surrounding microorganisms.
Virus-like particles (VLPs) Particles with the morphological and/or biochemical characteristics of viruses.

Introduction

Microorganisms are ubiquitous and abundant with a distribution limited by only a few environmental factors, i.e. extreme temperature, extremely acidic or alkaline pH, and water availability (Hendry, 2006). Microbes are found around almost every corner on this planet, and occur even in environments like hot springs, glacier ice, the atmosphere and the terrestrial subsurface including groundwater ecosystems (Griebler and Lueders, 2009). What has been overlooked for a long time is that every microbe has its virus, or two or three. Along with their hosts, viruses have been found in rocks, soils, all kinds of aquatic ecosystems, inside of organisms including human beings, as well as in the atmosphere (Reche et al., 2018). Although viruses pathogenic to animals and humans make most of the news, the large majority of viruses in natural ecosystems infect single-celled microorganisms without a cell nucleus named prokaryotes (i.e. bacteria and archaea, Jacquet et al., 2010). This chapter will focus exclusively on viruses of

prokaryotes which are here referred to as phages. Nonetheless, since most methods do not discriminate between phages and other viruses, occasionally we will also use the more generic term 'virus.'

Based on an estimated 4×10^{30} virus-like particles (VLPs) in the ocean alone, phages are considered to be the most abundant biological entities in the biosphere (Suttle, 2005). In many freshwater habitats, like streams and rivers (Peduzzi, 2016), lakes and ponds (Hennes and Simon, 1995), and man-made impoundments (Peduzzi and Schiemer, 2004), phages occur in concentrations comparable to those found in the ocean. Nonetheless, overall estimates of the total abundance of viruses in freshwater are missing so far. Besides the immense diversity of freshwater habitats, this is due to the fact that very little is known about phages in the largest freshwater ecosystem on our planet, i.e. groundwater. As is explained in detail in other chapters of this section, groundwater ecosystems form the largest freshwater biome on earth. While only 2.5% of the world's water resources are fresh and about 69% thereof is solidified in ice and snow, almost all of the remaining 31% are contained within groundwater. Taken together, rivers, lakes and ponds contain less than 1%. In fact, nearly ~100 times more freshwater occurs in the terrestrial subsurface than in surface water bodies (Danielopol et al., 2003). Recent estimates also indicate that >80% of all prokaryotic biomass on earth, including many novel phyla, is located in the subsurface (e.g. terrestrial aquifers, vadose zones, and below the seafloor; Bar-On et al., 2018; Castelle and Banfield, 2018). However, covered by soils, sediments and rock, hidden below the surface and with no light as energy source groundwater ecosystems are typically poor in organic carbon and energy and thus exhibit a comparatively low productivity (Aiken, 2002; Regan et al., 2017; Hofmann et al., 2020). This results, to some degree, in a dependence on organic matter, nutrients and energetically favorable combinations of electron donors and acceptors coming from the surface along with groundwater recharge (Pabich et al., 2001; Goldscheider et al., 2006; Shen et al., 2015). In consequence, the concentration and activity of prokaryotes, the predominant hosts of viruses in groundwater, is much lower compared to surface waters (Kyle et al., 2008; Roudnew et al., 2012; Kieft and Phelps, 1997; Lopez-Fernandez et al., 2018). As a result, groundwater environments have long been perceived as microbiological deserts (Griebler and Lueders, 2009) and, with the exception of human pathogens, viruses, and in particular phages have been very rarely studied. To our knowledge, this is the first compilation of data on prokaryotic viruses in groundwater ecosystems.

Groundwater environments as a habitat for phages

The large majority of studies on viruses in groundwater focused on human pathogenic viruses like noro- and hepatitisviruses (e.g. Macler and Merkle, 2000; Borchardt et al., 2007; Krauss and Griebler, 2011). While in rare cases, pathogenic viruses in groundwater have been shown to be responsible for outbreaks of water-borne diseases, these viruses do not reproduce in groundwater and at standard conditions they occur in very low numbers and are only occasionally detectable. As such, they do not contribute to groundwater habitats in an ecological sense, i.e. in terms of organic carbon supply and microbial food web interactions. Therefore, viruses specific to humans and/or animals are not the subject of this chapter and interested readers are referred to respective reviews (e.g. Krauss and Griebler, 2011). The following paragraphs will focus on ecological aspects of viruses infecting prokaryotes and build on basic concepts in phage biology.

In surface waters, be it salty or fresh, phages have been shown to affect basically all prokaryotic-driven processes via (i) the short-circuiting of nutrients within the microbial food web (Wilhelm and Suttle, 1999), (ii) the alteration of host-metabolism (Puxty et al., 2016; Zimmerman et al., 2020; Kieft et al., 2021), and (iii) the control of microbial community composition (e.g. Bouvier and Del Giorgio, 2007). However, groundwater deviates from surface waters in several aspects. The water saturated subsurface is composed of a complex sediment and rock matrix providing an enormous surface for microbial colonization. In fact, most microbes in aquifers are epilithic, forming colonies or even biofilms attached to rocks and loose sediment grains. These microbes outnumber the pore water suspended microbial fraction by 10–100 fold (Griebler and Lueders, 2009), a fact that may also be true for phage particles (e.g. Mindl et al., 2015). Due to the severe carbon and energy limitation, microorganisms in groundwater typically display low productivity and occur in 10 to 1000-times lower concentrations than in surface waters (Griebler and Lueders, 2009; Fillinger et al., 2019a; Griebler et al., 2014). On the other hand, the dark and comparably 'cold' environments – groundwater temperatures are rather constant and resemble the annual mean temperature at the land surface shielding subterranean microorganisms from extreme hot or cold conditions – may also substantially slow down the decay of viruses (Krauss and Griebler, 2011).

Taken together, this is expected to have several important outcomes for virus-host relationships in groundwater: (i) Contact rates between phages and hosts in the water column (proportional to the concentrations of both partners) can be expected to be extremely low. (ii) Carbon and energy limitation likely result in a small fraction of prokaryotic cells with pronounced metabolic activity and/or short time periods in which the prokaryotic community is metabolically active and able to support the reproduction of phages. Combined with an assumed long-term persistence of phage particles in groundwater, this might lead to an uncoupling of prokaryotic and phage abundances. (iii) Due to the intimate interaction between pore water and the huge sediment and rock surface area with its biofilms, phage particles frequently collide with surfaces leading to adsorption and potentially inactivation of phages (Fig. 1). However, contrasting the expected low contact rates of prokaryotes and phages in pore water, at the same time, this might also increase the likelihood of encounters between dispersed phages and epilithic host cells.

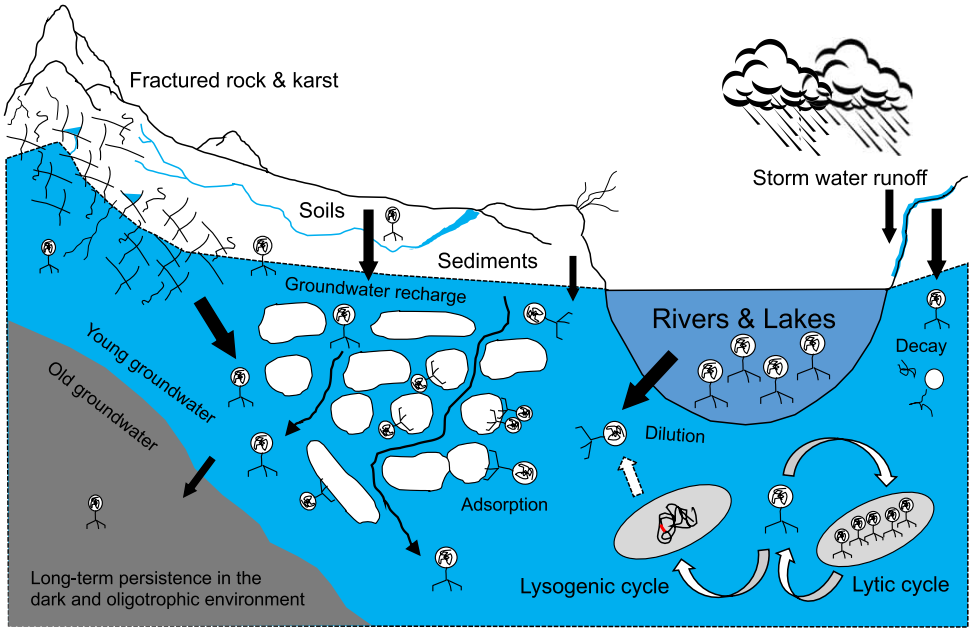

Fig. 1 Conceptual drawing of sources of viruses and processes that act at phages in groundwater ecosystems.

Virus abundance and the virus-to-prokaryote ratio (VPR) in groundwater

In groundwater ecosystems, phages and their potential ecological role have been ignored until the 2000s. Since then microbial ecologists have started to quantify phages in groundwater, repeatedly in the context of contaminated groundwater sites (e.g. Costeira et al., 2019; Holmes et al., 2015; Pan et al., 2017), but also in natural settings such as unconsolidated porous aquifers (Roudnew et al., 2014), karst systems and springs (Malki et al., 2020; Wilhartitz et al., 2013), as well as fissured aquifers like the Äspö Hard Rock Laboratory (HRL; e.g. Eydal et al., 2009; Kyle et al., 2008). Since viruses are extremely small and difficult to quantify, their abundances are often given as virus-like particles (VLPs), i.e. particles with the morphological and/or biochemical characteristics of viruses. The production of phage particles is based on prokaryotic cells and their metabolism. Therefore, prokaryotic and phage abundances are typically strongly correlated across ecosystems (e.g. $r = 0.86$, $P < 0.001$, $n = 524$ in Parikka et al., 2017). In an attempt to define a central parameter reflecting the relationships of phages and hosts in a given habitat, viral ecologists frequently determine virus-to-prokaryote ratios (VPRs) by measuring phage and prokaryote abundances in natural environments. However, the authors of the thus far most extensive meta-analysis of VPRs advise extreme caution with the interpretation of this ratio (Parikka et al., 2017). While VPR values of 10 have frequently been used as a rule-of-thumb, re-examinations of data on prokaryotic and viral abundances also suggest that VPRs are better described by a non-linear, power law function than linear relationships (Wigington et al., 2016). Parikka et al. (2017) found VPRs in groundwater averaging to 5.9 ($n = 11$), which is significantly lower than in marine waters (VPR of 26.5, $n = 233$). This could be explained by low nutrient concentrations and temperature in groundwater which, for other phage-host systems, have been found to lead to longer latent times and lower burst sizes and therefore lower viral production (Zimmerman et al., 2020). However, with only 11 samples, the data set for groundwater is ridiculously small and further studies are needed. For an overview of available data on viral abundances and reported VPRs in groundwater see Table 1.

Based on the estimated 4×10^{30} VLPs in the ocean (Suttle, 2005) at this point we may also attempt a quick estimation of total viral abundances in groundwater: Considering that (i) 2.5% of all water on earth is freshwater (= 2.56% of the amount of sea water), (ii) 30% of all freshwater is groundwater (Danielopol et al., 2003) of which 3% is less than 100 years old (termed young groundwater; Gleeson et al., 2016) and that (iii) young groundwater hosts prokaryotes and phages in concentrations comparable to those in the deep sea (below 200 m depth) which exceeds the volume of the sunlit ocean by 18-fold, we may estimate a minimum of about 10^{27} viruses (almost exclusively phages) suspended in young groundwater. Furthermore, assuming that $10\times$ more viruses are adsorbed to the sediment and rock matrix than are dispersed, this number rises to 10^{28} phage particles. This likely still underestimates actual abundances of phages in groundwater since in our simple calculation we have neglected 97% of the aquifers that are deep and contain old groundwater with so far unknown concentrations of phages. Reminiscent of the estimated prokaryotic biomass in the subsurface (Bar-On et al., 2018), it would not be a big surprise if subsurface phage biomass equals that of surface waters.

Controls of viral abundance in groundwater

Due to the limited amount of data on viruses in groundwater, general factors and principles governing viral abundance in aquifers have not been ruled out yet. For this reason, short summaries of individual case studies are presented in the following.

The first paper addressing the occurrence of phages in groundwater in an ecological context was published in the year 2008. Kyle et al. (2008) explored the occurrence of viruses in deep granitic groundwater in terms of quantity and morphology. Fluorescence microscopy counts of 10 groundwater samples originating from 69 to 450 m depth below land surface (b.l.s.) revealed 10^8–10^{10} VLP L^{-1} (VLP, virus-like particles) and 10^7–10^9 TCC L^{-1} (TCC, total prokaryotic cell counts). The authors reported a positive correlation of VLP with TCC ($r = 0.91$, $P = 0.0003$) and an average VPR of 12 (Kyle et al., 2008). Investigations of the vertical distribution of VLP in the water saturated terrestrial subsurface have been conducted by Roudnew et al. (2012) a few years later at the Ashbourne site in southern Australia. At this site, nested wells allowed sampling of groundwater from various depths between 15 m and 90 m below land surface. Ranging between 4.8×10^7 (90 m depth) and 8.8×10^8 VLP L^{-1} (60 m depth), VLP abundances varied significantly with depth ($p = 0.009$) but no general trend was observed. Also the VPR varied over the depth profile with values ranging from 0.2 to 6 (Roudnew et al., 2012). No relationship between either TCC or VLP abundance and inorganic nutrients was observed. The study revealed that, similar to their prokaryotic hosts, VLPs may experience small- and large-scale heterogeneity in groundwater systems, explained mainly by the geological setting and hydrological conditions, such as the groundwater recharge rate and the hydraulic conductivity of the system.

The first data on VLP abundance in karst waters was reported by Wilhartitz et al. (2013) who collected water from two hydro-geologically contrasting alpine springs, i.e. a limestone spring and a dolomite spring, for 3 years. Besides the long observation period, this study recorded for the first time the seasonal dynamics of naturally occurring microeukaryotes, prokaryotes and viruses in karst water. VLP abundance in the limestone spring and the dolomite spring averaged 9.4×10^8 and 1.1×10^8 VLP L^{-1}, respectively while TCC had mean values of 5.1×10^7 and 1.3×10^7 cells L^{-1}, respectively. The data revealed a strong dependence of the microbial communities on the prevailing hydrological situation. Unlike in the dolomite spring, the dynamic limestone spring revealed a clear difference between base flow and high discharge conditions. The VPRs in the dynamic limestone spring spanned a larger range of 8–43 (avg. 20) than the hydrologically less dynamic dolomite spring with VPRs of 3–12 (avg. 8). In general, the VPR at higher average water residence times was 2–3 fold lower (Wilhartitz et al., 2013).

Pan et al. (2014) performed laboratory experiments to investigate the production of phages and changes in microbial community structure within shallow alluvial aquifer sediment slurries amended with ^{13}C-labeled acetate and nitrate. This bio-stimulation resulted in phage production, concurrent with acetate oxidation, $^{13}CO_2$ production and nitrate reduction. Interestingly, the change in phage abundance was positively correlated to acetate consumption and CO_2 production whereas the change in prokaryotic cell abundance was not. Phage-mediated cell lysis had implications for microbial community composition. In the course of the incubation, representatives of the initially dominant Betaproteobacteria decreased in relative abundance while members of the Gammaproteobacteria increased. Interestingly, bio-stimulation also resulted in the production of filamentous phages from *Pseudomonas spp.*, which constituted >80% of the gammaproteobacterial community at late stages of the incubation. Although the experiment was conducted under quite artificial conditions, the authors concluded that phages are linked to carbon biogeochemistry and microbial community composition in terrestrial subsurface sediments (Pan et al., 2014).

Later the same authors assessed TCC and VLP abundances in groundwater from a uranium impacted alluvial aquifer adjoining the Colorado River near Rifle, CO (Pan et al., 2017). VLP abundance ranged from 8.0×10^7 to 1.0×10^9 L^1 and exceeded the number of prokaryotic cells in all samples analyzed (range 5.8×10^7 to 6.1×10^8 L^1). The VPR was between 1.1 and 8.1

(mean 3.0 ± 1.6 SD) with VLP abundance strongly correlated to prokaryote abundance (Spearman's $\rho = 0.73$, $p < 0.001$). Moreover, both VLP and prokaryotic cells were positively correlated to dissolved organic carbon (DOC). Groundwater uranium concentration was also strongly correlated with DOC content, VLP and TCC. Taken together the data indicates that local geochemical conditions likely control microbial host cell abundance which in turn controls phage abundance (Pan et al., 2017).

High-resolution depth-resolved quantification of prokaryotes and VLPs in a shallow tar oil polluted porous aquifer in north-west Germany, unveiled steep small-scale gradients in close relation to contaminant concentrations. A thin BTEX (mix of benzene, toluene, ethylbenzene, xylenes) plume with a vertical extension of only 50 cm exhibited a decline of contaminant concentrations by more than one order of magnitude within a few centimeters in the upper and lower fringe zone (Fig. 2, Zhou, Deng and Griebler, unpubl. data). High microbial activities and biomass, especially at the plume fringes and the slope of chemical gradients supported the concept that the latter are regulated by microbial processes and transverse dispersion, i.e. vertical mixing of electron donors and acceptors (Anneser et al., 2008, 2010). While prokaryote abundance was highest in sediment porewater collected at the plume fringes, the ratio of VLP to prokaryotic cells peaked at 250 m in the contaminant plume center (Fig. 2).

A lack of correlation between prokaryotic cell counts and virus-like particles in groundwater was found recently in a study in southern Austria (Fig. 3A). Following the River Mur valley in the federal provinces of Styria and Salzburg, 61 samples were collected from October to November 2020 during a five-week sampling campaign spanning a distance of around 300 km and an altitudinal gradient of around 1800 m. For a detailed description of the study area see Retter et al. (2020). Analysis of the whole data set, consisting of groundwater wells ($n = 46$), springs ($n = 2$), the Mur River ($n = 11$), and two tributaries ($n = 2$) revealed a reliable positive correlation between TCC and VLP for the river water samples alone (Fig. 3B). These river samples even force a correlation in the data set containing all water samples (Fig. 3C). However, the correlation disappears when groundwater samples are analyzed separately, without surface water samples (Fig. 3D). Also the VPR of river water and groundwater differed impressively. While the VPR was between 2.3 and 17.5 for the river samples (mean 7.6), it ranged between 1.2 and 728 (mean 94) within all groundwaters tested. This huge range indicates a pronounced heterogeneity within the groundwater sites sampled, revealing no detectable common relationship between prokaryotic abundance and viral production at the large scale. VLP and selected physico-chemical parameters showed only weak correlations, i.e. VLP were positively related to NO_2^- ($R^2 = 0.25$) and temperature ($R^2 = 0.20$) in groundwater, but negatively related to ammonium ($R^2 = 0.21$) and dissolved oxygen ($R^2 = 0.20$). However, as found for chloride ions by Kyle et al. (2008), groundwater electrical conductivity and VLP were significantly negatively correlated ($R^2 = 0.50$). Drawing from these findings as well as experimental results showing that virus particles may aggregate through changes in pH and salt concentration (Gerba and Betancourt, 2017), one might speculate that the quantification of VLP via direct counting may be significantly more sensitive to sample preparation than assumed previously. Moreover, the quantification of VLP from natural environments with pronounced heterogeneity in hydrochemistry and particularly with highly mineralized groundwater may be prone to underestimation.

Data on VLP in shallow groundwater has also been reported from an artificial groundwater recharge (AGWR) site. Here, Mindl et al. (2015) investigated the removal of bacteria and viruses during infiltration of surface water into the shallow aquifer through sandy and gravel sediments in infiltration ponds. The initial abundance of VLP in surface water was 5×10^{10} particles L^{-1}, which increased 3–4 fold to 1.5×10^{11} VLPs L^{-1} in interstitial water of the upper sediment layer of the infiltration basin before it decreased by a factor of 10–15 within the first meter of water saturated sediment. VLP attached to the sediment grains displayed only a minor decrease in abundance declining from about $3–30 \times 10^{11}$ VLP dm^{-3} down to 1×10^{11} VLP dm^{-3} with depth in the upper meter of sediment. It was shown that the number of viruses attached to the sediment matrix exceeded the number of free viruses by a factor of 2–20. VLPs were also quantified in the adjacent groundwater from up-gradient and down-gradient of the infiltration pond, accounting for 1.4×10^7–2.1×10^8 L^{-1}, respectively. The VPR in these latter groundwater samples was 5 (Mindl et al., 2015).

Viral diversity in groundwater: Phage morphologies, isolates and metaviromic data

In groundwater ecosystems, viral diversity is almost untapped, with culture-dependent and culture-independent studies being rare. To our knowledge, the only study characterizing the morphology of VLPs in groundwater was performed by Kyle et al. (2008). The authors observed VLPs down to a depth of 450 m in the Äspö HRL and found a diverse set of viral morphotypes resembling tailed phages (43% of observations, $n = 110$), polyhedral phages (31% of observations, $n = 78$), filamentous phages (8% of observations, $n = 21$) and fusiform archaeal phages (5% of observations, $n = 12$). Qualitatively, these results resemble viral morphotypes commonly found in surface waters (Brum et al., 2013) but more extensive datasets are needed to allow any further conclusion.

Eydal et al. (2009) isolated lytic *Podoviridae* with a very long latent period of ~70 h and a burst size of ~170 from five cultures of *Desulfovibrio aespoeensis* originating from the granitic aquifers in the Äspö HRL. This is in contrast to a recent report of a phage infecting *Pseudomonas* sp. isolated from groundwater which showed a short latent period of <2 h and a small burst size of ~20 (Hylling et al., 2020). In the same study, Hylling and coworkers isolated another phage infecting *Bacillus mycoides*. The genomes of both phages were sequenced and deposited under the genbank accession MK473373.1 and MG983742.1, respectively. It is important to note that the latent periods and burst sizes above were obtained under laboratory conditions and allow no inference of latent periods and burst sizes under in situ conditions in groundwater. Although virus particles resembling the morphology of archaeal phages have been observed in groundwater from granite aquifers (Kyle et al., 2008), no representatives have been isolated so far.

Since viruses lack a single conserved gene to be used for phylogenetic analysis and taxonomic classification, the only available method for investigating their genetic diversity in the environment is their metagenomic characterization. This process usually involves the separation of viruses and cellular organisms by filtration and the sequencing of the smaller virus fraction. However, science still has to deal with existing gaps and biases in sequencing databases which lead to a large proportion of unclassified reads (i.e. unexplored diversity) in metaviromes and an overrepresentation of well-studied phage groups such as the Caudovirales (Ackermann, 1998; Bruder et al., 2016). In addition, several studies have indicated that the morphological composition of viral communities in aquatic environments do not fully correspond to their metagenomic-based representation which results in prominent viral groups being overlooked (Kyle et al., 2009; Brum et al., 2013; Kauffman et al., 2018). In consequence, the large majority of metagenomes targeting viruses (metaviromes) in aquatic systems, including groundwater, show viral communities which are predominantly composed of double stranded (ds) DNA tailed phages or *Caudovirales* (Fig. 4; Costeira et al., 2019, Holmfeldt et al., 2021). As one of the first metagenomic, transcriptomic and proteomic studies targeting phages in groundwater, Holmes et al. (2015) circumvented these issues by only targeting phage-related sequences which the authors identified in five publicly available genomes of different *Geobacter* species. *Geobacter* sp. are important bacteria for the bioremediation of organic and metal contaminants in the subsurface. During a field experiment in which acetate was added to stimulate *Geobacter* activity in a contaminated aquifer, highly similar phage-sequences were detected in metagenomes suggesting that related phages were also present in situ. Further, concomitant with increased *Geobacter* activity, increased transcripts and peptide fragments relating to these phage-sequences could be detected which indicates also higher activity of the targeted *Geobacter* phages.

Another early metaviromic groundwater study by Smith et al. (2013) reported a high proportion of viral sequences in microbial and viral biomass collected on 0.2 μm filters, i.e. either very large viruses, viruses attached to cells or viruses within cells. A large proportion of these sequences were classified as ssDNA phages of the *Microviridae* family. Unfortunately, Smith et al. (2013) did not analyze the freely suspended fraction of viruses in their groundwater samples. Support for a high prevalence of ssDNA phages in groundwater also comes from a recent metagenomic study analyzing metaviromes of five springs fed by the Floridan aquifer (Malki et al., 2020). Furthermore, Roux et al. (2019) re-analyzed genomic and metagenomic datasets from various ecosystems which extended the 56 known members of the (ssDNA) *Inoviridae* family by >5000 putative *Inoviridae* genomes. While the newly identified sequences occurred in all major ecosystems they were especially prevalent in groundwater metagenomes.

Prokaryotic and viral activity in groundwater: Metatranscriptomic data

Recently Lopez-Fernandez et al. (2018) found metatranscriptomic evidence for the metabolic activity of all three domains of life (approximately 99% bacteria, 1% archaea and < 1% eukaryotes) in both 'young' (residence time of <20 years) and 'old' (thousands of years) groundwater. Many of the transcripts of the small ribosomal subunit (SSU) could not be mapped and included newly described candidate prokaryotic phyla (3%–31% of SSU-transcripts). Foremost, these findings indicate that microorganisms in groundwater ecosystems are active but still widely unexplored in terms of microbial diversity. In the young groundwater, microorganisms were inferred to carry out a diverse set of metabolic strategies, whereas microorganisms in the old groundwater were predominantly in 'metabolic standby' (i.e. ready to carry out translation but metabolically inactive). Notably, mapping of transcripts against Metagenome Assembled Genomes (MAGs) from the same sites yielded only a few hits for viruses. However, it

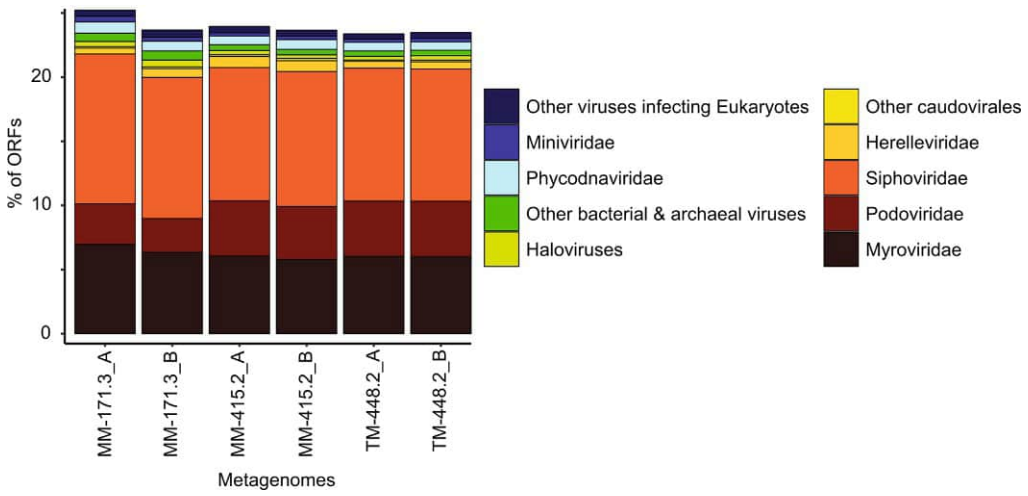

Fig. 4 Composition of the viral community in Aspö Hard Rock Laboratory based on gene homologies with known viral sequences. Three metaviromes at 171m (MM-171.3), 415m (MM-415.2) and 448m depth (TM-448.2) in two replicates (A and B). Myo-, Podo-, Sipho-, and Herelleviridae belong to the order Caudovirales. From Holmfeldt K et al. (2021) The Fennoscandian shield deep terrestrial virosphere suggests slow motion 'boom and burst' cycles. *Communications Biology* 4(1): 307.

should be mentioned that, especially in environments underexplored by metagenomic analysis, low fractions of identifiable viral reads are common (Bruder et al., 2016). In a more recent metagenomic and metatranscriptomic study with samples from the same sites, Holmfeldt et al. (2021) found that in the young groundwater up to 84% of identified viral genotypes showed transcriptomic activity. Paralleling the earlier findings for microorganisms, viruses in the old groundwater were mostly inactive or in 'metabolic standby' (0.1–3.8% active viral genotypes).

Phage lifestyles in groundwater

The relative importance of lytic and lysogenic phages in groundwater has not been addressed so far. Consequently, important variables like the frequency of visibly infected cells (FVIC), which have been seminal for initial estimates of the extent of phage mediated lysis in marine systems, are not available for groundwater (Fuhrman, 1999). From ultraoligotrophic arctic and Antarctic lakes extremely high FVIC (mean 26.1%) but low burst sizes and a large proportion of ssDNA phages have been reported (Säwström et al., 2007; De Cárcer et al., 2015). These findings indicate that highly oligotrophic environments do not necessarily prevent lytic dynamics but might keep them at an extremely slow rate or temporary halt their progression in a phenomenon called 'pseudolysogeny' until the environmental conditions change to their favor and allow the continuation of the infection cycle (Anesio and Bellas, 2011). While data on the frequency of lysogenic cells in groundwater is lacking, traditionally high frequencies of lysogenic cells have been reported from oligotrophic environments (Paul, 2008). Therefore, we might also expect a relatively high frequency of lysogenic cells in groundwater. The recent Piggyback-the-Winner model which postulates that temperate phages are more frequent under high microbial densities appears to be badly applicable to the diluted conditions in groundwater (Knowles et al., 2016). In addition, the validity of this model has been questioned based on contradicting experimental findings and theoretical considerations (Knowles et al., 2017; Weitz et al., 2017). Single stranded DNA phages of the *Microviridae* and *Inoviridae* families somewhat blur the dichotomous description of phage life strategies as either being lytic or lysogenic. While *Caudovirales* are known to encode complex machineries triggering the lysis of their host (Fernandes and São-José, 2018), *Microviridae* have significantly smaller genomes and employ much simpler mechanisms of cell lysis which are closely tied to their hosts growth (Székely and Breitbart, 2016). Both properties appear to be well suited for life in groundwater, where energy and nutrient limitations control viral production and drive organisms to a smaller genome size (Anderson et al., 2013; Tian et al., 2020). *Inoviridae* on the other hand cause chronic infections which lead to a continuous release of viral particles without lysing their host. Most of our knowledge about these phages stems from human pathogens like *Pseudomonas aeruginosa* and *Vibrio cholerae* where they have been found to impose only a low burden on their host (Hay and Lithgow, 2019). Despite their potential ecological roles only a handful filamentous phages have been isolated from aquatic environments (Wang et al., 2007). Their high frequency of occurrence in groundwater metagenomes and implication in biofilm formation raise the possibility that chronic infections by *Inoviridae* play a significant role in aquifers.

Potential ecological roles of phages in groundwater

Phages interact with their hosts but also with other phages and mobile genetic elements like plasmids. These interactions can either be antagonistic or synergistic (Díaz-Muñoz et al., 2017; Kothari et al., 2019). The interplay of phages and its consequences in aquatic ecosystems are therefore inherently complex and difficult to predict. For instance, in ocean waters a single prokaryotic strain can be targeted by more than 25 different phages at the same time (Deng et al., 2014). In groundwater, prokaryotic communities typically constitute hundreds to thousands of operational taxonomic units (OTUs or ASVs; e.g. Fillinger et al., 2019b). Due to the scarcity of studies investigating prokaryote-phage interactions in groundwater, this section on the potential ecological roles of phages in aquifers is speculative by nature. To further explore the potential role of viruses in groundwater ecosystems in the following, we address two related questions: (1) If the environmental conditions in groundwater impede viral production, why do we consistently find suspended phages in groundwater? (2) How could phage infection and reproduction be sustained under extreme carbon and energy limitations and in an environment where phages and hosts are extremely diluted? Possible answers include (i) insufficiently understood phage-host interactions between communities in pore water and those attached to sediment and rock surfaces (Hansen et al., 2019), (ii) 'boom and burst' cycles in slow motion (i.e. shifting regimes of metabolic activity and inactivity of prokaryotes and phages in groundwater, Lopez-Fernandez et al., 2018; Holmfeldt et al., 2021), (iii) frequently overlooked non-lytic viral life cycles (i.e. lysogenic and chronic infections) and (iv) groups of phages like *Microviridae* and *Inoviridae* which appear to be well adapted to carbon, nutrient and energy limitations but are hardly investigated in an ecological context (Székely and Breitbart, 2016; Roux et al., 2019).

Do phages sustain prokaryotic functional diversity in groundwater?

It is unknown how prokaryotic functional diversity can be sustained over extended periods of time when basic nutritional and energy requirements restrict essential cellular functions (especially in deep and old groundwater) such as the repair of damaged enzymes and DNA or the maintenance of the electrochemical potential (Jørgensen and D'Hondt, 2006). Phages might play an important role in this process by recycling nutrients from currently active members of the community to inactive members, e.g.

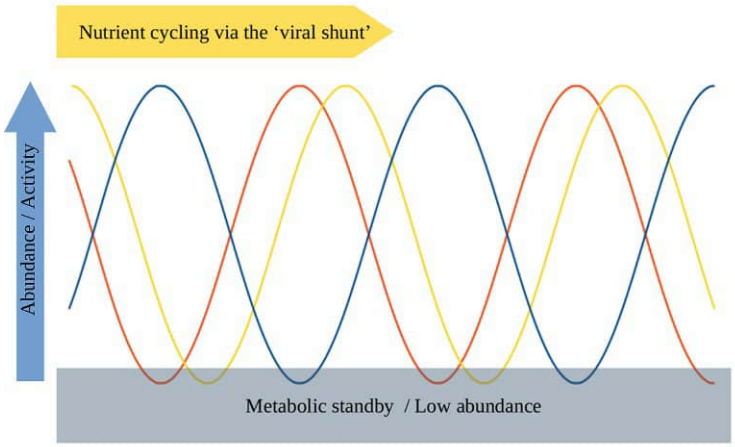

Fig. 5 Phages sustain prokaryotic functional diversity by oscillating between 'metabolic standby' and activity. Each line represents an idealized group of prokaryotes targeted by the same phages. These phages control the abundance of their hosts in a 'Kill-the-Winner' dynamic i.e. by preferentially targeting the most abundant and/or most active prokaryotes. Through host lysis metabolites are released which are recycled by other members of the prokaryotic community and thereby stimulate their activity and thereby ensure their persistence.

through 'boom and burst' cycles in slow motion (Danovaro et al., 2008; Heinrichs et al., 2020; Holmfeldt et al., 2021). In this concept, individual populations of prokaryotes oscillate between phases of metabolic activity and 'metabolic standby'. During an active phase, both prokaryotes and phages start to reproduce and phages impact the prokaryotic community following a 'Kill-the-Winner' (KtW) dynamic, i.e. the most abundant and most active prokaryotes would be preferentially targeted by lytic phages (Thingstad, 2000). As a consequence, phages would release nutrients through the lysis of their hosts via the 'viral shunt' (Wilhelm and Suttle, 1999) which could subsequently drive the activity of other members of the prokaryotic and phage community (Fig. 5). As proposed by the 'constant diversity' model, KtW is also expected to select against single prokaryotic genotypes which outcompete other, less competitive genotypes in terms of nutrient acquisition and energy usage. This allows other metabolic strategies to thrive as well and in consequence leads to a more efficient exploitation of resources by the prokaryotic community (Rodriguez-Valera et al., 2009). Both mechanisms could be essential for sustaining the functional diversity of prokaryotic communities in groundwater over long time scales. Lysogenic phages could play a key-role in the regulation of this process by either inhibiting its dynamic (e.g. by conferring resistance to other phages through 'superinfection exclusion,' van Houte et al., 2016) or promote it by switching from lysogeny to lytic reproduction. Oscillations between 'metabolic standby' and activity would also require stable intermediate stages for phages in times of 'metabolic standby' to counteract viral decay. A number of such intermediate stages like 'pseudolysogeny' (i.e. stalled stages of viral infections, Anesio and Bellas, 2011), lysogeny or chronic infections are known, which could play a key role in the persistence of phages in groundwater (Hobbs and Abedon, 2016).

Do phages alleviate metabolic bottlenecks?

Many phages contain auxiliary metabolic genes (AMGs) which during infection serve to optimize the host cell for viral reproduction by alleviating metabolic bottlenecks (Hatfull and Hendrix, 2011). Since the first description of AMGs (Mann et al., 2003), numerous examples have been identified in phages (e.g. Hurwitz et al., 2013; Kavagutti et al., 2019). Certain groups of AMGs are thought to have significant impact on the global carbon (Puxty et al., 2016) and sulfur cycle (Kieft et al., 2021). In groundwater, AMGs could keep the metabolism of an infected prokaryotic cell running even under conditions when it would normally enter starvation and halt metabolic functions. AMGs might therefore 'lubricate' the wheel of biogeochemical cycling in groundwater. How far AMGs are also involved in anabolic functions is currently unknown. As a recent example, Coutinho et al. (2020), identified AMGs in Lake Baikal which are presumably involved in dark carbon fixation and methylotrophy. These functionalities could also play a role during viral infections in groundwater.

Conclusion

Although our knowledge about the abundances and extent of metabolic and biogeochemical activities of subsurface prokaryotic and phage communities is still immature, a few conclusions can be drawn: (i) prokaryotes and phages are present in aquifers, (ii) some of these prokaryotes show metabolic activity which makes them potential hosts for phage reproduction, (iii) infective

phages are present and have been isolated from groundwater and (iv) viral RNA and viral peptides have been found to be expressed in recently recharged groundwater. Besides these facts, our knowledge about life strategies and the ecological role of phages in groundwater ecosystems is rather limited. While some studies underlined a statistical relationship between the number of prokaryotes and VLPs, other studies found no obvious connection. Moreover, no common key physical-chemical parameters have been identified governing phage abundance and production. A huge range in VPRs from less than one to >700 has been observed. Taking into account the substantially decreased contact probability of phages and their potential hosts in groundwater, in many aquifers prokaryotic and viral production (via the lytic cycle) seem to be decoupled. There is early evidence that also life strategies other than the lytic cycle, i.e. lysogeny, pseudolysogeny, and chronic infection, could play key roles in the persistence and reproduction of phages in groundwater.

Knowledge gaps

1. Which environmental factors drive viral abundances in groundwater?
2. Which environmental factors govern the activity of phages in groundwater?
3. Interactions of prokaryotes and phages in groundwater biofilms?
4. Frequency of visibly infected cells in groundwater?
5. Which lifestyles (lytic, (pseudo)lysogenic, chronic) do phages in groundwater preferentially adopt?

The Groundwater Mycobiome: Fungal Diversity in Terrestrial Aquifers

Alice Retter[a] **and Ali Nawaz**[b], [a]Department of Functional & Evolutionary Ecology, Division of Limnology, University of Vienna, Vienna, Austria; [b]Technical University of Munich, Munich, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Anamorph Asexual, mold-like reproductive stage of members of Dikarya.
Barcode Conserved to highly variable gene segments, such as the ribosomal gene cluster, proteins, or enzymes, that are universal within the target group of organisms. They are, for instance, utilized in metabarcoding efforts for rapid species identification of environmental samples.
Convergent evolution Organisms not closely related that develop traits with similar form or function, also called homoplasies.
Cryptic Morphologically indistinguishable.
Dark matter fungi Fungal taxa that are uncultured and poorly known, mostly belonging to lineages diverging early in the fungal tree.
Diversity The number and relative abundance of taxa, which are often species or functional groups of organisms, as well as the genetic variation within a taxon.
Fungi Taxonomically, fungi constitute their own kingdom. They are eukaryotic, heterotrophic, mostly mesophilic organisms that produce spores for reproduction and dispersal and branching hyphae (that make up the so-called mycelium) for propagation, organic matter decomposition, and uptake.
Groundwater Water that is located beneath the earth's surface in pore spaces and cracks of the solid, rocky crust of the earth.
Next-generation sequencing (NGS) Inexpensive, routine, high throughput method for sequencing short genetic barcodes, often from environmental samples.
Oogamy Fertilization by the fusion of a small, usually motile male gamete and a large, much less motile female gamete.
Teleomorph Sexual lifecycle stage of members of Dikarya, often producing macroscopic fruiting bodies.

Introduction

Fungi are among the dominating lineages within the ecosphere, ubiquitously present in both terrestrial and aquatic habitats. Evidence from fossil records even suggests that fungi/fungal-like organisms may have existed in the deep biosphere as early as about 2.4 billion years ago (Bengtson et al., 2017; Loron et al., 2019). Owing to their diverse life strategies as decomposers, symbionts, parasites, and pathogens, fungi play vital ecological roles in the organization of different biological communities and contributed to shaping the world as we know it in its present form. Fungi can survive and thrive under a wide range of oxygen, pH, temperature, water potential, and nutrient level conditions (Schlosser, 2012). Thus, these fantastic creatures have managed to establish themselves in various types of ecological niches and habitats such as the snow and ice as found naturally in glaciers, the tropics, deserts, the oceans, and any kind of freshwater habitat—which simply means that fungi are everywhere. Along with this omnipresence, global fungal diversity has for some time been estimated to lie between 3.5 and 5.1 million species (Blackwell, 2011). In contrast, a more recent study showed that fungal diversity probably ranges between 2.2 and 3.8 million worldwide

(Hawksworth and Lücking, 2017). However, with only ~150,000 formally described species so far (Kirk, 2021), the fungal inventory is far from being fully explored.

Fungi are talented decomposers of dead organic matter (saprotrophs) and recyclers of inorganic materials (e.g., N and P), and their bioavailability constitutes a critical factor for fungal activity. In aquatic environments, fungi display various trophic modes, often occurring as parasites or pathogens, harming the host's cells, which can be animals, plants, or sometimes even other fungi. Apart from being saprobes or pathotrophs, fungi can form mutualistic associations (symbiotroph) with animals, plants, and various microorganisms that bring forth a multitude of phenotypically distinct lifestyles, some examples being mycorrhizae or lichens (Fig. 1).

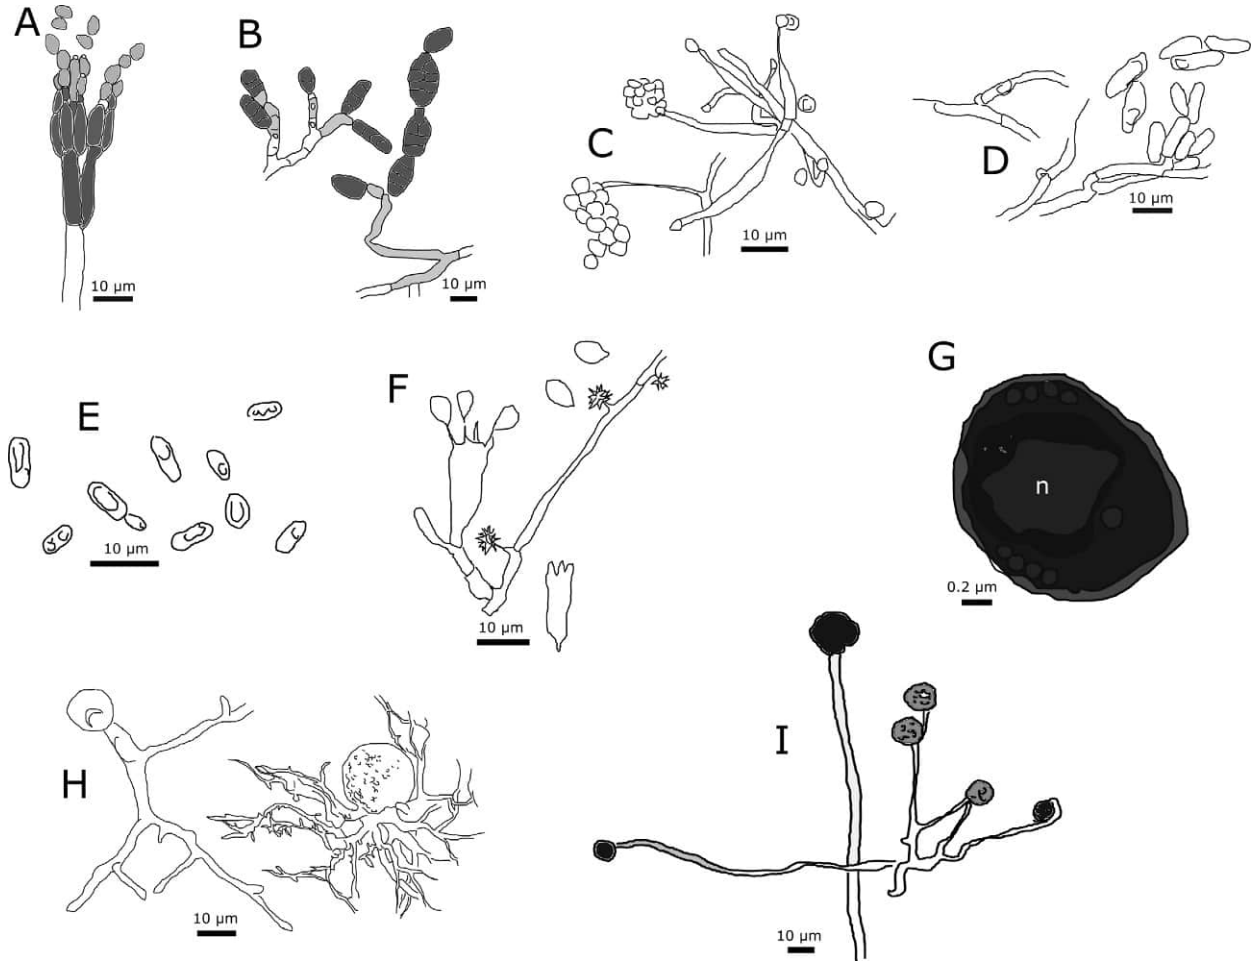

Fig. 1 Some examples of the variety of fungal lifestyles found within groundwater. (A) Ascomycetous saprotroph and plant pathogen/parasite (*Penicillium oxalicum*). (B) Ascomycetous plant- and animal pathogen, wood saprotroph (*Alternaria sp.*). (C) Animal pathogen (*Pochonia sp.*). (D) Saprotrophic, basidiomycetous yeast with filaments (*Dioszegia sp.*). (E) Low temperature tolerant, basidiomycetous budding yeast (*Vishniacozyma* sp.). (F) Saprotrophic basidiomycete (*Resinicium* sp.). (G) Microsporidian hyperparasite spore (n = nucleus). (H) Freshwater chytrid (Rhizophydiales). (I) Endophyte/saprotroph (*Mortierella* sp.).

About 90% of existing plants form such mycorrhizal associations, which, among other things, promote plant growth, increase plant resistance to biotic and abiotic stressors, and help plants acquire absorbed soil nutrients through fungal hyphae. Interestingly enough, some early diverging lineages of fungi, for instance, neocallimastigomycetes, even co-evolved within the digestive tracts of ruminant mammals, insects, and other invertebrates (Moore et al., 2011; Picard, 2017; Stefani et al., 2016). Consequently, fungi can take on a broad range of metabolic roles, naming just a few examples in Table 1. Fungi reproduce and disperse by means of spores,

Table 1 Metabolic roles of fungi.

Decomposing of OM (organic matter)
Organic and inorganic nutrient cycling (e.g., C, H, O, N, P, S, metals)
Translocation of water and nutrients
Change in local geochemistry (e.g., redox potential, pH, O_2)
Production of metabolites and exopolymers
Degradation of xenobiotics (e.g., pesticides, drugs, radionucleotides), complex compounds (polysaccharides, lipids, and proteins, and other complex structure polymers), and contaminants (e.g., fuel, oil, gas, explosives)
Mineral formation (e.g., carbonate, limestone) and dissolution (e.g., weathering and leaching)

Modified from: Watkinson SC, Boddy L and Money NP (2015) *The Fungi*, 3rd edn., pp. 189–190. Elsevier Ltd.

which are formed during meiotic- or mitotic reproduction. Different taxa can bring forth a great variety of spore types, all with an individual morphological and functional identity. Many aquatic fungal species, such as members of Chytridiomycota, and Blastocladiomycota can produce motile, flagellate spores (zoospores) (Fig. 2), or non-motile spores with a variety of unique shapes, optimal for dispersal in aquatic environments.

It is well established that fungi sometimes have complex and obscure life cycles that may involve stages of different growth forms (e.g., filamentous and/or unicellular, such as yeasts) (Fig. 1), hosts, and sexual states (e.g., anamorphs and teleomorphs in Dikarya) (Naranjo-Ortiz and Gabaldón, 2020). Fungi are largely cryptic, driven for instance, by convergent evolution, which is widespread throughout the fungal tree of life and can be caused by mechanisms such as interspecific hybridization (Shang et al., 2016; Steensels et al., 2021; Sun et al., 2019; Torruella et al., 2015). Traditional morphological taxonomic species identification is, in reality, often not possible, as stages of the life cycles in which fungi form characteristic fruiting bodies are unknown or not inducible during

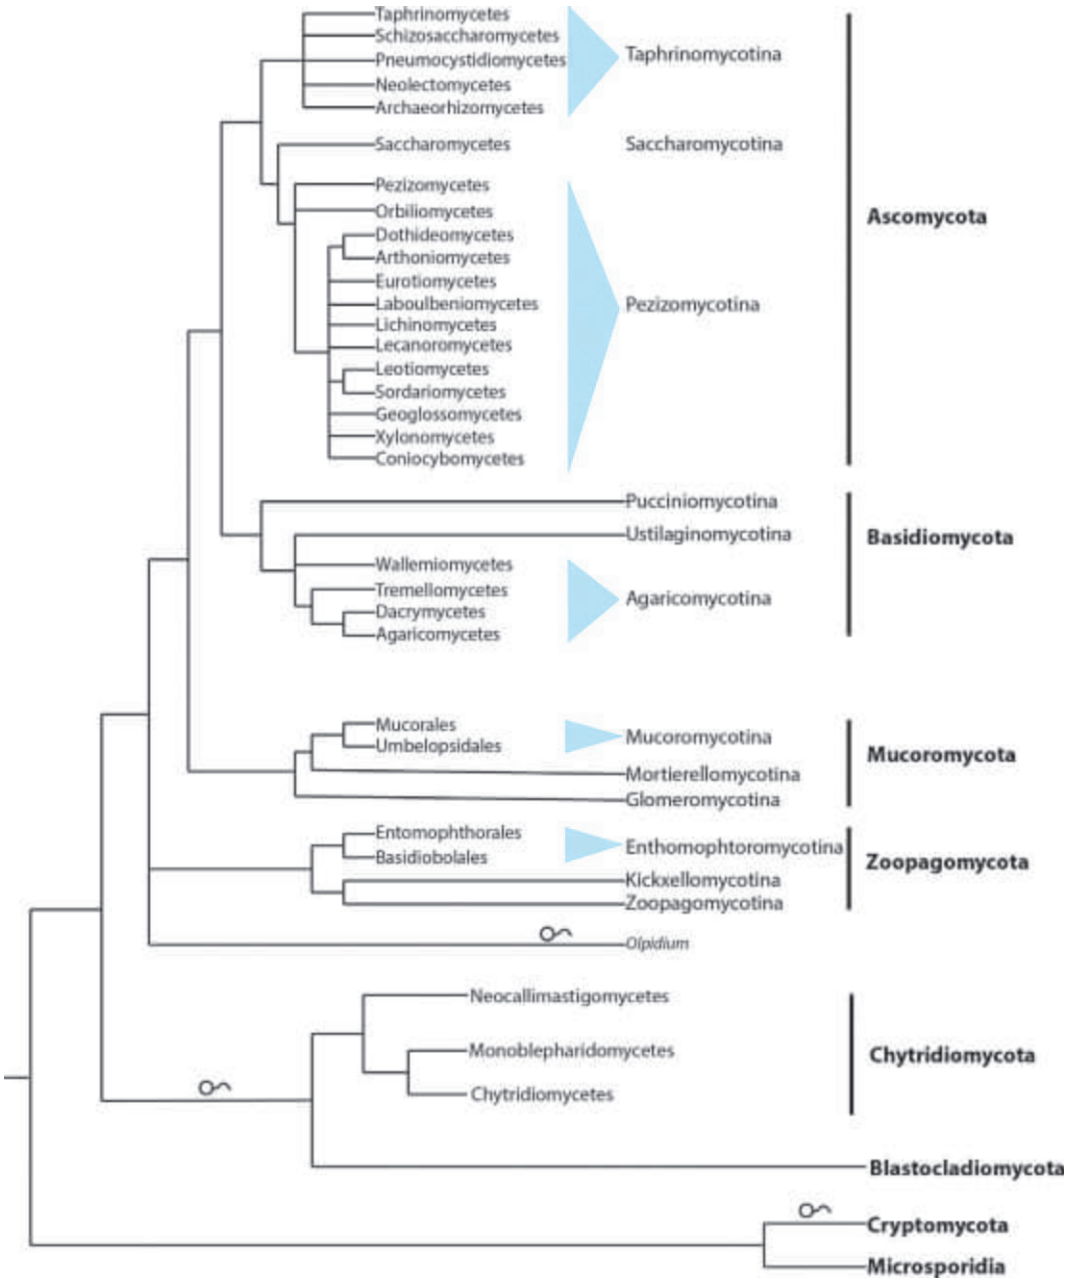

Fig. 2 Current understanding of the phylogenetic backbone of the fungal kingdom, compiled and negotiated from several phylogenetic studies (Gazis et al., 2012; Hibbett et al., 2007; James et al., 2006, 2013; Nguyen, 2015; Rosling et al., 2011; Schoch et al., 2009; Sekimoto et al., 2011; Spatafora et al., 2016; Tedersoo et al., 2018; Zhuang and Liu, 2012). Polytomies are representing yet unresolved relationships between lineages. Zoosporic fungi are indicated by a schematic drawing of a zoospore (James et al., 2006).

cultivation, and their somatic structures only show limited cell differentiation (Watkinson et al., 2015). Thus, purely phenotypic recognition of fungi is difficult, and it is no wonder that the taxonomic history of fungi resembles a roller coaster ride (Naranjo-Ortiz and Gabaldón, 2020).

The lack of knowledge about the sexual states of fungi and the fact that many species cannot be cultured in the laboratory consistently results in formal species descriptions being ambiguous or missing altogether. The large amount of molecular data derived from environmental sequencing creates an additional layer of complexity to this problem. Environmental sequencing, such as Next-generation sequencing (NGS) or Third-generation sequencing, is based on classifying a molecular barcode into a hypothetical species. These techniques enable rapid species identification in unprecedented numbers, utilizing subregions located in the nuclear ribosomal gene cluster, such as the formally accepted internal transcribed spacer (ITS) barcodes ITS1, or ITS2, or other, sometimes longer or more conserved parts of the rDNA (ribosomal DNA) (Heeger et al., 2018, 2019; Nilsson et al., 2019; Wurzbacher et al., 2019). The exactness of the classification depends a lot on the comprehensiveness and up-to-dateness of the various classification databases of choice. Additionally, these sequencing techniques are subject to several factors that may lead to biased species classifications, such as choice of primers, barcode, or sequencing technology (Tedersoo et al., 2015).

Unknown fungal richness in groundwater

Compared to the earth's terrestrial ecosystems, where many fungal global datasets are available, the aquatic environment has been historically understudied regarding its fungal diversity. It is important to mention that despite the huge estimates of ~2.2–3.8 million extant fungal species, currently, only a little over 4000 have been classified as aquatic (Jones et al., 2014) (Fig. 3). Such a small proportion of aquatic fungi within the global fungal diversity estimates may not hold when acknowledging that around 70% of the earth is covered with water and aquatic environments are potentially ideal habitats for many fungal species (Wurzbacher et al., 2011). This highlights the need to revise the extent of aquatic fungal diversity in the light of recent advances in molecular methods and their broader applications in biodiversity estimates of various ecosystems.

Similar to the deep oceans, the world's groundwater habitats are seriously underexplored for fungi (Grossart et al., 2019). Especially fungal members belonging to early diverging lineages (Fig. 2) are mostly underrepresented in fungal studies of aquatic systems (Picard, 2017; Retter et al., 2019). There are several reasons for such underrepresentation of aquatic fungi: first, many aquatic ecosystems/landscapes of the world are still not very well explored for their fungal inventory; second, reproduction life cycles in which fungi produce distinct fruiting bodies are often entirely missing (or yet undiscovered) for many fungal taxa; and third, due to molecular bias caused, for example, by choice of primers or the DNA barcode marker. The ITS—region, for instance, is not sufficient to target and resolve the taxonomy of fungi at a deeper level (Berbee et al., 2017; Grossart et al., 2019; Nilsson et al., 2019; Picard, 2017; Tedersoo et al., 2015).

Groundwater food sources and replenishment

The groundwater hydrosphere is generally regarded as an oligotrophic environment regarding the abundance and bioavailability of organic material. Due to the complete absence of light, an important energy source for primary production is missing. Even though chemoautotrophic organisms, for instance, as part of microbial biofilms, can sometimes contribute substantially to biomass production in groundwater, most of the energy is derived from the land surface (Herrmann et al., 2020). This includes organic material mainly in the form of allochthonous DOM (dissolved organic matter), which is supplied with seepage water. The availability and composition of DOM and essential nutrients are crucial for the survival and flourishing of the fungal communities

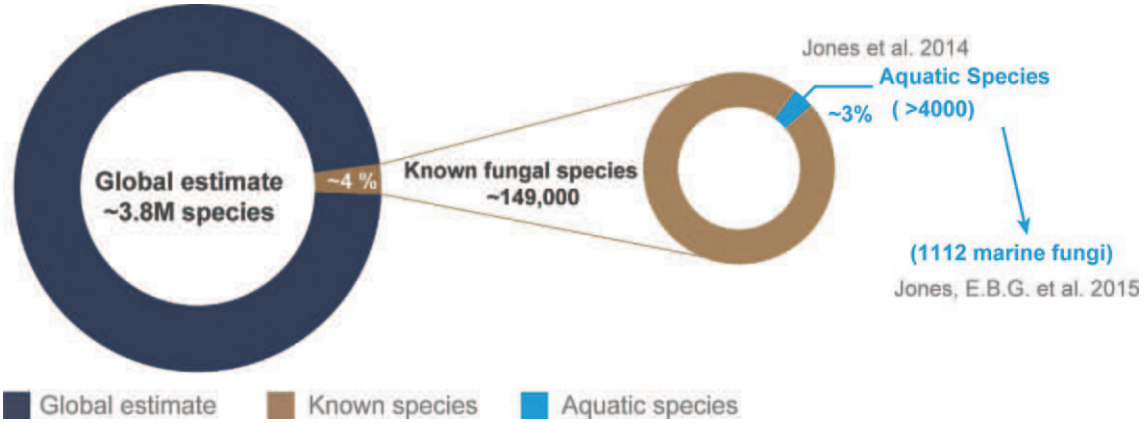

Fig. 3 The actual representation of known/described species of aquatic fungi (Jones et al., 2014, 2015) in the overall fungal diversity estimates.

in groundwater. In groundwater, the input of organic material will usually change dynamically during periods of precipitation and subsequent recharge or drought. Likewise, the quality and quantity of DOM that ultimately reaches the saturated zone is influenced by various biotic and abiotic factors, such as the surface land cover, surface water to catchment connectivity, the porosity, and the geology of the unsaturated zone, as well as the distance of the land cover to the aquifer (groundwater table depth). It is also dependent on the chemical and physical properties (e.g., polarity) of the dissolved organic compounds, if they have undergone photodegradation on the surface, and the degree of biodegradation by resident microbial communities in the soil layers through which the DOM passes (Shen et al., 2015). As a result, typical groundwater DOM is largely deprived of lignin-derived phenols, which are derivatives of secondary metabolites of vascular plants, and higher molecular weight (HMW) compounds (Shen et al., 2015). These fractions of DOM are highly reactive and have the ability to readily adsorb to the surface of solids (Rutlidge et al., 2021; Singh et al., 2016). Therefore, in terms of DOM composition, groundwater is similar to the deep ocean (Shen et al., 2015).

In contrast, in rivers, streams, and lakes, POM (particulate organic matter), e.g., animal and plant detritus, is an essential energy source. However, POM is not present in significant quantities in groundwater, as it is attenuated or degraded already within the pedosphere. From this point of view, groundwater represents a rather hostile environment for fungal organisms. On the other hand, some limiting factors such as UV-irradiation, competition for food or host species, or extreme temperature fluctuations do not exist or are less pronounced, which in turn may prove advantageous for the survival of various fungal species and their spores.

Not surprising, groundwater is different to surface water systems in several other aspects, such as high-water residence times (sometimes decades or millennia) and limited space, mainly in the form of (interconnected) pore cavities in unconsolidated sediments or fractures in the rock matrix. As a result, the groundwater hydrosphere may only serve to a limited extent as a vector for (long-distance) dispersal of fungal taxa and their spores. In summary, groundwater, represented by water in various types of aquifers, underground streams, and cave waters, forms a unique ecosystem with some potential limitations and advantages for its fungal and overall microbial life, on which the stability of this ecosystem is founded. Since groundwater is usually recharged by rain and snowmelt, as well as surface water passing through soil and sediment zones, this ecosystem provides a rare opportunity to study both transient and resident fungi in their natural settings.

The diverse ecological roles of fungi

Despite the challenging conditions prevailing in groundwater, there have been several studies conducted within the last decades that were able to detect both total and active proportions of fungal communities in various groundwater environments (Ekendahl et al., 2003; Jasrotia et al., 2014; Livermore and Mattes, 2013; Nawaz et al., 2018, 2019; Perkins et al., 2019; Schwab et al., 2017; Sohlberg et al., 2015; Wurzbacher et al., 2020). A study that has been published as early as 1989 already points at the highly diverse and distinct microbial communities, including fungi that could be recovered from a deep coastal plain aquifer (Fliermans, 1989), and fossilized fungi have also been reported from the subsurface (Reitner et al., 2006).

Concrete examples highlight the potentially important and yet unexplored roles that fungi play in the oligotrophic environment of the water-saturated subsurface. The first is that they can potentially restructure the groundwater matrix through their mineral weathering and mineralization properties, and thus also provide essential minerals for their (and other microorganisms) growth and metabolism (Ivarsson et al., 2018).

Second, they are excellent degraders of complex organic compounds, which they may mineralize to CO_2 and water in the presence of oxygen. Macropolymers often have a poor biological degradability, making them persist in the groundwater environment over a long period of time. Poorly biodegradable leftovers (refractory OM) of organic matter can be decomposed and transformed by fungi via particular enzymatic pathways, and they are also believed to have the capability to produce highly aromatic organic compounds themselves (Collado et al., 2018; Masigol et al., 2019). Some lignin-derived compounds, such as humic substances, make up a significant part of the refractory DOM available in groundwater (Hofmann and Griebler, 2018; Perkins et al., 2019). The effective degradation of such humic compounds by fungi seems to be dependent on, e.g., its concentration, oxygen availability, and temperature (Collado et al., 2018), possibly leading to slower degradation rates (i.e., supporting long-term growth) of complex organic substances by fungi in groundwater.

If pulses of DOM passing through the aquifer are long-lasting, at least bacterial communities were found to adapt and utilize the labile fraction of DOM. However, it appears that the more labile carbon there is available, the less it is converted into bacterial biomass for reasons that are still ambiguous (Hofmann et al., 2020). On the other hand, it seems that a more diverse composition of DOM promotes a higher bacterial diversity (Hofmann et al., 2020). Bacterial and fungal communities do not seem to be intimately connected, but as the structural setup of DOM is a primary driver for both, these scenarios could prove to be true for fungi as well (Fabian et al., 2017).

In other words, this could mean that if pulses of DOM are short, labile DOM is not converted into biomass to the same extent, as the microbial communities are highly adapted to the energy-poor conditions prevailing in groundwater. Thus, labile DOM may be retained in the gravel matrix or transported further down into the aquifer depending on hydrology and sorption capacities (Hofmann and Griebler, 2018). Fungi, especially saprotrophic taxa such as yeasts, are known to degrade substantial amounts of labile carbon (de Vries and Caruso, 2016), therefore potentially playing an important role in the degradation of this "unused" DOM fraction. Taking all of this into account, one can still only speculate about the dimension of the groundwater fungal biomass.

In situ sources of OM include microbial biofilms that form on the gravel matrix and rock surface of aquifers, byproducts of mineral-fluid interactions, chemolithoautotrophic primary production, production of secondary metabolites, fungal spores, as well

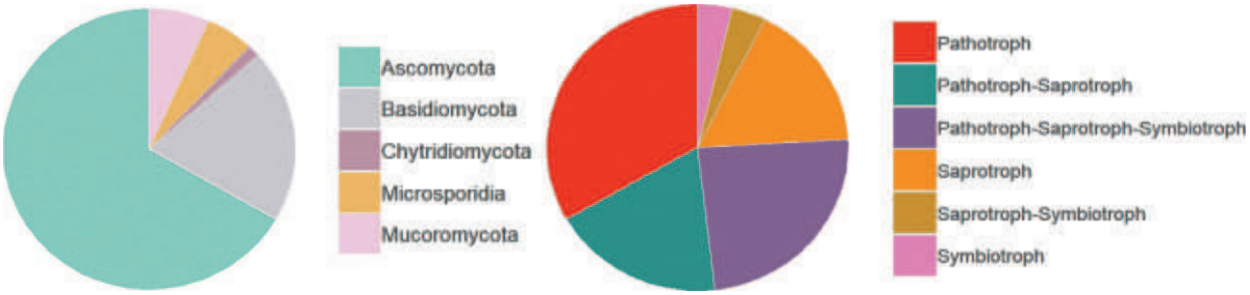

Fig. 4 Taxonomic affiliation on phylum level (left) and their trophic state (right) of 78 fungal taxa that represent the most commonly recovered fungi from groundwater habitats so far, summarized from several environmental sequencing studies (Bohu et al., 2016; Ekendahl et al., 2003; Euringer and Lueders, 2008; Fester, 2013; Grabner et al., 2020; Hoque and Fritscher, 2016; Jasrotia et al., 2014; Livermore and Mattes, 2013; Nawaz et al., 2018; Purkamo et al., 2018; Sohlberg et al., 2015; Wurzbacher et al., 2020). Trophic states of taxa were annotated, where possible, with FUNguild (Nguyen et al., 2016).

as dead groundwater biota (Drake and Ivarsson, 2018; Ivarsson et al., 2018; Kagami et al., 2014; Reitner et al., 2006). Although a certain percentage of groundwater fungal communities consist of saprotrophic species, Sohlberg et al. (2015) did not find a correlation between fungal diversity and activity and the input of dead organic material in their study of a deep groundwater mycobiome. This suggests that fungi potentially take on different ecological roles within the groundwater than those of pure decomposers, again emphasizing that fungi have complex life cycles and lifestyles within the groundwater habitat. This would be in line with the discovery that significant parts of fungi recovered from groundwater are parasites and pathogens (Fig. 4). For example, fungal members of Microsporidia have been found to parasitize groundwater amphipods - an ecological role that is still awaiting a more thorough exploration (Grabner et al., 2020). Other studies hint at the important role of fungi sustaining anoxic (deep) subsurface environments, for example, by recycling fossil DOM stocks (Perkins et al., 2019). Here they act as producers of substrates, such as small organic compounds or hydrogen gas that are readily available for autotrophic processes of other members of the microbial loop (Drake and Ivarsson, 2018; Pomeroy et al., 2007; Purkamo et al., 2018). Another study hints at the role fungi play in providing and transporting dissolved iron in anoxic to suboxic karstified groundwater environments (Schwab et al., 2017). These specific metabolic abilities indicate that fungi could play a role in sustaining bacterial communities locally, where bacteria are known to play an essential role in OM decomposition and biomass generation and effectively contributing to groundwater biomass themselves (Watkinson et al., 2015).

Where do groundwater fungi originate from?

The question of what the source of fungi recovered from groundwater forms is not so easy to answer. Nevertheless, aquatic fungi in general and groundwater fungi, in particular, can be divided into two broader groups. These are "resident fungi" and "transient fungi." Resident fungi are those specimens that can complete their life cycle in the aquatic realm and are not encountered in terrestrial habitats. In contrast, transient fungi are those that enter the aquatic environment from terrestrial sources and can adapt well to local conditions or remain inactive in the form of spores (Shearer et al., 2007). For instance, a robust adaptive capacity is exhibited by groundwater fungi found in karst aquifers, which make up the majority of the fungal OTUs found in these landscapes. These are presumably transported from the surface into the groundwater system, facilitated by fractures, underground drainage systems, as well as the large voids of karst during recharge events (Nawaz et al., 2016). The presence of terrestrial fungi in aquatic systems (transient fungi) raises a relevant question about the ability of different fungal taxa to adapt to the aquatic environment.

A recently published study on subterranean aquifers has shown the presence of various fungal OTUs of the terrestrial origin or known to be parasitic fungi of various crops in the active fraction of groundwater fungal communities recovered (Nawaz et al., 2018). This raises the question of whether and how the fungi have undergone specification in groundwater and whether obligate groundwater species exist at all. With the current state of information available on groundwater fungi, these questions are difficult to answer unless there are hypothesis-driven studies on these topics either in natural settings or in well-designated lab experiments.

Taxonomic composition and systematic overview of groundwater fungi

Fungal taxonomic and functional diversity in groundwater habitats is manifold, although there is currently no systematic overview of groundwater species. Keeping the fungal tree of life (Fig. 2) in mind, fungal taxa recovered from groundwater habitats so far are mostly affiliated with pathogenic and/or saprotrophic lineages, and a major part of them belong to Dikarya (Ascomycota + Basidiomycota) (Fig. 4). Wurzbacher et al. (2020) found that around 8% of the fungal diversity recovered from volcanic springs was made up of early diverging lineages of fungi, and a significant part belonged to yet unexplored yeast lineages. Yeasts, exclusively occurring within Dikarya, are especially remarkable, as they could be recovered from basically every habitat of the world (McLaughlin and Spatafora, 2015; Rojas-Jimenez et al., 2020).

Early diverging lineages

The following paragraphs attempt to address the ecology and systematics of the individual fungal phyla against the background of groundwater ecosystems. According to most recent phylogenetic studies, the branch diverging earliest in the fungal tree is the clade uniting members of Cryptomycota, and Microsporidia which are sister to the rest of the fungi. This clade is found to be almost as old as the entire fungal tree of life, and emerges mostly from environmental sequencing efforts, most often in marine ecosystems, but also from groundwater (Grabner et al., 2020; Letcher et al., 2018; Richards et al., 2012; Wurzbacher et al., 2020). Many cryptomycetes and microsporidians are endoparasites, for instance, of other fungi or fungal-like organisms (Gleason et al., 2012). Cryptomycetes have likely secondarily lost their chitin cell wall—a feature most members of the fungal kingdom share—in certain stages of their life cycle, such as during host infection (James et al., 2013; Jones et al., 2011; Richards et al., 2012). They also seem to have a degenerate mitochondrion, emphasizing the parasitic signature this group of early diverging fungi shares. Members of Microsporidia are also intracellular parasites that have evolved to infect a wide range of organisms, from insects to mammals, including aquatic species (McLaughlin and Spatafora, 2014). Microsporidians have to harvest their energy from a host as they have lost their mitochondria in the course of evolution, being left only with a reduced version called a mitosome (James et al., 2013).

Members of another ancient branch of fungi comprised of zoosporic chytrids and blastocladiomycetes have been found within groundwater ecosystems (Jasrotia et al., 2014; Nawaz et al., 2018; Sohlberg et al., 2015). The emergence of zoospores within this aquatic sister group to the "terrestrial fungi" once again underlines their adaptation to the aquatic realm. They are ubiquitous in various habitats, the majority of them being found in water. They have also been recovered from highly challenging environments, such as hydrothermal vents in the deep ocean (Le Calvez et al., 2009). Nawaz et al. (2018) discovered that the chytrid fraction made up the third-largest phylum detected in their groundwater study site. In the groundwater, chytrids are mainly parasites of other fungi or invertebrates. In surface water ecosystems, they also infect amphibians, and plants, including algae and phytoplankton. Some orders within Chytridiomycotina are also known to saprotrophically feed on various structural polymers (e.g., keratin and chitin). Monoblepharidomycetes, on the other hand, are exclusively saprotrophic and form a distinct clade, which is attributable to their oogamous sexual reproduction (McLaughlin and Spatafora, 2014). Neocallimastigomycetes are obligate anaerobic species, which can be found in terrestrial and aquatic anaerobic environments but are best known for their occurrence in the guts of ruminant herbivores. In the course of evolution, they came forth with a degenerate version of a mitochondrion that allows them to break down complex compounds, such as cellulose, by fermentation. Thus, together with facultative anaerobic fungal species, which include some members of Blastocladiomycota, they have the potential to sustain oxygen-deprived groundwater environments (Moore et al., 2011; Risse-Buhl et al., 2013).

Fungi belonging to the Zoopagomycota and Mucoromycota are thought to only occur sparsely within aquatic habitats. On the other hand, these claims are potentially obsolete as it is now well established that this group of fungi is underrepresented in environmental sequencing efforts, primarily due to molecular biases. They are non-flagellate fungi and known to comprise the earliest terrestrial lineages that are important to understand the transition of fungi from water to land (Heitman et al., 2017). Members of Zoopagomycota are mostly predators (for instance, of nematodes and their eggs, or amoebae), parasites (e.g., of other fungi), but also obligate symbionts, for instance, in the gut of arthropods (Heitman et al., 2017; Spatafora et al., 2017). Mucoromycetes are predominantly characterized by their associations with plants, for example saprotrophic, or mycorrhizal, and their most recent ancestors probably gave rise to the modern fungus-plant relationships. Evidence in favor of the theory of a molecular bias towards these lineages of fungi is given by Grossart et al. (2019), who name this phylum as one of the dominant lineages recovered from groundwater aquifers.

Dikarya

Most sequences recovered from groundwater metabarcoding efforts are affiliated with Dikarya, many of them yeast or yeast-like taxa (Fig. 4). In other words, they are probably dominating the subsurface hydrosphere from what we know so far. The largest fungal phyla are Ascomycota, containing around 65,000 described species, and Basidiomycota, which encompasses approximately 31,000 described species. All known yeast species are placed within Dikarya but do not form a monophyletic group. Yeasts consist of those taxa that are known to grow vegetatively by budding or fission, and they are usually single-celled, although there exist exceptions that can produce hyphae. They can be free-living, attached to the substratum, or living within a host. Besides that, the majority of members of Dikarya grow in filaments on all kinds of organic substrates, such as carbohydrates, some being able to function well even under oxygen-deprived conditions (facultative anaerobes). Many members cannot be unambiguously placed within existing phylogenetic clades (Jones et al., 2014), and a significant number of described species within this group have their binomial name only linked to their asexual state, and the description of sexual morphs is often missing.

Moving from unknowns to knowns of aquatic fungal diversity

As in the previous sections, we have established that aquatic fungi are highly diverse in their taxonomic composition and functional abilities. Unlike the conventional microbiology tools such as microscopic or direct observations of different fungal spores, the molecular-based environmental surveys employing metabarcoding techniques (e.g., NGS) helped to explore unusual aquatic fungal

niches, for instance, deep-sea sediments, subseafloor, hydrothermal vents, and terrestrial groundwater. However, apart from the environmental sequences that could be taxonomically assigned, a significant proportion of the sequences remained unclassified, a common observation in most aquatic fungal surveys. Likewise, from DNA and RNA-based analysis of groundwater samples from terrestrial aquifers, Nawaz and colleagues reported that a significant proportion of fungal sequences remained unclassified (Nawaz et al., 2018, 2019). Such high proportions of unclassified fungi detected in the sequence-based datasets from the aquatic habitats are primarily due to the lack of their representation in the reference databases (Grossart et al. 2019, Heeger et al. 2019; Hibbett et al., 2011) and Grossart et al. (2016) has termed these unknown/unclassified aquatic fungi as "fungal dark matter—FDM"—the composition and ecology of which is largely unknown.

At present, the fungal databases are dominated by sequences from two major lineages, namely Ascomycota, and Basidiomycota with little representation of early diverging lineages, such as Cryptomycota, Chytridiomycota, and Zoopagomycota. This explains the possible reason for a considerable proportion of unclassified aquatic fungal query sequences against the available databases. One way forward to resolve the problems associated with fungal dark matter is the unambiguous communication of such unclassifiable fungal species (Kõljalg et al., 2020), or the application of single-cell omics, which involves the lysis and subsequent single-cell whole-genome sequencing of uncultured fungi. In 2018, a team of scientists from the Joint Genome Institute (JGI) and the University of Michigan has successfully amplified the whole genomes of a group of uncultivated fungi (Ahrendt et al., 2018). Application of such methods in aquatic fungal diversity studies will help to expand the current scope of information of aquatic fungi from mere pieces of barcoding regions of fungal DNA to whole genomes of the representatives of different fungal lineages, which consequently not only help to catalog the early diverging fungal species but also to understand their evolution and unique metabolic potentials.

Outlook on fungal groundwater diversity and their protection

In aquatic ecosystems, both organic and inorganic matter sources are altered by influences such as human activities, changed groundwater characteristics, or extreme meteoro-hydrological events (climate change) (Retter et al., 2020), which ultimately affects the resident fungal communities. These events can also potentially influence important drivers for fungal diversity, such as pH (e.g., leading to possible heavy metal leaching), temperature, or salinity. A change in local salt concentration could have very specific consequences, as it is relatively more difficult for land and freshwater species to conquer marine habitats, and salinity, therefore, plays a fundamental role in shaping fungal diversity (Jones and Pang, 2012). To better protect fungal communities in groundwater and the aquatic realm, there is an urgent need to improve the understanding of their diversity, as well as functions they provide, to protect their habitats, to act against climate change, to reduce anthropogenic influences on water bodies, such as the unrestricted use of fertilizers and fungicides in agriculture, and to accelerate the description and accurate classification of yet undescribed fungal species.

Conclusion

In this article, we underlined the diversity and capabilities of groundwater fungi as well the bottlenecks and way-outs in studying groundwater fungi using next-generation molecular platforms. There is a general agreement that fungi in terrestrial habitats are well studied and researched compared to aquatic ecosystems and that terrestrial fungi can be described as both richer and more diverse. However, the advent and application of new molecular biological tools in the field of mycology has revolutionized the approach and understanding of mycologists towards aquatic fungi. Despite this technological progress, groundwater mycologists are still faced with fragmented, or distorted information and literature on certain fungal groups and taxa, while research on others is entirely lacking.

It is worth noting that although groundwater represents only a small fraction of the water available on the planet, nearly 1.6 billion people worldwide depend on this underground reservoir for domestic, agricultural, and industrial purposes. From this context emerges a lack of consensus on the occurrence of diverse fungal taxa in groundwater, as the focus lies mostly on disease-causing taxa or few others that provide potentially interesting functions for biotechnology. All of this gives rise to an incomplete puzzle of groundwater mycology.

Conversely, it can be concluded from the available information on groundwater fungi that, in terms of species diversity and occurrences, we are currently only scratching the tip of the iceberg. A coherent message from recently published literature on groundwater fungi using the most-recent molecular methods (based on sequencing) is that largely, fractions of unknown fungi represent the mycobiome of groundwater. This indicates a significant knowledge gap regarding the contribution of groundwater fungi to the sustainability of such a unique ecosystem, along with their evolution, ecology, metabolic properties, and interaction potential with other organisms in the aquatic groundwater food web.

Knowledge gaps

- Accounting for the proportion of fungal respiration in groundwater.
- Estimating the proportion of fungal biomass in comparison to other microorganisms, such as bacteria.

- Exploring ecological roles that fungi cover within groundwater and defining their contributions to the groundwater food web, carbon, and nutrient cycling dynamics, as well as quantifying their turnover rates.
- Determining fungal diversity and formally describing novel fungal species living in groundwaters to reduce the number of "dark taxa" and accurately assess the full taxonomic and functional potential of fungi in groundwater.
- Investigating the fungal spore hydrodynamics and their dispersal in groundwater.
- Determining the number of obligate and facultative groundwater species.

Microbial Biodiversity in Groundwater Ecosystems

Clemens Karwautz and Christian Griebler, Department of Functional & Evolutionary Ecology, Division of Limnology, University of Vienna, Vienna, Austria

Glossary

Abundance The total number of individuals of a taxon or taxa in an area, population, or community.
Aquifer An underground geological formation of sand, soil, gravel and rock able to store and yield water.
Dormancy Not active or growing but has the ability to be active at a later time.
Ecosystem services Benefits people obtain from ecosystems. (1) Provisioning services such as food and water; (2) Regulating services such as regulation of floods, drought, land degradation, and disease; (3) Supporting services such as soil formation, nutrient cycling and habitat provision; and (4) cultural services such as recreational, spiritual, religious and other non-material benefits.
Eveness The uniformity of abundance between species in a community.
Functional group Groups of organisms that respond to the environment or affect ecosystem processes in a similar way.
Genetic diversity A measure of the amount of distinct genetic characteristics within and among individuals of a population, a species, an assemblage, or a community.
Metabarcoding High throughput DNA-based identification of multiple species from environmental DNA.
Metagenome Complete DNA sequences recovered from an environmental sample, containing information on community structure and genetically encoded functions.
Natural habitat Areas composed of viable assemblages of species of largely native origin and/or where human activity had not essentially modified an area's primary ecological functions and species composition.
Phylogeny The evolutionary relationships among organisms; the patterns of lineage branching produced by the true evolutionary history of the organisms being considered.
Population A group of individuals of the same species, occupying a defined area, and usually isolated to some degree from other similar groups.
Species richness The number of species within a given sample, community, or area.
Syntrophy Interaction of different species of microorganisms that are mutually dependent on each other for growth and existence.
Taxonomy A system of nested categories (taxa) reflecting evolutionary relationships or morphological similarity.

Introduction

The term biodiversity (or biological diversity) describes the variability of life. It covers multiple scales spanning from the genetic to the ecosystem level. In general, the differences between the entities apply to the taxonomic, phylogenetic and the functional diversity (Escalas et al., 2019; Horner-Devine et al., 2004; Prosser et al., 2007). Looking into the microbial diversity, early microbiologist Lourens Baas-Becking (Baas-Becking, 1934; Wit and Bouvier, 2006) famously wrote "*Everything is everywhere*, but *the environment selects*." His statement acknowledges the ubiquity of microorganisms, and assumes virtually no dispersal limitations but a dominant structuring role of the environment. Almost 100 years later, this tenet of microbiology has been proven inaccurate as ecologists start to unravel the underlying mechanisms for the spatial and temporal distribution patterns of microbial communities. In this chapter we will discuss the available tools to measure and estimate microbial diversity in groundwater ecosystems, we will examine the drivers of diversity and the relevance of biodiversity for ecological processes.

Microbes, including all living single-cell organisms such as *Bacteria*, *Archaea*, protozoa, and some fungi, are ubiquitous in aquifers. Their diversity and versatility makes them the most important drivers of biogeochemical processes in the subsurface. A clear distinction to terrestrial and aquatic surface microbial communities is the absence of light and thus phototrophic life but also the limited supply of easily available organic carbon. The groundwater habitat (the terms groundwater, aquifer, and subsurface ecosystem are used synonymously) comprises a vast, mostly nutrient-limited and often heterogeneous environment. The different challenges for its inhabitants have been described for metazoans (Fišer et al., 2014) and microbes (Goldscheider et al., 2006; Griebler and Lueders, 2009) in aquifers alike.

Historically, microbiologists have focused on Eubacteria as the dominant group of microorganisms in most groundwater ecosystems, but recent analysis draw a more complete picture including all domains of life. Due to the enormous extent of the water-saturated subsurface, it forms the largest inland aquatic habitat for microbes and an immense pool of carbon on earth.

Groundwater ecosystems present not only vast but complex habitats for diverse microbial biocoenosis. Sequences of different geological layers and large vertical gradients for nutrients, substrates, temperature, pressure and redox conditions are characteristic for the subsurface. Especially, the mixing zones of groundwater and surface ecosystems are active spots of biogeochemical processes and high microbial biodiversity (Küsel et al., 2016).

Shallow groundwater systems are also highly impacted by the input of organic matter and nutrients from surface environments (Hofmann et al., 2020; Stegen et al., 2016). In terrestrial habitats land-use and meteorologic events, such as heavy rain, affect the shallow subsurface. Nonetheless, groundwater is most often characterized as a nutrient-deprived environment. Microbes deprived of carbon, nutrient and energy sources display several adaptions such as a reduced metabolism, dwarfism or even dormancy. In caves and aquifers, where organic input from upper layers is restricted, chemolithoautotrophic microorganisms may shape the ecosystem processes (Chen et al., 2009; Hutchins et al., 2016). Chemolithoautotrophs capture energy from oxidizing inorganic compounds and provide the base for foodwebs, which establish pathways of energy flow that give the system its character (Levin, 1998).

The microbial communities that drive the processes in the subsurface differ in their composition and structure from surface environments (Taubert et al., 2019). Despite the typically nutrient-poor conditions in the subsurface, microbial communities in groundwater can display high diversity. However, measuring microbial diversity in any environment is not a trivial task. The current estimates for the global microbial species richness ranges from several millions up to 10^{11} taxa (Locey and Lennon, 2016; Schloss et al., 2016). The great variability of estimates is related to technical and methodological shortfalls (Amann and Rosselló-Móra, 2016). Still, being aware of the different methods and concepts to describe biodiversity (e.g. depict the number of species, their relative abundance and distribution) allows us to draw informed conclusions.

A short history of groundwater microbiology

The first microscopic investigations of groundwater bacteria date back to van Leewenhoeck (1677) who observed, what he called "animalcules" in little droplets of well water. In the mid-19th and early 20th century several observations of microbes (e.g. methane-, iron-, and manganese-oxidizing bacteria) in diverse subsurface habitats (e.g. raw water from water works, salt mines, deep subsurface, oil-field water and reservoirs) were reported (Cohn, 1853; Ginsburg-Karagitscheva, 1933; Hassall, 1850; Namyslowski, 1913). It took until the 1980s that modern, aseptic sampling techniques allowed a more comprehensive analysis of inherent microorganisms within aquifers (Kölbel-Boelke et al., 1988; Ventullo and Larson, 1985; Webster et al., 1985). At that time, groundwater contamination and its effect on microbial communities were already in the scientific spotlight (Harvey et al., 1984; Tangley, 1984; West and McKinley, 1983) and would act as the main topic for the years to come. The vast amount of contaminated sites (e.g. gasworks, landfills, industrial waste) fostered a hands-on approach that led to new discoveries on bioremediation, corrosion and degradation processes. Following this hike in applied groundwater microbiology, more fundamental research started and ecological questions and patterns were studied. Groundwater microbiology is nowadays a multidisciplinary research field including geomicrobiology, hydrogeology, and biogeochemistry. Recurring questions in microbial ecology regard the distribution, structure and function of the communities often stated as "Who eats what, where and when" (Neufeld et al., 2007; Xu et al., 2014).

Methodological approaches

> As is the case with other statistics, such as the mean, the median, the mode, and the standard deviation, evenness (diversity) values are merely numbers: their relevance to an ecological problem must be judged by the ecologist on the basis of observed correlations with ecological or environmental variables of his or her interest.
>
> Molinari (1989)

Richness is the number of species present in a community, without considering their abundances, while diversity indices like Shannon or Simpson also take into account species abundances. Evenness is a measure of how evenly abundances are distributed among species in a community. Therefore, estimating diversity requires the observation and quantification of community members (i.e. individuals) and their classification into discrete units [i.e. species, operational taxonomic units (OTUs), amplicon sequence variants (ASVs), genes, functional traits] in a defined area or volume.

In addition to characterizing different features of community diversity (i.e. alpha diversity), geographic or temporal variation across communities can be quantified (i.e. beta diversity), and the total observed richness of all samples (i.e. gamma diversity) can draw a picture of biodiversity across scales (Hill, 1973; Jost, 2006; Walters and Martiny, 2020).

For the observation of microorganisms, the advances and availability of molecular tools since the 1990s have shifted the analysis from laborious, and bias-prone culture-dependent methods to gene-based community profiling [e.g. denaturing gradient gel electrophoresis (DGGE), automated ribosomal intergenic spacer analysis (ARISA), terminal restriction fragment length polymorphism (T-RFLP)] in the past decade and more recently to metabarcoding and high through-put sequencing methods.

The amplification and identification of the ribosomal 16S SSU rRNA (small subunit ribosomal ribonucleic acid) and functional genes has become a standard practice in microbiology (e.g. Earth Microbiome Project). The approaches have dramatically increased the resolution with which microbial community diversity and composition can be analyzed over previous gene fingerprinting techniques. However, although these approaches are now widely used and standardized, they present new challenges as they are also prone to bias the results by the choice of methods (e.g. DNA extraction, primers, polymerase chain reaction, etc.). Furthermore, the taxonomic classification of microorganisms is not always unambiguous as different, partially conflicting classification systems exist and reaching a consensus currently still is an active and evolving field (Parks et al., 2018; Waite et al., 2020).

DNA fingerprinting methods rely on the separation of amplicons (i.e. the product of an amplification reaction), based on different sequence composition (e.g. GC content, size). Each band or fragment represents and is counted as a distinct taxonomic unit. These techniques allow only a qualitative or at best a semi-quantitative measure for the abundance of OTUs.

With next generation sequencing (NGS) the sequence of nucleotides for each amplicon can be recorded. Bioinformatic tools (e.g. OTU clustering, or inference of ASVs) group similar amplicon sequences into distinct units, and abundances are computed based on the number of sequence reads for each of these units. The taxonomic classification can be inferred from alignments of the obtained sequences in relation to sequences of known taxa in a database. The acquired nucleic acid sequence information may be used to infer species similarity, which can be approximated using phylogenetic diversity indices (Faith, 1992; Leinster and Cobbold, 2012; Lozupone and Knight, 2008). In brief, microbial communities of low phylogenetic diversity consist of populations that are genetically more similar and are thus more likely to share a common ancestor and functional traits and *vice versa*.

The analysis of functional marker genes has been widely used to screen environmental samples. Typically, conserved genes encoding the key enzymes of catabolic pathways or dissimilatory electron transfer reactions are targeted. Functional groups that are regularly encountered in groundwater environments are methanotrophs and ammonia oxidizers, lithoautotrophs, sulfate-reducing microorganisms, denitrifiers and methanogens. With the advent of non-targeted sequencing methods such as high-throughput sequencing and metagenomic analysis, complete or nearly complete microbial genomes can be analyzed (Anantharaman et al., 2016; Lau et al., 2014) and led to the discovery of novel clades and metabolic pathways.

A metagenome analysis utilizes the entire genetic composition of microbial communities. After the extraction of nucleic acids from an environmental sample, direct sequencing yields a collection of genetic fragments (i.e. reads) that can be assembled using bioinformatic algorithms (Teeling and Glöckner, 2012). Consequently, metagenome sequences allows high resolution genomic analysis of phylogenetic and functional features.

Metagenomic analysis tackles two important questions: "Who is there?" and "What are they potentially capable of doing?" These investigations have provided unprecedented insights into the microbial life within aquifers and subsurface ecosystems. Recent studies have revealed a great micro-diversity within single taxonomic groups that can be described in terms of a pan-genome (i.e. all the genes present in a given species, across all isolates). This analysis allows to differentiate between core genes (common to all isolates) and accessory gene content, which would indicate the preference to a specific environmental setting (Brockhurst et al., 2019). The advances in sequencing technology allow high resolution analysis of microbes. Still, all the methodological approaches require a trade-off between comparability (e.g. same processing) and suitability (e.g. highest efficiency). In groundwater, the most common restrictions to community analysis are: low cell densities and activities, presence of PCR inhibitors (e.g. iron, humic acids) and underrepresentation of sequences from subsurface ecosystems in reference databases (Smith et al., 2018). It is absolutely necessary that the efforts in sequencing and bioinformatic data analysis are matched with a thorough investigation of the environmental conditions. In a pointedly critique, Prosser and Martiny (2020) warn of purely descriptive look-and-see studies which often mistake correlation and causality. The theoretical frameworks to study microbial diversity are available and should be used.

Microbial biodiversity in groundwater ecosystems

Ecological and evolutionary dynamics

Ecological and evolutionary processes (i.e. selection, drift, mutation, gene flow) determine the assembly of microbial communities. Abiotic factors (e.g. pH, temperature, nutrient concentrations and composition) affect the fitness and metabolism (i.e. biochemical reactions) of each individual microbe. The metabolic rate constrains the ability to grow, to be active and to reproduce (Brown et al., 2004) and thus influences population dynamics. The availability of nutrients and energy governs the microbial growth and activity in natural groundwater (Hofmann et al., 2020; Hutchins et al., 2016). The interaction rates (i.e. trophic dynamics: consumption, predation, parasitism) and population growth are determined by rates of individual metabolism. In natural aquifers large areas are populated by low numbers of microbes, phages and eukaryotic predators, which will narrow the chances for encounters and interactions. These mechanisms will be more important when microbial activity is increased. There is a direct link between the rates of ecological interactions and species diversity. This further illustrates that comprehensive analysis of the microbial biodiversity cannot be achieved isolated from the environment and the conditions in which the taxa live and processes are taking place.

In an aquifer, the most important abiotic factors are often described by the physico-chemical properties of groundwater such as the pH, electrolytic conductivity, temperature and oxygen concentration. In addition, major ions, dissolved gases and nutrient availability are factors that define the niches in groundwater. Furthermore, the hydrogeology (i.e. sediment structure and mineral composition as well as hydrodynamics) shape the environmental conditions in the subsurface (Humphreys, 2009). As a consequence, species lacking the relevant traits to thrive under those conditions will fail to colonize this groundwater environment, which is referred to as environmental (or abiotic) filtering (Kraft et al., 2015).

In addition, species interactions (e.g. competition, predation, mutualism and commensalism) will determine the community assembly (Little et al., 2008). Even though, little is known about the ecological role of heterotrophic protozoa (mainly flagellates) and phages (i.e. viruses) in the subsurface, they are considered to be important predators of microorganisms (Kyle et al., 2008; Novarino et al., 1997; Weinbauer et al., 2007). In addition, phages have been shown to be important drivers of microbial diversity by targeting the dominant species, but also acting as agents of gene transfer (Edwards and Rohwer, 2005). Besides predation, syntrophic and mutualisitc interactions between prokaryotic partners appear to be wide-spread in the subsurface. Especially in nutrient deprived groundwater, ultramicrobacteria (Anantharaman et al., 2016; Luef et al., 2015) with particularly small genomes and cell sizes (<0.1 μm) that may even lack essential biosynthetic pathways, are common. For these organisms syntrophy (i.e. species living off the metabolic products of another species) and interconnected populations are required for growth and survival.

The assembly of microbial communities is defined by the establishment and maintenance of local communities through the colonization and immigration of individuals from a regional species pool (Fukami, 2015; Leibold et al., 2004). Perturbations and disturbances create new chances for new populations to establish. In groundwater such perturbations and stressors can be related to water level fluctuations, temperature changes, nutrient inputs or pollution with xenobiotics (Cho et al., 2000; Griebler et al., 2016; Hemme et al., 2010; Herzyk et al., 2017; Pilloni et al., 2019).

Biodiversity and its impact on groundwater ecosystems

Why do we care about the microbial diversity in groundwater? Despite the high microbial diversity present in the environment, most biochemical reactions are driven by a limited set of metabolic pathways. Describing communities as functional entities (i.e. ecological guilds or clades) which encode enzymes for the same energy-yielding metabolic reactions reveals patterns of community structure (Louca et al., 2018). The functional diversity can be quite different from the taxonomic diversity which has major implications for the ecosystem functioning (i.e. the capacity of natural processes and structures to provide goods and services). Phylogenetically different microbes belonging to the same functional group contribute to the ecosystem functioning under varying environmental conditions. This functional redundancy will ensure that biochemical processes are carried out by substituting one species in case of disturbance by a functionally equivalent species.

In Cardinale et al. (2012) formulated consensus statements based on meta-analyses that describe the impact of biodiversity on ecosystem functioning. For marine environments, it has been shown that microbial functional diversity increases with taxonomic diversity (Galand et al., 2018). The following should also be considered for microbial communities in groundwater ecosystems:

- Diversity increases the efficiency, as differences in functional traits increase the total resource capture by which ecological communities capture biological resources, produce biomass, decompose or recycle nutrients.
- Biodiversity increases the stability of ecosystem functions over time through functional redundancy.
- The correlation between biodiversity and ecosystem processes is nonlinear.
- Diversity across trophic levels influences ecosystem functions more strongly than diversity within trophic levels.
- Functional traits of organisms have a large impact on ecosystem functions which may change after extinction of the organism.

Does scale matter? Species distribution across spatial and temporal scales

The number of observed individuals varies in relation to the spatial and temporal scale under investigation. Aquifers have long been considered as large uniform and unproductive environments, and are still underrepresented in global biodiversity studies. Even though the subsurface is immensely large, it is far from a homogenous and inactive biome. The comparatively low cell densities

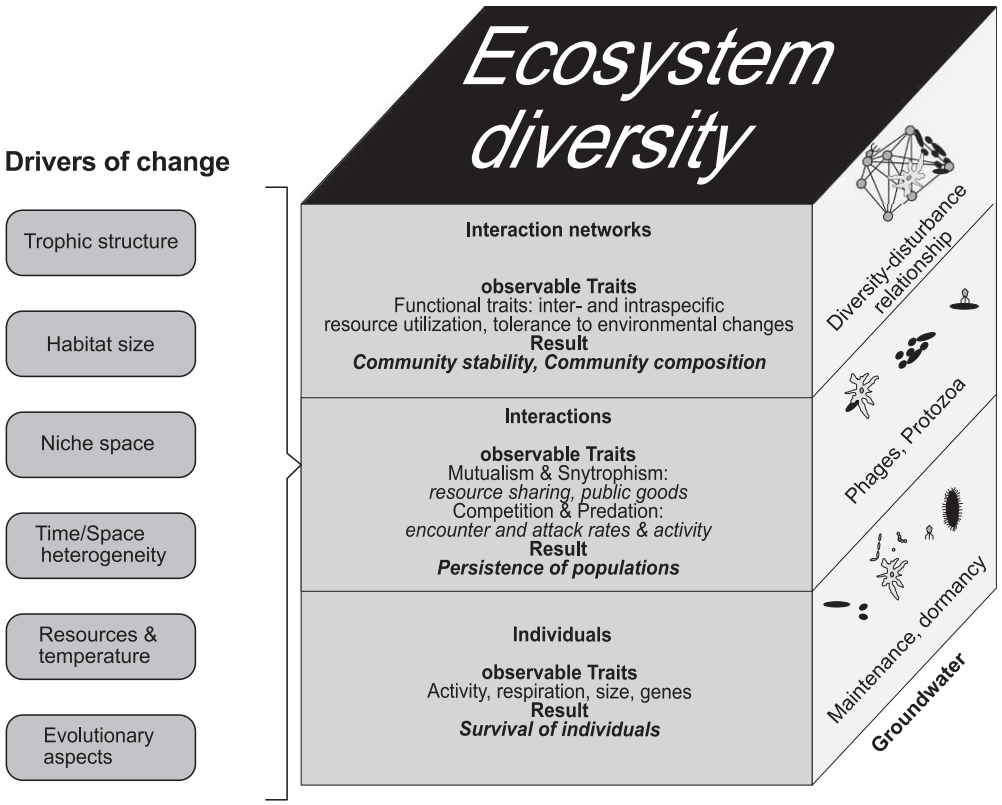

Fig. 1 From genes to ecosystems. The hierarchical structure of microbial biodiversity is driven by eco-evolutionary dynamics connecting one level to another. Trophic interactions dominate the energy flow through the ecosystem and thus shape diversity patterns. Examples relevant for the groundwater environment and measurable traits are given.

commonly found in those environments is compensated by the sheer volume and surface area the microbes colonize. These niches are shaped by abiotic (reduction-oxidation) and biotic (species interactions) gradients (Fig. 1). While the interaction range of microorganisms is in the range of a few μm to cm, fluctuations of the groundwater table can span several meters, and aquifers may extend over hundreds of kilometers. But even then, hydrological dynamics as well as small scale substrate heterogeneities are important when considering the microbial biodiversity. More than 90% of the microbial biomass in aquatic ecosystems are attached or bound to the sediment matrix (Griebler and Lueders, 2009). Hence, the free floating cells that are sampled by pumping groundwater represent only a limited fraction of the total microbiome. High resolution monitoring has revealed different populations within the range of a few millimeters to centimeters (Anneser et al., 2010; Meckenstock et al., 2015; Pilloni et al., 2019) where physical-chemical gradients occur. On the smallest scales (micro- to centimeter scale) species interactions and mass effects are important, but the importance decreases as spatial scales become larger where community composition becomes more affected by environmental selection, dispersal, and drift (Langenheder and Lindström, 2019). The small-scale variation and the restricted accessibility to groundwater has so far limited the success of identifying clear biogeographical patterns.

However, colonization of pristine sediments seems to follow the same mechanisms (i.e. succession) that are found in non-subsurface environments (Fillinger et al., 2019b). The subsurface seems to be also strongly influenced by the local terrain structure, which can be more relevant to landscape-scale ecosystem patterns (Fan, 2015).

Although recent meta-analyses of aquatic ecosystems suggest that biogeographic patterns exist across microbial taxa, they are weaker than for macro-organisms (Barberan et al., 2012; Hillebrand, 2004; Philippot et al., 2010; Stein et al., 2012). Moreover, with microbes a decoupling of taxonomic and functional community composition has been observed, which can be due to lateral gene transfer or functional redundancy (Boucher et al., 2003; Louca et al., 2018). In contrast to macroorganisms, many microbial functions are not continuously expressed and directly dependent on the environmental conditions (e.g. activity, community interactions) (Kundu et al., 2020). Several studies show that microbial populations contribute disproportionally more to the active community functions than their abundance may suggest (Jewell et al., 2016; Wegner et al., 2019). Hence, a conflict between the measured diversity of genotypes (conserved gene regions (i.e. 16S rRNA)) and the realized functional diversity (i.e. inferred from databases) arises. In microbial ecology, a trait-based approach which focuses on the ecological strategies and functions of a microbe is pursued (Escalas et al., 2019; Krause et al., 2014; Martiny et al., 2013).

In the subsurface the large range of spatial scales is match by the temporal variability of processes. Climatic change and seasonal patterns are typically dampened and time-delayed with the depth gradient. Most studies have investigated short-term effects of biodiversity on ecosystem functioning, but often relevant changes (i.e. climate) appear on much larger time scales. Investigating the temporal scale of groundwater biodiversity is limited by the few longterm monitoring sites (e.g. Hainich in Germany, Rifle in CO, USA or Äspö in Sweden). Shallow aquifers with a high hydraulic conductivity can exhibit seasonal fluctuations affecting biodiversity (Ben Maamar et al., 2015; Lohmann et al., 2020; Zhou et al., 2012). Seasonal effects such as the influx of allochthonous (i.e. originating from elsewhere) microorganisms (i.e. dispersal) and substrates can influence community composition but are mitigated compared to surface ecosystems.

Global groundwater models estimate highly variable groundwater turnover times ranging from decades in shallow aquifers to several thousands of years in less accessible and deep strata. This illustrates the different environmental conditions and process dynamics that groundwater microorganisms are facing. While some subsurface microorganisms are directly affected by adjacent ecosystems (e.g. losing streams, water table within plant root depth) others are more or less isolated from surface environment (Fig. 2).

In this respect, also the role of dormant and non-active microbes needs to be considered. Apparently a large proportion of microorganisms in the subsurface exhibit low activity or metabolically resting due to unfavorable conditions (e.g. starvation). Nonetheless, these microbes contribute to the potential microbial diversity (i.e. seed bank, (Lennon and Jones, 2011)) and are thus part of the metacommunity. Resuscitation of dormant cells is mostly coupled to changing environmental conditions. Considering the bias of blending active and dormant cells or even extracellular DNA when analyzing sequence data is especially important in groundwater systems where starvation is likely to be the rule, rather than the exception (Kundu et al., 2020).

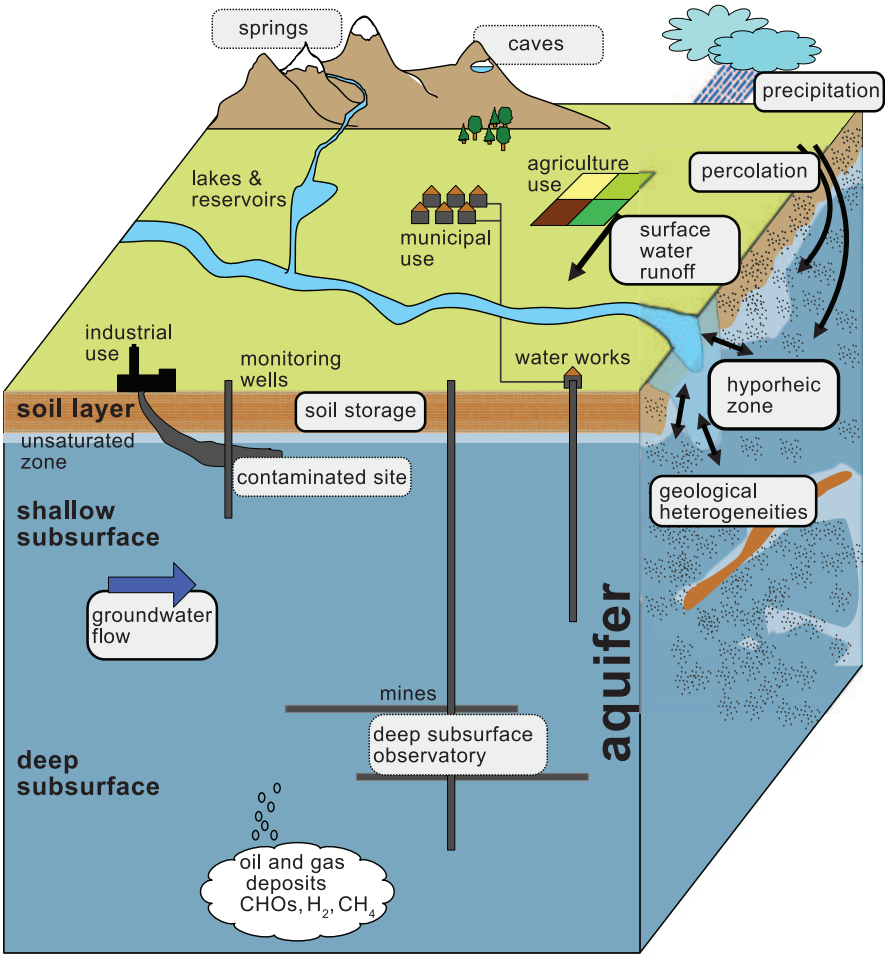

Fig. 2 A schematic overview of the subsurface and adjacent habitats. The groundwater environment links terrestrial and aquatic ecosystems. The intact water cycle provides humans with invaluable ecosystem services.

The characterization of microbial groundwater communities

Despite the great variability of subsurface ecosystems several parameters have been used to characterize the indigenous microbial biocoenoses. The total cell counts (i.e. abundance of prokaryotes) range from 10^2 to 10^6 cells suspended in one mL groundwater and a hundredfold more (10^4 and 10^8 cells per cm^3) can be found attached to the sediment matrix (Griebler et al., 2002). In all aquatic environments, microbes will attach to sediment particles, rock surfaces, larger organisms, and organic detritus. The physical aggregation of organic material at the water-solid interface makes the attached mode of life especially advantageous in carbon- and nutrient-poor environments. Furthermore, it has been shown that the phylogenetic, metabolic and functional diversity of planktonic and attached cells differs substantially (Alfreider et al., 1997; Smith et al., 2018; Stoodley et al., 2002).

Abiotic factors (e.g. pH, temperature) affect the microbial activity (i.e. biochemical reactions) of each individual cell. The metabolic rate constrains the ability to grow, to be active and to reproduce (Brown et al., 2004) and thus influences population dynamics (Fig. 1). The rates of individual metabolism (e.g. transformation and uptake kinetics, foraging) determines the interaction between cells (i.e. trophic dynamics: consumption, predation, parasitism) and population growth. Several methods have been developed mainly based on the incorporation of labeled substrate to estimate in situ microbial activities. Bacterial carbon assimilation rates based on uptake of radiolabeled substrate, revealed bacterial doubling times between a few days and thousands of days for groundwater sediments (Phelps et al., 1994).

The readily measured ATP (i.e. Adenosine triphosphate) concentration in groundwater gives a fairly good indication of the active microbial biomass. In pristine natural aquifers the ATP concentrations will be as low as a few picomol per litre (1 pM = 10^{-12} mol) and even lower in deep subsurface strata.

Where to look? Case studies of biodiversity in groundwater habitats

Today we know that the entire earth's underground (within the strict limits of life) is colonized by microbes. That microbial communities in the subsurface consist mainly of Bacteria and Archaea, but also of Protozoa and Fungi occur, and that these microbial communities are relevant for biogeochemical processes. The species richness in groundwater is highly variable ranging from highly specialized communities in extreme environments (e.g. deep hot subsurface, acid mine drainage) dominated by a few species to highly diverse microbiomes.

Microbial communities in groundwater can be very diverse and, depending on the depth and the hydraulic conductivity, they are more or less influenced from above (soil) layers or intrusion of surface water. Even though naming a complete list of microbial lineages in groundwater is elusive, several taxa are recurring and are likely to be found in aquifers (Griebler and Lueders, 2009).

The large and diverse bacterial phyla of Proteobacteria is also the most common in groundwater. The composition of the major subgroups alpha-, beta-, and gammaproteobacteria may indicate ecological gradients (Philippot et al., 2010). For example, Betaproteobacteria are abundant in freshwater, while they are less common in saline waters. Other phyla comprise: nitrite-oxidizing Nitrospirae (Gülay et al., 2019); Firmicutes, often as indicators of recent groundwater (Flynn et al., 2013); Bacteroidetes, associated with the breakdown of polysaccharides (Wegner et al., 2019); and Acidobacteria, which share a close ecological connection to the Proteobacteria (Kielak et al., 2016) The recent discovery of nanobacteria (Luef et al., 2015) and episymbiotic bacteria belonging to the Candidate Phyla Radiation (CPR, or Patescibacteria) demonstrate the potential for new discoveries (Anantharaman et al., 2016).

Archaea may be less abundant in shallow aquifers and often associated with extreme environments. However, they take a central part in mediating biogeochemical processes throughout the subsurface (He et al., 2021; Probst et al., 2014; Purkamo et al., 2018). Especially striking is the high efficiency of their chemolithoautotrophic pathways. *Nitrosopumilus*, a member of the phylum Thaumarchaeota is involved in nitrification and is capable of CO_2 fixation for the utilization of inorganic electron donors. Although evolutionary distinct, it shares this trade with several other lineages affiliated to the phylum of Crenarchaeota and Bathyarchaeota (Lazar et al., 2017). These phyla appear to be common, but are not abundant in groundwater.

The tight interconnection of Archaea and Bacteria is best illustrated by the methane metabolism. Archaea, are so far the only known microorganisms that conserve energy for ATP synthesis by producing methane gas (CH_4) called methanogensis. In the absence of oxygen, methanogens produce considerable amounts of methane from the decay of carbon (Kotelnikova, 2002) in the subsurface. Closely related to this process, is the anaerobic methane oxidation, which is hypothesized to be a reverse methanogensis (Hallam et al., 2004). A syntrophic consortium of archaea, termed (ANME), and a bacterial partner link the oxidation of methane to a wide range of electron acceptors (i.e. sulfate, nitrite, nitrate and metals). Specifically, in contaminated aquifers these processes might be dominant and structure community composition.

Fungi have long been neglected in microbial community analyses of groundwater ecosystems. The eukaryotic microbes are known saprophytes and parasites, mostly thriving from the decomposition of organic and inorganic materials. Thus, they are considered for monitoring groundwater quality (Lategan et al., 2012), and anthropogenic impacts (Nawaz et al., 2018). Consequently, the presence of fungi in the absence of organic deposits has been linked to a parasitic lifestyle and the fungal degradation of bacterially produced polysaccharides (Cunningham et al., 1995; Drake and Ivarsson, 2018). Recently, the discovery of deep diverging fungal lineages in aquatic systems (Grossart et al., 2016) has spurred the interest of microbiologists to expand the picture of the microbial biodiversity in the subsurface.

In the following, we provide some examples of groundwater habitats (Fig. 3) that resembles the breadth of investigations.

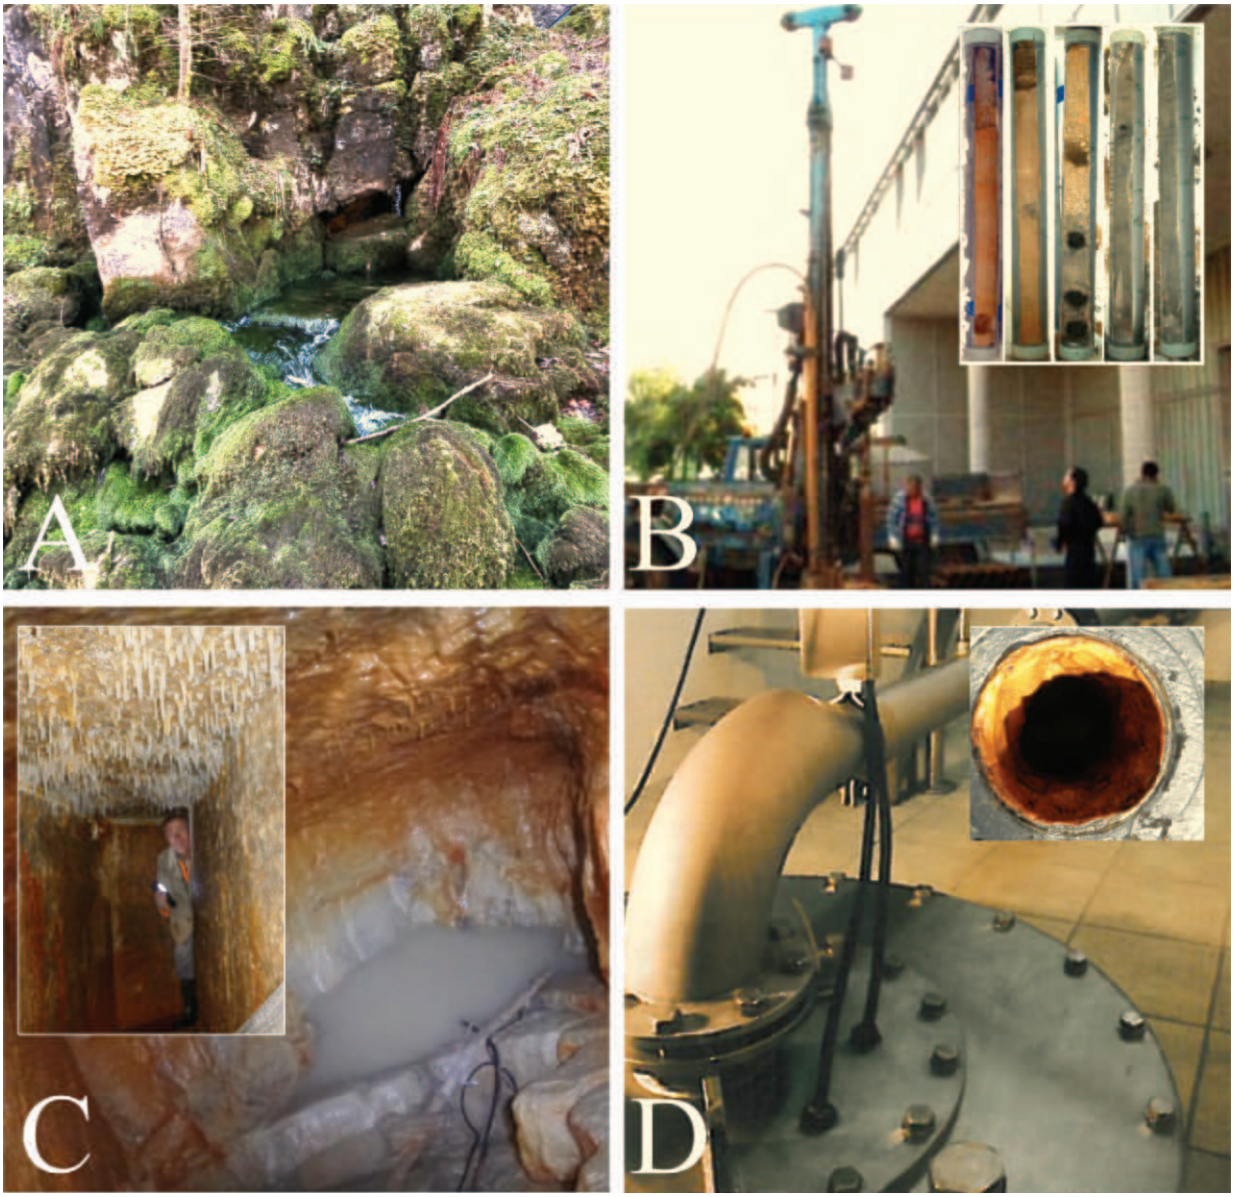

Fig. 3 (A) Groundwater emerges at the surface at a natural alpine spring. (B) Drilling monitoring wells and recovering borehole sediments from a contaminated aquifer to assess bioremediation processes. (C) Caves can host massive microbial biofilms, which often thrive on chemolithoautotrophic resources. (D) Drinking water distribution systems host a distinct microbiome.

Shallow groundwater ecosystems

Large metagenomic and proteomic studies have revealed novel bacterial and archaeal phyla in shallow aquifers. At the Rifle Integrated Field Research Challenge site close to the Colorado river (USA), biogeochemical processes in the subsurface have been studied in great detail (Campbell et al., 2012; Jewell et al., 2016). Sediment cores and groundwater were sampled from the shallow aquifer. The high levels of microbial biodiversity resulted in several thousand near-complete metagenome-assembled genomes. In addition to the well known bacterial phyla (e.g. Proteobacteria, Bacteroidetes, Actinobacteria) they found 47 newly discovered phylum-level lineages were found (Anantharaman et al., 2016).

Most often, not a single population will comprise more than 1% of the microbial community, indicating a very high species evenness. The relevance of this high biodiversity was shown by the metabolic analysis. Only few organisms within the community can handle multiple sequential redox transformations. Hence, metabolic byproducts need to be passed on to adjacent microorganisms that carry out specific steps in redox pathways (Hug and Co, 2018). The so-called metabolic handoffs highlights the importance of syntrophic interactions in subsurface environments.

A collaborative research project at the long-term monitoring site Hainich (Germany) investigates the soil-groundwater interface (termed the critical zone) of aquifers (Akob and Küsel, 2011; Küsel et al., 2016). There, a recent study (Yan et al., 2020) found fundamental differences in the microbial communities and biogeochemistry of multi-storey aquifer complexes. The availability of inorganic energy sources governs the microbial community, resulting in hot spots for chemolithoautotrophic processes (e.g. nitrification and anaerobic ammonia oxidation) (Wegner et al., 2019). In addition, differences were correlated to the distinct land uses in the respective recharge areas and the effects of precipitation events and groundwater recharge dynamics (Küsel et al., 2016) (Fig. 2). The interdisciplinary approach, combining molecular, geological and hydrological data which ultimately feed into conceptual models promotes the qualitative and quantitative characterization of subsurface processes.

Caves and karst pools

The accessibility of caves facilitates the observation and sampling of groundwater biota. However, there are some characteristics of caves that make them special in comparison to other groundwater environments. The different types of caves that form from hydrological and biogeochemical processes reflect the connection between the surface and subsurface. Most caves are structured into an entrance and twilight zone, where photosynthesis is still feasible and animals and debris may enter from the surface. In contrast, the deep cave zone is considered to be a low-energy environment, that resembles a "true" subsurface ecosystem.

The biodiversity differs within and between caves, because of the rock type, hydrological conditions, and biological properties such as larger animals inhabiting the cave. The habitat conditions are resembled in the active microbial metabolism, which connects to the overall biogeochemistry of the system (Shabarova and Pernthaler, 2010). Some groundwater filled caves have been studied in detail describing these metabolic and biological diverse ecosystems. The Movile Cave in Romania (Sarbu, 2000), the Frasassi Caves in Italy (Desai et al., 2013; Jones et al., 2012) and the Nullarbor Caves in Australia (Holmes et al., 2001) are only a few fascinating examples of habitats for chemolithoautotrophic microbes that form massive biofilms (Fig. 3C). Sulfidic caves, where supplies of reduced sulfur, hydrogen or methane support rich chemolithoautotrophic activity, feature microbial mats and pendulous biofilms (also known as Snottites). Multispecies aggregates of acidophilic, sulfur-oxidzing *Thiotrichaceae*, hydrogen-oxidizing "Knallgas" bacteria (e.g. *Aquificaceae*) and methylotrophic microbes dominate and actively form (i.e. biogenic speleothems) the cave habitats through mineral dissolution and breakdown products (i.e. moonmilk) (Boston et al., 2009; Engel et al., 2004). Another example of massive biofilm growth but fueled by methylotrophic production was described at the Sulzbrunn cave in Germany (Karwautz et al., 2017). Geogenic methane from deeper layers enters the shallow cave where a diverse microbial community resembles a clear zonation along the cave walls resulting in different rates of methane oxidation.

In contrast, the energy dynamics of carbonate and volcanic caves are less well-defined. The bacterial communities from these oligotrophic environments often display low phylogenetic diversity, but with a remarkable diversity of CO_2 fixation pathways (Barton et al., 2004; Ortiz et al., 2014; Tebo et al., 2015).

The deep subsurface

Deep drilling and ore-mining allows examining the microbial communities that thrive several thousand meters below the surface. Microorganisms at these depths are often classified as extremophiles. This refers to the extreme environmental conditions such as high temperature, high pressure, acidity, alkalinity or elevated concentrations of halides. In deep groundwater anaerobic microorganisms take over as the primary degraders of organic matter, as oxygen has been used up in the shallow subsurface. Hydrothermal fluids and reduced gases (e.g. methane, hydrogen) support the metabolic processes (Hallbeck and Pedersen, 2008; Newman and Banfield, 2002). Subsurface microbial communities are involved in hydrogen oxidation which is associated with autotrophic methanogenesis and contributes to the biogenic methane production. Therefore, it is necessary to take into account the activity of methane-producing Archaea and methane-oxidizing bacteria in groundwater when estimating the impact of subsurface environments to global warming (Kotelnikova, 2002).

Microorganisms might even contribute to ore deposition over geological time frames as they precipitate metals from solution. In contrast, microbes are also involved in the dissolution of minerals and metals [e.g. pyrite (FeS_2), spalerite (ZnS)]. Low-diversity communities of autotrophic and heterotrophic archaea and bacteria which catalyze iron and oxidize sulfur have also been found in acid mine drainage and deep subsurface environments (Baker and Banfield, 2003; Hallbeck and Pedersen, 2008; Tyson et al., 2004).

Notably, it was shown that metabolic active fungi in deep groundwater are present and that the fungal communities react to changes in the concentration of organic carbon sources in their environment (Sohlberg et al., 2015). They form synergistic consortia with sulfate reducing bacteria in deep granitic subsurface, where the role of the fungi is to provide H_2 for sulfate reducers (Drake et al., 2017). It is very likely that the fungi consume carbohydrates for their own heterotrophic metabolism by degrading microbial biofilms (Drake and Ivarsson, 2018). In turn the fungi release small carbon compounds that can function as electron donors and carbon source for bacteria and archaea.

Drinking water

Groundwater is the major source of drinking water in many regions of the world. The legal frameworks to safeguards high drinking water quality (e.g. Directorate-General for Environment, 2009; EC Council Directive, 1998) sets limits to the concentrations of microbial pathogens (e.g. Legionella) and fecal indicators (e.g. Enterococci). The microbial biocenoses of drinking water treatment

plants and distribution system (Fig. 3) has been the objective of numerous studies (Berry et al., 2006; Pinto et al., 2014). Drinking water production systems are an engineered environment providing different conditions to the microorganisms when compared to aquifers (Fig. 3D). While the milieu in aquifers seems to be mainly governed by sediment heterogeneity and microbe-mineral interactions as wells as nutrient availability, drinking water distribution systems are mainly governed by extreme hydrodynamics and pipe material characteristics (Yu et al., 2010). Even though cell densities and metabolic activity in drinking water are typically low (Hammes et al., 2008) the distribution system is colonized by diverse microbial communities (Fig. 3), typically dominated by Proteobacteria. Temporal variations of the microbial communities could also be of interest to drinking water providers that aim at proliferating water of continuous high quality (Pinto et al., 2014). In a rare study about fungi in drinking Göttlich et al. (2002) reported a significantly lower fungal diversity in the distribution network than in raw water and house installations, indicating a low durability under these conditions.

Contaminated aquifers

The anthropogenic impact has hit all earth ecosystems. Even the somewhat hidden and isolated aquifers are threatened by contamination and over-exploitation (Mammola et al., 2019). Especially, contamination with aromatic hydrocarbons and halogenated organic compounds poses a long-lasting hazard. The various pollutants (i.e. heavy metals, pesticides, pharmaceuticals, radionuclides) display differences in the way of entry (e.g. point and diffusive sources), concentrations, degradability and transport dynamics. The detrimental impact of contamination on human and environmental health has initiated immense efforts in understanding microbial communities in contaminated aquifers. In most cases, organic pollutants will increase the local microbial diversity and shift the community towards dominating degrader populations (Pilloni et al., 2019; Röling et al., 2001. In some cases, this increase in diversity is related to the dispersal of microbes introduced with the contaminant, such as manure (Cho et al., 2000). However, contamination of an aquifer will most often cause considerable stress to the autochthonous microbial communities and leads to biodiversity loss and long-lasting, potentially irreversible changes in microbial community composition and functioning (Herzyk et al., 2017; Ma et al., 2015).

In case of organic pollution, microbes will rapidly consume the available oxygen in groundwater to oxidize the contaminants (Fig. 3B). Therefore anaerobic degradation pathways are prevalent in organically contaminated aquifers. Consequently, microbes will reduce different electron acceptors such as nitrate, iron (III), manganese (IV) and sulfate, which will then determine the respiratory processes (Meckenstock et al., 2015). Pilloni et al. (2019) provided a good example that the composition of the degrading communities are far from being stable so that key degraders within the bacteria are replaced by functionally redundant counterparts under changing environmental conditions. Key degraders and microbial communities in contaminated aquifers can grow, mineralize or co-metabolize toxic substances. Nonetheless, this process known as bioremediation is severely limited by abiotic and biotic factors (Table 1).

Knowledge gaps

The challenges in groundwater microbial ecology remain very much the same as they were ten years ago (Larned, 2012). Many ecological questions that have been explored in surface-water systems remain unexplored in subsurface habitats. The wealth of observational studies based on pattern-detection and description needs to be matched by hypothesis-testing and mechanistic explanations (Prosser and Martiny, 2020).

Access to groundwater ecosystems is generally limited by the availability of monitoring wells and the logistical efforts (i.e. costs, regulations, flow of information) to create new study sites. Furthermore, groundwater sampling (i.e. pumping) provides only an overview of relatively narrow zones around wells and differences between attached and planktonic microbes are often neglected.

Attached microorganisms can be assessed by sampling borehole sediments (Anantharaman et al., 2016), introducing sediment cages into monitoring wells (Fillinger et al., 2019a, b; Griebler et al., 2002) or establishing groundwater mesocosm systems (i.e. columns, indoor aquifers) (Griebler et al., 2016; Herzyk et al., 2017).

Another challenge is the limited information about ecosystem boundaries and spatial heterogeneity, a lack of detailed habitat templates (Larned, 2012; Stein et al., 2012). Sampling design guided by hydrogeological methods can increase the spatial resolution by optimizing well positioning and interpolation between them.

In aquifers, the geology and distribution of sediments creates structural and hydraulic heterogeneity, which establish the spatial variation of nutrients and organic matter and thus biogeochemical processes. Groundwater flow models can characterize these heterogeneities of a study area and may help to identify ecologically relevant hydrological variables (e.g. preferential flowpaths, recharge zones, and aquifer boundaries).

Even with the wealth of molecular data, many groundwater microbes remain undescribed and uncultured. A greater effort to cultivate groundwater microorganisms will be needed to characterize their physiology, ecology and evolutionary processes (Imachi et al., 2019; Thrash, 2019).

Conclusion and outlook

The subsurface is one of the earth's largest yet for the most part untapped reservoir of microbial diversity. Multiple environmental gradients foster an immense biodiversity displayed in the genomic and functional versatility of groundwater ecosystems. Ecosystem functioning and services are a direct consequence of this biodiversity.

A large part of the scientific literature focuses on the characterization and remediation of contaminated groundwater sites. Nonetheless, even in low energy, pristine and natural systems microbes can display a great taxonomic and functional diversity which reflects their adaptability.

Factors that control microbial diversity in aquifers include physicochemical conditions, spatial heterogeneity, temporal variability and disturbances such as pollution with chemical anthropogenic contaminants. First insights into the importance of individual biogeochemical processes have been obtained from surveys of microbial diversity within functional groups and direct links to groundwater ecosystem functioning have been established for selected research sites (CRC AquaDiva, IFRC). Such long-term monitoring programs are essential to the understanding of microbial diversity and biogeochemical processes.

The rapid advances in microbiology have reshaped the scientific scope of biodiversity research in groundwater ecosystems. Metagenomic data and bioinformatic tools allow elucidating unprecedented details of the diversity and metabolic potential of microorganisms. Including all life forms (Bacteria, Archaea, Fungi, protozoa, metazoa, and viruses) in biodiversity analysis, and deciphering their interactions as well as how these interactions link to biogeochemical processes, is the next big step in the census of subsurface ecosystem research.

Biogeochemical Cycling of Carbon and Nitrogen in Groundwater—Key Processes and Microbial Drivers☆

Martina Herrmann[a,b] and Martin Taubert[a], [a]Friedrich Schiller University Jena, Institute of Biodiversity, Aquatic Geomicrobiology, Jena, Germany; [b]German Center for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Leipzig, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

☆*Change History*: October 2021. M Herrmann and M Taubert introduced a new section "Lysis of microbial cells", added new text to some of the sections, added two new points to section "Knowledge gaps", added new references to section "References", and made minor changes throughout the manuscript to address the comments and suggestions of two reviewers.

Glossary

Anammox Anaerobic oxidation of ammonium with nitrite to form N_2 as end product.
Chemolithoautotrophy Lifestyle that employs CO_2 as carbon source and obtains energy from the oxidation of inorganic compounds.
Denitrification Reduction of nitrate to gaseous nitrogen compounds (NO, N_2O, N_2).
DNRA Dissimilatory nitrate reduction to ammonium.
Fluid flow Movement of water driven by physical influences like gravity or capillary action.
Heterotrophy Lifestyle that employs organic carbon compounds as carbon source.
Metagenomics/Metatranscriptomics/Metaproteomics Study of the entirety of DNA/RNA/proteins present in a selected habitat at a selected point of time.
Microbiome Entirety of the microorganisms living in a specific habitat.
Mixotrophs Microorganisms able to use CO_2 and organic carbon as carbon source, concomitantly and/or consecutively.
Necromass Remains of dead microorganisms, including cell debris, biopolymers and dissolved molecules.
Nitrification Oxidation of ammonia to nitrate via nitrite.
Symbiosis Close and long-term biological interaction between two species. Can provide benefit and/or harm to the involved organisms.

Introduction

Role of microorganisms in biogeochemical cycles in aquifers

Microbially mediated biogeochemical processes in aquifers are central to the chemical composition of groundwater and its suitability as drinking water resource. Groundwater chemistry and the sources and sinks of key chemical compounds, including potentially hazardous chemicals, have been well studied for decades. Our understanding of microbial activities in these environments, microbial key players and the factors driving their community composition, distribution and activity, however, is still in its infancy. Heterogeneity of biogeochemical processes in aquifers is often directly linked to hydrogeological heterogeneity and the dynamics of groundwater flow (Utom et al., 2020), emphasizing the need for interdisciplinary research combining microbiology, biogeochemistry, and hydrogeology to improve our understanding of microbially driven transformation processes in these environments (Küsel et al., 2016).

Generally low microbial cell numbers and biomass in groundwater environments may substantially limit process rates compared to surface freshwater environments, marine environments, or engineered systems. However, as residence times in aquifers may range from several years to centuries, even processes that occur at very low rates may significantly contribute to shaping groundwater chemistry. In this chapter, we want to focus on nitrogen cycling and carbon cycling as two major biogeochemical cycles in aquifers that are tightly interconnected and that are also strongly linked to other element cycles like the sulfur or iron cycle. We introduce key processes and key microbial players, and explore how the role of these microbes in biogeochemical cycling is linked to their life styles and strategies to survive in oligotrophic groundwater.

Sources of carbon and nitrogen compounds in groundwater

Pristine groundwater is characterized by low concentrations of organic carbon and other nutrients. Traditionally, the shallow subsurface is believed to be driven by surface inputs, supporting a low biomass of heterotrophic microorganisms. Besides these surface inputs, heterotrophic life in the subsurface can also be fueled by the release of organic compounds from sedimentary rocks and the lysis of cells in the groundwater itself (Fig. 1) (Benk et al., 2019; Schwab et al., 2019). Increasing evidence of the relevance of chemolithoautotrophic CO_2 fixation by microorganisms for subsurface carbon cycling, however, has challenged this view of a predominance of heterotrophy (Akob and Küsel, 2011). Autotrophic microorganisms rely on fixation of inorganic carbon to produce all of their biomolecules, and are thus independent of external organic carbon. The availability of inorganic carbon strongly depends on the local geology but is also influenced by microbial activity and transport processes.

Similarly, nitrogen compounds in groundwater largely originate from surface sources but can also be derived from degradation of organic matter, cell lysis, and nitrogen fixation in the aquifer itself (Fig. 1). Due to its higher mobility in soils and subsurface, nitrate is usually the major surface-derived inorganic nitrogen compound. Nitrate is also one of the central chemical compounds in groundwater strongly affected by human activities. Increased nitrate levels resulting from excess fertilizer applications are a serious threat to the suitability of groundwater for drinking water production and may cause eutrophication of groundwater-fed water bodies (Vitousek et al., 1997; Stark and Richards, 2008). This has led to increasing interest in naturally occurring processes that enable or control nitrate attenuation in aquifers (Rivett et al., 2008). In contrast, subsurface transport of ammonium is largely controlled by sorption as a result of cation exchange processes occurring at negatively charged mineral surfaces such as clay minerals, and, quantitatively less important, by biological attenuation via incorporation into microbial biomass (Buss et al., 2004).

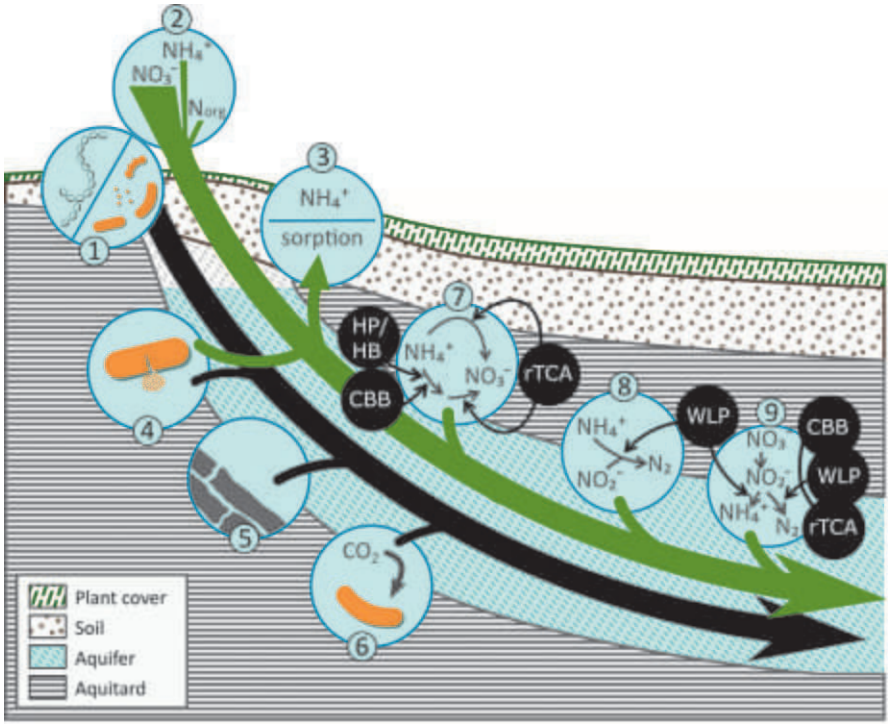

Fig. 1 Conceptional model of the surface input, flow and transformation reactions of carbon and nitrogen compounds in groundwater. Individual nitrogen transformation processes are linked to CO_2-fixation pathways utilized by the respective microbial groups (black circles). 1: surface input of organic carbon and microbial cells; 2: surface input of nitrogen compounds; 3: attenuation of ammonium by sorption processes; 4: cell lysis; 5: rock-derived organic carbon; 6: CO_2-fixation; 7: nitrification; 8: anammox; 9: denitrification and DNRA. CBB = Calvin-Benson-Bassham cycle; rTCA: reductive tricarboxylic acid cycle; WLP: Wood-Ljungdahl-pathway; HP/HB: 3-hydroxy-propionate/4-hydroxy-butyrate pathway.

As consequence, ammonium derived from microbial processes such as organic matter degradation or dissimilatory nitrate reduction to ammonium (DNRA) is likely the major source for ammonium-dependent transformation processes such as nitrification or anammox in the subsurface (Böhlke et al., 2006; Jahangir et al., 2017).

Effect of geologic setting on biogeochemical cycles in groundwater

Geologic setting shapes microbially driven biogeochemical cycles via two major factors: (i) its effect on groundwater chemistry, in particular pH and availability of suitable electron donors or electron acceptors for microbial metabolisms, and (ii) its effect on porosity and the structure of the aquifer bedrock material, affecting fluid flow, surface connectivity, water travel times or residence times, and linked to that, oxygen supply, and the structural heterogeneity of microbial habitats (West and Chilton, 1997).

Porous aquifers with low flow conditions versus fractured aquifers with rapid flow conditions may differ substantially regarding the prevalence of anoxic conditions or the extent of fluctuations in redox conditions. Fractured or karstic aquifers with locally or episodically rapid water flow can provide close connections between surface and subsurface, supporting oxic conditions even in deeper groundwater. In turn, systems with long water residence times are more likely to undergo oxygen depletion, resulting in a prevalence of anoxic conditions. While high surface connectivity in fractured or karstic systems may also enable more frequent and intense supply of fresh surface-derived organic carbon, low surface connectivity and long water residence times may favor the growth of slow-growing autotrophic bacteria (Taylor et al., 2013).

Effect of oxygen availability

Oxic conditions

Oxygen availability is one key driver of groundwater biogeochemical cycles. Oxic conditions in groundwater require an input from the surface (Lovley and Chapelle, 1995), which can occur via fluid flow, or via fluctuations of the groundwater table that rapidly suck air from the surface into the subsurface (Lehmann and Totsche, 2020). Along the groundwater flow path, oxygen is consumed by a variety of microbial processes. The higher the concentrations of reduced organic and inorganic compounds, the faster oxygen is depleted by the microbial activity, leading to anoxic conditions.

Anoxic conditions

Upon depletion of oxygen, the use of alternative electron acceptors such as nitrate becomes energetically more favorable, and a large range of facultative anaerobic microorganisms are capable of switching from aerobic respiration to nitrate reduction. Once nitrate is depleted, other terminal electron acceptors may become relevant, such as manganese, iron (III), sulfate, and finally hydrogen and CO_2 resulting in the formation of methane. These alternative electron acceptors can be derived from surface inputs, or from minerals of the aquifer rocks, such as sulfates and oxidized metal species (Fe^{3+}, Mn^{4+}, As^{5+} etc.) (Schippers et al., 1996; Oremland and Stolz, 2005; Kohlhepp et al., 2017). Furthermore, organic carbon can act as electron acceptor for regeneration of nicotinamide adenine dinucleotide (NADH) during fermentation, or during acetoclastic methanogenesis, where acetate acts both as electron donor and acceptor, leading to the release of CO_2 and methane (Demirel and Scherer, 2008).

Nitrogen cycling in groundwater

Microbially mediated nitrogen transformation processes

Nitrogen compounds leached from surface environments are subject to further transformation by complex dynamics and interlinkages of different biogeochemical processes in the groundwater, including mineralization of organic matter, nitrification, denitrification, DNRA, anaerobic ammonium oxidation (anammox), and sorption processes (Fig. 1). These processes can occur simultaneously in spatially structured heterogeneous environments, and linkages between aerobic and anaerobic nitrogen transformation processes may be especially intense under micro-oxic conditions or along transition zones from aerobic to anaerobic conditions. Altogether, they result in changes in the initial concentrations of the nitrogen compounds and may lead to their conversion into new nitrogen species (Burgin and Hamilton, 2007). While denitrification and anammox lead to nitrogen loss as dinitrogen gas, DNRA results in the conservation of inorganic nitrogen as ammonium.

Traditionally, heterotrophic denitrification coupled to the oxidation of organic electron donors was believed to be the most important pathway for nitrate removal from groundwater. However, recent findings suggest that chemolithoautotrophic denitrification linked to the oxidation of inorganic electron donors, anammox, and DNRA play a more important role than previously thought. Potential factors that determine which process prevails include electron donor availability and identity, and electron donor/nitrate ratios (Tiedje et al., 1982; Burgin and Hamilton, 2007; Strohm et al., 2007; Rütting et al., 2011).

Nitrification

The nitrification process

Nitrification is a key process of the nitrogen cycle, transforming ammonium to nitrate in a two-step process, ammonia oxidation (1) as the first and rate-limiting step, and nitrite oxidation (2).

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 4H^+ + 2\,H_2O \quad (1)$$

$$2NO_2^- + O_2 \rightarrow 2NO_3^- \quad (2)$$

As such, in addition to surface-derived inputs, nitrate can be formed in situ in the groundwater, and reported nitrification activities range from 0.012 μmol NO_x per L per day in oligotrophic, pristine groundwater to 6.72 μmol NO_x per L per day in groundwater contaminated with ammonium (Smith et al., 2006; Opitz et al., 2014). The process is primarily controlled by the availability of ammonium and oxygen, pH, and the presence of substances which might act as inhibitors of nitrification, such as heavy metals or organic contaminants (Buss et al., 2004). Nitrification can proceed at high rates even if apparent concentrations of ammonium are low, since ammonium is usually continuously replenished from the degradation of organic matter. Recently, Utom et al. (2020) also reported nitrite oxidation coupled to manganese reduction in an anoxic alluvial aquifer.

Microbial key players involved in groundwater nitrification

Although some of the microorganisms involved in nitrification have been isolated as early as 1890 (*Nitrosomonas europaea, Nitrobacter winogradsky*) (Winogradsky, 1890), the nitrification process has provided many surprises for researchers until today. These include the discovery of ammonia-oxidizing archaea (AOA) in Könneke et al. (2005), extending the metabolic capacity of ammonia oxidation beyond two distinct phylogenetic groups within the Proteobacteria, and the discovery of complete ammonia oxidizers (comammox bacteria of the genus *Nitrospira*) in Daims et al. (2015) and van Kessel et al. (2015). Until then, division of labor in nitrification had been an unchallenged concept, i.e., the strict separation of nitrification into a two-step process carried out by different guilds of organisms, the ammonia-oxidizing bacteria (AOB) or archaea, and nitrite-oxidizing bacteria (NOB).

Despite the high relevance of in situ nitrate formation for groundwater quality, studies addressing nitrifying microbial populations in groundwater are still scarce. Both AOA and AOB were reported from aquifers (Reed et al., 2010; Opitz et al., 2014) (Table 1). Interestingly, comammox bacteria are present or even especially abundant in engineered systems related to groundwater such as groundwater-fed biofilters (Fowler et al., 2018; Gülay et al., 2019) or drinking water systems (Pinto et al., 2016), suggesting that they might also play an important role in groundwater nitrification. In fact, the genus *Nitrospira*, including nitrite oxidizers as well as comammox bacteria, accounted for about 11% of the bacterial community in oligotrophic groundwater (Herrmann et al., 2020; Yan et al., 2020) (Table 1).

Table 1 Prominent examples of microbial taxa involved in nitrogen transformations, carbon cycling, or other biogeochemical processes, which have been reported from groundwater environments.

Under ammonium-limited conditions, utilization of alternative nitrogen sources that yield ammonia, such as urea or amino acids, has been described for all three groups of ammonia oxidizers (Koch et al., 2019) and could also be an important mechanism in groundwater nitrogen cycling (Reed et al., 2010). Nitrification is also tightly coupled to groundwater carbon cycling, as most nitrifiers are chemolithoautotrophs and employ different CO_2-fixation pathways such as the Calvin-Benson-Bassham cycle (AOB), the reductive tricarboxylic acid cycle (*Nitrospira*), and the 3-hydroxypropioniate/4-hydroxy-butyrate pathway (AOA) (Fig. 1; see also section "Pathways and key players").

Denitrification

The denitrification process

Denitrification is the stepwise reduction of nitrate to dinitrogen gas, including the following steps and intermediates (3) (Zumft, 1997):

$$2NO_3^- \rightarrow 2NO_2^- \rightarrow 2NO \rightarrow N_2O \rightarrow N_2 \quad (3)$$

Reported in situ denitrification activities in aquifers range from <0.001 to 0.986 μmol N L^{-1} d^{-1} under pristine or nitrate contaminated conditions, respectively (Kumar et al., 2017; Smith et al., 2004, 2015). The denitrification capacity of groundwater is mainly determined by the availability of reduced compounds acting as suitable electron donors. Lack of organic carbon as electron donor has been considered as the most significant factor limiting denitrification rates in groundwater and may further be influenced by the nature of DOC with low-molecular weight compounds such as acetate or organic acids being more biologically reactive than high-molecular weight compounds (Starr and Gillham, 1993; Baker and Vervier, 2004). Many denitrifiers can also reduce nitrate chemolithoautotrophically, with sulfide, thiosulfate, ferrous iron, and hydrogen as common electron donors. Availability of these alternative electron donors will strongly depend on the geological setting, e.g., availability of pyrite (see section "Electron donors"). Denitrification does not require completely anoxic conditions but takes places at oxygen levels below 2 mg L^{-1} (Rivett et al., 2008).

Denitrifying microorganisms

The ability to perform denitrification is a wide-spread feature across multiple bacterial and archaeal phyla. Consequently, denitrifier communities in groundwater are usually diverse but may be dominated by a few key players depending on the prevalent electron donor (Table 1). Kumar et al. (2018) found a large fraction of organisms affiliated with the genera *Sulfurifustis*, *Sulfuricella*, and *Sulfuritalea* in a karstic aquifer, pointing to a high relevance of sulfur compounds as electron donors. Most denitrifiers are facultative anaerobes that perform oxidative respiration as the most energy efficient process as long as oxygen is available and switch to nitrate reduction once oxygen is depleted. Many of the denitrifying microorganisms are also capable of switching between heterotrophic and chemolithoautotrophic denitrification depending on the availability of electron donors. Moreover, while some microorganisms are capable of doing the complete denitrification pathway, others can only perform selected steps out of the whole cascade, resulting in complete denitrification by exchange of intermediates within microbial consortia.

Anaerobic ammonia oxidation (anammox)

The anammox process

Anaerobic ammonia oxidation (anammox) is the oxidation of ammonia with nitrite under anoxic conditions to form dinitrogen gas (4) (Strous et al., 1999).

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O \quad (4)$$

Aquifers often provide suitable conditions for the anammox process to occur—presence of ammonium, nitrite and nitrate simultaneously, absence of oxygen, and slow movement of water. However, while the huge relevance of the anammox process for the nitrogen cycle in marine systems has been recognized for two decades now, the role of anammox for nitrogen loss in aquifers has to date only been addressed by a few studies. Recent findings by Wang et al. (2020) suggest that anammox is a major nitrogen sink in aquifer soils of a few meters down to 28 m depth on a global scale. In situ ammonium concentrations appear to affect anammox activities in groundwater with higher rates at contaminated sites (72–432 nmol L^{-1} d^{-1}) compared to pristine sites (<10 nmol L^{-1} d^{-1}), while the contribution of anammox to overall nitrogen loss, ranging from 18% to 90% across studies, was not linked to the contamination level (Moore et al., 2011; Smith et al., 2015; Kumar et al., 2017; Wang et al., 2017).

Anammox bacteria

The ability to carry out anaerobic ammonia oxidation is confined to a very distinct phylogenetic group within the Planctomycetes, the *Brocadiales*. Anammox bacteria are characterized by rather slow growth rates with doubling times of up to 2 weeks. As a consequence, they are thought to be only competitive in environments with minor water exchange rates, which might apply to a broad range of groundwater environments. In fact, a recent survey studying the distribution of anammox bacteria across different habitats even suggested that groundwater might be the preferred habitat for anammox bacteria (Wang et al., 2019).

Anammox bacteria are mostly known as obligate autotrophs using the Wood-Ljungdahl pathway for CO_2-fixation (see section "The Wood-Ljungdahl pathway") (Fig. 1). Molecular surveys revealed that the fraction of anammox bacteria in the total groundwater bacterial population can be as high as 10% under both low and high levels of nitrate or ammonium contamination. All five known genera of anammox bacteria—*Cand*. Brocadia, Jettenia, Kuenenia, Anammoxoglobus, and Scalindua—have been reported from groundwater environments but the genus *Brocadia* seems to be the most widely distributed in groundwater, represented by the species *Cand*. Brocadia anammoxidans and *Cand*. Brocadia fulgida (Kumar et al., 2017; Wang et al., 2017, 2020) (Table 1).

Dissimilatory nitrate reduction to ammonium (DNRA)

The DNRA process

DNRA is a two-step process that shares the first step of nitrate reduction to nitrite with denitrification but then performs direct reduction of nitrite to ammonium in a second step (5).

$$NO_3^- \rightarrow NO_2^- \rightarrow NH_4^+ \quad (5)$$

DNRA can be coupled to the oxidation of organic carbon compounds as well as to the oxidation of inorganic electron donors such as sulfide or hydrogen (Brunet and Garcia-Gil, 1996; Simon, 2002). Evidently, the potential relevance of DNRA for nitrogen cycling and its contribution to nitrate reduction had been by far overlooked and underestimated in many different environments such as soils (Rütting et al., 2011) or sediments (Bernard et al., 2015). In groundwater environments, DNRA has been considered insignificant for nitrate attenuation (Buss et al., 2005). However, this view was challenged by the observation that DNRA contributed 40–63% to total nitrate reduction in shallow groundwater beneath a constructed wetland system (Jahangir et al., 2017). Occurrence of DNRA was recently linked to low groundwater recharge conditions in an anoxic alluvial aquifer (Perovic et al., 2020).

Microorganisms performing DNRA

Similar to denitrification, the capacity to perform DNRA is widespread across the bacterial and archaeal domains. Many known denitrifiers also possess the genetic machinery for DNRA and may switch between the two different nitrate reduction pathways depending on environmental conditions. To date, our knowledge of the taxonomic affiliation of DNRA-performing microorganisms in groundwater primarily originates from metagenomic approaches. Those revealed that members of the Proteobacteria but also less well studied groups such as Nitrospirae or *Cand.* Omnitrophica harbor the genetic capacity to perform DNRA in groundwater (Anantharaman et al., 2016) (Table 1), suggesting that this metabolic feature is even more wide spread than previously recognized.

Carbon cycling in groundwater

Heterotrophy

Sources of organic carbon

Surface input

At the Earth's surface, the overwhelming majority of organic carbon is formed by photosynthetic primary production. Almost all heterotrophic organisms depend on this organic carbon produced. In terrestrial environments, mostly higher plants are responsible for the primary production. Structural polymers make up the largest part of plant biomass (Lynd et al., 2002). Consequently, the majority of plant-derived organic carbon is present as polymers of carbohydrates (e.g., starch, cellulose, hemicellulose) and polymers of phenolic compounds (e.g., lignin). This organic carbon is transported into the subsurface by fluid flow of infiltrating rain water (Baker et al., 2000; Griebler and Lueders, 2009; Küsel et al., 2016; Perrette et al., 2015). During transport, it undergoes major transformations (Kalbitz et al., 2000; Kaiser and Kalbitz, 2012). Already in soils, plant-derived polymers are broken down and assimilated by microorganisms. Microbial cells are lysed, and the resulting necromass is recycled again and again. The plant-derived organic matter is transformed into microbial-derived carbon (Roth et al., 2019). Within days to decades, depending on the conditioning of the groundwater microbial community (Einsiedl et al., 2007; Hofmann et al., 2020), only a minor part of the carbon transported into the subsurface still consists of remaining, more recalcitrant plant-derived organic matter.

Lysis of microbial cells

Together with dissolved and particulate organic carbon, also microbial cells are transported downwards (Herrmann et al., 2019; Pronk et al., 2009; Shabarova et al., 2013). When transitioning from the soil to the rock parent material, these cells experience drastic changes in environmental conditions. The pH, for example, can change from acidic conditions of pH 3–5 in soils by up to five orders of magnitude to slightly basic conditions of pH 7–8 when reaching carbonate rock (Yun et al., 2016). Such changes can lead to the excessive lysis of cells, increasing the input of microbial-derived biomass into the groundwater. Likewise, viral lysis leads to the release of bacterial necromass. Although there are about 10 times as many viral particles as prokaryotic cells in groundwater, we are still in the early stages of understanding the impact of viruses in the groundwater microbiome (Kyle et al., 2008; Smith et al., 2013). The top of the food web is formed by eukaryotes such as protozoans and metazoans that feed on prokaryotes or on other protozoans (Schmidt et al., 2017). This grazing may also contribute to the release of dissolved organic material originating from sloppy feeding (Møller, 2004, 2007) as described for marine environments.

Rock carbon

An alternative source of organic carbon in the groundwater are the rocks making up the aquifers (Nowak et al., 2017; Schwab et al., 2019). During the formation of sedimentary rocks, hundreds of millions of years ago, organic matter and microorganisms were trapped between the mineral particles. During diagenesis and aging, the organic carbon introduced underwent structural changes.

Exposure to high pressure and temperature resulted in a decrease in heteroatoms and an increase in the number of unsaturated bonds, leading to a higher fraction of aromatic and aliphatic compounds (Benk et al., 2019).

Microbial activity in the groundwater leads to the dissolution of rock material (Sánchez-Cañete et al., 2018). For example, microbial respiration releasing CO_2 as carbonic acid locally decreases the pH of the groundwater, which is compensated by the dissolution of carbonate minerals. Through the progress of dissolution, the aged organic carbon is released and becomes available for microbial degradation. Due to the high age and the chemical composition of these carbon compounds, they closely resemble organic material present in marine sediments (Benk et al., 2019).

In situ primary production

The primary production by autotrophic organisms (see section "Autotrophy") provides another source of organic carbon in the groundwater (Griebler and Lueders, 2009; Akob and Küsel, 2011). Compounds produced by this process can be released when autotrophic cells are lysed. The resulting microbial necromass is then available for heterotrophic growth. Furthermore, autotrophs might be involved in symbiotic interactions with heterotrophic organisms, supplying specific carbon compounds directly.

Other processes typically not considered "primary production" per se closely resemble the mode of carbon distribution through the microbial food web from CO_2 fixation. The assimilation of methane by methanotrophs is one example of such a process. Methane, a C_1 compounds like CO_2, is only available to a small number of organisms, which use it as carbon and energy source (Smith et al., 2010). Similar to chemolithoautotrophs, methanotrophs are frequently observed to supply more easily available carbon compounds to a heterotrophic microbial community, forming the basis of a microbial food web (Ruff et al., 2015; Yu and Chistoserdova, 2017; Taubert et al., 2019).

Compounds and key degraders

Plant polymers

Structural plant polymers, including carbohydrates and lignin, are typically too large for a direct uptake into bacterial cells. Extracellular enzymes, attached to the cell wall or outer membrane, or released into the environment, are used for the extracellular breakdown (Warren, 1996; Schellenberger et al., 2010). Carbohydrates are degraded by glycoside hydrolases, which hydrolyze glycosidic bonds and release oligo- and monomers. Glycoside hydrolase genes can be found in a variety of groundwater microorganisms (Danczak et al., 2017; Castelle et al., 2018) (see Table 1), and the expression patterns of these genes show independence of groundwater hydrochemistry (Wegner et al., 2019). Lignin is degraded by radical-producing peroxidases and laccases, yielding low molecular weight phenolic compounds. Fungi are mayor key players in this process in the groundwater (Nawaz et al., 2016, 2019), but also certain bacteria are involved (see Table 1).

Necromass

The composition of bacterial necromass resembles to large extents that of living bacterial cells. Proteins and nucleic acids are the main components of the bacterial cell, making up 50% and 20% of cell carbon, respectively. These polymers are broken down via proteases and nucleases. The resulting amino acids and nucleotides can be directly used for biosynthesis (Orsi et al., 2018; Starr et al., 2018; Hanajima et al., 2019). To make use of this easily available carbon source, groundwater microorganisms employ a range of transporters for amino acid and nucleotide uptake (Wrighton et al., 2012; Castelle et al., 2018) (see Table 1). Despite a widespread genetic potential for its degradation, assessing the importance of necromass to the microbial community is difficult due to its chemically diverse nature and rapid turnover.

Aromatics and alkanes

Aromatic and aliphatic compounds originate as ancient carbon from rocks (Benk et al., 2019; Schwab et al., 2019), from lignin degradation or as minor components of microbial necromass. These energy-rich but very stable compounds are degraded using mono- and dioxygenases under oxic conditions. Under anaerobic conditions, peculiar biochemical reactions are required for degradation, such as fumarate addition, O_2-independent hydroxylation and reductive dearomatization (Fuchs et al., 2011). Organisms able to perform such reactions are often found in pristine groundwater (see Table 1). In contaminated groundwater, these organisms become central key players and make up the majority of the microbial community.

C_1 compounds

C_1 compounds, containing no carbon-carbon bonds, can be assimilated by methanotrophic and methylotrophic microorganisms. In the groundwater, these compounds are derived from different sources: Methane can originate from volcanic activity, or from methanogenic microorganisms (Mills et al., 2010; McCollom and Seewald, 2013). Methanol is a byproduct of the degradation of plant material, and methylated amines are breakdown products of nitrogen-containing biomass (Neff et al., 2002; Gray et al., 2010). The corresponding assimilation pathways are highly modular (Chistoserdova, 2011), allowing methanotrophs and methylotrophs to use multiple C_1 compounds. Such pathways are primarily present in various *Proteobacteria*, but also *Bacilli* and *Verrucomicrobia* are C_1 utilizers occurring in groundwater (see Table 1).

Autotrophy

Requirements

Electron donors

As in groundwater no photosynthesis is possible, primary production has to rely on chemolithoautotrophic processes utilizing inorganic electron donors such as reduced nitrogen and sulfur compounds. The latter as well as metal ions like ferrous iron can be available from minerals in the aquifer rock, such as pyrite (Schippers et al., 1996; McCollom and Seewald, 2013; Kohlhepp et al., 2017). Various microorganisms able to oxidize reduced sulfur compounds were observed in groundwater (see Table 1). As ferrous iron is rapidly oxidized abiotically under oxic conditions, biological iron oxidation is primarily occurring in microoxic or anoxic groundwater. While arsenic is a common problem for drinking water production from groundwater due to its toxicity, arsenic-oxidizing autotrophic bacteria use it for autotrophic growth under oxic as well as anoxic conditions (Garcia-Dominguez et al., 2008).

Apart from inorganic compounds, also organic compounds can be oxidized to provide energy for CO_2 fixation via autotrophic pathways. Oxidizing organic carbon to CO_2 and then fixing CO_2 to produce biomass seems energetically expensive at first. Certain organisms, however, are employing such a 'chemoorganoautotrophic' strategy (Kang et al., 2011; Winkel, 2013; Taubert et al., 2017, 2018), which might provide an advantage when diverse organic carbon sources difficult to be channeled into the central metabolism are used.

Inorganic carbon

In aquifers made of carbonate rock, ample dissolved inorganic carbon for chemolithoautotrophic growth is available, as the groundwater is saturated with carbonate due to dissolution processes (Kohlhepp et al., 2017). However, the presence of cations forming carbonates with low solubility might restrict the availability of inorganic carbon. In contrast, in aquifers made of siliciclastic rock, the supply of inorganic carbon from carbonates is highly limited (Kunkel et al., 2018). In these environments, the input of inorganic carbon from the surface and the oxidation of organic carbon to CO_2 might be the only sources for inorganic carbon. Chemolithoautotrophs hence are restricted to re-fixing the carbon released by heterotrophic organisms.

Pathways and key players

The Calvin-Benson-Bassham cycle

The Calvin-Benson-Bassham (CBB) cycle is the dominant pathway for CO_2 fixation at the surface, due to its tolerance to oxygen (Berg, 2011). Despite being the energetically most expensive CO_2 fixation pathway, it is also widely distributed in subsurface habitats (Alfreider et al., 2009; Herrmann et al., 2015; Probst et al., 2017) (see Table 1). Transcripts of the key enzyme, Ribulose bisphosphate carboxylase/oxygenase, can represent up to 4% of all metatranscriptomic reads obtained from groundwater samples (Jewell et al., 2016; Wegner et al., 2019).

The reductive tricarboxylic acid cycle

The reductive tricarboxylic acid (rTCA) cycle is present in microaerobic and anaerobic bacteria of the phyla *Chlorobi*, *Proteobacteria*, *Aquificae* and *Nitrospirae* (Berg, 2011). In groundwater, it is employed by nitrite-oxidizing *Nitrospiraceae* (Herrmann et al., 2015; Wegner et al., 2019) (see Table 1). Despite the sensitivity of some involved enzymes to oxygen, the rTCA cycle is also found in oxic groundwater. The mechanisms behind this oxygen tolerance are yet not fully understood.

The Wood-Ljungdahl pathway

The Wood-Ljungdahl pathway represents a highly versatile metabolic module: It can be used for autotrophic growth by converting CO_2 to acetyl-CoA, but it can also run in reverse to oxidize acetate, or be used for the assimilation of C_1 compounds (Berg, 2011; Lemaire et al., 2020). Its presence thus is not strictly linked to autotrophy. In groundwater, it is used for autotrophic growth of anammox-performing *Planctomycetes* (Jewell et al., 2016; Wegner et al., 2019). Methanogens and acetogens also use it for autotrophic growth. The latter, however, also employ it during heterotrophic growth (Lemaire et al., 2020). It is also present in sulfate-reducing *Deltaproteobacteria* that can grow heterotrophically or autotrophically (Probst et al., 2017, 2018). This versatility makes it difficult to assign the Wood-Ljungdahl pathway to a clear lifestyle.

Other autotrophic CO_2 fixation pathways

Three other metabolic pathways for CO_2 fixation in autotrophs are known: The 3-hydroxypropionate cycle used by members of the *Chloroflexi*, and the 3-hydroxypropionate/4-hydroxybutyrate (HP/HB) cycle and dicarboxylate/4-hydroxybutyrate (DC/HB) cycle present in members of the *Crenarchaeota*. These organisms are present only in low abundance in groundwater habitats. The expression of genes of the HP/HB cycle by ammonia oxidizing *Archaea* has been reported (Ortiz et al., 2013; Wegner et al., 2019). As these pathways lack specific marker genes, it is difficult to determine whether they are used for CO_2 fixation by particular organisms, and activity-based measurements are required for support.

CO_2 uptake by heterotrophs

In addition to autotrophs, heterotrophs fix CO_2 during anaplerotic reactions (Alonso-Sáez et al., 2010; Erb, 2011). The carbon assimilated in this way can contribute 1–8% to total cell carbon (Braun et al., 2021). Certain carbon assimilation pathways lead to a

much higher contribution of CO_2. Type II methylotrophs obtain up to 50% of carbon from CO_2 via the serine cycle (Chistoserdova, 2011; Braun et al., 2021). Likewise, organisms assimilating acetate while lacking the glyoxylate cycle typically require the fixation of one or two molecules of CO_2 per acetate, resulting in 33–50% CO_2-derived carbon (Taubert et al., 2012). Hence, also in heterotrophs, a substantial amount of carbon can be derived from CO_2.

Methods

Sampling

Difficulties/challenges with accessibility

The special conditions encountered in the subsurface pose a number of challenges when investigating the groundwater microbiome. Methods to sample groundwater microbial communities available to date are limited in their ability to resolve spatial and temporal heterogeneity on the micro scale level, which is the relevant scale for growth and activity of microorganisms (Schmidt et al., 2017). Due to micro scale heterogeneity, not all microorganisms at a given location, e.g., defined by the volume of the sampled groundwater, are exposed to the same environmental conditions in situ (Thullner and Regnier, 2019). However, to obtain suitable amounts of biomass for analysis, high volume filtration of thousands of liters of groundwater might be necessary. This results in the mixing of water from different (micro scale) sources and in the integration of effects of several micro-environments with their distinct microbial communities. Moreover, the ultra-small cell sizes below 0.2 μm reported for various groundwater microbes are best captured using a sequential filtration approach (Castelle et al., 2015; Herrmann et al., 2019).

Similar to the observations on spatial scales, understanding temporal microbial community dynamics is generally limited by the temporal scales at which sampling can be conducted. To understand the assembly of groundwater microbial communities, the biogeochemical parameters influencing them and the role of surface input, a complex infrastructure as well as data acquisition in time series are advantageous (Küsel et al., 2016).

Methods of molecular biology

16S rRNA gene amplicon sequencing

Due to their low requirements for biomass and the high information on taxonomy and functional potential, primarily DNA-based methods were used to acquire first insights into the groundwater microbiome. 16S rRNA gene-based profiling has revealed a highly distinct makeup of communities encountered in the subsurface and allowed insight into parameters driving the assembly of groundwater microbial communities (Stegen et al., 2013, 2016; Hubalek et al., 2016; Yan et al., 2020; Fillinger et al., 2021).

Metagenomics, metatranscriptomics and metaproteomics

Advances in metagenomics have opened a window into the functional potential of groundwater microorganisms by providing thousands of metagenome-assembled genomes (MAGs) (Anantharaman et al., 2016; Parks et al., 2017). Genomic investigation of many groundwater bacteria has shown a high metabolic diversity, a widespread potential for chemolithoautotrophic growth and key roles in nitrogen and sulfur cycling (Anantharaman et al., 2016, 2018; Emerson et al., 2016; Probst et al., 2018; Wegner et al., 2019). These functional predictions have allowed researchers to develop hypotheses about microbial lifestyles in the groundwater, such as the frequent occurrence of metabolic handoffs between microbes (Wrighton et al., 2014; Anantharaman et al., 2016). Such hypotheses now warrant verification by using methods other than metagenomics that can illuminate microbial activities.

Activity measurements

Determination of bulk metabolic rates

A first step to unravel microbial activities in the groundwater is the determination of bulk rates on whole community level. Methods relying on the detection of heavy isotopes, both radioactive and stable, in substrates and products of microbial conversion reactions are ideal tools for this purpose, as they allow a distinction against environmental concentrations of the analytes and offer a supreme sensitivity. Analysis of natural ^{15}N isotope abundances in nitrate, nitrite, and ammonium, combined with the assessment of ^{18}O values in nitrate and nitrite, can provide first insights into potential sources and sinks of these compounds and which nitrogen transformation processes are likely to co-occur (Wells et al., 2016; Minet et al., 2017; Nikolenko et al., 2018). Short-term incubations following the transformation of ^{15}N-labeled ammonium, nitrate, or nitrite into oxidized or reduced nitrogen species allow the quantification of process rates of nitrification, denitrification, anammox, and DNRA, and of potential linkages between these processes (Berg et al., 2015; Roland et al., 2018).

The essential question regarding the contribution of in situ CO_2 fixation to the microbial carbon can currently be addressed by ^{13}C and ^{14}C-based methods to quantify the incorporation of CO_2 derived carbon in total microbial biomass (Nowak et al., 2015; Beulig et al., 2016; Akinyede et al., 2020; Overholt et al., 2021). For both nitrogen and carbon cycling, estimations of turnover rates for the whole aquifer system need to take into account that in many aquifers, the greatest proportion of subsurface process activity probably occurs in association with biomass present on mineral surfaces (Fredrickson and Fletcher, 2001).

Towards a generalized understanding of the subsurface

To understand the contribution of microbial taxa to ecosystem functions, their adaptation and strategies for survival in the groundwater, approaches connecting taxonomy, function and activity are required. Metabolic labeling techniques such as stable isotope probing (SIP) allow the identification of active microbial key players. Provided with heavy isotope labeled substrates, active microbes will incorporate isotopes like ^{13}C, D or ^{15}N into their biomolecules. This heavy isotope incorporation can be determined on the community level using omics techniques targeting different classes of biomolecules (Neufeld et al., 2007; Taubert et al., 2012). Furthermore, using Raman microspectroscopy or nanoSIMS, the isotope incorporation can also be detected on the level of individual cells (Musat et al., 2008; Berry et al., 2015; Taubert et al., 2018). Novel developments in the SIP methods are currently moving beyond the identification of key players, towards a quantitative assessment of carbon and nitrogen fluxes (Koch et al., 2018; Taubert et al., 2019, 2021).

However, these approaches typically rely on laboratory experiments conducted under conditions that aim to mimic but also strongly simplify the aquifer environment. Natural porous media are complex and often heterogenous structures, which imposes severe challenges in determining the exact physical, chemical and ecological conditions the microbial community is exposed to in situ (Thullner and Regnier, 2019). Future challenges lie in a better approximation of the micro scale heterogeneity of these conditions, and of the respective micro scale distribution patterns of microbial communities and processes.

A final challenge that scientists are facing is linking microbially driven processes on the micro scale level to landscape level observations. Refined modelling approaches that integrate micro scale heterogeneity are key to understanding individual systems on the catchment level as well as developing a generalized understanding of microbially mediated biogeochemical transformations in the subsurface (Fig. 2).

Synthesis: Strategies of the groundwater microorganisms combining lifestyles

Autotrophy and heterotrophy

One of the most interesting questions about microbial life in groundwater concerns the relative importance of CO_2 versus organic carbon as carbon source. Approaches targeting genetic potential for autotrophic or heterotrophic growth typically result in a clear bisection of the microbiome (Herrmann et al., 2015; Jewell et al., 2016; Long et al., 2016). However, here, we would like to address this aspect from the perspective of the groundwater microorganisms: aiming for survival. How can microorganisms utilize their genomic potential to thrive under the conditions present in the groundwater? What strategies have they evolved to be successful? Which energy-providing reactions are linked to these lifestyles, and how do they connect to biogeochemical cycles?

The "all-rounder"

In the sections above, multiple examples of organisms using both CO_2 and organic carbon were outlined. In oligotrophic groundwater, mixotrophy is a successful strategy allowing microbes to expand the range of accessible resources. Groundwater

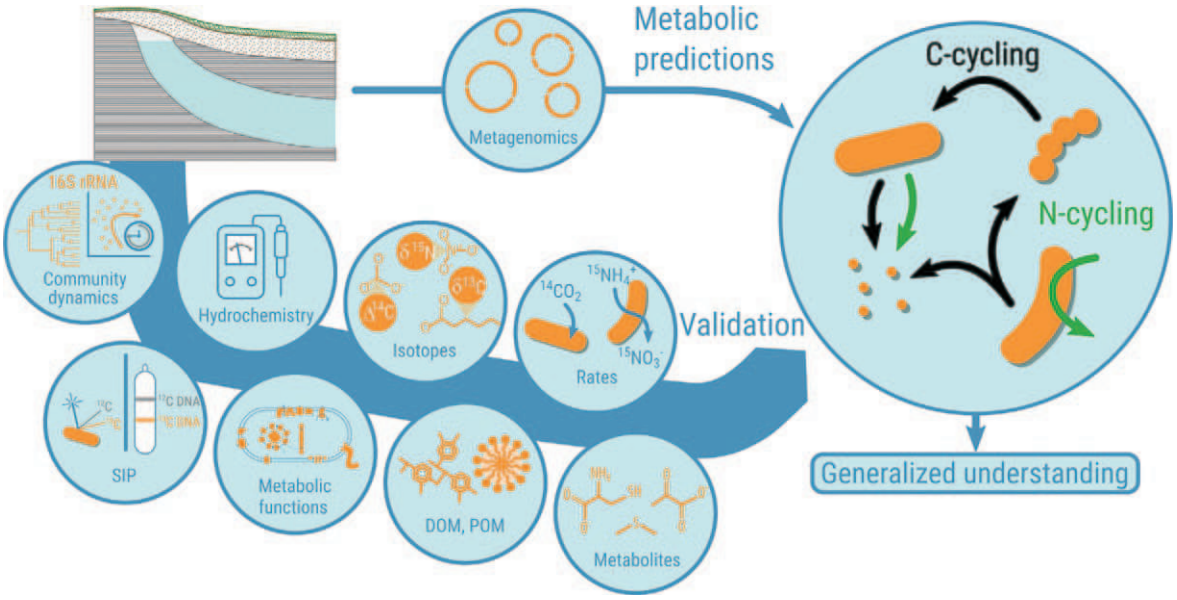

Fig. 2 Overview of methods employed in a comprehensive approach to understand microbially driven biogeochemical cycling in groundwater, interaction and metabolic handoffs between the key players, and key environmental controls on microbial consortia.

microbes with the potential to fix CO_2 thus often also exhibit uptake and assimilation mechanisms for various organic carbon compounds (Emerson et al., 2016; Probst et al., 2017) (see Table 1). To further enhance their metabolic capabilities, such organisms employing an "all-rounder" strategy can be able to utilize inorganic energy sources, such as reduced nitrogen and sulfur compounds, and multiple electron acceptors, such as oxygen and nitrate (Jewell et al., 2016; Wegner et al., 2019; Taubert et al., 2021). Similarly, many facultative anaerobic microorganisms are able to switch from oxygen respiration to nitrate reduction and thus adjust to fluctuating redox conditions. Using nitrate as electron acceptor, some microbial taxa found in groundwater can perform both denitrification and DNRA and can choose the nitrate reduction pathway that will be energetically more favorable under the given conditions.

The "minimalist"

A large amount of microbes found in groundwater feature ultra-small cell sizes below 0.2 μm (Castelle et al., 2015; Luef et al., 2015; Herrmann et al., 2019). These organisms are characterized by a minimalistic strategy, featuring reduced genomes that lead to restricted metabolic capabilities. The members of the Candidate Phyla Radiation (CPR), which are often present in high abundance in groundwater habitats, are prime examples of this strategy (Rinke et al., 2013). The CPR possess various glycoside hydrolases for the breakdown of carbohydrates and a high range of transporters to satisfy their minimal nutritional requirements: amino acids, nucleotides, and sugars for fermentation (Castelle et al., 2015, 2018; Danczak et al., 2017). Lacking pathways for synthesis of essential amino acids and nucleotides, these organisms likely exhibit a symbiotic lifestyle (Nelson and Stegen, 2015). Successful examples of co-cultivation of CPR with putative hosts have confirmed this assumption (Gong et al., 2014; Bor et al., 2020).

Individual strategies and links to biogeochemical cycles

Like autotrophic and heterotrophic lifestyles, the all-rounder and minimalist strategies should be seen as extremes on a wide gradient. Even minimalists like the CPR are proposed to contribute individual metabolic steps in the nitrogen or sulfur cycle to complement the capabilities of other organisms (Hug et al., 2016; Danczak et al., 2017; Castelle et al., 2018). Metabolic hand-offs can occur, where each of the involved organisms carries out some steps of a metabolic pathway (Anantharaman et al., 2016; Hug and Co, 2018). Mixotrophic all-rounders were found to rely less on CO_2 fixation the more organic carbon compounds they were able to utilize, and vice versa (Taubert et al., 2021).

To date, a huge body of literature exists where research either focused on biogeochemical processes in groundwater, or diversity and functional potential of groundwater microbial communities based on molecular surveys. New concepts and perspectives, along with a rapidly expanding toolbox of novel methodological approaches to link microbial identity, activity, and element flow within microbial consortia, will allow us to eventually achieve a mechanistic understanding of the groundwater microbiome. Starting from there, we will be ready to face the next challenge: To link microscale studies and concepts of microbial metabolism and interactions to aquifer-level observations of microbially-driven biogeochemical processes.

Knowledge gaps

- What is the contribution of planktonic versus attached microbial populations to nitrogen transformation processes in aquifers?
- How can we adequately account for large-scale and microscale heterogeneity in biogeochemical processes and microbial distribution patterns in our groundwater sampling designs?
- Which factors determine the major nitrate reduction pathway—denitrification, DNRA, or anammox—in groundwater, and what is the impact of geologic setting and land use?
- To what extent can we predict the groundwater's capacity for a given biogeochemical process based on abundances of the corresponding key microbial players?
- What is the fate of microbial-derived carbon in groundwater?
- What is the relative importance of heterotrophy and autotrophy in the groundwater, and which factors influence it?
- How does the genomic potential of groundwater organisms translate into phenotypes and metabolic strategies?
- How does interaction with symbiotic organisms like CPR affect groundwater microbial community composition and activity, and what is the role of CPR in biogeochemical processes?
- What is the role of viral lysis and protist grazing for the provision of labile organic carbon in groundwater?

Important case studies

See Table 2

Table 2 Collection of important case studies dealing with groundwater microbial diversity, functional potential, and the role of microorganisms in biogeochemical processes in aquifers.

The Ecology of Microbial Contaminant Degradation in Groundwater

Tillmann Lueders[a] and András Táncsics[b], [a]Chair of Ecological Microbiology, Bayreuth Center of Ecology and Environmental Research (BayCEER), University of Bayreuth, Bayreuth, Germany; [b]Department of Molecular Ecology, Institute of Aquaculture and Environmental Safety, Hungarian University of Agriculture and Life Sciences, Hungary

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Aquifer A geological formation in which subsurface water is transported and stored.
BTEX Complex contaminations of petroleum hydrocarbons including benzene, toluene, ethylbenzene and xylenes.
Co-metabolism Degradation of contaminants, often at low concentrations, by the fortuitous activity of enzymes expressed to degrade substrates other than the actual micropollutant.
Functional marker gene Catabolic or respiratory gene conserved within a functional group of microorganism, the targeting of which allows to detect and quantify respective process potentials in the field.
Microbiome A characteristic microbial community found in a defined habitat, including their specific metabolic activities and ecological interactions.
Micropollutants Pollutants typically found at low concentrations (ng–μg L^{-1} range) in the water cycle, often of emerging concern due to their bioactivity and toxicity at trace amounts.
Organohalides Halogenated hydrocarbons, aliphatic or aromatic.
Priority pollutants A list of the most widespread and concerning groundwater pollutants compiled by regulatory authorities.
Stable isotope probing Detection and identification of process-relevant populations within complex environmental microbiomes based on labeling with stable isotopes.

Introduction

Aquatic microbiomes are of crucial importance for the quality of inland waters. They regulate the turnover of carbon and nitrogen inputs, they degrade pollutants, and are crucial for hygienic water quality. While surface waters such as rivers and lakes are often more prominent in public awareness, the quantitatively most significant component of the terrestrial water cycle is groundwater (Shiklomanov, 1993). The use of groundwater is especially important for drinking water supply. A lack of access to hygienically safe drinking water is estimated to result in up to half a million of human mortalities p.a., mostly in less developed countries (World Health Organization, 2019). However, also chemical groundwater pollution is of increasing global concern. Rising environmental pollution, changes in land use, population growth and climate change are just a few of the most relevant factors leading to changes in the amounts of solutes entering our groundwater.

Chemical water contaminants can generally be defined as elements or compounds foreign to a water body, or with concentrations significantly raised compared to natural background concentrations, that are toxic, persistent and liable to bioaccumulate (Tornero and Ribera d'Alcalà, 2014). The canonical lists of ground- and drinking water "priority pollutants," routinely compiled by regulatory authorities (European Commission, 2008; US EPA, 2015), include many organohalide solvents, aromatic hydrocarbons and other petrochemicals, metals and other inorganics, but also certain biocides (Table 1). Many of these are considered as so-called "legacy contaminants," which have been released to and accumulating in the environment due to anthropogenic activities over many decades. Concentrations of such legacy contaminants in polluted groundwater can be quite high, typically in the mg L^{-1} range or even higher. In contrast, a further group of compounds summarized as "emerging contaminants" or "micropollutants" is typically found in the ng–μg L^{-1} range. Despite these low concentrations, they are of increasing stakeholder concern

Table 1 Examples of frequent ground- and drinking water pollutants, including priority pollutants.

Pollutant class	*Example compounds*	*Source*
Petroleum hydrocarbons	Alkanes, BTEX (benzene, toluene, ethylbenzene, xylenes), phenols	Petroleum industry
Polyaromatic hydrocarbons	Napthalene, anthracene, phenantrene, benzo(a)pyrene, fluoranthenes	Chemical industry, asphalt, combustion products
Halogenated hydrocarbons	Chloromethanes, chloroethanes, polychlorinated biphenyls (PCBs), pentachlorophenol (PCP), dioxins, polybrominated diphenylethers	Chemical industry, dry cleaning, degreasing, lubricants, flame retardants
Pesticides, other biocides	Atrazine, DDT, diuran, endosulfanes, isoproturon, triclosan	Agriculture, food industry, disinfection
Pharmaceuticals	Ethinyl estradiol, diclophenac, ibuprofen, metformin, carbamazepine	Hospitals, households
Additives	Methyl-*t*-butylether (MTBE), phthalates, bisphenol A, nonylphenols	Chemical industry, plastic production
(Heavy) metals, metalloids	Lead, cadmium, chromium, copper, mercury, nickel, arsenic, antimony, uranium and their compounds	Geogenic, mining industry
Other inorganics	Nitrate, ammonia, sulfuric acid, sulfide	Fertilizers, animal husbandry, mining

Curtailed from European Commission (2008), US EPA (2015) and based on the pollutants discussed in this chapter.

(Schwarzenbach et al., 2010). Micropollutants include many bioactive compounds such as pesticides, pharmaceuticals, hormones and antibiotics, but also chemical detergents, personal-care products, flame retardants or disinfection by-products (Table 1). In contrast to our understanding of the degradation of many legacy contaminants (a.k.a. "macropollutants"), research on the microbiology and biochemistry of micropollutant degradation remains a major analytical challenge today (Fenner et al., 2021).

Microbial contaminant degradation via redox processes

Microbes and especially bacteria, typically more abundant in aquifers than archaea or microeukaryotes, actively control groundwater quality with their biogeochemical activities. To understand the principles of microbial contaminant degradation, it is relevant to first classify the different pollutants into fundamental redox schemes (Fig. 1). I.e., petroleum hydrocarbons and other reduced organic pollutants like pesticides or pharmaceuticals will typically be utilized as electron donors and thus are subject to oxidative biodegradation. At the same time, the general redox setting of the water body and the availability of electron acceptors like oxygen, nitrate, ferric iron or sulfate will determine, whether oxidative degradation is driven by either aerobic or anaerobic degraders (Lueders, 2017). In contrast, some of the most widespread organohalide pollutants are higher-chlorinated ethylenes (perchloroethylene, PCE, and trichloroethylene, TCE), which are highly oxidized compounds, making them unattractive as electron donors or even inaccessible for oxidative biodegradation (Mattes et al., 2010). Here, biodegradation essentially relies on reductive processes and actually the use of the pollutant as electron acceptor by anaerobic degraders (Fig. 1). The redox setting of the aquifer will thus not only determine the mode of biodegradation, but control whether a pollutant can be degraded at all. The same also applies to another very prominent, but inorganic groundwater pollutant: Nitrate can typically also be eliminated from groundwater via reductive processes alone, canonical denitrification being the responsible respiratory process and dependent on the absence of oxygen, as well as the availability of suitable electron donors to fuel denitrifying microbial populations. Finally, reduced inorganics

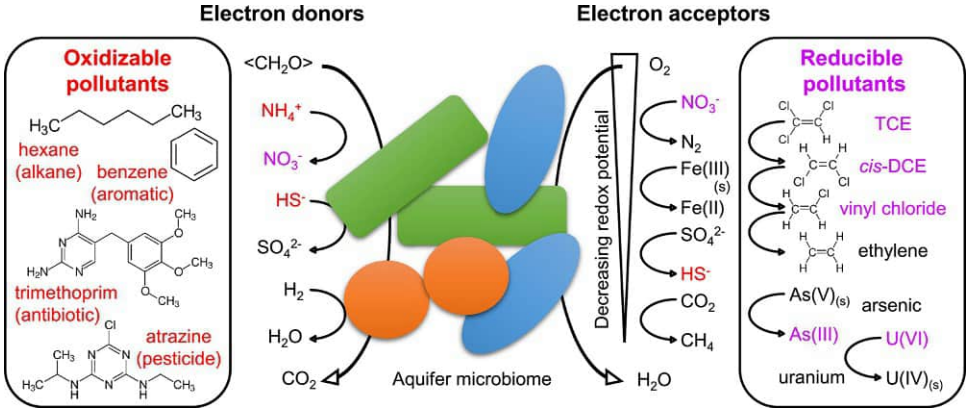

Fig. 1 Scheme of the coupling of electron donors and electron acceptors in redox processes mediating the degradation of pollutants by aquifer microbes. Oxidizable organic and inorganic pollutants are given in red, reducible water pollutants in purple. Modified from Meckenstock RU, Elsner M, Griebler C, Lueders T, Stumpp C, Aamand J, Agathos SN, Albrechtsen H-J, Bastiaens L, Bjerg PL, Boon N, Dejonghe W, Huang WE, Schmidt SI, Smolders E, Sørensen SR, Springael D, and van Breukelen BM (2015) Biodegradation: Updating the concepts of control for microbial cleanup in contaminated aquifers. *Environmental Science & Technology* 49: 7073–7081. doi:10.1021/acs.est.5b00715.

like ammonium or sulfide can also contaminate groundwater as a result of anthropogenic inputs. Their removal again depends on oxidative processes and their use as electron donors, mostly by aerobic chemolithoautotrophs incl. nitrifiers and sulfide oxidizers.

Thus in summary, the nature and ecophysiology of the microbes involved in the degradation of macropollutants in groundwater will primarily be dictated by the redox state of the pollutant itself (i.e., is the pollutant an attractive electron donor or acceptor?), and by the availability of appropriate partner reactants needed to drive the respective redox processes. In contrast, micropollutant degradation is taken to mostly rely on co-metabolic (or fortuitous) degradation mechanisms (Fenner et al., 2021; Schwarzenbach et al., 2010). These will be discussed in more detail further down.

Oxidative catabolism of groundwater pollutants

The most common way of contaminant biodegradation is oxidative catabolism, in which the organic contaminant serves as electron donor and carbon source for degraders. It may be surprising, but many of the above mentioned xenobiotic compounds are easily accessible substrates for a wide diversity of microbes. Since petroleum hydrocarbons (e.g., aliphatic alkanes and aromatic hydrocarbons) are amongst the most frequent groundwater pollutants, we have a deep knowledge on the oxidative microbial degradation of these compounds today. Especially monoaromatic hydrocarbons, such as benzene, toluene, ethylbenzene and isomers of xylene (the so-called BTEX compounds) pose the highest environmental hazard. Thus, their biodegradation pathways are well-characterized (Fig. 2). Under aerobic conditions, the initial step of degradation is always the activation of the aromatic ring in peripheral or upper pathways of degradation, catalyzed by a wide variety of mono- and dioxygenase enzymes. The largest group of enzymes that can activate the aromatic ring are the Rieske non-heme iron-dependent oxygenases. These enzymes play an important role in the degradation of benzene, toluene, phthalates, naphthalene and biphenyls (Gibson and Parales, 2000). They are multi-component enzyme complexes consisting of a terminal oxygenase component and various electron transport proteins. During the reaction catalyzed, two oxygen atoms are incorporated into the aromatic ring, eventually forming an aromatic *cis*-dihydrodiol. Followed by a dehydrogenation step, depending on the substrate, this results in a substituted or non-substituted catechol molecule. In the case of toluene, the product is 3-methylcatechol. Another important group of aromatic ring activating enzymes is the soluble di-iron monooxygenases, some of which are capable of monooxygenating benzene or toluene and thereby converting them to phenol or methylphenol, respectively. Subsequently, these are also further transformed to catechols. Their best-known representatives are toluene monooxygenases, which are able to hydroxylate toluene in all three possible positions (Parales et al., 2008). In the following step, the phenol or methyl-phenol will be transformed to a catechol or methyl-catechol. Eventually, all peripheral or upper pathways result in a catecholic molecule, which is the central intermediate of this aerobic degradation. These catecholic molecules will be further transformed by enzymes of the central or lower pathways of aromatic hydrocarbon degradation, in which the key step is the cleavage of the aromatic ring. Only two types of dioxygenases catalyze this ring cleavage: intra- or extradiol dioxygenases. Intradiol dioxygenases (ortho-cleavage dioxygenases) selectively cleave the aromatic ring between the hydroxyl groups of the catecholic substrate, while extradiol dioxygenases (meta-cleavage dioxygenases) cleave the C–C bond outside the two hydroxyl groups of catechols. Also methyl substituted aromatic compounds (toluene, xylenes) are metabolized via meta-ring cleavage. A well-characterized group of extradiol dioxygenases is adapted to limited oxygen availability (Kukor and Olsen, 1996), a favorable property in contaminated subsurface environments. Microbes harboring this type of ring-cleavage enzyme can play prominent role in the degradation of monoaromatic hydrocarbons in hypoxic aquifers (Táncsics et al., 2018).

Given the fact that the availability of oxygen is often limited in contaminated aquifers, microbes capable of degrading petroleum hydrocarbons under anaerobic conditions play a pivotal role in the clean-up of the contaminated subsurface environments. The most common mechanism for the anaerobic activation of aromatic compounds is fumarate-addition (Fig. 2). In this process, a glycyl radical enzyme decreases the stability of the aromatic ring by the addition of a fumarate molecule to the aromatic compound (i.e., to the methyl group of toluene). This process of benzylsuccinate formation, first described for the nitrate-reducing *Thauera aromatica*, is now widely recognized as a conserved key mechanism for the anaerobic activation of methylated aromatics and even alkanes (von Netzer et al., 2016). Such benzyl- and alkylsuccinate-synthases are highly conserved, and can be found not just in nitrate-reducing, but also in sulfate- and iron-reducing bacteria that degrade petroleum hydrocarbons. In analogy to the catechols in aerobic aromatics degradation, benzoyl-CoA is formed as the central intermediate then entering downstream catabolic routes. For alkanes, the alkysuccinates go through a carbon chain rearrangement, followed by a decarboxylation, resulting in a branched chain fatty acid, which can then enter central metabolic pathways and canonical β-oxidation. Overall, prokaryotic microorganisms have evolved many efficient oxidative pathways for the degradation of organic molecules, even for those having complex aromatic structures, or showing minimal solubility in water.

Reductive elimination of groundwater pollutants

Subsurface environments are typically oxygen-limited, thus providing a niche for bacteria which use electron acceptors other than oxygen for their respiration (Fig. 1). These alternative electron acceptors include both inorganic (sulfate, nitrate, ferric iron) and organic compounds (e.g., trimethylamine N-oxide). The fact that some organic contaminants can serve as electron acceptors is relevant in the bioremediation of groundwater ecosystems contaminated with chlorinated aliphatic (tri- and perchloroethylene—TCE/PCE) or aromatic compounds (e.g., chlorobenzenes, polychlorinated biphenyls, dioxins). Specific obligate anaerobic microorganisms, members of the class *Dehalococcoidea* in the phylum *Chloroflexi* (Löffler et al., 2013), can perform this organohalide respiration, resulting in the reductive dechlorination of the above mentioned compounds. This mechanism, which is catalyzed by

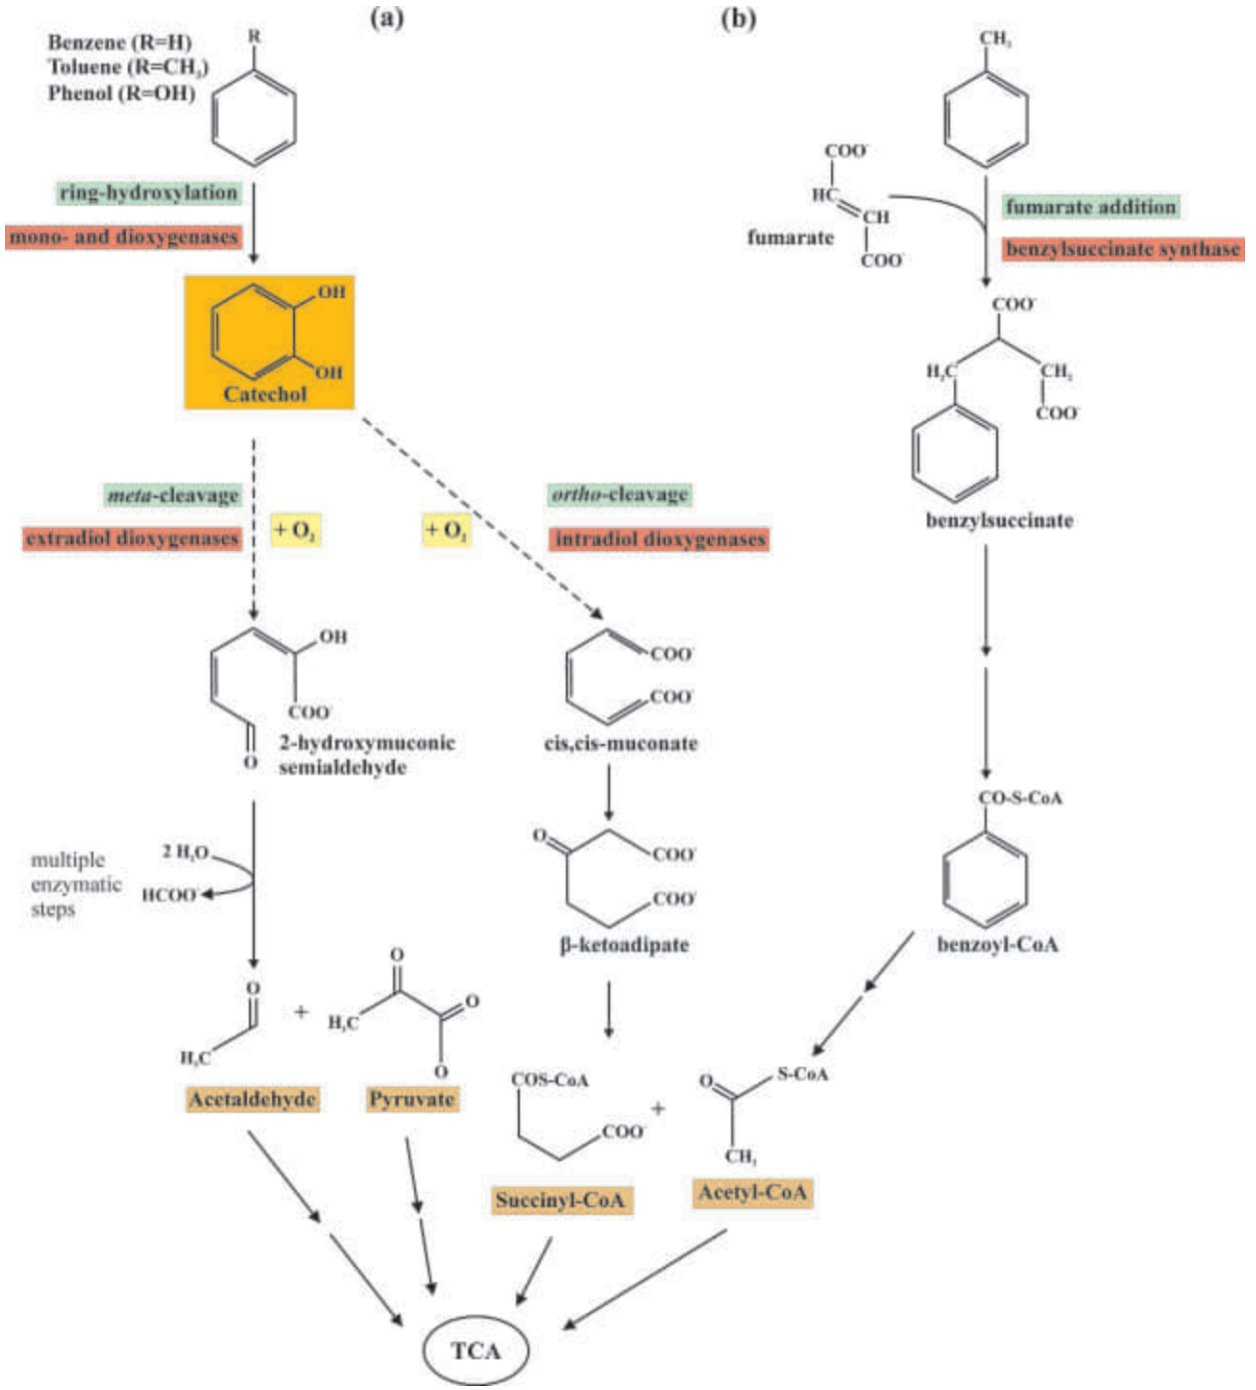

Fig. 2 Schematic representation of conserved (A) aerobic and (B) anaerobic degradation pathways of monoaromatic hydrocarbons. During aerobic degradation, enzymes of the upper or peripheral pathway are responsible for the activation of the aromatic ring, resulting in a catecholic central intermediate. Thereafter, enzymes of the lower pathway are responsible for the ring-cleavage of the chatecholic molecule. During anaerobic degradation, fumarate-adding enzymes play a key role in the initial activation of the aromatic ring. Ultimately, both aerobic and anaerobic degradation end-products can enter the TCA-cycle.

reductive dehalogenase (RDase) enzymes, involves the removal of the chlorine substituents as halogen ions and their replacement by hydrogen. The RDase homologous (*rdh*) genes are often used as molecular markers to reveal the diversity and activity of organohalide-respiring bacterial communities. One of the RDases, called vinyl chloride reductase (*vcrA*), plays a crucial role in the complete reduction of PCE and TCE into the harmless ethylene by catalyzing the reduction of vinyl chloride. This enzyme is mostly harbored by members of the genus *Dehalococcoides*, often obligate organohalide-respiring bacteria. Therefore, the bottleneck of the complete bioremediation of TCE/PCE-contaminated subsurface ecosystems is the presence of *vcrA*-harboring *Dehalococcoides* populations. The absence of such bacteria can lead to the accumulation of vinyl chloride, which is more harmful than the parent compounds.

A common inorganic electron acceptor in anoxic groundwaters, nitrate, is one of the most widespread and important groundwater contaminants if present in higher concentrations (typically above 50 mg L^{-1}). Its appearance in groundwater is mainly due to human activities, especially animal husbandry and the release of manure, fertilization, the desiccation and field application of sewage sludge, or irrigation with domestic wastewater. Given the fact that nitrate is a rather mobile anion, it is readily leached into groundwater when applied to surface soils. Nitrate, and nitrite as its initial reduction product, have serious health effects. It may form carcinogenic n-nitroso compounds in the intestinal tracts, and can cause methaemoglobinaemia in infants, thus prohibiting the use of nitrate-burdened groundwater for human consumption. Bioremediation of nitrate-contaminated aquifers is mostly based on the activity of heterotrophic denitrifying bacteria. However, denitrification will only be efficient in groundwater, when oxygen is absent and adequate electron donors are present. Aquifers are usually oligotrophic environments, thus the metabolic activity of denitrifiers can be stimulated by providing them with easily available carbon- and energy sources, such as methanol, ethanol, acetate or molasses. In canonical denitrification, nitrate will ultimately be transformed into nitrogen gas, thus eliminating the pollutant from the system. However, also inorganic electron donors like reduced sulfur species and hydrogen gas have been reported to drive autotrophic denitrification within aquifer microbes (Kumar et al., 2018).

Besides nitrate, also the reduction of other oxidized inorganics is of relevance for pollutant fluxes in groundwater (Fig. 1). Specifically, the microbial reduction of water-insoluble arsenate (As(V)) to soluble arsenite (As(III)) is a major mechanism for the mobilization of this known carcinogen in regions where aquifer sediments are naturally rich in arsenic, but human impact has caused oxygen depletion in previously oxic groundwaters (Hug et al., 2020). In contrast, the reductive immobilization of dissolved U(VI) to insoluble U(IV) by metal respiring aquifer microbes is an important and actually applied strategy for the containment of radioactive pollution at sites with respective subsurface contamination, e.g. at sites of former nuclear weapon testing (Williams et al., 2011). In summary, not only the catabolic but also the respiratory activities of aquifer microbes are involved in many ways in the degradation and attenuation of groundwater pollutants.

Co-metabolic degradation of micropollutants

In addition to the microbial elimination of notorious legacy pollutants, the widespread emergence and accumulation of a considerable range of micropollutants in the water cycle, complex mixtures of anthropogenic chemicals not only present, but also of concern in low concentrations, is receiving increasing attention (Schwarzenbach et al., 2010). As mentioned above, many of these compounds are biocides, detergents, pharmaceuticals and other bioactive chemicals (Table 1), entering the water cycle mainly via outflows of urban wastewater treatment, agriculture or industry. In contrast to the catabolism of macropollutants by degraders specialized to capitalize on the resulting carbon and energy fluxes, the degradation of micropollutants mostly depends on co-metabolic processes. The low concentration of micropollutants is recognized as the major limitation to potential degraders, effective availability mostly being below thresholds to trigger the induction of catabolic pathways. Co-metabolic degradation involves the fortuitous activity of enzymes expressed to degrade substrates other than the actual micropollutant, but capable to transform the latter due to structural or mechanistic promiscuity. While it is far from clear today, whether lower thresholds for catabolic degradation can be predicted by compound- or strain-specific parameters, there is an increasing understanding of the primary metabolic activities in aquatic microbiomes that can result in an increased co-metabolism of micropollutants. Intriguingly, next to "expected" metabolic activities by unspecific oxidative enzymes of heterotrophs such as laccases (Margot et al., 2013), there is increasing evidence for a role of autotrophic co-metabolism in wastewater systems. Hence, the monooxygenase enzymes of lithotrophs such as ammonia oxidizers and methanotrophs are also capable to oxidize certain micropollutants. For example, the elimination of a range of micropollutants typically subject to oxygenation reactions was significantly correlated to the abundance of ammonia-oxidizing Archaea in activated sludge (Helbling et al., 2012). Future research will have to show whether it is possible to more specifically stimulate and harness such co-metabolic activities, to counter micropollutant accumulation in the terrestrial water cycle. For this however, major challenges still remain to be met, both from a microbiological and an analytical perspective.

The ecology of contaminant degrading microbes in groundwater

Research on the microbial biodegradation of environmental contaminants such as alkanes dates back more than 100 years. A Dutch microbiologist, N. L. Söhngen, was the first to report on the microbial biodegradation of oil slicks floating on water and to describe that these hydrocarbons can serve as a source of carbon and energy for microorganisms (Söhngen, 1913). In the following decades of the era of classical microbiology, enrichment and isolation approaches have increased our knowledge on the diversity of xenobiotic degrading bacteria. Today, it is known that the ability of xenobiotic degradation is widespread among members of the bacterial domain, even some members of the Archaea have this ability. Until now, more than 320 genera of Bacteria and 12 genera of Archaea have been reported to include hydrocarbon-degrading species (Prince et al., 2018). As compiled in the first section of this chapter, the physiology and biochemistry of many microbial pollutant degraders with relevance in groundwater are now fairly well understood. That is, given that these microbes have been isolated and can be cultivated in the laboratory, and that biodegradation in laboratory culture is relevant to pollutant concentrations typically found *in situ*. Over the last 1–2 decades, considerable research efforts have addressed the retransfer of this understanding back to the field, to identify important degrader populations and the controls of their biogeochemical activities directly in contaminated subsurface ecosystems (Lueders, 2017; Meckenstock et al., 2015). This motivation has advanced the canonical field of biodegradation research toward a more ecological and microbiome-based perspective.

One primary approach facilitating this perspective involves the detection of degraders *in situ* by the use of so-called functional marker genes. On the oxidative side, this is relatively straightforward and firstly involves the development of PCR assays for catabolic genes conserved and ideally distinctive for a certain biodegradation pathway. Typically, this will be genes of initial activating enzymes of pollutants, or of the turnover of central metabolites. For aromatic hydrocarbons, this can be illustrated e.g. by work done on substrate-activating mono- and dioxygenases and on ring-opening dioxygenases for aerobic degraders (Junca and Pieper, 2009; Táncsics et al., 2010), or on fumarate-adding and dearomatizing enzymes of anaerobic degraders (von Netzer et al., 2016). The development of primer pairs with required specificity but still optimal coverage of diverse degrader lineages is often a major challenge. Still, the application of such functional marker gene assays to nucleic acids extracted from contaminated aquifer samples offers a number of important advantages over classical laboratory-based enrichment-and-isolation of degraders, and over pure biogeochemical assessment of biodegradation *in situ*. First, functional marker gene sequencing allows to trace degrader populations truly established at a given site, to affiliate them either to known degraders available in laboratory culture, or to provide evidence for as-yet unidentified degraders to be of relevance. Second, when applied in a quantitative manner (in qPCR), spatial distribution patterns or temporal dynamics of degrader populations at sites can be assessed. All insights generated via such marker gene approaches are utile to unravel important drivers and limitations of biodegradation processes at a given site, and to inform population-based monitoring and biostimulation measures in bioremediation.

Also on the reductive side of pollutant transformation, a host of utile functional marker genes is at hand. This especially concerns enzymes involved in the reductive dehalogenation of chlorinated ethylenes, where the terminal vinyl chloride reductase, detoxifying the highly toxic penultimate sequential reduction product of PCE, can be correlated to effective pollution levels and biodegradation potentials (van der Zaan et al., 2010). For other pollutant-reducing reductases, e.g. genes involved in canonical denitrification, a functional interpretation of field monitoring data can be less informative. In example, since many denitrifiers are not obligate but facultative anaerobes, the presence or local abundance of respective functional marker genes (e.g., the dissimilatory nitrite reductase (Yan et al., 2003)) may not be directly correlated to potential or actually ongoing denitrification in groundwater. In a general notion, the more strictly a certain gene product is associated with a specific pollutant-attenuating function, the more utile the respective functional marker gene is in bioremediation research. Beyond direct marker gene sequencing and qPCR of field samples, respective catabolic and respiratory gene patterns can also be targeted in metagenome mining, or genome bins assembled therefrom. This can produce evidence for a potential involvement of yet unidentified or uncultivated microbial lineages in pollutant degradation in the field.

A second, not gene-targeted strategy to detect specific pollutant degraders in contaminated aquifer samples relies on the use of labeled substrate queries. In what is called "stable isotope probing" (SIP), typically ^{13}C-labeled pollutants are exposed to complex degrader microbiomes, mostly in laboratory microcosms, with the idea of an assimilatory labeling of the microbes most actively involved in pollutant catabolism. A density- or mass-dependent resolution of biomarkers such as DNA, RNA or proteins of active degraders from unlabeled backgrounds then allows to unambiguously identify microbial lineages involved in a given biodegradation process, even if previously unknown or uncultivated, and even if no à-priori knowledge on catabolic routes involved is available. The SIP approach has been widely applied to unravel hydrocarbon-degrading microbial key-players in groundwater (Lueders, 2017; Vogt et al., 2016). That said, the approach also comes with its weaknesses, requires laboratory incubations or elaborate labeling microcosms deployed in the field, and a comparably high concentration of pollutants for efficient assimilatory labeling. This clearly limits its applicability to reductive pollutant degradation processes, or to the degradation of micropollutants degraded in a co-metabolic manner (Fenner et al., 2021). Still, no matter which experimental or analytical strategy is chosen, a successful detection and identification of the microbes involved in biodegradation at a contaminated site is always a prerequisite for the further delineation of their ecophysiology and ecology *in situ*.

Bottlenecks of pollutant degradation

One of the most paramount objectives of understanding degrader ecology in the field is the unraveling of the limitations of biodegradation processes *in situ* (Fig. 3). Aquifers contaminated with pollutants subject to oxidative biodegradation are often heavily overloaded with these electron donors, in a habitat, which would otherwise be mostly oligotrophic (Griebler and Lueders, 2009). This reductant overload typically exceeds local electron acceptor availability, making the replenishment of suitable electron acceptors for microbial pollutant oxidation one of the primary limitations of catabolic biodegradation in groundwater (Lueders, 2017; Meckenstock et al., 2015). Within contaminated aquifers, this typically results in highly reduced plumes of organic pollutants transported from the source area by groundwater flow, surrounded by zones of elevated biodegradation activities and degrader abundance at the plume fringes (Meckenstock et al., 2015). These are a result of the absence of efficient turbulent mixing in groundwater, and the very limited mixing by transversal dispersion and diffusion being the only mechanisms of sustainably replenishing both dissolved electron donors (from inside the plume) and acceptors (from outside) to degrader populations established in these "hot zones" (hot spots would not be correct in a 3D conception). Stakeholder measures aimed at enhancing natural attenuation at a given site should optimally capitalize on an understanding of both, the physicochemistry and the microbiology of the contaminated system. E.g., the injection of electron acceptors such as nitrate or oxygen into a plume of petrochemicals may be of limited use, if the dominant degraders established at the site belong to iron-reducing lineages.

Vice versa, electron donor supply is often a primary limiting factor for the reductive elimination of oxidized pollutants such as chlorinated solvents. Most organohalides-respiring bacteria rely on electron donors such as molecular hydrogen and other fermentation products, resulting in the introduction of cheap and fermentable organics such as molasses, or reactive barriers with

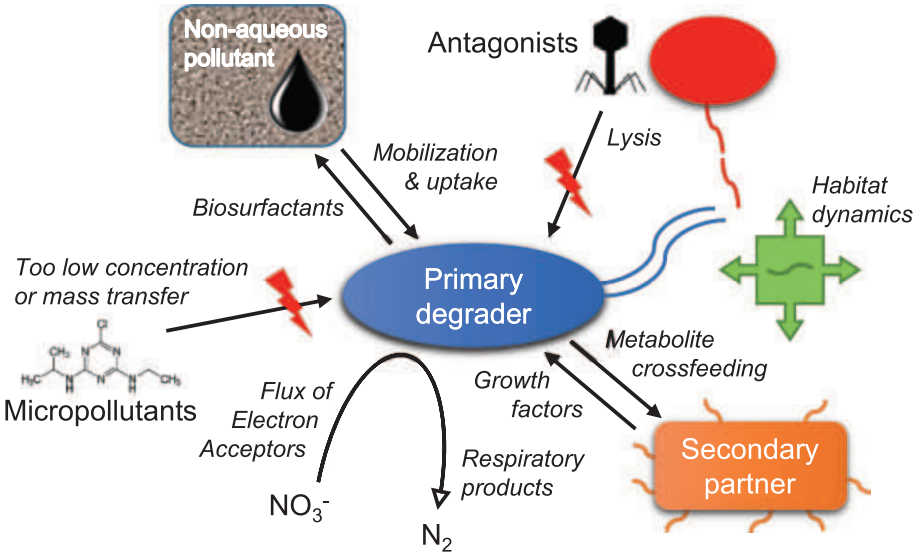

Fig. 3 Summary of key ecological factors that can positively or negatively influence biodegradation activities of organic pollutants by aquifer microbes.

hydrogen-releasing zero-valent iron into contaminated aquifers to stimulate degraders (Kocur et al., 2016). However, since hydrogen and other fermentation products are also attractive to many other anaerobic microbes in aquifers, reductive dehalogenation will typically only be efficient at comparably low redox potentials (<−250 mV), when other electron acceptors are mostly depleted.

Next to the supply of redox partners for pollutant turnover, access to and bioavailability of the pollutant itself can also represent a major limiting factor for biodegradation. This becomes especially apparent where (a) pollutants are present at high mass loads, but hardly water soluble, or (b) when pollutants are present at very low concentrations (in the ng–μg L^{-1} range), as discussed above. In the first case, as known also from natural oil reservoirs (Head et al., 2006), many hydrocarbon oxidizers can release biosurfactants to mobilize and internalize small micelles of non-aqueous phase liquids such as mineral oil. However, this strategy will be viable for degraders mostly in diffusion- and transport-limited microenvironments, such as within biofilms or the micropores of aquifer sediments. Vice versa, at low pollutant concentrations, the limitations of efficient mass transfer into the cell and cellular maintenance energy demands have been shown to cease the biodegradation of atrazine by *Arthrobacter aurescens* TC1, a well-known aerobic pesticide degrader, at the limits of ∼10 μg L^{-1} and below (Kundu et al., 2019). The further exploration of the adaptive strategies of degraders in the degradation of anthropogenic pollutants at limitingly low concentrations represents another prime challenge of environmental microbiology today.

Ecological adaptations and interactions within degrader microbiomes

While many of the factors influencing degrader ecology discussed above relate to habitat characteristics and reactant fluxes, there is also important ecological, population- or community-level adaptations that influence biodegradation outcomes (Fig. 2). Wherever a natural ecosystem is first exposed to a new incoming pollutant of anthropogenic origin, extant microbiomes will react by selecting for microbes capable of capitalizing on the new substrate, either as electron donor or acceptor, and under prevailing habitat conditions. Thus an enrichment of pollutant degraders within total microbiomes will become apparent especially in habitats with complex or highly concentrated contamination scenarios. The time scales for such adaptations to occur, however, will depend on the selective pressure and the natural background of microbes with a respective catabolic or respiratory capacity in the system before contamination, or on the influx of such organisms by organismic dispersal. In line with the postulate of Baas Becking, "Everything is everywhere, but the environment selects" (de Wit and Bouvier, 2006), it can be assumed that for all anthropogenic pollutants, there are natural sources or at least natural substrate analogs, which have resulted in the evolution of respective biodegradation pathways long before man-made pollution. Still, evolutionary processes within contaminant-degrading microbiomes have been reported and can result in the emergence of degradative enzymes with altered functionality, or which are newly acquired and integrated into its metabolism by a given strain. Many of these adaptations have been associated with the mobilization and redistribution of auxiliary functions within complex communities under contaminant exposure, resulting in novel recombinations of previously evolved catabolic functions and pathways in newly emerging degraders (van der Meer, 2006). Only rarely, such mechanisms may result in the emergence of completely novel catabolic functions with relevance to ground- and drinking water quality. One recent example may be the emergence of catabolic capacities for the degradation of acesulfame in wastewater treatment, a widely used artificial sweetener which had long been considered to be persistent in the water cycle (Kleinsteuber et al., 2019).

But even if the oxidative or reductive routes for the elimination of a given pollutant are known for specific microorganisms, these are present within a pollutant-exposed aquifer microbiome same as the needed reactants, this does still not imply that

biodegradation is always efficient. Adaptations and interactions within degrader microbiomes can also involve community-level responses to abiotic habitat dynamics. In example, a transient cease of contaminant degrading activities and a subsequent switching between dominant populations of sulfate-reducing toluene degraders has been reported upon hydrological fluctuations of the groundwater table and connected rearrangements of the redox zonation of a comprehensively characterized BTEX plume (Pilloni et al., 2019). Furthermore, in anoxic groundwater, pollutant degradation is often a community effort, involving essential metabolic interactions between different members of a degradative consortium, such as the mutual provisioning of metabolites and enzymatic cofactors for biodegradation (Fig. 2). In example, such aspects have been elaborately demonstrated for microbial interactions between primary pollutant degraders, secondary metabolite consumers, and even bacterial necromass scavengers in a benzene-degrading, sulfate-reducing enrichment culture from groundwater (Taubert et al., 2012). Similar interactions between primary hydrocarbon-oxidizing fermenters and methanogens as their syntrophic partners have long been established for methanogenic hydrocarbon degradation. Moreover, the activity of organohalide-respiring bacteria can essentially dependent on appropriate corrinoid cofactors of reductive dehalogenases to be provided by associated microbes within dechlorinating consortia (Yan et al., 2016). These examples illustrate that within contaminated aquifers, microbial pollutant degradation is often more a community effort than the activity of a single microbial population.

Beyond such mutualistic microbial interactions in pollutant degradation, antagonistic biological interactions can also shape contaminant degrading bacterial communities. As an example, members of the still enigmatic candidate phylum *Saccharibacteria* are widely distributed and have also been detected in contaminant degrading microbial communities (Figueroa-Gonzalez et al., 2020). These only 200–300 nm ultra-small bacteria have an extremely reduced genome (~1 MB) lacking the capacity of de novo biosynthesis of several important building blocks of the bacterial cell. They seem to be obligate host-parasitic epibionts, thriving on the surface of microbial cells and disrupting their hosts to consume released cellular compounds. The impact of such antagonistic microbial interactions on pollutant-degrading populations in contaminated aquifers is not at all understood, but subject to ongoing scientific investigation. Taken together, the relevance of such ecological controls of and interactions within groundwater pollutant degraders may still be vastly underestimated.

Conclusions

In summary, the extraordinary importance of understanding groundwater microbiomes for the protection and sustainable use of our ground- and drinking water resources is clearly apparent. For many present and future problems in drinking water supply, such as increasing pollution with nitrate and the spread of micropollutants, solutions may be offered via the modulation and harnessing of groundwater microbiomes, possibly upstream of drinking water wells. Also for currently still uncertain and unregulated hazards in our water cycle, such as microplastic pollution, a microbial perspective may contribute to solutions. Even at sites highly contaminated with legacy contaminants, groundwater microbiology has provided sometimes surprising new insights into the control of degradation processes and the degraders involved. A more precise understanding of these degrader populations and their activities and ecology *in situ* will be key to advance current measures and future options for protecting our groundwater resources.

Epikarst: An Important Aquatic and Terrestrial Habitat

Tanja Pipan[a] **and David C Culver**[b], [a]ZRC SAZU Karst Research Institute, Ljubljana, Slovenia; [b]Department of Environmental Science, American University, Washington, DC, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Aquifer A groundwater reservoir, usually a rock of high permeability capable of delivering water to wells or springs.
Chao estimates Estimates of total species richness based on the abundance or incidence of species occurring in one and two samples.
Hypotelminorheic A persistent wet spot, a kind of perched aquifer; fed by subsurface water in a slight depression in an area of low to moderate slope; rich in organic matter; underlain by a clay layer typically 5–50 cm beneath the surface; with a drainage area typically of less than 10,000 m^2; and with a characteristic dark color derived from decaying leaves which are usually not skeletonized.
Karst A terrane, generally underlain by limestone or dolomite, in which the topography is chiefly formed by the dissolving of rock, and which may be characterized by sinkholes, sinking streams, closed depressions, subterranean drainage, and caves.
Milieu souterrain superficiel (MSS) Interconnected cracks and crevices in the superficial layer of rocks, in scree slopes and similar habitats, usually covered with soil or vegetation.
Percolation water Autochthonous karst water which permeates directly through karst limestone without using a surface watercourse.
Recharge The process of addition of water to the saturated zone.
Secondary porosity Porosity created after rock formation due to fracturing, dissolution, etc.
Stygobiont Obligate, permanent resident of aquatic subterranean habitats.
Stygophile A species that completes its entire life cycle in subterranean waters but can also complete its entire life cycle in surface waters.
Vadose zone The zone above the water table in which water moves by gravity and capillarity. Water does not fill all the openings and does not build up pressures greater than atmospheric.

Introduction

Since its identification as a distinct feature of the karst landscape nearly 50 years ago, epikarst has drawn increasing attention from both hydrogeologists and biologists. It is an important component of most if not all karst regions, and is the source of significant

fraction of the subterranean biodiversity of many regions. We first briefly summarize the physical and hydrological aspects of epikarst, and then turn to epikarst communities.

Hydrogeological perspective

Epikarst as a perched aquifer

Epikarst was first described, studied and named by Mangin (1973), Bakalowicz et al. (1974), and Williams (1983) as the uppermost zone of karst that served as a perched aquifer, and among other things, providing an explanation of the persistence of cave streams during periods of drought. While perched above the major aquifer, it can have a large impact on water recharge and quality (Trček, 2007). Many hand dug wells, now primarily of historical interest, tapped into epikarst. In many road cuts and quarries, it forms an obvious top to the rock layer (Fig. 1), but perhaps not surprisingly, epikarst is difficult to precisely define. Participants in a workshop sponsored by the Karst Waters Institute on epikarst (Jones et al., 2004) decided on the following definition, which also illustrates some of the complexities of epikarst:

> Epikarst is located within the vadose zone and is defined as the heterogeneous interface between unconsolidated material, including soil, regolith, sediment, and vegetative debris, and solutionally altered carbonate rock that is partially saturated with water and capable of delaying or storing and locally rerouting vertical infiltration to the deeper regional, phreatic zone of the underlying karst aquifer.

The standard terminology is that water moving vertically out of the epikarst is percolating water, and the entire zone above the water table is the vadose zone. In a study of three German caves, using tritium as a dating method, water was retained in epikarst for one to 3 years (Kluge et al., 2010). While residence times certainly vary more widely than this, it shows the important feature of epikarst—it retards the downward movement of water.

Berthelin and Hartmann (2020) emphasize the diffuse nature of epikarst recharge, and explicitly do not include recharge through sinkholes and stream losses (swallets), although the Karst Waters Institute definition does not seem to exclude this direct recharge. A sketch of the epikarst is shown in Fig. 2.

The epikarst zone is also a very active zone of carbonate dissolution (Berthelin and Hartmann, 2020). The transformation of organic matter into CO_2 in the soil is the source of acidification and hence dissolution. The structure and thickness of epikarst is greatly influenced by soil conditions.

Another way to conceptualize epikarst is as a series of very small drainage basins. Kogovšek (2010) showed that the area drained in some epikarst drips in Postojna Planina Cave System in Slovenia was between 0.1 and 245 m^2, depending on both the year of measurement and the particular drip. The areas are not necessarily contiguous but it is useful as a way of scaling the system. Another small scale perched aquifer, the hypotelminorheic, which occurs at very shallow depths and underlain by clay, is a non-karst equivalent of epikarst, and a habitat that also harbors species specialized for subterranean life in small basins (less than 1 ha in size in Rock Creek Park in Washington, D.C., Keany et al., 2018). Basins are better defined but shallower in the hypotelminorheic than in the epikarst.

Fig. 1 Photo of an Acme Quarry in Greenbrier County, West Virginia. Epikarst here is between 4 and 10 m thick, generally becoming thicker to the right. Photo by William K. Jones, used with permission.

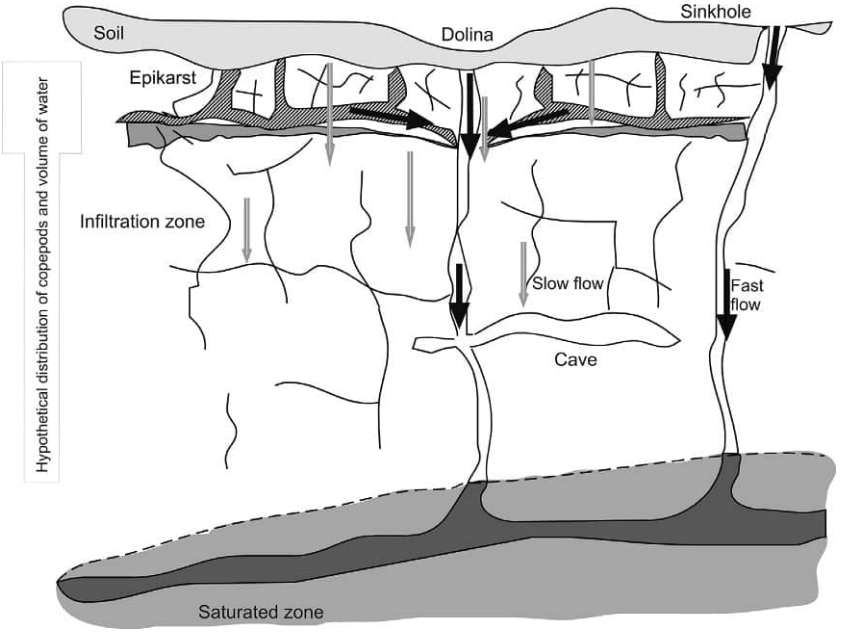

Fig. 2 Conceptual model of epikarst. Gray arrows indicate the direction of diffuse water flow and black arrows are faster flow. Some authors do not include the faster flow as part of epikarst. From Pipan T (2005). *Epikarst—A Promising Habitat*. Ljubljana, Slovenia: Založba ZRC, used with permission.

Physical structure of epikarst

Secondary porosity, as a result of carbonate dissolution is high, perhaps as high as 30% according to Williams (2008) or 10% according to Klimchouk (2004). The epikarst is rarely open enough to be enterable by humans, but some authors include upper level vadose cave passages only a few meters from the surface (Bichuette and Trajano, 2004; Fong, 2004). There are some cases where the epikarst layer becomes more open and uncovered, such as the stone forests of China (Williams, 2008). The depth of epikarst varies with soil and rock conditions, but Klimchouk (2004) states that it can be up to 15 m deep. According to the models of Gabrovšek (2004), it is nearly universal in its occurrence. The boundary between epikarst and the percolation zone can be gentle or abrupt (see Fig. 1).

Biological perspective

Epikarst as habitat

Although the term epikarst was first used in 1973, earlier biological studies included the epikarst fauna. Racovitza (1907) pointed out the cave-adapted organisms commonly occur in cracks and crevices, and that cracks and crevices may be the primary habitat of many species. Not all cracks and crevices are part of the epikarst, because they occur in the vadose and phreatic zones as well, but at least some of Racovitzan cracks and crevices belonged to the epikarst. It was the pioneer of ecosystem studies in karst areas, Raymond Rouch (1986), who demonstrated that zones containing spots of permanent water-saturation (what we now call the epikarst) occur above caves in the Baget basin in France, and harbor an abundant and diverse fauna. Other French biologists have studied the epikarst as well, but in general it was part of a more general study of the fauna of small interstitial habitats, including the vadose zone and the hyporheic zone (e.g. Delay, 1968; Gibert, 1986). Although little known, Petkovski (1959), working in the Dinaric karst, was an early pioneer who observed stygobiotic copepods in caves with no water aside from percolating water accumulating in drip pools. He called the small water filled depressions in cave walls the "realm of Parastenocarida." Brancelj's (2002, 2015) discovery of a rich copepod fauna in drip pools in the shallow Slovenian cave Velika Pasica, which has no other water, but with relatively few reproducing individuals, led him to conclude that reproduction was occurring in small cracks around the cave.

Sampling the epikarst fauna

Generally, it is impossible to sample directly in the epikarst itself because the solution holes and crevices are not large enough to enter. However, there are circumstances where caves are so shallow that they are either directly in or directly below the epikarst zone, depending on one's definition of epikarst. For example, Knapp and Fong (1999) used drip pools that drained the epikarst in a very shallow section of Organ Cave, West Virginia, to do a mark-recapture study of an epikarst dwelling amphipod, *Stygobromus emarginatus*.

Until the development of a device for sampling dripping water (Pipan, 2005, see below), the aquatic fauna was known exclusively from drip pools. After individuals fall from epikarst into drip pools, they may reproduce and establish populations. Copepods and other microcrustacean routinely fall out of epikarst because they are dislodged from the substrate in a manner analogous to particle mobilization in the water column (Hjulstrom curves). This process probably differentially dislodges smaller organisms (see Pipan and Culver, 2007 for details).

Brancelj and Pipan (Pipan and Brancelj, 2001; Brancelj, 2004; Pipan, 2005) developed a technique, while not sampling the epikarst directly, did sample dripping water continuously with the potential for measuring water volume as well. In their sampling device, water from a ceiling drip is directed via a funnel into a 500 ml rectangular filtering bottle fitted on two sides with plankton netting of 60 μm mesh size, and the filtering bottle is placed within a sampling container (Fig. 3). Each sampling container has a drain 3 cm from its base such that collected animals and a small amount of water remain in the filtering bottle while most of the water passes through the filtration unit. Samples, which typically have a volume of about 50 mL, are preserved in either formalin or alcohol, formalin having the advantage of requiring less volume of liquid. Samples are then sorted and identified in the laboratory. Pipan and Culver (2007) provide guidelines for how many such filters need to be used and for how long in order to sample completely the epikarst fauna.

Aquatic fauna

The epikarst fauna of a hotspot cave in Spain

Ojo Guareña is a large (>110 km) cave in Spain and also one of the most biodiverse caves in the world with 187 aquatic species, 49 of which are stygobionts (Camacho and Puch, 2021). The epikarst fauna, known only from the repeated sampling of 10 drip pools in the cave is likewise biodiverse (Camacho et al., 2006). The drip pool fauna, derived from the epikarst, contained a total of 53 species, 15 of which were stygobionts (Table 1), approximately 30% of the entire stygofauna of the cave. The data for pools is almost certainly an underestimate of the total epikarst fauna, based on Pipan et al.'s (2010) analysis of Slovenian cave data which showed that drips contained on average two more stygobiotic copepod species than the associated pools. In any case, the fauna is rich and highly endemic. No figures on the percentage of single cave endemics are present in the entire stygofauna, but it is 67% for epikarst pool stygobionts based on the Slovenian cave data. Camacho et al. (2006) found that pools with carbonate oversaturation, low pCO_2, and overall stability had the most stygobionts. Crustaceans, especially copepods had the most stygobionts, and copepods have been more intensively studied than other components of the epikarst fauna.

The copepod fauna – Patterns of biodiversity

Epikarst copepods are the most diverse and best studied group, although the best studied cases have been limited to Italy, Romania, Spain, Slovenia, and the United States (Table 2). While the numbers may seem low to the non-specialist, these species numbers often rival or even exceed the number of aquatic species specialized for other cave habitats. Especially impressive in this regard is Županova jama (Table 2; Blatnik et al., 2020) with 13 copepod species. A total of 10 copepod species were found in a single drip in

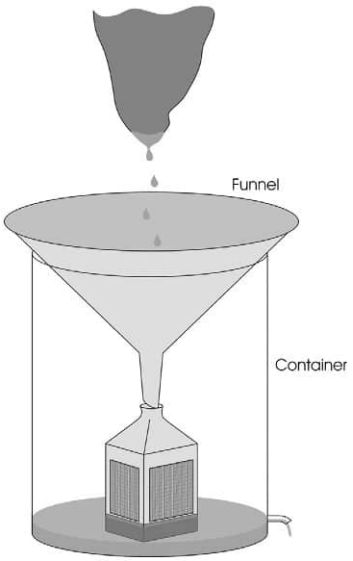

Fig. 3 Diagram of filtering device to continuously collect invertebrates from drips. From Pipan T (2005). *Epikarst—A Promising Habitat.* Ljubljana, Slovenia: Založba ZRC, with permission.

Gland, Switzerland: Springer Verlag.

this cave (Pipan, 2005; Pipan et al., 2018). Overall, the median number of copepod species for the data in Table 2 is 4, and most of the species rich caves are in Slovenia and Spain, and most of the species poor caves are in Italy and Romania.

Although the discovery and description of the epikarst fauna are in the very beginning stages in most regions, recent taxonomic work (Table 3) suggests a rich, largely undescribed fauna, and that this fauna is global in its distribution. Of the 21 species of epikarst copepods described since 2000, 10 are from Thailand (and one from Vietnam), suggesting that tropical epikarst may also

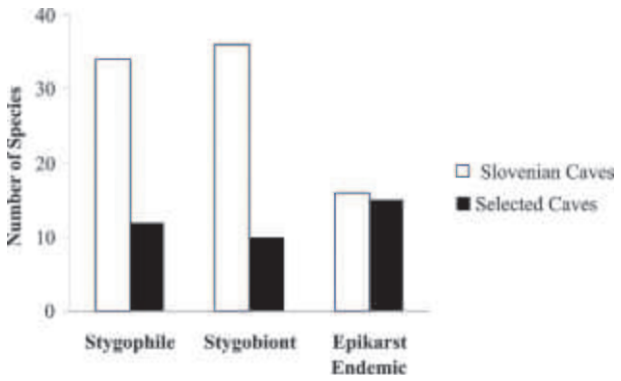

Fig. 4 Relative contribution of within drip (α-diversity), among drip, among cave, and among region (all β-diversity) to the overall diversity of 30 Slovenian epikarst copepod species, relative to random expectation. From Pipan T, Culver DC, Papi F, and Kozel P (2018) Partitioning diversity in subterranean invertebrates: The epikarst fauna of Slovenia. *PLoS One* 13: e0185991.

have a rich fauna (Table 3). Even in the case of relatively well studied Slovenia and Italy, 11 new species have been described from these two countries since 2000.

At the regional scale within Slovenia, the Dinaric karst had the richest epikarst fauna, with 25 copepod species, compared to 5 for the Alpine karst, and 3 for the Isolated karst (Pipan et al., 2018). A similar pattern is present with the aquatic and terrestrial cave fauna, but it must be noted that the Dinaric karst is much more thoroughly sampled for all the subterranean fauna. Overall, the epikarst copepod diversity is largely variable between sites, with regional differences (β-diversity) accounting for 60.9% of total richness, richness between caves in a region accounted for 19.7%, richness between drips in a cave 9.4%, and within drip richness (α-diversity) only 9.9% (Pipan et al., 2018, Fig. 4). The between-site diversity was largely due to replacement of species geographically (not surprising given the small ranges of many epikarst species) but nestedness (the occurrence of hotspots) was important as well (as evidenced by the hyper-diverse drip in Županova jama).

Even at the level of different drips within a cave, distances that range from 1 to 100 m reveal very high levels of heterogeneity. Hotspot caves like Županova jama are hotspots because of only a handful of drips (Table 4), and this heterogeneity has proven difficult to explain, or at least to draw general patterns. A number of authors have sought explanations, typically through Canonical Correspondence Analysis (CCA). A striking example is the negative correlation of the presence of most epikarst copepods with

Table 4 Distribution of number of epikarst copepod species per drip in 13 Slovenian caves.

ceiling thickness found by Pipan in her study of six Slovenian caves (Pipan et al., 2006) and the reverse in Zguba jama by Kozel and Pipan (2020). And when there does seem to be some generality emerging, such as the influence of NO_3^- (Pipan et al., 2006; Liu et al., 2017), it is difficult to explain. There are a number of possible reasons for this difficulty (see Moldovan et al., 2018), but one of them may be that there are too many variables that are correlated among themselves. Pipan et al. (2020) used the technique of recursive partitioning and random forests (Strobl et al., 2009) to create a decision tree for the presence/absence of epikarst copepods from drips in the six Slovenian caves originally studied by Pipan (2005). They found temperature, Ca^{2+}, and NO_3^- to be influential (Fig. 5).

The non-copepod aquatic fauna

There is a variety of non-copepod species found in dripping water, that are little studied, but likely are specialized for subterranean life in general or epikarst life in particular. Camacho and Puch (2021) reported that Cnidaria, Rotifera, Turbellaria, Tardigrada, Nematoda, Hirudinea, Acari, Diptera, Gastropoda, Oligochaeta, Ostracoda, Syncarida, Amphipoda, and Isopoda were present in

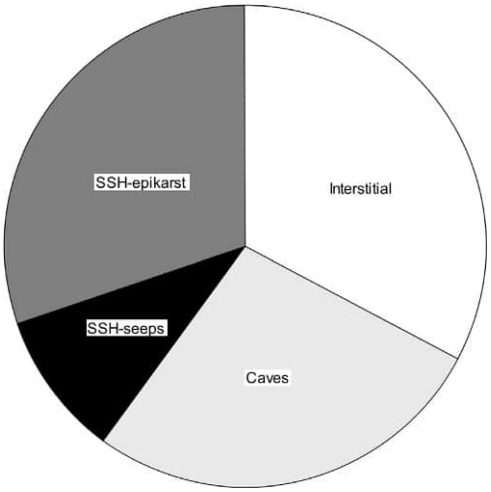

Fig. 6 Subterranean habitats of 125 species of the exclusively subterranean amphipod genus *Stygobromus* from eastern and central North America. From Culver DC and Pipan T (2014) *Shallow Subterranean Habitats. Ecology, Evolution, and Conservation.* Oxford, UK: Oxford University Press, based on data from J. Holsinger.

epikarst pools in Ojo Guareña, Spain (Table 1). In Pipan's (2005) study of Slovenian caves several of these groups were much more common in pools, including Ostracoda, Gastropoda, Oligochaeta. It is not surprising that some of these groups are rare in dripping water, even if they are common in the epikarst, because of their ability to cling to the substrate, such as Gastropoda. Among the non-crustaceans, nematodes and oligochaetes were the most common inhabitants in Ojo Guareña.

In eastern and central North America, one of the most common inhabitants of drip pools are amphipods of the genus *Stygobromus* (Culver and Pipan, 2014). Of 125 species, all are subterranean, but only 34 are known from caves. More are known from drip pools and presumably epikarst, i.e. 38 (Fig. 6). No phylogenetic analysis of the genus is available so far, but many of the epikarst species were previously placed in the genus *Apocrangonyx* (Holsinger, 1969).

Morphological adaptations of crustaceans and amphipods to epikarst

Habitat size is an important constraint and selective force in subterranean environments, and there is an overall correlation between body size and habitat size of subterranean habitats (Pipan and Culver, 2017). Slovenian copepods that are epikarst specialists tend to be smaller than non-specialists, both ones limited to subterranean habitat and ones found in surface habitats (Culver et al., 2009). North American *Stygobromus* amphipods that are epikarst specialists are smaller than cave stream species as well as species from other subterranean habitats with larger habitat size such as phreatic lakes (Fig. 7; Culver et al., 2010).

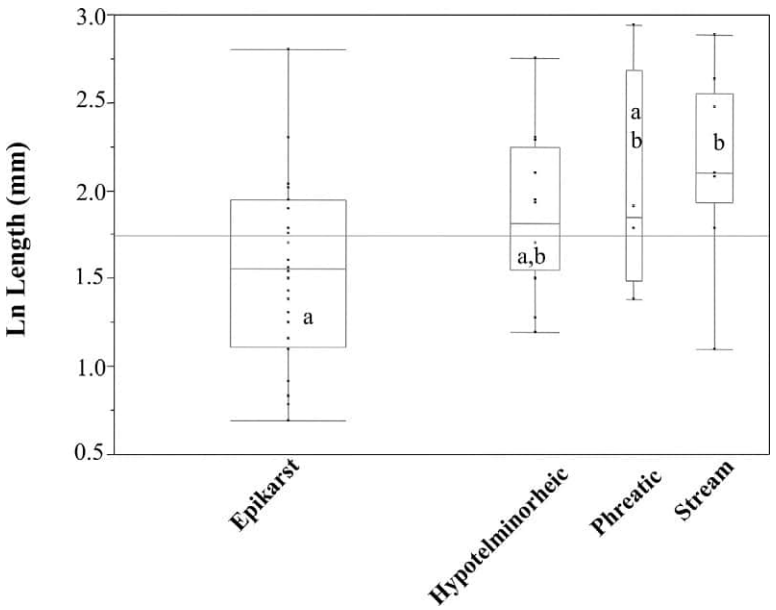

Fig. 7 Box and whiskers plots of ln female body length of species of the amphipod genus *Stygobromus* for epikarst, hypotelminorheic, cave streams, and phreatic habitats in North America. Overall mean represented by the line across the entire. Boxes: 50% of the data, line across each box: group median; whiskers: minimum and maximum values. The widths of the rectangles are proportional to sample size. Dots are individual data points. Plots with the same letter (a or b) do not differ according to the Tukey-Cramer HSD test. From Culver DC, Holsinger JR, Christman MC, and Pipan T (2010) Morphological differences among eyeless amphipods in the genus Stygobromus dwelling in different subterranean habitats. *Journal of Crustacean Biology* 30: 68–74.

Brancelj (2006, 2009) provided a number of intriguing suggestions about uniquely convergent features of epikarst copepods. Working with the genera *Morariopsis* and *Paramorariopsis*, he pointed out that animals living in the epikarst must have some morphological adaptations to prevent or minimize their transport downward. Combined with what he considers a low supply of organic carbon, he proposes that the following convergent features are present in specialized epikarst copepods to avoid being displaced by water flow:

- Reduction in endopodal segmentation to two or one;
- Reduction in number of spines and setae on the terminal segments of both endopods and exopods;
- Reduction in spines and setae on the caudal rami to one terminal seta;
- Tips of the terminal setae of the caudal rami are far apart;
- Short and robust setae on the endopodal lobe of fifth leg (P5) as well as very strong spinules at the base of the caudal rami.

Brancelj (2009) demonstrated that the genus *Elaphoidella* shows similar convergent features, especially the last two features listed above. He also proposed that there is convergent reduction on length of the antennules and that robust setae are probably an adaptation for moving through small spaces in fractured rock as well as a protection against washout.

Terrestrial fauna of epikarst

The terrestrial habitat

Epikarst is primarily considered an aquatic habitat because it was first described as a perched aquifer. However, it is not a permanent aquifer, or at least it is not always water-saturated. Drip samples almost always have some terrestrial species. While a few species may have gotten into the samples from the cave (flying or hopping), most are resident in the epikarst. Huda luknja in Slovenia is the most extreme example of the terrestrial nature of some epikarst. It had more terrestrial individuals than aquatic individuals (Pipan et al., 2008).

Epikarst also has a close connection with the MSS (milieu souterrain superficiel). The MSS has been defined variously since its discovery by Juberthie and his students in the 1970s, generally to become more inclusive of shallow subterranean terrestrial habitats. Mammola et al. (2016) define the MSS as "the underground network of air-filled voids and cracks developing within multiple layers of rock fragments usually covered by soil." The MSS is a very active research area, and Mammola et al. (2016) reported 235 papers on the MSS. While typically considered a non-karst habitat, the MSS, or its equivalent depending on definition, does occur on karst and grades into the epikarst. For example, Pipan et al. (2011) reported on closely adjoining terrestrial epikarst and MSS sites in a deep doline in Slovenia, the bottom of which is the entrance to the cave. The epikarst site, accessible from the surface, was directly connected to the cave while the MSS site was about 25 m distant. The primary difference between the two habitats was that the limestone at the MSS site was no longer solid, but consists of separated rock and boulders (the multiple layers of Mammola et al.'s, 2016 definition). Ortuño et al. (2013) suggested that a major MSS type is alluvial MSS, which is along streams and periodically floods. Environmental conditions in the alluvial MSS are likely very similar to terrestrial epikarst.

Inhabitants of terrestrial epikarst

The most extensive sample of terrestrial epikarst inhabitants comes from Huda luknja in Slovenia (Pipan et al., 2008), where terrestrial species and individuals outnumber their aquatic counterparts (Table 5). A wide variety of groups were found and it seems likely that many of these were soil inhabitants, given the close proximity of soil and epikarst. The aquatic fauna is depauperate, with only two copepod species reported, both species are rare. Either the relative isolation of the cave or the quality of the epikarst in terms of water retention may explain the low species numbers. While unusual with respect to the high numbers of terrestrial species, the near universal presence of terrestrial species suggests they are part of the overall community and worthy of further study.

Critiques of the epikarst concept from the biosciences

While the term epikarst is widely used in the speleological sciences, Sket et al. (2004) argued there is no distinct epikarst fauna. Part of this disagreement echoes back to Šušteršič's (1999) claim that epikarst is just a consequence of the karst erosional cycle, hence unimportant. But part of this disagreement stems from our inability to sample epikarst directly. To summarize the physical setting of epikarst, it rests at the top of the vadose zone, and is the site of primary water storage above the phreatic zone. Water in the epikarst moves laterally within the epikarst, analogous to small drainage basins (see Kogovšek, 2010), and it moves vertically as percolation water. The sampling of drips is the sampling of percolation water that originated from epikarst. There is likely few if any reproducing populations in vertically moving percolation water per se, but there are likely to be small water bodies in the vadose zone below the epikarst that do harbor epikarst populations. Sampling percolating water then samples both epikarst water and any other vadose water. An example of such a non-epikarst habitat are the "*Parastenocaris*" pools described by Petkovski (1959). Because most of the water (i.e., habitat) is in the epikarst, it is likely the most important habitat for animals trapped by percolating waters. It is a major habitat of the vadose zone. There are perhaps no species that never occur outside the epikarst zone, but the majority of populations

Table 5 List of taxa found in 12 epikarst drips during a 1 year sampling in Huda luknja in northeast Slovenia.

From Pipan T, Navodnik V, Janžekovič F, and Novak T (2008) First studies on the fauna of percolation water of Huda luknja, a cave in the isolated karst of Northeast Slovenia. *Acta Carsologica* 37: 141–151.

are almost certainly in the epikarst. Perhaps a more accurate term for the habitat is vadose macropore, to borrow a term from soil science. However, in our view, adding this term does little except add terminology to a discipline already suffering from an excess of jargon (see Martínez and Mammola, 2021).

Conservation

The protection of epikarst communities poses special challenges (Culver and Pipan, 2014). The main sites of collection for many species are drip pools, although drip pools are often not the primary habitat. The area immediately above known sites (drip pools and drips) is of the utmost importance in any protection scheme. Given the small drainage area of each drip, the population structure of epikarst species is likely to be that of a metapopulation, with subpopulations "blinking" on (colonization) and off (local extinction) (Moldovan et al., 2012). Adequate protection requires protection of the entire landscape of the metapopulation, regardless of whether a particular site currently harbors a population.

Each site, and its protection, has its own idiosyncrasies. Županova jama in Slovenia, the cave with the most diverse epikarst fauna known, is a show cave, with four main galleries with a total length of 682 m. The drips are in the midst of the highly decorated sections of the cave, but not near adjoining tourist trails. It has been a show cave since its discovery in 1926. The land above the cave is forested. In Slovenia, caves cannot be privately owned, but show caves are typically managed by local caving clubs, and this is the case for Županova jama. The land above the cave is privately owned, and the likelihood of logging above the cave is uncertain but logging in this area is typically selective and sustainable, with only a few trees taken at any one time. The cave itself is well protected since all Slovenian caves are protected by Slovenian national legislation, including the 2004 decree on the protection of wild animal species, including species living in caves and subterranean waters, and a 2004 act on cave protection, including restrictions on number of visitors and on amount of collecting.

Another kind of protection is that for Piddling Pit in West Virginia, USA. It has three species of amphipods in drip pools less than 200 m inside the cave—*Stygobromus emarginatus* (Hubricht), *S. nanus* (Holsinger), and *S. parvus* (Holsinger). This is a remarkable assemblage of epikarst amphipods, and no other epikarst site in the state has so many species of *Stygobromus* amphipods. Because of its unique biological characteristics, The Nature Conservancy, a non-governmental conservation organization, purchased the cave entrance in 1993, and fortunately purchased the land above the cave as well. Access to both the largely forested land and the cave are highly restricted.

Conclusion

Epikarst, the fractured and solutionally modified uppermost layer of karst, harbors an often rich aquatic fauna, with many species specialized for existence of this highly heterogeneous, variable habitat. Epikarst copepods may be a significant part of the aquatic fauna, as is the case in Ojo Guareña cave in Spain. Species show a number of morphological modifications, including small body size. Because of difficulties in sampling, the epikarst fauna has only been thoroughly sampled in a few European countries, especially Slovenia, Romania, and Spain. There appears to be terrestrial fauna, likely derived from the soil fauna, but it has been little studied. Because of its proximity to the surface, epikarst and epikarst fauna are highly vulnerable to environmental changes.

Knowledge gaps

- Many more caves will need to be studied before any continental or global pattern emerges.
- A careful study of the taxonomy of terrestrial epikarst species is needed to determine if it is distinct from the deep soil fauna.
- Long term studies of the epikarst fauna from a handful of caves, such as has been done by Pipan (2005) and Brancelj (2015), are likely to yield important insights in the temporal dynamics of epikarst populations.
- Studies of convergent morphology, beyond body size, are needed.

The Ecology of Aquatic Cave Environments

Anton Brancelj[a,b] **and Fabio Stoch**[c], [a]National Institute of Biology, Ljubljana, Slovenia; [b]University of Nova Gorica, Nova Gorica, Slovenia; [c]Université libre de Bruxelles, Bruxelles, Belgium

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Allopatric speciation (also vicariant speciation, or geographic speciation) A mode of speciation occurring when the ancestors of two or more closely related species became geographically separated in the past, preventing (or drastically reducing) gene flow among them.
Aquifer An underground water body in porous rock, rock fractures/voids/caves or unconsolidated alluvial deposits.
Biospeleology A branch of biology dedicated to the study of organisms that live in caves.
Capillarity A physical phenomenon where water, due to surface tension, rises in small voids/tubes ($<$ 1 mm dimensions).
Chemoautotrophic bacteria Bacteria getting their energy from oxidizing inorganic compounds, like iron, manganese, nitrogen, or sulfur compounds.
Doline Usually, rounded depression on a karst landscape, several tenth of meters in diameter and several meters/tenth of meters in depth; a result of chemical or mechanical dissolution/destruction of limestone; bottom with a layer of soil ("terra rossa"); an entrance into a vertical pit, or sometimes as temporary pool after heavy precipitation.
Drift Animals or organic particles (from plants or animals) transported by water flow, along with inorganic sediment.
Perched aquifer An aquifer which is situated between the main aquifer and the infiltration zone; it is disconnected from the main aquifer below the infiltration zone.
Scrapers Animals, collecting their food from substrate with specialized appendages (mouth parts or swimming legs) in a form of small particles rich in bacteria or mold.
Sinkhole A spot where surface water enters subterranean environment either temporarily (through local depressions after heavy rain) or continuously (permanent streams, rivers).
Source/sink habitats Source habitats support viable populations of stygobionts for long (geological) periods. Sink habitats are places where stygobionts are regularly/accidentally transported from source habitats; cannot reproduce or establish persistent populations and die within a generation.
Stygobionts Obligate dwellers in aquatic subterranean environment; when accidently conveyed to surface environment, they die soon due to light, temperature or predation.
Water flux A volume of water flows per area per unit of time; expressed as liters per square meter per hour ($L\ m^{-2}\ h^{-1}$).

Introduction

For a long time, cave habitats, both terrestrial and aquatic, were considered unfavorable environments (dark, cold, and monotonous), largely devoid of fauna and hosting only few, highly specialized species that have taken refuge there and became prisoners of their habitat (Danielopol, 1992). This view of cave ecology was based on the very first taxonomic descriptions of cave-dwelling

species, such as the olm (*Proteus anguinus* Laurenti, 1768) in the Dinaric Karst (south-eastern Europe) (Aljančič, 2019). This now-famous cave animal was discovered in a Slovenian karstic spring by Johann Weikhard von Valvasor, believing it to be a young dragon. Later, it was scientifically described by Laurenti (1768), who did not recognize it as a cave animal. During the century of research that followed, sampling sites were frequently designated as only "cave" or "spring," alongside with little geographical information (i.e., country, region). It was Emil Racoviță's essay (Racovitza, 1907) that turned the studying of cave biology became a real scientific discipline. The Romanian scientist is considered the founder of biospeleology, and one of the fundamental impediments of modern ecology is named in his honor (the "Racovitzan impediment": Ficetola et al., 2019). The Racovitzan impediment simply states that one cannot describe, map, analyze, and conserve the biodiversity of the environments that are unexplored and unmapped. Caves belong to the least explored environments on Earth. Sampling caves and their spring outlets requires intense fieldwork on small spatio-temporal scale, with hard-to-reach habitats, and often requires advanced caving techniques that further complicate overcoming the Racovitzan impediment (Pipan et al., 2020). Research in the past was mainly devoted to describing or studying the morphological or physiological adaptations of organisms that live in these dark environments, especially loss of eyes and pigments (troglomorphy *sensu* Christiansen, 1962). Nowadays, it is well known, that groundwater-dwelling fauna in caves is rich and the cave-spring continuum has been recognized (Botosaneanu, 1986). In a later paper, Botosaneanu (1998) called springs the "gates of Styx" and from this ancient myth, obligate groundwater-dwelling organisms are named stygobionts.

Caves are widely spread across the Earth's subsurface (Klimchouk et al., 2017). Most of them are formed in sedimentary carbonate rocks (limestone and/or dolomite, i.e., the true karstic environment) although some cave-like formations are common in other geological context too, like lava tubes, sandstones, gypsum formations as well as large crevices in metamorphic or igneous rocks (Gunn, 2004). All limestone/dolomite depositions started in ancient oceans and were later, due to tectonic activity, uplifted to present-day mountain ridges or plateaus, sometimes more than 2000 m above sea level. In this chapter we mainly focus on the true karstic environment, i.e., caves which developed in carbonate rocks. From an anthropogenic point of view, caves are defined as vertical or horizontal channels (pits and galleries) accessible by humans, i.e., spaces large enough to be practicable by human beings. This is a limited, partial vision of the subterranean karstic environment, which comprises two interconnected (eco)systems: terrestrial and aquatic. They consist mainly of very tiny fractures, cracks, and crevices, while caves – accessible to humans – are only a small part of the karstic environment. Undiscovered galleries, as well as galleries filled with sediments from older geological periods, complete the picture of the karstic environment. Present-day caves and karstic springs are only "windows" that open an immense subterranean karstic environment (Culver and Pipan, 2019).

Karstic zones as vertically connected functional systems

Over the last four decades, studies divided the karstic ecosystem into four distinct zones, from the surface to deeper aquifers: (I) epikarstic zone, (II) vadose zone, (III) epiphreatic (= flooded, amphibian) zone and (IV) phreatic zone (Fig. 1; Table 1) (Brancelj and Culver, 2005; Culver and Pipan, 2019). Each of the zones is connected with the surface environment through water

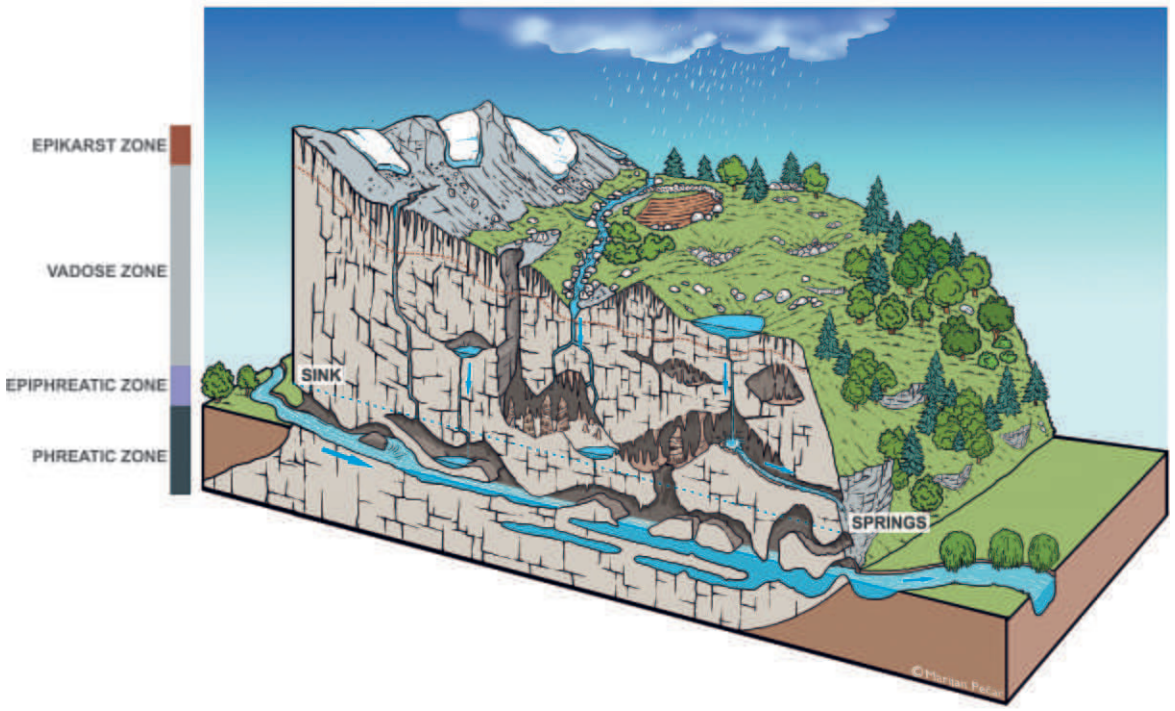

Fig. 1 Cross section through a karst massif with hydrological connections. Author: M. Pečar.

Table 1 Some characteristics of physical environment of the four main vertical zones (= habitats) in the karstic caves, including springs as horizontal connection with surface.

	*Epikarst zone**	*Vadose zone*	*Epiphreatic zone**	*Phreatic zone*	*Springs*#
main source of water	infiltrating precipitation (as rain or snowmelt)	epikarst zone and temporary sinking streams	epikarst and vadose zones, combined with sinking rivers and phreatic zone	epikarst, vadose and epiphreatic zones, combined with sinking rivers and/or sea	depends on their position along the vertical profile of a karst massif; includes also submarine springs
intensity of water flow	depends on weather conditions; single drops or low flow during droughts, intensive or very intensive soon after precipitations (within hours)	depends on weather conditions; low or high flow with some time delay after precipitations (usually hours/ days)	depends on weather conditions; heavily affected by discharge of sinking rivers (in a range of days) and less with infiltrating precipitation	depends on hydrological and hydrostatic conditions in an epiphreatic zone	depends on hydrological conditions in a catchment area and cave hydrological system
water flow direction	prevails vertical direction with some localized oblique and horizontal orientation	vertical in drips; oblique in torrents and streams; combination of riffles and pools	horizontal, with riffles, pools and lakelets; zone of floods	horizontal, as the galleries are completely filled with water	usually oblique or horizontal, with riffles or pools at a mouth; sometimes as a siphon from phreatic zone
water temperature oscillations	correlates with intensity of precipitation and soil temperature; normally in a range of few degrees (°C) around local average of annual air temperature	usually in a range of 1–2 °C around local average annual air temperature	depends on seasonal water discharge from surface rivers and distance from entrance/sink points; can vary by several degrees °C; higher at sink point and lowest near springs	low oscillations; usually in a range of 0.1–1 °C around local average annual air temperature	dependent on discharge and distance from sinking points
space size (maximal diameter)	usually < mm to cm	m or tenth of meters	m or tenth of meters	m or tenth of meters	depends on their position along the vertical profile of the karst massif (mm to meters)
food source for metazoan fauna (other than prey)	POM, bacteria+	POM, bacteria+, guano, dead animals"	POM, bacteria+, guano, dead animals", leaves, twigs	POM, bacteria+	POM, bacteria+

* – ecotone; # – discharge of water from four zones either temporary or permanent; POM – particulate organic matter:" – animals from surface or troglophiles/troglobionts;
+ – includes heterotrophic and chemoautotrophic bacteria.

inlets (sinkholes, crevices) and outlets (temporary or permanent springs), which reflect the hydrological and ecological "fingerprint" of their catchment area. Zones (= habitats) are determined by hydrological, energetic (= food), and biological parameters, including organisms' size and diversity. In the vertical direction, these zones are functionally interconnected through voids and channels of varying dimensions, which determine the physical, chemical, and biological parameters of flowing waters, driven by infiltration rate, volume, and speed of water flow. While cracks and fissures reduce speed and water flux and mainly retain groundwater (capacitive zones), pits, sinkholes, and galleries increase it (conductive zones) (Di Lorenzo et al., 2018).

The epikarst (Bakalowicz, 2019)

It is a thin zone just below the karst surface, extending from several dozens of centimeters to a few meters in depth. It is typically intensively fractured, enhancing the porosity and permeability of the carbonate rock. It is very heterogeneous and usually supports a perched aquifer, where vertical water flow prevails, even when some restricted lateral flow is also present. Flow is fed exclusively by precipitation and thus is very dynamic over hourly, daily, and seasonal scales (Kogovšek, 2010). Precipitation (rain or snowmelt) is collected from a relatively small surface area and directed to a specific drip-point within a cave. The area above each drip-point effectively represents an "island" from an ecological point of view (Brancelj and Culver, 2005; Pipan and Culver, 2013). Water from drip-points is discharged either into galleries, where it accumulates in small pools (from milliliters to tens of liters in volume), or into voids connected to the vadose zone. The living space in the epikarst is small, as crevices and voids are normally in the millimeter scale. This represents the primary, or exclusive, habitat for very specialized aquatic fauna, dominated by Copepoda (Cyclopoida, Harpacticoida), followed by other crustacean orders (Ostracoda, Syncarida), Oligochaeta, and free-living Nematoda, which may drift downwards to the vadose zone (Rouch, 1968; Brancelj, 2002).

The vadose zone (Hopmans and van Genuchten, 2005)

It is located just below the epikarst. Here, water flows through voids and channels with a more stable discharge, even though some trickles may dry-out during periods of no precipitation. This results in pools of drip water, with a volume up to several hundreds of liters, or permanent subterranean streams with riffles and pools, usually associated with compact speleothems such as stalactites and stalagmites. The living space for groundwater animals ranges from millimeters to several meters in size. This zone is controlled by daily precipitation, but with some time delay and a dampening of extreme values. In principle, the vadose zone represents the old and inactive part of a cave, which could be, over long time periods, filled with sediments from soil and deposition processes in sinking rivers or by formation of speleothems as a result of dissolution and deposition within the karstic massifs. This is also the zone usually visited by tourists in the show-caves.

The epiphreatic zone (Audra and Palmer, 2011)

It is also called the amphibious zone or flood zone. From a biological aspect, it is the most intensively studied, because many parts of the galleries are relatively easy to access for the cavers during low water level. An important source of water for this zone is from sinking streams and rivers, which flow through permeable and impermeable slopes entering caves. This zone can oscillate in its vertical extent over several tens of meters (Mihevc, 2004) as a result of differences in the infiltration rate from the surface and in the discharge rate of siphons and offers a virtually unlimited living space for stygobionts. It is characterized by fine sediment deposition (silt and clay mud), sometimes decorated with speleothems. This zone is characterized by seasonal inputs of allochthonous organic material during floods when connectivity with sinking rivers is high. During low water levels, stygobionts from the phreatic zone are trapped in pools, siphons and dead arms of subterranean rivers. When water levels rise, the epiphreatic zone becomes an ecotone between the unsaturated (vadose) and saturated (phreatic) zones.

The phreatic zone (Audra and Palmer, 2011)

It is more difficult to access, usually through natural or artificial wells and boreholes, or by speleodivers and remote-control vehicles. Alternatively, phreatic waters are sometimes accessed through deep-feeding springs. Water quality and discharge as well as the composition of fauna and biodiversity are relatively stable over long time periods, and the living space for stygobionts is unlimited as channels can be up to several meters in diameter and several kilometers in length. Food resources are quite limited but rather constant, except in cases where local surface eutrophication is present, or in phreatic habitats that are connected to sinking river channels (Di Lorenzo et al., 2019; Strona et al., 2019), or sulfidic water layers (Brad et al., 2021). Some phreatic aquifers in karstic caves close to the sea are a mixture of fresh and sea water, forming the so-called anchialine caves. Here voids or channels connect inland aquifers to sea water, and usually a density gradient is established (chemocline), with dense sea water underneath freshwater. The example of this type of habitat are the cenotes in the Yucatan peninsula, Mexico (Beddows, 2004), but similar examples can be found in all continents.

Springs

They are ecotones between subterranean and surface water habitats where surface and groundwater species co-exist. They often appear as tiny seepage-like springs (heleocrene) fed by the unsaturated karstic zone on the slopes of hills, as running springs (rheocrene) or in the valleys as lake-like springs (limnocrene). Like caves, springs can be present in other, non-karstic terrains, too, but with ecological parameters quite different from those on limestone/dolomite rocks (Stoch et al., 2011). Water coming from the karstic massifs is discharged through well-defined springs (usually called resurgences) when limestone rocks encounter alluvial sediments or less permeable terrains (Gibert et al., 2009; Brancelj et al., 2020). Spring ecology is quite specific and intensively studied. In this context, it is noteworthy to mention that they host both surface species, usually dominated by snails, crustaceans, insect larvae, and subsurface stygobiotic species, dominated by snails and crustaceans, rising to the surface from deeper aquifers (Stoch et al., 2016). The hydrology of karstic springs depends on the hydrological dynamics within the karstic massifs, and the dynamics of the discharge of subterranean fauna have been recently studied (Di Lorenzo et al., 2018). During high discharge periods, springs may convey a high number of stygobionts to the surface, from invertebrates to amphibians and fish. Figuratively, loss of groundwater animals was called the "hemorrhage" of karstic aquifer fauna (Rouch, 1970).

Springs connected to the phreatic zone are of different types. Estavelles (or inversacs), depending on weather conditions and seasonality, alternate between serving as sinkholes or true springs. Large karstic lakes and fields (named polje) are frequently fed by this type of springs. Another important category is represented by the Vauclusian springs (named after the famous Fontaine de Vaucluse in France) that originate from deep karstic system. Springs are not limited to continental areas. Several examples of submarine karstic springs (vruljas in the Mediterranean area) are peculiar habitats worth studying. As stygobionts are related to the groundwater that feed karstic springs, their use as hydrological biotracers to identify different aquifers that mix at a spring outlet has been advocated (Mori et al., 2015; Stoch et al., 2016; Brancelj et al., 2020).

Functional structure of the aquatic karstic environment

Structure of karstic habitats

The karstic ecosystem is a very complex three-dimensional system of locally interconnected small voids and fissures on a scale of fractions of millimeters to centimeters in size, as well as larger galleries, accessible by human. The Veryovkina Cave in Abkhazia, Georgia, is the deepest cave in the world (2212 m), followed by the Krubera-Voronja Cave (both located in West Caucasus), that ends in a siphon of phreatic water. The latter has been studied in detail and revealed an interesting subterranean community that lives over 2000 m below the surface, including several groundwater crustaceans described later as new to Science (Sendra and Reboleira, 2012). However, the community there includes both stygobionts and surface species that were transported 2140 m below the surface as drift. As with most caves, even the Krubera ecosystem depends on allochthonous sources of organic carbon originated from the surface. Nevertheless, there are few caves, which are energetically based on chemolithoautotrophic processes and microbial biomass; the most well-known examples are sulfidic caves (Palmer and Hill, 2019; Brad et al., 2021).

Limestone sediments, deposited in marine environments hundreds of millions of years ago, were uplifted to the surface as a result of tectonic activity and orogenesis. In addition, parts were exposed to the terrestrial environment because of the sea-level drop that occurred during the ice-age period. After the retreat of Quaternary glaciers, the sea level rose up to 130 m and lower parts of the caves near the shoreline were re-submerged in sea water, as was the case in several cenotes in the Yucatan, the Blue Hole complex in Florida, or the vruljas along the Mediterranean coasts (Stevanović, 2015). Formation of karstic caves is a result of water activity, including dissolution of carbonate rocks, corrosion, and erosion, i.e., increase of the channel diameter due to sediment transport (sand, stones, and gravel) by water flow. Very deep and long caves are frequently formed as a network of parallel and branched horizontal galleries, sometimes formed in two or three levels on an area of several tens of square kilometers. The galleries accessible for human there could be several tens or even hundreds of kilometers long (i.e., Mammoth cave system, Kentucky) (Buckner, 2019). Each level within these caves reflects different geological periods with different climate and hydrological cycles (Dumitru et al., 2021). Together with these type of caves (called epigenic caves), hypogenic caves were formed by rising, often solutionally aggressive, groundwater (Sendra et al., 2014; Klimchouk et al., 2017) with the most famous examples being sulfidic caves (Sarbu et al., 2018).

Pits and larger crevices act as entry points for relatively large particulate organic matter (POM) and surface organisms into the caves. Small crevices and fissures allow the transport of mainly dissolved organic matter (DOM) and occasionally fine POM, including drift from the epikarst (Pipan and Culver, 2013). Another common and important sources of surface water and organic material into the subterranean environment are sinking streams and rivers connected to the galleries, located at the level of the epiphreatic zone or sometimes directly feeding the phreatic zone. Water discharge varies from a few L sec^{-1} to hundreds of L sec^{-1} depending on rain and snowmelt, and has significant impact due to the considerable transport of POM and DOM.

It is evident that the living space, i.e., the size of fractures/voids/galleries in the subterranean environment, determines the size of animals living in these habitats as well as community structure (Dumnicka et al., 2020). Some of the worm-like organisms (free-living nematodes, flatworms, oligochaetes, and some tiny harpacticoid copepod crustaceans as well) can move easily between narrow spaces in micro-crevice habitats, together with rotifers and protozoans. The same is true for different developmental stages, like eggs or juveniles that can be passively carried through narrow passages by water flow, in contrast to adults, especially those with a rigid exoskeleton. For that reason, large-body representatives of crustaceans (like larger Amphipoda, Isopoda, and Decapoda), cave fish and amphibians can be found only in caves, i.e., in galleries or large springs.

Physical and chemical characteristics of karstic subterranean waters

Karstic subterranean waters are fed by precipitation and sinkholes (Fig. 1). A typical example of a catchment area with subterranean rivers is the network of the Ljubljanica river (Slovenia, Europe), which includes the well-studied Postojna-Planina Cave system (Zagmajster et al., 2021). It is a network of two branches of sinking rivers which enter caves several times (actually 11 times), before finally re-appearing as the Ljubljanica river in a series of springs south of Ljubljana that is part of the Danube river catchment.

Following the paths through the karstic system, water experiences changes in physical and chemical properties. Changes are determined by the distance from the surface as well as by seasonality and endogenous processes. Near the entrance points, water characteristics are defined by epigean parameters but get more uniform in the most remote parts of the karstic ecosystem, i.e., next to the springs. During intensive weather events, "fingerprints" of surface parameters last longer in time but are usually limited to few hours or occasionally days. In distance, they can extend several kilometers from the sink point, but this depends on flux and speed of water flow. During these events, discharge from storms or intensive snowmelt may substantially increase for a short period of time (i.e., hours) by factors of up to 10^1–10^2 in sinking rivers or even up to 10^3 in the epikarst/vadose zone (Kogovšek, 2010; Brancelj, 2015) (Fig. 2).

Carbonate geology defines the water pH in the karstic massif as neutral or slightly alkaline (i.e., pH 7.0–8.5), although there are some oscillations and the presence of aggressive waters (like in sulfidic caves) can turn the pH to acidic, either permanently or only in some seasons. Precipitation may also influence chemical and physical water properties for a short time (i.e., hours), including temperature, electrical conductivity, or the concentration of major ions (Ca^{2+}/HCO_3^-, Mg^{2+}, NO_3^-, SO_4^{2-}, . . .). This happens over a short distance of a few meters in the vertical direction in the epikarst zone (Kogovšek, 2010; Brancelj, 2015). Changes during intensive rain/snowmelt events are a result of the "piston effect", as incoming water from the surface push out resident water rich in

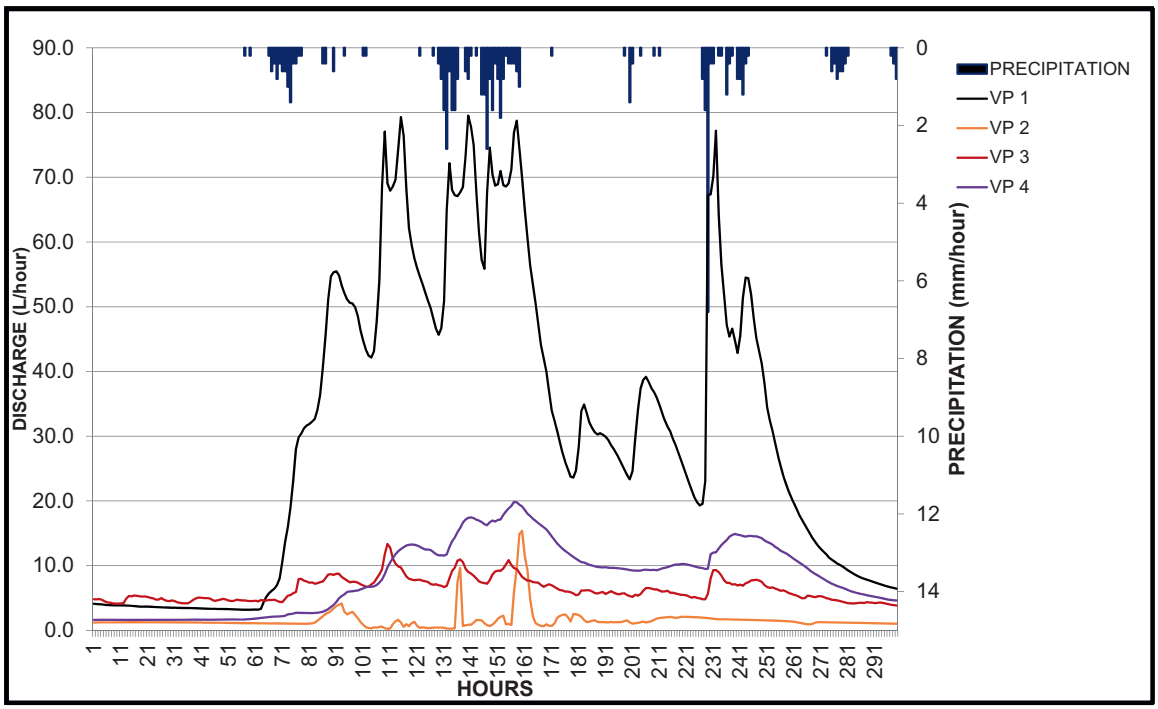

Fig. 2 Discharge of four drip points (VP1–VP4) from the epikarst zone of the Velika Pasica cave (Slovenia) related to precipitation. Distance from surface to a specific drip-point is between 5 and 8 m. Author: A. Brancelj.

ions from crevices. Later, the concentration of ions drops because of dilution with incoming water. Water temperatures at entry points (i.e., in the epikarst, as diffuse sources), or at sinkholes (as point sources), reflect surface weather conditions. Along their route in the subsurface, water temperature approaches the mean annual local air temperature, albeit controlled by discharge.

Food sources and feeding habits

For a long time, the karstic environment was considered a "truncated ecosystem" (Gibert and Deharveng, 2002) due to the absence of primary producers represented by photoautotrophs (green plants). This statement was based on the fact that most karstic ecosystems (except small parts of sinkholes and springs, measured at a meter scale) are in permanent darkness – as one of the most recognized and distinctive characteristics of the subterranean environment (Romero, 2009). The only source of organic material in caves were for a long time considered leaves, twigs, guano, and carcasses of epigean animals that actively entered, drifted by water flow, or accidentally fell into the caves, most of them through man-accessible openings (like pits, horizontal galleries, or sinkholes). More recent research indicates that important sources of food also include other organic material, either DOM or small fragments of POM as a substrate for decomposing bacteria (Kevin, 2019), which can subsequently be consumed by some cave-dwelling organisms, i.e., scrapers. An additional, and important source of food and energy in caves are chemoautotrophic bacteria using inorganic compounds (mostly reduced iron, manganese or sulfur species) in combination with oxygen for gaining energy used for proliferation and biomass production, which forms the food base of surface-independent chains/webs. These bacteria are in majority attached to mineral particles or rock walls and can sometimes form extensive mats, which are consumed by scrapers. Examples are the sulfidic caves such as the Movile cave in Romania (Sarbu et al., 2018; Palmer and Hill, 2019; Brad et al., 2021).

To date, there are about 3500 species worldwide that are recognized as stygobionts, both from unconsolidated (i.e., interstitial) or fractured (i.e., rocky) aquifers. There is not yet a clear separation between both systems possible based on smaller organisms (like Turbellaria, Oligochaeta, Ostracoda, Copepoda), although there are obvious differences in ecological parameters between the systems, like living space, food, hydrological conditions. At the same time, both systems share some common characteristics, like absence of light, scarcity of food, relatively stable physical and chemical parameters.

The most common invertebrate representatives in the karstic habitats are Mollusca (especially Gastropoda – several hundred species), Annelida (mainly Oligochaeta – several dozen species), Crustacea (among others, Ostracoda, Copepoda, Amphipoda, Isopoda, Syncarida, Decapoda – each group with several hundred species) and Coleoptera (especially the rich families Dytiscidae and Elmidae – several tens of species each). Most of the other aquatic invertebrate taxa have at least one or few representatives in the karst environment. For example, among Vertebrata, there are over 200 described species of obligate cave fish, most of them found in tropical or subtropical areas, albeit one stygobitic population of the genus *Barbatula* was recently discovered in caves of Germany

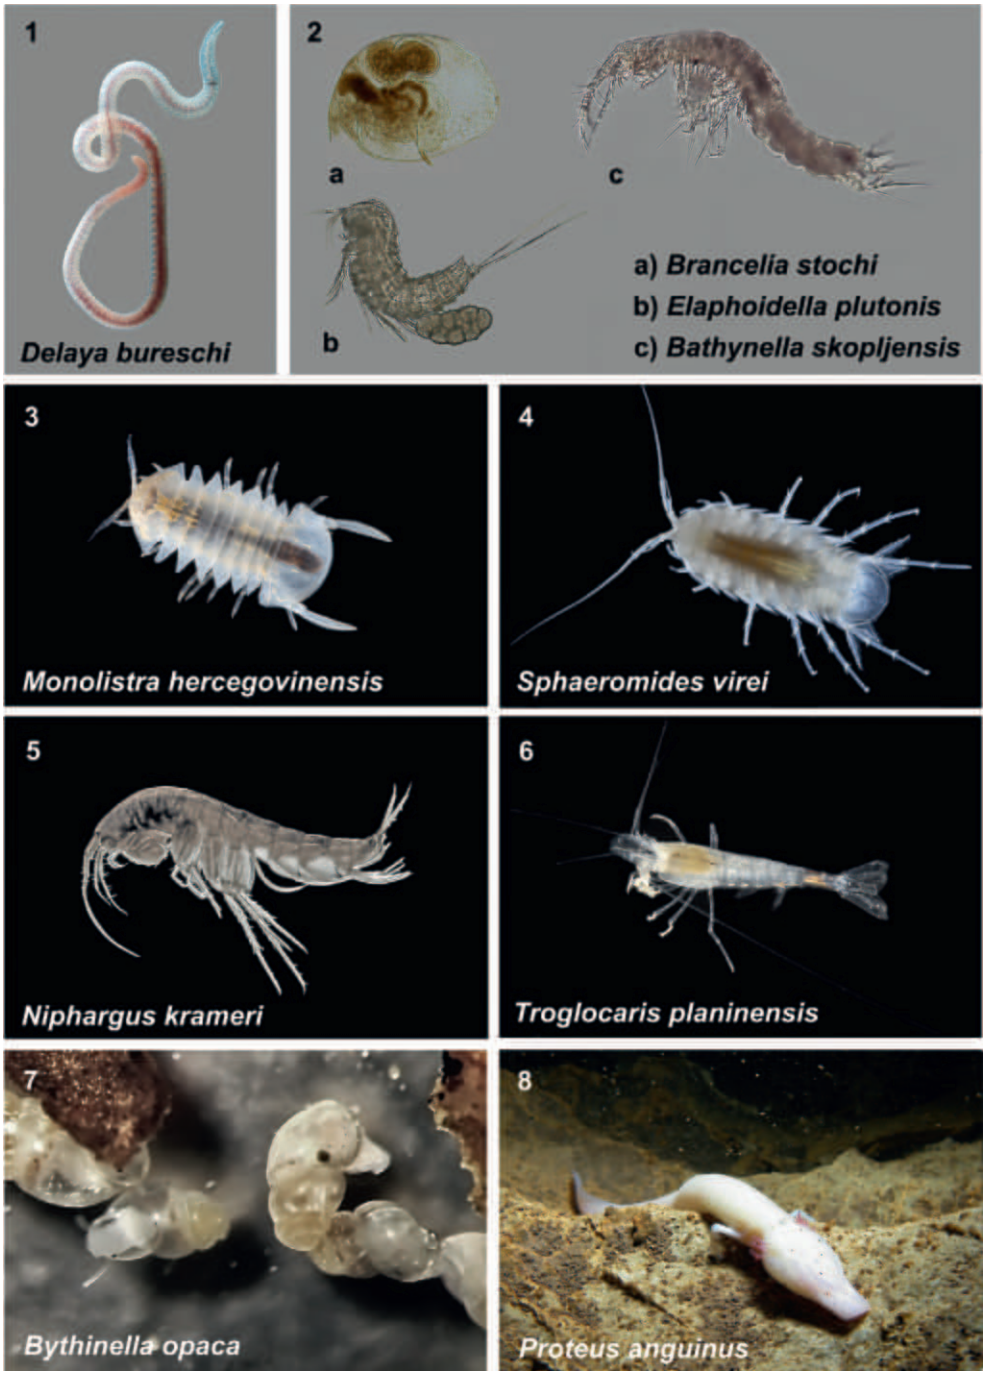

Fig. 3 Some stygobionts inhabiting aquatic cave environments. Photos by G. Balázs (8), A. Brancelj (2a), T. Delić (1, 3, 4, 6), F. Stoch (2b, 2c, 5, 7).

(Behrmann-Godel et al., 2017). Finally, Amphibia are represented in Europe by the famous olm (*Proteus anguinus*), while other species of aquatic cave salamanders are present in the U.S.A. Some representatives of karstic groundwater-dwelling species in Europe are presented in Fig. 3. Stygobionts share some common characteristics, like loss of pigments, eye reduction, elongation of body appendages, increased number of chemoreceptors and mechanoreceptors and lower metabolic rates (Christiansen, 1962).

Stygobionts practice several modes of food gathering, because distribution and amount of food do vary in time and space. For that reason, they can ingest fine sediment particles or scrape on surfaces of mineral or organic material, both covered with bacterial biofilms. This is practiced by most small-bodied animals, including Planaria, Gastropoda, Annelida, some families of water beetles (Coleoptera), and some microcrustaceans (Cladocera, Ostracoda, some Copepoda). Different groups of arthropods, especially representatives of crustaceans (some Copepoda, Isopoda, Amphipoda, Mysidacea, Decapoda) combine a detritivorous diet with predation – in principle they are omnivores, including the largest cave-dwelling species, *Proteus anguinus* (Bizjak-Mali and Bulog, 2004). Predators are represented by copepods, isopods, crayfish, crabs, dytiscid beetles, and several blind fish. Only a few

stygobionts are specialists, like some sessile filter-feeders, usually inhabiting caves near sinkholes (sponges – *Eunapius subterraneaus* Sket & Velikonja, 1984; mussels – *Congeria kusceri* Bole, 1962; polychaetes – *Marifugia cavatica* Absolon & Hrabe, 1930). These organisms are frequently associated with certain surface-dwelling relatives, that can survive for some time in such environments and were in the past often considered (erroneously) as representatives of cave-dwelling fauna, too. Planktonic filter-feeders are very rare in karstic environments and are represented worldwide by only about 10 species of Calanoida (Copepoda) (Brancelj and Dumont, 2007). They are not able to resist water current; thus they can only establish viable populations in environments with low water flow or standing water bodies.

Sampling methods for cave-dwelling aquatic fauna

Sampling methods for cave-dwelling aquatic fauna include most well-known and standardized techniques applied also for epigean aquatic environments (Downing and Rigler, 1984) alongside more specific devices.

(I) Pick-up sampling of larger individuals by hands, small hand nets, tweezers, and cups.
(II) Different types of traps usually left on site for one or exceptionally few days, with baits (usually rotten meat/liver) to sample fish or crayfish. For smaller mobile organisms, traps can be adequately modified; they are made from plastic bottles and equipped with fine mesh along the sides (Beladjal et al., 1992).
(III) Kick-up sampling for sediment-associated fauna with hand nets in the knee-deep sections of rivers/streams and pools.
(IV) Plankton nets for larger standing water bodies within caves used either from boat (vertical tow-samples) or from the shore.
(V) Plankton nets positioned horizontally in the spring-mouth to collect drift.
(VI) Specially designed filtering bottles connected to plastic sheets or funnels for sampling drips and trickles from the epikarst to collect specimens for several days/weeks (Fig. 4) (Brancelj, 2015).
(VII) Small pools (like rimstone pools) of one or tens of milliliters of water are sampled using plastic pipettes or sucking pumps (Fig. 5).
(VIII) Piezometers or man-made wells are usually sampled with small-size plankton nets or Cvetkov's nets (Cvetkov, 1968).
(IX) Samples can be collected by rotating pumps from piezometers and wells, but only small motile organisms can be collected undamaged (Copepoda, Ostracoda, Syncarida), and larger organisms (Amphipoda, Isopoda) are likely damaged by the pump's rotor, although some specific body fragments may be sufficient to identify animals to species/genus level (Brancelj et al., 2016).
(X) Environmental DNA (eDNA) techniques to detect whole communities (eDNA metabarcoding) or species within karstic systems collected in water samples, were applied for example to *Proteus anguinus* (Gorički et al., 2017; Vörös et al., 2017) or the North American amphipod *Stygobromus* (Niemiller et al., 2018).

Groundwater pollution

Historically, caves were used as shelters, sacred sites for graves of respected members of their community or were used for certain religious rituals/offerings. In more recent decades they become "dump sites," i.e., places heavily affected by factories, agriculture, and local communities as sites for waste deposition (Foster, 1987).

Karstic aquifers are very vulnerable to anthropogenic impacts from the surface, as galleries can act as corridors (channels) for fast and long-distance distribution of pollution. Assessing the vulnerability of karstic aquifers to pollution and other threats is essential for their conservation (Machiwal et al., 2018). Under the term "pollution," we may consider two main processes. One of them is eutrophication (as discharge of un-treated wastewater from households, farms as well as part of urban waters) leading to an increased productivity and the second one is a discharge of harmful or poisonous chemicals (from industry, traffic, agriculture) leading to a decreased productivity. Sources of both types could be point-sources and/or diffused in a karstic massif.

Eutrophication is caused by an increase of organic matter and nutrients triggering an elevated production in surface sections of sinking rivers or direct discharge into groundwater from septic tanks of households or farms. Organic material, either as POM or DOM, transported into the subterranean environment has a two-fold effect. During decomposition, it can induce (locally and/or temporally) anoxic conditions and exterminate local cave fauna. At the same time, increased energy sources (i.e., food) can support the presence of epigean species, even alien species, which can out-compete, and consequently trigger extinction of cave-dwelling organisms (Mazza et al., 2014).

Persistent and toxic chemicals may reflect actual surface activities (leaks/discharge from local factories, oil spills from traffic accidents, road maintenance during de-icing or weed removal) or past waste dumping of industrial or urban deposits. This kind of pollution can last in the karstic environment for decades and their effects depend on the quality and quantity of deposits. Heavy water extraction represents yet another pressure and karstic aquifers close to the coast are already subject to salt-water intrusion (Kresic, 2012).

Conclusion

Caves have been important for humans for almost 50,000 years, as shelters against harsh environmental conditions. People left striking signs of their presence in the caves in form of fireplaces, leftovers of food consumption (bones, seeds), artifacts or ritual places, including impressive mural paintings and burial places.

Nowadays scientists focus their attention to the evolution of karst formation from geological, geographical as well as biological aspects. From an ecological point of view, the karstic groundwater environment is still hardly explored. Many new species are discovered every year, especially since the development of modern molecular techniques, and/or in poorly sampled areas, particularly in sub-tropical and tropical regions in Asia, Australia, South America. Phylogenetic and genomic research revealed a very dynamic and highly diverse situation in this rather "conservative" environment. The karstic environment is much more diverse as was considered in the past. Its fauna is rich, specialized for peculiar environmental conditions (i.e. absence of light, constant temperature, low food levels), and with plenty of endemics mainly due to allopatric speciation in isolated karstic areas. More than one century after Racovitza's (1907) essay, overcoming the Racovitzan impediment in karst environments is still one of the major challenges for aquatic ecology.

Future research

- holistic approach to research of karstic habitats/ecosystems, i.e., combining physical, chemical, hydrological and biological parameters in the same studies
- study of karstic habitats/ecosystems in different geographical/climate zones
- biodiversity and phylogeny of stygobionts
- reactions of groundwater fauna to pollution, eutrophication and climate changes

Karst Groundwater Dependent Ecosystems—Typology, Vulnerability and Protection

Nataša Ravbar and Tanja Pipan, ZRC SAZU Karst Research Institute, Ljubljana, Slovenia; UNESCO Chair on Karst Education, University of Nova Gorica, Vipava, Slovenia

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Calcrete Carbonate deposits that form in the vicinity of the water table as a result of the evaporation of groundwater.
Convergence The independent evolution of similar traits in distinct evolutionary lineages, often as a result of similar selective pressures.
Divergence The independent evolution of different traits in distinct evolutionary lineages, often as a result of different selective pressures.
Ecological specialist Species that generally occupies a very restricted range or even a single habitat and feeds on a small range or even a single food source. In the case of subterranean habitats, animals are absolutely dependent on and they complete their life cycle in subterranean habitats.
Hyporheic Interstitial spaces with the sediments of a streambed; a transition zone between surface water and groundwater.
Karst Landscape in soluble rock where solution rather than erosion is the primary geomorphic agent, typically with caves, sinkholes and springs (see Fig. 2).
Phreatic zone The lower, saturated part of the aquifer where flow through the (sub)horizontal network of conduits predominates.
Stygobiont Obligate, permanent resident of aquatic subterranean habitats. Troglobiont is an analogy with terrestrial species.
Troglomorphy The occurrence of convergence, especially in morphology, due to natural selection acting upon subterranean populations or species.
Vadose zone The upper, unsaturated part of the aquifer, where the fast drainage through a vertical network of fissures and voids interacts with the slow percolation through low permeable volumes.

Introduction

Karst covers about 15% of the global land surface and more than a fifth in Europe alone (Chen et al., 2017). Among a variety of karst environmental assets, groundwater resources are certainly the most important (Bakalowicz, 2005). Karst aquifers meet around a quarter of the world's drinking water needs (Ford and Williams, 2007; Hartmann et al., 2014). They are important for agriculture, industry and hydropower, and their significance is gradually increasing.

At the same time, karst areas are also important due to the presence of unique ecosystems. Many of these ecosystems reside within or are reliant to karst groundwater and, like other groundwater dependent ecosystems, form complex communities of organisms in which groundwater is a key element for their existence (Merz et al., 2001). Karst groundwater dependent ecosystems (KGDEs) represent an essential interface between the biosphere and the karst hydrological systems. They often harbor a high regional biodiversity, especially at springs, and communities with a high portion of endemic species. KGDEs provide various ecosystem services, including water purification, ecological productivity, photosynthesis above ground and carbon sequestration (Goldscheider, 2019). Some are recognized as recreational areas, others are of religious, spiritual and cultural significance. KGDEs make an important contribution to water and food supply, improve water and air quality, and are of particular importance for flood mitigation (especially wetlands).

Although groundwater dependent ecosystems, and among them KGDEs in particular, are increasingly recognized for their ecological and socio-economic values, they have not yet been adequately documented and investigated (Bonacci et al., 2009; Cantonati et al., 2020). Studies in which groundwater ecohydrology has been discussed so far are few in number, at least as far as karst groundwater ecosystems are concerned, and focus mainly on surface water bodies. Only a few studies have been published where karst groundwater habitats and complex processes within them were closely investigated. Such integrated approaches are rare, mainly because underground biotic communities are hardly accessible and because conducting experiments and monitoring underground may require logistical, financial and physical efforts. As a result, KGDEs are poorly investigated and known and face major knowledge gaps in karst science (Culver and Pipan, 2014; Goldscheider et al., 2006; Kløve et al., 2011a).

To fill this gap, the present contribution provides an overview of karst groundwater and associated ecosystems, with a special focus on foremost ecohydrological processes and environmental conditions, as well as on the interactions between animate and inanimate nature.

Although groundwater is generally defined *sensu stricto* as subsurface water occupying the phreatic zone up to the water table (Fryar and Mukherjee, 2021), some authors allow the definition *sensu lato* referring to all water underneath land surface (Kresic, 2010). In karst, this is reasonable because the water table is not always continuous and hydrological systems can be quite anisotropic and heterogeneous. A special part of the vadose karst zone is its upper layer, called epikarst, which can form perched aquifers and is an important contributor to other parts of the aquifer, especially during baseflow conditions. It also represents a special karst habitat and is therefore considered here as part of the KGDEs. In order to better assess the vulnerability of KGDEs and to achieve proper adaptation strategies for their management, the most representative KGDEs types are presented together with indicator communities.

Ecohydrogeological processes and environmental conditions in karst

Karst is formed by the dissolution of host rock along discontinuities. Therefore, its internal structure is characterized by a unique triple porosity (Fig. 1). The primary porosity is related to the intergranular permeability of the rock matrix as well as small voids and microfissures. The secondary porosity consists of discontinuity planes, including joints, faults and bedding planes. The presence of well-developed solution channel pathways, which form the tertiary porosity, is a major difference with other types of aquifers (Atkinson, 1977; Jeannin and Grasso, 1997; White and White, 2005). A hierarchically organized network of hydraulically connected voids, the size of which varies from slightly enlarged cracks to conduits many meters in diameter and many kilometers long, enables flow over long distances (Gabrovšek and Dreybrodt, 2001; Worthington and Ford, 2009).

A large part of groundwater recharge takes place through openings either as rapid diffuse or concentrated infiltration, while the other part moves slowly through the matrix. In the subsurface, the flow through conduits and channels, where water storage is limited, is often fast and turbulent (Bakalowicz, 2005; Aquilina et al., 2006). The flow velocities can even reach several hundred m/h, in contrast to velocities in intergranular aquifers, where the maximum velocities are in the order of a few tens of m/day. The flow through micropores in the carbonate bedrock, where considerable storage occurs, is much slower, diffuse and often laminar (Ford and Williams, 2007; Fig. 1).

Due to the predominant channel flow, another specificity of karst hydrology is the fast and strong variability in response to meteorological conditions. This results in changes from open-channel to pressurized flow and changes from laminar to turbulent flow (Worthington, 1991; White, 2003; Williams, 2008). Water table fluctuations can reach several dozen meters within a short time and flow velocities can vary by several orders of magnitude. As a result, water overflows onto the surface and extensive surface-groundwater interactions may occur, such as the activation of temporarily active springs, swallow holes, intermittent lakes, etc. (Naughton et al., 2012; Mayaud et al., 2019). The hydrological status of estavelles also changes. Variations in flow directions and thus in contribution of different parts of the aquifer to a particular spring are also frequent (Ravbar et al., 2011).

In contrast to other (subterranean) ecosystems, where the hydrological conditions are much more stable (Boulton and Brock, 1999), the described flow characteristics have a significant influence on the buoyancy, structure and functioning of KGDEs. Baseflow periods are characterized by stable environmental conditions and generally higher water quality. Since the chemical composition of groundwater in carbonate aquifers is represented by the predominant dissolution products of carbonate minerals, groundwater carries continuous flux, rich in calcium-bicarbonate and low turbidity (Jeannin and Grasso, 1997; Bakalowicz, 2005).

Recharge events induce spatial and temporal variability of the flow, which has many implications for groundwater distribution, its physical and chemical properties. Water flow velocities, temperature and turbidity, transport of nutrients and concentrations of other substances can be subject to considerable variability (Ford and Williams, 2007; Bonacci et al., 2009). The temperature variance occurs because the water adapted to the surface temperature cannot fully adapt to the subsurface temperature on its way due to the rapid transfer of infiltrated water toward the spring (Petrič and Kogovšek, 2010). Water quality may deteriorate due to rinsing of soluble contaminants from an adjacent aquifer or other parts of the aquifer. Similarly, nutrients and particles of different shapes and sizes (dissolved and particulate organic matter, sediments along with small organisms and seeds) entering the system by various pathways can spread rapidly over long distances. Various types of pollutants may be attached to the transported particles (Pronk et al., 2006).

In the underground, very special environmental conditions prevail and animals have adapted in a very special and unique way (Table 1; Christiansen, 2012; Fišer, 2019). Darkness is the most defining factor that has the greatest influence on the organisms and is manifested by the reduced energy flux through food webs. In nearly all ecosystems, light-driven photosynthetic production by

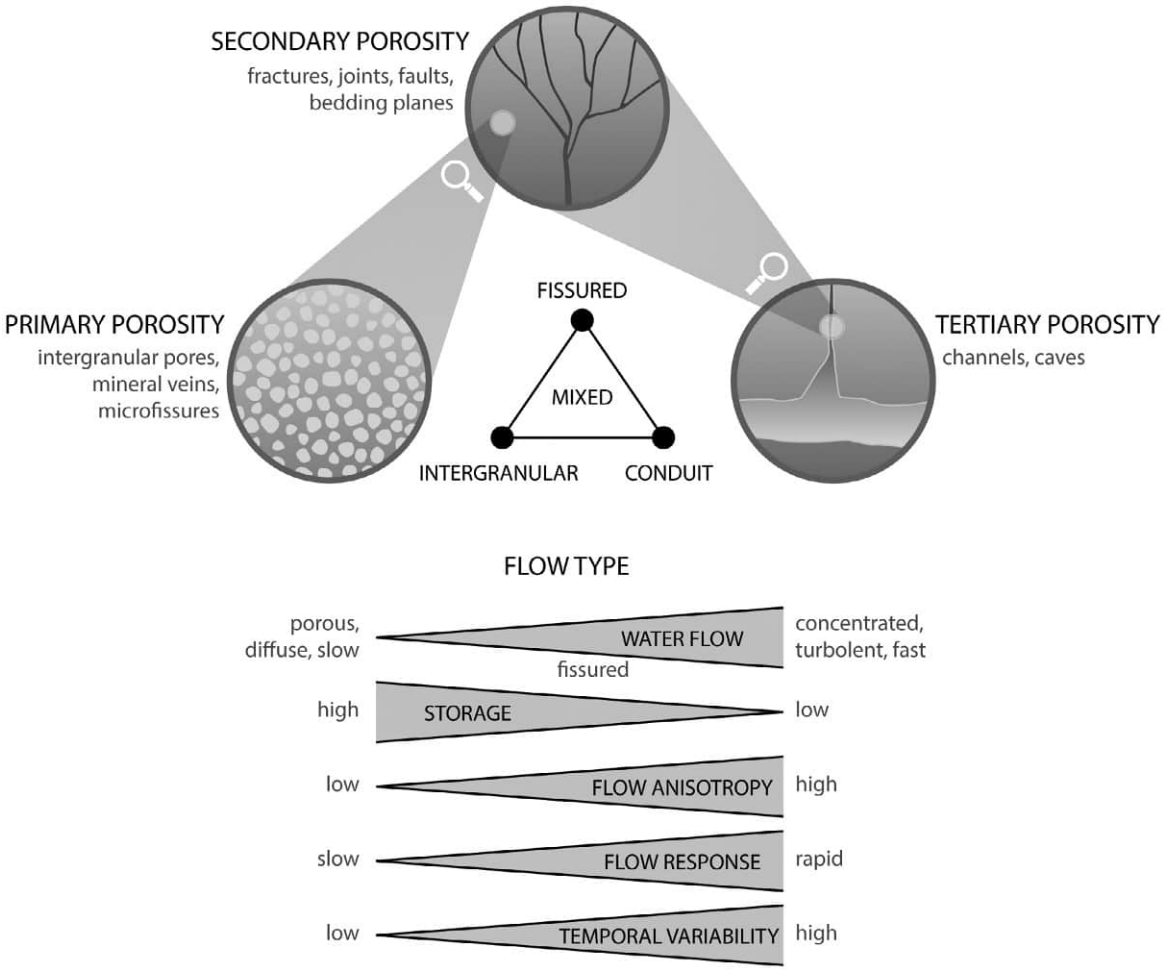

Fig. 1 Schematic description of the porosity types and the associated flow properties in karst. Table 1 Morphological, ecological, physiological, and behavioral adaptations of aquatic and riparian fauna to subterranean life.

Morphological	*Ecological and physiological*	*Behavioral*
Reduced eyes, pigments and brain parts connected with processing sensory information	Reduced metabolism	Reduced aggregation
Specialization of extra-optic sensory organs	Resistance to starvation	Reduced response to alarm cues
Cuticular thinning	Reduction of circadian rhythm	Increased sensitivity to vibrations
Modification of feeding structures	Reduced egg number; increased egg volume	Reduced intraspecific aggressive behavior
Reduction of scales and swim bladder (fish)	Increased life span	
Elongation of appendages		

microbes and plants is the key source of energy for heterotrophs, but in the absence of light primary production can only be based on chemical sources to produce microbial biomass. This chemical-driven microbial production, chemoautotrophy, can support food webs in caves and other subterranean habitats (Brad et al., 2021). The other source is dead organic matter from plants, detritus, dead animals, feces, or other material which is imported from the surface (Simon, 2019).

Compared with related surface-dwelling species, subterranean animals are characterized by the absence or reduction of a series of features, particularly eyes and pigments. Subterranean animals are also characterized by an elaboration of extraoptic sensory

structures as well as other morphological, ecological, physiological, and behavioral adaptations (Table 1). This represents a remarkable convergence among subterranean animals, the morphological aspects of which are called troglomorphy (Christiansen, 1962). But not all features are convergent. For example, interstitial and epikarst species tend to be smaller than surface-dwelling sister taxa while cave species tend to be larger (Fišer et al., 2012).

KGDE types and their representative subterranean communities

A prerequisite for better understanding of interactions between environmental elements and complex feedback mechanisms of KGDEs, of their vulnerability to specific environmental pressures and adequate protection is their classification (Fig. 2, Table 2). Addressing changes in ecosystem structure and functions requires an integrated approach from the (sub)surface to the vegetation and atmosphere, across scales and ecosystems, and it entails combining observation, ecosystem theories and modeling. Challenge of framing the KGDEs as a whole system approach, combining human-environment interactions, and cross-scale interactions with feed-back loops, is triggered by the theoretical basis and practical implementation. To identify the most representative ecosystem types, the position within the hydrological system, the morphology of the environment, the main hydrogeological processes (i.e., extent, duration and frequency of groundwater inflow), main biota and factors limiting the evolution of the species (e.g., darkness) are considered and briefly described.

The most spatially distributed habitat in karst and a major ecotone between surface and cave water is the soil–rock interface known as the epikarst (Bakalowicz, 2004). From a hydrogeological perspective, it represents an upper layer of the vadose zone, which can be from a few meters to several tens or even hundreds of meters thick. Due to its origin by weathering and corrosion processes, it is structurally different and much more karstified than the lower part of the unsaturated zone. As the degree of fracturing and the hydraulic conductivity decreases with depth, the concentration of infiltrated water is promoted. Consequently, perched aquifers are formed enhancing temporal storage of the water and its lateral flow before it is diverted to the main flow paths in the deeper parts of the system (Mangin, 1975; Williams, 2008; Berthelin and Hartmann, 2020). This is particularly important for the gradual recharge of the phreatic zone and springs during baseflow conditions (Perrin et al., 2003; Trček, 2003).

The epikarst layer also acts as a natural filter for pollutants and other substances contained in the seepage water. Due to its morpho-hydrological conditions, it hosts a variety of different microhabitats of rich and diverse aquatic fauna, e.g., in pores, voids, fissures, cavities and conduits that are permanently or temporarily flooded, as well as in drips, riffles, pools and ponds (Culver and Pipan, 2013). Direct sampling of epikarst habitats is not possible and epikarst communities are best sampled by collection and filtration of drip water over extended periods of time. Animals in dripping water are the ones that have been swept out of their primary habitat above the cave passage. Drips exhibited considerable environmental and biodiversity heterogeneity, represented mainly by copepod species (Pipan, 2005a).

At regional scale, however, the water enters the underground karst system via ponors and swallow holes and, together with the water percolating through the vadose zone finally reaches a cave stream (Fig. 3A–C), which in turn exits at a spring and flows into a surface river (White and White, 2005). The part that is located in the area of water level fluctuations is called the epiphreatic zone

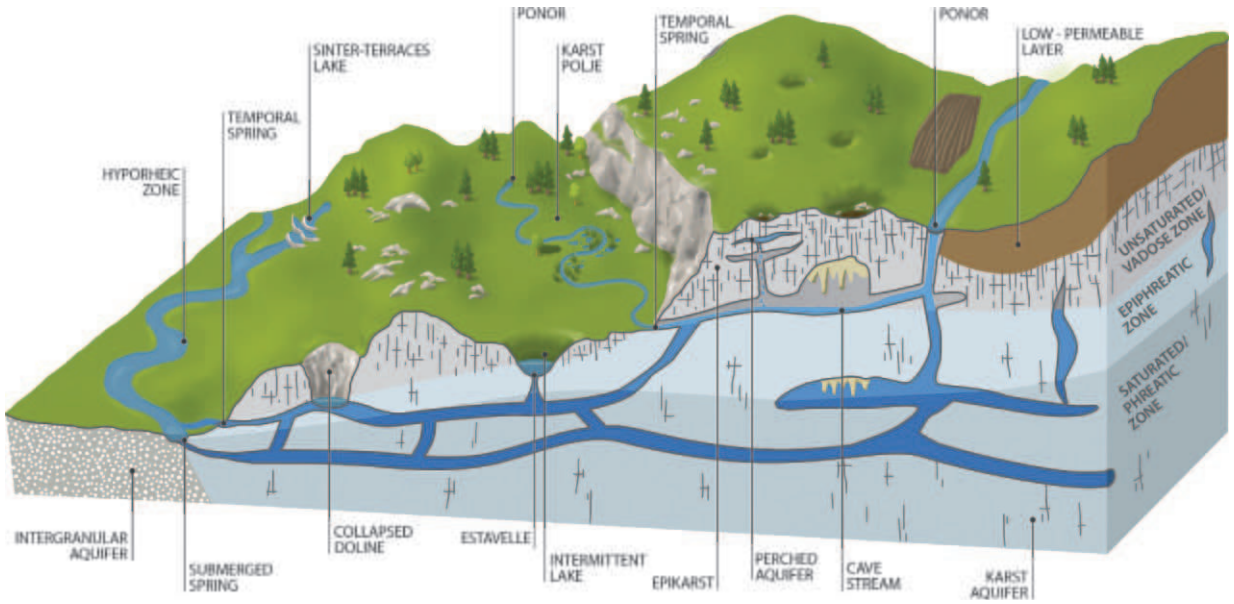

Fig. 2 Schematic presentation of the most representative KGDE types. The figure is not in scale. Modified from Ravbar N and Šebela S (2015) The effectiveness of protection policies and legislative framework with special regard to karst landscapes: Insights from Slovenia. *Environmental Science and Policy* 51: 106–116.

Table 2 An overview of KGDE types, foremost ecohydrological processes and environmental conditions, with the main representative groundwater taxa.

Ecosystem type	*Position within the hydrological system*	*Main ecohydrogeological processes*	*Type of habitats*	*Representative groundwater taxa*[a]
Epikarst	Subterranean	Storage, filter, transport, lateral flow	Pores, voids, fissures, cavities, conduits drips, riffles, pools and ponds	Microcrustacea, Oligochaeta
Cave stream in epiphreatic and phreatic zones		Transport, high temporal variability of flow	Conduit network, sediments	Microcrustacea, Decapoda, Gastropoda, cave salamander, cave fish
Cave in phreatic zone		Slow flow		Microcrustacea, Decapoda, Coleoptera, cave salamander; cave fish
Cenote	Surface-groundwater interaction zone	Slow flow	Water cave	Microcrustacea, Copepoda, Decapoda, cave fish
Ponor		Transport, high temporal variability of flow	Opening in the ground	N/A
Spring			Pores, voids, fissures, cavities, conduits, sediment	Microcrustacea, Gastropoda

[a]By representative groundwater taxa are meant the most diverse and best-studied subterranean groups known in the literature.

and is temporarily saturated, while the phreatic zone is permanently saturated. The habitats in these zones consist of networks of conduits of different sizes, from a few millimeters to dozens of meters in diameter. Usually during flood pulses they serve as transmitters of water, nutrients, mass and energy, which are of vital importance for cave biota (Gillieson, 1996). Transport in cave streams formed largely from percolating epikarst water tends to be more stable over time, while transport in cave streams formed largely from sinking surface streams shows greater temporal variability. The flow rates of cave streams range from a few mL/min to dozens of m^3/s.

The sinking rivers are usually inhabited by a rich assortment of stygophiles and accidental surface species, stygobionts are rare. Sinking rivers recharge aquifer in a concentrated manner and often have a direct link with the phreatic zone. Sometimes they develop a larger ponor-spring cave system, such as is the example of the Postojna-Planina Cave System (Slovenia; Fig. 3C). This cave system has a long history of biological research, dating back to the early 19th century and is considered as the cradle of biospeleology with at least 48 stygobiotic species known today. Representative communities in the cave river comprise European cave salamander *Proteus anguinus anguinus* (Fig. 4A), different species of snails and crustaceans, among which endemism is high, as well as hydrozoan *Velkovrhia enigmatica* and the cirolanid isopod *Monolistra racovitzae racovitzae*, both with a marine origin. Endemic cave salamanders are also known from caves of the south-eastern United States (i.e., *Eurycea spelaea, E. latitans, E. wallacei, E. tridentifera, E. rathbuni*, etc.). In terms of cavefish species diversity is richest in South China Karst, the Brazilian and Mexican karst regions with endemic species.

Aquifers are emptied through springs which usually feed streams or lakes (Fig. 3D). There are different types of springs in terms of geological, tectonic and morphological aspects and they can be permanently or temporarily active (Kresic, 2010; Kløve et al., 2011a; Culver and Pipan, 2013, 2014, 2019; Stevens et al., 2020). Springs are fed by a conduit network that contains abundant water and has highly variable flow rates of up to several dozen m^3/s (Bakalowicz, 2005), which are associated with recharge events. Accordingly, flow velocities, particulate and solute matter concentrations and temperature may strongly fluctuate. A particular hydrological form of the karst is the estavelle, through which the karst aquifer is fed or emptied and can therefore act as a spring when the water level rises or as a ponor when the water level falls. Where the aquifer empties in the riverbed or the seabed,

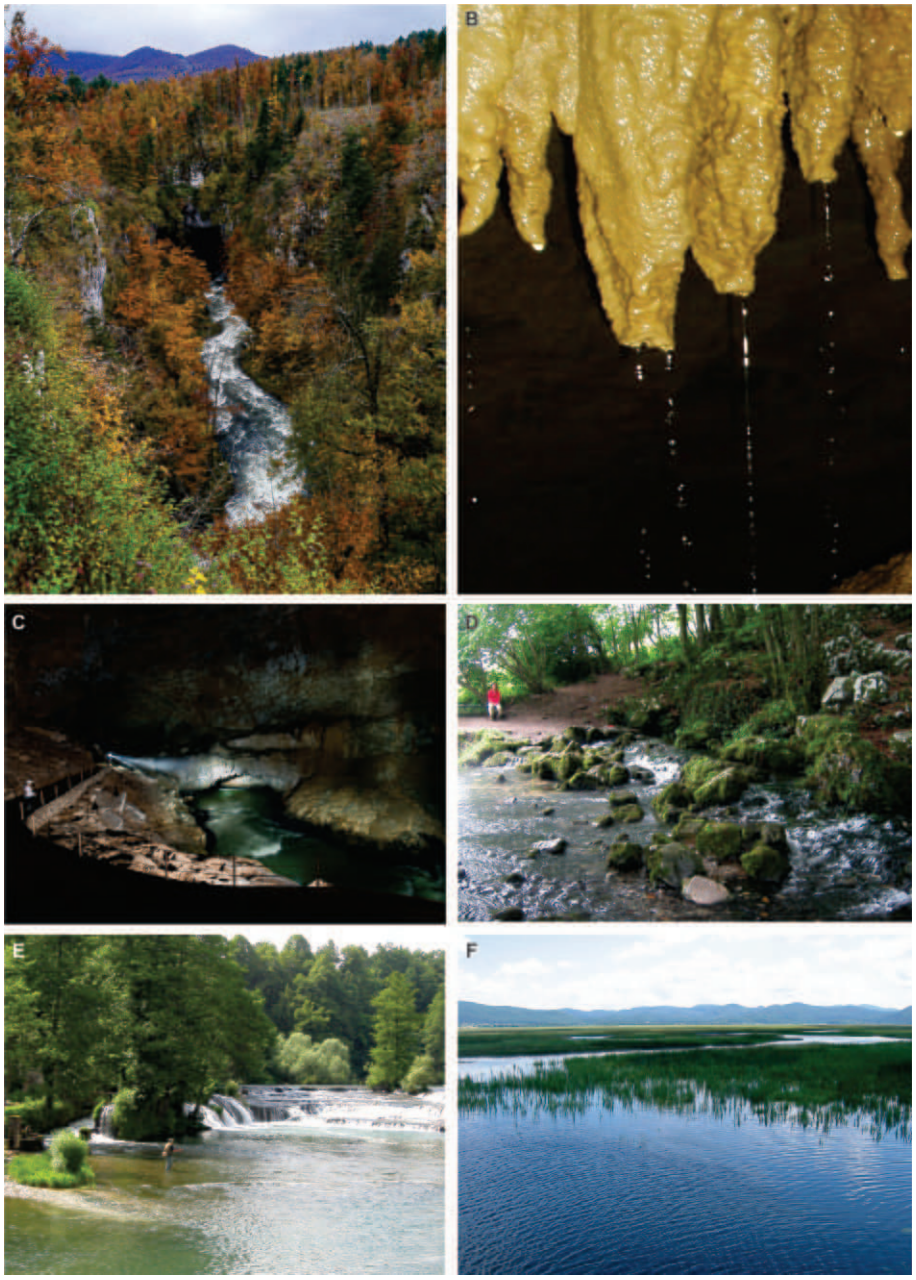

Fig. 3 Photographs of the most representative KGDE types: (A) ponor, (B) cave drip, (C) cave stream, (D) spring, (E) sinter-terraces, (F) intermittent lake. Photos: (A) M. Blatnik; (B) H. Hobbs; (C) B. Kogovšek, all with permission; (D, E, F) N. Ravbar.

subaquatic or submarine springs appear. In the later strong saline-freshwater interactions occur affecting both marine and KGDEs (Surić et al., 2015; Morrissey et al., 2020). Springs are ecotones between aquatic, riparian, or terrestrial habitats and are likely to affect habitat conditions, colonization, wildlife and human uses, as well as other ecosystem characteristics. Important microhabitats include springs' orifice, pools and streams, hyporheic zones, wet meadows, riparian habitats, waterfall spray zones, and barren rock habitats near springs. Springs are considered biodiversity hotspots, including calcifying mosses, cyanoprokariotes and diatoms, among macroscopic invertebrates, snail and crustacean fauna is rich (Cantonati et al., 2020; Culver and Pipan, 2013).

At some springs or in stream channels sinter- (tufa- or travertine-) terraces form (e.g., in Krka River and Plitvice Lakes in Croatia, Pamukkale in Turkey, Huanglong valley in Sichuan, China). Often a staircase of pools is created by CO_2 degassing from water in areas of strong aeration and under favorable temperature conditions (Fig. 3E). Predominantly chemical deposition of calcite arises through the intervention of biological activity (Wang et al., 2010). A range of cyanobacteria, algae, mosses and higher plants contribute to the retention and accumulation of tufa and in this way gradually form tufa barriers. When tufa is deposited, it covers the bottoms and sides of streams and even fossilizes other sediments and organic remains, such as fallen trees and leaves.

Fig. 4 Photograph of typical (A) *Proteus anguinus anguinus* and the pigmented, eyed subspecies (B) *Proteus anguinus parkelj*. Photo: G. Aljančič, with permission.

This chemically-precipitated porous limestone habitat is an ecotone between surface, mostly current water, and a vadose or occasionally shallow phreatic environment (Pentecost, 2005). It harbors also troglomorphic taxa, like isopod crustacean *Caecidotea stygia* in North America and snail species of *Iglica* and *Paladilhiopsis* in Slovenia (T. Novak, per. comm.).

Karst poljes are larger closed depressions in karst landscapes with flat bottoms. They are typical of the Dinaric karst, but can be found in most karst regions of the world (Ravbar et al., 2021). Common characteristics of the poljes are very complex hydrological and hydrogeological features of sinking water with outlets on the one side and swallow holes on the other, with cycles of extensive flooding (Fig. 4), followed by receding water levels and the formation of wetlands (Gams, 1978; Ford and Williams, 2007). Sometimes karst poljes follow one another in a row downgradient, so that the same water sinks and reappears several times (Bonacci, 2013).

Strong and direct interaction between the circulation and storage of ground- and surface water also occurs in areas of shallow karst, where bottoms of karst depressions reach the epiphreatic zone. The so-called intermittent lakes (in Ireland similar formations are termed turloughs) and other karst wetlands appear of widely varying sizes with different periodicities and have a role as reservoirs of biodiversity (Pipan et al., in press). In the case of Pivka intermittent lakes in Slovenia, for example, water flows underground most of the year, but after periods of intensive or long-lasting precipitation, the water table rises and emerges to the surface (Petrič and Kogovšek, 2005). Some of the intermittent lakes appear annually and last for up to 6 months, but some other lakes appear rarely, and only fill up in times of extreme hydrological events. Some of the smaller lakes recharge and discharge mainly through the alluvial sediments which cover their bottoms.

Extensive surface-groundwater interactions and flooding in these areas promote the exchange of nutrients and organisms between habitats. Human societies have developed grazing patterns for their domestic livestock and established cropland and agricultural methods that make optimal use of the fertilized land released after the floods. When the water is present, area is often used for agriculture and recreation. The transition from wet to dry (and vice versa) can be rapid, and thus karst poljes and areas of intermittent lakes create diverse habitats for specifically adapted communities. The crustacean fauna of the Pivka intermittent lakes includes two species of fairy shrimp (*Branchypus schafferi* and *Chirocephalus croaticus*; Fig. 5), three Cladocera species, nine Copepoda species, two Ostracoda species, one Amphipoda, and one Isopoda. While the species list is very incomplete and non-existent for insects, it includes stygobionts, generalist species, and species adapted to temporary waters (Pipan, 2005b; Pipan and Culver, 2019).

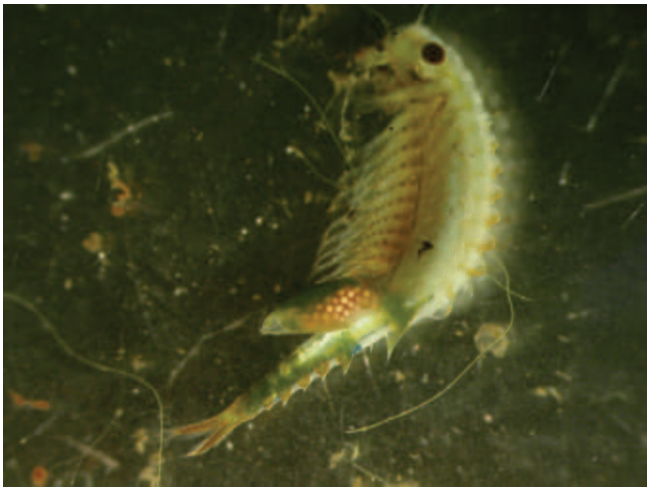

Fig. 5 *Chirocephalus croaticus*, a rare species of fairy shrimp limited to intermittent karst waters. From Pipan T (2005) Fauna of the Pivka intermittent lakes. *Acta Carsologica* 34: 650–659.

Typical of temporary wetlands, fairy shrimp have thick-shelled winter eggs that are resistant to desiccation. They also have a very high reproductive rate and in the case of *C. croaticus*, can complete their life cycle in 2 weeks, an obvious advantage in temporarily present waters. In general, open meadow-like flooded areas and dry meadows at the margin of the intermittent lakes are important habitats also for vegetation. In the areas that are flooded for longer periods, purple willow (*Salix purpurea*) overgrows meadows and pastures in the absence of cultivation or grazing. Due to zonation in the lake basin, related to flood duration, there are many endangered and rare species and plant communities still poorly examined (Pipan et al., in press), like mouse garlic *Allium angulosum*, Siberian iris *Iris sibirica*, wild gladiolus *Gladiolus illyricus*, and solitary clematis *Clematis integrifolia* (Mulec et al., 2005). Rare plant communities include the wild gladiolus—purple moor grass (Gladiolo-Molinietum), and tufted hairgrass—tall plantain (*Deschampsio-Plantaginetum altissimae*) communities.

Among the best known karst poljes is the Cerkniško Polje (Slovenia). Aquatic plant communities are very restricted, but adapted to hydrophilic conditions due to the intermittent nature of the lake that occurs in the polje (Fig. 3F). Most species die back during the dry phase. Among such species are *Charetea fragilis* and several species of *Potametum*. With regular draining and filling, the lake's reed beds provide shelter, food, and nesting sites for a variety of water and other birds. Amphibious species are ones where the species occur in both wet and dry phases and where the duration of the aquatic phase is at least 3–4 months. There are typical wetland species and species living on the edge of the inundation zone. Many of these wetland species are rare or endangered in Slovenia (Pipan and Culver, 2019). The Crustacea reported from Cerkniško Polje include a fairy shrimp, *Chirocephalus croaticus*, a rare species limited to intermittent karst waters. A total of 21 cladoceran species and 15 copepod species have been recorded from the lake, some species are obligate subterranean dwellers (stygobionts). The lake is also a hotspot for both Odonata and Trichoptera, with several species rare and endangered in Slovenia. The cave salamander *Proteus anguinus anguinus* has been reported from Cerkniško Polje and the Pivka intermittent lakes, where it washes in from subterranean channels as the lake fills (Pipan and Culver, 2019). During the dry season, these areas are an important terrestrial habitat for mammals, butterflies and beetles.

Other important aquatic habitats in karst landscapes include collapsed dolines when their bottoms reach the (epi)phreatic zone and form lakes (e.g., Red and Blue Lakes near Imotski, Croatia). This type of collapsed doline is also called cenote, which is characteristic of the low karst of the Yucatan in Mexico, where the term originated. Cases of collapsed dolines with a river flowing along the bottom are also common.

A specialized aquatic karst habitat has been found in extensive areas of western Australia. These are thin carbonate deposits in isolated, desert, though sometimes extensive pockets formed by evaporation of near surface waters in very arid climates (Humphreys, 2001). Shallow, up to 10 m thick calcrete aquifers are a feature of arid karst areas, that are colonized by a diverse fauna of stygobionts, including diving beetles (Dytiscidae), amphipods (Crangonyctoidea and Melitoidea), and isopods (Phreatocoidea; Halse, 2018). Because of their long geological history, some of the fauna is very ancient. The source of organic matter and nutrients is rain water percolating into the calcrete aquifers, and tree roots that penetrate the calcrete (Saccò et al., 2021). It is speculated that chemoautotrophy also occurs. Overall, regional diversity is high, but overlap among related species is low, and different isolated calcretes have different, but related species.

Vulnerability and protection

Karst groundwater dependant ecosystems and organisms living there are mainly threatened by human influence and pollution that changes the chemical or microbiological composition of the water. The use of fertilizers and pesticides in agriculture is the most

common contamination impact worldwide (Coxon, 2011). Due to the repeated, large-scale recharge of these pollutants, this activity is particularly problematic. Another important group of pollutants are hormonal disruptors that affect the reproduction of organisms. Other persistent contaminants and compounds of emerging concern (CEC), are used every day to promote human health and well-being (i.e., microplastic). Specific threats include spills from traffic accidents, illegal dumping in dolines and sinkholes. Epikarst is considered as one of the most vulnerable KGDEs as it acts both as a collector of toxic waste, because of its storage capacity and a dispersal path, and because of its vertical and horizontal connections (Loop and White, 2001).

Particularly threatening is the construction of various hydrotechnical structures that cause changes in water levels, e.g., hydraulic drainage of surface waters/flood reservoirs (Milanović, 2004; Zupan Hajna et al., 2010), and artificial aquifer recharge management (Daher et al., 2011). Such interventions destroy habitats, prevent the free passage of organisms and sediments and contacts between populations. The water regime and temperature may change and cause the oxygen content and water quality to decrease. Extensive water use is increasing worldwide due to growing water demand, leading to a decline in groundwater levels (Joodaki et al., 2014; OECD, 2015). Similar impacts are expected from changes in land use and vegetation cover (e.g., abandonment of traditional land use and natural vegetation encroachment; Kovačič et al., 2020).

Additional threats are associated with the introduction of invasive species, which often lack natural predators and thus proliferate rapidly. Invasive species may also be able to exploit a resource that native species cannot use, allowing them to establish themselves in the new environment. As a result, invasive species can rapidly decimate natural biota and cause widespread habitat loss (Mollot et al., 2017). An example of the spread of an invasive species is the release of a perch in an intermittent lake of Cerkniško Polje in the 1990s. Since then, its numbers have multiplied dramatically. The perch is a distinct carnivore that attacks and destroys natural populations in the lake and was recently tried to be removed.

In addition, poaching of rare and endemic species, which has recently become a very widespread activity, can also cause their extinction. Hundreds of illegal pitfall traps have been found in caves in Slovenia, Croatia, Bosnia and Herzegovina and Montenegro and organisms, especially beetles, would be sold on the black market (Simičević, 2017).

Proteus anguinus anguinus is the only European cave vertebrate, and by far the largest cave animal in the world, that lives in the subterranean waters of Dinaric karst. Around 300 localities (partly interconnected caves or cave springs) of proteus have been recorded, of which 200 are in Slovenia. In some localities proteus has become extinct due to negative anthropogenic influences from intensive agriculture, energy production (karst water damming), and unregulated urbanization (groundwater pumping and sewage disposal; Aljančič and Prelovšek, 2010). The morphologically most distinct of all proteus populations, discovered in 1986, is *Proteus anguinus parkelj* (the black proteus; Fig. 4B), limited to a single cave system in Bela Krajina (South East Slovenia, on less than 30 km^2) and thus extremely endangered. Even a single local pollution incident could have a devastating impact on the entire population.

Climate change can have a variety of serious negative impacts on ecosystems. Warming and precipitation changes already pose the greatest threat to World Heritage sites, which are protected at the highest level and a third of which are severely affected (Osipova et al., 2020). Little is known about the vulnerability of KGDEs to the direct effects of various environmental changes, and studies are urgently needed. However, observed records and climate simulations are consistent in projecting globally changing patterns of precipitation and temperature and in projecting impacts on the water cycle (IPCC, 2007).

Changes in the quantity, intensity and variability of precipitation could have implications on water quantity and quality in many karst areas. These may cause altered water level fluctuations and changes in seasonality of surface-groundwater interactions (Hartmann et al., 2014). As a result, smaller water bodies may be filled up or drained. Coastal areas can be severely affected by sea-level rise and saltwater intrusion. Consequently, the spatial extent or even ecosystem status of KGDEs may be changed.

In addition, changed abiotic conditions, intermittent exchange of oxic and anoxic conditions in sediments, conditions that accelerate the degradation of organic matter, and an imbalance of nutrients are to be expected (Urbanc-Berčič and Gaberščik, 2001). An increase in precipitation could cause acidification or accelerate pesticide leaching (Bertrand et al., 2012; Kløve et al., 2014). More frequent and more intense flood events could increase bacteria transport. On the other hand, a decrease in recharge may lead to decreased dilution, which is particularly important for the transport of pollutants concentration.

The temperature increase could pose a problem especially in smaller surface water bodies, such as intermittent lakes. It may have an impact on temperature dependant reaction rates and oxidation reactions, which further influence many biogeochemical processes (e.g., nitrogen and carbon cycle, fate and transport of pollutants; Kløve et al., 2014; Retter et al., 2020).

The species and habitats of KDGEs are regularly exposed to environmental stress and are therefore better adapted to natural fluctuations (water level, nutrients, temperature). However, changes triggered in fundamental ecological processes as a consequence of altered recharge and temperature regimes are difficult to predict and will most probably be regionally dependant. The composition and distribution of species will most likely depend on the intensity of environmental changes. It is likely that larger systems will be more resilient to environmental change. Nevertheless, the loss of specialist species can be expected.

The need to tackle the deterioration of aquatic ecosystems has been recognized by policy-makers and legislation has been adopted to halt further deterioration (Kløve et al., 2011b; Gunn, 2021). Some international treaties, such as the UN Convention on Biological Diversity, the Bern and Ramsar Convention on Wetlands, Natura 2000, IUCN Red List of Threatened Species and others, directly require preservation of biodiversity, water quantity and quality. Examples of legislation with similar aims on a regional level are e.g., European Water Framework Directive, Groundwater Directive and Habitats Directive, which form the basis for national legislation. In Switzerland, the Regulation for Water Pollution Control and in the USA the US Clean Water Act regulate water quality standards. On the other hand, the Slovenian Cave Protection Act represents a unique approach to the conservation of caves and the

monitoring of interventions, including their restoration (Ravbar and Šebela, 2015) but many sites still do not have any monitoring scheme or conservation action plan.

At least in the developed countries, many protection mechanisms have been evolved, but their provisions are rather general. They restrict selected human activities and determine, e.g., which species are protected to what extent, etc. However, not only selected species *per se* should be protected, but the entire ecosystem. Therefore, more precisely defined measures are necessary, but first a better understanding of the processes that determine groundwater dependant ecosystems, their biological function and their vulnerability needs to be assessed.

Conclusion

Karst groundwater dependant ecosystems are highly underexplored and lack information especially about the underground ecosystems and related ecohydrological processes. Although speleological research allows direct observation of water flow in aquifers, water caves are not always accessible and only form a part of the entire water network. Other access points to karst subterranean habitats, such as wells, provide easier access, but are also rare. Although surface KGDEs are more intensively studied, little is still known, how different environmental changes and pressures influence environmental conditions of individual KGDEs.

As KGDEs host a large number of endemic species, they are *a priori* threatened with extinction for this reason alone. Only a slight environmental change can cause the extinction of the most vulnerable species and possibly trigger complex feedback mechanisms that would lead to degradation of habitats. Since KGDEs (in particularly the subterranean ones) are unconnected habitats and not subject to majority of exogenous processes, repopulation is almost impossible. Once damaged, KGDEs may take a long time to recover, and the rehabilitation process is a difficult task. For these reasons, KGDEs must be holistically managed in an appropriate and careful manner. Because population worldwide rely on the same groundwater bodies that support KGDEs species for their freshwater needs, protecting groundwater quality and quantity benefits both wildlife and humans.

Appropriate protection requires a thorough understanding of the hydrogeology of karst aquifers and the specific processes of their groundwater dependant ecosystems. A step toward is the presented KGDEs classification that considers the special characteristics of karst environments and driving processes, and the interactions between different elements of the environment. By protecting these ecosystems, we also contribute to the benefit of mankind.

Knowledge gaps

- KGDEs are underexplored, therefore processes, vulnerability and impacts are poorly understood.
- More in-depth research and monitoring is needed, taking advantage of karst specific research methods and approaches (e.g., natural and artificial tracers monitoring, GIS and remote sensing, modeling).
- Due to the high regional biodiversity of the KGDEs with a high degree of endemism, regional studies are necessary.
- There are also gaps in knowledge about the impact of living organisms on the karst geomorphology.
- For proper protection of KGDEs, the recognition of indicator organisms, habitat specialists and the intensification of species variability and distribution monitoring is necessary.
- A more complete protection of KGDEs requires a shift of emphasis from protection of isolated groundwater ecosystem to protection of wider surface karst area. KGDEs are mainly ecotone habitats, below the surface or in the surface and land-use changes can pose a threat to populations.
- A fundamental understanding of KGDEs should lead to improved prediction of how KGDEs and their services will evolve and adapt under global challenges, with climate, land use and societal changes as the key drivers.

Important case study—Slovenian karst

Its location in the area of very high geodiversity and between different climate types place Slovenia among hot spots of biodiversity on a global scale (Culver et al., 2021). Slovenia is a small country within the EU, where half of the country is underlain by carbonate rocks. Due to long tradition of karst science development and an area of pioneering speleo(bio)logical research, it is considered the cradle of karstology (Gams, 2004; Shaw and Čuk, 2015).

The interaction between the orographic, climatic, hydrological and edaphic conditions, as well as the fact that the area served as a hub for various species and as a refuge during the glaciation periods determines the very high biodiversity of the country's karst areas. Due to deforestation in prehistoric times, man has even contributed to the diversification of the flora by creating space for the occurrence or expansion of habitats that are now considered natural (e.g., dry meadows; Kaligarič et al., 2006). An important factor for the preservation of a particularly rich diversity of karst flora and fauna is also the low level of human impact and the very well preserved landscape in its natural state.

A selection of the most important KGDEs in Slovenia is presented in Fig. 6 and Table 3.

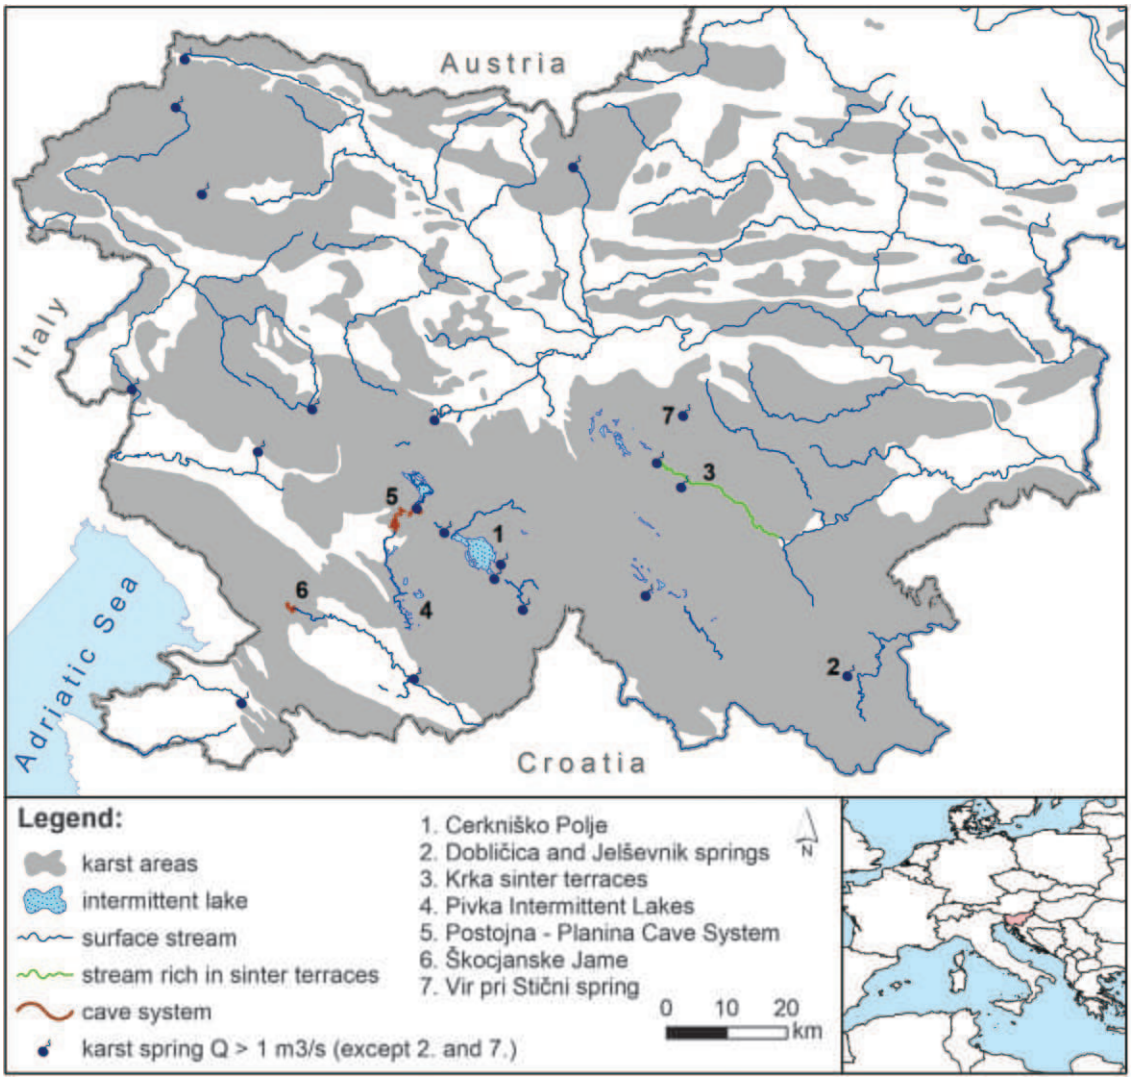

Fig. 6 Map of Slovenia showing karst areas and locations of selected KGDE sites. For more information about the selected sites see Table 3.

Table 3 A list of the main KGDE sites in Slovenia indicating type of ecosystem and charismatic groundwater species, compiled from the literature.

Name of location (in alphabetical order)	*Ecosystem type*	*Rare, endemic and/or iconic groundwater species*	*Selected reference*
Cerkniško Polje (Fig. 3F)	Karst polje	*Chirocephalus croaticus*	Brancelj (2003)
Dobličica, Jelševnik	Karst spring	*Proteus anguinus parkelj*	Sket and Arntzen (1994)
Krka sinter terraces (Fig. 3E)	Sinter terraces	*Kerkia kusceri, Paladilhiopsis kostanjevicae*	Bole et al. (1993)
Pivka Intermittent Lakes	Karst wetlands	*Chirocephalus croaticus*	Pipan (2005b)
Postojna-Planina Cave System (Fig. 3C)	Cave system, water cave	*Proteus anguinus anguinus*, *Velkovrhia enigmatica, Monolistra racovitzae racovitzae*	Culver and Pipan (2013)
Škocjanske Jame	Ponor cave	*Proteus anguinus anguinus*, *Zospeum spelaeum spelaeum, Marifugia cavatica, Dendrocoelum spelaeum, Elaphoidella karstica*	Prelovšek et al. (2021)
Vir pri Stični	Karst spring	*Proteus anguinus anguinus*	Sket and Velkovrh (1978)

For location of the sites see Fig. 6.

Acknowledgments

The contribution was prepared within the context of the projects Ecohydrological study of spatio-temporal dynamics in karst critical zones under different climate conditions, No. NK-0002, and Infiltration processes in forested karst aquifers under changing environment, No. J2-1743, and the programme Karst Research, No. P6-0119, all financially supported by the Slovenian Research Agency. Several EU projects are also acknowledged: eLTER Preparatory Phase Project (eLTER PPP), eLTER Advanced Community Project (eLTER PLUS) and "Development of research infrastructure for the international competitiveness of the Slovenian RRI space—RI-SI-LifeWatch."

Groundwater Metazoans

Florian Malard, Univ Lyon, Université Claude Bernard Lyon 1, CNRS, ENTPE, UMR 5023 LEHNA, Villeurbanne, France

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Biodeposition Deposition in the environment of biogenic material in the forms of feces and pseudofeces (expelled material unsuitable for food that has not passed in the digestive tract).
Bioturbation Reworking of sediments by animals by burrowing, ingestion, and defecation of sediment particles.
Chemolithoautotrophic bacteria Bacteria that acquire energy via the oxidation of inorganic compounds, including sulfide, methane, ammonium, iron, and manganese, which is then used to fix organic carbon for growth.
Ecosystem processes Ecological processes that control the fluxes of energy, nutrients and organic matter through the ecosystem. These include primary production, decomposition of dead organic matter and nutrient recycling.
Groundwater ecology The study of the interactions between groundwater organisms and their external environment, be it the immediate aquifer or a connected terrestrial system (*in* Hancock et al., 2005).
Groundwater habitats The subterranean open spaces within the rock and sediments that are partially or entirely filled with water. Habitats vary in terms of void space available to metazoans, interconnectedness of the voids and hydrological linkages to surface ecosystems.
Heterotrophic bacteria Bacteria that obtain their energy from the oxidation of organic compounds or fermentation. In groundwater, heterotrophic bacteria at the base of the food chain rely on inputs of dissolved and particulate organic matter from the surface environment.
Intrinsic vulnerability of aquifer The vulnerability of groundwater to human perturbations: it depends on the geological, hydrological, and hydrogeological characteristics of the aquifer but is independent of the nature of perturbations.
Molecular delimitation of species A diverse array of DNA-based methods to determine species boundaries.
Specialist groundwater species Species showing strict dependence on groundwater either because they complete their entire life cycle exclusively in groundwater or because they necessarily complete a part of their life cycle there. The term obligate groundwater species is also in use.
Species accumulation curve A plot of the cumulative number of species collected in a particular area as a function of the cumulative effort spent searching for them.
Troglomorphic syndrome A hypothesis predicting that specialist groundwater metazoans show convergent traits because of a convergent selective environment.

 https://doi.org/10.1016/B978-0-12-819166-8.00176-6

Introduction

Groundwater metazoans belong to the invisible component of biodiversity on Earth. Even groundwater scientists and managers outside the field of biological sciences have little awareness. For the public and media, life in groundwater is associated to the existence of a few hyper-specialized creatures that would naturally find their place in a cabinet of curiosities. As often, reality is very different from collective imagination: groundwater metazoans are many, show varying degrees of specialization and are likely to be found wherever there are open spaces within the water-filled subterranean rock and sediment matrix. Since shallow fresh groundwater represents by far the largest reservoir of liquid freshwater on Earth (Ferguson et al., 2021), and groundwater biologists have only explored a minor fraction of it, groundwater metazoans are likely to represent an important, yet largely underestimated, proportion of Earth's freshwater biodiversity (Culver and Holsinger, 1992; Sket, 1999).

The history of research on groundwater metazoans is marked by a series of influential events that explain the current state of our knowledge on their diversity, biological traits and roles in the ecosystem. The first mention of a blind and depigmented groundwater metazoan probably dates back to report of the Chinese hyaline fish *Sinocyclocheilus hyalinus* from the Alu Limestone caves, Yunnan, China by Jie in 1541 (Romero, 2001). Chen and Yang formally described that species in 1993. In Europe, J.W. von Valvasor commented in 1689 on the European cave salamander, *Proteus anguinus*, which was described 80 years later by J.N. Laurenti (Aljancic, 1993). However, the systematic inventory and sampling of groundwater metazoans only began at the beginning of the 20th century, notably with launching of the "Biospeologica" international research program (Racovitza, 1907). Biological exploration of groundwater was mostly restricted to caves until the sixties (Ferreira et al., 2007). Subsequently, it was extended to groundwater in all types of consolidated rocks and unconsolidated sediments thanks to the development of different sampling methods (Camacho, 1992a). Early attempts to explain geographic patterns of biodiversity focused on the importance of groundwater colonization from surface ancestors, leading to the formulation of different hypothetical scenarios of transition from surface to subterranean life (Howarth, 1987; Coineau and Boutin, 1992). This approach prevailed until the nineties when it was replaced by macroecological analyses that disentangled the relative influence of broad factors including spatial heterogeneity, climate and history on regional species richness and the size of species ranges (Culver et al., 2006; Eme et al., 2015).

Perhaps more than in any other habitat, evolutionary research is a hallmark of studies on life in groundwater (Juan et al., 2010; Kowalko et al., 2020). Since the sixties, the often-remarkable morphology of cave animals has stimulated on-going evolutionary research on the causes of reduced features, i.e. the lack of eyes and pigments, and the importance of convergent selective forces in shaping similar elaborated features—for example, the occurrence of elongated appendages—among distantly-related species (Christiansen, 1961, 1962). The search for convergent traits among specialist groundwater metazoans—a hypothesis often referred to as the troglomorphic syndrome—was extended to life history, behavioral and physiological traits in several taxon-specific studies (Ginet, 1960; Poulson, 1963; Hervant and Renault, 2002). Recent works have questioned the troglomorphic syndrome and emphasized divergent selective pressures that resulted in a diversity of phenotypes among groundwater metazoans (Culver and Pipan, 2015).

Until the seventies, caves were the basic physical unit in ecological studies. The concept of groundwater ecosystems, particularly the physical boundaries of groundwater ecosystems, were elaborated in the seventies thanks to Raymond Rouch's research at the Baget karst basin, France (Rouch, 1986). Rouch showed that the physical boundaries of the karst environment in which organisms interacted with each other extended well beyond the cave walls to include all the aquifer and its surface drainage basin. The concept of groundwater ecosystem was extended to groundwater in unconsolidated sediments (Marmonier et al., 2000; Danielopol and Griebler, 2008), and served as a basis for the study of the flow of energy and material in groundwater ecosystems (Simon, 2019). Groundwater ecology gained international recognition with the publication of the first textbook dedicated to that discipline in 1994 (Gibert et al., 1994a). The nineties brought new knowledge of the importance of interactions between surface water and groundwater in regulating fluxes of carbon, nutrients and organisms between the two ecosystems. A special emphasis was on the parafluvial—hyporheic zone, the interface between streams, groundwater and the riparian zone (Peralta-Maraver and Robertson, in press). Research led to the publication of the first book dedicated to the structure and function of surface water—groundwater ecotones (Gibert et al., 1997), a special issue on the hyporheic zone (Valett et al., 1993) and the first textbook on the interactions between streams and groundwater (Jones and Mulholland, 2000). Since the 2000s, functional ecology has become a prominent aspect of groundwater ecology. Major research developed along three directions: the structure and function of groundwater food webs (Venarsky and Huntsman, 2018), the role of metazoans on ecosystem processes (Marmonier et al., 2012), and the importance of metazoans in regulating important ecosystem services delivered by groundwater ecosystems to humans (Boulton et al., 2008; Griebler and Avramov, 2015).

Modern research on groundwater metazoans embraces concepts and tools from multiple disciplines to address questions on the evolution, distribution and functional role of biodiversity (Griebler et al., 2014). Studies are increasingly integrative to address intertwined questions such as (i) How many groundwater species are there? (ii) Where do they live and how are they distributed over space? (iii) How do they evolve? (iv) What are their roles in groundwater ecosystems? Here, we describe groundwater habitats, the composition of groundwater metazoan assemblages, and the characteristic features of specialist groundwater organisms. Then, we emphasize the role of metazoans in groundwater ecosystems and discuss how scientific knowledge on their diversity is reflected in current groundwater policies that frame the management of groundwater resources.

Groundwater habitats

It is difficult for most people to comprehend the notion of groundwater habitats because most are invisible to human eyes. For many people, their notion is limited to the subterranean areas they can access, the rivers and lakes in caves. For scientists and managers, it can be difficult finding a balance between using too specialized scientific terminology of habitat types and too broad and imprecise descriptions. The tendency among scientists to name each of the subterranean habitats that they discovered has led to a profusion of specialized terms that are impenetrable to most readers (Camacho, 1992b). Conversely, the typology of freshwater habitats used in the European red list of habitats includes 25 items devoted to surface water but all groundwater habitats are grouped into a single item "Underground standing and running waterbody" (Jansen et al., 2016). It is important, yet often difficult to avoid classifying groundwater habitats based on the organisms they contain. Here, we provide a physical characterization of groundwater habitats, emphasizing abiotic characteristic features that are likely to account for differences in the composition of metazoan assemblages among different groundwater habitat types.

A simple way to comprehend habitats is to view groundwater as a sponge-like matrix in which water circulates through an interconnected network of voids. Voids are open spaces within the rock and the sediments, which provide the habitats for groundwater metazoans. The voids can be partially or entirely filled with water, a characteristic that is used by hydrogeologists to distinguish between the unsaturated (or vadose) and saturated zones of aquifers. Three characteristics of the voids can be used to classify habitats: void size, their degree of connectedness and their degree of connection with the surface environment.

Void size influences the diversity of organisms by setting an upper limit on the maximal body size (Pipan and Culver, 2017). Void or pore size is different from porosity, which defines the entire volume of the void space in the aquifer. Hence, clay has a higher porosity than sand but pore size is too small (1–10 μm) for harboring metazoans other than burrowers. The pore space available between sand particles allows for the occurrence of meiofaunal organisms (body size: 63–1000 μm), whereas macroinvertebrates (body size >1 mm) can be found in gravel aquifers. Pore space is no longer a physical constraint in carbonate rocks where the size of fissures is considerably enlarged by weathering of the parent rock. Cave water bodies may thus harbor large groundwater organisms including amphibians and fish (Proudlove, 2006).

In groundwater, water flows from high to low energy-head locations but the ability of the aquifer to transmit water depends on having connected pores. This ability is referred to as permeability. Permeability is another important feature to classify groundwater habitats because it influences the fluxes of nutrients, dissolved oxygen (DO) and organic carbon that supports life. Interconnectedness of the voids may also influence the movement of animals, hence their foraging capacity, although no experiments have yet tested this hypothesis. Cornu et al. (2013) used information on groundwater flow type, void size and permeability contained in the international hygrogeological map of Europe to provide the first groundwater habitat map for Europe (Fig. 1). The map portrays the

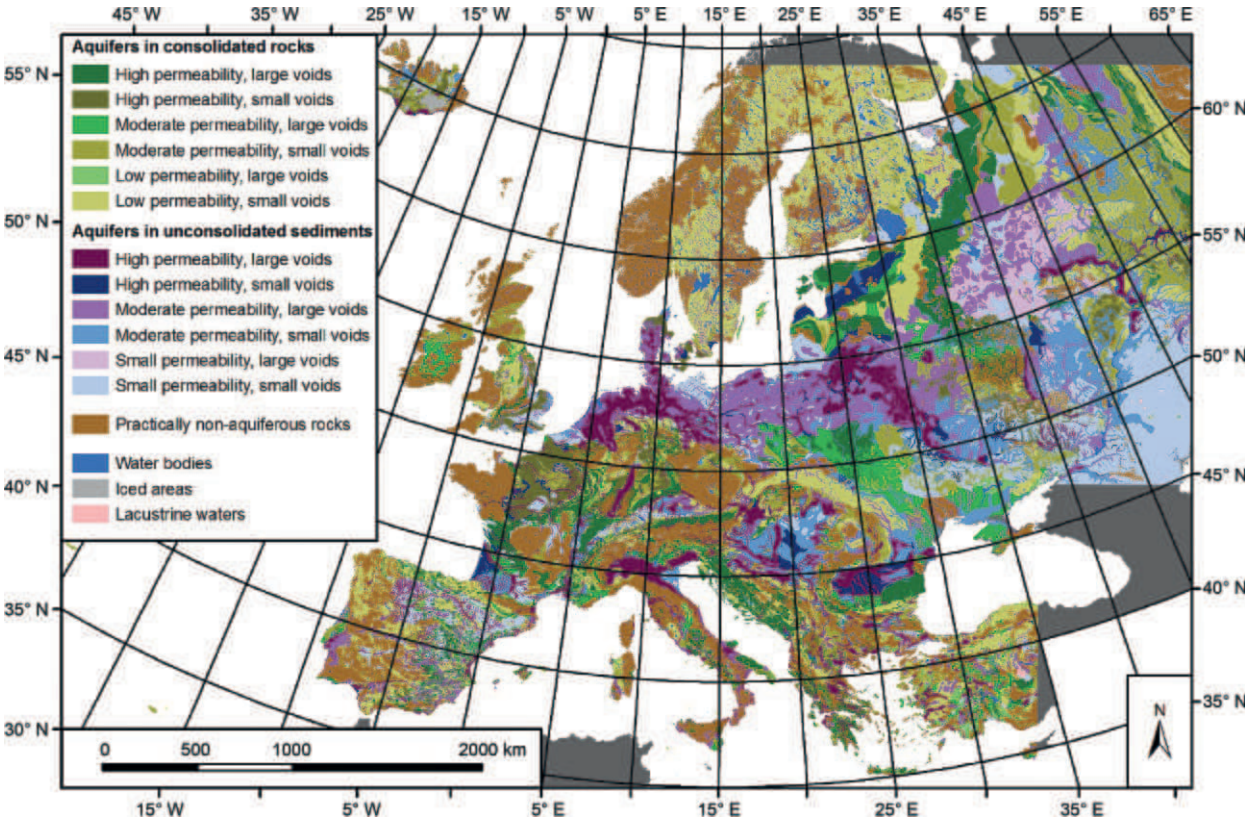

Fig. 1 The groundwater habitat map of Europe (Lambert azimuthal equal-area projection). From Cornu JF, Eme D, and Malard F (2013) The distribution of groundwater habitats in Europe. *Hydrogeology Journal* 21: 949–960.

areal distribution of 13 habitats types and it has provided a useful resource for testing the role of groundwater habitat area and heterogeneity on geographic patterns of species richness in Europe (Eme et al., 2015; Bregović and Zagmajster, 2016).

Another key feature for ecologically classifying groundwater habitats is their degree of connection to the surface environment, which strongly influences their temporal variability and the amount of organic resources they receive from surface terrestrial and aquatic ecosystems (Hahn, 2009). This feature was not integrated into the groundwater habitat map of Europe (Fig. 1). It is difficult to assess at the landscape scale but several hydrogeological surrogates are becoming available. One potential surrogate is depth to the groundwater table. The annual thermal amplitude of groundwater temperature decreases with increasing depth below the soil surface, until it becomes constant throughout the year at a depth of about 10–15 m. There is an inverse relationship between the concentration of dissolved organic carbon (DOC) in groundwater and vadose zone thickness, indicating stronger DOC retention with increasing water residence time in the vadose zone (Pabich et al., 2001). However, depth to the groundwater table may be a poor surrogate of hydrological connection to the surface in karst aquifers where conduit flow in pipe-like channels can result in short travel time of water despite considerable distances from the soil surface. Another surrogate is intrinsic vulnerability of the aquifer, a hydrogeological feature that is becoming easier to characterize and map due to the development of geographical information system-based methods (Machiwal et al., 2018).

Pore size, permeability and hydrological connectivity to the surface are hydrogeological features that have gained a large consensus among groundwater ecologists for characterizing groundwater habitats (Hahn, 2009; Cornu et al., 2013; Weitowitz et al., 2017). Hydrogeological criteria accounted for the largest proportion of variance in groundwater metazoan composition among sites in a number of studies (Dole-Olivier et al., 2009a; Hahn and Fuchs, 2009; Johns et al., 2015; Korbel and Hose, 2015). However, features such as permeability and pore size are often qualitatively assessed using geologic types of aquifers as surrogates rather than quantitatively measured in the field. However, most aquifers are intrinsically heterogeneous and exhibit changes in hydraulic conductivity and pore size over short distances, which may affect the distribution of metazoans. In addition, hydrogeological criteria do not account for regional variation in the composition of groundwater metazoans that may result from historical events such as the longstanding effect of Quaternary glaciers (Foulquier et al., 2008).

Composition and diversity of groundwater metazoan assemblages

Generalist and specialist species

Groundwater metazoan assemblages are often a mix of species that show different degrees of dependence on the groundwater environment. That extent of dependence has been widely used to classify groundwater species into different ecological categories. The categories shown in Fig. 2 were published by Gibert et al. (1994b) in the first edition of the Groundwater Ecology textbook. They apply specifically to aquatic species and groundwater in unconsolidated sediments, including the hyporheic zone. Yet, they are similar to earlier categories proposed by Schiner (1854) and Racovitza (1907) for the subterranean environment in general. Gibert et al. (1994b) recognized three top categories, two of them are further subdivided into subcategories. Stygoxenes have no affinities with groundwater: they occur accidentally in groundwater. For example, black fly insect Larvae (Simulidae) can be passively transported into caves. Stygophiles comprise three subcategories of species that all have higher affinities for the groundwater environment than do stygoxenes. The occasional hyporheos are essentially insects whose early instar larvae can reside in the hyporheic zone, whereas later life stages occur in the surface stream. Amphibite species have a life cycle that necessitates both a groundwater and surface water stage. The stonefly *Isocapnia* spends all its larval stage in deep layers of the hyporheic zone before dispersing to surface stream and emerging as mating adults (Stanford and Gaufin, 1974). The permanent hyporheos comprises species with no aerial stage, including nematodes, oligochaete worms, crustaceans and tardigrades that can complete their entire life cycle either in surface water or in groundwater. The last category, the stygobites (or stygobionts) are obligate groundwater species that complete their life cycle exclusively in groundwater. Gibert et al. (1994b) further distinguished between phreatobite (phreatobiont) species that are restricted to the deep strata of alluvial aquifers and ubiquitous stygobiont species that occur in a large variety of groundwater habitats.

In an article to be published in the second edition of the Groundwater Ecology textbook, Culver et al. (in press) argumentatively questioned the need and justification for such an elaborated classification and terminology of groundwater metazoans. Their argument is twofold. First, the terminology is meaningless to most non-subterranean biologists, whereas many terms have equivalence in the general ecological literature. Instead, they propose to use the more general terms of specialist and generalist species. Specialist groundwater species have a strict dependence on groundwater because they complete their entire life cycle exclusively in groundwater (stygobites) or because they necessarily complete a part of their life cycle there (amphibites). Generalist species exploit a wide range of resources that they can draw from both groundwater and surface water (occasional and permanent hyporheos), and trogloxenes can be referred to as surface water specialist species. Second, the terminology derives from the idea that the composition of groundwater communities shows a distinct zonation with predictable changes in the relative proportion of the different categories of species with distance to the surface environment. Yet, studies conducted in different surface water—groundwater transition zones (ecotones), including springs (Plenet et al., 1992), sinking karst rivers (Vervier, 1990) and the hyporheic zone (Peralta-Maraver et al., 2018) showed that zonation of groundwater communities, when it exists at all, are temporary and strongly influenced by the intensity and direction of water fluxes between surface and groundwater environments. Hence, groundwater specialists may occur in the upper sediment layers of the streambed in areas of groundwater upwelling, whereas generalists may occur at greater depths into the streambed in areas of strong surface water downwelling. Compositional shifts in

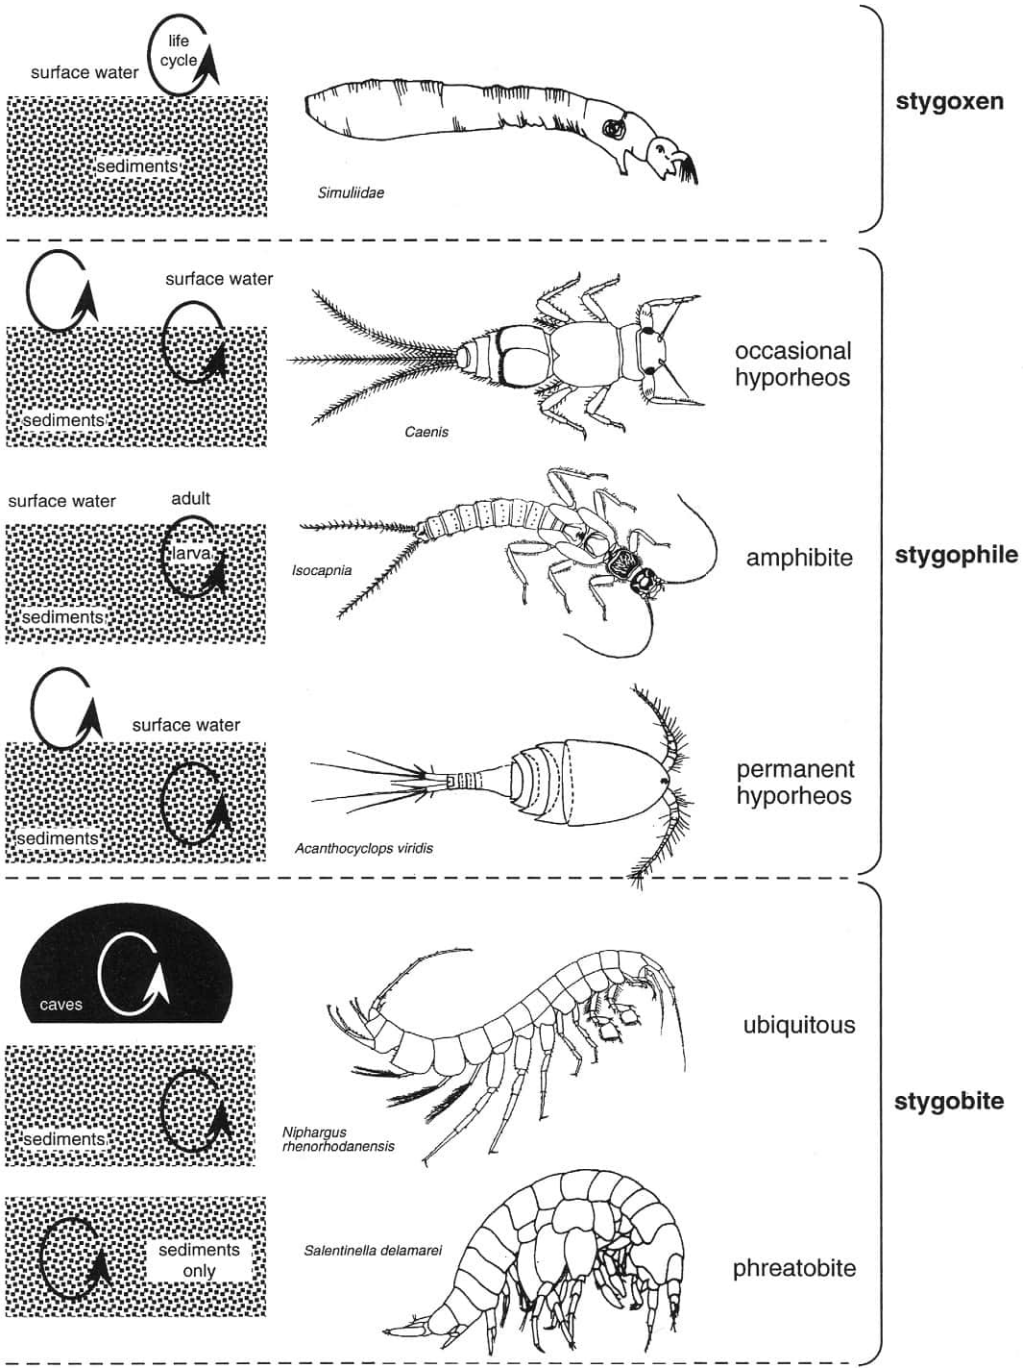

Fig. 2 A classification of metazoans based on their extent of dependence on groundwater. From Gibert J, Stanford JA, Dole-Olivier M-J, and Ward JV (1994) Basic attributes of groundwater ecosystems and prospects for research. In: Gibert J, Danielopol DL, and Stanford JA (eds.) *Groundwater Ecology*, pp. 7–40. San Diego, USA: Academic Press.

groundwater communities are also influenced by biotic factors. In their clinal model of interstitial communities, Brunke and Gonser (1999) proposed that the colonization of deep groundwater by generalist taxa was limited by the availability of organic matter, whereas the colonization of shallow groundwater by obligate groundwater species was restricted by interference competition with generalists. There may also be substantial variation in the habitats occupied by different populations within the same species. Eme et al. (2014) found that populations of the eyeless and depigmented isopod *Proasellus valdensis* were restricted to subterranean habitats of low elevation, whereas they formed dense populations in surface aquatic bryophytes extending several meters downstream of high-elevation Alpine springs.

How many species are there?

Estimates of the number of specialist groundwater metazoan species at global to continental scales are scarce. The faunistic, distributional and ecological synthesis of the World fauna inhabiting subterranean waters published by Botosaneanu (1986) contained more than 5500 species of metazoans. From the synthesis of the European PASCALIS research project, Deharveng et al. (2009) enumerated 1047 specialist groundwater metazoan species in western-central Europe (Belgium, France, Italy, Portugal, Slovenia and Spain). A total of 1570 obligate groundwater crustacean species are known from Europe (Zagmajster et al., 2014). Groundwater metazoans are dominated by crustaceans (Fig. 3; Dole-Olivier et al., 2015): they represent more than 70% of species known in western-central Europe, followed by mollusks (16%) and oligochaete worms (6.1%) (Deharveng et al., 2009). Stoch and Galassi (2010) showed that the number of obligate groundwater crustaceans in Europe exceeded the number of surface-dwelling crustacean species, even though their description lagged behind that of surface species (Fig. 4). Many groundwater crustacean taxa are either phylogenetic relicts (i.e., they have no close living relatives) or distributional relicts (i.e., relatives are in disjunct geographical areas) (Humphreys, 2000).

Species numbers provided above are underestimations of the true number of species for three reasons. First, a small fraction of the Earth's groundwater has been sampled. Second, even in highly sampled regions, species accumulation curves never reach saturation because of the high proportion of species with extremely narrow ranges (Dole-Olivier et al., 2009b). Third, molecular delimitation of species indicates many species are overlooked by traditional morphological taxonomy. In a Europe-wide study of groundwater niphargid amphipods and asellid isopods, Eme et al. (2018) found that molecular delimitation provided putatively 2.5 times more species than morphological delimitation. Breakthroughs in molecular methods can considerably speed up the inventory of groundwater species. Species molecular inventory has simultaneously shifted from the sampling of specimens to that of environmental DNA (eDNA) and to the identification of a single organism (barcoding) to the simultaneous identification of a whole community (metabarcoding) (Niemiller et al., 2018; West et al., 2020).

Explaining the richness of groundwater species within clades

Here, we briefly draw the reader's attention to the inherent difficulty of disentangling the relative influence of processes that influence the number of extant obligate groundwater species within a clade. That number directly depends on the addition of species through speciation and their subtraction through extinction over time (Scholl and Wiens, 2016). Extinction of groundwater

species is difficult to quantify in the absence of fossil records. It may be high because of the narrow ranges of many species (Hugueny et al., 2011) or low because of the environmental stability of deep groundwater layers (Mammola et al., 2018) and it is expected to vary strongly across regions (Zagmajster et al., 2014). Speciation events that can contribute to the addition of species are of two types. The first is that of a speciation occurring during the transition of a surface ancestor to groundwater. The second is that of a speciation caused by the divergence of populations of an obligate groundwater species. Ecological and/or non-ecological processes may drive both types of speciation (Van Bocxlaer, 2017). The difficulty is that the two types of speciation cannot be distinguished by phylogeny alone (Trontelj, 2019), unless molecular markers can be used to pinpoint when transitions from surface water to groundwater occurred along branches of a phylogeny (see e.g., Lefébure et al., 2017). Until these markers or any other alternative approaches are available and robust, the relative contribution of transition from surface to groundwater life and groundwater speciation events to groundwater species diversification cannot be quantified.

Geographic distribution patterns and their explanations

Species richness

Attempts to document global patterns of species richness of obligate groundwater metazoans are few. Culver and Pipan (2013) mapped the worldwide distribution of biodiversity hotspots, defined as sites containing more than 25 obligate groundwater species (see also Pipan et al., 2020). Zagmajster et al. (2018) mapped the number of obligate groundwater crustacean species per country (corrected for country area). Both studies indicated species richness was highest in temperate regions, not in the tropics. The reasons for this unusual pattern are unclear: the tropics are undersampled or some factors limit biodiversity at upper bounds of productivity.

Continental patterns of groundwater crustacean species richness are well documented for Europe (Deharveng et al., 2009; Eme et al., 2015). When mapped using 10,000 km^2 grid cells, species richness of crustaceans peaks at mid latitudes ranging from ca 42° to 46°N. At these latitudes, the combined beneficial effects of a high surface productivity and high groundwater habitat heterogeneity on groundwater species richness are not counteracted by cold (northern Europe) or arid (southern Europe) historical events (Eme et al., 2015). Mapping of biodiversity hotspots of groundwater harpacticoid crustaceans in Europe using a multi-metric approach also revealed the important roles of historical factors and habitat heterogeneity (Iannella et al., 2020).

Range size

Groundwater obligate species often exhibit a small range size, some being restricted to a single aquifer. Yet, range sizes show large geographic variation. In Europe, Zagmajster et al. (2014) showed that the median range size of groundwater crustacean assemblages increased markedly with latitude above a latitudinal threshold of 43°N (Fig. 5). They demonstrated that this pattern was best accounted for by the effect of temperature anomaly—the difference in mean annual temperature between the present and the last glacial maximum—which was used as a surrogate for long-term climatic variability. Three non-mutually exclusive explanations were proposed to explain why species showed larger ranges in northern regions of high historic climate variability. These are a disproportionate extinction of small-range taxa, a stronger selection for generalism and vagility, and colonization of vacant habitats by species showing high dispersal ability following cold periods (Zagmajster et al., 2014).

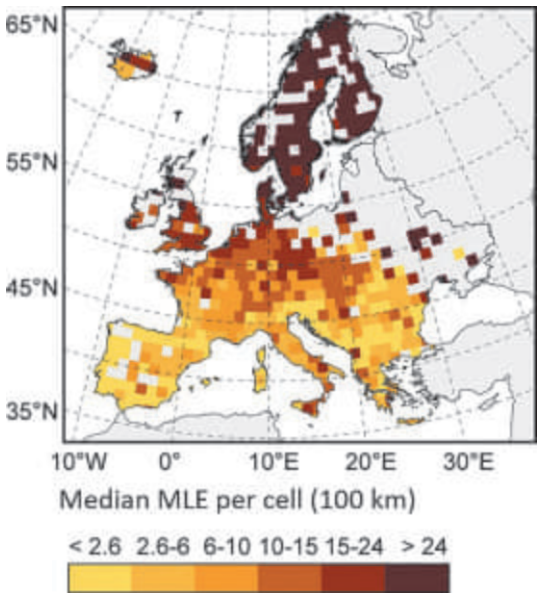

Fig. 5 Geographic distribution of median range size of obligate groundwater crustacean species in Europe. The maximum linear extent (MLE) is the straight-line distance between the two most distant known localities of a species. Grid cell area is 10,000 km^2. From Zagmajster M, Eme D, Fišer C, Galassi D, Marmonier P, Stoch F, Cornu JF, and Malard F (2014) Geographic variation in range size and beta diversity of groundwater crustaceans: Insights from habitats with low thermal seasonality. *Global Ecology and Biogeography* 23: 1135–1145.

Community composition

A striking feature of groundwater metazoan communities is their high spatial turnover. Species composition differs markedly among aquifers within a region as well as among regions within a continent. In Europe, Malard et al. (2009) showed that dissimilarity in species composition between karst aquifers and unconsolidated sediment aquifers of six European regions increased with increasing regional species richness. Dissimilarity among karst aquifers increased with regional species richness but there was no significant relationship for unconsolidated porous aquifers. Zagmajster et al. (2014) found that spatial turnover in species composition among regions increased with decreasing latitude. A number of explanations were put forward to explain these patterns. First, high species turnover in species-rich regions that have experienced a long historically stable environment reflects the addition of species over time and short dispersal from their place of origin. Second, competition among species may promote habitat specialization and reduction in species range. Third, lower hydrological connectivity among karst aquifers than among unconsolidated porous aquifers reduces dispersal.

Species traits

Describing and explaining the phenotypes of groundwater species, including morphological, behavioral, life history and physiological traits, would warrant a full chapter. Here, information is restricted to the description of two contrasted, yet non-mutually exclusive, views of trait variation among groundwater species. An organism's lifetime reproductive output depends on a number of components including fecundity, mating success and survival (Pincheira-Donoso and Hunt, 2017). Environmental selective pressures induce changes in phenotypic traits that influence each of these components of fitness. Of course, interactions do occur among these components, known as trade-offs (Stearns, 1992): a large body size female can produce more or larger eggs (fecundity increases), but the probability that it is caught by predator may increase (survival rate decreases).

An historical view of groundwater species traits is that of convergence by which distantly related species show similar phenotypes because of a convergent selective environment that includes no light, reduced food availability and low environmental variability (Culver and Pipan, 2015). This hypothesis referred to as the troglomorphic syndrome (Christiansen, 1962, 2012) was originally formulated for morphological traits but it was then extended to physiological and life history traits. Reduced eyes, loss of pigment and development of non-visual sensory systems occur in almost all groundwater obligate metazoans. Loss-of-function mutations under conditions of relaxed selection for pigmentation and light detection caused loss of pigment and visual photoreceptors in species as different as groundwater diving beetles (Leys et al., 2005), cave fish (Protas et al., 2006; Niemiller et al., 2013), cave planthoppers (Bilandzija et al., 2012) and asellid crustaceans (Lefébure et al., 2017). In the Mexican cave fish *Astyanax mexicanus*, the same pleiotropic genes control the reduction of eyes and development of non-visual sensory receptors such as the number of taste

buds (Yamamoto et al., 2009) and the number of superficial neuromasts within the cavefish eye orbit (Yoshizawa et al., 2012). A physiological trait that is supposedly common among specialist groundwater metazoans is their capacity to withstand starvation and hypoxia (Hervant and Malard, 2019). That capacity results from a combination of traits including a high-energy reserve (mainly lipid stores), low energetic requirements, and a depressed locomotory and metabolic activity during stress (Hervant and Renault, 2002). The troglomorphic syndrome hypothesis also predicts that specialist groundwater metazoans show *k*-selected life history strategies, which include maturity at older ages, slower growth rate, longer life span, fewer but larger eggs per reproductive event, and a higher or more irregular number of reproductive events per lifetime than their surface relatives (Fišer, 2019). However, data on physiological and life history traits of groundwater metazoans are few, concern a limited number of model taxa, and are from inter-specific comparative studies of groundwater and surface water species that do not account for phylogenetic relationships among taxa (Fišer, 2019).

Another more recent and potentially more realistic view emphasizes the non-uniform and hence divergent evolution of species traits among specialist groundwater metazoans (Culver and Pipan, 2015). Konec et al. (2015) examined morphological changes in two surface-subterranean population pairs of the isopod *Asellus aquaticus* and found that only 18 traits of 63 evolved convergently. There are at least two reasons why divergence may be common. First, the only selective pressure that acts repeatedly across all subterranean habitats is the absence of light. This important pressure may have cascading effects: prey may develop characteristic morphologies to escape predators, which rely on non-visual receptors for foraging. However, many other selective pressures including the size of voids, water current, temperature seasonality, and the availability of food and DO can vary markedly among groundwater habitats. Accordingly, a number of traits including body size and appendage length (Trontelj et al., 2012; Delić et al., 2016; Pipan and Culver, 2017), thermal tolerance (Mermillod-Blondin et al., 2013), resistance to starvation (Salin et al., 2010), and metabolic rate (Simčič and Sket, 2019) vary markedly among groundwater metazoans. However, identifying the combination of environmental pressures responsible for these variations has remained a difficult task. Second, a particular selective pressure may imply different responses in terms of trait evolution. The loss of eyes may be compensated by an increase in the size of sensory organs (e.g., antennae), the number of sensory units or a change in locomotory behavior leading to an improved food finding ability.

Functional roles of metazoans

Indirect and direct effects of metazoans

The potentially important role of organisms in maintaining hydraulic attributes of sediments and ecosystem processes in the hyporheic zone and shallow alluvial groundwater have been the subject of several reviews (Boulton, 2000; Boulton et al., 2008; Marmonier et al., 2012). Metazoans act as ecosystem engineers: they modify the habitats of microorganisms through their bioturbation and biodeposition activities. By building and irrigating biogenic structures such as tubes and burrows, they modify the movement of water (Hose and Stumpp, 2019), and they increase the fluxes of nutrients and DO available to microorganisms (Navel et al., 2012). Metazoans also expel fecal pellets and pseudofeces that inoculate the sediment with bacteria and serve as organic-matter rich substrates for microbial colonization and exploitation. Grazing of biofilm by metazoans promotes the turnover of microbial communities, thereby potentially stimulating their productivity and respiration activity (Boulton et al., 2008). Mermillod-Blondin (2011) proposed that the influence of metazoans on ecosystems processes in sediment was controlled by the interaction between functional species traits and interstitial flow rate (Fig. 6). They emphasized five species traits of importance for determining the significance of bioturbation and biodeposition: sediment mixing rate, burrowing depth, the type of biogenic structures (tubes and burrows), bioirrigation rate and biodeposition rate. They further proposed that the effects of bioturbators and biodepositors on sediment metabolism would be high in sedimentary habitats with low interstitial water flow rates (diffusion-dominated habitats in Fig. 6), but considerably reduced in habitats with high flow rates (advection-dominated habitats in Fig. 6). Thus, U-shaped tube burrowers and gallery-diffusor invertebrates increase microbial respiration in diffusion-dominated sediments by up to 250%, but only by up to 50% in advection-dominated sediments (Mermillod-Blondin, 2011). Although the proposal in Fig. 6 is essentially for water-sediment interfaces and it has been validated with aquatic surface metazoans such as tubificid worms, chironomid larvae and asellid isopods, it provides a solid conceptual framework for assessing the functional role of specialist groundwater metazoans.

Despite growing recognition of the potentially important role of metazoans in groundwater ecosystems, quantitative studies are still rare, essentially because of the difficulties to breed and manipulate obligate groundwater metazoans in the laboratory. Studies provided equivocal results, potentially reflecting large differences in the role of species and strong density effects. Foulquier et al. (2010) showed that the bioturbation/feeding activity of the amphipod *Niphargus rhenorhodanensis* significantly increased DO removal in the uppermost layers of flow through sediment columns, but it did not affect the number and biomass of bacteria. Microbial production and activity were essentially influenced by fluxes of DOC (bottom-up control) and the feeding rate of *N. rhenorhodanensis* was too low to regulate bacterial biomass (top-down effect). In contrast, the cave isopod *Caecidotea tridentata* was shown to stimulate the abundance and activity of attached bacteria (Edler and Dodds, 1996), and the cave amphipod *Gammarus minus* to reduce the bacterial production on rocks (Cooney and Simon, 2009). Weitowitz et al. (2019) demonstrated that the amphipod *N. fontanus* and isopod *P. cavaticus* increased protozoan abundance in biofilm attached to stone tiles, but they did not affect bacterial abundance. The number of protozoans also increased over time in the presence of the amphipod *N. kochianus* and the effect was more pronounced with high density of amphipods. Hose and Stumpp (2019) showed that even in low numbers,

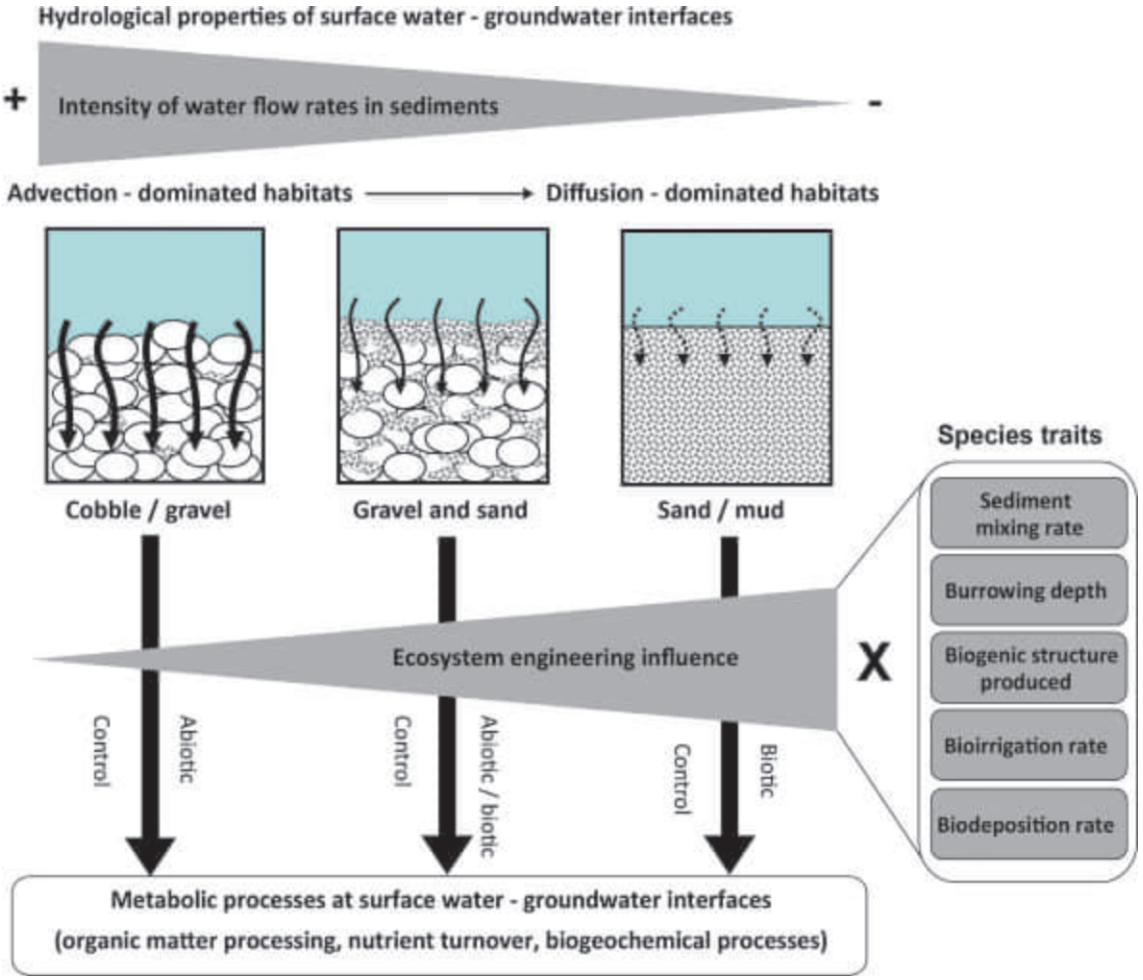

Fig. 6 The intensity of water flow rate in sediments and functional species traits interact to determine the influence of metazoans on metabolic processes. Modified from Mermillod-Blondin F (2011) The functional significance of bioturbation and biodeposition on biogeochemical processes at the water–sediment interface in freshwater and marine ecosystems *Journal of the North American Benthological Society* 30(3): 770–778.

the amphipod *N. inopinatus* maintained the amount of pore space that actively contributed to water flow in sediment columns. Although microcosm experiments provide growing evidence that metazoans influence hydraulic properties of sediment and ecosystem processes that sustain important ecosystem services such as groundwater provision and purification, research is needed to upscale these microcosm observations at the aquifer scale (but see Boulton et al., 2008).

Food webs

Metazoans directly contribute to energy flow through groundwater ecosystems via trophic linkages. Until the 2000s, groundwater food webs were predicted to be relatively simple, having no autotrophs and strict predators, and containing up to two trophic levels predominantly occupied by generalist consumers and omnivores (Gibert and Deharveng, 2002). However, the quantitative investigation of trophic linkages using stable isotope analysis, compound specific isotope analysis on amino acids and DNA metabarcoding of bacteria in the gut of metazoans is offering a new perspective of groundwater food webs (Saccò et al., 2019, 2021). First, groundwater food webs are primarily fueled by microbial biomass but the importance of biomass produced by chemolithoautotrophic bacteria relative to that of heterotrophic bacteria might have been under-estimated (Hutchins et al., 2016; Venarsky et al., 2018). The study by Herrmann et al. (2020) suggested that biomass produced by chemolithoautotrophy represented a rather stable resource that supported complex food webs with several trophic levels in oligotrophic groundwater. Second, François et al. (2016) recently challenged the assumption of generalist feeding by demonstrating that some cave isopod species showed a strong trophic specialization on sedimentary biofilm, a resource that is both abundant and stable in caves. Third, feeding sources appear to vary both among and within species with the abundance of resources in the environment. Francois et al. (2020) showed that asellid isopods, among which there are a number of obligate groundwater species, fed more selectively when the availability of

resources in the environment was high. Saccò et al. (2021) showed that high rainfall periods triggered a trophic cascade effect: increased input of organic matter led to proliferation of microbial biofilm that was grazed by primary and secondary consumers (copepods and amphipods), which constituted the prey of top predators (larvae and adults of beetles). Fourth, groundwater food chains are longer than previously thought because they contain four or even five trophic levels and include strict predators in the most species-rich aquifers (Hutchins et al., 2016; Premate et al., 2021).

Conclusion/outlook

Groundwaters contain diverse assemblages of metazoans that represent an important yet underestimated component of the Earth's freshwater biodiversity (Deharveng et al., 2009). The characteristic traits of obligate groundwater metazoans are sources of unexpected scientific discoveries that have wide theoretical and applied implications (Griebler et al., 2014; Mammola et al., 2020). Metazoans play a potentially important, albeit insufficiently documented role, in maintaining goods and services delivered by groundwater ecosystems to humankind (Boulton et al., 2008; Griebler and Avramov, 2015). Yet, they are neither recognized as conservation priorities, nor integrated into management policies of groundwater resources (Mammola et al., 2019). In Europe, the assessment of groundwater resources is still exclusively based upon criteria of water quality and aquifer productivity, whereas that of surface water bodies is largely based upon the concept of ecological status. This discrepancy has persisted since the 2006 iteration of the European groundwater directive, even though methods have been developed for assessing the health of groundwater ecosystems (Korbel and Hose, 2017), estimating the risk that groundwater alterations may pose to metazoans (Strona et al., 2019) and defining conservation priorities for groundwater metazoan communities (Michel et al., 2009; Asmyhr et al., 2014). Methods relying on metazoans are diverse, using either the composition of local metazoan communities (Korbel and Hose, 2017), exposure of sentinel organisms (Marmonier et al., 2018), or toxicity tests (Di Lorenzo et al., 2019; Castaño-Sánchez et al., 2021). Given the high diversity, important role and bioindicator value of groundwater metazoans, there would be substantial benefits in fully integrating them into conservation planning, monitoring practices, and assessment schemes for groundwater in the future.

Knowledge gaps

- The groundwater metazoan fauna is yet to be surveyed in many regions of the World: molecular methods for sampling, identifying and delimiting species can significantly contribute to fill knowledge gaps on the diversity and geographic distribution of groundwater metazoans.
- Comparative studies of surface and groundwater metazoans are key for understanding eco-evolutionary shifts during transition to novel habitats. This understanding has long been from comparisons of cave and surface dwelling populations. Phylogenetic comparative analyses of clades containing multiple surface and groundwater species are needed to consider evolutionary processes taking place over time periods longer than the lifespan of natural populations.
- Studies of species traits, including morphological, behavioral, physiological, and life-history traits, are crucial to understand how variation in selection pressures within groundwater shape the diversity of phenotypes. A next important step is linking phenotypes to the role of organisms in ecosystem processes.
- In functional ecology, a significant research effort is urgently needed to understand the links between the diversity of metazoans, their role in groundwater ecosystems, and the services these ecosystems deliver to humans.
- We lack knowledge about the tolerance of groundwater species to abiotic conditions, including temperature and toxicants. Acquiring such knowledge is important to forecast biodiversity change in response to global warming and developing environmental risk assessment of pollutants in groundwater.
- Scientific knowledge on the diversity and function of groundwater metazoans does not yet translate into policies that frame the characterization, management and assessment of groundwater. Solutions should be found for implementing the knowledge of groundwater biodiversity into management strategies for assessing the health of groundwater ecosystems and their capacity to deliver important ecosystem services.

Springs—Groundwater-Borne Ecotones—A Typology, with an Overview on the Diversity of Photoautotrophs in Springs

Marco Cantonati, MUSE—Museo delle Scienze, Research & Collections Department (Limnology & Phycology), Trento, Italy; Department of Biological, Geological and Environmental Sciences, Alma Mater Studiorum, University of Bologna, Bologna, Italy

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Aquifer hydrostructure System of relationships between three-dimensional hydrogeological complexes, homogeneous within them, identified by the ways in which water circulation happens, and by the limits that separate them from adjacent complexes.
Crenobiont or Spring-dependent species Species well adapted, and confined, to springs.
Crenophile Species that live in springs, but not exclusively.
Cyanotoxin Secondary metabolite produced by cyanobacteria, of varied chemical nature and toxic effects.
Diazotrophic Diazotrophs are bacteria, cyanobacteria, and archaea that fix atmospheric nitrogen gas into a more usable form such as ammonia.
Euaerial Taxa colonizing habitats that receive moisture solely from the atmosphere.
Gushet Spring type, refers to a waterfall pouring out of a cliff.
Heterocyte A specialized nitrogen-fixing cell formed by some filamentous cyanobacteria.
Hydroperiod Length of time and portion of the year a waterbody holds water.
Hypocrene Spring type: groundwater doesn't reach the surface and is only recognizable by vegetation.
Invertebrates Animals without backbones.
Karst spring or Karstic spring Spring that is part of a karst hydrological system.
Karst Landform produced by the dissolution of soluble rocks such as limestone, dolomite, and gypsum. It typically has underground drainage systems with sinkholes and caves.
Phanerogams Seed plants.
Piston flow In hydrogeology, conditions under which any given water front would advance uniformly downwards to the aquifer, with the same velocity and negligible dispersion and mixing.
Pseudaerial Taxa thriving on rocks or other substrata moistened by a steady source of water, such as springs and waterfall spray.
Refugium An area in which a population of organisms can survive through a period of unfavorable conditions.
Rheophilic Organism preferring or living in flowing water.
Spring Concentrated point of outflow of groundwater.

Springs as habitats, ecosystems, multiple ecotones

By definition, a spring is a discrete site where groundwater emerges to the Earth's surface (e.g., Scarsbrook et al., 2007; Glazier, 2009), with its characteristics (e.g., hydroperiod) determined by the hydrogeological features of the parent aquifer (Van der Kamp, 1995).

Springs are widely recognized as important **habitats** (Cantonati et al., 2012a, 2015), and biodiversity hotspots (e.g., Taxböck et al., 2017; Cartwright et al., 2020; Pascual et al., 2020). More precisely, individual sites can be species rich or species poor (α-diversity) while diversity at the landscape level (γ-diversity, regional pool of diversity) is typically high (Cantonati et al., 2020a). When examined at the regional scale, springs harbor a very high total number of taxa, including several new species, and many Red-List taxa (Cantonati et al., 2012a, 2021). This pattern indicates that there is a high species turnover among springs, as well as

high distinctness of individual spring systems. This high regional species richness is generally linked to the variety of geological conditions (geodiversity, namely lithotypes and aquifer hydrostructure), which lead to wide variation in the hydrochemistry, especially in conductivity and pH. In addition, chemical conditions can be altered by agricultural and industrial activities, especially in the lowlands, resulting in nutrient enrichment and other forms of pollution. High geological diversity translates into high spring ecomorphological and hydrochemical diversity, which in turn, is reflected in high γ-biodiversity (Cantonati et al., 2020a). An applied consequence of the highly individualistic nature of springs, is that it is imperative to protect entire regional groups of springs, including representatives of the different ecomorphological spring types, lithologies, and degrees of human influence (Cantonati et al., 2020a). Springs also host many sensitive, rare, threatened, Red List relict, and exclusive species. Some springs, particularly desert springs, frequently support a rich collection of endemic flora and fauna (Rossini et al., 2018; Fahey et al., 2019). Spring snails are the poster child of endangered, highly stenotopic, spring endemic species, e.g.: 11 species of *Floridobia* silt snails in Florida, as well as hundreds of highly endemic truncatelloidean springsnails globally (Hershler et al., 2014; Cantonati et al., 2020b). Aquatic ecologists recognized springs as distinct habitats with unique biotas deserving their own discipline ("crenobiology") almost 60 years ago (Illies and Botosaneanu, 1963). The habitats of springs are heterogeneous both within, the mosaic of microhabitats recognized already by Illies and Botosaneanu (1963), and among sites. Stevens et al. (2020a) pointed out that large springs can include up to a dozen of different microhabitats, each with its own array of species and more or less interacting, but in any case strongly contributing to the way in which diversity builds up in springs. Taxböck et al. (2020), working on the diatom communities of Swiss springs, could show that diatom species richness increases with microhabitat complexity within springs and elevation. Some springs are extremely isolated (a typical example are artesian springs generating desert oases) and individualistic freshwater habitats, whereas many others (e.g., permanent flowing springs with medium to high discharge) are well connected to a surface system of running waters. Acknowledging this isolated nature, springs in general have been considered island-like, "azonal" habitats (e.g., Cantonati et al., 2012a). However, there are also many examples of well-connected springs. Cantonati et al. (2010), for instance, discovered a new species of diatoms in the Brenta Dolomites in the south-eastern Alps, and its ecological characterization showed that it is typical of the uppermost part of the headwaters (eucrenal) of streams on carbonate substrata (limestones, dolomite, etc.) while it is replaced by other species downstream. Stevens et al. (2021) underline that connectivity is generally not a positive feature for springs since it favors colonization by non-native invasive species. Many springs contain relict species (including glacial and Tertiary relicts), and provide hospitable refugia for many other taxa (e.g., Taxböck et al., 2017). In highly impacted geographic areas with dense human populations, species sensitive to disturbance (Least-Impaired Habitat Relicts: LIHRe) may be found only in springs, because the quality of other freshwater habitats is no longer sufficient to meet their needs (Cantonati et al., 2012a). In arid landscapes some springs may provide stable hydrologic refugia in drying climates (Cartwright et al., 2020).

Spring environments are very diverse and often extreme with respect to specific ecological factors (e.g., pH, electrolyte content, temperature, etc.). Spring organisms representing many kinds of taxa have thus evolved diverse biochemical, physiological, morphological, behavioral and life-history adaptations (e.g., Cantonati et al., 2015). Some organisms (crenobionts, or springs-dependent taxa according to Stevens et al., 2020b) only live in spring habitats. Gerecke et al. (2017) pointed out that no other group of invertebrates includes a share of species with a particular relationship to spring habitats as high as water mites (Hydrachnidia): in their revision of the European fauna, they found that about one fifth of the species has a preference for spring habitats, and 14% can be reliably classified as crenobiontic. However, the causes of "crenobiosis" are not yet completely understood. Several environmental factors might be important for a better understanding including a constant low temperature (e.g., Glazier, 2012), the existence of a permanently non-frozen area of wet soil around seepage springs (Fischer, 1996), lower levels of competition due to shorter trophic food chains and the sparsity of top predators. Crenophilous species, on the other hand, do not have their distributional center in springs but can reproduce in them. They can be of various origins (e.g., Martin et al., 2015), and, in addition to springs, prefer standing water (lentic crenophiles), streams (rhitrobiontic crenophiles), groundwater (stygobiontic crenophiles), or colonize aquifers and the hyporheic interstitial (stygo- and hyporheobiontic crenophiles). Finally, crenoxenic species have no relation to sources, but appear here as "random guests." However, they can play a dominant role in degraded springs (Gerecke and Di Sabatino, 1996).

Despite their usually small size springs have a high ecological value (e.g., Odum, 1971). They can also be viewed as **ecosystems** (see the conceptual model presented by Stevens et al., 2020a). The term "crenoecology" has been used sporadically in the literature over the last two decades (e.g., Cantonati et al., 2012a). In spite of springs having been the cradle of ecosystem ecology (Odum, 1957), only four large springs have been in-depth investigated from an ecosystem perspective: Silver Springs (e.g., Odum, 1957), Montezuma well (e.g., Blinn, 2008), springs in Yellowstone National Park (e.g., Payne et al., 2019), and Cuatro Ciénegas (e.g., Hendrickson et al., 2008). Permanent springs with stable discharge are excellent sites for long-term ecological research (Gerecke et al., 2011). Springs are unique systems, and their productivity levels may be among the highest worldwide (Odum, 1957; Perla and Stevens, 2008). Many springs are "keystone ecosystems" because they supply an important habitat together with other ecological resources and services for many kinds of organisms that live in them and neighboring terrestrial and downstream ecosystems (Perla and Stevens, 2008; Cartwright et al., 2020). Glazier (2012) pointed out negative nonlinear relationships between food-chain length and temperature as well as between macroinvertebrate species richness and temperature. Both deviated from predictions based upon metabolic theory, and the negative effect of temperature on species richness contrasted with positive relationships observed at larger regional scales. Thermal tolerance limits are likely to play a major role in causing these relationships. Fluxes of resources (water, nutrients, and food sources), i.e., complex multi-directional subsidy exchanges, between groundwater, springs and neighboring habitats are still poorly understood but essential for supporting life and basic ecological functions in these highly connected ecotonal "springscapes" (Reiss and Chifflard, 2017). Barzaghi et al. (2017) showed biomass subsidies (exchanges) between two aquatic ecosystems (cave and spring pools) driven by a biphasic predator, the fire salamander (*Salamandra salamandra*).

Environmental conditions (e.g., water temperature, chemistry and flow rates, resource availability, and substrate type and diversity) strongly influence the productivity, trophic complexity, species composition and diversity of springs, but much work still has to be done to improve our understanding of the ecological structure and functions of springs.

Geothermal springs are model ecosystems to investigate microbial biogeography as they represent discrete, relatively homogenous habitats, which are distributed across multiple geographical scales, encompass broad geochemical gradients, and have limited metazoan interactions (Power et al., 2018). Li and Ma (2019) analysed the microbiome of 165 hot spring samples at the global scale covering wide ranges of temperatures (7.5–99 °C) and pH (3.3–9), and assessed population- and community-level spatial heterogeneities using the quantitative models of Taylor's power law and its extensions. They found that hot-spring microbiomes located in different regions, in spite of different environmental conditions, shared a fundamental heterogeneity scaling parameter, which may vary slightly depending on altitude and latitude but is invariant overall.

A small number of springs, but including several of those best-studied from the functional (ecosystemic) standpoint, are very large, actually resembling lakes, and can themselves be considered ecosystems, with local energy and matter cycles, whereas the large majority of springs are small, and therefore maybe easier to conceptualize as transitional environments (ecotones). However, most of these smaller springs feed groundwater dependent ecosystems (GDE) such as spring-fed headwater streams, lakes, etc. More precisely, when viewed as ecotones, springs should be considered **multiple** (3-way) **ecotones** linking ground- and surface-water, aquatic and terrestrial environments, and the spring-source with the spring-fed stream (spring-brook) (Fig. 1). In some spring types (e.g., seepages) the aquatic-terrestrial ecotone is very developed, and these are thus excellent sites to study the transition from submerged to subaerial.

Springs are mostly small but numerous: according to Glazier (2014), who provides a well-grounded estimate, there are worldwide on land (not counting Antarctica) > 3 springs/10 km^2, which means a global total of >43 Mio springs on Earth (and >7 thermal springs/10,000 km^2, leading to a global total of >100, 000).

Springs also have an enormous societal, cultural, and economic relevance (e.g., Glazier, 2009, 2014; Knight, 2015).

The main aim of this chapter is to review the characteristics and reasons for the uniqueness of springs and how they have been and are classified against a background of the biodiversity of the photoautotrophs, mainly algae, that inhabit them. The effects of increasing anthropogenic stresses, and the current efforts for spring ecology, conservation, and restoration are discussed.

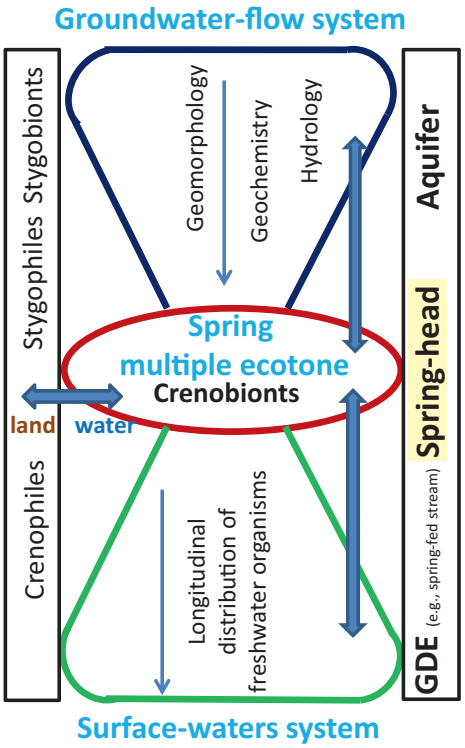

Fig. 1 Hourglass model pointing at the spring environment as a multiple—three ways—ecotone *(double arrows)*. Modified after Cantonati M, Stevens LE, Segadelli S, Springer AE, Goldscheider N, Celico F, Filippini M, Ogata K, Gargini A (2020b) Ecohydrogeology: The interdisciplinary convergence needed to improve the study and stewardship of springs and other groundwater-dependent habitats, biota, and ecosystems. *Ecological Indicators* 110. DOI: 10.1016/j.ecolind.2019.105803.

Springs as the iconic environments of ecohydrogeology

The disciplines of hydrogeology and ecology converge at spring sources, with emphasis on hydrogeology retreating in the post-emergence environment, while emphasis on ecosystem ecology generally increases from the point of emergence into ecotones in the surface environment (Cantonati et al., 2020b). Thus, for hydrogeologists the source is the final point of their targeted interest in the aquifer, while for freshwater ecologists the source is the initial point of interest, from which originating surface water generates a surface groundwater-dependent ecosystem seepage or a flowing channel, associated fens or mires, lakes, as well as lacustrine, palustrine, or fluvial riparian zones (Fig. 2).

Recently, an integration between the interdisciplinary approaches of the Earth's Critical Zone and hydropedology has bridged multiple spatial scales from the individual substratum type to the catchment and landscape (springscapes, Reiss and Chifflard, 2017). Springs represent a water-dominated critical zone at the interface between lithosphere, hydrosphere, and biosphere, but none of these fields of science by itself can fully embrace the phenomenology of physical, biological, and cultural interactions over time that constitute a spring ecosystem. On the geological side of spring research, hydrogeology is multidisciplinary among earth sciences and hydrological sciences, whereas ecosystem ecology is also multidisciplinary but emphasizes a strongly differing lexicon, suite of concepts, variables, and study approaches (Cantonati et al., 2020b).

Spring-ecosystem ecohydrogeology has been insufficiently studied by the scientific, and insufficiently recognized as worth of protection by the public and the management/governance communities.

"*Tales sunt aquae quales terrae per quas fluunt*" Pliny the Elder, *Naturalis historia*, 74 D.C. This statement ("Waters take on the properties of the rocks through which they pass"), which now constitutes the First law of Hydrogeochemistry, dates back almost 2100 years and yet is fully modern and topical. The physical and chemical characteristics of the water are indeed determined by the geological settings and regional climate features in pristine environments, and are modified by the indirect and direct impacts of human activity elsewhere (compare with Fig. 1 where the environmental influences and impacts on the aquifer-spring-surface-water system were not explicitly shown for the sake of clarity and simplicity). These interactions directly influence algal, macrophyte, invertebrate, and vertebrate spring biodiversity and assemblage structure.

The water demands of approximately one quarter of global human population are met using groundwater obtained from karst aquifers (Ford and Williams, 2007). The huge practical relevance of karst aquifers fostered, among other initiatives, the World Karst Aquifer Mapping (WOKAM) project (Chen et al., 2017). WOKAM succeeded in generating a world map and data-base of karst aquifers, also including selected karst springs and caves, acknowledging that karst springs are the "entrance" to karst conduits and

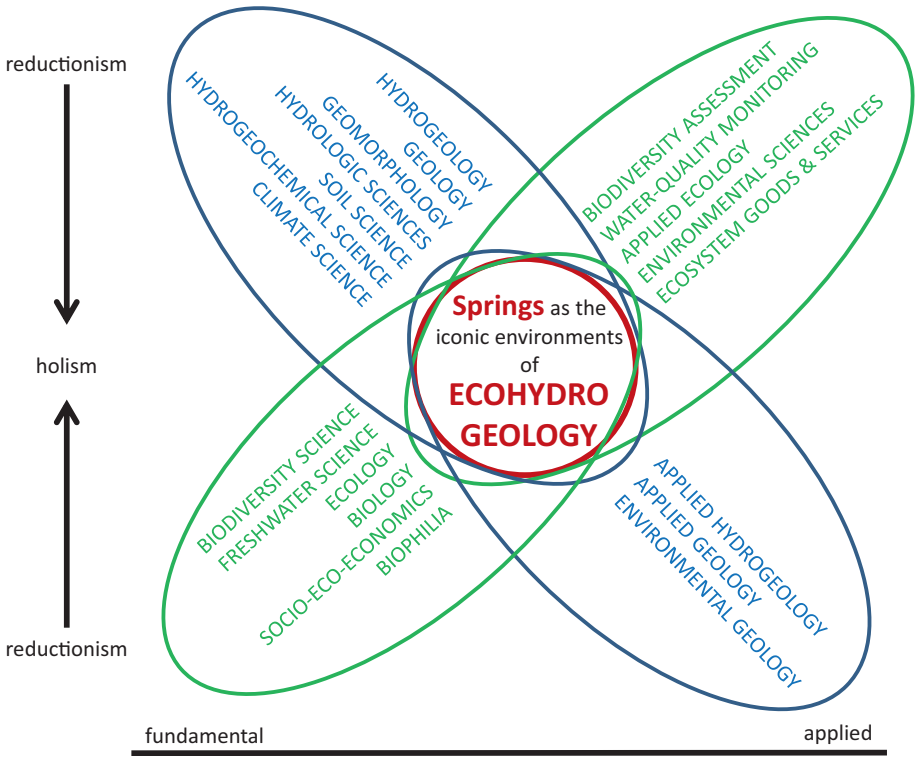

Fig. 2 The scientific domain of the unifying, integrative, multi-disciplinary field of ecohydrogeology. Modified after Cantonati M, Stevens LE, Segadelli S, Springer AE, Goldscheider N, Celico F, Filippini M, Ogata K, Gargini A (2020b) Ecohydrogeology: The interdisciplinary convergence needed to improve the study and stewardship of springs and other groundwater-dependent habitats, biota, and ecosystems. *Ecological Indicators* 110. DOI: 10.1016/j.ecolind.2019.105803.

caves. Cantonati et al. (2020b) used this as an example of the importance of interdisciplinary collaboration to improve understanding and management of karst ecohydrogeology.

Our knowledge on how the geological history of an environment shapes its physical and chemical properties and how these, in turn, influence community assembly is still limited. However, Payne et al. (2019), in a study of a moderately acidic hot spring (pH 5.6, 77.4 °C) in Yellowstone National Park, showed that geologic legacy (seismic activity) influences community assembly of archaeal-dominated and anaerobic microbial assemblages.

Sugiyama et al. (2018) determined signatures of direct impacts of rainfall on groundwater, using microbial, stable isotopic $\delta^{18}O$, and chemical analyses (silica concentration) to clarify the route of groundwater in systems at Mt. Fuji, Japan. Their findings indicated a rapid flow of rain through the shallow part of the aquifer, which appeared within a few weeks of torrential rain extracting abundant microbes from soil. Archaea were considered to be embedded in the geologic layer and to have been extracted to the examined groundwater by means of enforced piston flow caused by heavy rain.

On a similar note, Cantonati et al. (2020b) report the compelling correspondence between main precipitation peaks, flow-rate increases, and occurrences of depigmented, stygobiontic niphargid amphipods in basal springs. They hypothesized that the direct link between increased stygobiontic niphargid amphipods occurrences and electric conductivity values is due to enhanced spring flow rates, mainly caused by the arrival in the feeding aquifer of newly infiltrated waters with the consequent sudden increase in the hydraulic load. This abrupt increment and the subsequent pressure wave likely favor the mobilization of large volumes of deeper and more mineralized waters, along with the displacement of the hypogean organisms that live in the immediate vicinity of the spring.

Springs classification

The focus of this chapter is on land-surface springs but there are also springs emerging underwater in rivers, lakes (e.g., Ólafsdóttir et al., 2019), and oceans (Post et al., 2013).

The broad array of proposed classifications is generally related to "natural conditions," not to springs that have been diverted for human use or created by anthropogenic activities. However, the majority of springs in many landscapes have been dominated by human activities for millennia (e.g., Haynes, 2008 in North America; Cuthbert and Ashley, 2014 in the Old World), and are today partially or fully diverted, ecologically impaired, or obliterated (e.g., Stevens et al., 2021). Also, all spring types can be created or altered by human actions (e.g., Stevens et al., 2020a), with wells and fountains being the "artificial" counterparts of the springs found in nature.

Springs are usually regarded as very stable environments, but this applies only to some spring types, whereas in others (e.g., many karst springs), fluctuation of environmental factors/disturbance can be very high (e.g., Cantonati et al., 2012a).

Besides present-day, extant springs, paleosprings might be recognized as springs of the distant past but that no longer flow, and are identified from geologic or paleontological evidence (e.g., paleo deposits of spring-associated limestones). Paleosprings may contain important paleoclimate and archeological archives (Stevens et al., 2020a).

The existence of different spring types (from both the hydrologic and chemical points of view) is due to the interaction between different factors, such as (i) aquifer geology and geomorphology, (ii) vegetation and topsoil features, (iii) hydraulic properties of rocks and heterogeneity, (iv) groundwater pathways and residence time, (v) thermal gradients, (vi) weather conditions and precipitation regime, etc.

Many classification systems in several disciplines have been developed to define and identify spring types (Fig. 3), and one of the main features is the extreme diversity/heterogeneity of environments included in the definition of springs. Springs can be characterized by different regimes (variation of discharge over time) and cover an extremely wide range of water chemistry, temperature, and environmental settings. Spring types have been classified on the basis of diverse indicators (Alfaro and Wallace, 1994; Kresic, 2010): hydrology (discharge rate, e.g., Meinzer, 1923; recession coefficient, e.g., Gargini et al., 2008), hydrogeology (e.g., Civita, 1973), geology and morphology (e.g., Springer and Stevens, 2009), physical and chemical characteristics (e.g., electrical conductivity, Total Dissolved Solids, e.g., Clarke, 1924), temperature (cool, ambient, i.e., MAAT Mean Annual Air Temperature-, thermal, hot; e.g., Glazier, 2009), flow conditions at the spring head (Thienemann, 1924), and biological characteristics, in particular vegetation (bryophytes + vascular plants; e.g., Ellenberg, 2009) and invertebrate communities (e.g., Gerecke and Di Sabatino, 1996; Schröder et al., 2006; Martin and Brunke, 2012). Furthermore, biota-based spring types can be recognized by using benthic algae forming colorings and/or structures identifiable with the naked eye (Cantonati et al., 2012c), or their diatom microflora (Cantonati et al., 2012b). A comprehensive multi-taxon classification by "Procrustes" analysis showed that each group of organisms provides useful specific spring characters that however are related to other groups only at the level of broad ecological categories (e.g., photoautotrophs, meiofauna, etc.; Spitale et al., 2012). In the United States, 12 spring types were distinguished by geomorphology and recurring species (Springer and Stevens, 2009).

Springs are complex composite hydrogeological and ecological ecosystems and deserve a dedicated classification in order to provide a systematic framework necessary to study them. A variety of classifications have been presented in the literature from the hydrogeological stand-point, as well as from the ecological, crenobiological, and ecosystem services perspectives. These two groups of classifications are very useful and are utilized in an intra-disciplinary fashion by hydrogeologists or ecologists (Cantonati et al., 2020b).

From the hydrogeological standpoint, basic classifications rely simply upon: parent rock geology (lithology, stratigraphy) and structural geology of the groundwater basin; driving force mechanisms (gravity, pressure or density/temperature dominated discharge), groundwater quality including water temperature and/or geochemistry; discharge quantity (magnitude, variability,

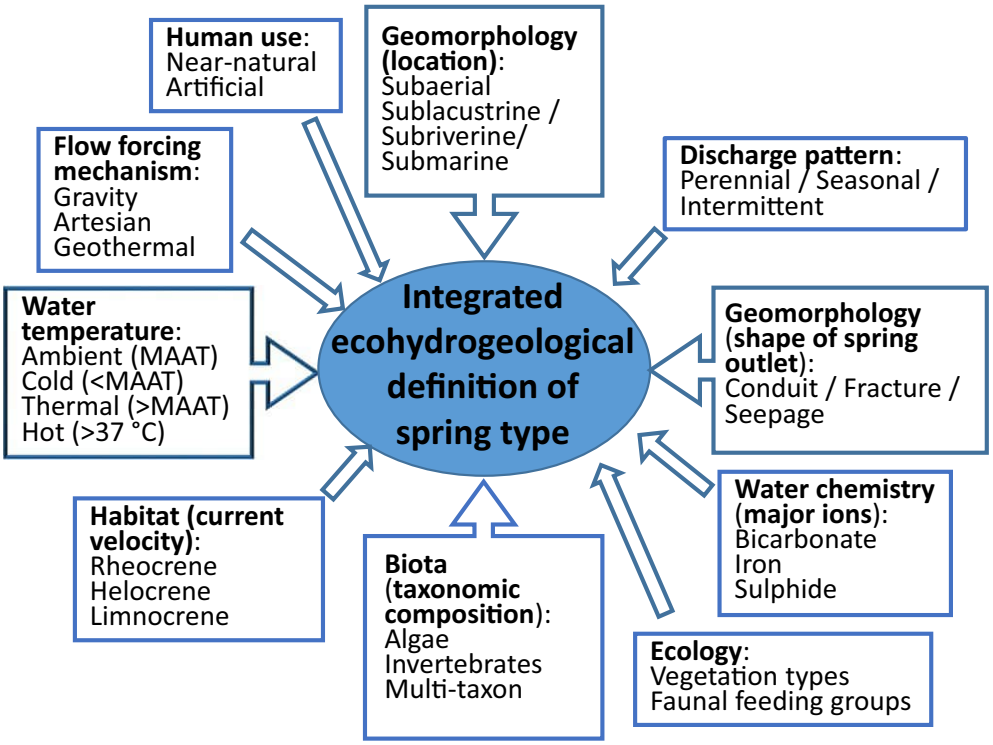

Fig. 3 Schematic diagram synthesizing spring classification approaches.

and recession); or the geomorphology of the discharge point of the spring (the "sphere of discharge" as landform pattern at the springs source; Meinzer, 1923).

From an ecological and anthropogenic uses perspective, the focus of the classification can be physical and/or biological, depending on taxonomic composition, and structural or functional parameters of the associated biota and assemblages. Early attempts to identify features determining spring characteristics particularly relevant for the colonizing biota are attributable to Van der Kamp (1995), who demonstrated that the hydrological stability of many springs and springs-associated biota is determined by the hydrogeological features of the parent aquifer.

Meinzer (1923), Alfaro and Wallace (1994), Springer et al. (2008), and Glazier (2009, 2014) review the many springs classification approaches that have been proposed (Springer and Stevens, 2009). There is a growing body of literature revealing a suite of species not only dependent on springs but selective of different spheres of discharge of springs (e.g., Sinclair, 2018).

Glazier (2009, 2014) provided an exemplary recapitulation of classification attempts, with detailed tables with cross-citation of references. Cantonati et al. (2020b) offer a synthetic review of the main classification approaches that have been proposed with a summarizing table, along with examples of references, some of which are collectors of other references. Stevens et al. (2020a) emphasize that of the proposed classification factors, only geomorphology clearly and unambiguously distinguishes spring types, and consequently propose a practical, geomorphology-based classification with a dichotomous key for 13 spring types. Their spring types are based on those identified by Springer and Stevens (2009) but also include paleosprings, differentiate between floodplain and upland subtypes of helocrenic and hillslope springs, and distinguish three subtypes of mound-forming springs. Besides common types discussed in this and the following section, they also deal with more peculiar ones, such as hypocrenes and gushets.

Kinds of springs

A limnological spring type is grounded only on the hydromorphological shape of the source (i.e., the discharge type). This becomes a spring typology when it is accompanied by information on the characteristic colonizing organisms (Martin et al., 2015). Based on preliminary work by Steinmann (1908) and Bornhauser (1913), Steinmann (1915) provided the first detailed definition of the three "classic" spring types according to hydromorphological criteria, the distinction of which is still valid today (they are shown in Fig. 4 using artwork by a German painter):

- **Flowing springs** or **rheocrenes** (German: *Sturzquellen* or *Rheokrenen*) are "characterized by a waterfall-like discharge." "The substratum is coarse, sandy or stony, mostly also poor in plants."

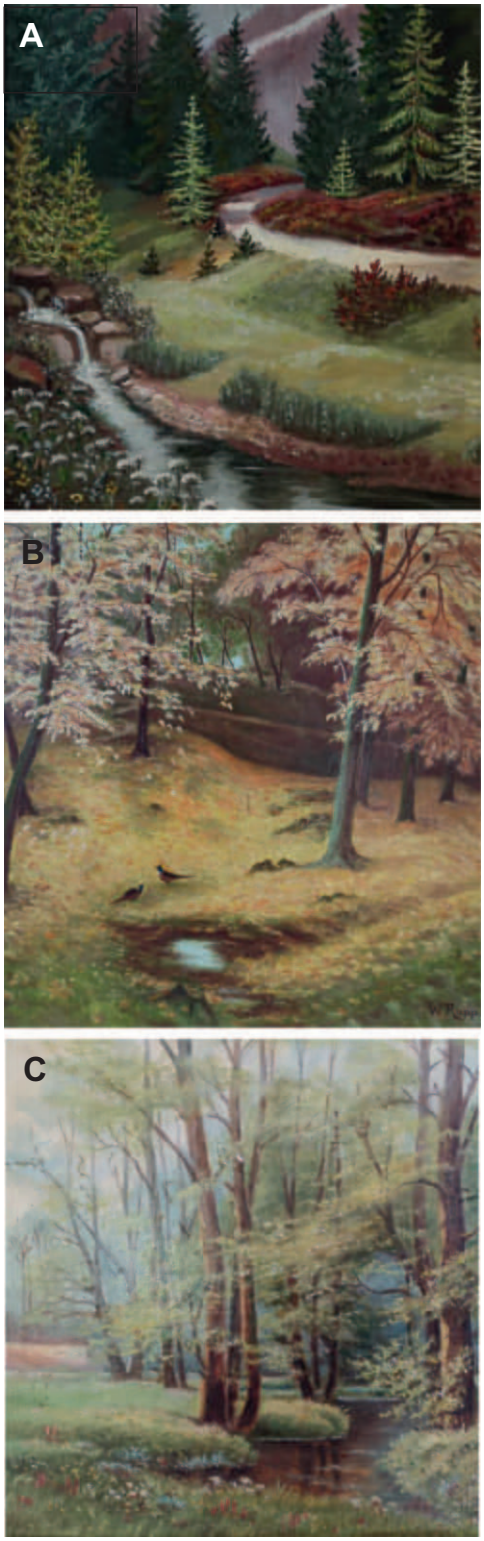

Fig. 4 An artwork representation of the three classic Naumann-Thienemann spring types A. flowing spring/B. seepage/C. pool spring using paintings by Wilhelm Rupp (Leipzig, 1899–1994).

- **Pool springs** or **limnocrenes** (German: *Tümpelquellen* or *Limnokrenen*) are "basin-like springs that are filled with water from below. The spring brook forms by overflow. The limnocrenes usually have a muddy or sandy substratum and sometimes abundant vegetation."
- **Seepages** or **helocrenes** (German: *Sickerquellen* or *Rinnquellen*, known as *Helokrenen* since Thienemann, 1922) are seen by Steinmann (1915) as a transition type between rheo- and limnocrenes, and he notes that these "show pronounced relationships with semi-terrestrial habitats."

Since Thienemann (1924) this division into three types of springs can be found in most textbooks, and has often been used uncritically for spring classification (Martin et al., 2015). More differentiated systems have only recently been developed for regional use (e.g., Howein and Schröder, 2006; Martin and Brunke, 2012). It often turned out to be useful to combine the classic terms for transitional situations (e.g., rheohelocrenes, limnorheocrenes, etc.).

The "linear spring" (German: *Wanderquelle*, Zollhöfer, 1997) represents a special type of spring, the springhead of which is not stable at one point but "migrates" up and down in the spring-brook channel, depending on the groundwater level. Hydromorphologically, these are mostly rheohelocrenes.

Relationships between spring types and settling organisms, i.e., spring typologies, have only recently been developed on the basis of thorough geomorphological descriptions (e.g., Zollhöfer et al., 2000; Howein and Schröder, 2006; Martin and Brunke, 2012), whereby the composition the inorganic substrata and the type of runoff proved to be the most important determinants of the invertebrate communities. Together with the geogenic variables (e.g., conductivity), shading, nutrients (especially nitrates), and elevation were the factors most important for the algae-based characterization of spring types in the Alps (Cantonati et al., 2012b, 2012c). A statistical comparison between the spring types obtained using different groups of organisms (diatoms, bryophytes, vascular plants, nematodes, molluscs, oligochetes, water mites, copepods, ostracods, chironomids, mayflies, stoneflies, and caddisflies) showed that the groupings obtained with the mentioned groups of organisms were different, and that the results obtained with one group of organisms, in particular for nature conservation concerns, cannot be transferred directly to other groups. However, of course there were affinities: the subdivisions of the photoautotrophs, of the meiobenthos groups, and of the EPT (mayflies, stoneflies, and caddisflies) groups were most similar to each other (Spitale et al., 2012). Broad-based, comprehensive biodiversity studies are therefore indispensable for thoroughly scientifically-informed nature conservation at springs.

In order to define targets for restoration measures, the representation of reference springs is of particular importance (Martin et al., 2015). The detailed knowledge required for this purpose of all spring types in a geographic area and their potential natural status is difficult to obtain in the many regions in which most springs have been anthropogenically impaired (Zollhöfer et al., 2000; Martin and Brunke, 2012). Spitale (2007) names as the most important typological parameters: (a) georeferencing, gradient situation and external appearance, (b) shape and area, (c) substrata, (d) discharge, (e) light conditions, (f) buffer zones and disturbances.

Hydrogeologically oriented classification systems (e.g., Schönborn, 2003) differ very much from the limnological typology in that they pay special attention to the characteristics of the groundwater (i.e., flow of the water underground before it reaches the spring-source). Some of the criteria investigated used there are unlikely to deeply influence the biological colonization of the spring. In principle, however, one should keep a close eye on the conditions in the aquifer when developing an ecological/biological regional spring typology, if possible in cooperation with hydrogeologists (Martin et al., 2015). Questions about the length of the time the water has stayed underground (flow path), the fracturing characteristics of the conductive rocks and their geological composition can be very important for understanding spring-dwelling communities (e.g., Van der Kamp, 1995).

Karst springs represent a special type of springs in this respect (Martin et al., 2015), in which water emerges from crevices and large underground cavities in karst areas (e.g., Schönborn, 2003). Since they only discharge as long as the groundwater level is higher than the lower edge of the runoff gap, their discharge is intermittent and difficult to predict, influenced by storms, snowmelt, and seasonal fluctuations in the amount of precipitation. Karstic springs are not only found in limestone mountains (very typical, e.g., in the Swiss-South German Jura) but occasionally (and surprisingly) also in landscapes in which limestone influences aquifers without being visible on the surface. The comparatively rapid groundwater passage, with little exchange with the conductive rock, determines the atypical characteristics of karstic springs (discharge fluctuations, turbidity after rainfall, oxygen content, often anthropogenic pollution), all phenomena that are related to a particular susceptibility to external influences. This also explains the peculiarities of the flora and fauna, which are often characterized by the occurrence of eurythermic running-water species, and occasionally by indicators of increased saprobicity (compare, e.g., Martin and Zaenker, 2007). Some karst springs have achieved real fame due to their exceptionally-high discharge, e.g., Vrelo Bune (Bosnia Herzegovina; with an average discharge of 43 m^3/s, is considered the spring with the largest discharge in Europe; Fig. 5A) (Martin et al., 2015).

The main characteristics of the different kinds of springs will succinctly be recalled in the following using seven "macro-types" (examples shown in Fig. 5):

- **Flowing springs** (**rheocrenes**): Springs are most common in mountainous areas, and rheocrenes are by far the most frequent kind of springs on mountains. Flowing springs can be characterized by swift current already in the spring-head area that degrades in the following spring-fed stream with few immediately-perceptible changes. In these last cases, morphological (e.g., changes in slope), physical and chemical (e.g., longitudinal temperature changes), or biological (e.g., overall bryophyte cover and presence of spring-dwelling invertebrates, such as water mites) criteria must be used to try to delimit the eucrenal (Cantonati et al., 2006, 2007).
- **Hygropetric springs** or **rock-face seepages** (Fig. 5B) are more common on carbonate substratum. Cantonati et al. (2012c) identified the cyanoprokaryotes *Rivularia* spp., *Plectonema tomasinianum*, *Ammatoidea normannii*, *Chamaesiphon minutus* (mainly as an epiphyte of other cyanobacteria), and *Calothrix parietina* as indicator taxa of this spring type. Gesierich and Kofler (2010) noted a large proportion of pseudaerial taxa (e.g., from the genus *Gloeocapsa*) in a carbonate rock-face seepage. Cantonati et al. (1996) found the highest number of cyanobacterial taxa in this spring type, and attributed this finding to the fact that hygropetric springs include transition microhabitats to other biotopes (dripping and wet rock walls).

Fig. 5 Examples of the seven spring macrotypes presented more in detail in this chapter: (A) large flowing spring (Vrelo Bune, karstic spring in Bosnia Herzegovina, photo credit: wikimedia); (B) small flowing spring in the Northern Apennines forming a rock-face seepage (p.c.: Dr. Stefano Segadelli); (C) seepage (helocrene in the south-eastern Alps; p.c.: Dr. Daniel Spitale); (D) large pool spring (Silver Springs, Florida; photo credit: Brad Stith and John Moran); (E) hot spring (Yellowstone; photo credit: David Mark from Pixabay); (F) iron spring in the south-eastern Alps (p.c.: MUSE—Museo delle Scienze); (G) limestone-precipitating spring in the south-eastern Alps (p.c.: Dr. Daniel Spitale); (H) Crescent spring in the Gobi Desert (photo credit: whitewaltz from Pixabay).

- **Seepages (helocrenes**; Fig. 5C): Helocrenic springs are those where groundwater emergence is diffuse and generates wetlands. Dystrophic habitats (seepages, mire pools) were pointed out to be of special importance, not only for the diatom assemblages (e.g., Cantonati et al., 2009a; Cantonati and Lange-Bertalot, 2011) but also for the meiofauna (e.g., Gerecke et al., 2011). Helocrenes are the most species rich habitats both for invertebrates and for diatoms (Gerecke et al., 2011). Spring-fed desert

wetlands, or *ciénegas*, spanning the borders of Arizona (United States) and Sonora in México are regions of high biodiversity in the American deserts. These environments contain an estimated 19% of endangered, threatened and candidate species (Minckley et al., 2013).

- **Pool springs (limnocrenes)**: Limnocrenes have played a very special role in springs science: Silver Springs (Fig. 5D) was the place where ecosystem ecology originated, and Montezuma Well is considered the site with the highest concentration of unique species of any point in North America (Schenk et al., 2018). Springs with a distinct pool at the springhead and an outflowing streamlet are classified as limno-rheocrenes. They are frequent only in specific geographic areas (e.g., Finland; Lehosmaa et al., 2017), and in many cases this special morphology has been accentuated by human alterations such as digging of the pool and/or damming of the outlet.
- **Thermal springs** (Fig. 5E): Recent, continuous progress in technologies (metagenomics, culturomics, high-throughput culturing, comparative genomics, 16S amplicon sequencing, etc.) have opened unprecedented possibilities to the study of spring (and groundwater) microbial communities (e.g., Pedron et al., 2019). This resulted in the overall spring-habitat literature of at least the last decade being dominated by microbiological studies of thermal springs (Cantonati et al. unpublished). Power et al. (2018) measured bacterial and archaeal community composition, 46 physical and chemical variables from 925 New Zealand thermal springs to identify factors that determine biogeographical patterns. They determined that diversity is primarily influenced by pH at temperatures $<70\,^{\circ}C$, with temperature having a significant effect only for values $>70\,^{\circ}C$. Further, community dissimilarity increased with geographic distance, with niche selection driving assembly at a localized scale, with two dominating genera (*Venenivibrio* and *Acidithiobacillus*). Decades of research into geothermal-spring Bacteria and Archaea have generated great insight into the diversity and adaptations to extreme environmental conditions while microbial eukaryotes (protists), which are also ubiquitous in most thermal springs, surprisingly remained understudied. Oliverio et al. (2018) used high-throughput sequencing to study the diversity and structure of microbial eukaryotic communities found in 160 New Zealand geothermal springs. Protistan communities were moderately predictable in composition and varied most strongly across the wide gradients in pH and temperature, and this variation mirrored patterns observed for bacterial and archaeal communities. While extreme pH values were associated with dropping protist diversity, high temperature springs still allowed for substantial amounts of protist diversity.
- **Mineral springs**: Springs that have waters that were enriched in dissolved substances during their underground flow path. They thus possess hard water, that can contain dissolved minerals, salts, sulfur compounds, and gases. Iron springs (Fig. 5F) are characterized by the regular occurrence of iron-oxidizing Proteobacteria (Dyer, 2003) whereas they are frequently very poor in macroscopically visible benthic algae (Cantonati, 2008). Aguilera et al. (2019) described a new fish species of the genus *Jenynsia* (Anablepidae) from a sulphide spring in Northwestern Argentina. Sulphide springs have extreme environmental (toxic and hypoxic) conditions that only few vertebrate species can tolerate. Cantonati et al. (2019) described a new diatom species in the genus *Halamphora* from a large, fast flowing, inland-saline (Triassic gypsum), mineral (chloride, sulphate, sodium, calcium) spring in the Northern Apennines, characterized by very high electric conductivity and slightly alkaline pH. Stepanek and Kociolek (2019) suggest that inland-saline habitats like this are of particular interest because diatom groups, such as *Amphora* and *Halamphora*, that have representatives colonizing smaller inland waters with high conductivity, might have used these waterbodies as potential intermediate habitats from which the colonization of surrounding freshwaters could have taken place. The diversity of mineral springs is amazing and includes for instance:
  - Chocolate Pots hot springs, which are present-day systems that support active Fe redox cycling, and can provide insight into how life could have functioned in such environments; iron redox-based metabolisms likely supported life on early Earth and may support life on other Fe-rich rocky planets such as Mars (Fortney et al., 2018).
  - Polyextreme springs, such as the unique Dallol hot springs (Northern Afar, Ethiopia), which are highly acidic (pH ca. 0) and saline (saturation) with maximum temperatures ranging between 90 °C and 109 °C, and from which Gómez et al. (2019) reported for the first time evidence of life existing within these hot springs using a combination of morphological and molecular analyses: ultra-small structures, identified as members of the order Nanohaloarchaea, were shown to be embedded within mineral deposits.
  - A nuclear geyser system, identified by Maruyama et al. (2019) as the most likely site for origin of life on Earth on the basis of the nine essential requirements for the first emergence of life on our planet.
- **Limestone-Precipitating Springs (LPS)** (Fig. 5G): LPS are ambient-temperature (non-geothermal) freshwater springs that achieve sufficient oversaturation for $CaCO_3$ by physical CO_2 degassing and activity of photoautotrophs to deposit limestone, locally resulting in scenic carbonate structures. The most characteristic organisms in these springs are those that contribute to carbonate precipitation, e.g.: the bryophytes *Palustriella* and *Eucladium*, the crenophilous desmid (green algae) *Oocardium stratum* (Rott et al., 2012; Linhart and Schagerl, 2015; Tran et al., 2019), and cyanobacteria (e.g., *Rivularia*). These organisms appear to be sensitive to phosphorus pollution. To verify if *Oocardium stratum* is often overlooked because it develops in a habitat type rarely visited by phycologists, Trobej et al. (2017) studied algal communities only in springs with associated SAL (Spring-Associated Limestones) deposits. They found the species in 50% of the sites studied, and concluded that this species is more common than often believed, but that it occurs exclusively in habitats with very specific hydrogeological characteristics, as described above for LPS (Cantonati et al., 2020b). Invertebrate diversity is modest, and highest in pools with an aquatic-terrestrial interface. Animal species able to persist in the petrified channels are mostly mountain-stream generalists which migrate from their preferred habitat into spring brooks. An exception is the case-less larva of the caddisfly *Rhyacophila pubescens*, which can be considered an outstanding element of LPS in Europe. Analysis showed a rather high genetic isolation of local populations, probably due to a

fragmentation of areas with suitable habitats, combined with a low dispersal rate of the adults (Engelhardt et al., 2011). LPS is the only widespread spring type included in the EU Habitat Directive, mainly because of landscape esthetics. Pre-requisites for the occurrence of LPS are: an aquifer lithology that enables build-up of high bicarbonate and Ca^{2+} to sustain $CaCO_3$ oversaturation after spring emergence, combined with intense groundwater percolation especially along structural discontinuities (e.g., fault zones, joints, schistosity), and a proper hydrogeological structure of the discharging area. The main threats to LPS are water diversion, nutrient enrichment, and lack of awareness by non-specialized persons and administrators (Cantonati et al., 2016a).

- **Desert springs** (Fig. 5H): Desert springs form oases in otherwise inhospitable landscapes and occur across the globe. They frequently support a rich collection of endemic flora and fauna (Fahey et al., 2019). Rossini et al. (2018) studied endemic biodiversity and its conservation value in Australia's artesian desert springs, and found 96 species and subspecies of fishes, molluscs, crustaceans, and plants endemic to these arid-climate freshwater springs. The majority of these endemic species are invertebrates with a limited geographical distribution pattern. Cantonati et al. (2015) highlighted that the ambient springs in warm climate settings, including the freshwater arid ecosystems, host rich, interesting, and diverse cyanobacterial communities, that, however, are typically poorly-known so far. Also, the diverse cyanobacterial and algal adaptations to the arid-climate freshwater spring habitats are understudied. However, Garcia-Pichel et al. (2002) studied a thermal spring in the Cuatro Ciénegas karstic region of the Mexican Chihuahuan Desert, and found unusual centimeter-sized water-warts built by an *Aphanothece*-like unicellular cyanobacterium: these were suspended within a central, conically-shaped, 6-m deep well by upwelling waters, and supported a community of other epiphytic filamentous cyanobacteria and diatoms. This unique structure of jet-suspended, calcite-ballasted, colonial cyanobacterial community shows relevant adaptations to this desert-spring habitat. The morphotaxonomic surveying by Shaaban et al. (2015) of the freshwater ambient-to-slightly hot springs (*ains*) and drilled wells (*birs*) in the El-Farafra Oasis in the Western Desert of Egypt highlighted that these important habitats are affected by direct human and cattle impacts (organic pollution). This was confirmed by the main cyanoprokaryote taxa found that were typical bioindicators of eutrophicated thermal freshwater habitats. The over-use of the Nubian aquifer system (NAS), the world's largest non-renewable (fossil) water resource, has already resulted in the abandonment of oasis settlements (Powell and Fensham, 2016). A clear relationship between the ever increasing number of wells and the dramatic decrease of active flowing springs has been observed (e.g., in oases of the Western Desert of Egypt) and is predicted to exacerbate due to the lack/non-compliancy with sustainable exploitation plans (Voss and Soliman, 2014). In most of the springs (and even wells) in oases of the Western Desert of Egypt, ecological integrity, as shown, e.g., by benthic algae, is low because of human impact due to the use of the water for drinking, cattle watering, irrigation, recreation, etc. Near-natural springs, likely to host unique biota, exist in protected areas and in remote, difficult-to-access sites. Fahey et al. (2019) described a new grass (Poaceae) species, *Chloris circumfontinalis* Fahey et Fensham, from arid-environment artesian springs of inland Australia. The new species occurs only in the saline scalds that form around the springs, and population surveys indicated a threat status of "Endangered" under the IUCN Red List criteria.

The main environmental determinants of photoautotrophs in springs

To complement a chapter in the present Encyclopedia by Williams (2022) on springs' biodiversity, which focuses on the fauna (namely invertebrates), an overview of the photoautotrophs ("flora") that can be found in springs is provided here.

According to Cantonati et al. (2007) "**phytobenthos**" in the broader sense includes not only benthic algae but also aquatic lichens, bryophytes, and vascular plants, i.e., all photoautotrophic organisms that live in close proximity to the water-influenced substrata (Figs. 6 and 7). The term "benthic algae" is also used there for a large number of lower plants that do not develop any real tissue, flowers or fruits. These groups differ from one another not only evolutionarily (both eu- and prokaryotes) but also in their biochemistry, physiology and metabolism. The phytobenthos of mountain springs (especially that of the rheocrenes) shows striking similarities to that of mountain streams. However, there are also a number of characteristic features, which are described below for the most important groups. In addition to cyanobacteria and diatoms, chlorophytes (green algae), rhodophytes (red algae), chrysophytes (golden-brown algae), and xanthophytes (yellow-green algae) also play an important role in springs (see Cantonati et al., 2007). A discussion of the relationship of the individual groups with springs, as well as with other habitats, is hardly possible without considering the following key environmental variables:

- **Lithology**: The relevance of lithology is expressed, for instance, in the fact that vicarious species of the same genus replace each other on siliceous vs carbonate rocks (e.g., the cyanoprokaryotes *Chamaesiphon fuscus*/*C. geitleri*—Fig. 6A–B, the diatoms *Meridion constrictum*/*M. circulare*). The importance of lithology-related abiotic parameters (conductivity, pH) has been confirmed many times (e.g., Cantonati et al., 2012b, 2020a). Werum and Lange-Bertalot (2004) showed that spring diatom communities in a lithologically heterogeneous region can be assigned to different geological formations on a statistically significant basis.
- **Current velocity**: Flow velocity is an important influencing factor, especially in rheocrenes (e.g., in large karst springs, gushets, or mountain springs emerging on steep slopes). Species that occur in rivers and springs with heavy pouring can also be found in small rheocrenes if there are microhabitats with particularly strong currents, e.g., the rheophilic golden-brown alga *Hydrurus foetidus* (Cantonati, 2008; Cantonati et al., 2009b) or the diatoms *Achnanthidium pyrenaicum*, *Hannaea arcus*, and *Cocconeis placentula* (Cantonati and Spitale, 2009). In contrast, other algae have developed adaptations to extremely reduced flow or even to dehydration, e.g., the cyanobacterium *Chamaesiphon polonicus*, and the diatoms *Humidophila perpusilla*, *H. contenta*, and

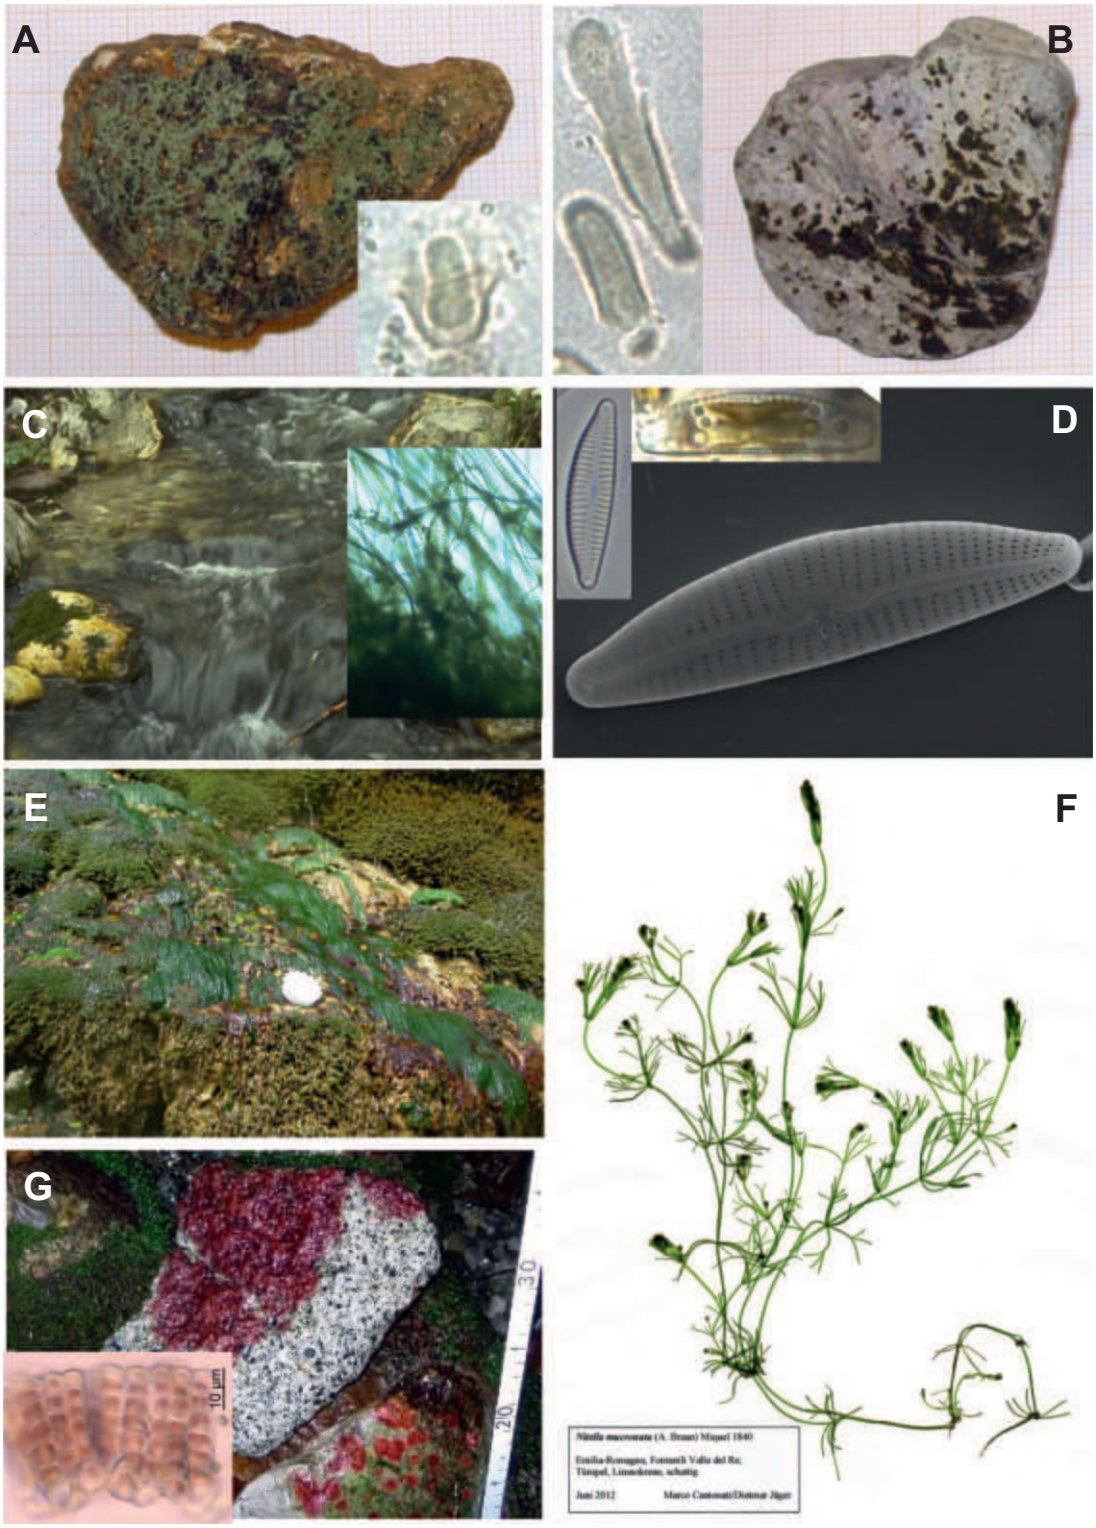

Fig. 6 Examples of spring (Northern Italy) benthic algae and cyanobacteria presented more in detail in this chapter: (A–B): macroscopic aspect of colonies of two vicariant species of cyanoprokaryotes: siliceous vs carbonate rocks, *Chamaesiphon fuscus* (A)/*C. geitleri* (B) (the inserted images show the microscopic aspect); (C) macroscopic aspect of a benthic bloom of the diatoms *Odontidium mesodon* + *O. hyemale* (the inserted image shows the microscopic aspect); (D) the diatom *Cymbella tridentina* seen at the scanning electron microscope (the inserted images show the aspect of this species under the light microscope: *left*: prepared material, *right*: living cell with plastid); (E) Macroscopic aspect of the filamentous red alga *Bangia atropurpurea*: red patches intermingled with the green patches of the green alga *Cladophora glomerata* (splash zone of a waterfall formed by a large limestone-precipitating spring in the Northern Apennines); (F) the stonewort *Nitella mucronata* (herbarium sheet) sampled from a shaded pool spring in the Po plain in Northern Italy (p.c.: Dietmar Jäger); (G) crusts of the red alga *Hildenbrandia rivularis* in a small shaded flowing spring in the south-eastern Alps.

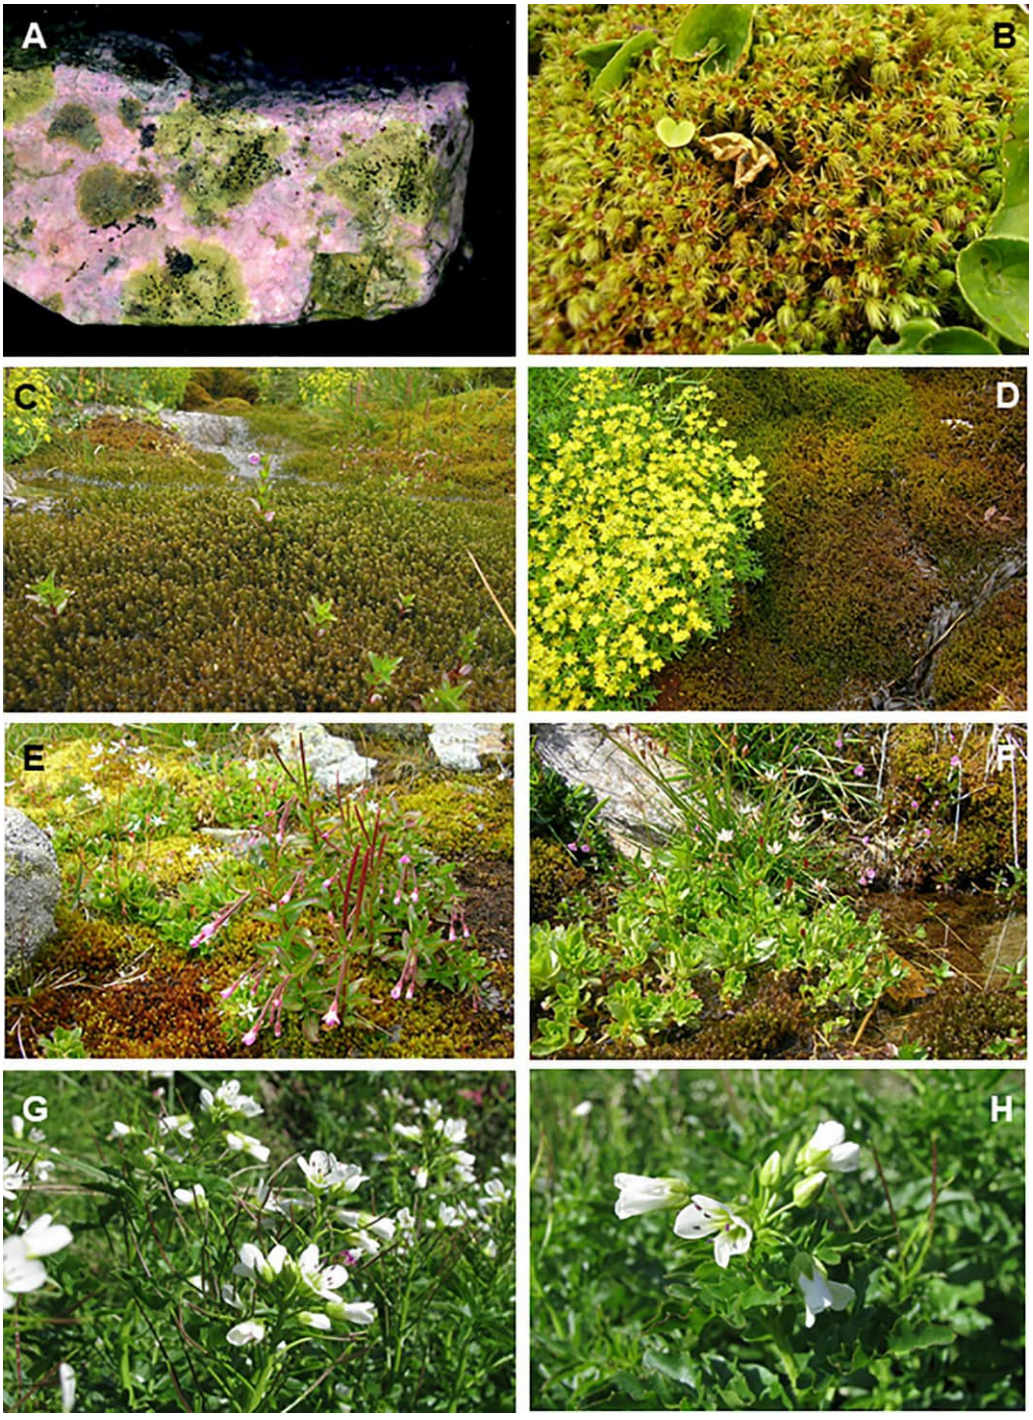

Fig. 7 Examples of common lichens, bryophytes, and vascular plants in springs of the Alps: (A) the epilithic aquatic lichen *Verrucaria funckii*; (B) the moss *Philonotis fontana*; (C) *Epilobium alsinifolium* (chickweed willowherb, Onagraceae) "immersed" in the moss *Palustriella falcata*; (D) *Saxifraga aizoides* (yellow mountain saxifrage, Saxifragaceae) and the mosses *Palustriella commutata* and *P. falcata*; (E) *Epilobium alsinifolium* and *Saxifraga aizoides*; (F) *Saxifraga stellaris* (starry saxifrage, Saxifragaceae); (G–H) *Cardamine amara* (large bitter-cress, Brassicaceae). (B–H): photo credit: Dr. Daniel Spitale.

Orthoseira roeseana (Cantonati et al., 2006, 2007; Cantonati and Spitale, 2009). Hofmann et al. (2018), in their diatom Red List, designate a number of species as (eu- and pseudo-)aerial. In a similar way, van Dam et al. (1994) designate species living at the periphery or mainly outside waterbodies with the numbers 4 and 5 in a moisture (M) scale of 1–5. Cantonati et al. (2012c) identified different spring types in the south-eastern Alps, which differ in environmental parameters and species communities of benthic algae (without diatoms). Their most common spring type was, for example, carbonate rheocrenes located at middle and higher elevations with medium conductivities, mainly characterized by shade-tolerant (Chroococcales) or rheophilic (*Tapinothrix varians*) cyanobacteria.

- **Light**: Another important determining factor are the light conditions. Benthic freshwater diatoms, like many cyanobacteria and red algae, can tolerate shading or are even specially adapted to it (e.g., Poulíčková et al., 2004). In contrast, at high elevations or periodically exposed sites that are affected by high levels of radiation, cyanobacteria can protect themselves against UV stress by producing the photoprotective pigment scytonemin, which is stored in the sheaths where it causes a yellow-brown color (e.g., *Ammatoidea normanni* and *Tolypothrix* spp.; Cantonati et al., 2007). Another strategy is the production of UV-absorbing mycosporine-like amino acids (MAAs), small, colorless and water-soluble molecules that effectively absorb wavelengths in the range between 309 and 360 nm. Presumably, such components generally play an important role above the tree line; Sommaruga and Garcia-Pichel (1999) found them in both planktonic and benthic taxa in high mountain lakes.
- **Nutrients**: Since nutrient levels in springs are generally low under natural conditions, nutrient availability is of fundamental importance in the ecology of spring algae. Nutrient enrichment can be direct (e.g., through grazing cattle or game) or indirectly (e.g., deposition of airborne nitrogen compounds). Even small amounts of nitrate obviously favor non-heterocytic cyanobacteria and certain diatoms (e.g., *Cocconeis placentula*, *Planothidium lanceolatum*; Cantonati et al., 2006). In springs exposed to organic pollution, diatom species indicating eutrophication are typically found (e.g., *Gomphonema parvulum*, *Navicula tripunctata*, *Nitzschia palea*; Cantonati and Spitale, 2009). Cantonati and Lange-Bertalot (2010) found the lowest number of species and the lowest Shannon-Wiener diversity values in springs with the highest nitrate concentrations in the north-eastern Alps, with an important occurrence of the eutraphentic diatom species *Planothidium lanceolatum* (56%) and *Gomphonema micropus* (7%). Anthropogenic disturbances and higher nutrient concentrations are obviously the main explanatory factors for differences in species composition between springs in more or less densely populated areas (e.g., Aboal et al., 1998; Angeli et al., 2010).

The main groups of photoautotrophs in springs

The following is a summary of photoautotrophs known to inhabit springs. In average ("normal") conditions, the bottom of a spring is not barren but sparkles with shades of color ranging from dark-brown or black, to reddish, to all nuances of green and blue-green. Springs owe their bright colors to algae, aquatic lichens, and bryophytes (whereby German scholars use the term *Vegetationsfärbungen* = colors due to aquatic vegetation) (Figs. 6 and 7). Also the land-water ecotone, unless artificially altered with concrete or otherwise, is never bare but richly covered with aquatic plants, bushes (and sometimes trees) which need increasingly less water and become more and more intolerant of submersion with distance from the spring. While aquatic and hygrophilous bryophytes are frequent in shaded springs while higher aquatic plants prefer the muddy bottoms of wetland springs, rheocrenic springs with fast moving waters are well colonized by benthic algae and aquatic lichens.

- **Cyanoprokaryotes** or cyanobacteria (Fig. 6A–B), the former blue-green algae, are one of the dominant groups in oligotrophic waters and thus also in springs. Their prokaryotic nature is meanwhile known since many decades but they are traditionally treated as algae due to their similar growth form but also because they carry out an oxygenic photosynthesis comparable to other photoautotrophs and thus play a comparable functional role in ecosystems. The term cyanoprokaryotes is a compromise trying to acknowledge both these aspects. Due to both under-appreciation of spring studies, and increasingly complex approaches required for the characterization of cyanobacteria assemblages in near-natural habitats, the literature on cyanoprokaryotes in ambient springs is very limited (Cantonati et al., 2015). However, some generalizations are possible. The marked heterogeneity of the spring habitat requires a diverse set of adaptations. Different ambient springs are thus colonized by rheophilic, UV and radiation resistant, shade-tolerant, non-diazotrophic, P-specialist cyanoprokaryotes. Cyanobacteria can successfully be used to statistically characterize the diverse types of ambient springs (Cantonati et al., 2012c). Some morphotypes, e.g., *Phormidium retzii* in large karstic springs at low elevation, and *Homeothrix juliana* in ambient springs in arid regions, are regularly reported from these habitats even from distant geographic locations. Coccoid types appear to dominate in ambient springs in temperate climate while filamentous types appear to prevail in ambient springs in warm and arid climates (Cantonati et al., 2015). The in-depth characterization of ambient-spring cyanoprokaryote assemblages is important because, if adequately known, spring cyanoprokaryotes might provide a valid contribution to the assessment of the ecological integrity, quality, and value for nature protection of spring habitats (Cantonati et al., 2015). In the last decades it has become apparent that cyanobacterial toxin production extends to many more freshwater habitats than previously believed. Aboal et al. (2005) demonstrated that also occurs in high-ecological-integrity calcareous Mediterranean streams, and Cirés et al. (2017) brought to the forefront the presence of cyanotoxins in extreme environments, including hot springs. The exact adaptive meaning of cyanotoxin production in these environments still has to be elucidated. One of the most plausible interpretations is that cyanoprokaryotes may use these toxins for successful competition for space and nutrients with other primary producers, in particular other algae, and as an anti-grazing defense.
- **Diatoms** (Fig. 6C–D): Diatoms, unicellular microalgae characterized by an amorphous silica frustule formed by two valves with a complex ultrastructure, are the most species-rich group of algae (Mann, 1999). The global diversity of diatoms may be one or more orders of magnitude higher than the current number of species described (Vanormelingen et al., 2008), with as many as ca. 100,000 but at least 30,000 extant diatom species (Mann and Vanormelingen, 2013). They contribute to global primary production with a proportion as large as 20%, possessing global significance in the carbon and silicon cycles (Mann, 1999). Diatoms can be found everywhere where there is a little bit of moisture, and in all aquatic habitats. Most of them have very precise preferences for ecological conditions of pivotal relevance in environmental quality assessments, such as pH, mineral

content, nutrients, etc. A combination of mechanisms (active urea cycle, probably used to improve nitrogen storage; fatty acids oxidation in mitochondria; chemical information exchange among cells; "melting pot genome" of ca. 10,000 genes with many diatom specific genes but also extensive documented gene transfer from bacteria to diatoms) may underlie the rapid diversification rates, and may explain why diatoms have come to dominate several contemporary systems in a relatively short period of time (Bowler et al., 2008). A large multi-disciplinary project (CRENODAT) allowed to study 110 ambient springs in the south-eastern Alps, considering a wide range of elevations, lithologies, types, mineral content, and pH. Diatoms in the different kinds of springs were found to be as follows. Iron springs typically harbored species-poor assemblages with low numbers of individuals. Helo- and rheohelocrenes and some very-low alkalinity rheocrenes had *Eunotia* as the most species-rich genus, and were characterized by the mire-species *Frustulia crassinervia*, the acidophilous *Tabellaria flocculosa*, the very low-alkalinity indicator *Psammothidium acidoclinatum*, and several *Eunotia* species (*E. borealpina*, *E. exigua*, *E. tenella*). Well-buffered rheocrenes on siliceous substrata had *Odontidium* as the most species-rich genus, and the following common species: *Odontidium mesodon*, *O. hyemale* (Fig. 6C), *Eunotia minor*, *Encyonema minutum*, *Navicula exilis*, *Planothidium lanceolatum*. Carbonate flowing springs with lower conductivities and/or affected by seasonal desiccation had *Humidophila* as flagship genus: *H. perpusilla*, *H. contenta*, *Planothidium frequentissimum*, *Meridion circulare*, *Achnanthidium dolomiticum*. Rheocrenes on carbonate substrata with different situations of current flow had *Achnanthidium* as characteristic genus: *A. pyrenaicum*, *A. lineare*, *Rossithidium pfisteri*, *Gomphonema elegantissimum*, *Nitzschia fonticola*. This group can be subdivided into sub-assemblages defined by decreasing *A. lineare* and increasing *A. pyrenaicum* with increasing current velocity. Carbonate rheocrenes affected by moderate nitrate enrichment and/or shading had *Cocconeis* as outstanding genus: *C. euglypta*, *C. lineata*, *C. pseudolineata*, *Amphora pediculus*, *A. micra*, *A. inariensis*, *Caloneis fontinalis*, *Reimeria* spp., *Eunotia arcubus*. Hygropetric rheocrenes and some LPS springs had *Encyonopsis* as most characteristic genus: *E. microcephala*, *E. cesatii*, *Delicatophycus delicatulus*, *D. minutus*, *Gomphonema lateripunctatum*, *Denticula tenuis*, *Cymbopleura austriaca*. Many diatom species showed a significant substratum preference for stones or bryophytes. Bryophyte-dwelling assemblages were found to have higher taxa numbers and species diversity but average diversity did not differ among the most frequent bryophyte species (Cantonati et al., 2012b). Our knowledge of diatoms in springs comes mainly from alpine regions and low mountain ranges. Żelazna-Wieczorek (2011) showed that they also abundantly occur in lowland springs with species-rich populations. Even if there is hardly any crenobiontic species there, diatoms allow well-founded nature conservation statements about springs. In addition to the ecological informative value of the species communities described above, it is possible to identify rare species according to the Red List of Diatoms in central Europe (Hofmann et al., 2018; Cantonati et al., 2021) gaining further scientific grounds to campaign for the protection of their habitats.

- **Green algae** (Fig. 6E–F): Among the chlorophytes (green algae) in the broadest sense, filamentous and unicellular algae of the orders Zygnematales and Desmidiales are abundant, especially in slightly acidic helocrenes (Cantonati et al., 2012c). The species *Klebsormidium rivulare* often grows on bryophytes or large stones, mostly in only partially water-covered areas. Species of the genus *Cladophora* (Fig. 6E) can be found in nutrient-richer springs of various types, and charophytes (stoneworts, Fig. 6F) typically occur in limnocrenes, including desert springs (e.g., Saber et al., 2021). *Rhizoclonium*, though reported from a variety of habitats, also seems to be more common in limnocrenic springs, for example in the lowland pool springs in alluvial deposits of the Italian Po plain, locally called *fontanili* (Saber et al., 2017).
- **Red algae** (Fig. 6E and G): Among the rhodophytes (red algae), tufts of species of the genus *Audouinella* are most common in mountain springs, epilithic crusts of *Hildenbrandia rivularis* (Fig. 6G) occur in heavily shaded sources, especially in low to medium-elevation locations (Cantonati et al., 2016b) while the long, branched, threadlike filaments of *Batrachospermum* species are most likely to be found at lower elevations, where they colonize rheocrenic springs as well as streams. In springs with large discharge where splash-zone, spray-zone microhabitats can develop the filamentous red alga *Bangia atropurpurea* (Fig. 6E red patches intermingled to the green patches of *Cladophora glomerata*) can sometimes be found (MC unpublished observation). The unicellular and colonial red alga *Chroothece* sp. was found in an inland-saline spring by Cantonati et al. (2019).
- **Yellow-green algae**: Xanthophytes (yellow-green algae) are particularly represented in springs of the Alps by species of the genus *Vaucheria* (e.g., Cantonati et al., 2012c), whose rough, cushion-like thalli on carbonate substrates can cover extensive areas. Filamentous representatives (*Tribonema*) of the yellow-green algae often appear in different source types including helocrenes.
- **Golden-brown algae**: The golden alga *Hydrurus foetidus* (chrysophytes) is widespread in the mountains in streams and rheocrenes. This species is rheophilic and does not tolerate water temperatures above 15 °C. Therefore, it occurs in streams only during a defined time window (late winter-spring) (Rott et al., 2006) but can be observed in springs all year round (Cantonati et al., 2016b).
- **Lichens** (Fig. 7A): Originating from a symbiosis between a "photobiont," an alga or a cyanobacterium, and a fungus, lichens are found with a restricted number of species in freshwater habitats. They are quite common in springs of the Alps, but so far they have received relatively little attention (e.g., Cantonati et al., 2007). One of the determining environmental factors for the distribution of freshwater lichens is light (Thüs, 2002). In addition to species that are adapted to very little light (e.g., *Verrucaria hydrela*, *Porina chlorotica*), others prefer higher light intensities. Most lichens are quite insensitive to dehydration, but some spring-dwelling species (e.g., *V. funckii*) cannot even tolerate short-term exposure outside the water (Cantonati et al., 2007). Dependent on stable lithic substrata, they are missing, for example, in wetland springs where fine detritus dominates among substrates. The different demands on light or moisture result in a characteristic vertical zoning in relation to the lowest or highest water level, which is typically visible on larger boulders at the margins of the spring (Cantonati et al., 2007). Other important environmental factors are the lithology (different species communities in silicate and carbonate springs) and the pH (acidification is hardly tolerated) (Thüs, 2002). In spring streams, especially on silicate substrates, Mühlenhoff (1994) was able to

identify typical associations of lichens and bryophytes, which are probably also suitable to provide information on the overall quality and integrity of rheocrenic spring habitats. Nascimbene et al. (2011) tried to apply to springs the bioindication potential of lichens widely applied in terrestrial habitats, and identified *Verrucaria elaeomelaena* on carbonate rocks and *V. funckii* (Fig. 7A) on silicate substrata as typical spring species.

- **Bryophytes** (Fig. 7B–D): Bryophytes (mosses and liverworts), treated together with the phanerogams in many spring studies and contrasted with the algae and fungi, with which they could be summarized as "cryptogams" (Martin et al., 2015), are often very narrowly restricted to the source area (eucrenal) in the longitudinal zonation (compare, e.g., Petraglia, 2007, Tomaselli et al., 2011), abundantly colonize the substrata available there (Ortler, 1997), and accommodate a characteristic microflora (see above) and fauna (e.g., Hajkova et al., 2011). Bryophytes proved to be more suitable than the higher plants for a classification of springs of the south-eastern Alps on siliceous and carbonate substrata, as they were more strictly bound to springs (Ortler, 1997). Out of 58 bryophyte taxa found by Ortler (1997), 12 had their ecological optimum in the springs (crenophiles: *Cratoneuron* spp., *Dicranella palustris*, *Brachythecium rivulare*, *Bryum pseudotriquetrum*, *Philonotis* spp. (Fig. 7B), and *Scapania undulata*), and another three were key species of bryophyte communities (*Fontinalis antipyretica*, *Chiloscyphus polyanthos*, and *Hygrohypnum dilatatum*). As regards carbonate springs, phytosociological characterization revealed three, mainly *Cratoneuron*-dominated, associations along an elevation gradient. With increasing altitude, the montane *Cratoneuretum commutati* is replaced by the subalpine *Cratoneuron decipiens*-association, and then, in the alpine zone, by the *Cratoneuretum falcati*. In springs on siliceous substratum, associations were more variable and bryophytes were altogether more frequent, especially springs with large discharge. In addition to lithology, the most important environmental variables turned out to be substrate-particle size, discharge, soil moisture, elevation, and contact-vegetation composition while light conditions were apparently only of secondary importance (Ortler, 1997). In boreal springs, in which bryophytes are as well the dominant group of plants, Heino et al. (2005) observed drastic shifts in the species spectrum between 1986 and 2000. Some species became noticeably rarer and were regarded as acutely endangered (e.g., *Philonotis fontana*, Fig. 7B), while *Sphagnum* species (e.g., *S. warnstorfii*) occurred more frequently. Depending on specific conditions in different areas, either water chemistry (in turn dependent on the lithology, the elevation, and on possible acidification; Beierkuhnlein, 1999, Beierkuhnlein and Schmidt, 1999) or light conditions (Peintinger and Beierkuhnlein, 1999) proved to be the main determinants of the spring-vegetation composition. Species occurring in forest seepages obviously differed both in their life cycle and in terms of their ability to adapt to different light and temperature conditions (Beierkuhnlein and Gräsle, 1998). Submerse mosses generally have great potential as bioindicators. The occurrence of the *Cratoneuron* association is one of the characteristics used to describe the EU Habitat Directive FFH priority habitat "Petrifying springs" (Natura 2000 code 7220; EU-HD, 1992). *Chiloscyphus polyanthos*, a characteristic species for non-acidic spring-brooks with stable discharge, is sensitive, for example, to pollution and fine-sand deposits, which may cover the vegetation after floods (Himmler and Tremp, 1992). *Fontinalis antipyretica* is typically found in cold, but rather nutrient-rich springs, is absent from acidic springs, and is a good indicator in spring waters with different pH values and different contaminant levels. Trace elements, such as Cd, Pb, Cr, Cu, and Hg, are strongly accumulated, and saturation is reached already after a few days to weeks but the release is slow and occurs over some months (Cenci, 2000). *Scapania undulata* lives in springs on siliceous substratum, submerged in acid water, both submerged and on exposed substrates in the spray zone at approximately neutral pH, but exclusively above the mean water-level line at pH values greater than 7 (Frahm, 1992). In forest seepages the species can thus be used as acidification indicator. In a study by Audorff and Beierkuhnlein (1999), calcium and magnesium could only be determined at neutral pH or when the springs were exposed only to rare acidification events; the concentrations of these elements in *S. undulata* were correlated with their concentrations in the water and the pH value.
- **Vascular plants** (Fig. 7D–H): In terms of degree of cover, bryophytes dominate in most spring habitats over higher plants (vascular plants or phanerogams) (Martin et al., 2015), which are also more likely to be found at the spring margins rather than inside the spring-head (Zechmeister and Mucina, 1994). Thus, in a spring study in the south-eastern Alps, out of 344 recorded species of higher plants, only 67 occurred exclusively in places directly influenced by the springs, and only seven could be described as character species of the spring vegetation in the phytosociological sense, namely *Arabis soyeri*, *Epilobium alsinifolium* (Fig. 7E), *Cardamine amara* (Fig. 7G–H), *Pinguicola alpina*, *Saxifraga stellaris* (Fig. 7F), *Silene pusilla*, and *Stellaria alsine* (Ortler, 1997). In the lowlands and in medium-altitude mountains *Chrysosplenium oppositifolium* is an important indicator of spring sites, occurring at and, in part, also in springs (compare Hinterlang, 1996). Higher plants appear generally unsuitable for a spring classification, although they can dominate the spring flora at lower elevations, where mosses are less competitive (Petraglia, 2007). Due to the special conditions in springs, rather unusual plant species grow here, which, for example, have to be adapted to the stenothermal conditions (Zechmeister and Mucina, 1994). The environmental determinants are similar to those for other groups of photoautotrophs, i.e.: water temperature, flow velocity, pH as well as nutrient availability and concentrations (Warncke, 1980; Audorff et al., 2011). Anthropogenic nutrient enrichments are quickly reflected in changes in the phanerogamic communities (see Tomaselli, 2007, also for an overview of the typical spring flora of the Alps). Plant communities at spring locations can serve as an indicator for the degree of naturalness, and their analysis can provide valuable information for nature conservation and biotope improvement measures (Hinterlang, 1993). Sources on siliceous substrata are particularly suitable as monitoring sites for acidification processes. When the pH value falls, the *Chrysosplenietum oppositifolii* association is replaced by the *Caricetum fuscae polytrichetosum communis* association, and this happens already at a stage in which the forest vegetation is not yet responding to acidification (Beierkuhnlein, 1996).

Conservation concerns and restoration efforts at springs

Stevens et al. (2021) conducted a preliminary global analysis on the ecological integrity of springs, reviewing information on an estimated 250,000 spring ecosystems from 78 countries. Literature on springs ecological integrity is sparse, widely scattered, and spatially erratic, with major gaps in knowledge. There are large differences in the quality and extent of information among countries and continents, with only moderate data availability even among developed countries, and limited information across most of the developing world. Where data are available, ecological impairment of springs is rampant everywhere, sometimes exceeding 90% in developed regions (Stevens et al., 2021).

Cantonati et al. (2020c) report that humans and their livestock impact springs in manifold direct and indirect ways. Many springs have been dewatered through aquifer overdraft. A striking example is that approximately 33% of the 259,000 km^2 Floridan Aquifer has been appropriated for human uses, and existing permitted withdrawals equal about 50% of the aquifer's recharge, which historically fed more than thousand artesian springs (Knight, 2015). Further impacts, directly or indirectly related to climate change and land-use alteration, include reduced precipitation and aquifer recharge, excessive nutrient enrichment (e.g., nitrogen from agricultural and urban development), non-native species introduction, physical disturbance, and geomorphic alteration, livestock watering and trampling, flow diversion, water-bottling operations, and recreation impacts (Cantonati et al., 2020c).

The Habitat Directive of the European Union (EU) recognizes only one major spring habitat type, namely Limestone Precipitating Springs (LPS; Annex I: "Petrifying springs with tufa formation—*Cratoneurion*" EU-Code 7220, Cantonati et al., 2016a). Australian artesian springs in the Great Artesian Basin are protected under Federal Australian Law by the Environment Protection and Biodiversity Conservation Act. However, few other nations have similar legislation, an exception being Finland, which protects its springs through the Water Act and the Forest Act. In the United States, groundwater and springs are scarcely considered in federal legislation, with jurisdiction over those waters largely deferred to individual states (Florida, New Mexico, Wisconsin, and a few other states recognize the importance of protecting their springs). Comprehensive local, national, and international legislation for conservation of springs is urgently required (Cantonati et al., 2020c).

According to Cantonati et al. (2020c), reducing the global loss of spring ecosystems requires reinvigorated scientific effort, education and outreach, and improved policy (Glazier, 2014). All spring types and their recharging groundwater basins should be included in relevant conservation and assessment legislation worldwide. On the scientific side, improved mapping, broad agreement on a consistent lexicon, and adoption of standardized inventory and assessment protocols are needed. Basic information about the location of springs is lacking for most areas of the world (compare Stevens et al., 2021).

According to Cantonati et al. (2020c) and Stevens et al. (2021), the global silent crisis of the demise of springs can be slowed or reversed by using sound scientific data and through informed debate among stakeholders. Global conservation efforts require the collective recognition of the importance of springs for humans and nature. Given their significance as biodiversity havens for many rare and endemic species, as well as their cultural and socio-economic values, improving stewardship of springs and their supporting aquifers will yield major environmental advantages and societal benefits.

Restoration efforts at springs (e.g., Martin et al., 2015) have so far only rarely been scientifically documented. Documentation of the pre-restoration state would have to be undertaken before the intervention, followed by a multi-year success-control study (e.g., Wächter and Rüther, 1994). In a flowing spring in pastureland, Zollhöfer (1997) observed a gradual increase in spring-dependent species after fencing of the spring-source area. A definitely important factor for a recolonization is certainly an existing potential for species re-establishment from the surrounding area. Unfortunately, technology and experience from case studies about using flow-splitters to allow for a residual ecological flow after spring capturing to feed purposely-designed secondary spring biotopes are still in a very early phase (Cantonati et al., 2009b). Barquín and Scarsbrook (2008) pointed out that unsustainable exploitation of springs also impairs their capability to provide ecosystems goods and services. Eller and Katz (2017) proposed the Nitrogen Source Inventory and Loading Tool, developed as an ArcGIS and spreadsheet-based approach that provides spatial estimates of current nitrogen inputs to the land surface and loads to groundwater from nonpoint and point sources within the groundwater contributing area, as an integrated approach toward restoration of water-quality impaired karst springs. One of the few countries in which spring-habitat restoration is a serious concern both politically and scientifically is Finland. Lehosmaa et al. (2017) evaluated the effectiveness of spring restoration using data from near-natural, restored, and human-impacted springs, the major impact being degradation of spring hydrology by forest drainage. They used both taxonomic (bryophytes, macroinvertebrates, and leaf-decomposing fungi) and functional (leaf breakdown) measures of restoration success. The contribution of surface water was greatly reduced, and thus restored springs were thermally more stable than impacted springs. Bryophytes and macroinvertebrate did not differ among restored and natural springs. Bryophytes were more abundant in restored than in impacted springs, and invertebrates differed between restored and impacted springs. Species diversity and functional attributes showed weaker responses to restoration. Due consideration of the responses of springs to climate change will foster the long-term effectiveness of their conservation and restoration (Cartwright et al., 2020).

Knowledge gaps

- Improve the theoretical framework of springs as ecosystems
- Springs, studied in an ecohydrological perspective, as ideal systems in which to further investigate and understand geo-biodiversity relationships

- Further develop efforts to raise societal and political awareness of springs as unique systems and effective protocols for springs conservation and restoration
- Build and strengthen a global network for spring ecology and conservation (compare Spring Stewardships Institute at MNA)
- Further expand knowledge on the theoretical foundations of spring-habitat restoration, and develop restoration technologies

Acknowledgments

I thank Colleagues who share my passion for springs and with whom I have repeatedly discussed, over the years, the topics of spring-aquifer relationships and spring typology, most notably: Larry Stevens, Rod Fensham, Doug Glazier, Reinhard Gerecke, Stefano Segadelli, Nico Goldscheider, Alessandro Gargini.
I am grateful to Christian Griebler, Managing Editor of the section on "Groundwater habitats" of the *Encyclopedia of Inland Waters*, and Paula Davies, Elsevier Ltd. Content Project Manager, for their assistance while I was preparing the chapter and their patience with delays.

Biodiversity of Invertebrates in Springs

D Dudley Williams, Department of Biological Sciences, University of Toronto Scarborough, Scarborough, ON, Canada

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Introduction

From a simplistic hydrological viewpoint, a spring represents a concentrated point of natural discharge of groundwater that is sufficiently high to maintain flow on the land surface (Van Everdingen, 1991). The flow of water from a spring often comprises a mixture of water that has infiltrated the subsurface at different times and places. The rate of this recharge varies according to the balance between precipitation, infiltration, runoff and evapotranspiration, and as the contributions from different recharge points change, so too will the output of the spring vary. Van der Kamp (1995) illustrated such variation in hydrogeology with examples of two spring types: (1) a spring fed by slow seepage through small pore spaces (e.g., sand and rock with fine fractures, typically $<$0.1 mm wide) with strong filtration which produces stable flow and water devoid of any large particulate matter; (2) a spring fed through cavernous carbonate rock – such 'karst' springs typically have strong, but variable, flow and higher particulate loads. In some instances, a spring may be fed by a very shallow or small aquifer resulting in intermittent surface flow. Such contrasting discharge patterns can be predicted to radically affect the nature of the community capable of living in these respective springs. From an ecological perspective, springs have been traditionally subdivided into three broad types (Fig. 1): *rheocrenes* – in which the source emerges into a rapidly flowing stream; *limnocrenes* – in which the source first enters a basin with slow flow; and *helocrenes* – in which emerging water percolates into a marshy holding area, frequently rich in mosses (Bornhauser, 1913). There are, of course, some springs that do not fit neatly into these definitions, for example, where a limnocrene has sufficient discharge such that the water spills out of the basin forming a fast-flowing stream, which might be termed a 'rheolimnocrene.'

If we examine a simple water budget for springs, it is clear that groundwater is their primary source. Precipitation directly on the relatively small surface areas of, for example most rheocrenes, is likely to be low, although that on limnocrenes may be higher. Of the main water losses (outputs), evapotranspiration is likely to be low – but again related to spring surface area, together with the characteristics of local vegetation. Water lost to floodplains may be retained in wetlands or flow down-gradient in springbrook channels. In the case of helocrenes, water may diffuse away as overland flow into surrounding depressions, soil and vegetation. Depending on local topography and soil infiltration capacity, some spring waters may re-enter shallow downstream aquifers, perhaps to re-emerge at down-slope springs. Emergence of groundwater, as described above, occurs globally, making springs commonplace in all but the most arid or cold regions – although even the latter have their own characteristic upwellings (e.g., those found in the Chihuahuan Desert in Texas, Wallace et al., 2005; and on Axel Heiberg Island in the High Arctic, Lay et al., 2013).

The main aim of this chapter is to review the properties of springs and how they have been classified against a background of the biodiversity of the animals, chiefly invertebrates, that inhabit them.[1] Emphasis is placed on our past and current understanding of the structural and functional links between these organisms and their environment. The effects of increasing anthropogenic stresses are discussed.

Alternative typologies of springs

There is an over-abundance of imprecise terms to describe springs (e.g., spring source, spring-fed stream, springbrook, headwater spring, spring run, seep, spring seep). Some definitions are based on the immediate physical and chemical environment, while others focus on the communities of organisms living there. These differences stem, largely, from the disparate backgrounds of the

[1]Larger, permanent springs may sometimes support small fishes, such as bullheads, especially where underground, cave-dwelling populations come to the surface. However, such occurrences are rare.

 https://doi.org/10.1016/B978-0-12-819166-8.00072-4

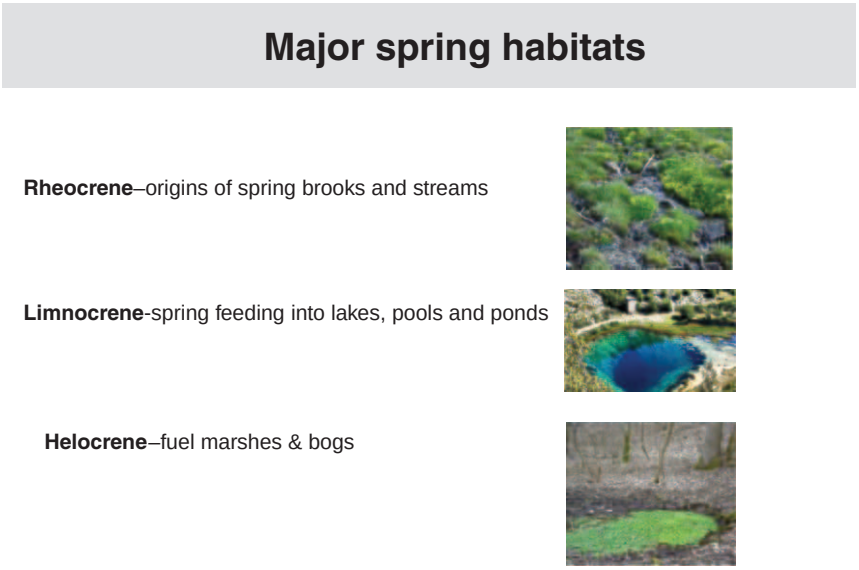

Fig. 1 The three broad types of spring: rheocrene (top), limnocrene (middle), helocrene (bottom).

scientists who study them. For example, geologists tend to define thermal springs with respect to temperatures more than 5 °C above the local mean-annual air temperature (Van Everdingen, 1991) – which reflects geothermal warming. Biologists customarily define thermal springs in reference to temperatures above the local annual mean (warm), as well as above the annual mean maximum (relatively hot), and above 40 °C (absolutely hot) (Tuxen, 1944). Biologists also sometimes categorize habitat temperatures in a manner that best coincides with the distribution of a given taxon. For example, Smith (1991) defined a 'hot' spring as one above 30 °C as none of the Canadian water mites he studied occurred in waters that hot. However, some insects and other invertebrates can be found in springs exceeding 40 °C, requiring a different cut-off level for 'hot' (for further discussion, see Pritchard, 1991).

In any given spring, all or some of these factors come together to characterize the size, rate and pattern of flow, temperature regime, and chemical composition of the habitat. The community of invertebrates that subsequently develops reflects tolerance of and/or adaptation to these factors, together with colonization abilities from neighboring or distant sources. The latter is particularly important in regions where new habitat has been created, such as by shifts in regional geology, affecting the level of the groundwater table, or by the retreat of glaciers during the Pleistocene (Williams and Williams, 1999). The role of these factors will be re-visited later in the chapter.

As noted, strictly speaking, a spring can be defined only in its proper geological setting, taking into account numerous variables that characterize its nature and potential as a habitat. These variables include some that are easily measured, such as pH, temperature, current speed, and dissolved oxygen, but others that are much more difficult to quantify, such as size of underlying aquifer and nature and length of groundwater flow paths (both of which may influence habitat stability). Given limitations in acquiring measurements of some of these variables, and in preference to a rigid classification of springs, for which there will always be exceptions, Danks and Williams (1991) proposed using a minimum of five key descriptors to characterize each habitat sampled for biological data (Table 1). These descriptors are seen as providing sufficient characterization of fundamental elements of springs as habitats, and comprise: source geometry; rate of water supply; temperature; chemistry; and persistence. Thus, for example, the following minimum description provides a useful and comparable characterization: 'low volume, warm, freshwater, annual, temporary rheocrene.' Where logistically possible, such a basic description should always be supplemented by additional information, measurements and photographs.

A few words about seeps

In addition to springs, *senso stricto*, most of the world's major biomes support another form of habitat fed by groundwater, namely 'seeps.' Unfortunately, the latter have been far less studied. While both these habitats are fed by groundwater and may have stable temperature and chemical properties, they can differ markedly in their physical characteristics. For example, springs are likely to have a more defined footprint at their point of issue, deeper water and greater discharge, whereas seeps are shallow (often just a film of water over rock surfaces), and typically discharge more diffusely – the water typically infiltrating into surrounding soil and/or vegetation, such as mosses. Their rate of flow is generally insufficient to form an outflow stream. The limited data available (Williams, 2016) show an apparent global absence of a few major taxa in seeps (e.g., bivalves, isopods, mayflies), and, at the genus level, approximately 41% of the diversity seen in springs. The two habitat types share 100 genera, which include many freshwater

Table 1 Recommended minimal key descriptors of springs for biological data.

Key descriptors	*Status observed*		
	Low	*Intermediate*	*High*
Nature of source	Helocrene (discharge or seep into marshy/mossy substrate)	Limnocrene (discharge into basin)	Rheocrene (rapid flow into defined channel on discharge)
Discharge at source	Low volume (<0.01 m^3 s^{-1})	Medium volume (0.01–0.5 m^3 s^{-1})	High volume (>0.5 m^3 s^{-1})
Water temperature	Cold (<10°C)	Warm (10–40 °C)	Hot (>40 °C)
Chemistry: as total dissolved solids	Fresh water (<1000 ppm)	Mineral (1000–35,000 ppm)	Saline ($>35{,}000$ ppm)
Persistence[a] (as approx. interval between major disturbances)	Intermittent (typically annual, but up to 5 years)	Apparently permanent (>5 years i.e., some signs of inconsistency)	Permanent (>50 years; no disturbance)

[a]Unless historical records are available (e.g., from paleoecological evidence - see Williams and Williams, 1996), interpretation here is likely to be largely subjective, based on observations of physical and biological conditions made at the site.

From Danks HV and Williams DD (1991) Arthropods of springs, with particular reference to Canada: Synthesis and needs for research. *Memoirs of the Entomological Society of Canada* 155:203–217.

generalists (e.g., *Ischnura*, *Hydroporus*, *Chironomus*, and *Hydroptila*), but there are 55 genera found only in seeps, which include some seep specialists (e.g., *Stolonicyclops*, *Trichothyas*, *Viehoperla*, *Oconoperla*, *Ochterus*, *Antillocladius*, *Orethalia*, *Chilostigma*, and *Clostoeca*). These records suggest that the invertebrate faunas of seeps contain a component that is a sub-set of the fauna found in springs, but also a second component that is comprised of seep specialists. Further studies are required to test these hypotheses.

General habitat conditions in springs

For aquatic invertebrates, it is important to remember that environment and community are intimately linked and that springs represent a range of habitats from the 'classical' highly stable (especially in terms of temperature and discharge) type to those with a more seasonably variable hydroperiod, such as those associated with wetlands (Danks and Rosenberg, 1987). Many factors influence habitat conditions in springs, including those associated with the terrain (e.g., local geology, topography, and groundwater reserves) and geographical position (e.g., latitudes and glacial history), alongside smaller-scale influences such as vegetation (submerged, emergent, and riparian, especially if it shades the water) (Danks and Williams, 1991).

Terrain features dictated by geology and topography determine the supply of water and how it varies, together with the level and variability of its temperature and chemical composition. Thus, large groundwater reservoirs buffer the habitats from erratic drying and other major changes, they tend to enhance the rate of flow but reduce its variation, and they stabilize temperatures. Longer groundwater residence in softer rocks increases mineralization, but depending on the composition of the rocks may either increase or decrease pH (Van Everdingen, 1991). Permanent springs are fed by groundwater with at least a 1-year residency underground, but the water of many springs is fossil water that emerges from the ground long after it entered, often 10,000 years later (Downing et al., 1977).

Conditions above the ground surface are modified on a broad geographical scale by local climate and other regional elements - such as photoperiod, known to promote the seasonal succession of invertebrate species and algae that occurs in springs despite oftentimes very constant temperature (Teal, 1957) - and on a yet smaller scale by the size of the spring, its vegetation, and habitat diversity. These influences especially affect temperature, primary productivity, allochthonous food (such as dead leaves) supply, and other ecological factors. Thus while a spring may have very uniform abiotic conditions, there may be considerable annual variation in its biotic conditions (Varza and Covich, 1995). High mineral content creates mineral springs, including salt springs (Ring, 1991); high temperature groundwater creates thermal springs (Pritchard, 1991); and erratic or surficial discharges produce intermittent springs. Discharge has an important effect on spring-bed substrates, which have a major influence on the invertebrate community. For example, constant or intermittent high flow rates remove fine particles thus increasing the mean particle size on the bed and reducing the amount of detrital food materials. In contrast, where the water wells up into a basin, fine particles accumulate. Highly mineralized springs may precipitate flocculent substrates.

Broad characteristics of the fauna

Within the last couple of decades, there have been several attempts to bring together the collective knowledge of spring faunas with the aim of galvanizing further study, synthesis, and conservation (Williams and Danks, 1991; Ferrington, 1995; Hinterlang and Lischewki, 1996; Botosaneanu, 1998; Glazier, 2014). However, while the spring faunas of some regions (e.g., Europe and North America) and some taxa (e.g., Trichoptera, Diptera, and Acari) are becoming better known, the information base for spring communities in most geographic regions of the world is very sparse (Yule, 2004).

In lotic systems, the diversity of invertebrates generally increases downstream. Typically, therefore, the section of channel immediately below the outlet (springbrook) will have a lower diversity than the stream, whereas the spring itself will have the least (Ward and Dufford, 1979). However, this is not always the case (Resh, 1983), and certain taxa may be particularly species rich at the source. For example, Gathmann and Williams (2006) recorded 38 species of Limoniidae (Diptera) from 30 coldwater springs in southern Ontario, Canada. Interestingly, of the total of 86 insect species found, 55% were found at three or fewer sites, and only for very few of these rare species were more than 10 individuals m^{-2} collected. Inter-annual differences were also apparent, with emergence records from a single year, on average, containing around 50% of the total number of species found in the entire study. Temperature and discharge correlated most strongly with insect community similarity among springs.

Invertebrates collected in or near springs range from permanent residents to those that are just visiting - to avail themselves of food or use these habitats as 'stepping-stones' in an attempt to reach other waterbodies. Many of these non-residents do not breed in springs yet they may dominate the fauna. For example, of the 33 species of aquatic beetle found in a spring in North Dakota, 64% were non-resident (Roughley and Larson, 1991). Resident species are derived from several different sources (Fig. 2). At the core, are species (termed 'crenobionts') that are confined to springs and/or seeps and which exhibit suitable adaptations to cold water and constant abiotic conditions (Danks and Williams, 1991). Another important component comprises the phreatic species of turbellarians, micro-crustaceans, mites, plecopterans, and other taxa that live in suitable, oxygenated groundwaters and enter the springs that emanate from them. Generalist species from downstream coldwater brooks also enter where there is sufficient flow (rheocrenes). Limnocrenes and helocrenes may contain some lentic species, although not those that cannot tolerate very cold water (e.g., pond species). Some species are associated with spring margins, especially where there is abundant moss or organic materials, or a distinct splash zone, for example, mites, collembolans, and various semi-aquatic dipterans. Other species may be derived from the wet soil at a spring's edge (e.g., rotifers, mites, nematodes, snails). Such species living in springs, but not exclusively so, are often termed 'crenophiles.' Hot springs and saline springs are populated by a low diversity of extremely tolerant species, typically, in the case of insects, belonging to the Diptera, Coleoptera, and Hemiptera (Ring, 1991) - additionally, Odonata may occur in hot springs (Pritchard, 1991).

Specifics of the fauna

The following is a summary of invertebrates known to inhabit springs. These records, wherever possible to the level of genus, are taken from a global synthesis (Williams, 2016) which should be consulted for greater details. The data-set is by no means complete, but hopefully will serve as a useful first step toward creating a global framework to which new occurrences of species in springs can

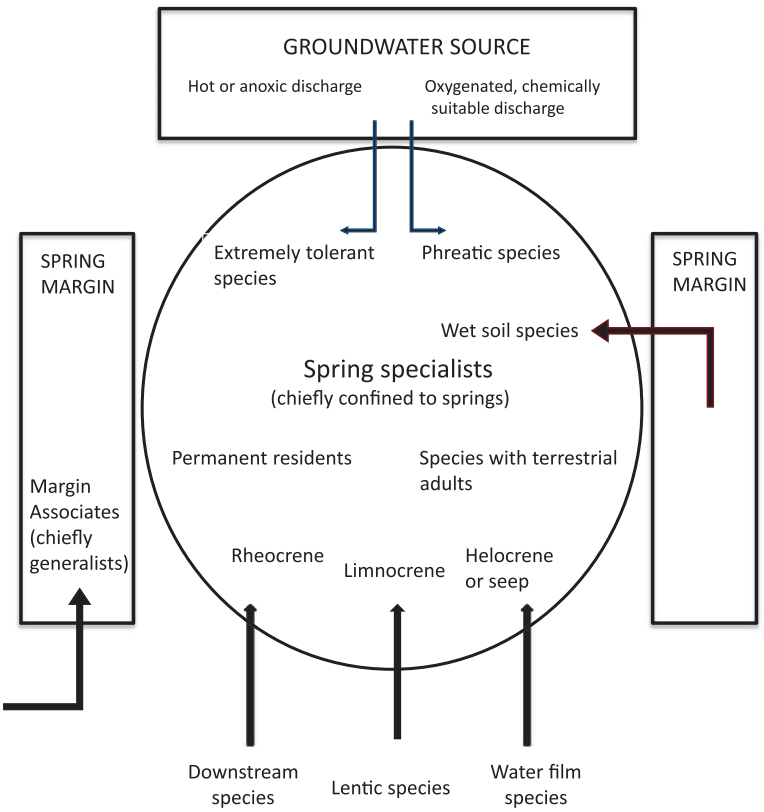

Fig. 2 Components of the faunas of springs and seeps. Modified after Danks HV and Williams DD (1991) Arthropods of springs, with particular reference to Canada: Synthesis and needs for research. *Memoirs of the Entomological Society of Canada* 155:203–217.

be added. Taxa range from the more sessile forms, such as sponges and hydrozoans, through small motile forms, such as gastrotrichs, rotifers and nematodes, to micro-crustaceans, mites and many insect orders. Groups that have freshwater representatives but appear to be absent from springs include bryozoans (more restricted to warmer lentic and lotic waters; Wood, 2010), branchiopods (more characteristic of lentic waters that have a drying phase; Williams, 2006), and aquatic orthopterans, lepidopterans, and hymenopterans. The data-set comprises 379 genera, across all taxa. See also photographs of some of these taxa in Fig. 3 (Tricladida, Gastropoda, Tardigrada, Ostracoda, Isopoda, Acari, Collembola, Coleoptera, Diptera - Chironomidae, Trichoptera).

- *Porifera* - freshwater sponges in the genus *Spongilla* are widespread in cold fresh waters, but also occur in thermal springs (Hooper and Van Soest, 2002).
- *Hydrozoa* - the widespread genus *Hydra* has been found in springs. *Velkvrhia enigmatica* (Family Bougainvilliidae), has been found in springs in Slovenia (Zagmajster et al., 2011).

Tricladida - over 100 species of freshwater planarian are associated with cold waters, with genera such as *Crenobia*, *Polycelis* and *Phagocata* occurring commonly in springs (Reynoldson, 1967). Habitats of the, largely unidentified, Microturbellaria include springs (Kolasa and Tyler, 2010).

Gastrotricha - freshwater gastrotrichs (Family Chaetonotidae) have been recorded from springs (Balsamo et al., 2008; Nesteruk, 2008).

Rotifera: rotifer species in the genera *Dipleuchlanis*, *Ptygura* and *Wierzejskiella* have been collected from spring/seep complexes (Segers, 2004), and species within the genus *Lindia* are known from hot springs (Wallace et al., 2005).

Nematoda: species within the orders Monhysterida and Plectida (Subclass Chromadoria) are among the most widely reported nematodes from fresh waters, likely including springs (Abebe et al., 2008). At least eight families of nematode contain species capable of living in hot springs (Poinar, 2004, 2010).

Oligochaeta: around 100 species of aquatic oligochaete are found exclusively in groundwater environments, some of which are deemed important centers of endemism (Martens et al., 2008). A number of tubificid genera (e.g. *Ilyodrilus*, *Limnodrilus* and *Varichaetadrilus*) are associated with karst systems (Webb et al., 1996). Several genera within the subfamily Naidinae have been recorded from springs and/or seeps (e.g. *Allonais*, *Dero*, *Pristina*, *Stylaria*).

Gastropoda: springs and springbrooks support snail taxa not typically found in larger running waters, although individual sites tend to have low species richness (1–6 species, but at very high densities). Regionally these habitats support highly diverse assemblages of snails – especially of hydrobiids (Strong et al., 2008). Other families known to live in springs include: Melanopsidae, Assimineidae, Pomatiopsidae (saline springs), Planorbiidae, and Physidae. The high level of endemism in gastropods occurring in spring and related groundwater systems is associated with the extinction of many freshwater snail species as these habitats become degraded or destroyed by human activities, such as water abstraction, trampling of outflows when used for watering livestock, and irrigation or mining (Williams et al., 1990; Keleher and Sada, 2012).

Bivalvia: while clams are important members of the benthic communities of rivers and lakes, their occurrence in springs appears to be much rarer. Indeed, the only records are of the sphaeriid genus *Pisidium*, which has a cosmopolitan distribution (Cummings and Graf, 2010) and is capable of living in a very wide range of waterbodies.

Tardigrada: most waterbears are 'limnoterrestrial,' living in the thin films of water on the surfaces of moss, lichens, algae and leaf litter. Some live in wet soils or in aquatic sediments, and others are associated with water margins (Garey et al., 2008). Five, widely distributed genera, from three families, live in springs or at their margins (*Bertolanius*, *Eohypsibius*, *Isohypsibius*, *Microhypsibius*, *Murrayon*).

Crustacea – Ostracoda: ostracods are common inhabitants of springs, where their ecology appears to be a complex product of many environmental variables, including water chemistry, thermal regime, and hydrogeology (Forester, 1991). Spring-dwelling ostracod are well represented by genera belonging to the Cyprididae and Candonidae. A number of genera are known from thermal springs, for example: *Chlamydotheca*, *Cypris*, *Potamocypris*, and *Thermopsis*.

Diplostraca: several of the more common genera (*Alona*, *Daphnia*, *Diaphonosoma*) contain species that are associated with springs, others live in wet *Sphagnum* moss.

Copepoda: a number of highly vagil and cosmopolitan species live in a range of subterranean waters, including springs (e.g., *Acanthocyclops*, *Diacyclops*, *Eucyclops*, *Attheyella*, *Bryocamptus*).

Peracarida - Isopoda: species within the genera *Asellus*, *Caecidotea* and *Lirceus* are found commonly in cool springs, and *Thermosphaeroma thermophilum* lives in hot springs (Wilson, 2008).

Amphipoda: amphipod diversity is highest in subterranean environments (45% of species), and especially so in the karst regions of Central and Southern Europe (Niphargidae), North America (Crangonyctidae), and Australia (Paramelitidae) (Vainola et al., 2008). Some genera are widespread, including in springs (e.g., *Gammarus*).

Decapoda: there appear to be relatively few decapods that inhabit springs per se (e.g., *Palaemonetes*), but there are burrowing crayfishes (e.g., *Fallicambarus*) that inhabit seepage areas where they excavate shafts down to the water table (Williams, 2006).

Acari: the super-order Acariformes contains a wide variety of aquatic mites, those belonging to: the Hydrachnidia (true water mites); the Halacaridae (a primarily marine family); and the Oribatida (a primarily terrestrial order).

Smith (1991) produced a detailed synthesis of the Hydrachnidia from springs in Canada and recorded, at that time, over 115 species in 57 genera and 25 families collected from springs across the country. He divided the water mite fauna into three ecological groups related to the mites' preferences for helocrene, rheocrene or limnocrene habitats. Families with genera very commonly found in springs include the Hydryphantidae, Lebertiidae, Pionidae, and Arturidae. The genus *Thermacarus* lives in hot springs.

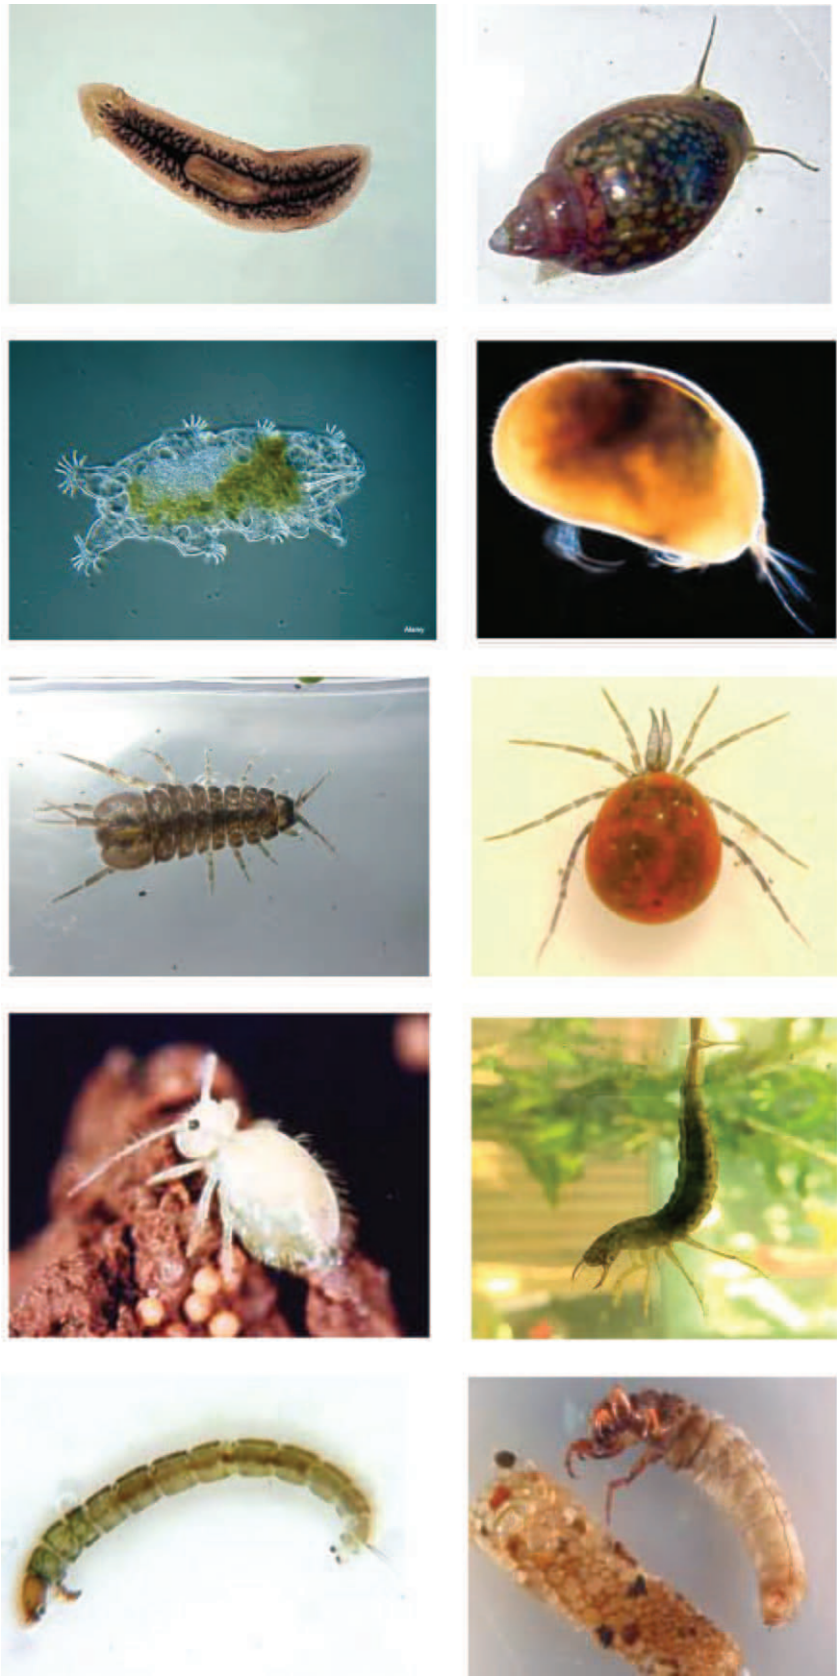

Fig. 3 Photos of representative invertebrate taxa found in coldwater springs.

Of the more than 1000 species of Halacaridae, only around 56 are known to occur in fresh water. These occur in both surface and subterranean waters, and have been recorded from springs. Genera collected from springs in Europe include *Copidognathus* and *Halacarellus* (Benfatti et al., 1989). Halacarids have a very low dispersal ability yet many genera and even some species are widespread (Bartsch, 2008).

Oribatid mites are largely associated with soil, forest litter, mosses and lichens, and only about 90 species, from 10 genera, can be considered truly aquatic. Habitat preferences in many are quite specific, and include springs (Schatz and Behan-Pelletier, 2008). Despite low diversity, aquatic oribatids can occur at very high densities. Some spring-dwelling species are very ancient, for example *Mucronothrus nasalis* is thought to pre-date the breakup of Pangea, about 200 million years ago. The distribution of this species is global, but discontinuous, and seems to be limited by temperature to cold, spring-fed water and cold bogs (Norton et al., 1988).

Collembola: springtails are particularly abundant in wetlands. In springs, they are most often encountered on the surfaces of helocrenes and limnocrenes, around the water margins, on saturated soil or on low vegetation (especially mosses) close to the water (Deharveng et al., 2008). Cosmopolitan genera commonly found in spring pools include *Isotomurus*, *Podurus*, and *Sminthurus*.

Ephemeroptera: despite being most often found in running waters, mayflies are neither abundant nor diverse in springs. Their life cycles are known to be tied closely to changes in water temperature, with small increases, for example, resulting in a different number of nymphal molts and early adult emergence. Perhaps the more constant temperature regimes of many springs lack cues essential to the timing of important mayfly life cycles events. Genera occasionally collected in springs\headwaters include: *Baetis*, *Serratella*, *Ecdyonurus*, *Epeorus*, *Rhithrogena*, and *Stenonema*.

Odonata: a number of dragonfly and damselfly genera, representing at least 10 families (Cordulegastridae, Petaluridae, Gomphidae, Libellulidae, Corduliidae, Hemicorduliidae, Calopterygidae, Coenagrionidae, Lestidae, and Megapodagrionidae), are associated with coldwater springs. Moreover, and perhaps reflecting their evolution in tropical regions, several genera support species that live in thermal springs, for example: *Cordulegaster*, *Ophiogomphus*, *Erythemis*, *Libellula*, *Orthemis*, *Pantala*, *Haeterina*, *Amphiagrion*, *Argia*, *Ischnura*, and *Lestes*.

Plecoptera: stonefly nymphs live, typically, in cold, clean running waters but are not particularly common in springs. A number of species (e.g., belonging to the Leuctridae, Nemouridae, Peltoperlidae, and Perlodidae) inhabit seeps and splash zones (Stewart and Stark, 1993).

Hemiptera: heteropterans can be found in a range of spring types. For example, corixids, notonectids and belostomatids occur in weedy limnocrenes and helocrenes, ochterids in shallow seeps with exposed rock surfaces, species of *Saldula*, *Micronecta*, *Anisops*, *Ambysus*, and *Limnocoris* in thermal springs, and species of *Diplonychus* in peat-mound springs.

Neuroptera: the megalopteran families Corydalidae and Sialidae have fully aquatic larvae that live in a wide variety of lotic and lentic waters (Cover and Resh, 2008). These include springs, with species of *Sialis* having been found in slow-flowing limnocrenes in several regions, and the corydalid genus *Neohermes* recorded from seeps in North America (Merritt et al., 2008).

Coleoptera: in Canada, up to 1991, the distribution of the 663 known aquatic beetle species among its major freshwater habitats was: lentic 61%, lotic 23%, springs 8%, other <1%, unknown 8%. The 63 spring-dwelling species belonged to: Dytiscidae (38 species), Hydrophilidae (9), Hydraenidae (8), Chrysomelidae (subfamily Donaciinae 6), Haliplidae (1), and Dryopidae (1)- (Roughley and Larson, 1991). Relatively diverse families deemed absent from the Canadian survey were: Gyrinidae, Scirtidae, Curculionidae, Amphizoidae, Elmidae, and Psephenidae. The occurrence or absence of these families broadly agrees with more global findings (Williams, 2016). Notable exceptions are the occurrence of Hydroscaphidae in seepages and thermal springs; the Scirtidae in seepages adjacent to lotic margins; the elmid genera *Heterelmis* and *Stenelmis* in springs (the latter also in warm springs); *Hydrochus* (Hydrochidae) in mound-springs and limnocrenes; and *Lutrochus* (Lutrochidae) in mineral springs.

Diptera: of the 150 families of Diptera, 27 can be considered to be 'marginally' to 'exclusively' aquatic. Nineteen of these have representatives that inhabit springs and seeps, many of them occurring on a global scale. Among the Nematocera, the following genera contain species that are especially notable for being spring/seep specialists: the tipulids *Brachypremna*, *Dactylolabis*, *Pedicia*, *Thaumastoptera*, and *Tipula* - further, many members of the subfamily Limoniinae are increasingly being captured in springs (see Gathmann and Williams, 2006). Among other nematocerans, the chironomids are well represented in springs: Podonominae – *Boreochlus*, *Paraboreochlus*, *Parochlus*; Tanypodinae – *Krenopelopia*, *Macropelopia*, *Pentaneurella*, *Zavrelimyia*; Diamesinae – *Diamesa*, *Pseudokiefferiella*, *Syndiamesa*; Orthocladiinae – *Antillocladius*, *Doithrix*, *Heleniella*, *Krenosmittia*, *Lymnophyes*, *Parachaetocladius*, *Parametriocnemus*, *Psilometriocnemus*, *Stilocladius*; Chironominae – *Krenopsectra*, *Neozavrelia*, *Stempellinella*. Many of the above genera specialize in specific temperature ranges. Alongside these stenotherms are generalist chironomid genera that frequently form part of the spring community: *Ablabesmyia*, *Procladius*, *Corynoneura*, *Cricotopus*, *Eukiefferiella*, *Heterotrissocladius*, *Orthocladius*, *Psectrocladius*, *Thienemanniella*, *Chironomus*, *Polypedilum*, *Micropsectra*, *Paratanytarsus*, *Stempellina*, and *Tanytarsus*. Ferrington (1998) estimated that at least 111 genera of chironomid, comprising at least 185 species, occur in North American springs, representing 19% of the total described species. For cold springs in Europe, the comparable statistics are 85 genera and over 200 species, representing 20% of the described fauna (Lindegaard, 1995). In springs in the Central High Plains of North America, Blackwood et al. (1995) found that the Orthocladiinae were more prevalent in rheocrenes, while the Chironominae were more abundant in limnocrenes.

Among the Brachycera, the following families contain species associated with springs and/or seeps: Stratiomyidae (*Beris*, spring margins); Empididae (*Hemerodromia*, *Oreothalia*); Dolichopodidae (raised peat-mound springs); Syrphidae (raised peat-mound springs); Sciomyzidae (snail-predators in seeps); Ephydridae (*Ephydra*, *Ephydrella*, *Paracoenia*, and *Scatella* in thermal springs).

Trichoptera: currently, 616 genera and 49 families of caddisfly are known (Trichoptera World Checklist, 2015). Of these, at least 21 families, comprising at least 59 genera, have larvae that live in springs and/or seeps, including both cased and net-spinning forms. Some genera show distinct microhabitat preferences (e.g., *Homoplectra* – rockface springs and seeps in montane areas,

Moselyana – subalpine forest seeps, *Chilostigma* – seeps in wet meadows, *Pseudostenophylax* – cool spring runs and small intermittent streams), whereas others encompass a wider range of habitats that include springs (e.g., *Cheumatopsyche*, *Polycentropus*, *Lepidostoma*, *Anabolia*, *Hesperophylax*, *Limnephilus*, *Platycentropus*, *Helicopsyche*, and *Oecetis*). An analysis of the caddisfly larvae living in springs across Canada showed some general trends together with some regional and habitat-related differences (Williams, 1991a, b). Notably, the number of species present in the springs increased with habitat diversity, and around 35% of the species recorded were from the Limnephilidae. Limnocrenes and rheocrenes with a weak current and small substrate particles supported few species, but often large populations. Grazers, shredders and predators were common, but filter-feeders were rare – an exception being the hydropsychid genus *Parapsyche*. Ordination of the data confirmed an east/west difference in caddisfly communities with influential variables including elevation, extent of groundwater source, and summer temperature. Factors strongly influencing the composition of the spring communities in both the west and east included riparian vegetation, substrate particle size, current, and pH. Springs in which caddisfly larvae were strongly involved in the processing of detritus were dominated by *Homophylax* in the west, but by *Frenesia* and *Lepidostoma* in the east. Predators and scrapers were abundant only in springs having relatively high microhabitat diversity, current speed, and pH.

Ecological controls

Comparisons among springs - Most permanent freshwater springs are stable environments, with many of their physical and chemical properties fluctuating less than in streams, rivers, and lentic waterbodies. In some springs, however, chemical composition, suspended solids, and even discharge and temperature, show both seasonal and sudden variation. This is especially evident in seasonal springs discharging from aquifers of limited storage capacity and in temporary springs discharging from shallow systems. However, it also occurs in some perennial springs (Van Everdingen, 1991). Springs characterized by such variation have not been studied extensively, but are known to be common in alpine headwaters (Maiolini et al., 2011). Most of the following discussion is aimed at 'classical,' coldwater springs, those with low environmental variability.

Although one of the first studies done on springs incorporated standing crop and energy flow models (Silver Springs, Florida; Odum, 1957), most of our knowledge on these habitats has come from a taxonomic rather than a quantitative ecological approach. Hence, there persists a weak understanding of the community dynamics of springs, and especially seeps, particularly in terms of how their communities develop, are organized and function. There is also much that is not known of the life histories and physiological properties of spring-dwelling species – adaptations that enable these organisms to live and persist in these habitats.

It is clear that springs support faunas that, collectively, include most of the major taxa of invertebrates capable of living in fresh waters. From sponges, hydras, gastrotrichs, rotifers, nematodes, and oligochaetes, to mollusks, mites, and a wide variety of insects, all have representatives that have adapted to the oftentimes constant physical and chemical environments that springs present. Further, their faunal composition has similarities across much of the world, even to the family and genera level. However, in some regions global processes have impinged on these patterns. For example, within the last 15,000 years coldwater springs in some temperate regions have been destroyed by Pleistocene glaciation. Springs re-formed since ice retreat often have had insufficient time to repopulate fully such that, in Southern Ontario, Canada, for example, faunas are dominated by the more vagil insects – typically, nemourid stoneflies, chironomids, and caddisflies (Williams and Williams, 1998). Unlike in non-glaciated parts of North America, mollusks and triclads are not well represented.

At the local regional level, studies show differences in species from spring to spring, and also in their abundance and time of adult emergence (e.g., in Plecoptera, Trichoptera, and Diptera; Erman, 1998; Gathmann and Williams, 2006). From a study of the insects living in 75 springs in the south-eastern Alps, Maiolini et al. (2011) concluded that springs have an island-like property, with each spring having its own specific history and abiotic characteristics which select for unique faunal patterns. In a separate study in the same vicinity, Stoch et al. (2011) concluded that, for the meiofauna (oligochaetes, mites, and crustaceans) spatial patterns of assemblages at the regional scale were best explained by altitude, water chemistry (related to geology), and water-flow regime – as was earlier found for macroinvertebrate assemblages by Barquin and Death (2006), Ilmonen et al. (2009), and Glazier (1991). To these controlling influences, Myers and Resh (2002) added spring permanence, lack of disturbance, and coldwater temperatures as factors responsible for explaining higher species richness of Trichoptera. Ferrington (1998) further added within-spring habitat heterogeneity, operating on a local scale, as a determinant of the taxonomic composition of individual springs. Mattson et al. (1995) provided evidence for spring-bed substrates being among such determinants in that woody substrates in karst-fed springs in Florida were dominated by chironomids, mayflies and caddisflies (with snails and amphipods occasionally abundant), but sandy substrates were populated with other chironomids, snails, bivalves, and oligochaetes. In Stoch et al.'s (2011) study, such microhabitat features, together with human disturbance, were less influential, but these authors conceded that where anthropogenic pressure is high (see Sarkka et al., 1997), it can become the foremost influence on spring faunal assemblage structure and distribution. For example, Ferrington (1998) showed that the chironomid genera of two North American springs that had become contaminated by cattle dung came to resemble those found in similarly enriched lower-order streams – the important spring specialists having been lost.

Specialists versus *generalists* - Another issue to address is what adaptations define spring and seep generalists and specialists. In an analysis of life history traits, Williams (1991a,b) concluded that, in terms of life history theory, the limited information available for spring species showed most support for a deterministic view, based on the predictions of r-, K- and A-selection (Greenslade, 1983). Permanent, coldwater springs are habitats characterized by low disturbance and low adversity – assuming that

low water temperature is not an adversity for lotic organisms, many of which have their ancestry in cold, headwater streams. According to the predictions, most of the fauna should be K-selected in that: (1) the community should show intermediate to high diversity (see Lindegaard, 1995; Ferrington, 1998), and consist primarily of sessile grazers/gatherers (see Anderson and Anderson, 1995) and filter-feeders with narrow, specialized niches due to heavy competition; (2) productivity and individual growth rate should be high (see Williams and Hogg, 1988), although growth may be low in non-cold-adapted species (Iversen, 1976); (3) survival rate may be low, and length of life, time to maturity, and fecundity intermediate (see Tilly, 1968); (4) population densities should be near carrying capacity; (5) incidence of dormancy should be low, as should that of parthenogenesis (but see Norton et al., 1988); (6) predators should be rare; and (7) vagility should be low to intermediate.

Community assembly - Permanent coldwater springs, perhaps more so than seeps, present highly persistent habitats for invertebrates and may contain a disproportionately high number of unusual species for their relatively small size (Erman and Erman, 1995). Species presence may be the result of several different entry pathways into the faunal assemblages of individual springs. These pathways result in various species statuses that include (with trichopteran species examples): (1) *habitat specialists* – (e.g., *Crunoecia irrorata*, *Anagapetus debilis*) which are largely crenobiontic species arriving from similar habitats that may be adjacent or at some distance, depending on migration abilities; (2) *habitat generalists* – (e.g., *Ptilostomis ocellifera*, *Hesperophylax designatus*) including crenophilic species that may arrive similarly, but also by range extension from downstream springbrooks; (3) *relict species* – (e.g., *Apatania muliebris*, *Rakiura vernale*) previously abundant species that have undergone range contraction (often through climate change, but increasingly through human activity) and now occur in only one or a few adjacent springs; and (4) *endemic species* – (e.g., *Agarodes ziczac*, *Lepidostoma ojanum*) species which originated in a single, stable and persistent spring locality that is ecologically isolated and to which they are now highly adapted. Given these different components to spring faunas, it is important to consider whether spring faunas are stochastic aggregates of habitat- (temperature)-limited species or true, coevolved communities. A relevant observation in this regard was made by Myers and Resh (2002), who found that among the caddisfly assemblages from 28 springs in the Great Basin, USA, although several springs had very similar physicochemical characteristics, none was identical, indeed the assemblage totals ranged from four to 18 per spring. Lack of assemblage repeatability suggests a more stochastic colonization process. Further, given the somewhat eclectic nature of the faunal source-pathways, it seems unlikely that such a resulting mix of species would be able to function as a true, cohesive and fully interactive community. Clearly, we need many more studies on the development of spring communities in order to resolve these issues. Toward this goal, the main environmental factors thought to shape the composition of these invertebrate assemblages/communities are outlined in Fig. 4.

As noted earlier, knowledge of spring invertebrates has arisen from two, largely uncoordinated, approaches: the first based on the taxonomy of particular invertebrate groups whose range of habitats includes springs (e.g., Feldman, 1974); the second comprising a relatively small, unconnected series of population or community studies from single springs (e.g., Teal, 1957; Tilly, 1968; Winterbourn, 1973). Specific, regional surveys of spring faunas have been rare in the past (e.g., Tuxen, 1944; Botosaneanu and Negrea, 1961), but are now becoming more common and informative. For example, from a study of the mayflies, stoneflies and

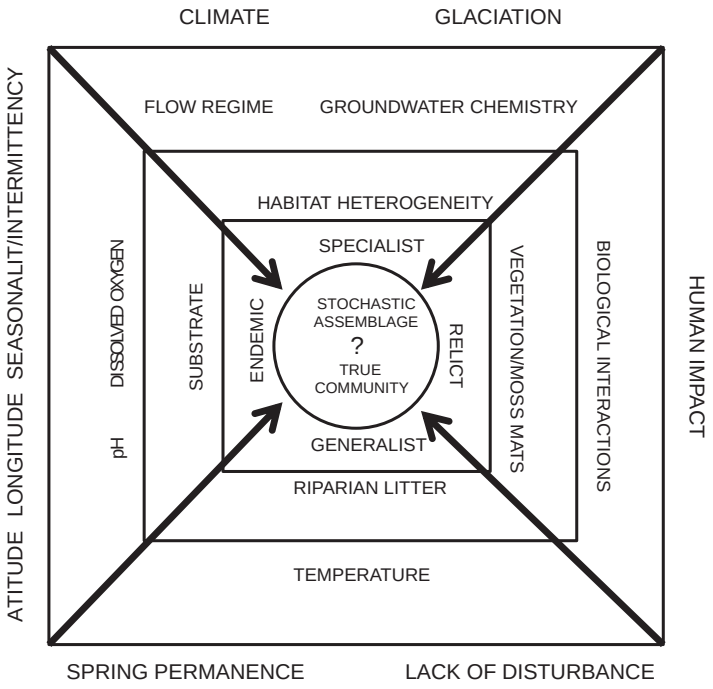

Fig. 4 Summary of the main environmental factors thought to shape the composition of invertebrate assemblages/communities in freshwater springs (the arrows indicate the general direction of flow of the factor influences).

caddisflies found in springs of the Trentino Region of Italy, Maiolini et al. (2011) were able to propose three important functions of coldwater springs in alpine landscapes: (1) in such harsh environments, the mild and stable environmental conditions of springs contribute to maintaining and enhancing the regional biodiversity; (2) springs act as refugia for stream biota, providing more benign conditions during spates and drought – common features in alpine headwaters; and (3) springs provide specialized habitats for strictly crenobiontic species.

Community and population ecology - Perhaps the greatest ecological utility that springs and seeps represent is their potential to contribute to our understanding of community ecology and ecosystem function. Indeed, Odum (1971) proposed that springs are natural, constant-temperature laboratories, and pointed out that their study had pioneered development of the trophic dynamics approach to ecosystem studies in general. In 1998, Williams and Williams identified the following features of springs that had the potential to advance community ecology: (1) their communities are naturally less complex than those occurring in most other aquatic habitats yet, as far as is known, they possess the structural (e.g., a wide range of species representing many major taxa) and functional (e.g., producers, various levels of consumers, and decomposers) elements seen in other communities; (2) the natural variation in community structure, and presumably in function, seen among natural springs represents an ideal testing ground for questions of community trophic efficiency, predator-prey dynamics, and competition – particularly in the more extreme spring types (thermal and saline) which have very simple community structures (see Collins et al., 1976). A number of population-level research avenues also could be explored using springs, for example: (1) given the high degree of specificity of many spring-dwelling species to this habitat type, alongside the oftentimes isolated nature of individual springs, they could provide ideal habitat island models for the experimental analysis of Metapopulation Dynamics Theory (Gathmann and Williams, 1998); (2) they could be used to compare the population traits of coexisting species that differ widely in their status (e.g., specialists versus generalists), as shown by spring species with very narrow habitat requirements (e.g., the endemic caddisfly *Lepidostoma ermanae*) and the widespread caddisflies *Chyranda centralis*, *Wormaldia occidea*, and *Rhyacophila grandis* (Erman and Erman, 1995); and (3) using thermal springs to tease apart the influences of important abiotic habitat variables, such as water temperature and chemistry, on populations – effective, natural elimination of thermal differences among adjacent sections of spring or seep complexes (and thus removal of a strong environmental variable) has been proposed as an ideal test condition for the study of the influence of habitat heterogeneity on species richness (Ferrington et al., 1995; see further examples in Williams and Williams, 1998).

Conservation concerns

Knowledge of spring faunas has the potential both to address zoogeographical issues and to monitor environmental change. An example of the former is the proposal that for mites, in Canada, springs have played important roles as both refugia and routes for migration. As in Europe, not only have present-day, temperate lowland springs allowed the survival of cold-adapted species after ice retreat, but they also may have allowed the survival of such species in marginal refugia during glacial maxima (through maintenance of interstitial spring habitats in glacial deposits near the southern limits of ice sheets). Refugial survivors then were able to repopulate newly created habitats upon subsequent glacial retreat. It is possible that such 'leading-edge' colonization at glacial margins may subsequently have produced a spatial assortment of genomes, perhaps promoting divergence and speciation (Hewitt, 1996).

Monitoring environmental change involves the very close relationship, as part of the hydrological cycle, between groundwater and the atmosphere, where changes to the latter (such as a rise in global air temperature) are likely to affect the former. Such a change is likely to have serious consequences for spring discharge, in that permanent springs may become intermittent, and also for the typically stenothermic communities of organisms that live in springs. A study of a spring in which the water temperature was artificially raised by 2 °C to 3.5 °C to simulate global warming, resulted in a suite of changes to the fauna including: a decrease in total invertebrate numbers; earlier onset of adult insect emergence; increased growth rates and precocial breeding in amphipods; smaller size at maturity in stoneflies; and altered sex ratios in caddisflies (Hogg and Williams, 1996). Such responses to environmental change make spring faunas very useful in detecting changes in water quality of their source aquifers and hence the potability of these important reservoirs (70% of freshwater is bound in ice and snow. 30% is freely available, in liquid form, of which 99.6% is groundwater). Williams et al. (1997) showed that, in a series of springs in Southern Ontario, Canada, there was a strong relationship between the fauna and chloride – a major contaminant of the groundwater in the study area and believed to be derived from the application of road de-icing salt. Several taxa were closely associated with high chloride levels (e.g., the dipteran families Tipulidae and Ceratopogonidae), whereas others occurred only in springs with low chloride (e.g., Turbellaria and *Gammarus pseudolimnaeus*). Not only can spring faunas be used as indicators of contemporary spring health, where sufficient sediment depth occurs coring can yield chitinous remains that may allow reconstruction of the past history of source aquifers and their catchments, especially during the Anthropocene. For example, a core taken from the bed of a Canadian spring showed evidence of changes in land use over a 200-year period. Fossil sclerites of, predominantly, caddisfly and chironomid larvae indicated a shift from pre-European settlement forest, through a land clearing/agricultural phase, to a present-day increase in urban development (Williams and Williams, 1996).

Spring faunas provide unique information on endemism and also on post-glacial colonization patterns. Springs are habitats where relict species of these former times have endured, protected from large oscillations in climate. Springs hold a position of importance as study areas that is far out of proportion to their size and number. However, the same cannot be said about their global knowledge base. Some collections of specific taxa from springs exist in the general holdings of national or regional museums,

but these collections seldom have sufficient accompanying habitat description or quantification to make them useful except in an introductory capacity. This dearth is occurring at a time when they and their source aquifers have come under extreme pressure from human activities. Springs themselves are being destroyed by, for example, use as stock watering holes, water-bottling sites, spas, and as a consequence of logging and transportation routes (Brune, 1981) - whereas their water sources are being rendered unfit for use by both invertebrates and humans (Liu and Liptak, 1999). Some causes of contamination are localized, while others, such as acid rain, may be widespread. However, contaminants may migrate along subsurface paths, many of which emerge at the surface as springs before flowing into streams, lakes and wetlands. This form of contamination is increasing primarily because the diversity of chemicals used in industry and agriculture is high and many of them persist in the groundwater zone (Bowler, 2014). Detection involves costly and repetitive sampling at depth. Biomonitoring of spring faunas has been proposed as a viable alternative, as these organisms are continually subjected to the emerging water and integrate the effects of geology, vegetation and climate over time (as many have at least a one-year life cycle) (Biological Survey of Canada, 1990). Where palaeoecological information is available, it is possible to build up an accurate index of groundwater quality and the history of individual aquifers.

Williams and Danks (1991) drew up a series of recommendations for the protection of springs that comprised: (1) preparing inventories of spring types and their distributions, at both regional and continental levels; (2) surveying their floras and faunas so as to enable the detailed study of representative spring types and regions; (3) making, alongside the biota, detailed descriptions of local geology, hydrology and climate, together with comprehensive analyses of water chemistry; and (4) preserving rare and regionally characteristic spring types and their biotas – the latter to be accomplished through: restricting the capping of springs for commercial use; establishing and enforcing protective areas (e.g., woodlands) around springs, including fencing to prevent trampling by livestock; raising public awareness of the importance of springs; and establishing appropriate protective legislation, perhaps most effectively focused on maintaining high quality groundwater. Groups identified as needing to take responsibility for the implementation of these recommendations include federal and local governments, natural history and other societies, individuals, and landowners. Such action is to be strongly encouraged.

Knowledge gaps

- expand the taxonomic base of spring faunas to cover poorly known groups, such as the porifera, hydrozoa, rotifers and nematodes.
- encourage autecological studies of individual, particularly keystone species, but also of species that may be widely distributed yet occur at very low densities in individual springs.
- undertake more quantitative analyses of spring communities, paying particular attention to food/energy pathways and to the link between species and their microhabitats.
- how are food resources shared given the high number of species feeding on the same materials (e.g., fine particular organic material and epilithon, via similarly-structured mouthparts, e.g., chironomid larvae and limoniid larvae) - are all of the food niches filled?
- determine the role of metapopulations, especially in the survival of regionally rare species.
- explore the utility of using spring communities as biological indicators of the health of source aquifers.
- examine the potential of springs to be used as natural, constant-temperature field laboratories in which ecosystem-level hypotheses on physiological and ecological properties can be tested - e.g., on cold stenothermy and climate change.
- seek answers to questions on endemism and zoogeography.
- further develop effective conservation protocols for springs subject to single or multiple human use - e.g., water abstraction or livestock grazing.

Acknowledgments

I thank colleagues past and present who have shared my interest in springs and their invertebrate faunas, but most notably the late Dr. Lazare Botosaneanu, Dr. Hugh Danks, Dr. Oliver Gathmann, Dr. Dirk Hinterlang, Dr. Ian Hogg, the late Prof. Noel Hynes, Dr. Nancy Logan, Dr. Ian Smith, and Dr. Catherine Yule.

Importance of the Micro-scale for the Macro-scale—What Can We Learn From Groundwater Ecosystems?

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Aquifer Groundwater-bearing subsurface material; may be unconsolidated with sedimentary grains (boulders, gravel, sand, silt, clay) or consolidated rock. In the latter case, the groundwater flows through uncemented porosity or secondary porosity in the form of fractures and/or karst features (resulting from rock dissolution).
Contamination Input of unwanted or even poisonous substances. May be organic or inorganic, anthropogenic, or from a natural disturbance.
Eukaryotes Unicellular or multicellular organisms where cells have a nucleus.
Fauna Generic notion, usually meaning multicellular eukaryotes of the animal kingdom.
Groundwater Subsurface water that saturates all pores and voids and only moves by gravitational force; the limit to surface-characterized interstitial zone is imprecise.
Individual-based models (IbM) A type of agent-based model (ABM) where individuals or agents receive properties per cell or agent, not just average properties, and where they are equipped with behavioral rules and their stochastic likelihood. These stochastic parameters are set to be different in each run. Running this model many times though produces a range of results for the desired outcomes, which can be interpreted as emerging properties.
Metazoa "Higher" animals, i.e. eukaryotic, multicellular organisms.
Micro-scale In the strictest sense, the scale between the nanometer and millimeter scale; for the purpose of this chapter, in the wider sense, the scale of the water-saturated pore, or network of pores in sediments.
Microbes Summary notion for eukaryote and prokaryote microorganisms, i.e. unicellular organisms.
Natural attenuation Self-cleaning by abiotic and biotic processes.
Pore A void space in an aquifer material such as the space between the sedimentary particles or the fractures within rock.
Prokaryotes Unicellular organisms without a nucleus.
Protozoa Unicellular "animal-like" organisms; generic, non-taxonomical notion encompassing unicellular eukaryotes, i.e. flagellates, ciliates, amoebae.

Introduction, with aim of the chapter

The ecological patterns of groundwater systems are usually overlooked because they are out of sight, and thus, out of mind. However, groundwater ecosystems are as fascinating as the deep sea, harboring phylogenetically ancient organisms which have adapted to their environment, among which many are endemics (species that occur only within a geographically narrow area; Wilkens et al., 2000). Prokaryote functions unknown, or untypical, from other environments are found in deep groundwater

(Chivian et al., 2008). Groundwater organisms in karstic, porous and fissured aquifers generally consist of eubacteria and archaea, fungi, protozoa, and often also small metazoa such as worms (nematodes, oligochaetes, polychaetes), tardigrades, mites, and crustaceans (mostly amphipods, copepods, isopods, ostracods). More important than their diversity, their biogeographical distribution, and their ability to survive in a scarce environment, is the fact that groundwater organisms contribute to the self-cleaning of aquifers: groundwater microorganisms provide important ecosystem services (Griebler and Avramov, 2015) such as degrading organic carbon, be it natural or contamination ("natural attenuation"; Rivett et al., 2008), with fauna sometimes further increasing degradation rates by rejuvenating microbial growth, and keeping the pore spaces open (bioturbation; Schmidt et al., 2017). Increased pore space variability leads to increased flow variability. This in turn results in higher oxygenation of the subsurface water in some parts (Schmidt et al., 2017). Due to these—anthropocentrically speaking—ecosystem services, groundwater is—depending on the region—a major source for drinking water (Quevauviller, 2007). Worldwide, drinking water production relies on groundwater to almost 50% (The United Nations—World Water Development, 2009).

Natural attenuation, i.e. the natural self-cleaning of the groundwater, including contaminant degradation, is an ecosystem service which is threatened by climate change (Retter et al., 2020) and increasing contamination of all types. In addition, an increase in groundwater temperature accelerates changes in the groundwater food web diversity and composition (Brielmann et al., 2009), and fauna's behavior (Avramov et al., 2013) and consequently their ecosystem functions. Some of the groundwater fauna representatives are larger than 1 mm and thus, strictly speaking, use space beyond the micro-scale. But even on the centimeter or decimeter scale, observations in-situ in the aquifer are hardly possible, and laboratory observations are still rare. We will focus here on porous aquifers because that is where most of the studies are performed. Most studies were motivated by the need for removing contaminants, and thus, disproportionally many results from contaminated aquifers and laboratory set-ups are available. The aim of the chapter is to conceptually describe in which ways the micro-scale variability influences the larger scales in the aquifer, and then to show with three (complexes of) case studies what researchers have found. The case studies originate from laboratory experiments and computational exercises and thus lack a geographic reference. Field-investigation on the micro-scale, if micro is taken literally, as smaller-than-millimeter, and/or pore scale, are virtually non-existent.

Main topics/concepts

Concepts

We argue that micro-scale processes are the basis for the groundwater food web. The relevant transactions contributing to attenuation and degradation are shaped not only by macro- and meso-scale conditions such as net recharge, net carbon import, climate, hydrogeochemical background from rock weathering, but also by micro-scale processes which form e.g. through temporally and spatially small-scale redox reactions resulting in the overall biogeochemical transformations. Fig. 1 shows this conceptually—a

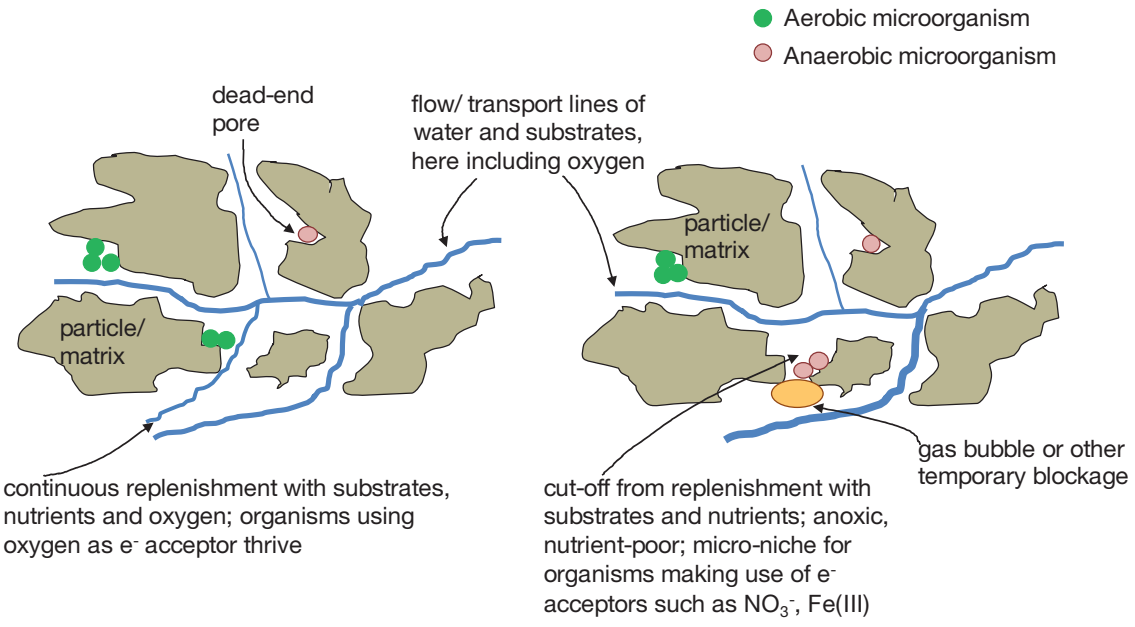

Fig. 1 Conceptual sketch of the micro-scale variability in pores and their hydraulic situation. Modified from Fig. 1 in Schmidt SI, Cuthbert MO, and Schwientek M (2017) Towards an integrated understanding of how micro scale processes shape groundwater ecosystem functions. *Science of the Total Environment* 592: 215–227, with permission from Elsevier B.V.

temporary blockage by gas bubbles or microbial growth creates zones that stop being replenished by flow-through (Thullner et al., 2002b). Gas bubbles have, depending on circumstances, however also the potential to reorganize sediments and thus increase flow diversity further (Liu et al., 2018).

Variabilities on the micro-scale interact with the meso- to macro-scale trends. The biogeochemical properties of groundwater are the result of the interplay of rock weathering and recharge from the surface—both replenish the aquifer with ions, nutrients, organic carbon, and electron acceptors. Inorganic carbon and ions enter the aqueous phase by dissolution and erosion, i.e. weathering, from the inorganic particles and the rock matrix. These processes depend on the physical and chemical properties of the rock matrix on the micro-scale properties, e.g. inclusions in the rocks. A considerable fraction of the weathering is mediated by microorganisms (Bennett et al., 2000). Microorganisms are known to occur patchily in aquifers, in micro colonies of up to 100 cells (Harvey et al., 1984; Fig. 2A). Such microcolonies have been confirmed in those laboratory settings, where resources were set to be limiting (Iltis et al., 2011; Fig. 2B).

Concurrently, the organisms act, use resources, and produce extracellular polymeric substances (EPS) and metabolites, in micro patches. However, they act not only by dissolving the mineral matrix and/or by shuttling electrons, they e.g. degrade organic material. Aerobic degradation reactions usually offer the highest energy gain for the organisms. Thus, such reactions will be performed preferably and fastest. This might lead on the micro-scale of the dead-end pore or colony to the complete depletion of oxygen, so that only compounds and ions such as nitrate, Fe(III), Mn(IV), sulfate, or CO_2 may act as electron acceptors. The energy that can be gained from such reactions is less than that gained from aerobic respiration. Since the products of these processes may be very different from those resulting from aerobic degradation reactions, the chemical conditions of the aquifer become a mixture of substances resulting from reactions at different redox states. The degradation of the substrate is limited by the transport of suitable reaction partners to the degradable compound and the microorganisms (Thullner et al., 2002b; Chu et al., 2005; the degradable compound may also be a contaminant: Anneser et al., 2008). In those cases, degradation was found to be most intense in the fringes where resources and favorable environmental conditions are in the optimum relationship to each other (van Breukelen and Griffioen, 2004). This fringe zone is often only a few millimeter wide (Bauer et al., 2008), but its effects are also measurable on the meso-scale in the field (Anneser et al., 2008). Natural attenuation and contaminant remediation thus rely on degradation in such fringe zones which themselves depend on the micro-scale environment (Meckenstock et al., 2015). Note that mass transfer limitations to the cells occur also when concentrations of contaminants decrease below a cell-relevant limit, independently of the amount and distribution of biomass (regime (ii) in Sun et al., 2021). However, if and where biomass has adapted after a contaminant was in abundance, degradation takes place even though the contaminant has decreased to a limiting level (regime (iii) in Sun et al., 2021). Such adaptation and the mass transfer limitation through the cell wall are usually not taken into account in models so far.

In Schmidt et al. (2017) we have conceptualized what difference the micro-scale might make for the degradation of organic matter and contaminants through the whole food web. In Fig. 3 the ways in which the micro-scale features may influence larger scales, and vice versa, are shown. The temporal dimension is given on the *x* axis in Fig. 3 and the spatial dimension on the *y* axis. The exchange with the surface is one dominant driver, in that it delivers overall organics, oxygen, but also e.g. contaminants. Despite the overall conditions, Fig. 3 shows how situations which are very different in their physical, chemical, and hydraulic properties, may exist in close vicinity both spatially and temporally within the same macro scale framework. They provide the environments for differing biological communities and ecosystem functions. These ecosystem functions vice versa shape their physical and chemical

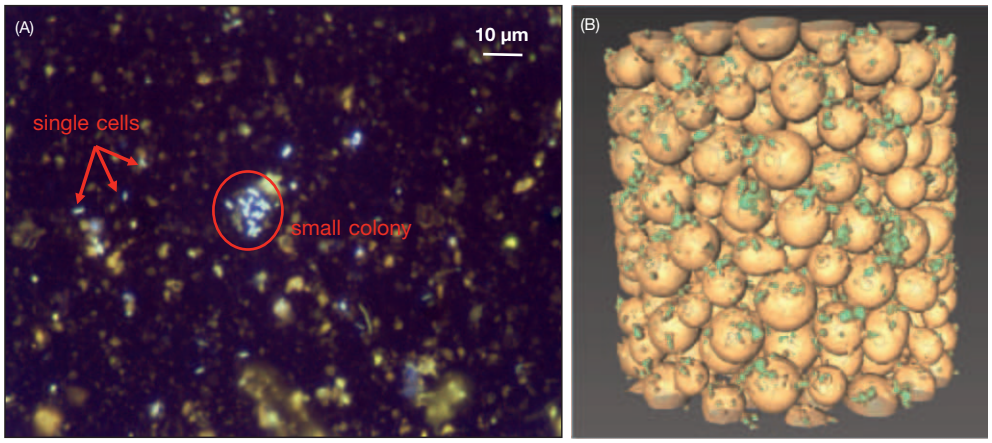

Fig. 2 (A) DAPI stained attached bacteria in a subsurface sediment sample. Reproduced with permission from C. Griebler, University of Vienna (pers. comm.). (B) Result of the three-dimensional X-ray computed microtomography (CMT) biofilm imaging. Biofilm (green) was grown in a glass bead pack of neutrally buoyant, silver-coated hollow glass microspheres (10 µm diameter; gold). The interpretation is that the silver particles have attached to the biomass that had grown within the bead pack and that the silver particles thus reflect the spatial arrangement of biomass. Reproduced from Iltis GC, Armstrong RT, Jansik DP, Wood BD, and Wildenschild D (2011) Imaging biofilm architecture within porous media using synchrotron-based X-ray computed microtomography. *Water Resources Research* 47: 1–5, with permission from the American Geophysical Union.

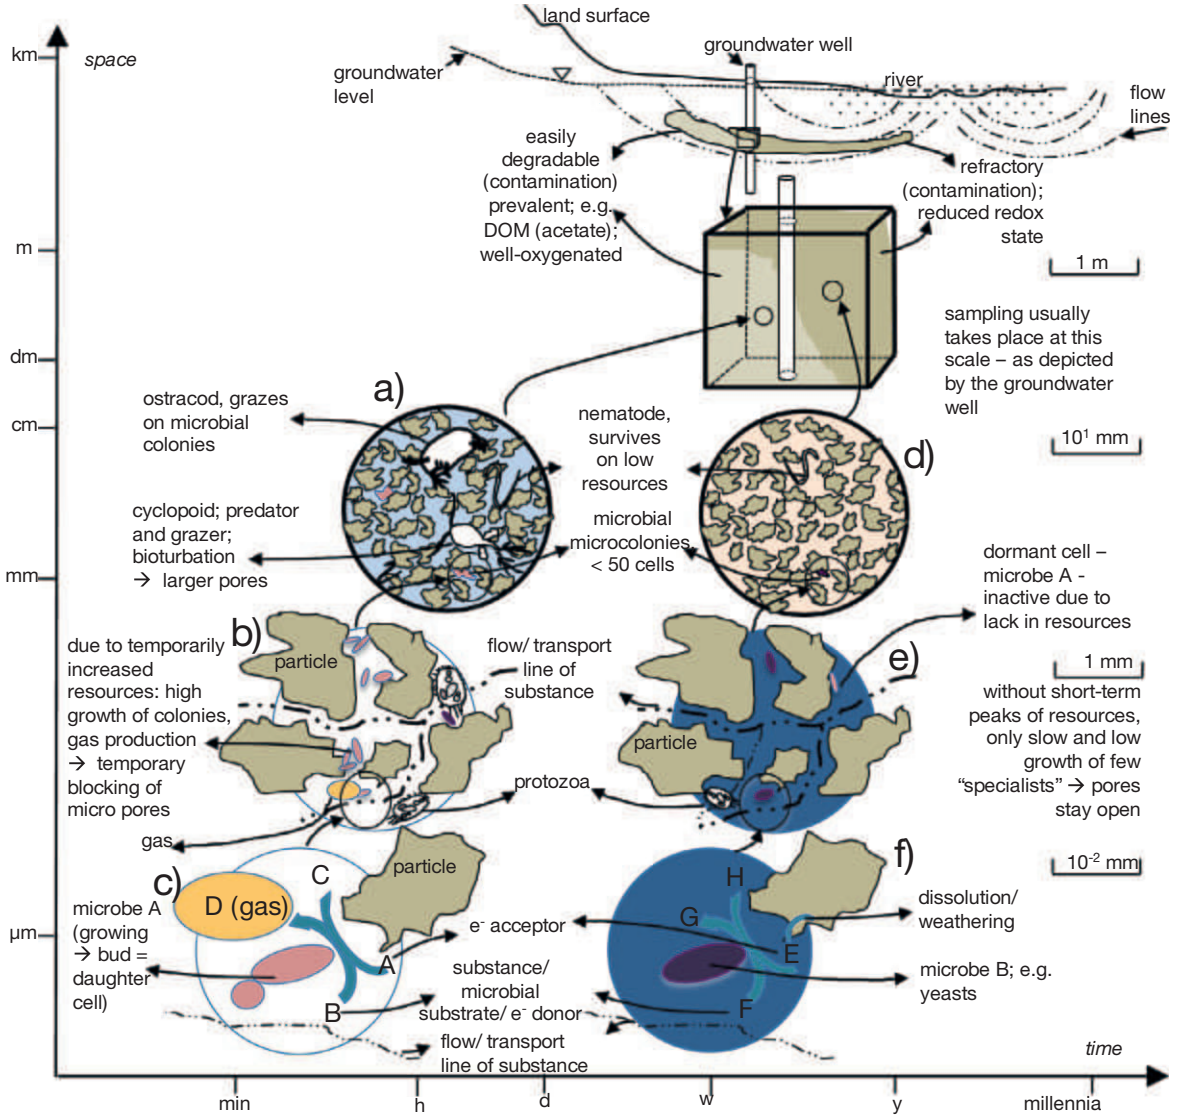

Fig. 3 Micro-scale conditions and their relation to patterns on larger scales. This is illustrated on two examples of zones that might be temporally or spatially apart. They might be different stages of an ongoing contamination degradation, which leads to different background with carbon compounds of varying complexity. The temporal scale is depicted on the *x* axis; and the spatial scale on the *y* axis. The axes give, however, only the general direction, but are not to scale. Further explanation in the text. Reproduced from Schmidt SI, Cuthbert MO, and Schwientek M (2017) Towards an integrated understanding of how micro scale processes shape groundwater ecosystem functions. *Science of the Total Environment* 592: 215–227, with permission from Elsevier B.V.

environment. While the macro scale sets the scene for organism growth, on the micro-scale, the actual food web depends on the prevalent pore environment, but also the consequently patchy microbial growth and how the micro environments then develop, and on the way in which the organisms react to them. Fig. 3A–C represents a well-replenished aquifer situation, with fast processes, while Fig. 3D–F depicts an impoverished situation, with fewer organisms, slower processes, and less transformations.

The situation in Fig. 3C builds the basis for the fast-growing food web on the left side, with Fig. 3B and A representing higher levels in the food web. The biochemical transformations yield energy for microbial growth. This microbial growth is grazed upon on the *meso* level by protozoa (Fig. 3B), and by small metazoa such as rotatoria. Further up the food web, larger metazoa such as crustacea feed on the small metazoa and protozoa (Fig. 3A). Since the degradation of the available substrates in a situation depicted in Fig. 3C, with higher concentrations of more easily degradable substrates than in Fig. 3F, yields more energy than in (F), more organisms find enough resources to thrive in (B) and (A), than in (E) and (D). Growth is faster in (C) than in (F), and microbial colonies may grow to larger sizes and maybe even higher diversity in (C) than in (F). E.g. resource-poor environments in deep mines, one extreme case of Fig. 3F, harbored microbial communities of less than 10 OTUs (operational taxonomic units; Chivian et al., 2008), while groundwater environments with regular input from the surface, represented in Fig. 3C, typically harbor several thousands of OTUs, or ASVs (amplicon sequence variant; Griebler et al., 2010). The reactions at the basis of the food web (Fig. 3C) might e.g. be the degradation of the molecule acetate (substrate B in Fig. 3C) under the reduction of nitrate (substrate A in Fig. 3C).

This denitrification yields among other products N_2O or N_2 (substrate D in Fig. 3C; Strohm et al., 2007) which might form gas bubbles (Bauer et al., 2008; Fig. 9). Such bubbles are (temporary) flow hindrances, even on the mm scale (Figs. 1 and 3B; Cuthbert et al., 2010).

In the right half (Fig. 3D–F), in contrast, less and more-difficult-to-break-down substrates, or less favorable conditions (high or low pH, etc.) prevail, and/or substrates such as the easily degradable acetate have been used up. Growth takes longer and is more resource-demanding: more activation energy is required, and consequently less biomass and products are the result. One example is the anoxic feldspar dissolution (feldspar represented by substrate E in Fig. 3F) which was shown to occur only where feldspar contains phosphorus which is limiting in many groundwater ecosystems (Bennett et al., 2000). The dissolution is enabled either by the local excess production of CO_2 forming an equilibrium with carbonic acid, or by organic acids produced from degradation of (contaminating) aromatic compounds, e.g. benzoic acid (Bennett et al., 2000)—these acids are represented by the letter F in Fig. 3F). The products are dissolved carbonate ions (letter H in Fig. 3F) and benzoate (letter G in Fig. 3F). Since this reaction is energetically not as yielding as denitrification coupled to the oxidation of acetate, the growth of individual microbial cells, and consequently, growth of colonies, is slower and sparser (right hand side of the μm scale in Fig. 3F) than that for acetate-grown cells (Fig. 3C). This low productivity only supports low numbers of protozoa and metazoa (e.g., nematodes; Fig. 3D and E).

In direct comparison with the situation where a less degradable substrate prevails, the situation of the easily degradable substrate (Fig. 3A–C), at the respective scales, shows that there are faster reactions on the cell level (around 0.001 mm), higher numbers of more active microorganisms (bacteria, archaea, fungi, protozoa) on the scale of 0.01–0.1 mm, as well as higher numbers of grazing metazoa on the millimeter to centimeter scale. Such increased growth leads to more and faster bioturbation (i.e., reworking of sediments by organisms, see also section "Additional remark on small scale food web—Fauna grazes on microbes and engineers the environment"), than with a refractory substrate. These two situations depicted may occur in close vicinity both spatially and temporally. The major reason for the right-hand side situations to occur are zones where hydraulic conductivity is lower (e.g., due to fine sand or clay) than in the left-hand side situation, or micro-scale spots that are clogged by fine materials and bioclogging. This clogging may, however, be unstable over time and thus, a left-hand situation may develop into a right-hand situation and vice versa. Conventional sampling which usually means pumping large volumes (liters), will mix this micro-scale variability. The spatial scale on which these two (or more) situations occur may be as small as from one pore to the next. Also, on the temporal scale, the two situations may occur at the same spot, but in succession.

Measuring on the micro-scale

Measuring on the micro-scale is challenging—the environment, the processes, and the biota in the system have to be measured simultaneously and over time, since all these features are in fact interconnected—hydrological and hydrogeological patterns shape chemical reactions, which provide the resources for organisms. Vice versa, organism by their actions change the chemical and physical environment and may change hydrogeological patterns such as flow paths. The results obtained on the micro-scale depend highly on specific circumstances. When doing experiments and ascertaining developments, particularly where microbial growth is involved, imaging may be one of the first aims. Depending on the imaging method, the resulting pictures emphasize certain properties and may ignore other properties. E.g. the colonies in Fig. 2B seem to be clearly delineated, while in reality, extrapolymeric substances (EPS) produced by the cells might not be as compact as the picture suggests but might be organized in thin threads of biomass, e.g. Flemming and Wuertz (2019), which are captured better with other methods, such as epifluorescence light microscopy (Nadell et al., 2017 and compare Fig. 4).

The results gathered from micro-scale investigations, be they observational, experimental (laboratory and field), or computational, depend thus highly on the methods. However, all observational and experimental methods applied so far to pore-scale biomass growth unequivocally demonstrate the patchy, heterogeneous growth where resources become limiting (e.g., Bauer et al., 2009; Davis et al., 2010; Iltis et al., 2011; Neu et al., 2004; Wagner et al., 2009; Fig. 3). Micro-scale growth patterns were found to be influenced by flow velocity (Coyte et al., 2017), Reynolds number (which is the ratio of inertial to viscous forces in a moving fluid; Wagner et al., 2010), permeate flux (Valladares Linares et al., 2016), Péclet and Damköhler numbers (the ratio of velocity to pore diameter, and the ratio of the rate constant to the velocity, respectively, Jung and Meile, 2019), and by pore throat size (Jaiswal et al., 2014). In turn, microbial growth and thus, the increase of biomass, influenced physical properties such as porosity (Thullner, 2010), conductivities (Peszynska et al., 2016), the ability of compressional waves to pass through a sediment core (Davis et al., 2010), the wettability of polar substances within water (Armstrong and Wildenschild, 2012; Khajepour et al., 2014), flow velocity and T2 magnetic relaxation which can be used to image flow (Seymour et al., 2004), and the arrangement of aggregates and thus the distribution of pores in soil (Bucka et al., 2019). Microbial biomass may block pores (Thullner et al., 2002a; Thullner and Baveye, 2008) and thus, prevent some cells from receiving nutrients. Most of these studies did not, however, focus on groundwater ecosystems explicitly, and almost none used groundwater ecosystem-specific conditions, neither in experiments nor in modeling.

Many studies with a clear connection to groundwater have been performed in the context of oil recovery or CO_2 storage—in both applications, knowledge on the pore structures and behavior is undeniably paramount (Steefel et al., 2013). However, such studies mostly ignore microorganisms and always ignore food webs. Here, we give three groundwater-specific case studies. With the first case study we briefly show experimental work related to biofilm response to pH changes which may be one side effect of CO_2 storage. The second "case study complex" collates work form one group using a microfluidic cell which has proven adequate for a high range of questions, including mineral precipitation which is one feature complicating CO_2 storage (Singh et al., 2015). The third case study demonstrates, in a proof-of-principle approach, the effect of colony size and colony location on degradation

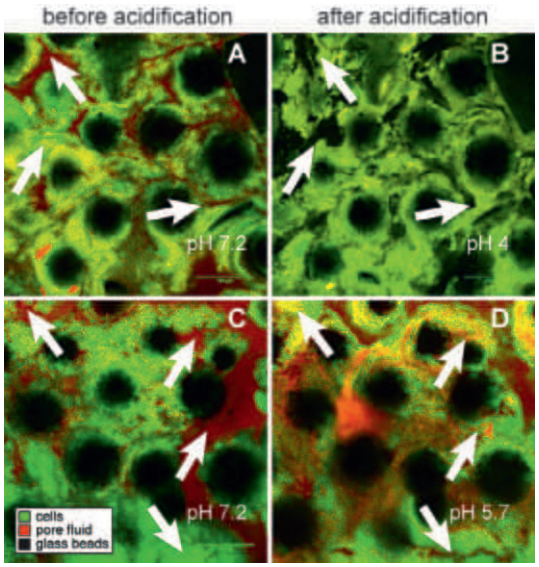

Fig. 4 Microbial biomass in porous media, visualized by confocal microscopy, before and after acidification to pH 4 (images A and B) and to pH 5.7 (images C and D). The legend specifies the material represented by each color in the images. Flow was from left to right through the porous media in the images. Arrows indicate spots where biomass shifted from one picture to the next. The contrast of the image (B) was adjusted to highlight the biomass in the image and therefore, the pore fluid in image (B) lacks red color. Reproduced from Kirk MF, Santillan EFU, McGrath LK, and Altman SJ (2012) Variation in hydraulic conductivity with decreasing pH in a biologically-clogged porous medium. *International Journal of Greenhouse Gas Control* 11: 133–140, with permission from Elsevier Ltd.

within an idealized single pore. Such set-ups allow to study competition among functional organism types and to study how food webs develop in detail in a controlled situation. Some studies have combined laboratory experiments with modeling (e.g., case study complex 2). This might result in bespoke models that may not be easily transferrable, neither in terms of the boundary conditions and implementation, nor in terms of the results. However, combining experiment and model is important for verifying modeling approaches and outcome. All three case studies so far cannot be generalized, and in all cases, upscaling to the meso-scale and further to the global scale is fundamental to the applicability of the results for field scale evaluations. The second and third case studies have tackled upscaling—a growing field, not discussed here.

Case study 1: Clogging of aquifer sediments due to pH changes—Experimental study

Kirk et al. (2012) devised micro columns (1 mm^2 cross-sectional area), filled with 105–150 μm diameter glass beads, which they studied under the confocal microscope, to clarify whether the microbial biomass involved in clogging of pores would survive a sudden pulse of low pH. This is important knowledge in developing strategies for carbon dioxide storage in geological structures. Sustainable storage relies on reservoirs that can be sealed against the surface so that the carbon dioxide remains trapped in the underground. Stimulating growth of microorganisms which clogs pores, could be one way to ensure that potential leakage pathways remain blocked, but the question arose whether the microbial biomass would stay intact, even if the microorganisms did not survive a pulse of super critical carbon dioxide which might result in a sharp decrease of pH. In the initial phase of the experiment, before acidification, microorganisms grew into colonies which clogged individual pores and reduced hydraulic conductivity (Fig. 4A and C). This was partly due to the formation of EPS. In the ensuing acidification phase, many cells died (Fig. 4B and D), and hydraulic conductivity increased measurably. However, much of the dead biomass remained in place, and continued to clog the pores considerably which would result in the cap on the carbon dioxide storage reservoir remaining in place. In this study, the medium and macro scale properties of the aquifer, i.e. hydraulic conductivity, were one of the response variables, but the low changes in hydraulic conductivity despite a pH detrimental to living cells, could only be understood by observing the distribution of live and dead biomass on the micro-scale.

Case study 2: Biomineralization alters porosity and flow patterns—Experimental and modeling studies

Microbial growth may develop in situations where electron donors and acceptors meet and occur in the optimal relations. This may happen e.g. during in situ bioremediation along the fringes of a point-scale input (e.g., contaminant plume) where oxygen from the ambient groundwater mixes with a dissolved organic pollutant from the plume. This mixing results in a narrow "reaction zone" which is habitat for organisms along the plume fringe. It was described for the centimeter and millimeter scale by Bauer et al. (2008). That such plume fringe effect scales up to the decimeter scale, was shown by Anneser et al. (2008). Werth and co-workers

(e.g., Nambi et al., 2003) have used 2-D micro fluidic pore networks to investigate such transverse reaction processes experimentally on the micro-scale. With a depth of 15 μm, a close-packed array of 300 μm diameter silicon posts separate 35 μm pore throats (Nambi et al., 2003). The flow chamber accepts two inlets, so that an electron donor can be fed into one inlet, and an electron acceptor into the other inlet. With the flow through the system, the two substrates meet around the central mixing zone. With this system, Werth and colleagues studied how biomineralization induced by urea hydrolysis and denitrification processes (Singh et al., 2015) altered porosity and flow patterns significantly, both in observations and accompanying models. In parallel to the laboratory-scale experiments, pore-scale numerical models were developed, capable of handling complex dynamic solid–liquid boundaries, in order to couple flow, solute transport, and biofilm growth at the pore scale (Fig. 5).

While the focus of this first set of studies was on the effects of microbial biomass on flow and mixing patterns, in another set of investigations the group concentrated on the effects of microbial degradation on distribution of chemical compounds in groundwater. They used the same experimental setup for this, but also a set up where the columns and thus the pore sizes varied—these had aggregates of small pore sizes, interrupted by larger pore sizes, thus introducing further flow heterogeneity (Zhang et al., 2010). Tang et al. (2013) injected as electron donor (*R*)-2-(2,4-dichlorophenoxy)propionate (*R*-2,4-DP) into one inlet. Dissolved O_2 served as electron acceptor and was fed through a separate inlet. The researchers inoculated the microcosm with the bacterial strain *Delftia acidovorans* MC1 and studied e.g. degradation rates. Both in the flow cell (Fig. 6E and F) and in the model (Fig. 6A–D) they showed how the biomass growth led to different flow and concentration fields. The interplay between biomass and substrate availability resulted in heterogeneity in the biomass, forming bridges between columns, and thus closing pores for flow (Fig. 6). The effects of bioclogging on hydraulic conductivity and flow were in agreement with comparable studies by e.g. Thullner et al. (2004), Bauer et al. (2008), and Sun et al. (2021).

For simulating the effect of the transverse mixing, Tang et al. (2013) used a Lattice Boltzmann code to model the 2-D pore-scale flow field and the advection–diffusion–reaction equations (with dual Monod kinetics), and coupled a Cellular Automaton model for biofilm spreading. Fig. 6 shows the good agreement between the growth pattern in the model (Fig. 6A–D) and the micromodel experiment (Fig. 6E and F). In the model, most of the biofilm developed on the downstream side of the cylindrical posts, and then extended out into the pore body.

Case study 3: Microbial colony growth patterns influence biodegradation of acetate—Modeling study

There is no "plug and play," "out of the box" model applicable straight away to any given problem in groundwater ecology, neither on the macro-scale nor on the micro-scale. It very much depends on the question, the framework, boundary conditions, the scales, the complexity, which method could be most useful to address the question. With the study presented in this third case, care was taken to represent groundwater conditions not only in terms of physical properties (temperature, and the temperature-dependent physical constants set accordingly), in terms of chemicals (hydrochemical concentrations representative for groundwater), but also in terms of the microbial kinetics (kinetical parameters adjusted from laboratory temperatures to groundwater temperature;

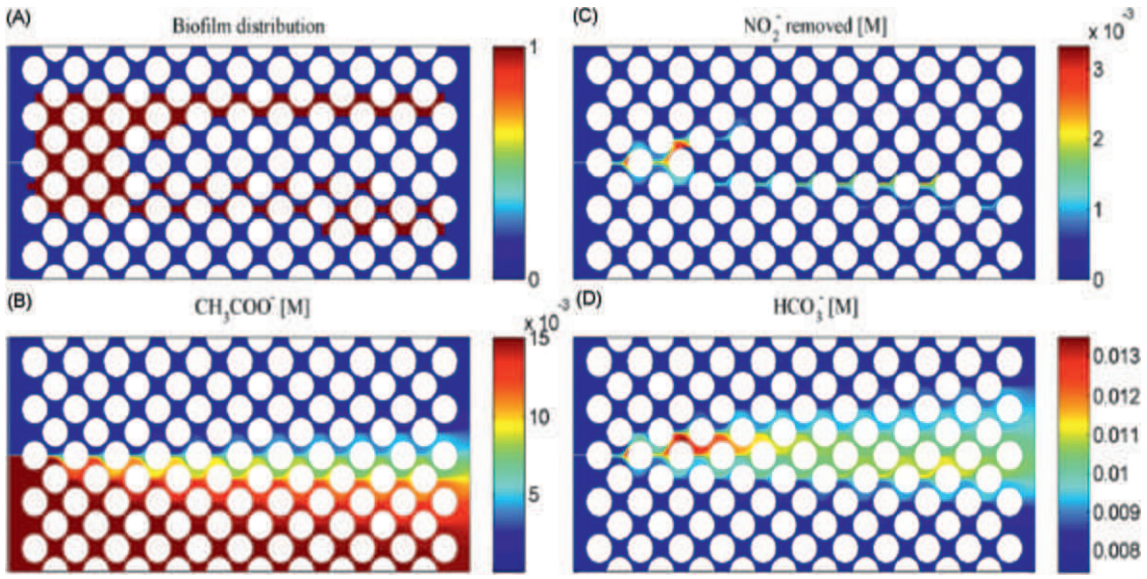

Fig. 5 Modeling biomineralization induced by urea hydrolysis and denitrification processes. Aqueous solution flow from left to right. (A) Spatial distribution of biofilm as observed in microfluidic cell experiments and implemented in the model. The following substrates and their spatial distribution were simulated: (B) CH_3COO^-, (C) removal of NO_2^-, (D) formation of HCO_3^-. All concentrations are in mol L^{-1}. Modified from Singh R, Yoon H, Sanford RA, Katz L, Fouke BW, and Werth CJ (2015) Metabolism-induced $CaCO_3$ biomineralization during reactive transport in a micromodel: Implications for porosity alteration. *Environmental Science and Technology* 49: 12094–12104, with permission from the American Chemical Society.

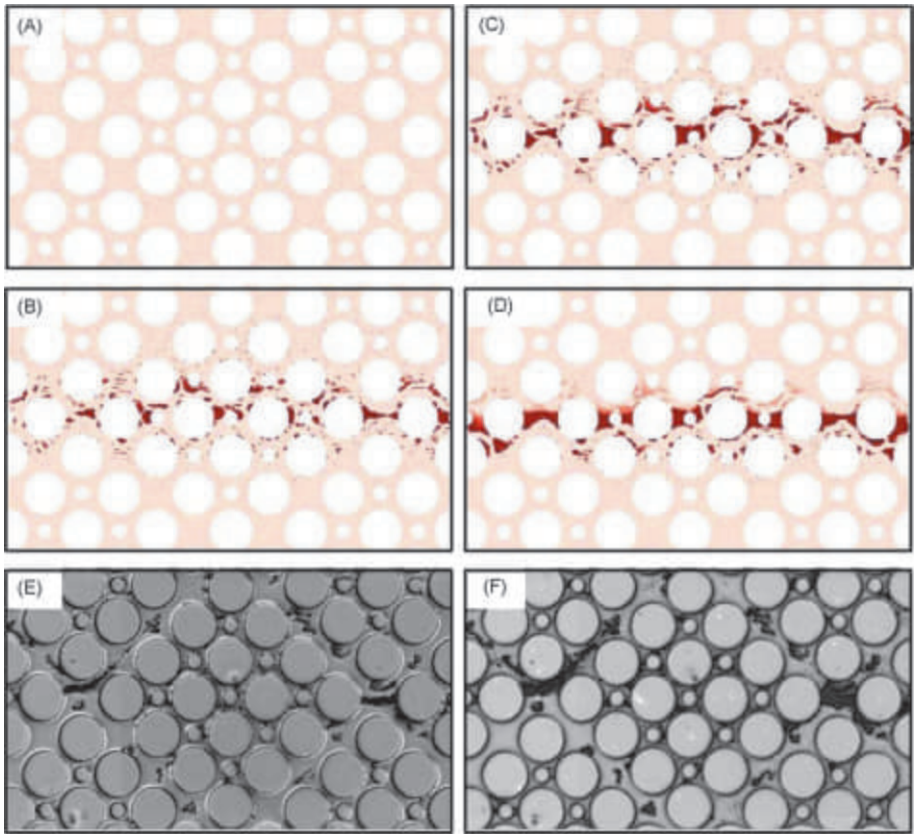

Fig. 6 Simulated (A–D) and experimental (E and F) pore-scale visualization of biofilm distribution in a heterogeneous pore-network microfluidic flow cell. (A) 1st, (B and E) 11th, (C) 16th, and (D and F) 24th day. Reproduced from Tang Y, Valocchi AJ, Werth CJ, and Liu H (2013) An improved pore-scale biofilm model and comparison with a microfluidic flow cell experiment. *Water Resources Research* 49: 8370–8382, with permission from the American Geophysical Union.

Schmidt et al., 2018). While many modeling studies have provided concepts and methods to tackle subsurface porous flow, this study remains one of the very few implemented with groundwater conditions. We will first introduce some complexities about modeling the micro-scale in the groundwater ecosystem in more detail—the following paragraphs apply to all models, but are given here in the context of this "modeling-only" study. The backbone for all groundwater ecosystem modeling is to simulate the flow adequately. Micro-scale approaches need to ascertain either directly or indirectly a parabolic flow profile within a pore with no flow at the pore walls and maximum flow at the largest distance from the pore walls (Benioug et al., 2015), in contrast to the macro-scale Darcy equation which implements pores implicitly only as hydraulic conductivity of a representative volume containing solids and fluids. However, in order to be informative for the whole aquifer, micro-scale models also should provide interfaces for coupling to large scale solutions.

In this third case study, the focus was on how to incorporate biomass that is in a steady state, i.e. neither growing nor decreasing in biomass, while the subsequent section "Additional remark on small scale food web—Fauna grazes on microbes and engineers the environment" discusses the modeling of microbial growth, i.e. increase or decrease in biomass. The steady state is a simplification which might be appropriate in groundwater ecosystem situations that are in (pseudo-)equilibrium, but will not suffice if a pulse of e.g. a contaminant is to be modeled. As mentioned above, in many observational studies representing groundwater ecosystem situations, and by many methods, heterogeneous distribution of microorganisms on the micro-scale has been demonstrated. Thus, models that consider biomass to be homogeneously distributed like in Fig. 7A, seem inappropriate, but are still used.

Modeling the biomass as distributed like a film along the wall (Fig. 7B) is slightly more appropriate, since the majority of cells are attached and the proportion of active cells is higher among the attached ones than among the suspended ones (Grösbacher et al., 2018)—thus, most activity takes place along the wall. A cell positioned at the wall is more mass-transfer-limited than biomass or enzymes within the fastest flowing region—diffusion becomes all the more important, the more advection decreases toward the wall (compare flow profile in Fig. 7A). Such film-like distribution was implemented in modeling studies several decades ago (Baveye and Valocchi, 1989; Molz et al., 1986).

However, to derive effective rates in case of heterogeneous colony-like distributions of microbial cells, such as they were observed in e.g. X-ray computed microtomography (CMT; Fig. 2), is more complex. Scheibe and Wood (2003) point out that particles such as microbial cells do not experience zero velocity, when simulated as single cells attached to the wall, because they are

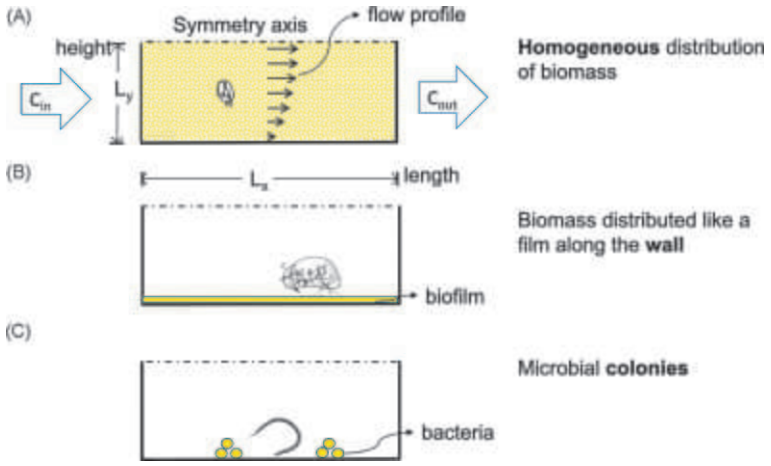

Fig. 7 Three simulation scenarios. Left boundary: laminar flow profile with a set average velocity and fixed concentration; lower boundary: impermeable wall (zero flow (no slip), zero solute flux normal to the surface); upper boundary: symmetry axis; right boundary: set pressure and zero diffusive flux perpendicular to the boundary. (A) Most frequently, biomass is treated as distributed homogeneously in the aqueous phase. The biomass does not oppose flow; (B) distribution of the biomass along the pore wall in a thin film—biomass shows uniform thickness and is often treated as impermeable to flow; (C) the biomass is distributed in discrete colonies built from spherical cells. The colonies are flown through with high viscosity. In the figures, sketches of organisms feeding on microbes are shown, out of scale, to indicate that the bacterial biomass is food for other organisms: (A) protozoon, (B) ostracod (drawing from Dole-Olivier et al., 2000), (C) nematode (photo: Eisendle-Floeckner, pers. comm.); not to scale. Simulating feeding was not performed in the set-up presented here, but is one of the next steps (see also remarks in section "Additional remark on small scale food web—Fauna grazes on microbes and engineers the environment"). Modified from Schmidt SI, Kreft J-U, Mackay R, Picioreanu C, and Thullner M (2018) Elucidating the impact of micro-scale heterogeneous bacterial distribution on biodegradation. *Advances in Water Resources* 116: 67–76, with permission from Elsevier Ltd.

at a physical distance from the wall, either from their own diameter, or due to charges. This means, that already for one single cell attached to the wall, the velocity distribution is truncated. This may also be (one of) the reason(s) for microbial cells preceding inert tracers' pulses (summarized in Dong et al., 2002).

Schmidt et al. (2018) coupled a pore-scale reactive transport model to an IbM code. In this proof-of-principle study, microbes were modeled in pseudo-equilibrium, i.e. they did not grow or decay. One next step, minor changes to the code to implement growth, were later taken and are the basis for further simulations (http://micro-scale-groundwater.online/). In all scenarios, the same biomass was active (200 cells/domain or the equivalent of it in the homogeneous and biofilm case), but it was distributed in different ways. The modeled outcomes for the homogeneous and wall scenarios reflected published results. The substrate was most efficiently degraded in the fictitious situation of microbial enzymes being distributed homogeneously in the fluid (Fig. 7A and top line of Fig. 8). In the also fictitious situation of biomass being distributed continuously along the wall, such as in Fig. 7B and second line in Fig. 8, degradation was shifted toward the wall, but due to diffusion and advection, the substrate was degraded almost as completely as in Fig. 7A. However, if biomass occurred in colonies (Fig. 7C), degradation was decreased all the more, the smaller the number of colonies, into which the biomass was condensed (Fig. 8, third to sixth line). This means that the lowest degradation occurred when all biomass was concentrated in one colony (extreme case of Fig. 7C; third line in Fig. 8). Please note that the apparent degradation upstream, i.e. to the left, of the colony, is due to the pseudo-equilibrium with continuous flux of acetate together with the colony using up more resources than advection and diffusion can replenish toward the pore wall—in the regions upstream of the colony, diffusion toward the bacterial colony results in degradation and no acetate diffuses back upstream, while in regions without colony, diffusion occurs in all directions, and thus also in the upstream direction. The diffusion of acetate toward the colony, and thus loss from the system, outweighs advection and diffusion toward the pore wall (see the flow profile approaching zero toward the pore wall in Fig. 7A). The acetate distribution in the pore would look different in the non-pseudo-steady state where acetate is entering as a pulse. Downstream colonies are shadowed by upstream colonies and the diffusion of substrate from the fast-flowing areas of the pore to the attached cells is a further limitation to the cells.

Fig. 9 shows how the concentration computationally decreased toward a wall-attached colony (down to dash-dot line), because of the decreasing advection and the increasing importance of the slower diffusion. In addition, it shows how the substrate, in this case acetate, decreased within the colony (below point-dashed line) due to the more viscous biomass, which further slows down diffusion. This is in contrast with most models studying biologically mediated reactions, e.g. Bottero et al. (2013) and Tang et al. (2013), who considered biofilms or colonies as impermeable, reactive surfaces. But a model incorporating transport also within the colony is important to study ecological questions such as which colony size is advantageous—as a compromise between the protection against grazing and abrasion within a colony versus receiving less substrate and thus, being the more substrate-limited, the deeper down a cell is located within the colony.

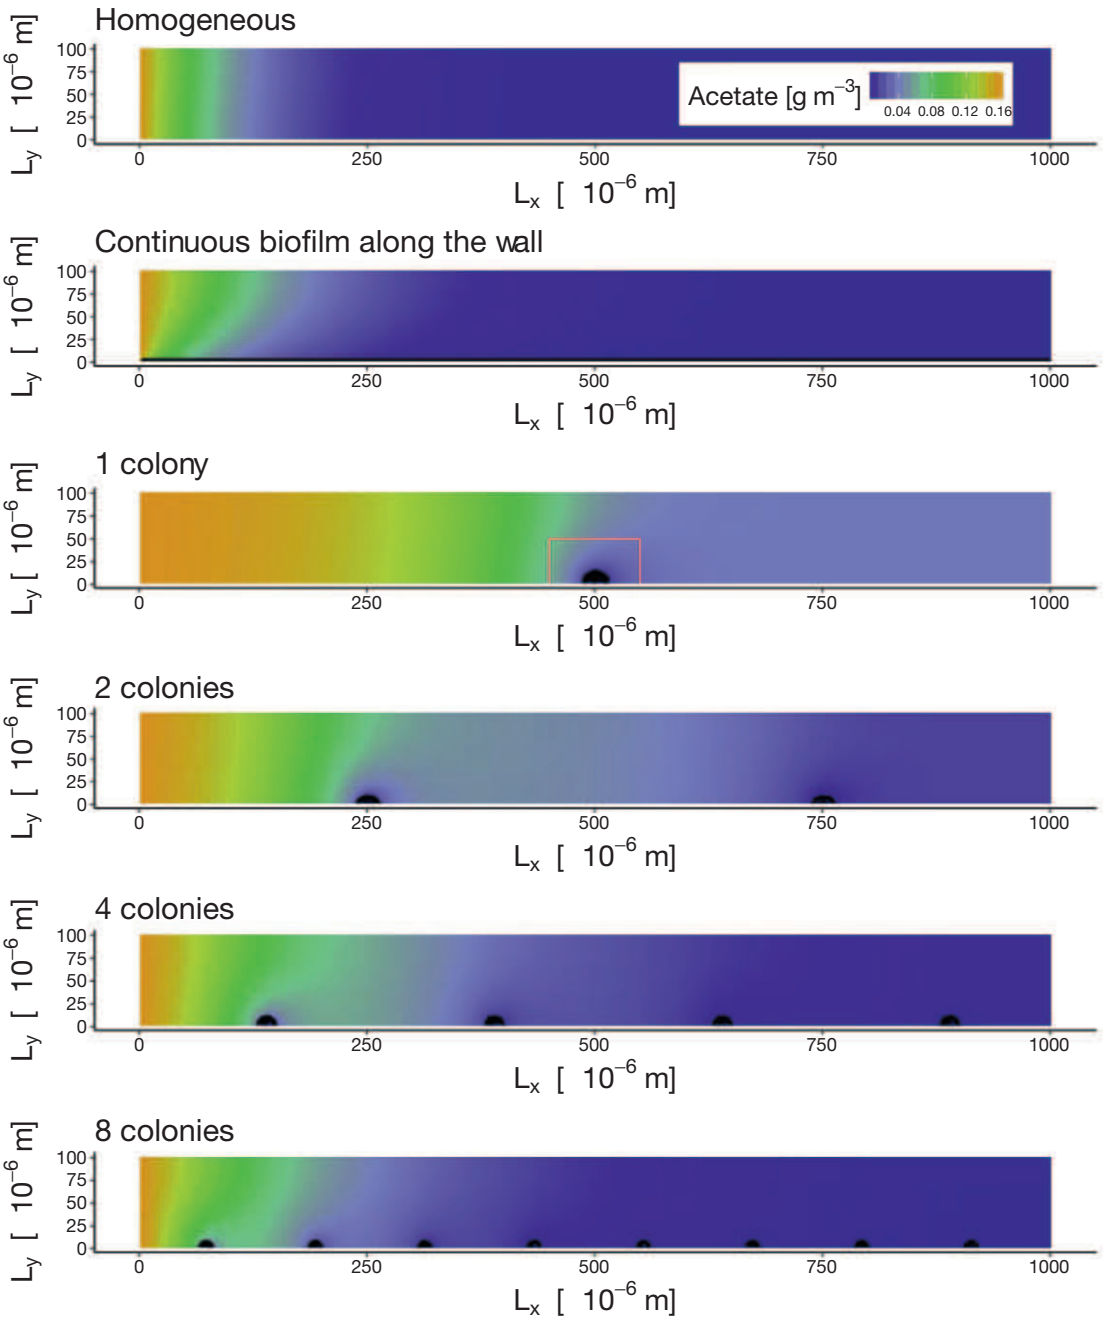

Fig. 8 Computed steady state concentration distributions within a pore channel, for different biomass distribution models. In all scenarios, the same biomass was active (200 cells/domain or the equivalent of it in the homogeneous and biofilm case), but it was distributed in different ways. These 2D simulation results are for the base case scenario (flow velocity 5×10^{-6} m s^{-1}, 200 cells or the equivalent biomass per pore, acetate as substrate). Homogeneous = uniform concentration of biomass suspended in liquid; Wall = continuous biofilm with uniform thickness along the pore wall; Colonies = the same total biomass aggregated into 1, 2, 4, or 8 equidistant colonies, respectively. L_x = length along the *x* axis; L_y = length along the *y* axis. The section within the red box is enlarged in Fig. 9. Modified from Schmidt SI, Kreft J-U, Mackay R, Picioreanu C, and Thullner M (2018) Elucidating the impact of micro-scale heterogeneous bacterial distribution on biodegradation. *Advances in Water Resources* 116: 67–76, with permission from Elsevier Ltd.

Jung and Meile (2019) tested cases of Fig. 7B and C along irregularly shaped pores, but did not clarify whether their scenarios were based on groundwater conditions or not. Like Schmidt et al. (2018), they found that microbial distribution in colonies, instead of in biofilms, decreased bioavailability and thus biodegradation of a substrate. Modeling microbial degradation in setups such as in Fig. 7A and B has thus been confirmed repeatedly to overestimate microbial degradation.

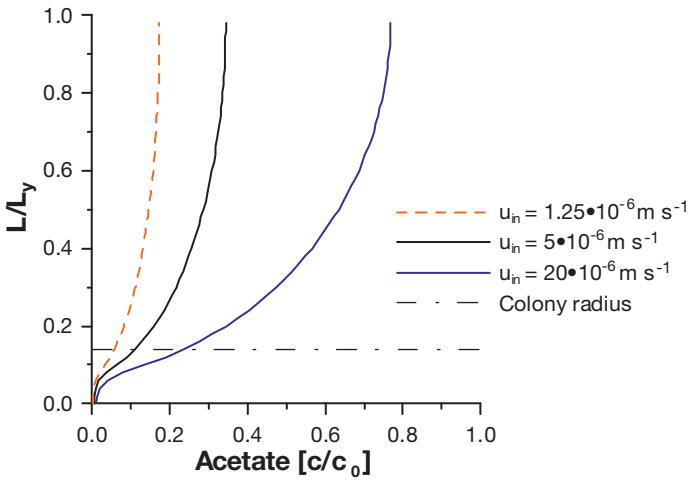

Fig. 9 Computed acetate concentration profiles along L_y ($L_y = 0$ is the wall and L/L_y is the relative distance from the wall with L being the respective metric distance the unit of which depends on the respective set-up) at the L_x position of the center of one colony (line for colony radius marks interface between biomass and pore water) in the base case simulation in Schmidt et al. (2018): one colony comprising 200 cells, with physiological parameters as given in Table 1 in Schmidt et al. (2018), and with three different velocities of the water flowing past the colony. c is the concentration prevailing at the particular point, scaled to the inflow concentration c_0 which is degraded within the colony so that the prevailing concentration can be maximum 1, but is mostly a fraction of the inflow concentration. Modified from Schmidt SI, Kreft J-U, Mackay R, Picioreanu C, and Thullner M (2018) Elucidating the impact of micro-scale heterogeneous bacterial distribution on biodegradation. *Advances in Water Resources* 116: 67–76, with permission from Elsevier Ltd.

Additional remark on small scale food web—Fauna grazes on microbes and engineers the environment

While microbial growth has been studied both experimentally and computationally, as shown in the three case studies above, small scale (impacts of) food webs have been completely ignored so far in laboratory micro-scale experiments and in models. This is despite the role of protozoan grazing on the biodegrading activity of biodegrading bacteria has been suggested decades ago (Mattison and Harayama, 2001). Protozoa are food for metazoa, such as nematodes and crustacea, which are among the most important players in the groundwater food web. Incorporating the food web in observations and modeling is, however, not only important because of the feeding relationships, but also because larger organisms, so far ignored in models, shape the environment through bioturbation—they thus act as micro-engineers (Mermillod-Blondin and Rosenberg, 2006; Hose and Stumpp, 2019).

Since bioturbation is performed mainly by larger organisms, the methods do not always require visual magnification as in microscopy—some phenomena are even visible to the naked eye, e.g. Hose and Stumpp (2019). These authors demonstrated how the burrowing activity of the higher and larger organisms led to bioturbation in mesoscale column experiments, observed through transparent column walls. Metazoa are frequently found in sediments where the porosity would indicate that the pore is too small for metazoa to pass (e.g., Schmidt et al., 2007). Their presence thus indicates secondary porosity not inferable from the grain size distribution alone. That the actual geometry of pore size distributions does often include macropores, e.g. from bioturbation or from decaying roots, has meanwhile been visualized repeatedly, e.g. by axial tomodensitometry (Dufour et al., 2005; Mermillod-Blondin et al., 2003b). Bioturbation results in some pores being widened, while others decrease in size, when the material is relocated. Thus, new micro environments are created. Bioturbation (Fig. 3A), based on sufficient microbial growth (Fig. 3C), lays the foundation for increased spatial and temporal heterogeneity (Fig. 3B and A versus Fig. 3D and E). Bauer et al. (2009) had increased flow pattern diversity by incorporating a lens of coarser substrate grains in their flow cell. The increased degrader activities that they observed, will also apply for situations with bioturbation, but this was not tested yet for the groundwater ecosystem. Indirectly, this effect of increased microenvironment heterogeneity was observed to affect microbial degradation in a study by Mermillod-Blondin et al. (2003a), where denitrification and hydrolytic activity were higher in columns with fauna than in those without fauna. For soils, oligochaete burrows have been described to be clad by an environment of microbially highly active burrow linings, the so-called drilosphere (e.g., Kuzyakov and Blagodatskaya, 2015). They have been shown for different environments to exhibit higher degradation, with more diverse redox situations and thus higher diversity of processes and products (Haas and Horn, 2018). Due to the increased mixing, reaction times are expected to decrease. This will further increase productivity. Similar effects may be expected for oligochaete or crustacea burrows in groundwater sediments, and along root canals where the roots reach into the saturated zone.

Conclusion/synthesis

The micro-scale is so far not at all addressed in field investigations, since adequate techniques are lacking. The importance of the micro-scale for the meso- and macro-scale is only beginning to be acknowledged and it will take more investigations to understand

their interplay more completely, and to gather enough details from which more general patterns can be derived. The distribution of microbial biomass and activity on the micro-scale (pore-scale) is heterogeneous and as such, all investigations and models that assumed homogeneous patterns fail to simulate in situ conditions and processes, in most cases overestimating process rates. As derived from model exercises, organization of sediment attached microbes in discrete colonies (as is indicated by many microscopic studies) instead of homogeneous biofilms (as assumed in most modeling studies) leads to significantly lower process rates, which is more realistic to natural aquifer conditions.

Similar to other habitats (e.g., soils), micro-scale heterogeneity in the distribution of reducing potential (organic matter, reduced inorganic compounds and minerals), electron acceptors, microbial biomass and activities will allow a high diversity of aerobic and anaerobic processes to occur simultaneously, e.g. denitrification and sulfate reduction in a predominately oxic aquifer sediment. Although many processes that are active and detectable at the micro-scale become invisible at the meso- and macro-scale, they nevertheless substantially contribute to the overall transformation and flux of matter. We are (still) at a stage where all disciplines are learning from each other in respect to micro-scale ecology. Studying the micro-scale in groundwater systems is more challenging than studying the micro-scale in the laboratory, in a petri dish at room temperature. This is one explanation why micro-scale investigations in groundwater ecosystems are not much ahead of micro-scale investigations in other ecological settings. However, from the need to understand subsurface processes better, for e.g. CO_2 storage, contaminant degradation to achieve drinkable water, etc., arise studies and results that may help to answer questions for other systems as well.

Understanding micro-scale processes in the groundwater system may thus inform research in other systems, such as the sediment-water interface in lakes (Tankéré et al., 2002), even if the specific experimental tools have to differ. Indeed, micro-scale processes such as studied in a unique laboratory system by Bauer et al. (2009) reflected the results from one of the highest-resolved meso-scale field studies (Anneser et al., 2008). Upscaling from the micro-scale to the meso-scale and from there to local and global scales, is challenging, but is the prerequisite for sustainable water management. Techniques are (at least partly) mature enough to tackle such questions for the groundwater ecosystem, and the near future will see exciting results. Where methods are limited, modeling can provide insights, depending on the chosen framework conditions, and may, via sensitivity analyses, identify potential major drivers which may steer method development.

Knowledge gaps

(a) Conceptual models for groundwater fauna grazing on microbes and impacts on all scales
(b) Qualitative feeding relationships within the food web on all scales
(c) Parameters, i.e. standing stocks, viscosity of microbial colonies on all scales
(d) Rates, i.e. pore-scale flow rates, feeding rates, growth rates, degradation rates, attachment/detachment rates, maintenance rates, reproduction rates, death rates (protozoa and metazoa) on all scales
(e) Conceptual and quantitative models for bioturbation in the groundwater ecosystem and impact for the micro-scale
(f) Generalized upscaling from the micro-scale to the meso-scale and then to larger scales

Important case studies (where appropriate)

There are no field studies on the micro-scale, therefore, here, we focus on laboratory studies and modeling studies. These, however, almost all lack in at least one of the following features: relevant for the groundwater ecosystem, discrete biomass and not just unrealistic biofilm, reactive transport, bacterial growth.

Glossary

Allochthonous Originated from a place other than where it was found.
Biofilm Consortium of microbial organisms able to live on many different surfaces and environments.
Chemoautotrophy The process of obtaining energy through the oxidation of inorganic chemical compounds.
Chemosynthesis The biological production of organic compounds and nutrients by bacteria using chemical reactions (redox reactions) as the energy source, rather than sunlight.
DNA metabarcoding "The automated identification of multiple species from a single bulk sample containing entire organisms or from a single environmental sample containing degraded DNA (soil, water, feces, etc.)" (Taberlet et al., 2012).
Endemism Native to a single defined geographic location.
Fatty acids Carboxylic acids containing long saturated or unsaturated aliphatic chains.
Guano The accumulated excrement of bats and birds.
Hyporheic "The saturated portions of streambeds, banks, and floodplain containing water that originates from a stream and returns to the channel" (Woessner, 2017).
Karst Geological formation derived from dissolution of soluble rocks such as limestone, dolomite and gypsum.
Oligotrophic Refers to an environment with a very low productivity caused by low concentrations of nutrients and carbon sources.
qPCR Quantitative polymerase chain reaction, a technology used for measuring DNA using PCR.
Vadose Relating to or denoting underground water above the water table.

Introduction

The first reported subterranean species dates A.D. 1541 and is a cavefish from the Alugu Cave in the Chinese Yunnan Province, although only formally described in 1993, as *Sinocyclocheilus hyaline* Chen and Yang, 1993 (Borowsky, 2018). Subterranean species have been embedded in folkloric belief and recognized as novelties, but they were subsequently seen as posing challenging issues in evolutionary studies in both aquatic and terrestrial organisms (Racoviţă, 1907).

The solution and fracture cavities that develop in **karst** are large, which is one of the discriminating features between karst and non-karst habitats, the latter having small cavities in the interstitial spaces within gravels and finer grained sediments. Sampling of terrestrial cave fauna (inhabitants as well as transient occupants from the interstices) was initially carried out mostly by hand collection and was limited by the availability of suitable (human-sized) caves as access points to the subterranean habitat. However, the recognition that the subterranean habitat within scree slopes—the *milieu souterrain superficiel* (MSS) of the French Pyrenees (Juberthie, 1983)—could be sampled by means of baited traps buried within them, led to a rapid expansion of such sampling to a broad range of suitable subterranean habitats especially in Europe, United States, and Australia (Culver and Pipan, 2019). Moreover, the ability to sample aquatic habitats remotely, at cave outflows and at springs and wells, has led to a rapidly expanding knowledge in ecological studies during the last 50 years.

Inhabitants of the subterranean lightless world have been defined by many terms—such as cavernicolous, hypogean, stygian, troglobites, troglobionts, stygobionts—and they are typically referred to as blind and translucent (Culver and Pipan, 2019). All categories are recognized by their regressive attributes, especially lack of eyes and pigment in addition to a range of morphological traits that may include vermiform shape, elongate appendages and elaborated extra-optic sensory structures (Figs. 1 and 2).

According to their life cycles and ecological niches they occupy, subterranean fauna can be broadly separated into two categories: stygofauna and troglofauna. Stygofaunal specimens—e.g., amphipods, syncarids, ostracods, cavefishes (Fig. 1), etc.—are obligate aquatic species inhabiting interstices and voids within the groundwater matrix. Troglofauna comprises organisms such as spiders, scorpions and millipedes (Fig. 2) that live in caves, cavities and fractured rocks between the water table and the superficial soil layer. Both groups play a key role in regulating the nutrient cycles and energy flows shaping groundwater ecosystems (e.g., Simon et al., 2003; Venarsky and Huntsman, 2018; Saccò et al., 2019a and references therein) (Fig. 3). However, while the diversity and global

occurrence of subterranean species was recognized early, studies of subterranean habitats as functional ecosystems developed much later. It is now recognized that subterranean systems are comparable in complexity to surface ecosystems (Gibert et al., 1994) but with a truncated trophic structure owing to the lack of primary producers, except in the special case of **chemosynthesis** (Brankovits et al., 2017). Globally, it is only in the last decades that the magnitude of biodiversity present in subterranean waters has been recognized and given prominence (e.g., Danielopol et al., 2000).

The aim of this article is to report the current knowledge on groundwater trophic dynamics. First, we describe the key ecological mechanisms sustaining aquatic (stygofauna) and terrestrial (troglofauna) subterranean biota. Next, we illustrate the current analytical techniques employed to unravel energy flows and food web interactions of subterranean systems. Finally, we explore future research avenues that will hopefully allow the incorporation of new holistic approaches within the small but rapidly growing field of groundwater ecology.

Main topics

Stygofauna: Shaping the subterranean aquatic framework

Energy flows and ecological patterns in groundwaters

Groundwaters are crucial components within the global water cycle and also play a vital role in providing services to nature, society and industry (Griebler et al., 2014). However, subterranean environments host challenging conditions for life, due to the lack of primary production and the overall shortage of organic sources (Gibert et al., 2009). Organic matter (OM) in groundwaters has usually an **allochthonous** origin, and gets incorporated from the **hyporheic** and surficial aquatic and terrestrial zones *via* water flow, percolation, gravity or animals falling into the aquifer (Humphreys, 2006). The ecological dynamics sustaining these usually **oligotrophic** subterranean ecosystems are therefore directly influenced by the biogeochemical continuum between groundwater and **vadose**/surficial zones. A vast range of these newly incorporated organic components is utilized, mainly in their dissolved state, by microbial communities (Simon et al., 2003; Foulquier et al., 2011). Groundwater microorganisms also display a plethora of highly adapted **chemoautotrophy** metabolisms involving variedly abundant inorganic compounds such as nitrates, nitrites, ammonia, phosphates, sulfates and carbon dioxide (Brankovits et al., 2017) (Fig. 3B).

Stygofaunal communities display functional and morphological traits carved by evolutionary processes, such as high resistance to starvation, omnivorous diets (Humphreys, 2006; Bradford et al., 2014) but also specialized feeding habits (Francois et al., 2016, 2020), that have allowed them to cope with these "extreme habitats" (Danielopol et al., 2000). As a result of these adaptative mechanisms, subterranean aquatic communities characterize high rates of local **endemism** shaping short-range biodiversity patterns (Humphreys, 2006).

Stygofauna also play a crucial role in maintaining the natural conditions within subterranean ecosystems (Humphreys, 2006). They preserve the hydraulic connectivity between groundwater and surface environments *via* sediment bioturbation, burrowing and grazing (Saccò et al., 2019a and references therein). In addition, depuration from the excess of contaminants and nutrients is mediated by stygofaunal communities through their biological cycles, and **biofilm** proliferation is stimulated through their consumption of microbial biomass (Francois et al., 2016, 2020).

Groundwater food web dynamics

Despite their vast array of ecosystemic functions, stygofauna have only recently gained prominence as key drivers in shaping groundwater ecological dynamics (Hancock et al., 2005). In fact, the archetype of short and simplified food chains has been substantially reviewed recently, bringing new crucial perspectives into the food web interactions casting groundwater ecosystems (Francois et al., 2016; Hutchins et al., 2016; Saccò et al., 2019b). We now know that composite pathways for the incorporation and transfer of OM exist in subterranean ecosystems, and groundwater trophic interactions are likely to be shaped by a combination of opportunistic strategies and evolutionary driving forces (Venarsky et al., 2014).

The basal members of the stygofaunal food chains—i.e., copepods and ostracods (Fig. 1), usually referred as meiofauna—play a key role in transferring OM along the food chain. They filter the particulate OM available in water and also graze on biofilm, triggering the vital transition between microbially-derived OM and the higher levels of the food web (Fig. 3A). Bat **guano** —when present and falling in the water column from the top of a cave—can provide an alternative source of OM that is ultimately targeted by subterranean meiofauna (Cruz-Hernández et al., 2002) (Fig. 3D), aquatic nematodes and mites (Fletcher, 1982) as well as vertebrates such as the Ozark cavefish and salamander (Fenolio et al., 2006).

Stygofaunal amphipods (Fig. 1) and syncarids are globally distributed crustaceans and display a broad array of plastic feeding habits including biofilm grazing (Fig. 3B), filter feeding, predation (mainly on copepods and ostracods) and scavenging (Hutchins et al., 2014). Other widely distributed taxa capable of OM processing include gastropods (deposit feeders) as well as isopods and decapods (both filter feeders and biofilm grazers). These groups, together with copepods and ostracods, often shape the energy flows that sustain groundwater biota. The influence of these taxa on energy flows is extremely relevant considering that groundwater communities are usually bottom-up regulated by the availability of OM, a dynamic that can influence trophic cascade effects (Foulquier et al., 2011).

Higher in the trophic chain, predators such as blind dytiscid beetles, flatworms or cave fishes (Fig. 1), among many others, exert the equally important top-down control on their prey, maintaining the delicate ecological balances shaping groundwater ecosystems. However, groundwater predators are often scarce, a characteristic that triggers redundancies in feeding strategies and overlaps between niche occupations of consumers and predators (e.g., Saccò et al., 2020a). In addition, trophic competition at the species level shapes subterranean food webs, with the degree of trophic (dis)similarity among individuals (i.e., intra-population diet variability) being likely to drive the strength of trophic competitions among conspecifics.

Nonetheless, our understanding of the ecological and functional linkages among stygofaunal groups, and their interaction with the microbial community, is still in its infancy (Griebler et al., 2014). However, recent investigations are bringing to light a wide range of complex stygofaunal interactions (i.e., Ercoli et al., 2019; Francois et al., 2020), stressing the need to consider groundwater biota as components of functionally integrated aquatic and terrestrial subterranean ecosystems.

Troglofauna: The cave-dweller inhabitants

The food web processes in terrestrial and aquatic subterranean environments are broadly similar, as both have: (i) communities composed of obligate and non-obligate subterranean species, (ii) chemolithoautotrophic, photoautotrophic or detrital sources of energy that fuel community productivity, and (iii) strong consumer-resource interactions that influence community composition, abundance, and distribution (Venarsky and Huntsman, 2018). However, aquatic and terrestrial communities obviously live in different media, water versus air, and in this section we explore how this difference appears to influence the food web processes in terrestrial subterranean communities.

Microbial activity in terrestrial subterranean environments

Microbes transform dissolved and particulate OM into high quality microbial biomass, which in turn supports the productivity of larger terrestrial subterranean consumers. Similar to aquatic habitats, terrestrial subterranean microbial productivity can be limited by the availability of both carbon and nutrients. Chelius et al. (2009) tracked the response in microbial abundance following a cave amendment experiment using lint (low quality carbon source) and bat guano (high quality carbon source). Microbial abundance increased in both amendments, but the strongest response was found in the combined lint-bat guano treatment, indicating that microbial communities were co-limited by carbon and nutrient availability. However, terrestrial subterranean microbial communities can also be limited by a factor that is omnipresent in aquatic habitats, water availability.

Humphreys (1991) conducted a litter amendment experiment in an arid Australian cave and found that macroconsumer density did not increase until the litter was misted with water. Similarly, in caves that receive large inputs of guano, the abundance of consumers is often reported to be higher on fresh guano deposits compared to older deposits (Ferreira and Martins, 1999). While microbial processing decreases the quality of guano deposits overtime, authors have suggested that the primary reason for lower consumer abundance on older guano deposits is the result of reduced microbial activity due to lower moisture content in older guano deposits (Pellegrini and Ferreira, 2013). While these studies provide indirect evidence for the influence of water availability

on terrestrial subterranean microbial activity, this mechanism is widely reported in surface habitats (Baldrian et al., 2010). Collectively, these studies suggest that terrestrial subterranean microbial communities are co-limited by multiple interacting factors, including carbon-, nutrient-, and water-availability.

Another difference in aquatic and terrestrial habitats that can influence microbial activity is the spatial and temporal variability in environmental characteristics. For example, measures of temperature and pH will likely vary little throughout a cave stream due to the flow of water, while in terrestrial habitats these variables can change in proximity to surface connections (cave entrances, large cracks and fissures) (Kozel et al., 2019). While we are unaware of studies that have explored spatial variability in terrestrial subterranean microbial activity, factors such as temperature and pH are known to influence microbial activity in general, and we suspect similar mechanisms likely influence microbial activity in terrestrial subterranean habitats. Interestingly, spatial variability in substrate pH is known to influence the distribution of terrestrial taxa, which could be interpreted as circumstantial evidence that spatial variability in pH is influencing microbial activity and thus influences where terrestrial subterranean taxa spend time foraging, but more studies are needed to provide more robust support for this hypothesis (Kozel et al., 2019).

Mediation of surface connectivity on terrestrial subterranean food web processes

Terrestrial subterranean environments are composed of networks of cavities ranging in size, length, and depth from the surface (Venarsky and Huntsman, 2018). Ecotones are created when these cavities are close to the surface and environmental factors, such as temperature and humidity, change in relation to surface environmental conditions. Additionally, ecotones can be rich in energy sources, including animal carrion and wind-blown detritus (Moseley, 2009). While these energy-rich areas often attract consumers, the temporal variability in environmental conditions can prevent foraging during certain seasons. For example, during warmer and more humid seasons (spring and summer) many obligate and non-obligate subterranean taxa will forage in these ecotones and then move deeper into the subterranean environment during cooler and drier seasons (winter and fall). These movements are especially prevalent in obligate subterranean species as many have thinner cuticles which increases integument permeability and thus cannot tolerate low humidity environments (Howarth, 1980). The cavities that connect surface and subterranean environments also direct the flow of water across terrestrial subterranean environments. This water delivers dissolved and particulate OM as well as nutrients which support terrestrial microbial and macro-consumer productivity (Fig. 3F). However, this water can also create micro-habitats suitable for chemolithoautotrophic production. Thin layers of slowly flowing water create hygropetric habitats which have very low OM content, but seemingly with sufficient dissolved allochthonous organic carbon to support chemolithoautotrophic bacteria that are fed upon by terrestrial beetles (Paoletti et al., 2011). Thus, while subterranean environments are generally considered to be more stable than neighboring surface environments, environmental conditions in subterranean terrestrial environments can exhibit strong spatial and temporal variability, which in-turn can influence consumer-resource interactions.

Many surface species utilize subterranean habitats for shelter, breeding, and foraging (bats, crickets, salamanders) and the presence of these species can influence terrestrial subterranean community composition through several food web processes (Fig. 3G). For example, cave crickets and bats forage in surface habitats at night and then use subterranean habitats for shelter during the day (Taylor et al., 2007). Guano is an important energy source to terrestrial subterranean food webs, with some terrestrial taxa showing preferences for different types of guano, such as hematophagous (feed on blood) or frugivorous (feed on fruit) bat guano (Zepon and Bichuette, 2017). Additionally, some obligate cave beetles specialize on cave cricket eggs (Studier, 1996). However, surface species not only support terrestrial subterranean communities *via* the input of resource subsidies (sensu Polis et al., 1997), but they can also influence terrestrial community composition *via* top-down mechanisms. For example, invasive fire ants are regularly observed foraging in caves throughout the United States (Pape, 2016). The top-down influence from surface species is not limited to terrestrial subterranean taxa, as adult salamanders use subterranean terrestrial habitats for shelter and will often lay eggs in aquatic subterranean habitats where larval salamanders can have a strong top-down influence on aquatic subterranean taxa (Venarsky and Huntsman, 2018; Manenti et al., 2020) (Fig. 3E).

Current analytical approaches and future research avenues

The analysis of faunal ecological functions in subterranean environments is constrained by the cryptic nature and small size of the species. *In situ* ecological observation is often impossible, while sampling of the ecosystems is dependent on the availability of appropriate access points (i.e., caves, groundwater, wells, etc.). The relatively low abundance of fauna limits the number of individuals and amount of tissue to work with. These challenges collectively explain why the ecological functioning of subterranean systems is understudied compared with surface terrestrial and freshwater habitats.

The analytical approaches applied to subterranean invertebrates can be divided into four groups: morphological analysis of the mouth parts and feeding appendages (e.g., Hutchins et al., 2014); examination of the gut contents (e.g., Saccò et al., 2021); and chemical, primarily isotopic, proxies derived from either bulk tissue (Bradford et al., 2014; Hutchins et al., 2014; Saccò et al., 2019b, 2020c, 2021) or specific compounds (Saccò et al., 2019b, 2021) (Fig. 4).

Mouthpart analysis rests on the morphological assessment of invertebrate feeding apparatus, and the resultant assignment to a feeding niche (herbivorous, predatory, etc.). Mouthpart and accessory feeding apparatus morphology has been widely assessed across multiple invertebrate groups from a range of environments (e.g., Fryer, 1964; Schram and Lewis 1989; Arndt et al., 2005), including groundwater habitats (see Hutchins et al., 2014 and references therein). Key characteristics include the shape of the mandibles relative to the processing of different sized food items, including the possession of cutting blades; the formation of the

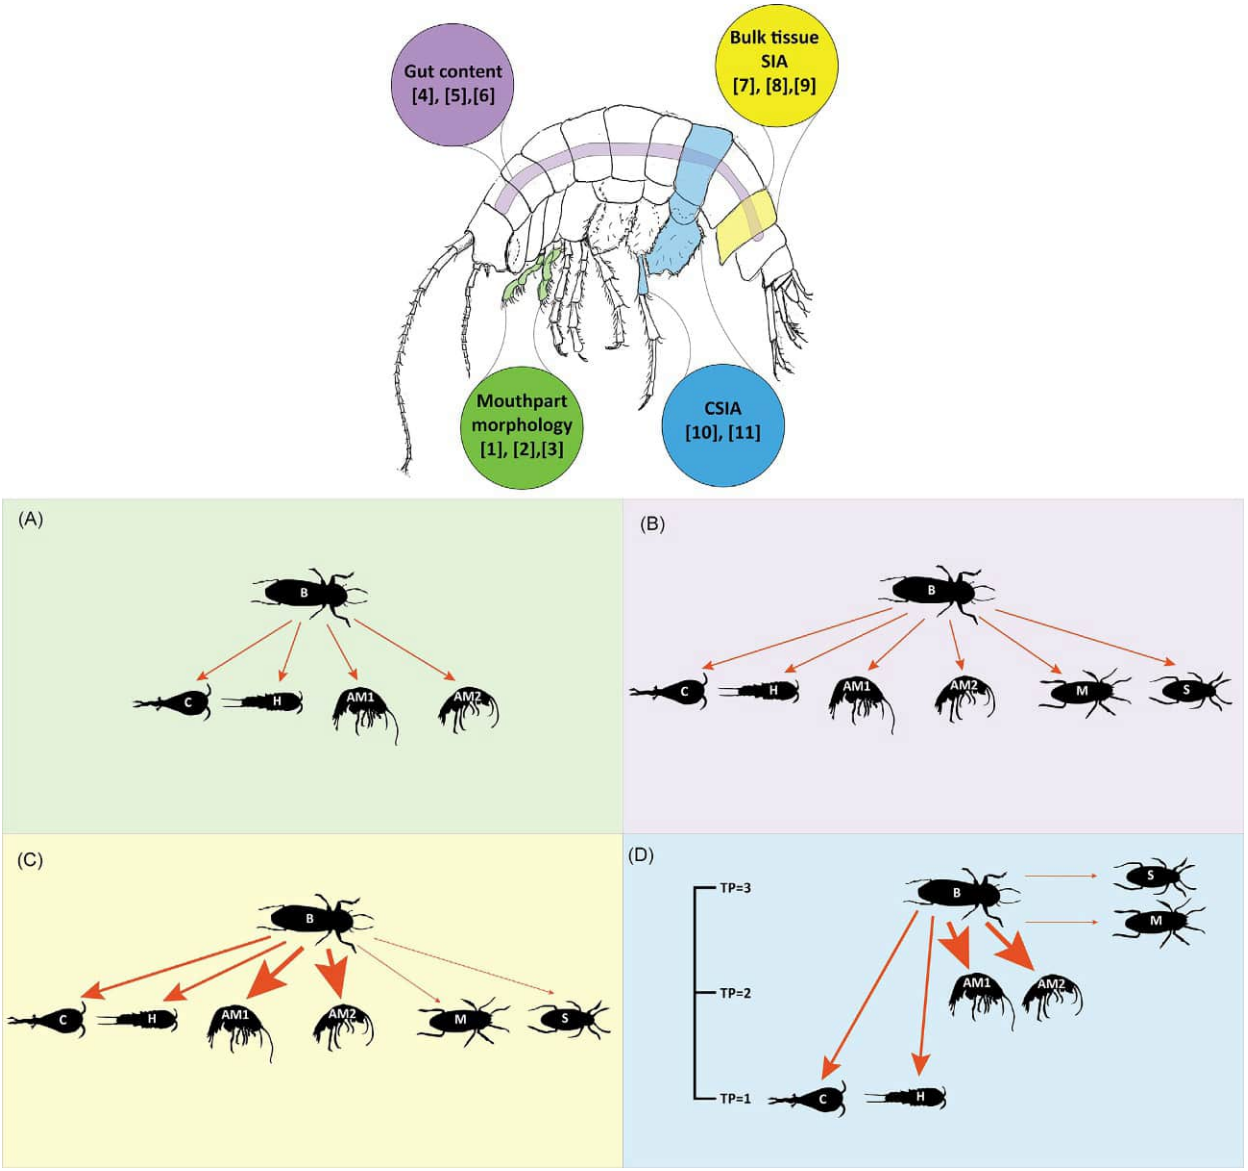

Fig. 4 Analytical techniques currently employed to study subterranean food web interactions (top figure) ([1] Fryer, 1964; [2] Schram and Lewis, 1989; [3] Enghoff, 1985; [4] Humphreys and Feinberg, 1995; [5] Bradford et al., 2014; [6] Weitowitz et al., 2019; [7] Simon et al., 2003; [8] Francois et al., 2016; [9] Ercoli et al., 2019; [10] Saccò et al., 2019b; [11] Venarsky et al., 2018) and schematic representation of the insights provided by each technique (lower 4 graphs): (A) mouthpart morphology studies, (B) gut content analyzes, (C) conventional bulk tissue stable isotope analysis (SIA) studies and (D) Compound Specific Isotope Analysis (CSIA) investigations. The diagrams are based on the empirical data gathered from Bradford et al., 2014 and Saccò et al., 2019b. Beetles—B: *Paroster macrosturtensis* Watts and Humphreys, 2006, M: *Paroster mesosturtensis* Watts and Humphreys, 2006 and S: *Paroster microsturtensis* Watts and Humphreys, 2006; amphipods—AM1: *Scutachiltonia axfordi* King, 2012 and AM2: *Yilgarniella sturtensis* King, 2012; copepods—C: Cyclopoida sp. Burmeister, 1834 and H: Harpacticoida sp. G. O. Sars, 1903. Thicker arrows indicate more marked feeding preferences inferred from the application of each technique. TP: trophic position.

dactylus to allow manipulation of particles; and the morphology of the gnathopods (Arndt et al., 2005). However, while extremely useful for preliminary assessments, this rather descriptive approach provides only indirect evidence of the real feeding behaviors of specimens, and may be biased considering the usually opportunistic trophic habits of subterranean fauna (Fig. 4A).

Gut content analysis is used widely in ecology, and although applied in subterranean fauna (e.g., Humphreys and Feinberg, 1995; Bradford et al., 2014; Weitowitz et al., 2019), it poses specific challenges in the case of smaller invertebrates, especially in terms of obtaining sufficient biomass for analysis. Another unavoidable issue with the use of gut contents alone as a trophic indicator is that they capture only a single snapshot of time. Although reliability can be improved by sampling multiple individuals, unless the food resources within the habitat are very stable, or unless samples are taken across multiple time periods (e.g., seasons, or different levels of rainfall recharge), there is a risk that the results represent a single feeding episode rather than the full range of trophic behaviors (Fig. 4B). Advances in **qPCR** and **DNA metabarcoding** have the potential to improve identification of food items

within invertebrate guts (Saccò et al., 2021), as well as develop estimates of feeding behavior, such as feeding rates (Durbin et al., 2012). Although DNA metabarcoding is increasingly popular in ecology, the application of the approach to subterranean systems is still in its infancy (Saccò et al., 2019a).

The use of stable isotopes in ecology for trophic analysis is well established (see Boecklen et al., 2011 and references therein). The technique rests on the fact that metabolic processes in primary producers create a specific isotopic signature that can either be preserved within the food chain (for example the $\delta^{13}C$ signature of C3 and C4 plants) or amplified with trophic stage (Boecklen et al., 2011). Careful analysis of the ratios of specific isotopes, most commonly carbon and nitrogen, can therefore provide information on both food source and trophic level in specific organisms (Marshall et al., 2019). The focus is most commonly on carbon or nitrogen isotopes, although oxygen, hydrogen and sulfur have also been assessed in surface environments (Vander Zanden et al., 2016).

The analysis of stable isotopes is not without complications (Ishikawa, 2018). Stable isotopic analysis is conventionally undertaken on bulk tissue samples, which in invertebrates may be whole organisms or indeed samples composed of multiple individuals owing to their small mass. This means that the isotopic fractionation within different tissue types is combined, essentially blurring the signal. Additionally, source signal preservation and degree of trophic enrichment varies with organism type. Consequently, interpretation of the results requires both an understanding of the degree of isotopic fractionation occurring with trophic enrichment within the target organism, and a comprehensive isotopic survey of potential food source items.

One way to address at least some of these issues is to use Compound Specific Isotope Analysis (CSIA). This approach uses chemical preparation followed by gas or liquid chromatography to separate out different molecules within the tissue. By analyzing the isotopic ratios within single molecular groups (e.g., specific amino acids or **fatty acids**), it is possible to generate a signal with a closer constraint on their biochemical pathways.

In trophic ecology, a key molecular target for nitrogen isotope analysis is amino acids (see Ishikawa, 2018 and references therein). These are of particular value because some compounds, such as glutamic acid, show isotopic enrichment with each trophic step, while others, such as phenylalanine, retain the value or close to the value of the primary producers in the food web. This essentially means that the data contains an internal isotopic baseline for the system, and that by developing a ratio between the trophically enriched and source value amino acids, taking into account the trophic enrichment factor for the groups concerned, it is possible to calculate a numerical trophic level for the sampled organism (Steffan et al., 2013) (Fig. 4D). Although CSIA has some limitations around sample size and cost, it is recognized as of increasing use in ecology.

The application of stable isotope analysis to subterranean systems has come later than in surface ecosystems, simply because the interest and capacity for studying subterranean functional ecology is a more recent development (Saccò et al., 2019b, 2021). Bulk tissue stable isotope analysis has been most widely used (Fig. 4C), sometimes in combination with other approaches such as the morphological assessment of mouthparts (Hutchins et al., 2014). Although compound specific approaches are likely to give a higher level of precision in trophic estimates (Saccò et al., 2019b), bulk tissue analysis has the advantage of being cheap, and easily accessible. At least some of the complexity deriving from the combined biogeochemical pathways can be resolved by applying Bayesian modeling to the data, incorporating additional geochemical information, or prior information derived from morphology, ecological observation or DNA (Saccò et al., 2020c, 2021).

An important additional geochemical proxy that can be incorporated in modeling to provide a better understanding of energy flows is radiocarbon analysis. Carbon-14 decays with time, so the signal present within the tissues of a modern organism depends partly on the age of the OM providing carbon to the food chain (Larsen et al., 2013 and references therein). This means that detritivores feeding on old or microbially recycled OM will develop an "older" radiocarbon signal than organisms feeding on live or very recently dead plant matter. This approach has been successfully demonstrated in soil and surface freshwater systems (Larsen et al., 2013). It holds particular potential in groundwater systems, as many of these environments offer the opportunity to deconvolute carbon inputs from surface inflow, and those from chemolithotrophic bacteria, or stored older carbon (Saccò et al., 2020b, 2021).

Isotopic analysis and DNA metabarcoding (alone and in combination) have redirected much analysis of trophic behaviors from ecological observations and invasive techniques to small sample tissue analysis, and in many ways have revolutionized methods in trophic ecology (Vander Zanden et al., 2016; Marshall et al., 2019). These approaches are of particular value in cryptic environments such as subterranean systems (Saccò et al., 2019a, 2020c). However, as stressed before, isotopic analysis in particular is not without caveats (Ishikawa, 2018), and each technique—isotopic analysis, DNA metabarcoding, morphology, and gut content analysis—provides only one piece of the picture (e.g., trophic level, feeding niche, dietary composition, energy flows). Therefore, as is frequently the case in studying complex natural environments, one technique alone is less powerful in elucidating the trophic function of subterranean systems than the application of a carefully considered combination, with data from a range of analyzes being integrated *via* robust modeling approaches (Majdi et al., 2018; Saccò et al., 2019a, 2020b).

Knowledge gaps

The field of groundwater trophic ecology is still in its infancy and as a result multiple knowledge gaps still exist (Mammola et al., 2020). Some of the most relevant aspects to be considered in future studies are:

- Expanding our knowledge on the diversity and functional dynamics of subterranean microbial communities
- Untangling the carbon flows and their role within microbial transitions over time and space
- Unveiling the fate of organic matter and unraveling energy flows through the food webs
- Elucidating the food web interactions between stygofauna, troglofauna, epigean fauna and superficial flora
- Understanding the role of invasive species in groundwaters and their effect on food web dynamics
- Widening our understanding on the ethology of subterranean species and bring light to the food assimilation rates of vertebrates and invertebrates in groundwaters
- Unraveling the specific biogeochemical role of the hyporheic zone and its terrestrial inputs (carbon and nutrients) within subterranean food webs
- Understanding the impact of climate change and anthropogenic pressures on the ecological mechanisms sustaining biota underworld

Anthropogenic Pressures on Groundwater

Robert Luetkemeier[a,b], Linda Söller[b], and Fanny Frick-Trzebitzky[a], [a]ISOE—Institute for Social-Ecological Research, Research Unit 'Water Resources and Land Use', Frankfurt am Main, Germany; [b]Goethe University Frankfurt, Institute of Physical Geography, Frankfurt am Main, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

The following list contains key terms of importance when considering anthropogenic influences on groundwater resources. The definitions are based on Bierkens and Wada (2019).

Consumptive water use Volume of evaporative losses from withdrawn water during the process of utilization (e.g., crop transpiration).

Freshwater withdrawal Extraction of a volume of surface water or groundwater from the environment to meet the water demand.

Groundwater depletion Natural average rate of groundwater recharge is exceeded by withdrawals leading to declining groundwater tables and volumes.

Groundwater mining Almost indefinite depletion of an aquifer due to withdrawals from non-renewable groundwater bodies.

Return flow Withdrawn water that is not lost due to evaporation and thus returns to surface water or groundwater bodies after usage.

Sustainable groundwater use Withdrawals do not exceed natural average groundwater recharge in the long-term, resulting in stable groundwater tables.

Water demand Volume of water requested by a sector (e.g., agriculture) or stakeholder (e.g., farmer) at a certain point in time and space to fulfill their needs.

Water use efficiency Ability to minimize resource use in human water appropriation in terms of volume of water used for unit of process (e.g., irrigation volume per crop unit over time).

Human-groundwater interactions

Globally, groundwater is one of the most important sources of drinking water (IGRAC, 2018), a key resource for food production (Dalin et al., 2017), and characterized by unique biodiversity and essential ecosystem services (Griebler et al., 2014). It is considered as central for human development as aspired in the Agenda 2030 (Velis et al., 2017). At the same time, groundwater bodies are threatened by massive overexploitation (Döll et al., 2014), pollution (Shukla and Saxena, 2018) and increasingly entangled in telecoupling effects (Luetkemeier et al., 2021). In quantitative terms, recent experiences from the prolonged droughts of 2015, 2018, and 2019 in Western Europe have shown how declining groundwater levels limit drinking water production (EurEau, 2020), dry out groundwater-dependent ecosystems (Schuldt et al., 2020) and generate conflicts between cities and surrounding areas. In terms of quality, contamination of groundwater bodies from nitrate and trace substance inputs in many parts of the world (Shukla and Saxena, 2018) lead to human health risks, high costs for drinking water treatment (Uzun and Debik, 2019) and negative impacts on ecosystems (Kløve et al., 2011).

From a natural science perspective, groundwater is stored in the saturated zone of the subsurface, where pores or fractures are filled with water (Domenico and Schwartz, 1998). This storage is replenished by recharge from precipitation, irrigation, and seepage from surface waters (Alley, 2009; Green et al., 2011; Taylor et al., 2013) as a function of local climate, geology and soil, topography, land cover, land use and atmospheric CO_2 concentrations (Green et al., 2011; Taylor et al., 2013; Reinecke et al., 2021). Especially in humid regions, groundwater is discharged into surface waters, such as rivers or springs (Margat and van der Gun, 2013) providing water even during dry periods, which is crucial for habitat quality of river ecosystems (Döll et al., 2014). In comparison, groundwater extracted by wells is a major source of groundwater discharge in semiarid and arid areas, where groundwater is usually the only permanent source of freshwater (Margat and van der Gun, 2013).

While this hydrogeological description of groundwater provides us with the means of studying groundwater theoretically, it often falls short in explaining actual groundwater phenomena as introduced above. In the Anthropocene epoch, the societal dimension becomes increasingly relevant in determining the state of groundwater bodies worldwide (Gleeson et al., 2020), just like for many other Earth System processes. Notions like hydro-social cycle (Budds, 2008), socio-hydrology (Sivapalan et al., 2012) and socio-hydrogeology (Re, 2015) attempt to consider anthropogenic activities not just as external variables, but rather as internal processes that closely interact with hydrological parameters. The idea of close feedback loops between hydrological processes and human activities shapes the way societies interact with water (Pande and Sivapalan, 2017) and groundwater in particular (Castilla-Rho et al., 2015). In this regard, a recent study found that to avoid critical tipping points in groundwater systems, cultural values of stakeholders involved in managing aquifers have to be understood and incorporated into integrated assessment models and actual management (Castilla-Rho et al., 2017).

Against this background, we seek to elucidate how groundwater systems are impacted by human activities in the Anthropocene. We do not claim to review the complex interactions of human-groundwater systems in its entirety, but we intend to highlight core areas and respective pressures that critically affect groundwater bodies. In this regard, we distinguish between "direct" and "indirect" pressures on groundwater. First, we explore the direct interactions in the field of agriculture, domestic uses of water and the industrial sector. Second, we focus on the indirect pressures in the form of the likely impacts of climate change. Finally, we discuss current approaches in groundwater governance and show how these could help to make human-groundwater interactions more sustainable.

Direct pressures: Societal water uses

Societal actors make use of groundwater resources for multiple purposes and with various consequences. Here, we consider the direct anthropogenic pressures on groundwater bodies as the actual processes of quantitative withdrawals and qualitative impairments. Regarding the volumes of groundwater withdrawn from the environment, this trend is increasing globally (Huang et al., 2018) with hot-spot regions being India, China and United States, primarily triggered by a growing population, irrigated agriculture and socio-economic developments (Siebert et al., 2010). Fig. 1 confirms this global pattern by showing modeling results from WaterGAP 2.2b that compare mean annual net abstractions from groundwater (accounting for return flows e.g., from irrigation and surface water infiltration) to the mean annual groundwater recharge rates (Herbert and Döll, 2019). Though, global estimates of groundwater depletion deviate by a factor of three between 113 km^3/year (Döll et al., 2014) up to 362 km^3/year (Pokhrel et al., 2012), current assessments indicate that even the largest aquifers show negative long-term storage trends (Famiglietti, 2014). Groundwater depletion and groundwater mining in particular (Bierkens and Wada, 2019) can lead to consequences such as land surface subsidence, saltwater intrusion in coastal regions and decoupling of groundwater dependent ecosystems (Lall et al., 2020).

Alongside quantitative withdrawals, qualitative contamination is equally important. In this regard, nitrate is the most widespread substance of concern, introduced by agricultural activities. However, other emerging contaminants that originate from residential (waste-) water management and industrial processes of manufacturing or mining are increasingly being focused on (Burri et al., 2019).

As the modeling results in Table 1 indicate, the agricultural sector accounts for about 66% of total water withdrawals, globally. Though, only 25% of this amount is obtained from groundwater, the total volumes outperform those of the other sectors by a factor of three. Groundwater covers about 36% of domestic demands, while for industrial purposes only 8% are withdrawn from groundwater. These global values, however, do only provide a broad and unidimensional illustration of the importance of groundwater since local particularities are essential and can show a completely different picture. Against this background, the following sub-sections will explore the three sectors in more detail and selectively shed light on human-groundwater interactions and the likely feedback processes involved.

Agriculture: Groundwater depletion and pollution

Globally, agriculture is the dominant water consumer, accounting for 88% of total consumptive water use. Irrigation is the major driver behind with 37% of the consumptive water being withdrawn from groundwater (Müller Schmied et al., 2021). Following an increasing trend, today about 114 million hectares of agricultural land are equipped with groundwater irrigation systems, primarily in India, China and United States (Siebert et al., 2010). Respective food production systems are not necessarily driven by local consumer demands, but rather international food trade, which significantly adds to groundwater depletion (Dalin et al., 2017). Irrigation efficiency is an important driving factor in how water use in agriculture contributes to groundwater depletion. However,

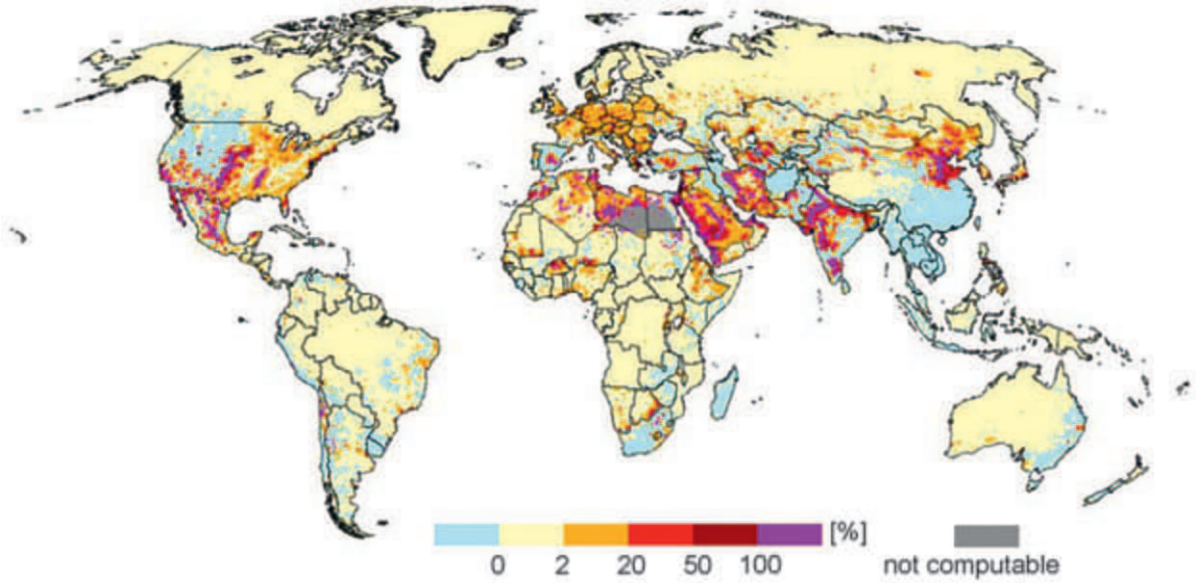

Fig. 1 Groundwater stress spatially depicted as the quotient between mean annual net abstractions from groundwater and mean annual groundwater recharge (WaterGAP 2.2b results). Values of more than 100% indicate groundwater depletion as groundwater withdrawals exceed groundwater recharge. Modified from Herbert C and Döll P (2019) Global assessment of current and future groundwater stress with a focus on transboundary aquifers. *Water Resources Research* 55 (6): 4760–4784. doi:10.1029/2018WR023321, pp. 4768.

Table 1 Withdrawal water use per sector in total volumes and with the share of groundwater therein as simulated by WaterGAP 2.2d for the time period 1991–2016.

Sector	*Water volume withdrawn (km^3 $year^{-1}$)*	*Share taken from groundwater (km^3 $year^{-1}$) (%)*
Agriculture	2392	591 (25)
Domestic	348	125 (36)
Industry	871	73 (8)
Total	**3610**	**789 (22)**

Values provided are results of the WaterGAP 2.2d model and sums can deviate due to rounding errors.
Müller Schmied H, Cáceres D, Eisner S, Flörke M, Herbert C, Niemann C, et al. (2021) The global water resources and use model WaterGAP v2.2d: model description and evaluation. *Geoscientific Model Development* 14(2): S1037–1079. DOI: 10.5194/gmd-14-1037-2021.

simply increasing water use efficiency may not be a sustainable solution as irrigation water was found to act as a significant recharge component for local groundwater bodies via return flows (Lankford et al., 2020). On the other hand, return flows from irrigation mixed with surface water can cause problems such as salinization and the mobilization of pollutants like arsenic (Taylor et al., 2013).

As humans transformed about 55% of the Earth's ice-free land surface for anthropogenic uses, agriculture is today the most area-intensive activity (Ellis et al., 2010) and thus interferes with groundwater bodies the most. Respective agricultural practices are hence critical for both quantity as well as qualitative pressures on the resource. In this regard, three broad types of contaminants can be distinguished that primarily threaten groundwater bodies in a spatially diffuse manner, being fertilizer application (e.g., nitrates and phosphates), crop protection (e.g., pesticides and herbicides) as well as veterinary substances (e.g., antibiotics and hormones) (Burri et al., 2019).

Nitrate is considered the most important and widespread substance of concern. Though, nitrate concentrations of 1–3 mg/L in groundwater can have geogenic origins (Madison and Brunett, 1985; Dubrovsky et al., 2010), the major trajectory for groundwater contamination are anthropogenic activities—primarily agriculture (Shukla and Saxena, 2018). According to the World Health Organization, a threshold of 50 mg/L in drinking water should be targeted (WHO, 2011), which is the current formal benchmark for many regions worldwide. However, in particular North America, Europe, India, China and South-East Asia show critically elevated nitrate levels, being a potential threat to both groundwater dependent ecosystems (e.g., aquatic animals) (Camargo et al., 2005) and human health (Shukla and Saxena, 2018).

Moreover, persistent organic pollutants (POP) remain of concern, despite international agreements (e.g., the Stockholm Convention) to phase out or limit their application. Pesticides (insecticides, rodenticides, herbicides and fungicides) are a major group in POP that enter the soil and groundwater compartment via agricultural application, bio-accumulate persistently (particularly at low concentrations (e.g., Kundu et al., 2019)) and spread across the aquatic environment with severe and partly unknown consequences for ecosystems and human health (Mosharraf et al., 2012). Similarly, the application of antibiotics e.g., in livestock farming (but also in the health care system) can significantly elevate respective concentrations in groundwater bodies. This is likely to support the development and spread of antibiotic resistance among bacteria in the environment. Though, current knowledge is still limited, the ingestion of antibiotic resistant bacteria via drinking or bathing in contaminated water as well as consuming food produced with contaminated irrigation water can pose human health risks (Amarasiri et al., 2020).

Driven by increasing consumer demands and preferences worldwide (e.g., meat consumption), agricultural intensification is critically building up pressures on groundwater resources. Quantitative and qualitative impairments do not just undermine a continued agricultural utilization, but can critically feedback to the consumer via a conflictual competition with ecosystem water requirements and the domestic (drinking) water demand.

Domestic: New peak demands and emerging contaminants

The domestic sector (sometimes referred to as the urban sector) accounts for about 16% of total water volumes withdrawn from groundwater, globally (Table 1). Quantitatively, these volumes are far behind the agricultural sector on a global level but public water withdrawals can locally sum up to significant amounts. In particular, in densely populated regions where irrigated agriculture is less widespread like in Germany, groundwater primarily serves for public drinking water supply (ATT et al., 2015). Qualitatively, major threats to groundwater from the domestic sector can be found in leakages of wastewater and landfills but also from events such as storm water discharge and flooding in urban environments that show a high level of sealing. Especially the exfiltration of substances from wastewater treatment plants and sewer systems is likely a key trajectory for groundwater contamination (Nguyen et al., 2021). In addition, the increasing use of shallow groundwater bodies for geothermal energy (e.g., for heating or cooling of buildings) was found to have major impacts on water chemistry and biodiversity (Griebler et al., 2016).

Public water demand primarily scales with population development but responds to variations in socio-economic and climate conditions (Rinaudo, 2015). During hot and dry seasons, for instance, people tend to use significantly more water, which apparently coincides with a period in which groundwater tables receive less recharge and overall water yield is reduced. Hence, peak demand periods coincide with low availability, potentially creating bottlenecks as happened in the drought years from 2018 onwards in Europe (EurEau, 2020). The societal processes behind water demand patterns are complex as it turned out during lockdown periods of the COVID-19 pandemics with restrictions in public life (Lüdtke et al., 2021).

Urbanization is projected to continue especially in smaller agglomerations as large cities are expected to slow their urban growth (UN-Habitat, 2020). The demand for drinking water will hence continue to increase with pressures on local and distant groundwater bodies (e.g., via inter-basin water transfers) for supplying drinking water. This will trigger conflicts with stakeholders who feel disadvantages and especially the rural-urban divide in water supply will challenge both the urban poor and the rural population (Shi et al., 2021). With growing urban agglomerations (population and area), the transformation of land surfaces due to sealing significantly lowers groundwater recharge rates and thus has a negative effect on the replenishment of groundwater volumes. The change of urban landscapes was found to significantly relocate recharge zones with an overall decrease in recharge rates (Han et al., 2017).

In residential water management, emerging contaminants are a major source of concern. In particular, pharmaceuticals and personal care products (PPCPs) are increasingly being focused on. This group includes substances such as antibiotics, anti-inflammatories, lipid-regulators, and caffeine from wastewater leakages and landfills. Their toxicity is not yet fully known and monitoring schemes are not implemented, yet (Sui et al., 2015). In addition, *per*- and polyfluoroalkyl substances (PFAS) are likewise coming into the focus as they are non-biodegradable and thus highly persistent in the environment. These synthetic organic chemicals can be found in various products and production processes due to their properties of e.g., stability under heat. Hence, a precautionary principal is requested in handling these substances (Cousins et al., 2016).

Domestic water use can be considered as the most direct and apparent interaction between people and groundwater resources, though mediated through infrastructure. In this respect, the recent drought years and qualitative challenges can be conceptually considered as part of an ongoing feedback loop, that might raise awareness of the population for groundwater challenges. This could trigger a more conscious handling of drinking water in the domestic sector and thus contribute to groundwater resources protection.

Industry: Point pollution and localized depletion

The third distinctive sector we consider is industry, which encompasses a wide range of activities from energy production (e.g., cooling of thermal power plants) over manufacturing (e.g., paper, chemistry, machinery, food and beverages) and waste disposal (e.g., dumping sites) to mining activities (e.g., open pit lignite mining) (Flörke et al., 2013). As Table 1 reveals, only 27% of total water withdrawals in this sector originate from groundwater, owing to the fact that the energy sub-sector is the most water-intensive process, which primarily draws on surface water resources (Wada et al., 2016). However, though these values might suggest a lower importance on the global level, industrial water use can have significant effects in terms of lowered quantity and deteriorated quality

on the local scale. With respect to the latter, a wide range of substances can be traced back to various industrial activities like volatile hydrocarbons (e.g., non-aqueous phase liquid (NAPL) like oil), heavy metals and acids (Lall et al., 2020).

The increase in water withdrawals for manufacturing particularly rose in China (Flörke et al., 2013). Researchers found that the increasing number of manufacturing plants (e.g., electronics sector) had significant influence on local groundwater levels (Zheng et al., 2021). Especially the fact that manufacturing plants are increasingly scattered over the country and not concentrated in certain industrial zones of larger agglomerations correlates with falling groundwater tables. Zheng et al. link this development with local governments competing with one another for attracting new companies to invest in certain counties. This results in lowered taxes and environmental standards, which has negative consequences for drinking water supply (e.g., increased costs) as extensive industry-induced well drilling activities create a diffuse pressure on groundwater bodies, lacking adequate monitoring infrastructure (Zheng et al., 2021).

Though, groundwater contamination can have geogenic origins with loads of mobilized arsenic and fluoride (Jadhav et al., 2015) as well as uranium, the mining sector contributes significantly to respective concentrations (Byrne et al., 2021). Mining activities create a massive intervention into natural hydrological patterns (Agboola et al., 2020). As a prerequisite for mineral extraction, lowering groundwater tables for several hundreds of meters via pumping is required to enable personnel and machinery to operate safely. In Germany, for instance, lignite open pit mining strongly altered groundwater conditions in Eastern and Western Germany with depression cones of about 2.100 km^2 like in the case of the Lower Lusatian Region (Koch et al., 2005). The impacts are manifold such as reduced surface water discharge (e.g., drying out of riverbeds), groundwater contamination (e.g., heavy metals) and land subsidence (e.g., damaging buildings) (Agboola et al., 2020). As a consequence from long-term mining activities, the remediation of respective regions affects both people and the ecosystems via rewetting and acidification (Hangen-Brodersen et al., 2005).

Overall, industrial groundwater uses have the ability to strongly interfere with social-ecological conditions due to their intense impact in a certain location. This may be most obvious in the case of mining, as the initiation of a pit fundamentally alters the social-ecological conditions—hydrogeology, ecosystems and communities are fully transformed. This is also true for the abandonment of respective sites when areas are remediated after decades of artificial human influence.

Indirect pressures: Climate change impacts

Climate change is human-induced, but pressures on groundwater due to climate change are rather indirect as they arise from rising temperatures in the atmosphere and changing precipitation patterns. Compared to direct pressures on groundwater from humans, such as the physical extraction of groundwater and the (unintentional) leaching of chemicals into the aquifer, the impacts of climate change on the resource are therefore considered diffuse and uncertain.

Rising temperatures and changing precipitation patterns

Climate change and groundwater have a complex relationship. Changes in groundwater recharge alter groundwater levels and outflows, which affect ecosystems and ecosystem services (Kidmose et al., 2013; Kløve et al., 2014; Griebler and Avramov, 2015). Due to the long residence times of groundwater in the subsurface, ranging from days to tens of thousands of years (Green et al., 2011), the visibility of climate change impacts on groundwater is delayed (Cuthbert et al., 2019; Riedel and Weber, 2020). A variety of climate change impacts on groundwater has already been studied as briefly discussed below.

The Intergovernmental Panel on Climate Change (IPCC) estimates a global warming of 1.5 °C above the pre-industrial global mean temperature until at least 2050 under all emission scenarios (IPCC, 2021). Global warming has multiple impacts on the hydrologic cycle and on groundwater resources. Precipitation and evapotranspiration are the two most important variables for groundwater recharge, yet they are altering due to climate warming (Fallah et al., 2020). Rising temperatures increase the atmospheric vapor pressure deficit of the air and thus, potential evapotranspiration rates, which might decrease groundwater recharge (Vicente-Serrano et al., 2019). However, increasing atmospheric CO_2 concentrations might reduce transpiration of plants due to reduced stomatal conductance, which might lead to increasing groundwater recharge rates (van Roosmalen et al., 2009; Milly and Dunne, 2016) if not balanced by increased leaf area. Moreover, the global warming-induced increasing length of the growing season may increase actual evapotranspiration and thus decrease diffuse groundwater recharge (Ruosteenoja et al., 2016). Rising temperatures and potential evapotranspiration might lead to higher irrigation demand (unless precipitation increases) (Taylor et al., 2013; Riedel and Weber, 2020). Precipitation is likely to increase in many already humid climates, e.g., northern Europe, North America and India, and decrease in many already arid or semi-arid climates, e.g., in the Mediterranean region, South Africa and north eastern Brazil (Anders et al., 2014; Jacob et al., 2014; Spinoni et al., 2020). Simultaneously, household water demand increases due to rising temperatures, especially during hot seasons (Vandecasteele et al., 2014; Simon et al., 2019). Therefore, the combined effect of climate warming and water demand results in "[. . .] amplification of the climate signal by the regional human response" (Lall et al., 2020).

Due to climate change, heavy rainfall events and long-lasting droughts are predicted to increase in frequency, severity and global spatial extent (O'Gorman, 2015; Donat et al., 2016; IPCC, 2021; Mianabadi et al., 2020; Lange et al., 2020). Hydrological droughts and the concomitant decrease of diffuse groundwater recharge may be evident due to the alteration of precipitation rates in combination with increasing evapotranspiration caused by global warming (Hänsel et al., 2019). Such droughts will increase in

regions that already suffer from water scarcity, e.g., the Mediterranean region, southern Africa and southern Australia (Spinoni et al., 2020). However, heavy rainfall events do not automatically lead to an increase in groundwater recharge and water availability (Donat et al., 2016). Depending on the hydraulic conductivity of the soils, heavy rainfall might lead to increased surface runoff, e.g., when the infiltration capacity of the soil is exceeded (Riedel and Weber, 2020). Thus, a smaller proportion of rainfall can recharge groundwater compared to evenly distributed rainfall (ibid.).

Other components that affect groundwater and are caused by climate change, but are not discussed in detail here, include the following: rooting depth of vegetation (deeper roots cause a decrease of groundwater recharge) (Li et al., 2018), forest cover and type (Teuling et al., 2019), snow cover in mountainous areas (Roudier et al., 2016; Bormann et al., 2018), soil moisture (Moeck et al., 2020), and aquifer and soil temperature (Riedel, 2019; Hemmerle and Bayer, 2020).

In addition to the quantitative impacts of climate change, groundwater quality is also expected to respond to changes in climate as groundwater recharge, runoff, and land use affect the groundwater system (Green et al., 2011). Increasing groundwater recharge can lead to quality problems as both geogenic and anthropogenic stressors might be flushed out by the increased recharge, which can increase contaminant transport or mobilize new contaminants and pollute groundwater (Green et al., 2011; Taylor et al., 2013). Increasing irrigation demand due to the reasons mentioned above, might increase recharge under cropland and might affect groundwater quality negatively (e.g., due to infiltration of nitrates, pesticides, fungicides) (Iglesias and Garrote, 2015). Besides quality issues, an increase of groundwater recharge may cause slope instability and landslides (Green et al., 2011).

Alteration of surface water and groundwater interaction

Climate change causes variations in the interaction of surface water and groundwater. Gaining streams (streamflow is recharged by groundwater, Fig. 2A) may turn into losing streams (streamflow infiltrates into the groundwater body, Fig. 2B) caused by changes in groundwater recharge (Green et al., 2011) and hydraulic heads (Jasechko and Perrone, 2021). Hydraulic heads are altered among others by groundwater pumping and may cause quality issues, e.g., groundwater salinization in coastal areas.

Additionally, the process of colmation (clogging) of river channels affects the interaction between surface and groundwater qualitatively. The physical clogging of the heterogeneous interstices affects stream ecology and the biochemical function of interstitial pore water, the hyporheic zone, and groundwater (Nogaro et al., 2010). While still uncertain and in need of further investigation, changing precipitation patterns and increasing temperatures caused by climate change affect the streamflow regime and likely influence this sedimentation (Wharton et al., 2017).

Uncertainties in groundwater recharge under climate change

Groundwater recharge cannot be measured directly, such that observed groundwater recharge rates over large areas or over longer periods are rare (Earman and Dettinger, 2011; Smerdon, 2017; Moeck et al., 2020). Currently and in the recent past, its calculation is based on hydraulic head observations or water-balance calculations (Moeck et al., 2020; Reinecke et al., 2021). However, several sources of uncertainty accumulate in the estimation of groundwater recharge caused by the various water-balance parameters on which groundwater recharge depends, such as evapotranspiration, surface-groundwater connections, or local geology and land use (de Vries and Simmers, 2002; Refsgaard et al., 2016; Reinecke et al., 2021). Thus, groundwater recharge, as part of the hydrologic cycle, is one of the most difficult components to estimate, especially on a global scale (Reinecke et al., 2021).

In addition, significant uncertainties arise in estimating alterations in groundwater recharge in the future due to climate change (Döll et al., 2015; Reinecke et al., 2021). In this process, impact models, such as hydrological models, are combined with climate models. While climate models are rather accurate in projecting temperature increases, they struggle in projecting atmospheric moisture content and thus precipitation (Kent et al., 2015; Fatichi et al., 2016; Fallah et al., 2020). This uncertainty results from complex atmospheric processes and spatial downscaling (Hübner, 2016; Bender et al., 2021). Therefore, both the uncertainty of

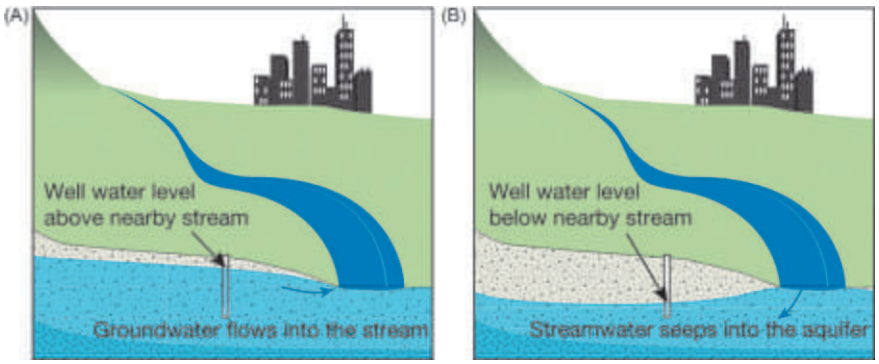

Fig. 2 Cross-section of a gaining (A) and losing stream (B). Gaining streams are prevalent in humid regions of high topographic relief, while losing streams tend to occur in arid climates, flatter topography and in regions of intensive groundwater pumping. Modified from Jasechko, S (2021) Widespread potential loss of streamflow into underlying aquifers across the USA. *Nature* 591.

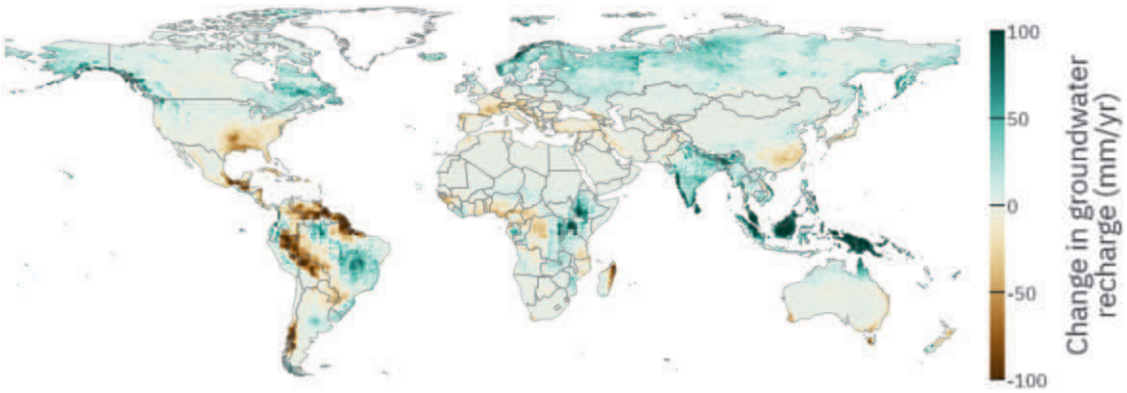

Fig. 3 Mean change in groundwater recharge (in mm/year) between present day warming of the atmosphere of 1 °C and 3 °C (3 °C global warming is projected between 2046 and 2082). Calculation of mean groundwater recharge is based on a multi model ensemble of eight global hydrological models and four global climate models. Reinecke R, Trautmann T, and Müller Schmied H (2021) *How Will Climate Change Impact Groundwater Resources? A Key But Not Yet Fully Resolved Question*. Potsdam Institute for Climate Impact Research. Available online at https://www.isipedia.org/report/how-will-climate-change-impact-groundwater-resources-a-key-but-not-yet-fully-resolved-question/, (Accessed on 13th November 2021).

climate and hydrological models contribute to the overall uncertainty of estimated changes in groundwater recharge (Reinecke et al., 2021). As the annual precipitation and seasonality of temperature have been identified as paramount predictive variables for groundwater recharge rates (Moeck et al., 2020), reliable modeling of future temperature and precipitation changes is crucial to estimate groundwater recharge changes in the future.

As briefly mentioned earlier, another major source of uncertainty in groundwater recharge estimates is the calculation of the effect of increasing CO_2 concentrations and their impact on vegetation transpiration (Milly and Dunne, 2016). Without accounting for active vegetation in global climate models total runoff could be underestimated and groundwater recharge could therefore increase in model output. This might lead to overestimating the decrease in groundwater recharge. As this process is complex and highly uncertain, it is currently neglected in many global hydrological models (Reinecke et al., 2021; Milly and Dunne, 2016).

Groundwater recharge changes due to climate change have been recently simulated between present-day atmospheric warming of 1 °C and 3 °C on a global scale (Reinecke et al., 2021). Despite the aforementioned uncertainties, this simulation showed a statistically significant decrease in groundwater recharge in the central United States, southern Chile, parts of Brazil, and the Mediterranean, and an increase in groundwater recharge in some parts of the Arctic, East Africa, India, and South-East Asia (Fig. 3).

Shaping human-groundwater interactions more sustainably

The challenges from both direct and indirect pressures on groundwater resources require sustainable solutions to prevent critical tipping points in human-groundwater interactions, in particular against the background of global change processes. In the following sub-sections, we briefly explore approaches to manage groundwater resources, take a closer look at groundwater governance and explore potential pathways for adapting current approaches for the future.

Managing groundwater

Being a vital source for potable water supply and food crop irrigation, groundwater is managed through wells, pipes and pumps in most places. Not least because of excessive well drilling, aquifers are affected by salinization and pollution from land and water use above ground (Foster et al., 2013). Aquifer management thus intensely links to land use management—aquifer protection measures include, for instance, land use restrictions (an example are groundwater protection zones in vicinity to groundwater wells for potable water supply). Further practices that interfere with hydrogeological processes such as the discharge of used waters into water bodies are tried to be contained by aquifer protection measures. Monitoring aquifer pollution is an important strategy in managing groundwater quality. Balancing groundwater recharge and abstraction is equally important. One approach to uphold the balance is managed aquifer recharge (MAR) where treated surface water is infiltrated and left to percolate in the ground for eventually contributing to groundwater recharge. Overall, management challenges become more complex where aquifer boundaries transgress administrative ones for which transboundary aquifer management is an important approach (Conti and Gupta, 2014).

However, even where aquifer protection policies exist (e.g., regulating agricultural and other land use), monitoring is often inadequate to detect pollution incidents (Foster et al., 2013). "Safe groundwater exploitation" is commonly misinterpreted, taking the mean recharge rate over 30 years in the past as the reference point, which is untenable under conditions of (global) environmental change (Molle et al., 2018). Groundwater management currently occurs under the framework of Integrated Water Resource Management (IWRM) in hydrologically defined spatial zones (river basins). This management approach potentially collides with the spatial extend of hydrogeological entities. As Foster et al. (2013) argue, "improved integrated groundwater planning" is needed to reduce cross-sectoral and cross-scalar feedbacks that negatively affect groundwater status.

Groundwater governance

Governance refers to "the exercise of authority, by different social actors in a society, through the development and implementation of explicit and implicit substantive and procedural rules to manage resources for the social good" (Gupta and Pahl-Wostl, 2013). Groundwater governance is shaped by multiple rules such as water allocation rights, ownership and rights of use of wells and pumps, land use regulations and pollution rights, that may be written and formalized or not, and that may have been formed "from above" or "from below." As a "common good" that can be found in every country of the world (Conti and Gupta, 2014), groundwater has been used as a case example for studying governance arrangements of natural resources. The work by Elinor Ostrom has been seminal in this regard and is a key reference in subsequent research on sustainable natural resource management (e.g., Ostrom et al., 1994).

Establishing rules in favor of sustainable groundwater management requires knowledge of hydrogeological processes in their interaction with social processes, as well as respective prioritization of managing groundwater sustainably by a multitude of actors involved. However, the field of socio-hydrogeology is only emerging (Re, 2015). Key processes on future developments affecting groundwater are barely understood (Kraemer et al., 2021 and other parts of this chapter). A further barrier to sustainable groundwater governance is the time lag in groundwater deterioration becoming visible and detectable: Because groundwater is hidden underground, changes in quality and quantity become visible only late, for instance when groundwater-dependent ecosystems fall dry or react to pollution. Political attention tends to arise only at this late stage when it may already be too late to take protective measures (Foster and Custodio, 2019). Moreover, concentrations of pollutants in groundwater measured today indicate pollution loads that date back to between 5 and 30 years ago. Accordingly, holding those responsible accountable and implementing the "polluter pays" principle is difficult, as contestations and contradictions between agriculture and water sectors in the implementation of the Nitrates Directive in Europe illustrate (Musacchio et al., 2020).

Against the background of groundwater's "physical vulnerability that has resulted in political invisibility" (Fried et al., 2018), irregular groundwater use and pollution could thrive in most parts of the world. Limited knowledge on relevant biophysical processes, lack of financial and personal resources to monitor groundwater pollution and abstraction, as well as conflicting political interests have been identified as limiting factors in sustainable groundwater governance (Molle et al., 2018). Some countries, such as India for example, even subsidize electricity costs for pumping to encourage greater agricultural productivity at the expense of falling groundwater levels (Shah et al., 2008). In addition, the current governance system in which aquifers fall under diverse jurisdictional entities (608 transboundary aquifers have been listed as of 2014; Conti and Gupta, 2014) implies that multiple legal arrangements govern a single aquifer. This is often linked to contradictory arrangements that spur groundwater over-abstraction. However, when purposefully designed, 'legal pluralism' may also strengthen the protection of groundwater resources, as has been established for the European Union (Conti and Gupta, 2014).

Pathways for the future

While groundwater has long been studied and regulated at local scale, recent publications point to the interlinkages of the resource with other places and scales (Molle et al., 2018; Falkenmark et al., 2019; Luetkemeier et al., 2021). At the same time, the conditions of groundwater bodies are place-specific and locally embedded and therefore difficult to steer at higher levels (Foster et al., 2013). In particular, the definition of "safe yields" for groundwater abstraction has been identified as so complex and riddled with uncertainties that it amounts to a political decision. A series of questions arise in this context, as Molle et al. summarize in the following quote:

> This political question leads directly to an examination of the governance of groundwater development and abstraction. Is the state, as the putative guardian of the public interest, better placed to establish guidelines and policies that offer ways to solve the trade-off? Are the concerned "users," ideally together with the affected constituencies, more likely to be able to address the trade-off? Alternatively, does a form of co-management between the state and citizens have the potential to combine the strengths of the two sides? Is groundwater over-abstraction a local issue or do the spatial (via the hydrologic cycle) or temporal (inter-generational) forms of externality call for its treatment at much larger scales?

(Molle et al., 2018).

Governing groundwater is thus symptomatic of the complexity entailed in sustainable water governance in general that calls for adaptive governance approaches that are flexible in reacting to dynamics and multiple bodies of knowledge on human-water interactions (Pahl-Wostl, 2019). The EU Water Framework Directive and its Daughter Directive on Groundwater are considered a "best practice" example of sustainable groundwater governance, partly because it has been designed in a strong exchange at the science-policy interface. Nevertheless, challenges persist with regard to meeting knowledge needs on complex human-groundwater interactions while also developing and communicating in formats that can be handled by decision-makers (Fried et al., 2018; Foster and Chilton, 2021). Calls for pluralizing groundwater governance research highlight that "there is merit in complementing the current focus on government efforts to better regulate and control extraction, with efforts to document and learn from community initiatives to care for, share or recharge the aquifers they depend on for livelihoods and incomes" (Zwarteveen et al., 2021). Here, adaptive governance approaches are helpful, not least to strengthen the capacity to adapt to change in access to groundwater among those most directly impacted from deterioration and depletion of the resource.

Conclusions

In this chapter, we explored the various pressures humans put on groundwater resources worldwide. We elaborated on sector-specific "direct" impacts in agriculture, the domestic sector and in industrial uses of water. We furthermore looked into the "indirect" effects that stem from climate change, as precipitation patterns and temperature are likely to change. Based on these insights into human-groundwater interactions, we discussed the current state of knowledge with respect to groundwater management and governance and elaborated how respective strategies may contribute to a more sustainable groundwater use.

While departing from a unidirectional notion of anthropogenic stressors on groundwater, the multiple human-groundwater interactions that we have discussed here, and the uncertainties involved in predicting future interactions and trends point to the need for rethinking this clear directionality. As we illustrated at the examples of agriculture, domestic water use and industrial water use, in the Anthropocene, groundwater is thoroughly shaped by dynamic social-ecological interactions. Global trade patterns shape local groundwater (over)use and deteriorations, potentially inflicting with longstanding practices and rules in protecting groundwater in order to enable its use. Climate change impacts alter groundwater ecosystems, the functioning of groundwater-dependent ecosystems and trigger adaptation to new conditions, such as shifting from rain-fed to irrigated agriculture—again reconfiguring groundwater use, directly or indirectly. What is at stake is therefore not so much the protection of groundwater resources from human "pressures." Instead, the politics of establishing a "safe groundwater yield" highlight the need to rethink what the desired condition of groundwater is, who and what has the legitimacy to define this condition, who and what is to be held accountable, and how we understand and govern sustainable human-groundwater interactions in the future.

Against this background, we conclude that for sustainable groundwater use, we need to explicate social-ecological processes—their origins, meanings, purposes and dynamics—to better understand and identify critical trends today and potential traps in the future.

Knowledge gaps

- How can water supply security be ensured under climate change-induced alterations of groundwater recharge and changes in societal water demands?
- How to prevent elevated nitrate concentrations in groundwater bodies against the background of established market-mechanisms (e.g., consumer preferences) in the industrialized agricultural sector?
- How do we incorporate uncertainty attached to data on groundwater availability and demand into decision-making?
- How to account for diverging scales in groundwater management, considering groundwater as a localized resource with complex multi-scalar societal demands?

Glossary

Biostability The concept of biostability describes the ability to distribute and store water in a distribution system without detrimental quality changes due to microbial growth based on the available substrates (Savio et al., 2018).

Disinfection Inactivation process of microorganisms which causes the loss of their ability to proliferate. Disinfection does not destroy *all* microorganisms but rather reduces the number of disease-causing microorganisms to an acceptable level (Gerba et al., 2003). QMRA can be used to achieve a specified acceptable level of risk.

Epidemiology Epidemiology is the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems (Last, 2001).

Fecal indicators A group of organisms that indicates the presence of fecal contamination, such as the bacterial groups thermotolerant coliforms or *E. coli*. Hence, they only infer that pathogens may be present (Ashbolt et al., 2001).

Fractured aquifer Often synonymously used for 'karst aquifer' (see below).

Gastrointestinal diseases (GID) Gastrointestinal diseases are those that affect any section of the gastrointestinal tract, from the oesophagus to the rectum, and the accessory digestive organs—liver, gall bladder and pancreas. The term encompasses acute, chronic, recurrent or functional disorders and covers a wide range of diseases, including inflammatory bowel disease and functional dyspepsia (Nature, 2021).

Groundwater vulnerability Groundwater vulnerability is a term used to represent the natural ground characteristics that determine the ease with which groundwater may be contaminated by human activities (European Commission, 2021).

Hydrogeology Hydrogeology is defined as the science of the occurrence, distribution, and movement of water below the Earth's surface (Ravier and Buoncristiani, 2018).

Karst aquifers Karst aquifers form by the chemical dissolution of soluble rock (Goldscheider et al., 2020).

Karst Karst is the term used to describe a special style of landscape containing caves and extensive underground water systems that is developed on especially soluble rocks such as limestone, marble, and gypsum (Ford and Williams, 2013).

Microbial source tracking (MST) Microbial source tracking is an area of research which aims to identify the origins of microbial contamination and so remedial action can be appropriately targeted (Morris et al., 2017).
Microbiome The microbiome is the sum of the microbes and their genomic elements in a particular environment (Ho and Bunyavanich, 2018; Berg et al., 2020).
Perennial spring A spring that continuously discharges water, in contrast to intermittent or periodic springs.
QMRA Quantitative microbial risk assessment (QMRA) is an approach that allows for the quantitative expression of risk in terms of infection, illness or mortality from microbial pathogens (Gerba, 2015).
Standard fecal indicator bacteria (SFIB) Intestinal bacteria used as fecal indicators, for which internationally agreed standard methods are defined (International Standard Organization, ISO).
Water transmissible (intestinal) pathogen Pathogenic microorganisms that are transmitted via water and cause disease (i.e., waterborne disease).

Introduction

Karst aquifers are essential sources for the global supply with drinking water. Most recent estimates state that 15.2% of the global ice-free continental surface area are covered by karstifiable carbonate rock (Goldscheider et al., 2020). In regard to global water supply, latest reports estimated that around 9.2% of the world's population is partly or entirely supplied with freshwater from karst aquifers—accounting for 127 km^3 per year or 13% of the global groundwater withdrawal (Stevanović, 2019b). Only in Europe, six capital cities—namely Podgorica, Rome, Sarajevo, Skopje, Tirana and Vienna—are partly or entirely supplied with drinking water from karst aquifers (Goldscheider et al., 2020). Considering this important role of karst aquifers for global (drinking) water supply, broad knowledge on all factors influencing both quantity and quality of these water resources is needed in order (1) to allow an adequate management of these vulnerable water resources, and (2) to anticipate challenges mankind will likely face in the next decades. When using karst aquifers as drinking water resources, karst water users typically face two potential challenges: (i) temporally variable (i.e., unstable) discharge regimes, and (ii) vulnerability to allochthonous pollution (Fig. 1).

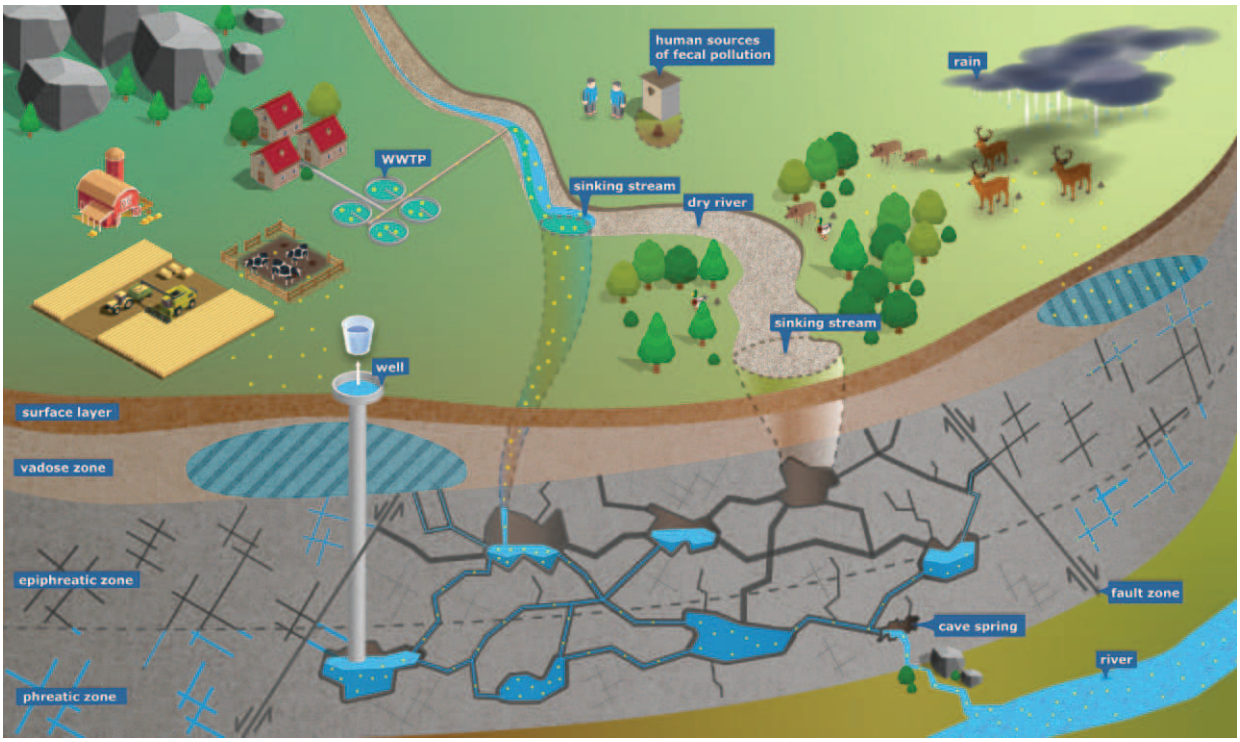

Fig. 1 Schematic illustration of the structure of different karst aquifer types and potential sources and pathways of (fecal) pollution into the groundwater. Aquifers of different geological and weathering status are illustrated: left & right: dense, little weathered karst with small fissures (e.g., dolomite karst); center: highly weathered karst with cave system (e.g., limestone karst); Yellow dots: feces borne pathogens; Potential sources of fecal pollution: wildlife, livestock (cattle), human: open defecation, leaking wastewater infrastructure or its effluent waters, manure application for fertilization.

The hydrogeological setting, the general characteristics of the catchment, as well as the climatic conditions are the most important factors determining the variability in discharge. While the rapid infiltration of (fecally) polluted surface waters in response to (extreme) precipitation events represents a major factor affecting the (microbiological) water quality in the humid regions of the world, water scarcity will likely play an even greater challenge than today in arid regions (Stevanović, 2019a). According to the WHO drinking water guidelines, the greatest risk to public health from microbes in water is associated with the consumption of drinking water that is contaminated with human and animal excreta (World Health Organization, 2017). The majority of outbreaks of waterborne diseases are associated with the inadequate management of water resources and drinking water distribution systems (DWDS), or the insufficient treatment of raw water.

According to data from 2021, worldwide 829,000 people are estimated to die from diarrhea as a result of unsafe drinking-water, lack of sanitation and insufficient hand hygiene every year (World Health Organization, 2019a). The most vulnerable members of our societies—children at the age between 0 and 5 years—suffer from lethal diarrhea in estimated 297,000 cases per year (World Health Organization, 2019a). Only in the year 2010, the United Nations General Assembly declared access to safe drinking water a human right (UN resolution A/RES/64/242). In order to reduce the burden of waterborne disease and deaths, the WHO provides guidelines for drinking-water quality since more than 50 years, and by that a secure basis for national regulations and standards for water safety and public health (World Health Organization, 2017). These include recommendations for contextual hazard identification and risk management through the establishment of health-based targets, catchment-to-consumer water safety plans and independent surveillance.

The aim of this chapter is to give an overview of the current knowledge on the microbiology in karst aquifers, with special focus on factors affecting the health-related microbiology and the sustainable management of karst water resources. Besides a basic introduction on the hydrogeology and catchment settings of karst aquifers, their vulnerability to and common sources and pathways of fecal pollution, and the biogeochemistry of karst aquifers and this also includes an overview of the composition and role of their native microbiomes including their promising potential as biological indicators for the characterization of these aquifers. Main focus of this chapter is on the issue of microbial fecal pollution, the epidemiology of waterborne diseases, and the proper management of karst water resources. In this context, also a recently proposed framework for the comprehensive analysis of microbial pollution with the objective to support the sustainable and high quality management of drinking water resources in accordance with recent World Health Organization guidelines is being introduced. The pollution of karst aquifers with chemical substances is another important issue of global concern, but not in focus of this chapter. Further information on that topic can be found elsewhere (Kalhor et al., 2019; Vesper et al., 2000).

Hydrogeology and catchment characteristics of karst aquifers

The following section provides an overview about the hydrogeology of karst systems based on the reports of Barton et al., 2019, Ford and Williams, 1989, and Taylor and Greene, 2008. For more in-depth information, the reader is referred to the original references.

Basics on hydrogeological characteristics of karst aquifers

A karst aquifer is a hydrological system with a variety of surface and subsurface input, throughput and output flows. Karst aquifers form from the dissolution of soluble rocks such as limestone, dolomite and gypsum by flowing water enriched with carbon dioxide (CO_2) from the atmosphere and produced by biological processes. Karst systems are characterized by underground drainages such as sinkholes, caves (speleogenesis), and conduits (cf. Fig. 1). They typically feature a dendritic or branching network of conduits. The permeability of conduits is interconnected with, but distinctive from the permeability of the bedrock pore matrix and fractures. Due to the complex interplay between the bedrock matrix and the fracture and conduit systems, karst aquifers are characterized by extremely heterogeneous and anisotropic characteristics. Karst *springs* are the natural outlets from the conduit networks (cf. Fig. 1). *Underflow springs* are perennial springs carrying the base-flow discharge of the conduit network. In contrast, so-called *overflow springs* are intermittent, functioning as temporary outlets during high discharge periods. The groundwater is abstracted either directly from springs, or from wells drilled into the aquifer, caves or underground storages (cf. Fig. 1). The spring discharge regime is typically driven by precipitation, snow melt, and may as well be (temporarily) connected to surface water bodies. When precipitation is directly falling on karst terrane, one refers to *autogenic* recharge of a karst aquifer (cf. Fig. 1), if precipitation is falling on non-karstic terrane, one refers to *allogenic* recharge. Moreover, one can distinguish between *concentrated* and *diffuse recharge*. *Concentrated* recharge occurs through the conduits and fractures during heavy rainfall or surface runoff periods. *Diffuse* autogenic recharge is the infiltration through the soil and the unsaturated *aeration zone* (Lehmann and Totsche, 2020), often contributing a considerable part of the recharge of karst aquifers (Taylor and Greene, 2008). *Diffuse allogenic* recharge can be transferred into a karst aquifer from non-karstic aquifers or drains vertically from overlaying layers of non-soluble rocks or sandstone.

Methods to study karst aquifer systems

Besides topography, geological structure and stratigraphy, the following basic information is of relevance for the characterization of karst systems (Taylor and Greene, 2008): (1) the area of the karst catchment, (2) the portion of allogenic recharge, (3) the carrying capacity of the conduit system, (4) the hydraulic conductivity of the matrix and fracture system, (5) the response of the conduit

system over time, (6) the interaction of fractures and conduits and (7) the water budget. Karst springs and cave streams often show highly variable flow rates. For a proper characterization of a karst aquifer, it is therefore important to continuously monitor the spring discharges, surface water inflows as well as climatic variables in the karst catchments. The karst (drainage) catchment (1) is defined by the total area of surface and subsurface drainage contributing to the outlet spring or springs. Its boundaries may vary depending on the groundwater level as well as the geometry of conduits. The most accurate method to identify flow paths (e.g., between sinks or swallow holes and springs) and to delineate karst spring catchments is to conduct tracer tests (Benischke, 2021). The allogenic recharge contribution and conduit carrying capacity (2 & 3) can be evaluated by analyzing the simultaneous measurements of the stream discharges above the recharge locations (e.g., sinkholes/sinking stream as depicted in Fig. 1) and at the spring outlet (e.g. cave spring as depicted in Fig. 1). Conduits and subsurface channels are important groundwater flow paths which can be identified e.g., by geophysical methods applied on the ground surface. They often flow into caves that only in rare cases can be directly accessed—only then allowing direct insights into the channel network. The hydraulic conductivity (4) of the matrix is typically investigated by conventional hydrogeological tools such as laboratory permeability tests of representative soil or rock core samples. The fracture hydraulic conductivity is determined using straddle packer hydraulic tests and borehole flow meters (Sauter, 1991). The integrated matrix and fracture system transmissivity can be measured by time-drawdown, distance-drawdown, or slug tests of the aquifer (Taylor and Greene, 2008). The conventional analytical methods are based on Darcy's law, requiring additional consideration of the presence of turbulence effects (Streltsova, 1988). The response of the conduit system (5) can be investigated by analyzing the time series of spring discharges, such as the ratio between peak and base-flow discharge, by chemical hydrograph separation, or by analyzing the changes in spring discharge and water quality during storm events (hydrological pulse analysis). The partitioning between conduit and non-conduit flow (6) is complex and depends on the hydraulic pressure. The exchanging water volumes can be evaluated by deconvolution of spring discharge time series, comparison of the response of hydrographs during storm events as described by Shevenell (1996), or by analyzing the unit base flow (UBF). Water budgets (7) can be evaluated for different time periods such as a water year, a season, or the duration of a storm event. A conventional water-budget equation reads as follows:

$$I = O + ET + \Delta S,$$

where I is precipitation, O is the discharge at the karst basin outlet, ET is evapotranspiration, and ΔS is the change in groundwater storage (Bassett, 1976). Storm events are often of concern for the spring or well water quality (cf. Section "Fecal pollution in karst water resources and implications for human health" of this chapter). On the event scale, the water budget (i.e., the recharge contribution during a storm event) can be calculated from the change in storage over the time period of an event.

Vulnerability of karst aquifer catchments

Depending on the degree of karstification, karst aquifers are often highly vulnerable to any kind of contaminations from surface-environments (cf. Fig. 1). Contaminants—whether microbiological or chemical—can easily and quickly reach the groundwater and may be transported over large distances via conduits. As stipulated by the Water Framework Directive (Council Directive 2000/60/EC, n.d.), drinking water protection zones in karst systems are delineated based on spring or well intrinsic vulnerability maps. Due to the high heterogeneity and uncertainty that is intrinsic to many karst aquifers, the protection zones often cover the entire catchment of a spring. In the literature, several vulnerability mapping methods have been proposed to assess the vulnerability of karst aquifers (Barton et al., 2019; Marín et al., 2015). Overall, these methods are not universally applicable due to site-specific characteristics of karst terrains. This is especially noticeable on mantled karst areas, where properties of soil cover layers influence the attenuation of contaminants depending on their saturation and hydrological characteristics. Therefore, it is important to account for the site-specific conditions when creating vulnerability maps. *EPIK* is the most widely used method for carbonate media based on multiple criteria to chart the vulnerability (Doerfliger, 1996). The EPIK method accounts for the specific groundwater dynamics of karst aquifers based on the following criteria: (1) development of the epikarst (E), (2) protection efficacy of the surface layer (P), (3) infiltration characteristics (I), and, (4) development of the karst network (K). Newer methods are the so-called *COP* or *COP + K* approaches (Andreo et al., 2009; Vías et al., 2006), the Slovene approach (SLV) (Ravbar and Goldscheider, 2007), and PaPRIKa (Kavouri et al., 2011). COP is based on three main factors: concentration of water flow (C), overlapping layers considering both soil and rock substrate (O), and precipitation (P) (Citrini et al., 2021). The K factor additionally takes into account the development of the karst network. For the protection of groundwater, the attenuation of contaminants is accounted for as a function of soil texture and thickness, lithology, thickness of the unsaturated zone, and the degree of aquifer confinement. The Slovene Approach incorporates and extends several karst-related vulnerability mapping methods and is the only method including risk and hazard maps. PaPRIKa stands for the Protection (P), Infiltration (I), Reservoir (R) and Karstification (K) criteria being used, and is an extension of the EPIK method. PaPRIKa considers both the vulnerability of the resource and the source, by evaluating the transfer speed based on the results of tracer tests. Fig. 2 shows an example for a vulnerability map based on the COP method(Aragão et al., 2019; Tayer and Velásques, 2017). Vulnerability maps of the source are then used for delineating protection zones (Kavouri et al., 2011). The intrinsic vulnerability of karst springs can also be quantified by means of numerical modeling (Butscher and Huggenberger, 2008). Mathematical models can help to better understand the speleogenesis and the flow and transport in karst aquifers, but often involve high uncertainties when delineating well catchment zones or predicting the water quantity and quality of karst springs.

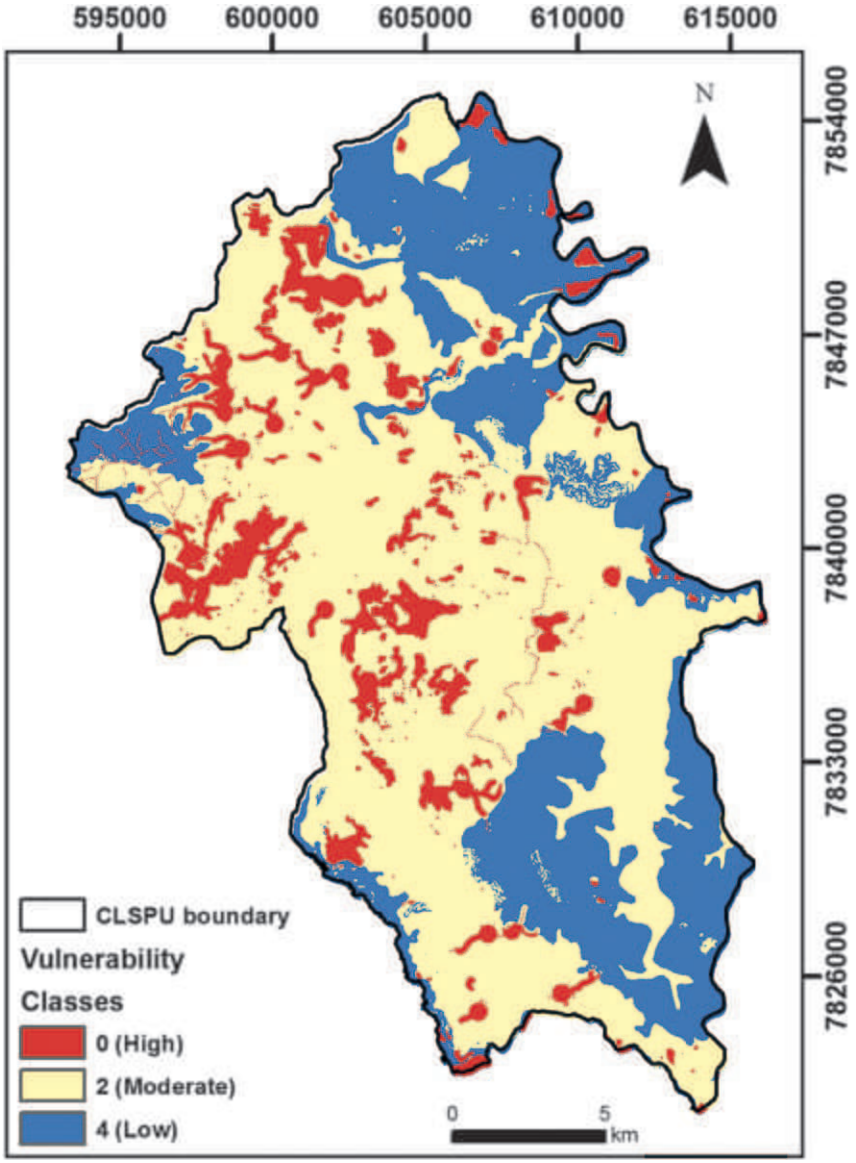

Fig. 2 Example for an intrinsic vulnerability map of the Carste Lagoa Santa karstic region based on the COP method. Adapted from Tayer TDC and Velásques LNM (2017) Assessment of intrinsic vulnerability to the contamination of karst aquifer using the COP method in the Carste Lagoa Santa Environmental Protection Unit, Brazil. *Environmental Earth Sciences* **76**: 445.; Aragão F, Velásquez LNM, Galvão P, De Castro Tayer T, Lucon TN and De Azevedo ÚR (2019) Natural background levels and validation of the assessment of intrinsic vulnerability to the contamination in the Carste Lagoa Santa protection unit, Minas Gerais, Brazil. *Environmental Earth Sciences* **79**: 31.

Microbial ecology and biogeochemistry of karst aquifers

The groundwater habitat and role of the groundwater microbiome

Apart from the potential occurrence of pollution-related, water-transmissible (intestinal) pathogens, karst aquifers also harbor a native microbiome that does not pose a risk to human health. Even the best protected and most pristine groundwaters are far from being sterile (cf. Table 1), and all feature their own characteristic 'signature' in terms of chemistry, physical conditions, and microbiome (Farnleitner et al., 2005). Deep subsurface habitats fascinate microbial ecologists as these habitats harbor the majority of bacterial and archaeal biomass on Earth, with approximately 70 gigatons of carbon (Bar-On et al., 2018). About 60% of all microbial cells of the entire biosphere are estimated to reside in the deep oceanic (4×10^{29} cells) and continental (3×10^{29} cells) subsurface, with an estimated fraction of 20–80% considered to live as single sessile cells or biofilms (Flemming and Wuertz, 2019). About 5×10^{27} cells are globally considered to thrive in groundwaters. While epidemiologically irrelevant to humans, the native subsurface microbiome — comprised of prokaryotes (archaea and bacteria), protozoa, viruses as well as fungi — has positive effects

Table 1 Overview on typically observed prokaryotic cell concentrations (Total Cell Counts; TCC) as reported from different karst aquifers.

Karst system	*Altitude*	*Study site and Situation*	*TCC [$\times 10^3$ cells/mL]*		*Geographic region*	*Method*	*References*
			Mean/Median	*TCC Range*

TCC, Total Cell Counts; EM, Epifluorescence Microscopy; FCM, Flow cytometry; SG, Sybr Green; AO, Acridine Orange.

on the water quality. Anthropogenic contaminations in the form of chemical compounds, nutrients and even water transmissible (intestinal) pathogens, that cannot thrive in groundwater, can serve as carbon and/or energy source for subsurface microbes, finally leading to carbon dioxide and dinitrogen gas. This natural 'self-cleaning' effect is considered of paramount importance to obtain water of high *biostability* and represents only one of many valuable ecosystem services provided by groundwater microbes to humans (Griebler and Avramov, 2015; Van Der Kooij, 1995). Another benefit from the native groundwater microbiome arises from their intrinsic potential to serve as natural biological indicators that can be used to study a variety of questions related to (microbiological) water quality (Derx et al., 2022, in press). For example, Sinreich et al. (2014) proposed a set of microbiological parameters—including the simple parameter of the prokaryotic abundance in the suspended community fraction—in combination with hydrological data for the classification of karst aquifers in respect to the dynamics and the vulnerability of karst springs to (fecal) pollution (Fillinger et al., 2019).

Groundwaters are unique ecosystems, dominated by microbial life, complete darkness that accounts for the absence of light-driven primary productivity, little to no oxygen availability, and nutrient scarcity (Akob and Küsel, 2011; Griebler and Lueders, 2009). Due to the oligotrophic conditions in pristine groundwaters, prokaryotic abundances can be orders of magnitude lower than in aquatic surface habitats like rivers and lakes, and often do not exceed 10^8 cells per liter in groundwater (cf. Table 1). The absence of seasonally varying primary production, low temperature variation, dispersal limitation and limited input of surface-derived, easily available fresh organic matter result in relatively constant living conditions. This lack of periodic or frequent disturbances might explain the sensitivity of the groundwater fauna and microbial communities to anthropogenic impacts. At low levels of disturbances, more competitive organisms will push subordinate species to extinction and, according to the intermediate disturbance theory, dominate the ecosystem (Dial and Roughgarden, 1998). Thus, surface point-source chemical contaminations can have severe and/or long-lasting effects on aquifer community structures and their metabolic activities.

Shallow aquifers are constantly recharged with water from the land's surface. Episodic high-flow events, like those following lasting rainstorms and snow melts, contribute to groundwater flooding (Reiss et al., 2019; Zhou et al., 2012) and the export of suspended organic material from soils into the aquifers (Lehmann et al., 2021). Time-series analyses revealed that also the microbial communities in shallow karstic aquifers vary over time despite the constant living conditions, with groundwater recharge being the driving factor for the observed patterns (Yan et al., 2021). During recharge, not just dissolved and particulate organic matter (DOM and POM), but also soil-borne microbes are translocated via seepage into karstic aquifers (Dibbern et al., 2014; Herrmann et al., 2019; Krüger et al., 2021) (cf. Fig. 1). Specific bacterial taxa can be associated with recharge phases and are responsible for a fraction between 9% and 65% of the groundwater microbiome depending on the surface connectivity (Yan et al., 2020). Surprisingly, the seepage microbial communities do not reflect the soil community, as the susceptibility to seepage-mediated translocation is taxon-specific (Krüger et al., 2021). Especially members of the *Candidatus* Patescibacteria belonging to the candidate phyla radiation (CPR) (Hug et al., 2016) often dominated seepage bacteria with up to 50%, although representing only a tiny fraction of 0.6% in the soil of the studied recharge area (Herrmann et al., 2019).

Challenges affecting groundwater microbiome studies

Today, we know that members of the CPR dominate many groundwaters (Castelle et al., 2018; Luef et al., 2015). These novel lineages have long been overlooked as many pass the widely used 0.2 μm pore-size filters for biomass enrichment due to their small cell size, and their 16S rRNA genes do not amplify well with commonly used universal primers due to mismatches (Schulz et al., 2017). In addition to these ultra-small bacteria, also members of the *Alpha-* and *Gammaproteobacteria* are preferentially mobilized from soil, but with much lower preference than *Cand.* Patescibacteria. This preferential mobilization and transport of specific taxonomic groups must also be kept in mind when focusing on the analysis of microbiological water quality based on fecal indicators whose presence or absence in a particular groundwater sample might not reflect the mobilization and transport behavior of potential fecal-associated pathogens. These considerations highlight just two of the many challenges that groundwater researchers are facing when studying the different aspects of groundwater microbiology. Another very fundamental limitation is that the sessile, biofilm-associated fraction will be missed in most studies if we just focus on the easily accessible water phase (Smith et al., 2018). Nonetheless, this limitation must be accepted as microbial analyses of karstic bedrock need expensive and contamination-free drilling techniques, which contradicts with a high temporal resolution. In contrast to ecological studies focusing on biogeochemical processes and microbial functionality, this limitation is of lesser concern when studying the microbiological water quality which typically focuses mainly on the microorganisms suspended in the water column. In this context, karst springs—as the natural outlet of karst aquifers—are valuable spots for the hydrogeological and microbiological characterization and assessment of the vulnerability of karst aquifers on a larger regional scale (Savio et al., 2018; Sinreich et al., 2014). In contrast, groundwater sampling via well-pumping yield more local information on the groundwater microbial community composition and hydrogeochemical characteristics. As mentioned above, both approaches have in common their limitation to shed light on only the planktonic (free-living) fraction of the groundwater community, and may therefore not adequately represent all members of the microbial subsurface ecosystem that are responsible for biogeochemical cycling and the provision of important ecosystem services.

Groundwater microbiome composition

The hydrogeological settings control subsurface life fundamentally by determining the overall patterns of fluid flow, weathering rates, spatial and temporal distribution of inorganic/organic matter as well as the pH, which is a main driver structuring

subsurface microbial communities and their metabolism (Küsel et al., 2016). A unique feature of karst aquifers is the extreme heterogeneous and anisotropic permeability. Karstic caves, large fractures and fissures alternate with very dense parts of the bedrock matrix (cf. Fig. 1). Thus, both porosity and connected pore space affect not only the water residence time and local geochemical conditions that in turn impact microbial life, but also the vertical and lateral transport of living organisms (Lehmann and Totsche, 2020). Only a fraction of surface derived microbes can thrive or temporarily persist under the oligotrophic conditions in groundwater; the rest will die, with their necromass being recycled, contributing to the DOM pool, or washed out of the aquifer via karst springs.

Microbial communities in karstic aquifers can show high variability even on a local scale. For example, groundwater microbial communities in a multi-storey fractured aquifer system differed substantially even along a 6 km hillslope monitoring transect (Yan et al., 2020). Groundwater collected from surface-near wells is dominated by rare species (here defined as bacterial taxa with a relative abundance of less than 0.01% of the total community), whereas bacteria of the core microbiome (here defined as bacterial taxa present in 80% of the samples collected in the same well over time) increase in downstream direction suggesting increasing environmental selection stress. Local hydrochemical characteristics explain most of the microbial community variation which reflects the importance of local heterogeneity (Yan et al., 2020). The most abundant groups in oligotrophic karstic aquifers are *Cand.* Patescibacteria, *Proteobacteria*, followed by *Nitrospirae*. While *Cand.* Patescibacteria have a fermentative lifestyle (Castelle et al., 2018), many members of the *Proteobacteria* and *Nitrospirae* present in groundwater are shown to be able to assimilate CO_2 with energy derived from reduced sulfur or nitrogen compounds (Wegner et al., 2019). Carbon fixation rates in carbonate aquifers can even reach 10% of the median rates reported in oligotrophic marine surface waters (Overholt et al., 2021).

Similar to shallow karst aquifers, *Cand*. Patescibacteria, *Proteobacteria* and *Nitrospirae* bacteria were also shown to be abundant taxonomic groups in alpine karst systems (Farnleitner et al., 2005; Pronk et al., 2009; Savio et al., 2019). While detailed studies on the assembly mechanisms and origin of the microbes in mountainous karst aquifers are still missing (Savio et al., 2018, 2019), sediments from alpine karst aquifers appear to show a high potential for processes contributing to the self-purification processes in the water. Heterotrophic production rates in the sediments can be significantly higher when compared to the suspended, planktonic fraction (Wilhartitz et al., 2009), and sediment- or surface-associated bacteria might serve as a reservoir contributing cells to the suspended microbial community fraction (Farnleitner et al., 2005; Savio et al., 2018, 2019).

The vast heterogeneity of karst landscapes both on regional and local scale makes it very difficult to propose a universally valid classification system allowing for direct comparisons of karst aquifers. Different systems for mapping the vulnerability of a karst aquifer and its catchment have already been introduced above. As natural spring outlets can generally be viewed as the sum of (suspended) information from an entire aquifer, Stevanović (2015) proposed a classification system of karst springs based on their discharge regime (i.e., 'stable', 'variable' and 'extremely variable'), while Sinreich et al. (2014) proposed a microbiological classification system to characterize karst aquifers in respect to their spring dynamics and vulnerability to fecal pollution. Yet, further studies are urgently needed to gain a deeper understanding on the dynamics and the role of the karstic groundwater microbiomes, which will also enable us to utilize them for water quality indication. In this regard, the recently emerging high-throughput DNA sequencing methods combined with bioinformatics already have, and further will prove as powerful tools to shed light on the highly complex microbiology of karst aquifers.

Fecal pollution in karst water resources and implications for human health

Since more than 100 years, fecal pollution in water is commonly monitored by the detection of so-called 'fecal indicator organisms'. Considering that many commonly applied fecal indicator organisms are bacteria, the term 'standard fecal indicator bacteria' (SFIB) is widely and often synonymously used. This concept aims to detect bacteria (or other microorganisms) that inhabit the digestive system of animals and humans in high abundance. These organisms themselves are not necessarily pathogenic or harmful to human health, but simply *indicate* the presence of fecal pollution influence—and as a logic consequence the eventual presence of fecal-borne *pathogens*—when detected in water. Most widely used indicator organisms today are intestinal bacteria or viruses (often bacteriophages that infect intestinal bacteria). Examples for routinely used bacterial fecal indicators are *Escherichia coli* bacteria or intestinal enterococci (Derx et al., 2022, in press).

Regarding the question of generally observable levels of fecal pollution in freshwater resources, Kavka et al. (2006) proposed a classification system based on SFIB concentration ranges in order to classify surface waters according to their fecal pollution load. In this system, the authors define five classes of fecal pollution, ranging from *little* to *excessive* pollution (cf. Table 2).

Regarding fecal pollution in karst aquifers, a large number of studies has been published that report typically observable SFIB concentrations in karst aquifers with distinct geological and climatic settings (Table 3). While one might intuitively expect rather low (fecal) pollution levels in groundwaters, Table 3 clearly illustrates that karst aquifers globally show an extremely wide range of fecal pollution levels as indicated by SFIB concentrations. These even reach levels usually only detected in highly polluted surface waters, although streams, rivers or lakes in many aspects are not directly comparable with karst aquifers. In regard to their vulnerability to fecal pollution, however, parallels can indeed be drawn. Due to the high porosity of many karst formations, the therewith associated direct connectivity to surface habitats, and in response to precipitation events occasionally low water retention times, fecal material can be rapidly flushed into and through karst aquifers (cf. Fig. 1). The infiltration and retention time of (polluted) surface-water mainly depends on the particular geological settings, the degree of weathering, and most importantly the

Table 2 System for the classification of surface waters in regard to their level of fecal pollution according to Kavka et al. (2006); CFU, colony forming unit.

Classification of fecal pollution						
Pollution class		*I*	*II*	*III*	*IV*	*V*
Fecal pollution level		*Little*	*Moderate*	*Critical*	*Strong*	*Excessive*
Microbiological indicator/parameter [CFU/100 mL]	*E. coli*/fecal coliforms	<100	>100–1000	>1000–10,000	>10,000–100,000	>100,000
	Intestinal enterococci	≤40	>40–400	>400–4000	>4000–40,000	>40,000
	Total coliforms	≤500	>500–10,000	>10,000–100,000	>100,000–1,000,000	>1,000,000

prevailing discharge conditions as a result of precipitation events (cf. Section "Hydrogeology and catchment characteristics of karst aquifers" of this chapter). The lower the water retention time of infiltrated surface water, the higher is the chance for pathogenic microorganisms to reach the groundwater aquifer unharmed and to pose a risk to human health (Allocca et al., 2018; Borchardt et al., 2011; Bucci et al., 2015, 2017; Murphy et al., 2015; Stadler and Skritek, 2003).

Sources and pathways of fecal pollution

In developing countries, the lack or absence of proper sanitation and regionally widespread practice of open defecation still today represents a major source of fecal pollution of groundwaters (GWPP, 2019; UN News, 2019; World Health Organization, 2019b). But also in middle- and high-income countries, fecal pollution originating from human sources represents the main cause in a majority of outbreaks of acute gastrointestinal disease (GID) (Wallender et al., 2014). There, the contaminations typically originate from poorly maintained sewer infrastructure (e.g., septic tanks) or from diffuse or direct discharge of sewage or treated effluent waters from wastewater treatment plants (WWTPs) into rivers (Fig. 1) (Boehm et al., 2018; Holcomb and Stewart, 2020; Kirschner et al., 2009, 2017). When compared to raw sewage, the treated effluent water from WWTPs typically contains significantly lower, but still relatively high loads of fecal associated microbes (Mayer et al., 2016, 2018). In addition to anthropogenic sources—including pollution from livestock farming—also wildlife animals represent a considerable reservoir for human relevant (i.e., zoonotic) pathogenic microorganisms which regularly caused outbreaks of GID in the past and therefore must not be neglected (Wallender et al., 2014).

In conclusion, fecal pollution levels in karst aquifers as indicated by SFIB concentrations can show an extremely wide range, from non-detectable to few colony-forming units (CFU) of *E. coli* per 100 mL in protected or little polluted karst aquifers, to concentrations reaching 10,000 and more *E. coli* CFU per 100 mL in highly dynamic and vulnerable aquifers (cf. Table 3). The main factors determining the extent of fecal pollution are the hydrogeological background of the aquifer, the prevailing or foregoing weather situations and the available sources of fecal pollution in the catchment (cf. Sections "Suggested framework for integrated fecal pollution and health risk analysis" and "Microbial water quality management options for karst water resources" of this chapter and Fig. 1).

Potential infection risks from improperly managed drinking water supplies

The detection of fecal pollution in water based on the enumeration of SFIB is a strong and important indication for the potential presence of fecal-borne pathogens. However, the association between the presence of fecal pollution, the occurrence of infectious pathogens, and an actual risk to human health from the exposure to water depends on many different and case-specific factors (Derx et al., 2022, in press). To gain a general understanding on the specific health-related impact from fecal pollution of karstic drinking water resources, valuable information can be retrieved from epidemiological studies (compare also with site specific QMRA, section "Suggested framework for integrated fecal pollution and health risk analysis"). Although a literature search on available epidemiological studies on acute gastrointestinal disease (GID) outbreaks caused by contaminated karstic drinking water resources revealed only a limited and geographically non-representative number of studies, these clearly highlight the potentially high health risks arising from fecal pollution of these water resources when used for water supply despite improper management, treatment or disinfection.

For the period between 1990 and 2020, we analyzed eight major peer-reviewed epidemiological studies from Europe and North America that reported outbreaks of GID caused by contaminated drinking water from karst aquifers (Table 4).

In these studies, the main GID causing pathogen were human noroviruses, *E. coli* strain O157:H7, *Campylobacter* spp., *Shigella sonnei* and *Salmonella* spp. (Table 4). A leaking septic tank was the only source of pollution in the study on a restaurant-connected outbreak by Borchardt et al. (2011), and one of several suspected sources in a multifactorial outbreak on a highly frequented island in Ohio as reported by O'Reilly et al. (2007). In three of the studies, heavy precipitation or flooding preceding the fecal contamination of the groundwater resources was the suspected trigger of ground and drinking water contamination (Bruce-Grey-Owen Sound Health Unit, 2000; Lawson et al., 1991; O'Reilly et al., 2007). The comprehensive study by Beaudeau et al. (2008) by itself reports four independent GID outbreaks with connection to drinking water abstraction from karst water resources in France in the period between 1998 and 2006. There, the contaminations occurred each two times at the water resource, and two

Table 4 Overview on the selected epidemiological studies reporting acute gastrointestinal disease (GID) outbreaks as a result of fecal contamination of non-properly managed drinking water supplies from karst aquifers.

Outbreak region	*Outbreak date*	*Reported cases*	*Karst system description*	*(likely) causative OR detected pathogens*	*Site of contamination*	*(likely) contamination source and details*	*Level(s) of treatment*	*Study design*	*References*
Podgorica, Montenegro, Europe	August 2008	1699 reported, 10,000–15,000 estimated	limestone and limno-glacial sediments	detected: Norovirus, Rotavirus, Adenovirus	distribution network	ingress of fecally contaminated water or raw sewage into the drinking water distribution system	chlorination	Case-control	Werber et al. (2009)
Wisconsin, United States	June 2007	229	fractured dolomite	detected: Norovirus	septic system	inflow of sewage into aquifer as a result of a septic tank leak	no treatment; after outbreak: filters + UV irradiation	Case-control	Borchardt et al. (2011)
Upper Austria, Austria, Europe	August 2006	160	limestone	unknown	water resource	introduction of fecal bacteria after heavy rainfalls	no treatment; after outbreak: UV irradiation	Case report	Meusburger et al. (2007)
Miskolc, Hungary, Europe	June 2006	3673	limestone	detected: *Campylobacter* spp., Norovirus, Adenovirus, Cryptosporidium, *Giardia* sp.	water resource	multiple potential sources: illegal communal waste dumps, pit latrines, liquefied manure treatment facilities, treated wastewater	marginal chlorination following increased precipitation	Case study	Dura et al. (2010)
Ohio, United States	August 2004	1450	fractured limestone	detected*: E. coli*, *C. Jejuni*, Norovirus, Salmonella and Giardia species	water resource	application of septage and/or illegal sewage deposition and infiltration into groundwater via a sinkhole	municipal water treatment facility; after outbreak: chlorination + UV irradiation	Case-control	O'Reilly et al. (2007)
Vesoul, France, Europe	September 2003	200	borehole in karst + alluvial aquifer (no geological information)	*Cryptosporidium* sp. + *Campylobacter jejuni*	distribution network	cross-connection with industrial network containing contaminated river water + backflow	filtration + disinfection (chlorine dioxide)	Descriptive + case study	Beaudeau et al. (2008)
Divonne-les-Bains, France, Europe	August 2003	1040	karstic springs + borehole in urban area (no geological information)	*Cryptosporidium parvum* and *hominis*	distribution network	cross-connection with WWTP effluent network + backflow	filtration + disinfection (chlorine)	Descriptive study	Beaudeau et al. (2008)
Gourdon, France, Europe	August 2000	2600	borehole in karst (no geological information)	Rotavirus + *Campylobacter coli*	water resource	polluted river water entering the karstic aquifer + chlorination failure	disinfection (chlorine)	descriptive + retrospective cohort	Beaudeau et al. (2008)
Walkerton, Ontario, Canada	May 2000	1346 reported, >2300 estimated	limestone	*E. coli* O157:H7 + *Campylobacter* spp. (detected in the environment)	water resource	well contamination by surface water after heavy rain and water treatment system failure	water treatment system (not further specified)	case-control	Bruce-Grey-Owen Sound Health Unit (2000)
Se` te, France, Europe	September 1998	>150 children	karstic spring (no geological information)	*Cryptosporidium* sp.	water resource	surface runoff water backflowing into a karstic outlet	disinfection (chlorine dioxide)	descriptive + case study	Beaudeau et al. (2008)
Le Neuville, Switzerland, Europe	August 1998	1607	limestone	detected: *C. jejuni*, *Shigella sonnei*, Norovirus	septic system	pump failure resulting in sewage spill into the groundwater	natural filtration with injection of pure oxygen into the groundwater	retrospective cohort	Maurer and Stürchler (2000)
Arizona, United States	April 1989	110	limestone	detected: Norovirus, *E. coli*, fecal Strepto- and Enterococci	water resource + treatment plant	failure of automatic chlorinator in waste water treatment plant and fully saturated leach fields	chlorination	retrospective cohort	Lawson et al. (1991)

times in the drinking water distribution network (Beaudeau et al., 2008). Another comprehensive study by Wallender et al. (2014) investigated the contributing factors to disease outbreaks that were associated with untreated groundwater (not only karst groundwaters) used for drinking water supply in the United States between 1971 and 2008. These authors report that heavy rainfall or flooding accounted for 21%, rapid pathogen transport through hydrogeologic formations such as karst limestone for 26%, and improper design, maintenance or location of the water source nearby wastewater disposal systems such as septic tanks for 67% of the investigated 248 outbreaks (Wallender et al., 2014). The latter also applied to three of the here presented studies for which the GID outbreaks were associated with mechanical failures at drinking or wastewater treatment plants or in the water distribution network (Lawson et al., 1991; Maurer and Stürchler, 2000; Werber et al., 2009).

Summing up these studies from Europe and North America, there is clear evidence that fecal pollution of karst water resources can have severe impact on public health. Inexistent or ineffective treatment of water may allow pathogenic microorganisms to be transported from the well or spring to the tap, and as a final consequence to cause disease. That contaminated karstic groundwaters may have significant health impacts also in high-income countries highlights the need for an adequate health-risk management including monitoring, protection and treatment (disinfection) of these often highly vulnerable drinking water resources.

From other regions of the world, epidemiological data on acute GID outbreaks resulting from contamination of karstic drinking water resources are limited. This is very unfortunate considering the different societal and behavioral practices in different regions of the world. In particular, in developing, low-income countries, diffuse fecal pollution can be expected to play a much more important role than in Europe or North America. According to estimates by UNICEF from 2015, 13% of the world's population at that time still practiced open defecation, and further 10% had only access to unimproved toilet facilities (Griffiths, 2017, World Health Organization and United Nations Children's Fund (UNICEF), 2017). Numbers from 2004 estimated that globally, 2 billion people did not have access to basic sanitation facilities (Prüss-Üstün et al., 2006).

Water transmissible intestinal pathogens on a global scale

Taking a global perspective, bacterial pathogens such as *Salmonella, Shigella,* pathogenic *E. coli* and *Campylobacter* cause much of the burden of water transmissible diseases (Griffiths, 2017). Further diseases with high impact are infectious hepatitis, norovirus infection, amebiasis, leptospirosis, poliomyelitis, other enteroviruses infections, schistosomiasis, giardiasis, and cryptosporidiosis (Griffiths, 2017; Neil et al., 2018). While deaths from acute, watery diarrhea (such as cholera and rotavirus diarrhea) have declined over the years, increasing attention is paid to the development of antibiotic resistance in many bacterial pathogens that cause dysentery (i.e., bloody diarrhea, often caused by *Shigella*) as well as to emerging pathogens (Griffiths, 2017). Anthroponotic and zoonotic contamination sources have to be considered and are of potential importance (GWPP, 2019; Stalder et al., 2011).

Suggested framework for integrated fecal pollution and health risk analysis

Despite its high relevance for water supply and public health, microbial fecal pollution of fractured groundwater aquifers still today is often considered a "black box" problem. The lack of detailed knowledge on the sources and transport characteristics of fecal pollution hinders a target-oriented and sustainable water quality and safety management. To promote the pro-active and sustainable water quality management of drinking water resources, a new strategy for advanced fecal pollution analysis was recently proposed based on research activities at alpine karst aquifer springs in the Northern Calcareous Alps (NCA) in Austria (Farnleitner et al., 2018). The framework is based on three interacting levels ("3-step approach") that are addressed by the following questions and define the backbone of the concept (cf. Fig. 3): (1) is there a problem with fecal pollution? (2) if yes, what is the pollution source? and (3) what is the actual health risk associated with the fecal source(s) that contribute to the observed pollution? The defined framework can also be viewed as a "bottom-up" approach as one usually starts with the most general analysis (i.e., determination of bulk fecal pollution levels, comprising all potential sources of fecal sources: wildlife, life stock, human, others) and getting more specific towards the top of the approach (cf. Fig. 3). Although suggested for alpine areas, the conceptional approach is also thought to be useful for other types of karstic and fractured groundwater aquifers in order to guide fecal pollution analysis and management. The concept will be briefly outlined in the following steps 1–3.

STEP 1: Detection and monitoring of general microbial fecal pollution

Detection of general microbial fecal pollution can be realized by cultivation-based standardized enumeration methods (Derx et al., same issue, Farnleitner et al., 2010). To achieve robust enumeration, a sound sampling design (e.g., sampling volumes, spatial and temporal resolution) as well as an appropriate selection of fecal indicators (e.g., *E.coli*, intestinal enterococci, *Clostridium perfringens* (spores), somatic coliphages) is essential. In this context, there is an increasing trend towards the combined application of bacterial and viral indicators (bacteriophages) for general fecal pollution. Moreover, to assess the vulnerability of an aquifer to fecal pollution, it is essential to gather knowledge on its hydrological (e.g., discharge dynamics, seasonality) and the pollution dynamics in the catchment (i.e., variability and importance of sources; Reischer et al., 2008, 2011). Time-series analysis during strong thunderstorm events in periods of high levels of fecal pollution in the catchment (e.g., times with maximum numbers of pasturing animals or tourists) can give a good conservative estimate on the overall potential of fecal pollution (Stadler and Skritek, 2003). Information on the aquifer hydrogeology and the microbial ecology of the ground or spring water (e.g., abundance and dynamics of

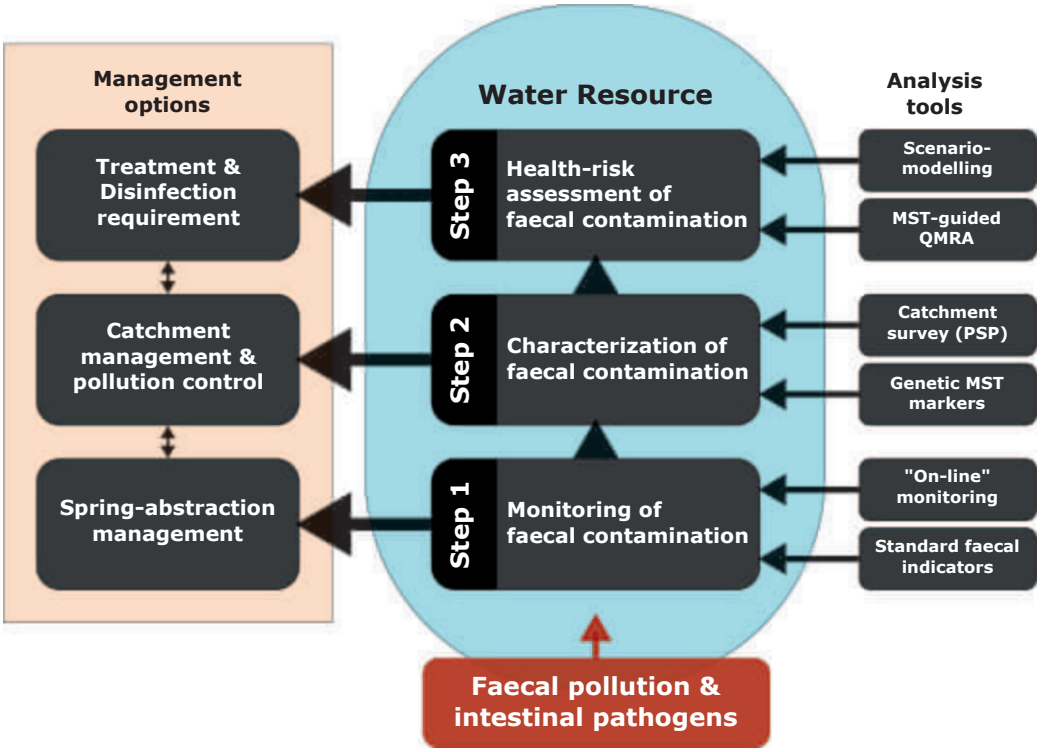

Fig. 3 Overview figure on the proposed "*framework for integrated fecal pollution analysis and management*" to guide sustainable spring water quality management in accordance with World Health Organization criteria as previously suggested by Farnleitner et al. (2018). The three interacting levels ("three-step approach") include (1) the monitoring of fecal pollution levels, (2) the characterization and identification of potential sources of fecal pollution in the catchment, and (3) the assessment of the actual health risk from human exposure to fecal contamination (consumption); MST, microbial source tracking; QMRA, quantitative microbial-risk assessment; PSP, pollution source profiling.

total cell counts, cf. Section "Microbial ecology and biogeochemistry of karst aquifers" and Table 1) are complementing the vulnerability characterization.

For karst water resources with strong fluctuations in fecal pollution levels, it can be very helpful to establish (on-line) automated near-real time measurements to characterize pollution dynamics with sufficient temporal resolution. In this regard, different technical solutions are available. The optimal choice of the respective on-line and/or automatization methodologies thereby depends on the specific question(s) to be answered, and the type and catchment characteristics of the karst aquifer of interest. In general, indications on fecal contamination can be generated either directly or indirectly via proxy parameters. For example, chemo-physical on-line probing to measure discharge, turbidity and spectral absorption coefficient at 254 nm (SAC 254) can be very helpful to generate near-real time information on surface influence and surface water infiltration into the aquifer (Pronk et al., 2007; Stadler et al., 2010). In this context, also on-line flow cytometry was successfully applied by detecting total cell count dynamics (Besmer et al., 2014, 2017). Depending on the aquifer and the specific catchment and pollution characteristics, associations between surface influence and fecal pollution can be observed at least for some periods of time (Stadler and Skritek, 2003). Direct indications on fecal pollution can be obtained either by automatization of standardized approaches for fecal pollution detection (Tryland et al., 2015), or by biochemical/microbiological on-line proxies such as enzymatic glucuronidase activity (Demeter et al., 2020; Ryzinska-Paier et al., 2014). Online and automated fecal pollution detection is a very young discipline, and many activities are currently ongoing to develop reliable and robust solutions for the future (Demeter et al., 2020).

STEP 2: Characterization and source identification of fecal pollution

Cultivation-based enumeration of general fecal indicators such as *E. coli* or somatic coliphages by standardized methods (cf. STEP 1) does not give information on the sources of fecal pollution since these organisms occur in the intestinal tracts of both humans and animals. In contrast, the targeted detection of host-associated or host-specific fecal indicators can give direct information on the sources responsible for fecal pollution, which is the central question of the discipline of *Microbial Source Tracking* (MST). MST indicators can also be combined with information from general fecal indicators to elucidate their origin. First applications of host-associated genetic MST-markers in the NCA catchments could proof that ruminants were the predominant source of fecal pollution in these spring water resources (Reischer et al., 2006, 2008, 2011). Strong statistical associations between general fecal indicators (*E. coli* and intestinal enterococci) and the abundance of ruminant-associated MST markers could be observed especially during periods of increased surface run-off (Reischer et al., 2008, 2011).

Since then, MST technology has also been successfully applied to other karstic water resources. For example, studies available from Midwestern United States and Israel investigated fecal pollution sources in lowland karst aquifers (Ohad et al., 2015; Zhang et al., 2014). The study from Israel reported different MST profiles for three lowland karst springs although these are located in close proximity to each other (Ohad et al., 2015). The study from the US covered a total of 40 springs and wells in four US states (IL, WI, KY and MO) and distinguished between fecal pollution of human, bovine and swine origin (Zhang et al., 2014).

Before applying MST to spring water resources, it is recommended to start with a catchment survey to compile a catchment pollution source profile (PSP, i.e., quantitative estimation of fecal pollution sources). For example, a PSP performed for a certain sub-catchment in der NCA area (Reischer et al., 2011) revealed that wildlife (42.4%) and livestock ruminants (57.6%) together accounted for as much as 99.9% of the total daily *E. coli* cell production in this catchment. Although such a PSP only indicates the daily produced amount of fecal contamination equivalents in the catchment (i.e., the fecal contamination potential) and does not provide information about the quantitative contribution of the respective source to the actual spring water contamination (i.e., the actual transport of fecal sources to the groundwater) a PSP can guide the hypothesis formulation on the relevance of different pollution sources for spring water contamination (Reischer et al., 2011). On that basis, appropriate MST indicators/markers can then be selected and applied to the catchment and spring of interest to evaluate the hypothesis (Linke et al., 2019).

STEP 3: Infection and health risk assessment of microbial fecal pollution

The assessment of the infection or health risk associated with the use of a respective karstic water resource for drinking water abstraction represents the last step of the suggested approach. The drinking water resource can be considered safe or unsafe if the estimated infection risk is below or above the suggested health-based drinking water quality target. Health-based drinking water quality targets (DWQT) are recommended by the World Health Organization (2017) and set to very low levels to ensure a high level of public safety.

The estimation of infection or health risks for individual drinking water resources is suggested by the statistical-mathematical method of quantitative microbial risk assessment (QMRA). On the contrary, epidemiological studies can only be recommended to estimate infection risks (as reported in the previous section) when either the health burden is expected to be considerably high, or the studied populations are very large (World Health Organization, 2017). The principal of QMRA, including the important steps of pathogen exposure assessment and dose-response modelling is described in detail in Derx et al., 2022, in press. QMRA relies on the appropriate choice and quantification of reference pathogens (RP). Commonly used RP include representative pathogens from enteric bacteria, enteric parasites and human enteric viruses. The suggested "bottom-up" approach (Fig. 3) uses information from STEP 2 to guide the selection of appropriate RP for STEP 3 by integrating results from PSP and MST. For example, this approach guided researchers to focus on zoonotic pathogens in the NCA systems where the quantitative occurrence of *Cryptosporidium* sp. and *Giardia* sp. was studied directly in the fecal pollution sources collected in the catchment as well as in the spring water during high-discharge events (Farnleitner et al., 2018). QMRA is currently the least developed part of the suggested 3-step approach for karstic systems (Savio et al., 2018). Practical modelling approaches linking hydrology, microbiology and infection and disease risks—as previously developed for other systems (Demeter et al., 2021; Derx et al., 2021; Schijven et al., 2015)—are increasingly needed. Such simulation tools will not only describe the status quo, but will also allow the evaluation of future scenarios in regard to global change phenomena and challenges.

Microbial water quality management options for karst water resources

Depending on the catchment, the karstic aquifer characteristics, the type of water abstraction system and treatment method, as well as other potentially influencing background conditions, an appropriate and situation-specific set of management measures is required to guarantee a safe and practicable drinking water supply (WHO Regional Office for Europe, 2019; World Health Organization, 2017). Possible management options include spring abstraction management (i.e., spring water abstraction for drinking water production only when raw water quality is appropriate), catchment protection and pollution control (e.g., installation of proper sewage disposal measures), and sufficient treatment and/or disinfection of raw water. In this respect, the suggested framework for microbial fecal pollution analysis and management provides a conceptual basis to select optimal management solutions that are in accordance with the health-based water quality safety criteria at each level of the analysis (Fig. 3) (Farnleitner et al., 2018). The framework also highlights that target-oriented catchment protection and optimized spring water abstraction management helps to minimize the required treatment and disinfection efforts and to keep the final drinking water close to natural conditions for a safe and high-quality drinking water supply. Spring abstraction management can also reduce the input of nutrients and copiotrophic microbes, likely improving the biostability of the water during treatment and distribution. Nevertheless, spring abstraction management requires advanced management efforts, and thus might only be implementable for larger community supplies. However, according to WHO philosophy, highest possible efforts should be put into the protection of the catchment and pollution control, including human and animal fecal contamination sources. In most cases—and especially when direct influence from the surface to the groundwater (such as during rain fall events) is possible—adequate basic disinfection remains an essential requirement to produce safe drinking water and to allow proper infection control for karst spring water. Basic disinfection can be realized by UV-irradiation (Hijnen et al., 2006; Sommer et al., 2008). For a detailed description of water

treatment and disinfection options, the reader is referred to specialized literature (LeChevallier et al., 2004). Finally, it is important to emphasize that the legal requirements in context of the respective national regulations for a safe drinking water supply have to be met. In this context, WHO gives recommendations which are translated into the national legislation by the respective governments.

Conclusion

Karstic drinking water resources can be highly vulnerable to fecal pollution, and in turn pose a direct risk to human health when used for (public) water supply and not properly managed. As shown based on standardized fecal indicator enumeration by a large number of studies, karst aquifers around the world show a wide range of fecal pollution. Available epidemiological studies—mostly conducted in North America and Europa—highlight the high potential of insufficiently protected or treated water from karstic or fractured groundwater aquifers to cause outbreaks of waterborne diseases. The fact that waterborne infections, and gastrointestinal disease in particular, cause a disproportionally higher burden in low- and middle-income countries highlights the existing need for appropriate strategies to provide safe drinking water from these water resources. Several possibilities regarding microbial diagnostics and health risk assessment—including the detection of fecal pollution, pollution source profiling, microbial source tracking (MST), quantitative microbial (infection) risk assessment (QMRA) as well as water quality management methods (e.g., catchment protection, abstraction management, treatment and disinfection)—exist. Depending on the given situation (low vs. high income country, large vs. small supply systems, urban vs. rural impacted catchments, hydrogeology, etc.), the right measures have to be selected in order to guarantee for a safe drinking water supply according to WHO criteria. If fecal contamination cannot be ruled out, adequate basic disinfection constitutes an essential requirement.

Knowledge gaps

- How will expected future changes in climatic conditions and water availability affect microbial water quality of karst water resources both on local and global scale?
- What are the emerging pathogens of potential future concern in karst water resources both on local and global scale?
- What are the epidemiological consequences and societal costs of (diffuse) fecal pollution of karstic drinking water resources worldwide?
- Can high-throughput DNA-sequencing and bioinformatics help us to identify indicator microbes for the future assessment of the vulnerability of karstic groundwater resources?

Glossary

Aquifer An aquifer is an underground layer of permeable materials (gravel, sand or silt) or rock that can contain or transmit groundwater.

Dose response model In the QMRA framework, dose response models are mathematical functions that describe the relationship between the risk of infection, illness or death (response) given a known dose of a pathogen for specific pathogens, transmission routes, and hosts (dose) (QMRA Wiki).

Epifluorescence microscopy (EFM) A specialized type of optical microscopy that uses fluorescence and allows to detect fluorescently labeled cells or objects.

Fecal indicator A group of microorganisms that indicates the presence of fecal contamination such as *E. coli*. They indicate that pathogens may be present.

First-order decay A decrease in quantity at a rate proportional to the current value. First-order microbial decay rates depend on the microbial concentration and follow exponential decay (www.wikipedia.org).

Flow cytometry (FCM) A method that allows gathering statistical data on individual cell populations from a heterogenous cell sample by optically analyzing single cells that have been separated prior to analysis.

Fluorescence-activated cell sorting (FACS) A special type of flow cytometry allowing the analysis and physical separation, sorting and isolation of subpopulations of a heterogeneous cell sample. To do so, cells have to be stained with fluorescence dyes prior to analysis and sorting.

Groundwater protection zones Zones around the drinking water abstraction sites in which any type of pollution must be prevented and land use is not permitted. In these zones, groundwater sources are at a certain level of risk from contamination. The closer the contamination source, the greater is the risk (Environment Agency, 2021).

High-throughput DNA-sequencing (HTS) DNA sequencing technologies that are capable of processing massive amounts of DNA sequences in parallel, enabling researchers to decipher full genomes or to resolve the composition of complex microbiomes. HTS methods are often synonymously referred to as "Next-generation sequencing."
Microbiome The microbiome is the sum of microbes and their genomic elements in a particular environment.
Natural isotopes Differing ratios of the oxygen and hydrogen isotopes exist that constitute the water molecule. Isotopes such as deuterium, tritium or $_{18}O$ are hydrogen or oxygen atoms that have a different number of neutrons in their nuclei. The water molecules carry distinct fingerprints based on differing proportions of the hydrogen and oxygen isotopes.
Quantitative Microbial Risk Assessment (QMRA) A tool for estimating human health risks from exposure to pathogens via any route such as food, water, air, and the environment.
Surrogate A particle or solute that serves as a substitute for pathogens for studying pathogen treatment and transport characteristics, experimental tracer tests, analytical and numerical transport models and QMRA.

The WHO approach for safe drinking water in the 21st century

To achieve safety of drinking-water, the World Health Organization (WHO) recommend a risk assessment and risk management approach called water safety plan (WSP) (Davison et al., 2005). This approach includes all steps in a water supply from catchment to tap and includes water resource protection (Fig. 1). To implement such a plan is an interdisciplinary challenge, requiring the expertise from many different fields. The national strategies for protecting drinking water serve as input to the WSP. In many countries, groundwater protection in the vicinity of drinking water wells are based on a water travel time of 50–60 days from the borders of the protection zones. These travel times were historically adopted based on die-off rates of *E.coli* (Knorr, 1937). The parameter *E.coli* is an important representative of the standard fecal indicator bacteria (SFIB) used in water regulations worldwide e.g. (EU, 2020). Many pathogens, especially viral and protozoan representatives, can survive considerably longer than bacteria. However, information about their quantitative occurrence in water resources is very limited. Alternative water quality indicators and methods to estimate the pathogen transport and required treatment have therefore been proposed for a long time (Gyllenberg et al., 1960). The conceptual framework for implementing the WHO guidelines for safe drinking water include health-based targets, the WSP, and a system of independent surveillance that verifies the proper operation (WHO, 2017). The health-based targets can be defined either as maximum tolerable infection risk (maximum number of infections per person and year) or as maximum tolerable illness risks which are often expressed as disability adjusted life years (DALYs). Models and planning tools are needed for quantifying the potential sources and transport pathways of fecal-borne pathogens and the pathogen treatment reduction by soil

Fig. 1 Microbial fate and transport processes in a risk assessment for water supply according to water safety plans (WSP) (Davison et al., 2005).

passage and subsequent disinfection steps. Such tools can be also useful for investigating the impact of future changes such as in climate or wastewater management and thus support the sustainable water safety management (Demeter et al., 2021; Okaali et al., 2021). Climate change, together with population growth, increasing urbanization and increased water demand, is expected to present an additional burden to water supply. Increasing insight into impacts of global change phenomena and required adaptation initiated some shift towards global and climate resilient water safety planning (WHO, 2017).

How do microbial pathogens move through groundwater?

When microbial pathogens enter subsurface environments from land discharges of human and animal fecal matter, how do they move through the underground water systems called aquifers? Pathogens are bio-colloids ranging in size from nanometers to micrometers. Once pathogens enter aquifers, they can be transported with the groundwater through pores in the aquifer media that are larger than them and they disperse towards low concentration areas, they can attach to the surfaces of the aquifer matrix, to the air-water interface, or they can be strained out by pores that are smaller than them. Some immobilized pathogens can remobilize if the water flow or its chemistry changes. Pathogens become inactivated and non-infectious over time.

Depending on the degree of aquifer heterogeneity and the rates of attachment and detachment processes, the average speed of pathogen transport in groundwater can be faster or slower than that of non-reactive solutes which do not adsorb or desorb (Sen, 2011; Ginn et al., 2002). In heterogeneous aquifers, pathogens tend to move through larger pores and cracks where water moves more quickly, because they are excluded from small pores where water moves relatively slowly. Thus, if their attachment rate is slow or their detachment rate is fast, the average speed of pathogen transport in heterogeneous aquifer media with large pores, for example, alluvial gravel, karst and fractured rock aquifers, can be faster than that of non-reactive solutes (Schijven et al., 2017; Sen, 2011; Ginn et al., 2002). Such aquifers are therefore particularly vulnerable to contamination such as from fecal-borne pathogens (Savio et al., 2021). Conversely, the average speed of pathogen transport in groundwater can be slower than that of non-reactive solutes in uniform fine-grained aquifers, such as coastal and river sand, or if the pathogens are very strongly attached to the aquifer matrix.

In summary, the attachment and detachment to and from soil particles, straining, detachment, and inactivation are the most important transport mechanisms of colloids on top of the convection and dispersion (Sen, 2011; Ginn et al., 2002). The degree of pathogen attenuation and transport in groundwater is largely determined by the properties of the aquifer media and pathogens, groundwater chemistry (such as redox conditions, cf. Section "Modelling pathogen transport in surface water and groundwater") and flow conditions. Pathogen transport and survival in groundwater are favored by coarse-grained heterogeneous porous media with preferential flow paths, highly negatively charged and hydrophilic pathogens, high flow velocities, high pH values, low ionic strengths, high dissolved organic carbon levels, low dissolved oxygen levels and low groundwater temperatures (Schijven et al., 2017; Sen, 2011; Ginn et al., 2002). These environmental factors enhance pathogen transport by increasing the quantities of pathogens travelling through and/or by releasing pathogens previously retained by the aquifer media.

Pathogens can associate with other colloids (such as clays, metal oxides and organic matter) in effluent and environmental waters, and, thus, they can hitch rides on other colloids when they travel through aquifers. Colloids play a dual role in pathogen transport. Mobile colloids that travel through large pores and cracks increase the pathogen transport velocity and facilitate the transport of colloid-bound pathogens. Conversely, immobile colloids with pathogens bound to them reduce the quantities of pathogens travelling through the aquifer (Sen, 2011; Ginn et al., 2002). Which of these two processes dominate depends on the number of large pores available for the transport of colloids and colloid-bound pathogens. Understanding how microbial pathogens move through groundwater and the dual role of colloids in transporting pathogens have important implications for risk analysis and remediating contaminated sites.

Observational methods in surface water and groundwater

Hydrological and physical-chemical parameters and monitoring design

The groundwater flow, and its recharge via precipitation or adjacent river water strongly control the microbial transport. It is therefore important to monitor the levels and the geochemical status of the groundwater and river water from a network of observation wells surrounding the area of interest. Loggers recording continuous datasets are immensely valuable in this respect, as the conditions commonly vary along rivers. Standard physical and chemical parameters include e.g. the temperature, pH, electric conductivity (EC), and oxygen content (Stuyfzand et al., 2006). The monitoring design is aligned to the type of drinking water abstraction site. Managed aquifer recharge systems, such as riverbank filtration, are among the most widely used treatment systems for drinking water production (Regnery et al., 2017). In case of riverbank filtration, the flow mechanisms are either driven by pumping or are periodically changing such as when the flow direction reverses during receding flood events (Derx et al., 2010). Suspended particles tend to infiltrate deep into the sediments of the gravelly river bed and riverbank. A clogging layer can drastically reduce the groundwater flow velocity and strongly enhance the removal of pathogens (Blaschke et al., 2003). It is therefore important to monitor the groundwater quantity and quality in wells that are situated within the first meters of soil passage from the river towards the well. Fig. 2 shows an example of such a well setup at the Danube riverbank, where piezometer pipes are installed underneath the river bed and in the riverbank.

Fig. 2 Groundwater piezometers located underneath the Danube river bed and bank in Vienna, Austria, to monitor the groundwater quantity and quality in wells that are situated within the first meters of soil passage from the river towards the well.

Microbiological characterization of surface water

Fecal indicators and genetic fecal markers

The concept of fecal indicators was developed over a hundred years ago and is still successfully applied worldwide and are an obligate part of guidelines and legislation (WHO, 2017; European Union, 2020). Required properties for a suitable fecal indicator are that it is universally present in large numbers in the feces of humans and animals, readily detected by simple methods, not able to proliferate in natural waters and soils as well as having a persistence in water and resistance to water treatment comparable to other waterborne pathogens. However, there is no one single fecal indicator which can serve as a surrogate for all different waterborne pathogens. Depending on the aim of the investigation, a set of indicators has to be selected. The most important fecal indicator organisms (FIO) used as microbiological parameters are described below. Standard detection methods for these indicators are based on cultivation, meaning that the organisms detected are capable of proliferation, which is the prerequisite of pathogens to be infective.

Escherichia coli (*E. coli*) and enterococci bacteria normally live in the intestines of humans and animals. Most *E. coli* are harmless and actually are an important part of a healthy human intestinal tract. However, some *E. coli* strains are pathogenic, meaning they can cause illness, either diarrhea or illness outside of the intestinal tract. *E. coli* and enterococci have proven sensitive and reliable general fecal indicators in alpine mountainous water resources (Farnleitner et al., 2010). *E. coli* is the most prominent member of the coliform bacteria group. In contrast, coliform bacteria cannot be seen as reliable indicator for fecal contamination, as they represent a very heterogeneous group, also including environmental species, which are even capable to proliferate in water (Stevens, 2003).

Clostridium perfringens has been successfully used to detect fecal pollution in the aquatic environment in various geographic areas (Fujioka and Shizumura, 1985). *C. perfringens* is able to form spores that allow prolonged detection of fecal contamination in the environment. In contrast, the fecal indicators *Escherichia coli* and enterococci are considered to be short-lived in aquatic systems and not representative for the behavior of the more resistant pathogens, including viruses and parasites. Monitoring of spores of *C. perfringens* has shown to be useful to assess the water quality during the stages of natural and technical water treatment. The spores can serve as surrogates for protozoan cysts and oocysts of *Giardia lamblia* and *Cryptosporidium* (Ryzinska-Paier et al., 2011; Vierheilig et al., 2013; Payment, 1991).

(Bacterio)phages are viruses that infect prokaryotic cells. Phages are more persistent and resistant than fecal bacteria and can serve as surrogates for human pathogenic viruses (Mesquita and Emelko, 2012). Coliphages (somatic and F-specific coliphages) are fecal viral indicators using *E. coli* as host (Jofre et al., 2016). A European study on surface bathing water quality revealed the high abundance of somatic coliphages and its usefulness as fecal viral indicator (Contreras-Coll et al., 2002). Regulatory authorities are therefore beginning to implement coliphages as parameter of water quality (European Union, 2020).

The enumeration of cultivation-based fecal indicator bacteria described above still represents the gold standard for the investigation of fecal pollution of water sources. However, due to their ubiquity in both human and animal fecal sources, source determination without further analysis is not possible (Farnleitner et al., 2010; Ishii and Sadowsky, 2008; Ahmed et al., 2015). Today, molecular techniques are available which enabled the development of methods for source identification (e.g. discrimination between human and non-human sources), referred to as Microbial Source Tracking (MST) (Hagedorn et al., 2011). Many of these approaches are library-independent DNA-based methods, most commonly targeting the 16S rRNA gene of highly abundant

host-associated intestinal bacteria (Hagedorn et al., 2011). These library-independent methods are opposed to library-dependent methods which require the development of a so-called catchment-specific library, i.e. a dataset of characteristics of the target microorganisms from relevant source hosts (Mott and Smith, 2011).

Detection of MST parameters usually involves enrichment of cells by filtration, followed by DNA extraction and finally detection of the specific DNA target sequences by (quantitative) polymerase chain reaction (PCR). Currently, a plethora of methods targeting fecal contamination of human and animal sources, including traditionally used fecal indicator bacteria, are available (e.g., Reischer et al., 2013; Bernhard and Field, 2000; Boehm et al., 2013; Wuertz et al., 2011; Roslev and Bukh, 2011; Harwood et al., 2017). Besides of methods targeting host-associated intestinal bacteria, also methods targeting viruses as MST tools become increasingly available (e.g., Rusiñol et al., 2014; Rusiñol et al., 2016; Ahmed et al., 2020; Farkas et al., 2020). Finally, also molecular methods targeting mitochondrial DNA of both humans and different animal species are emerging. These methods have the advantage of enabling the assignment of a contamination source with certainty since the mitochondrial DNA sequence is unique to a species (Schill and Mathes, 2008; Malla and Haramoto, 2020). However, there is contradictory information here if meat consumption, either by humans or predators, can cause carryover of mitochondrial DNA from the consumed meat source possibly resulting in false positive signals (Schill and Mathes, 2008; Malla and Haramoto, 2020).

The use of such molecular markers is a good complement to the use of traditional fecal indicators, especially when applied to surface waters and waste- or stormwater impacted areas where genetic marker concentrations are high and sample volumes of 200–500 mL are sufficient for reliable detection and quantification. By the application of such MST methods, for example, the dominance of human fecal impact in the River Danube could be proven (Kirschner et al., 2017). In ground water environments however, much lower concentrations of these genetic fecal markers are observed. Here, tracer tests can aid in estimating the fate and transport (cf. section "Natural and artificial pathogen surrogates to characterize transport in groundwater").

No matter to which water source they are applied to, it is necessary to properly evaluate the methods used. Most of these procedures have been developed and used in temperate latitudes. However, it could be shown that geographical differences in the composition of the gut flora of humans and animal groups exist (Reischer et al., 2013). A direct transfer of such procedures to other regions might therefore not always be straightforward and have to be evaluated (e.g. temperate zones versus tropics) (Reischer et al., 2013; Boehm et al., 2013; Odagiri et al., 2015; Mayer et al., 2018).

Pathogens

Fecal-borne pathogens are pathogens that are introduced into aquatic systems by animal or human point or non-point fecal pollution, e.g. by discharge of human sewage or washing in by rain events (GWPP, 2015), and transmitted by water to the human (or animal) target. Infectious fecal-borne pathogens include bacteria and viruses as well as protozoa and helminths (Leclerc et al., 2002; Ramírez-Castillo et al., 2015; Aw, 2018). Considering the large number of different fecal-borne pathogens known today, it is practically impossible to target all of them to assess the microbiological water quality and estimate risks. Unless there is no specific reason (e.g. epidemic occurring), pathogen detection is therefore focused to so-called reference pathogens. These are representative members of each of the microbial groups mentioned (Ashbolt, 2015; Stalder et al., 2011b). Ideally, a reference pathogen provides a conservative estimate of risk by representing a bad to worst-case combination of high occurrence, high concentration and long survival, low removal and/or inactivation during treatment, and high pathogenicity. Detection methods, preferably standardized cultivation-based or equivalent methods capable of testing for viability and infectiousness, must be further available (Health Canada, 2019). Reference pathogens include norovirus, rotavirus, adenovirus, *Cryptosporidium sp.*, *Giardia lamblia*, *Campylobacter spp.*, *Salmonella enterica spp.*, and *E. coli* O157:H7 (USEPA, 2010; Soller et al., 2010; Stalder et al., 2011a,b). Sound water safety management measures have to be based on carefully and appropriately chosen reference pathogens. The aim is to ensure sufficient protection from fecal-borne pathogen infections and diseases based on conservative assumptions.

In contrast to host-associated intestinal bacteria used for MST applications, fecal pathogen concentrations are often very low in water resources simply due to dilution effects. However, they show higher persistence and resistance to environmental conditions which is why they may be transferred into groundwater systems and might be further distributed (cf. Section "Quantitative microbial risk assessment (QMRA) and required treatment barriers"). For pathogen detection their very low abundance often represents a great challenge. Large sample volumes and complex procedures for target enrichment and concentration might precede detection (Ramírez-Castillo et al., 2015; Bofill-Mas and Rusiñol, 2020). Although culture-dependent detection methods are the gold standard for detection and identification of many bacterial and viral pathogens (Haramoto et al., 2018; Maurya et al., 2020; McKee and Cruz, 2021), molecular methods such as (quantitative) PCR methods are increasingly used. Culture-based methods are often time consuming. However, they provide evidence of the presence of viable/infectious pathogens (Girones et al., 2010). Because pathogens can also exist in the environment in a viable but nonculturable state, culture-dependent methods can lead to an underestimation of risk (Girones et al., 2010; Law et al., 2015). Molecular methods, on the other hand, cannot distinguish between viable and nonviable pathogens, so these methods tend to overestimate potential risk (Girones et al., 2010; Knight et al., 2013; Farkas et al., 2020; McKee and Cruz, 2021). Therefore, a combination of different methods like integrated cell culture and molecular detection can be useful, as for example for the detection of viruses (Farnleitner et al., 2018; Savio et al., 2018). Representative estimates of the reference pathogen concentration in the considered water resource are an essential prerequisite to support QMRA (cf. Section "Modelling pathogen transport in surface water and groundwater").

Microbiological characterization of groundwater

Molecular tools for the characterization and vulnerability assessment of groundwater

As discussed in the above sections, the direct detection of pathogens in groundwater is challenging in many respects. The most important limitations are related to low pathogen concentrations in the environment, insufficient sensitivity and high limits of detection (LOD) of the respective methods – constraining their usefulness for health risk assessments. To overcome these limitations and to address more specific issues related to water quality, efforts were made to discover additional indicators. In this context, the natural water microbiome has been considered a valuable, but hidden treasure since many years.

Even the most pristine ground waters harbor an abundant and often highly diverse microbiome (Karwautz and Griebler, 2021). These microbial communities comprise autochthonous and – depending on the vulnerability and type of the respective aquifer – also allochthonous, transient microorganisms (Savio et al., 2018; Farnleitner et al., 2005; Pronk et al., 2009; Sinreich et al., 2014; Smith et al., 2018). These microorganisms carry an intrinsic potential to serve as natural indicators (or 'biomarkers') for characterizing aquifers or studying the water quality. For example, autochthonous surface water bacteria could serve as alternative tracers for tracking infiltrated surface water through the aquifer (Harvey et al., 2018; Savio et al., 2019). On top of that, bacteria may serve as indicators for the general ecological water quality and stability of the aquifer (Korbel et al., 2017; Fillinger et al., 2019). Recent progress in molecular and optical methods such as High-throughput DNA-sequencing (HTS) or fluorescence-activated cell sorting (Bonner et al., 1972) (from hereon abbreviated as FACS) will fuel the efforts towards discovering novel indicators (Tan et al., 2015; Vartoukian et al., 2010; Kurm et al., 2019; Ben-Amor et al., 2005; Cichocki et al., 2020).

The analyses of the compositional community dynamics are advanced in terms of morphology and physiology. Epifluorescence microscopy (EFM) and automated flow cytometry (FCM) are additionally used to study the dynamics of the bulk microbial community abundance at high temporal resolution (Besmer et al., 2014, 2016). The *total prokaryotic numbers* – also referred to as *total cell counts* (TCC) – for example can reveal valuable information on the stability and vulnerability of a (ground) water resource (Sinreich et al., 2014; Fillinger et al., 2019; Retter et al., 2021). TCC have therefore potential as early warning parameter for water quality deficiencies (Besmer et al., 2014, 2016).

Novel HTS methods have proven extremely valuable by opening the 'black boxes' of the diverse aquatic microbiomes and aiding in identifying novel indicator microorganisms (Newton et al., 2013; Mclellan and Eren, 2014; Tan et al., 2015). In combination with FACS, specific subpopulations can even be physically separated prior to genetic analyses based on morphological or physiological characteristics or taxonomy (Müller and Nebe-von-Caron, 2010). The search for an alternative indicator generally starts by looking for a specific taxonomic group (e.g. genus, species or strain) whose abundance (or physiology) is directly related to temporary changes in hydrological conditions or physico-chemical water quality (Savio et al., 2019). Since the advent of HTS methods, such correlations between the dynamics of specific taxonomic groups and environmental parameters can be identified (Ramette, 2007; Buttigieg and Ramette, 2014; Savio et al., 2019; Tan et al., 2015). The causality of these correlations, however, is in most cases not understood.

Once identified, novel alternative indicator organisms can be detected by a variety of molecular or optical methods, including DNA-based methods such as qPCR and digital PCR (dPCR) or EFM and FCM in combination with fluorescence in situ hybridization (FISH). Different taxonomic groups can inform about different water quality aspects such as potential (fecal) pollution-related health risks, the deterioration of the ecosystem status (e.g. toxigenic algae/cyanobacteria), or the influence of surface water in an aquifer (e.g. prokaryotic or eukaryotic photoautotrophs).

Natural and artificial pathogen surrogates to characterize transport in groundwater

Pathogen removal in groundwater can be investigated either by monitoring indicator organisms which are present in the infiltrating water (as a consequence of fecal pollution, Section "Fecal indicators and genetic fecal markers") or by conducting classical injection tracer tests. Indicator organisms are part of the infiltrating water mass and often occur in moderate concentrations (Table 2). Common surrogates include bacteriophages for viruses (e.g. enteroviruses in the Netherlands), *E. coli* for bacteria such as *Campylobacter*, and anaerobic spores such as *C. perfringens*, which are commonly used as indicators for protozoa such as *Cryptosporidium* and *Giardia* (Section "Fecal indicators and genetic fecal markers"). Thus far, MST markers have rarely been used for groundwater protection studies. This is because, in groundwater environments, these genetic fecal markers occur in low concentrations due to low persistence and resistance of the target organisms to environmental conditions and due to filtering effects of soils (e.g. retention due to sorption on soil particles) (Krauss and Griebler, 2011). MST markers, however, have been used for the characterization of karst springs (Diston et al., 2018; Reischer et al., 2011). Therefore, it could be demonstrated for the first time that ruminants, rather than human sources, were the cause of fecal contamination (Reischer et al., 2008, 2011; Savio et al., 2018).

To study microbial transport in groundwater, tracers can be added on purpose in high concentrations (artificial surrogates or lab strains of fecal indicators, Table 2). The classical tracer test in the field is with a conservative salt or dye tracer that is injected upstream of a well or piezometer where samples are taken. Tracer tests can be performed with a natural gradient (between piezometers) or with a forced gradient created by a pumping well. From the breakthrough curve of tracer concentration over time, one can calculate different parameters analytically or numerically, such as the dispersivity, pore velocity and hydraulic conductivity (cf. Section "How do microbial pathogens move through groundwater?"). A tracer can also be introduced into a surface water body and monitored in groundwater, to determine the extent of surface-groundwater interaction.

Examples of common solute tracers are the dyes uranine (also known as fluorescein) (Buzady et al., 2006) and rhodamine WT (Pang et al., 1998), or chloride and bromide salts (Harvey et al., 1989), as well as naturally occurring isotopes such as deuterium,

tritium or ^{18}O (Mali et al., 2007). A disadvantage of the dye tracers is that transport may be retarded due to sorption, depending on the dye and type of aquifer matrix (Kasnavia et al., 1999). High seasonal variation in the background concentration of chloride may confuse results; conversely, low natural background concentrations of bromide make it a favorable tracer. Synthetic DNA tracers are promising as a way to detect connections between surface water and groundwater (Ptak et al., 2004; Pang et al., 2017). These tracers can be applied as free molecules or encapsulated in microparticles, and therefore acting like colloids, which usually travel faster than a conservative tracer through heterogeneous aquifers (Pang et al., 2020).

Potential pathogen transport in groundwater can be estimated or predicted using tracer tests with pathogen surrogates and numerical modelling (Schijven et al., 1999) (cf. Section "Modelling pathogen transport in surface water and groundwater"). A pathogen surrogate is usually a synthetic colloid or another microorganism that is not dangerous to humans or the environment and comparable in its behavior to pathogens. Aspects that need to be considered when searching for an appropriate surrogate are: inactivation, adsorption to soil material, chemical reactions (geological chemistry), size, surface electrical charge, hydrophobicity, and biological interactions.

Due to their small size, bacteriophages, such as MS2, PRD1 and φX174, are commonly used as surrogates for viruses (Schijven and Hassanizadeh, 2000). Spores, such as *Bacillus subtilis* (Pang et al., 2005) and *Clostridium perfringens* (Hijnen et al., 2005), as well as harmless *Escherichia coli* strains (Sinton et al., 1997), have acted as surrogates for pathogenic bacteria (Table 1). Examples of synthetic colloids are silica or polystyrene nanoparticles or microspheres that have a similar density to a pathogenic microorganism. These surrogate particles can have carboxyl surface functional groups (Bales et al., 1995) or other coatings to mimic the surface charge of the pathogen in question. For example, it has been found that glycoprotein-coated microspheres imitated the transport of the protozoa *Cryptosporidium parvum* better than carboxylated microspheres of the same size (Pang et al., 2012; Stevenson et al., 2015). Likewise, DNA-labeled-protein-coated silica nanoparticles were found to have outperformed MS2 in mimicking rotavirus attenuation in coastal sand (Pang et al., 2014), organosilane coated silica sand (Farkas et al., 2015) and silt loam over gravels dosed with onsite wastewater (Clemens et al., 2020). The transport of pathogen surrogates in the field can be compared to column tests in the laboratory, using the aquifer material taken from drilled boreholes. In this way, it is possible to compare the transport of the surrogate and corresponding pathogenic microorganism in the column (usually 10–100 cm one-dimensional transport) and the surrogate transport observed at the field site (Hijnen et al., 2005; Weaver et al., 2013).

Observational data uncertainty

A critical aspect of interpreting quantitative microbial data is that concentrations of pathogens or other target microorganisms in water are not measured directly; they are estimated from raw data such as analyzed sample volumes (that may reflect only a portion of a collected sample) and microscopic counts, colony counts, arrays of presence-absence data, or numbers of PCR cycles. This estimation can be relatively straightforward for enumeration-based methods, and it may involve more elaborate statistical methods such as most probable number (MPN) estimation or standard curves in detection-based methods and quantitative molecular methods, respectively (Cochran, 1950; Rutledge and Côté, 2003). Microbial concentration values reported by commercial laboratories or in research investigation are often perceived as exact measurements. In fact, they are estimates and therefore reflect some degree of uncertainty that may impact or even mislead interpretation or decision-making.

Quantitative microbial methods inherently feature random variation (i.e., error), as may be evidenced by repeated analyses yielding variable results—even when samples and methods are controlled to be as identical as possible. When evaluating the microorganism concentration in a source, random error adds variability to observed data and conversely adds uncertainty to concentration estimates obtained from raw data. As a result, all microbial concentration estimates are uncertain, though some are more precise than others. Selecting a sample size leading to observation of at least 10 microorganisms where possible is a useful target for reducing this uncertainty (Emelko et al., 2008). Of course, lower counts remain valid but they do yield concentration estimates with greater uncertainty. Ignoring the effect of random error in microbial concentrations presumes that it is trivially small in relation to the spatial or temporal variability among samples (Emelko et al., 2019), which can be quite incorrect in some environmental analyses.

Beyond basic uncertainty, concentration estimates also may be biased if losses in the analytical methodology are ignored or incorrectly quantified. For some types of methods (e.g., plating, MPN) and/or microorganisms, it is common to implicitly presume that there are no losses. For others (e.g., enumeration-based methods for waterborne protozoa), substantial losses are widely recognized (Reynolds et al., 1999; U.S. EPA, 2005). Analytical recovery studies are designed to quantify these losses. Recovery is evaluated by spiking samples with known quantities of microorganisms and may vary among water matrices and labs. Analyses in matrix water must account for background quantities of target microorganisms using split samples or spiked microorganisms that are distinguishable from native microorganisms. Correcting concentration estimates through division by recovered fractions is a common practice, but this may introduce substantial bias when recovery values are small (Schmidt et al., 2013).

In settings with low numbers of target microorganisms, non-detects may be prevalent. It is common practice to regard non-detects as concentrations below some limit of detection, but this practice is fundamentally flawed and is known to lead to biased data analysis (Chik et al., 2018). Instead, the result may be reported as a concentration estimate of zero, recognizing that all concentration estimates—not only non-detects—are uncertain. Availability of raw data is particularly critical to the interpretation of non-detect data. Limits of detection in microbiology may have value in communicating the capacity of a method to detect low concentrations, but they are not thresholds partitioning reliable and unreliable data.

Table 1 Overview of different groups of organisms and exemplary naming of explicit procedures (cultivation - and molecular based techniques) for assessing microbiological water quality.

Organism group	*Target organism/ population*	*Fecal specificity*	*Often used detection and example methods*	*Additional characteristic*	*Example references*[a]
Bacteria	*Escherichia coli*	general	Cultivation, qPCR methods (e.g., EC23S857, *uidA*405, *rodA*984)	Indicates recent pollution event, not persistent in the environment, might occur autochthonous and replicate in the environment under certain conditions	ISO (2001a) and Chern et al. (2011)
	Enterococci	general	Cultivation, qPCR methods (e.g., ENT)	Indicates recent pollution event, ENT more persistent than *E. coli*	ISO (2000b) and Haugland et al. (2005)
	Clostridium perfringens	general	Cultivation, qPCR methods	Produces persistent spores, very conservative indicator	ISO (2013), Chern et al. (2009), and Maheux et al. (2013)
	intestinal *Bacteroidetes*, *Firmicutes*	Human associated	HF183/BacR287, BacHum, Lachno3,	Detects human associated gut bacteria, more persistent compared to *E. coli*, detects DNA and cannot distinguish between living and dead organisms or free environmental DNA	Green et al. (2014), Kildare et al. (2007), and Feng et al. (2018)
	intestinal *Bacteroidetes*, *Firmicutes*	Ruminant/cattle associated	BacR, BacCow, BoBac	Detects ruminant/cattle associated gut bacteria, more persistent compared to *E. coli*, detects DNA and cannot distinguish between living and dead organisms or free environmental DNA	Reischer et al. (2006), Kildare et al. (2007), and Layton et al. (2006)
	intestinal *Bacteroidetes*, *Firmicutes*	Pig associated	Pig2Bac	Detects pig associated gut bacteria, more persistent compared to *E. coli*, detects DNA and cannot distinguish between living and dead organisms or free environmental DNA	Mieszkin et al. (2009)
Viruses	Bacteriophages, somatic, F-RNA, *Bacteroides fragilis*	general,	mainly cultivation based methods, some qPCR assays recently developed (e.g., CPQ056)	More persistent in the environment compared to bacteria, culture methods detect viable particles, qPCR assays detect DNA only and cannot distinguish between living and dead particles or free environmental DNA	ISO (2000a, 2001b), USEPA (2001a, b), European Committee for Standardization (1995), Jebri et al. (2017), and Stachler et al. (2018)
	Virus	specific, human	NoV, HAdV, HPyV,	More persistent in the environment compared to bacteria, culture methods detect viable/infectious particles, qPCR assays detect DNA only and cannot distinguish between infectious and dead particles or free environmental DNA	Rusiñol et al. (2014), Kirs et al. (2016), Ahmed and Harwood (2017), and Farkas et al. (2020)
		Specific, Ruminant/cattle	BAdV, BPyV	More persistent in the environment compared to bacteria, culture methods detect viable/infectious particles, qPCR assays detect DNA only and cannot distinguish between infectious and dead particles or free environmental DNA	Wong and Xagoraraki (2010), Hundesa et al. (2010), Ahmed and Harwood (2017), and Farkas et al. (2020)
		Specific, pig	PAdV	More persistent in the environment compared to bacteria, culture methods detect viable/infectious particles, qPCR assays detect DNA only and cannot distinguish between infectious and dead particles or free environmental DNA	Hundesa et al. (2009), Ahmed and Harwood (2017), and Farkas et al. (2020)
	Enteroviruses	human	Cell culture	Mainly poliovirus and Coxsackievirus B serotypes are detected, they replicate and form plaques in BGM cells, only infectious viruses can be analyzed	CEN (2005)
Protozoa	*Giardia lamblia*	general	Direct laboratory methods mainly, some qPCR assays	Very persistent in the environment, form resistant cysts	ISO (2006) and Guy et al. (2003)
	Cryptosporidium sp.	general	Direct laboratory methods mainly, some qPCR assays	Very persistent in the environment, form resistant cysts	ISO (2006), USEPA (2005), Fayer et al. (2000), and Hassan et al. (2020)

Abbreviations: BAdV: bovine adenovirus, BPyV: bovine polyomavirus, HAdV: human adenovirus, HPyV: human polyomavirus, NoV: norovirus, PAdV: pig adenvirus.

[a]Please note that only a few examples of methods currently used are given here. Furthermore, MST procedures for sources other than humans, cattle, and swine also exist in the literature.

Table 2 Concentration ranges of representative culturable or synthetic microbial indicators naturally occurring in water and artificial pathogen surrogates that can be injected into groundwater during tracer tests.

Fecal pollution indicators available in the environment		*Laboratory strains of indicators or synthetic surrogates*	
Escherichia coli	n.d./100 ml (groundwater) – 10^8/100 ml (raw sewage)	Phages, bacteria and spores (e.g. *Bacillus subtilis*), synthetic particles, synthetic DNA tracers	Total amount per tracer test (number per amount injected): 10^{10}–10^{12}
Clostridium perfringens	n.d./100 ml (groundwater) – 10^5/100 ml (raw sewage)		
Somatic coliphages	n.d./100 ml (groundwater) – 10^7/100 ml (raw sewage)		

Modelling pathogen transport in surface water and groundwater

To encompass the full pathway of pathogens from the fecal sources towards the drinking water well, it requires models for the microbial overland transport, infiltration via the unsaturated zone into groundwater, in-river transport, and transport via river-groundwater exchange (Bradford et al., 2013; Drummond et al., 2018). Microbial transport models in rivers or lakes generally account for mixing, dilution and microbial decay (Derx et al., 2016; Demeter et al., 2021). Flow velocity is described by the Manning formula for open channel flow (Manning, 1891) or by hydrodynamic modelling (Tolouei et al., 2019). To validate such models, data of fecal indicators, host-associated genetic fecal markers or pathogens in the wastewater source and surface water can be used (Derx et al., 2016).

The actual pathogen treatment reduction by attenuation towards the abstraction wells can be estimated using groundwater flow and microbial transport models. As for conservative tracers and solutes, the microbial transport in groundwater is described numerically by the advection – dispersion equation (ADE). Advection refers to the movement of solutes as a function of groundwater flow velocity. Diffusion is the result of the thermal motion of individual molecules or particles. Mechanical or hydrodynamic dispersion results from solutes or microbial particles moving at different rates than the average velocity in groundwater. This causes spreading of the contaminant plume in the porous media. Dispersion is a function of the dispersivity coefficient and groundwater flow velocity. The dispersivity relates to the aquifer grain size distribution and generally increases with the travel distance (Gelhar et al., 1992). Microbial subsurface transport is most commonly coupled with attachment – detachment and first-order decay (Schijven et al., 2002). Attachment and detachment lead to immobilization and remobilization of microbial particles to and from the solid matrix. In order to account for heterogeneity of the geochemical soil properties, two-site attachment – detachment rate models can be used in groundwater (Schijven et al., 2002; Yang et al., 2019). Dual-porosity or dual-permeability approaches can be used to account for the enhanced microbial transport in groundwater via preferential flow paths (Šimůnek et al., 2003).

The attachment of microbial particles can be described by the colloid filtration theory (Yao et al., 1971), as the product of two probabilities: the collector and the collision efficiency. The former is the probability that microbial particles collide with soil particles when approaching the soil particle surface. The latter is the probability that they attach during the collision (Auckenthaler and Huggenberger, 2003). The virus and microbial attachment and detachment rates are influenced by the soil geochemical properties and changes in hydraulic flow conditions, as shown in soil laboratory column experiments (Sadeghi et al., 2011). If applying the removal rates derived from laboratory experiments at the field scale, this can lead to strong underestimations of the risks from groundwater contamination. It was therefore proposed to compare laboratory with field-site experiments (Stevenson et al., 2021). Some of the uncertain parameters shown to affect microbial transport at pore scale may become irrelevant in complex hydrological and porous systems at field scale. For instance, bacterial inactivation, straining, size of the bacterial cells, and the permeability of the clogging layer with bed sediments (influencing the residence times) were found to determine the bacteria transport during riverbank filtration at field scale (Knabe et al., 2021). The hydraulic and microbial transport parameters are commonly obtained from fitting the models to the observed breakthrough concentrations at the observation wells. At a more general level, studies relied on literature values, e.g. for providing recommendation guidelines. Blaschke et al. (2016) used a wide range of reported hydraulic and virus transport parameters to model the virus removal by soil passage in the unsaturated and saturated soil zone. They modelled safe setback distances for drinking water at on-site disposal sites of biologically treated wastewater for different scenarios and types of aquifer media.

Quantitative microbial risk assessment (QMRA) and required treatment barriers

This chapter describes QMRA for drinking water, and specifically, how it is conducted in the Netherlands, because, since 2005, the Dutch drinking water companies are obliged by law to demonstrate that less than 1 per 10,000 persons per year (health based target; WHO (2011)) acquire an infection by consumption of unboiled drinking water (Schijven et al., 2011). To that aim, a guideline

document (Ilent, 2020) and computational tools (Schijven et al., 2010, 2011) have been developed. The drinking water companies – producing drinking water from surface water and vulnerable groundwater sites – conduct QMRA of index pathogens (enterovirus, *Campylobacter*, *Cryptosporidium*, *Giardia*, and occasionally other relevant pathogens) based on the reduction of indicator organisms (bacteriophages for enterovirus, *E. coli* for *Campylobacter* and anaerobic spores for the (oo)cysts of *Cryptosporidium* and *Giardia*) to determine treatment efficiency (Ilent, 2020). The risk of infection is estimated as follows:

$$C_{drw} = C_{raw}/S * Z \tag{1}$$

$$D = C_{drw} * V \tag{2}$$

$$P_{inf} = f(D, drpars) \tag{3}$$

Where C_{drw} is the drinking water concentration, C_{raw} is the raw source water concentration of the index pathogen, S is the sensitivity (or recovery efficiency) of the detection method and Z is the fraction of pathogens able to pass treatment. $Log_{10}Z$ is the log removal by treatment. Commonly Z entails a sequence of treatment steps (multibarrier principle). Indicator organisms (cf. Section "Natural and artificial pathogen surrogates to characterize transport in groundwater") are used as proxy for removal of the corresponding index pathogens. Dose D is the number of pathogens ingested by consuming V ml of unboiled drinking water. P_{inf} is the infection risk for a given D as a function of dose response with parameters *drpars*.

The QMRA is repeated every 4 years. QMRA*spot* is the computational tool that is available to conduct the QMRA, entailing fitting of the data to distributions, computing the risk using Monte Carlo simulations and dose response models including variability and uncertainty (Schijven et al., 2011).

The drinking water companies - producing drinking water from groundwater - have to protect the groundwater source. If adequately protected, additional treatment of the collected water to remove pathogens is not necessary. Basically, Z in Eq. (1) has to be sufficiently small so that the probability of infection will not exceed the health based target. For a sufficiently small Z, the setback distance between a fecal source of contamination and the groundwater production well must be large enough to enable removal of pathogens by attachment to soil particles and/or inactivation and die-off of pathogens. The QMRA for groundwater is mainly identical to the QMRA for surface waters, although limited to virus as index pathogen assuming that if virus removal is sufficient, this applies to other pathogens too (Schijven et al., 2017). Even though this assumption is valid for homogeneous sandy aquifers commonly found in the Netherlands, bacteria and protozoa may be likewise of concern in heterogeneous soil and sediment. As described in the guideline document (Ilent, 2020), the risk analysis for a groundwater production site assumes no problems with wellhead integrity. It also states that vulnerable groundwater aquifers require a QMRA to demonstrate compliance to the legal infection risk of less than 1 in 10,000. To assess vulnerability, groundwater production sites are ranked from high to low in terms of vulnerability, followed by QMRA of the most vulnerable sites. The vulnerability of a site (geohydrologic system) for pathogens is determined by the intrinsic properties that affect survival of an index pathogen on its way from the contamination source to the production well. A site is less vulnerable if confining (clay) layers are present, permeability is lower, the aquifer is thicker and deeper, the well screen is deeper, the sand is finer, there is less heterogeneity and preferential flow paths are absent, anisotropy is higher, the vadose zone is thicker and the groundwater has a higher ionic strength, lower pH, higher temperature, and conditions are anoxic (Ilent, 2020; Schijven and Hassanizadeh, 2000).

Based on QMRA, the size of the protection zone is determined using a standard contamination scenario. A risk assessment is needed if a contamination source is found within the protection zone. A monitoring program of 4 years is required if the determined protection zone is larger than the protected zone. If fecal contamination is detected, the source needs to be found and, if possible, to be removed. The QMRA required to determine the protection zone is based on a standard contamination scenario of 100 enteroviruses per liter leak at $Q_{leak} = 1$ m^3/day from a sewage pipe, and the following conditions of the aquifer: a groundwater temperature of 10 °C–12 °C and under anoxic conditions virus inactivation is 0.01 per day on a $\log_{10}$-scale and attachment of virus is conservative (sticking efficiency 10^{-5}), resulting in a removal rate coefficient $\lambda = 0.030$/day (0.013 $\log_{10}$/day). If (sub)oxic, then virus attachment is 100 times higher and $\lambda = 1.1$/day (0.49 $\log_{10}$/day). The virus source concentration must be reduced by 8.5 $\log_{10}$ for an infection risk of <1 per 10,000 persons per year. Log_{10} reduction by dilution of the source by the pumping at the production well, Q_{well}, and by dilution of the water from a single production well by the water from the complete well field, Q_{total}, are included. Virus removal in the unsaturated zone is set at 0.5 $\log_{10}$ per meter unsaturated zone. Following the standard scenario, a protection zone can be computed using a numerical hydrologic model that includes first-order decay (λ), or using a hydrological model to compute groundwater travel times to determine the size of the zone that provides enough travel time for the required virus removal, or by using computational model QMRA*well*, with an empirical formula specifically developed for this purpose (Schijven et al., 2010). The required travel time T can be computed as follows:

$$T = [8.5 - log_{10}(Q_{well}/Q_{leak}) - log_{10}(Q_{total}/Q_{well}) - log_{10} unsat]/\, log_{10}\lambda \tag{4}$$

The computational model QMRAcatch (Schijven et al., 2015; Demeter et al., 2021; Derx et al., 2021) calculates the microbial concentrations in rivers and the needed pathogen reduction treatment during drinking water production. It allows integrating data of fecal indicators, MST markers and reference pathogens and to evaluate future scenarios to pro-actively determine robust and sustainable water safety management options. Please also refer to the overview documents on QMRA by Teunis and Schijven (2019) and WHO (2016).

Conclusion

A number of analytical and modelling methods exist to estimate suitable and required catchment protection and drinking water treatment measures. The pathogen fate and transport processes in rivers and groundwater towards drinking water wells are subject of ongoing research. A good understanding of these processes is needed to model the fecal microbial flow and transport and predict the concentrations in raw water resources. Based on health-related water quality targets one can determine the status of drinking water safety and for deriving required infection barriers.

Current knowledge gaps

- Interaction between microbial pathogens and diverse environmental surfaces, a multitude of physical, chemical, and microbiological factors, and (emerging) contaminants in aquifers
- Upscaling tracer transport from the column scale to the field scale
- Tracer testing in heterogeneous material with preferential flow paths
- Identification of taxonomic groups from the water microbiome that can be used such as for the assessment of fecal pollution sources, or as indicators for biostability, eutrophication, biofilm-formation, pipe corrosion, and surface water infiltration
- Dose response models for specific genotypes of pathogens such as protozoan cysts and oocysts of *Giardia lamblia* and *Cryptosporidium* spp.
- Standardization of approaches for reporting non-detects and associated data needs to quantify uncertainty in microbial count data
- Extension of quantitative description of uncertainty in microbiological data to next generation sequencing approaches

Further reading

- Schijven et al. (2017) provides an overview of tracers and surrogates for studying the transport of pathogenic microorganisms, describes the major transport processes in terms of governing equations, lists typical removal rates of microorganisms (mainly bacteriophages and fecal indicator bacteria) during soil passage.
- Sen (2011) and Ginn et al. (2002) reviewed the processes of pathogenic biocolloidal contaminant transport in saturated and unsaturated porous media.
- Allaire et al. (2009) reviewed different tracer techniques to quantify preferential flow in soil.
- Chik et al. (2018) reviews approaches and provides guidance regarding approaches for reporting non-detects in microbial count data.

The High Plains Aquifer, USA—A Case Study

Erin MK Haacker, Department of Earth and Atmospheric Sciences, University of Nebraska-Lincoln, Lincoln, NE, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editor Christian Griebler.

Glossary

Baseflow The contribution of groundwater to a stream, often expressed as a percentage.
Ephemeral A term indicating that a body of surface water, such as a stream or pond, does not contain water year-round.
Hydraulic conductivity The ability of a rock or sediment to transmit (conduct) water.
Perennial A term indicating that a body of surface water, such as a stream or pond, contains water year-round.
Playa lake A depressional feature that collects rainwater from a small surrounding area, and is inundated for only part of the year.
Recharge Water that travels from the land surface to the saturated zone, replenishing groundwater.
Specific yield The proportion between the volume of water withdrawn and the dewatered volume of the aquifer, often expressed as a percentage.
Spring A location where groundwater naturally discharges to surface water, due to the intersection of the water table and the land surface.

Introduction

The High Plains Aquifer—often referred to as the Ogallala Aquifer—is one of the largest and most heavily developed groundwater resources in the United States (McGuire, 2017; Scanlon et al., 2012; Dennehy et al., 2002). The vast majority (about 97%) of all water withdrawn from the aquifer is used for irrigation, mostly of corn, soy, and cotton (Gurdak et al., 2009; Sahoo et al., 2017). Although it is a vital resource, it is most famous for its declining water levels (Smidt et al., 2016; Gleeson et al., 2012). The High Plains Aquifer is often used as a poster child for unsustainable water withdrawals, but this only applies to some areas of the aquifer. The aquifer is very large—the High Plains comprises roughly 452,000 km^2 of land area (Qi, 2010)—and if the entire volume of water in the High Plains Aquifer were collected into a lake, it would be close to the volume of Lake Huron (Fig. 1; Haacker et al., 2016). Therefore, generalizations about the aquifer usually fail to describe many of the aquifer subregions.

Physical geography

Many people believe that groundwater is found in underground lakes, but an aquifer is more like a gigantic stone sponge. The body of rock that makes up the largest part of the High Plains Aquifer is called the Ogallala Group (Gutentag et al., 1984). The Ogallala Group is a series of geologic formations that were deposited across the Great Plains as sediment eroded from the Rocky Mountains, mostly during the Miocene Epoch, from about 19–5 million years before present (Joeckel et al., 2014). Other formations, such as the Brule Formation and Arikaree Formation in western Nebraska and unconsolidated gravels in central Kansas, have distinct geologic histories and hydrologic properties, but exchange groundwater with the Ogallala Group (Gutentag et al., 1984).

Climate is a major factor determining groundwater resources. The High Plains has a north-to-south gradient in temperature, with colder temperatures in the north, and an east-to-west gradient in precipitation, with drier average conditions in the west. This means that the northeast corner of the aquifer gets the most precipitation relative to the evaporative demand, while the southwest corner receives much less precipitation, and has much greater potential evaporation. This balance between precipitation and evaporation helps to determine how much water can percolate past the root zone and eventually recharge (replenish) the aquifer. The climate

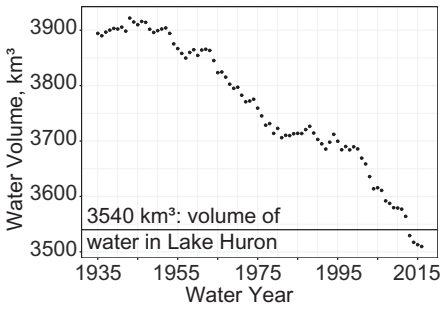

Fig. 1 A graph of water volume in storage over time in the High Plains Aquifer, from predevelopment to 2016. The volume of water in the modern aquifer is close to the volume of water in Lake Huron, one of the US Great Lakes. The methods for this figure are described in Haacker et al. (2016).

also affects the availability of alternative water sources (Crosbie et al., 2013). In the Texas portion of the High Plains, where the climate is hot and dry, groundwater is the only truly reliable source of water for agriculture. On the other hand, in eastern Nebraska, where the climate is cooler and wetter, much of the irrigation water supply can be sourced from surface water. Surface water irrigation and transport of water in unlined canals can induce additional recharge to the aquifer, which in a few locations has caused the water table to rise almost to the land surface (Cherry et al., 2020; Sueltenfuss et al., 2013).

Both the land surface and the base of the High Plains Aquifer have an elevation gradient, tilted from the west to the east (Houston et al., 2013). Major streams tend to run west-to-east, and the natural movement of groundwater tends to parallel stream gradients, even in places where the surface water has a somewhat different direction of flow. This is not a coincidence; springs can encourage erosion (Lapotre and Lamb, 2018). The box valleys in the Southern High Plains are likely features of groundwater erosion. Erosional features also cut through the aquifer materials of the High Plains in several locations, such as the Canadian River Valley in Texas, and the Republican River in Kansas and Nebraska. When rivers erode through the aquifer to expose the rock below, which is unable to transmit water as efficiently, groundwater cannot effectively flow across these barriers from one side of the river to the other. This means that the High Plains Aquifer does not circulate water across its entire extent, and could not, even if regional gradients were more conducive to north-south flow. The idea that it would be possible to contaminate the entire aquifer from a chemical spill in one location, or similarly drain the entire aquifer as a result of pumping in one region, is one of the most common misconceptions about the High Plains Aquifer. At the same time, this lack of flow throughout the region is one of the many factors that make it difficult to generalize science and policy across the aquifer. Hrozencik et al. (2017) showed that even within a relatively small area, a given groundwater management policy will not have the same effect for every farmer that is using water from the High Plains Aquifer (Fig. 2).

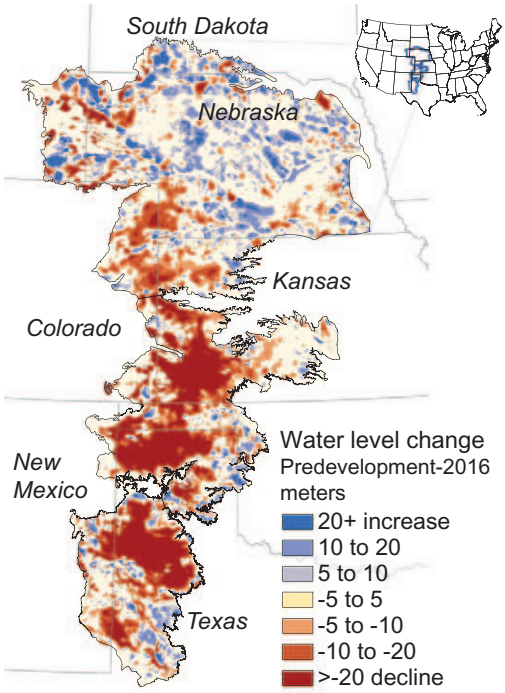

Fig. 2 A map of water level change from predevelopment to 2016, in meters. The top right shows the location of the High Plains Aquifer with respect to the conterminous United States. The methods for this figure are described in Haacker et al. (2016).

Groundwater is the primary source of irrigation water in most of the High Plains. As a result of irrigation withdrawals, saturated thickness (the distance from the top of the saturated zone to the base of the aquifer) has declined by more than 50% in a few places (McGuire, 2017). Overall, the aquifer has lost roughly 360 cubic kilometers of water in storage, representing about 10% of its total water volume (Haacker et al., 2016). However, most of that loss has occurred in places without alternative reliable water resources. The uneven distribution of water in the High Plains Aquifer has meant that close to 20% of the land area of the High Plains overlies a portion of the aquifer that can no longer efficiently sustain pumping for irrigation (Haacker et al., 2016). This is particularly important for irrigation, because declines in the water table can lead to lower well capacities, making it more difficult for farmers to irrigate effectively (Rad et al., 2020).

Hydrogeology

The High Plains Aquifer is primarily an unconfined aquifer. This means that the water table is the top of the saturated zone (Freeze and Cherry, 1979). In other aquifers, and in a few parts of the High Plains Aquifer, there is a confining unit of rock with low permeability that affects both the supply of water to wells and the connection between groundwater and surface water. The water table is the theoretical surface at which the pressure between sediment particles is equal to atmospheric pressure. Pore spaces above this surface might not contain air—only water—but the water is held against the force of gravity, due to capillary action. If a well is drilled into the aquifer, the water level in the well will be equivalent to the water table elevation in an unconfined aquifer.

The characteristics that govern the movement of water in the subsurface include hydraulic conductivity and specific yield, among others. Hydraulic conductivity describes how effectively a geologic material can transmit water (Freeze and Cherry, 1979). Hydraulic conductivity varies widely across the High Plains Aquifer, but values are highest in the Sandhills of central Nebraska, where there is a thick deposit of sand that transmits water very rapidly (Gutentag et al., 1984). Most of the water volume in the High Plains Aquifer is stored in this portion of the aquifer (Haacker et al., 2016).

Specific yield is the amount of water that can be extracted from a unit volume of the aquifer, often expressed as a percentage. If one cubic meter of the High Plains Aquifer is drained, one might expect to derive 0.15 cubic meters of water, meaning that the specific yield is roughly 15% (McGuire et al., 2012). Like hydraulic conductivity, specific yield is difficult to measure, and may change significantly over short distances. The idea that one cubic meter of water withdrawal will only dewater one cubic meter of aquifer material is another common misconception about aquifers.

Natural water quality in the High Plains Aquifer tends to be good (Gutentag et al., 1984). Some parts of the aquifer have high nitrate concentrations resulting from agricultural applications (Juntakut et al., 2019). The water quality of the Northern High Plains, where the depth to water is much shallower, is at greater risk than the areas of the Central and Southern High Plains, where water travels longer distances through thick unsaturated zones to reach the water table (Juntakut et al., 2020).

History of development

Prior to widespread displacement of Native American tribes, springs originating in the High Plains were an important water source (Wood et al., 2002). These springs were fed by groundwater where the water table intersected the land surface.

In the 1800s, ranchers installed windmills that pumped water from the High Plains Aquifer into stock tanks for livestock. As well technology developed and pumping became cheaper, more wells were installed for irrigating vegetables, particularly in the Southern High Plains where flood irrigation from surface water sources was not an option (Green, 1981). Irrigation remained highly labor-intensive for much of the 1900s. Center pivots were invented in Nebraska in the late 1940s and became widespread in the decades that followed (Ashworth, 2006). Satellite images of the High Plains show the now-ubiquitous "crop circles" that distribute groundwater across farm fields; recently, scientists have begun mapping the irrigation on the High Plains using remote sensing and machine learning techniques (Deines et al., 2017). Modern irrigation technology continues to improve, from more efficient pivot attachments such as drop nozzles that deliver water closer to the soil surface, to complex variable-rate irrigation equipment (Barker et al., 2018).

Aquifer management

As water levels in the aquifer decline, calls for management have increased. Much of the groundwater management of the High Plains Aquifer has been relegated to management areas within states. These management areas have widely different goals, styles, and histories. Many of them were implemented for the purpose of protecting irrigators' interests, which did not always include prolonging the life of the aquifer (Green, 1981; White and Kromm, 1995). Nevertheless, most local management areas have now adopted conservation goals, and farmers in the region are increasingly committed to groundwater conservation (Lauer et al., 2018).

Haacker et al. (2019) found that there was a slight positive effect in water within 10 years of establishment of a local groundwater management area in the High Plains Aquifer, but the effects of climate variability and crop prices were much more significant. It is also possible that management districts were systematically established after drought years, and that the positive effects were the result of rebound associated with wetter conditions.

Groundwater-surface water connections

In the Northern High Plains, in the states of Nebraska, South Dakota, and Wyoming, the High Plains Aquifer supplies a substantial proportion of water to surface streams. This baseflow ensures that the streams run all year, and helps maintain beneficial ecosystem features such as relatively cold summer water temperatures. The water table also intersects with the land surface to create wet meadows, particularly between dunes in the Sandhills region of Nebraska (Shrestha et al., 2021).

In contrast, the Central and Southern High Plains Aquifer is less well-connected with surface water. These areas had numerous springs prior to widespread development, but many of these streams have disappeared as the water table elevation declined. Some formerly perennial streams have become ephemeral. Ephemeral streams in the southern Great Plains show an overall increasing trend in zero-flow days, meaning that there are more days that the streams are not flowing (Zipper et al., 2021).

In the Southern High Plains, and to some extent in the Central High Plains, playa lakes are a primary source of groundwater recharge (Scanlon and Goldsmith, 1997). Playa lakes are ephemeral features that are fed by rainwater. The collection of surface water creates a strong enough gradient to push water through the root zone. Water that is absorbed by the soil between playa lakes is generally evaporated or extracted by plant roots before it can reach the deep unsaturated zone. There are also locations in the Southern High Plains where groundwater is discharged to lake basins. However, these basin lakes are saline, as a result of evaporative concentration of salts in the water (Wood and Jones, 1990).

Lifespan of the High Plains Aquifer

Several researchers have forecast the expected lifespan of the High Plains Aquifer, if current rates of pumping continue (Scanlon et al., 2012; Haacker et al., 2016; Steward et al., 2013). The expected lifespan varies across the Southern, Central, and Northern High Plains, with depletion expected in parts of the Southern High Plains within the next few decades (Deines et al., 2020). It is worth noting that as the aquifer declines, it is unlikely that pumping can be sustained at historic rates (Foster et al., 2014). When the water table drops close to the base of the aquifer, then pumping becomes less efficient, in addition to the increased cost of lifting the water from the saturated zone to the land surface (Rad et al., 2020). This may slow the depletion of the aquifer, extending its lifespan. However, this will also limit the usefulness of the aquifer for irrigation, and potentially create tension between economic and environmental sustainability goals (Young et al., 2021).

The High Plains Aquifer is rightfully famous for its unsustainable use, but this is a complex problem that will require tailored solutions in different parts of the High Plains. Lamb et al. (2021) demonstrated that water policy, local hydrology, weather, agricultural practices, and economic factors are all significant in determining irrigation demand in the Kansas High Plains, showing that there is no simple answer to decrease groundwater pumping. Conservation efforts for the High Plains Aquifer tend to focus on areas where the water table has declined substantially. Although this is an intuitive approach, it centers the needs of irrigators, and therefore economic and community goals. Water tables are relatively stable in most of the Northern High Plains (Haacker et al., 2016; Sahoo et al., 2017), but this region is also the last major region of the aquifer that sustains surface habitats through natural groundwater discharge. If the water table in this region were to drop, or if water quality declines substantially, the environmental consequences would be significant. There is no single policy or practice that can ensure future generations of irrigated agriculture on the High Plains, but lawmakers, researchers, and farmers are working toward local solutions in all of the states that share this vital resource.

Knowledge gaps

- How can irrigation and environmental demand be balanced in the short term and long term?
- How will communities be sustained when certain parts of the aquifer can no longer sustain irrigation?
- What is the role of soil health in groundwater conservation for agriculture?

Glossary

Aquifer An *aquifer* is a body of rock or unconsolidated sediment whose porosity allow the storage and transport of groundwater.

Environmental DNA (eDNA) metabarcoding *Environmental DNA (eDNA) metabarcoding* allow to determine the presence of species in an environmental sample, e.g., water or sediment, and is therefore a suitable method for biodiversity research. Since the organisms themselves do not have to be collected directly, as is the case with DNA metabarcoding or morphologically based species identification methods, *eDNA metabarcoding* allows representative sampling of aquifer water. Thus, species that occur in only low individual densities can be recorded. Furthermore, as a molecular tool, it allows for detection of cryptic species in contrast to morphological approaches.

Hyporheic zone The *hyporheic zone* is the transition zone between surface water e.g., streams and a nearby aquifer. This transition zone is characterized by a mixing of surface water and groundwater. As a result, organisms from surface water, stream sediment and groundwater commonly occur in this habitat.

Piezometers *Piezometers* are monitoring wells used for groundwater level measurements and sampling.

Quantitative sampling For ecological studies of groundwater communities, the data must be at least *semi-quantitative*. *Quantitative sampling* also allows calculating individual densities. For this, the sampled water volume must be known. Sampling methods where the sampled water volume can only be approximated, such as net samplers, are therefore referred to as *semi-quantitative*, while pumping aquifer water allows to determine the water volume. *Qualitative sampling*, i.e., recording the presence and absence of species, is often sufficient for biodiversity research.

Representative sample A *representative sample* reflects the community composition and diversity of the sampled habitat. For this, groundwater must be taken directly from the aquifer. This is done, for example, in representative sampling for microbiological or hydrochemical analyzes. Here, groundwater is pumped from the aquifer until key physical-chemical parameters such as the electrical conductivity are stable. In terms of groundwater fauna, eDNA for metabarcoding can be collected in a similar way to study its diversity.

Introduction

Groundwater ecosystems are dimensionally extremely large and therefore, difficult to access which is why most ecological research initially focused on related ecosystems such as springs and caves. Moreover, aquifers are highly heterogeneous in structure and hydrologically complex habitats, where faunal species are patchily distributed and often occur in low numbers of specimen

(Griebler et al., 2010; Hahn, 2006). This, in combination with the difficult access to most groundwater ecosystems, place special demands on sampling strategies and methods, and is one reason why basic ecological information, such as species distribution pattern and population sizes, are largely unknown for many aquifers worldwide. This knowledge is urgently needed for an adequate risk assessment, biomonitoring, and the development of sustainable concepts for the management and protection of these ecosystems (Gibert and Culver, 2009; Boulton et al., 2003b).

Since the onset of groundwater ecology, more than 100 years ago, various methods have been developed for the collection of groundwater fauna. The choice of an appropriate sampling method strongly depends on the objectives of the research. For example, some sampling methods aim to record species diversity as comprehensively as possible, while others allow for a repeated and reproducible sampling, qualitative data comparability and statistical analyzes.

In biodiversity research the goal is to document the overall repertoire of species at a site. The PASCALIS project (Protocols for the Assessment and Conservation of Aquatic Life In the Subsurface) made an important contribution by developing first standardized sampling procedures and methods for biodiversity assessment already 15 years ago (Gibert et al., 2005; Malard et al., 2002). The project focused on recording the European biodiversity in groundwater and related ecosystems, including shallow aquifers, springs, cave waters and the hyporheic zone of rivers and streams (Malard et al., 2002). Key findings, among others, included large scale biogeographic distribution patterns. Moreover, it revealed that groundwater fauna (stygobionts) is characterized by a high proportion of endemic species (Gibert et al., 2005; Dole-Olivier et al., 2009). A manual summarizing standardized sampling procedures and methods for assessing the faunal biodiversity of groundwater ecosystems has been published by Malard et al. (2002). However, modern approaches for the assessment of aquatic fauna biodiversity, such as selected molecular tools, i.e., environmental DNA (eDNA) and metabarcoding, may require different sampling methods than the classical approaches compiled in Malard et al. (2002). In fact, molecular approaches ideally complement traditional efforts in biodiversity research as they allow for the bridging of taxonomic knowledge gaps and the discovery of further cryptic species.

Community ecology studies aim to understand biotic and abiotic dynamics. For example, information is collected on spatial and temporal distribution changes. It is necessary that sampling is reproducible and representative of the corresponding habitat, i.e., the surrounding aquifer, (DVGW, 2018; Guderitz and Hahn, 2012). However, access points to the groundwater ecosystems may differ in kind, e.g., monitoring wells and large farm wells. This raises questions about the representativeness of one sampling method for all. It is also necessary to clarify how many sampling events and at what spatial resolution are needed to capture the heterogeneity of these habitats.

The goal of this chapter is to describe common sampling methods for the collection of groundwater faunal communities suitable for ecological studies, taking into account taxonomic analyzes by comparative-morphology and molecular tools. Their accuracy, efficiency and applicability will be discussed in terms of potential application areas in biodiversity and community ecology research. Groundwater related or dependent ecosystems others than shallow aquifers are not considered here.

Study design for representative sampling

Species occurrence depends largely on the hydrogeology and history of the region, the type of aquifer, and other habitat characteristics such as depth below the water table and sediment properties (Hutchins and Orndorff, 2009; Hancock and Boulton, 2009; Dole-Olivier et al., 2009). In consequence, groundwater faunal biodiversity and distribution patterns are characterized by a high spatial and temporal heterogeneity and variability (Gibert, 2001; Griebler and Mösslacher, 2003; Hahn and Matzke, 2005; Dole-Olivier et al., 2009; Hahn and Gutjahr, 2014). This is a real challenge for representative sampling needed for ecological studies (Hahn, 2006) raising questions about (1) the required number of sampling sites and their spatial distribution, (2) timing and frequency of sampling, (3) the type and condition of available access points, (4) and the dedicated analysis of the sample, e.g., fauna, hydrochemistry, eDNA, among others.

Spatial variability

Assessing species distribution patterns requires sampling at different spatial scales and depths (Hahn and Fuchs, 2009). For choosing appropriate sampling sites, basic hydrogeological information such as groundwater catchment boundaries, flow direction, temporal dynamics of oxygen concentration and temperature dynamics as well as potential surface water intrusion and land use patterns should be considered. Malard et al. (2002) recommend a set of criteria for the selection of regions and sites. For groundwater ecological studies on a small spatial scale, we would propose a minimum number of 5 to 10 sampling sitesto be required (Thulin and Hahn, 2008). Other studies suggest sampling at least six sites at once in order to determine absence or presence of stygofauna and individual species (Hutchins and Orndorff, 2009; Eberhard et al., 2009; Hahn and Gutjahr, 2014).

Temporal variability

Species composition and abundance have also been found to vary seasonally (Hutchins and Orndorff, 2009; Dole-Olivier et al., 2009). An Australian study revealed that new taxa were still being collected in the fourth sampling event (seasonal samples), indicating that there is a need for repeated surveys that account for temporal variability (Hancock and Boulton, 2009). Gutjahr et al. (2013) showed that the success of sampling is the result of both sampling efficiency and stability of the populations

investigated. Another challenge in assessing basic ecological parameters such as community structure and biodiversity is that many stygobionts tend to be rare and patchy distributed. Overall stygobiont densities are often low, making difficulties for the collection of sufficient specimens (Hancock and Boulton, 2009). In addition, particularly rare and endemic species that occur only in small ranges could easily be overlooked. Therefore, to account for temporal variability and to minimize the risk of missing rare species, sampling effort (i.e., number of sites and sampling events) should be increased (Dole-Olivier et al., 2009; Hancock and Boulton, 2009).

At least semi-annual sampling up to quarterly sampling per site is highly recommended in order to uncover spatio-temporal faunal community distribution patterns (Eberhard et al., 2009; Avramov et al., 2022). Well-studied sites that do not show a pronounced seasonal variation in abundance and species composition, as well as in key environmental parameters such as temperature and oxygen content, allowing for an annual sampling routine. In case sampling at a site takes place several times a year, there should be a minimum break of 4 weeks in between to allow the site to recover (Avramov et al., 2022).

In order to assess the entire faunal diversity at a site, published species accumulation curves indicate that at least 10–12 sampling events are needed (Hose and Lategan, 2012), however, these estimations are largely dependent on the spatial and temporal heterogeneity present at a site and the specific research purpose. For example, with the study of groundwater-surface water interaction need an extra high spatio-temporal resolution of faunal sampling (Bork et al., 2009a).

Access to groundwater ecosystems

Direct natural access to groundwater ecosystems is in most cases limited. Thus, taking a sample, i.e., collecting a representative water volume from the aquifer, is challenging. However, good access is often provided via groundwater monitoring wells, large farm wells and piezometers. In addition, research has already early focused on springs, caves and the hyporheic zone (Malard et al., 2002). However, faunal communities found in these habitats may differ significantly in composition from those in the aquifer (Matzke, 2006).

Groundwater monitoring wells are suitable sampling sites that allow direct access and are typically well distributed in most countries worldwide. Thus, existing groundwater networks of water authorities and waterworks are frequently used for ecological studies, especially on a larger scale. However, monitoring wells are designed for a hydrological and physical-chemical monitoring and therefore the chosen sites and their distribution may not be ideal for recording groundwater species composition and distribution patterns (Thulin and Hahn, 2008; Hahn and Fuchs, 2009).

In order to allow an easy entry of groundwater fauna into wells the well-screening should have a filter slot width ≥ 0.5 mm. Furthermore, wells should ideally tap the shallow aquifer (max. depth 40 m), especially in porous aquifers. For fauna to occur, an oxygen concentration ≥ 1 mg/l on the long term was found a basic requirement. Moreover, high amounts of iron hydroxide precipitation (ocher) and/or a high proportion of very fine sediments (e.g., silt), impair the colonization by groundwater invertebrates (Avramov et al., 2022).

Standing water sampled in monitoring wells or large farm wells is not always considered a representative sample of the adjacent aquifer (Korbel et al., 2017). However, a qualified comparison of different sampling sites to each other is still possible if the same sampling methods are used. Groundwater is routinely sampled from monitoring wells via pumping, having replaced the well water volume three times and when electrical conductivity, temperature and pH in the withdrawn water is stable. However, the representativeness of a faunal sample taken from the pumped aquifer depends strongly on the type of the pump and type of aquifer and hence selective filter effects of the surrounding rocks or unconsolidated sediments.

Many Groundwater species accumulate at the bottom of monitoring wells or large farm wells feeding on detritus and sediment (Hakenkamp and Palmer, 1992; Hahn and Matzke, 2005). As a result, samples collected from the well bottom show elevated densities (Bork et al., 2008). Whether the faunal community found in monitoring wells is representative for the community of the adjacent aquifer is still poorly investigated. Wells represent microhabitats that are selective to the species that congregate there, depending on feeding and habitat preferences or pipe design (Eberhard et al., 2009). However, individual studies found that (besides of varying densities), species composition from the well was representative for the adjacent aquifer (Hahn and Gutjahr, 2014; Hahn and Matzke, 2005; Matzke and Hahn, 2002) if the surrounding sediment shows a high hydraulic conductivity (Bork et al., 2008).

Another study by Korbel et al. (2017) found similar results for wells. Total abundance of invertebrates per liter was higher in wells than in surrounding aquifer water. The same taxa occurred in both standing water of the well and aquifer water, except that amphipods were not found in the aquifer samples. Thus, the proportion of individuals per taxa differed between well and aquifer water. Korbel et al. (2017) suggest selection of the sampling techniques depending on the research question. With ecological studies that investigate the species community dynamics (abundances, proportions of species), Korbel et al. (2017) recommends sampling water from the aquifer. Several sampling events may be necessary over a longer period of time in order to capture all species present.

Sampling requirements for different species identification methods

Species can be identified morphologically or by using molecular tools, i.e., metabarcoding and eDNA metabarcoding. The main difference between these three methods lies in the source of sample material (see Table 1). In order to identify species morphologically or to perform metabarcoding, it is necessary to take a faunal sample. For a morphological analysis, the organisms have to be well preserved. The identification of juvenile or damaged organisms is often not possible. The eDNA, on the other hand, is composed of DNA from organisms or parts of them (e.g., faunal sample) as well as free, accumulated DNA. It can also be extracted

Table 1 Comparison of different species identification methods in ecological and biodiversity research.

	Morphological analysis	*eDNA metabarcoding*	*Metabarcoding*
Sample source	Faunal sample	Aquifer water & sediment samples	Faunal sample
Representative sampling of aquifer water	Uncertain	Yes	Uncertain
Data	Number of individuals per species (quantitative)	Number of species (qualitative)	Number of species (qualitative)
Application areas	Ecological research and biodiversity research	Biodiversity research	Biodiversity research

from water or sediment samples that are routinely used for microbiological or hydrochemical analyzes (Creer et al., 2016). Thus, for a representative analysis of groundwater fauna to be obtained, a water sample of the aquifer is possible when applying the eDNA approach (Siemensmeyer et al., 2019). The same is true for microbiological sampling, in contrast to faunal samples from standing water or pumped aquifer water which are affected by selective filtering effects of the matrix.

Molecular tools allow to detect cryptic species (Pfenninger and Schwenk, 2007). Thus, studies comparing molecular biological and morphological approaches, found that molecular biological methods reveal more species, if appropriate references are available (Elbrecht et al., 2017). Although new molecular approaches are rapidly being developed, estimation of organisms abundances, often needed for empirical, ecological studies, is still hardly possible (Elbrecht and Leese, 2015). For this, it is still necessary to identify the species also morphologically.

Sampling techniques and equipment

Depending on the access to groundwater and the depth of the groundwater table, different sampling techniques and materials are applied to access faunal communities. An overview of sampling methods is provided by Malard et al. (2002), Pospisil (1992), Griebler and Mösslacher (2003), Hahn (2002), Bork et al. (2008), and Hose and Lategan (2012). Guderitz and Hahn (2012) also provide detailed suggestions for the application of sampling methods (i.e., piston pumps, net sampler and unbaited traps).

Collecting samples for microbiological and molecularbiological analysis

For microbiological or molecular biological investigations of water or sediment samples, it is particularly important that the sample is not contaminated. Therefore, sterile material should be used if possible and samples must be taken carefully. It must be ensured that the sampled area is representative of the surrounding aquifer. This is ensured by pumping aquifer water. The well water should not be sampled for this purpose. Additional faunal samples collected by net samplers from the well bottom can be taken prior to pumping of water for micro- or molecular analysis (Guderitz and Hahn, 2012).

Collecting faunal samples

In general, there are three techniques to sample groundwater fauna either for morphological or metabarcoding analysis: (1) net samplers (2) pneumatic piston pumps with or without double packers and Bou-Rouch pumps and (3) unbaited traps. A summary of the characteristics of sampling methods to collect groundwater fauna is provided in Table 2. Comparative studies of all three mentioned sampling techniques did not reveal significant differences in community composition but higher densities found in traps and at the bottom of monitoring wells sampled by net sampler (Dumas and Fontanini, 2001; Matzke, 2006; Scarsbrook and Halliday, 2002; Boulton et al., 2003a; Hahn, 2005; Hahn and Matzke, 2005; Allford et al., 2008; Bork et al., 2008). It is important for ecological studies that the chosen methods allow representative sampling and leave the surrounding substratum largely unchanged (Guderitz and Hahn, 2012). The chosen sampling method should also leave the animals as intact as possible to allow subsequent taxonomic and molecular biological analysis (Guderitz and Hahn, 2012).

Net sampler

A net sampler (also phreatic or haul net) is used to collect faunal samples from the bottom of groundwater monitoring wells and large farm wells (Schmidt et al., 2004; Dumas and Fontanini, 2001). It is a combination of a plankton or Cvetkov net that is used in lakes (Cvetkov, 1968) and a net used for sampling springs (Noll, 1939). The net sampler consists of a plankton net (mesh size 74–100 µm, diameter 49 mm) which is connected to a sample vial (50 ml) via a closure with a filter system. It is suitable for sampling monitoring wells with a diameter $\geq$5 cm (Guderitz and Hahn, 2012; Hahn and Fuchs, 2009). The net sampler is lowered into the groundwater monitoring borehole e.g., with the help of a winch or a fishing rod (DVGW, 2018). By pulling the net sampler up quickly (approx. 1 m) and letting it fall onto the bottom, the sediment in which the animals are located is stirred up. This process is repeated 10 times in a standardized manner in order, and also to detect rare species (Dumas and Fontanini, 2001; Malard et al., 2002; Guderitz and Hahn, 2012; Avramov et al. 2022; Eberhard et al., 2009). Hence, the net sampler collects fauna, sediment and detritus from the bottom of the monitoring borehole or well.

Table 2 Comparison of sampling methods for groundwater fauna (Guderitz and Hahn, 2012)[a].

	Pneumatic piston pump with double packers	*Bou-Rouch pump*	*Net sampler*	*Unbaited trap*
Application area	stratified sampling of existing monitoring wells and wells	small-scale investigations with high spatial resolution, repeated sampling	High number of monitoring wells and wells, large-scale investigations, repeated sampling	stratified sampling of monitoring wells, small-scale investigations with high spatial resolution, repeated sampling
Representativeness	good	Good	Good	Good
Stratified sampling	restricted, only together with double packer	very good	No	very good
Depth limitation	50–60 m	Groundwater levels lower than 2 m	Theoretically none, unproblematic up to 200 m	Groundwater level lower than 8 m
Effects on surrounding substrates	moderate[b]	Moderate	No	No
Costs	high	Low	Low	Moderate
Work effort	high	Moderate	Low	Moderate

[a]Submersile pumps can damage the organisms, thus are not appropriate sampling methods for groundwater fauna and not further specified here.
[b]Guessed, no studies available according to Hahn (2002).

The net sampler method is time saving and cost efficient for sampling many monitoring borehole and thus suitable for large-scale studies (Bork et al., 2009a; Guderitz and Hahn, 2012). Stratified sampling is not possible unless specific monitoring sites are sampled at different depths (Bork et al., 2009a). A quantitative sample to calculate species densities and thus be able to compare different samples, can only be taken if the sampled water volume is known. Thus, net samplers are considered semi-quantitative sampling methods. Due to the fact that the filtered water volume can only be estimated roughly and samples from groundwater monitoring wells show increased densities (trapping effect), no conclusions can be made about the total abundance of stygobionts in the aquifer. However, the method allows a comparative and representative assessment of species diversity and community composition at different monitoring wells (Hahn, 2005; Bork et al., 2008).

An Australian study found differences in sampled community composition between net sampler and pump, suggesting that pumping larger volumes of water multiple times reflects species abundance and the proportion of different taxa better than the net sampler which would underestimate species richness (Hancock and Boulton, 2009). Another study suggested a combination of net hauls and pumps when sampling stygofauna (Eberhard et al., 2009). Allford et al. (2008) considers haul nets (phreatic nets) as an efficient sampling method in terms of the number of taxonomic groups and abundance of individuals. In this study, the haul net captured all taxa which were subsequently also collected by pumping. They propose haul nets as a useful method for long-term monitoring focusing on the occurrence of different species and changes in the proportion of taxa, since it is cost-efficient, easy to use and allows taking multiple samples in a short time (Allford et al., 2008) (Fig. 1).

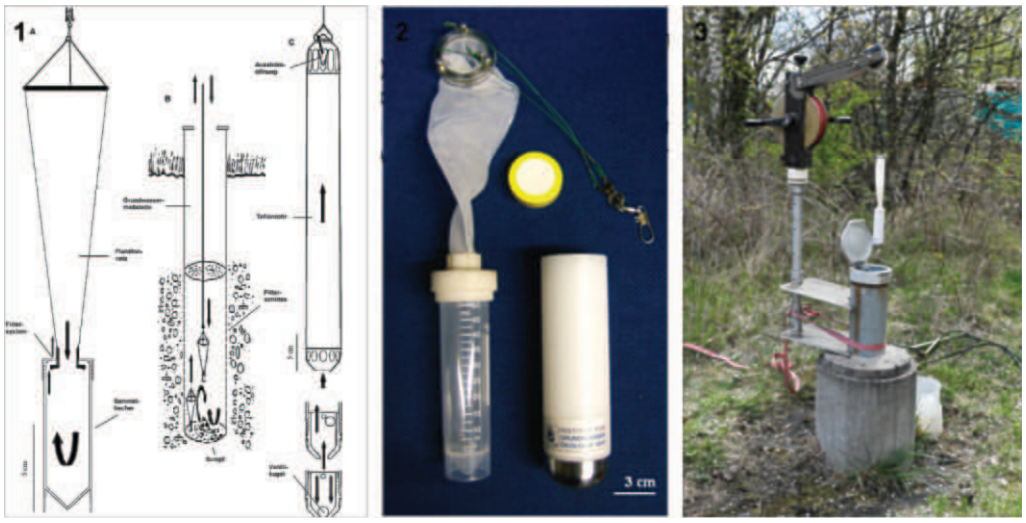

Fig. 1 **1** Net sampler and sampling vessel (A); Use of the net sampler (B); (C) Setup of the Aqua sampler © (Fuchs, 2007). **2** Photo of a net sampler with attached sampling vessel at the lower end of the net, in which the sampled groundwater fauna is collected (Avramov et al., 2022). **3** Sampling of a groundwater monitoring well. In this example, the net collector is moved up and down with the help of a winch (Avramov et al., 2022).

Pumps

Faunal samples can also be taken by using pumps, e.g., piston pumps with or without packer systems and simple piston (Bou-Rouch) pumps (Malard et al., 2002). In order to calculate the pumping rate, the time it takes to fill a container of known volume is measured. A difficulty in using pumps is to ensure that animals are not collected from multiple microhabitats. This depends largely on the pumping rate and matrix permeability (Allford et al., 2008). Repeated sampling is necessary to capture all species at a site over time (Hancock and Boulton, 2009). Pumping can alter sediment structure in the direct surrounding of a well, i.e. with repeated pumping high portions of fine sediment and detritus is removed (Guderitz and Hahn, 2012; Hahn, 2003). Especially in aquifers composed of fine sediments, mobile and small species are over represented relative to larger species in the samples due to the filtering effect of sediments (Boulton et al., 2004; Dumas and Fontanini, 2001; Fraser and Williams, 1997; Scarsbrook and Halliday, 2002). Representativeness can be improved by turning the pump off and on (approximately 30–60 s) so that organisms that have clung to the substrate during pumping can be captured more easily (Guderitz and Hahn, 2012).

The *pneumatic piston pump with double packers* is lowered into the well at the depth of choice. At least a volume of 20–1000 l should be pumped (Hakenkamp and Palmer, 1992). Malard et al. (2002) recommends pumping a minimum of 50 l. The pumped water is filtered through a plankton net. This allows the groundwater animals to be transferred to a sampling vessel. The pump does not harm organisms during sampling (Sinton, 1984; Malard et al., 2002). Since it is time consuming and labor intensive, the piston pump is a suitable method to sample deep (<70 m), but fewer measuring sites (Malard et al., 2002; Guderitz and Hahn, 2012). However, they seem less suitable for exploratory sampling.

The pneumatic piston pump with double packers allows for stratified sampling at discrete depths by inflating the double packers with compressed air. However, this method is time and labor consuming and it is recommended to take only a small sample volume (50 l) at a time (Guderitz and Hahn, 2012).

Standards for e.g., sampled water volume, pumping frequency, do not yet exist, and thus variations in the application of this method occur. Uniform standards are needed because abundance and species composition change as sample volume and pumping rate vary (Hunt and Stanley, 2000; Dumas and Fontanini, 2001; Boulton et al., 2004) (Fig. 2).

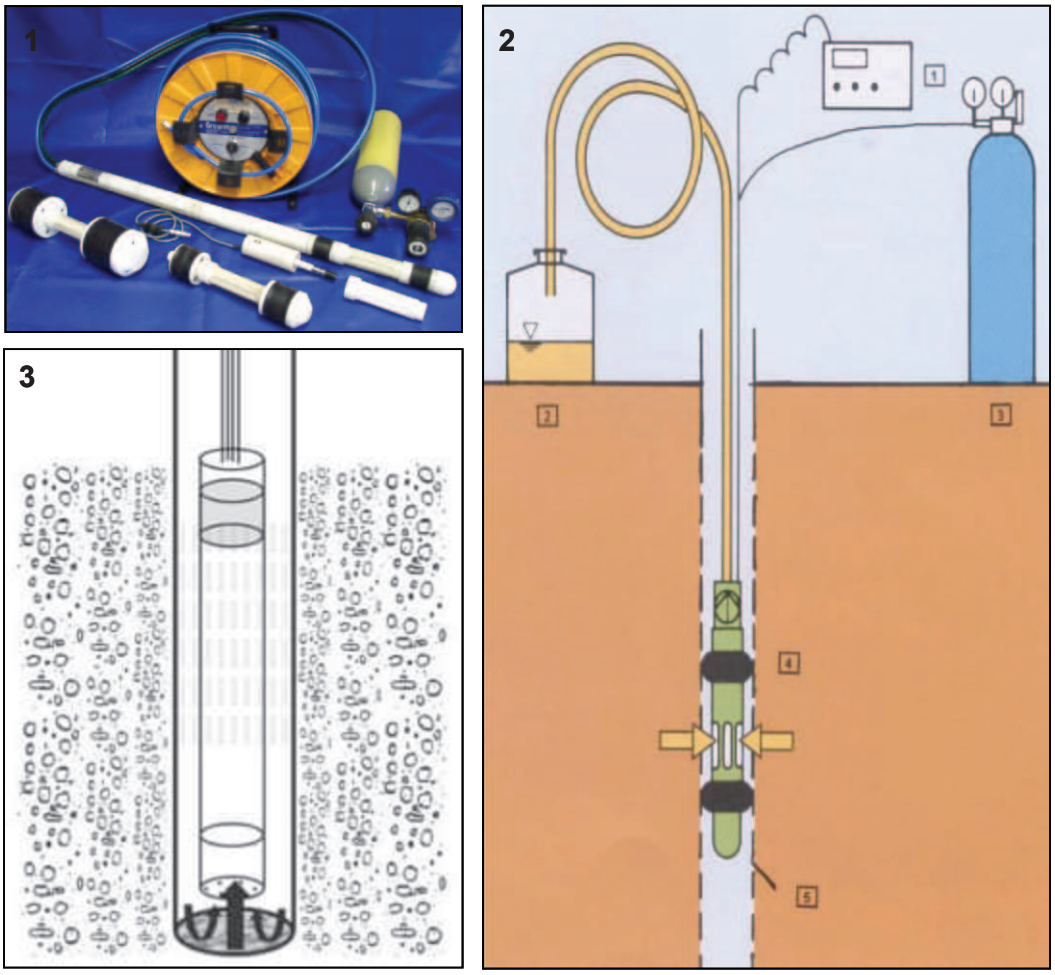

Fig. 2 **1** Pneumatic piston pump with double packers (Umwelt und Wissenschaftstechnik (UWITEC, Niederreiter). **2** Pumping of aquifer water. **3** Pumping of standing water in monitoring well.

The *Bou-Rouch pump* is a hand operated piston pump that can be used to sample groundwater close to the surface (down to 1.5 m) or the hyporheic zone (Bou and Rouch, 1967; Griebler and Mösslacher, 2003; Malard et al., 2002).

For this purpose, a pipe, a galvanized iron tube, which is perforated at the tip, is inserted into the sediment to a desired depth. The pipe should ideally be inserted days before sampling, as the process disturbs the faunal community and the sample might not be representative. When installing the pipe, channels can form that attract water from different depths, which is why in such a case, an assignment of the sample to a discrete depth would no longer be possible (Griebler and Mösslacher, 2003). If a pipe is sampled multiple times, it should be noted that pumping might alter the sediment structure in its surrounding (Griebler and Mösslacher, 2003). Thus, with this method only qualitative data of community composition can be obtained. If the pipe is installed beforehand and sampled once only, then a representative sampling for ecological studies is possible (Griebler and Mösslacher, 2003).

The Bou-Rouch pump is placed on top of the pipe. The pump maintains an interstitial flow by which floating organisms as well as organisms from the surrounding sediment are brought up into a 10 l sampling vessel (Malard et al., 2002). The sample should be thoroughly rinsed with filtered water so that the organisms are washed out of the sediment (Malard et al., 2002). Malard et al. (2002) recommend collecting a maximum of 5 l of water since these typically contain 76–100% of the taxa found in 10 l. Boulton et al. (2003a) recommend to pump between 1 and 10 l.

Submersile pumps are generally not suitable for sampling groundwater fauna, because they damage the animals, making their proper morphological identification impossible. Many wells used for drinking water supply or irrigation have a permanently installed submersile pump. Malard et al. (2002) state that sample intensively used wells is not recommended.

Unbaited traps

Unbaited traps can be used to collect fauna in groundwater and in the hyporheic zone (Hahn, 2003, 2005, 2006; Bork et al., 2009b). Baited traps are selective and therefore not suitable for ecological studies whose aim is estimating invertebrate abundances and community composition. However, baited traps are an effective sampling method when specific species are targeted for collection (Hutchins and Orndorff, 2009).

The groundwater inhabiting organisms accumulate at the bottom of the trap and can be brought up with a suction pump and transferred into a sterile, preferably wide-necked sample vessels consisting of acrylic glass (Bork et al., 2009a). The traps consist of vessels with a diameter of 98 mm and a height of 150 mm (Guderitz and Hahn, 2012). The organisms can enter through vertical rows of holes (diameter 15 mm) and accumulate at the bottom, where there is another row of holes closed with a plankton net (63 µm), from which the animals cannot escape and a hydrochemical gradient is prevented (Guderitz and Hahn, 2012). Top and bottom sealing rings enable connection to the groundwater monitoring well (diameter 100 mm). The traps allow for stratified sampling to a maximum depth of 8 m below groundwater table due to technical limitations of the suction pump (Bork et al., 2009b). Traps are applied for instance to investigate surface-groundwater interactions (e.g., bank filtration) (Bork et al., 2009b). They are often used for repeated measurements and where high spatial resolution is needed. Sampling is not time expensive but it needs special wells to be equipped with traps since the traps stay in place for some time (Guderitz and Hahn, 2012). Similar to the net sampler, the samples collected with traps show a higher density of invertebrates than with pumping methods, but the community structure can be recorded in high spatial and temporal resolution representative for the aquifer or hyporheic zone (Hahn, 2005; Bork et al., 2008) (Fig. 3).

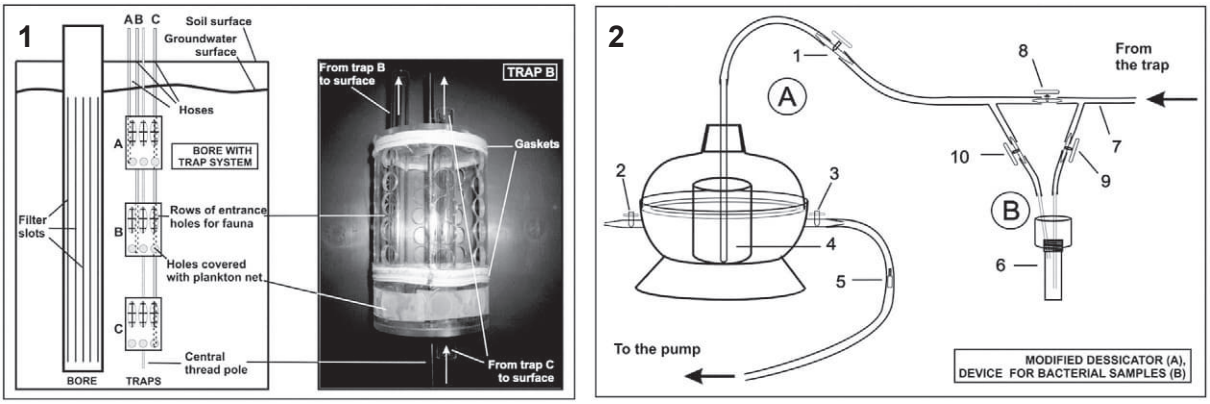

Fig. 3 **1** Bore with unbaited traps for taking stratified samples. **2** Desiccator with vacuum pump for taking samples from a trap. Institute of Groundwater Ecology (IGÖ GmbH).

Karaman-Chappuis method

Another sampling technique is the Karaman-Chappuis method, where a hole is dug into the loose sediments of the river bank or a gravel bar. The incoming water during digging takes with it organisms from the subsurface (Malard et al., 2002). The water is then collected and filtered to collect the organisms (Chappuis, 1942).

Sample processing and analysis

Microbiological and molecular biological samples (eDNA and metabarcoding analyzes)

Once the sample is taken, it is important that the chemical-physical conditions remain the same. Otherwise, changes in the DNA and RNA or in the composition of the microorganisms can occur quickly. Thus, the sample needs to be transported and stored in opaque insulated containers under cool and dark conditions (5 ± 3 °C, according to DIN EN ISO 19458). The analysis should be done as soon as possible. Microbiological samples can also be preserved with aldehydes (10–20 g/l formaldehyde or 10 g/l glutaraldehyde). However, only if the organisms are not required alive for the subsequent investigation, such as for culture experiments or metabolic activity studies (Guderitz and Hahn, 2012).

Organisms dedicated for later molecular biological analysis can be preserved in Ethanol 100% (Creer et al., 2016). They can be stabilized by adding ammonium sulfate or tetradecyltrimethylammonium oxalate for eDNA samples (also called Catrimox-14) (Guderitz and Hahn, 2012).

The collected DNA and RNA will be extracted and stored at −70 °C to −80 °C. For molecular analyzes the DNA and RNA will be amplified and sequenced. In order to identify the species of a faunal community, the sequences are then aligned with a reference database (Creer et al., 2016; Shaw et al., 2016).

Faunal samples for morphological analysis

After taking the sample, the plankton net is thoroughly rinsed with filtered tap water until the entire sample is transferred into the sample vial. The sample should be stored cold (10 °C) and in the dark for transport, and then washed and fixed as soon as possible (same day). If the organisms should stay alive, they must be kept under the same conditions, i.e., at a cool place, protected from light and in the same water from which they were sampled (Griebler and Mösslacher, 2003).

Later, samples are carefully washed with filtered water through a sieve (63–100 µm) in order to separate the organisms from the sediment for improved examination (Guderitz and Hahn, 2012; DVGW, 2018; Avramov et al., 2022; Malard et al., 2002). Following this, sediment type and quantity can be estimated which allows a "qualitative" classification (Hahn, 2006). A quantitative assessment can be made by using several sieves with different mesh sizes to assess sediment quantity and particle size distribution. The smallest sieve must have a mesh size equal to or smaller than 150 µm (Malard et al., 2002).

Faunal samples are preserved in Ethanol 70% or 96% (Malard et al., 2002; Guderitz and Hahn, 2012) in order to store the sample until taxonomic identification of organisms which is especially recommended for high sample numbers or high animal densities. Please consider fixation methods for specific taxonomic groups (see Table 3). After fixation, the sample is stained by adding Eosine B (1%) or Bengal red for at least 24 h in order to stain the organisms for a better distinguishing from other organic and inorganic particles (Malard et al., 2002; Guderitz and Hahn, 2012). Note, the use of Bengal red conflicts with later genetic analyzes.

Table 3 Fixation and preservation procedures for morphological species identification according to different taxonomic groups.

Taxonomic group	*Fixation and preservation procedures*
Cyclopoida, Harpacticoida	Ethanol (96%) with glycerol Ethanol (80%) with CaCO
Ostracoda, Gastropoda, Bivalvia	No glycerol (Guderitz and Hahn, 2012) Fixation and preservation in ethanol (70%) (Griebler and Mösslacher, 2003), no higher concentrations since it can dry out and make shell brittle
Acari	Koenike's fluid, a mixture of Glycerol (50%), acetic acid (10%), and water (40%) (Guderitz and Hahn, 2012; Griebler and Mösslacher, 2003), 70% Ethanol
Oligochaeta	Ethanol (80%) with 3 drops formol
Nematoda, Rotatoria, Copepoda, Cladocera, Bathynellacea	Formol (4%), glycerol for preservation
Insecta	Ethanol (70%)
Turbellaria	Fixation with Bouin's fluid and preservation with ethanol (80%)

For molecular biological analysis only ethanol (96%) should be used.

Morphological species identification

Samples are sorted under the binocular or microscope (magnification of at least 20 times). Small quantities of the sample are transferred to a Petri dish. A grid facilitates orientation when viewing the sample cell by cell. The organisms are sorted into taxonomic groups, counted and transferred with forceps into small vials filled with ethanol (70%). A sorting sheet is provided by Malard et al. (2002), which simplifies the taxonomic identification later on.

Conclusions

The choice of the appropriate sampling method and effort depends as much on the research objectives, i.e., biodiversity or ecological research, and field conditions, as on its efficiency and accuracy. Both influence the sampling success and must be considered for data interpretation and comparison with results from other studies using other sampling methods. Because groundwater ecosystems are highly heterogeneous habitats and species are often rare, endemic, and occur at low individual densities, sampling effort must be adapted to this situation (Dole-Olivier et al., 2009; Eberhard et al., 2009; Hancock and Boulton, 2009; Hutchins and Orndorff, 2009). Access to groundwater ecosystems is often limited to farm wells or monitoring wells. However, these reflect well the species that occur in the surrounding aquifer. However, abundances, proportions of certain taxa, and individual densities may differ from the total numbers in the adjacent aquifer (Hahn and Matzke, 2005; Korbel et al., 2017). Assessment approaches of the ecological status of an aquifer based on abundances or proportions of taxa within a community may therefore be biased should only water from monitoring wells or large farm wells be sampled (Korbel et al., 2017; Korbel and Hose, 2017). Faunal samples which are needed for morphological species identification or metabarcoding are difficult to obtain by representative sampling of the aquifer water. In contrast, the eDNA approach allows for a representative sampling of the aquifer. Thus, for the first time it is possible to look for groundwater in the same water sample that is dedicated to microbiological and hydrochemical analysis.

The most common sampling methods each have advantages and disadvantages for sampling groundwater fauna. Net sampling is a cost-efficient method to collect many samples from near-surface aquifers that reflect species diversity and community composition of the surrounding aquifer (Hahn, 2005; Bork et al., 2009a). Thus, it is well suited for exploratory sampling or for biomonitoring (Allford et al., 2008). Pumping is more cost and labor intensive than net sampling, but is advantageous for sampling deeper aquifers (Allford et al., 2008). In combination with a double packer it allows for stratified sampling at discrete depths in screened wells and collection of quantitative data (Guderitz and Hahn, 2012). The Bou-Rouch pump is especially useful to take samples from the shallow aquifer close to the surface or the hyporheic zone (Bou and Rouch, 1967; Griebler and Mösslacher, 2003; Malard et al., 2002). Unbaited traps are particularly useful because of their efficiency and ability to collect fauna from discrete depths.

Several studies show that molecular approaches offer promising applications for biodiversity research and monitoring (Elbrecht et al., 2017; Keck et al., 2018; Valentini et al., 2016). Currently even though approaches are under development to estimate the abundance of individuals, this is to date not possible with the eDNA approaches in place (Elbrecht and Leese, 2015). In the next few years, molecular tools such as eDNA metabarcoding will gain in importance, so that sampling techniques might be further adopted. Environmental DNA metabarcoding together with microbiological and hydrochemical analyzes allow a representative sampling of the faunal community directly from a common aquifer water sample. A combination of both, morphological and molecular biological species identification can complement each other well to meet the requirements of monitoring aquatic ecosystems (Harvey et al., 2017).

Some suitable sampling methods are available, and important progressive steps have already been taken toward standardization of sampling methods (Malard et al., 2002). However, further research is needed to better evaluate the ability of sampling methods

to representatively and quantitatively record adjacent aquifers and their faunal communities. For this, it is also necessary to investigate the sources of spatial and temporal heterogeneity affecting species communities (Dole-Olivier et al., 2009; Gutjahr et al., 2013).

Knowledge Gaps, Obstacles, and Research Frontiers in Groundwater Microbial Ecology

Christian Griebler[a], Lucas Fillinger[a], Clemens Karwautz[a], and Grant C Hose[b], [a]Department of Functional & Evolutionary Ecology, Division of Limnology, University of Vienna, Vienna, Austria; [b]Department of Biological Sciences, Macquarie University, Sydney, NSW, Australia

Glossary

Allochthonous Material and organisms that are from outside the (eco)system; have been introduced from outside.
Autochthonous Material and organisms that are from inside the (eco)system; have its origin in the system.
Chemolithoautotrophy Microorganisms that gain cellular energy from converting inorganic compounds—such as hydrogen, reduced iron, nitrite, or hydrogen sulfide—and fix inorganic carbon into organic carbon.
Ectosymbiotic Form of symbiotic relationship in which one partner lives on the body surface of the host (other partner).
Endosymbiotic Form of symbiotic relationship in which one partner lives inside the body of the host (other partner).
Syntrophic Species of organisms that live in a metabolic relationship in which one species depends on the nutrients, growth factors, or substrates provided by the other partner.
Ultramicrobacteria Bacteria that are smaller than 0.1 μm^3 or less than 0.3 μm in diameter in active state.

Summary

Groundwater ecology, and groundwater microbial ecology in particular, are comparably young disciplines that have gained momentum in recent decades. Nevertheless, groundwater ecosystems still belong to the least explored environments worldwide and as such there are more open questions than we have answers. The aim of this chapter is to critically highlight existing knowledge gaps, obstacles, and research frontiers in groundwater microbial ecology. Without doubt, a major issue is the difficult accessibility of the subterranean habitats. Analyzing microbial communities in groundwater that is withdrawn from observation wells or collected at springs and in caves, we deliberately ignore the vast majority of microbes that live attached to the aquifers' sediment and rock matrix that are inaccessible with routine sampling methods. Only recently, we learned that active members of the microbial community have been overlooked because of their small size ($\leq$0.2 μm). Moreover, there is increasing evidence that chemoautotrophic primary production does play an important role in carbon cycling of aquifers that have so far been perceived as solely heterotrophic domains. Overall, our knowledge about carbon pools, fluxes and transformation in the subsurface is still extremely poor and needs rapid improvement. Similarly, our ideas about groundwater food web interactions and the link between microbes and fauna is immature. Modern molecular tools in combination with the analysis of groundwater fauna microbiomes open new doors to study micro-meio-macro relationships. In light of the anthropogenic pressures on groundwater ecosystems, it is necessary to study the resistance and resilience of microbial communities and their key ecosystem functions that provide essential ecosystem services, i.e. purification and storage of drinking water. From the perspective of basic research, it is timely to test established ecological concepts and principles for their validity in groundwater ecosystems.

Introduction

The discipline of groundwater ecology started to develop late in the 19th century with natural history observations about organisms living in subsurface habitats accessible to humans. During the first part of the 20th century, naturalists targeted subterranean habitats in order to sample strictly stygobiotic animals. Our current knowledge of the unique attributes of groundwater environments and its inhabitants, such as (i) the extreme oligotrophy of many cave water habitats, (ii) the relative thermal stability of the subsurface, (iii) the reduced organismic diversity, and (iv) for some species, their reduced abundance, date back to this period (Danielopol and Griebler, 2008). While groundwater fauna ecology already had some momentum in the 1950s, microbiological research was just beginning. Interest in subsurface microbial life was initially related to drinking water quality from aquifers and the corrosion and clogging of oil production pipes. The effective birth of subsurface microbiology involved the development of aseptic sampling techniques in the beginning of the 1970s (e.g., Dunlap et al., 1977). Since then, the ubiquitous presence of microbes in the subsurface, as well as their intimate involvement in biogeochemical cycles and ecosystem services has been well established. Today, groundwater microbial ecology is a modern sub-discipline within limnology and environmental microbiology. However, the difficulties accessing subsurface habitats, with its hidden heterogeneity, and invisible ecosystem boundaries is a major reason why knowledge of groundwater microbial ecology still lags behind that in surface fresh and marine waters. Groundwater ecosystems are among the most unexplored habitats in the world, with entire regions, even continents (e.g. Africa) that have not been extensively studied.

The biologically active terrestrial subsurface extends several kilometers below the land surface (Ghiorse, 1997). Although there are records of the occurrence of fauna in caves and aquifers deeper than 2000 m (Borgonie et al., 2011; Sendra and Reboleira, 2012), deep aquifers, particularly in porous systems, are anoxic and do not support higher organisms. Even in shallower and oxic subsurface zones, microbes dominate in terms of numbers, biomass, and activity. Microbes are the drivers of all biogeochemical cycles. They are responsible for cycling nutrients, the biodegradation of organic contaminants, the (im)mobilization of metals, and the formation of minerals. Most of our knowledge on microbial processes come from controlled laboratory experiments, while in situ measurements and field studies are exceptionally rare (Schroth et al., 2001; Mailloux and Fuller, 2003; Fischer et al., 2006). The limited accessibility of the subsurface is a major hurdle to making observations in situ. Costly drilling is possible only in exceptional cases, and the installation of the many groundwater observation wells worldwide have not been accompanied by microbiological investigations.

In many areas groundwater ecological research is still dominated by observational studies that focus on biotic distributions and taxonomic description, rather than hypothesis-testing, mechanistic understanding, and delineation of general principles. Larned (2012) pointed out critical obstacles that limit the progress of the discipline. These include the structural and hydraulic heterogeneity of the subsurface, the lack of physical habitat templates and classification schemes for groundwater habitats, but opportunities include emerging molecular methods that will, in combination with traditional morphological methods, improve our taxonomic resolution. Finally, he advocates laboratory and field experiments to quantify ecological relationships and test hypotheses. Although Larned (2012) did not specifically focus on groundwater microbial ecology, all of the presented arguments are transferable also to this sub-discipline.

Recent 'horizon scanning' identified the highest priority research questions in subterranean ecology (Mammola et al., 2020). These research questions covered six subject areas, i.e. (1) adaptation, (2) origin and evolution, (3) community ecology, (4) macroecology and biogeography, (5) conservation ecology, (6) microbiology and applied topics. Rather than repeating knowledge gaps already identified in previous works (Larned, 2012; Mammola et al., 2020), we will complement their list of research questions with respect to microbial ecology. We provide below 10 topics where there is an urgent need for microbiological research in groundwater.

Free swimming vs. matrix associated microbes in aquifers – Informed overlook?

The majority of microbial cells in aquifers live attached to rock or sediment surfaces as single cells, in small colonies (Fig. 1), or occasionally in thin biofilms (dense biofilms are usually absent). The number of surface-attached cells can be 10–10,000 higher than are suspended in an equal volume of groundwater (Pedersen and Ekendahl, 1992; Alfreider et al., 1997; Lehman et al., 2001; Griebler et al., 2002; Smith et al., 2018). In addition to being more abundant, surface-attached microbial cells are generally bigger and have higher metabolic activity (Fig. 1) (e.g. Kölbel-Boelke and Hirsch, 1989; Wilhartitz et al., 2009), and assemble into communities that are taxonomically different and more diverse than planktonic communities (e.g. Flynn et al., 2008, 2013; Zhou et al., 2012; Fillinger et al., 2018). Moreover, the colonization of mineral surfaces and particles by microbes from the surrounding groundwater is determined by selective forces (Fillinger et al., 2018; Graham et al., 2017), causing not only differences in community composition between surface-attached and planktonic communities, but also heterogeneous distribution of microbes across different aquifer zones (Bennett et al., 2000; Rogers and Bennett, 2004; Grösbacher et al., 2016).

The difficulties of observing and sampling microorganisms from the subsurface apply even more so to surface-attached cells. Drilling is generally prohibitively expensive and rarely an option. As such, most research on microbial communities and their functionality in groundwater environments ignore 90–99% of the present microbial cells. The 1–10% that reside as planktonic cells may not be fully representative of their attached counterparts in terms of community composition, function, or in situ process rates.

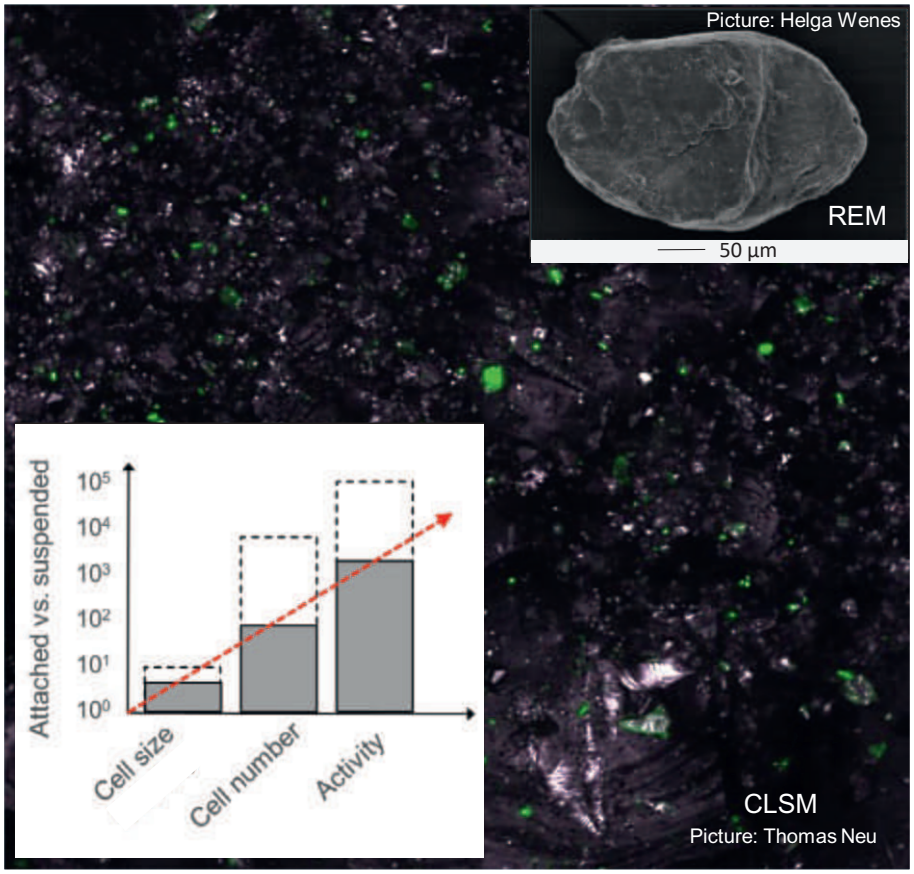

Fig. 1 Surface-attached microbes dominate in aquifers in terms of cell size, cell numbers, and activity (bottom right). A raster electron microscopy (REM) picture of a quartz grain is shown in the top. The left lower CLSM (confocal laser scanning microscopy) picture depicts the distribution of microbial cells over the particle surface made visible by the fluorescent stain SYBR Green.

In terms of community functions, the differences between surface-attached and planktonic communities are less well understood. Anantharaman et al. (2016) found functional redundancy in processes involved in the cycling of carbon, sulfur, nitrogen, hydrogen, and iron in both attached and planktonic communities in a shallow porous aquifer. However, other studies found individual groups of microbes, such as those associated with iron reduction or methanogenesis, to dominate in either the attached or planktonic communities (Flynn et al., 2008, 2013). Similarly, the microbial degradation of hydrocarbons can be differently associated with sediments or groundwater in contaminated aquifers, depending on the partitioning of contaminants between sediments and water (Anneser et al., 2010). To partly overcome this bias, various substrata have been incubated in groundwater observation wells for microbial colonization for a re-creation of natural attached microbial communities (Hirsch and Rades-Rohkohl, 1990; Alfreider et al., 1997; Griebler et al., 2002; Stelzer et al., 2006; Fillinger et al., 2018), accepting new constraints (e.g. artificial substratum, well water conditions). In fact, considering the striking differences in terms of abundance, activity, and composition between surface-attached and planktonic microbes in groundwater, the implications on a functional level and overall impact on biogeochemical processes is certainly a key focus for future research.

Occurrence of ultra-small prokaryotes

For a long time, prokaryotes smaller than 0.2 µm have been overlooked in the aquatic environment and largely ignored in microbial ecology (Velimirov, 2001). The so-called 'ultramicrobacteria' (UMB) or 'nanobacteria' (nanobes) were originally perceived as starving and dormant states of cells (Lappin-Scott and Costerton, 1992). UMB are now considered ubiquitous and to constitute a significant fraction in terms of cell numbers and active members of the microbial community (Hahn, 2004; Wang et al., 2009). Not surprisingly, UMB are also found in groundwater ecosystems (Castelle et al., 2015; Miyoshi et al., 2005; Luef et al., 2015; Herrmann et al., 2019; Nazina et al., 2020). Described as the 'minimalists' by Herrmann and Taubert (2022), these organisms are characterized by a minimalistic strategy, having reduced genomes and, as a consequence, restricted metabolic capabilities. Members of the bacterial Candidate Phyla Radiation (CPR) and archaeal DPANN phyla, which are often present in high abundance in groundwater habitats (Liu et al., 2018; Herrmann et al., 2019), are prime examples of this strategy (Rinke et al., 2013). Lacking pathways for

synthesis of essential amino acids and nucleotides, these organisms likely exhibit a symbiotic lifestyle (Nelson and Stegen, 2015). Taking into account that the nanobes are quite robust to stress (Liu et al., 2018) and can be transported widely through the subsurface (Lappin-Scott and Costerton, 1992), their ecological role is of fundamental interest. The minor switch from using 0.1 μm instead of 0.2 μm filters when collecting microbial biomass from groundwater will definitely extend our common understanding of groundwater prokaryotic communities.

Primary production in the subsurface – Importance in carbon cycling and the groundwater food web

It has long been believed that microbes in the terrestrial subsurface are predominantly heterotrophic, and therefore depend on the import of organic matter originating from photoautotrophic primary production at the surface. However, chemoautotrophic prokaryotic microbes do exist in groundwater, such as sulfidic cave waters and springs (Sarbu, 2000; Sarbu et al., 2000; Engel et al., 2003; Hutchins et al., 2016; Engel, 2019).

Inorganic carbon (carbon dioxide, hydrogen carbonate and bicarbonate) is typically available in excess in groundwaters, with the exception of highly alkaline systems. A basic requirement, however, is a chemical gradient that offers a sufficient flux of an electron donor (H_2, NH_4^+, NO_2^-, HS^-, S^0, $S_2O_3^{2-}$, CO, Fe^{2+}), and an electron acceptor (O_2, NO_3^-, SO_4^{2-}, S^0, $S_2O_3^{2-}$, Fe^{3+}, CO_2) in an appropriate combination to gain energy for CO_2 fixation. There is limited knowledge of how frequently these requirements are met in aquifers and cave water bodies.

The fixation of inorganic carbon consumes ATP and thus is energetically costly. In the absence of light, insufficient energy gain from redox reactions often limits growth of chemoautotrophs in groundwater. However, there is a diversity of pathways among prokaryotes for CO_2 fixation in the dark, which increases the chance that primary production in the subsurface is more important than traditionally expected. However, its importance and contribution to the subsurface carbon cycle may vary substantially from site to site.

In aquifers below agricultural land that receive regular pulses of ammonium derived from fertilizers, chemoautotrophy may play a particularly important role. Here, ammonium can fuel the activity and growth of nitrifying bacteria, and although abundances of these chemoautotrophs can be lower than heterotrophs, they may contribute significantly to the total gene expression in a microbial community (Jewell et al., 2016; Wegner et al., 2019). Recent studies of an oligotrophic limestone aquifer found that up to 17% of the microorganisms relied on autotrophic growth via denitrification coupled to the oxidation of reduced sulfur compounds or hydrogen, or aerobic ammonium oxidation in oxic zones (Herrmann et al., 2015; Kumar et al., 2018; Wegner et al., 2019). Interestingly, metazoan predators occurred at sites with elevated abundances of microbial genes associated with chemolithoautotrophy (Herrmann et al., 2020), suggesting that chemoautotrophic primary production has a role in sustaining trophic interactions in groundwater ecosystems (Taubert et al., 2021).

Another important yet frequently overlooked aspect in the carbon cycle is heterotrophic CO_2-fixation. Virtually all heterotrophic organisms—from microorganisms to humans — incorporate CO_2 via a variety of pathways involving carboxylases in the central and peripheral metabolism (Erb, 2011; Spona-Friedl et al., 2020). Up to 10% of the carbon biomass in heterotrophic prokaryotic microorganisms may derive from these reactions and in cases where the organic substrate degraded by prokaryotes is more reduced than their own biomass, then the contribution from CO_2 fixation can be even higher. For example, in methanotrophs it is up to 50% of the cell carbon. However, in contrast to photosynthesis and chemolithoautotrophy, the overall ecological role of heterotrophic CO_2 fixation remains unclear (Braun et al., 2021).

Carbon cycling in groundwater ecosystems

Whereas there are comprehensive estimates of the carbon pools and fluxes into and from major ecosystems of the world (e.g. Ciais et al., 2013), estimates for the subsurface mainly refer to remaining stocks of fossil fuels (coal, oil, gas) in the deep subsurface. Data for groundwater ecosystems are scarce and have not been compiled in a systematic way. For a fundamental understanding of groundwater ecosystems and its communities, we need a better knowledge of the carbon cycle from the local to the global scale. Below, we provide first simple estimates of carbon stocks in the subsurface compared to data from inland surface waters.

Based on estimates by Drake et al. (2018), inland waters receive about 5.1 Pg (10^{15} g = giga tons) of terrestrial carbon per year, of which 0.6 Pg $year^{-1}$ are stored in sediments, 3.9 Pg $year^{-1}$ are emitted to the atmosphere, and 0.9 Pg $year^{-1}$ are exported to the sea. Only about 0.3 Pg of organic carbon result from photoautotrophic production. Referring to these numbers, we may address a few open questions. (1) How much carbon enters and leaves groundwater ecosystems, and where does the exported carbon go? (2) How much carbon and what kind of carbon is stored in aquifers? (3) How much carbon is processed in aquifers, and (4) is the subsurface a sink or source for carbon and under what conditions?

Aquifers contain about 30% of all freshwater on earth, while 69% is stored in ice and snow, and less than 1% is stored in inland surface waters (Danielopol et al., 2003). Most of the groundwater is old and not involved in what we would call a modern hydrological cycle. Modern (≤50 years) and young (≤100 years) groundwater, as calculated by Gleeson et al. (2015), accounts for only 1.5% and 2.8% of the total groundwater, respectively, which still is 3.5 times and 6.3 times the volume of surface water. Downing and Striegl (2018) estimated turnover times of 10 years for groundwater to a depth of 25 m below land surface and 350 years to a depth of 100 m; the latter equals 3.1% of the total groundwater (8–23.4 million km^3). In consequence, the putatively

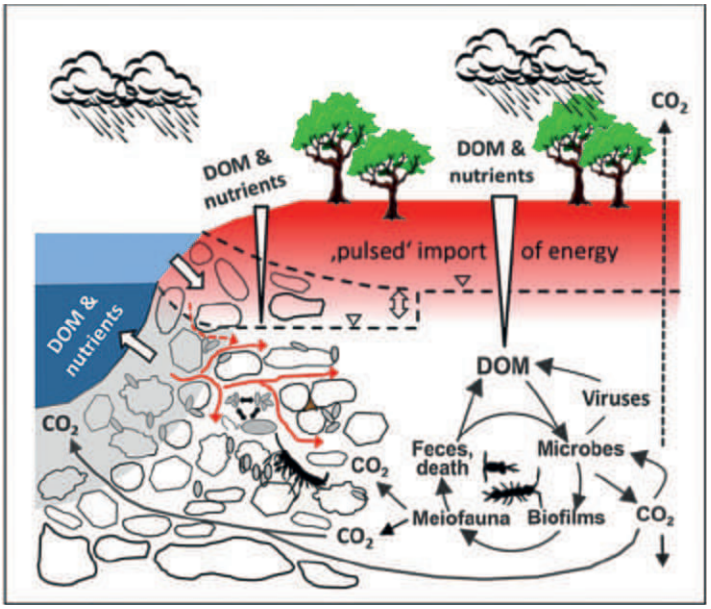

Fig. 2 Carbon cycling in groundwater ecosystems.

large stock of carbon in the subsurface (e.g. Whitman et al., 1998; McMahon and Parnell, 2014; Bar-On et al., 2018; Magnabosco et al., 2018) only partly participates in the 'modern' carbon cycle.

Import of organic matter (OM) into the subsurface is facilitated by precipitation and high water levels in rivers and streams. As such, influx of OM often occurs in irregular pulses (Fig. 2). Estimates of global groundwater recharge range from 5 to 497×10^3 km^3 year^{-1} (Gleeson et al., 2015). If we assume that seepage water that passes through soils and the vadose zone contains 1–2 mg dissolved organic carbon (DOC) L^{-1} and 30–40 mg dissolved inorganic carbon (DIC) L^{-1}, then 0.005 to 1 Pg DOC and 0.15 to 20 Pg DIC are entering aquifers each year. Downing and Striegl (2018) estimated that the global mass of carbon in groundwater (down to 2000 m) is about 145 Pg, which is about the same as all marine sediments and about one-sixth of the carbon in the ocean. Modern and young groundwater contains 2–9 Pg carbon. These values ignore any carbon in the sediments and rocks, which may account for several thousand peta gram. Magnabosco et al. (2018) assume 4–13 Pg biomass carbon in the terrestrial subsurface (to a depth of several kilometers). Although around 80% of the water discharged (exported) from aquifers comes from the top 40 m and 99% from the upper 100 m of the subsurface (Downing and Striegl, 2018), the overall transport of carbon into surface waters via groundwater discharge is estimated to be 0.68 Pg carbon year^{-1}, which is similar to that exported to the sea via river discharge. If we acknowledge that subterranean groundwater discharge to the oceans is 3–4 times that of rivers (Kwon et al., 2014), significant amounts of carbon from aquifers are exported to surface waters every year.

While the values provided here are broad estimates, dynamic changes of carbon pools and fluxes may be expected along with global and climate change. Here, one final example may highlight the immense gaps in knowledge of groundwater geochemistry we are facing. Groundwater is typically super-saturated in CO_2 and may contain significant amounts of methane (CH_4) (Bell et al., 2017) and dinitrogen oxide (N_2O) (Laini et al., 2011; Jurado et al., 2017). The quantitative contributions of greenhouse gases contained in groundwater to surface waters and into soil air, as well as its emission at springs or during irrigation of arable land with groundwater, have never been estimated in detail (e.g. Macpherson, 2009).

It is not only the quantity and flux of organic carbon into and through the subsurface that matters for our improved understanding of carbon cycling. Crucial are also the factors that determine the degradability of OM, such as composition, quality, and element stoichiometry. To date only a few studies have addressed the fate of OM in groundwater and its link to microbial carbon use efficiency and overall prokaryotic production (e.g. Baker et al., 2000; Shen et al., 2015; Hofmann and Griebler, 2018; Hofmann et al., 2020). Connected to that, all of our current ideas about the interactions within the groundwater microbial food webs are based on experience from surface waters, but have rarely been tested for groundwater.

Microbial loop and viral shunt – Bottom-up versus top-down control

Microbes are an integral part of groundwater food webs (Fig. 3). The available resources (e.g. organic matter and nutrients) and the biomass of primary producers (i.e. autotrophs) form the 'bottom' of the trophic pyramid, above them may be several trophic levels leading up to the highest order consumers at the 'top'. Ecological theory predicts two opposing, but co-existing forces occur in food webs: "top-down" control via predation/parasitism and "bottom-up" control via availability of resources regulating the number of trophic levels, the biomass in each level, and ecosystem productivity. The overall structure and dimensions of a food web are determined by the diversity of resources and environmental constraints.

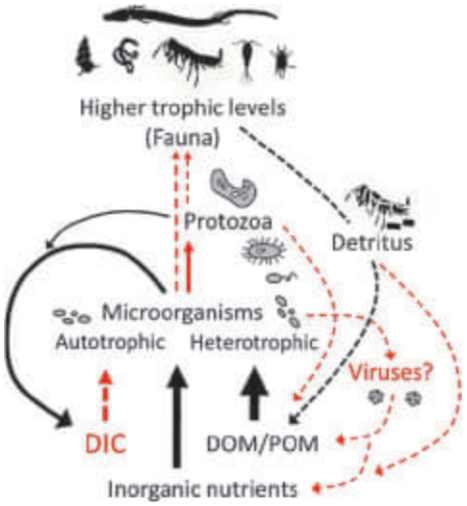

Fig. 3 Groundwater food web with a focus on putative interactions within the microbial food web.

Without doubt, in terms of functionality, aquifers are run by microbes. Ignoring chemoautotrophic primary production (discussed above), heterotrophic prokaryotes rely on DOC and are grazed by heterotrophic protozoa (flagellates, ciliates, amoeba) as well as being infected and lysed by bacteriophages (Fig. 3). In surface waters, top-down control by protozoa and viruses each removes 20–50% (in total 40–100%) of the daily prokaryotic biomass production. However, prokaryotic cell numbers in groundwater are 10–100 times less than in surface waters (Griebler and Lueders, 2009). This dramatically lowers the probability for predators to find their prey. As a consequence, the expected ratios of bacteria-to-protozoa (BPR) of 100 and virus-to-bacteria (VBR) of 10 in surface waters are not generally valid for groundwater and top-down control seems questionable (Karwautz et al., 2022; Schweichhart et al., 2022), with the exception of organically contaminated aquifers (e.g. Zarda et al., 1998; Kinner et al., 2002).

Natural groundwater ecosystems are most likely bottom-up controlled (Figs. 3 and 4) with prokaryotic production always limited by the amount of bioavailable DOC and/or co-limited by individual nutrients like phosphorus (Hofmann and Griebler, 2018). Within the microbial food web, heterotrophic nanoflagellates are the main grazers of prokaryotic cells; however, at a PBR of >500 (Zarda et al., 1998; Sintes et al., 2004; Karwautz et al., 2022). Production of prokaryotic cells and lytic phages seem decoupled (Schweichhart et al., 2022). Whereas in top-down controlled systems a predator or parasite maintains the biomass of prey below the carrying capacity of the system (Konopka, 2006), microbial biomass in groundwater may well reflect the system's carrying capacity (Fig. 4). However, many details remain unclear. As mentioned above, most studies to date have overlooked the importance of sediment-attached microbes, which is relevant here given that protozoa in aquifers are mainly sessile, while for viruses, adsorption to particles and surfaces may lead to (temporal) inactivation. Studies dissecting interactions in groundwater microbial food webs are without doubt urgently needed.

Research on microbes and fauna in groundwater ecosystems are still generally conducted separately, with only a few exceptions of studies in karstic environments in which a tight connection between microbial biofilms and stygo- and troglofauna has been

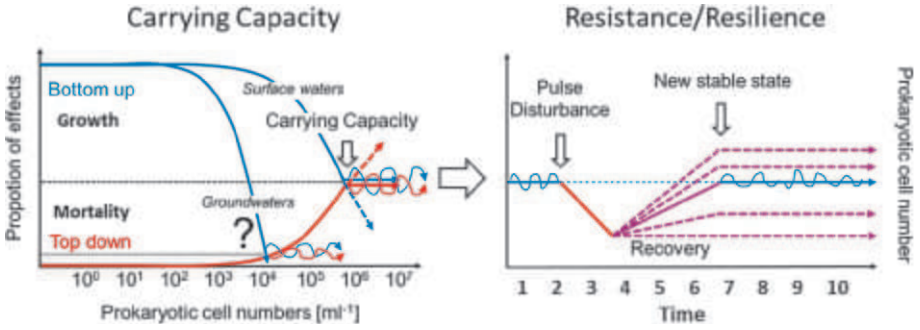

Fig. 4 Conceptual proposal for the microbial carrying capacity and the resistance and resilience of groundwater ecosystems. In comparison to surface waters, the microbial carrying capacity in groundwater is low and almost exclusively bottom-up controlled (left picture). Whereas in top-down controlled systems a predator or parasite maintains the biomass of prey below the carrying capacity of the system, microbial biomass in groundwater may well reflect system's full carrying capacity, taking into account multiple limitations. Environmental fluctuations are dampened in the subsurface causing only little fluctuation in microbial abundances (thin blue line). Microbial communities adapted to living in low-energy systems like groundwater can be expected to have low resistance to environmental changes and perturbations. A pulse disturbance changes community composition and functions (right picture). With time, a new stable state establishes, often with a new community composition and functions. Functions regularly fully recover when the disturbance (pollution) disappear. Community composition often do not return to ints original composition.

shown (Sarbu, 2000; Sarbu et al., 2000; Simon et al., 2003; Cooney and Simon, 2009; Hutchins et al., 2016; Saccò et al., 2019; Weitowitz et al., 2019). Such relationships have been suggested to exist also in sedimentary environments (Barlocher and Murdoch, 1989), but are not yet supported by empirical data. Taking into account that the microbial biomass in natural pristine aquifers is low and dense biofilms are largely absent, a detritus-based food web is more likely than a food web based on microbial production alone.

The 'missing link' between microbes and fauna

Animals are a hot spot of organic carbon and nutrients and provide a habitat for microorganisms. Early investigations on the microbiome of aquatic invertebrates have mainly focused on marine environments (Harris, 1993). A lack of concepts, process-oriented studies and the persistent interest in the role of microorganisms in the physiology of their hosts has propelled this research topic in the recent past (Petersen and Osvatic, 2018). In particular, the development of molecular tools and the start of the "omics era" have enabled research into eco-evolutionary dynamics and processes. A prominent example is the hologenome theory, based on the hypothesis that selective forces act on the collective genomes of the organism (e.g. host) and its associated microbial community (Zilber-Rosenberg and Rosenberg, 2008). In nature, some tight connections between the host and the gut microbiome are known (Engel and Moran, 2013; Ceja-Navarro et al., 2019), while some organisms seem to be unaffected by the often transient microbial communities (Hammer et al., 2019).

The strength and specificity of host-microbe interactions may vary with time. For example, microbes that colonize the exterior will be shed during molting, intestinal bacteria may be released with feces, and different microbial communities are involved in the degradation of dead host biomass (Tang et al., 2010) (Fig. 5). Moreover, host microbiomes can be specific to different life stages (Reis et al., 2020). However, the influence of environmental factors, ontogenetic and evolutionary time scales, and life history traits on these symbiotic interactions remain largely unknown in nature (Leung and Poulin, 2008). Studying host-microbe consortia and interactions may give new insights on the fitness (e.g., reproduction, longevity, nutrient scavenging, parasites) of groundwater fauna. For example, syntrophic relationships between ectosymbiotic bacteria and groundwater amphipods provide the bacteria with mobility, an active dispersal mechanism, and access to favorable conditions as the host seeks its own nutrient resources. The bacteria provide the crustaceans a ready food source and detoxification (Dattagupta et al., 2009; Smith et al., 2016). Additionally, endosymbiotic prokaryotes can use a host as a refugium against environmental stress (Fig. 5). This trojan horse hypothesis is well established and typified by the interaction of pathogenic *Legionella* sp. inside amoeba and ciliates (Taylor et al., 2009). Certainly, all stygobionts constitute niches and opportunities for the interaction with microorganisms, and may act as important bioreactors, and stores of energy and resources (Fig. 5).

The gastrointestinal tract and hemolymph appear to be the preferred organs for endosymbiotic colonization in aquatic invertebrates. So far, the bacteria have been the focus of microbiome studies, but it is well known that viruses, protozoa, and fungi may also be involved (Anderson and May, 1981). Several important, yet unanswered research questions relate to the trophic specialization of groundwater invertebrates and their associated microbiome. How are the microbiomes transmitted? How are the invertebrates, microbes and viruses interacting? Symbiotic relationships are now investigated in the light of network interactions between the host, the endosymbiont, and the wider microbiome, which are all affected by the environmental conditions (Brinker et al., 2019). These interspecies relationships are likely to be dynamic. Consequently, many symbioses do not fit into the traditional categories of mutualism, commensalism, or parasitism.

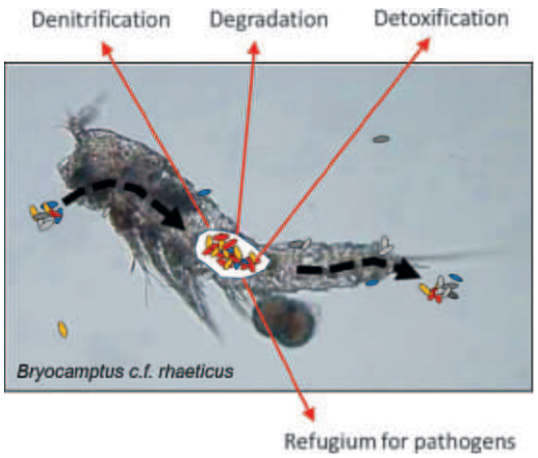

Fig. 5 The microbiome of groundwater invertebrates as hotspot of key processes.

Resistance, resilience and vulnerability

Pristine aquifers are generally characterized by relatively stable environmental conditions and low levels of nutrients and energy compared to surface environments (Gibert et al., 1994). These constraints have a large impact on microbial community composition by selecting for organisms that are adapted to living and competing in such stable, oligotrophic environments. Coping with environmental stress consumes energy and can reduce the metabolic flexibility of microorganisms as well as their ability to compete for nutrients (Ferenci and Spira, 2007). Hence, microorganisms adapted to living in groundwater can be expected to have low resistance to environmental changes and perturbations. Indeed, low resistance of microbial communities in situ and in experimental aquifer meso- and microcosms have been demonstrated with respect to sudden contamination with high loads of hydrocarbons (Herzyk et al., 2017; Ma et al., 2015a, b; Zhou et al., 2014), micropollutants such as herbicides (Mauffret et al., 2017) and antibiotics (Haack et al., 2012), or surface water intrusion (Fillinger et al., 2021). A common pattern that has emerged from those studies is that changes in microbial community composition is driven by loss and replacement of resident taxa following perturbations. To date, few studies have investigated microbial community resilience, i.e., the ability to recover to their original state in terms of composition and functions once a perturbation has ceased. However, there is evidence suggesting that changes in community composition caused by perturbations can persist for long periods of time, if not permanently, even if the initial stressor is removed (Herzyk et al., 2017; Ma et al., 2015a, b; Zhou et al., 2014). Recovery of functions may take place in more reasonable time scales (weeks to months).

The link between microbial community composition and function is not always clear, and loss of resident taxa following a perturbation may in some cases be compensated on a functional level through immigration of functionally similar taxa (Konopka et al., 2015). However, there are examples of low functional resistance and resilience of groundwater microbial communities (Ma et al., 2015b; Zhou et al., 2014). Nevertheless, overall understanding of the resistance and resilience of groundwater microbial communities, and the role of functional redundancies remains limited.

Besides the need for a better understanding of the impact of perturbations on community functioning, we still lack a more nuanced approach to investigating microbial community resistance and resilience with regard to different types and intensities of perturbations. For instance, short-term perturbations occurring as pulses (e.g. pulses of surface water during a flood) may affect communities differently to persistent pressures occurring over longer time scales (e.g. chronic exposure to contaminants; increasing groundwater temperatures resulting from climate change, urbanization, or heat discharge) (Fig. 4). Applying ecological frameworks of community resistance and resilience to targeted studies of press versus pulse disturbances will be key to understanding the responses of groundwater microbial communities to environmental pressures, identifying tipping points, and designing countermeasures (Shade et al., 2012).

Finally, the ability to buffer the loss or inactivation of resident taxa in a microbial community following a perturbation critically depends on the recruitment of microorganisms from surrounding unaffected areas via dispersal (Comte et al., 2017; Ferrenberg et al., 2013; Székely and Langenheder, 2017). Therefore, the integration of theoretical concepts from metacommunity ecology (Langenheder and Lindström, 2019; Leibold et al., 2004) and microbial community coalescence (Mansour et al., 2018; Rillig et al., 2015) as well as tools such as community assembly models (Stegen et al., 2013) and microbial source tracking (Knights et al., 2011; Shenhav et al., 2019) are valuable means to assess the potential of microbial communities to be recolonized following perturbations.

Biodiversity and ecosystem functioning

Understanding how microbial community composition and diversity (e.g. taxon richness) relate to ecosystem functioning is one of the central questions in microbial ecology in general (Antwis et al., 2017), which, however, has rarely been addressed in groundwater ecosystems. Although functional redundancy and horizontal gene transfer may blur this relationship in certain cases (Martiny et al., 2015), microbial taxonomic richness is often positively correlated with functional diversity, for example, in soil and sea water (Fierer et al., 2013; Galand et al., 2018). Moreover, experiments with lake water microbial communities have shown that increasing taxon richness can enhance respiration rates and broaden the spectrum of carbon sources that can be degraded by a community (Zha et al., 2016). Considering these findings, it is reasonable to assume that high microbial diversity at least bears the potential to increase functional diversity and accelerate biogeochemical processes. However, the actual effect of diversity may vary depending on the process in question (Graham et al., 2016) as well as substrate availability and microbial interactions (Langenheder et al., 2010).

Especially in anoxic groundwater, microbial diversity and the interaction between different functional microbial guilds appear to be essential for key processes such as the turnover of organic matter and electron acceptors. Different stages of nutrient and energy cycles are driven by metabolic handoffs between different microbial taxa that would be unable to conduct the complete cycle in isolation (Anantharaman et al., 2016; Wrighton et al., 2014). Similarly, anaerobic hydrocarbon degradation is driven by syntrophic interactions between primary degraders and terminal electron-accepting species (Kleinsteuber et al., 2012; Lueders, 2017; Lueders and Táncsics, 2022). Reductive dehalogenation of chlorinated organic contaminants also relies on interactions between fermenting organisms that provide suitable electron donors and cofactors for specialized dehalorespiring organisms (Weatherill et al., 2018; Yan et al., 2013).

The examples above suggest that at least a certain microbial diversity is necessary to sustain important ecosystem functions in groundwater. However, we still lack information on whether functional diversity scales with taxonomic richness as shown for other environments (Fierer et al., 2013; Galand et al., 2018). Apart from biogeochemical processes, diversity is also important for ensuring community stability in response to environmental fluctuations and disturbances. Here, organisms that may be rare or dormant at a given time or under certain conditions, may play a critical role in maintaining long-term community functioning under changing conditions (Jousset et al., 2017; Lennon and Jones, 2011; Shade et al., 2014). However, the role of conditionally rare taxa and their contribution to microbial community diversity and function in groundwater are still largely unexplored (see discussion on 'ecological laws' below).

Biogeography in microbes – Where do they come from – Everything is not everywhere

Aquifers are hydrologically connected to the surface, even though exchange times may vary strongly depending on depth and geology. At a coarse taxonomic resolution (e.g. phylum, class, order, genus), microbial communities in groundwater often contain organisms that are common in surface freshwaters or soil (Akob and Küsel, 2011; Griebler and Lueders, 2009). However, the characteristic environmental conditions in groundwater act as an environmental filter that only allows a fraction of the microorganisms derived from the surface to colonize and establish in aquifers (Fillinger et al., 2021; Graham et al., 2017; Herrmann et al., 2019). Consequently, at a finer taxonomic resolution, microbial communities in groundwater can be distinct from other habitats (Smith et al., 2012) and markedly different even from communities in connected surface waters or overlying soil (Fillinger et al., 2021; Graham et al., 2017; Herrmann et al., 2019).

Microbial communities in groundwater not only differ from communities in other habitats, but they can also show distinct compositions between different aquifers. So far only a few studies have compared microbial communities across geographically distinct aquifers, mainly based on 16S rRNA gene amplicons (Ben Maamar et al., 2015; Danczak et al., 2018; Fillinger et al., 2019; Korbel et al., 2022), but also species-level comparisons based on MAGs (He et al., 2021). These studies unanimously showed little overlap in microbial community compositions between aquifers. While differences in environmental conditions and microbial interactions likely were the primary factors that selected for distinct organisms at each site in those studies, neutral processes like dispersal limitation across aquifers and ecological drift can be significant contributors to observed differences in microbial community composition (Danczak et al., 2018; Fillinger et al., 2019).

The fact that dispersal limitation does affect microbial community composition across aquifers (particularly shallow aquifers as cited above), is an indication that "everything is not everywhere". We expect that this must especially be true for microorganisms in aquifers at depths of several kilometers with water residence times of millions of years (Chivian et al., 2008; Lin et al., 2006; Nyyssönen et al., 2014). These environments have been habitable for ~1 billion years and were likely colonized by microorganisms from the surface via rock fissures in the ancient past (Drake and Reiners, 2021). While reasoning would suggest that evolutionary drift should play a strong role in the diversification of microbes across different deep subsurface zones, recent evidence suggests that this might not necessarily be the case. Evolutionary rates in the deep subsurface may be extremely slow, leading to the conservation of microbial lineages in different parts of the globe over geological timescales (Becraft et al., 2021).

While we are starting to better understand the factors that determine microbial community composition within as well as across aquifers, several biogeographic patterns of species diversity that are frequently observed in classical ecology, such as species-area relationships, gradients of species richness along latitude, altitude, and depth, or richness-productivity relationships, still await being assessed in groundwater microbial ecology. In addition, we are still lacking insight into the global distribution of individual taxa in groundwater. To tackle this issue, studying microorganisms at a sufficient taxonomic resolution is key. We now know for microorganisms in surface environments that similar habitats in different regions can harbor distinct microbial ecotypes with virtually identical 16S rRNA genes but different environmental optima and metabolic properties (Chase et al., 2018; Choudoir and Buckley, 2018; Hahn et al., 2016; Larkin and Martiny, 2017). However, only a few studies to date have looked into the diversity and distribution of microorganisms in groundwater at the species or sub-species level using genome-resolved analyzes, for instance based on MAGs or single-cell genomics (He et al., 2021; Probst et al., 2018), leaving room for further exploration in the future.

Ecological concepts and laws

Several prominent scientists stated that microbial ecology lags behind macroecology in terms of a conceptual framework, with general principles and ecological laws missing (e.g. Konopka, 2006; Prosser et al., 2007). However, there are a number of theories and principles that have been established in microbial ecology, in some cases their origin indeed is in macroecology. One of the few universal laws in ecology (Lawton, 1999) is the relationship between species richness and habitat size. Data supporting this taxa-area relationship (Fig. 6) are available for bacteria in surface waters (Reche et al., 2005) and salt-marsh sediments (Horner-Devine et al., 2004), but so far not for groundwater ecosystems (Griebler and Lueders, 2009). Microbial phylogenetic and functional diversity was suggested to peak at intermediate intensities or frequencies of disturbances (Ibekwe et al., 2002; Fierer et al., 2003). Today, the intermediate disturbance hypothesis (Connell, 1978) is controversially discussed in particular in aquatic ecology (Moi et al., 2020). Disturbances in aquifers can be the result of multiple concurrent stressors, including hydrological events and pollution (e.g. Bugnot et al., 2019). Although there are numerous studies focusing on microbial communities in disturbed

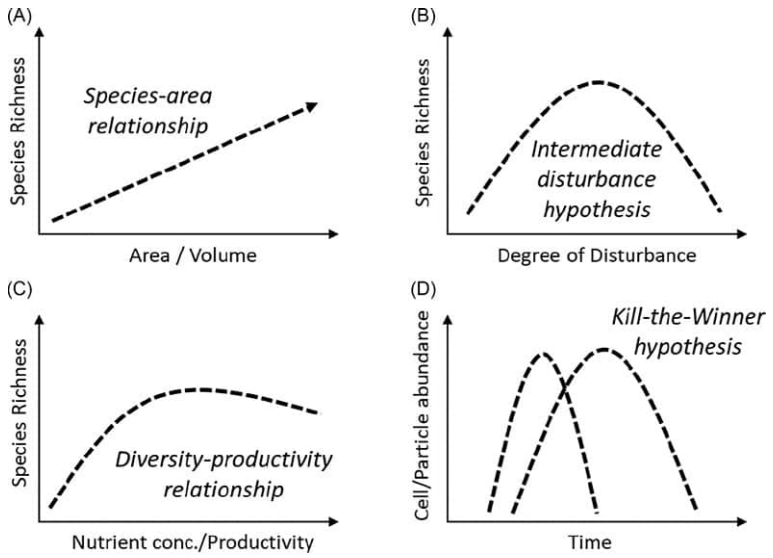

Fig. 6 Ecological principles and laws that await to be tested in different groundwater ecosystems.

groundwater systems, only a few have addressed ecological concepts such as the intermediate disturbance hypothesis, the functional redundancy concept (Allison and Martiny, 2008), and the insurance hypothesis (Baho et al., 2012; Awasthi et al., 2014). In the same way we may mention the diversity-productivity relationship (Smith, 2007) and the Kill-the-Winner hypothesis (Winter et al., 2010). In conclusion, repeating the lines of Larned (2012), tests of causal hypotheses, which characterize more mature branches of ecology, are rarely undertaken in groundwater ecology. Many principles and patterns established in other fields of ecology await testing in groundwater ecosystems (Griebler and Lueders, 2009).

Conclusions

Microbial ecology is a rapidly evolving discipline, perhaps more than other branches of ecology, as new technologies and declining costs are transforming our ability to characterize communities and identify and quantify their functions. While the discipline moves forward, there remain a suite of key research questions that are specific to groundwater ecosystems that require urgent further research. The often stable and simplified groundwater environment provides a unique test bed for experimentation and observation, and provides opportunities for progressing deep-seated ecological theories.

Addressing the questions discussed here will undoubtedly progress understanding of microbial and groundwater ecology, but will also have immense social and economic benefits given the importance of groundwater microbes to water quality and the delivery of ecosystem services on which the majority of earth's population relies.

Klement Tockner is director general of the Senckenberg Society for Nature Research and professor for ecosystem sciences at Goethe University, Frankfurt am Main. He was president of the Austrian Science Fund—FWF (2016–20), full professor for aquatic ecology at the Free University Berlin (2007–20), and director of the Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin (2007–16). He received a Ph.D. from the University of Vienna (1993) and a Titulary Professorship at ETH Zürich (2005).

Klement Tockner is an internationally leading freshwater scientist, in particular in the research domains biodiversity, ecosystem science, and environmental management. He has published about 250 scientific papers including 180 ISI papers. He was editor-in-chief of the journal *Aquatic Sciences* (2005–2014) and is subject editor of the journal *Ecosystems*. He has published about 250 scientific papers including 180 ISI papers. In 2009, he edited a comprehensive book on European Rivers (Rivers of Europe, Elsevier; 2nd Edition in 2021). He is elected member of the Austrian Academy of Sciences and the German Academy of Sciences, Leopoldina.

Thomas Mehner is vice director and senior researcher at the Leibniz Institute of Freshwater Ecology and Inland Fisheries in Berlin, Germany. He is limnologist and fisheries biologist by training, and has got his Diploma and Ph.D. at the University of Rostock (formerly East Germany) in 1992. In 1999, he had received his habilitation and venia legendi in limnology, which allowed him to start teaching as Privatdozent at universities. Since 1997, he has been working at IGB in several positions. He has published about 170 ISI papers, with primary focus on fish communities, lake food webs, and species interactions. However, his topical interests are broader, and he has authored and co-authored several publications on freshwater fisheries management, fish population genetics and evolutionary and behavioral ecology of aquatic organisms. He has been Handling Editor of the journals "*Aquatic Ecology*" and "*Freshwater Biology*" for several years, and he is currently member of the Editorial Boards of "Global Change Biology" and "Limnologica." Since spring 2018, he has been the president of the International Society of Limnology (SIL), the oldest and most international scientific society devoted to the study of inland waters. Thomas Mehner has taught M.Sc. courses at universities on limnology, fish ecology, fisheries management, and behavior and evolution. His one-week course on "Scientific Writing" for Ph.D. students has been run at 3 universities and in total 18 times, with >120 international students participating. He has trained many M.Sc. and Ph.D. students and supervised their theses, and he is actively mentoring undergraduates, graduates, and post-doc researchers.

EDITORIAL BOARD

Editorial Board Names and affiliations

SECTION EDITORS

Damien Bouffard is leader of the aquatic physics lab at Eawag (Switzerland). He holds a Ph.D. from EPFL (with Ulrich Lemmin). After his Ph.D. he worked in Canada with Leon Boegman (Queen's U.), Ram Yerubandi (Environment Canada), and Joe Ackerman (Guelph U.) before returning to Switzerland as first assistant at EPFL with Alfred (Johny) Wüest. He has published over 70 peer-reviewed papers in aquatic physics and serves as associate editor for JGLR, AS, and HESS. His program research is focused on two axes: (i) linking the small-scale turbulence to the large-scale forcing with today a special interest in convective processes in lakes and (ii) aquatic physics as a tool to understand lake ecosystems. The later includes the use of 1D and 3D operational hydrodynamic models such as simstrat.eawag.ch or meteolakes.ch. Bouffard is also involved in promoting multidisciplinary and high-tech research on lakes, notably as member of the steering committee of the LéXPLORE floating research platform in Lake Geneva and in promoting open science in limnology with the web platform Datalakes-eawag.ch.

Debbie Chapman as a graduate of the University of London, Deborah Chapman started her research career as limnologist at the Freshwater Biological Association in the English Lake District. She subsequently became interested in monitoring the impacts of disposal of sewage sludge on aquatic organism and the potential for human health impacts from aquatic pollution. In 1986 she joined the United Nations Environment Programme's (UNEP) Monitoring and Assessment Research Centre (MARC) in London, participating in the international monitoring and assessment activities of UNEP and the World Health Organization (WHO), and assisting in global environment assessment programs. In 1988 she became the deputy director of MARC and took responsibility for the developing country workshops and training program, and global environment data review and compilation. After moving to Ireland in 1990, she worked as a freelance Environmental Consultant engaged mostly on international and developing country projects for WHO, UNEP, and other international organizations. She has assisted with the compilation of State of the Environment reports and has contributed to, edited, and produced more than 20 books on water resources and environmental management, including the internationally successful *Water Quality Assessments: A guide to the use of biota, sediments and water in environmental monitoring.*

In 1998 she joined UCC becoming the first lecturer in Environmental Science and then Head of Environmental Science in 2013. In recent decades her research interests have focused on water resources management, especially recreational and amenity lakes and reservoirs, developments and current practice in design and implementation of water quality monitoring programs, and human health risk assessment in relation to the use of freshwater resources and wastewater disposal. Drawing on 30 years of international experience, in 2015 she established the UNEP Global Environment Monitoring System for Water (GEMS/Water) Capacity Development Centre at UCC. This center delivers capacity development activities in water quality monitoring and

assessment worldwide for UNEP, including support for the Sustainable Development Goal indicator for good ambient water quality. She retired as director of the center in June 2021 and now acts in an advisory role and as an independent consultant.

Kendra Spence Cheruvelil is professor of limnology and co-director of the Data-intensive Landscape Limnology Laboratory at Michigan State University (MSU) in the Department of Fisheries and Wildlife (https://www.canr.msu.edu/fw/). She is also serving as Interim Dean of the Lyman Briggs College, which is MSU's residential college for studying the sciences and maths within their societal and global contexts (www.lbc.msu.edu). Kendra co-established the discipline of landscape limnology (https://bigdatalimno.org/research-themes/landscape-limnology/) and co-leads the LAGOS research program that is creating the research infrastructure to conduct big-data research on U.S. lakes (https://lagoslakes.org/). This large, collaborative, and interdisciplinary research program has been funded by the U.S. National Science Foundation and seeks to understand how global changes such as climate change and land use intensification affect lakes across regions and continents and through time. Dr. Cheruvelil also pushes the boundaries of how to conduct limnology research by using data-intensive science, science of team science, and open science approaches, tools, and perspectives to answer complex scientific questions. She also has an active research program to advance diversity and inclusion in the sciences (https://ee-stem.weebly.com/) and serves as an associate editor for the journals *Limnology & Oceanography Letters* and *Frontiers in Ecology & the Environment*. Prior to joining MSU, Dr. Cheruvelil was a faculty member in the Purdue University system. She has a dual Ph.D. from MSU in Fisheries & Wildlife and Ecology, Evolution, & Behavior (2004).

Catherine Febria is a Tier 2 Canada Research Chair in Freshwater Restoration Ecology and assistant professor at the Great Lakes Institute for Environmental Research (GLIER) & Dept. of Integrative Biology at the University of Windsor. Her research focuses on the ecology and restoration of small streams and wetlands in human-impacted landscapes, and the role of small waterways in supporting good ecosystem health in the Laurentian Great Lakes. She launched her lab—the Healthy Headwaters Lab—in 2019 and also wears multiple hats as co-director of the GLIER Organic Analysis & Nutrients Laboratory (a central research facility), associate director of FishCAST (an NSERC CREATE graduate student training program in Canada), co-chair of the International Science Advisory Panel for New Zealand's Biological Heritage National Science Challenge, coordinating editor with the journal *Restoration Ecology* and alumni fellow and contributing author with the Intergovernmental science-policy Platform on Biodiversity and Ecosystem Services (IPBES). She previously held a postdoctoral role at the University of Maryland's Chesapeake Biological Laboratory (USA), the University of Canterbury (Aotearoa New Zealand). Her research has been published in the *Science*, *Nature Geoscience*, *Canadian Journal of Fisheries and Aquatic Sciences*, *Environmental Science & Technology*, and *Frontiers in Microbiology*, *Restoration Ecology*, *Proceedings of the Royal Society*, to name a few. She is co-founder of the Kindness in Science global initiative, and contributes actively to actions, scholarship and mentorship to advance justice, equity, diversity, and inclusion in academia.

Christian Griebler is full professor and head of the Limnology unit at the University of Vienna, Austria. He is a dedicated groundwater ecologist with core expertise in microbial ecology and biogeochemistry.

Kenneth Irvine has a broad range of multidisciplinary experience working on aquatic ecology, ecological assessment of surface waters, especially lakes and wetlands, and policy and related policies and management. After gaining a Ph. D. in 1987 at the University of East Anglia (U.K.) for a study on trophic ecology of shallow lakes, he worked for the U.K. Nature Conservancy Council, before moving to study ecosystem structure of Lake Malawi in Africa. He moved to Trinity College Dublin in 1994 Ireland. There, he continued work on the African Great Lakes, as well as building a research group working on ecological assessment in support of the EU Water Framework Directive. In 2011 he moved to IHE Delft Institute of Water Education, the Netherlands, as chair of Aquatic Ecosystems. Current work focusses on wetlands and capacity development in Sub-Sahara Africa. Recent work also includes a review of hydromorphology and links to policy. He currently sits on the Board of the Board of the *African Center for Aquatic Research and Education* (ACARE) and on the Scientific Advisory Board of the *Leibniz Institute of Freshwater Ecology and Inland Fisheries* (IGB), Berlin.

Wolfgang Junk was scientist of the Max-Planck-Institute for Limnology, Dep. Tropical Ecology, Plön during 1970–75.He was scientist of National Amazonian Research Institute, leader of the Dep. of Hydrobiology and Inland Fishery at Manaus, Brazil during 1976–79. and leader of the Working Group "Tropical Ecology" at the Max Planck Institute for Limnology in Ploen, Germany during 1980–2007.He is expertise in ecology and sustainable management of floodplains, land-water interactions, wetland classification. His main research areas arestudies on biomass, primary production, and decomposition of wetland plant communities; nutrient fluxes between land and water; adaptations of plant and animals to periodical drought and flooding; ecology of aquatic macrophytes and fish communities; biodiversity; conceptional considerations on river-floodplain systems, sustainable management of wetland resources and wetland protection with emphasis on the Amazon River floodplain and the Pantanal of Mato Grosso, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 300 peer-reviewed publications, including several books and book chapters on Amazonian wetlands and the Pantanal of Mato Grosso. He received many honors, among them the Award of the Grande Cruz (the highest distinction of Brazil) for exceptional scientific performance, and the Cross of Merit First Class of the Federal Republic of Germany. He is corresponding member of the Academy of Sciences of Brazil.

Krantzberg is professor and lead for the engineering and public policy in the School of Engineering Practice and Technology at McMaster University offering Canada's first master's degree in engineering and public policy. Gail completed her M.Sc. and Ph.D. at the University of Toronto in environmental science and freshwaters. She worked for the Ontario Ministry of Environment from 1988 to 2001, as coordinator of Great Lakes Programs, and senior policy advisor on Great Lakes. Dr. Krantzberg was the director of the Great Lakes Regional Office of the International Joint Commission from 2001 to 2005. In 2007 she was appointed as an adjunct faculty member of the United Nations University Institute for Water and Environmental Health and participated in the twinning of the Laurentian and African Great Lakes (principally Lake Victoria). She has co-authored and edited 9 books and more than 200 scientific and policy articles on issues pertaining to ecosystem quality and sustainability and is a frequent speaker to media and the public. Her research interests include investigating Great Lakes governance capacity, analyzing interjurisdictional co-management arrangements internationally for application to the Great Lakes regime, and methods to better integrate science and engineering in policy formulation and decision-making.

Marie-Elodie Perga is associate professor of limnology at the University of Lausanne in Switzerland. Since receiving her Ph.D. from the University of Savoie-Mont Blanc (France), she has worked at the University of Victoria in Canada, and the French National Institute for Agronomy and Environment (France), before moving UNIL.

Because she is a Lindeman's groupie, her research lies at the interface of community ecology and biogeochemistry, through lake food webs and carbon processes. More recently, she added a pint of hydrodynamics with the intent to bridge physical and biogeochemical mechanisms, especially in alpine and high-altitude lakes. Her work covers centennial up to minute timescales through the combination of high-resolution paleo-records and high-frequency data from autonomous sensors.

She is also involved in promoting high-tech research on lakes, notably as a member of the steering committee of the LéXPLORE floating research platform in Lake Geneva, and in connecting science and management through a transdisciplinary network involving National Parks in France. She has published over 75 peer-reviewed papers and serves as associate editor for WIRES Water.

N. LeRoy Poff is professor of biology at Colorado State University and holds a partial appointment as distinguished professor at the University of Canberra, Australia. Since receiving his Ph.D. in 1989, his research has focused on understanding how natural and human-caused hydrologic variability regulates the interactions among species and the structure and function of riverine ecosystems. By developing techniques to quantify streamflow variability in ecologically meaningful terms and using species (functional) traits as generalized, mechanistic response variables, he has been a leader in advancing the field of hydroecology. Through his interdisciplinary and collaborative work, he has contributed fundamentally to the development of the field of "environmental flows," which aims to support sustainable management of streams and rivers at local to regional to global scales in the face of growing human water demands. His current interests are on developing better conceptual frameworks and decision support tools for science-based management of streams and rivers in our current period of rapid climate and ecological change.

Lars Rudstam is professor of fisheries and aquatic sciences in the Department of Natural Resources and the Environment, Cornell University (USA) and the director of the Cornell Biological Field Station. He has a master's degree from the Center for Limnology, University of Wisconsin-Madison and a Ph.D. from Stockholm University, Sweden. Rudstam has published over 250 papers ranging from lake physics to phytoplankton, zooplankton, mussels, mysids, fish, birds, and anglers, mostly about processes associated with food web interactions and ecosystem dynamics. He has worked in lakes in North America, Europe, and Asia as well as the Baltic Sea.

Stuart Warner works with the United Nations Environment Programme with a focus on helping countries to monitor and assess their freshwaters. He was born in England, he moved to Ireland in 2001 to work at University College Cork. Stuart has published in the areas of water quality monitoring and assessment and citizen science approaches to data collection. He has written reports on the capacity of countries to understand their freshwaters which highlight the challenges faced in different world regions. Recent efforts have focused on the development and implementation of a global water quality indicator, and the delivery of capacity development targeted at improving freshwater management. His professional interests include using both traditional and innovative approaches to understand and protect freshwater ecosystems.

Florian Wittmann is professor for physical geography and head of the Department of Wetland Ecology at the Karlsruhe Institute for Technology, Germany. He studied geography, geology, and botany at the Universities of Mannheim and Heidelberg, got his Ph.D. in physical geography at the University of Mannheim, and his lecturer qualification at the University of Bayreuth, Germany. He held post-doc positions at the Max Planck Institutes for Limnology and Chemistry, Germany, where he was working at the bilateral project between the Max Planck Society and the National Institute for Amazonian Research in Manaus, Brazil, for more than 15 years.

His research focuses on neotropical wetlands, with special interest in biogeography, plant species distribution, species diversity, forestry and sustainable management, remote sensing, biomass and primary productivity, and botany and vegetation ecology. Actually, he teaches at the Institute for Geography and Geoecology of the Karlsruhe Institute for Technology, Germany, and in the post-graduate program of Tropical Ecology—Botany at the National Institute for Amazon Research—INPA, Manaus, Brazil. He supervised numerous M.Sc. and Ph.D. students and published more than 150 peer-reviewed publications, including several books and book chapters on Amazonian wetlands.

CONTENTS OF VOLUME 4

Human pressures and management of Inland Waters

This page intentionally left blank

Section introduction: Human Pressures and Management of Inland Waters

Kenneth Irvine[a,b], Stuart Warner[c], and Deborah V Chapman[c], [a]IHE Delft, Institute of Water Education, Delft, The Netherlands; [b]Aquatic Ecology and Water Quality Management, University of Wageningen, Wageningen, The Netherlands; [c]UNEP GEMS/Water Capacity Development Centre, Environmental Research Institute, University College Cork, Lee Rd, Cork, Ireland

Overview of section

Human pressures leading to degradation of inland waters are multiple, widespread, interacting and increasing (Dudgeon et al., 2006; Tickner et al., 2020; Vörösmarty et al., 2010). Pressures occur across a range of scales from global to extremely local, and arise from drivers that can occur far removed (distal) from a water body or close to (proximate) where the impact occurs (van Asselen et al., 2013). The chapters of this section of the Encyclopedia address *Human pressures and Management of Inland Waters* and have been generally organized so that an overview of a particular human pressure is followed by a chapter elaborating some key issues, and a chapter of either illustrative case studies or an important associated topic. The topics covered mostly reflect those pressures that are of current and known concern. For some of these, such as agriculture, the level of understanding is quite advanced while for others, such as emerging chemical micropollutants and microplastics, research is still identifying potential and real impacts.

The first series of three chapters is concerned with Measuring Impact, with a focus on how assessment is based on a comparison with estimated reference states (Irvine, 2022), followed by the use of biotic indicators and rapid assessment through use of citizen science (Simaika et al., 2022). The application of citizen science and underlying philosophies and methodology is a growing discipline involving greater understanding of the motivation of citizens and how measurement taken by citizens can help with environmental monitoring and co-management. This is covered by Wehn (2022).

Agriculture is a major pressure on inland waters; an overview is provided by Vero and Fenton (2022) and best practices for the protection inland waters are illustrated by Pacioglu et al. (2022). A series of case studies addresses different pollutant risks and their management (Vero et al., 2022). Potential impacts from agriculture can also involve a number of physical modifications that affect the rate of transfer of water and material from land to water, and modification of, especially, river channels. The effects of such *hydromorphological* alterations are an increasing topic of importance for the management of land and water, and across scales from that of the catchment to individual parts of water bodies. An overview of hydromorphology and the impacts of human pressures on it, focusing mainly on rivers, is provided by Sandin and Kemp (2022), and Miler, 2022) discusses how hydromorphological alterations affect different habitats and interact with other pressures. Case studies from individual water bodies to whole catchments are described by Porst (2022), identifying many of the challenges that these changes have for management. The hydromorphology theme is highly relevant to the next three sub-themes on Hydropower and Dams, Mining Impacts, and Sediment Extraction; illustrating how so many human pressures on inland waters are interconnected. Management of these can be addressed by strong sector regulation, but are often bedeviled by multisectoral interests and diverse groups of stakeholders, operating within formal or informal institutions (Cleaver and De Koning, 2015).

An overview of the evolving perspectives on hydropower, focusing on the need to balance societal benefits and environmental aspects is given by Bradley (2022). This is followed by a case study on the Danube River by Bradley and Habersack (2022), illustrating some of the difficulties posed by hydropower on large rivers with many international interests in their catchments. Hayes et al. (2022) highlights hydropeaking (an important but understudied hydromorphological pressure) and its consequences for balancing ecosystem needs and energy generation from dams. These are complemented by a chapter on case studies in hydropower sustainability by Ulibarri et al. (2022), including the improvements that are being made to small hydropower schemes. At the other end of the scale is the mega hydropower development of the Three Gorges dam in China, which also has associated impacts on the water quality of the impounded reservoir and its tributaries, described by Zhang (2022).

Impact from, and management of, mining is covered by an overview by Wolkersdorfer and Mugova (2022) and case studies addressing different mining operations by Wolkersdorfer et al. (2022). In-between, a chapter by Esterhuse et al. (2022) focuses on environmental damage and future risks from hydrocarbon extraction. The extraction of sediment from water bodies is of increasing concern. Despite being widespread, it has not had the attention, or global management, that this pressure requires. Like some mining practices in the world, it is often executed by an informal sector, often involving illegalities and criminal enterprises.

An overview by Juez and Franca (2022) outlines the key issues, followed by a policy perspective by Bussettini and Schmidt (2022). Both chapters demonstrate that the knowledge base to effectively manage sediment extraction (often referred to as sand mining) is lacking basic principles of sediment movement in rivers, and is not properly considered in environmental planning and management. Clear recommendations of good practice and licensing processes are, nevertheless, available and implemented in some countries. The case studies by Franca et al. (2022) illustrate the dramatic consequences when there is insufficient attention to principles of hydromorphology and sediment mobility. While sediment extraction may not be new phenomenon, there are also many new or recently emerging pressures on inland waters, and for which management approaches and policies to address the problems are still developing. Emerging organic contaminants are covered by Bacci and Campo (2022), and microplastics, a topic that is very much building in global awareness, by Jansen et al. (2022). These pressures are still a matter of much ongoing research into their detection, distribution and potential impacts on freshwater ecosystems and on human health, in order to effectively monitor and manage them and to support policy development and the necessary policy interventions.

Man-made constructed wetlands can play an important role in mitigating impacts from contaminants in freshwater systems, as well as enhancing semi-natural and biodiversity networks in both urban and rural settings. Rousseau et al. (2022) provide an overview of the use of constructed wetlands in the urban environment, and Hatvani et al. (2022) discuss how constructed wetlands can be used to mitigate agricultural pressures on inland waters. These complementary chapters are followed with a series of case studies using wetlands to treat point and non-point pollution sources in very different settings by Bhomia et al. (2022).

While the chapters described above are largely focused on the effects of physical and chemical pressures, the next six chapters consider more explicitly those arising from biotic exploitation and species translocations. In many parts of the world, fisheries are a major source of livelihoods, not just for food but also for recreation and therefore require careful management. The first of three chapters on fisheries addresses fisheries management in relation to their need to sustain livelihoods (Elliot, 2022a,b), while the second chapter considers the implications of climate change on fisheries and some of the knowledge gaps that have implications for fisheries management (Kelly et al., 2022). The third chapter presents a suite of case studies viewed from different perspectives of the use and management of inland fisheries (Elliot, 2022a,b). The exploitation of fish has also involved the effects of species introductions, which is the topic of the following three chapters. The first of these by Jeschke et al. (2022a,b,c) provides an overview of biological invasion and the conditions needed for the establishment and spread of invasive species. This is followed by more details on the impact and management options for invasive species (Jeschke et al., 2022a,b,c) and a concluding case studies chapter under this theme (Jeschke et al., 2022a,b,c). The final chapter in the section on *Human pressures and Management of Inland Waters* demonstrates how the concept of water retention can be used for city water management in so-called Sponge cities (Fu et al., 2022). This is also an emerging topic of considerable interest and importance for sustainable cities and, like constructed wetlands, employs Nature Based Solutions for water management (WWDR, 2018).

Sustainable development

The chapters in this section of the Encyclopedia are all connected with the idea of managing water resources and the pressures in them in a sustainable way, and how knowledge and understanding of processes can be best employed to provide evidence informed management (Adams and Sandbrook, 2013; Haddaway and Pullin, 2013; Sutherland and Wordley, 2017). This is a common tenet of environment management and the policy cycle of adaptive management (Kingsford et al., 2021; Owens, 2009; Pahl-Wostl et al., 2007). Nevertheless, for many pressures using knowledge to design effective monitoring and management (Lovett et al., 2007) is not sufficient to adequately protect inland waters. There are many reasons for that, but it is also clear that more concerted efforts employing multiple sectors and stakeholders are urgently needed (Carpenter et al., 2009).

The threats to, and degradation of inland waters and other habitats on Earth have been recognized for decades:

- The 1972 UN Conference on the Human Environment (World Commission on Environment and Development, 1987) identified the choices required for human development without major impact on life-supporting ecosystems;
- The international Convention on Wetlands (www.ramsar.org) dating from 1972 (UNESCO, 1994) provided an international Agreement on the protection of wetlands;
- The 1992 Rio Earth Summit (United Nations, 1992) highlighted the need for sustainable development; the 2002 Johannesburg Declaration on Sustainable Development (United Nations, 2002), (re)affirmed the interdependence of natural, economic and social pillars;
- The Millennium Ecosystem Assessment (2005) placed an emphasis on the importance of ecosystem services for human well-being;
- The Aichi targets of the Convention on Biological Diversity (CBD, 2012) fed into the first stage targets of the UN Sustainable Development Goals;
- Agenda 2030 (https://sdgs.un.org/2030agenda) set a plan of action for people, planet and prosperity based on 17 Sustainable Development Goals (https://sdgs.un.org/) (Fig. 1) for which there are 169 targets with between 1 and 3 indicators used to measure progress for each target.

The call for urgent action has also been sounded for a long time, and endorsed by world governments. Paragraph 13 of the Johannesburg Declaration (United Nations, 2002) could hardly have been clearer:

Fig. 1 Outline of the SDGs, attributed to where the goals fit within societal support systems. From: https://revistaidees.cat/en/biodiversity-time-for-action/.

The global environment continues to suffer. Loss of biodiversity continues, fish stocks continue to be depleted, desertification claims more and more fertile land, the adverse effects of climate change are already evident, natural disasters are more frequent and more devastating, and developing countries more vulnerable, and air, water and marine pollution continue to rob millions of a decent life.

Since 2002, the loss of habitats and their species, particularly high in inland waters, have continued (Tickner et al., 2020) and the term 'crisis' is an increasingly familiar adjective, not only for inland waters but across other sectors and biomes (Groves et al., 2002; Irvine, 2018; Kamp et al., 2021). Addressing the pressures and impacts does not occur because of good intent, or even strong and legally binding policies (Carvalho et al., 2019; Hering et al., 2010), but through environmental management to reduce pressures and mitigate impacts. National or international policies do not necessarily lead to local action (Egoh et al., 2012). That there is overall so little international protection of aquatic and other ecosystems raises fundamental questions about society and the choices made for environmental protection (Ellis, 2018).

While the SDGs together represent the ambition for an integrated approach to sustainability, there is also fragmentation within the structure for policy coherence (OECD, 2019). Nevertheless, the SDGs are probably the best current opportunity to steer the globe towards sustainable management of resources, including inland waters. It is not a clear path, but one that involves considerable challenges and inevitable conflicts between goals and their targets. The section on *Human pressures and Management of Inland Waters* connect to a number of the SDGs. For an overview of interrelationships across the SDGs see Miola et al. (2019).

The key goal for water is SDG 6, with six targets, and two supplementary ones. Each Target has a series of Indicators (Table 1). SDG 6 needs to connect with all other SDGs, but is particularly closely connected with the other so-called 'Biosphere Goals', SDGs 14, 15 and 16. In particular, SDG target 6.6 (protect and restore water-related ecosystems) is intertwined with SDG 15 (halt biodiversity decline) and to the Aichi Biodiversity targets under the Convention on Biological Diversity (CBD, 2012; Coates, 2018). The timetable for SDG Target 6.6 and the Aichi targets not only had overly ambitious timelines of 2020, ahead of other targets, but which cannot ever be met without a dramatic change in how ecosystems are considered and valued in decision making (Irvine, 2018). This requires a greater focus on holistic and systems thinking across sectors and society at large (Darwall et al., 2018; Tickner et al., 2020; van Rees et al., 2020). The chapters on Fisheries and Biological Invasions in the Section on *Human pressures and Management of Inland Waters* connect strongly with SDG 15. For the other SDG 6 Targets we focus here on SDG indicators 6.3.2, 6.6.1, and both of these indicators link with SDG 6.5.1.

Management of Inland Waters is strongly related to water quality. Even within well structured processes such as that required by the EU Water Framework Directive (Council of the European Communities, 2000), meeting environmental quality objectives with reliable connection between indicators and quality status can be problematic (Poikane et al., 2020). Across the overall policy network of the EU, with its myriad of environmental legal protections, difficulties in cross-compliance demonstrate the importance and need for a better 'systems thinking' approach (Nilsson et al., 2012; Voulvoulis et al., 2017).

Table 1 Sustainable Goal 6 targets and indicators.

Targets	*Indicators*
6.1 - By 2030, achieve universal and equitable access to safe and affordable drinking water for all	**6.1.1** - Proportion of population using safely managed drinking water services
6.2 - By 2030, achieve access to adequate and equitable sanitation and hygiene for all and end open defecation, paying special attention to the needs of women and girls and those in vulnerable situations	**6.2.1** - Proportion of population using safely managed sanitation services, including a hand-washing facility with soap and water
6.3 - By 2030, improve water quality by reducing pollution, eliminating dumping and minimizing release of hazardous chemicals and materials, halving the proportion of untreated wastewater and substantially increasing recycling and safe reuse globally	**6.3.1** - Proportion of wastewater safely treated **6.3.2** - Proportion of bodies of water with good ambient water quality
6.4 - By 2030, substantially increase water-use efficiency across all sectors and ensure sustainable withdrawals and supply of freshwater to address water scarcity and substantially reduce the number of people suffering from water scarcity	**6.4.1** - Change in water-use efficiency over time **6.4.2** - Level of water stress: freshwater withdrawal as a proportion of available freshwater resources
6.5 - By 2030, implement integrated water resources management at all levels, including through transboundary cooperation as appropriate	**6.5.1** - Degree of integrated water resources management implementation (0–100) **6.5.2** - Proportion of transboundary basin area with an operational arrangement for water cooperation
6.6 - By 2020, protect and restore water-related ecosystems, including mountains, forests, wetlands, rivers, aquifers and lakes	**6.6.1** - Change in the extent of water-related ecosystems over time
6.A - By 2030, expand international cooperation and capacity-building support to developing countries in water- and sanitation-related activities and programs, including water harvesting, desalination, water efficiency, wastewater treatment, recycling and reuse technologies	**6.A.1** - Amount of water- and sanitation-related official development assistance that is part of a government-coordinated spending plan
6.B - Support and strengthen the participation of local communities in improving water and sanitation management	**6.B.1** - Proportion of local administrative units with established and operational policies and procedures for participation of local communities in water and sanitation management

Modified from https://www.unwater.org/publications/sdg-6-indicators-tiering-system.

Outside of countries with a history of legally mandated environmental objectives, the situation is more acute and accentuated by gaps in data collection and limits of institutional capacities (Irvine et al., 2016a). A key to the implementation of the SDGs, is the capacity to monitor and manage inland waters, and the known disparity between high, middle and low-income countries was highlighted in stark terms in the most recent progress report on *Global Indicator 6.3.2 Updates and Acceleration needs* (UNEP, 2021). In 2020, those countries at the lower end of the income spectrum used a fraction of the number of water quality measurements compared with wealthier countries, and often, the classification method applied was performed with little insight into natural conditions of these water bodies. This is supported in a review of the progress with the SDG 6 on water and indicator 6.3.2. Kirschke et al. (2020) found a negative relationship between the global human development index (HDI) that aggregates a small set of metrics on health, knowledge and standard of living (UNDP, 2016) and capacity challenges that need to be met to monitor water quality and to report on SDG indicator 6.3.2.

Integrated water resource management (IWRM) as a process for management of freshwater resources is considered within the SDG framework under indicator 6.5.1. This indicator requires country surveys to be completed that provide a broad overview of water-related policy, institutional arrangements and activities in countries. The most recent information available makes clear that huge improvements are needed in many countries. For example, approximately 50% of countries report limited management instruments for pollution control, and these are ad hoc, spatially limited and are rarely enforced (UNEP, 2021). On a positive note, this same report identified that with targeted efforts, rapid improvement is possible, but also that a "business as usual" approach is not an option.

The SDGs offer an important mechanism to take stock of the global capacity to monitor and assess the quality of inland waters and make clear the capacity gaps that urgently need to be filled. Many countries are near the start of this journey, but it is an essential one if there is to be any conclusion on whether the SDG targets have been reached by 2030. Target 6.3 is about improving water quality, but for those countries without suitable monitoring systems in place that struggle to collect information on their inland waters, it will be impossible to know whether this target has been reached. Putting the appropriate systems in place is becoming increasingly urgent given climate change and the predicted population growth in regions such as sub-Saharan Africa (UNDESA Population Division, 2019) and the associated increased pressure on water resources that come with it.

Looking forward for effective environmental water management

As pressures continue and are amplified by climate change (Moss, 2015), meeting the management challenge requires much more than the metaphor of Alice In Wonderland running faster to stay still (Carroll, 1865), but increased and concerted global efforts. The

challenges for environmental management in the global south are particularly daunting (Irvine et al., 2016a), stemming from a combination of increasing pressures to meet economic and food security and capacity to meet those challenges (Kirschke et al., 2020; Zimmerer, 2000). There are, however, powerful economic and business arguments for conservation of inland waters (Costanza et al., 2014; Russi et al., 2013), and greater employment of nature based solutions (Green et al., 2015; Vörösmarty et al., 2021; WWDR, 2018) that can support on-going economic needs and development (Lucas et al., 2013; van Asselen et al., 2013). It is also abundantly clear that progress in addressing multi-layered environmental challenges requires better alignment of economic, environmental and educational policies. The need to address these challenges so as not to sleep-walk into an environmental catastrophe is clearer now than at any other time in human history. The SDGs provide a mechanism to do that. From the science perspective this requires effective monitoring and common understanding of what the data are indicating (Lu et al., 2015). But this is not enough, and can only be at best a supporting mechanism, albeit an essential one. The real means to a more sustainable management of inland waters is the application of knowledge, as illustrated for a number of pressures in the following chapters and elsewhere in this Encyclopedia, connected and supported by policy mechanisms and political will. There is no doubt that achieving effective trade-offs between development and economic objectives and the ecological health and integrity of inland waters is a major challenge. Although national economies and local livelihoods ultimately depend on ecosystem services and benefits, public and political acceptance of this, although building, is not yet so clear and accepted, as Tickner et al. (2020) call for to "bend the curve" of aquatic ecosystem declines.

Solutions will not lie in the attempted preservation of designated 'protected areas', especially in the tropics where scientifically valid conservation planning can collide with social and historical realities (Adams and Hutton, 2007; Naughton-Treves et al., 2005; Sarkar and Montoya, 2011), and where protected areas do not necessarily safeguard river ecosystems and related livelihoods because of the influence of upstream impacts (Abell et al., 2007; Castello and Macedo, 2016; Feld et al., 2011; Nel et al., 2009). Throughout the world, accommodating human social structures for water management is crucial (Nel et al., 2007; Norgaard et al., 2009). Transitioning from traditional 'top down' authority to local management of resources is also not an assurance of better management (Etiegni et al., 2020; Lane and Corbett, 2005), or where poor design of new governance structures fails to meet community expectations (Kahmann et al., 2015).

Governance structures provide the setting for effective and sustainable resource management and practice (Pahl-Wostl et al., 2007), but even high quality evidence does not guarantee that decisions are made by rational actors. Sustainable development requires skills that can communicate across institutional structures (Irvine et al., 2016b). Effective environmental management requires the necessary investment in human and financial resources. The model employed with some success, but still with quite some variability, in more developed countries has relied on technically competent scientists producing verifiable information, reported and acted upon to develop and implement policy. While the value of long-term monitoring is well known(Lovett et al., 2007), in many parts of the world monitoring networks have declined over recent decades (Houghton-Carr and Fry, 2006). At the same time, the global agenda should interrogate how hidden assumptions, implicit biases and structural obstacles are built into 'best practice'. Collecting representative data of water and ecosystem quality needs effective institutional structures, and can be greatly assisted by the involvement of locally empowered communities in the monitoring and reporting of their own resources (Aceves-Bueno et al., 2015; Fritz et al., 2019). Engagement of this type with citizens can also provide an important bridge between the formal and informal institutions (Cleaver, 2012).

Ultimately achieving sustainable development, and effective protection and management of inland waters within that framework, will almost certainly need a re-assessment of dominant extractive economic models. The use of GDP as an indicator of societal wealth and successful growth has been recognized as a key obstacle to sustainability since the 1960s. GDP disregards the wealth of human capacity and the loss of natural capital (Perez-Carmona, 2013; Steffen et al., 2007). A shift from the outdated economic paradigm towards more equitable social systems may become a necessity rather than an ideological choice, but one that will bring considerable societal challenges, and likely conflict. It comes down to the capacity and willingness to adapt to change and new collective understanding (Figueroa et al., 2002; Pahl-Wostl et al., 2008).

In the face of difficult choices, environmental protection, and the management needed to achieve that, seems often to be viewed as a dispensable luxury. Yet, the evidence is clear and stark that insufficient environmental safeguards lead to more costly options and a diminishing of human well-being. Environmental degradation has been defended with the logic of the Environmental Kuznets Curve (EKC) (Grossman and Krueger, 1991). This supports a policy that allows environmental degradation in the interests of economic growth, and that the clean-up can come later (Azadi et al., 2011). While de facto this has occurred throughout global North, where attention to environmental protection becomes sequential, not simultaneous, with industrial development, the EKC has not stood up well to critical analysis (Mills and Waite, 2009; Rudi et al., 2012). In the sayings of the wise, the idea that "prevention is better than cure" is a much more logical and critical path (Spears et al., 2021).

Measuring Impact, Overview and Reference Conditions

Kenneth Irvine, IHE Delft, Institute of Water Education, Delft, The Netherlands

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Baseline syndrome The tendency to judge change based on a view constrained by experience or life-span of an individual. A similar phenomenon can occur at the collective, or policy dimension.
Designated beneficial use A numerical or narrative statement identifying maximum concentrations of various pollutants compatible with its use.
Driver A policy or economic demand that leads to a change in human activities that have the potential to change the structure and function of an ecosystem.
Ecosystem service The goods and benefits that humans derive from an ecosystem.
Impact The consequence of a pressure or stressor that leads to observable and measurable change in the structure and function of an ecosystem, affecting the use or value of the ecosystem.
Indicator A component of an ecosystem that can be measured and which provides a surrogate of the extent of change from defined pressure(s) or impact. An indicator can be a single measurable metric, or a combination of metrics that are assessed together to form a multi-metric.
Palaeolimnology The study of the history of a waterbody through the examination of the sediment that enables a reconstruction of environmental conditions over time.
Pressure This results from the driver, and usually applies to the input of a harmful chemical, alteration of physical condition, or the activities of an invasive species. Pressures can occur in isolation or in combination.
Reference State The character and quality of an ecosystem against which changes, usually from human activities, can be compared.
Response A policy or management action that is intended to reduce pressures, stressors or mitigate impact or improve the state of an ecosystem.
State The character of an ecosystem.
Stressor Sometimes used as a more precise descriptor of a factor that can have a direct effect on components of the ecosystem.

Introduction

The aim of this chapter is to introduce an overview of the environmental assessment of water bodies and how the concept of Reference Condition is a fundamental part of that. The chapter outlines the commonly used DPSIR model for managing impact. Establishing a baseline is essential for measuring the current state of the ecosystem, and the Reference State provides a means of comparison for judging the health of an ecosystem, for setting targets of what might be the limits of acceptable change, or to guide ambitions for restoration.

The driver (D), pressure(P), state (S), impact (I) and response (R) model

Measuring impact on an ecosystem depends fundamentally on the expectation of change as a result of something that can lead to that change. For environmental management, that something arises from a "Pressure" that leads to an increase of a "Stressor," resulting in a change of the environmental condition, or "State." This idea is captured in the now commonly used drivers, pressures,

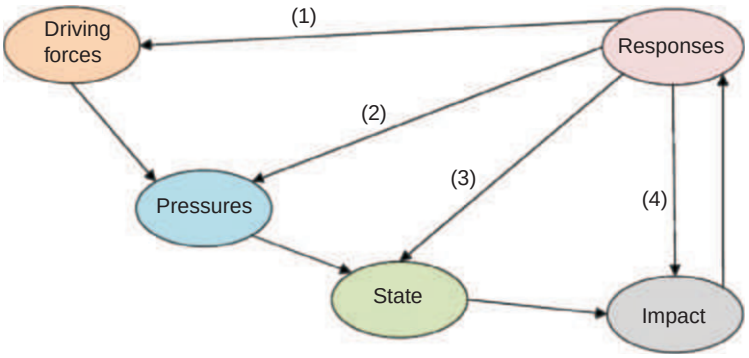

Fig. 1 Conceptual links between drivers, pressures, state, impact and response proposed by Smeets and Weterings (1999). In the diagram a separate Response can be effected to address each of the other components. See text for further details. Diagram adapted from www.eea.europa.eu.

state, impact, response (DPSIR), originally proposed by Smeets and Weterings (1999) to support environmental assessment and decision making, and using environmental indicators that:

1. "supply information on environmental problems, in order to enable policy-makers to value their seriousness;
2. support policy development and priority setting, by identifying key factors that cause pressure on the environment; and
3. monitor the effects of policy responses."

The DPSIR model (Fig. 1) that supports these objectives is conceptually straightforward, can be applied across a wide spectrum of environments and circumstances, and can incorporate multiple sectors.

The use of the DPSIR model is very common, used as both a means to communicate information of the state of the environment to stakeholders and interested parties (van Asselen et al., 2013) and to frame major environmental policy such as the EU Water Framework Directive (Council of the European Communities, 2000). An overview of definition and interpretations of the DPSIR model are:

Driving forces: The underlying causes/origins of pressures on the environment. These are normally considered to be human induced (anthropogenic) and brought about by social, demographic and economic change and developments, although some authors include natural drivers of change in their definition. Distinction can be made between Direct Drivers, usually manifest at local scales, and Indirect Drivers, resulting from wider policy, economic decisions or circumstances. For example, political decisions to promote or regulate a commodity for export in one part of the world can lead to environmental pressures in another.

Pressures: The outcomes of the driving forces, which influence the current/future environmental state. Pressures can be considered as potentially damaging to the environment, or demonstrably damaging, the latter suggesting that there are thresholds below which the e.g., emission of a pollutant or a change in land use is not of concern. A potential misgiving of this approach is that it is very susceptible to particular political or stakeholder interests. The term stressor is sometimes used to illustrate when an individual pressure, such as increased nutrient emissions to water are likely to cause an impact (see below).

State: The physical, chemical or biological condition of the environment, often described by physical or chemical variables, or single or a combination (multi-metric) of physical-chemical, biotic or even socio-economic indicators. State has also been defined in terms of vulnerability and risk of damage (Fassio et al., 2005). Generally speaking the state can be measured, either directly (e.g., extent of a wetland; or by in situ environmental sampling of key variables) or judged by expert opinion or perceptions of interest groups. This can lead to contradictions. A productive fishery may be viewed as being in a good state, even though chemical and other biological measurement may indicate some impact from pressures.

Impact: The effect of changes of a state on human population, economy or ecosystem in terms of damage (or benefit) to ecosystem functions and services. This could be, for example, in terms of biodiversity loss or changes, reduced flood regulation capacity, lower fish yields, or reduced quality of water supply. It can also be from a socio-economic perspective, and considered as a negative (the more common), neutral or positive effect. The combinations of these perceptions can be viewed in terms of a utilitarian view of ecosystem services (Millennium Ecosystem Assessment, 2005). Maxim et al. (2009) identified that "it is clear that different disciplines are dealing with different aspects of Impacts, and are addressing different things with this same concept." The view of impact can be in the "eye of the beholder."

Responses: These are mechanisms put in place at a political or societal level to remove or reduce drivers, ameliorate pressures, improve a state or mitigate an impact. Response can comprise e.g., a policy instrument, commercial incentives, educational awareness program, or on-site management measures. Any given response can target any, or several, of the drivers, pressures, state or impact. Policy responses can reverse previous policy decisions that were instrumental in promoting the relevant drivers in the first place. By way of example, applying the notations in Fig. 1 to nutrient enrichment of waterbodies from dairy production could be: (1) trade agreements that reduce incentive for high local cattle numbers that rely on an export market of dairy products; (2) national regulations that reduce spreading of slurry and fertilizer so to maintain concentrations of soil phosphorus below permissible levels; (3) maintenance of riparian vegetation that reduces nutrient loss from land to water, or provides shade to reduce temperature and light intensity on the waterbody; and (4) manipulation of fish stocks in a lake to remove small fish that feed

preferentially on those species of plankton that can efficiently remove algae, so that concentration of nuisance algae are reduced. In this example, the likelihood of the response being successful reduces along the D-P-S-I chain.

It can be seen that while the DPSIR framework provides a useful structure for the description and evaluation of the environment and impacts on it from pressures, there are a number of features open to interpretation, and even contradiction. Uncertainty inherent in natural systems can influence its use (Maxim et al., 2009). It is for this reason that clarification of meaning and use of the terminology in each circumstance is advisable. This applies in some way to all components of the DPSIR model, but is of particular importance for defining and measuring state and impact. This becomes more difficult when considering the effect of a combination of pressures, leading to multiple stressors that can lead to combined, and often unpredictable, effects on the character of an ecosystem. Impact from multiple pressures can be additive, synergistic, or neutralizing (O'Toole and Irvine, 2006).

Judging impact

Measuring an impact on an ecosystem requires making a judgment of the condition in the absence of pressures. It is often easy, even for the untrained eye, to see when a waterbody is grossly polluted. Anyone looking into the Bagmati River flowing through Katmandu (Image 1) would be hard pressed not to recognize that discolored water, an assortment of rubbish, even dead cattle on the banks, its use as a crematorium site and the pungent odor as unmistakable clues that this was an unhealthy river. However, even where a waterbody may look like it is in good condition, or where water policy standards have been set to define acceptable water quality, this does not equate necessarily to no impact. Making a judgment about environmental impact requires two, not necessarily compatible decisions. First, what would be the state of the waterbody in the absence of a stressor? Second, what is the acceptable threshold of water quality or ecosystem health? Answering the first question is often technically challenging. Answering the second question reflects a societal, often governmental, choice.

Inland waters have been disturbed by humans since the Neolithic. Early impact would have arisen from alterations of the landscape, notably forest clearance, and the subsequent mobilizing of sediment loss to waters. As humans congregated into larger communities, adjacent waterways became the conduits of human waste, with urban rivers noted for their pungent smells and, increasingly, associated with fevers from unseen pathogens (Image 2). Global industrialization of the 18th and 19th centuries led to further emissions of pollutants. These included toxic substances such as heavy metals in effluent entering waterbodies; and aerial deposition of pollutants from factory chimneys, carried by the wind and polluting waterbodies even at considerable distance from their origin.

Recent, and projected, changes in climate patterns can profoundly affect the physical structure of waterbodies, and their ecological response to pressures and stressors. These include single or combined pressures from e.g., nutrient enrichment, alien species, reductions of large mammals, and patterns of fish migrations through over exploitation and obstructions to fish movements (Moss, 2015; Penk et al., 2015; Zarfl et al., 2015). Climate mediated changes in the structure of ecosystems and their response to pressures raises the question if it is even reasonable that reference state is a valid concept in a rapidly and profoundly changing Anthropocene (Kopf et al., 2015). The answer depends on what an estimate of a reference value is used for and, hence, the purpose of having one.

Setting reference conditions

Assessing the state of a waterbody requires a judgment based on expectation compared with a defined baseline condition. Early monitoring of rivers in the US and Europe focused on measurements of pathogens and assessment of biota downstream of public sewerage outfalls as an indicator of river pollution (Hawkes, 1998; Hynes, 1960). The presumed, if often unstated, reference value was the conditions upstream of an organic-rich point source of pollution from an outfall of sewage or organically rich industrial emission.

Modern views of reference state are much more encompassing than the previous upstream-downstream comparisons, with wider reaching considerations of what would be the condition of a waterbody in the absence of human pressures. Assessment of surface waters in the US is often based on "Designated Beneficial Use," outlined in the U.S. Clean Water Act (1972), and supported by quantitative or qualitative descriptors (Davies and Jackson, 2006; Goldfarb, 2020).

A healthy ecosystem would be expected to support a diversity of life compatible with natural background water quality and hydrology, intact habitats and a low level of human disturbance. The idea of naturalness provides a very simple mental picture of the baseline or reference state. It is along these lines that a number of national water policies, including the very comprehensive EU Water Framework Directive (Box 1), are predicated on.

Under the WFD, each waterbody "type" is defined in terms of broadly recognized character (e.g., lakes, rivers), physical features (e.g., size, depth), geography (e.g., ecoregion, high altitude, low altitude), and background water chemistry (e.g., acid neutralizing capacity). The principle is that waterbodies with similar natural geological and landscape settings are compared with each other. As waterbodies lie across multidimensional continua, it is clearly a compromise between the practical need to keep the number of types as low as possible and maintaining the power to discriminate between natural variability and human impacts.

The seemingly simple and attractive idea is that each waterbody type has an expected natural composition of plants and animals, and when that composition is minimally disturbed it can provide an anchor (or reference state) with which to evaluate changes to the waterbody brought about through human activities. The environmental quality of any waterbody can then be assessed along a

Box 1 General definition of the upper tier (High Status) of a waterbody type under undisturbed conditions from Annex V of the EU Water Framework Directive (WFD, 2000).

"There are no, or only very minor, anthropogenic alterations to the values of the physico-chemical and hydromorphological quality elements for the surface waterbody type from those normally associated with that type under undisturbed conditions. The values of the biological quality elements for the surface waterbody reflect those normally associated with that type under undisturbed conditions, and show no, or only very minor, evidence of distortion."

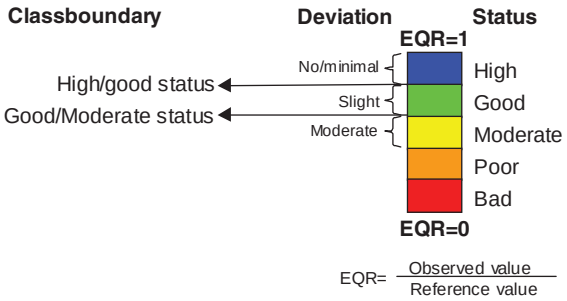

Fig. 2 The five-category classification of the EU Water Framework Directive. Waterbody status is derived for a measurement of critical biological and supporting chemical and hydromorphological elements. Source www.epa.ie.

five-category scale (Fig. 2) based on departure from reference state, and measured by an "Ecological Quality Ratio" derived for each of a number of biological "elements" appropriate to the waterbody type being assessed. Since its ratification by European Member States in 2000, the WFD has generated multiple official guidance documents and thousands of reports and publications. A good overview of the early progress is provided by Hering et al. (2010). More critical reflections are provided by Moss (2008) and Bouleau and Pont (2015). For many aquatic ecosystems where habitats are complex and subject to stochastic changes such as vegetated wetlands, the description of a reference condition can seem an elusive concept (Beuel et al., 2016).

Variations in meaning and interpretation of the reference state concept are widespread (Gibbons et al., 2008; Stoddard et al., 2006; Verdonschot, 2000), including: "totally or nearly totally undisturbed conditions" (WFD, 2000); "best available" (Clarke et al., 2003), "least disturbed" (Davies, 2000; Reynoldson et al., 1997; USEPA, 2002; Wigand et al., 2010); "best attainable" (Harrison and Whitfield, 2006); sites with low pressures (Lougheed et al., 2011); "relatively undisturbed biological communities" (Logan and Taffs, 2011); departure from full ecological integrity (Fennessy et al., 2004); and "historical condition" (Nijboer et al., 2004; Young and Sanzone, 2002).

Reference conditions are commonly understood to refer to sites in near-natural conditions at one end of an ecosystem health continuum. It is clear, however, that perception of reference condition, on which assessment of impact must logically be based, is anything but straightforward. The difference between expert subjective opinion and objective verification can be marked (Nõges et al., 2009; Oberdorff et al., 2001). In Ireland, a test using diatom records preserved in sediment cores on the validity of expert opinion, showed that only 11 out of 35 candidate lakes were verified as being in reference condition (Leira et al., 2006). All had mean water column concentrations of total phosphorus (TP), a measure of nutrient status, of less than 20 μg L^{-1}. Misperceptions of water bodies considered as having no or minimal impact from human pressures can lead to errors in classifying a site along a gradient of impact (Oberdorff et al., 2001). Guidance documents from the EU (European Commission, 2003) recommended that pressure criteria be used to screen for potential reference because the reference community is expected where there is no or only very minor human induced disturbance. Nevertheless, natural variability can sometimes mimic an impact (Hartnett et al., 2011), and, in a type-specific approach to the setting of reference state, can have a large effect on the perceptions of the biotic composition of average reference state.

Type-specific reference (Bailey et al., 2004) assumes concordance of biotic communities among similarly-typed water bodies, or influenced similarly by natural changes within a regional reference network (Bates Prins and Smith, 2007). Nevertheless, even in similar types of waterbodies, there can be a distinctiveness among individual sites. Given that separate water bodies have their own character, this is not surprising. While this does not invalidate the idea of assessing type-specific waterbodies to detect overall patterns of change, it does raise questions about the validity of the approach. This led to the view among a number of workers involved in the implementation of the EU WFD, that "site-specific" estimates of "true" reference state is the most valid approach (Carvalho et al., 2009; Jyväsjärvi et al., 2009); so that the ecological health of a waterbody site is only compared with itself over temporal scales and not across a network of albeit similar sites. However, this approach necessitates long-term monitoring, or use of robust site-specific mathematical models (Aroviita et al., 2009; Cardoso et al., 2007; Carvalho et al., 2009; Clarke et al., 2003).

Estimates of reference state

For pollutants, such as aromatic hydrocarbons, pesticides and herbicides, pharmaceutical residues and plastic particles, natural background concentrations can be considered as zero. Detecting these in water samples indicates pollution of some degree. The extent that this is viewed as an environmental problem depends on establishing a relationship between concentrations and effect, as for all other stressors, but there is little doubt the site is not at reference state unless concentrations of the pollutants are considered to represent trace background amounts. Some pollutants have dispersed through the atmosphere to the most remote parts of the globe. For many pollutants, establishing reference state can be also very uncertain. Heavy metals, for example can be common in many soils and, hence, contained in the runoff to waterbodies. Many metals occur naturally at concentrations that can pose a risk to public health. Water quality standards for such toxicants are derived from toxicity studies rather than the use of reference values discussed here. Reference state for invasive alien species might be considered as zero presence, although that raises interesting questions on the status, and our views of species that may have been introduced by humans centuries ago, and are now considered as naturalized.

The EU WFD defined Reference State as synonymous with High Status, but raised further discussion if reference should be anchored at the upper, higher quality, end of the High Status category (Pardo et al., 2010). This has intuitive value, otherwise the

reference bench mark will be set where minor impact has already occurred. However, it is difficult to separate the top of the range from others in the same quality category (Erba et al., 2009). Similarly, it is difficult to reliably distinguish ecological boundaries between successive status classes (Ellis, 2006; Hering et al., 2010; Irvine, 2012).

The WFD allows type-specific reference conditions to be "either spatially based or based on modeling, or may be derived using a combination of these methods. Where it is not possible to use these methods, EU Member States may use expert judgment to establish such conditions. In defining high ecological status in respect of concentrations of specific synthetic pollutants, the detection limits are those which can be achieved in accordance with the available techniques at the time when the type-specific conditions are to be established."

Guidelines provided for similar purpose in Australian/New Zealand (ANZECC/ARMCANZ, 2000) are that reference conditions can be derived from: (i) historical data collected from the site being assessed; (ii) spatial data collected from sites or areas nearby that are uninfluenced by disturbance; or (iii) data from other sources if there are neither suitable historical data nor comparable reference sites nearby. The South African River classification scheme (Roux et al., 1999) evaluates river health across four categories, the highest quality of which is "negligible modification of instream and riparian habitats and biota."

Irrespective of the method used to set a reference value, its purpose is to provide a fixed point for which monitoring can be used to assess change, and thereby enabling classification of a waterbody across a continuum or among categories of quality. The principle is more straightforward than the practice. In northern Europe, for example, widespread changes to catchment have occurred since the Neolithic period, but using that as a baseline has little merit for modern day water management. More recent comparison with a time before industrialization or intensive agriculture have greater appeal, but is susceptible to unfounded assumptions. A reference date of ca 1850, and prior to establishment of major 19th century industrialization, may be appropriate for the United Kingdom, but in nearby Ireland this period coincided with high impact to lake water quality from an increasing human population in the century leading up to 1850, and followed by a major de-population caused by the Great Irish Famine (Donohue et al., 2010). In other parts of Europe, major changes to water quality were associated with the introduction of the plough, as shown for Danish lakes (Johansson et al., 2005).

The Irish and Danish records mentioned above were based on the historical record captured in the sediment (Image 3). This enables quite an accurate reconstruction of the state of many lakes when samples can be collected from relatively undisturbed sediment. Inputs of materials from the catchment and the residues of internal production that settle out of the water column can be used to trace the history of geological events, landscape changes, industrial production and climate shifts. The study of the sediment of lakes (or "palaeolimnology"), developed over the first half of the 20th century (e.g., Pennington, 1943, 1947), but came to widespread attention in the 1980s in the investigation of lake acidification (Flower and Battarbee, 1983; Renberg and Hellberg, 1982), and

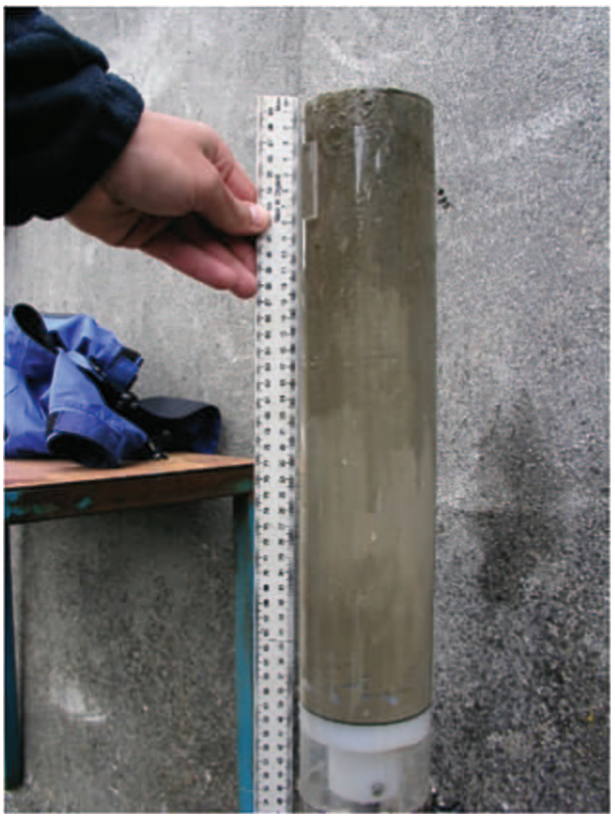

Image 3 A core of sediment extracted from a shallow lake contains an historical record from chemistry and remains of biological organisms. Photo credit: David Taylor.

supported by the development of accurate dating from the radioactive decay of ^{210}Pb in the sediment. Dating of sediment is important because rates of accumulation of material raining down from the water column is neither constant within or across lakes. Other signals that assist in the accurate dating of sediment profiles are ^{137}Cesium-137, from nuclear weapons testing, or other locally applicable events that relate to a specific period, including volcanic ash and carbon deposits, related to e.g., 19th century industrialization. Palaeolimnology is now a standard technique used for reconstructing the history of lakes from the recent or distance past. For a very readable overview see Smol (2008).

For some slower flowing rivers, sediment deposits can provide a sufficiently readable historic record, but generally speaking palaeolimnology is not suitable for rivers because of dynamic hydrology and frequent disturbance of the river bed. In marshes and swamps, sediment profiles have been used successfully to trace shifts and historical development of agriculture, largely from pollen analysis (Lejju et al., 2006), although of limited use is assessing a true reference condition relevant to contemporary wetland management. Assessing quality of swamp or marsh like habitats often uses contemporary observation of wetland ecological structure and function against perceived, or theoretical reference state, to assess current wetland health (Brinson and Rheinhardt, 1996; Kotze et al., 2020).

For dynamic systems, such as vegetated wetlands and rivers, direct in situ measurements as a means to estimate what might be considered as true reference state is not possible. Additionally, the lack of suitable reference sites in some regions (Bennion et al., 2004; Borja et al., 2007) has led to selection of "least impacted" or "best available" as description of reference sites. This is not the same as reference state (O'Toole and Irvine, 2006), although it is a view that can influence (we could say distort) policy decisions (Dodkins et al., 2005). Selecting best available sites as the reference value is, at best, ecologically useful if based on the assumption that these sites are subject to low pressures (Erba et al., 2009). A notable example where comparison with a reference network of sites with a similar nature has been used to set the reference anchor is the River Invertebrate Prediction and Classification System (RIVPACS) (Clarke et al., 2003) and the Australian River Assessment System (AusRivAS) (Davies, 2000). In RIVPACs, the condition of a sampled site (the Observed site) is compared with that of the "expected" metric from the reference network. Reference state in this sense is not un-impacted per se. In some countries long-term monitoring that has coincided with widespread decline of water quality serves as a reasonable baseline, with those sites originally classified in the top tier of quality a reasonable estimate of reference state (White (née Ní Chatháin) et al., 2014).

Baseline syndrome and users' perception

Over the last several decades, water quality objectives have been developed as a means to safeguard surface and ground waters from impact considered detrimental either to human or ecosystem health. Criteria for protecting human and ecosystem health are not necessarily the same. The World Health Organization (WHO) estimates of safe limits of nitrate of 50 mg L^{-1} in drinking water provides allowance for a concentration of nitrate an order of magnitude higher than that which would have an ecological effect, through stimulating primary production, in surface water. Across a range of toxicants there can be different national standards for the protection of human and ecosystem health (Lijzen et al., 2001).

In some jurisdictions, such as under the US Clean Water Act (CWA) 1972, quality standards that represent "beneficial use" (see above), designations for public water resource and quality consider a water's assimilative capacity for pollutants, based in an assessment of total maximum daily loads (TMDLs). Highest quality waters can be designated as "Outstanding National Resource Waters" nominated by stakeholders. This level of public participation in identifying high quality waters introduces a very interesting level of public perception of local value in ecosystem water management. It raises questions such as "What does a "healthy" river mean, and for whom does it have benefit?" This very much relates to utilitarian ideas of ecosystem services, and the goods and services that humans derive from ecosystems (Millennium Ecosystem Assessment, 2005). It also evokes questions of human perception and decision making of what merits protection and at what cost? Technically justified ecosystem standards may or may not be in-line with local views and needs. Fishing for species of coarse (a general term applied to non-salmonids in United Kingdom) fish commonly found in canals and moderately polluted waterbodies is an extremely common recreational activity in the United Kingdom (for overview of recreation fishing in United Kingdom see Winfield (2016)). Formal evaluation of the state of United Kingdom surface water bodies by Carvalho et al. (2019) shows widespread degradation, but many of these degraded waters provide very suitable habitat for coarse fish and extensive recreational benefit. If a society's desire was to catch more fish on a Sunday afternoon, then investment in the restoration of the coarse fishers' hobby location may not be popular. However, perceptions of the quality of the habitat will almost certainly be influenced by the experience and memory of those who use it.

Shifting baseline syndrome (SBS) is when perception of worth, be it water quality or anything else, is determined by individual or collective memory (Soga and Gaston, 2018). If the perception of ecosystem health is compared by succeeding generations based on life-time experience, motivation or restoration or higher degree of protection are reduced (Ainsworth et al., 2008; Campbell et al., 2009; Pauly, 1995). Perceptions of quality can transcend to estimation of reference state, and can be particularly troublesome for views of regional water quality. A scientific career working in shallow lowland eutrophic lakes with high pressures from nutrient loadings provides a very different baseline perception compared with those working on similar lakes subject to much lower intensity of human pressures. For management, SBS can erroneously set targets of high quality for what in truth are degraded habitats (Humphries and Winemiller, 2009). Examples that apply to the EU WFD are the association of high nutrient concentrations with Good Status (Moss, 2008), not considering alien invasive species in ecological assessment (Irvine, 2009), and misperceptions of contemporary ecological state compared with putative reference state (Leira et al., 2006).

If professional expert judgment is susceptible to SBS, the risks for other stakeholders are likely to be greater. The increasing engagement of citizen and community science and of institutions such as River Trusts and other interest groups in water and ecosystem assessment, raises important issues of how perception affects management goals and the democracy of water quality objectives.

Decision making

It is common for national water quality assessment schemes to depend on categories of quality, typically comprising four or five quality classes, such as occurs under the EU WFD (Fig. 2). While the anchor point is implicitly or, preferably, explicitly based on a reference state with defined characteristics, successive boundaries separating quality classes are in effect also applying criteria of baselines between adjacent classes. Very often these classes have legal meaning and are used to define a quality class and need for water quality improvements, raising some crucial considerations for management and environmental compliance (Howarth, 2006).

In any management plan, it is important to identify minimally impacted sites, and decide if these represent a true baseline (as discussed in "Setting reference conditions" section) or the best available, least disturbed, sites. This is important for setting management targets. In many situations, setting targets for "best attainable condition" (BAC) may be the more reasonable approach (Stoddard et al., 2006) while appreciating that it is not the same as a true reference state. Targets are only achievable if there is sufficient understanding of the link between pressure and impact to be able to set relevant indicators for monitoring (Lovett et al., 2007). In assessing quality, the closer a metric score is to a class boundary, the greater the statistical probability of misclassification (Clark, 2002; Ellis, 2006). Uncertainty can be reduced with more sampling effort, and, for biota, targeting representative habitats, although that loses information on e.g., total species richness. Resource limitation also prevents more detailed sampling effort. In any case, appreciating uncertainty in ecological assessment can liberate the over-reliance on using fixed-boundaries for waterbody classifications (Irvine, 2012). Uncertainty in all stages of water quality management can be reduced through quality assurance at all stages of the process, from sampling to reporting. Communicating uncertainty to stakeholders improves transparency and makes for better decision making. Adopting a philosophy of no-deterioration and continuous reduction of risks to water quality, checked by periodic monitoring, is recommended.

For water quality and ecological management, it is impossible to ignore that assessment of quality depends on monitoring, and the interpretation of monitoring results depends on understanding of the link between pressure and impacts (Fig. 1). This guides the selection of relevant indicators to be monitored (Lovett et al., 2007). Attributes for a successful indicator (http://www.epa.gov/bioindicators/html/about.html) are that "the indicator is objective; the indicator is transparent and reproducible; the underlying data are characterized by sound collection methods, data management systems to protect their integrity, and quality assurance procedures; data are available to describe changes or trends; the data are comparable across time and space, and representative of the target population; and the indicator used is relevant for the system(s) studied." The reliability of the indicator is influenced by natural and operation variability. Natural variation, is inherent in all ecosystems, and if monitoring fails to account for that, reliability of results, and hence policy relevance, is reduced (Irvine, 2004).

Naturally, the use of any indicator of water quality is part of a cycle of environmental management, within which water quality monitoring is just one, albeit crucial, part. Many representations of the monitoring cycles can be found, but the purpose is to put in place a well-structured series of connected processes designed to detect, report and act on changes of water quality (Timmerman et al., 2000) (Fig. 3).

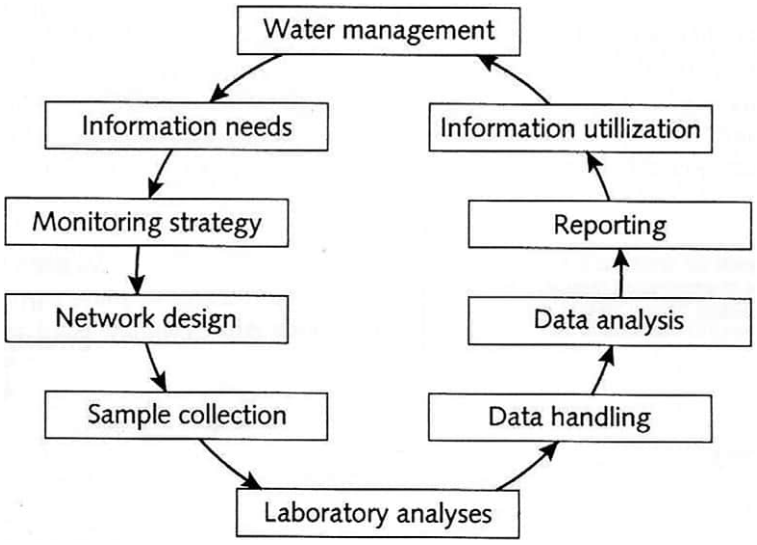

Fig. 3 An example of the monitoring cycle. Laboratory analysis can be for any physical, chemical or biotic variable, including those measured in situ in the water body. After Chapman D (ed.) (1996) Water Quality Assessment—A Guide to the Use of Biota, Sediments and Water in Environmental Monitoring. London: E & FN Spon.

Connecting the components of water management is an ongoing process of planning, setting objectives compatible with relevant policies, monitoring, reporting and reviewing. Adapting to new circumstances and development of knowledge maintains the relevance of management objectives (Pahl-Wostl, 2009). However, no matter what the adaptive capacity entails, assessing the current state of a waterbody compared with a robust description of reference state should remain an essential element of the process.

Conclusion/Synthesis

Key points covered in this chapter are:

(i) An assessment of anthropogenic impact of a waterbody requires an estimate of the State of environmental condition in the absence of, or subject to only minimal, disturbance. This Reference State enables a judgment on how far an ecosystem has departed from no or minimal impact. It aids decisions in protecting remaining high quality sites and setting realistic restoration targets where impact has occurred. Estimating the true reference state, can however be difficult. In contrast, relying on the best available condition as a reference point, concedes the acceptability of an ambition limited to lesser quality sites and increasing the risk of further biodiversity loss and diminished ecosystem services.

(ii) Measures of ecological quality range from simple metrics of quality derived from expert opinion to complex multi-metrics techniques developed across waterbody types. However, all quality metrics reflect some agreed view of quality, involve some uncertainty, and are ultimately subject to the judgments of scientists, policy makers, and citizens.

(iii) Whatever the approach adopted, descriptions and rational of reference state and how this is used to assess ambient ecosystem quality should be clearly outlined in relevant policy and management plans. The use of a natural (no impact) or historical reference using available data from the past, is recommended, but it may be necessary to consider reference condition from the commencement of monitoring, or other well-defined criteria This can include the use of mathematical modeling that predicts the ecological state commensurate with minimal impact.

(iv) Adopting a philosophy of no-deterioration and continuous reduction of risks to water quality, checked by periodic monitoring, is recommended. This follows an Environmental Management approach where the goal is to prevent ecosystem deterioration or work towards continuous improvement.

Knowledge gaps

(i) Estimating reference state and incorporating uncertainty in both the initial estimate and departure from it, are poorly understood and controversial. Even when applied within a systematic typology, establishing baseline/reference conditions can be controversial, with varying definitions and interpretations potentially legitimizing the lowering of targets and baselines.

(ii) The setting of reference conditions for policy compliance remains a significant challenge. There are largely unresolved discussions of what is natural or how to include invasive alien species in the assessment of reference state.

(iii) Estimating probabilities around quality class designation provides a more realistic, and in the longer-term, useful approach for management compared with dependence on fixed-boundary schemes. It remains challenging how to apply these in data-poor situations and considerable further work is required to link uncertainty to boundary conditions.

(iv) Because there are various views of reference conditions, as described in this chapter, there is a need for greater consistency in the terminology. Reference condition can be used as a term to depict the naturalness of the structure and function of ecological communities. Further discussion and resolution is needed in describing minimally disturbed condition (MDC), historical condition (HC), least disturbed condition (LCD) and best attainable condition (BAC) following Stoddard et al. (2006).

(v) It remains challenging how to apply classification boundaries in data-poor situations, as now required for the global implementation of water quality assessment for the Sustainable Development Goals (UN Environment, 2018).

Freshwater Biota as Indicators of Impact: Case Studies and Examples of the Major Groups in Surface Water Assessment

John P Simaika[a], Isabel Bishop[b], Martyn Kelly[c], and Rowshyra Castañeda[d], [a]Department of Water Resources and Ecosystems, IHE Delft Institute for Water Education, Delft, The Netherlands; [b]Earthwatch Europe, Oxford, United Kingdom; [c]Bowburn Consultancy, Bowburn, United Kingdom; [d]Great Lakes Laboratory for Fisheries and Aquatic Sciences, Fisheries and Oceans, Toronto, ON, Canada

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Allochthonous organic material Organic material (e.g., leaves, twigs, pollen) that enters a freshwater ecosystem.
Autotroph An organism, such as an alga or green plant, that fixes inorganic carbon using light energy in the process of photosynthesis.
Beta diversity A measure of compositional heterogeneity between two sampling points.
eDNA (environmental DNA) Genetic material from organisms present in sediment and water which can be used to detect biota.
Hydromorphology A subfield of hydrology (the scientific study of water in the environment) which is concerned with understanding the change in the physical structure of waterbodies, and their water content, over time.
Meso-habitat A distinct habitat type in a habitat patch, such as a river reach with pools, runs or riffles. The presence of these habitat types increases the compositional heterogeneity of the habitat patches, which in turn leads to an increase in biological diversity.
Metabarcoding A method of identifying species based on a genetic sequence unique to that species (the barcode). In the process a sample of e.g., macroinvertebrates is homogenized, the genetic material of interest isolated and amplified. The amplified genetic barcodes are then read, and the species in the homogenized sample identified suing a database of known species barcodes.
Ordination An analytical method used in statistics, also known as gradient analysis, that orders objects along axes based on the similarity of their character values. Once plotted, similar objects will appear to cluster together, while dissimilar objects will be further apart.

River reach A short stretch of a river with similar hydrological conditions.
Taxonomic classification A hierarchical system in which organisms are classified into groups based on their physical similarities. There are eight main ranks in the system, from the general Domain rank, to the specific Species rank, they are: Domain, Kingdom, Phylum, Class, Order, Family, Genus, and Species.
Trophic guild A guild is a grouping of species based on similarities in function or feeding. A tropic guild is a group of species that feed on the same food (e.g., planktonic, algae-eating herbivores).

General introduction

The ecological impacts of pressures on freshwater environments are typically assessed by evaluating the extent to which conditions deviate from "reference conditions" (i.e., the conditions we expect to find in the absence of significant anthropogenic influence (Bennion et al., 2011; Stoddard et al., 2006). These can be defined in a variety of ways, including (a) analysis of historical data; (b) space-for-time substitution, in which conditions from similar unimpacted systems are taken to represent nearby reference conditions; and (c) expert judgment (in cases where data is absent) (Wallin et al., 2003). In order to assess the extent of impacts on freshwater systems, modern policies such as the EU Water Framework Directive (WFD) (2000) and the U.S. Clean Water Act (CWA) of 1972, require that methods be developed to assess, interpret and report on the ecological state of surface waters in relation to their reference conditions. These policies require both methods and data for defining baseline conditions against which past or future change can be assessed.

The assessment methods that have been developed for surface waters are diverse. Most rely wholly or in part on measurements of various freshwater biota that respond to general pressures, or more precise stressors. In this chapter we focus on the biota, discussing how impacts are reflected in various different taxonomic groups. We present case studies of methods that can be used to measure impacts based on monitoring of algae, macrophytes, invertebrates, and fish. We then discuss challenges associated with acquiring data, and show examples of some novel techniques that can be used to fill spatial and temporal data gaps.

Policy relevance for monitoring

Policies such as the EU Water Framework Directive (WFD) (2000) and the U.S. Clean Water Act (CWA) of 1972 require that methods be developed to assess, interpret and report on the ecological state of surface waters. The assessment methods developed for surface waters are diverse, and most rely on the different taxonomic groups discussed in this chapter, as well as information on water chemistry and hydromorphology. The bioassessment protocols developed for the WFD and CWA are comprehensive, making use of several indicator groups to assess the ecological state of a system. Across Europe, countries have for historical reasons, developed their own assessment methods. Still, these needed to be harmonized, meaning that conflicting or redundant standards had to be minimized, in order to report on the ecological status of European water bodies. Many of the biologically-based national methods are now intercalibrated (Poikane et al., 2014).

Freshwater biota as indicators of impact

Freshwater ecosystems are remarkable in that they cover a tiny 0.01% fraction of the Earth's surface, and at the same time are home to nearly 10% of its genetic diversity (WWF, 2018). The vast majority of faunal diversity is represented by the invertebrates (86%) and the rest by vertebrates. The most diverse animal taxon are the insects, followed by crustaceans, arachnids and mollusks. The least diversified groups are the rotifers, annelids, nematodes and platyhelminths (Balian et al., 2007). Freshwater algal diversity may well exceed 100,000 species when taking into account taxonomic uncertainty and the fact that many species in freshwater ecosystems still await discovery and taxonomic description (Balian et al., 2010). Many major taxonomic groups have been used for the assessment of water quality and ecological status, including bacteria, protozoans, algae, macrophytes, benthic macroinvertebrates, fish and birds (Moog et al., 2018). The most commonly used groups are the algae, macrophytes, invertebrates and fish. For use as indicators of ecosystem health, each organism group has distinct advantages over the others, and used for different purposes. Indeed, there is a general proliferation of bioassessment methods, with nearly 300 ways to assess surface waters in Europe alone (Birk et al., 2012).

Algae occur anywhere where there is enough light, moisture and nutrients. For monitoring in the short-term or to measure the effects of sudden changes, algae are ideal indicators in lakes and rivers, because they have short lifespans and high reproductive rates, leading to high community turnover. The turnover in the algal communities, benthic algal communities in the case of rivers and planktonic algal communities in the case of lakes, can be used as an indicator of impact (Ortiz et al., 2020). Also, as long as there is some water, algae are relatively insensitive to extreme hydrological conditions (e.g., high water velocity), which helps to reduce the number of variables that need to be considered when evaluating the status of an ecosystem.

Macrophytes, like algae, are autotrophs and thus respond to changes in available light and nutrients in both surface water and sediment, but are longer-lived and have lower reproductive rates. Responses to changes take longer as macrophytes respond to changing conditions over longer timespans. They are, therefore, ideal indicators of longer-term changes in the prevailing nutrient regimes of both rivers and lakes. Unlike algae, macrophyte sensitivity to hydromorphology is useful in ecological assessment (Hering et al., 2006).

Invertebrates, particularly benthic macroinvertebrates, are by far the most commonly used indicator group in freshwaters (Moog et al., 2018). They are visible to the naked eye, and mostly readily identified at least to the broad taxonomic classification of family. Invertebrates are an ubiquitous and diverse group, and taxonomically relatively well known. The tolerance across different invertebrate groups to reduced oxygen caused by organic pollution has provided the underlying mechanism for their use in early monitoring schemes (Resh and Jackson, 1993). The relatively long lifecycle of benthic macroinvertebrates allows for the analysis of temporal disturbances (DeWalt et al., 2010). Although mobile, macroinvertebrates generally stay close to their local habitats and thus are also sensitive indicators of spatially-dependent disturbances, such as hydromorphological alterations.

Fish are present in most surface waters and because of their large sizes their identification is relatively easy, at least in temperate waters. Their taxonomy, life-histories and environmental requirements are largely well-known. Fishes can be categorized according to their feeding preferences (Sánchez-Hernández, 2020) into detritivores, herbivores, planktivores, piscivores, benthivores and omnivores. There is a close relationship between what a fish eats and its shape. For example, bottom-feeders like catfishes tend to be chunky, while predatory fish like salmon are streamlined. Fishes are highly mobile, and thus are affected by hydromorphological changes on the meso-habitat and reach-scale. Lateral and longitudinal connectivity play a huge role for both fishes (Shao et al., 2019) and macroinvertebrates (Wang et al., 2020), although the latter are less well-documented.

In the following sub-sections, the uses of major taxonomic groups, the algae, macrophytes, macroinvertebrates, and fishes, in surface water assessment are discussed and case-study examples presented of common group-specific assessment methods.

Case study: Algae

Algae are major primary producers in freshwater systems and, along with bacteria and allochthonous organic material, form the base of the aquatic food chain. The disruption to natural algal assemblages by addition of nutrients such as nitrogen and phosphorus, which typically limit primary production, can lead to ecological cascades with negative implications for ecosystem structure and the human use of water bodies for a wide range of purposes. Increased concentrations of the nutrients that normally limit algal growth can lead to alterations of algal community composition and increased biomass. The water industry has long had an interest in the algae that inhabit water supply reservoirs, and the problems they can cause particularly at high biomass, because of the direct risks to potable water supplies through clogging of filters (Henderson et al., 2008), taste and odor problems (Perkins et al., 2019), and cyanobacterial toxins (Carvalho et al., 2011). The risk of cyanobacterial toxins can limit the use of water for recreational uses (Carvalho et al., 2013) and increase the cost of water treatment, while deoxygenation of nutrient enriched waters can affect the viability of commercial fisheries (Gerdeaux et al., 2006). Algal blooms are particularly acute in lakes and reservoirs (Harper, 1992), where most primary production is due to suspended algae (phytoplankton). However, in recent years, interest has also extended both to benthic habitats in lakes (Vadeboncoeur et al., 2002, 2003) and to rivers. Phytoplankton blooms can also develop in slow-flowing rivers (Moorhouse et al., 2018) but the focus in rivers is more typically on attached benthic algae.

Lakes and other standing waters

There is a long history of the use of chlorophyll *a*s a proxy for the quantity of algae present in lake water. In 1982, terms such as "oligotrophic," "mesotrophic," and "eutrophic" were defined in terms of nutrient and chlorophyll concentrations (OECD, 1982) and this provided a basis for many subsequent trophic classification schemes. However, chlorophyll concentrations alone give little indication of the types of algae present and are, therefore, of limited value for estimating risks from cyanobacterial blooms. For these more detailed insights, estimation of taxonomic composition is required. A standard working procedure using inverted microscopy has existed for some time (Lund et al., 1958) and has, more recently, been standardized (Comité Européen de Normalisation (CEN), 2015a). Results are commonly expressed as biovolume of each taxon present—calculated from the cellular dimensions as measured during the analysis and standard formulae for each of the many shapes and forms of phytoplankton (Comité Européen de Normalisation (CEN), 2015b). This gives an indication of the relative proportion that each taxon makes to overall primary productivity, which means that contributions of key species can be evaluated and risks computed (Carvalho et al., 2011). Calculation of biovolume is, however, time-consuming and World Health Organization guidelines for managing toxic cyanobacteria are expressed in simpler terms (World Health Organization (WHO), 1999): the numbers of cyanobacterial cells per milliliter, with 20,000 cells/mL representing a threshold above which there is a low probability of adverse health effects, and 100,000 cells/mL representing the threshold for a "moderate probability" of adverse health effects.

Assessment of chlorophyll concentrations, nonetheless, provides either adjunct information or, in some situations, a viable alternative to enumeration and identification. Procedures for analyzing chlorophyll are well-established and the lower cost means that higher frequency sampling is possible, and is more commonly used than full enumeration and estimation of biovolumes. Long-term trends in chlorophyll provide evidence of the benefits of reducing nutrient inputs to lakes (e.g., Reynolds et al., 2012).

Rivers and streams

Assessment practices in flowing waters differ in two significant ways from that in lakes: algal assemblages are assumed to be vulnerable to a wider range of stressors than just nutrients and applied analyzes focus particularly on one group of benthic algae, the diatoms. Nutrients are one of a number of simultaneous stressors in rivers, and several metrics also capture toxic effects of ammonium-N, deoxygenation, heavy metals and salinity/conductivity, often referred to collectively as "general degradation."

Most of the metrics used to assess ecological health in rivers use diatoms as proxies for the entire algal community (Fig. 1), either to indicate general degradation (e.g., Indice de Polluosensibilié Specifique, IPS, Coste in CEMAGREF, 1982) or eutrophication (e.g., Trophic Diatom index, Kelly and Whitton, 1995). In addition, a few metrics have been developed to assess acidification (Juggins et al., 2016), and a few focus on soft-bodied algae rather than diatoms (e.g., Schneider and Lindstrøm, 2011). As for phytoplankton in standing waters, the type of water body has an effect on the observed communities, which then needs to be compared against an estimated reference condition (Kelly et al., 2020; Charles et al., 2021) provide a summary of all the benthic algae metrics used in the European Union and the United States.

Implications for the assessment of freshwaters using algae

If algal-based tools are to detect long term trends of change, then forward and backward compatibility of data is essential. For diatoms, in particular, this can be achieved by archiving slides to give the option of re-analyzing samples as taxonomic knowledge increases. A second important criterion is that methods are harmonized and, where possible, conform to national and international standards (Comité Européen de Normalisation (CEN), 2014a,b). This provides confidence that comparisons focus on the environmental "signal" rather than on "noise" introduced by sampling and analytical differences. Thirdly, most algae-based methods depend on the identification of groups of highly diverse organisms, but that often appear to be morphologically similar, and whose differentiation therefore depends on working at the limits of optical microscopy. Awareness that cryptic and semi-cryptic species both exist (Kahlert et al., 2019),and have differences in ecological profiles that may influence classifications (Kelly et al., 2015), raises questions about the potential for microscopy-based methods in the future. There are two plausible alternatives: first, to aim for a simpler generation of metrics based on traits that link to ecosystem functioning rather than simply aiming to maximize correlations with water chemistry and, second, to shift to alternative means for identifying and quantifying algae, such as metabarcoding (Kelly et al., 2020).

These observations reflect a general poor level of awareness among policy makers and managers of the important roles that algae play in freshwater ecosystems. Algae predominate media headlines when they cause problems. Yet, the time-consuming nature of

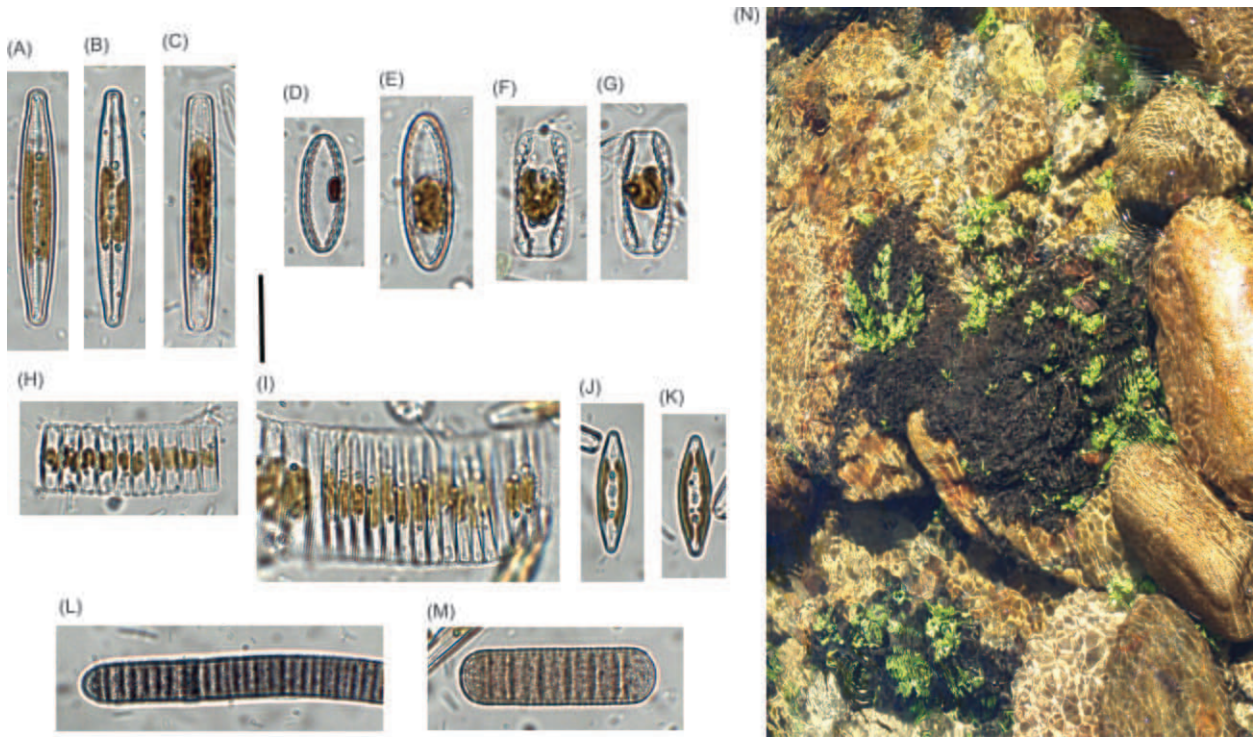

Fig. 1 Diatoms and other algae collected from mosses in a stream in the Sierra de Estrela, Portugal. (A–C) *Navicula angusta*; (D–G) Surirella cf. roba; (H and I) two different chain-forming Fragilaria sp.; (J and K) Navicula cf. cryptocephala; (L and M) Oscillatoria sp.; (N): a view of the moss habitat. the analyzes required is often regarded as an extravagance in light of budgetary constraints that state regulators have to work with. Moreover, expanding the ecologist's toolkit to include sensitive organisms such as diatoms more often than not increases the number of water bodies that fail to meet regulatory standards, therefore requiring investment, with costs borne by consumers and other stakeholders. This could be a potential barrier to political will.

Case study: Macrophytes

In healthy ecosystems, aquatic macrophytes (Fig. 2) play an important role as primary producers, as habitat for benthic algae, invertebrates and fish, and in nutrient and carbon cycling (Carpenter and Lodge, 1986). In shallow lakes, macrophytes also provide resilience to ecosystem-wide shifts towards algal dominance in cases of nutrient enrichment by providing habitat for algal-grazing fauna (Jeppesen et al., 1998). Given their important structuring and functional roles, any human impacts from eutrophication, climate change, acidification, alien species introductions, and other pressures that lead to reduced macrophyte diversity and abundance can also lead to knock-on impacts across the aquatic ecosystem (Chambers et al., 2007). Changes in macrophyte species composition are, therefore, a key indicator that pressures lead to, or have the potential to, cause significant ecological change.

Important influences on macrophyte species composition and distribution are often locally-driven and include water and sediment nutrient concentrations, organic carbon availability, light, temperature, and water flow (Alahuhta et al., 2021). Most commonly, changes in macrophyte species composition are used to monitor changes in (a) hydrology/morphology, and (b) trophic status as a result of eutrophication or, sometimes, acidification (Birks et al., 2005). As a result of the EU Water Framework Directive, a large number of different multi-taxon macrophyte indices have been developed and used across Europe to assess trophic impacts and deviation from reference conditions in both rivers and lakes. These are based on a number of different approaches, including total species or functional group richness, relative abundances of "sensitive," "tolerant," and "indifferent" species, and Lake Trophic Rank score approaches based on individual species responses to eutrophication (Penning et al., 2008). Examples include LEAFPACS, which has been applied to monitor eutrophication in both rivers and lakes (Willby et al., 2012), the Macrophyte Biological Index for Rivers (IBMR), which has been used to detect organic pollution (Furse et al., 2006; Szoszkiewicz et al., 2006), and the German macrophyte-based assessment for lakes, which has been used to assess deviation from reference condition in lakes across Germany (Stelzer et al., 2005). Beyond Europe, the development and use of macrophyte indices has been limited to site-specific

applications. Examples include the use of a wetland macrophyte index to detect water quality impacts on fish habitats in the Great Lakes (Croft and Chow-Fraser, 2007), and a submersed macrophyte index used to assess pollution in the Upper Mississippi River (Moore et al., 2012).

One of the most common critiques of the use of macrophyte community change as an indicator of environmental impact is the fact that relationships between plant species composition and specific environmental conditions are ambiguous (Demars et al., 2012). On a global scale, the factors that define macrophyte beta diversity (i.e., the ratio between regional and local species diversity) are understood now, and are strongly linked to habitat heterogeneity (Alahuhta et al., 2017a,b). Because of this, recent attempts to monitor macrophyte responses to environmental impacts have often taken a multi-indicator approach. In the EU Water Framework Directive, for example, macrophyte indices are often combined with algal indices to give an overall assessment of the status of primary producers (Cellamare et al., 2012; Kelly et al., 2020). Palaeoecological studies focussing on macrophytes typically also use multiple proxies, including the remains of crustacean cladocerans, diatoms, and pollen (Bishop et al., 2020; Salgado et al., 2010; Smol, 2008).

Implications for global assessment of freshwater systems using macrophytes

Historically, data on macrophyte abundance and species composition was difficult to obtain, and aquatic macrophytes were relatively poorly studied compared with other freshwater taxa (Alahuhta et al., 2021). However, new techniques for monitoring species and/or functional composition offer opportunities to increase global coverage of macrophyte data. These include both image-based survey techniques, such as satellite, aerial, or automated autonomous vehicle (AUV) surveys (e.g., Visser et al., 2015), and hydroacoustics (Spears et al., 2009).

If these advances in monitoring and availability of new data are to be used to assess changes in macrophyte species composition on a large scale, further research must be done into the macroecology of macrophytes. Alahuhta et al. (2021) identify a number of limitations to the current understanding of large-scale macrophyte responses to global environmental change, including: (a) excessive focus on local patterns and processes, (b) lack of temporal studies, and (c) few studies focussing on biotic interactions. This lack of macroecological understanding is reflected in the wide array of different macrophyte indices that are currently applied in different circumstances around the world. If these challenges can be overcome, macrophytes have the potential to act as indicators for whole-ecosystem responses to a wide variety of pressures (O'Hare et al., 2018). This potential has yet to be fully realized.

Case study: Invertebrates

The ecological and economic importance of invertebrates cannot be overstated. Invertebrates are functionally vital to aquatic ecosystems and can directly or indirectly affect human health and well-being. Invertebrates play major roles in the regulation of rates of primary production, decomposition, water clarity, thermal stratification, and nutrient cycling in lakes, streams and rivers (Strayer, 2006). Aquatic invertebrates are the primary food source for most fish species and many vertebrate species that live in or around freshwater. Some species, particularly in the Mollusca and Decapoda, are harvested from the wild or farmed, supporting regionally important fisheries. Some invertebrates are intermediate hosts or vectors of disease, such as malaria, schistosomiasis, and river blindness. Recent analyzes of long-term monitoring data reveal the ongoing decline in insect biodiversity, which is higher in freshwaters than other ecosystem types (WWF, 2018).

Cairns and Pratt (1993) offer a detailed history on biological monitoring with an overview of the differences in the European and North American traditions. The European tradition has its roots in saprobity (the degree of pollution) measured in rivers from the severity of organic enrichment (sewage) and its related decrease in dissolved oxygen. The presence and absence of pollution intolerant organisms is the basis on which the Saprobien system functions. The North American tradition started in the 1870s. This work focussed on the indicator value of benthic fauna. Further developments were made in the mid-1900s in which stream conditions were assessed using community indicator groups. Surveys were then adapted based on new and refined concepts about functional feeding groups and species assemblages and stream gradients.

Multi-taxon indices: Benthic invertebrates

Traditionally, water quality monitoring relies on multi-taxon indices, such as the Biological Monitoring Working Party (BMWP) (Hawkes, 1997) and an adaptation of that method, the South African Scoring System version 5 (SASS5) (Dickens and Graham, 2002). The advantage of multi-taxon indices is that they are relatively rapid assessments, as they usually operate at a coarse taxonomic resolution (family-level). The indices include multiple functional feeding groups, which have different tolerances to stressors. These advantages also lead to significant limitations. In the multi-taxon scoring system, sensitivity to pollution scores are set at the family level, and taxa identified to the family level. This ignores taxonomic and ecological sensitivities to stress at the taxonomic genus and species levels that make up a family. Secondly, these methods do not account for the sensitivity of individual functional feeding groups (e.g., shredders which feed of leaf litter, grazers which feed on periphyton, or predators which in turn feed on the grazers and shredders and other predators). An alternative, therefore, might be to use a single-taxon assessment method instead. The next section focusses on the use of a group of invertebrate predators in rivers and wetlands (dragonflies), but there are some notable uses of single-taxon approaches, for example using Chironomidae (Nicacio and Juen, 2015) in other habitat types including lakes.

Single taxon approach: Dragonflies

Dragonflies and damselflies (Odonata) are frequently identified as bioindicators (Samways and Simaika, 2016; Simaika and Samways, 2011, 2012), and are considered ideal candidates for medium to long-term monitoring (Oertli, 2008). The use of dragonflies as indicators for riverine ecological integrity is widespread (Chovanec et al., 2015; De Marco Júnior et al., 2015; Silva et al., 2010). They have also been used as indicators of wetland quality (Kutcher and Bried, 2014; Rosset et al., 2013), shallow lake restoration (D'Amico et al., 2004), and climate change in lakes and ponds (Fennessy et al., 2007; Rosset et al., 2010).

The Dragonfly Biotic Index (DBI) provides a measure of ecological integrity for both lotic and lentic freshwater systems (Simaika and Samways, 2008, 2011). It is a weighted measure based on the quantitative assessment of three sub-indices of: species distribution, threat status (i.e., IUCN Red List assessment) and sensitivity to disturbance. The total DBI of a river or stream reflects the total dragonfly assemblage, thus enabling water bodies to be compared and restoration success monitored.

The DBI, being based on the incidence of adult dragonflies at a monitoring site, has the advantage that it operates at the species level, and makes use of only one functional group, the predators. In comparing the performance of SASS with the DBI, a comparative assessment found that the DBI performs equally well to SASS and that dragonflies as a single taxon from a single functional group at the species level respond more clearly to habitat changes than multiple taxa from multiple functional groups (Simaika and Samways, 2011). Additionally, the value of adult dragonflies is their dependence on the overall "health" (ecological integrity) of both the terrestrial and aquatic parts of their habitat (e.g., Dolný et al., 2013). Lastly, practitioners do not need to enter the water, that can present safety concerns, and constraints to accessibility to sites.

Multivariate systems

Multivariate systems of macroinvertebrates are complex models that predict the aquatic community composition of a site based on the environmental conditions at that site. The multivariate model can be used to predict which taxa will be present at the site under given undisturbed environmental conditions. The site is then assessed based on the deviation between the observed and expected (reference or other baseline) condition. In order to be effective at prediction, multivariate systems require large amounts of data on the taxa used in the assessment. Taxa need to be well sampled and their spatial and temporal distributions and variability well documented. Similarly, the environmental parameters chosen to predict the presence of the taxa need to be relevant. Few such systems are in use, the most notable one is RIVPACS (Wright et al., 2000) developed in the United Kingdom. Similar systems have been developed in Australia, Canada, Czech Republic, Sweden and some states of the United States (see Paisley et al., 2014).

Implications for the globalization of freshwater invertebrate assessment approaches

Many nations have clear policies that call for the protection of biodiversity and ecosystem resources. Implicit to these policies is that appropriate indicators are used, or created where they do not exist (Stephenson et al., 2020). In terms of the DBI, this means that national DBIs need to be established. In terms of cross-country monitoring and co-operation, a pan-African DBI already exists (see Vorster et al., 2020). In Africa, the challenge is similar for the South African Scoring System, adaptations of which have been developed for Tanzania (TARISS) (Kaaya et al., 2015) and Zambia (ZISS) (Dallas et al., 2018). In many countries, the development of multivariate systems is not an option yet because of the enormous amounts of data required to build response models. It is more likely that where multi-taxon approaches exist, they will be supplemented with environmental DNA (eDNA) surveys. Where multi-taxon approaches do not exist, it is likely that traditional methods will give way to modern monitoring methods like eDNA, acoustics and remote sensing.

Case study: Fishes

Fish span multiple trophic levels, and the general public has an emotional connection to fishes. In Europe, there are at least 24 fish-based ecosystem assessment methods in use by 21 different countries for lakes alone (Ritterbusch et al., 2022). The situation is a bit different in North America (the United States and Canada), which has settled on a single method, the fish index of biotic integrity (IBI). In the 1980s in the United States, Karr (1981) developed a preliminary IBI framework. The12-metric IBI considered species composition and richness, and ecological factors such as abundance, trophic guild (group of species with similar diet), and condition of the fish. The multimetric IBI calculates a final score that reveals the integrity of the sampled site ranging from "very poor" to "excellent" (Minns et al., 1994). Integrity is defined as "the capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of natural habitat of the region" (Karr and Dudley, 1981).

How do fish communities reflect habitat integrity?

Fish species vary in their tolerances to environmental change. The most common metric when calculating the biotic integrity of a site using fishes is the presence and abundance of intolerant species (Ruaro et al., 2020). Fish species intolerant of human-induced changes in their environment cease to persist at a site or occur at very low numbers. Intolerance can be classified as a sensitivity to

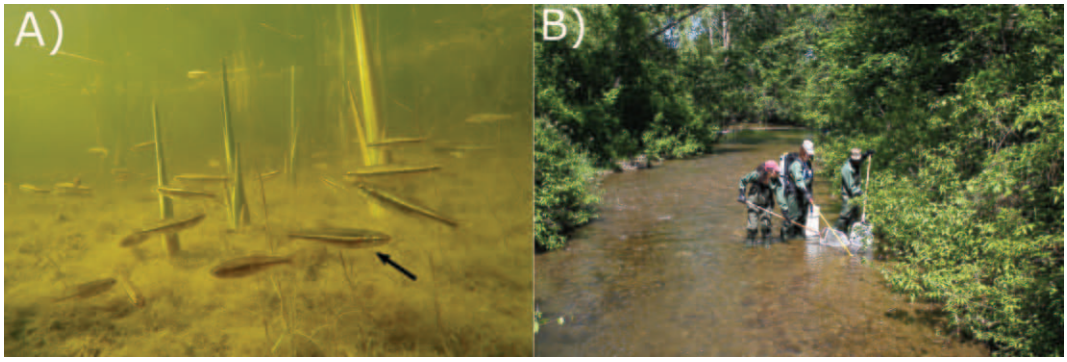

Fig. 3 (A) Underwater image of Redside Dace (*Clinostomus elongatus*, indicated by a black arrow) among several other fish species at a restored site; (B) sampling fishes using a backpack electrofishing unit in a wadeable stream. Photo credits: R.A. Castañeda.

one or multiple human-induced stressors, depending on the stressor(s) of interest of the biotic integrity study. In many cases, intolerant species are more likely to be endangered or imperiled as these fishes are the first to disappear with habitat degradation. For example, in Canada, an endangered minnow, the Redside Dace (*Clinostomus elongatus*), is considered to be a positive indicator of stream water quality as it is sensitive to loss of canopy cover, and increasing turbidity and water temperatures. These stressors are often associated with urbanization (COSEWIC, 2017) (Fig. 3). Other positive indicators of biotic integrity include species richness, endemic taxa richness, and the presence of piscivores (top predators) and habitat specialists (Ruaro et al., 2020).

Some species are very tolerant to changes and as a result would be considered negative indicators of biotic integrity. Other negative indicator criteria include the presence and high abundance and biomass of generalists, omnivores, hybrids, and non-native species; and the number of individuals with signs of failing health (Hughes et al., 1998). The presence of non-native species, for example Round Goby (*Neogobius melanostomus*) in Canada (Raab et al., 2018) and Largemouth Bass (*Micropterus salmoides*) in South Africa (Weyl et al., 2015), is a strong negative indicator of ecosystem integrity because of their often destructive impacts on local biotic communities and environment (Kennard et al., 2005).

Context- and region-dependence of the IBI

Karr (1981) cautioned that each region will need to create its own index based on fundamental ichthyological knowledge of the region, i.e., the index is context- and region-specific. For example, a fish community in a Canadian river is inherently different from, and less speciose than, a fish community in a river in the Amazon basin. As such, different information on species tolerances and diversity are needed to populate the IBI variables. Additionally, assigning species to the metrics for the IBI score should be specific to the type of waterbody, e.g., lakes, wetlands, rivers, streams, and at the appropriate scale (Bacigalupi et al., 2021). Further, knowledge on fish species natural distributions and on the identification of hybrids and trophic guilds for each region is necessary to accurately score the integrity of a study site.

Fish sampling approaches to inform IBI scores

Given that the most used metric is the presence of intolerant species, conventional sampling methods are being restricted to mitigate the impacts of stress and mortality that may result from using these gear types, for example, seine nets and electrofishing (Castañeda et al., 2020). The use of underwater cameras and eDNA, methods that do not require physical handling of fishes, are becoming increasingly popular for detecting fishes in temperate and tropical waterbodies, especially in remote areas (Ellender et al., 2012). Nevertheless, rigorous replicable sampling protocols still need to be developed. Lastly, investigations on the optimal number of sampling sites is needed to ensure variance in IBI scores is not an artifact of non-fish related parameters (Kindree et al., 2020).

Using the fish IBI is a useful and practical method to assess the health of a waterbody, however, as highlighted in this section careful attention is needed when used. Reference conditions need to be defined, and detailed relevant regional ichthyological knowledge and sampling protocols need to be established and tested to ensure comparability between sites and to ensure that differences in indicator scores are due to human-related impacts and not just natural variability (Ruaro et al., 2020).

Global assessments of impact using freshwater biota: Filling data gaps

Sizeable gaps remain in the availability of data describing freshwater taxa and their habitats, both geographically (e.g., sub-Saharan Africa) and for specific groups (e.g., freshwater mollusks) (Tickner et al., 2020). Furthermore, datasets covering periods of decades or longer are rare, despite the fact that many pressures are active over these timescales (Sayer et al., 2010). Both spatial and temporal data are vital for defining reference conditions and measuring changes in state. Gaps in data also have implications for applying the bioassessment methods described above (see discussion).

Several techniques for filling these data gaps have already been discussed in this chapter and elsewhere. In the specific context of measuring deviation from reference state, the best approaches are those that seek to provide continuous data over long timescales

(Roberts et al., 2020). Paleoecology is often used both to define reference conditions (e.g., Bennion and Simpson, 2011) and to investigate the extent of ecological impacts on lakes (e.g., Bishop et al., 2020; Salgado et al., 2010). New technologies can also help to increase the spatial resolution of available data in the present day. Analysis of the genetic material present in water and sediments (i.e., environmental DNA or eDNA) is increasingly being used as a biomonitoring technique that allows rapid detection of biota (Díaz-Ferguson and Moyer, 2014).

Image-based surveys (Spears et al., 2009) also show promise. However, most of these techniques rely on the use of proxies to detect species presence. The most promising means of increasing the spatial resolution of in-situ observations exists in the rapidly-growing field of citizen science.

Case study: Collecting data from across the world using citizen science

Citizen science (i.e., the involvement of non-scientists in scientific research) is increasingly being cited as a potential source of data to fill the gaps that exist in global descriptions of freshwater taxa and habitats (Turak et al., 2017). Given careful consideration of methodological design, data management, and volunteer training, well-designed citizen science projects can collect high quality data (Fig. 4; Anhalt-Depies et al., 2019; Wehn et al., 2021). Citizen science can also be used to harness and interpret local and indigenous knowledge, and to provide contextual information about observed impacts and their associated drivers, pressures, and appropriate management responses (Danielsen et al., 2019). Through their involvement in citizen science, volunteers can be encouraged to become more active participants in freshwater ecosystem management (van Noordwijk et al., 2021).

Citizen science bioassessments and impact monitoring

There exist a huge variety of citizen science monitoring schemes that can be used to measure impacts on freshwater ecosystems. Perhaps the most well-known are the many biodiversity recording schemes that exist around the world and allow volunteers to record species sightings (Chandler et al., 2017). From a public engagement perspective, species monitoring schemes that focus on a single charismatic species can be particularly effective. For example, single species of dragonflies have been used to raise conservation awareness in citizen science, e.g., the Amani Flatwing (*Amanipodagrion gilliesi*) in Tanzania has been used as a symbol of conservation and good water quality, and has at the same time been used as a tourist attraction at a local village (Clausnitzer et al., 2017). Crowdsourcing platforms like iNaturalist allow data from multiple projects to be uploaded and accessed in one place, meaning that data are available for use in bioassessments (Matheson, 2014).

Where citizens are involved in monitoring impacts more directly, simplified bio-indices are a common approach. Perhaps unsurprisingly, they most commonly use invertebrates as a bioindicator. In the United Kingdom, the Angler's Riverfly Monitoring Initiative (ARMI) has created a simplified version of the BMWP score based on eight easily-recognizable taxa, and volunteers use this score to detect biological responses to pollution (Brooks et al., 2019). SASS5 has also been adapted for use by citizen scientists

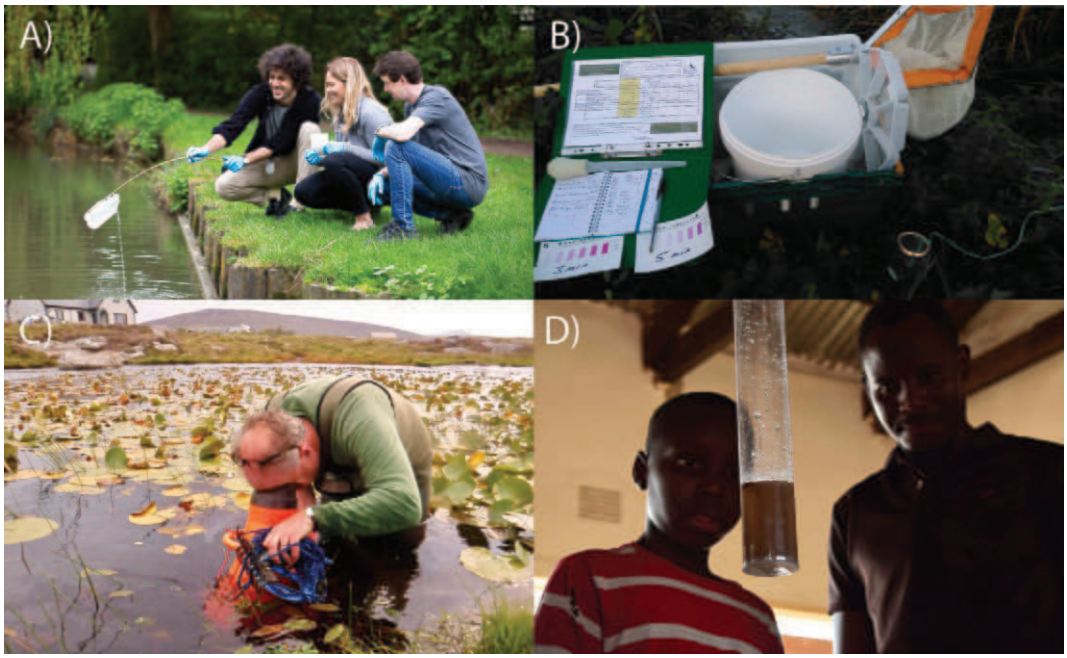

Fig. 4 Citizen scientists, professionals and in practice (A) FreshWater Watch volunteers sampling for water quality with a water bottle on a stick, (B) water quality and macroinvertebrate sampling equipment and appropriate forms for filling-in; (C) professional macrophyte survey using a double-sided rake grapnel and bathyscope; and (D) demonstration of water quality assessment using a turbidity tube to school children and staff in Zambia. Photo credits: (A) John Hunt, (B) John Pratt, (C) Isabel Bishop, and (D) WWF Zambia.

(Graham et al., 2004). The DBI has not yet been explicitly employed in citizen science, but its development has benefitted from citizens compiling distribution maps of dragonflies across Africa (Clausnitzer et al., 2012).

Algae are relatively easy for citizen scientists to collect, but identification is challenging, particularly without access to a microscope. This puts taxonomy-based algal assessments beyond the reach of all but the most specialist citizen scientists. Recent innovations in sensor technology allow citizen scientists to easily measure either chlorophyll *a* fluorescence or hyperspectral water color as a proxy for chlorophyll using low cost sensors or smartphones (Busch et al., 2016; Friedrichs et al., 2017). Less high-technology approaches involve asking citizen scientists to report visual algal blooms or to observe changes in water color over time. Both of these approaches have been used to successfully quantify phytoplankton increases in systems that have an impact from nutrient enrichment (Castilla et al., 2015).

Fish populations can be monitored using angler catch data. Often, these datasets extend over long time periods and it is, therefore, possible to assess long-term community responses to ecological pressures (e.g., Snyder et al., 2019). Other approaches have mostly focused on single species of conservation interest and/or invasive species, allowing them to use targeted trapping (e.g., monitoring movement of the European Eel (*Anguilla anguilla*) (Pecorelli et al., 2019)). The development of eDNA methods that can be used by citizen scientists offer future opportunities for more complete bioassessments to be carried out by volunteers beyond the angling community (Biggs et al., 2015).

Citizen science programs that assess changes in macrophyte community structure as an indicator of impacts on freshwater systems are rare. One exception is the global citizen science project FreshWater Watch (see below), which asks volunteers to record the presence of submerged, emerging, and floating leaved plants as part of the standard method. This information has been used to assess differing responses of macrophyte- versus phytoplankton-dominated ponds to nutrient inputs (Scott and Frost, 2017).

Considerations for global implementation

There is a huge variety of different types of citizen science projects, each of which has different characteristics and different volunteer motivators (Ceccaroni and Piera, 2017; van Noordwijk et al., 2021). Typically, citizen science projects that are successful in engaging volunteers over a longer time period are strongly place-based, often tapping into participants' vested interest in environmental impacts that directly affect themselves or their communities (Jollymore et al., 2017). While short term or highly localized projects are often best suited to volunteers, they are less well-suited to gathering information about impacts on freshwater systems on regional or global geographic scales.

A solution to this challenge is to link local or short-term clusters of citizen science activity to a more extensive global network of freshwater volunteer monitoring. This is the approach taken by the FreshWater Watch project (https://freshwaterwatch.thewaterhub.org/). FreshWater Watch volunteers use a globally consistent core protocol to monitor the state of freshwater systems worldwide. This protocol is built around the basic building blocks of freshwater systems, and includes simple observations of hydrology, ecology at family level, and land-use context, as well as measurements of turbidity and nutrient concentrations (Thornhill et al., 2018). This method has been applied to investigate localized issues, such as phytoplankton dynamics in urban watercourses in Brazil (Cunha et al., 2017). Uniquely for a freshwater citizen science project, it has also been used to assess the ecological impacts of nutrient enrichment in both lotic and lentic waters on a global scale (Loiselle et al., 2016). Because of this globally standardized approach, FreshWater Watch is now being explored as a potential tool that can be used to monitor global progress towards the Sustainable Development Goal 6 indicator for ambient water quality, indicator 6.3.2 (Bishop et al., 2020; Quinlivan et al., 2020).

Conclusion/Synthesis

The use of organisms for measuring the impact of human activities on inland waters is important and has found application globally. It makes sense to measure the condition of organisms and the composition of assemblages and communities to assess the state of ecosystems to get a measure of their "health" over time, and to use water chemistry as complementary information, rather than to rely on water chemistry alone. However, an enormous variety of assessment methods exists, many with similar goals (Birk et al., 2012).

In order to manage and reverse the effects of increasing pressures on the freshwater environment, comprehensive monitoring and evidence gathering is necessary on a global scale (Winfield, 2014). A key recommendation for safeguarding freshwaters for the future is to fund and implement globally standardized monitoring strategies (van Rees et al., 2020), and to more explicitly include freshwater ecosystems across the UN Sustainable Development Goals framework. This means including freshwater ecosystems not only as part of SDG 6 "Clean Water and Sanitation," but also SDG 15 "Life on Land" and SDG 14 "Life below Water." In addition to this, individual nations and regions have implemented their own policies that include specific requirements for monitoring impacts on freshwater systems, such as the European Union's Water Framework Directive. Assessment methods, therefore, need to be fit for purpose not only within their local and national context, but also on international scales. This means that methods need to be harmonized and underpinned by national and international standards (Comité Européen de Normalisation (CEN), 2014a,b), to give confidence that comparisons focus on the environmental "signal" rather than on "noise" introduced by sampling and analytical differences. Across Europe, countries have for historical reasons, developed their own assessment methods. In practice, only a few methods have become standard methods used at national levels. Still, these needed to be harmonized, meaning that conflicting or

redundant standards had to be minimized, in order to be able to communicate clearly on the ecological status of water bodies using a continental-scale European standard. Indeed, this has been achieved, and the different national methods are now intercalibrated (Birk et al., 2013), albeit critical issues remain (Poikane et al., 2014).

Data are fundamental to measuring impact, not only because they allow us to understand the current state of the environment relative to reference conditions, but also because they underpin our ability to develop harmonized bioassessment protocols. Bioassessments require, by nature, a fundamental understanding of the responses of individual taxa and/or functional groups to defined pressures. Often, multiple interacting pressures are involved, each of which acts on different spatial and temporal scales. This means that bioassessment methods are often location-specific, and the availability of protocols varies globally in accordance with the availability of data. For fish, region-specific IBIs have been developed worldwide (Ruaro et al., 2020), in North and South America (Moncayo-Estrada et al., 2015; Petesse et al., 2014), Europe (Aparicio et al., 2011), Asia (Jia et al., 2013), Africa (Kamdem Toham and Teugels, 1999), and Oceania (Joy and Death, 2004). For invertebrates, national DBIs need to be established. In terms of transnational monitoring and co-operation, a pan-African DBI already exists (see Vorster et al., 2020). In Africa, the challenge is similar for the South African Scoring System, adaptations of which have been developed for Tanzania (TARISS) (Kaaya et al., 2015) and Zambia (ZISS) (Dallas et al., 2018). The development of multivariate systems is not an option yet in many countries, and thus transnational protocols are a far way off also. Historically, data on macrophyte abundance and species composition was difficult to obtain, and aquatic macrophytes were relatively poorly studied compared with other freshwater taxa (Alahuhta et al., 2021). This has led to a limited understanding of macrophyte ecology and response to global change. As a result, macrophyte-based indices are currently under-utilized outside of Europe. Algae present a specific challenge because they are highly diverse, often morphologically-plastic organisms for which differentiation depends on working at the limits of optical microscopy. Awareness that cryptic and semi-cryptic species both exist (Kahlert et al., 2019) and have differences in ecological profiles that may influence classifications (Kelly et al., 2015) raises questions about the potential for microscopy-based methods in the future. Possible solutions are to work out simpler metrics or to shift to more modern methods in species identification, such as metabarcoding (Kelly et al., 2020).

We now know that freshwater environments are under pressure from a huge number of stressors, on both local and global scales (Tickner et al., 2020). The differences in sampling protocols and sampling effort make comparisons across methods difficult. There is therefore a need to identify which protocols yield the most information across local, regional or continental scales, keeping in mind also that many waterbodies cross several national boundaries, and water authorities have to, in order to effectively manage waterbodies, communicate consistent information with each other, preferably based on standardized sampling protocols. While in Europe there have been efforts to harmonize sampling protocols, these have also presented some challenges in consistency across national and biogeographical boundaries. There is an important need to develop agreed protocols globally and for greater use of biotic indicators. This can particularly assist in the progress towards the assessments needed for the implementation of the internally agreed Sustainable Development Goals (sdgs.un.org/goals). As a result of this, the importance of cross-sector collaborations cannot be underestimated. Involving multiple stakeholders in monitoring impact, for example using citizen science, will facilitate this consistent communication, as well as opening up opportunities to harness new sources of knowledge and involve wider populations in waterbody management.

An example of good practice is the Freshwater Biodiversity Observation Network (FWBON, geobon.org/bons/thematic-bon/freshwater-bon/), a volunteer network of freshwater practitioners, researchers, citizen scientists, and decision makers. It is the aim of FWBON to globally harmonize monitoring sampling protocols that can be used to measure and analyze changes in the abundances of taxa, which is particularly useful for tracking climate change. At the same time, FWBON has also recognized the need to standardize assessment protocols for better management of aquatic ecosystems and ecosystem services. Ideally, a globally harmonized monitoring network would function on top of a globally harmonized ecosystem assessment network, thereby collecting information about the state of the ecosystems, while at the same time delivering important information on changes in the richness, abundance and phenology of key species.

Knowledge gaps

- Aim for a simpler generation of metrics based on traits that link to ecosystem functioning.
- Shift to alternative means for identifying and quantifying algae, such as metabarcoding.
- Further research must be done into the macroecology of macrophytes.
- Development of eDNA methods that can be used by citizen scientists.
- Implement globally standardized monitoring strategies.
- Development of assessment methods for multiple pressures on aquatic ecosystems.

Citizen Science for Co-monitoring and Co-managing Impact on Ecosystems and Inland Waters

Uta Wehn, Hydroinformatics and Socio-technical Innovations Department, IHE Delft Institute for Water Education, Delft, Netherlands

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Citizen science The involvement of members of the public in data and knowledge generation.
Co-management Involves the sharing of power and responsibility between government and local resource users (Berkes, 2009).
Co-monitoring The involvement of citizens and communities in measuring the status of ecosystems, and/or monitoring the effects of policy responses.
Knowledge co-production Different constellations of scientists, members of the public, decision makers, industry and other stakeholders collaborating in the generation of data and knowledge in line with the scientific method.
Participation The practice of involving members of the public in agenda setting, decision-making, and policy-forming activities of organizations/institutions responsible for policy development' (WeObserve glossary).
Stakeholder All persons or groups who can affect or can be affected by a project, program or organization.

Introduction

This chapter introduces citizen science as a means for co-monitoring and co-managing impact of ecosystems and inland waters and explains what comes into play when implementing citizen science. In essence, citizen science constitutes the involvement of members of the public in data and knowledge generation. Citizen science has been used, for example, for inland water quality assessment (Malthus et al., 2020), for hydrological monitoring and ecosystem services management (Njue et al., 2019; Assumpção et al., 2018), and for comparing temperature difference between air and inland waters and its link to global warming (Weyhenmeyer et al., 2017).

This chapter focuses specifically on citizen science as an approach to the management of ecosystems and inland waters. This can entail identifying driving forces (especially direct drivers at local scale) and pressures (e.g., increased nutrient emissions to water), measuring the status of water bodies (e.g., in terms of pollution) as well as impact (e.g., changes in fish yields) and results of policy responses (targeting drivers, pressures, state and/or impact).

Over the past three decades, co-monitoring and co-management of the environment, including ecosystems and inland waters, have been recognized in, and encouraged by, international policy guidelines, e.g.:

- Principle 10 of the Rio Declaration on Environment and Development: "Environmental issues are best handled with participation of all concerned citizens, at the relevant level" (UNGA, 1992).
- Two articles of the Aarhus convention: "public participation concerning plans, programs and policies relating to the environment" (Article 7), "public participation during the preparation of executive regulations and/or. . .legally binding instruments" (Article 8) (UNECE, 1998). In 2021, recommendations adopted by the Parties of the Aarhus Convention explicitly state citizen science as ways to collect and imprvove accessibility of environmental data, and to implement effective public participation in decision making in environmental matters (UNECE, 2021).
- Article 14 of the Water Framework Directive: "Member States shall encourage the active involvement of all interested parties in the implementation of this Directive, in particular in the production, review and updating of the river basin management plans" (EC, 2000).

- Target 6b of the Sustainable Development Goal #6: "Support and strengthen the participation of local communities in improving water and sanitation management" (2030 Agenda for Sustainable Development, adopted by the United Nations in 2015).

The body of literature on what is citizen science and what works well when implementing citizen science (and what does not) is steadily evolving. As citizen science requires the involvement of people, paying attention to their motivations, skills and resources, constraints and expectations provides the basis for sound and successful implementation. The aim of this chapter is to introduce different forms of citizen science and what comes into play when involving citizens in co-monitoring and co-managing inland waters, i.e., the practicalities and key challenges involved when implementing citizen science.

Definitions and typologies of citizen science

The term citizen science is often used to refer to the involvement of the public in data collection for scientific purposes or other steps of the scientific method (Shirk et al., 2012), not least to fill data gaps. Others consider citizen science as a novel form of stakeholder engagement to address societal challenges (Fritz et al., 2019), democratizing science and policy (Irwin, 1995), and improving transparency, equity, inclusiveness and justice (e.g., Wehn et al., 2021a,b; Cooper et al., 2021).

Owing to the diversity of contexts and applications of citizen science as a concept, there is no single agreed definition for citizen science (see also chapter by Latimore and Lowry, 2022, in press) Haklay et al. (2021a) identified more than 30 definitions and argued that while definition of citizen science center around the notion of public participation in scientific research, most definitions lack precision and hence can be interpreted in different ways. The chosen definition should fit the context, aim and purpose of use.

De facto, by now citizen science has become an "umbrella term" for a wide range of activities and interactions related to data and knowledge co-production among different constellations of scientists, members of the public, decision makers, industry and other stakeholders (Fig. 1).

Fig. 1 Illustration of stakeholders and their interactions in citizen science, the Ground Truth 2.0 project. Source: Wehn U, Alfonso L, Lobbrecht A, van de Giesen N, van der Kwast H, Joshi S and Masó J (2015) Ground Truth 2.0 – Environmental Knowledge Discovery of Human Sensed Data, Horizon 2020 Project, Description of Action.

Wiggins and Crowstone (2011) created a typology focused on project goals and their use of technology, based on an examination of a variety of project characteristics across 32 projects and clustering, resulting in five mutually exclusive and exhaustive types of projects:

(1) **Action**—Action-oriented citizen science projects encourage participant intervention in local concerns, using scientific research as a tool to support civic agendas. They are most commonly grassroots or "bottom-up," are not conceived or planned by scientists, and usually involve long-term engagement in local environmental concerns.
(2) **Conservation**—Conservation projects support stewardship and natural resource management goals, primarily in the area of ecology; they engage citizens as a matter of practicality and outreach, and they tend to be regional in scope.
(3) **Investigation**—Investigation projects are focused on scientific research goals requiring data collection from the physical environment. Education is frequently a strongly valued but unstated purpose, and task structures often support ongoing learning. These projects range from regional to international in scope, and can achieve very large scales of participation.
(4) **Virtual**—Science-oriented Virtual projects are ICT-mediated with no physical elements whatsoever, they are formed through top-down organizing by academics, and most projects' affiliations are exclusively academic.
(5) **Education**—Education projects make education and outreach their primary goals, with relevant aspects of place. They can be split into those focusing on informal compared with formal learning opportunities, and are sometimes explicitly designed to permit cumulative learning experiences.

Shirk et al. (2012, p. 4) distinguished five models of citizen science, based on the degree of participation of citizens and communities in scientific research:

- "*Contractual* projects, where communities ask professional researchers to conduct a specific scientific investigation and report on the results;
- *Contributory* projects, which are generally designed by scientists and for which members of the public primarily contribute data;
- *Collaborative* projects, which are generally designed by scientists and for which members of the public contribute data but also help to refine project design, analyze data, and/or disseminate findings;
- *Co-Created* projects, which are designed by scientists and members of the public working together and for which at least some of the public participants are actively involved in most or all aspects of the research process; and
- *Collegial* contributions, where non-credentialed individuals conduct research independently with varying degrees of expected recognition by institutionalized science and/or professionals."

What these five models of citizen science (the so-called 5C) imply for the involvement of the public in each step of the scientific method is illustrated in Fig. 2 by Haklay (2019) partially based on Cooper et al. (2007).

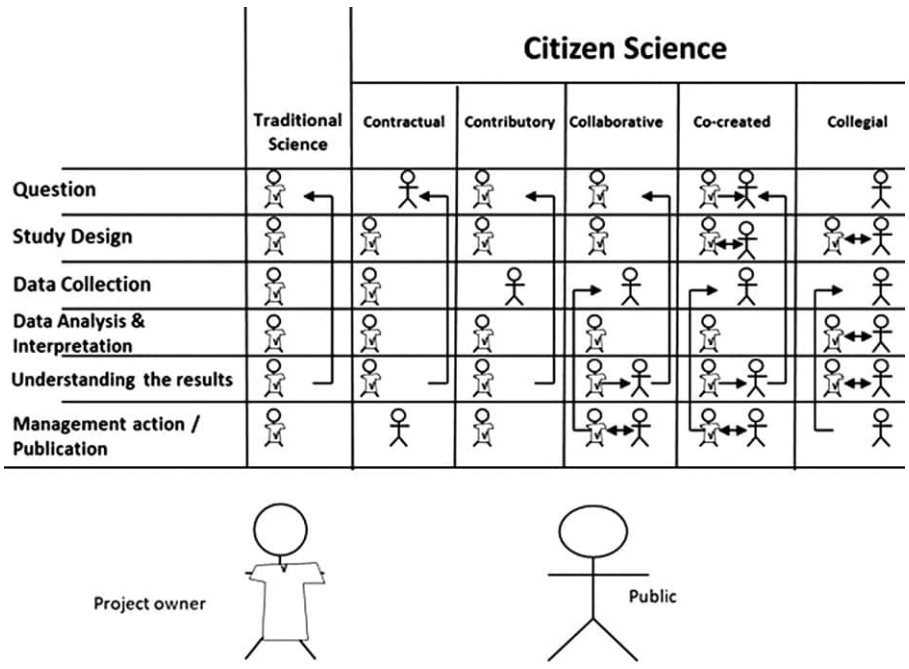

Fig. 2 Illustration of the five citizen science types. Source: Extracted from Haklay MM (2019) Introduction to Citizen Science & Scientific Crowdsourcing, Lecture Notes, UCL., partially based on Cooper C, Dickinson J, Phillips T and Bonney R (2007) Citizen science as tool for conservation in residential ecosystems. *Ecology and Society* 12 (2).

This categorization highlights that the roles of citizens and communities, on the one hand, and scientists (including those in public agencies), on the other hand, can differ substantially when engaging in citizen science in terms of "who takes the lead" and "who invites whom." This is often also distinguished more simply as either "top down" (science-driven or authority-driven) and "bottom up" (community-driven) initiatives.

Combining both aspects—the goals of projects and the degree of participation—Schäfer and Kieslinger (2016), based on Bonney et al. (2009), Shirk et al. (2012) and Wiggins and Crowston (2011), mapped citizen science projects that differ in terms of the main knowledge "producers" (citizens compared with scientists/researchers) and in terms of the project aims (answering a scientific question compared with implementing interventions in the socio-ecological system) (Fig. 3).

This illustrates that a range of different knowledge co-production activities can be considered citizen sciencei.e., pursuing civic agendas related to local environmental concerns; creating learning opportunities and awareness raising). It also positions the role and application of the produced knowledge in terms of its contribution to either science (answering a scientific question) or policy and local action (intervention in socio-ecological systems).

Co-monitoring and co-management via citizen science

Co-monitoring and co-managing ecosystems and inland waters entails the involvement of citizens and communities in measuring the status of ecosystems, monitoring the effects of policy responses, and/or setting targets for limits of acceptable change or ambitions for restoration. Citizen science projects and initiatives can contribute to co-monitoring and co-managing ecosystems and inland waters, albeit to differing degrees (see case studies Table 1).

Some argue that community-based monitoring encompasses the activities and relational dynamics of both, community-based "monitoring" and community-based "management" (Conrad and Hilchey, 2011). Specifically, Whitelaw et al. (2003) define community-based monitoring as "A process where concerned citizens, government agencies, industry, academia, community groups and local institutions collaborate to monitor, track and respond to issues of common community concern" (p. 410).

The distribution of both rights and responsibilities related to a particular resource appears to be pivotal to different definitions of co-management (Plummer and Fitzgibbon, 2004), e.g.:

- Co-management involves "the sharing of power and responsibility between government and local resource users" (Berkes et al., 1991, p. 12).
- "Co-management can be thought of as a spectrum of institutional arrangements in which management responsibilities are shared between the users (who may or may not be community-based) and government" (Yandle, 2003, p. 180).

Contributory approach to generate data for calibration of satellite information, and a synoptic overview of rivers, lakes and coastal water quality for natural resource management.	https://www.eyeonwater.org/ www.citclops.eu

The power-sharing arrangements and institutional relations are conceived as differing degrees of role sharing between government and resource user communities (Molle and Closas, 2019). Some suggest to not get stuck on the specific institutional arrangements, but consider co-management as a "continuous problem-solving process" (Carlsson and Berkes, 2005, p. 65). In this sense, co-monitoring has been proposed as a strategy to facilitate or improve co-management (Berkes, 2009), involving local partners and stakeholders in deciding what is to be monitored and including local traditions of reading and interpreting environmental signs (Kofinas, 2002; Mutimukuru et al., cited in Berkes, 2009). The long-standing tradition of community science, linked to social action for improving environmental injustice, protecting of human rights and addressing public health issues, has even been regarded to "elevate local experts and place-based issues above scientific experts and publication-driven research agendas" (Cooper et al., 2021, p. 1387).

The use of citizen science in co-monitoring and co-management enhances and changes existing forms of public participation (Wehn et al., 2015b): this varies depending on who is selected to participate in decision making (including in decisions on what data to collect); how participants interact in decision making (e.g., spectator compared with negotiator) and when and how citizen-generated data and knowledge are included; and how and by whom the generated knowledge and insights are acted upon and turned into formal decisions. It thus still holds that the precise definition of co-management should be considered in context- and application-dependent (Berkes, 1994), including—or especially—the role of citizen science. Similarly, the changes resulting from co-monitoring and co-management via citizen science are also location-specific and locally-shaped (Wehn et al., 2015a).

Overall, the role of citizen science in co-monitoring and co-management can be grouped into three, partially overlapping, categories (Fig. 4) Wehn et al. (2019a), all of which entail some form of community-based monitoring: (i) environmental monitoring via implicit and explicit data collection by citizens; (ii) cooperative planning via stakeholder engagement and interactions, including among citizens, communities and decision makers, in consultation, feedback and discussions; and (iii) environmental stewardship, i.e., communities, authorities and other stakeholders jointly taking care of the environment via fully realized dialogs and shared responsibility for natural resource management.

Moreover, the role of citizen scientists in co-monitoring and co-management is not necessarily fixed and can—and is even intended to—evolve over time: their initial awareness of and involvement in water health may be raised, for example via personal interest as in the Swim Drink Fish initiative in Canada or the Drinkable Rivers initiative in Europe (Table 1); this can then evolve into stewardship of waterbodies, using citizen science data and influence to advocate and negotiate for upgrades of their local waterbodies to higher classification and designation.

In Europe, efforts to seize the opportunities presented by the increasing popularity of citizen science and the rapid diffusion of Information and Communication Technologies (ICTs), for co-monitoring and co-management purposes have led to the emergence of citizen observatories (COs) for a wide range of thematic issues (Fig. 5) (WeObserve, 2021), including water quality and the health of ecosystems.

As a particular form of citizen science and community-based monitoring schemes, from the outset and very directly and deliberately, COs seek to foster citizen and community participation in environmental management and to contribute to policy

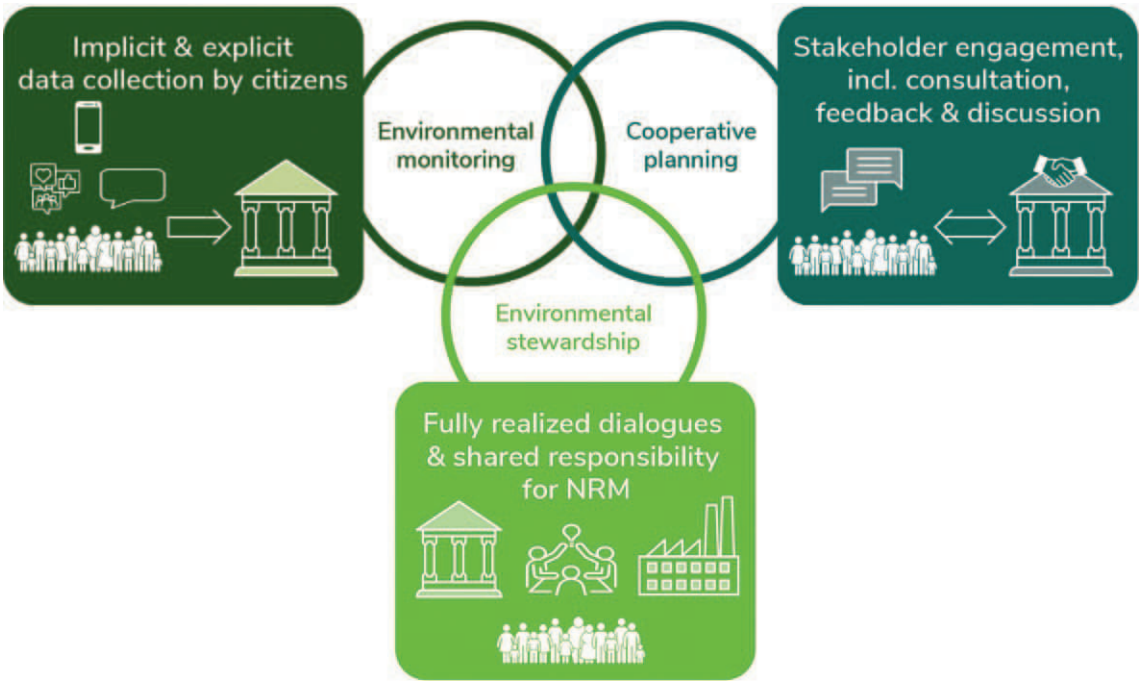

Fig. 4 Different roles of citizen science in co-monitoring and co-management. Source: Wehn U, Pfeiffer E, Anema K, Joshi S, Vrancks S, van der Kwast H, Giesen R, Masó J, Gil-Roldàn E, Ceccaroni L, Almonani A, and Gharesifard M (2019a) Co-designing Local Knowledge Co-Production for Sustainability: The Ground Truth 2.0 Methodology, Presented at the ASSIST-UK Conference (Association of Science, Technology and Innovation Studies UK), 9–10 September, University of Manchester.

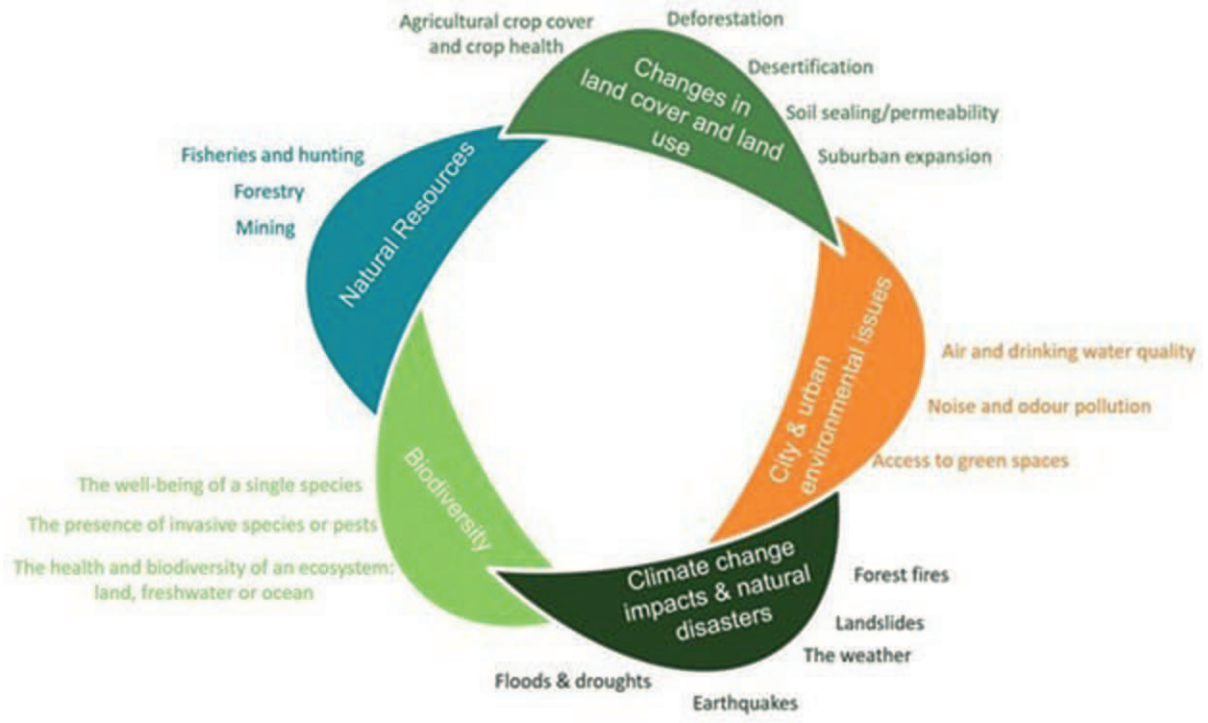

Fig. 5 Examples of thematic issues monitored by citizen observatories. Source: WeObserve consortium (2021). WeObserve Cookbook: Guidelines for creating successful and sustainable Citizens Observatories, www.weobserve.eu/weobserve-cookbook.

and decision making, ideally beyond the project lifetime (Wehn et al., 2015a). In essence, COs consist of a set of stakeholders, interactions and a platform: citizens, decision makers and scientific experts (and other stakeholders) are interacting to improve natural resource management, using a technical platform to facilitate their interactions (Wehn et al., 2019b). In such an information ecosystem for citizens and communities (Mazumdar et al., 2016), tailored ICT infrastructure serves to support joint monitoring activities, communication, data and information flows (Liu et al., 2014) and place-based actions (Ciravegna et al., 2013) to improve the local environment (see also illustration in Fig. 6). Nevertheless, deliberate and substantial efforts are required to set up,

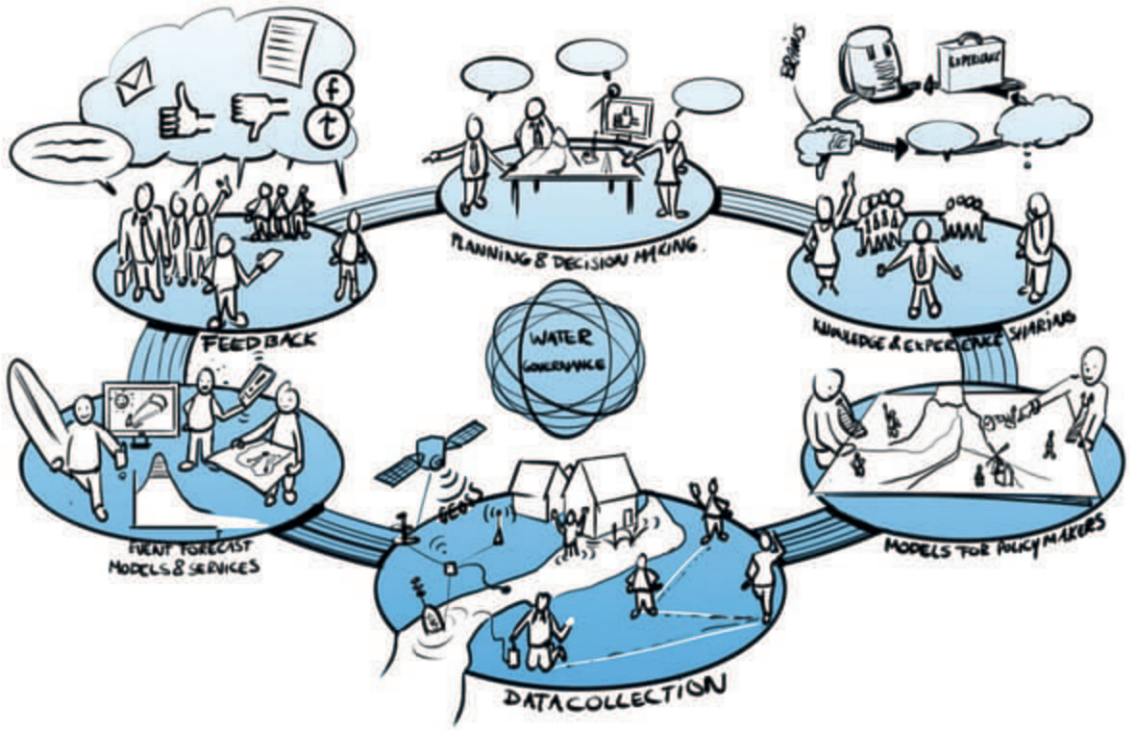

Fig. 6 Citizen observatories according to the WeSenseIt project. Source: wesenseit.eu.

implement and sustain COs (Hager et al., 2021); and achieving the envisaged institutional changes to citizen participation in environmental management is typically outpaced by much faster technological changes (Wehn et al., 2015a).

In summary, the mere intention to implement citizen science, in whatever form, is not sufficient to result in meaningful co-monitoring and co-management of impact on ecosystems and inland waters. Careful attention needs to be paid to the context in which citizen science is used, the process by which it is implemented, who is involved when and how, and how the expectations of different stakeholders can be managed and met. These aspects are addressed in the next section.

Practicalities and challenges of co-monitoring and co-management via citizen science

The increasing use of citizen science in co-monitoring and co-management of inland waters and ecosystems is resulting in a growing experience base with this practice, including evidence of the actual practicalities and challenges. The systematic review of water-related citizen science initiatives by Walker et al. (2020) identified the wide range of benefits (Table 2). It also specified distinct and salient negative impacts, specifically related to livelihoods and disempowerment that have been experienced and reported in the literature.

The set of "demotivational impacts" in fact refers to issues with the implementation of such water-related citizen science initiatives (e.g., boring nature of some tasks for participants or mismatches in the goals of citizen science organizers and participants). This in turn can lead to high dropout rates of participants and reduce the chance of improving the physical environment (e.g., water quality, health of ecosystems) as well as the governance mechanisms. A core difficulty in maintaining participants' interest and motivation stems from the inherent delays involved in manifesting impacts such as improvements in the state of inland water and ecosystems and changes in policy. In the case of the long-standing Alabama Water Watch, a water quality monitoring program established in 1992 covering all of the major river basins of the state of Alabama (United States), this lead to disillusionment and "volunteer fatigue" (Deutsch and Ruiz-Córdova, 2015; see Table 1).

Experience has shown that the success of implementing citizen science depends on the careful consideration of five dimensions of citizen science (Fig. 7) and their interactions.

- ***Thematic, geographic & temporal dimension of citizen science:*** citizen science is composed of the characteristics and priorities (of stakeholders) in a specific geographic area, the thematic focus (e.g., water, biodiversity) and the timing of the resource/object/issue observed.

Table 2 Summary of benefits and negative impacts of water-related citizen science initiatives.

Benefits	*Negative impacts*
Inferred benefits[a]	**Livelihood impacts**
▪ Awareness raised	– Overburdening the public, especially low-income areas (e.g., farmers)
▪ Reduced disaster risk	– Health and safety issues (flooding, water quality)
▪ Environmental stewardship	– Decreased self-reliance and damage to existing community institutions (post funding)
▪ Educational (knowledge gained, increased scientific literacy, social learning)	– Increased sensitization to hazards (over pre-occupation)
Observed benefits[b]	**Disempowerment**
▪ Enhanced capacity	– Process-based exclusion (reinforcement of existing power structures; continued marginalization)
▪ Democratization of science	– Technology-based exclusion (affordability, adoption issues)
▪ Combination of raised awareness, increased scientific literacy, social capital leading to behavior change and decreased risk/improved health	– Relinquished responsibilities by authorities (substitute labor)
▪ Empowerment to contribute to mitigation action, e.g., combat water pollution	– Conflict creation (selective acceptance of citizen science data)
▪ Livelihood improvements and conflict reduction	– Data privacy (identification, location of participants)
Investigated benefits[c]	**Demotivational impacts**
▪ Appreciation and elicitation of local knowledge	– Time consuming, boring, difficult tasks, leading to high drop out rates/low participation
▪ Human and social capital, personal and leadership skills	– Mismatched goals between organizers and participants
▪ Knowledge gained of socio-ecological systems, water quality and ecosystem services	– Disappointment if lack of or delayed impact
▪ Science literacy	– Erosion of confidence, trust and social capital
▪ Increased political participation	– Problems caused by financial incentives
▪ Trust, community building and recognition; networking	
▪ Empowerment of indigenous/disadvantaged communities	
▪ Decreased risk, changes toward more environment friendly behavior	
▪ Fun and learning	

[a]Benefits inferred based on reports but not investigated.
[b]Benefits provided based on specific observations.
[c]Benefits based on research of outcomes.

Fig. 7 Dimensions of citizen science implementation. Source: the author.

- ***Socio-political dimension of citizen science:*** the social dimension of citizen science encompasses the involvement of non-experts in knowledge co-creation, with differing perceptions, motivations, expectations, capacity, priorities and local, traditional and/or indigenous knowledge backgrounds; citizen science is also a political multi-stakeholder process in terms of who decides what is measured by whom, how and when; what data (and how) are included with respect to reporting requirements, monitoring objectives and decision-making processes;
- ***Scientific dimension of citizen science:*** in terms of scientific discipline, citizen science needs to be integrated with, and validated for, specific scientific/knowledge fields; in terms of scientific method, citizen science constitutes a change to the traditional scientific paradigm—from providing merely a new data source for scientific enquiry, to fully involving citizens and communities in the scientific method;
- ***Technological dimension of citizen science:*** the technological dimension of citizen science entails new (inexpensive) sensors; the use of new or adaptation of existing interaction platforms; and citizen science data access, interoperability, compatibility, complementarity and integration with standard data sources;
- ***Economic dimension of citizen science:*** this dimension of citizen science pertains to the influence of financial resources on the scope, success and sustainability of citizen science activities, as well as to the economic benefits derived from generated citizen data, e.g., for the public good and/or for the benefit of private sector actors from value-added services.

The need to consider these different dimensions of citizen science and their interactions highlights that citizen science is not a "one size fits all" plug for co-monitoring and co-management; rather, citizen science requires careful implementation to serve agreed environmental and institutional purposes and impacts in a given bio-physical context. Fundamentally, since citizen science requires the involvement of people, paying attention to their motivations, skills and resources, constraints and expectations provides the basis for sound and successful implementation. Extensive guidance is available in various online resources on how to address these practicalities and challenges of implementing citizen science, such as dedicated toolkits, a "cookbook" and MOOCs (see resource section) that bring together and synthesizes experience from a range of citizen science project implementations in Europe and beyond.

Fig. 8 Reinforcing success cycle for citizen science initiatives. Source: Hager G, Gold M, Wehn U, Ajates R, See L, Woods M, Tsiakos C, Masó J, Fraisl D, Moorthy I, Domian D, Fritz S (2021) Onto new horizons: Insights from the WeObserve project to strengthen the awareness, acceptability and sustainability of citizen observatories in Europe. *JCOM* 20 (06), A01. doi:10.22323/2.20060201.

Moreover, the WeObserve project (H2020, 2017–2021) investigated overarching issues encountered by citizen science projects across the board and found that the key challenges facing citizen science projects and COs are awareness, acceptability and sustainability:

- **Awareness**: Citizens are often unaware of opportunities to address and help monitor environmental issues. Likewise, public authorities, SMEs and NGOs are often unaware of the potential of COs to support decision making and create business opportunities.
- **Acceptability**: COs and citizen science are often assumed to lack the required quality standards to generate insights for decision making and environmental governance. Public authorities are hesitant to accept data from citizen science efforts to complement authoritative data.
- **Sustainability:** Although local and continent-wide projects have shown great promise, the existing processes, infrastructures, measures of success, and legislation are currently insufficient to sustain or scale-up citizen science projects across various sectors. Deficiencies in transition governance, funding systems and standards of data preservation and data interoperability are limiting the long-term potential of citizen science and COs (Hager et al., 2021, p. 5).

The WeOberve project demonstrated that these challenges are closely interlinked. If they are addressed as such, a cycle of positive reinforcement can be created, whereby progress with addressing one issue can likely trigger improvement of the others (Fig. 8).

The WeObserve project found that it is critical to:

(1) build awareness and engage established, place-based communities and facilitate exchange across stakeholders;
(2) foster data quality and trust in data and technologies within context and for their intended use and deploy methods that ensure data quality as well as the use and accessibility of data;
(3) continuously demonstrate impact through impact stories and create value for all stakeholders;
(4) consider initial project funding as seed-money and establish sustainability elements in the project design with the aim to establish the COs longer-term (Hager et al., 2021, p. 18).

Conclusion/synthesis

This chapter has introduced different conceptualizations of citizen science and the challenges and practicalities for implementing citizen science as a means for co-monitoring and co-managing ecosystems and inland waters. The field of citizen science—both in terms of its theory and its practice—is still evolving. Citizen science is a fast expanding field of study in itself: how we define citizen science, how we implement citizen science in different ways and what this means in terms of impact of the respective initiatives for the health of ecosystems and inland waters as well as individual citizens, communities and society at large.

Knowledge gaps

- The field of citizen science is evolving—so are terminology, definitions and even the name itself (Haklay et al., 2021b; Cooper et al., 2021) The plurality and diversity of interpretations of citizen science in terms of definitions, typologies and descriptors need further attention (Haklay et al., 2021b).
- Important challenges for citizen science, and for citizen observatories in particular, consist of awareness, acceptability and sustainability of these initiatives (Hager et al., 2021) as well as inclusivity and process (Cooper et al., 2021).

- Cases that present sound evidence of positive environmental changes in local ecosystems monitored by citizen scientists need to be compared in order to distill factors for their success (Conrad and Hilchey, 2011).
- Experiences with the implementation of citizen science are accumulating and increasingly well-documented in the academic literature as well as in online resources; however, measuring the impact of these initiatives in sound and comparable ways is lagging behind and suffering from conceptual and methodological inconsistencies (Wehn et al., 2021b). This is particularly the case with respect to claims and ambitions of citizen science to serve for behavior change toward sustainable lifestyles.
- Moreover, limited understanding by citizen science practitioners of policy needs and processes means that communication about the impacts of citizen science remains challenging (Wehn et al., 2021a).
- There is a danger of re-inventing the wheel in citizen science: existing insights and sound scientific practices from relevant behavioral science disciplines are being disregarded and therefore re-invented (often in inferior ways), for example, when examining and addressing the motivations, attitudes, incentives and challenges for stakeholder participation (Wehn and Almomani, 2019).

Important case studies

Citizen science as an approach for co-monitoring and co-management of inland waters is becoming increasingly popular and has been implemented across the globe, as illustrated by selected case studies (Table 1).

Agricultural Pressures on Inland Waters

Sara E Vero[a] **and Owen Fenton**[b], [a]School of Science, Waterford Institute of Technology, Co. Waterford, Ireland; [b]Teagasc, Environment Research Centre, Co. Wexford, Ireland

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

The agricultural landscape

Agriculture is a dominant land use and economic activity worldwide (Chen et al., 2018), occurring on every continent barring Antarctica (Fischer et al., 2001). It accounts for approximately 42% European Union (Castillo et al., 2019), >50% Asia (Zhao et al., 2016), 52% United States (Bigelow and Borchers, 2017), 38% Africa (Food and Agriculture Organization of the United Nations, 2020) and 58% Australia (Australian Collaborative Land Use and Management Program, 2016) land areas, respectively. Agricultural systems vary widely depending on location. This reflects resource availability, climate, soil type, market orientation, and history. Consequently, the nature and intensity of farming impacts the magnitude of the pressures exerted upon local watercourses. Production of meat, dairy, crops, and non-food produce including fuel and fiber is a crucial activity for human survival. It is estimated that 42% of world population is employed in agriculture (Anzar-Sánchez et al., 2019). Agriculture could be reasonably considered to be the primary and most important enterprise without which our population could not be sustained. While we cannot do without agriculture, and benefit from it economically and culturally, it does exert pressures on water bodies which impacts their capacity to supply adequate drinking water and to sustain aquatic life (Vitousek et al., 2017). Agricultural land delivers and impacts, to varying degrees, multiple ecosystem services (ES): food/fiber/fuel production; habitat; carbon sequestration; nutrient cycling; and water storage and purification (Schulte et al., 2010). While synergies exist between some of these ES (for example, recycling of nutrients from livestock can replenish soil stores and support plant growth), there are also trade-offs in which freshwater quality and quantity can be negatively affected (Rodríguez et al., 2006).

Under national and international legislation, frameworks have been set for attainment of water quality, for example the Water Framework Directive (WFD; EC, 2000) in the European Union (EU) or the Clean Water Act (CWA; United States Congress, 1972) in the United States (USA). Identification of the activities which are impacting watercourses at a local or regional scale allows appropriate management plans to be designed. Taking the WFD as an example, section 1.4 of that directive stipulates that member states must identify the type and magnitude of anthropogenic pressures to which water bodies in each river basin distract are subject, via both diffuse and point sources. Pressures are categorized into urban, industrial, agricultural, and other, and must be accompanied by characterization of land use. The 2018 report on the status and pressures influencing WFD attainment indicated that agriculture is the primary driver of diffuse source pollution, with 38% of surface waters failing to reach targets as a consequence. At the time of writing (2020) results indicate that 29% of EU groundwater (by area) exhibits poor chemical status as a result of agriculture with 9% impacted by abstraction, primarily for irrigation (European Environment Agency, 2018).

Agricultural pressures

Nutrients

Application of organic and inorganic fertilizers is crucial for maintaining the fertility of agricultural soils and sustaining plant growth. Organic fertilizers include livestock manures and slurry, biosolids, composts, and seaweeds. Synthetic or 'chemical'

fertilizers include refined or processed nutrients which are extracted from mineral resources held within rock reserves (e.g., phosphorus) or converted from other forms (e.g., transformation of gaseous to mineral nitrogen (N) via the Haber-Bosch process). There is an increasing emphasis to use organic wastes from a variety of sources, as this reduces reliance on finite, mineral stores and allows recycling of agricultural and processing by-products. However, research is needed into the agronomic availability and environmental footprint of organic sources, as well as technical and infrastructural supports. Ideally, nutrients would be applied at times and in quantities which allow them to be completely utilized by the growing plant, whether that is a crop which will be harvested for anthropogenic use or grass/forage which will be grazed by livestock and recycled within a closed agricultural system. Such systems are considered to be 'balanced' (Fig. 1). Achieving this balance, however, is rarely simple. Inefficiencies in the utilization of applied nutrients by plants, processes of attenuation and immobilization in soil, rainfall patterns, and hydrologic pathways all reduce the balance of the system and allow nutrients to be lost to water or the atmosphere. Furthermore, poor nutrient management by the farmer, including both over-application and mis-timing of fertilizers relative to crop requirements or weather patterns can encourage greater losses. While plants require a variety of nutrients, it is N and phosphorus (P) are in greatest demand, but which also present the most significant pressures to water quality. However, it is not only terrestrial plants which flourish in response to abundant nutrients. Enrichment of surface-waters with nutrients is known as 'eutrophication'. Under such conditions and in the presence of sufficient light, algal blooms can proliferate, leading to anoxic conditions, reduced vertebrate and invertebrate life, out-competing of desirable plant species, impaired taste and portability, and negative impacts on amenity use.

Pollution of watercourses by nutrients within agricultural settings can be organized within the nutrient transfer continuum framework (Haygarth et al., 2005; Wall et al., 2011). This framework identifies four tiers: sources, mobilization, delivery, and impacts. Sources represent inputs to the system; in this case, chemical or organic fertilizers such as manures, seaweeds, or biosolids. At catchment scale there are several co-occurring nutrient sources (e.g., diffuse agricultural, point agricultural, domestic, and industrial) and discrete transport pathways operating simultaneously. Ascertaining the contribution of agricultural components, independently of other factors, relies largely upon source apportionment models used to evaluate the contribution of various pressures. These models may utilize statistical approaches to disentangle hydrochemical data from monitoring stations or may utilize conceptual, physical, or empirical data to quantify catchment hydrology. Apportionment models range in the complexity of their approach (Yuan et al., 2020) which has concomitant demands on the level of skill of the operator and of data requirements. Notably, many (though not all) models focus on non-point agricultural sources (diffuse runoff and subsurface pathways), excluding point sources. However, point-source models may be coupled or integrated with diffuse models. As with all modelling, selection of the appropriate model can be challenging due to the wide variety of options. Factors including desired outputs, data requirements and availability, spatial scale, and budget should all be considered (Yuan et al., 2020). Nutrient source apportionment is applied as an investigative tool to identify priority areas/issues for mitigation, in the design of agricultural best management practices, and to forecast and trial potential future scenarios.

Mobilization is the initial separation of nutrients from their source. For example, P sorbed to soil may become solubilized, or may be physically detached by erosion. Delivery refers to the physical transport of the nutrient through surface (overland flow) or subsurface (leaching—vertical movement through the unsaturated zone, lateral flow, or groundwater) pathways to a receptor. Delivery is subject to hydrologic and biogeochemical time lags (Schulte et al., 2010; Fenton et al., 2011; Hamilton, 2011; Chen et al., 2019) which confound the direct relationship between management practices and water body response, subject to delays. The distinct transport pathways operate within agricultural catchments simultaneously. This is due to the topography of the landscape, presence or absence of barriers which disrupt overland connectivity, and distribution of soil types, depths, and geology.

Finally, impacts are the 'change or perturbation' (Haygarth et al., 2005) in the water body receiving the nutrient input. These changes are primarily chemical, but this in turn has consequences for the portability and ecology of the water body. The two principal nutrients which are of concern as agricultural pressures, P and N, will be discussed hereafter. These are summarized according to the nutrient transfer continuum in Fig. 2.

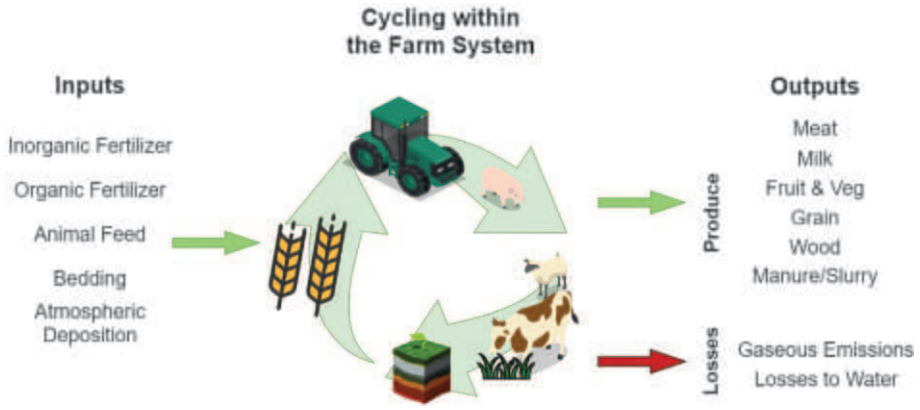

Fig. 1 Conceptual balance of farm nutrient inputs/outputs.

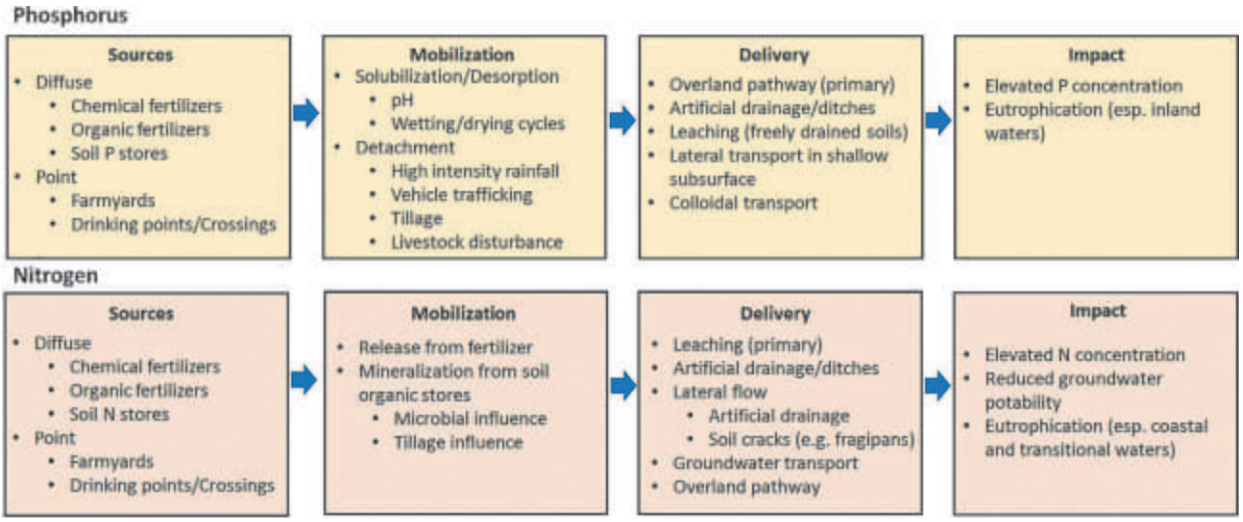

Fig. 2 Stages of the nutrient transfer continuum as relates to phosphorus and nitrogen.

Phosphorus

Phosphorus is frequently considered to be the limiting nutrient for freshwaters, particularly rivers, although nitrogen limitation or co-limitation does also occur especially in headwater streams (Jarvie et al., 2018). It's propensity for attenuation to soils and sediments means that reduction in losses can only be achieved subject to time lags driven by soil chemistry. Schulte et al. (2010) modelled soil P decline from high to moderate agronomic indices, which are also considered to indicate risk of loss to watercourses (Daly and Casey, 2005). Declines to optimal indices were estimated to range between 7 and 15 years; however, significant variability was observed with worst-case scenarios exceeding 20 years. Subject to these prolonged lags, diffuse losses of P from the soil to watercourses will continue if not abated by crop uptake. P stores within the soil may also become solubilized or desorbed subject to changes in pH (McDowell et al., 2001), or due to wetting and drying cycles (Turner and Haygarth, 2001; Pezzolla et al., 2019) which influence microbial activity. This P may be vulnerable to accelerated transport as drying processes create cracks, particularly in clay-rich soils, through which preferential transport may occur. Overland flow is typically the main pathway for delivery of P (either dissolved or particulate) to watercourses. However, leaching may also occur in freely-drained soils (Dupas et al., 2017) or those in which preferential pathways such as artificial drainage or naturally occurring macropores are present (King et al., 2015). While the focus of environmental research is frequently on inorganic P forms due to their bioavailability, dissolved organic P may also leach, and subsequently become available at a later date (McDowell et al., 2021). High levels of soil organic matter exhibit low sorption capacities, meaning that applied P tends to stay in solution in pore water (Daly et al., 2001). This P is at greater risk of loss during either runoff or leaching events, compared with mineral soils. There is also a diversity of agricultural point sources of P. Overland flow from farmyards includes relatively uncontaminated runoff from rooftops and clean collecting areas, but also highly contaminated effluents created during silage production (Gebrehanna et al., 2014), cleaning of dairy parlours (Minogue et al., 2015), and the collection and storage of livestock slurry and manures if these factors are not managed correctly. Other common point sources in agricultural landscapes are septic tanks, as rural dwellings tend not to be connected with municipal waste processing. While the loads contributed by these discharges tend to be relatively small in the context of overall losses, they have been observed to have a disproportionate impact on water quality during low-flow river conditions (Arnscheidt et al., 2007; Macintosh et al., 2011). From a catchment management perspective, it is important that these non-agricultural point sources which are nested within the rural landscape are recognized as a separate and distinct factor.

Nitrogen

Since the advent of chemical N fertilizer resulting from the development of the Haber-Bosch process in the early 20th century production has increased exponentially supporting a vastly enlarged population (Smith et al., 2019). This was facilitated by an increase in synthetic N fertilizer from 12 Tg N $year^{-1}$ in 1960 to 110 Tg N $year^{-1}$ by 2013 (Battye et al., 2017; Peoples et al., 2019). As a conservative nutrient it tends not to attenuate to soils and sediments but rather, is highly mobile and dynamic within the environment. Although some nations do not specify threshold criteria for N in lakes and rivers based on the premise that P is the limiting nutrient, research has shown that N is a factor in eutrophication of inland waters, particularly when it co-occurs with anthropogenic P (Lewis Jr. et al., 2011). Poikane et al. (2019) and Dodds and Smith (2016) recommended that both nutrients should be considered in assessing the ecological status of water bodies. The source of N which is vulnerable to loss has increased, and inefficiencies in balancing inputs vs outputs are a financial and environmental challenge. The increase in N load translates to an increase in N surplus, where crop offtake is not equivalent to inputs from fertilizers, manures, and atmospheric deposition. Surpluses vary depending on landuse type, cropping system, management practices and climate (Lord et al., 2006). These surpluses

represent the N which is vulnerable to transport, however the magnitude of surpluses correlates poorly to both groundwater and surface water N concentrations, due to the complexity of transport and transformation processes (Rosário Cameira et al., 2021).

The sub-surface pathway is generally dominant in N transport and large N loads may accumulate as a result of antecedent management practices. Stores of nitrate (NO_3^-) in the vadose zone (soil and unsaturated bedrock) have been estimated to range between 605 and 1814 Tg worldwide (Ascott et al., 2017). This load is subject to two issues which render the impact of agricultural practices on water body N complex to unravel. Firstly, N cycles dynamically within the soil, shifting between occluded forms within soil organic matter, gaseous forms which can be emitted to the atmosphere (ammonia (NH_3), dinitrogen (N_2), nitrous oxide (N_2O)), and soluble forms which may be transported hydrologically (ammonium (NH_4^+), NO_3^-, nitrite (NO_2^-)). This cycle is mediated by microbial activity and a variety of influencing factors, including soil saturation, nutrient inputs, pH, temperature, etc. (Bingham and Cotrufo, 2016). Consequently, the understanding of this cycle is constantly evolving. The second confounding factor is the issue of time lag. Time lag is the delay in response of water bodies to changes in management practices including delays in implementation, effect, delivery, response, and finally in measurement within the water body (Meals et al., 2010). Hydrologic time lag refers exclusively to the time taken for physical transport of NO_3^- through vertical (leaching) or lateral subsurface pathways (including fractures and artificial drainage) (Fenton et al., 2011). Total hydrologic lag (t_T) can be divided into two portions: unsaturated zone (t_U) and groundwater (t_S) (Sousa et al., 2013). The duration of t_U is controlled by soil physical characteristics (porosity, conductivity, etc.), moisture regime, and depth to the water table (Fenton et al., 2011; Vero et al., 2017). The t_S component, being constantly saturated, is dictated by distance to the watercourse. Duration of t_T varies widely within agricultural landscapes, but evidence from Europe (Vero et al., 2017; Granlund et al., 2005; Kim et al., 2020), United Kingdom (Wang et al., 2013), North America (Van Meter and Basu, 2015), Asia (Wu et al., 2020) and Oceania (Wilson et al., 2014) (amongst other references to exhaustive to list here) all indicate decadal scale responses. Consequently, the expected timeframes for water quality improvements (such as those prescribed under the WFD in Europe) should be set based on biophysical limits, rather than timeframes which are politically oriented (Ascott et al., 2021).

Nutrient impacts

The impact of nutrients on ecology and water quality depends not only on the gross quantities delivered to the watercourse, but on the degree of dilution and on their timing with respect to season. Regarding dilution, rivers vary in their rate of discharge over time and consequently, a certain load of N or P may result in a greater or lesser concentration depending on the time at which it is delivered to the watercourse. Low-flow conditions offer the least dilution and incidental transfers due to flashy storms (Jordan et al., 2012) have potential for high impact. Furthermore, persistent point sources such as nutrient-laden washings from farmyards (Edwards and Hooda, 2008), domestic septic tanks (Arnscheidt et al., 2007; Macintosh et al., 2011), animal drinking points or stream crossings (O'Callaghan et al., 2019) can become pronounced. These low-flow inputs may reflect a small proportion of total annual fluxes (Arnscheidt et al., 2007) and may be relatively small at each delivery point. However, the cumulative effect of multiple such sources across entire river networks can result in increasing concentrations moving from headwater to outlet (Vero et al., 2019).

Regarding timing, stream ecology is subject to ecologically sensitive periods corresponding to the lifecycles of aquatic species. These periods may also align with periods of high risk of eutrophication during summertime, when flow is often lower due to limited precipitation, and sunlight hours are greatest. These conditions promote photosynthesis of harmful macroalgae and are difficult to influence in many cases. This may force ex-situ measures to control nutrient inputs to be emphasized (i.e., those which limit nutrient sources such as caps on fertilizer application rates, and those which disrupt the transport pathway such as buffer strips), over in- or near-stream measures. However, some options do exist. For example, shading of streams by encouraging riparian cover has been observed to significantly lower gross primary production in-stream even in the presence of elevated nutrient concentrations (Nebgen and Herrman, 2019). Such approaches may have utility where time lag or orientation of highly productive agricultural catchments makes reductions in nutrient loading challenging in the short to medium term.

Certain aquatic species show particular sensitivity to eutrophication and thus act as indicators for the pollution status of the water body. Other, more resilient species may inhabit even degraded waters. The individual taxa which reflect good or poor water body status varies geographically, and for the purposes of assessment individual criteria and indices are determined regionally. Generally, there is a preference for fish and macroinvertebrate species as indicators (O'Brien et al., 2016), likely because they can be easily identified, compared to algae, biofilms, and bacteria. Similarly, high status water bodies and those existing in environmentally sensitive or conservation areas are least tolerant to additional nutrient inputs and require rigorous efforts in order to avoid declines in status. A feature of agricultural wastes, particularly effluents originating from silage production or manure storage, is a high biochemical oxygen demand (BOD). This is the quantity of oxygen which is required by micro-organisms to break down organic matter at a specific temperature. Regarding water quality, this is observed over five-day assays, and so BOD_5 is a reference measurement, although longer observations are also possible. As organic matter decays, oxygen in the water column is depleted. Hypoxic conditions are unsuitable for both vertebrate and invertebrate species. For this reason, effluent discharges are particularly associated with sudden fish kills. These discharges may result from persistent point sources (e.g., leaky effluent tanks or silos) but also from accidents such overflows of storage, pipe failures, or tanker spills.

Sediment

Erosion and deposition of sediments from stream banks are a fundamental process controlling the dynamics and evolution of surface water bodies; as is the translocation of soil particles from the landscape to the watercourse. As a consequence, the

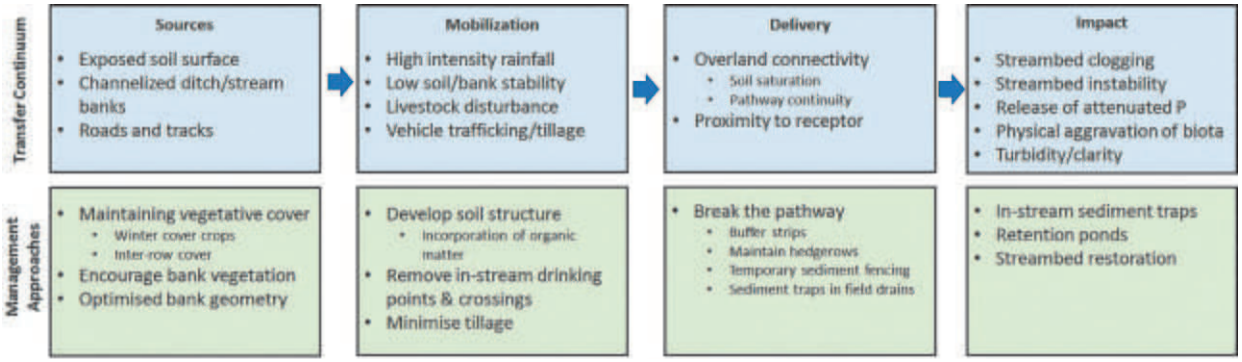

Fig. 3 Conceptual framework of sediment transfer to water bodies. Adapted from Haygarth et al., (2005) The phosphorus transfer continuum: Linking source to impact with an interdisciplinary and multi-scaled approach. *The Science of the Total Environment* 344: 5–14.

hydromorphology of rivers and the topography of the surrounding landscapes changes with time which can impair agricultural productivity and cause declines in ecosystem health (both in terrestrial and freshwater systems). Concurrently, erosion causes loss of soil and nutrients and therefore affects primary productivity and crop production. It has been estimated that tolerable rates of erosion not exceeding rates of soil formation are (in Europe) at maximum 1.4 t ha year^{-1} (Verheijen et al., 2009). In reality, rates of erosion are often much higher, and rates of both soil formation and erosion vary widely both worldwide and even between nearby catchments. Similar to nutrient pollutants, factors influencing sediment deposition in watercourses can be understood using the source to impact framework (Fig. 3) described by Haygarth et al. (2005). This framework was originally used to understand P transport.

Sediment sources

Exposed soils are vulnerable to erosion during high intensity rainfall, trafficking by livestock, and during cultivation. Sediment fingerprinting using distinctive inorganic properties such as radionuclides has been used to apportion sediments arising from various sources within agricultural catchments (Sherriff et al., 2019; Lamba et al., 2014). Sources within individual catchments include both arable (crop) and grassland (or other forage used for livestock grazing), public roads (a non-agricultural source nested within agriculturally dominated catchments), tracks used by livestock and agricultural vehicles, riverbanks and beds which have become disturbed by livestock accessing the watercourse to drink or to cross (Sherriff et al., 2015, 2019; Lamba et al., 2014; Lefrançois et al., 2007). The proportion of total sediment load derived from each of these sources varies by location, depending on their land use, hydrology, soil type, and management.

Mobilization and delivery

Land use affects the mobilization of sediments from the soil surface. The conventional understanding is that arable land typically exports greater sediment loads to watercourses than equivalent grassland areas. This is due to the greater proportion of exposed soils, more frequent tillage, large field areas, and fewer hedgerows (i.e., boundaries consisting of shrubs or trees) in arable land. However, some grassland catchments, exhibiting high surface connectivity as a result of low soil infiltration capacity as well as prolonged saturation, have been documented to yield greater loads of sediment to receiving water bodies than more freely drained arable catchments (Sherriff et al., 2015). This is a function of the hydrology of the catchment. Reduction in the extent of hedgerows due to intensification of agriculture and merging of small fields into larger, single units (White and Roy, 2015; Sheridan et al., 2011) has increased the surface connectivity via overland flow pathways. This allows sediment, once it has become detached from the soil surface, to be transported to receiving water bodies, rather than being retained at the field margin.

Impacts of agricultural sediment on watercourses

Suspended sediment within the water column is a feature of natural waters (Vercruysse et al., 2017) however, excessive sediment poses several problems which constrain the desired functioning of watercourses. Accumulation of sediment in the streambed may destroy the habitat of freshwater biota. The freshwater pearl mussel (*Margaritifera margaritifera L.*), for example, requires a stable, aerated gravel bed with <20% fine sediment (particles measuring <1 mm) constituents (Denic and Geist, 2014). Deposition of fine sediment arriving from outside the watercourse or from upstream reaches has been documented to choke gravel streambeds. This renders these beds uninhabitable for pearl mussel (Österling et al., 2010; Niraula et al., 2017) and other sensitive species such as trout (Lange et al., 2013), salmon (Walling et al., 2003), amphibians (Schmutzer et al., 2008; Muenz et al., 2006), and macroinvertebrates (Davis et al., 2019; Beerman et al., 2018). Considering the variability of bed substrates both across regions and along individual watercourses, it is difficult to set qualitative thresholds for sediment accumulation. Macroinvertebrates are a common indicator of water quality. They are subject to multiple ecosystem stressors, making it difficult to disentangle the influence of any one factor. In a recent mesocosm study mimicking instream ecosystems, manipulated nutrient and sediment dynamics (Davis et al., 2019) sediment was the most influential stressor, negatively impacting the total abundance of sensitive taxa and the

diversity of species. Sediment also interacted with P concentrations; however, this could occur in either a synergistic (exacerbating the impacts of P on ecological status) or an antagonistic (reducing the impacts) fashion. The nature of the interaction may be related to the P sorption capacity, such that additional sediment may in some cases bind soluble P from the water column.

In other scenarios, sediment arriving from agricultural land may bring high quantities of P sorbed to the surface of particles, as a legacy of antecedent fertilizer application. In-stream P reserves may be released to the water column via desorption, precipitation and dilution, and advection and diffusion processes (Withers and Jarvie, 2008). The characteristics of the sediment itself influences release, with low Ca/P ratios facilitating P mobilization (Shore et al., 2016). The indeterminate timing of P mobilization from transported sediment adds uncertainty to interpretations of agricultural impacts on water quality.

Emerging agricultural contaminants

Within the agricultural setting, emerging contaminants include those that have only recently become a concern due to their increased use in line with intensification, and pollutants which have only recently been developed or identified. Emerging contaminants from agriculture include veterinary medicines, biocides, steroids, disinfectant residues, and metals (Snow et al., 2012). Veterinary medicines may be excreted by livestock to which they have been administered. Runoff contaminated by contact with these manures may consequently carry dilute concentrations (Sinclair et al., 2007). Antibiotics (Bailey et al., 2015; Wei et al., 2011), hormones (Boxall, 2012), and anti-coccidials (Mooney et al., 2020) have been observed in the surface- and groundwater bodies of agricultural catchments. While absolute loads and concentrations may be extremely small compared to nutrients, the impact on aquatic species may be significant even at trace exposures. Concentrated animal feeding operations have been correlated to high river concentrations of veterinary medicines, due to the reliance on treatments in these systems and the high density of animals (Burkholder et al., 2007).

Biocides including herbicides and insecticides are widely recognized emerging contaminants. Impacts on aquatic species has been a factor in regulation of the industry including withdrawal of high-risk active ingredients (e.g., the herbicide atrazine in the United Kingdom (Stuart et al., 2012)). These have high acute toxicity and/or chronic effects on aquatic species. For example, exposure to atrazine has been observed to reduce egg production by 17–39% in fathead minnow (*Pimephales promelas*) with significant reductions occurring by day 20 even at concentrations observed in agricultural settings (Tillitt et al., 2010). The neonicotinoid variety of broad-spectrum, systematic insecticides has been widely observed in surface and groundwaters, due to its high solubility and mobility (Morrissey et al., 2015). These insecticides are common in tillage production however, they have well-established toxic effects on aquatic macroinvertebrates. Multiple treatments can act synergistically and furthermore, their lethality varies between affected non-target species making hazard and impact assessment challenging (Morrissey et al., 2015). Biocides may also have secondary poisoning effects, wherein predators consuming contaminated species in-turn become exposed (Hinck et al., 2009), particularly for contaminants which bioaccumulate in tissues. Legislation such as the EU Sustainable Use Directive (European Parliament, 2009) outline structures to mitigate risks posed by biocides. These rules include use of low-drift applicators, avoidance of watercourses and drainage networks, and directions regarding handling, storage, and disposal. A central feature of biocide regulation is requirements to implement integrated pest management (IPM), which gives preference to non-toxic measures to control weeds and invertebrate pests. While there are several approaches to IPM, they typically emphasize preventative rather than reactive measures. This prioritizes monitoring, encourages mechanical and biological controls, and promotes chemical controls only as necessary and at minimum.

Notably, not all emerging contaminants now recognized within the agricultural system are a de facto feature of farming itself, but rather, originate elsewhere within the circular bioeconomy. Personal care products (PCPs) and pharmaceuticals for the treatment of humans have been identified in landspread biosolids recycled from domestic wastewater treatment (Clarke and Cummins, 2015; Healy et al., 2017). The objective of landspreading is to utilize nutrients within biosolids and sludges, thereby limiting their loss to watercourses. The extent of this recycling is likely to increase subject to legislation such as the European Union's Urban Wastewater Treatment Directive (Clarke and Cummins, 2015). However, emerging contaminants within these biosolids exhibit similar ecological hazards as those originating from livestock or crop production; specifically, high persistence in soils and sediments, bioaccumulation in aquatic organisms, and frequently, chronic toxicity to exposed species. However, the risks associated with biosolid application can be reduced through pre-treatment and application method. Decisions surrounding use of these fertilizers should be supported by analysis of the potential risks and benefits, with strategies imposed to offset risks.

Land drainage and abstraction

The primary impact of agriculture on hydromorphology is via artificial drainage and the modification of rivers and streams. Artificial drainage improves the suitability of land for production and is a hallmark of agricultural production. Valipour et al. (2020) documented the long history of this practice in civilizations worldwide, citing evidence from Iran dating as early as c. 4000 BCE, though the modern phase of land drainage could be considered to have developed first in the Netherlands during the 16th Century (Harris, 2017). While it is difficult to estimate the extent of artificially drained land worldwide due to limited records and differences in approach, Schultz et al. (2007) estimated it to be av. 13%, ranging from 3% in least developed countries to 25% in developed countries. Climate and soil type influence the extent of artificial drainage, with drained area as a percentage of cropped area being 29%, 8% and 4.5% for temperate-humid, arid/semi-arid, and humid/semi-humid areas, respectively (Zimmer et al., 2005). It should also be recognized that funding and resources also play a role in the degree of investment in drainage (Schultz et al., 2007).

While artificial drainage in itself is not a pressure on water quality, it does provide an accelerated pathway for contaminant transport (Lowrance et al., 1984). Review of the literature indicates strong consensus that nitrate loss is particularly amplified in artificially drained soils due to hydrologic connectivity (Castellano et al., 2019). This may be exacerbated by a concomitant reduction in storage time and consequently, in denitrification (Jahangir et al., 2012; Rivas et al., 2020). There is a trade-off between the beneficial implications of land drainage, which increases the area available for agriculture and improves the productivity of existing farmland versus negative impacts on habitat, species, and on flood mitigation.

On a positive note, by creating greater storage and infiltration capacity within the vadose zone artificial drainage may reduce runoff during peak flows from saturated soils (Gramlich et al., 2018). This will influence the timing and type of nutrients lost, and potential for attenuation and transformation prior to reaching a water body. As a consequence of reduced runoff, sub-surface drainage has also been observed to limit erosion on mineral soils (Gramlich et al., 2018). However, erosion may still occur along the banks of open drains. The cross-sectional profile of the open drain influences its capacity to slow the flow of water and allow sediment to drop out before reaching the main watercourse. In Ireland, Shore et al. (2015) identified three classes of sediment retention potential for open drains (Table 1), although crucially, soil type will affect the stability of side slopes (Tuohy and Fenton, 2013). Furthermore, the chemistry of ditches influences their potential to either attenuate or mobilize P (Shore et al., 2015; Moloney et al., 2019) (Table 1). Similar research has been conducted in New Zealand (Nguyen and Sukias, 2002) and elsewhere. Correct design and management of ditches can be used to moderate their role as a nutrient pathway to receptors (Sharpley et al., 2007) while retaining their intended function of removing water from the landscape. Efforts to retain sediment will reduce particulate P reaching watercourses. Indeed, two-stage ditches and sediment traps have been developed to amplify this effect (Davis et al., 2015). A major advantage of in-ditch mitigation measures is that they offer potential solutions without reducing farmed area.

Modification of rivers and streams is an intrinsic element of artificial drainage. More rapid delivery of soil water to the surface watercourse as a result of subsurface drainage creates greater discharge in the watercourse itself. This discharge exerts force, causing erosion of banks and straightening (or 'channelization') of the profile of the river. Aerial photography of watercourses has revealed significant channelization over decades (Hajdukiewicz and Wyzga, 2019; del Tánago et al., 2016). As a consequence, water travels with greater energy which increases the erosion of riverbanks. This sometimes contributes to flooding of downstream reaches. Increased flow as the result of channelization can lead to streambed instability, decreased habitat variability, and consequently decreased fish assemblage (Lau et al., 2006). Excessive or prolonged low flows as a result of abstraction may impair the migration of fishes upstream which is critical for the reproductive cycle of certain species (Ohlberger et al., 2018).

The area of land under irrigation has expanded worldwide, from 151 M ha in 1961 to 284 M ha in 2014 (Pellegrini and Fernández, 2018). This expansion has been greatest for 12 countries heavily dependent upon irrigation: Bangladesh, Chile, China, Egypt, India, Italy, Japan, Nepal, The Netherlands, Pakistan, Peru, and South Korea, which together account for an expansion of 64 M ha within that timeframe. Along with drainage, irrigation has been a core factor in bringing uncultivated land into production. Abstraction of surface and groundwater resources for irrigation is common, along with rainwater harvesting in some regions. It should be recognized that geographic regions have a natural predisposition for certain types of agriculture, which reflects water availability inter alia (Rijsberman, 2006). For example, the water footprint (WF) (indicating the direct and indirect consumption or use of water) per kg beef produced under the Irish pasture-based system has been estimated at 8,391 L kg (the majority of which is 'green water'—utilized rainfall, as opposed to 'blue water'—abstracted ground- or surface waters) (Murphy et al., 2017). Conversely, the WF of beef produced in Brazil in either grazed of mixed systems exceeds 20,000 L kg (Gerben-Leenes et al., 2013). This calls into question the equitability of importing produce from less water-efficient to more efficient systems. This 'offshoring of pollution' (Li and Zhou, 2017) has occurred in other industries where production is shifted to low-wage or low-regulation countries, rather than those which are the most efficient or where the goods are actually consumed. While the goods and money exchanged may be displaced, the pollution remains in situ (Hoekstra, 2010). This is not restricted to water pollution, but to other environmental aspects such as habitat and biodiversity loss (Dalin and Rodríguez-Iturbe, 2016).

Table 1 Drainage ditch characteristics and sediment and nutrient transport potential.

Sediment Retention Potential	*Ditch Slope*	*Phosphorus Retention Potential*	*Calcareous Soils Al/P[a] Ratio*	*Non-Calcareous Soils Ca/P[a] Ratio*
High	≤2%	High	>11.7	≥74
Moderate	2–5%	Low	<11.7	≤74
Low-Moderate	≥5%

Summary

The effects of agriculture on inland waters are significant, widespread, and diverse. While it is beyond the scope of this chapter to exhaustively document all scenarios, priority issues and processes have been outlined. Agriculture is a pivotal activity, underpinning and supporting human populations and societies. Therefore, there is a need to balance its essential, positive consequences (food and material production, employment, secondary industries, land stewardship, etc.) with its detrimental impacts. The challenge of agriculture is to balance the food production required to support the current and expanding population against environmental protection and the provision of other ecosystem services (Falkenmark et al., 2007). Best management practices can mitigate contaminant losses and impacts; however, sufficient time and investment are required to allow them to have full effect on waterbodies.

Knowledge gaps

- What mitigation measures will be most effective for individual pollutants, watercourses, and landscape scenarios?
- What are the trade-offs between agricultural production, the delivery of other ecosystem services, and pollution and abstraction of water?
- How will changing agricultural practices and demands impact on water bodies?
- What are the time frames by which improvement in water quality can be expected subsequent to interventions?
- How can water use efficiency be improved for various livestock and crop systems?
- How should the costs of water quality and the delivery of water-related ecosystem services be reflected in food and fiber prices?
- How do we achieve a balance between the positive (e.g., food production) and negative impacts (e.g., pressures on waterbodies) of agriculture?

The Best Management Practices in Agriculture for Protection of Inland Water Ecosystems

Octavian Pacioglu[a], Iris M Tuşa[a], Manuela E Sidoroff[a], and Corina Ițcuş[a,b], [a]National Institute of Research and Development for Biological Sciences, Bucharest, Romania; [b]Romanian Young Academy, University of Bucharest, 90 Panduri Street, Sector 5, Bucharest, Romania

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Best management practices Proposed methods that are most effective for reducing non-point source pollution to attain inland waters' quality goals. Such practices include measures to prevent and mitigate pollution.

Conservation management of buffer zones Efficient implementation of multilayer plant based structure between grasslands or crops and water bodies, aiming for diminishing the nutrients, pesticides and fine sediment runoff into aquatic habitats.

Conservation management of crop nutrients A mixture of traditional and more recent methods that optimize nutrients (i.e., N, P and K) cycling in crops, aiming for a healthy balance between their demand by crops and inland water eutrophication.

Conservation management of irrigation waters Efficient irrigation methods that aim to diminish salts, pesticides and nutrients release into inland waters and efficient water transportation from the aquatic source to crop, as such as to limit water losses.

Conservation pest control management A complex package of measures for the prevention of pest issues and reduction of pesticides usage. Such measures comprise a combination of biological control of pests, cultivation of pest-tolerant plant varieties and crop rotation, as well as the monitoring of pests evolution.

Conventional tilling Comprise various sequences of soil tillage, such as ploughing and harrowing and the removal of most of the previous crop. This practice is opposed to conservation tillage (definition provided in text).

Management of grazing activities Proposed package of measures to diminish the impact of livestock on aquatic habitats through their permanent fencing, alternative water sources, controlled grazing and supplemental feeding.

Management of intensive animal feeding operations Methods employed for limiting the quantity of manure release into inland waters, by limiting its ground application rate and through off-farm diverting toward pelletization industry, power factories, as well as through changes of animals' diet.

Introduction

Globally, intensive agricultural practices have a substantial impact on inland waters. The array of stressors with detrimental effects for freshwater habitats is multiple: fine sediments, nutrients, pesticides and emergent pollutants acting alone or in synergy (Yates et al., 2007). Both point and diffuse types of pollution, mixed with improper land usage (e.g., tilling, nutrients leaching or overgrazing) can affect all types of freshwater habitats in the proximity of agroecosystems (Meals et al., 2010).

In the attempt for reconciliation between most intensive agricultural practices and aquatic ecosystems degradation, a variety of structural and management conservation practices have been proposed, generally named Best Management Practices (hereafter BMP's, Haas et al., 2017; Liu et al., 2017; Napier and Bridges, 2003). One of the aims of these practices is to minimize the release and impact of stressors from agriculture on inland waters.

This article introduces the basic types of agricultural practices that are suitable for reducing the detrimental impact on water quality and ecological status, and which can be applied as part of an overall watershed approach. Categories include the management of:

- Tillage: activities that leave in place the vegetal remains following crop harvest as such as to reduce runoff, soil erosion, nutrients and pesticides leaching through soil (Fig. 1);
- Crop nutrients: the assessment of proper nutrient concentrations to maintain a healthy balance between crop needs and water eutrophication (i.e., enrichment of surface and groundwater ecosystems with nutrients such as nitrogen and phosphorus);
- Pests: the trade-off techniques between the use of pesticides and alternative methods involved in the control of invertebrate pests, plant disease agents and weeds and inland waters' pollution issues (Fig. 2);
- Buffer zones: techniques that ensure the efficient functionality of aquatic and riparian vegetation working as buffers in capturing pollutants and to impede livestock's direct access to water bodies (Fig. 3);
- Irrigation: techniques to reduce surface and groundwater pollution within irrigation systems;
- Grazing: techniques to minimize the impact of livestock grazing on aquatic ecosystems (Fig. 3); and
- Animal feeding operations: techniques to control the impact of animal feeding activities and waste discharge within inland water habitats (Fig. 4).

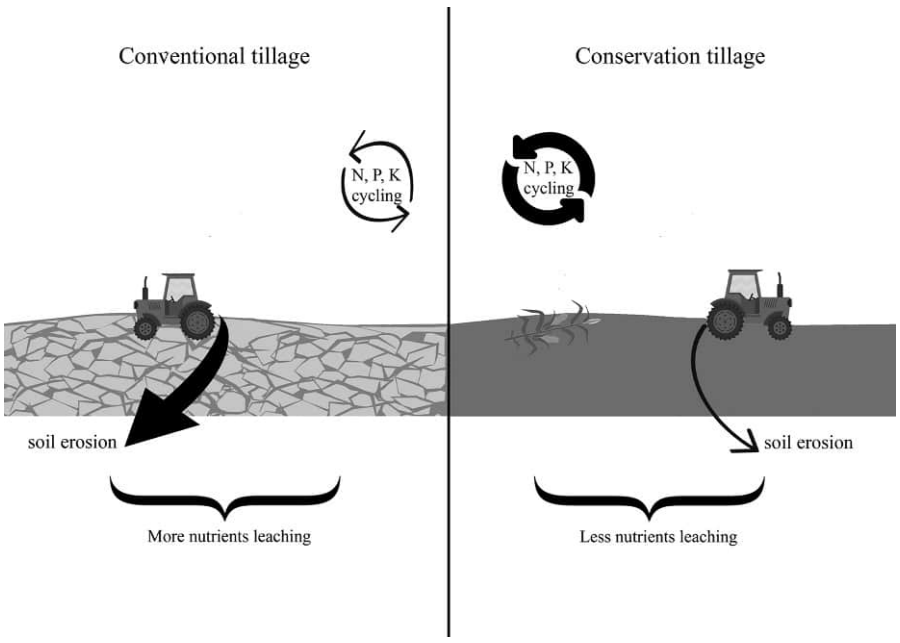

Fig. 1 Example of effects produced by conventional (left panel) versus conservative (right panel) tillage techniques on the magnitude of cycling rate of nutrients (i.e., N, P and K) at air—soil interface, as on soil erosion and nutrients leaching in a water body situated in the vicinity of an arable crop. The tractor symbolizes the tilling techniques and the corn the crop. The magnitude of the cycling rate at air—soil interface, soil erosion and nutrients leaching rate in the recipient water body is represented by arrows of different widths.

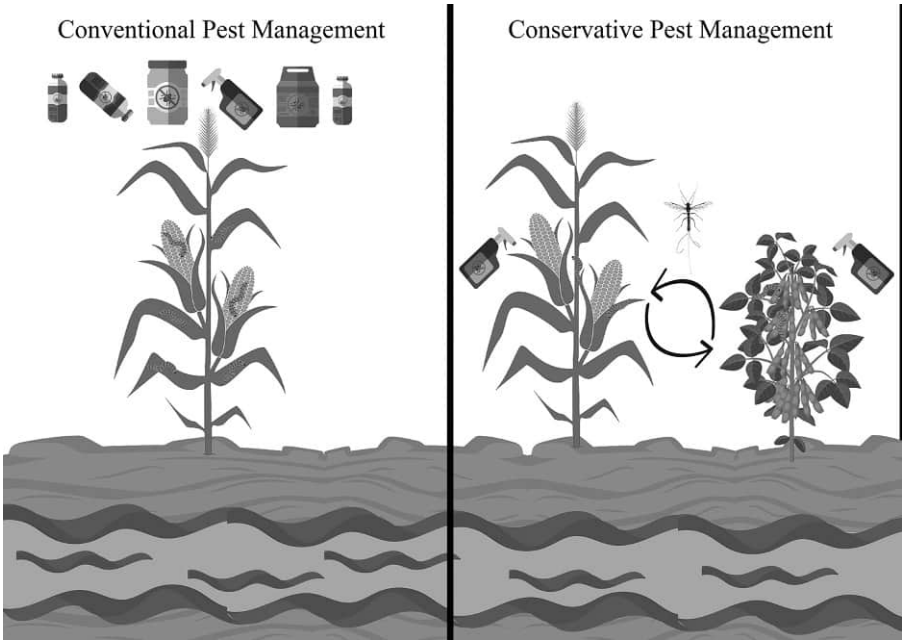

Fig. 2 Example of effects produced by conventional (left panel) versus conservation (right panel) pest management techniques and their effects on watersheds. The conventional techniques involve heavy application of pesticides that end up in the watercourse, threatening the health status and biodiversity. The conservation techniques, whilst not excluding the application of pesticides, albeit used at a lower rate, comprise additional environmental-friendly methods, such as the biological control of pests (in this example with the aid of parasitoid wasps) combined with crop rotations that interrupt the life-cycle of species-specific pests.

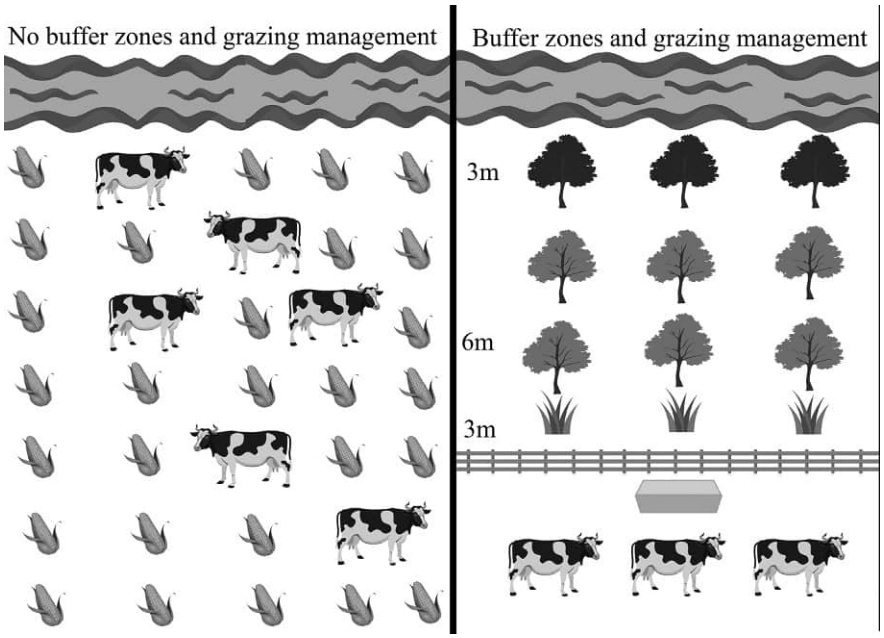

Fig. 3 Example of combination of conventional (left panel) versus conservative (right panel) buffer zones and grazing management techniques. The design of an appropriate buffer zone comprises a three-layer structure (sensu Christen and Dalgaard, 2013): a first layer (3 m wide) comprising grass (e.g., reed canary grass), followed by two layers of riparian tress (6 m wide layer of green alder and another 3 m wide strip of black alder trees). The grazing is mainly rotational and less intense, complemented sometimes with permanent fencing of livestock, and provided with supplementary water sources (e.g., trough) as compared to traditional management practices.

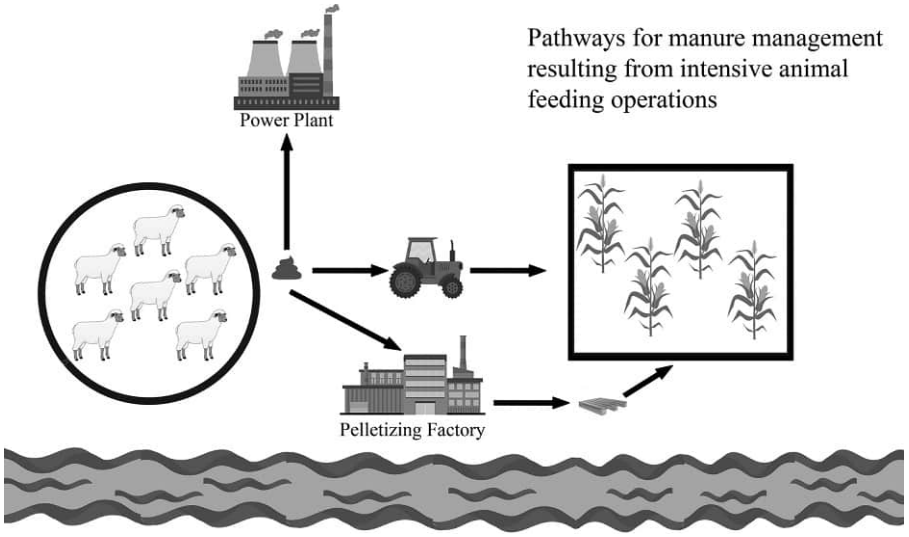

Fig. 4 Example of best management techniques for intensive animal feeding operations. Whereas the usual practice is ground application of untreated manure in crop fields, the alternatives are either the pelletizing technology or their usage as fuel for power plants.

Conservation tillage

Conservation tillage is broadly defined as any tillage technique with at least a third of the previous crop's residues remaining on the soil surface after seeding and represents one of the most popular BMPs that have been promoted around the world (Lal, 2003). However, its efficiency is strongly dependent on local characteristics of soil and climate; hence, it is paramount to understand how these factors interact whenever recommending conservation tillage measures to reduce and control nutrients and sediment export (Fig. 1). Conversion to conservation tillage has been shown to reduce the annual export of suspended sediments (considered as an indicator for sediment export) situated in the vicinity of crops by up to 65% compared with classic tillage systems (Seta et al., 1993; Tiessen et al., 2010; Reicosky, 2015). However, its efficiency depends strongly on local climate conditions. In the northern hemisphere, where snowmelt often exceeds rainfall runoff over the year, the efficiency of conservation tillage on sediment export is stronger during winter and spring compared with summer season, because snowmelt is usually less erosive, due to lower available kinetic energy than raindrops and occurs when the soil is frozen (Rekolainen et al., 1997). However, snowmelt in spring increases runoff significantly, hence increasing nutrient leaching. With respect to nutrient budgets, the results are conflicting, but with a general acceptance that overall, the proper implementation of site-specific tillage measures is effective in reducing nutrients leaching to water bodies (Fig. 1). As such, the situation of nitrogen (N) and phosphorus (P) retention is very much case-dependent. In the case of N export, its reduction was explained through a combination of diminished rainfall-induced runoff and effective tillage measures (Power et al., 2001). Other important factors involved in N retention could be the differences in its mineralization rate (i.e., the conversion of organic nitrogen to inorganic forms) as induced by proper implementation of conservation tillage. As a result of tillage, N mineralization can increase, leading to the build-up of nitrates in the uppermost soil layers of 0–15 cm (Campbell et al., 2008).

With respect to P retention and more specifically, various fractions of P-bound chemical species, conservation tillage can have mixed effects. The particulate phosphorus export in runoff can be directly dependent on the total export of eroded sediments and local runoff events (e.g., strong precipitation summer events), hence expectedly to be highly correlated to the amount of suspended sediments in the nearby water bodies (Sharpley et al., 2008). If the conservation tillage measure is effective, then this form of particulate P export should be equally diminished. However, the export of dissolved fraction of phosphorus in runoff is directly related to its fraction in soil and chemical reactivity (Tiessen et al., 2010). Previous investigations showed that the fraction of dissolved P can be higher in soils after implementation of conservation than under conventional tillage (Jennings et al., 2003; Selles et al., 1999).

The management of crop nutrients

The modern concept of crop nutrient management represents a mixture between old and new methods into a complex package of measures that is both environmentally friendly and economically sustainable. These management methods optimize most aspects of nutrients (i.e., N, P and K) cycling, aiming for synchronizing their demand by crops whilst diminishing their release in nearby water bodies (Kassam et al., 2011).

Barren fields and rotation crops

Barren fields left as gaps between crops represent both an economic and environmental issue. The replacement of such arable fields with other crops is considered nowadays one of the basic, but crucially important aspects for an efficient management of crop nutrients (Drinkwater and Snapp, 2007). The crop covering can reduce nitrate leaching up to 70% and avoids supplementary associated environmental risks (Howarth, 2005). Moreover, it was observed that the vegetal residues left in the field following crop harvest were followed by the increase of both N and P mass through the addition of organic matter used by the following crops (Howarth, 2005). Such an impact on microbial communities alters the timing of carbon (C) input and increases its conversion into microbial biomass (Jans-Hammermeister et al., 1998).

The introduction of legumes in crop rotations is seen as a viable means of reducing current dependence on synthetic N-fertilizers (Wu and Ma, 2015). This method has been proven to be highly influential in changing N cycling among soil, plants and atmosphere. The efficiency in N cycling is attained due the ability of legumes to fix atmospheric N_2 through symbiosis with bacteria and greater rate of residues turnover due to their biochemical composition (Plaza-Bonilla et al., 2015). Leguminous residues increase soil mineral N availability as a consequence of their turnover and accelerate the decomposition of soil organic matter (Wu and Ma, 2015). In order to avoid nitrogen losses, such as nitrate leaching and/or nitrous oxide emission to the atmosphere, the introduction of legumes needs to carefully consider the N balance between plants' requirements and its chemical availability in soil (Plaza-Bonilla et al., 2015).

In tropical systems, where P is often a major limiting nutrient easily lost in runoff in nearby water bodies, alternative environmentally friendly solutions represent an operative method. Experimental plots of various crops indicated that in such environments, the mixture of legumes lupin (*L. albus*) and pigeon pea (*C. cajan*) enhanced P availability for maize crops (Abawi and Widmer, 2000). The classic long-term experiments combining grass and legumes in pastures indicated larger P pools available compared with any of these two families of plants cultivated alone (Oberson et al., 2001). Moreover, by increasing plant diversity, the arthropod community is diversified, leading to enhanced number of natural biological top-consumers for various pests and decreasing the costs for herbicide or pesticide application and abundance of weeds (Abawi and Widmer, 2000).

Plantation of winter crops

The plantation of winter crops can be highly beneficial for crop nutrient management. Winter crops can reduce nitrate leaching into groundwater during winter and spring seasons, when highest infiltrations into soil tend to occur. Winter crop plantations reduced nitrate loss by three-fold compared with barren soils in a study undertaken in Maryland, United States (Staver and Brinsfield, 1998).

Application of fertilizers only when the time needed

A still very common practice among farmers from the northern hemisphere is to apply fertilizers, otherwise a very cheap product, during autumn, when the farmer has time. Because of this, much fertilizer (comprising various forms of N-related compounds) is leached into groundwater, leading to often serious degradation of water quality, given the long-term time period necessary to naturally remove these compounds from these water bodies. The optimal time to spread fertilizers is, however, during spring and summer. Autumn applications of fertilizers have been shown to increase N leaching into groundwater by 30–40% compared with spring and summer applications (Randall and Mulla, 2001).

The management of pests

Such measures comprise a holistic approach for the prevention of pest issues and reduction of pesticides usage that may adversely affect the inland water bodies (Barzman et al., 2015). Rather than simply decreasing the usage of pesticides, several complementary methods have been suggested in order to reduce detrimental effects on aquatic environments:

Pest-tolerant plant varieties and closely monitoring of their efficiency

The use of pest-tolerant and resistant crops helps decreasing dependence on pesticides in arable crops (Fig. 2). However, for efficient pest management this should be combined with the monitoring of pathogens carrying resistance genes (Haverkort et al., 2008).

Crop rotation

Crop rotation represents one of the most efficient alternatives to pesticides use (Fig. 2). Alternating winter and spring-summer crops is highly recommended, since this action breaks the life-cycle of many pests more efficiently than the classic rotation with winter or summer crops (Bartoli et al., 2014). Another example is the one of legumes used either for leaf products or root. However, the usage of crops within the same family is highly discouraged, since the selection for pathogens can increase in such conditions. Therefore, this method is efficient solely for those species-specific pathogens; others, with a broad spectrum of hosts (e.g., the bacteria *P. syringae*) may require alternative solutions (Lamichhane, 2014). The rotation of maize with soybeans is another example applicable on large scale in United States, in order to discourage the invasive Western corn rootworm (*D. virgifera virgifera*) to complete its life-cycle (Vasileiadis et al., 2011).

Monitoring

Besides crop rotation and cultivating pest-resistant varieties, another complementary method is the monitoring of pests at regular intervals or upon issue of local warnings. In European countries such as Denmark, Germany, France and Switzerland such systems are operational and provided good results for local farmers and landowners (Barzman et al., 2015). The changes that occur naturally in weed populations create favorable conditions to generate predictive models with their forecasted geographic distribution (Samietz et al., 2011). This way, the monitoring can prove a useful BMP method in pest control.

Alternative protective methods, excluding the application of chemical solutions

Soil solarization and biological control of pests represent an alternative to the usage of pesticides; however, their availability and efficacy varies considerably. One of the most widespread techniques is pheromone-based mating disruption. This technique has been shown effective in controlling the population size of several insect pests, with success of up to 50% in apple orchards and 60% in vineyards and reducing the usage of synthetic pesticide use by two thirds (Samietz and Höhn, 2010). The use of live natural enemies represents another important tool in pest management (Fig. 2). A very successful example is the application of *Trichogramma* sp. against the European corn borer *O. nubilalis* (Barzman et al., 2015). Therefore, although applied with variable success, this environmentally friendly approach represents a desirable method in the control of insect pests.

For the management of weeds, alternative methods to pesticides application exist. One such approach considers the differential vertical distribution of seeds in the soil and has the potential to affect weeds emergence and population dynamics, upon the application of complementary BMP's, such as appropriate tillage techniques (Chauhan et al., 2010). Another approach involves weeds' seeds consumption by granivore fauna, such as ants and other insects. Seed predation could be an important BMP in agricultural crops where newly produced weed seeds remain on the soil surface, for example, in no-till systems (Chauhan et al., 2010). When combined with other methods of weed control, seed predation may help to minimize the usage of herbicides (Chauhan et al., 2012).

The management of irrigation waters

The main environmental concerns related to irrigation waters are the discharge of salts, pesticides and nutrients into inland waters (Ramos et al., 2011). Appropriate management practices for irrigation need to take into consideration several aspects, such as arable terrain slope, soil moisture and the water necessities of plants (Najafi and Vatanfada, 2011). Additionally, the chemical characteristics of the soil and the quantity and quality of the irrigation water should determine whether this technique represents a sustainable BMP or not (Schaible and Aillery, 2012). Very often, the irrigation waters are overused, being delivered in higher quantities than needed by a particular crop, mostly because of processes such as evaporation, runoff, wind drift and percolation losses (Benfetta and Ouadja, 2020). Additionally, in arid regions, salinity represents another environmental issue, requiring usage of additional water to flush the soil (Niyazov et al., 2012). The accumulation of salts in excess in the root zone of plants leads to the partial or complete loss of soil productivity, hence compromising the crop (Benfetta and Ouadja, 2020).

We consider that five important steps and priorities of any irrigation-related BMP should be considered prior and during their implementation:

1. Appropriate timing for irrigation. This measure should consider carefully the overexploitation of water resources as such as to minimize the impact on the source itself, usually an inland water habitat. Prior knowledge on minimum humidity level of soil for each crop and the amount of water applied to the field to support a feasible yield is helpful (Irmak et al., 2000).
2. Irrigation water application efficiency. Such aspects should consider the suitable water usage and distribution, bearing in mind potential detrimental impact on the environment, and finally on the recipient water body (Smith et al., 2005). Minimizing surface runoff or deep percolation toward the phreatic layer and soil erosion represent targets for any BMP of irrigation water (Howell, 2001).
3. Irrigation water transport efficiency. The technical measures applied in water transport from source to crop should be designed and managed as such as to minimize water evaporation and seepage from irrigation canals (Wriedt et al., 2009). The technical solutions, beyond the aspect of this article, should consider the improvement of the transportation systems (e.g., lining of canals and ditches, pipes).
4. Irrigation water re-use efficiency. Surface runoff is sometimes re-used for irrigation of crops. This method is very practical, since it reduces the amount of water lost from irrigation systems, and simultaneously diminishes the quantity of dissolved pollutants or suspended sediment in the recipient aquatic ecosystems (Budd et al., 2009). Therefore, this practical measure should be considered as a must in any appropriate BMP package of measures tackling the irrigation water issue (Robinson et al., 2003).
5. The management of drainage water. Complementary BMP's, such as buffer strips, tillage works and crop nutrients (see above) should be considered to minimize the detrimental aspects of current irrigation practices on aquatic ecosystems. Moreover, surface (i.e., ditches to collect excess water in field) and subsurface (i.e., pipes installed beneath the ground collect drainage water) drainage systems should be applied appropriately in irrigation strategies (Malash et al., 2008).

The management of buffer zones

Buffer zones on agricultural land are generally acknowledged to be effective in protecting inland aquatic habitats by reducing soil erosion and diffuse nutrients pollution (Christen and Dalgaard, 2013). The implementation of this method is still limited to date, but the increasing demand for efficient measures in the vicinity of agriculture fields or grasslands calls for improved solutions (Irvine and Ni Chuanigh, 2011; Mayer et al., 2007).

Out of all potential suggested designs for buffer zones situated nearby agricultural fields, one of the most efficient is a three-zone structure comprising: a zone with grass and shrubs, followed by a second zone with trees where the main maintenance activities are forestry rotation and coppice and finally, a third component comprising permanent and intact woody vegetation along the water banks (Christen and Dalgaard, 2013, Fig. 3).

The first layer (i.e., grass and shrubs strip, Fig. 3) decreases runoff speed, filters sediment and halts soil erosion, and helps significantly in nutrients bioaccumulation in vegetal tissues and enhances denitrification (Liu et al., 2008). Moreover, the grass can be easily harvested, used further as hay or grazing site for livestock. The second component is efficient in retaining suspended sediment particles and dissolved pollutants, enhancing the bioaccumulation of nutrients and denitrification processes from the first component (Schultz et al., 2004). The third component mainly reduces bank erosion, and has an important role in mitigating flood effects and continues the buffering capacity of the previous two sectors (Zhang et al., 2010). Moreover, it plays a direct beneficial role in maintaining the aquatic habitats' wellbeing, through shading (that prevents overgrowth of macrophytes and algae) and addition of woody debris and litter (fuelling basal resources for aquatic food webs) (Hefting et al., 2006; Seitzinger et al., 2006, see Fig. 3).

If the cropland is flat, as it occurs in most agricultural areas worldwide, the buffer strip can comprise fast growing species of grass (e.g. reed canary grass (*P. arundinacea*), see Fig. 3), followed by a narrow strip of fast growing and cheap to maintain riparian trees, such as willow (*Salix sp.*), poplar hybrids (*Populus* sp.) and alder (*Alnus* sp.) (Uri et al., 2008). The grass strip may be replaced by a ditch, acting as sedimentation basin depending on local conditions. If the slope is of medium- to high gradient, the buffer zone is essentially of the same structure, but with different species of choice (Schultz et al., 1995). On steep slopes, however, the scope of the buffer strips is rather shifted toward erosion prevention and particularly P loss in runoffs (Dorioz et al., 2006). Hence, the first layer could comprise rather scattered trees with light foliage over stiff stemmed grass, to maximize infiltration capacity. Moreover, tree species should be different in such particular case, such as oak (*Quercus* sp.), black locust (*R. pseudoacacia*) or maple (*Acer* sp.) (Vidon et al., 2010).

The management of grazing activities

The management of grazing activities should primarily focus to adjust the intensity and duration of livestock presence in the water body vicinity, as the animals' movement control (Papanastasis, 2009).

Permanent fencing

One of the best known radical measures is the permanent fencing and the restriction of livestock from entering waterways (Fig. 3). The effects of this practical measure comprise the removal of animals' movement in adjacent aquatic habitats, the maintenance of riparian buffer zones (see above), given reasonable length of fencing from the targeted water body, hence reducing soil and vegetation damage by trampling (Mosley et al., 1997).

However, alternative solutions, of less drastic nature, have been proposed, with variable success (Fig. 3).

Alternative water sources for livestock

Such measures include providing alternative water sources (i.e., trough) to improve the nearby targeted water body's quality (Fig. 3). Applied with variable success, researchers noticed changes in animals' behavior upon the instalment of troughs. Cattle changed their behavior, rather preferring the closer water source (Kaucner et al., 2013). Moreover, depending on how humid the season was, horses rather preferred to consume less water, given wet pasture conditions (Mosley et al., 1997).

Controlled grazing

Continuous grazing degrades aquatic habitats adjacent to pastures or meadows (Gassman et al., 2006). Up to 60% increase in sediment loss was registered in water bodies experiencing both summer grazing and winter-feeding compared to those that supported only the former type of livestock impact (Gassman et al., 2006). Whereas such measures maximize the profit for a farmer, the impact on aquatic habitats, mainly as leached nitrates, besides sediment loss, is significant (Agouridis et al., 2005). The alternative solution is the rotational grazing, which was already proved efficient in reducing stream banks erosion, fine sediment delivery in river channels, as better functionality and status of buffer zones, when applicable (Lyons et al., 2000).

Supplemental feeding

This represents a complementary method that goes well with alternative water supplies that can reduce significantly the impact of livestock on nearby aquatic habitats. However, both methods, when used, changed significantly the amount of time spent by cattles in the water body vicinity, hence with a positive aspect on the manure quantity and nutrients leaching in the adjacent freshwater bodies (Agouridis et al., 2005).

The management of intensive animal feeding operations

One of the most pressing detrimental effects stemming from intensive animal feeding operation units has its source in the amount of manure produced (Fig. 4). The detrimental effects of manure on aquatic ecosystems are multifaceted and are intimately associated with the array of contaminants they provide, essentially a cocktail of nutrients (e.g., nitrogen and phosphorus), pathogens, growth hormones, antibiotics, chemicals used to clean equipment, animal blood and copper sulfate used in footbaths for cows (Government Accountability Office, 2008).

Large intensive animal operation unit manure production can surpass the waste production of big cities (Ribaudo et al., 2003). Instrumental is the example of a feeding operation with 800,000 pigs which produces over 1.6 million tons of waste a year, one and a half times more than the annual sanitary waste produced by the city of Philadelphia in the United States (Government Accountability Office, 2008). Annually, it is estimated that livestock animals in United States produce each year somewhere between 3 and 20 times more manure than people produce (Environmental Protection Agency, 2003). Such huge amounts of manure do not benefit from treatment plants, as human waste usually does, threatening all types of freshwater bodies in the vicinity of such large farms (Government Accountability Office, 2008).

The handiest management solution for untreated manure, the ground application (due to its low cost) can equally prove cumbersome for the environment, given the aforementioned array of detrimental pollutants it contains (U.S. Department of Agriculture, Natural Resources Conservation Service, 2000). Currently, nutrient management policies recommend the use of a dual approach: nitrogen and phosphorus standards. Manure application rates that are based on a nitrogen standard would supply all the nitrogen recommended for the crop. Manure applied at a nitrogen standard will usually result in overapplication of phosphorus. Alternatively, when using the phosphorus standard, the environmental policies allow the application of phosphorus equal to the amount contained in the biomass of multiple years of crops grown on the site, provided that the nitrogen recommendation rate for the first year is not exceeded (Ribaudo et al., 2003).

Alternatives solutions to spreading manure on land are currently used (Fig. 4). Such technologies redirect the manure off-farm toward industrial use. Several processes have been developed to make the nutrients and organic matter in manure more uniform, manageable, and marketable (Lichtenberg et al., 2002). An example is offered by the pelletizing technology and process developed by companies that converge the raw litter into organic fertilizers (Fig. 4). The final product comprises a pasteurized organic fertilizer, with an optimal nutrient (N: P: K ratios), specially designed for agriculture (Government Accountability Office, 2008).

Alternatives for reducing nutrients concentration in manure comprise the modification of animals' diet. However, so far, the lack of economic and regulatory incentives leads to little advances on this direction (Council for Agricultural Science and Technology (CAST), 2002). Such approaches focus toward developing the appropriate nutrients requirements of animals by gender and growth phase, developing ways to increase feeding efficiency and for minimizing the usage of phytase and synthetic amino acids for alternative ration components (Ribaudo et al., 2003).

Summary

This article comprises an overview on the main Best Management Practices required for reducing the direct or indirect detrimental human impact on inland waters' quality and ecological status. For each proposed management measure the positive and negative aspects were highlighted, suggesting that, when applicable, they should consider site-specific characteristics for crop needs, climate and land use intensity. This proposed package of measures, if properly applied, can be more efficient compared with conventional techniques and comprises a set of recommendations that should be considered carefully by environmental scientists, stakeholders, farmers and land-owners alike.

Glossary

Abstraction Removal of water from waterbody for irrigation, drinking or other use.
Adsorption Accumulation of molecules to a solid surface. Adsorption is usually reversible (desorption) and typically occurs until an equilibrium is reached.
Aquifer A saturated body of groundwater held within sub-surface porous rock or soil.
Baseflow Index The proportion of river discharge coming from groundwater.
Cambisol A soil group which is in the early stages of development and differentiation into distinct horizons. Cambisols are the second most abundant soil group worldwide.
Colloidal A mixture of insoluble, microscopic particles suspended in a fluid. Soil colloids are organic and mineral particles <0.0001 mm, which have large surface area and may carry adsorped nutrients.
Cross-border Referring to a geographic area such as a river catchment that includes land in two or more countries.
Deltaic sediments Sediments derived from where the mouth of river intersects with an estuary.
Derogation An exemption or relaxation of regulations. In the context of Irish water quality, it refers to permission to exceed the standard upper threshold for application of nitrogen fertilizers (from 170 to 250 kg ha).
Dredging The excavation of sediment from a river, harbor or ditch.

Ecological indicator species A species whose presence or absence reflects the conditions of a habitat. Ecologically sensitive species are vulnerable to pollution or other pressures, whereas insensitive species are tolerant and may be present even in degraded environments.
Eutrophication Excessive plant or algal growth in watercourses due to the presence of available nutrients and exposure to sunlight.
Extensive With reference to grassland or grazing, this means that fertilizer inputs are low and only small animal numbers are grazed on the area. Extensive grasslands are frequently less productive than other systems but offer a harbor for biodiversity and add esthetic value to the landscape.
Fluvial Relating to rivers. Fluvial sediments are deposited by rivers or streams.
Intensive With reference to grassland or grazing, this means that the system relies on high fertilizer inputs to drive productivity and usually entails high livestock stocking rates. Additional feed may also be significant to maximize the productivity of animals in intensive systems.
Mineralization In relation to nitrogen, mineralization is the process by which organic forms are converted to inorganic forms (ammonium and nitrate) which can be used by growing plants.
Nitrates Directive (ND) Irish legislation introduced in 1991 that aims to protect water quality through good agricultural practices.
Podzol Soils with high organic matter typically developed under forestry.
Potable Water which is safe for human consumption.
Pyrite A sulfide mineral that is common in the geology of the Bengal basin and which often co-occurs with arsenic.
Recharge The mechanism by which water percolates through the soil and bedrock to refill the aquifer.
Redox Chemical reaction involving electron transfers which is responsible for the release or retention of molecules such as arsenic or phosphorus, in the case studies presented here.
Time Lag The delay in contaminant transfer from a source to a receptor, such as a watercourse.
Unconsolidated aquifer A body of rock or sediment which has high porosity, such as gravel or sand.
Water framework directive (WFD) Overarching European legislation introduced in 2000 that commits member states to achieve good ecological status within fixed timelines.

Introduction

Agriculture is intrinsically linked to water quality and availability, as discussed in chapters 6004 and 6005. The demands exerted on waterbodies due to production type and intensity vary widely and considering the reliance of modern societies on either subsistence or commercial agriculture, some impacts are to be expected although management practices are implemented in many regions to mitigate some of the harmful effects. Presented here are examples of regional water quality issues resulting from agriculture and the management approaches implemented in response to those pressures. It is beyond the scope of this chapter to provide a comprehensive overview of agriculture and waterbody interactions, but the case studies discussed herein demonstrate priority issues in diverse regions of the world.

The four case studies presented here are:

- Nutrient pressures in an intensive grassland catchment in the Republic of Ireland,
- Groundwater abstraction and arsenic contamination in the Bengal Basin, India,
- Herbicide impacts on freshwater in Northern Ireland, United Kingdom,
- Sediment and nutrient dynamics arising from wetland conversion in Rwanda.

Case study 1: Nutrient pressures in an intensively managed grassland catchment

Overview of the catchment

The south-west of Ireland is dominated by highly productive grassland agriculture, particularly emphasizing grass-based dairy production (Fig. 1). It represents an important area of permanent grassland within Europe (Kempen et al., 2011). The Timoleague study catchment (Fig. 2) is a 7.6 km^{-1} river catchment, predominated by dairy production (51°38′59 N, −8°45′59 W). Land use is 77% grassland, and 11% arable, with the remainder in non-agricultural use. The catchment reaches its greatest elevation at 120 m a.s.l., and the stream drains into Courtmacsherry bay. The geology of the area is old red sandstone and mudstone, overlain by freely drained brown earth soils, ranging between 0.5 and 10 m in depth. A small area of gleyic brown alluvial soil is present bordering the stream. Average annual rainfall is c. 1120 mm. The stocking rate of the catchment is among the highest in the country at 1.9 livestock units per ha, and 54% of the land in derogation (2010–18) to the EU Nitrates Directive (European Commission, 1991). This derogation allows application of fertilizer ≥ 170 kg N ha^{-1}. The freely drained nature of these soils encourages a long growing season and grazing throughout much of the year, including early turnout of housed cattle to grass in spring. Diffuse nitrate loss is

Fig. 1 The Timoleague catchment in Southwest Ireland is a highly productive grassland dominated by dairy production.

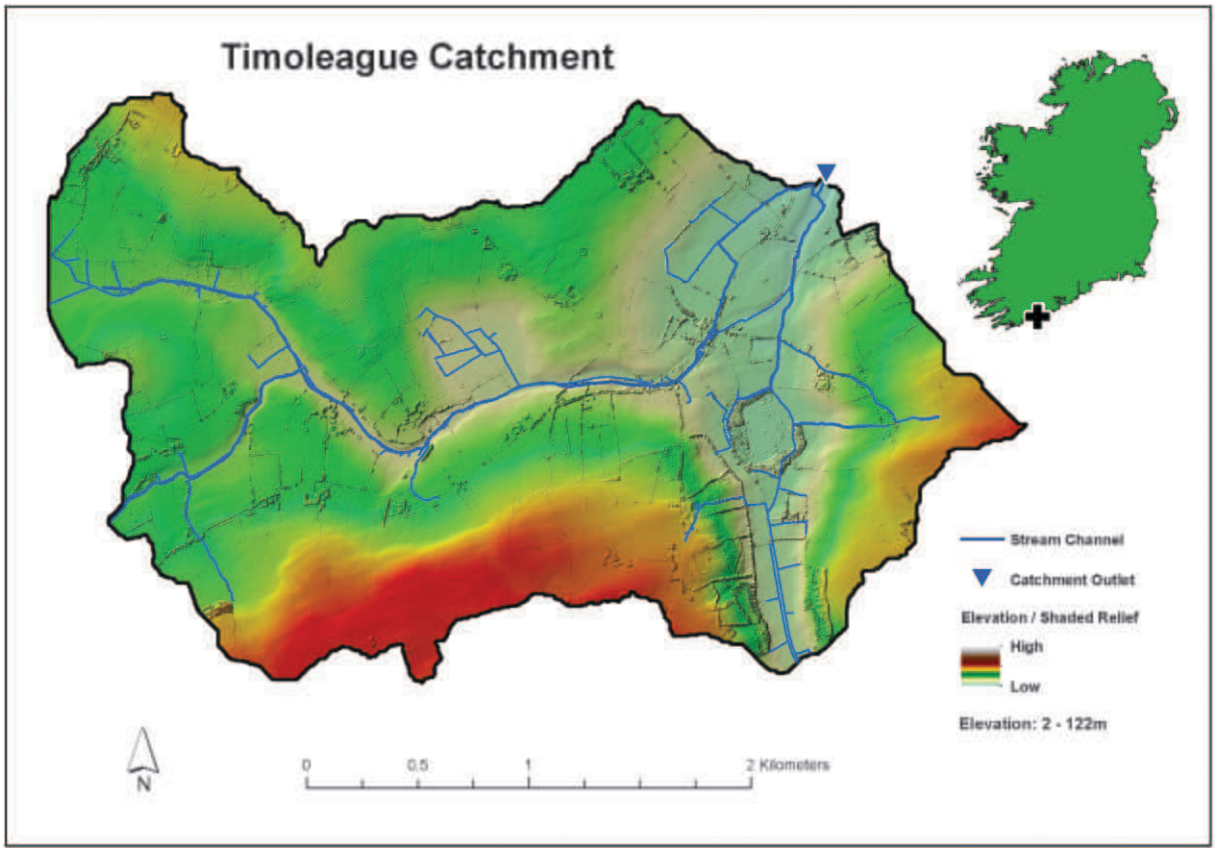

Fig. 2 Map of the Timoleague grassland catchment in Ireland.

potentially the highest nutrient risk to water quality in this setting, as a result of (a) high loading and (b) presence of a sub-surface pathways. The catchment exhibits a high baseflow index (73%), indicating a substantial proportion of streamflow contributed by groundwater (McAleer et al., 2017).

Nutrient pressures and pathways

Monitoring at the outlet of the watercourse has shown that nutrient loss to water is an issue in the catchment. The annual average NO_3-N concentration (2009–19) was 6.1 mg L^{-1} which is lower than the Water Framework Directive (WFD) (EC, 2000) drinking

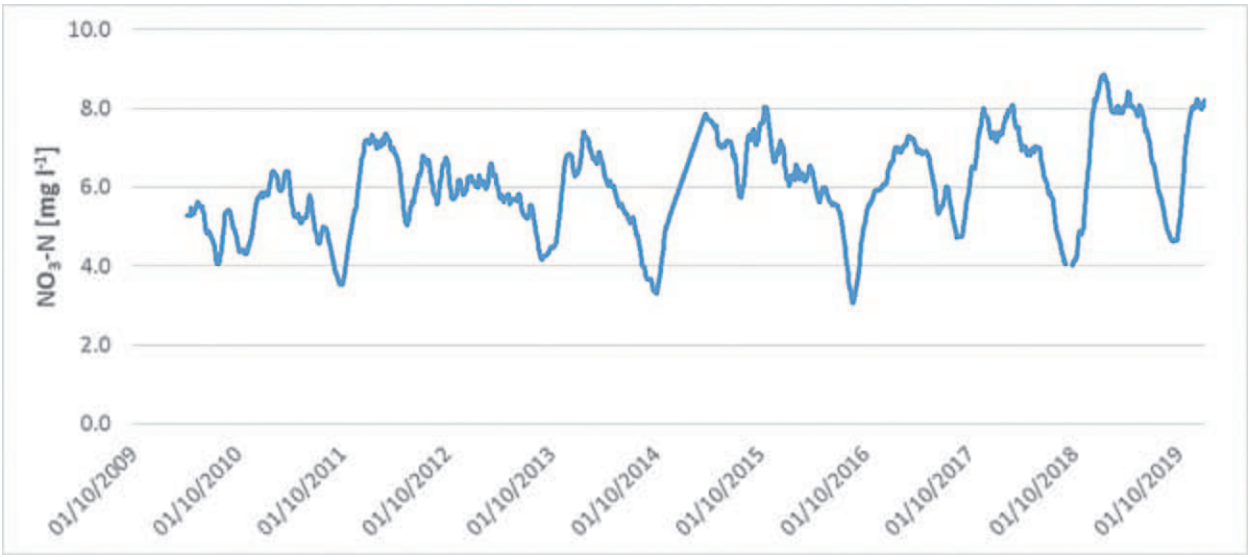

Fig. 3 Nitrate fluctuations over time (10-min sampling resolution) as measured at the catchment outlet (2009–19).

water standards (11.3 mg L^{-1}) but substantially higher than the NO_3-N concentration considered to be commensurate with good ecological status (2.6 mg L^{-1}) (Fig. 3) (S.I. 272). The annual average total reactive phosphorus (TRP) concentration was 0.066 mg L^{-1} which is above the Water Framework Directive target value for rivers (0.035 mg L^{-1}) (Fig. 4) (S.I. 272). There were large temporal variations in both NO_3-N, TRP, and total phosphorus (TP) associated with both natural temporal variability and changes in hydrometric, biogeochemistry and agronomic conditions. There has been an increase in the NO_3-N concentration over the monitored period (2010–20), particularly during the last 3 years. The organic nutrient load has increased during the period and changes in weather patterns has likely enhanced nutrient loss, with warmer and drier summers reducing the plant nutrient uptake and enhancing mineralization, together with more large rain events in autumn and winter allowing for nutrient flushing (Mellander et al., 2018). In-stream vegetation in parts of the catchment is high at times, particularly during peak growing conditions during summer months (Shore et al., 2017). Nitrate (NO_3^-) loss does occur through the vertical pathway in this catchment, with subsequent delivery to the watercourse via groundwater (McAleer et al., 2017). Decadal time lags of NO_3^- through the soil and groundwater components delay observation of the full effect of programs of measures intended to reduce nutrient emissions under the Water Framework Directive (Vero et al., 2017). The impact of past nutrient management, therefore, continues to impact NO_3^- loads delivered to the watercourse. However, prolonged transit through anoxic groundwater does provide opportunity for denitrification, thus reducing overall loads to surface waters (McAleer et al., 2017). Spatial variability in NO_3^- removal capacity is observed across the catchment, influenced by water table depth, conductivity of the bedrock, and presence of denitrifying bacteria and substrates. McAleer et al. (2017) observed a 43% reduction in groundwater compared with stream NO_3^- concentrations. While offsetting NO_3^- loads by denitrification to water is a benefit from an aquatic ecological perspective, there are trade-offs as the end products (N_2O) is a potent greenhouse gas. This pollutant swapping is important to consider for the agricultural landscape. Not only are there direct emission from agricultural soils but also indirect emission of N_2O from groundwater to the atmosphere (Jahangir et al., 2012) and both must be accounted for in accordance with International Panel on Climate Change (IPCC) protocols.
