Elevated baseflow concentrations of dissolved reactive phosphorus (DRP) measured using a Phosphax automated analyzer had mean values across the catchment exceeding the Water Framework Directive threshold for good ecological quality (0.035 mg L^{-1}) during summer but declining to concentrations below the threshold specified under Irish legislation (SI 272, 2009) over autumn and winter as dilution predominates (Fig. 4) (Vero et al., 2019). During low-flow periods, diurnal fluctuations in DRP concur with typical timings of morning and evening milking of cows. This indicates recurring point discharge of soiled dairy wastewater, which is obscured during high-flow periods. The importance of multiple agricultural (e.g., farmyards, livestock crossings) and rural-domestic (single house septic tank and group wastewater treatment facilities) point sources is crucial, as their cumulative loads supplement diffuse losses, and their impact may be under-estimated. While P loss in agricultural landscapes is most frequently attributed to the overland pathway, monitoring of groundwater wells and concentrations in stream baseflow indicate high sub-surface loads arriving in this catchment. Soils in Timoleague are rich in iron and have high P concentrations (~50% soils at Index 3 or 4 (Thomas et al., 2016)), favoring mobilization of P into soluble forms with potential for leaching particularly during saturated conditions (Mellander et al., 2016), or movement in colloidal form in areas of the catchment with cambisol or podzol soils (Fresne et al., 2020). While the catchment might not be identified as being of particularly high risk of P loss compared with landscapes with a greater propensity for runoff, evidence from long-term monitoring and an abundance of peer-reviewed publications indicates that it is indeed a threat to the ecological status of the catchment. Indeed, runoff is frequently considered to be the chief pathway for P loss, however, leaching is increasingly recognized as an important pathway (Smith et al., 2021). Declines in legacy P in soil stores have been estimated to take decades to reach agronomic and environmentally optimal ranges (Schulte et al., 2010) and so mitigation of losses from soil requires commensurate timescales.

Impacts

Following removal of Irish national milk quotas in 2015, the productivity of the Irish dairy sector has increased over recent decades, a trend typified by expanding herd numbers, reduction in small farms, expansion of large farms, and increasing number of farms availing of derogation (Kelly et al., 2020), The proportion of grazed grass in the cows' diet has a close relationship with cost of milk production per liter, meaning that dairying in this region is likely to remain an attractive land use. National agricultural plans predict a 65% increase in primary agricultural productivity by 2025 (Department of Agriculture, Food and the Marine, 2017). The updated goals described in FoodVision 2030 (Department of Agriculture, Food and the Marine, 2021) emphasizes reduction of nutrient losses, increases in efficiency, and overall improvements in sustainability. This suggests that intensity of production, which naturally is accompanied by nutrient loads which must be effectively managed, is unlikely to reduce in this catchment, and others like it.

The Courtmacsherry bay into which the Timoleague catchment discharges has not improved from poor ecological status over the 2010–18 period. Nevertheless, modeling of the bay has indicated that flow-load relationships of dissolved inorganic N and dissolved inorganic P suggest improvement in agricultural practices between 2010 and 2016, particularly the retention of inorganic P within the catchment by breaking hydrologic pathways (McGovern et al., 2017). That study suggested that amounts of the green macroalgae genus *Ulva* (indicative of eutrophic growth) in the bay would have increased from 380 t wet weight in 2016 to 1391 t if the 2010 flow-load relationships prevailed. While this suggests a positive effect of integrated catchment management practices organized by local authorities and agricultural advisors, sustained adherence to best practices by farmers as regards diffuse pollution and suppression of point sources are crucial to achieve future targets, particularly under intensified production scenarios. Best practices must be designed for specific land uses and landscapes and there is no one-size-fits-all approach. Consequently, selection of measures for maintaining and improving water quality should be on a case-by-case basis. Certain measures such as use of buffer strips to break the runoff pathway or use of cover crops, are promoted by agri-environmental schemes and as research develops, newer novel methods will likely arise. High temporal water quality monitoring and improved quantification of land use, characteristics, and management has allowed clearer elucidation of trends and patterns in watercourses and to connect those with both agricultural and non-agricultural activities.

Case study 2: Groundwater abstraction and arsenic contamination in the Bengal Basin, India

Overview of the catchment

The Bengal Basin is a 200,000 km^2 catchment in West Bengal, India and Bangladesh, and home to some ~120 million people, approximately 2% of the world's population. The catchment is drained by three major rivers: the Ganges (2510 km), the Brahmaputra (2900 km), and the Meghna (270 km), flowing ultimately into the Bay of Bengal, and is sometimes referred to as the Ganges-Brahmaputra-Meghna basin. The supply of potable water is largely dependent upon groundwater abstraction. Increasingly, this resource is also utilized for irrigation of cropland. The Bengal basin is a low-lying landscape (~1.8 masl) of meandering channels, meander scrolls, and natural levees formed by the river and its tributaries. The geology of the basin consists of Holocene sand, silt and micaceous clays deposits. The aquifers are composed of sandy unconsolidated Pleistocene to Holocene fluvial and deltaic sediments. Shallow groundwater is largely relied upon for drinking water supplies, despite recommendation that deeper reserves (>150 m bgl) are less likely to be contaminated (Chakraborty et al., 2015).

Arsenic (As) contamination is believed to affect up to 90% of drinking water wells in some districts (Chakraborty et al., 2015), particularly in low-lying regions. Districts at greater elevations are relatively unaffected. Arsenic presents a significant health threat; causing arsenicosis, characterized by impaired childhood development, skin disorders, cancers, and a variety of chronic organ conditions. The threshold concentration for drinking water is set at 50 $\mu g\ L^{-1}$ and exceedances have been estimated present a health risk to c. 30–35 million and 15 million people in the Bangladesh and West Bengal, respectively (Chakraborty et al., 2015). Still greater numbers rely upon sources which exceed the World Health Organisation (WHO) threshold of 10 $\mu g\ L^{-1}$ with 42% of wells in Bangladesh exceeding this concentration. While contamination of drinking water is frequently associated with industrial production, in this case, the scientific consensus identifies geologic origins of As contamination. Young groundwater is moderately oxygenated but undergoes reducing conditions in the subsurface, facilitating microbial degradation of iron compounds within the sediments. Dissolution of ferric oxyhydroxides releases sorbed As to the groundwater, which may then be abstracted. Although As is naturally occurring within certain sediments, abstraction of groundwater with high As concentrations for agricultural irrigation causes adds to the pollution of surface waterbodies.

Irrigation as a pathway for geogenic arsenic

Although widespread use of groundwater abstraction wells began during the 1960s (Burgess et al., 2010), abstraction is not restricted to drinking water. Contamination of drinking waters with As escalated significantly during the 1990s along with a surge in abstraction of groundwater for irrigation (Kinniburgh et al., 2003). By 2001, over 1 million irrigation wells were installed in Bangladesh, with a further quarter of a million in West Bengal (Michael and Voss, 2009). These pumps abstract water at a 10 times greater rate than traditional or drinking-water wells. Irrigation has facilitated increases in crop production essential to support the growing population, and agriculture represents the largest employment sector nationally. Despite negligible expansion in the area

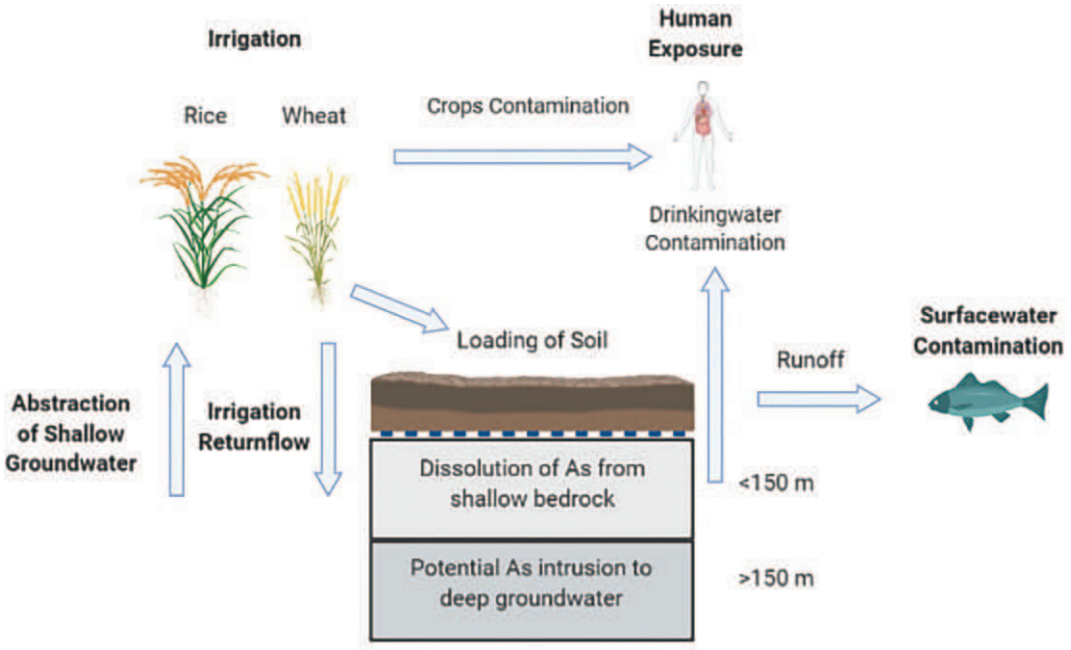

Fig. 4 Conceptual diagram of arsenic mobilization and circulation.

under cultivation, irrigation has been responsible for an increase of 70–80% of rice and wheat production between 1970 and 2004 (Zaveri et al., 2016). The increase in abstraction was supported by government subsidy schemes during the 1980s (for deep tube wells), superseded by a later preference for shallow, less expensive, tube wells.

The pyrite-reduction hypothesis suggests that not only does agricultural abstraction transport As contaminated water to the surface, but may also promote mobilization from pyrite stores in the bedrock due to oxidization as the water-table is lowered (Hossain, 2006). This creates a potential feedback in which abstraction of contaminated shallow groundwater leads to contamination of the previously higher quality deeper aquifers over decades. It must be noted that this is one hypothesis, and there is not yet consensus whether this is the only action contributing to the As problem and multiple processes may simultaneously contribute to mobilization (Chakraborty et al., 2015). A conceptual model of this hypothesis is presented in Fig. 4. Correlation of As-related disease with patterns of irrigation suggests a relationship, although data for the region is incomplete prior to the 1990s (Ravenscroft et al., 2005). It also seems likely that there are other concurrent mechanisms of geochemical release of As.

Irrigation return flow recirculates irrigation water within the hydrologic system. Enhanced recharge mechanisms (including injection and percolation) are, in particular, used to accelerate the return of contaminated water, both replenishing the vadose zone and eventually deep groundwater aquifers. The exchange rates of As between vadose and groundwater zones is still not fully explored and is likely to be spatially and temporally variable. Return flow is frequently charged with various elevated ions, in this case As, which presents a hazard to drinking water supplies abstracted from the shallow aquifer where maximum recharge occurs. In this way, As which would otherwise be occluded within the subsurface is mobilized by initial abstraction that creates a change in redox stability in the aquifer, and then brought into circulation within the agricultural and surface-water systems.

Impacts

The abstraction of groundwater has been, and continues to be, crucial for continued agricultural production in the region. Depletion of accessible groundwater reserves is a concern, with depth to the water table increasing, however, there is also an acute threat to human health as irrigation mobilizes As-rich water to the environment. Besides contamination of otherwise potable water, As bio-accumulates within crops, particularly rice grains, providing a further mechanism of exposure to humans. Furthermore, the application of contaminated groundwater has increased soil As concentrations (Saha and Ali, 2007), reaching 40 mg kg^{-1} in some areas (Chakraborty et al., 2015). Mobilization of soil particles during storm events may result in sediment-bound As being transported to surface-waters as a result of erosion. Similarly, during the monsoon period saturated top-soils which have become laden with As may release bound P into solution and transported to rivers (Chakraborty et al., 2015). This is due to the process of

competitive adsorption. Where soils which are rich in phosphate also have a considerable proportion of adsorbed arsenates, under saturated conditions P may be released along with As. This may deliver a combination of both As and nutrient enriched leachate to groundwater.

In addition to the direct impacts on human health from consumption of As-contaminated food and water, there is an ecological impact. Freshwater fish species such as pangasius have shown acute response (lethal concentration - LC_{50} 28–34 mg L^{-1}) to As which is exacerbated at elevated temperatures (>38 °C) (Kumar et al., 2019), as well as bioaccumulation within tissues during sub-acute exposure. Sub-lethal exposure also has damaging effects upon the gills of freshwater mollusks, which are key ecological indicator taxa (Chakraborty et al., 2010).

Shifting towards abstraction of deeper groundwater may offer an alternative to continued utilization of unsafe shallow groundwaters, however, aquifer depletion and indeed, intrusion by contaminated water are potential risks associated with this approach (Burgess et al., 2010). Indeed, over-abstraction of the deep aquifer for irrigation purposes may effectively eliminate this resource as a source of safe drinking water (Burgess et al., 2010). An integrated approach to planning involving national and international policymakers, agricultural representatives, and scientific expertise is therefore essential to protect the future of the hydrologic basin, and the communities living there.

The abstraction-irrigation-contamination cycle demonstrated in the Bengal Basin is an example of an indirect pressure on water quality as a result of agriculture. Although elevated As concentrations are a natural characteristic of the area based on its geology, the agricultural system and intensity of rice and wheat production exacerbates the associated impacts on both of surface and groundwater resources.

Case study 3: Herbicide impacts on freshwater in Northern Ireland, United Kingdom

Overview of the catchment

The Derg catchment (54 N°40′, 7°42′W) is a rural catchment straddling the border between Northern Ireland (UK) and the Republic of Ireland. The area has a maritime climate, with a mean annual temperature of 9.0 °C and mean annual rainfall of approximately 1800 mm. The main uses of water in this catchment are the supply of drinking water and agricultural uses. The drinking water catchment, which is the focus of this case study, is 384 km^2 (Fig. 5) (Morton et al., 2021). The river headwaters originate in the highlands of County Donegal, Ireland, and flow eastward from Lough Derg and Lough Mourne as the River Derg and Mourne Beg River, respectively. These rivers are joined by a multitude of minor tributaries, and converge just west of Castlederg, Northern Ireland, the catchment's main town with a population of around 3000 people.

The rolling upland hills in the west of the catchment are dominated by peat soils, with blanket bog and coniferous forestry plantations covering most of this area and together comprising nearly half (47%) of the land use within the catchment. While the river channels are composed of sand, silt and alluvium, the soils in the lower eastern part of the Derg catchment and the broad valley bottom comprise mainly brown earths and brown podzols. Rough grazing (unmanaged grassland) and extensive grassland (lightly managed with low stocking rates) border the bogs and forestry plantations, with agriculture intensifying to permanent pastures and hay and silage meadows towards the catchment outlet. These permanent pastures are more heavily managed and often grazed year-round. Similarly, the silage meadows are subject to intensive management and mowing. Arable agriculture covers only 0.2% of the catchment, mainly in the east of the valley. Sheep are grazed mostly on the more extensive grassland, while cattle (both beef and dairy) occupy the more intensive (heavily managed) grassland in summer and are usually housed indoors during winter.

Description and use of MCPA

MCPA (2-methyl-4-chlorophenoxyacetic acid) is a phenoxyalkanoic acid herbicide. This group of chemicals simulates the action of auxins, which are plant growth hormones. For herbicide applications, MCPA is usually supplied in a salt form, although chemical ester formulations are also used. While the formulation plays little role in the efficacy of MCPA, it affects the volatility and solubility, with esters being more volatile than salts and salts being much more soluble than esters. As a selective herbicide, MCPA is used mainly to control broad-leaved weeds such as wild mustard, docks, volunteer oilseed rape and thistles in arable, horticultural and grassland settings.

MCPA can also be used to treat rushes (*Juncus* spp.) (Fig. 6). Rushes, particularly soft rush (*Juncus effusus*), are common across Ireland, occurring most prevalently on waterlogged ground in the west and north. MCPA is one of the few herbicides that is effective against rushes. Even so, rushes are only moderately susceptible to MCPA, with treatment tending to reduce the spread of rushes and kill most of the aboveground portion of the plant. However, rushes produce thousands of seeds which can remain dormant yet viable for over 60 years in the soil (USDA NRCS Plant Materials Program, 2002) until brought to the surface or exposed to light (Moran, 2015). This means that, even if the rushes were not allowed to reach flowering stage the previous season, farmers with rush problems typically spray annually (or biannually) between March and September to prevent the returning rushes from out-competing the grass.

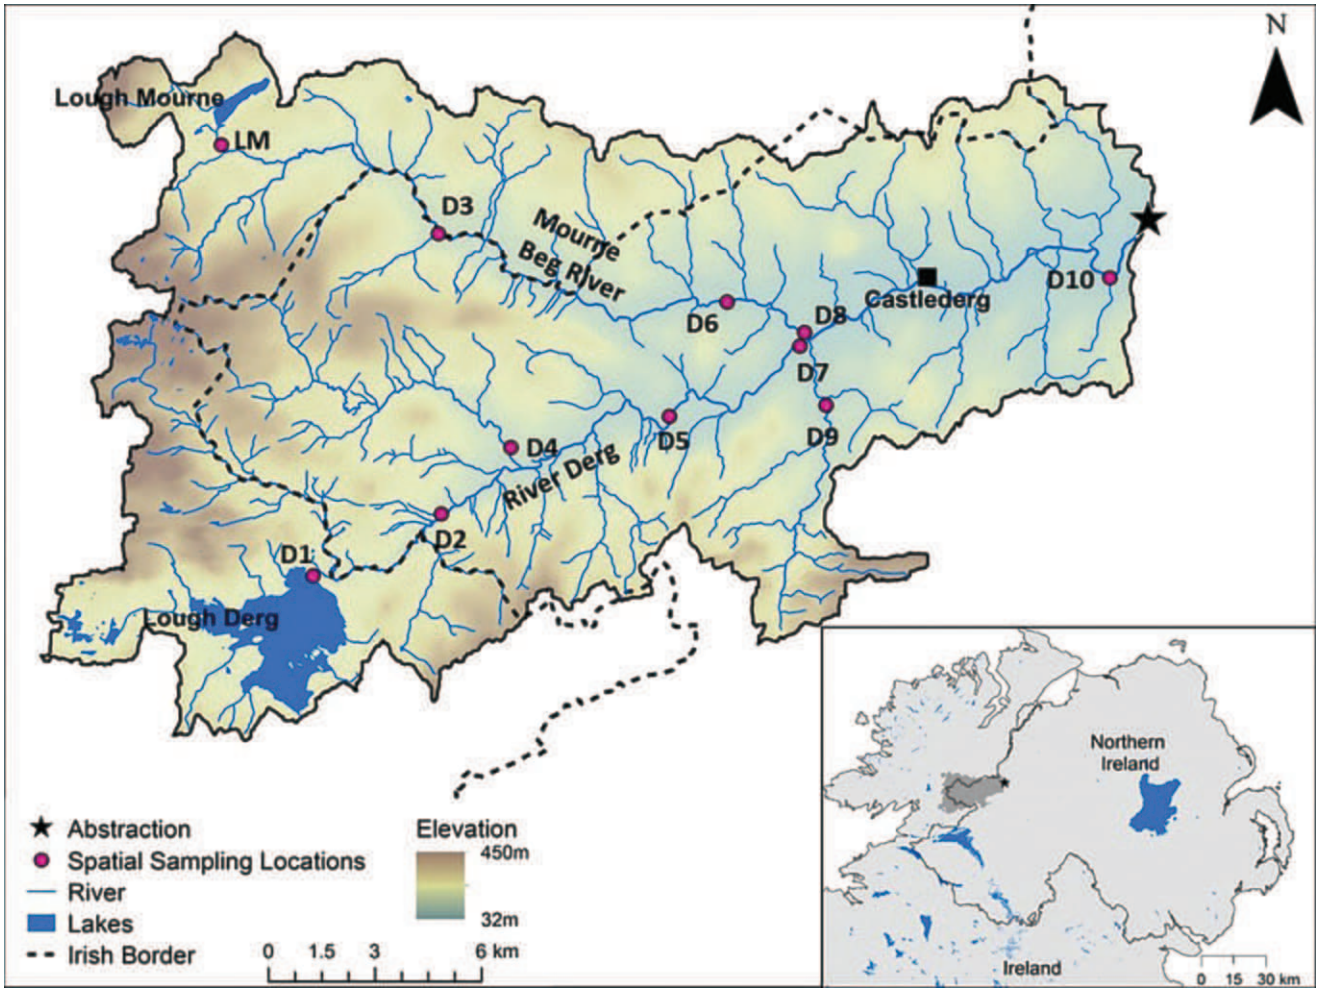

Fig. 5 Map of the Derg catchment, with the inset showing its cross-border location on the island of Ireland (gray shaded area). The two main tributaries, the River Derg and the Mourne Beg River, and their minor tributaries are shown with spatial sampling locations. The main town of Castlederg is on the River Derg after the confluence. The drinking water abstraction point is also the catchment outflow and the location of the temporal sampling. Reproduced from Morton PA, Cassidy R, Floyd S, Doody DG, McRoberts WC and Jordan P (2021) Approaches to herbicide (MCPA) pollution mitigation in drinking water source catchments using enhanced space and time monitoring. *Science of The Total Environment* 755: 142827.

Impacts

In the European Union (EU), MCPA is only licensed for use in a boom sprayer (Fig. 6). This can create spray drift, particularly in windy conditions, which can deposit MCPA droplets directly into watercourses (Kreuger, 1998). However, while only small quantities of the applied MCPA are likely to reach non-target areas via spray drift, far greater quantities can be lost via runoff and sub-surface flow. This is because MCPA is highly soluble, with up to 866 g of MCPA salt able to dissolve in a liter of water (Hornsby et al., 1996), and has low adsorption to soil (log K_{OC} 1.73–2.07) (Mackay et al., 2006). Areas with a high prevalence of MCPA use, high rainfall and low soil permeability are, therefore, most at risk of MCPA transfer to watercourses.

The Derg catchment fits all three of these criteria: MCPA is frequently used throughout the catchment, annual rainfall can be in excess of 1800 mm annually and is well distributed across the seasons, and soils across the catchment are poorly-drained and often waterlogged. An intensive (7-hourly to daily) sampling program demonstrated that concentrations in the main river at the catchment outlet reached 4.3 μg L^{-1} (Fig. 7) and a spatial sampling program found concentrations up to 9.0 μg L^{-1} in one of the tributaries (Morton et al., 2021). To put this into perspective, legally, drinking water in EU countries must not contain more than 0.1 μg L^{-1} of any single pesticide or more than 0.5 μg L^{-1} of all pesticides combined (Council of the European Commission, 1998). Additionally, the World Health Organisation recommends a maximum of 2 μg L^{-1} of MCPA in drinking water (World Health Organisation (WHO), 2017). The intensive sampling programme found that 25% of the samples taken from the river between April 2018 and April 2019 contained more than 0.1 μg L^{-1} of MCPA, 6.5% contained over 0.5 μg L^{-1} and 1.3% contained over 2 μg L^{-1} (Fig. 7) (Morton et al., 2021). As the Derg catchment is the drinking water source for about 30,000 people, these MCPA concentrations present a major problem for drinking water quality. Treatment options, such as granular activated carbon filters or ozonation, are available are available—with the former used in the Derg water treatment works—but these are costly and energy-intensive solutions. Furthermore, with such high concentrations in the river, it is not always possible to remove all of the MCPA from the treated water, or even a high enough proportion to bring concentrations below the EU limits, even with treatment options in place.

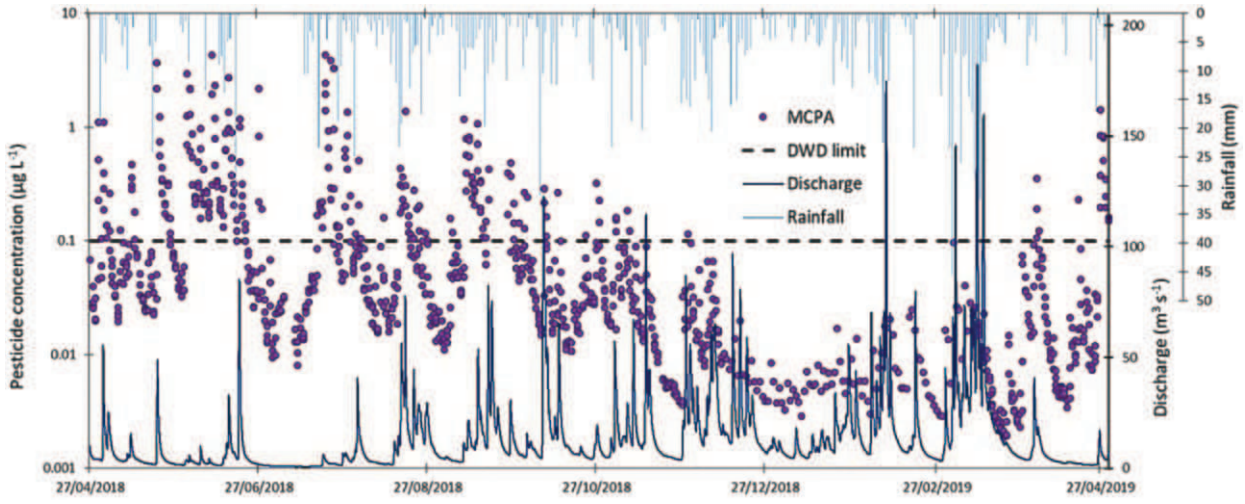

Fig. 7 Concentration of MCPA in the River Derg at the catchment outlet and abstraction point, the River Derg discharge 7 km upstream of the monitoring point at Castlederg, and Malin Head daily rainfall between 27/04/18 and 30/04/19. The single pesticide drinking water limit for treated water is shown for reference as a dashed line. Note that the pesticide concentrations are shown on a log scale on the left y-axis. Reproduced from Morton PA, Cassidy R, Floyd S, Doody DG, McRoberts WC and Jordan P (2021) Approaches to herbicide (MCPA) pollution mitigation in drinking water source catchments using enhanced space and time monitoring. *Science of The Total Environment* 755: 142827.

Due to the short term nature of many studies, there is very little evidence on long-term health effects of drinking water containing MCPA nor on whether there are any potential interactions between MCPA and other common compounds found in drinking water sources (Morton et al., 2020). However, public health limits tend to be very conservative, with considerable safety margins built in, as evidenced by the 20-fold difference between the EU drinking water limits and the WHO recommendation for MCPA, thus the MCPA concentrations allowed by the drinking water limits are well below any thought to pose a risk to human health. Similarly, ecotoxicology studies for other organisms indicate that the MCPA concentrations found in the Derg catchment are unlikely to have ecological implications but the majority of these studies were of the effects of just MCPA on single organisms tested under laboratory-controlled conditions and were relatively short-term (Morton et al., 2020).

The short-term nature of most toxicological tests means that there still could be potential ecological consequences over longer periods of time. The degradation half-life of MCPA has been reported as between 5 and 78 days (European Commission (EC), 2008), depending on the conditions, and therefore it tends to be assumed that concentrations would be very low or negligible outside of the spraying season. However, in the Derg catchment, concentrations did not fall below the limit of detection (0.0005 μg L^{-1}) at any point during the year of intensive monitoring and concentrations over 0.1 μg L^{-1} occurred up to the end of November (Fig. 7) (Morton et al., 2021). Not only did this indicate that the MCPA was not degrading as quickly as expected, but also that heavy autumn rainfall did not flush all MCPA from the catchment. This is possibly due to the high organic content of the soils in the Derg catchment, that increases the retention of MCPA (Hiller et al., 2012) and the waterlogging of these same soils reduces the oxygen available to pesticide-degrading organisms (Vink and van der Zee, 1997). As a result, aquatic organisms in the Derg catchment are exposed to MCPA throughout the winter, albeit mostly at low concentrations. The effects of long-term, multi-generational exposure are unknown.

Wider context

MCPA has been found in both surface water and groundwater in countries around the world, usually at low concentrations but occasionally above the highest recorded in the Derg catchment (e.g., EPA, 2017; Loos et al., 2017). However, most monitoring of MCPA to date is by local authorities or governmental organizations and is thus relatively infrequent. Therefore, the finding that a high proportion of concentrations in the Derg catchment that were above 0.1 μg L^{-1} indicates a more significant problem than was previously recognized here. This could also be the case elsewhere, where similar monitoring regimes are in place. Further monitoring is needed to determine whether the Derg catchment is representative of other locations throughout Ireland and across the world. Furthermore, it is not known whether MCPA is detectable in other waterbodies in Ireland throughout the non-spraying period. Given that these winter detections are likely due to the highly organic and waterlogged soils in the catchment, the Derg catchment is probably representative of a significant number of catchments on the island of Ireland and possibly some in other countries.

Regardless, there are alternative measures to costly water treatment processes that may help to reduce MCPA concentrations in the river. One such measure being trialed in the Derg catchment is to discourage farmers from boom spraying MCPA. Instead, they are incentivized to apply glyphosate using weed-wipers to get rid of rushes, thus greatly reducing the total pesticide used. Weed-wipers are devices mounted on off-road vehicles which apply herbicides directly to the surface of the plant. This prevents spray-drift and allows far smaller volumes of chemical to be used. Other potential measures mainly focus on discouraging rush growth through adding lime to fields to increase the pH, cutting rushes and draining waterlogged areas, as well as controlling grazing so as to encourage grass growth. Less soluble pesticides may also act to prevent the growth of unwanted plant species whilst also reducing the amounts of pesticide reaching waterbodies.

Case study 4: Sediment and nutrient dynamics due to wetland conversion in Rwanda

Overview of the region

Rwanda, known as the Country of a Thousand Hills, and located in central Africa just south of the Equator (2°00′S 30°0′E), has the highest population density in Africa (415 inh/km^2; National Institute of Statistics of Rwanda (NISR), Ministry of Finance and Economic Planning (MINECOFIN), 2012). Most of its landscape is high altitude at 950 m, with a peak at 4507 m. The climate is temperate tropical humid with a moderate average temperature of 20°C and annual precipitation between 1000 and 1400 mm. Peak rainfall occurs in November and April, and a dry period in June–August. Water covers c. 8% of the Rwandan territory (210,000 ha), including 100 lakes (128,000 ha), 861 rivers (7260 ha) and wetlands (77,000 ha) (MINAGRI, 2017). A wetland inventory in 2008 showed that about half of Rwandan wetlands were covered by natural vegetation (often dominated by *Cyperus latifolius* or *Cyperus papyrus*), and the other half were converted to rice paddies or fishponds (REMA, 2009). These freshwater resources provide essential ecosystem services (e.g., drinking water provision, biodiversity) and offer high potential to support irrigation and fish farming (Millennium Ecosystem Assessment (MEA), 2005).

Agriculture in Rwanda is predominantly small-scale, subsistence, rain-fed, and highly vulnerable to climate variability, but represents the primary occupation of c. 70% of the population (Niyagaba and Peng, 2020). On average, a single household cultivates 0.6 ha, with c. 80% of farm households practicing traditional farming and 70% located on steep (5–55%) slopes (MINAGRI, 2017). This results in dramatic soil degradation and erosion with annual soil losses estimated between 20 and 150 t ha^{-1} (MINAGRI, 2017). The national average fertilizer application has increased steadily, from an average of about 4 kg ha^{-1} in 2006 to 30 kg ha^{-1} in 2013 and 46.42 kg ha^{-1} in 2019/2020 and is projected to reach 75 kg ha^{-1} in 2024 (MINAGRI, 2014, 2020).

Fig. 8 Conversion of valley-bottom wetlands to rice farming in Migina catchment, southern Rwanda. Photo: Anne van Dam.

Recently, valley-bottom wetlands have attracted the attention of the Government of Rwanda as fertile lands with high water availability that can contribute to national food production, mainly rice, fish and vegetables. With government policies aiming to convert up to 80% of these wetlands, large areas of natural wetland have been converted to agriculture, thereby expanding the national farmed area fourfold between 2006 and 2020 (MINAGRI, 2009, 2010a). Wetlands are also drained for land reclamation, settlement, urbanization, industrial development, and road construction (e.g., Nhapi et al., 2011; Usanzineza et al., 2011). Wetlands converted to agriculture are used mostly for rice production, but also for other crops such as sugarcane, maize, beans, vegetables and for subsistence-level pond aquaculture (MINAGRI, 2009, 2010a). Due to its high productivity compared to other crops ($\geq$7 t ha^{-1}), rice was regarded as one of the most appropriate crops in Rwandan inland valleys (MINAGRI, 2010b). Strategies to increase rice production include increasing the area under cultivation (with vast areas of valley bottom wetlands converted into rice farms; Fig. 8), the use of modern inputs such as seeds, fertilizers, pesticides, and the construction of small dams and ponds to support irrigation and fish production. Rice farming area increased from <4000 ha in 2000 to c. 35,000 ha in 2018 and is expected to reach c. 51,000 ha by 2024 (MINAGRI, 2013, 2018). Similarly, aquaculture production of 4038 Mt. in 2007 (Mwanja et al., 2011) is expected to reach 90,000 Mt. by 2020/2021 (MINAGRI, 2018).

Agricultural pressures

Wetland conversion to agriculture and intensification of production have become the preferred options for increasing food security and economic development under the government's Strategic Plans for the Transformation of Agriculture (PSTA) and the Rwanda Irrigation Master Plan (MINAGRI, 2009, 2010a, 2013). However, expansion may also result in negative environmental impacts due to the alteration or destruction of wetland ecosystems and biodiversity, and disruption of regulating ecosystem services, particularly water purification and hydrological regulation (flood control). The valley-bottom wetlands of many headwater catchments in the region have been converted to agriculture. Consequently, the original natural wetland vegetation has almost disappeared, and valley-bottom land cover changes from bare soil immediately after hoeing to a densely cultivated crop canopy at the end of the season. Farming practices including plowing, fertilizer application, and weeding make the soil more vulnerable to runoff of soil particles and nutrients, whereas wetland vegetation, a dense established crop, or ponds and reservoirs facilitate attenuation within the catchment (Dabney, 1996; Dabney et al., 2001). Like in many farming systems in sub-Saharan Africa, the peak of activity coincides with the beginning of the rainy season, when valley bottoms are most vulnerable to the loss of sediment and nutrients. At the onset of high rainfall, loose material from the plowed soil and built-up material accumulated during the dry season are mobilized and exported (Uwimana et al., 2017). Similarly, effluent discharge from reservoirs and fishponds during periods of water release, or when ponds are drained for fish harvesting or dredging, is a major loss pathway of sediments and nutrients. The loss of the nutrient retention function of wetlands has consequences for both local (e.g., surface water quality, drinking water production) and downstream ecosystem services (e.g., eutrophication in Lake Victoria, impacts on fishery).

Wetland conversion research in the Migina catchment

The effects of wetland conversion to agriculture on the sediment and nutrient retention of valley bottom wetlands in the Migina catchment, located in the Southern Province of Rwanda and one of the uppermost catchments of the Akagera river, the largest tributary of Lake Victoria in the Nile Basin has been the subject of recent research. The landscape is mountainous with small valley bottom wetlands, streams, and rivers (Fig. 9; Centre for Geographic Information Systems & Remote Sensing, 2008). In the upper catchment, the hillsides are dominated by urban areas and settlements. The valley bottoms are dominated by rice cultivation, vegetables (maize, beans, potatoes, carrots, tomatoes), clay, silt and sand mines, grassland, and fishponds and dams (standing water), with some patches of natural wetlands.

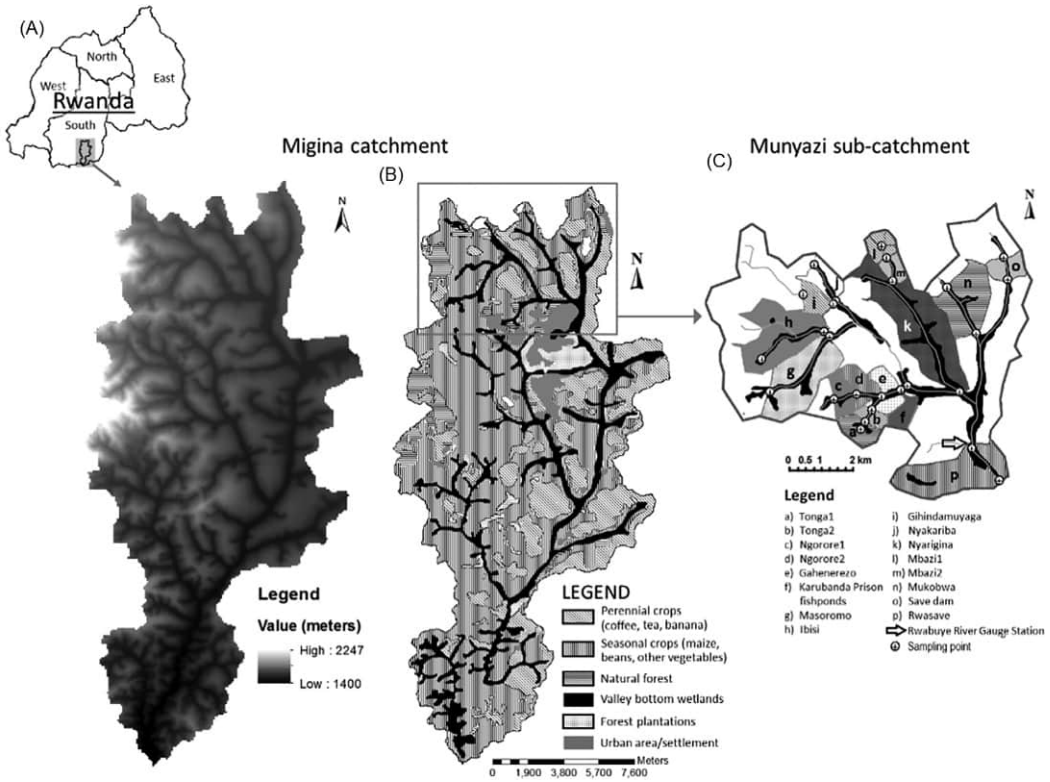

Fig. 9 The Migina catchment: (A) Digital Elevation Model; (B) land use; and (C) 16 reaches of the upper Migina River in the Munyazi sub-catchment, southern Rwanda. (A) From: Centre for Geographic Information Systems & Remote Sensing (2008) University of Rwanda).

The study used landscape-scale synoptic surveys to study relationships between land use and land cover (LULC: farms, fishponds/dams, forest, wetlands), stream discharge and water quality parameters (nitrogen, phosphorus, suspended solids). A Digital Elevation Model (DEM) with LULC information helped to identify the hydrological network, river reaches and land use (Fig. 9). Rainfall and stream discharge data were collected from May 2009 to December 2011 from rain and river gaging stations in the whole Migina catchment (Fig. 9). Water quality was measured during two storm events that started during field sampling on 23 March 2013 and 5 April 2013. More detailed field surveys were conducted in 16 reaches of the Munyazi sub-catchment in the period May 2012–May 2013, using a combination of visual estimates and GPS measurements/mapping to classify LULC into five groups (plowed land, rice farming, vegetable farming, grass/forest, and ponds/reservoir). Monthly net yields of nutrient loss were calculated from measurements of discharge, total suspended solids (TSS), and total nitrogen (TN) and phosphorus (TP) upstream and downstream of reaches with different LULC. Full details of the study are described in Uwimana et al. (2017, 2018).

Impacts

The results of catchment scale surveys showed that farming activities coinciding with heavy rainfall and high flows mobilize high concentrations of TSS, TN, and TP. During the dry season N and P accumulate in the catchment, then are washed into the water courses during the early stages of the higher flows, with subsequent lower concentrations at the end of the rainy season due to dilution. Human activities such as plowing, weeding, fertilizer application, fishpond drainage, and dredging of canals were the main source of sediments and nutrients in water when these activities coincided with high flow. The study estimated that 93%, 60% and 67% of the annual loads of TSS, TP and TN, respectively, were transported during 115 days with rain (Uwimana et al., 2018).

In the 16 reaches, the net yields of water, TSS and nutrients were different among LULC types and varied seasonally. Overall, reaches with plowed soil or dominated by rice and vegetable farming showed negative net yields, while reaches dominated by ponds/reservoir and grass/forest had positive net yields of sediment and nutrients (Fig. 10; Uwimana et al., 2018). Differences in net yield among LULC types were more pronounced during periods of high stream flow (in May 2012, November 2012 and April–May 2013), with higher exports of especially sediment and P in the agricultural reaches (plowed, vegetables and rice) and higher retention in reaches with ponds/reservoirs and natural land cover. Over the whole experimental period, mean net yields of sediment and nutrients were positive in reaches with standing water or natural land cover, and negative in reaches with agricultural land uses (Table 1).

The observed variation in water quality parameters with discharge in the Migina catchment can be interpreted as a "build-up, washout and dilution mechanism" (Uwimana et al., 2017). During base-flow conditions, urban and agricultural areas, wetland grass and ponds or dams act as sinks for sediments and nutrients, which are subsequently released (flushed out) during the early stages of high flows. The more detailed study in stream reaches with different land uses confirmed that sediment and nutrient

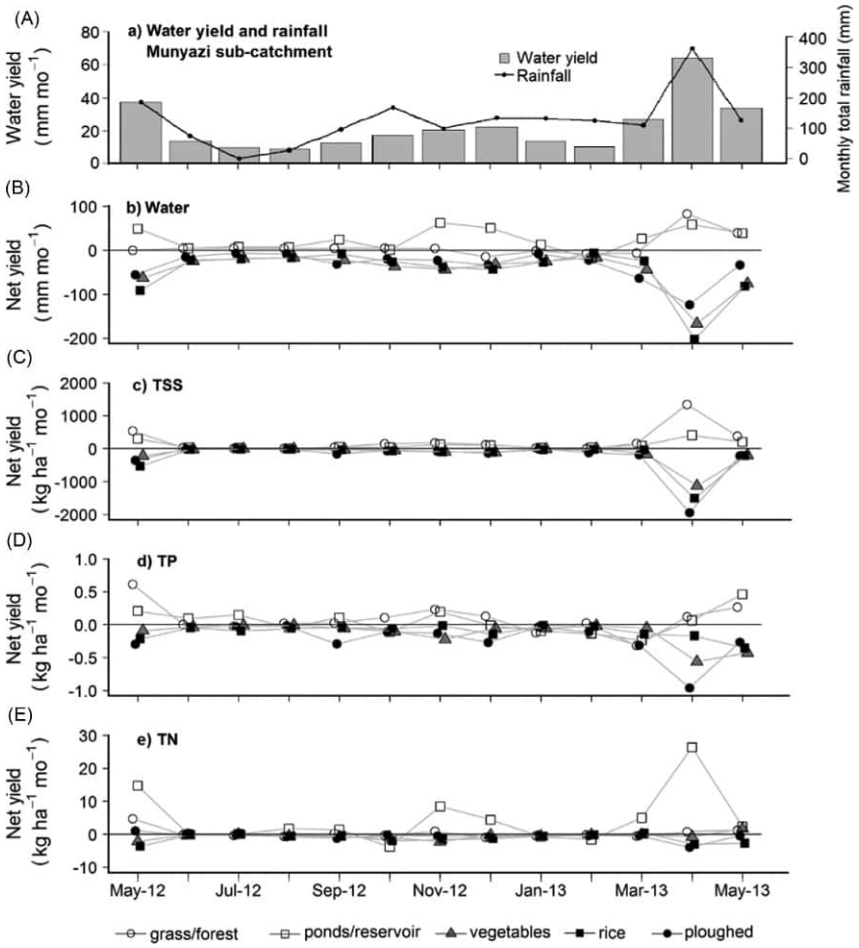

Fig. 10 Seasonal dynamics of water, sediment, and nutrients in Munyazi sub-catchment, Rwanda: (A) water yield at the outlet of Munyazi sub-catchment, and rainfall at Rwasave station; (B–E) Net yields of water (B), total suspended solids (C: TSS), total phosphorus (D: TP) and total nitrogen (E: TN) in 16 reaches of the Migina River (Munyazi sub-catchment), southern Rwanda. Data are means of reaches ($n = 3$–5) with different land use/cover, estimated monthly between May 2012 and May 2013.

retention are strongly related to both land use and water flow. Generally, reaches converted to farming exported, whereas reaches with grass/forest cover or water bodies (ponds or reservoirs) retained TSS and nutrients. These differences were fairly consistent throughout the year, although some individual reaches could shift from being a source to a sink. The more pronounced differences and higher exports during periods of higher rainfall and streamflow ("washout") emphasize the importance of preventing erosion and nutrient runoff during these periods. This could be done by responsible irrigation management and land preparation, including accounting for rainfall in land preparation and irrigation and various erosion control measures such as e.g., mulching, minimum tillage, contour-strip cropping, and terracing (FAO/IWMI, 2018). Other options include land use arrangements that make use of the different retention capabilities, with LULC types with high retention placed downstream (as buffer zones) from LULC types that export sediment and nutrients. In this way, runoff to downstream systems can be reduced. Quantitative data from studies like these can support the design of more sustainable land use configurations in highland valley systems like the Migina catchment.

Table 1 Net yields of water, total suspended solids (TSS), total phosphorus (TP) and total nitrogen (TN) in reaches of the Migina River in the Munyazi subcatchment in southern Rwanda with different land uses.

Land-use category	*Net yield*							
	Water (mm month^{-1})		*TSS (kg ha^{-1} month^{-1})*		*TP (kg ha^{-1} month^{-1})*		*TN (kg ha^{-1} month^{-1})*	
Grass/forest	−1.87	ab	224.8	b	0.0503	b	0.408	ab
Ponds/reservoir	28.1	b	117.0	ab	0.0940	b	4.638	b
Rice	−60.5	a	−246.9	a	−0.108	ab	−1.368	a
Vegetables	−27.6	ab	−91.6	ab	−0.0861	ab	−0.516	a
Plowed	−34.5	ab	−269.1	a	−0.240	a	−0.564	a

Numbers are means of 13 monthly net yield estimates in 3–5 river reaches (total $n = 16$). Means within a column with different superscript letters were significantly different ($P < .05$; repeated measures ANOVA).

Concluding statement

The case studies presented are just four examples of the diverse relationships which agriculture has with waterbodies in various geographic regions. Many other issues surrounding the use of water and impacts of agriculture on waterbodies exist. For example, depletion of groundwater in areas depending on irrigation for intensive crops, runoff and leaching of veterinary products from feedlots, and straightening of river channels due to re-routing and excessive land drainage are among the scenarios in which agricultural needs must be balanced against the pressures they exert upon waterbodies. Crucially, both the waterbodies themselves and the hydrologic catchments in which they are located, deliver multiple ecosystem services and trade-offs and synergies must be explored in light of all of these.

The solutions to these problems will necessarily be specific to the pollutant in question and to the agricultural, geographic, and climatic contexts. Approaches to these problems can be broadly divided into implementation of best management practices and mitigation measures, legislation and regulation to co-ordinate response to serious and eminent public health issues, and basic research into the underlying mechanisms of pollutant transport and impacts. In many cases, some element of each of these three approaches is needed. Strong scientific evidence provides the basis for agri-environmental legislation, which in turn specifies measures implemented to bring about the desired improvements. As research more clearly identifies the factors driving pollution, legislation and measures may change. In all cases, a concerted effort of these three approaches is required, with the involvement of multiple actors and crucially, balancing the trade-offs and synergies with different types of pollution and with the other services required of agricultural land such as food and fiber production, provision of habitats, and cultural values.

Knowledge gaps

- The types and impacts of pollution on inland waters is diverse and no one-size-fits all approach to management is likely to be successful in mitigating declines in quality.
- Nutrient pressures largely arise from agriculture. Better understanding is needed regarding how to use fertilizers with less environmental impact and how to balance the need for increased productivity while protecting water and biodiversity.
- Pollutants such as arsenic that are native to certain environments present hazards to drinking water supplies, particularly where large demands are exacerbated by the need for irrigation or in some cases, to support industry. Greater investigation of geology and hydrology are needed in these basins and policy design should reflect the natural risks implicit in certain environments.
- The effects of emerging contaminants such as pesticides are only now becoming apparent. Increased research is required to understand the dynamics of these chemical in the environment. These new formulations may require different and novel application methods to ensure their safe and effective use and further research and technological innovation is needed in this area.
- The conversion of land to agriculture fundamentally changes the hydrologic dynamics of those basins, with consequences for habitats and ecology. The consequences of land conversion as regards trade-offs and benefits need to be explored.

Hydromorphology: Overview and Assessment Methods

Joanna Lynn Kemp and Leonard Sandin, Norwegian Institute for Water Research (NIVA), Oslo, Norway

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Anabranching River divided into a branching network of smaller channels divided by vegetated, longer-lived islands.
Bar A depositional sediment feature, usually made of cobbles, gravel and/or sand, which occurs on the inside of bends, at the side of the channel, or mid-channel.
Biological Indicator An indicator based on the function, population, or community of organisms that can reveal qualitative status of the environment.
Braided rivers A network of river channels separated by, often dynamic, bars.
Confinement The degree to which a river is constrained by its valley. A wide valley has low confinement and a v-shaped valley has high confinement and the river has little opportunity for lateral movement.
Connectivity The connectedness of different parts of a system (e.g., a river). Can refer to longitudinal connectivity, for example, sediment connectivity or migratory fish passage, but also to connection with floodplain.
Dynamic equilibrium All processes are in balance leading to no net change in the system.
Hydrograph A graph showing the change in flow (discharge) in relation to time at a specific point in a river etc.
Hydromorphology The hydrological and geomorphological elements and processes of waterbody systems.
Hyporheic The water-filled spaces within and along the bed of a river or stream where stream water and local groundwater mix.
Interstitial The spaces between individual sand, gravel and stone etc. grains within the aquatic sediment.

Introduction

This chapter focuses on hydromorphology and the assessment of hydromorphological change in running water ecosystems with some references also to lake ecosystems. The term hydromorphology stems from soil science (Vogel, 2011) but was 'appropriated' with the implementation of the EU Water Framework Directive (WFD) to mean "the hydrological and geomorphological elements and processes of waterbody systems" (European Commission, 2000) and has been defined as 'the suite of hydrological and geomorphological processes and forms that occur within catchments and their river systems' (Gurnell et al., 2015). Hydromorphology links hydrology and geomorphology, with physical stream characteristics and processes at the center of management and restoration (Belletti et al., 2015). Orr et al. (2008) defined hydromorphology as the physical habitat constituted by the flow regime (hydrology and hydraulics) and the physical template (fluvial geomorphology) of rivers, whereas a wider definition states that hydromorphology is the: "science that deals with problems relating to the structure, evolution, and dynamic morphology of hydrologic systems over time" (Vogel, 2011). Rivers and lakes have been, and are increasingly, physically modified, degraded and exploited by humans through e.g., regulation, river channelization and straightening, flood-defence engineering, damming, urbanization, water abstraction, land-fill, reclamation, and dredging (e.g., Malmqvist and Rundle, 2002; Ostendorp et al., 2004) (Fig. 1).

 https://doi.org/10.1016/B978-0-12-819166-8.00199-7

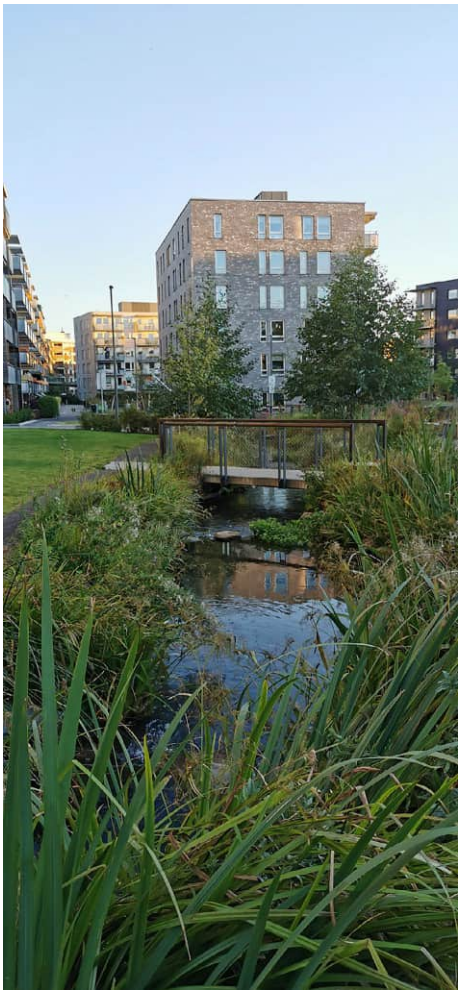

Fig. 1 Hovindbekken—a reopened stream channel in Oslo city, Norway.

Within the WFD, the hydromorphological components of rivers are divided into: hydrological regime; river continuity (quantity and dynamics of flow and connection to groundwater) and morphological conditions (depth and width variation, structure and substrate of the river bed, and structure of the riparian zone). In lakes they consist of: hydrological regime (quantity and dynamics of flow, residence time, connection to the groundwater) and morphological conditions (depth variation, quantity, structure and substrate of the lake bed, structure of the shore). In the WFD the hydromophological status of rivers and lakes underpins their 'ecological status,' with 'high' hydromorphological status of rivers defined as: "Channel patterns, width and depth variations, flow velocities, substrate conditions and both the structure and condition of the riparian zones correspond totally or nearly totally to undisturbed conditions" (European Commission, 2000).

Human activities affecting physical and hydrological aspects of freshwaters

Interrelatedness of hydrology and morphology

Human activities affect the hydromorphology of rivers and lakes in profound and numerous ways, creating a complex web of impacts and multiple feedbacks (Newson, 1994). It has become increasingly clear that understanding the interlinkages within and between these ecosystems are of great importance to better understand and manage freshwater ecosystems (Lamberti et al., 2010). Hydrological alterations are caused by activities that change the natural run-off and flooding pattern of a catchment, the flow regime of a river or the water circulation and retention in a lake. These hydrological changes cause morphological changes to waterways, as the amount of water and the height and duration of flood pulses and low-flows change. Humans then cause further impact by directly modifying the physical shape and material structure of river and lake morphology. Indirect hydrological changes and direct human alterations change the physical shape, sediment composition, dynamics, patterns of erosion and deposition, depth and velocity patterns of waterbodies. Changes to waterbody morphology can then cause hydrological changes, for example by reducing time that floodplains are flooded and, therefore, decreasing soil moisture content, changing water retention times or even altering local weather patterns (Collow et al., 2014).

Any change in land use away from its natural state will change the pattern and velocity of runoff. It can even influence the total amount of precipitation falling on the catchment, as some ecosystems, forests in particular, cause and create rainfall, both locally and further afield (Ellison et al., 2017). In general, complex vegetation, such as natural forests, tends to slow the speed at which water reaches waterways and can help rainwater penetrate the ground, leading to the slower, subterranean recharge of rivers. Floodplains can have an important moderating affect too. A natural floodplain acts to store water and release it slowly, giving a smoother hydrograph.

Human alterations across catchments, such as plantation forestry or clearing and/or draining of land for grazing or crops often increase the rate at which rainwater or snowmelt reaches waterways, which can increase the flood peaks and make rivers more 'flashy,' with higher high-flows and lower low-flows. Farming often causes soil compaction and topsoil erosion, which also exacerbate these effects. No till farming, in contrast, helps to reduce compaction and erosion and increases soil-water retention. Urbanization is an even more direct and obvious cause of rapid runoff, with hard, impermeable surfaces and drainage systems providing a direct pathway to waterways (Rhoads, 2020).

Water withdrawal

Water is removed from rivers, lakes, reservoirs and groundwater for myriad purposes. At the global scale, agriculture, mostly irrigation, is the largest use (about 70%) and is, in many cases, unsustainable, especially as it is most useful during periods and in areas, of low rainfall. Industrial use comprises 20% of water consumption (3/4 of which is used for power production), and domestic use comprises 10% (Boretti and Rosa, 2019). About 30% of world freshwater is groundwater (Hendriks et al., 2015). Overexploitation of aquifers can be thought of as 'groundwater mining,' taking water out of the ground faster than it is replaced. In some aquifers ancient 'paleowater' is being mined. In Libya, for example, the groundwater taken by the Great Man-Made River dates from the last ice-age, with no hope of replenishment (Kuwairi, 2006). At the global scale, around 15% of groundwater abstraction was non-renewable between 2000 and 2009 (Döll et al., 2014).

Forecasts of water demand compared with water availability are truly alarming. Global water demand is about 4600 km^3 a year and estimated to increase by 20–30% by 2050, due to population and economic growth. About half of the world's population already live in areas that suffer water scarcity for at least 1 month a year and almost a third of humans live in potentially severely water-scarce areas. Worldwide, clean freshwater is decreasing and the timing and pattern of its availability is changing (Boretti and Rosa, 2019). The damage water abstraction does to surface waters ranges from drying of wetlands and lakes, drying, shrinkage and low-flow in rivers, to salinization and coastal saline intrusion and even land subsidence (Boretti and Rosa, 2019). The reduction of wetted-channel width of streams causes a decrease in ecosystem processes, such nutrient uptake and organic matter breakdown. Low-flow velocities decrease biofilm biomass and activity as the boundary layer gets larger, decreasing diffusion rates (Arroita et al., 2016).

Morphology and dynamic equilibrium

River morphology is affected by hydrology, sediment, riparian and instream vegetation as well as direct, physical alteration of river channels. Changes to the hydrograph alter channel morphology. Higher and more frequent peak-flows means a greater water power to rework the channel, potentially causing increased erosion and deposition, changes to channel shape and dimensions, and even to channel type (Knighton, 1998). Lower low-flows bring their own problems, for example, sediment deposition, clogging of hyporheic interstitial spaces, organic matter deposition, overgrowth of vegetation, less aeration of water, increase in water temperature, and increase in water retention time. Humans directly impact river morphology in many ways, including straightening, deepening, widening, removal of vegetation or other flow obstructions, reinforcement, embankment and damming. These tend to be carried out to increase flood conveyance, drain and reclaim land, improve navigation, and for impoundments of water for water storage and/or hydropower. Rivers are often constrained to a single, convenient, straight and unmoving channel (Knighton, 1998).

The knock-on effects of these modifications can be less obvious. Actions that diminish natural processes of a river often require regular intervention to be maintained. Consequences can be serious, unintended and unpredictable. A river is not just a flow of water, but also a flow of sediment and organic matter, and often of woody material. Understanding the physical and ecological processes within a river is crucial to predicting how a river will respond to alteration and mitigating any adverse effects. Many natural rivers maintain a state of dynamic equilibrium, meaning that the channel form is adapted to its hydrograph, with balanced sediment transport, erosion and deposition (Knighton, 1998; Wampler, 2012). Rivers in dynamic equilibrium range from being relatively stable to highly mobile, depending on the type of river. If dynamic, then they are predictably so and retain a characteristic morphology and are considered to be geomorphologically stable (Shields et al., 2003).

Being cognizant of dynamic equilibrium, it is then easy to understand how artificial modifications can trigger disequilibrium. A sinuous river actually has a lower bed slope than a straight river. Think of a road of hairpin bends winding down a steep hill. Making the road a straight line down the hill would be much too steep. As river gradient is directly linked to energy of the water, a straightened river means that the water has more power to erode the bed and banks. Straightening a section of river can create a knick-point at the upstream end, due to the abrupt change in bed slope, and this will erode the bed and the knick-point will move upstream (fast or gradually), mobilizing more and more bed sediment. The sediment can then travel all or part of the way through the straightened section (with increased flow velocities) and deposit downstream, thereby creating another problem that needs solving. The banks may also slump in the straightened section, adding further material to the downstream sediment dump (Knighton, 1998).

Water flow down a straight channel does not 'obediently' go in a straight line, but tends to swing from bank to bank, meaning that without reinforcement or structures such as weirs to use up the water's energy, the river will tend to return to a more sinuous condition (Knighton, 1998). In lowland environments widened, deepened, and straightened channels can be relatively stable as the low channel slopes mean the stream has little power to re-shape its channel (Urban and Rhoads, 2003; Grabowski and Gurnell, 2016). They do, however, tend to fill up with silt, sand and gravel and may suffer from excessive plant growth. In such systems coarse sediment can be scarce and dredging can cause long-term loss of riffle-pool morphology and cobble and gravel habitat causing negative effects on e.g., fish populations (Freedman et al., 2013).

Dams that hold back water, also block sediment transport, causing downstream channel incisement and ultimately, coastal erosion. Loss of delta areas is not just loss of their associated ecosystems but as landform features they can mitigate sea level rise (Warrick et al., 2019). Wampler (2012) captures the idea of sediment-starved water *consuming* the river-bed and banks below impoundments with the term 'hungry water.' Given that many dams are relatively new and that channel adjustment may take over a hundred years, many rivers worldwide are currently actively suffering the consequences (Knighton, 1998).

Biogeomorphology

Instream, bankside and riparian vegetation influence and control geomorphological processes through their physical structure. The effects vary according to biogeographical area and hydromorphological type (Gurnell et al., 2014a). The presence and type of vegetation is itself controlled by substrate type, water availability (soil and groundwater) and the river flow regime (reliability and disturbance) (Gurnell, 2014). The river Tagliamento in Northern Italy demonstrates well the interplay between vegetation and hydromorphology. The river has both braided and anabranching sections (both types have multiple channels, but anabranching channels are more stable and more likely to form islands). Large woody debris such as tree trunks is crucial to the formation of islands and it is predicted that simple changes in the water table could completely change the character of sections of the river by altering the vegetation. A fall in the water table could trigger a change from anabranching to braided due to changes in woodland structure and a reduction in the supply of wood to the channel. In contrast, a rise in the water table could cause more pronounced anabranching and even a change to a single-thread, sinuous river. Numerous activities could potentially trigger such changes, e.g., flow regulation, abstraction, gravel mining, tree cutting and removal of wood from the channel (Gurnell et al., 2014a).

Animals themselves also have their own impacts on hydromorphology; from the direct ecosystem engineering of beavers (Levine and Meyer, 2019) to the indirect and unforeseen impact of wolves. Attributed to the reintroduction of wolves to Yellowstone National Park, United States, are changes to the behavior and grazing pattern of their prey, rocky mountain elk, leading to taller riparian willows, narrower, less incised and more flood-prone creeks (Beschta and Ripple, 2019); although Marshall et al. (2013) suggest that this may be an oversimplified interpretation.

Burrowing activities of native mammals are sometimes considered a nuisance when they threaten dams and embankments (Harvey et al., 2019). Non-native species are another significant human-mediated impact on river morphology. Non-native burrowing animals are a global problem and include mammals (e.g., *Myocastor coypus*), reptiles (e.g., *Iguana iguana*), and fish (e.g., Loricariidae) and various invertebrates (Harvey et al., 2019). Invasive crayfish (*Pacifastacus leniusculus*) in the river Thames catchment directly excavated an estimated 2 L of fine sediment per meter of affected bank and bank collapses caused by the burrows will also have greatly added to this sediment load (Faller et al., 2016). Non-native plants are also implicated—Himalayan Balsam (*Impatiens glandulifera*) may cause increased erosion along European rivers, due to seasonal die-back leaving unprotected banks (Greenwood et al., 2018). Modelling colonization of an invasive plant, based on Japanese Knotweed (*Reynoutria japonica*), van Oorschot et al. (2017) found that the effects of high propagule pressure on morphology could be profound, including preventing colonization of trees and other native vegetation, reduced summer erosion rates and increased winter erosion rates and higher autumn water levels.

Magnitude of anthropogenic impacts

Anthropogenic impacts on river systems are often extreme. Worldwide, 87% of wetlands have been lost since 1700 (Boretti and Rosa, 2019). Numerous large lakes are shrinking, drying, becoming more saline and disappearing. Lake Chad, once the fourth largest in Africa, has shrunk to 1/20 of its former size and is forecast to disappear by 2030. The causes are a reduction in rainfall due to deforestation, irrigation, overgrazing and global climate change. Hydromorphological alterations have been estimated to affect 38% of all lakes by lake area in the European Union (Poikane et al., 2019). In the drought-prone Murray-Darling, Australia's largest river basin, 69% of its water was abstracted during the 2000s, causing severe and probably irreversible ecological damage, including to its 16 Ramsar wetlands (Overton and Doody, 2012).

One of the major driving forces of change in river systems are dams as they fragment rivers and alter their flows (Aguiar et al., 2016). This is especially true for rivers with dams built for hydropower production (Renöfält et al., 2010) (Fig. 2). Hydropower can have huge ecological impacts based not only on changes to water volumes, but also through changes to water temperature and gas saturation, for example, by causing oxygen saturation levels high enough to kill fish and invertebrates (Demars et al., 2021). There are an estimated 2.8 million dams with reservoir areas $>10^3$ m^2 worldwide and only 37% of rivers longer than 1000 km are completely free-flowing, the majority of these being in the Arctic, the Amazon and the Congo (Grill et al., 2019). Large dams (walls higher than 15 m) are estimated to have a combined storage capacity equivalent to one-sixth of the total annual river flow into the

Fig. 2 Harsprånget hydropower plant in Stora Lule river, Sweden.

oceans (Mulligan et al., 2020). More than 800,000 dams world-wide obstruct approximately two-thirds of the fresh water flowing to the oceans and over 70% of the large rivers of Europe, North America and the former Soviet Union are strongly regulated (Giller, 2005) (Fig. 3).

Lack of data prevents an estimate being made for the number of barriers in smaller rivers on the global scale (Grill et al., 2019), but in Europe there are an estimated 1.2 million instream barriers (a density of 0.74 barriers/km) with 68% of these structures being small (less than two meters in height) (Belletti et al., 2020). The largest impoundment in the world, the Three Gorges in China, has caused deadly landsides (Tang et al., 2019), massive sediment problems, drought, hydromorphologically-mediated ecosystem damage and downstream saline intrusion (Zhang et al., 2016). Large dams can alter weather patterns (Degu et al., 2011) and the Three Gorges dam has caused earthquakes (Tang et al., 2019) and is even calculated to slow the speed of rotation of the earth (JPL, 2005).

Forty percent of European rivers have been estimated to be affected by hydromorphological pressures (Buijse, 2016): and 23% and 16% affected, respectively, by changes in hydrology and morphology (Lemm et al., 2021), and this was the most common reason rivers failed to reach "good ecological status", as required by the WFD (Kristensen et al., 2018). A huge proportion of the rivers worldwide have been straightened, which has resulted in a drastic loss of river length and hydraulic complexity, and consequently habitat and biodiversity (Zhou and Endreny, 2020). A hydromorphological assessment of Europe's second-largest river, the Danube, categorized it as 0% nearly natural, 40% slightly modified, 28% moderately modified, 29% severely modified and 3% totally modified. The banks were 17% nearly natural, 22% reinforced in small sections, 40% reinforced in large sections, 18% continuous bank reinforcements and 3% totally reinforced (Liška et al., 2008).

Increases in stream power after straightening of a river channel can be dramatic. Guzelj et al. (2020) calculated that stream power had increased by 13.3 times, based on a sixfold increase in stream slope and a more than doubling of bankfull discharge, in a formerly meandering lowland river. This meant that the erosive power of the water was such that attempts to move back towards the historical reference by creating a partially meandering river would be unsuccessful as the river would be too active. Designing restoration projects that aim for an imagined past or static reference state is flawed thinking. For example, in many countries in Europe, 100–200 years ago, sediment delivery to rivers was much higher than now because of active deforestation and expanding agriculture (Rinaldi et al., 2015b).

Aiming for a combination of processes, which could be a set of reference dynamics, can be ideal if the situation allows, but in other situations a more practical approach is needed (Dufour and Piégay, 2009). Much of the loss of wet habitats worldwide (lakes, ponds, wetlands, oxbows, side channels) comes from damage and draining of floodplains. Tockner and Stanford (2002) describe cultivated floodplains in Europe and North America as "functionally extinct," with a view that up to 90% of European and North American floodplains are like that. The SOER report (EEA, 2019) agrees with this assessment for Europe. Damage to floodplains in the developing world is accelerating.

Although the European Water Framework Directive (European Commission, 2000) requires the quantification of hydromorphological and ecological damage to waterbodies, many of these former habitats are simply gone, drained or constrained, sometimes hundreds of years ago and are not included, or possible to be included, in current statistics. The ecological assessment of rivers tends to focus entirely on the instream sampling of, usually, single channel rivers, which ignores the vast array of other habitats within an undamaged river (Peacock, 2003). With the WFD monitoring approach it is clear that it does not include the riparian zone vegetation, therefore hydromorphological alteration will be greatly underestimated as there is an intimate relationship between in-stream physical and biological conditions and riparian zones (Gurnell, 2014). A proper definition of a river includes the width of its floodplain, which needs to be an integral part of hydromorphological and ecological assessment. Floodplains are a hotspot for biodiversity, with far more species living there than in any other type of landscape unit in most regions of the world (Tockner and Stanford, 2002). Mismanagement of floodplains is literally killing people, with over half of people who died as a result of natural disasters in recent decades, dying in floods (Habersack and Schober, 2020).

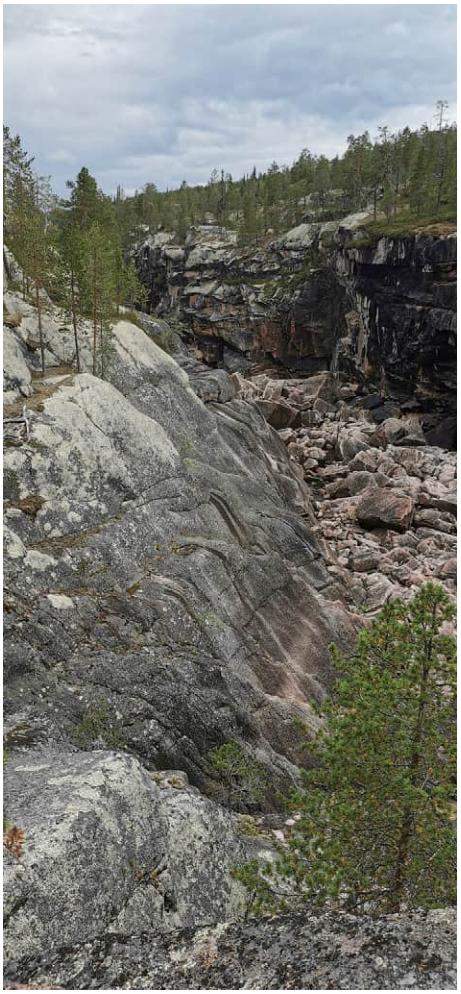

Fig. 3 Harsprånget, a former river stretch in the Stora Lule river which used to have a discharge of 268 $m^3 s^{-1}$ now the water is diverted to the hydropower station.

Assessing human induced hydromorphological alteration

Hydrological, physical and geomorphological state

There are three basic strands to the assessment of hydromorphological condition of waterbodies: hydrological, physical morphological (including riparian/floodplain), and geomorphological process. Gathering such data relies on field measurements and surveys, as well as map-based, historic, paleo- and remote-sensed information, each having benefits and drawbacks (Gurnell et al., 2014b). Techniques range from recording habitat types, to describing and quantifying processes and using mathematical models for predicting change. Assessment methods vary greatly in scale, from reach or lake-scale to catchment or region, and from instream up to riparian and floodplain zones. Most methods look at the smaller scales, with a tendency to focus on physical habitat, riparian habitat and morphology; while underlying physical processes have often not been considered, partly because they are more difficult to assess rapidly (Belletti et al., 2015).

The EU FP7 funded REFORM project undertook a thorough evaluation of current practices (Rinaldi et al., 2013). They proposed a process-based, hierarchical, flexible and open-ended framework to guide future hydromorphological assessments (Rinaldi et al., 2015b). This helps the practitioner think about every scale and factor, including oft-ignored dimensions, such as catchment-scale variables and a consideration of geomorphological adjustment over different timescales. The hierarchy of scales is: region, catchment, landscape unit, segment, reach and geomorphic units/hydraulic units/river elements (Rinaldi et al., 2015c). Suggested information to be gathered includes geology, topography, hydrology, land use, vegetation cover, river morphology, lateral confinement, channel dimension, river energy, hydraulics, bed and bank sediments, flow regime, floodplain, groundwater—surface water interactions (based on valley confinement, substrate character, geology and climate), riparian and aquatic vegetation. See tables 3.2 and 3.3 in Rinaldi et al. (2015b), see Rinaldi et al. (2015c) for an exhaustive list of indicators.

Drivers of physical processes such as sediment sources (e.g., landslides, soil erosion, bank erosion) should be identified and recruitment of large wood examined. Physical controls on the pattern of channel morphology and floodplain features should be

understood, including the physical pressures and human impacts on river processes and morphology (such as structures altering longitudinal and/or lateral continuity, flow regulation, dredging, mining, other structures, reinforcement, instream and riparian vegetation removal, embankments, riparian buildings and infrastructure).

Given the complexity of interacting factors on a river and the wide range of physical environments found globally, it is a useful simplification to define river types, by looking at the characteristics of their morphology, flow regime and floodplain. Knowing river type helps to predict its behavior. Rinaldi et al. (2015c) suggest using three typologies to encompass morphology, flow regime and floodplain character.

Morphological typology: an extended river typology (Rinaldi et al., 2015c, 2016) with 22 morphological types, based on confinement—whether lateral movement of a river is constrained by its valley (confined, partly confined, unconfined), dominant bed material caliber—how coarse or fine its substrates are (bedrock, boulder, cobble, gravel, sand, silt), and planform—the pattern it makes in the valley when viewed from above (straight-sinuous, meandering, pseudo-meandering, wandering, braided, island-braided, anabranching).

Flow regime typology: based on intermittency, river-aquifer interaction, prevailing type of river-flow source.

Floodplain typology: based on river energy and cohesive or non-cohesive floodplain sediments (Rinaldi et al., 2015c; Nanson and Croke, 1992). An additional useful method, published after the REFORM project, is the floodplain evaluation matrix (FEM) (Habersack and Schober, 2020) focusing on floodplain functionality and damage, and considered from a flood-mitigation and hydrograph smoothing perspective.

Assessing hydromorphological change trajectories

It is not enough simply to look at the condition of a river on the day of survey. Many factors affecting hydromorphology are not constant over time, even without human impacts, and hydromorphologically damaged rivers are often in a prolonged non-equilibrium state. Thinking in terms of longer and shorter timeframes can be helpful as the trajectory of change in each case can be opposite (e.g., long-term incision, with recent aggradation). Another important question is whether a river is in a state of dynamic equilibrium or instability. A river is in dynamic equilibrium if its average properties (width, depth, slope, sediment input and output) remain stable over 10 years or more. Such a river can still be highly dynamic (Rhoads, 2020).

Instability of a river's hydromorphology is caused by changes to water or sediment inputs or outputs and can be progressive (e.g., climate or land use change), impulsive (floods), transient disturbance—(e.g., sediment mining) or long-term (e.g., by dams). Particular attention should be paid to rivers close to geomorphic thresholds, where even a small change to pressures can trigger a dramatic change in the state of the river (e.g., from a multi-thread to a single-thread channel).

When critical reaches or reaches of particular interest have been identified, their hydromorphological condition can be assessed in detail. Four types of assessment are useful:

Hydrological assessment: to understand changes compared with previous or unaltered conditions. Methods are based on "Indicators of Hydrologic Alteration," developed by Richter et al. (1996) and Olden and Poff (2003).

Morphological assessment: this is different to a simple physical habitat assessment as it considers processes, change over time and impacts. A number of methods tackle this, including the MQI (Morphological Quality Index) (Rinaldi et al., 2015d), which is applied at the river reach scale (reaches are fairly morphologically homogeneous and usually stretch over kilometers—whereas physical habitat surveys are usually carried out at a smaller scale). MQI uses 28 indicators based on channel forms, processes, sediment and wood fluxes, vegetation, channel mobility, channel adjustment, historical and future changes, dynamic equilibrium (reference condition) to evaluate the reach in terms of: (1) geomorphic functionality; (2) artificiality and (3) channel adjustments (morphological changes indicating instability due to human impacts).

Riparian vegetation assessment: as vegetation is fundamental to hydromorphological processes, it must be included (e.g., RQI Riparian Quality Index (González et al., 2011)). Among other vegetation features, vegetation processes, such as age diversity and plant regeneration are assessed.

Geomorphic unit assessment: assesses the presence and diversity of physical habitats, thereby linking hydromorphology with biology (using e.g., GUS—Geomorphic Units survey and classification System (Rinaldi et al., 2015a)).

Using hydromorphological assessment in restoration planning

In restoration planning, it is vitally important to understanding *if* and *how* rivers will change under different scenarios (Rinaldi et al., 2015b). Predicting the response of a river to geomorphic change can be used to determine an appropriate restoration strategy. In a river where there is little potential for re-establishing natural processes, as can be the case in lowland, low-slope environments, 'morphological reconstruction,' physically re-building lost habitat features such as riffles, bars and meanders may be most appropriate. The more sustainable and often cheaper option is to use the river's own dynamics, processes and energy to re-shape habitats. Working out the sensitivity of a river to geomorphic change relies on many of the assessments previously described. River type gives a good, first clue. In general, channels in confined valleys with large substrate size and low-gradient, lowland rivers are not highly sensitive to change. Whereas a multi-thread, high power river on mobile substrate in a wide valley is highly sensitive (Reid and Brierley, 2015).

Detailed geomorphological sensitivity can be used to work out, for example, conditions under which bed material starts to move, bank stability and thresholds of channel-pattern change (Rhoads, 2020). Understanding geomorphic thresholds and

anticipating state changes is particularly important as sensitive rivers can dramatically change character with only small changes to the pressures. A river which is highly sensitive to geomorphological change can be more easily nudged to change its morphology than a stable one, but more care will be needed to avoid unforeseen consequences (Schumm, 1979).

Biological indicators

The importance and influence of river physical habitat on freshwater ecological response is widely recognized (e.g., Maddock, 1999; Urban and Daniels, 2006). Bunn and Arthington (2002) identified four key principles that form the link between the flow regime and the biota: instream flow conditions determine habitat and therefore biota, the lifestyles of the biota have evolved to live in synchrony with the natural flow regime, longitudinal and lateral connectivity (floodplain) is necessary for undamaged communities, and disturbances to natural flow regimes create opportunities for non-native species. A number of conceptual frameworks have been developed that emphasize these links, for example biotic and ecological integrity (Karr and Dudley, 1981) and ecological health (e.g., Karr (1999)). It is clear that biota utilize specific habitat types and these are relatively well understood in terms of hydrological and hydraulic habitats and to some extent micro-morphological habitat, particularly for fish (e.g., Moir et al., 2004; Chovanec et al., 2003). There is also evidence that larger scale morphological habitats determine biotic response (e.g., Montgomery, 1999; Pess et al., 2002).

Many attempts have been made to find biological indicators that give a useful measure of hydromorphological impact, but this has proven challenging in both lakes (Poikane et al., 2019) and rivers (Poikane et al., 2020; Friberg et al., 2013). This partly reflects the problems inherent in coming up with any type of impact-specific biological indicator, in that organisms respond to the entire range of natural and anthropogenic effects at work in their ecosystem and different impacts working together sometimes have surprising and additive, synergistic or antagonistic effects (Ormerod et al., 2010). One of the most basic and popular river biological index for benthic invertebrates, Average Score Per Taxon (ASPT) (Hawkes, 1998; Armitage et al., 1983), responds strongly to poor water quality (organic pollution, its target impact), but is also affected by other anthropogenic impacts such as nutrients, toxic pollution, hydromorphological damage, as well as by the full range of natural variation such as climate and river type. Many therefore also consider ASPT to be a general indicator of river health (Eriksen et al., 2021) and Friberg et al. (2016) found it to be just as responsive to hydromorphological damage as some indices designed specifically to measure hydromorphological impact. While it is often possible to find significant correlations between impacts and biological responses over large datasets (Göthe et al., 2015), using the biological community found at one site to give an accurate and impact-specific assessment of that site is difficult and unreliable (Demars et al., 2012; Sandin and Johnson, 2004), and indeed based on outmoded ideas according to Woodward et al. (2013).

Assessing effects of hydromorphological alterations can be particularly difficult, as it is very clearly not a single impact but a complex web of interactions (Göthe et al., 2019). A damaged community at one site may resemble a more natural community at another. Floodplain and riparian damage cannot be readily detected by instream sampling. Contraction in wetted area of a river (resulting from hydropower for example) may not give a strong biological signal if the remaining smaller stream still has a good habitat and only the wetted area is sampled. The quest for biological indicators of river health has generally been at the level of organism groups, usually algae (phytoplankton—lakes, phytobenthos—rivers—often only diatoms), macrophytes (including macroalgae and bryophytes), macroinvertebrates and fish (Furse et al., 2009). Within these groups various aspects are considered, with metrics belonging to four general types: (1) composition/abundance; (2) richness/diversity; (3) sensitivity/tolerance metrics; and (4) functional. Across these categories, literally hundreds of metrics exist (Birk et al., 2012). Examples of the more widely applied macroinvertebrate hydromorphology-specific indices in rivers include PSI (Turley et al., 2016)—designed to target fine-sediment impacts and LIFE (Extence et al., 1999)—targeting low-flow impacts. Efforts have also been made to combine existing indices into multi-metrics, in an effort to synthesize different facets of hydromorphological impacts into one measure (Hering et al., 2006).

Examining biological ecosystem processes (functional indices) is another way to assess impacts on ecosystems. These can either be species-trait based or involve other measurements of biological processes (Sandin and Solimini, 2009). Indices based on traits still require the taxonomic determination of the organisms present but can give information about ecosystem functioning; for example, by looking at how the dominant lifestyles change in relation to hydromorphological damage. Traits also have the benefit of being independent of biogeography. Friberg et al. (2016) looked at the future potential for using both taxa-based and species-trait based indices in the different organism groups to detect hydromorphological impact in rivers. They found diatom communities to be more strongly related to nutrient impacts than hydromorphology, except in the case of fine sediment impacts, where they showed potential. Macrophyte traits showed potential as indicators, but macrophytes are likely to be useful in only a subset of river types (e.g., lowland, macrophyte dominated). Macrophytes should also be a focus of attention, however, as aquatic and riparian vegetation are key drivers of hydromorphological processes. Although hydromorphological impacts on invertebrates are well known, these authors did not find any community or trait-based measures that did not also respond to other stressors. Some fish are very sensitive to hydromorphological stress and offer the potential for successful development of metrics. In river types having naturally low diversity, then other factors such as community size-structure would need to be considered (Friberg et al., 2016).

It is also possible to measure or infer biological processes such as stream metabolism without looking directly at the organisms. No such biological hydromorphological indices have yet been developed, although existing studies suggest that it could be a fruitful direction to follow. For example, Kupilas et al. (2017) found that river restoration increased ecosystem metabolism. Li et al. (2010)

see the future of river biomonitoring as involving a range of functional indicators, potentially including microbial enzyme activity, bacterial luminescence, photosynthesis, respiration, locomotory activity, fluctuating asymmetry, community metabolism (primary productivity and respiration), nutrient uptake and spiraling, and secondary production.

Management of hydromorphology

Both rivers and lakes provide many benefits for humans (Postel and Carpenter, 1997). As hydromorphological factors and human-induced changes have strong impacts on rivers and lakes, the understanding of these variables and their interactions are crucial for freshwater management and restoration (Del Tánago et al., 2016). There are a large number of hydrological and geomorphological processes that occur across spatial and temporal scales in freshwater ecosystems. Processes at smaller spatial and temporal time scales are nested within larger scales (Frissell et al., 1986). This, together with the interaction between hydromorphology and ecology needs to be taken into account in freshwater management, especially with a changing climate, as this will affect both the physical template and biological response in these systems (Vaughan et al., 2009). Climate change also means management targets need to be adapted. In many areas, rainfall is predicted to become more extreme, causing intensified flooding and an increased demand for hydropower is expected, which will negatively affect rivers and lakes and their hydromorphological status (SOER, 2019). These more powerful high flows will shape larger channels, increase sediment transport and could change the dynamics and character of the channel, leading to channel instability for example (Shrestha et al., 2020).

Planning is key for accomplishing targets in hydromorphological management of freshwater ecosystems (Angelopoulos et al., 2017). There are several relevant management guidelines for running waters (Beechie et al., 2008; Gurnell et al., 2015), but in many instances parts of these guidelines are not taken into account and investments in river restoration and management over the last decades have failed to halt declines in habitat quality, ecosystem function, and biodiversity (Bernhardt et al., 2005; Almond et al., 2020). One major aspect that needs to be better taken into account is the improvement of monitoring and evaluation of management and restoration actions (Jansson et al., 2007; Palmer et al., 2010). These are integral parts of management and restoration programs. The management program also needs to include quantitative predictions of outcomes and setting appropriate targets and expectations for the magnitude and response of management actions (Beechie et al., 2010). Understanding the limitations of potential management actions and evaluating earlier efforts are key to improving guidance and execution of future efforts (Angelopoulos et al., 2017). This is especially true in the Anthropocene with changing hydromorphological conditions affecting multiple aspects of management and restoration in freshwaters (Downs and Piégay, 2019; García et al., 2021) where e.g., increased intensities of peak flows or drought could have strong negative effects on fish habitat restoration (Battin et al., 2007).

At the international level, the UN Sustainable Development Goal 6.6 (Protect and restore water-related ecosystems) focuses on protecting and restoring water-related ecosystems to ensure they continue to provide sustainable social and economic services and benefits to society. The aim of target 6.6 is to halt ecosystem degradation and destruction and to assist in recovering already degraded water-related ecosystems (United Nations, 2018). The United Nations conclude in the report that there is insufficient data to satisfactorily measure progress towards the SDG target on water and sanitation (SDG 6) but the data that does exist shows that artificial waterbodies (often related to hydromorphological pressures on natural ecosystems) such as dams, reservoirs and rice paddies have increased across the globe. One available dataset is on large dams, known as GOOD (GlObal geOreferenced Database of Dams) includes c. 58,000 large dams worldwide with a total storage capacity about as large as one-sixth of the total annual river flow into the oceans (Mulligan et al., 2020). Most of these dams have been built in the last 60 years and about 50% of the dams have been built for irrigation.

It has become evident that 'hydromorphic limits' are becoming important factors restricting the ecological quality of freshwater ecosystems (Vaughan et al., 2009). In the European Union, the legally binding Water Framework Directive (WFD) (European Commission, 2000) has highlighted the importance of hydrological processes and the morphodynamics of river channels and floodplains and their effects on ecological status and management actions (Rinaldi et al., 2016). The aim of the WFD is to achieve 'high status' (reflecting totally, or nearly totally, undisturbed conditions) with an environmental objective of at least 'good status' and no deterioration of classes in water bodies (rivers and lakes) corresponding to unaltered hydromorphological and physico-chemical conditions in comparison to type-specific reference states. In the European Union 40% of the water bodies do not reach 'good ecological status' because they have been affected by hydromorphological pressures for centuries. On the global scale, the United Nations decade on Ecosystem Restoration (2021–2030) will increase the momentum on freshwater ecosystem restoration. Within the European Union, the EU Green Deal and The EU 2030 Biodiversity Strategy (BDS 2030) call for urgent action to restore damaged aquatic and terrestrial ecosystems with a specific target to establish at least 25,000 km of free-flowing rivers by 2030.

Evaluating the physical characteristics (in terms of hydrology and morphology) of rivers and lakes is important to fulfill the requirement in public policies such as the EU Water Framework Directive, the US Clean Water Act, the Swiss Water Law, the Australian National Strategy for Sustainable Development, the New Zealand Resource Management Act, the Canadian Environmental Protection Act, and the National Water Act (NWA) in South Africa. To implement such policies and water management initiatives, guidelines are needed, such as the one developed by UNEP, the International Water Quality Guidelines for Ecosystems (IWQGES) (UN Environment, 2018). This guide contains a cyclical step-by-step process to ecosystem assessment in freshwaters, which includes: (i) agreeing on a vision and setting objectives, (ii) assessing ecosystems, formulating guidelines, monitoring, reporting, evaluating successes and weaknesses, and (iii) identifying future management goals, before the cycle begins anew.

The IWQGES includes physical, chemical, biological, and hydromorphological indicators applicable to different freshwater ecosystem types, and methods to define water quality targets and threshold values that are appropriate depending on context.

Conclusion

Hydromorphological components in river systems include: hydrological regime, river continuity (quantity and dynamics of flow and connection to groundwater), and morphological conditions (depth and width variation, structure and substrate of the river bed, and structure of the riparian zone), whereas in lakes it consists of: hydrological regime (quantity and dynamics of flow, residence time, connection to the groundwater) and morphological conditions (depth variation, quantity, structure and substrate of the lake bed, structure of the shore). Rivers and lakes are increasingly physically modified, degraded and exploited by humans and hydromorphology in freshwaters links hydrology and geomorphology with physical characteristics and processes and are thus at the center for management and restoration of these ecosystems. In order to assess and manage lakes and river systems from a hydromorphological perspective, data from field measurements and surveys, map-based, historic, paleo and remote-sensed data and information are needed. There are three basic strands to such assessment of hydromorphological condition of waterbodies: hydrological, physical morphology (including riparian/floodplain), and geomorphological process. It has been challenging to find appropriate biological indicators to measure the degree of hydromorphological impact in freshwaters, but a fruitful direction might be the development of functional and ecosystem process-based indicators for hydromorphological management and restoration.

The importance and influence of the physical habitat (hydromorphological condition) on freshwater ecological response is widely recognized and there are a number of conceptual frameworks that have been developed to assess these links. There are several such management guidelines available for running waters, but in many instances parts of these guidelines are not taken into account and investments in river restoration and management over the last decades have failed to halt declines in habitat quality, ecosystem function and biodiversity. Both rivers and lakes need to be managed for a multitude of purposes as they provide many different benefits for humans. As hydromorphological factors and human induced changes have strong impacts on river and lakes, the understanding of these variables and their interactions are crucial in freshwater management and restoration. Evaluating the physical characteristics of rivers and lakes is thus important to fulfill the requirement in public policies, and guidelines are also needed to guide such policies and water management initiatives, such as the UNEP, the International Water Quality Guidelines for Ecosystems (IWQGES) (UN Environment, 2018).

Knowledge gaps

- The fundamental and theoretical understanding of hydrological and geomorphological processes are generally well developed. The important gaps are between the specialists and those that actually take the practical, everyday decisions about land and water management.
- The difficulty of bridging this gap is that hydromorphological science does not provide an easy set of prescriptive steps for decision-making, there is not a one-size fits all solution and apparently sensible actions can have unforeseen and dramatic consequences.
- Easy to use methods for predicting the outcomes of catchment management decisions and physical interventions are lacking.
- The understanding that the general public have of land-use effects on watersheds and river dynamic processes is close to zero and this extends, to a greater or lesser extent, to those with decision-making power, from the politician giving the green light to floodplain development to the landowner who wants “their” river to be “tidy” and go in a straight line.
- This knowledge gap can extend to those funding and executing improvement measures, with many projects undertaken considering only habitat improvement, without considering whether these habitats are appropriate and sustainable over time.
- The science of river restoration is in its infancy, with a shortage of geomorphologically-trained specialists with practical experience. Many projects have been driven by ecologists, with an understanding of organisms and habitats, but without support from those with the knowledge of the processes that create and maintain these habitats.
- Even specialists need to change mindsets, as current monitoring strategies treat rivers and floodplains as separate entities and the Water Framework Directive, the single most important piece of legislation for hydromorphology, does not consider floodplain habitats such as wetlands, or the fundamental role of riparian vegetation in shaping rivers.
- Currently available ecological indicators are inadequate for assessing hydromophological impacts on lakes and rivers. Future developments may focus more on ecosystem functioning and developments in molecular ecology.
- Many or even most restoration projects fail to carry out adequate pre- and post-project physical and ecological monitoring, meaning that lessons are learnt more slowly than they should be.
- Change is coming, with many strong example projects appearing across the world. The number and experience of practitioners is going up and funding is rising in many countries. Process-based restoration is to be treasured as the standard method at the EU level.
- This general positive trend is not spread evenly across the globe, however. In many countries hydromorphological restoration does not exist and old mistakes are being repeated, destroying natural systems that many, more developed, countries are now struggling to recreate.

Hydromorphology—Interactions and Habitats

Oliver Miler, Northwest Indian Fisheries Commission, Olympia, WA, United States

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Connectivity in streams

- Longitudinal connectivity: linear connectivity along the entire length of a stream, with the physical gradient changing from source to mouth and chemical systems and biological communities shifting and changing in response (see also Vannote et al., 1980).
- Lateral connectivity: floodplain connectivity, i.e. the periodic inundation of the floodplain and the resulting exchange of water, sediment, organic matter, nutrients, and organisms.
- Vertical connectivity: connection between the atmosphere and a stream via (1) precipitation falling onto land and then flowing over land or percolating through the groundwater (the hyporheic zone, i.e. the zone below the stream bed) to the stream and (2) transfer of water from the streambed itself to surrounding aquifers.
- Temporal connectivity: connectivity of continuous physical, chemical, and biological interactions over time; occurs on several scales, e.g. seasonal, multiyear, generational.

CWD (coarse woody debris) Fallen dead trees and the remains of large branches (snags) in rivers and lake littoral zones, mostly originating from the riparian zone.

Rip-rap Erosion-resistant layer of large, loose, angular stones or chunks of concrete at a lake shore or river bank, often on an artificial embankment.

Xylophagous macroinvertebrate taxa Macroinvertebrate taxa feeding on or boring into wood and having a close association with coarse wood debris in lakes and rivers.

Effects of morphological degradation on macroinvertebrate, macrophyte and fish communities

Aquatic ecosystems worldwide are influenced by human alterations of their hydrological and morphological environmental conditions. These are often described and assessed together as hydromorphological alterations and have manifold impacts on biotic communities, for example on macroinvertebrates, fish and macrophytes (Leps et al., 2015; Noges et al., 2016; Strayer and Findlay, 2010). With respect to morphological degradation in lakes and ponds, human activities often reduce the overall diversity of littoral mesohabitats available for biota. This can occur through a replacement of natural habitats by anthropogenic structures, such as retaining walls and rip-rap (Fig. 1), recreational beaches (Fig. 2), docks and marinas (Fig. 3) and boat houses (Brauns et al., 2011; Strayer and Findlay, 2010). Physically complex habitats such as CWD (coarse woody debris), tree roots, submerged and emergent macrophytes often have a low relative frequency of occurrence at degraded lake shores (Brauns et al., 2007b; Francis and Schindler, 2006; Miler et al., 2015; Ostendorp et al., 2020). Submerged and emergent macrophyte stands are impacted by anthropogenic wave action via boat and ship traffic, which is amplified by retaining walls (Gabel et al., 2017; Ostendorp et al., 2020). At recreational beaches, submerged and emergent macrophytes are either cut back by controlled removals or negatively impacted via mechanical stress (trampling) by swimmers (Johnstone, 1986; Liddle and Scorgie, 1980; Ostendorp, 1989).

Hydromorphological degradation can occur in a floodplain/catchment and affect the entire lake basin. The presence of a functioning riparian zone with trees and shrubs provides the littoral zone with CWD and other organic material as well as submerged tree roots as a living organic habitat (Brauns et al., 2007b, 2011; Francis and Schindler, 2006; Miler et al., 2015).

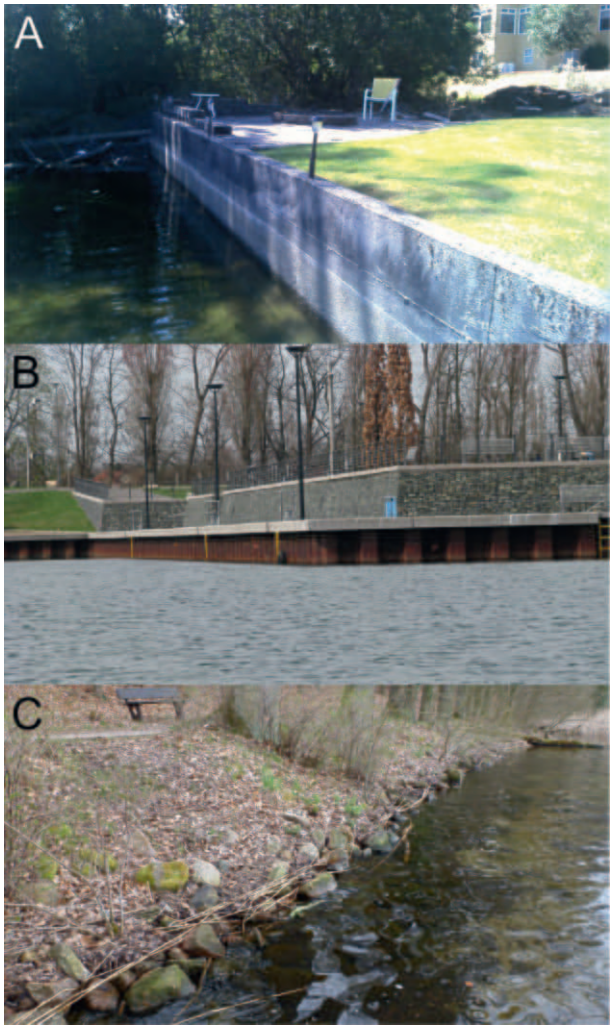

Fig. 1 Examples of hard shore modifications: (A) concrete wall in Fivemile Lake, Washington State, United States of America, (B) retaining steel wall in Lake Goitzschesee, Sachsen-Anhalt, Germany, (C) rip-rap in Lake Arendsee, Sachsen-Anhalt, Germany.

Consequently, if the native riparian vegetation is absent or diminished in its spatial extent, composition and functioning due to residential, commercial and industrial uses, this will affect the occurrence of physically complex habitats such as CWD, CPOM (coarse particulate organic matter) and tree roots and the biota inhabiting these, including xylophagous macroinvertebrate taxa (Brauns et al., 2007b; Christensen et al., 1996; Czarnecka, 2016; Francis and Schindler, 2006). Furthermore, shoreline urbanization has been shown to significantly reduce the input of terrestrial insects inhabiting riparian vegetation to the water where they serve as a food source for fishes (Francis and Schindler, 2009).

In streams and rivers, how morphological degradation manifests itself depends on scale. Large rivers often exhibit types of shore degradation characteristic for lakes, such as docks, retaining walls and recreational beaches (Noges et al., 2016). With decreasing stream width, the importance of the riparian vegetation for a stream increases, providing essential habitats for the adult stages of aquatic insects, buffers from terrestrial runoff and sources of shade and organic matter input for aquatic organisms (Death and Collier, 2009; Harrison et al., 2000; Harrison and Harris, 2002). In small and mid-sized streams, impacts on the channel morphology as well as sedimentation and other types of stream bed modifications have been identified as major morphological stressors on physical habitat quality (Gieswein et al., 2017; Piggott et al., 2012; Townsend et al., 2008).

Effects of hydrological degradation on macroinvertebrate, macrophyte and fish communities

The hydrology of lakes is frequently affected by modified water levels and/or regulations of the seasonal regime of water level fluctuations (Evtimova and Donohue, 2016; Mjelde et al., 2013; Smith et al., 1987; Wilcox and Meeker, 1991). Artificial water-level fluctuations alter the taxonomic and trophic structure of benthic consumers (Evtimova and Donohue, 2016) and reduce benthic algal biomass and the density and taxonomic distinctness of benthic invertebrate assemblages (Carmignani and Roy, 2017; Evtimova and Donohue, 2014). Furthermore, high water-level fluctuations reduce the cover and density of macrophytes and

Fig. 3 Examples of docks and marinas: (A) Docks in Lake Süßer See, Sachsen-Anhalt, Germany, (B) Docks in Lake Arendsee, Sachsen-Anhalt, Germany.

change the taxonomic composition of macrophyte communities by adversely affecting submerged macrophyte species propagating mainly via rhizomes, e.g. *Myriophyllum spicatum* and *Nuphar lutea*, and species sensitive to ice scour, e.g. isoetids (Carmignani and Roy, 2017; Hellsten and Mjelde, 2009; Mjelde et al., 2013; Smith et al., 1987). Stands of the reed *Phragmites australis* showed severe declines in area and vitality after an extreme flood in Lake Constance in 1999 (Ostendorp et al., 2003).

Another aspect of hydrological degradation in lakes, riverine lakes and large rivers, including many navigable water ways, is the presence of anthropogenic wave action. This is caused mainly by recreational and commercial boat and ship traffic and results in

increased mechanical stress on macrophyte, macroinvertebrate and fish communities, similar to the effects of human activities at recreational beaches (Gabel et al., 2011b, 2017; Weber et al., 2012). Increased wave action has been shown to decrease the time for feeding and to increase energy expenditures of benthic invertebrates and fish (Gabel et al., 2011a,b; Stoll et al., 2008). These effects tend to be more pronounced for native compared with non-native species, as shown for benthic invertebrates by Gabel et al. (2011a). High mechanical stress caused by anthropogenic wave action can lead to aquatic macrophytes either getting uprooted or parts of plant stems and leaves breaking off (Riis and Biggs, 2003; Schutten et al., 2004, 2005), thereby reducing macrophyte densities and influencing species composition.

Flow regulation structures, such as dams and weirs, are placed in many streams and rivers, with consequences for the hydrologic connectivity of lotic ecosystems (Bellmore et al., 2019; Dynesius and Nilsson, 1994; Fullerton et al., 2011). The loss of longitudinal, but also lateral, vertical and temporal, connectivity in streams has detrimental effects on many biota and their metapopulations, especially freshwater megafauna and fish species, impeding fish migrations and reducing genetic and taxonomic diversity (Fullerton et al., 2011; He et al., 2018; Turgeon et al., 2019). Furthermore, human alterations of the flow regime, i.e. changes in magnitude, frequency, duration, rate of change, and timing of flow, which are frequently measured via indicators of hydrological alteration (IHAs) (Olden and Poff, 2003; Schmutz and Sendzimir, 2018) can have significant impacts on macroinvertebrate, fish and aquatic plant community composition, population dynamics and food web structure (Bunn and Arthington, 2002; Haslam, 2006; Meißner et al., 2019; Mims and Olden, 2013; Palmer and Ruhi, 2019).

Types of multiple stressor interactions

Hydromorphological alterations are often accompanied by other stressors, leading to multiple stressor interactions affecting the population dynamics, diversity and food web structure of freshwater biota. In general, multiple stressors can interact in additive (sum, i.e. the simple addition of the effects), synergistic (i.e. larger than the sum of the effects) or antagonistic (i.e. smaller than the sum of the effects) ways (Cote et al., 2016; Jackson et al., 2016; Piggott et al., 2015). While freshwater ecosystems often integrate environmental effects over several scales and are hence sensitive to multiple stressors, only in recent years have increased efforts been made to comprehensively and systematically quantify these (Jackson et al., 2016; Lemm and Feld, 2017; Noges et al., 2016). How multiple environmental stressors interact in their effects on freshwater communities and how these can be optimally assessed for ecosystem management decisions are important fields of ongoing research (Craig et al., 2017; Noges et al., 2016). Ecological assessments based on biota must be calibrated based on well-defined stressor types, which can be single stressors, such as eutrophication or hydromorphological degradation, or alternatively multiple stressors (Hering et al., 2006; Karr and Chu, 1999). Hence, understanding the effects of specific stressors on metrics, i.e. assessment relevant characteristics of ecological communities, is vitally important to precisely describe stressor-response relationships and to develop statistically robust assessment tools (Johnson et al., 2018; Lemm et al., 2019; Miler and Brauns, 2020).

Interactive effects of hydromorphological degradation and other stressors on lake biota

In lentic ecosystems, eutrophication together with hydromorphological degradation are considered as the major ecological stressors (Miler and Brauns, 2020; Noges et al., 2016; Wetzel, 2001). The relative effects of eutrophication and hydromorphology on benthic invertebrates vary between the depth zones of a lake (Bazzanti et al., 2012; Pilotto et al., 2012; Saether, 1979; Wetzel, 2001). Invertebrates inhabiting the profundal zone, especially chironomids, strongly react to eutrophication pressures and have been used for several decades to reliably indicate eutrophication (Pinder, 1986; Saether, 1979; Wiederholm, 1980), with several early studies having established the ecological relationships between oxygen content and profundal invertebrate community composition (Brinkhurst, 1974; Lenz, 1925; Thienemann, 1918). The influence of hydromorphology relative to eutrophication increases from the profundal over the sublittoral to the eulittoral/infralittoral zone (Bazzanti et al., 2012; Pilotto et al., 2012).

Anthropogenic stressors have been shown to act on eulittoral invertebrate communities in a hierarchical manner and can be ranked according to their importance (Johnson et al., 2018; Miler and Brauns, 2020; Pilotto et al., 2015). In a study on 14 Italian lakes, Pilotto et al. (2015) identified that morphological alterations explained approximately 2.5 times more of the variation in eulittoral macroinvertebrate composition than eutrophication. Similarly, Miler and Brauns (2020) found a significantly higher influence of hydromorphological alterations compared with eutrophication on eulittoral macroinvertebrates. Previous studies on lakes in Finland, Germany and Ireland have found substantial effects of trophic state on eulittoral macroinvertebrate composition (Brauns et al., 2007a; Donohue et al., 2009; Tolonen et al., 2001; Tolonen and Hämäläinen, 2010). However, the focus of these studies was on hydromorphologically undisturbed sites and did not include sites with hard or soft shore modifications, in contrast to Pilotto et al. (2015) and Miler and Brauns (2020). Furthermore, Pilotto et al. (2015) and Miler and Brauns (2020) distinguished in their analyses between shared and unique variation and also used composite macroinvertebrate samples comprised of several meso-habitats that were representative of the overall habitat composition at a site (as opposed to habitat-specific samples in the other studies).

Habitat-scale effects (hydromorphological degradation) on eulittoral macroinvertebrate communities are often more significant than larger scale effects, e.g. effects at the catchment scale (eutrophication) (Johnson et al., 2004; Johnson and Goedkoop, 2002; McGoff and Sandin, 2012). This highlights the importance of scale for analyzing multiple pressures and their effects on biota.

Trophic effects on eulittoral macroinvertebrate communities have been shown to be nested within meso-habitats, i.e. they are more influential when analyses are stratified by habitat types such as stones, sand, macrophytes etc. (McGoff and Sandin, 2012; Tolonen et al., 2001; Tolonen and Hämäläinen, 2010).

Acidification is another important stressor for lake biota, especially in regions with granite rock geologies, for example in Scandinavia and the United Kingdom (Johnson et al., 2018; Muniz, 1990; Schartau et al., 2008), Canada and the Northeastern United States (Keller et al., 1999; Lacoul et al., 2011; Schindler et al., 1989) and in former mining pits in Germany (Klapper et al., 1996; Nixdorf, 1999; Nixdorf et al., 2005). Depending on lake geology, acidification can become the dominant stressor for macroinvertebrate communities and can interact with other stressors, e.g. hydromorphological degradation and eutrophication (Johnson et al., 2018).

Interactive effects of hydromorphological degradation and other stressors on stream biota

Noges et al. (2016) have argued that in rivers and streams, hydromorphological stress is a more important stressor than eutrophication due to high benthic-to-pelagic habitat ratios, and low water retention times and directional flows. The presence of flowing water reduces the environmental impacts of nutrients (and other chemical substances), while it increases the importance of hydraulic stress (Noges et al., 2016; Wetzel, 2001). While hydrological stressors are highly localized in lakes, for example at wind-exposed shore-lines, the nature of uni-directional flow in rivers strongly affects geomorphological processes, e.g. erosion and sedimentation, along the whole lotic system (Lampert and Sommer, 2007; Strayer and Findlay, 2010; Wetzel, 2001). The higher benthic-to-pelagic habitat ratios in rivers compared with lakes lead to a higher influence of morphological stress on biota in rivers than in lakes (Noges et al., 2016). This also explains the need to stratify stressor analyses in lakes by water depth, with for example macroinvertebrates only reliably indicating hydromorphology in the eulittoral zone (Bazzanti et al., 2012; Pilotto et al., 2012).

Overall, the total impacts of stressors (indirect and direct) act hierarchically on stream biota, depending on spatial scale (Frissell et al., 1986), and can be ranked in their importance as decreasing from watershed over stream and reach to habitat scales (Dahm et al., 2013; Meißner et al., 2019; Villeneuve et al., 2018). Catchment land use often comprises a varied mix of stressors, such as agriculture and urbanization, and hence encompasses and overrides more specific stressors at finer spatial scales, e.g. hydromorphology (Dahm et al., 2013; Leps et al., 2015; Meißner et al., 2019). A study of mountain streams in Germany found total (i.e., direct and indirect) effects on macroinvertebrates decreasing from catchment-scale land use over stream-scale hydrology and reach/local-scale physical habitat structure to local-scale physico-chemistry (Meißner et al., 2019). However, focusing on the direct (unique) effects, hydrology had the largest influence on macroinvertebrate metrics (Meißner et al., 2019). The effects of site-scale stressors on macroinvertebrate communities can also differ between stream types: Villeneuve et al. (2018) showed that in hard water (lime stone) streams hydromorphology (and land use) constituted major stressors for macroinvertebrate assemblages compared with physico-chemical variables, whereas physico-chemistry was the dominant stressor in soft water streams.

Interacting effects of multiple environmental stressors on benthic macroinvertebrates have been determined in lotic mesocosm experiments (Beermann et al., 2018; Elbrecht et al., 2016; Matthaei et al., 2010). Using experimental streams, the effects of sediment addition and flow reduction on benthic macroinvertebrates and algae were twice as common as nutrient enrichment, with additive effects of the former two stressors (Matthaei et al., 2010). Similarly, fine sediment addition was identified to be a more significant stressor than nutrient enrichment for macroinvertebrates, with both stressors acting in additive, antagonistic as well as synergistic ways on macroinvertebrates, depending on the respective analyzed metrics and traits (Townsend et al., 2008; Wagenhoff et al., 2011). Elbrecht et al. (2016) found "triple" additive effects of nutrient enrichment, sediment addition and reduced flow velocity on several disturbance-sensitive stream macroinvertebrate taxa. Field survey data from European lowland rivers show that additive interactions of hydromorphological, physico-chemical and land use stressors on benthic macroinvertebrates prevailed with 80% of the studied interactions (Lemm and Feld, 2017). Antagonistic and synergistic interactions were, in accordance with Noges et al. (2016), approximately equally common (Lemm and Feld, 2017). Ortho-phosphate and fine sediment addition were the most commonly found interactions and most of these were synergistic in nature (Lemm and Feld, 2017). Mechanistically, sediment addition affects macroinvertebrate communities more directly, whereas the effects of nutrient enrichment are indirect, via an increase of the stream phytobenthos biomass (Doledec et al., 2006; Wagenhoff et al., 2011; Yuan, 2010). Since the latter is also impacted by a multitude of other environmental factors, the relative strength of both stressors and their interactions can display considerable variability (Lemm and Feld, 2017; Wagenhoff et al., 2011; Yuan, 2010).

Invasive species

Invasive species influence and modify the effects of hydromorphology on aquatic biota in several ways. Firstly, in many lakes and streams, invasive macroinvertebrates and macrophytes often constitute a major component of biotic communities and often significantly modify native biological structures and impact the ecological functioning of aquatic systems (Magliozzi et al., 2020; Schultz and Dibble, 2012; Strayer, 2010). For the biotic assessment of stressors, such as hydromorphology, usually the determination of the reference condition of a specific water body type is required (European Commission, 2000; Karr and Chu, 1999). This complicates the biotic assessment of hydromorphology in more densely populated regions impacted by human pressures, where water bodies are connected by navigable water ways or where vessels carrying invasive species are routinely transported between water bodies (Leuven et al., 2009; Panov et al., 2009; Rothlisberger et al., 2010).

Secondly, invasive macrophyte species can constitute littoral or in-stream habitats or form part of the riparian zone at lake shores and stream banks (Haslam, 2006). The condition of the riparian zone (together with the eulittoral zone) is generally considered when assessing hydromorphological degradation (Miler et al., 2015; Strayer and Findlay, 2010). In Europe and North America, knotweeds (*Reynoutria* spp.) are widely distributed invasive plants colonizing the riparian zone and have been shown to be catalysts for streambank erosion and to negatively impact plant and arthropod species richness in riparian zones (Colleran et al., 2020; Gerber et al., 2008). In North America, the European subspecies of the reed *Phragmites australis* is an aggressive invader that grows more densely than the North American subspecies and has replaced native vegetation in many regions (Kettenring et al., 2012; Schultz and Dibble, 2012). The effects on aquatic fauna are however less clear and negative as well as beneficial effects have been reported (Holomuzki and Klarer, 2010; Kettenring et al., 2012). The invasive benthic zebra mussel (*Dreissena polymorpha*) has been shown to increase the physical complexity of bottom substrates in lakes and rivers and consequently influences benthic invertebrate community composition (Burlakova et al., 2012; DeVanna et al., 2011; Ward and Ricciardi, 2007). In addition, the biodeposition of feces and pseudofaeces by *Dreissena polymorpha* affects the structure of benthic invertebrate communities and provides a food source for example for Amphipoda (DeVanna et al., 2011; Gergs et al., 2011; Mörtl and Rothhaupt, 2003). Furthermore, many floating and submerged aquatic macrophytes outcompete native vegetation and can form dense stands or floating mats, thereby changing the hydromorphology of the littoral zone and the conditions for other aquatic biota, such as macroinvertebrates (Kovalenko et al., 2010; Schultz and Dibble, 2012; Stiers et al., 2011). In streams, the presence of macrophytes is controlled by water velocities, discharge and sedimentation, but macrophytes also modify these feedback relationships (Franklin et al., 2008; Haslam, 2006; Miler et al., 2012; O'Hare, 2015). Consequently, the establishment of dense and dominant invasive macrophyte stands, such as *Myriophyllum aquaticum* (Kuehne et al., 2016) and *Egeria densa* (Collier et al., 1999; Yarrow et al., 2009) can change macrophyte community composition, impede water flow and cause flooding events (Franklin et al., 2008; Yarrow et al., 2009).

Restoration projects

Stream hydromorphology restoration efforts in recent decades often consisted of geomorphic restructuring that reconfigures the shape of the channel and depends on stream corridor and watershed form, e.g. straight/meandering/braided/anastomosing streams, sinuosity (establishment of meanders) and stream-type appropriate cross-sections and depth to width ratios (Palmer et al., 2014; Poppe et al., 2016). This also includes changes to in-stream structures, e.g. the creation of riffle-pool sequences, coarse woody debris addition, diversification of bed materials and elevation patterns, and the re-structuring of the stream bank to a natural slope, height, shape, riparian vegetation and substrate composition (Harrison and Harris, 2002; Kail et al., 2007; Poppe et al., 2016). There is an increasing trend toward process-based river restoration that aims to reestablish natural flow and sediment regimes which in turn affect the environmental conditions, ecosystem structures, as well as the biotic and ecosystem processes in rivers (Beechie et al., 2010; Booth et al., 2016; Palmer and Ruhi, 2019). According to the current literature, the majority of river hydromorphology restoration projects worldwide has been conducted in Europe, the United States, Canada, Australia and Japan (Brierley and Fryirs, 2009; Friberg et al., 2016; Nakamura et al., 2006; Palmer et al., 2007; Pike et al., 2010). Lake shore restoration projects are increasingly conducted in recent years, but studies are still rare compared with stream hydromorphology restoration efforts (Ostendorp et al., 1995, 2020).

Restoring hydromorphological connectivity by removing dams, weirs, culverts and other obstacles impeding the free flow of water and sediment is another major component of the restoration of hydromorphological functioning (Bellmore et al., 2019; Palmer and Ruhi, 2019). These restoration efforts have primarily occurred in Europe and North America, with only few projects conducted in Africa, Asia and South America (Al-Zankana et al., 2020; Koebel et al., 2014; Palmer et al., 2014). In North America, there has been a focus on dam removal projects in recent years with the removal of larger dams, for example in the Pacific Northwest, such as the Elwha river dams (East et al., 2015; Morley et al., 2020) and the planned removal of the Klamath river dams, but also smaller dams all over the United States (and to a lesser extent in Canada) that are now obsolete remnants from previous industrial activities (Bellmore et al., 2017; Foley et al., 2017a,b). In contrast, worldwide, but largely concentrated in Africa, South America, Southern Asia, the Mediterranean and the Middle-East, there is an ongoing dam construction boom (Zarfl et al., 2015). Additionally, the monitoring and evaluation of the effectiveness of restoration efforts is often insufficient (Al-Zankana et al., 2020; Kail et al., 2007; Roni et al., 2008; Stoll et al., 2014). For the evaluation of the success of stream hydromorphology restoration projects, the most common criticisms are (1) the frequent absence of Before–After–Control–Impact (BACI) study designs, (2) sampling often only for one season, (3) infrequently applied multi-habitat sampling and (4) rare inclusion of macroinvertebrate metrics other than taxa richness and diversity (Al-Zankana et al., 2020). This observed lack of a proper methodology to assess effectiveness might contribute to the reported highly variable success of stream restoration efforts on fish, benthic invertebrates, and macrophytes that has been attributed to confounding stressors, e.g. nutrient pollution, or the characteristics of the regional species pool (Al-Zankana et al., 2020; Haase et al., 2013; Kail et al., 2015; Stoll et al., 2014).

Conclusions

In summary, hydromorphological stressors affect freshwater macroinvertebrates, macrophytes and fish in a multitude of ways, depending on the water body type (lotic/lentic), size and morphology (e.g. shallow lakes, deep lakes, ponds, rivers, streams, creeks etc.) and other environmental characteristics (Fig. 4). Interactions between hydromorphology and other environmental stressors,

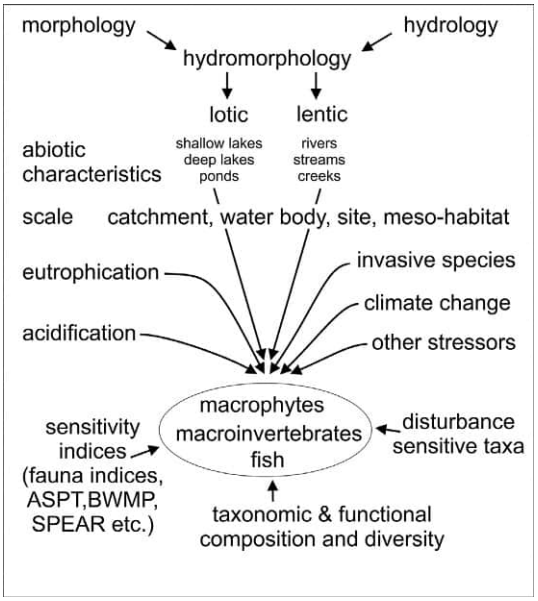

Fig. 4 Schematic overview of hydromorphological and other pressures acting on lake and stream biota and their assessment.

most importantly eutrophication/nutrient enrichment, are specific to the studied biota and water bodies. The scale at which the environmental stressor acts (eutrophication: catchment scale, hydromorphology: meso-habitat scale) is important as well as the type of interaction (additive, synergistic, antagonistic). Invasive species can constitute an important component of hydromorphological degradation, e.g. as riparian or aquatic vegetation. In addition, they can modify the effects of hydromorphological degradation or complicate its assessment. Numerous hydromorphological restoration projects have been conducted to date, but their scope and geographical location has been comparatively limited so far (mainly to Europe, the United States, Canada, Australia and Japan). Furthermore, the monitoring and evaluation of the effectiveness of restoration projects needs to be further improved. With a world-wide increasing human population, hydromorphological degradation will remain an important stressor for freshwater biota and interactions with multiple other stressors are receiving increasing attention and will most likely increase in importance, for example in the context of global anthropogenic pressures such as aquatic invasions and climate change.

Knowledge gaps

- Effectiveness of restoration projects, especially of lake shores, but also streams and rivers
- Better disentanglement of the effects of multiple stressors (hydromorphology, eutrophication, acidification etc.) and quantification of unique and shared variation of stressor effects on macroinvertebrates, macrophytes and fish especially in lakes, but also streams and rivers
- Increased and more specific incorporation of functional metrics and functional diversity in the assessment of hydromorphological stress with macroinvertebrates, macrophytes and fish
- Better quantification of the relationships between physical habitat survey parameters and biotic assessment metrics (macrophytes and macroinvertebrates), especially in lakes

Hydromorphology: Case Studies

Gwendolin Porst*, Chair of Water Resources Management and Modelling of Hydrosystems, Technische Universität Berlin, Berlin, Germany

This article was reviewed for the *Encyclopedia of Inland Waters*, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Anthropogenic Man-made; relating to, or resulting from the influence of human beings on nature.
Biodiversity Biological diversity in an environment as indicated by numbers of different species of plants and/or animals.
Channelization Method of river engineering that widens or deepens rivers to increase the capacity for flow volume at specific sections of the river.
Dam A barrier constructed to hold back water and raise its level, forming a reservoir used to generate electricity or as a water supply.
Flood plain An area of low-lying ground adjacent to a river, formed mainly of river sediments and subject to flooding.
Hydromorphological modification Change to the physical habitat, and/or a water bodies' natural functioning (i.e. water flow dynamics).
Invertebrate Any animal that lacks a vertebral column, or backbone, in contrast to the cartilaginous or bony vertebrates.
Irrigation The artificial process of applying controlled amounts of water to land to assist in production of crops.
Littoral zone Part of a lake, river or stream that is close to the shore and is illuminated.
Riparian zone Interface between land and a lake, river or stream.
Water abstraction The process of taking water from any source, either temporarily or permanently for irrigation, industry, recreation, flood control or treatment to produce drinking water.
Wetland Distinct ecosystem that is flooded by water, either permanently or seasonally.

Introduction

Inland waters worldwide are subject to major modifications, such as morphological alterations, straightening and canalization, the disconnection of flood plains, water abstractions and water flow regulations by dams, weirs, sluices or locks. The aim of this article is to exemplify a range of hydromorphological pressures under a series of case study headings and illustrated by a variety of key examples, highlighting the different pressure types comprising the array of main physical alterations of water bodies modifying their shores, riparian and littoral zones, water level and flow on a global scale. It also provides examples for possible and already implemented restoration measures for hydromorphologically altered waters.

Case study 1: Morphological alterations of shore zones

Freshwater shores have been modified by humans in a variety of ways over the last centuries (Strayer and Findlay, 2010). While these zones typically are highly diverse in terms of habitats and consequently provide shelter for many faunal communities, this heterogeneity and high biodiversity is typically diminished or even lost when these zones are altered morphologically (Brauns et al., 2011; Christensen et al., 1996; Elias and Meyer, 2003).

Modifications of shore structures, such as the construction of erosion control measures, are usually accompanied by massive reductions or even clear-cutting of natural habitats, such as removal of shoreline vegetation, littoral macrophytes and reed belts. A typical feature of anthropogenically altered shore sites is the absence of riparian woodland, which leads to a reduction of coarse woody debris (CWD) and tree roots within the lake (or river) and thus a loss of important habitats and ecosystem processes

*Current address: Senatsverwaltung für Umwelt, Verkehr und Klimaschutz, Abteilung Integrativer Umweltschutz (II), Berlin, Germany.

(Brauns et al., 2011; Porst et al., 2012). These changes in habitat structure, which accompany morphological alterations in shore zones, affect different parts of the freshwater community, both fauna and flora, in different ways.

In a study by Christensen et al. (1996) on 16 north temperate lakes in the area of Wisconsin, United States, the relationships among coarse woody debris, riparian vegetation, and shoreline residential development was assessed. This study related the density of CWD within lakes to the tree density and thus the density of residential housing along the shore, with lakes situated in less populated areas showing higher densities of woody remains in lake shore zones. The observed loss of important habitats such as tree roots, tree branches and leaves in turn has direct effects on littoral faunal communities in lakes subject to residential development (Brauns et al., 2011).

Several studies carried out in lakes across Europe acknowledged the negative effect of morphological alterations in littoral shorelines on their macroinvertebrate communities (Brauns et al., 2007; McGoff et al., 2013; Porst et al., 2019). In a pan-European study across 51 European lakes situated in Denmark, Finland, Germany, Italy, Ireland, Sweden and Great Britain, comprising a gradient of nutrient states, macroinvertebrate biodiversity was detected to decline drastically when lake shore zones were altered (Porst et al., 2019). Types of modifications at lake shores investigated ranged here from "hard alterations," comprising retaining walls, rip raps or boulders to "soft alterations," such as recreational beaches and riparian clear cutting or grassland (Fig. 1). These hard and soft modifications were compared with lake shores, which showed a (near) natural state, such as unmodified shore stretches, at each lake under investigation. The observed decline in macroinvertebrate biodiversity, which was apparent across all four European demographic regions, was shown to be a result of the reduced variety of habitats in morphologically altered shore types and here especially the loss of complex habitats such as macrophytes. While at natural lake shores a great number of habitat types such as macrophytes, sand, stones, woody debris or tree roots is usually present, morphologically altered shores are typically characterized by one to two habitats only (Elias and Meyer, 2003; Radomski and Goeman, 2001).

In altered lake shores, both soft and hard, structurally complex habitats such as macrophytes or tree roots are typically replaced by structurally less complex habitat types like sand or stones (Miler et al., 2015; Porst et al., 2012, 2019). At soft altered shores such as beaches or grazing pastures/grassland, the most dominant or often only available aquatic habitat sand is quite unfavorable for many macroinvertebrate species, as it cannot provide many ecological niches or shelter from predators or wave-action and does not offer a great variety of food-sources. This structurally very simple habitat, which has been shown to be the most dominant at most morphologically altered shorelines across European lakes, is often dominated by only a few taxa groups (e.g., in the pan-European study: fly larvae and oligochaetes). While this decrease in biodiversity is quite dramatic, it is furthermore accompanied by extremely high densities of fewer species in altered lake habitats (McGoff et al., 2013; Porst et al., 2012, 2019). More sensitive macroinvertebrate groups such as caddisflies, crustaceans, dragonflies, gastropods and mayflies typically get reduced in their densities and diversity or might be even totally absent from modified shorelines (Porst et al., 2012, 2019). Morphological shore alterations consequently also have a strong influence on macroinvertebrate food-webs, by changing their structures and trophic basis (Brauns et al., 2011). The comparatively low diversity of food sources and associated consumers at morphologically altered shorelines leads

Fig. 1 Shore embankment (retaining wall) at Lake Müggelsee, Berlin, Germany.

to a reduction of the number of trophic links in macroinvertebrate food webs of up to one order of magnitude lower at morphologically altered shorelines when compared to natural lake shores (Brauns et al., 2011).

Using a subset of the European lakes studied by Porst et al. (2019) for the study mentioned above, McGoff et al. (2013) found clear evidence, that macroinvertebrate communities of European lakes are being homogenized by lake shore development on a whole lake-level. The study showed that morphological alteration of lakeshores and near shore, and the surrounding habitats have an even greater effect on macroinvertebrate community diversity than nutrient enrichment.

Fish assemblages seem to be equally negatively affected by anthropogenic alterations to shore zones (Lewin et al., 2013), as further demonstrated in a study of 17 north temperate lakes in the area of Wisconsin, United States (Jennings et al., 1999). The study, which compared littoral fish assemblages of lakes subject to extensive residential and recreational development, found that different types of erosion control structures such as riprap and retaining walls had a strong influence on fish biodiversity in the shore zone, similar to the studies on macroinvertebrates (McGoff et al., 2013; Porst et al., 2019).

As described above, anthropogenic shoreline alterations have a strong effect on lake ecology, including lake fauna and flora and, thus, lake ecosystem state. In order to restore morphologically altered lakes and lake ecological status, conservation should focus on preserving the structural integrity of littoral zones. Potential restoration measures, as for example demanded by the EU Water Framework Directive (EEC, 1992) in order to reestablish good ecological state of lakes in the European Union, include the re-establishment of coarse woody debris, reed stands and root habitats in lake shores. These lake restoration measures have already proven to be a cost-efficient method to improve degraded lakeshores (Sondergaard and Jeppesen, 2007) and consequently the ecological state of lakes.

Case study 2: Channelization of running waters

During the last 2000 years, many rivers and streams have been subject to engineering measures, which typically include manmade morphological changes to their course, their river features, or flow regime, with the purpose to result in some defined benefit (Brooker, 1985; Hohensinner et al., 2018). Channelization of rivers or streams usually has the purpose of either diverting water for irrigation, draining wetlands/floodplains for agriculture, increasing "usable" land, improving river channels for navigation or preventing flooding (Brookes, 1985). These hydromorphological changes to natural river courses and their floodplains, however, have wide implications on their ecology (Brooker, 1985). General environmental effects of river channelization include the alteration of the natural flow regimes, habitat loss and loss of habitat complexity within the river or stream, loss of floodplains and associated wetlands and consequently the decline of natural biodiversity (fauna and flora) within the river system (Wilcock and Essery, 1991). While many rivers and streams were still actively engineered and channelized during the last century, in recent decades the focus has shifted towards restoring previously channelized running waters to their natural state as free flowing rivers or streams (Brookes, 1990; Koebel Jr et al., 2014).

One impressive example of a river, which has been subject to substantial channelization measures, with the purpose to prevent extensive flooding, is the Kissimmee River located in Central Florida. The river, which belongs to the Kissimmee Basin forming the headwaters of Lake Okeechobee and the Everglade (the Kissimmee-Okeechobee-Everglades (KOE) system), formerly meandered freely over a stretch of about 166 km from Lake Kissimmee to Lake Okeechobee (Koebel Jr, 1995). Its natural floodplains reached a width of up to 3 km in the past and were inundated for long periods of time during times of heavy seasonal rainfall (Toth et al., 1998). In its natural state, diverse animal and plant communities characterized the river and its floodplains, which included at least 39 species of fish and 38 species of water birds (Koebel Jr, 1995). Prolonged flooding of the Kissimmee basin and surrounding residential areas in the late 1940s (caused mainly by hurricanes), lead to a public outcry demanding flood protection measures in the area.

Consequently, between 1960 and 1971, this once beautiful meandering river was transformed into a 90 km-long, 10 m-deep and 100 m-wide canal, known as the C-38 canal, to provide flood control for central and southern Florida. While these measures controlled the flooding well, about 60% of the rivers' wetland habitats were lost and its natural hydrological cycle was greatly modified, with the river placed under stage-fluctuation management (Harris et al., 1995). This led to a dramatic decline of the river systems natural biodiversity in terms of vegetation, invertebrates, fish, wading birds and waterfowl (Harris et al., 1995; Koebel Jr, 1995). Studies reported a 90% decrease in waterfowl and a 70% decrease in Bald Eagle (*Haliaeetus leucocephalus*) populations in the Kissimmee River Basin (Koebel Jr, 1995). Biologists predicted the devastating ecological consequences of the channelization project already while the engineering measures were still in progress. Their concerns have since been confirmed, and there is wide consensus that the channelization project has damaged the river and its floodplains greatly, which among other things led to major environmental problems in the Kissimmee Valley and Lake Okeechobee.

After the Florida Legislature passed the Kissimmee River Restoration Act in 1976, three major restoration and planning studies were carried out, which resulted in a dechannelization plan (Koebel Jr, 1995), and finally the Kissimmee River Restoration Project. The main purpose of the project is to restore ecological integrity to the Kissimmee river-floodplain ecosystem (Koebel Jr et al., 2014). After an extensive planning phase, the Kissimmee River Restoration Project began in 1999 by backfilling about 14 km of the C-38 canal, with the purpose to restore the river's natural flow patterns. Today, three restoration phases have been finalized, and near natural water flow has been re-established to about 65 km of the meandering Kissimmee River. As a result, seasonal rains and changing flow patterns once again periodically inundate the floodplains in the restored area. The Kissimmee River Restoration Project is expected to restore the flow conditions to about 70 km of the historic river channel and to reestablish about 104 km^2 of

Fig. 2 The Kissimmee River was straightened to drain surrounding swampland and control the flooding within the region (left before and right after restoration). Found at: https://www.npr.org/2014/10/19/356647396/the-kissimmee-a-river-recurved—Courtesy South Florida Water Management District.

the rivers' floodplain ecosystems (Fig. 2). This will include 11,000 ha of wetland habitat, which is expected to benefit over 320 species of fish and wildlife (Koebel Jr, 1995).

The Kissimmee River clearly illustrates the change from a pure flood-controlled management of a river system to a management taking into consideration conservation issues such as ecological integrity and biodiversity protection.

Case study 3: Dams and weirs

Together with channelization of rivers and streams, damming is one of the most common hydromorphological alterations found in river systems around the world (McCartney, 2009; Van Looy et al., 2014). Worldwide, more than 45,000 large dams exist and more are meant to be built in the future (McCartney, 2009).

Dams and weirs are usually built to support water supply, particularly for irrigational purposes, to generate hydropower, control floods or for navigational purposes. However, the construction of firm, solid walls built across a river valley or catchment to block the flow of the river, leads to a great variety of negative effects, such as landslides, a great deal of ecological problems, together with a general decline in water quality within the river systems and floodplains. While each dam's environmental impact is very unique and dependent on the dam's structure, the characteristics of the resident biota, the local climate and geomorphology, a variety of negative effects of the construction of these very sturdy structures within a river system cannot be denied (McCartney, 2009). Dam construction has severely altered rivers and their wetlands around the world, which has global implications on river and, especially, wetland biodiversity (Nilsson et al., 2005). Dams always alter the flow regime of a river greatly. The robust structure prevents the movement of sediments and nutrients downstream and causes slower flows upstream, which in turn leads to increased settling of sediments in this part of the river and is accompanied by more unpredictable flows downstream of the dam (Wu et al., 2019). Additionally, annual flood-pulses are also disturbed by dams or weirs, which severely interrupt the exchange of nutrients between the river and its floodplains (Benke et al., 2000; Wu et al., 2019). Other negative effects of dams are the interruption of fish migration within the river system, the loss of many foraging and spawning habitats within the river floodplains and a general change in plant and animal communities, often resulting in lower biodiversity below the dam (McCartney, 2009; Wu et al., 2019).

The Yangtze River, the largest river in East Asia and the 3rd longest in the world, is the most important river in China, on which more than 400 million people depend (Kaifeng et al., 2013). To facilitate irrigation, to generate hydropower, to store water and to manage flooding in the area, between 1950 and 2010 more than 50,000 dams have been built in the Yangtze River basin (CCYRA, 2006, Yang et al., 2011). Since 2012, the Three-Gorges-Dam (TGD), located in the Yangtze River, is presently the largest dam and hydropower project in the world (Fig. 3). The benefits and costs of this huge dam have been under debate since the planning stage and have continued since the dam became fully functional (Zhang et al., 2012). Especially the environmental and ecological effects of the TGD on the ecosystem of the Yangtze River and here especially its biodiversity, have been of increasing concern in recent years (Wu et al., 2004, 2019). The construction of the dam and its reservoir has implications on the entire river system, both upstream and downstream (Fu et al., 2010), as well as associated wetlands, floodplains and terrestrial systems (Wu et al., 2004). Quite a number of studies have been carried out looking at the environmental effects of the TGD on its faunal communities. Research observing the implications of the changed hydrological regime and movement of sediments and nutrients along the river in the TGD reservoir region, for example indicated an increase in densities/biomass together with a decrease in biodiversity of many macroinvertebrate taxa downstream of the TGD (Wu et al., 2019), similar to the effects of morphological lake shore alterations.

Very devastating effects were, furthermore, found for many fish species inhabiting the Yangtze River. The main reasons for the observed dramatic changes in different fish populations are explained by the obstruction of migratory routes, with no effective mitigation through construction of fish passes (Shi et al., 2015), habitat fragmentation, changing from lotic to lentic water in

Fig. 3 In this picture released by China's Xinhua News Agency, water flows out from sluiceways at the Three Gorges Dam on the Yangtze River near Yichang in central China's Hubei Province. Fount at: https://thehimalayantimes.com/world/china-blasts-dam-to-release-floodwaters-as-death-toll-rises—China's Xinhua News Agency—Wang Gang/Xinhua via AP.

impounded areas, and changes in hydrological flow regimes, especially in downstream reaches (Wu et al., 2004, 2019; Zhang et al., 2012). An example for these adverse effects of the construction of the TGD on fish populations is the drastic decline of catches of the four "major carps" (known as grass carp *Ctenopharyngodon idella*, silver carp *Hypophthalmichthys molitrix*, black carp *Mylopharyngodon piceus* and bighead carp *Aristichthys nobilis*), which naturally inhabited the middle and lower stretches of the Yangtze River. These commercially very important species grow and mature in the Yangtze River floodplains and migrate into the river between April and July to spawn, when temperatures increase and water levels rise during the flooding season. Larvae and juveniles enter the nursery areas in the flood plains again when transported downstream by the river flow (Zhang et al., 2012). Through the construction of the TGD, most of the natural spawning areas of the carps were lost and temperature and flow conditions changed, which resulted in a dramatic decline of the juvenile carp that had drifted into the floodplain below the TGD (Xie et al., 2007; Zhang et al., 2012). Negative effects of the changed hydrological regimes associated with the construction of the TGD were furthermore described for plant communities in the drawdown area of the dam (Wang et al., 2014). As a consequence of the hydrological alteration in the area, the number of vascular plant species in the Three Gorges reservoir declined noticeably from 175 to 127 after the full impoundment (Wang et al., 2014). The Yangtze River Dolphin (baiji; *Lipotes vexillifer*) was declared extinct in 2007 probably because of pollution, unsustainable fishing and a high shipping pressure in the river. The Three Gorges Dam is assumed to have added an additional pressure to the already highly endangered species, by further reducing its natural living space through the alteration of river flow downstream, and facilitating an increase in ship traffic along the Yangtze River (Wu et al., 2019).

Additionally, the impoundment of the 660 km long reservoir behind the TGD has almost certainly led to an increase of seismic activity in the region (Tang et al., 2019). After the filling of the reservoir in 2003, the number of earthquakes per year increased from approximately two per year to approximately 14 earthquakes per year after full impoundment of the reservoir in 2008, together with hundreds of landslides (Tang et al., 2019).

Despite providing water for drinking, irrigation and electricity, the TGD shows impressively the implications the constructions of dams and weirs can have on rivers, streams and associated floodplains. Dams are one of the most noteworthy anthropogenic interventions in the hydrological cycle (McCartney, 2009) and have (had) severe impacts on freshwater systems through the disruption of physicochemical and biological processes worldwide. Plans for new large dams continue, especially in tropical regions (Vörösmarty et al., 2010; Zarfl et al., 2015). In the planning and design of most already existing dams, potential environmental issues did not play a major role, but environmental awareness has led to more holistic planning and management of dams in recent decades in order to decrease the most damaging effects of dams. These should include, among other things, the implementation of effective fish passages in the design of all dams (big or small) to ensure river connectivity and migratory fish conservation.

Case study 4: Water level changes

Many lakes worldwide are experiencing changes or fluctuations in water levels, which severely affect their hydrological regimes and consequently their inherent natural faunal and floral communities (Baumgartner et al., 2008; Wantzen et al., 2008). Changes in water levels can be caused by actively abstracting water from the lake, for example for irrigational purposes or drainage. These anthropogenic changes to lake hydrology can be augmented further by temperature changes or other climate change effects (Coe and Foley, 2001; Coops et al., 2003). Excessive water abstraction from lakes together with changes in regional hydrological budgets will especially affect shallow and/or groundwater-fed lakes, as their hydrological budget is directly dependent on changes in groundwater levels.

A dramatic example of the influence of increased water consumption for irrigation and drainage and a grown water demand of a growing population on water levels is Lake Chad (Fig. 4). The Lake Chad Basin is a large, hydrologically closed drainage system in West Sahelian Africa (Coe and Foley, 2001). For the states of Chad, Cameroon, Nigeria, Niger, the Central African Republic and Libya the Lake Chad Basin signifies an important area both economically and environmentally, as it contains vast pasture and arable land together with rich fish stocks. The water levels of Lake Chad largely depend on the inflow from rivers, particularly the Chari/Logone River from the south and, seasonally, the Komodugu-Yobe River from the northwest, together with smaller tributaries and groundwater discharge (Lemoalle et al., 2012). Lake Chad and the Chari/Logone river system, which transports 90% of the runoff generated in the Lake Chad Basin, are significant water resources for the local multi-ethnic population of about 38 million people (GIZ, 2015). The lake itself is shared by Chad, Cameroon, Nigeria and Niger. It is situated 250 m above sea level and has an average depth of only 7 m. Owing to its natural monsoon climate and variable rainfall patterns together with its shallowness, Lake Chad has experienced natural seasonal and inter-annual water level fluctuations in the past. However, the warming climate and a general expanding desertification in the Sahel region have led to a dramatic decrease in minimum lake area of only 1350 km^2 compared with former average dry season extent of about 10,000 km^2 (Coe and Foley, 2001). Since the early 1960s the Northern Africa Sahel region has faced several devastating droughts, as prolonged rainfall events such as the monsoon rains, which typically occur between June and August, have decreased substantially (Coe and Foley, 2001). As the region becomes drier, the use of water, particularly for irrigation, is increasing (Coe and Foley, 2001). While agricultural water use has dramatically increased as a response to a drier climate and the discharge from the Chari/Logone river system has decreased by almost 75%, water levels of Lake Chad have been reduced enormously. Consequently, Lake Chad has shrunk in size by about 90% since the 1960s. The study by Coe and Foley (2001) on human and natural impacts on the water resources of the Lake Chad Basin suggested that, while climate variability controlled the fluctuating water inflow to the Basin and Lake Chad, water abstraction for irrigational purposes and drainage accounted for about 50% of the decrease in lake area since the 1960s/1970s. With a drier climate, the problem is expected to worsen in the years to come as the population within the Lake Chad Basin is growing and the water demand for irrigational use is increasing.

As a response to the ever-worsening situation in the Lake Chad Basin, in 1964 the intergovernmental organization Lake Chad Basin Commission (LCBC) was founded by the lake's bordering states Chad, Cameroon, Niger and Nigeria. The Republic of Central Africa joined the organization in 1996 and Libya was admitted to join the LCBC in 2008. The commission's main aim is to regulate the use of the waters of Lake Chad and the Lake Chad Basin for irrigational, farming and drinking water purposes and with regard to fisheries. It has the mandate to conserve natural resources, monitor and coordinate cross-border water projects, regulate and control water use and resolve disputes in the Lake Chad Basin region. As a part of this, the LCBC has also attempted to find ways to reverse the drastic decline in the size of the lake. Its mandate also includes advising member states on dealing with the effects of climate

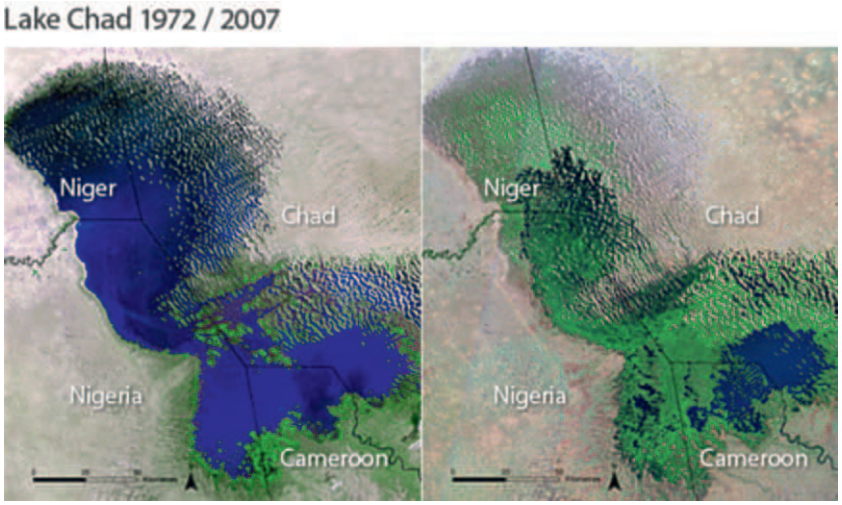

Fig. 4 The pictures show the area covered by Lake Chad in 1972 (left) and 2007 (right). Found at: https://ourworld.unu.edu/en/sucking-dry-an-african-giant—UNEP Atlas of Our Changing Environment.

change, particularly with regard to agricultural development (food security). There are several projects and action plans coordinated by the LCBC, which have the aim to conserve Lake Chad and its basin on different levels. The current "Lake Chad development and climate resilience action plan" aims at a climate-resilient, integrated ecosystem-based management of the Lake Chad Basin through implementation of intergovernmental policy, legal and institutional reforms, and investments that will improve the water quality and quantity of Lake Chad and protect its biodiversity, while sustaining livelihoods of the resident population (Lake Chad Basin Commission, 2016). Future management of the Lake Chad Basin under the LCBC should include proper assessment of further wetland conversions in the area. This should include the development of more integrated techniques for assessing ecosystem services across diverse stakeholder groups. This holistic management approach should ideally be accompanied by a total economic value assessment (Russi et al., 2013).

Conclusions

The examples of hydromorphological alterations described in this article affect inland waters in a variety of ways and occur globally. Consequences of hydromorphological alterations can be generalized as changes to the structure of surface waters, such as modification of shore structures, sediment/habitat composition, alterations of natural flow and discharge regimes by channelization or dams and changes in water levels through water abstraction, damming or climate change. As described above, altering the physical condition of surface waters can cause detrimental damages to ecosystems and has the potential to negatively impact the water's ecological status. In order to maintain the ecological integrity, biodiversity and quality of inland waters, a sustainable, holistic, ecosystem-based management is required to ensure the protection of freshwaters and their biodiversity worldwide.

Evolving Perspectives on Hydropower: Balancing Societal Benefits and Environmental Impacts

Chris Bradley, School of Geography, Earth and Environmental Science, University of Birmingham, Birmingham, United Kingdom

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Diadromous fish Fish that migrate between freshwater and marine environments.
Diatom Photosynthesizing algae with a siliceous shell.
Gigawatt (GW) Unit of power equal to 1000 MW (MW).
Hydropeaking Artificial water level fluctuations due to electricity generation at times of peak electricity demand.
Pumped storage plant Hydropower plant in which water is released from an upper reservoir to generate electricity during times of peak electricity demand; and water is pumped back to the upper reservoir using off-peak electricity.
Run-of-river Hydropower plant which raises upstream river levels slightly but does not significantly impede river flow.

Introduction

Over the past century free-flowing rivers on every continent have been progressively impacted by hydropower developments seeking to utilize a river's potential to generate renewable energy. Hydropower has become an increasingly important source of energy, enabling a reduction in fossil fuel use and reducing the costs of energy generation. Global installed hydropower capacity has been estimated at 1330 GW in 2020, with an increase of 21 GW over the year mainly in SE Asia (IHA, 2021). While only 22% of the world's total hydropower potential is thought to be currently utilized (Zarfl et al., 2015), hydropower developments have progressively impacted individual river basins with widespread environmental, social and economic consequences (Moran et al., 2018). This chapter summarizes the chronology of hydropower developments and reviews recent work that emphasizes the need to balance the potential benefits of new hydropower developments, against their environmental and socio-political impacts. This is a somewhat contested area: some argue that further developments of potential hydropower sites are essential if we are to achieve a significant reduction in greenhouse gas emissions and reach net zero. However, individual hydropower developments differ widely in their potential benefits and in the associated social and environmental impacts. Hence hydropower schemes require careful scrutiny to determine whether the benefits of individual schemes exceed the environmental and societal costs.

Currently, one third of all countries globally rely on hydropower for >50% of their energy requirements and hydropower contributes ~20% of total energy supply (IHA, 2021). These developments have made a substantial contribution in reducing fossil fuel use, but the environmental impacts include increasingly fragmented river catchments (Nilsson et al., 2005), reduced sediment transport (Habersack et al., 2016), changing river regime (Hecht et al., 2019), and loss of biodiversity. The effects on local communities are also difficult to quantify: in some cases surrounding areas have benefited from infrastructure improvements, employment and security of energy supply. However, Richter et al. (2010) suggest that between 40 and 80 million people have been directly displaced by dams (not solely hydropower), with as many as 472 million people affected downstream. While these estimates are more than 20 years old, and are for dams generally, they illustrate the need to consider impacts throughout the river catchment, where a succession of small or moderate dams or hydropower plants (HPPs) can have a cumulative impact comparable to that of a single large development. In many cases, this wider, holistic, perspective has been lacking. However, this is an opportune time to (re)consider the case for hydropower. Many plants, which were constructed during the peak years of hydropower development in the mid- 20th Century, now require upgrading and refurbishment, and elements of their design and operating procedures can potentially be revised to reduce their environmental impact and increase their efficiency.

A hydropower chronology

Current hydropower schemes are but the latest developments in a >2000 year process of harnessing water to generate power (Table 1). In Europe, one of the main legacies of the Greco-Roman empire was the water mill. These were used to produce flour, cut wood and stone, and iron working. While this was generally at a small scale, Passchier et al. (2020) describe a complex of 16 water mills at Barbegal, S France, with 2 lines of 8 mills arranged in parallel, and fed by a complex water distribution system (Fig. 1). This development, in the second century CE (Common Era), was not exceeded in scale until the 16th Century. More widely, throughout Europe, small free-flowing rivers were increasingly harnessed for water power: >5000 water mills were recorded in England in the Domesday Survey of 1086. These primarily used mill-stones to grind corn, but from the 12th Century onwards, they were used increasingly for industrial purposes: for wool and metal processing (fulling; lead smelting). The culmination of these developments were the large industrial complexes of the Derwent Valley Mills, Saltaire and New Lanark in the British Isles. Technology was imported from Italy to throw silk (1721) and Richard Arkwright harnessed water power for cotton production in a series of mills in the Derwent valley (Derbyshire, England) constructed between 1777 and 1782. These industrial developments were soon replicated in other countries, where conditions allowed, in (inter alia) North America, Germany, France and the Czech Republic.

While water power was soon superseded by other sources of energy in the industrial revolution, hydro-electric developments transformed river catchments globally through the 20th Century as engineering advances enabled larger rivers to be impounded, and with run-of-the river and pumped storage schemes providing more opportunities to generate electricity. One of the earliest hydroelectric power (HEP) developments, albeit on a relatively small scale, was at Cragside, N. England, where in 1879–1882 a Newcastle industrialist, William Armstrong, generated electricity using a small stream flowing through his estate. The first

Table 1 Historical timeline of hydropower developments.

Year	
300	Romans major water-powered mills
1000	Water mills widespread in Europe
1500	Water: major source of power for food processing (flour; corn), textile (fulling) and manufacturing (iron works)
1800	Water: drives the Industrial Revolution supporting urban and industrial development in upland valleys
1880	First Hydroelectricity schemes (Cragside, NE England; Salmon Leap Falls, N. Ireland)
1900s	Development & operation of hydropower scheme on the Niagara Falls with power transmission to urban centers (e.g., New York)
1930s	First 'mega' hydropower developments (e.g., Hoover Dam on the Colorado River)

Table 2 Selected 'mega' hydropower projects developed over the past century.

Year	*Dam*	*River*	*Generating Capacity*
1928	Hoover	Colorado R	2080 MW
1937	Bonneville	Columbia R	1242 MW
1942	Grand Coulee	Columbia R	6809 MW
1961	Volga GES	Volga	2671 MW
1964	Aswan High	Nile	2100 MW
1969	Guri	Caroni R	10,235 MW
1972	Iron Gates I	Danube	2281 MW
1976	Tarbela	Indus R	4888 MW
1984	Itaipu	Parana	14,000 MW
1984	Tucurui	Tocantins R	8370 MW
2008	Three Gorges	Yangtze	22,500 MW
2013	Xiluodu	Yangtze	13,860 MW
2016	Belo Monte	Xingu R	10,621 MW
2022	Baihetan	Jinsha	16,000 MW
?	Inga Falls	Congo	40,000–70,000 MW

commercial HEP station was commissioned soon afterwards, at Salmon Leap on the River Bush in N Ireland in 1883, which powered a local tramway. However, the Niagara Falls HEP scheme in N. America, developed between 1890 and 1910, was on a much larger scale and included long-distance transmission of the power generated to the city of New York >550 km away.

The Niagara development was the precursor to the hydroelectric power (HEP) 'mega-projects' which transformed many river catchments in the 20th Century (Table 2). These included a suite of HEP schemes developed by the Tennessee Valley Authority, and the construction of large dams on the Colorado, notably the Hoover Dam. These developments in the United States, were matched in the Soviet Union, by large HEP schemes on the Rivers Don, Dneiper and Volga as HEP developments were seen as providing opportunities to support and encourage economic development, and manage water availability with benefits for irrigation, flood control and drinking water supply (Zarfl et al., 2015). While the geographical distribution of these large HEP developments has changed in recent years (e.g., to China with the Three Gorges Dam on the Yangtze), the primary motivation for these schemes is largely unchanged, although the scale is much larger, and could be dwarfed by proposals to construct a series of 7 HEPs on the Congo River at the Inga Falls which could potentially generate between 40 and 70 GW of electricity.

Environmental impacts of hydropower

The proliferation of hydropower plants of varying scale has had widespread environmental impacts on physical, chemical and biological processes both within catchments, but also in coastal deltas and seas. While it may be difficult in some cases to attribute problems solely to hydropower development (given the many interacting anthropogenic modifications to rivers and catchments) in many rivers, the physical impacts extend throughout the basin, and >40% of global river volume is either moderately or severely impacted by fragmentation (Grill et al., 2019; Hoeinghaus, 2018) and 6% of European surface-water bodies have been affected by hydropower barriers (Schwartz, 2019), to the extent that only five free-flowing river reaches remain on the Danube (Habersack et al., 2016). Hydrophysical disturbances below impounded reaches are highly variable, depending upon the individual site, the catchment context, and the type of HPP (i.e., pumped storage, barrage, or run-of-river; Fig. 2; Lumbroso et al., 2014) but include the introduction of an artificial flow regime downstream (typically lower peak flows, reduced flow variability), hydropeaking (sharp increases and falls in river levels as storage plant release water during times of high energy demand), the interruption in sediment transfer and changing channel dynamics with evolving process-form relationships as described below (Petts and Gurnell, 2005). Individual reaches below dams may experience sediment starvation, leading to river bed incision, while there may be periods of aggradation elsewhere (e.g., during reservoir construction) due to reduced channel capacity and ability to transport sediment. For example, on the Yangtse, river reaches immediately below the Three Gorges Dam experienced increased channel erosion, due to reduced suspended sediment concentrations and the increased frequency of high flows; mid-channel bars downstream have been eroded, with lower water levels at low discharges (Li et al., 2019). These process-form relationships are complicated by wider changes in riparian vegetation and in the lateral connectivity between river and floodplain.

The hydromorphological implications of HPPs are widely evident in basins where hydropower developments are relatively mature (in Europe and N. America), but the potential implications of a similar density of HPPs in tropical catchments in S. America (the Amazon), SE Asia (the Mekong) and Africa (the Congo) have been highlighted only recently. Proposed hydropower dams in the Andean headwaters of the Amazon will impact the sediment, water and nutrient fluxes to the main stem of the river. In 2018, there were 142 hydropower plants (largely <50 MW) operating in the Andean tributaries, but a further 160 were in different planning stages, including several >100 MW (Anderson et al., 2018). The effects are likely to be particularly marked on riparian

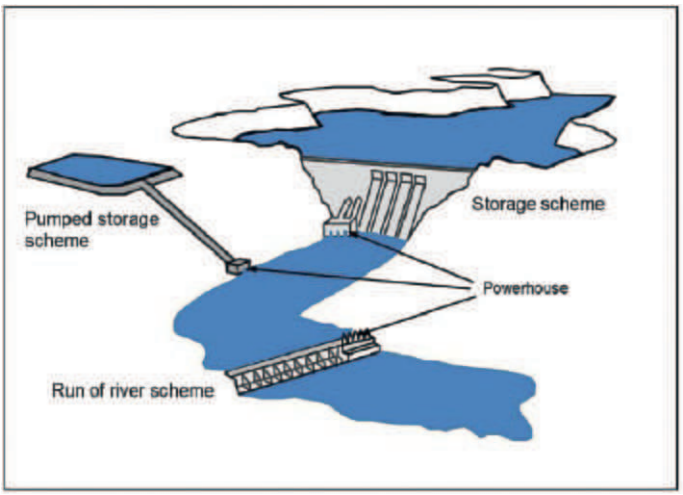

Fig. 2 Schematic illustrating the three main types of hydropower scheme. From Lumbroso, D, Hurford AP and Winpenny J (2014) Synthesis report: Harnessing hydropower. *Evidence on Demand*. Institute of Development Studies, p. 80. https://doi.org/10.12774/eod_cr.september2014.lumbrosoetal2.

forests in nutrient-poor catchments (i.e., igapó forest communities) downstream due to changing river flow dynamics and particularly any reduction in high river flows which would affect the annual flood pulse (Latrubesse et al., 2017). Similarly in SE Asia, 141 HPPs have either been constructed or planned on the Mekong (Hecht et al., 2019) resulting in reduced high (flood) flows which had formerly been responsible for the majority of river flow and sediment transport. If planned HPP proceed as anticipated, it is suggested that suspended sediment fluxes might fall by as much as 96% from their pre-development total of an estimated 160×10^6 t/year which could affect the rate of coastal and deltaic accretion downstream (Kondolf et al., 2014). The total volume of water storage within the basin is currently estimated as approaching 60 km^3 (Hecht et al., 2019) with substantial evaporative loss and modification to the catchment water balance.

Nutrient flows are similarly impacted by HPPs with nutrient retention through sedimentation above the dam, or gaseous emissions which may offset some of the environmental benefits of hydropower. The latter is particularly serious in tropical climates where emissions of greenhouse gases may be as much as 22 times higher than before dam construction, due to deforestation (Fearnside, 2015). Reductions in nutrient loads (N, P, Si) are facilitated by longer water residence times (Maavara et al., 2020), generally with P eliminated preferentially and with N:P ratios increasing in proportion to residence time. However, in catchments with residence times <50 days, Si may be eliminated by enhanced diatom activity. While reduced nutrient fluxes may be beneficial in eutrophic rivers, changing biogeochemical cycles can have widespread implications (Friedl and Wüest, 2002) with impacts on freshwater and marine food webs. In the Danube, for example, dam construction throughout the catchment led to a >60% reduction in Si transported to the Black Sea which led to a change in plankton species in the Black Sea and more frequent harmful algal blooms (Humborg et al., 1997) and a dramatic decline in what was formerly (<1970) a very productive marine fishery.

The consequences of hydropower development and limited connectivity are particularly marked for diadromous fish, such as sturgeon, houting, shad, and salmon, which migrate between freshwater and marine ecosystems (Duarte et al., 2021). Historical records indicate that there was a 90% decline in salmon stocks in NW Europe from the Early Middle Ages (450–900 CE) to Early Modern Times (~1600), with reduced fishing yields that tracked the development of vertical water mills on major rivers (Lenders et al., 2016). The salmon fishery was particularly impacted due to the degree to which water mills affected stream oxygenation, flow velocity, water depth and substrate. Cumulative declines of <99% in the salmon fishery have been suggested over this period, illustrated by the annual salmon catch at Montchaton, Normandy, France, falling from 300 to 350 in the 14th Century to 3–4 by the end of the 15th Century, and with an annual biomass loss across the Rhine catchment estimated to be >230,000 t (Lenders et al., 2016). More recently, in the Danube, the sturgeon has been particularly impacted by hydropower developments on the main stem of the river (Bănăduc et al., 2016) and even run-of-the river plants have the potential to impact local fisheries significantly (Bilotta et al., 2016).

In tropical catchments proposed hydropower developments have the potential to impact freshwater fish diversity: particularly species that are morphologically adapted for fast flowing, high gradient streams, which generally are amongst the first to be developed for hydropower. In the upper reaches of the Amazon, a decline in fish diversity has been linked to catchment fragmentation due to hydropower development (Anderson et al., 2018) as migrating fish are impacted by a combination of physical barriers, artificial fluctuations in flow and changing thermal regime. In such cases it is difficult to isolate the effects of changes in hydrology (due to hydropower operations) from the effects of reductions in suitable habitat and wider environmental degradation emphasizing the importance of holistic, basin-wide, approaches to assess the individual and in-combination consequences of hydropower developments.

The societal context of hydropower

The many environmental consequences of hydropower development are complex, often inter-related and site specific, but should not be considered in isolation from the societal benefits that these developments potentially offer (Biswas, 2004, 2012). Through much of the 20th Century hydropower offered a vision of tamed rivers, with improved infrastructure, increased (low cost) electricity production and improved flood control (Schulz and Adams, 2019). Many OECD countries have benefited from the availability of low-cost energy, which has enabled socio-economic development, and was considered (with dams) as one of 'the most essential aspects of man's attempts to harness, control and improve his environment' (Smith, 1971). Trefon (2016), for example, summarizes the potential for hydropower developments in the Congo to foster economic growth, notwithstanding problems with siltation and maintenance at the Inga I and II plants, constructed in 1972 and 1982. However, more recently perspectives on hydropower have been increasingly polarized with economists and engineers focusing on the economic benefits and development opportunities while environmental scientists highlight the negative impacts summarized in the previous section (Schulz and Adams, 2019). There are also concerns with social capital and the negative impacts on displaced people: 400,000 people are thought to have been affected directly in Africa (United Nations World Water Assessment Programme (WWAP), 2014) and the food security of many communities below HPPs have also been impacted by, for example, reduced fish or farming yields due to the effects of hydropower operations on water and sediment fluxes (Intralawan et al., 2018).

These problems, together with wider questions over the costs and benefits of individual hydropower developments, led to the development of the Hydropower Sustainability Assessment Protocol (HSAP) which summarizes best practice in balancing environmental, social, technical and economic elements in hydropower projects (IHA, 2018). The protocol provides key criteria that can be used to assess the sustainability of HPPs: from planning, through to implementation and operation. The funding landscape has also changed, as a result of lobbying by pressure groups, the need for detailed cost-benefit analysis and full environmental impact assessment. While some developments can circumvent these requirements, there is a widely recognized need for improved stakeholder engagement and social inclusion to ensure that the benefits of improved infrastructure and energy availability are realized. However, this pre-supposes that it is possible to balance objectively the environmental impacts of hydropower against the benefits that hydropower potentially offers to society. Here it helps to look separately at perspectives in countries where the technology is relatively 'mature', i.e., in North America and Europe, and in developing countries where there is unfulfilled hydropower potential, recognizing that in both cases innovative approaches to hydropower may reduce environmental impacts and/or increase the benefits to society.

Basins with a 'mature' level of hydropower development

In basins with a long history of hydropower development, there are relatively few free-flowing reaches, whether due to individual 'mega-projects' or chains of smaller plants. In these rivers, the challenges include: (i) how can the existing hydropower infrastructure be operated to maximize the opportunity to supply green energy; (ii) Is it possible to upgrade existing facilities to reduce environmental impacts; and (iii) Where relatively old HPPs come to the end of their operational life, is it possible to upgrade the facility, or is decommissioning potentially viable.

Hydropower is widely assumed to be central in our transition to a low carbon society, and Wagner et al. (2019) argue that pumped storage plants make a particularly important contribution in providing energy at times of peak demand. This requires more research on technologies, and operating procedure, to ensure environmental sustainability, and to manage the problems posed, for example, by hydropeaking. At the same time, there is a strong argument for systematic basin planning and integrated water resource management to look at basin-wide impacts of hydropower operations and their vulnerability to climate change (e.g., the potential for energy generation to be compromised by reduced water availability during drought). Where possible, environmental flows may also be prescribed to mitigate specific environmental impact [cross-reference to another chapter in the volume].

The potential to upgrade current HPPs so they conform to current standards is also a promising area to explore. This could include improved hydropower designs to allow fish passage, recognizing the limitations of current designs (e.g., of fish ladders; Fig. 3) which may not be as effective as originally intended (Moran et al., 2018). More fish friendly solutions are needed (e.g., Quaranta et al., 2020) to improve fish passage and hence fish biodiversity and abundance. In many cases, however, there may be no easy solution to enable continued hydropower operations and in recent years ~5000 dams have been removed in Denmark, Estonia, Finland, France, Germany, Italy, Portugal, Spain, Sweden, Switzerland and the United Kingdom. While the financial costs of dam removal may be considerable, it is generally accepted that these dams are either too expensive to upgrade, or are associated with unacceptable environmental problems, and dam removal provides the opportunity for river restoration.

Hydropower in less economically developed countries LEDCs

There may still be considerable potential for new hydropower developments on rivers in many LEDCs, which could potentially address the very real problems of limited availability of energy and water in some regions (e.g., the household electrification rate in Sub-Saharan Africa is the lowest in the world, averaging 42% in 2016) (O'Brien et al., 2021). However, there are many challenges including: (i) maintaining and upgrading current HPPs to ensure continued operation; (ii) assessing proposed new developments

Fig. 3 A fish ladder in SE Alaska. © Prof. Sandy Milner.

to ensure that their environmental and social impacts are fully quantified; and (iii) Exploring the potential to take advantage of new technologies to provide energy for local communities in remote areas with little environmental impact. Here, the difficulties are how to balance the opportunities provided by improved energy availability, with protecting the environment and ensuring that the development benefits (and costs) of hydropower are shared equitably.

It has been suggested that the projected benefits of many large dams were overly optimistic (World Commission on Dams, 2000) and HPPs require ongoing maintenance and investment to ensure that individual plants remain operational. The two operational dams on the Congo: Inga I and II were constructed in 1972 and 1982 respectively, with a generating capacity of 351 and 1424 MW, but both dams are only generating a fraction of their potential, because of maintenance and sedimentation problems, to the extent that half the turbines are inoperable (Trefon, 2016, p. 79). A wider review of the case to support the development of 12 large dams in Africa, including the Inga III dam on the Congo and the Grand Renaissance Dam on the Blue Nile, argues that the benefits of large dams in the past had been undermined by substantial cost over-runs, illustrated by costs to construct Inga I and II which totaled $1.1 billion, against an initial estimate of $250 million (International Rivers, 2015). While the 12 dams could potentially generate 15 GW of electricity, as many as 100,000 people would be directly affected, and key ecosystem services lost: the Fomi Dam in the Guinea highlands would impact the Inner Niger Delta wetlands in Mali; and the Congo Plume (freshwater discharged by the Congo to the Atlantic Ocean) would be impacted by the Inga III Dam on the Congo. There are also questions over the extent to which local communities would benefit, as the Inga III scheme envisages energy export to S. Africa and E. Congo with the construction of >3000 km of transmission lines. Accordingly, where hydropower developments do proceed, this should be within the context of basin-wide planning and taking stakeholder views into account, with an integrative assessment of environmental and social impact (O'Brien et al., 2021).

While there are questions over the costs and benefits of large hydropower schemes, smaller chains of HPPs may be equally problematic. Chaudhari et al. (2021) have highlighted the potential to use in-stream turbines harnessing the river's kinetic energy to generate power, suggesting that these systems could be used to generate ~63% of the energy supplied by HPPs on the Amazon. While this technology is still likely to have an ecological impact (Moran et al., 2018), it is more environmentally benign because it removes the need for water storage with its associated loss of riparian and floodplain habitat, thereby potentially stabilizing greenhouse gas emissions. There are wider opportunities though, to explore the use of small-scale hydropower plants, i.e., the so-called pico-hydro schemes generating <5 kW, operated by independent power producers. These have the potential to provide energy for remote communities, because they have relatively little environmental impact and do not require significant infrastructure and transmission lines. Pico-hydro schemes are particularly appropriate in mountain basins which, outside Europe such as in the Himalayas, have been described as one of the last frontiers for hydropower (Lord et al., 2021).

Knowledge gaps

- How can the existing hydropower infrastructure be managed most efficiently?
- How feasible is it to upgrade existing facilities to reduce their environmental impact.
- How can recent advances in hydropower technology be utilized to provide energy in remote areas with minimal environmental impact?

Conclusions

Hydropower has a relatively long history and has made a significant contribution to reducing the use of fossil fuels and greenhouse gas emissions. However, the scale and extent of hydropower developments over the past century has had widespread environmental and social impacts. These impacts are, to a large extent, site- and basin-specific. However, it is essential that the benefits and impacts of hydropower are fully quantified, to determine the extent to which we can continue to generate hydropower and satisfy stakeholder concerns, whilst preserving vulnerable ecosystems.

Hydropower in the Danube River Basin: Current Status and Emerging Challenges

H Habersack[a] and Chris Bradley[b], [a]University of Natural Resources and Life Sciences, Institute of Water Management, Hydrology and Hydraulic Engineering, Christian Doppler Laboratory for Advanced Methods in River Monitoring, Modelling and Engineering, Vienna, Austria.; [b]School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Free flowing reaches A river reach that is not impacted by downstream impoundments.
Hydrogeomorphology The inter-disciplinary study of the links between on the interaction between hydrological processes and landforms.
Hydropeaking Artificial water level fluctuations due to electricity generation at times of peak electricity demand.
Run-of-river Hydropower plant which raises upstream river levels slightly but does not significantly impede river flow.

Introduction

In this case study chapter, we summarize the current state of hydropower developments on the River Danube and the wider Danube River Basin (DRB). Over the past century, a widely distributed network of hydropower plants has been constructed throughout the Danube River Basin in response to a societal pressure to increase the proportion of energy requirements that are satisfied by renewable energy. Currently, across most of the DRB (with the exception of Germany, Hungary and Moldova), hydropower is the most important component of renewable energy production, contributing ~45% of the total electricity generated within the catchment (ICPDR, 2013a). However these developments, in association with river management, and wider climatic and environmental changes in the DRB, have contributed to a suite of impacts on the Danube, its tributaries and on coastal environments downstream. The situation is further complicated in the DRB by the wider political context. The basin is the most international river basin globally with a catchment that spans 19 countries.

The scale and complexity of the basin are such that the DRB exemplifies the difficulties in managing catchments sustainably: by ensuring water security and flood protection, whilst conserving biodiversity, and enabling navigation and electricity generation. While it is difficult to look at one of these pressures (i.e., hydropower) in isolation, the cumulative effects of hydropower developments have been the progressive loss of free-flowing river reaches, and the lack of continuity from the basin headwaters, along the main stem of the Danube and its tributaries, down to the Danube Delta. Over time, this has substantially changed the hydromorphology of the Danube and its tributaries, impacting the biodiversity of the river corridor (Hein et al., 2017), and contributing to reduced water and sediment fluxes to the Danube Delta and Black Sea downstream (Habersack et al., 2016; Panin and Jipa, 2002). Resolution of these problems requires new approaches to inter-disciplinary river science that consider the whole basin and encourage stakeholder engagement and knowledge exchange to identify realistic and sustainable solutions to current problems.

Hydropower in the Danube River Basin

Before summarizing recent hydropower plants developments in the DRB, it is essential to understand the wider geography of the basin which provides the context within which these developments have occurred. The River Danube is 2857 km long: flowing east from the Black Forest Mountains and discharging into the Black Sea where its mean annual discharge is ~6550 m^3/s (Sommerwerk et al., 2009). River flow fluctuates seasonally, reflecting variations in annual precipitation across the basin ranging from ~3000 mm in the West to ~500 mm in the East. The DRB extends over more than 800,000 km^2 of Central and South-Eastern Europe (Fig. 1). One third of the DRB is mountainous extending from Piz Bernina (4052 m asl) in the West and Peak Krivan (2496 m asl) in the North. The Danube flows through a series of basins and gorges: below the confluence of the Danube and the Morava, the river enters

Fig. 1 The Danube River Basin (Sommerwerk et al., 2009).

the Devin Gate below which the Danube forms an internal delta as it crosses the Pannonian Plain. Here the Danube is joined by the Drava, Tisza and Sava rivers which rise in the Southern Alps, the Western Carpathians, and the Julian Alps respectively. As a result, the flow of the Danube is strongly supported by flows generated in alpine areas. Prior to regulation, the Danube used to experience two floods in a typical year: the first in early spring due to snow-melt, and the second in early summer, reflecting peak runoff. Downstream the Danube flows through the 117 km long Iron Gate gorge in the Southern Carpathians before the river crosses the Romanian and Bulgarian lowlands and flows through the Danube Delta to the Black Sea.

The River Danube and its tributaries have been progressively managed from the 16th century onwards for navigation, flood protection, and increasingly over the last century, for hydropower (Habersack et al., 2016), and to the extent that today there is an extensive network of 44 hydropower plants on the Danube with a further 1610 plants on the Danube's tributary rivers (Hein et al., 2017). This includes ~646 hydropower plants in catchments of tributaries of the Danube in Bosnia and Herzegovina, Croatia, Montenegro, Serbia and Slovenia, and currently >1000 additional plants are planned, mainly along the Sava River (Huđek et al., 2020). Over the course of the 20th century, and following construction of the Kachlet dam on the Danube in Germany in 1927, there has been a rapid expansion in engineering works that sought to harness the potential of the basin for hydroelectric power. The consequence of these relatively recent developments is that hydropower plants are now widely, but unevenly, distributed across the basin reflecting the hydrological and geomorphological potential for hydropower in the DRB, as well as the recent political and economic history of countries within the basin (Fig. 2). Hydropower plants of ~100 MW capacity account for between 50% and 80% of the total installed capacity in Austria, Bosnia-Herzegovina, Serbia, Slovakia, and Romania (ICPDR, 2013b), while plants smaller than 1 MW make a relatively small contribution to the total installed hydropower capacity (<10% for Austria, Germany, Croatia, Bosnia-Herzegovina, Moldova, Romania, Serbia, Slovakia, and Ukraine).

The ongoing development of hydropower, coupled with extensive channel re-engineering for navigation and flood control, have extensively modified the river course and floodplain connectivity to the extent that at present >1100 km of the length of the Danube is impounded by 78 barriers, the majority of which are situated at points where there is the greatest change in channel gradient (Fig. 3A). In Austria and Germany, chains of hydropower plants impound 269 km of the Danube (77% of the Austrian Danube). The largest hydropower scheme, at the Iron Gates, is situated at a point where there is a step change in channel elevation: Iron Gates I impounds 310 km of the Danube up to the city of Novi Sad (11% of the total length of the Danube; Fig. 4) and the two Iron Gates plants (I and II) together have an installed capacity of ~2840 MW. Further large hydropower plants are situated progressively upstream on the Danube: Gabčíkovo (720 MW) which impounds 17 km of the middle Danube downstream of Bratislava and Freudenau (172 MW) a run-of-the-river plant on the Danube at Vienna.

Environmental implications of hydropower schemes

While the increasing potential to generate renewable energy has been beneficial, these hydropower developments have had many environmental consequences in the DRB. The extensive chains of dams along the Danube and its tributaries have wide-ranging hydromorphological consequences including changes in runoff, in the water balance, sediment transport and river morphology.

Over the period 1950–80, 69 reservoirs were constructed in the DRB with an estimated total storage volume of 7300×10^6 m^3 (Habersack et al., 2013). The Danube itself is now split into many impounded reaches and only five free-flowing river reaches remain on the main stem of the Danube. The longest of these extends from the Iron Gates 2 hydropower plant to the Black Sea coast and the second longest free-flowing reach lies in the Hungarian Plain. In Austria only two free-flowing reaches remain: 48 km between Vienna and Bratislava and 33 km in the Wachau area, while in Germany the last free-flowing reach on the Danube is between Straubing and Vilshofen. Impounded reaches which are affected by dams downstream typically experience increased water temperatures, a decrease in dissolved oxygen and sediment deposition (Grill et al., 2019). Below dams, hydropeaking (described by the ratio of Q_{max} to Q_{min} over a given time period) may be problematic. Hydropeaking is associated with an increase in hydraulic stress downstream, with impacts on benthic fauna. At least 44 water bodies in the DRB are affected by hydropeaking, in some cases with daily river level changes of >1 m (ICPDR, 2013a).

The impoundments have significantly affected water and sediment fluxes through the basin: with increased sedimentation in impounded reaches, and changing sedimentary composition downstream. Coarse sediment, derived from alpine headwaters is progressively lost through sedimentation in impounded reaches, to the extent that in the Danube below Budapest, there is relatively

Fig. 4 The Iron Gates (I) dam on the River Danube(© www.all-free-photos.com).

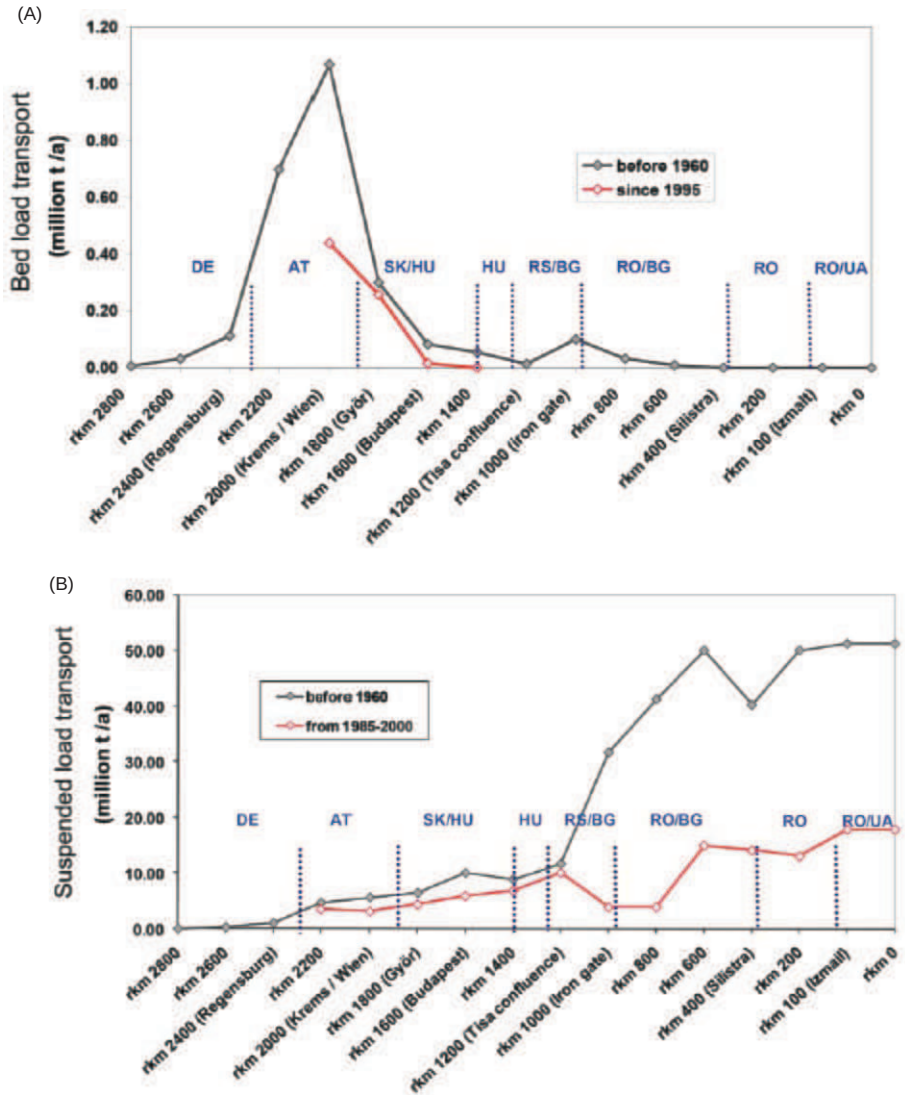

Fig. 5 Bedload (A) and suspended sediment (B) transport in the Danube River: prior to 1960 and from 1985 to 2000. From Habersack H, Jager E, and Hauer C (2013) The status of the Danube River sediment regime and morphology as a basis for future basin management. *International Journal of River Basin Management* 11(2): 153–166.

little coarse sediment transport (e.g., gravel), unless contributed by major tributaries. This is illustrated dramatically by reductions in sediment fluxes in some of the upper tributaries of the Danube. In Austria/Germany, for example, sediment fluxes on the River Lech at its confluence with the Danube have fallen from 180,000 t/year prior to hydropower development, to effectively zero, and at the Danube's confluence on the River Inn, from 540,000 to c. 180,000 t/year (Habersack et al., 2013). Elsewhere, on the Drava River over the period 1918–1967, hydropower developments have contributed to reductions in sediment fluxes from 9.5×10^5 to 4.1×10^5 t/year, primarily due to the trapping of bed-load, with extensive hydrogeomorphological changes as discussed below (Kiss and Andrasi, 2017). The sedimentary load of the Danube has also fallen from an estimated 1.7×10^6 t annually at the beginning of the 19th century, to about 300,000 t in 1995 (Schwarz et al., 2008), with marked changes in bedload and suspended sediment transport (Fig. 5A and B). Sedimentation in impounded reaches upstream of dams accounts for between 25% and 30% of the sediment load of the Danube that would formerly have been transported to the Danube Delta and the Black Sea.

In the Lower Danube, the suspended sediment load is estimated to have fallen from 876 kg/s (1971–1984) to 790 kg/s (1950–1971) and then 311 kg/s (1985–2000) (Bondar and Teodor, 2008). These trends are, at least partly, due to the construction of the Iron Gates I and II dams. Iron Gates I was completed in 1972, and is estimated to retain >30% of the total sediment input from upstream, and as much as 44% of the suspended sediment, with sediment retention over the 22 years from 1972 to 1994 of 325×10^6 t by the Iron Gates I dam alone, filling an estimated 10% of the reservoir capacity (Klaver et al., 2007). With an approximate capacity of 2.1 km^3 (2.1×10^9 m^3) this suggests that the indicative volume of sediment stored within this impounded section alone is $\sim 2 \times 10^8$ m^3, which is likely to include some sedimentary units with high concentration of, inter alia, Al, Cr, Fe & Mg from historic mining, industry, and sewage (Szabo et al., 2020), as well as micro-plastics. The consequent reduction in sediment transport downstream has led to channel incision in sediment-starved reaches immediately below dams, and increased coastal erosion on the Black Sea coast where the Danube Delta is experiencing rates of coastal retreat in some areas that is approaching 20 m/year (Panin and Jipa, 2002). In addition to changes in the volume of sediment transported annually in the DRB, the timing of sediment fluxes has also changed: during floods a strong remobilization of sediment from reservoirs occurs, whereas previously sediment transport was more evenly distributed through the year (Nachtnebel et al., 2004).

Throughout the DRB, river management has led to progressive hydromorphological changes at different scales: ranging from the whole catchment, to the individual river reach/section, and extending down to the characteristics of specific sites. The observed changes reflect changes in the equilibrium between hydraulic processes and the fluvial morphology with multi-dimensional impacts that extend throughout the basin. These include changes in instream structures: with the loss of gravel bars in upstream river reaches, above HPPs, and changes in the form of sand bars downstream. On the Drava, below HPPs, Kiss and Andrasi (2017) noted changes in flood dynamics, decreasing river stage, and hydropeaking (for example, with 1–1.2 m high flood peaks in reaches below the Donja Dubrava hydro-electric power plant). Since the 19th century the river has evolved from a state in which the river was characterized by a multiple channel system in its upper reaches (either braided or anastomosing) and a single, meandering, channel downstream, to a predominantly single thread river characterized by river incision below impoundments.

Over the period of rapid hydropower developments, the DRB experienced widespread ecological changes and a decline in biodiversity. While these may, in part, reflect wider anthropogenic impacts (pollution, navigation, flood control), there are recorded instances of biological invasions tracking hydropower developments in the DRB (Fig. 3B; Hein et al., 2017). This illustrates the complexities of biotic and abiotic interactions following dam construction, which are difficult to quantify and manage. There has been widespread morphological degradation (less variability in flow, increased sedimentation) although it is difficult to attribute specific ecological changes that have been observed to a single cause (such as hydropower developments) given the extent to which the basin is responding over different time-scales to multiple stresses. However, anadromous (migratory) fish, such as the sturgeon, have been particularly affected because they live in saltwater, but return to freshwater to spawn (Bănăduc et al., 2016). Rheophilic fish (living in flowing waters) have also been impacted by river regulation, the loss of floodplain habitats in impounded reaches, and the disconnection between rivers and floodplains (Waidbacher et al., 2018). These problems highlight the need for improved understanding of ecosystem functioning, but there are also challenges in how to enable fish migration (for example by retrofitting fish bypass structures to impoundments), maintaining river bed substrate (for spawning), and determining appropriate ecological flows to mitigate the effects of artificially stabilized flows in impounded reaches. In response, the Sturgeon 2020 action plan calls for no new hydropower plants in river reaches where sturgeon may have been present in the past. Environmental Impact Assessments of any new hydropower plants are also required to take account of sturgeon migration and habitat requirements (Sandu et al., 2013).

The future of hydropower in the DRB

These challenges illustrate some of the wider problems in how to reconcile the benefits of increased renewable energy generation by hydropower (such as reduced greenhouse gas emissions), with the resulting environmental problems. A report by the ICPDR on sustainable hydropower in the DRB highlighted the need for holistic and basin-wide assessment of hydropower development with appropriate mitigation of past engineering works (ICPDR, 2013b). This requires a balance between environmental, social and economic impacts, but in some parts of the DRB the potential for hydropower is already fully realized. Attention should, therefore, be focussed on specific problems, such as how to improve sediment management, and on investigating the potential to apply new technical solutions, such as using hydrokinetic energy conversion systems, that are environmentally more benign, as well as on fish bypass structures (Quaranta, et al., 2020). ICPDR (2013b) indicate that where the development of new HPPs is permitted, there

should be strict criteria for minimum ecological flows, limited hydropeaking, and in-stream structures should be designed in order to maintain upstream/downstream continuity.

At present, hydropower developments in the DRB include work on existing power plants to increase capacity: for example, 68 MW of additional capacity was installed on the run-of the river Iron Gate I plant on the Danube in 2017, and currently there are proposals to extend the Iron Gates II plant from 270 to 320 MW. However, throughout the basin as a whole, there are only limited opportunities for new HPPs, except in the Balkans and in some headwater reaches on tributaries of the Danube. In Serbia, hydropower generation is currently c. 10,000 GWh/year against a potentially feasible total of 17,000 GWh/year (Panic et al., 2013). The focus is on construction of small hydropower plants (<10 MW), potentially re-using sites of former water mills. However, in some cases, construction costs are high, and there are constraints in minimizing environmental impacts downstream. Elsewhere in the DRB, in Romania for example, 26% of the electricity generated is from hydropower, with the first (small) plant constructed in 1884 at Peles Castle (Nastase et al., 2017). A total of 115 HPPs were constructed over the period 1950–90 but, as in Serbia, the focus is on small scale HPPs with a total, estimated, micro-hydraulic potential of 1600 MW. However, a chain of 19 HPPs have been developed, largely since the 1960s along the Olt River, a south-flowing tributary of the Danube with headwaters in the Carpathian Mountains (Dragomirescu, 1993). There are also proposals to develop new HPPs that would impact Natura 2000 sites at Defileul Jiului National Park and Rastolita.

Ultimately, the extent to which future hydropower developments are allowed to proceed will depend upon political and social factors. Hydropower remains an essential component of the energy mix as part of the transition to a lower carbon society, and on-going research is seeking to reduce the environmental impacts of individual developments. For example, hydro-kinetic energy conversion systems (HKEC), such as the Strom-Boje turbine on the Austrian Danube, have the potential to generate electricity from free-flowing waters without impounding a river (Wagner et al., 2019). Some HPPs, particularly pumped storage schemes, also have considerable potential to store energy, and thereby alleviate problems of fluctuating energy demand and supply. However, a supporting economic justification is essential, given potential cost overruns on large projects, including pumped storage facilities. Aside from questions related to unexploited HEP potential, which is relatively low across much of the DRB, more work will be needed to assess old HPPs as they approach the end of their operational life and to determine whether to remove or renew individual plants. Inevitably however, improvements in sediment management will be required whether at a catchment-scale (to reduce erosion and hence sedimentation in impounded reaches), in reservoirs (sediment removal) or in relation to flow hydraulics and sedimentation immediately above dams (Hauer et al., 2018).

Additional areas of concern include the impacts of climate change and increasing water use (Lehner et al., 2005) which will affect the functioning and efficiency of HPPs. For example, a severe drought in 2003 substantially reduced hydroelectricity generation in Austria, leading to the lowest annual HEP production since 1955. HEP generation in the DRB is subject to additional uncertainties relating to climate change: Koch et al. (2010) suggest that, under the IPCC A1B scenario, hydropower generation in the basin may potentially decrease by 2% between 2011 and 2035, and by as much as 11% between 2036 and 2060. These estimates largely reflect changes in precipitation, and flow regime through the basin. The impacts will be compounded by changing sediment dynamics, possibly with increased fine sediment deposition. Hence the benefits of operating HPPs, and their further development, must be balanced against potential environmental impacts as "with every new dam, additional environmental challenges emerge, and there are often contradictory energy and environmental targets" (Wagner et al., 2019). This illustrates the need to look at new ways to advance the scientific base for river basin management, and to ensure that the individual and cumulative effects of current developments are fully quantified.

Conclusion

The Danube River has been progressively impacted by hydropower developments that extend throughout the basin. At present only five free-flowing reaches remain on the Danube itself and hydromorphological processes have been impacted throughout the basin. While the basin is now relatively "mature" with respect to hydropower, many small hydropower plants have been proposed in the South and East of the DRB, and there are questions over how the basin might be managed to reconcile the need for continued hydropower generation, with the individual and cumulative environmental impacts of HPPs, throughout the basin.

Glossary

Flexibility (of the power system) The extent to which a power system can modify electricity production or consumption in response to expected or unexpected variability.

Hydraulic stress The measure of the internal force per unit area acting on liquids. In hydropeaked rivers, flow ramping leads to an increase of hydraulic stress for aquatic organisms, often facilitating involuntary downstream displacement (drift) or encouraging them to colonize shoreline areas in the ramping zone that will later fall dry, leading to stranding if organisms are not capable to follow receding water levels.

Hydropeak diversion power plant A hydropower plant that aims to prevent artificial flow fluctuations from occurring in the residual flow stretch created by the construction of a diversion weir.

Hydropeaking The discontinuous release of turbined water due to fluctuations of energy demand. Synonyms include *flow ramping*, *rapid flow fluctuations* or *artificial (sub-)daily flow alterations*.

Pumped-storage power plant Storage power plant which, in addition to turbines, also has electric pumps that enable energy storage by pumping up water to a higher reservoir for later hydropower use.

Ramping zone River area that is exposed to periodic wetting and drying due to fluctuations in water level caused by hydropeaking.

Re-regulation or compensation basin An artificial reservoir below the hydropower plant that retains turbine outflows to reduce hydropeaking intensity in the downstream river section.

River morphology The morphology of a river refers to the patterns and changes in river channel size, shape and bed material over time. It depends on the composition and erodibility of the bed and banks, the availability of sediment, the transport rates in relation to flow intensity, and riparian vegetation. Human activities such as hydropower affect river morphology by altering one or more of these elements and processes, and the equilibrium between them.

 https://doi.org/10.1016/B978-0-12-819166-8.00171-7

Run-of-river hydropower plant Hydroelectric power plant with limited water storage capacity where water is released at roughly the same rate as the natural flow of the river.
Sediment transport The movement and transfer of solid particles (from clay and silt to sand, gravels, and boulders) reacting to the shear forces exerted by a fluid (i.e., water) on the earth's surface, in particular regarding particle mobilized from the erosion areas (catchment's headwaters, river bed, slopes, landslides, etc.) through the fluvial network until distal deposition zones (deltas, estuaries, coasts).
Storage hydropower plant Hydroelectric power plant that stores water in a reservoir and converts the energy of the water into electricity when needed.

Introduction

The energy production scheme inducing 'hydropeaking' was first described in the 1930s in Europe (Vibert, 1939), and is now found throughout the world. Hydropeaking operations are defined as rapid and frequent changes in river flow to optimize hydropower operation (Widén et al., 2021). This rapid operation mode is closely linked to energy markets, which can exhibit quick shifts between production and demand, even changing at sub-daily scales. Fluctuations in energy availability and demand, therefore, directly translate into changes in turbine outflows to ensure grid stability, while generating highest profits (Olivares et al., 2021).

Hydropeaking comes with environmental costs, causing high variability of river flows on a daily or sub-daily basis in the receiving waterbodies. Hence, hydropeaking operations transform a river's hydrological signature and modify morpho-sedimentary dynamics, typically altering the downstream river ecosystem—to an extent that hydropeaking is regarded as one of the most significant impacts downstream of hydropower plants (Hayes et al., 2019).

The ecological effects of hydropeaking have been examined in a growing body of literature, and mitigation options, including dam operational changes and structural arrangements, are considered. This chapter builds upon the current knowledge to provide an overview of hydropeaking processes, effects, and mitigation. In particular, it aims to illustrate how the drivers of peaking-power production and the associated pressures are linked to river ecosystem structure, function and integrity, with a focus on hydro-ecological relationships. Finally, the chapter seeks to provide a process-based overview of mitigation measures from a river- and energy-grid-specific perspective (Fig. 1).

Drivers and pressures of hydropeaking: From a rising demand for renewables to artificial flow fluctuations

Pressing issues such as climate change, fossil fuel resources depletion and decommissioning of nuclear power plants call for an energy transition towards a low-carbon economy. Within this context, hydropower construction is on the rise (Zarfl et al., 2015). Indeed, hydropower is the only system that currently exists to store energy effectively, making up 99% of the global electricity storage capacity (World Energy Council, 2016). Also, hydropower is considered a mature technology that contributes to climate change mitigation by constituting a fundamental building block of today's energy systems. The last decade saw a sharp rise in renewable energy production, with wind and solar sources being increasingly developed (Berga, 2016). Energy production through wind and solar technologies is, however, very variable, but combined with storage hydropower, it can balance out irregularity in the system and supply peak load. These renewable energy sources complement each other well, particularly considering that hydropower from large reservoirs is to date the only reliable method of flexibly producing electricity—besides fossil fuels (Fig. 2).

At the hydropower facility, hydropeaking operations respond to market demands by quickly turning their turbines on (start of production) and off (stop of production). Start-stop operations can occur within minutes and they are difficult to predict in today's de-regulated energy market. In the future, hydropower production will have to increasingly buffer the inevitable energy grid

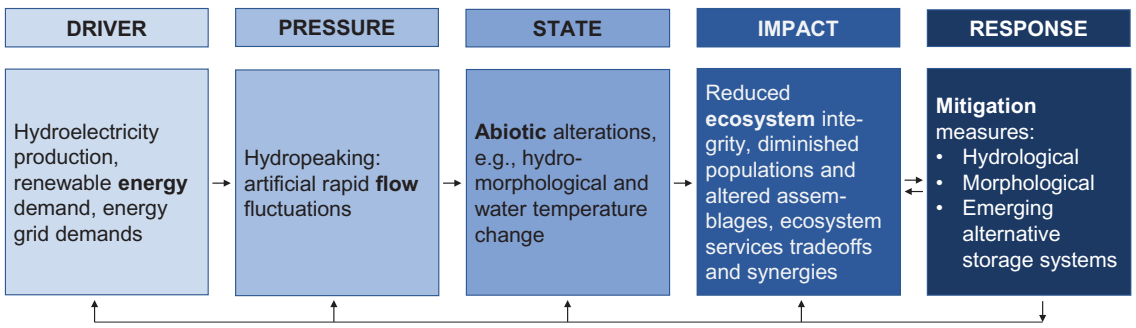

Fig. 1 A conceptual Driver-Pressure-State-Impact-Response (DPSIR) framework for hydropeaking research and management showing causal links and feedback loops.

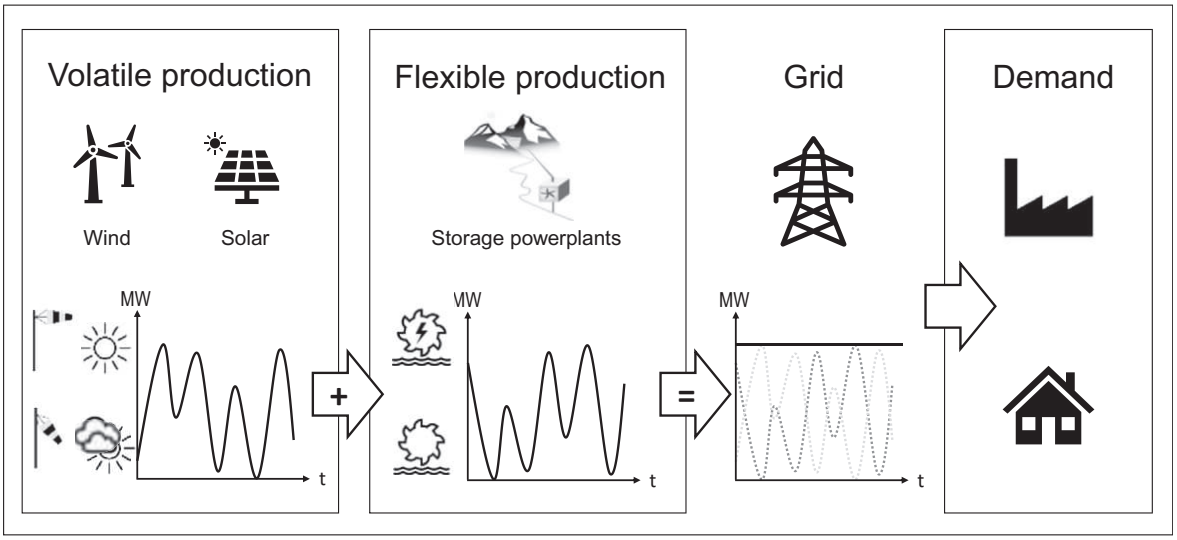

Fig. 2 Hydropeaking power production plays a key role in energy systems with increasing shares of renewables. Due to its flexibility, storage hydropower plants (and other flexible sources) can buffer volatile or intermittent energy sources such as wind and solar, thereby ensuring grid stability and security of supply—a systematic sketch.

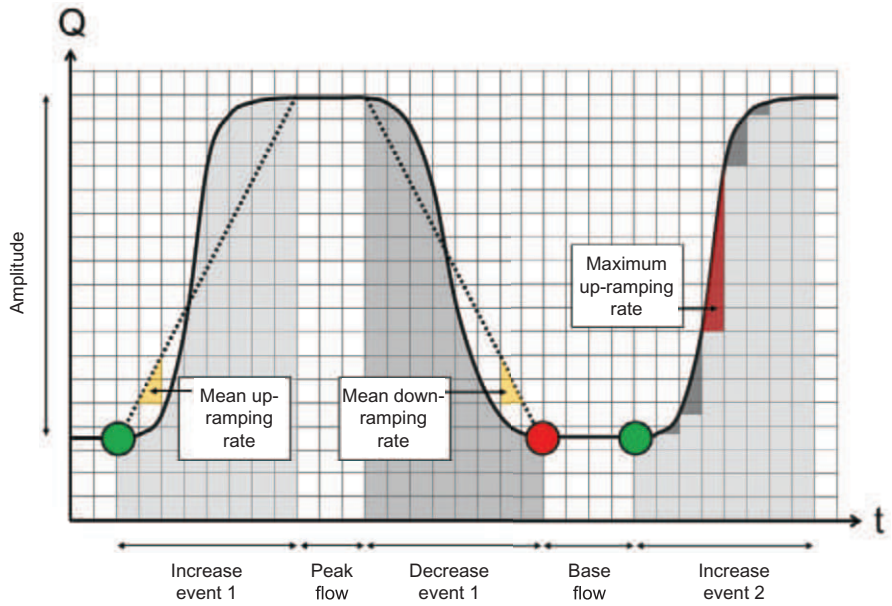

Fig. 3 A scheme of a hydropeaking hydrograph, linking operation start (green circle) and stop (red circle) to the flow regime components: peak amplitude, mean and maximum rate of change during up- and down-ramping, and peak flow or baseflow duration. The frequency and timing of hydropeaks (not illustrated here) describe how often and when (season, time of day) such flow events occur in a river. Modified after Greimel F, Zeiringer B, Höller N, Grün B, Godina R and Schmutz S (2016) A method to detect and characterize sub-daily flow fluctuations. *Hydrological Processes* **30**: 2063–2078. doi: 10.1002/hyp.10773.

fluctuations caused by intermittent renewable energy sources such as wind or solar. In essence, this current and future key function of the hydropower industry is linked to its capability of running hydropower turbines under peak-load conditions and shutting them off during phases of low electricity demand, possibly increasing hydropeaking events (Fig. 3). Indeed, such production schemes not only answer well to market demands but also constitute the backbone of the electricity production of mountainous countries such as Switzerland, Austria, Norway, and Sweden.

In addition to storage hydropower plants, also run-of-river hydropower plants may run a hydropeaking scheme, albeit at lower ranges between minimum and maximum production. A special sub-category of peak-operating hydropower plants are pumped-storage facilities that pump water to reservoirs at higher elevations during periods of low energy demand or costs. Once

the demand rises again, the pumped water is released and used to run the hydropower turbines (McManamay et al., 2016; Greimel et al., 2016). Moreover, other human activities can also cause hydropeaking-like conditions, e.g., manipulating gate structures, discharging effluents of wastewater treatment plants, or withdrawing river water for agricultural irrigation.

Hydropeaking hydrology principles

The hydrology of hydropeaked rivers differs from natural river hydrology in two distinct ways. Firstly, reservoirs store water (i.e., incoming river flow) to release it later when needed. Depending on their size, they can either cut off flood peaks (smaller reservoirs) or completely eliminate small and large floods (larger reservoirs). Such flow regulation results also in a homogenization or even total inversion of the seasonal flow regime downstream from the dam (Fig. 4A). Secondly, hydropeaking turbine operations, triggered by peaks in energy demand, result in rapid and often sudden flow changes which are not typical in natural river systems. Such operation schemes entail unnatural flood events in the downstream river section during peak-flow operation. During the shutdown, no or only little water remains in the river (Widén et al., 2021). In between these two flow scenarios, river levels rise (up-ramping) and drop (down-ramping) fast, thereby increasing the rate of change between flows of certain magnitudes (Figs. 3 and 4B–C).

These hydropeaks can be distinguished from natural flow fluctuation events by different intensity parameters such as the five flow regime components commonly used to describe river flows on various temporal scales (Poff et al., 1997). These flow regime components are flow amplitude or ratio, rate of change (also called ramping rate), peak frequency, event duration, and timing. For example, hydropeaking waves exhibit much faster ramping rates than flood waves occurring from rainfall or snow-glacier melt. Similarly, on a daily basis, hydropeaks also entail a higher baseflow: peak flow ratio, peak amplitude, and a shorter peak flow duration than natural flow fluctuation events. Moreover, the different stages of a hydropeaking wave—up-ramping, peak flow, down-ramping—are directly linked to the hydropower operational mode (Fig. 3).

The panels show differences (A) in annual river flows, weekly river flows (B) in summer and (C) in winter, and weekly water temperatures (D) in summer and (E) in winter. Data resolution: 1 h. Data source: Casas-Mulet R, Saltveit SJ and Alfredsen KT (2016) Hydrological and thermal effects of hydropeaking on early life stages of salmonids: A modelling approach for implementing mitigation strategies. *Science of the Total Environment* **573**: 1660–1672. doi: 10.1016/J.SCITOTENV.2016.09.208.

Effects of hydropeaking

Hydrological regime alterations

Hydropeaking completely transforms the hydrological characteristics of a river on an annual, seasonal (Fig. 4A), daily and sub-daily time scale (Fig. 4B and C). In Europe's mountain rivers, for example, hydropeaking is most pronounced during winter when high peaks of energy demand—resulting in high-intensity hydropeaking—occur during the low flow period when runoff is held back in the form of snow and ice cover. Daily fluctuations of such magnitude only occur rarely and at specific times in free-flowing rivers, and with smoother ramping rates. Regarding peak frequency, glacier-influenced rivers can experience around 100 days per year with significant melt-events; but in hydropeaked rivers, peaks can occur even more frequently, for example, more than 300 days per year in Alpine rivers of Austria (Greimel et al., 2016), although this number can be quite variable—depending on the region, river, or season. In California rivers, for instance, more peaking generally occurs during the dry season than during the wet season. Also, drought years feature increased hydropeaking frequencies over non-drought years (Li and Pasternack, 2021).

Overall, such daily or sub-daily patterns of rapid flow fluctuations are typical of many storage hydropower plants and run-of-river facilities. In addition to characterizing hydropeaking stretches through analyses of single gauges, it shall be noted that flow parameters such as peak ratio, amplitude or ramping rates change along a river's course, underlining the necessity to also incorporate longitudinal viewpoints into more holistic assessments. Due to water retention effects, flow parameters such as peaking intensity usually reduce in the downstream direction. Often, the first few kilometers downstream from the turbine outlets feature the highest hydropeaking intensities. However, the peaks can often still be measured up to 40 km or further downstream of the tailrace (Moog, 1993).

Thermopeaking: Water temperature changes due to hydropeaking

Artificial reservoirs exhibit seasonally different temperatures and tend to form distinct thermal layers during warm and cold weather at the surface, through the water column, and at the bottom. Under such conditions, the release of hypolimnetic (i.e., bottom-layer) water from stratified reservoirs can lead to abrupt sub-daily changes in water temperature in the receiving water body. The pattern of these temperature changes, called 'thermopeaking', is closely linked to hydropeaking (Zolezzi et al., 2011). In temperate regions, these thermal waves lead to a sharp decrease in the stream temperature in summer—cold thermopeaking (Fig. 4D)—and to an increase in winter—warm thermopeaking (Fig. 4E). Similar to hydropeaking waves, the magnitude of temperature changes decreases with the distance from the turbine outlet (Vanzo et al., 2016a) and often there is a decoupling of hydrological and temperature waves (Toffolon et al., 2010; Zolezzi et al., 2011; Fig. 4B–E).

Geomorphological alterations

It is known that changes in sediment transport and deposition alter fundamental characteristics of the streambeds over long time scales and that those changes can alter flow hydraulic conditions, which in turn enable feedback processes that may be critical in hydropeaked rivers (e.g., regarding marked changes in turbidity). Hydraulic changes alter the sedimentary structure and processes acting on the river bed; these include mobility and transport (Vericat et al., 2020), particle entrainment (López et al., 2020), and fine sediment deposition, infiltration (clogging) or porosity (Casas-Mulet et al., 2018; Hauer et al., 2019). Streambed morphology can have a key role in buffering the ecological effects of hydropeaking. Also, considering that sediment transport is fundamental in shaping river habitat, preserving morpho-sedimentary dynamics may aid in reducing undesirable effects derived from peak-energy production (Batalla et al., 2021).

In hydropeaked rivers, changes over time become particularly evident at the river reach scale, and morphological conditions entail direct ecological consequences. For example, as sediment size and bed topography influence the movement of water through the river bed, any changes related therewith entail implications for the delivery of oxygen to fish eggs and embryos that develop within the subsurface zone (Batalla et al., 2021). Overall, braided reaches are considered rather resilient to hydropeaking as they offer the highest habitat diversity and very limited base-to-peak variation, thereby entailing only low drift rates of macroinvertebrates. Alternate bars, in contrast, are extremely sensitive environments to drift, but they do offer safer regions from stranding (see section "Ecological impacts linked to flow alterations" for more information). In turn, transitional morphologies between single-thread and multi-thread offer the best eco-hydraulic trade-offs, according to hydraulic modelling approaches (Casas-Mulet et al., 2015a; Vanzo et al., 2016b). Sedimentary structure at the patch scale is critical to sustain species micro-habitats and it is also affected by hydropeaking (Table 1). However, the exact mechanistic causes of all these bio-physical alterations and feedback mechanisms remain unclear; hence more research is still needed in this direction, also as a sound base to support rehabilitation programs.

Other abiotic changes due to hydropeaking

Hydropeaking can further entail changes in dissolved gases saturation ('saturopeaking'; Pulg et al., 2016) or underwater sounds ('soundpeaking'; Lumsdon et al., 2018). Saturopeaking refers to fluctuations of gas saturation that follows the pattern of hydropeaking waves, and soundpeaking describes temporal variations in the sound frequency composition; the reader is referred to

Table 1 Examples of abiotic river attributes affected by continuous hydropeaking.

Attributes	*Effect*	*Causal processes*	*Scale*
Water turbidity	Increase	River bed resuspension, bank erosion	River reach, i.e., 10^2 m
Bed armor	Increase	Selective particle entrainment, fine sediment depletion (winnowing)	Particle and patch, i.e., 10^{-3}–10^{-1} m
Bed roughness	Increase	Selective particle entrainment	Patch to reach, i.e., 10^{-1}–10^2 m
Bank stability	Decrease	Unsteady wave heights, pore pressure variation, peak flow duration, discharge amplitude	Reach, i.e., 10^2 m
Water surface width	Highly variable	Sudden and repeated flow increases and decreases	Patch to reach, i.e., 10^{-1}–10^2 m

Moreira et al. (2019) for a concise overview on these topics. Recently, also 'carbopeaking' has been described as CO_2 leaks downstream of hydroelectric reservoirs (Calamita et al., 2021).

Ecological impacts

Hydropeaking is considered a key stressor in river ecosystems, altering habitat conditions, local food webs, and a suite of ecological processes. To illustrate flow-ecology relationships in hydropeaked rivers, the following section describes specific processes linked to separate flow parameters and phases of a hydropeak as described in section "Hydropeaking hydrology principles". Indeed, river biota shows distinct responses to those different flow alterations (Fig. 3; Table 2), which are also directly linked to morphological conditions and other physical changes (sections "Geomorphological alterations" and "Other abiotic changes due to hydropeaking").

The main biotic response variables used to quantify effects of hydropeaking are organism drift (involuntary downstream displacement) and stranding. Indirect effects include reduced food availability, decreased growth rates, as well as reduction in reproduction success and fitness. In time, these adverse effects lead to altered biotic community structures and changes in species composition in rivers subject to hydropeaking (Schmutz et al., 2015; Smokorowski, 2021).

Ecological impacts linked to flow alterations

Peak amplitude and base: peak flow ratio. Hydropeaked rivers experience fluctuating hydraulic forces. An increase in discharge leads to an increase in flow velocity and bottom shear stress. To cope with such quickly changing conditions, aquatic organisms such as macroinvertebrates and fish must invest significant amounts of energy to avoid detachment from the substrate or downstream displacement. Field and experimental studies have shown that this so-called involuntary or catastrophic drift of organisms is strongly linked to the amplitude and the flow maximum of hydropeaking events, which are key determinants of river hydraulics. The tolerance towards hydraulic stress differs between species and life cycle stages, which may exhibit varying sensitivity towards flow as well as different behavioral and physical adaptations to flowing water (Hayes et al., 2019; Smokorowski, 2021). Nevertheless, an increase in flow-related parameters, such as water depth and flow velocity, leads to increased physical stress acting on the animals and hampers vital processes, such as feeding. Further, the exceedance of hydraulic thresholds leads to detachment of organisms from substrates and downstream transport, which, if exceeding natural drift rates, depletes the populations (Schülting et al., 2016; Auer et al., 2017). Thus, tolerant species (which own morphological or behavioral adaptations like claws or the ability to quickly crawl into the interstices) often dominate over sensitive ones (e.g., surface-dwelling taxa that are exposed to flow changes) in hydropeaked rivers, which feature altered biotic community structures as well as reduced biomass (Moog, 1993; Hayes et al., 2021). Further, the flow amplitude is directly linked to the area of the dewatered shoreline, which in turn affects stranding of organisms. Flooding and drying of shore areas additionally lead to challenging conditions for riparian vegetation, since processes like germination and plant establishment are constantly disturbed. The water level and related parameters such as drag forces are directly linked to the flow amplitude and were found to be a key parameter determining plant survival. Under hydropeaking, species that own adaptations like adventitious roots are therefore favored (Bejarano et al., 2018, 2020).

Ramping rate. Another feature of hydropeaking waves are the fast rates of change in the flow increase and decrease (Figs. 3 and 4B–C). There is evidence that the up-ramping rate is significantly linked to stream organism responses: fast flow increases reduce the time response for seeking shelter, thus leading to increased drift rates of aquatic organisms when hydraulic conditions exceed tolerance thresholds (Schülting et al., 2019; Smokorowski, 2021). The decrease of discharge during a hydropeaking event plays a minor role regarding downstream drift. However, down-ramping strongly affects the risk that aquatic organisms strand on previously inundated areas that fall dry as water recedes back into the main channel. This phenomenon is especially relevant for fish (e.g., Young et al., 2011; Auer et al., 2017) but has also been documented for macroinvertebrates. As a general rule, the faster the down-ramping rate, the higher the stranding risk as animals fail to conduct timely lateral shifts with the receding water table. Fish larvae, in particular, are at greater risk of becoming stranded. On the one hand, larvae are still weaker swimmers; on the other hand, fish larvae inhabit river areas especially prone to drying out or being cut off from the river after a hydropeak (Greimel et al., 2018b;

Table 2 Summary overview that links hydropeaking flow alterations to abiotic properties, ecological processes and impacts, and describes associated mitigation options.

Flow parameter	*Abiotic effects/change in state*	*Ecological process*	*Ecological impact*	*Response: mitigation recommendation*	*Key references*
Peak amplitude, flow ratio, magnitude	Change in hydraulic forces Change in water level and wetted width Increased (sub-) daily maximum flow magnitude Substrate mobilization/ scouring Decreased (sub-) daily minimum flow magnitude Fine sediment deposition, clogging of gravel bars	Habitat shifts (to refugial habitats) Hydraulic stress Downstream displacement of fish and macroinvertebrates (catastrophic drift) Scouring of algae from the substrate Inhibition of germination and growth performance Fish (egg) damage and macroinvertebrate removal Soil moisture deficit and water stress for plants Desiccation or freezing of fish eggs or macroinvertebrates Restricted fish movements Reduction of suitable aquatic habitats and oxygen supply, habitat loss within interstices	Increased mortality Reduced reproduction success Food depletion Reduced population biomass Reduction in community richness Selection of tolerant species	Reduce peak flow amplitude and flow ratio, especially during critical seasons/times Decrease maximum peak flow magnitude Increase minimum flow magnitude between hydropeaks	Bretschko and Moog (1990), Moog (1993), Casas-Mulet et al. (2015a,b), Irvine et al. (2015), Bondar-Kunze et al. (2016), Bejarano et al. (2018) and Hayes et al. (2021)
Ramping rate	Up-ramping: unnaturally rapid flow increase, quick increase in hydraulic forces Down-ramping: unnaturally rapid flow decrease, quick drying of previously wetted areas	Downstream displacement of fish and macroinvertebrates (catastrophic drift) Hampered plant germination Stranding Hampered plant germination	Increased mortality Reduced population biomass Selection of flow tolerant species	Lower ramping rates below ecologically relevant rates of change	Young et al. (2011), Bruno et al. (2016), Hayes et al. (2019), Moreira et al. (2019), Schülting et al. (2019) and Bejarano et al. (2020)
Duration	Extended periods of minimum and maximum flows	Increased likelihood of macroinvertebrate and fish (egg) desiccation and death following stranding Aquatic plant stress when emerged too long Riparian plant stress when inundated too long	Increased mortality Reduced population biomass Changes in species composition	Smoothen (sub-) daily hydrograph curves	Perry and Perry (1986), Casas-Mulet et al. (2015a,b) and Bejarano et al. (2018)
Peak frequency	Increased number of flow reversals entail recurring fluctuations of water level and hydraulic forces	Habitat shifts (to refugial habitats) Involuntary drift Stranding Frequent inundation of riparian areas	Higher energy consumption and less feeding time Reduced population biomass Reduced growth and reproduction success Increased mortality Changes in species composition (selection of tolerant species)	Lower hydropeaking frequency, especially of large peaks and during critical seasons (e.g., reproduction or early life-cycle stages)	Bauersfeld (1978), Schmutz et al. (2015) and Hayes et al. (2019)
Timing	Seasonality Time of day Thermopeaking	Increased macroinvertebrate drift during warm period Increased fish stranding at larval stages and/or during cold period Increased macroinvertebrate and fish larval drift and fish stranding during night Thermal modification can lead to increase or decrease in above mentioned drift- and stranding patterns depending on direction and organism	Increase in above-mentioned impacts if hydropeaking occurs during sensitive times Changes in structural and functional community patterns Altered life cycle patterns Possible intensification or mitigation of some of the above-mentioned impacts	Adapt mitigation frameworks such as flow rules to ecologically-sensitive times, e.g., by implementing an 'emergence window' Reduce amplitude of temperature changes	Kennedy et al. (2016), Greimel et al. (2018b), Hayes et al. (2019) and Moreira et al. (2019) Bruno et al. (2013), Casas-Mulet et al. (2015a,b, 2016), Schülting et al. (2016), Vanzo et al. (2016a) and Bondar-Kunze et al. (2021)

Hayes et al., 2019). In this context, the local morphological characteristics play an important role: The risk of stranding is potentially higher if low sloped and heterogenous riverbanks with coarse sediment are present. However, such river banks also provide better habitat conditions for young fish, compared with steep and homogenous riparian structures (Larrieu et al., 2021). Finally, studies showed that both rapid flow in- and decreases reduce germination success of flood-intolerant species of riparian vegetation (Bejarano et al., 2020).

Frequency and duration. Drift of macroinvertebrates was found to decrease quickly during the extent of the peak flow phase; in contrast, stranding often increases with the duration of peaking due to higher colonization rates of the shore habitats (Perry and Perry, 1986). The duration of dewatering in the ramping zone is also key to determine the potential survival of stranded organisms in isolated pools (Young et al., 2011) as well as in the subsurface or hyporheic zone (Casas-Mulet et al., 2015b). The frequency of general hydrological disturbances is known to affect aquatic communities. In the case of hydropeaking, some species, such as juvenile grayling (*Thymallus thymallus*) may show (temporal) adaptation behavior to recurring peaking (Auer, unpubl. data). However the effects may also accumulate with increased peaking frequency (Bauersfeld, 1978; Bruno et al., 2016). Increasing frequency and duration of hydropeaking was found to intensify stress on riparian vegetation and affect germination as well as plant survival (Bejarano et al., 2018, 2020).

Timing. The effects of hydropeaking on aquatic organisms can largely vary between seasons and even between different times of the day. One major reason for seasonal variation is that the sensitivity towards hydraulic stress is strongly life stage-specific. For example, as mentioned above, stranding can be observed mostly for fish larvae as fish become less susceptible to stranding as they grow in size (Hayes et al., 2019). In addition, the seasonal changes in water temperature strongly affect organism responses to hydropeaking as lower water temperature during winter lowers the activity of most species and subsequently affects drift and stranding patterns. Studies have shown that the drift and stranding differ between day and night because of a combination of light intensity and organism activity (Smokorowski, 2021). For example, macroinvertebrate drift is commonly lower during the night because insects actively seek flow-exposed areas during the night for feeding, among other reasons.

Ecological impacts linked to thermal alterations

Water temperature is a key physical property of river flows and a primary driver for community patterns of riverine organisms and for ecological processes. Hence, thermal modifications caused by the operation of hydropower can significantly affect river biota. However, the effects of thermopeaking on aquatic communities have not been extensively studied, and it remains a challenge to disentangle the effects of hydro- and thermopeaking (Bruno et al., 2013). In any case, thermal modification may act as an additional stressor on periphyton, macroinvertebrates and fish, leading to changes in structural and functional community patterns as well as to altered life cycle patterns. A study on periphyton development under combined hydro- and thermopeaking showed that sudden fluctuations in flow and water temperature affect biomass and community structure: cold thermopeaking in summer enhanced algal biomass and diatom development, whereas warm thermopeaking in winter led to decreased algal biomass development and an increase in green algae (Bondar-Kunze et al., 2021). Through a modelling approach, Casas-Mulet et al. (2016) illustrated how warm thermopeaking events encourage early salmonid embryo hatching in winter, and increase stranding mortality in alevin stages during dewatering events, with egg stages being less susceptible to desiccation. Further experimental studies have shown that hydropeaking-induced macroinvertebrate drift and fish stranding patterns may change in combination with warm and cold thermopeaking (Carolli et al., 2012). The directions of response are, however, quite variable and more research is needed to identify general patterns (Smokorowski, 2021) (Table 2).

Socio-cultural impacts: Ecosystem services

Hydropower production schemes and hydropeaking affect not only the biotic river community, but they can also influence other ecosystem services that river systems provide. In principle, hydropeaking can impact each ecosystem service that depends on the biotic and abiotic parameters previously described as flow, morphology, and sediment transport. In contrast to river biota, hydropeaking shows positive and negative relations with ecosystem services. For example, in late summer to early fall, only hydropeaking events provide suitable conditions for recreational services such as rafting and kayaking in Alpine rivers: during baseflow conditions, water depth and water velocity—two parameters directly linked to river flow—may not be sufficient to enable boating (Carolli et al., 2017b). Higher river flows due to hydropower production have also been linked with enhanced user preferences and with a higher aesthetical value (Pflüger et al., 2010). In contrast, hydropeaking also shows negative effects on ecosystem services: by affecting fish habitat and species communities. Hence, hydropeaking can negatively influence recreational services such as angling (Carolli et al., 2017a).

Mitigation measures

The heavily altered state of many hydropeaked rivers calls for the timely implementation of effective measures to counteract many of the above-described environmental effects (Table 2). In this regard, hydropeaking mitigation measures can be grouped into two broad categories: (i) hydrological and (ii) morphological measures. While the first group of measures aim to modify the peak hydrograph directly, the second group seeks to mitigate adverse effects indirectly by improving hydraulic conditions in the affected river section (Greimel et al., 2018b; Table 3).

Table 3 Hydropeaking mitigation measures and emerging alternative storage systems—a non-exhaustive overview.

Measure group	*Measure type*	*Details*	*Related costs and concerns*
Hydrological mitigation: operational	Increase of residual flow magnitude	Higher environmental flow allocation to reduce drawdown range, esp. during critical periods	Decline in revenue Loss of flexibility
	Turbine flow limitation	Lower peak flow magnitude	Decline in revenue Loss of flexibility
	Anti-cyclical operation of different hydropower plants	Lower peak flow and increase baseflow for a more constant flow in the whole river system	Decline in earnings due to production during low demand Loss of flexibility Legal constraints (e.g., water table prescription in reservoir)
	Lower up- and down-ramping operations	Decrease flow ramping to avoid drift and stranding of organisms	Decline in revenue Loss of flexibility
Hydrological mitigation: constructional	Powerhouse outflow into a lake (or ocean or fjord)	Turbine outlet directly connected to a lake to avoid hydropeaking in the river	Lake too far away Construction costs Impact on lake ecosystem
	Powerhouse outflow into a side channel or tunnel	Parallel side channel or tunnel to evacuate the turbine water without impacting the river	Land availability Construction costs Groundwater impacts
	Compensation basin	Powerhouse outflow into a storage basin with a controlled outflow to the river	Land availability Construction costs Fluctuating water level (recreation) Volume depending on the turbine outflow
	Compensation cavern	Powerhouse outflow linked with an underground retention basin with a controlled outflow	High construction costs Volume depending on the turbine outflow
	Powerhouse outflow into a basin (of a run-of-river power plant)	Basin located on the river, controlling flow through turbines or weirs	Land availability Construction costs Fish migration, sediment transport
	Powerhouse outflow into lake and residual run-of-river flow release	Existing hydropower plant used in run-of-river mode for environmental flows release and new parallel system for peak flow production	Construction costs Decline in earnings due to run-of-river operations during low energy demand
Morphological mitigation: indirect measures	Channel widening	Widening of river cross-section to reduce peak amplitude and hydraulic forces	Land availability Construction costs
	Reconnection of tributaries and creation/ maintenance of side channels	Establish connectivity to instream flow refugia	Land availability Construction costs
	Channel restructuring: instream measures	Increase macro-roughness and enhance habitat structures	Legal and environmental constraints
Emerging alternative energy storage systems and complementary measures	Floating solar panels on reservoirs	Add additional energy generation source whilst lowering water evaporation losses	Construction costs Possible environmental constraints
	Inflatable balloons in reservoirs	Displacing water by balloons allows for a higher flexibility of energy production	Construction costs Operating costs Possible environmental constraints
	Compressing air into excavated caverns (air cushion underground caverns)	Underground caverns give additional water volume to the adjacent reservoir. In the caverns, air is used to displace water and subsequently to adjust water levels for hydropower production	Construction costs Operating costs
	Energy storage in batteries	Store energy in batteries and extract during phases of high demand	More research and development needed Construction costs
	Pumped-storage facilities	Turning storage hydropower into pumped-storage facilities guarantees production flexibility while not releasing all of the water into the river	Land availability Construction costs
Measure integration	Combination of measures	Combinations of different mitigation measures may lead to more cost-effective outcomes, for example, by combining a compensation basin and channel widening measures as depicted in Fig. 6.	

Modified from Person É (2013) *Impact of Hydropeaking on Fish and Their Habitat.*; Greimel F, Schülting L, Wolfram G, Bondar-Kunze E, Auer S, Zeiringer B et al. (2018b) Hydropeaking impacts and mitigation. In: Schmutz S and Sendzimir J (eds.), Riverine Ecosystem Management, pp. 91–110, Springer.

Hydrological mitigation measures

Hydrological improvements can be attained by either (a) operational or (b) constructional measures. The first adjusts the hydropower plant's mode of operation to reduce peak-intensity parameters such as lowering ramping rates, flow amplitude, or hydropeaking frequency. These hydrological changes may bring direct environmental improvements; for example, by reducing down-ramping to below critical thresholds fish stranding can be avoided (Fig. 5). Also, higher baseflows can be released to avoid critical river reaches falling dry between peaks (Hayes et al., 2019; Moreira et al., 2019). However, from the economic perspective, mitigation approaches that restrict turbine operation lead to lost profits due to loss of flexibility (Greimel et al., 2018a; Table 3).

The second sub-group, structural measures, includes add-on constructions to the existing hydropower facilities. If the river valley offers enough space, the construction of re-regulation or retention basins is an effective option to dampen hydropeaking intensity and increase minimum flows. The hydrological effects in the tailrace can be similar to those of operational measures mentioned earlier (Figs. 5 and 6). Depending on its size, retention basins usually do not require changes in the hydropower plant's operational mode as they catch and retain the peak flow in the basin, and ensure a smoother water release to the river. Except for reservoir construction investments, retention basins do not incur permanent losses of profits (Greimel et al., 2018a; Anindito et al., 2019). Another option to change hydropeaking hydrology is to build a hydropeak diversion power plant that pipes peak flows to a downstream facility. From an operator's perspective, this measure can increase economic revenue after investments are redeemed. From an ecological perspective, results may be far from optimum since the affected river reach turns into a residual flow stretch that requires specific environmental flow allocations. Hydro-numeric simulations for the Austrian GKI case study (see Table 4) show that peak-diversion can indeed lower fish stranding risk (Moreira et al., 2020). However, the hydropeaking stretch is only moved further downstream—albeit larger rivers can potentially cope better with (comparably smaller) peaks than smaller rivers. A further solution to avoid hydropeaking in rivers is to divert the peak into a lake or construct a retention basin at the turbine outflow of the diversion hydropower plant (Table 3).

Morphological measures: Indirect mitigation

The second mitigation block includes physical modifications in the channel of the hydropeaked river to improve habitat structures and/or to create refugial areas. Such morphological measures seek to mitigate adverse effects by indirectly improving hydraulic conditions in the river, but not affecting hydropower operation (Fig. 6). Channel widening or side channel maintenance can reduce flow amplitude and associated hydraulic forces, and tributary reconnection can aid recruitment of aquatic biota by providing spawning and rearing areas without hydropeaking. Placement of large blocks and deflectors may also enhance structural heterogeneity of the channel, helping to dissipate flow energy and offering refugia to fauna. A recent fish population study, however,

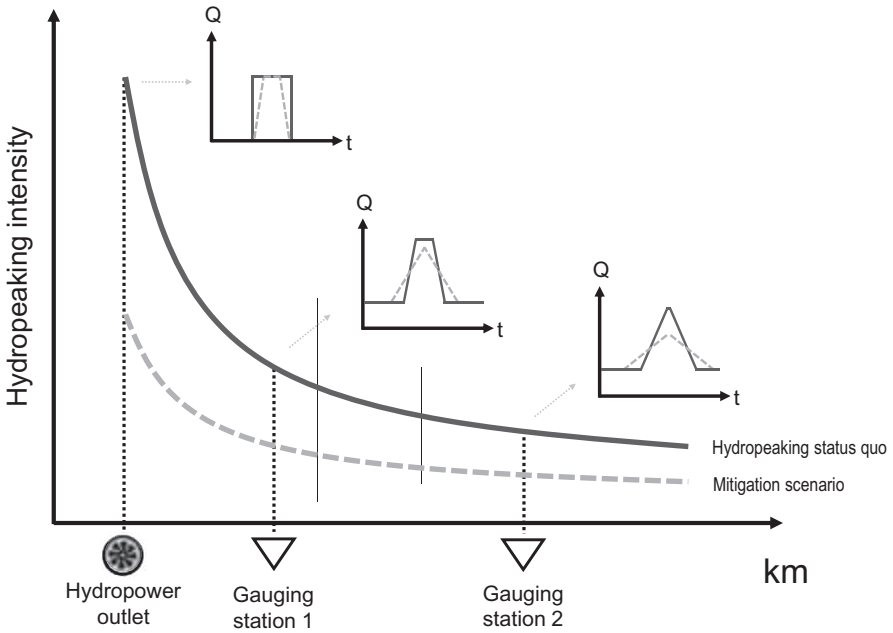

Fig. 5 Hydrological changes through operational and/or constructional measures can lower hydropeaking intensity in the affected river reach. Shown here is how hydropeaking intensity, such as down-ramping rate, changes in downstream direction (bottom graph) and how these hydropeaking waves are measured at the hydropower outlet and at two successive gauging stations (top three graphs). The dark grey solid line illustrates a hydropeaking status quo, the light grey dashed line a mitigation scenario based on hydrological improvements. Modified from Muhar S, Arnaud F, Aschwanden H, Binder W, Broggi M, Greimel F et al. (2019) Restoration. New life for the rivers of the Alps. In: Muhar S, Muhar A, Egger G, and Siegrist D (eds.), *Rivers of the Alps. Diversity in Nature and Culture*, pp. 320–343, Berne: Haupt.

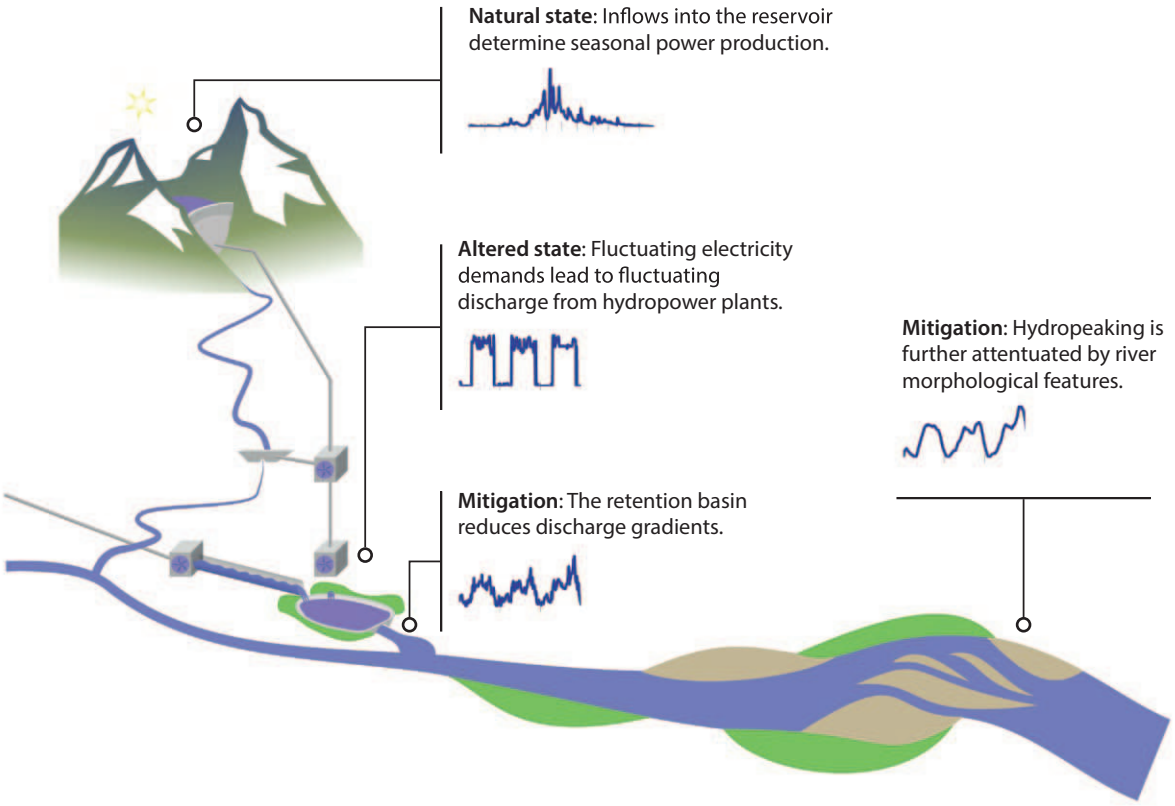

Fig. 6 A systems perspective on hydropeaking mitigation: how retention basins and morphological measures (e.g., channel widening, side channel creation) reduce peak intensity. Modified from Philipp Falke (MeteoSwiss).

indicated that 'the full benefits of river rehabilitation measures can only become visible if hydropeaking intensity is reduced at the same time' (Hayes et al., 2021). In this regard, it is not surprising that the combination of hydrological and morphological measures is projected to lead to greater ecological improvements at national scale (Greimel et al., 2018a).

Emerging alternative energy storage systems and complementary measures

Aside from the measures described above, which have hardly changed since the mid-1980s (Smokorowski, 2021), new (energy system-specific) methods or storage systems are arising. These solutions include, for example, the use of floating solar panels on reservoirs (Farfan and Breyer, 2018), inflatable balloons in reservoirs, or compressing air into excavated caverns to displace water (Storli and Lundström, 2019; Table 3). Also, electricity storage in electric vehicles to compensate for peak energy demands has been suggested (Román et al., 2019). A recent study suggests that by 2025 batteries will become economically viable to aid hydropeaking mitigation (Anindito et al., 2019). Indeed, affordable energy storage and solar systems are deemed sufficient to avoid severe hydropeaking in the renewable energy systems of the future (Haas et al., 2019).

Overall, such 'traditional' and new innovative measures or storage systems are needed to guarantee a *quasi*-green energy system and sustainable peaking production in the future, despite inevitable impacts (as discussed above). To date, however, hydropeaking is, at its heart, still a controversial issue. It is commonly recognized that hydropeaking cannot (yet) be entirely avoided. In this regard, its socio-economic benefits and balancing role must be weighed against its environmental effects.

Mitigation case studies

Despite the phenomenon of hydropeaking being globally widespread, there is still a lack of mitigation measures to be comprehensively implemented. Indeed, the literature contains only few such case studies. Most of them are from North America and Europe (Moreira et al., 2019). Some of these case studies are highlighted in Table 4 and include mitigation through a compensation basin, diversion hydropower plant, or operational restrictions.

For instance, the Upper Inn River, Austria, is affected by frequent hydropeaks with ramping rates exceeding ecological thresholds, heavily impacting fish populations. As a mitigation measure, a diversion power plant is currently being constructed. Once in

Table 4 Case studies illustrating hydropeaking and mitigation measures worldwide.

Name of site	*River, country*	*Coordinates*	*Current state and mitigation approach*	*Evaluation of mitigation measures*	*Key reference(s)*
Gemeinschaftskraftwerk Inn (GKI)	Inn River, Austria and Switzerland	47°4′4.78″N, 10°39′54.37″E	Newly constructed hydropower station diverting water from the Upper Inn River at the Swiss border 23 km downstream to the Austrian powerstation Prutz. Environmental flows and operational hydropeaking restrictions are implemented in the diversion stretch.	Construction still in progress.	Moreira et al. (2020) https://www.gemeinschaftskraftwerk-inn.com
Hydropower plant Alberschwende	Bregenzerach River, Austria	47°28′25″N, 9°50′ 59″E	In 1992, a new diversion hydropower plant was built together with a retention basin (volume: 150,000 m³) to buffer hydropeaking. Additionally, base flow is increased slowly 24 h prior to peaking operation to reduce total peak amplitude.	Reduction of peak flow ratio and ramping rate lead to macroinvertebrate biomass recovery, but regarding fish no improvement was documented.	Grasser et al. (1998) and Parasiewicz et al. (1998)
Hydropower plant Innertkirchen	Hasliaare River, Switzerland	46°42′30″N, 8°13′29″E	The following measures were realized from 2013–2016: construction of retention basins (total volume: 80,000 m³), morphological instream structures, increase of base flows.	A decrease of ramping rates led to an increase of macroinvertebrate biomass and fish productivity; however, fish stranding could not be significantly reduced.	Tonolla et al. (2017) and Schweizer et al. (2021)
Sokna kraftverk	Lundesokna River, Norway	63°08′59.5″N, 10°18′23.1″E	Constructed in 1964, the Sokna hydropower plant affects the Lundesokna River 5 km before it reaches the unregulated Gaula River. The upcoming relicensing process will consider either operational or constructional measures, given the legal requirements and the high conservation interest of the Gaula River.	Not yet implemented.	Casas-Mulet et al. (2016)
Steephill Falls hydropower plant	Magpie River, Canada	48°4′41.17″N, 84°44′18.23″W	From 2002–2007, an adaptive management experiment was run to test the notion that minimum flow allocations and ramping rate restrictions provide ecological benefits.	Macroinvertebrate abundance and diversity decreased after ramping restrictions were lifted, implying that restricted operations were protective of river biota.	Smokorowski (2010)
Gordon Power Station	River Gordon, Tasmania, Australia	42°44′25.79″S, 145°58′56.73″E	Adaptive management principles were applied to establish an optimal ramp-down rule to minimize seepage while allowing operational flexibility. Down-ramping is deemed necessary when bank saturation exceeds defined trigger values and power station discharge is above 150 $m^3 s^{-1}$.	The revised ramp-down rule was monitored and assessed since 2012 and was found to reduce seepage erosion.	https://www.hydro.com.au/environment/environmental-management/monitoring-the-gordon-river

operation, this facility will reduce ramping rates to levels considered adequate for protection of young-of-the-year fish, whilst enabling increased energy production in the region (Moreira et al., 2020). A diversion power plant and a compensation basin was constructed at the Austrian Bregenzerach River in the early 1990s, and evaluations of this measure showed a positive trend for macroinvertebrates but not for fish (Parasiewicz et al., 1998). The Swiss Hasliaare River is one of the best-known examples of compensation reservoirs. Recent evaluation revealed that particularly the combination of basins and instream measures led to achieving sought ecological targets (Schweizer et al., 2021; Table 4). The heavily hydropeaked Lundesokna River, Norway, is a major tributary of the Gaula River, one of the last unregulated rivers in Norway of high conservation value that entails special requirements for environmental protection. To date, no mitigation measures have been set in place. However, the upcoming relicensing process of the Sokna hydropower station pushes the conversation between the local council and the energy company to implement either operational constraints or structural measures to target key environmental needs in both rivers (Table 4). The Gordon Power Station is the largest power station in Tasmania, Australia. Hydropeaking at the Gordon was projected to increase following the commissioning of an undersea power cable to connect Tasmania with mainland Australia. A research and monitoring program was implemented from 2002 to 2020 to detect impacts on the ecology and fluvial geomorphology of the Gordon River caused by hydrologic changes resulting from joining the national electricity market. Under the program, a ramp-down rule to minimize seepage erosion due to hydropeaking was devised, implemented and refined through adaptive management (Table 4).

Synthesis

In this chapter, we illustrated links between peaking-power production and ecosystem integrity/function, as well as gave an overview of mitigation measures from a river-specific and energy-grid-specific perspective. In summary, hydropeaking remains a controversial topic. Storage hydropower offers to date the best way to store energy at the large scale, and the flexible energy generation capacity of start-stop production makes peaking power an indispensable part of the power fleet, in particular that of renewable energy systems with increased grid volatility due to solar and wind power generation. However, considering the manifold ecological impacts, it is necessary to establish and implement timely mitigation measures, despite their potential effects on energy market hydropeaking drivers. When considering mitigation strategies, both socio-economic and environmental values should be considered in trade-off analysis. However, it is necessary to acknowledge the existence of strong legislative frameworks than can be contradictive, for example, pertaining to the expansion of renewable energies and ecosystem conservation, making the decision-making process difficult. Future research should focus on evaluating and adjusting implemented mitigation measures based on complex realities, as well as acknowledge the diversity of bio-physical processes in rivers affected by hydropeaking worldwide.

Knowledge gaps

The following list presents a set of open core questions that, if answered, would aid the sustainable management of hydropeaked rivers.

1. To what extent does the impact of hydropeaking differ between scales and river types, for example, pertaining to different flow regimes (glacier-melt vs. non-glaciated regimes; temperate, tropical vs. semi-arid), river morphologies and sedimentary structures (straight vs. braided rivers; armoured vs. loose (mobile) bed rivers), groundwater influence (e.g., hyporheic vs. surface-dominant flows), or biocoenotic regions such as fish regions (headwaters vs. lowland rivers)?
2. How do prior river conditions influence ecosystem impacts of hydropeaking?
3. What are the direct consequences of organism drift and stranding on the individual organism and population level?
4. What are the effects of hydropeaking on the food-web structure in different river types and regarding the longitudinal gradient of a river?
5. Which biological metrics are most sensitive and could be included into a stressor-specific biological assessment method?
6. What are functional processes that govern hydropeaking impacts? Are results of impact analyses consistent through different spatio-temporal levels (e.g., from an event at the gravel bar to multi-year effects on wider regional hydroclimatic scales) so that generalized processes can be deducted?
7. How does the ecosystem stressor of hydropeaking interact with other pressures such as channelization, river-floodplain disconnection and tributary fragmentation, land-use change, water quality alteration, or (piscivorous) predators?
8. How can ecosystem impacts be assessed from the context of climate change and future socio-economic priorities?
9. What economic and social constraints hinder the spatial and temporal implementation of mitigation measures?
10. What kind of measures best mitigate the (ecological) consequences of hydropeaking, and how can their effectiveness be best quantified to serve as a decision-support for sustainable hydropeaking management?

Glossary

Dam decommissioning Removal of hydroelectric generation facilities from a dam.
Dam removal Partial or full removal of a dam and appurtenant structures.
Environmental flows Dam releases dedicated to maintenance of environmental health.
Small hydropower Hydropower facilities with a small generating capacity, mostly less than 10 MW, often run-of-river.
Stoplogs Hydraulic control elements that are manually set to adjust water level or discharge in a river, canal, or reservoir.
Sustainable hydropower Hydropower facilities that minimize impacts on a river's flow regime and aquatic and riparian ecosystems.
Trash rack Structure that prevents water-borne floating debris from entering water intake.

Introduction

As a renewable, low carbon, and relatively low cost source of electricity, hydropower brings numerous benefits for economic development and a transition away from fossil fuels. However, hydropower facilities come with numerous social and environmental impacts, including altering aquatic and riparian ecosystems, displacing people, causing deforestation and species loss, impacting river-based subsistence and livelihoods, and altering coastal sediment fluxes. Globally, efforts to minimize the environmental impacts of hydropower dams are increasing. These efforts generally aim to:

- Minimize change in the river flow regime and flow velocities;
- Allow sediment to move upstream and downstream of the hydropower facility;
- Protect fish from mechanical injuring by rotating parts;
- Allow fish and other aquatic species a safe, easily detectable way upstream and downstream; and
- Minimize influence on habitats used for reproduction by fish and other aquatic life.

While these aspirations may not be achievable in all settings, new ways of building and operating hydropower facilities can lessen their environmental impacts. This chapter describes three increasingly-used advances in the design, operations, and management of hydropower facilities that aim to enable a more sustainable balance between energy production and social and environmental impacts. First, it discusses environmental flows, managing water releases to provide habitat and other ecosystem functions. Second, it explores small hydropower (plants that generate less than 10 MW) and the addition of energy generation facilities to existing dams and infrastructure. Finally, it discusses the decommissioning and removal of dams, an approach that is growing in prominence for dams that no longer meet their stated needs, or whose upgrades to address safety and/or environmental concerns would be prohibitively expensive. Each section begins with an overview of the approach and the challenges that it is trying to address, and then discusses how the approach works, best practices, and key challenges in implementation.

Environmental flows and hydropower

Hydropower facilities return water to rivers after it is used to generate electricity, but the magnitude and timing of the return flow may be significantly different than the natural flow regime in the river. Single-purpose hydropower facilities generally release water according to the schedule of electricity demand rather than the schedule of water needs by downstream ecosystems and other river users. Releases from multi-purpose dams may also adhere to schedules related to flood protection, reservoir recreational

services, or downstream water rights unrelated to ecosystem or other instream water needs. Because riverine ecosystems are adapted to natural flow levels, altered flow regimes can stress on riverine biota, alter geomorphic processes, and lead to fundamental changes in ecosystem condition over time (Poff and Zimmerman, 2010; Rolls and Bond, 2017). The temperature, dissolved oxygen, and sediment concentrations of water released from hydropower facilities may be significantly altered from natural levels, exerting further stress on downstream ecosystems (Olden and Naiman, 2010; Schmutz and Moog, 2018). Degraded downstream ecosystems provide fewer ecosystem services, reducing the benefits enjoyed by riverside communities and others using the river (Anderson et al., 2019).

Environmental flow releases are an operational measure intended to mitigate the impacts of altered flow regimes downstream of hydropower facilities or other water infrastructure. They are also applied more broadly in water allocation planning and management to mitigate the effects of excessive water withdrawals for agriculture and other consumptive use (Horne et al., 2017). Effective environmental flow releases mimic essential components of the natural flow regime and include a range of flow levels that create aquatic habitats, are synchronized with the life history patterns of aquatic organisms, maintain lateral and longitudinal connectivity, and discourage invasions of exotic species (Bunn and Arthington, 2002).

Awareness of and guidelines for environmental flow releases from hydropower facilities are becoming more prominent. For example, the International Hydropower Association includes environmental flows as one of the topics in its Hydropower Sustainability Assessment Protocol (International Hydropower Association, 2020). The International Finance Corporation (IFC) of the World Bank Group has issued guidance on environmental flows for hydropower projects that are aligned with its sustainability policies and standards (IFC, 2018). The European Commission has issued guidance on the requirements for hydropower in relation to EU Nature legislation, which includes environmental flows (European Commission, 2018). However, the implementation of environmental flows at hydropower facilities and in other water management settings remains limited, prompting calls for a global action agenda to accelerate their implementation for protection of rivers with hydropower plants (Arthington et al., 2018).

The potential for a hydropower facility to alter a river's flow regime depends on the volume of water stored in its reservoir relative to the flow of the river. A commonly used index for this potential is the *degree of regulation (DOR)*, which reflects the proportion of a river's annual flow that can be stored (Lehner et al., 2011). DOR values range from near zero for run-of-river facilities to greater than 100% for reservoirs large enough to store all water flowing in the river during an average year. Akosombo Dam on the Volta River and Kariba Dam on the Zambezi River represent extreme cases, as both have a DOR index greater than 300% (Lehner et al., 2011). Consideration must also be given to the cumulative effects of multiple hydropower facilities in a single river basin, which compound the impacts and limit the effectiveness of implementing environmental flow releases in any one facility.

The actual degree of flow alteration downstream of hydropower facilities depends on how the dam is operated, the schedule of hydropower production, and the design and configuration of the facility. Operating rules will change depending on the purpose of the dam and water levels in the reservoir throughout the year. Some hydropower facilities have the objective of contributing to the electrical base load and are operated to generate steady levels of electricity, while others vary electricity production hourly depending on demand and changing electricity prices. Hydropeaking associated with hourly variations in electricity generation produces some of the most severe flow alteration, with rates of change so large that biota are flushed downstream when flows ramp up, and fish and other organisms are stranded on river banks when flows are subsequently reduced (Moreira et al., 2019). Facilities that position the power plant some distance away from the dam will create a depleted (or de-watered) reach between the dam and the tailrace where water from the turbines is returned to the river. The length of depleted reaches can be tens of kilometers. When a power plant is located in a separate river basin, water losses from the dammed river may be permanent.

Advances in environmental flow science and practice provide solutions to address each of the flow alteration situations described above. Implementing environmental flows is enabled by policy and legislation prioritizing minimal environmental water objectives over other uses, knowledge of the flow requirements to meet downstream environmental objectives, and hydropower facilities operationally capable of releasing the required environmental flows (Owusu et al., 2021).

Environmental flows appear both explicitly and implicitly in major water policy and legislation around the world. In some cases such as South Africa and Peru, environmental flows are mentioned in national water laws and prioritized over other water uses (Ley No 29338-Ley de Recursos Hidricos, 2009; National Water Act 36 of 1998, 1998). In Ecuador, environmental flows even appear in the country's constitution (Constitución de la República del Ecuador, 2008). In federal republics like the United States, environmental flows are incorporated into state laws and statutes (Boyd, 2003). The European Union recognizes environmental flows as an element of river hydromorphic condition, which together with biological and chemical elements determine the ecological status of water bodies. The EU has set a goal of achieving *good* ecological status of all of its water bodies and issued guidance on how environmental flows factor into achieving this goal (European Commission, 2015). In the absence of legal treaties but in the spirit of cooperation, some countries like those comprising the Nile River Basin have agreed on a basin-wide strategy for assessing and implementing environmental flows. The strategy describes a common framework for incorporating environmental flows into water resources management in the basin countries, but the legal and regulatory details remain specific to each country (NBI, n.d.), and procedures for implementation are still under development.

While laws, regulations and international agreements provide the enabling conditions for environmental flows in hydropower facilities, critical points for their assessment and implementation are the initial design phase of a new project and the relicensing phase of existing projects. Each of these involve environmental assessments, which include the impact of downstream flow alteration. Specific guidance on environmental flows in hydropower environmental assessments has been published by the IFC and the World Bank (IFC, 2018; Krchnak et al., 2009), and the Inter-American Development Bank has issued a White Paper on the

topic (Anderson, 2013). Relicensing processes, such as those conducted by the Federal Energy Regulatory Commission (FERC) of the United States, require environmental assessments that consider environmental flow releases (Schramm et al., 2016).

An illustrative case for environmental flow implementation during the relicensing process is the 2016 revision of the Water Control Plan for John H. Kerr Dam and Reservoir in the United States (US Army Corps of Engineers, 2016). Kerr reservoir was completed in 1952 for purposes of flood control and hydropower production. Environmental flow requirements were not assessed and the natural variability of the downstream flooding regime was reduced significantly. This resulted in the degradation of floodplain forests and other riparian and in-stream biota and communities (Pearsall et al., 2005). During the FERC relicensing process, the operation of Kerr Reservoir was changed to release a flow approximately equal to the average unregulated inflow to the reservoir over the preceding week. This converted the facility to a quasi-run-of-river operation, intended to more closely mimic natural flow variability (US Army Corps of Engineers, 2016).

Frameworks and specific methodologies for the assessment of environmental flow requirements downstream of hydropower facilities are well established and adaptable to different spatial scales, level of detail, and local capacity. Decisions about the specific assessment methodology to be applied will depend on the known or potential impact of the hydropower facility on downstream river reaches (IFC, 2018). For example, low-resolution environmental flow assessment methodologies considering only hydrological data may be sufficient for run-of-river hydropower facilities resulting in small alterations in the downstream flow regime. Conversely, high-resolution methodologies should be applied for facilities resulting in major downstream flow alterations, especially in cases where downstream reaches are of high conservation, social, or economic value (Opperman et al., 2018). Determination of final environmental flow levels requires societal choices about the level of ecological condition to be maintained. These choices are often reflected in laws and regulations but case-based choices are also needed. Incorporating these social dimensions into environmental flow assessment requires effective stakeholder engagement (O'Keeffe et al., 2019).

In addition to releasing sufficient base flows, studies have emphasized the need to reintroduce more regular flood pulses downstream of hydropower facilities (Olden et al., 2014). Numerous facilities have changed their operation to release more effective environmental flows. Notable examples include Kerr Dam mentioned previously, Three Gorges Dam on the Yangtze River in China, and Katse Dam on the Malibamals'o River in Lesotho (Brown and King, 2012; Cheng et al., 2018).

Once quantified, a range of strategies have been devised to re-operate hydropower facilities in ways that also minimize losses in power production. These include the construction of re-regulation (or compensation) reservoirs downstream of hydropower facilities, use of pumped storage facilities, balancing re-operation measures among multiple facilities in a cascade, and optimizing power generation across multiple energy sources, including wind and solar (Richter and Thomas, 2007). Environmental flow releases into depleted reaches may also be used to generate electricity using smaller turbines. Measures to address water quality issues include sluice gates to increase downstream fluxes of sediment, intake points from various levels in the reservoir to better control water temperatures, and aeration techniques to reduce hypoxia in released waters. Re-operation of hydropower facilities and implementation of the measures mentioned may be limited by the engineering design of facilities (e.g. facilities physically incapable of releasing prescribed environmental flows) as well as contractual or licensing issues.

Small hydropower

Small hydropower (SHP) is often formally defined by the power plant capacity, defined in megawatts (MW). The specific capacity varies considerably around the world. Differences in a country's hydropower potential, hydropower development, and history result in small hydropower limits that vary from 1 MW (Burundi, Ghana, Nigeria, Zimbabwe) to 10 MW (European Union, United States) to 50 MW (China, Canada) (Liu et al., 2019).

While large hydropower often entails big dams and reservoirs that store a large quantity of water, small hydropower schemes are mainly run-of-river plants with little or no storage impoundments and only a small dam or weir that diverts a portion of the river's flow. The absence of a storage facility minimizes alteration of the river's flow, lessening impact on the hydrological regime. Water leaving the turbine has the same quality and quantity as upstream of the plant. SHP schemes can also assist in the maintenance of the river basin by recovering flowing waste from the river stream and providing a site to monitor hydrological conditions. As any floating waste accumulates on the inlet trash racks and must be collected and deposited out of the river, small hydropower helps in reduction of floating debris and especially plastics in the rivers. Additionally, most SHP plants have a hydrological monitoring station that provides data useful for power generation and river management more generally.

While small hydropower mostly has less environmental impact than larger hydropower facilities, attention to sustainable developments can minimize possible negative impacts. Sustainable small hydropower aims to minimize the facility's influence on the river flow regime, flow velocities, and river dynamics, influence on transport of sediment and seeds from plants along the river, and influence on fish mortality and migration. In recent years, small hydropower developments are concentrated on minimizing these negative effects and adjusting facilities to given site conditions and environmental needs. Small hydropower, therefore, is not just a copy and downsizing of the standard large hydropower; rather it comprises new environmental developments and improvements that make hydropower more sustainable.

New hydropower technologies are enabling more environmentally friendly small hydropower. One such advance is the shaft power plant concept (Sepp et al., 2016), which minimizes the negative environmental influences on the river. In a shaft power plant, the whole power plant, turbine, and generator unit are located completely underwater (Fig. 1). Water feed takes place via a horizontal inlet, situated on the original riverbed upstream of the existing weir structure. A drop-in inlet equipped with a horizontal

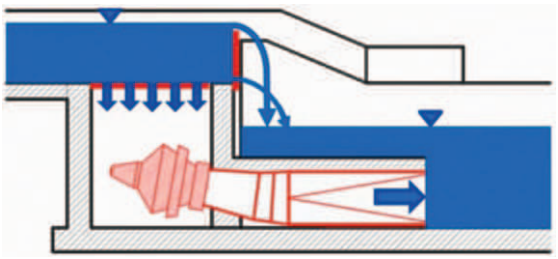

Fig. 1 Concept of the shaft turbine solution (Sepp et al., 2016).

trash rack suppresses entrance of debris and larger sediment in the shaft and subsequent damage to the equipment. Because of its simple rectangular form, the shaft can be constructed directly in the riverbed and avoids costly diversion infrastructure. The relatively simple and not hydraulically optimized structure increases hydraulic losses, but this disadvantage is compensated by the low velocities on the trash rack and within the shaft. As the weir determines water level and flow velocity in the upstream river course, the plant does not affect flow velocities, and the box-type hydropower plant has no additional negative effects on the flora and fauna of the river. Fish migrating downstream should not be sucked through the trash rack because of the low flow velocity. A specially developed gate with an opening in the weir downstream the screen enables fish migration downstream and flushing of the trash rack. Upstream migration is achieved by standard fish migration systems and fish ladders or ramps. The primary disadvantage of the outlined concept is accessibility in case of maintenance. Owing to the underwater setup, the hydro machinery and the generator access have to be achieved by setting mobile stop logs to prevent water access. The system has been tested on a laboratory version at Technical University Munich and at a plant built on a weir in Loisach, Bavaria. The power plant with two shafts and 420 kW power produces 2.4 GWh per year, enough energy for 800 households.

Fish mobility and fish mortality are common concerns at hydropower plants. Fishways, including fish ladders, lifts, ramps, or bypass channels, can help mitigate impacts to fish and are commonly included as part of sustainable hydropower design. While many fishways include various forms of pool passes, recent developments in fishway design include the well-known Denil passage (Seidl, 2021) and a specially developed Fishcon lock (www.fishcon.at) and double hydropower screw (Fig. 2). In the Fishcon solution, fish migrate in both directions through a specially regulated pipe system and a double rotating Hydroconnect screw (www.hydroconnect.at) provides a fish lift and acts as a turbine to generate electricity. The internal screw drives water and migratory fish upstream, while the external screw is used for energy production and downstream fish migration. The Fishcon system is designed to

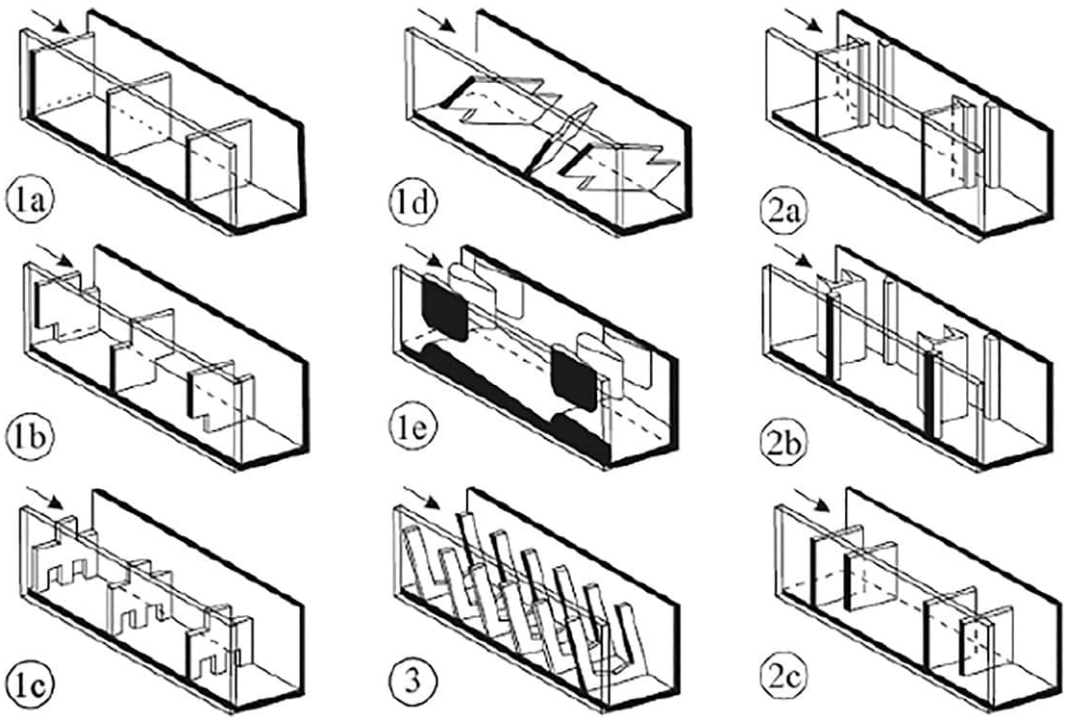

Fig. 2 Types of fishways: (1) pool passes, (1a) without and (1b-c) with orifices, (1d) rhomboid pass, (1e), ridge pass, (2a-c) slot and vertical slot passes, (3) Denil pass (Giesecke and Mosonyi, 1997).

satisfy the EU Water Framework Directive (European Parliament 2000/60/EC) requirements to minimize effects on fish movement. Specially formed blades, minimized gaps and low rotational speed reduce the possibility for fish to be harmed by the Hydroconnect screw, but similar philosophy is also used by other fish-friendly turbines, such as the Alden turbine (EPRI, 2011).

The development of alternative hydropower plants in existing hydro-technical structures represents an additional and profitable solution for energy generation with low environmental impact (Marence et al., 2016). Possible implementations are drinking water or sewage systems, irrigation dams and channels, old water mills, dams that are not used for hydropower, navigation locks, hydraulic industrial systems, cooling and heating water, or desalination systems. The addition of hydropower can also contribute to the partial completion of a circular energy cycle, allowing hydraulic infrastructures to reduce (or even revert in a long term) the anthropogenic impact of such systems. Hydropower incorporated into existing hydraulic infrastructures, where electricity generation was not a primary objective, can be an attractive solution for implementation in developed and developing energy systems for several reasons (Marence et al., 2018):

- the environmental and social impacts of the existing hydro-technical structures are known, defined and mostly accepted;
- installation of new hydropower in the existing system reduces construction costs, construction time, and GHGs emissions during the construction phase;
- lower construction costs with a shorter payback ratio make the solutions attractive for investment;
- uncertainty related to resource availability, especially obtainable water flow and energy head, is reduced;
- operational costs can be lessened by synergies in operation; and
- modifications to add hydropower create the possibility for additional social and environmental improvements to the facility.

An example of the implementation of such hidden hydropower is the hydropower plant integrated in the weir structure developed for water management on Dommel River in Sint Michielsgestel in the Netherlands (Marence et al., 2016). The weir, which has just 1.8 m head (vertical elevation difference), was constructed in 1970, but was not used for electricity generation until 2015 when a screw turbine with the maximal discharge of 10 m^3/s was installed. The plant delivered 120 kW in the local grid. The innovative project was financed with 75% crowdfunding, as almost 500 participants from the region bought certificates in the power cooperative. Participants receive a return in free power and dividends. The expected return for the crowdfunders is 4–8% annually.

Finally, small hydropower is a valuable energy source for rural electrification and support of local grids. Providing electricity to rural areas, especially in the developing world, often requires high investment costs owing to geographical barriers (distance and terrain). Extending the grid with renewable energy sources is a valuable alternative. Small hydropower, in contrast to solar and wind, can provide continuous day and night energy supply for a community, although it may vary with seasonal changes in river flows.

Dam decommissioning

Dam decommissioning refers to removal of hydroelectric generation facilities and often the entire dam. Decommissioning emerges as a solution when a dam poses a safety risk, no longer serves its intended purpose, or no longer meets current social, environmental, and/or economic values. In these instances, removing the dam can be less expensive than repairing or maintaining the dam, let alone upgrading the facility to meet new needs. Rates of decommissioning have increased, especially in Europe and North America; these continents have seen the most dam removals to date, with an estimated 1700 in the United States (USA) and 5000 to 6000 in Europe (American Rivers, 2019; Gough et al., 2018; Vahedifard et al., 2021). Available statistics do not distinguish hydropower dams from other types, but the motivations and responses for dam removal are relatively similar across project types.

Aging is a common factor underlying dam removal. In North America and Europe, many dams were built in the 20th century, making many of these dams past their 20- to 40-year designed lifespan. While age is not the only cause of dam failure, older construction materials are more prone to structural problems. If a dam poses a safety risk, removal often becomes a favored option. Even if the dam is still structurally sound, the original demand for hydroelectricity may have waned. For instance, the Sofieholm power plant in Sweden was built in 1909 to power a textile factory, but the factory has long since closed; combined with impacts on local fish populations, the lack of power demand led to the facility's removal (Sofieholm Hydroelectric Powerplant, River Nianån, Sweden, 2017).

A second common reason for removal is sediment accumulation in the reservoir. Sediment build up increases safety risks, reduces the usable capacity of the reservoir, and can damage turbines. Depending on current or historic upstream land uses, reservoir sediment can also be contaminated, with common contaminants including heavy metals, Dichlorodiphenyltrichloroethane (DDT), polychlorinated biphenyl (PCB), and radionuclides (Evans and Wilcox, 2013; Foley et al., 2017). Sediment build-up can be addressed without removing the dam (e.g., through dredging or pulsed flows through low-lying outlets). However, if the cost of sediment removal outweighs the benefits of power generation (or other water supply/flood control purposes), decommissioning the dam is economically favorable.

Sediment volumes that are large or contaminated can complicate the decommissioning process, requiring a slower and/or more expensive removal to allow for remediation. For instance, decommissioning and removal of the Glines Canyon and Elwha Dams on the Elwha River, United States–the largest hydropower dam removal to date, with 21 million m^3 of trapped sediment—required a phased removal, with staged drawdowns over multiple years (Magirl et al., 2015). Likewise, the Milltown Dam on the Clark Fork River, United States, contained mining-derived sediments with elevated concentrations of arsenic, copper, lead, and zinc; removing the dam without releasing large volumes of contaminants downstream required both a phased drawdown and dredging of the removed sediment (Evans and Wilcox, 2013).

A third common reason for removal is the hydropower facility's impacts on ecosystem function. As understanding of dams' impacts on aquatic and riparian ecosystems has expanded, social pressure for their removal has increased. Dams may be removed to provide upstream habitat for migratory fish, to restore natural (undammed) flow regimes, and/or to reconnect coastal sediment systems. All three motivations underlay the Elwha Dam removal. Ecologically-inspired dam removals often occur because of regulatory triggers, as updating the facility or its operations to meet new environmental requirements (e.g., for fish passage or water quality) may not be cost-effective. In the United States, the conversation about decommissioning hydropower dams often arises when the facility needs to renew its operating license from the Federal Energy Regulatory Commission (FERC) (Doyle et al., 2003). Likewise, in Japan, water rights renewals often trigger debates about dam removal in rivers with declining fish abundance (Noda et al., 2018) (Fig. 3).

The decision to decommission a dam is rarely straightforward. Many decommissionings for larger dams are subject to intense debate, with politicians, regulators, business interests, and members of the public variably raising concerns about impacts on energy supply, costs, flooding, and cultural preservation. This debate often delays removal. For instance, removal of two dams on the Sélune River, France was decided in 2009, but was followed by substantial criticism by local elected officials (Germaine and Lespez, 2017), and it took over a decade to actually remove the dams. Similarly, after local fishermen suggested removing the Arase Dam, Japan in 2003, a newly elected government reversed the decision; the dam was not removed until 2018 (Noda et al., 2018; Ohno, 2019).

Even in cases where the decision is met by widespread support, regulatory hurdles can also delay removal. The proposed removal of the Klamath Hydroelectric Project (a series of four dams in California and Oregon, United States) resulted in 2010 from a large-scale negotiation between the electrical utility, multiple American Indian tribes, irrigators, fisherman, and multiple federal and state agencies (Gosnell and Kelly, 2010). However, the removal timeline has been delayed numerous times because congressional and administrative leadership-both of which are required for formal approval–changes with each presidential administration.

Scientific studies on the environmental outcomes of dam removal is a growing area of research. For instance, only 10% of dam removals in the United States have been scientifically evaluated, with many of those studies focusing on relatively short-term timescales (Bellmore et al., 2017). Nevertheless, some general trends have been observed. First, impounded sediment moves relatively quickly, with the majority of sediment from the reservoir being transported downstream within several years (Foley et al., 2017). In some cases, erosion can occur very rapidly (in under a year). In the Condit dam removal in Washington State, United States, erosion extended upstream of the reservoir and occurred so rapidly that it blocked fish migration at the mouth of the river (Wilcox et al., 2014). However, phased removal–in which the dam is breached to allow some passage of water and sediment, but with a delay before removing the full dam-appears to slow down the sediment transport process (Foley et al., 2017).

Second, fish communities often respond quickly to removal of the barrier, with both fish species richness and life-history diversity increasing shortly after removal (Foley et al., 2017). Species recovery and distribution depends on species abundance and diversity pre-removal. For instance, decommissioning the Irving Power Plant in Arizona, United States, had no effect on native fish abundance except in stream reaches where exotic species had been removed (Marks et al., 2010).

Third, with few exceptions (like the Condit example), upstream environments and species are typically not altered by dam removal. The overall downstream response to removal varies substantially case by case. How and where sediment deposits depend on the volume of sediment, flow rates, the underlying geomorphology, and grain size distribution. This deposition is a critical factor shaping habitat post-removal. Downstream response also depends on whether there are other dams in the watershed. As for the former reservoir, ecosystems tend to be dominated by fast-growing riparian species, including some invasive species (Foley et al., 2017).

Fig. 3 Before and after removal of Elwha Dam. Left: September 2011. Right: May 2013. (Ben Cody, wikipedia).

Conclusion

As hydropower increasingly responds to demands to reduce negative social and environmental impacts, the provisioning of environmental flows and the development of small, run-of-river hydropower each provide promising ways to make hydropower more sustainable. In cases where sustainability cannot be improved or the dam is not operational, the decommissioning and removal of existing facilities can return the river to a more natural state. Each approach is growing in use, with new regulations and guidance to support its implementation. Likewise, the science behind these approaches is expanding, providing new knowledge that will help tailor their design and implementation for different sized dams, different hydrological systems, and different ecological needs.

However, there are still a number of key knowledge gaps. New technologies for more environmentally friendly small hydropower, such as fish-friendly turbines and permeable weirs, are in development but not yet widely deployed. Understanding how to optimize environmental flows (e.g., balancing instream flow requirements with flood pulses) for different hydrological and species contexts will enable more targeted implementation of environmental flows. In many jurisdictions, widespread deployment of environmental flows will also depend on enhanced legal provisions. And most dam removals to date have been relatively small systems; as more large dams are removed, the science will enable better guidance on how to phase breaching and removal.

Finally, across all three domains, a key challenge and opportunity is in making decisions at the scale of the watershed rather than the individual facility. Dams are often regulated as individual entities, but thinking at the basin scale can create opportunities for creative balancing between power generation and ecosystem needs (Opperman et al., 2011). Achieving basin-scale management may require new regulatory frameworks that coordinate multi-dam operation, collaboration across multiple government and civil society organizations, and—in transboundary rivers—multinational coordination (Zeitoun et al., 2013). However, designing and operating basin-scale hydropower systems can expand opportunities to promote sustainable hydropower generation.

Knowledge gaps

- Release of ecologically sufficient environmental flows at hydropower facilities. Too many hydropower facilities today fail to release adequate environmental flows to meet the needs of downstream aquatic ecosystems. Meeting ecosystem water requirements will require strengthening environmental performance standards and developing new hydropower technologies (e.g., low head hydropower turbines).
- Developing low head hydropower solutions. Existing turbine types are not suitable for generating in low head difference (few meters head) conditions. Developing new turbine types that could be used in such conditions can expand use of small hydropower solutions to locations without a large weir or dam.
- Building fish friendly turbines. Fish passing hydropower turbines can be injured mechanically, by pressure difference, and by cavitation. Development of turbines that reduce such injuries can make hydropower less harmful to aquatic species.
- Integrating hydropower into existing hydraulic structures. Many hydraulic structures are operated without associated hydropower. Installing hydropower facilities in these hydraulic structures can increase renewable energy production without requiring new dams to be built.
- Development of modular, environmentally friendly solutions. Using modular and predefined solutions for the new hydropower plants can reduce the construction costs and improve the project acceptance.
- Basin-wide optimization of dam decommissioning. Within a watershed, removing some dams and expanding power generation capacity at others can balance power generation and environmental benefits. Doing so will require new regulatory frameworks and multi-criteria optimization approaches.

Impacts of Large Dams on Harmful Algal Bloom Formation in the Tributaries of the Three Gorges Reservoir

Lei Zhang[a,b] and Amechi S Nwankwegu[a], [a]College of Resources & Environment, Southwest University, Chongqing, China; [b]Great Lakes Institute for Environmental Research, University of Windsor, Windsor, ON, Canada

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Algal blooms Proliferation of large populations of algae across the aquatic system (freshwaters/coastal margins) as a result of nutrient over-enrichment and associated factors.
Anthropogenic actions These are all human activities directly or indirectly affecting the environment, including the growth of harmful algae in aquatic systems.
Cyanobacteria The most problematic and widely studied phytoplankton taxon characterized by food web-disrupting, hypoxia-generating, toxin-producing, and large surface scum-producing blooms, especially during the summer.
Dam A barrier that stops or restricts the flow of surface water or underground streams. Reservoirs created by dams not only suppress floods but also provide water for activities such as irrigation, human consumption, industrial use, aquaculture, and navigability. Hydropower is often used in conjunction with dams to generate electricity. A dam can also be used to collect or store water which can be evenly distributed between locations.
Dissolved nutrients The fractions of the nutrients, composed of the organic and inorganic intermediates, which are highly soluble and readily utilized by a wide range of microorganisms in the water.
Epilimnion This is a term used to describe the upper layer of water, particularly in a stratified aquatic ecosystem due to high temperature and low mixing regimes.
Eutrophication Over-enrichment of the aquatic ecosystem with nutrients induced either naturally or artificially (anthropogenic).
Stratification Formation of vertical layers from the top (epilimnion) to the bottom (hypolimnion) waters of a lake or reservoir mediated by temperature differences and water density.
Surface density layers (SDLs) a very thin layer at the surface (<2 m deep) where the temperature changes rapidly with depth, leading to the development of strong density layering.
Three Gorges Reservoir (TGR) A large artificial reservoir formed by the direct hydraulic operations of the world's largest hydroelectric project, the Three Gorges Dam (TGD) in the Yangtze River Basin, China.
$\mathbf{Z_{mix}}$ Also referred to as the mixed layer depth, represents the top part of the water column where temperature and solute concentrations are vertically homogeneous due to wind-driven turbulence (mixing regimes).

General overview

Eutrophication, from human-induced, nutrient-over enrichment in freshwaters and coastal margins, has intensified globally. The anthropogenic form of eutrophication, referred to as cultural eutrophication (Domingues et al., 2011), is largely linked to the direct

consequences of human activities and has become a serious problem for many inland waters. This far exceeds the impacts from any natural increase of nutrients arising from weathering and natural buildup of nutrients (natural eutrophication) in the catchment. Aquatic ecosystems are vulnerable to multiple anthropogenic stressors, which are still increasing despite decades of awareness of the problems. One interacting pressure is the change of ecosystem and function of reservoirs created by damming or rivers, which are increasing globally to meet energy demands (Zarfl et al., 2015). There are many examples of freshwater ecosystems disturbed by the heavy proliferation of cyanobacterial blooms. Indicative examples are the Guadiana estuary bearing the Alqueva Dam, Portugal (Domingues et al., 2012) and the Yangtze River hosting the Three Gorges Dam, China (Ji et al., 2017). However, considering the pattern and economic incentive for urbanization and industrialization from damming, meeting the challenges of reducing eutrophication and harmful algal blooms (HABs) is extremely difficult. River damming is essentially driven by economic needs, representing a cardinal indicator for both social and economic developments across the world (Domingues et al., 2014). The Three Gorges Dam (TGD), is the world's largest hydroelectric project (Wang et al., 2013), with a total capacity of 22.5 million kW and a net annual power generation of 100 billion kWh, designed to meet the electricity demands in the middle and eastern China. The TGD constantly provides electricity to central, eastern, and southern China within an economic transmission distance of 400–1000 km, including the provincial regions of Henan, Hubei, Hunan, Jiangxi, Chongqing, Shanghai, Jiangsu, Zhejiang, Anhui, and Guangdong. The Aswan Dam (AD) is another example, constructed to regulate the flow of the River Nile, which serves as an electric provider to almost all of Egypt. The Aswan Dam contributes more than half of the total power supply in Egypt (Harold et al., 1996). Similarly, the large Alqueva Dam, built in 2002 in the Guadiana River (southern Portugal) and which provides electricity the whole Alentejo region, has highly controlled the freshwater flowing into the Guadiana estuary (Domingues et al., 2014). Other benefits of damming include providing water for drinking, irrigated agriculture, flood control, tourism, and navigation (Lehner et al., 2011; Ji et al., 2017). Freshwaters around the world are heavily regulated with $\geq$45,000 large dams built since the 1930s (World Commission on Dams, 2000; Mei et al., 2015).

There is a constant search for eutrophication and algal bloom abatement strategies that could guarantee a relatively eutrophication and algal bloom-free society without using global developmental indices, such as dams, as the opportunity costs. In this regard, different mitigation measures (physical, chemical, and biological) have been proposed and tested in both field- and laboratory-scale studies over the years, with some successes documented in a few applications (Nwankwegu et al., 2019; Paerl et al., 2016). Although, with the recent surge, succession, and evolution of more problematic algal bloom species in response to the exponential increase in anthropogenic activities, it appears that these abatement steps have not reversed the situation on a global scale (Nwankwegu et al., 2019). Damming has been shown to affect adversely downstream rivers, causing notable changes including alteration of ecology, change of channel morphology, modification of water level, disruption of downstream sediment transport, change in net water balance and regulation of flow regimes (Mei et al., 2015). This chapter, therefore, captures the impacts of dams, especially in promoting the global expansion of algal blooms with special reference to the two tributaries in the Three Gorges Reservoir (TGR), which are severely impacted by blooms due to accumulated dam operations over the years. Furthermore, it identifies anthropogenic actions, largely dominated by damming and urban discharge as the primary stressors for ecosystem vulnerabilities and algal blooms worldwide.

The Three Gorges Reservoir

There are 16.7 million reservoirs larger than 0.01 ha (surface area) on Earth (Lehner et al., 2011), and another 3700 major dams are either planned or under construction (Zarfl et al., 2015). Water flow control programs have fragmented over half of the large rivers on Earth (Wu et al., 2019). Reduced connectivity of rivers resulting from dam construction changes both physicochemical conditions and habitat utilization. Although there are substantive benefits for flood regulation and hydropower, dams modify the natural landscape of ecological functions across whole river basins (Simon, 2002; Maavara et al., 2020). Altered tributaries in the catchment change from lotic to lentic ecosystems (Resh et al., 1988), which, when combined with nutrient loading, provide favorable conditions for HABs composed of species such as *Microcystis*, *Dolichospermum*, *Anabaena* and *Aphanizomenon* (Cirés et al., 2013; Zhang et al., 2018; Xin, 2021).

The Three Gorges Reservoir (TGR) is the largest hydroelectric and flood control reservoir in the world. Its annual electricity production allows for a reduction of 50 million metric tons of coal consumption, preventing 120 million metric tons of CO_2 and 10,000 metric tons of CO emissions per year (Zhang et al., 2015). Completed in 2009, the impoundment of the reservoir resulted in a 100-m water-level rise, reaching 175 m above sea level. This project transformed a 660-km reach of the Yangtze River into a highly regulated reservoir. At high water levels, the serpentine reservoir contains 40 billion m^3 of water with an increased water surface area of 645–1200 km^2 (Fu et al., 2010). There are over 40 major tributaries (watershed areas $>$100 km^2) flowing directly into the TGR (Ji et al., 2017). These characteristics of the TGR provide a unique opportunity to study how dam construction and water flow management can result in novel threats to human and environmental health.

Before the construction of the dam, algal blooms were not common in the TGR basin (Zeng et al., 2007) but, following construction, the frequency and magnitude of HABs have intensified and become a serious concern (Zeng et al., 2007; Li et al., 2011; Zhang et al., 2015). Many studies have attributed these blooms to excessive nutrient inputs to the TGR (Zeng et al., 2006; Ye et al., 2007; Zhang et al., 2010; Gao et al., 2016). The elevated concentrations of nutrients, such as total nitrogen (TN), total phosphorus (TP), and silica (Si), are two- threefold higher than the reported threshold for eutrophication (Thomann and Muller, 1987). Drivers of these changes are high population densities and intensive agriculture in the TGR basin.

(A) The location of the Three Gorges Reservoir in the Yangtze River Basin, China; (B) The location of Pengxi River in the Three Gorges Reservoir area; (C) The distribution of sampling points in the mainstream of Pengxi River; (D) The locations of the sampling point in Gaoyang Lake.

Decreased water velocities in tributaries have also been linked to the formation of HABs (Wang et al., 2013) as has the development of stable water columns (Davis and Koop, 2006; Yang et al., 2015; Liu et al., 2012; Conroy et al., 2014; McKay et al., 2018). As a result of flow control, water velocities in the tributaries of the TGR have declined from 0.5–1 m s^{-1} to 0.05 m s^{-1}. The main channel, however, has maintained a constant flow of 1.0 m s^{-1} (Wang et al., 2013).

The TGR is located in the middle stem of the Yangtze River, between Chongqing and Yichang City, receiving 40 1st order tributaries (watershed areas >100 km^2) (Fig. 1B) (Ji et al., 2017). Following impoundment of TGD, 50% of these major tributaries have had spring algal blooms (Yang et al., 2017; Zhang et al., 2020; Xiang et al., 2021) in most years, and a few of them have suffered from summer algal blooms (Nwankwegu et al., 2019). This shows the diversity of the mechanisms of algal blooms in different 1st order major tributaries in the same TGR catchment. Two major tributaries, Pengxi River in the middle reach of TGR catchment, and the largest 1st order tributary in catchment's northern bank and Xiangxi Bay, the second last 1st order tributary from the TGD, have been chosen to illustrate the diversity.

The eutrophication in Pengxi River, middle of the TGR

Brief description and geographical location

At the highest water level in winter, 175 m above sea level, TGR surface is 1080 km^2 with a storage of 39.3 billion m^3 (Zeng et al., 2019). The annual average water velocity in the main stem is 0.4 m s^{-1}, contrasting with the much slower flow, 0.01–0.21 m s^{-1}, in its tributaries (Lu et al., 2020; Zhang et al., 2020). The water level is maintained at 175 m above the sea level in winter to generate electricity, and 145 m in summer to create capacity for flood control. Nutrients in the main stem of the Yangtze River are considerably higher than in its tributaries, and water from the main stem flows back into the tributaries when the water level increases (Luo et al., 2007).

The Pengxi River(30°49′ ~ 31°42′ N, 107°56′ ~ 108°54′ E), also known as Xiaojiang, is the largest tributary on the northern bank of the TGR catchment (Zhang et al., 2020) with the main river channel of 182.4 km, with an annual average runoff of 3.41 billion m^3 and basin area of 5173 km^2 (Fig. 1). It is within a subtropical moist monsoon area, where the climate is temperate and sub-humid, with an annual average temperature of 18.6 °C, and annual average precipitation of 1100–1500 mm (Li et al., 2015). The Pengxi River is one of the TGR tributaries that are most prone to algal blooms, which tend to happen in April and May (Guo et al., 2011; Zhou et al., 2016; Zhang et al., 2020).

Gaoyang Lake (31°05′27.4″N′108°40′41.6″E) was formed in 2003 as a result of the water level increase associated with the TGD, and is in the middle reach of the Pengxi River. It has a surface area of 4–5 km^2 and a maximum width of 1 km (Fig. 1D) when the water table is at 145 m above sea level. The lake is affected by water level regulation in the TGR, and alternates between shallow (max depth: 10 m) in summer and deep (max depth: 40 m) during the rest of the year (Zhang et al., 2020). Since 2007, Gaoyang Lake has had the most severe algal blooms in the Pengxi River (Guo et al., 2011; Zhang et al., 2015, 2020).

Surface density layers (SDLs) with algal blooms in Pengxi River

Existence of SDLs in Pengxi River

Algal blooms in the tributaries in the TGR area are generally concentrated in the spring of each year, from March to May (Fig. 2) (Xiang et al., 2021). When blooms occur, the concentration of chlorophyll *a* (Chl-*a*) in the water body can exceed 400 μg L^{-1} (Zhang Xin, 2021). This does not conform to algal blooms typically observed in temperate lakes, where the increased algal biomass is frequently associated with periods of maximum heat content in late summer (Paerl and Huisman, 2008).

Thermal stratification is often critical to forming an algal bloom (Davis and Koop, 2006). Stable stratified systems ensure algae stay in the euphotic zone for photosynthesis, hence leading to algal blooms. In spring, in subtropical and temperate lake systems, the long fetches caused by wind on wide lake surfaces lead to unstable stratification and low water temperatures, hence preventing blooms from developing. In late summer, on the other hand, short-term (a few days) high temperatures enable stratification which creates an epilimnion (Fig. 3A) where the algal blooms occur (Paerl and Huisman, 2008).

Stratification in the tributaries in TGR including Gaoyang Lake does not create epilimnetic layers. The reason is related to the special topography of the TGR area. Over 95% of the TGR region is mountainous (Peng et al., 2006) with large elevation differences (~2000 m) between the water surface and mountain peaks (Li et al., 2001), resulting in very low wind speeds over the surface of the reservoir (e.g., 0.9–2.1 m s^{-1}, Yang et al., 2017). These characteristics, coupled with the limited fetch at the water surface width (<1 km), can prevent the development of breaking waves and the formation of an epilimnion. Instead, tributaries in the TGR form a unique stratification characterized by surface density layers (SDLs), a very thin layer from the surface (<2 m deep) where the temperature changes rapidly with depth. This leads to the development of strong density layering within the SDLs (Fig. 3B) with the minimal influx of nutrients from the lower water column (Zhang et al., 2020). For example, the change in water density from 30 °C to 33 °C is approximately 0.95 kg m^{-3}, whereas water density changes from 4 °C to 8 °C, commonly observed in lakes, is 0.12 kg m^{-3} (Tanaka et al., 2001).

Note the depth of the surface mixing layer (epilimnion). (B) Water stratification of Gaoyang Lake, Pengxi River from spring to summer in 2013. 04–30 represents month and date, and so on. Note that there is almost no surface mixing layer.

SDLs is related to the algal blooms in the Pengxi River

Algal blooms in Gaoyang Lake are repeated events that develop with the onset of SDLs and disappear with the stabilization of SDLs. The algal blooms in Gaoyang Lake in 2019 are examples. During the 33-day continuous sampling process from April 15 to May 17, 2019, Chl-*a* in the surface water fluctuated daily (Fig. 4A). These fluctuations corresponded to the stratification at the same time (Fig. 4A and B). Stratification began from April 19 (4/19 in the figures) and dynamically changed afterwards (Fig. 4B). During April 21–23, April 28 to May 1, May 4–6, May 7–10, May 13–16, the mixing depth (Z_{mix}) of surface water bodies increased significantly because of wind disturbance, which resulted in several peaks of different magnitude of Chl-*a* concentrations. Especially on May 7–10, a wind speed of only 5.4 m s^{-1} (in the spring of Pengxi River, this is considered a strong wind) brought soluble phosphorus from the lower water column to the SDL (Fig. 4C), resulting in a severe bloom with Chl-*a* as high as 413 μg L^{-1} at the surface.

Why did the above-mentioned blooms die out? We found interestingly that during April 18–19, 24–27, May 2–3, and May 11, Z_{mix} of the water body was almost zero, i.e., as the temperature rose and stratification developed, the SDLs appeared, leading to minimal influx of nutrients from the lower water column, preventing further growth of algae. For example, from April 28 to May 2, the water changed from normal stratification to the formation of SDLs and Chl-*a* only increased slightly, because the dissolved total phosphorus (DTP) of the surface layer decreased to 0.003 mg L^{-1}. Similarly, the algal bloom with Chl-*a* as high as 250 μg L^{-1} from May 3–6 once again was brought to an end due to SDL formation, which reduced DTP in the surface water. This process illustrates an interesting phenomenon where even in a hyper-eutrophic system, the growth of algae sometimes faces the dilemma of nutrient deficiency due to nutrient limitation resulting from the formation of SDLs.

Implications of SDLs theory

SDLs theory can also explain why the tributaries in the TGR area rarely have blooms in the summer. The high temperature and low wind in the summer maintain the SDLs in summer leading to water surface temperature as high as 30 °C (Zhang et al., 2020). Nutrition and high-temperature stress might prevent the occurrence of algal blooms. Some studies have also attributed the lack of algal blooms in the summer to discharge of water from the TGD, which could make the flow faster than in spring, hence not suitable for algae to multiply. In fact, the average flow velocity of the Pengxi River in Gaoyang Lake from May to August is only 0.32 m s^{-1} (Zhang et al., 2020), which would not be high enough to prevent the occurrence of blooms (Wang et al., 2019; Li et al., 2021).

Eutrophication in Xiangxi Bay (XXB)

Xiangxi River

The Xiangxi River is the largest tributary in the lower reach of TGR in the Yangtze River. It has a length of 94 km, an average annual flow of 47.4 $m^3 s^{-1}$, watershed area of 3099 km^2 and is located within the latitude 31°04′–31°34 N′ and longitude 110°25′–111°06E′. It originates from Shennongjia National Park, Northwestern Yichang City, Hubei province, China. The Xiangxi River flows through Xingshan and Zigui Counties, north to south and empties into the mainstream of TGR in Xiangxi Town (Yang et al., 2015). Only 32 km away from the Three Gorges Dam, it is the second first-order tributary from the dam (Fig. 5).

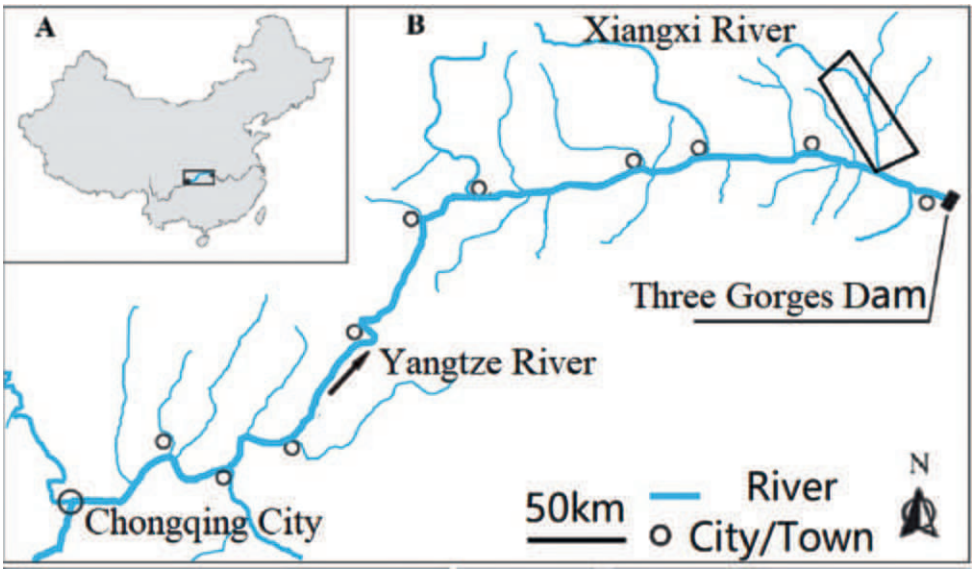

Fig. 5 Xiangxi River in the Three Gorges Reservoir. (A) The map of China; (B) The Three Gorges Reservoir.

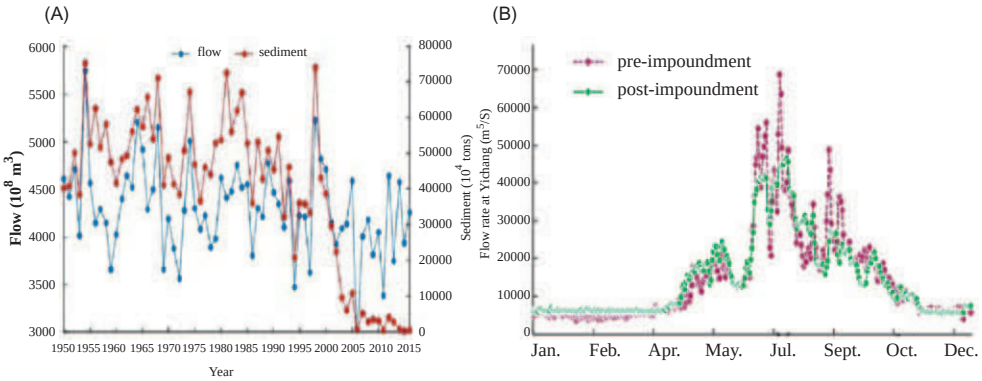

Fig. 6 (A) Variations in annual discharge (10^8 m^3), sediment discharge (10^4 metric tons), and (B) monthly flow rate (m^3 s^{-1}) in Yichang from upstream Yangtze River before (2002) and after (2012) the TGD impoundment.

The hydrodynamic conditions of Xiangxi River including annual flow volume, sediment discharge, and flow rate (Fig. 5) changed remarkably between the pre (1950–2002) and post (2003–2015) TGR impoundment eras. The backup effect of the mainstem of the Yangtze River caused the Xiangxi River to transform from fluvial (lotic) to a static state (Fig. 6), which is manifested by its long water retention time (179 days) and high suspended solids concentration. The first impoundment of the Three Gorges Reservoir in 2003 turned Xiangxi River into a deep bay (39.6 ± 22 m). Therefore, all the studies on the Xiangxi River after impoundment directly refer to the river as Xiangxi Bay (XXB).

The hydraulic operations of TGR have created four distinct phases of hydrodynamic cycles in XXB on a yearly basis: (i) phase of water supply between April to May (ii) phase of the flood around August, (iii) phase of impoundment (September) and (iv) phase of high-water level (December) (Li et al., 2020; Yang et al., 2015; Xu et al., 2011). In 2010 when the TGR finally reached its maximum water level of 175 m, the hydrodynamic backwater from the main stem of the Yangtze River extended to 40 km upstream in XXB (Ji et al., 2017; Jiang et al., 2018; Zhu et al., 2013).

The XXB receives nutrients from several anthropogenic sources including the chemical mining industries localized within Xiakou Town, most of which are close to the bank of the bay. XXB also has numerous drainage inlets through which highly concentrated domestic sewage from surrounding counties, is directly discharged into the bay (Zhou et al., 2012). Furthermore, there is a huge increase in dissolved N resulting from the influence of non-point sources into the tributary due to fertilizer from the extensive crop and animal agriculture in surrounding counties: Xingshan and Zigui both of which are located in Xiakou town. The increasing sewage discharge and constant point-source P loading from mining activities, also raise high P inputs. Consequently, the dramatic change in XXB hydrodynamics and nutrient budget has led to massive cyanobacterial blooms characterized by protracted water quality deterioration throughout the year, particularly in summer and spring. The blooms threaten public health and need urgent remedial attention.

Interactions between hydrodynamics and nutrient supply in XXB

Nutrient cycling in XXB shows strong sensitivity to the hydrodynamic factors, such as the stratified density current and water level fluctuations, intensified by the operations of the TGR. These hydrodynamic influences accentuate the anthropogenic nutrient loading and the development of cultural eutrophication. Yang et al. (2018) gave three potential classifications of the XXB density currents notably: the bottom layer intrusive current, dominant in winter; middle layer intrusive current, prevalent in both spring and summer; and the surface layer intrusive current, which is dominant during autumn. These density currents are reported to drive the mechanisms that supply a large amount of nutrients into the XXB exacerbating eutrophication in the bay. The middle layer intrusive current was identified to be responsible for the thermally stratified condition in those seasons (spring and summer). The critical depth hypothesis suggests that as long as the middle layer intrusive current continues to occur, unabated algal blooms outbreaks in XXB have a high probability to persist (Fig. 7).

Regulation of daily water-level fluctuations has been used by the reservoir managers to reduce the relative water column stability in order to mitigate HABs in some tributaries (e.g., Xiangxi River) but with limited success (Yang et al., 2013; Sha et al., 2015; Ji et al., 2017). Similar approaches to modifying water column stability have proven effective in controlling HABs in a relatively small reservoir in Spain (Rigosi and Rueda, 2012). However, the size of the TGR (660 km long and an average of 1 km wide) limits the use of water flow to manage water column stability for HAB control. Water-level fluctuations in tributaries far from the dam are relatively minor.

Previous studies (Ji et al., 2017; Yang et al., 2018) demonstrated that the operations of the TGD have a significant impact on water level regulations following the so-called eco-environmental friendly operation (EEFO), which involves closing for water retention and opening for discharge during the low flow and the high peak seasons, respectively (Ding et al., 2019). The TGD storage and discharge have potentially stimulated the massive phytoplankton growth in XXB. Specifically, the dam storage for water retention in low flow seasons (max. Water level = 175 m) allows water with high TN/TP to flow from the mainstream into the XXB while dam discharge during high peak seasons (min. Water level = 145 m) allows water with low TN/TP to flow into the mainstream (Chuo et al., 2019). The periodic water exchanges and nutrient fluxes, therefore, promote bloom development. This supports the concept that hydrodynamic factors, are important characteristics that control the mechanism of nutrient supply into the XXB, together with the anthropogenic nutrient inputs from agricultural runoff and urban discharge (N input), industrial wastewater, and domestic sewage (P input). These hydrodynamic characteristics essentially make the XXB different from the Taihu Lake, China and other freshwaters and reservoirs across the world. Lang et al. (2019) recently suggested that the primary cause of algal blooms, especially the spring bloom in the XXB, lies in the prevention of the upstream inflow from entering TGR, with nutrients enriching the upper and middle reach of XXB from winter to early spring. Furthermore, they proposed that bloom mitigation measures, such as improving the upstream hydrodynamic conditions and forcing the nutrients to flow into the TGR in the winter, should be prioritized to avert risks of HABs rather than the artificial tide operation of TGR (transitory water level regulations) frequently recommended in several studies (e.g., Liu et al., 2012).

It is important to note, however, that the development of algal blooms in the XXB could partly be attributed to point and non-point source pollution. Blooms were not reported in that area before the TGD impoundment, thereby implicating anthropogenic stressors as the principal triggers of blooms in the XXB, assisted by the hydrodynamic conditions and the nutrient cycling pattern.

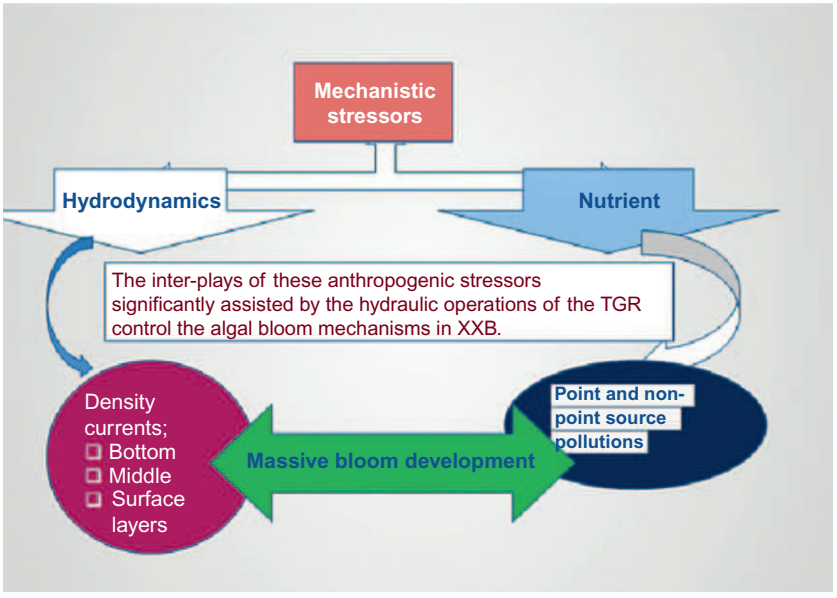

Fig. 7 Summary of the mechanisms underlying the proliferation of harmful algal bloom in the Xiangxi tributary in the Three Gorges Reservoir.

Management implications

Dammed tributaries with different morphologies and land-use activities can experience different intensities of algal blooms. Management of algal blooms in the TGR will need to account for differences among the tributaries with respect to how sensitive they are to dam operation and their varying morphologies and land-use patterns. For example, in order to disrupt the formation of stratification, regulation of daily water-level fluctuations is effective in the tributaries close to the dam including Xiangxi Bay. By contrast, local artificial mixing of the water column, including aeration, would not be effective to control algal blooms in the tributaries in the middle and upper reach of the TGR due to nutrient resupplies from the lower water column to the algae at the surface, associated with SDLs. Therefore, we suggest that tributary-specific management plans will be more effective than an overall reservoir management strategy in the TGR.

The construction of dams results in reservoirs that vary in their susceptibility to HABs. Our study demonstrated that the upper reaches of tributaries, are more vulnerable to algal blooms because of dam operations and formation of SDLs. The formation of SDLs, are a phenomenon that might be unique to reservoirs that are confined within deep canyons that prevent surface wind mixing. A long-term nutrient reduction policy is proposed as it is unlikely that nutrient management within the TGR will immediately address the control of algal blooms. Therefore, future research should address the interaction of hydrological phenomena, such as the formation of SDLs and nutrient bioavailability. Furthermore, our studies have demonstrated that during the algal bloom seasons in either Pengxi River or XXB, the nutrient cycling between the upper and lower water column and the sediment is key to initiating algal blooms. Reducing diffuse nutrients inputs takes decades (Müller et al., 2014; Fastner et al., 2016), but using floating macrophyte mats to absorb N & P in the upper water layers during the bloom season could be effective for mitigating the blooms and speeding up the removal of nutrients, especially P (Wang et al., 2020; Colares et al., 2020).

Conclusions and knowledge gaps

This chapter evaluates the impact of human pressures on the environment, especially in promoting harmful algal blooms in freshwaters. It uses as a reference, the two rivers (Pengxi and Xiangxi) in the Three Gorges Reservoir to explore the effect of these anthropogenic actions on the aquatic ecosystems. In summary, the studies on eutrophication in the two TGR 1st order tributaries, Pengxi River in the middle reach, and Xiangxi River near the TGD, demonstrate that the mechanism of algal blooms is case-based. The continuous blooms of Pengxi River and Xiangxi River cannot be simply attributed to the excess of nutrients although these systems are hyper-eutrophic. The important findings/knowledge gaps, therefore, include:

- The TGR is exposed to multiple anthropogenic pressures, dominated by dams and nutrient enrichments from point and non-point sources;
- Dam closure in the TGR has resulted in the creation of numerous artificial and vulnerable tributaries, which are severely impacted by HABs;
- The mountainous topography of the TGR catchment leads to the formation of unique surface density layers where nutrient deficiency could happen during algal bloom season among the hyper-eutrophic waters;
- Strong nutrient regulations (multiple reduction strategy) would greatly assist in HABs abatement in the TGR;
- Although both Pengxi and Xiangxi Rivers are freshwater systems in the TGR, they show different severities in their bloom seasons, while maximum HAB events occur during summer in the Xinagxi River, the most severe HAB event is reported during spring in the Pengxi River.

Glossary

To date, a comprehensive English language mine water glossary does not exist. In most cases, the glossary in the GARD Guide (www.gardguide.com) or in McLemore (2008) might be a first stop.

Acid/Acidity Acid/Acidity are two different concepts. "Acid" refers to the proton acidity and is measured with a pH-meter. Acidity is the sum of the proton acidity, metal acidity and other naturally occurring acids. It is determined by titration.

Adit Adit is a horizontal or close to horizontal tunnel or gallery that connects the surface with an underground mine.

Barite Barite is a sulfate mineral with the formula $BaSO_4$.

Calcite Calcite is a carbonate mineral with the formula $CaCO_3$.

Dolomite Dolomite is another carbonate mineral with the formula $CaMg[CO_3]_2$.

Electrical conductivity Electrical conductivity is a measure for the potential of a liquid to conduct electricity. In general, the more ions are dissolved in a liquid, the higher this value will be, which is usually measured in mS cm^{-1} or µS cm^{-1}. It is compensated to either 25 °C or, more seldom, to 20 °C. Because of this characteristic, the electrical conductivity can be used for a quick indication of a mine water's contamination status.

 https://doi.org/10.1016/B978-0-12-819166-8.00036-0

Feldspar Feldspar is a collective name for a large group of silicate minerals with the formulae $KAlSi_3O_8$, $NaAlSi_3O_8$, and $CaAl_2Si_2O_8$.
Heavy metal Heavy metal is a music style. According to the International Union of Pure and Applied Chemistry (IUPAC), no other usage is recommended (Duffus, 2002), as there are more than 40 definitions, thus rendering the meaning vague.
Marcasite Marcasite is a sulfide mineral with the formula FeS_2. Though chemically identical to pyrite, it has another crystal structure.
Mine water Mine water or mining influenced water (not: mine wastewater, mining impacted water, mining affected water) is all the water in a surface or underground mine or seeping through waste rock. Strictly speaking, the water from the processing plant and the tailings is process water, as it contains human-induced process chemicals.
Ochre Ochre is a collective term for yellow to dark orange iron oxides with a clayey to sandy composition.
Orphaned Orphaned mines are abandoned mines that are ownerless.
pH pH is a parameter that expresses the activity of protons (positively charged hydrogen ions) in liquids. There is nothing such as a "pH-scale" and it has no units as it results from the calculation of a logarithm. The lowest, that means most acid, ever measured pH in nature is −3.6 and the highest alkaline one 13. It is measured with a pH-probe.
Pyrite Pyrite is a sulfide mineral with the formula FeS_2. Though chemically identical to marcasite, it has another crystal structure. When pyrite or marcasite come into contact with water and oxygen, acid mine drainage or acid rock drainage forms.
Pyrrhotite Pyrrhotite is a sulfide mineral with the formula $Fe_{(1-x)}S$; $x = 0–0.2$. In contact with water and oxygen, this mineral also forms acid mine or rock drainage.
Redox potential This parameter indicates the sum of all oxidation and reduction reactions in a liquid and is an expression for the "free" electrons in a solution. It provides a measure of the oxidizing or reducing tendency of this solution. A redox potential below zero millivolt (mV) indicates reducing and a redox potential above zero millivolt an oxidizing environment. It is measured with a redox probe and must be corrected to the standard hydrogen electrode (www.Wolkersdorfer.info/orp).
Semi-metals Semi-metals (metalloids) are elements that show characteristics of both metals and non-metals or either of them. Commonly recognized semi-metals are arsenic, boron, germanium, antimony, silicon, and tellurium.
Suspended Solids (SS) Suspended Solids are all the smaller particles in a liquid that stay suspended. They may settle once the liquid's velocity slows down or when time passes.
Tailings Tailings are the fine-grained residues of mineral processing and contain currently uneconomic crushed and milled rock and chemicals from the processing plant. Tailings are stored in sludge ponds, called tailings dams or are dry stacked in tailings disposal sites.
TDS (total dissolved solids) TDS are indicative for the sum of all inorganic and organic ions dissolved in a liquid. The higher the TDS concentration, the more ions are dissolved, which means the water is more mineralized. In mining influenced water, it must be measured by gravimetry and not approximated by a simple calculation from the electrical conductivity (Hubert and Wolkersdorfer, 2015).
Trans-drainage basin diversion Trans-drainage basin diversion means that water from one river drainage basin is transferred into another drainage basin by way of pipes or channels.

Introduction

Mining includes modern, small-scale, and artisanal surface mining, strip mining, placer mining, underground mining, solution mining, *in situ* mining, quarrying, or the extraction of groundwater. Approximately 240,000 km^2 of the Earth's surface are covered by abandoned, closed, or orphaned mines (Wolkersdorfer, 2008). There, pollution pathways include surface, groundwater as well as aerial deposition (Fig. 1), and potentially contaminated sediments might collect in the stream beds and lakes. Mining influenced water can develop acid (below pH 5.6), circumneutral (between pH 5.6 and 8), or basic pH values (above pH 8), and in terms of dissolved matter, it can be dilute, mineralized, or saline (Nordstrom et al., 2015). Once inland waters are contaminated by mine water, their remediation can take long and may involve large financial burdens (ERMITE Consortium et al., 2004).

Protecting the environment from pollution, both from tailings and from the mine workings is a complex problem (ERMITE Consortium et al., 2004), and its solution takes the combined efforts of many partners. Unquestionably, the best protection of the ecosphere would be to prevent mining entirely or, alternatively, recycle all used metals, rocks or aggregates (European Innovation Partnership on Raw Materials, 2016). Yet, both options are currently not feasible in face of the demand of a growing world population for raw materials. Therefore, responsible and sustainable mining uses a life cycle assessment including the "mining for closure" principle and the "cradle-to-grave" approach (Idowu et al., 2013; Northey et al., 2018; Peck et al., 2005; Wörlen et al., 2005).

Examples in this article are not chosen to single out individual mine sites or mining houses, but as relevant examples describing a particular mechanism or case. Many of the well documented mine sites are operated by responsible companies that openly discuss their problems, while many heavily polluting mine sites (Earthworks and Oxfam America, 2004) are inadequately documented,

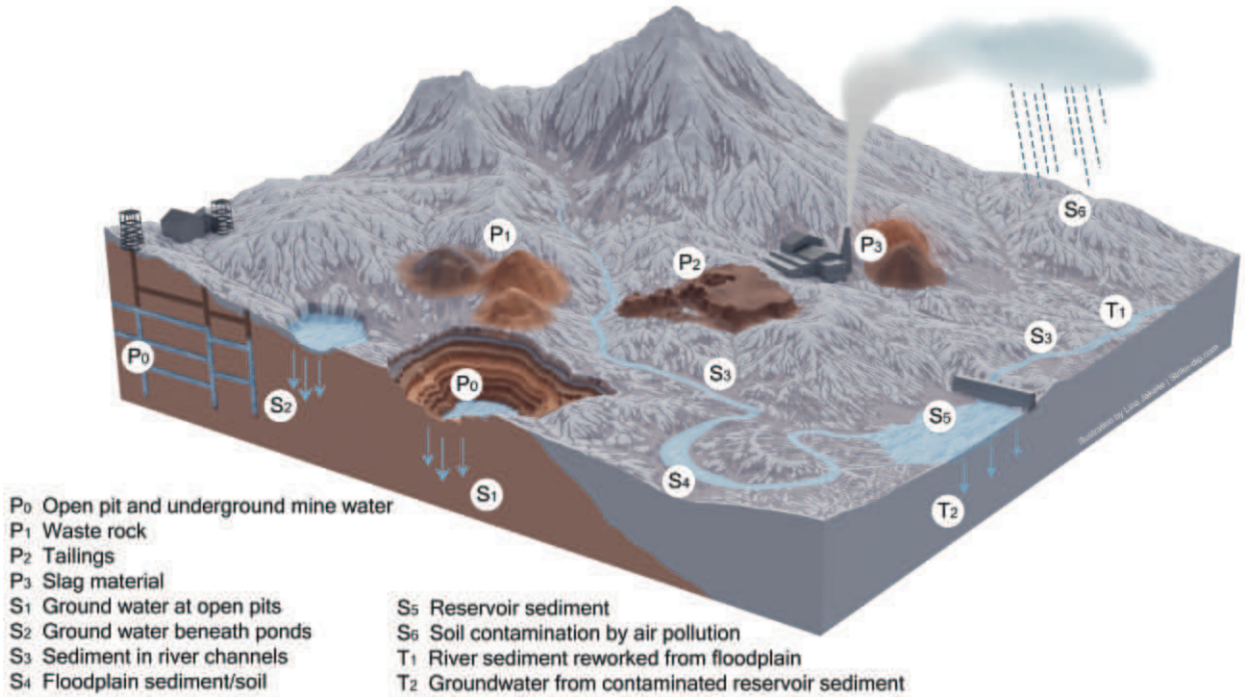

Fig. 1 Pollution pathways in the mining environment. P: primary contamination, S: secondary contamination, T: tertiary contamination. Modified after Moore JN and Luoma SN (1990) Hazardous wastes from large-scale metal extraction—A case study. *Environmental Science & Technology* 24(9): 1278–1285, https://doi.org/10.1021/es00079a001.

because the owners restrict publication of unwanted results or access to these sites. In addition, it is noteworthy to state that responsible mining tries to avoid lasting environmental damages. Responsible mining ensures that the mining operation has its social license to operate and mining remnants are mitigated as well as remediated to near pre-mining conditions as best as possible (International Council on Mining and Metals, 2008).

What is mining influenced water

Evolution of mining influenced water

Mining interferes with the natural geological conditions and transforms an often reducing environment, in which the minerals were thermodynamically stable, into an oxidizing one. These changes to the environment bring the minerals in contact with water, oxygen and an abundance of microbes that immediately take advantage of the new thermodynamic conditions and possibilities (McLemore, 2008; Wildeman and Schmiermund, 2004).

Sulfate enriched mine water predominantly results from the microbially catalyzed oxidation of the iron-sulfides pyrite, marcasite and pyrrhotite to sulfate and acid (Fig. 2), whereby pyrite and marcasite are the most common of these minerals in coal, base metal and gold deposits (Blowes et al., 2014; Nordstrom, 2011). In total, the process involves four steps, which shall be described for pyrite (Stumm and Morgan, 1996). Firstly, pyrite reacts abiotically with water and oxygen (I) or is used biotically by microorganisms for their metabolism. This results in high concentrations of dissolved sulfate, ferrous iron (Fe^{2+}) and protons. In the next step (II), the ferrous iron is oxidized to dissolved ferric iron (Fe^{3+}) which either oxidizes the pyrite to form more ferrous iron (III) or it reacts with the water and oxygen to form iron-oxihydrate precipitates (IV). Microorganisms, such as *Acidithiobacillus thiooxidans*, accelerate these relatively slow abiotic reactions 1 million times (Wolkersdorfer et al., 2020).

When carbonate or silicate minerals are present, they partly counteract the above reactions, as they buffer the produced protons. This means that the protons react with minerals such as calcite, dolomite, or feldspars, resulting in their dissolution and releasing their elements into the water. As the pH of the receiving inland waters will buffer pH from these reactions, many metals or metalloids will precipitate (Fig. 3) or co-precipitate, subsequently improving the water quality (Stumm and Morgan, 1996).

In the case of saline mine waters, the evolution is completely different. It is normally a physical process, by which solid salts are dissolved until they reach a (semi)stable equilibrium with the mine water. In mines with soluble salts, the physical and chemical reactions involved can be complicated, as the various solubilities of salts substantially change with temperature, saturation of the salts and the brine's composition (Herbert and Sander, 1987).

When pyrite oxidation as well as saline waters combine, the results are saline mine waters with elevated (semi-)metal and sulfate concentrations. This is often seen in coal mine discharges regardless of where on Earth they occur.

Cravotta III, pers. comm. 2013.

Mine water—Surface water linkages

To keep a mine operating, it needs a sustainable water management plan in place that accounts for pumping the water from the mine workings, supply of water for ore processing, dust suppression and human use. All these water streams in and around the mine need to be known to manage the water balance reliably (Punkkinen et al., 2016). Predominantly, the mine dewatering affects the groundwater, but in several cases also ecological affects might occur as surface water is diverted around a mine site, especially when trans-drainage basin diversion occurs (Marcus, 1997).

As long as a mine is operating, pumped water, as well as tailings dam and waste rock dump seepage water will come into contact with surface water, mostly following treatment—unless a mine operates in dry areas with a lack of groundwater. Once mining commences, the open voids will start to be filled with groundwater and the mine starts to flood, a process that usually takes years to decades. When the water level in the mine reaches the lowest discharge point, the mine water will start to discharge into the receiving water courses (Wolkersdorfer, 2008) or terminal pit lake sinks (McCullough et al., 2013). Those linkages between mine water and surface water can take many different forms: seepage from shallow underground workings, discharges from pit lakes, bore holes, adits, inclines, or shafts. Seepage can also occur through overburden and especially from collapsed hanging wall areas and may contribute notably to surface water contamination. For protecting the environment, shaft or adit discharge is preferable, as the water can be directed towards an active or passive mine water treatment plant.

Tailings are nearly always connected to inland waters, except when located in arid areas or they undergo submarine disposal (Dold, 2014). Tailings dam water sees various forms of linkage to surface water such as overflow, seepage water into surrounding water courses or indirectly though seepage into the groundwater, which might then emanate to the surface downstream of the tailings dam (Fortuna et al., 2021).

Waste rock usually contains residues of the mining operation that are deemed currently economically unviable. If this material is chemically inert, the seepage water should pose no detrimental effects on the surface water other than modest increases of electrical conductivity or suspended solids content. Should the waste rock contain minerals (e.g., disulfides or efflorescent minerals) that produce acidity or elevated contaminant concentrations during weathering, the discharged seepage water may cause detrimental effects to the receiving water bodies.

Physico-chemical characterization

Mining influenced water can be characterized by its physico-chemical parameters such as temperature, electrical conductivity, pH, redox potential, turbidity, color, and oxygen saturation. These are mainly interdependent from each other and normally there is no correlation between them, though temperature affects the solubility of oxygen, or pH the solubility of many metals. In addition, all these variables and parameters show high variability, ranging, for temperature, pH, and redox potential for example, from −2 °C to 58 °C, −3.6 to 13 and −500 to 900 mV, respectively.

High suspended solid loads and turbidity are common for many mining influenced waters. Turbulence keeps colloid-sized particles or flocculated oxyhydroxides in suspension and results in high concentrations of iron and aluminum in the water. Metal attenuation reactions can sometimes be recognized in the water by turbidity in certain places (Schmiermund and Drozd, 1997).

Mine water can discharge at elevated temperatures of up to 58 °C, resulting from either exothermic reactions or the geothermal gradient. For surface waters, the discharge of warm water can then provide habitats for non-native species, with sightings of released aquarium fish at mine water discharge points in Germany (personal observations), and a reduction of less heat tolerant species.

Very often, mining influenced water is colored, whereby the color depends on the water's constituents and colors the receiving inland waters. Iron rich water has usually colors that range between orange, brown and red, whilst copper rich effluents are greenish to blueish and nickel rich mine water has light blue to green colors. Aluminum and elevated alkalinity results in white colors. This coloring can either be due to dissolved metals (e.g., iron, copper, nickel) or to suspended precipitates, for example gibbsite.

Chemical composition

The chemical composition of mine water shows a high degree of variability (Table 1). This is due to the large spectrum of geological settings (Smith and Huyck, 1999) and the biological, chemical and physical processes involved (Plumlee et al., 1999). In addition, the solubility of the metal hydroxides controls their concentrations in the mining influenced waters and the receiving water courses (Fig. 3).

Some of these elements in mining influenced water will appear in cationic species, such as calcium, others in anionic species like chloride—writing about an element as a constituent of mine water, therefore always implies it is in its ionic form. Extremely rarely, mine water will contain elements in their elemental form; exceptions might be the non-reactive and non-toxic noble gasses. Some of these elements are found more often in mine water, such as protons, iron, copper, aluminum, arsenic, chloride or manganese, others are less abundant, such as molybdenum, selenium, mercury, vanadium, or chromium. Yet, mine water contains water, H_2O, at a concentration of 55.5 mol L^{-1}. The next group of mine water constituents comprise the main ions of water: calcium, sodium, potassium, magnesium, hydrogen carbonate, sulfate, chloride, nitrate at an average concentration of around 0.5 mol L^{-1} and the trace ions at an average concentration of 0.005 mol L^{-1}, which accounts to just 0.01% of the molar composition of water. These are average numbers, as in the case of the Iberian Pyrite Belt, the sulfate concentrations in the mine water account for approximately 2.9% of the water's ionic composition.

Not only does mining influenced water have a different chemical composition depending on the type of ore deposit, host and country rock, and the chemistry of the receiving water itself, but it also changes over time. When water discharges from underground mines, the first flush effect results in elevated concentrations of the most relevant components (Younger, 1997) for a longer time span. These elevated concentrations and the low pH values will impair and color inland waters for years to decades and will have negative effects on the ecological balance compared to pre-mining conditions. One of the reasons is that many elements usually show a higher solubility and often bioavailability at low pH values (Neil et al., 2009; Smith and Huyck, 1999).

Mine types and characteristic effluents

Introduction

Every ore body or mine type develops its characteristic effluent chemistry (Table 1). Reasons for this are the geochemical and hydrogeochemical reactions occurring during water–rock interaction. By knowing the geological, mineralogical, and climatic background of a mine site as well as the mining method applied, first estimates about the mine water chemistry and potential effects on surface water can be made (Plumlee et al., 1999). As described in the previous chapter, the final composition of the mine water is an interplay of various chemical and microbiological reactions and usually shows a high temporal and spatial variability. Their principles are identical at all mine sites around the world. Yet, the particulars are controlled by the site-specific conditions (Table 2).

Table 1 Composition of different mine waters with the most predominant mine water constituents.

In the absence of disulfides or pyrrhotite in the host rock, (di-)sulfide weathering will not occur, and the mine water will not be acid. Yet, this does not guarantee that the mine water will be of good quality, as some elements are mobile under circumneutral or alkaline conditions. Such examples are elevated antimony concentrations in carbonate rocks (Wolkersdorfer and Wackwitz, 2004) or zinc-enriched mine waters in carbonate-hosted lead/zinc deposits (Johnson and Younger, 2002). When neither disulfides nor (semi-)metals that are mobile under elevated pH values nor water-soluble salts exist, the mine water quality will be within regulatory limits. In these cases, the mine water might even be used as drinking water without treatment (Wolkersdorfer, 2008).

Because the number of working and abandoned mines is large, mining influenced water can become a burden to humans and the environment when this water is polluted. Plumlee et al. (1999) compiled which type of ore body will very likely develop what type of mine drainage. Though their compendium is quite U.S.-based, it is of uniform relevance, as the geological, physical, biological, and chemical processes of mine water geochemistry are identical all around the world.

Coal and lignite

Coal and lignite often contain varying proportions of disulfides because the depositional conditions favored the precipitation of these minerals (Pohl, 2020). Occasionally, the sulfur content of coal can reach up to 6%, which can produce substantial amounts of acid when not buffered by carbonate rocks. A general rule is that the higher the sulfur content, the higher the concentrations of the potential pollutants sulfate and iron (Younger, 2002). Common potential pollutants of concern from coal or lignite mines are acid, iron, sulfate, sodium and chloride.

Nearly all coal or lignite mining operations develop acid mine drainage if no precautions are taken, such as mixing the overburden with lime or co-depositing disulfide-rich material with buffering material. Mining methods substantially influence the final mine water quality after mining stops (Mentz et al., 1975). When the coal mine can be flooded, the water quality may gradually improve due to the first flush effects. Many long abandoned coal mines discharge water of good quality (Wolkersdorfer and Bantele, 2013). Yet, when large portions of the mines are open to the atmosphere, pyrite oxidation will continue in perpetuity and the discharge water quality may not substantially improve over time. pH values can be below pH 4 and sulfate as well as iron concentrations can be in the upper milligram to lower gram per liter range (McCullough et al., 2008; Prediction Workgroup of the Acid Drainage Technology Initiative, 2000). A contaminant that only received attention in recent years are PCBs (polychlorinated biphenyl) from hydraulic fluids discharged from German hard coal mines. Although most of the PCBs are below the detection limit in the water phase, they can be detected at some selected sites and concentrate in the sediments (Landesamt für Natur Umwelt und Verbraucherschutz NRW et al., 2018). Underground coal mines often have mine water with an elevated mineralization resulting from brines with high chloride and sodium concentrations. In some coal mine waters, barium concentrations cause barite precipitation when this mine water comes into contact with sulfate rich waters (Gombert et al., 2019).

Gold

One of the largest environmental impact areas of a historic mining operation is the Spanish Unesco World heritage site Las Médulas. Using a special type of hydraulic mining, called *ruina montium*, the Romans removed substantial amounts of overburden to access alluvial gold, making the site their largest gold operation (Revuelta, 2018). During the operation, about $84 \cdot 10^6$ m^3 of gravel, sand and silt were moved (Sanchez-Palencia et al., 2000) and sedimented into the receiving water courses and lakes. Similar situations can still be found in other parts of the world, where gold is mined by hydraulic mining. Yet, the most common mining method for gold in modern times is surface and underground mining combined with cyanide leaching. As gold co-occurs with disulfides, and sometimes uranium, gold mining usually results in highly acidic water with low pH values and elevated sulfate and iron concentrations. Because gold is not only mined in large scale operations, but in small-scale as well as illegal operations, often referred to as artisanal mining, environmental pollution from gold mining sees various forms (Riaz et al., 2019). They include mercury and suspended solids pollution and river course modifications from small or illegal mining operations as well as acid mine drainage and sulfate pollution from abandoned large scale operations. During large-scale active operations, mine and runoff water treatment ensures compliance to regulatory requirements, but cyanide or sulfate pollution is a common problem in these operations when not handled properly (Acheampong et al., 2010). Large areas in the Colorado's Rocky Mountains are polluted by acid mine drainage from abandoned gold mines. Waste rock piles, tailings and unremediated mine galleries discharge large amounts of metals into the receiving water courses, such as the Animas River Watershed (U. S. Department of the Interior—Bureau of Reclamation, 2015). Common parameters of concern from gold mines are acid, iron, sulfate, mercury, cyanide, suspended solids and arsenic.

Salt

Common salt and potash mining for NaCl, KCl and some Mg-salts, results in large residues of unwanted salt bearing material that is open to the atmosphere and is prone to weathering (Fig. 4). This causes elevated total dissolved solids concentrations as well as chloride, sodium and potassium-concentrations in the receiving water courses. An additional source of contamination is water pumped from the underground workings or the accidentally collapsed salt domes (Kolesnikov and Laskina, 2019). In France, for example, salt is mined by dissolving large salt domes until they purposely collapse and form surface depressions that will fill with water. This mining technology will alter surface water courses in addition to the groundwater regime. Parameters of concern are

Fig. 4 Salt waste rock piles of the Unterbreizbach and Hattorf mines in Germany. In the foreground the receiving water course Werra. Photograph: Christian Wolkersdorfer.

elevated electrical conductivity and the before mentioned ions. These types of lakes can develop pH values of up to 9 and electrical conductivities of 134 mS cm^{-1} (Żurek et al., 2018). Some of these collapse lakes are used for balneological applications in Romania (Mara et al., 2008), and the Wieliczka salt mine in Poland is a UNESCO world heritage site. During the course of time, salt mines will commonly stratify with a less mineralized water body overlaying highly mineralized mine water (Wolkersdorfer, 2008). Common parameters of concern are elevated electrical conductivity, sodium-, chloride- and potassium-concentrations.

Iron

From a pollution point of view, iron or pyrite mines can be classified into two types: carbonate/oxide (hematite)- and sulfide-based ores. While iron oxides, such as these in Australia's Pilbara or Brasilia's Iron Triangle seldom pose a chemical threat to water courses, the opposite is true for iron disulfide mines such as California's Iron Mountain or Finland's Pyhäsalmi mines. Most of the banded iron formation mines in Brazil discharge mine water with electrical conductivities between 100 and 300 µS cm^{-1}, as low as rainwater (Quadros Amorím et al., 1999). If pollution into water courses occurs, it is mainly related to processing plants or to adjacent gold mining operations. Similar situations occur for iron carbonate mines, such as those in the German Siegerland area, where the pH values are circumneutral and metal concentrations are low (Heyl, 1954). Yet, the weathering products of iron (di-) sulfide minerals such as pyrite, marcasite and pyrrhotite pose a substantial threat to surface water courses. While pyrite and marcasite in mining wastes tend to oxidize to sulfuric acid, pyrrhotite oxidation seems to produce elemental sulfur with a lower acidity in the resulting mine drainage (Schumann et al., 2015). In the vicinity of sulfidic iron mines, pH values of 2–3, iron concentrations of several grams and high sulfate concentrations in the several hundred grams concentration range are common (Adams et al., 2007). The lowest natural pH value ever measured is from the Californian Iron Mountain pyrite mine and was as low as −3.6 (Nordstrom et al., 2000). Common parameters of concern are low pH values, high iron and sulfate concentrations.

Copper

In nearly all copper mines in the world (di-)sulfide minerals are present (Pohl, 2020) and therefore, there is a high likelihood that the mines will discharge acid mine drainage or highly mineralized mine water. Besides copper and iron, these deposits contain a large set of other potentially toxic, chalcophile metals (Arndt et al., 2015), which comes as no surprise as the term chalcophile derives from the Greek word *χαλκός* for copper. Copper is mined in surface, underground and solution mines, and there is no substantial difference in the list of elements that can be found in the effluent. One exception is the effluent of solution or heap mining, which is usually extremely acid, but normally not discharged without treatment (but might leak into the subsurface). Main contaminants or parameters of concern from copper mines, independent of type, are low pH values, elevated electrical conductivities, and sulfate as well as iron concentrations that are the higher the lower the pH value is (Šerbula et al., 2016). At Parys Mountain in Wales, pH values of 2.5–3.7 and sulfate concentrations of 0.4–3 g L^{-1} were reported with Fe showing 67–708 mg L^{-1} and Cu 7–44 mg L^{-1} (Rees, 2005). Similar conditions occur at other copper mines in the area (Mullinger, 2004), but the Welsh Parys

mountain site has the fate of the highest pollution rank. Very similar conditions occurred at the Mount Lyell copper-gold mine in Tasmania, Australia, with pH values around 3, concentrations of sulfate 0.2–14, Fe 53–2200, and Cu 9–180 mg L^{-1} (John and Partners Pty. Ltd., 1996).

Lead/Zinc/Silver

Potential effects of lead and zinc mining on water courses highly depend on the geological setting of the deposit. Some European lead/zinc mines pose only small or negligible effects, while geologically similar lead/zinc mines in the U.S. cause detrimental environmental effects from secondary minerals and efflorescent salts (Alpers et al., 2000) around mine waste piles and processing plants (Besser et al., 2009). In these carbonate-hosted deposits, as long as the buffer capacity of the carbonates is not consumed, the pH values will be in the upper circumneutral range. Lead and to a lesser extent zinc are less mobile at these pH values (Fig. 3), and therefore the effects on the water courses are normally small, with exceptions such as the Swedish Lovisagruvan mine (Fahlqvist et al., 2012), where lead and zinc concentrations are ecologically relevant and pose a threat to the aquatic environment.

There might be some immediate increases of electrical conductivity after a mine is flooded, which results from the dissolution of secondary minerals in the open mine voids. Contamination also occurs when the pyrite- and marcasite-rich zones of these deposits are exposed to oxygen and humidity for a longer time. In these cases, the buffer capacity of the carbonate host rocks might become exhausted and acid or metal enriched mining influenced water develops, such as in the case of the Polish Chrzanów or the Picher, Oklahoma Mining Districts (Czop et al., 2007; DeHay et al., 2004). When conditions such as in the Alaskan Red Dog mine (Knapp, 2004) or the Picher Mining District (Tar Creek Superfund) occur, which can be considered one of the most polluted mining areas in the world, then the effects on the water courses will be detrimental. Reason for this pollution is the co-occurrence of lead and zinc with large deposits of disulfides. At the Red Dog mine, pH values of 3–5 with Zn concentrations between 0.3 and 3.3 g L^{-1} and TDS of up to 15.4 g L^{-1} have been reported. In Germany's long-abandoned central Harz Mountains silver/lead/zinc mining area, pH values are relatively high and elevated metal or semimetal concentrations can only be found in selected hot spots (Bozau et al., 2017). Common parameters of concern are lead, zinc, electrical conductivity, and a low pH value.

Uranium

Uranium mining operations can be underground or in open pit mines. The mining technologies involved are either conventional mining or solution mining (Woods, 2018). Due to the high mobility of uranium in oxidizing environments and the co-occurrence with (di-)sulfides, uranium mining sites can often be considered problematic for the aquatic environment. Besides suspended solids from tailings sites and waste rock repositories, sulfate, uranium, radium, and low pH values are commonly found around working or abandoned uranium mine sites (Metschies et al., 2016; Vaupotič and Kobal, 1999; Woods, 2018). Immediately around the mine, tailings or waste rock sites, macrozoobenthos can be impaired when the metal concentrations in the receiving water courses exceed toxic concentrations (Humphrey et al., 2012; Trontelj and Ponikvar-Zorko, 1998). These effects of surface water contamination can last for a substantially long time when the groundwater is infiltrating surface water (Baacke et al., 2015). As iron is also mobile in low pH-environments, elevated iron concentrations are common in uranium mining areas. When the pH values increase over the course of the stream, ironoxides and the sorbed (semi-)metals can precipitate or co-precipitate. This can cause elevated (semi-)metal concentrations in the stream sediments (Neiva et al., 2014). Common potential pollutants are uranium, radium, arsenic, sulfate and low pH-values.

Diamonds

Reports about environmental pollution of river courses resulting from diamond mining are comparably rare—contrary to the connected social issues known under the term "blood diamonds" (Bieri, 2010). Yet, the large tailings dams and open pits as well as placer mines impair the local water courses with suspended solids and minor chemicals from the extraction process (Yelpaala and Ali, 2005). The reason for the relatively low effects on water courses is the host rock (kimberlite, lamproite, or lamprophyre), which is not prone to acid production (Ochieng et al., 2009). Some of the largest diamond mines in the western world are in areas that need to be protected because of their pristine character and the interests of indigenous peoples (van Luijk et al., 2020) and therefore discharges from these mines are strictly regulated. Yet, some diamond mines might develop an elevated mineralization and metal toxicity (McCullough and Sturgess, 2020).

In northern Canada, diamond mine water might have elevated electrical conductivities due to an increasing mineralization trend with depth (Herrell et al., 2018), and in some cases elevated nitrate or ammonia concentrations evolved as a result of explosives being abundant in the tailings and waste rocks (Bailey et al., 2013). In addition to that, high phosphate and chloride-concentrations exist.

A rare source of pollution to surface waters in the Russian Yakutia (Sakha, Якутия) diamond mining district is worth mentioning: radioactive nuclides from 12 "peaceful" underground nuclear explosions. Nuclides from the "backfired" nuclear explosions polluted the nearby environment. In addition, surface waters are contaminated with potentially toxic elements which also impair the people's health (Yakovleva et al., 2000). Common pollutants of concern are mineralization, nitrate, ammonia.

Aggregate mining, building stones, quarries

Gravel and building stones comprise the world's largest amount of mined raw materials (Langer and Arbogast, 1998). Chemically, these types of mines seldom pose a risk for inland waters, but the suspended solids can cause a substantial change to water courses and aquatic life (Fig. 5). When aggregates are mined in alluvial deposits and the number of mines along a stream is large, they disturb fish and other wildlife (Marcus, 1997). Because of the high transport costs of aggregates and building stones, quarries are usually built in the vicinity of built-up areas (Langer and Arbogast, 1998). There, they often pose a visual threat in the landscape, and locals might complain about noise, vibration, or dust pollution (Schneider and Wolkersdorfer, 2021; Vandana et al., 2020), even though they can be advantageous as they provide recreational areas and new habitats for aquatic ecosystems.

A case of acid mine drainage formation was the greywacke quarries Großthiemig and Brößnitz, Germany, where pH values of 2.9 and iron concentrations of up to 80 mg L^{-1} were measured (Gerstenberg, 2005) and a pilot passive treatment system was installed (Hubrig et al., 2014). Highly alkaline conditions developed in the Górka limestone quarry, Poland, with average pH values between 12 and 13, resulting from industrial waste deposited into the quarry during its operation (Czop et al., 2008). Pollutants that can be seen more often in water courses around quarries are nitrogen compounds, originating from unused explosives (Karlsson and Kauppila, 2015).

Some of the negative effects of aggregate mining or quarries is the modification of water sheds as the rocks or sediments are removed. This can result in changes of water courses as the water is flowing into different directions compared to pre-mining conditions (Langer and Arbogast, 1998). In addition, instead of diffuse flow of water into receiving steams, point sources with sometimes elevated flow might develop. Because groundwater levels might fall during mining, water courses could also fall dry during the duration of the quarrying. Even after quarrying ceases, and when the quarry is large, a cone of depression might persist and impair surface water courses. Common parameters of concern are elevated concentrations of suspended solids and modification of water courses and arsenic in limestone quarries.

Others

Platinum mining usually results in contaminated effluents from the tailings areas, but seldom from the mine drainage *per se*. These effluents contain elevated concentrations of nitrogen oxide and TDS (Skinner, 2018). Around vanadium processing plants, ground and surface water has been reported to contain elevated vanadium concentrations (Kamika and Momba, 2014). Apatite and Iron-Apatite mines sometimes develop elevated phosphate concentrations in mine and tailings waters (Makarov et al., 2019; Reta et al., 2019). In recent years, selenium has been a matter of environmental concern in a range of mines, with Sudbury/Canada possibly leading this list (Warren, 2013). Elevated concentrations of the semi-metal Sb regularly occur in carbonate-hosted mines (Ilavský and Barloková, 2019; Wolkersdorfer and Wackwitz, 2004).

Potential contaminants that are seldom discussed within the mining context are organic compounds. They might be PAH, PCB, or oil from the mine workings itself or organic chemicals used in mineral processing.

Listing common pollution indicators for "other" mines is not useful, as they are highly variable and depend on the deposit type and the respective mine site. Yet, experience suggests, these are low pH, high sulfate, and TDS as well as suspended solids.

Fig. 5 Aggregate mining in the Nakkhu Khola River valley (नखखु खोला), Katmandu, Nepal. Photograph: Christian Wolkersdorfer.

Chemical and physical effects on surface waters

Lakes

Acidity, mineralization, metal toxicity, and suspended solids are the main pollutants influencing lakes by mining influenced water. In most cases, these have negative effects on the ecosystems and to variable extent individual species (Tuovinen et al., 2012), especially where the mining influenced water directly enters the lake (Hartwig et al., 2005). Acid mine drainage increases the acidity in lakes, and as a result of the low pH values the metal concentrations increase (Castendyk and Eary, 2009; Gray, 1997). Pit lakes strongly differ from natural lakes and their shape and size influence their chemical and physical parameters, as their relative depths are markedly higher (Geller et al., 2013). Lake stratification is a function of the lake's wind fetch and solar irradiation as well as forces such as surface and groundwater density and heat (Hipsey et al., 2019). Due to their great depth, pit lake stratification occurs with an increase of total dissolved solids and electrical conductivity with depth (Castro and Moore, 2000). Influenced by high concentrations of dissolved substances, the color in mine lakes can vary between red (due to ferric iron with pH below 3) and blue/turquoise (aluminum buffer reactions at pH around 5). Besides the chemical changes of the natural lake's composition (Borvinskaya et al., 2017), suspended solids impair the lakes' ecosystem and physical conditions, though the low energy environment of lakes supports a fast settling. These sediments can even be used as geochemical markers and allow to reconstruct the mining history (Callender, 2000). Because lake sediments are large repositories of potentially toxic elements, changes in the pH or redox conditions can remobilize these elements (Azcue and Nriagu, 1993).

Streams

In flowing waters there is a constant exchange of water with various physico-chemical parameters, and, consequently, the effects of mine water on the streams are characterized by dilution and buffering. Well-buffered streams are less affected by acidification compared to sedimentation or elevated metal concentrations (Bell and Donnelly, 2006; ERMITE Consortium et al., 2004). Once the buffer capacity is consumed, and depending on the pH, mineralization, hardness and dissolved organic matter, streams can develop eco-toxic concentrations of metals and metalloids and the ecosystem will be under pressure (van Dam et al., 2019) as described in the section "Biological and ecosystem effects".

Depending on the chemical composition of the discharged water, adsorption of metals onto sedimentary particles and plants can occur. If oxidizing conditions and neutral pH values dominate, metals can adsorb on clays, organic matter as well as on Mn-, Al- and Iron-oxides (Dong et al., 2007; Miller et al., 1996). Dissolved iron, which occurs most commonly in mine water influenced streams typically precipitates as oxides and hydroxides in the streambed close to the discharge point and is often visible (Mestre, 2009). These suspended iron oxyhydrate solids and the reddish color of dissolved iron in low pH-conditions cause many mining influenced streams and rivers to appear in reddish to orange colors (Fig. 6). In addition, the mining influenced water sometimes reduces the surface tension in the stream, which results in the formation of foam (Lottermoser, 2010).

When streams or rivers are used as raw water for drinking water production, discharges of mining influenced water can substantially impair the fresh water supply chain (McCarthy and Humphries, 2013). Remediating these surface water courses, especially in rural areas, can be challenging as well as time and cost consuming (ERMITE Consortium et al., 2004; Sumi and Gestring, 2013).

Fig. 6 Mine Water discharge of the Heinrich colliery, Germany, into the river Ruhr. Suspended iron oxyhydrates flocculate as they get oxidized. On the left of the discharge, the precipitates stain the riverbanks, and, on the right, the fresh water of the Ruhr can be seen. Photograph: Marlene Julia Fromm.

Precipitates in surface waters

Changing environmental conditions, such as aerating mixing processes when mining influenced water discharges into surface waters (Máša et al., 2012), initializes various physical and chemical processes which might result in precipitation. These processes are evaporation, oxidation of reduced species, changes in pH value and redox potential, flocculation, or coagulation. In mining influenced water, the most common precipitate is ochre ("yellow boy") which is a mixture of iron oxyhydrates and sulfate minerals, although the formation of ferrihydrite ($Fe_5HO_8{\cdot}4H_2O$), goethite (α-FeOOH) or schwertmannite [$Fe_8O_8(OH)_6SO_4$] differs based on the local conditions (Kairies et al., 2005; Schwertmann et al., 1995). Additionally, the visual appearance of ochre is quite different, ranging from gelatinous flocculants, suspended colloids, medium soft mud, foam on the water surface, coating on rocks to hard and thick encrustations. Most precipitates sorb or co-precipitate with trace elements like arsenic, cobalt, nickel, and zinc, as the ochre has a high specific surface area and is therefore responsible for mobility, fate and transport of trace elements in mining influenced waters (Kairies et al., 2005; Schemel et al., 2000). Other precipitates are aluminum oxyhydrates, which also sorb potentially toxic elements and contribute to the improvement of the waters conditions (Rothenhöfer et al., 2000). These characteristics of accumulating (semi-)metals are widely used as a means of geochemical exploration in natural waters (Förstner, 1981).

Biological and ecosystem effects

Biological effects of mine drainage on the aquatic ecosystem range from severe effects that kill most macroinvertebrates and fish to improvements of the water quality when unpolluted mining influenced water drains into a polluted water course. These effects can result from large mining operations, mining accidents or by artisanal mining (Dabrowski et al., 2013; Hernandez et al., 1999; Macdonald et al., 2014, 2015). Effects on fish can vary depending on the animal's age: whilst juvenile fish might avoid mine water influenced streams, adults might be able to survive in the elevated pollutant concentrations. Ecosystem management programs need to be site specific, taking into consideration the high variability of geological and climatic conditions. When all the relevant factors are considered, potential negative effects of such a program can be avoided (Kruse Daniels et al., 2013).

A common pollutant is particulate matter like clay, silt, or sand from tailings dams, waste rock piles, or aggregate mining (Greig et al., 2005). Examples for this are the Ok Tedi mine in Papua New Guinea (Low and Gleeson, 1998) or the abandoned Mount Lyell Copper deposit in Australia (McPhail et al., 2001). Increased turbidity due to suspended solids also decreases light penetration into the water and therefore reduces photosynthesis (Wood and Armitage, 1997). Additionally, fish gills can become clogged, or fish eggs can suffocate due to settled suspended matter (Bilotta and Brazier, 2008; Butler and Ford, 2018). This inhibits the growth of algae or microorganisms and therefore prevents macroinvertebrates or fish from getting enough food, as the functioning of the food web for the biological survival of surface waters is interrupted. Additionally, biofilms might accumulate potentially toxic elements that concentrate in the higher organisms (Hobbs et al., 2019). Consequently, they move away or die, and the surface water becomes biologically dead. Yet, this does not necessarily imply that the water is *a priori* toxic. Another negative effect on livestock is the reduction of oxygen by processes that oxidize reduced constituents or organic matter (Weiner, 2010).

A positive biological effect on mine water quality is the filtering effect of sediments and the biota in natural wetlands. In many cases, it has been observed that the quality of mining influenced water substantially improves downstream of natural wetlands (Fyffe et al., 2015; Haarstad et al., 2012). This known effect has been used to construct the first artificial wetland for mine water treatment (Kleinmann et al., 1985). Yet, as the contaminants accumulate in the natural wetlands, unexpected incidents like flood events, droughts, or earthquakes might impair the pollutant deposits and could release them to downstream receptors.

Management and mitigation of mining influenced water

Principles of mine water management

Mitigation of the effects caused by mining influenced water is performed in one of five ways: avoidance, natural attenuation, active treatment, passive treatment, and *in situ* treatment. During a mining operation, negative effects on the environment cannot be completely avoided. However, because society relies on an input of raw materials, managing the risks from potential contaminants in mining influenced water to acceptable levels is a trade off against benefits acquired from operation. Ultimately, pollution arising from mining operations must be reduced by modifying the mining methods or averted by technical means (Skousen et al., 2019; Wolkersdorfer, 2021).

One of the key requirements to understand and optimize management and mitigation of mining influenced water and its effect on the surrounding inland water systems is monitoring (McLemore et al., 2014). This could also include participatory water quality monitoring (International Council on Mining and Metals, 2015), which assists in engaging local communities in developing remediation options.

Avoidance

In principle, the best avoidance strategy would be to separate disulfides from water and oxygen to inhibit oxidation. In the context discussed herein avoidance includes all measures that prevent and slow down the evolution of mining influenced water or keep

water away from the mines. The latter is achieved by installing cut-off walls, or surface water can be diverted around open pit mines (Steffen Robertson and Kirsten (B.C.) Inc and Norecol Environmental Consultants and Gormely Process Engineering, 1990). By reduction or segregation of acid-producing materials, the weathering processes are minimized, and (di-)sulfide oxidation is reduced. This requires sophisticated prediction and mine planning methods that allow a controlled flow of inert, acidic, and neutralizing rock material. In modern mining operations, exploration data, real time data, block models and artificial intelligence are used to direct the waste material to an appropriate location (More et al., 2020). In open pit mines, thorough mine planning including mixing of alkaline with acid producing material is recommended (Drebenstedt and Struzina, 2008; Wisotzky, 2004). Dams in underground mines separating disulfide rich areas from water and oxygen can prevent the formation of acid water or its discharge. Dry seals at mine entrances reduce oxygen contact with disulfide rich strata, while wet seals prevent oxygen contact and water discharge (Foreman, 1971). Tailings and waste rock can be managed with dry or wet covers, which can substantially reduce oxygen diffusion and slows down pyrite oxidation. Dry covers are layers of soil and gravel above mining waste repositories while wet covers could be ponded water on top of tailings (European Commission, 2009; Moncur et al., 2015).

Natural attenuation

Natural or intrinsic attenuation is a process by which nature without human interaction mitigates the negative effects of mine effluents on receiving water courses, and this process has occurred since humans first mined. In general, attenuation is a slow process but an effective one, and in many cases, several decades of attenuation processes results in acceptable environmental conditions. Natural attenuation uses energy, such as solar energy and potential energy, and is assisted by microbes which oxidize or chemically reduce various contaminants in the mining influenced water. Very often, (semi-)metals are sorbed to suspended solids and by their removal in natural wetlands or when iron flocculants settle, the water quality continuously improves. Other mechanisms are simple settling of suspended solids while the water's velocity decreases, e.g., during flow into lakes. Natural attenuation also depends on dilution effects during rain events and on time, as several natural processes are a function of time. A commonly observed effect in flooded mines is the first flush, which lasts 3–5 times as long as it took the underground mine to be flooded (Younger et al., 2002). While the mine workings are flushed by relatively clean ground or rainwater, effluent salts and secondary minerals are washed out into the receiving water courses (Wolkersdorfer, 2021; Younger et al., 2002).

Active treatment

Active treatment implies the use of chemical reactants, the supply of energy, and a continuous monitoring of the plant (Skousen et al., 1998; U. S. Environmental Protection Agency, 2014). This active process removes unwanted substances and ensures discharge criteria are met. Criteria for the selection of the various active treatment methods are the concentration, load, and chemical composition of the mining influenced water. Among the most common active processes are neutralization (especially Low Density Sludge and High Density Sludge treatment), and membrane processes (e.g., reverse osmosis). Although there are more than a dozen different active processes on the market, most of them are of marginal importance in the mining industry as they are unsuitable for high volumes of water or the cost of operation are high.

Passive treatment

Passive mine water treatment is the improvement of water quality using only naturally available energy sources in gravity-flow treatment systems (such as wetlands or subsurface-flow bioreactors) which are designed to require only infrequent (albeit regular) maintenance to operate successfully over their design lives (literally from PIRAMID Consortium, 2003). Treatment is achieved entirely through potential (differences in altitude), solar or biological (bacteria) energy, and systems like that are operating from cold to warm climate zones. Passive systems include oxic or anoxic limestone drains, constructed aerobic or anaerobic wetlands, reducing alkalinity systems (RAPS, also called SAPS), settlement ponds, permeable reactive walls or vertical flow reactors (Brown et al., 2002; Wolkersdorfer, 2021). Passive systems, compared with active systems, usually cannot handle large volumes of mining influenced water or elevated pollutant concentrations.

In situ-treatment

In situ-treatment is of particular importance for surface waters. One of the most common processes is in-lake treatment such as adding lime to pit lakes by boats or pipes (Benthaus et al., 2020). Water courses are sometimes treated by applying alkaline material directly into the flowing wave (Gusek and Figueroa, 2009; Uhlig et al., 2016). Especially for diffuse inflow of mining influenced waters, the construction of reactive walls (Bowden et al., 2005) can be used as an *in situ* option. Another avoidance or *in situ* method is stratification in flooded mines, which reduces the discharge of mine water with poor quality, as higher mineralized, thus more polluted mine water, remains in the deeper parts of the mine (Wolkersdorfer, 1996). A general recommendation which method to apply cannot be made before a detailed site investigation is first undertaken.

Synthesis

Mining influenced water commonly evolves around underground and open pit mining operations through microbially catalyzed pyrite oxidation. For pH, these waters can be acid, circumneutral or basic, and from a mineralization point of view, dilute, mineralized or saline. Depending on the type of raw material, the pollution load of the mining influenced water and the pollutants of concern can vary substantially. This, consequently, has different effects on inland waters, which can be minimal in the best case and detrimental in the worst one. Potential effects are suspended solids, diversion of water courses, highly variable flows and a toxicity that impairs the ecosystems of the lakes, streams, and rivers. Many mining influenced waters have no effect on the receiving inland waters at all, some are even used as drinking water, because the first flush already passed. Yet, the most prominent effect on inland waters are red to orange stains from precipitates, a reddish to orangish color of the water, and a change of the aquatic ecosystem composition. Various mitigation options are available, ranging from doing nothing, commonly referred to as natural attenuation, to passive treatment and to active mine water treatment. *In situ*-treatment options are rarely used, but future developments will see these options more often.

To increase the public acceptance of mining operations, there is a need for improving communication and the availability of information. This ensures that the reasons for mining influenced water are understood and the measures of the mining houses to mitigate these effects are better known. Yet, the best solution would be if future developments and innovations would reduce the pollution emanating from mining operations such, that there are no effects on inland waters at all.

Knowledge gaps

In relation to mining influenced inland waters, there are no knowledge gaps *per se*. Yet, there are many questions that need to be answered to increase the acceptance of mining in the public and to protect aquatic ecosystems. To a large degree, most of the solutions already exist, but economic pressures or irresponsible behavior often restrict their utilization. One of these solutions would be the valorization of mining residues, such as waste rock piles, tailings, or polluted mine water. Yet, much research will be needed to find applications for all the relevant water pollutants and mining residues. In addition, many treatment options for mine water are cost intensive, i.e., expensive, and financial restrictions or the competition on the market restrict their implementation. Therefore, there is a need for cheap and reliable treatment solutions, or, at least, treatment solutions which leave water, valuables and not much more than a footprint. Especially research on *in situ* remediation including the understanding of the mines' hydrodynamic conditions is needed. A knowledge gap is also the exact interplay between mining influenced water and the groundwater, the resilience of ecology to mining pollutants and how, precisely, contaminants affect humans and livestock too.

One gap is the site specific and temporal prediction of the water quality of working and abandoned mines and where diffuse mine water discharges will occur after mining ceases. Therefore, a world equation for mine water would be needed. This means, modeling and simulations should be able to predict exactly what mine water quality might be expected in each single stage of the mining operation, including the prediction of the mine water's potential toxicity on various aquatic species. Though first approaches for the chemical composition exist (Chetty et al., 2020; Van der Sloot and Van Zomeren, 2012), the mining community is still a large step away from a unifying solution.

On the monitoring and information side there is a need for new sensors where scaling would be inhibited, and no wipers or shutters are necessary to remove the fouling on the electrodes. As larger data sets are continuously collected during mining operations, big data operations and artificial intelligence are needed to optimize mining operations and reduce pollution. Additionally, an improved information policy and true information to the public is a key requirement to increase the acceptance of mining on one side and to reduce pollution by artisanal miners on the other side.

Modern civilization will need raw materials forever. Because a circular economy will not be able to supply a growing world demand while the population increases, mining operations will also be needed in the future. Therefore, it is essential that future mining operations and the mining houses will do everything that is needed to protect inland waters and groundwaters alike.

Acknowledgments

We acknowledge our colleagues Altus Huisamen, Stephanie Lohmeier, Nikolai Georgievich Maksimovich, Cherie McCullough, Jesús Montero, Maria Almudena Ordoñez Alonso, Carlos Ruiz Cánovas, Oliver Totsche, and Anne Weber for commenting on early versions of this section. This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Biotic homogenization Biotic homogenization is defined as the increase in similarity (or decrease in beta-diversity) among ecological communities over time, at the genetic, taxonomic or functional levels.

Coal seam gas Coalbed methane is known as coal seam gas in Australia.

Coalbed methane Natural gas contained in coal beds. Although extraction of coalbed methane was initially undertaken to make mines safer, it is now typically produced from unmineable coal seams.

Command-and-control regulations: Command-and-control regulations are by far the most commonly used to minimize damage caused by unconventional oil and gas extraction. They are most often used by countries where regulators are under-capacitated to police self-regulation, such as developing countries.

Conventional oil and gas Conventional oil and gas resources are produced from conventional reservoirs. Conventional oil is trapped underneath seals in deep porous geological formations. Gas that occurs in association with this oil, is called associated gas. This oil and gas migrated from unconventional reservoirs like shale. Gas that occurs in a porous formation underneath a seal and that is not associated with oil, is called non-associated gas.

Conventional reservoir For oil gas reserves, conventional hydrocarbons refer to hydrocarbons that are produced from reservoirs that do not require stimulation to produce the gas. These reservoirs typically have permeabilities larger than 1 milliDarcy. The oil in these reservoirs migrated from source rocks and accumulated in the reservoirs (commonly porous sandstone or carbonate). Conventional reservoirs are capped by impenetrable material (often shale or salt) that keeps the conventional oil in place.

Darcy A unit of permeability. A medium with a permeability of 1 Darcy permits a flow of 1 cm^3/s of a fluid with viscosity 1 cP (1 mPa•s) under a pressure gradient of 1 atm/cm acting across an area of 1 cm^2.

Depressurization Depressurization is the act of lowering the reservoir pressure below the saturation point (i.e., the critical desorption pressure), which causes gas to desorb from the microporous structure and flow toward the wellbore, where the gas can be produced, processed, and delivered to market. Depressurization can be accomplished by allowing free gas within the naturally occurring or induced fractures in the coal to flow to the surface, or by pumping out any natural fluids occupying the connected cracks and fractures. This fluid can be a combination of formation water and free gas.

Ecosystem engineers Keystone species that create, modify, maintain or destroy a habitat. Their behavior strongly affects other organisms (e.g., impact on species richness) and landscape heterogeneity.

Ecosystem services The benefits provided by the natural environment and from healthy ecosystems to humans.

Enhanced oil recovery (conventional oil and gas): Enhanced recovery can follow primary recovery during conventional oil and gas extraction to maintain pressure and keep up the oil production rate. Enhanced recovery is divided into secondary and tertiary recovery and may use large volumes of water.

Environmental crime Any violation of an environmental regulation for which criminal liability may be imposed. Regulations must contain provisions that establish criminal liability for violations. Criminal enforcement of environmental regulations is often used in only the most egregious cases, where the actual or potential damages are excessive or where the violator is a repeat offender. Although criminal enforcement actions are mainly taken to deter future misconduct by the individuals charged, their greater impact may be to deter those who are contemplating similar offenses.

Environmental justice/injustice Environmental justice implies that everyone in society, regardless of their social class, status, background, race, ethnicity or gender must share equally in the benefits, risks and negative impacts of developments. Environmental injustice occurs when some people or groups, as a result of their social class, status, background, race, ethnicity or gender, experience most of the harm and risk associated with development, while not receiving a fair share of the benefits.

Flowback (unconventional oil and gas) Fluid that is returned to the surface after hydraulic fracturing has occurred, but before the well is placed into production. It typically consists of returned fracturing fluids in the first few days following hydraulic fracturing which are progressively replaced by produced water.

Groundwater Water that occurs below the surface of the Earth, where it occupies all or part of the void spaces in soils or geologic strata.

Hydraulic fracturing fluid Fluid used to perform hydraulic fracturing; includes the primary carrier fluid, proppant material, and all applicable additives.

Hydraulic fracturing The act of pumping hydraulic fracturing fluid into a formation to increase its permeability. Hydraulic fracturing has been used in the industry in various forms, for either stimulation of water wells to produce water, or for stimulation of oil and gas wells to produce oil and/or gas. Various technologies can be combined or used separately during hydraulic fracturing. It may involve the use of only water (for water well stimulation) or a combination of any or all of four separate technologies, viz. directional drilling, the use of high volumes of fracturing fluids, the use of chemical slickwater additives, and the use of multi-well drilling pads. When all four technologies are combined it is more specifically called 'high-volume slickwater long-lateral' (HVSLL) stimulation. Hydraulic fracturing as used in the oil and gas industry commonly includes the usage of 0.5–2% slickwater additives, large volumes of proppant as well as large volumes of fluid. Base fluids that may be used may include water, liquid petroleum gas, or other gases such as nitrogen or carbon dioxide. Synonyms for hydraulic fracturing as used in the oil and gas industry include 'slickwater fracking' (slickwater in short), "high volume hydraulic fracturing,", or just "fracking."

Hydrocarbon A naturally occurring organic compound comprising hydrogen and carbon. Hydrocarbons can be as simple as methane [CH_4], but many are highly complex molecules, and can occur as gases, liquids or solids. The molecules can have the shape of chains, branching chains, rings or other structures. Petroleum is a complex mixture of hydrocarbons. The most common hydrocarbons are natural gas, oil and coal.

Injection well An injection well is used to place fluid underground into porous geologic formations. These underground formations may range from deep sandstone or limestone, to a shallow soil layer. Injected fluids may include water, wastewater, brine (salt water), or water mixed with chemicals.

Market-based regulations Market-based regulations encourage behavior through market signals rather than through explicit directives regarding pollution control levels or methods and allow companies to determine the best way to control or minimize pollution (Zhang, 2013).

Peak oil The hypothetical point in time when the global production of oil reaches its maximum rate, after which production will gradually decline.

Primary recovery (conventional oil and gas) Primary recovery is used in the first stage when natural pressures in the oil reservoir are sufficient to bring oil to the surface. No additional water is needed during this stage of conventional oil extraction.

Produced water Natural fluids that are displaced from the geological formation that holds the hydrocarbons, which can contain substances that are found in the formation, and may include dissolved solids (e.g., salt), gases (e.g., methane, ethane), trace metals, naturally occurring radioactive elements (e.g., radium, uranium), and organic compounds. It includes water moving in from adjacent aquifers or formations. In conventional oil formations it also includes water injected in the formation during water and steam flooding.

Regulations Environmental regulations are rules to protect public health and the environment from adverse effects by the oil and gas industry. There are three types of regulations: command-and-control, market-based and voluntary.

Reserves (proved) The quantity of energy sources estimated with reasonable certainty, from the analysis of geologic and engineering data, to be recoverable from well-established or known reservoirs with the existing equipment and under the existing operating conditions.

Reservoir (oil or gas) A subsurface, porous, permeable or naturally fractured rock body in which oil or gas has accumulated. A gas reservoir consists only of gas plus fresh water that condenses from the flow stream reservoir. In a gas condensate reservoir, the hydrocarbons may exist as a gas, but, when brought to the surface, some of the heavier hydrocarbons condense and become a liquid.

Resource curse The resource curse (or the paradox of plenty) refers to the failure of many resource-rich countries to benefit fully from their natural resource wealth (such as oil and gas, land and water), and for governments in these countries to respond effectively to public welfare needs. Sharing resources such as land, water, and minerals can create conflict between the extraction companies and the communities. While one might expect to see better development outcomes after countries discover natural resources, resource-rich countries tend to have higher rates of conflict and authoritarianism, and lower rates of economic stability and economic growth, compared to their non-resource-rich neighbors.
Secondary recovery (conventional oil and gas) Secondary recovery employs water in the form of waterflooding, or gas injection, to displace the oil and drive it to the surface.
Shale gas Natural gas that remains tightly trapped in shale and consists chiefly of methane, but with ethane, propane, butane and other organic compounds mixed in. It forms when black shale has been subjected to heat and pressure over millions of years, usually at depths of 1500–4500 m below ground level.
Shale A fine-grained sedimentary rock composed mostly of consolidated clay, silt or mud. Shale is formed from deposits of mud, silt, clay, and organic matter, usually laid down in calm seas or lakes.
Subsistence lands Land areas where indigenous/local communities hunt, fish, and gather wild-growing fruit and vegetables.
Surface water Any body of water above ground, including streams, rivers, lakes, wetlands, reservoirs, and creeks.
Tertiary recovery (conventional oil and gas) Tertiary recovery employs steam or gas to change the makeup of the oil reservoir to enhance the recovery of oil in the reservoir.
Tight sands A geological formation consisting of a matrix of typically impermeable, non-porous tight sands.
Unconventional oil and gas Unconventional oil and gas resources are produced from unconventional reservoirs. Unconventional oil and gas include oil sands, oil shale, shale gas, and coalbed methane.
Unconventional reservoir Reservoirs, which require hydraulic fracturing for the extraction of hydrocarbons occurring in these reservoirs, where the permeability is less than 1 milliDarcy.
Voluntary regulations Voluntary regulations are usually innovative voluntary actions that oil and gas companies take to improve environmental quality, natural resource utilization or their environmental performance.
Waterflooding A form of enhanced oil recovery where the energy required to move the oil from the reservoir rock into a producing well is supplied from the surface by means of water injection and the induced pressure from the presence of additional water.

Hydrocarbon extraction overview

This chapter explains hydrocarbon extraction processes and discusses its effects on inland water resources. Oil and gas are important energy sources for human society, with the oil industry being the largest international industry in the world. The transportation of goods, manufacturing of plastics and fertilizers, and electricity generation all depend to a large degree on oil and gas (Robbins et al., 2014). Societies have, therefore, invested heavily in oil and gas infrastructure and equipment, such as vehicles and roads (Van Vactor, 2010). However, this industry also uses substantial amounts of freshwater (Spang et al., 2014) and influences water resource quality, and as such, has a considerable impact on the world's freshwater resources (see section "Risk and impacts on water resources").

Although oil has been extracted since the early 1900s, it became the dominant form of energy with the discovery of many of the largest conventional oil reserves in the Middle East just before and after World War Two. Before then, coal was far more important. Since the end of World War Two, the use of oil for energy generation has been a critical factor in increased global prosperity (Van Vactor, 2010). To ensure ongoing economic development, countries tried to procure sufficient and stable supplies of oil and gas from countries with such resources or, where possible, by producing their own. This has contributed to energy crises, such as the 1973 oil embargo by oil-producing nations that triggered worldwide oil shortages (Harper and Snowden, 2017).

Oil and gas derive from compressed and cooked organic matter that was buried to significant depths over millions of years and occurs in conventional and unconventional deposits (Fig. 1). From the 1970s to the 1990s conventional oil was produced in surplus, after which conventional oil supplies started to decline. Since the early 2000s, alternative hydrocarbon sources in the form of unconventional oil and gas were targeted, enabled by hydraulic fracturing and horizontal drilling (Van Vactor, 2010; Bilgili et al., 2020). The United States lead in the extraction of unconventional resources, where it accounted for 44% of gas production in 2014 (Bilgili et al., 2020). Natural gas production in the United States may more than double over the coming 30 years (Bilgili et al., 2020). Because unconventional resources step in where conventional resources are declining, there is no foreseen imminent peak in oil production (peak oil).

Risk and impacts on water resources

Hydrocarbon reserves are increasingly being targeted in some of the most remote and pristine areas on our planet (Morley, 2017), including the East African Great lakes area (Verheyen et al., 2016) and Amazonia (Fig. 1 and Box 2: Oilfields in Amazonia). Oil production in developing countries increased over threefold from 1973 to 2008, often involving the use of controversial

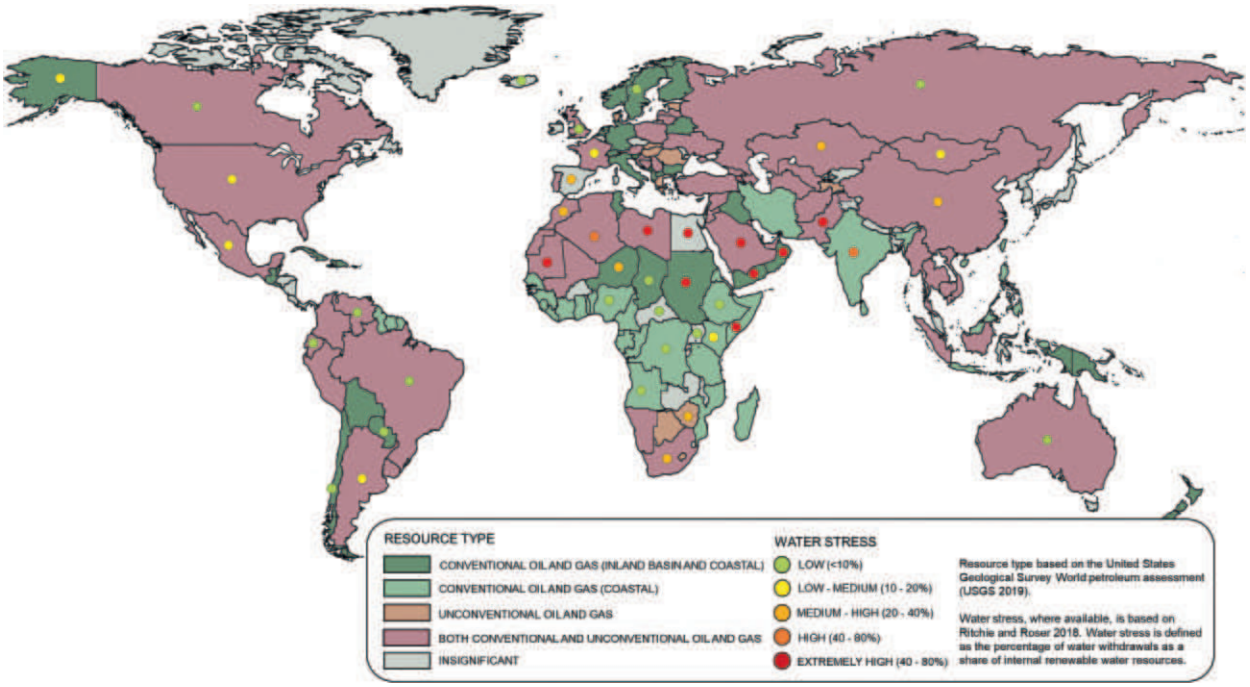

Fig. 1 Global distribution of conventional and unconventional oil and gas resources and associated water stress per region. Image source: S Esterhuyse.

technologies such as hydraulic fracturing. The oil industry uses approximately 40% of the annual 52 billion m^3 of freshwater that is consumed to meet the global requirement for energy and fuel (Spang et al., 2014). With the emergence of unconventional oil and gas extraction techniques, this share is expected to rise, with dire effects on water-scarce countries (Fig. 1).

It is estimated that most future oil and gas projects will be situated in developing countries, to allow for export and to address increased energy needs as their economies grow. Although technological advances make the extraction easier and less risky, poor management and lack of oversight often lead to environmental degradation and water resource pollution. Impacts on water resources occur at the exploration, extraction, and post-extraction stages of hydrocarbons. Fig. 2 illustrates the main impacts for conventional and unconventional oil and gas extraction, while Tables 1 and 2 provide detailed information on the possible impacts.

The negative impacts of hydrocarbon extraction on water resources are viewed as one of the most significant biophysical impacts (Rosa et al., 2018), both in terms of the effects on water quantity and water quality, while water-related negative socio-economic and biophysical impacts are also far-reaching. These impacts are discussed in detail below. As oil and gas are increasingly being extracted in biologically rich regions of the world, it will likely pose a greater threat to biodiversity, especially in areas with high aquatic biodiversity such as in South America, see Boxes 1 and 2 (Harfoot et al., 2018) and Africa (Verheyen et al., 2016, Box 3).

Conventional oil and gas extraction impacts

The effects of conventional oil and gas extraction on water resources are less than for unconventional extraction, although impacts can still be significant. Water use during conventional oil extraction is typically less than for unconventional resources (Scanlon et al., 2014), but largely depends on the geological characteristics of the reservoir. Primary recovery is used during the first stage of oil recovery when natural pressures in the oil reservoir are sufficient to bring oil to the surface. However, as reservoir pressure declines, enhanced oil recovery methods may be employed to increase oil production. Primary recovery may be followed by secondary recovery that includes waterflooding and even tertiary recovery that includes steam injection, to drive residual oil to the production wells (Parra et al., 2020). Water use during primary production is minimal, but can be significant during the secondary production phase (Scanlon et al., 2014). The additional water demand of conventional oil and gas extraction on local water resources can lead to conflicts between water users in water-stressed areas or in times of drought (Sohns et al., 2016).

In terms of water quality impacts, conventional oil and gas extraction generates wastewater in the form of produced water and spent drilling fluids. Produced water is the largest wastewater source by volume. It can contain metals, sediments, and chemicals that may be radioactive and toxic (Parra et al., 2020). Produced water disposal is a concern—if it is injected into wells for disposal or enhanced oil recovery, it may induce seismicity. The alternative is the disposal of this wastewater at hazardous waste sites or treatment at wastewater treatment plants equipped for these types of waste, which many countries are not equipped to handle.

Unconventional oil and gas extraction impacts

Of the negative environmental effects of unconventional oil and gas extraction (Esterhuyse et al., 2016a,b), the most immediate effects are those on water resources. Because a stimulation method such as hydraulic fracturing is typically required to extract

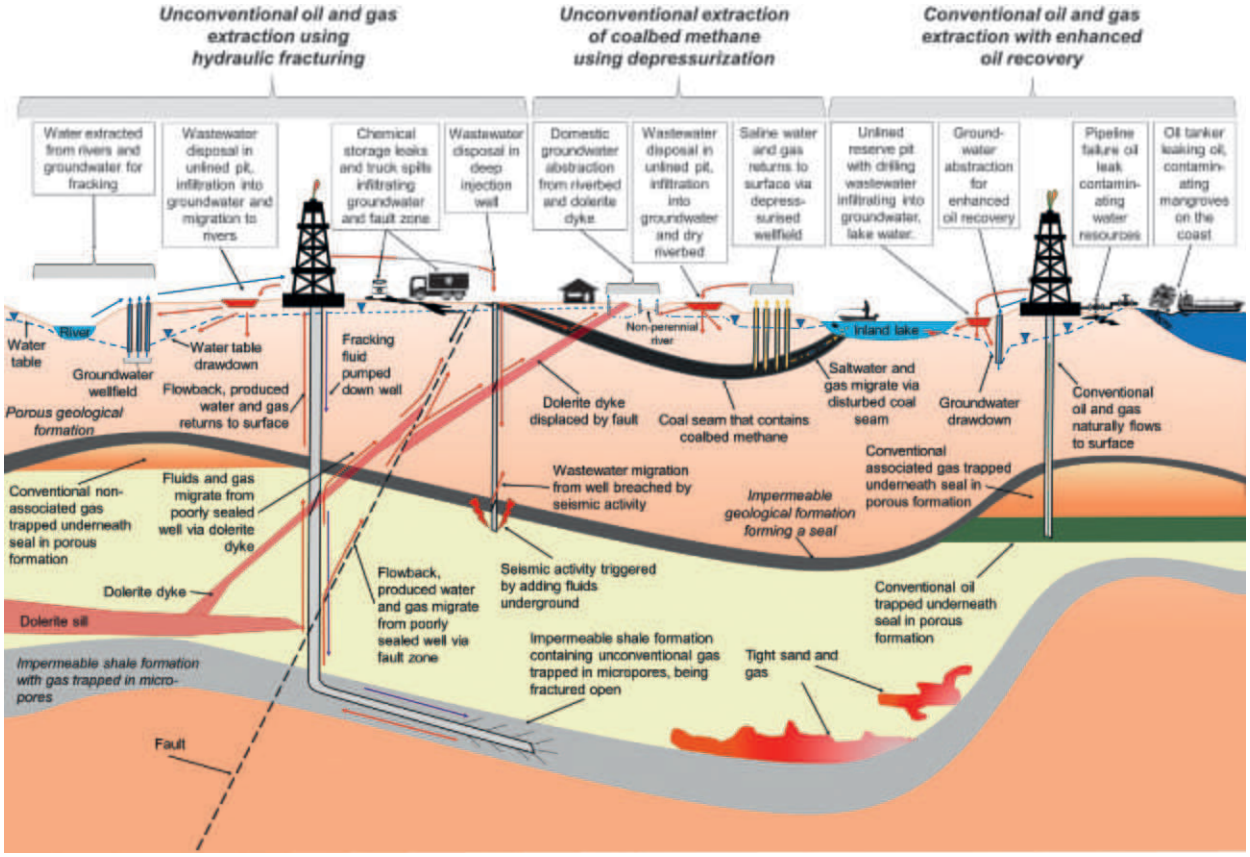

Fig. 2 Conventional and unconventional oil and gas extraction processes and their impacts. Image source: S Esterhuyse.

unconventional resources, it is often more water-intensive than conventional oil extraction (Kondash et al., 2018). Where one drilling well operation could consume approximately 500 m^3 of water without fracking, a fracking well consumes 20 times that amount (Goodwin et al., 2012). Water for fracking is often sourced in the vicinity of the fracking well, making local groundwater reserves a common target. In 2015 in the Eagle Ford shale, US, fracking operations consumed approximately 30% of the area's total groundwater (Steadman et al., 2015). Compared with conventional oil and gas extraction, fracking will lead to even higher localized competition between water users in water-scarce and drought-prone areas (Fig. 2, Tables 1 and 2).

Next to produced water, an additional wastewater stream in the form of flowback is generated during unconventional oil and gas extraction. The chemistry of the flowback depends on the chemical makeup of the hydraulic fracturing fluid and may contain various toxic and carcinogenic organic contaminants (McIntosh et al., 2018). The water quality impacts of unconventional oil and gas extraction are therefore typically larger than for conventional oil and gas extraction. Produced water and flowback can contaminate freshwater aquifers due to poor oil and gas well integrity, or due to migration of these fluids via fracture zones. Fracking fluid and wastewater can contaminate surface waters via leaks and spills. Wastewater disposal in underground injection wells can also cause seismicity and has significantly increased induced seismicity in Canada, the United States, the United Kingdom, and China, in some cases causing earthquakes as large as magnitude 5.7 (Schultz et al., 2020). The density of oil and gas wells, which are higher than for conventional oil and gas production, can also have cumulative negative effects on aquatic ecosystems (Entrekin et al., 2011a,b; Dauwalter, 2013).

Acute impacts from spills and leaks

Marine oil spills in coastal areas often have dire effects on mangroves (see Box 1). Mangroves form a relatively small, but distinctive biome that delivers unique ecosystem services to coastal communities, and that serves as a nursery for many marine species.

Even though marine oil spills are more publicized, inland oil spills occur more frequently, often affect sensitive freshwater environments and have larger impacts on public health (Yoshioka and Carpenter, 2002; Kingston, 2002; Azevedo-Santos et al., 2021). The acute impacts from oil spills are more severe than the chronic impacts of extraction and processing (Etkin, 2011). Spills can occur in any phase of the process, including the extraction of crude oil and the transportation of refined fuels. During the extraction phase, oil spills tend to cause acute impacts, whereas small chronic spillages occur most frequently in the transportation

Table 1 Biophysical impacts of conventional and unconventional oil and gas extraction present in the landscape.

Activity	*Phase*	*Aspect*	*Possible positive impacts*	*Possible negative impacts*
Conventional oil and gas	Exploration phase	Surface water and vegetation	• Possible new species identified	*Seismic exploration:* • Increased sediment load in rivers due to increased erosion from seismic exploration (A) • Seismic vibration affects freshwater invertebrates and vertebrates (e.g., fish) (A) *Drilling fluid and produced water discharge, leakage or spill:* • Drilling fluids leaching into surface water via groundwater or via overland flow from surface spillages contaminate rivers, pans, lakes (A) • Diesel pollution reduces abundance and diversity of freshwater organisms (e.g., invertebrates and fish) (A) *Infrastructure development (seismic lines, road development, river crossings, limited wellpad development):* • Increased sediment delivery to river may impact critical habitats (e.g., fish spawning habitat), cause turbidity and reduce visibility for predators (A) • Native species richness and abundance tend to decrease, and the introduction, establishment and spread of nonnative species are favored (A/C) • Disruption of fish migration due to increased sedimentation, pollutants, turbidity and fragmentation (from road crossings in rivers) (A) • Road construction to remote areas allows entry of deforesters and consequent vegetation loss • Declined plant biodiversity, habitat loss and fragmentation (for drill site and road construction) (A) • Favors the introduction, establishment and spread of nonnative species (A/C) • Surface spills of hazardous material (drilling fluid and produced water) impacting on vegetation (A) *Water sourcing from rivers for drilling:* • Reduced streamflow in perennial rivers (A) • Loss of critical habitats (e.g., refuge and spawning) in rivers and lakes (A) • Loss of river migratory passages lead to loss of mobility, reduced food availability, fragmentation and isolation of fish assemblages (A) • Water quality changes, heat death of fishes in isolated pools and lakes, higher contaminant impact on fish during low stream discharge or isolation periods (A) • Reduced fish fitness and health due to increased predation, intra- and interspecific competition and crowdedness in isolated pools (A)
		Groundwater	• Develop a better understanding of the deeper geology and geohydrology	*Unknowns:* • Difficult to identify aquifers at risk for contamination since deeper geology and structures are unknown (C) • Artesian basin conditions may cause upward migration of formation water (C) *Saline water produced during drilling:* • May contaminate aquifers via well or via reserve pit leak (A/C) *Drilling fluid and produced water discharge, leakage or spill:* • Drilling fluids (e.g., diesel) leaching into groundwater or via overland flow from surface spillages contaminate rivers, pans, lakes (A/C) *Water sourcing from groundwater for drilling:* • Reduced groundwater levels and quality (A/C)
		Seismicity	• Not known	*Increased seismicity during drilling:* • Level of seismicity may increase, but extent of increase is uncertain (A/C) • Possibility to observe or induce and/or trigger a strong seismic event (A/C)

Table 1 (Continued)

Activity	*Phase*	*Aspect*	*Possible positive impacts*	*Possible negative impacts*
Conventional oil and gas	Extraction phase	Surface water and vegetation	• Possible new species identified	*Wastewater and oil discharge to water bodies* via *leaks and spills*: • Flowback and produced water contaminate rivers/lakes (A/C) • Water quality changes in isolated pools and lakes, heat death of fishes in isolated pools, higher impact of contaminants on fish during periods of low stream discharge or isolation (A) • Reduced fish fitness and health due to increased predation, intra- and interspecific competition and crowdedness in isolated pools (A) • Reserve pit leaks may lead to contamination and/or mortality of fish and waterbirds (A) • Changed community structure and/or high mortality of organisms (e.g., zooplankton, macroinvertebrates, fish, water snakes, waterbirds) via oil spills from tanker trucks and pipelines (A/C) • Spills from pipelines and boats cause direct impacts on mangroves forests (e.g., loss of native mangrove growth and favoring nonnative plants), and indirect impacts on other organisms that inhabit these ecosystems (e.g., crustaceans and fish) (A) *Infrastructure development (roads, river crossings, extensive wellpad development, wastewater treatment)*: • Fragmentation of habitat and reduced colonization and fish diversity (C) • Truck traffic accelerates erosion, leading to changes in sediment delivery to river, reduced habitat and visibility, lower fish productivity and fitness, lower levels of recruitment and possible effects on the food web (A/C) • Changes in macroinvertebrates diversity and density, and in fish assemblage structure (A) • The introduction, establishment and spread of nonnative species (A/C) • Impacts on vegetation same as for the exploration phase but on a larger scale, and: • Decreased habitat complexity and loss of ecosystem services (A/C) *Land-use changes*: • Increased sediment delivery to river may impact critical habitats (e.g., fish spawning habitat), cause turbidity and reduce visibility for predators (A) • Increased sediment in stream/river can contribute to eutrophication (A) • Loss of fish, amphibians and invertebrates diversity, and disruption of fish migration due to increased sedimentation, pollutants, turbidity and fragmentation (from road crossings in rivers) (A) • Land use change could isolate rivers, pans and lakes, resulting in genetic isolation and reduction in number of refugia (C) • Displacement and decrease in richness/abundance of native species (A) • Favors the introduction, establishment and spread of nonnative species (A/C) *Water sourcing from rivers for drilling:* • Removal of water from rivers may affect hydrology of water resources, change the interactions of freshwater communities and ecosystem functions (A) • Reduced streamflow in perennial rivers (A) • Loss of critical habitats (e.g., refuge and spawning) in rivers and lakes (A) • Loss of river migratory passages lead to loss of mobility, reduced food availability, fragmentation and isolation of fish assemblages (A) • Decrease in resource connectivity, reduction in abundance and diversity of invertebrates and fish, increase in tolerant species (A) • Groundwater abstraction leads to loss of baseflow to springs, loss of hyporheic flow, loss of refuge habitat, water quality and volume changes (C)
		Groundwater	• Same as for exploration phase	• Same as for exploration phase and: • Larger scale sourcing of water from local aquifers may induce aquifer connectivity, change groundwater levels, cause contamination and seismic activity. • Large scale surface activities contaminate aquifers via surface water-groundwater interaction. • Large scale wastewater poses serious challenges if not managed properly. • Poor well integrity may cause leakage of gas or fluids and groundwater contamination.
		Seismicity	• Not known	• Same as for exploration phase but on a larger scale

(*Continued*)

Table 1 (Continued)

Activity	*Phase*	*Aspect*	*Possible positive impacts*	*Possible negative impacts*
Conventional oil and gas	Post-extraction phase	Surface water and vegetation	• Risk of surface water contamination lowers	*Wastewater and oil discharge from leaks and spills:* • Long-term impacts of contamination on rivers, pans, lakes (C) • Unknown impact of specific chemicals on individual species or on freshwater communities (A) • Reduced habitat quality, reduced fish fitness and health and increased freshwater mortality due to exposure to toxic substances (A/C) • Reduced availability of food sources (e.g., invertebrates) (A) • Bioaccumulation of toxic substances in the food web (A) *Poor oil well integrity and well leaks:* • Possible contamination over long-term via surface water/groundwater connectivity if oil wells leak over long-term (A/C/L) *Disturbed area:* • Continued stream/river degradation (C) • Susceptibility to nonnative species invasion may continue for years (C) • Resuspension of pollutants after clean-up (C) • Migration of polluted ground- and/or surface water pollution to the rooting zone—vegetation die-back (A/C) • Success of vegetation rehabilitation uncertain (C/L) • Continued habitat fragmentation, due to poor upkeep of existing infrastructure, roads or nonnative invasive species control (C) • Continued loss of plant biodiversity and ecosystem services (A) • Possible establishment and spread of nonnative plants (A/C) • Illegal trade of endangered plants due to access roads (A)
		Ground-water	• Pollution risk in the area where fracking is ceased, lowers	• Aquifer pollution from oil production may only surface years after a pollution incident (A/C/L) • The extent of possible long-term contamination in freshwater aquifers could not be predicted (A/C/L) • Inability to rehabilitate contaminated aquifers in complex geology (physically and economically) (A/C/L) • Well abandonment and long-term monitoring may be problematic (A/C/L) • Oil and gas well casing failure and leakage may pose long term legacy issues and lead to inevitable groundwater contamination (A/C/L)
		Seismicity	• Not known	• Possible post-extraction seismicity
Unconventional oil and gas	Exploration phase	Surface water and vegetation	• Possible new species identified	*Seismic exploration*: • Same as for conventional oil and gas exploration *Drilling fluid, fracking fluid and wastewater (produced water and flowback) discharge during fracking pilot well testing*: • Drilling fluids, fracking fluids, wastewater leaching into surface water via groundwater or via overland flow from surface spillages contaminate rivers, pans, lakes (A/C/L) • Pollution reduces abundance and diversity of freshwater organisms (e.g., invertebrates and fish) (A/C) *Infrastructure development (road development, river crossings, limited wellpad development, seismic lines)*: • Impacts on surface water and vegetation same as for conventional oil and gas exploration, and: • Surface spills of hazardous fluids (drilling fluid, fracking fluid and wastewater [produced water and flowback]) during fracking pilot well testing can cause impact on vegetation (A) *Water sourcing from rivers for UOG extraction:* • Same as for conventional oil and gas exploration, but on larger scale, since fracking uses much larger volumes of water *River sand mining to obtain proppant for fracking:* • Increased surface water turbidity (A) • Removal of sand may impact on freshwater organisms in alluvial aquifer/hyporheic zone (A) • Increased sediment deposition in rivers could increase turbidity and limit habitat and food available to invertebrates and fish (A)

Table 1 (Continued)

Activity	*Phase*	*Aspect*	*Possible positive impacts*	*Possible negative impacts*
		Groundwater	• Develop a better understanding of the deeper geology and geohydrology	*Unknowns:* • Same as for conventional oil and gas exploration *Drilling in shale:* • Possible shale instability with associated borehole problems such as hole collapse, stuck equipment, plastic flow, fracturing, circulation loss and poor well control may cause contamination (C) *Saline produced water during CBM extraction* • Large quantities of saline water produced by CBM contaminate aquifers if aquifers and coalbed formations co-occur (A/C/L) *Hydraulic fracturing pilot testing* • Groundwater contamination if hydraulic fracturing is allowed during the exploration phase, both for coalbed methane and shale gas formations (A/C/L)
		Seismicity	• Not known	*Increased seismicity:* • Same as for conventional oil and gas exploration but on a larger scale
	Extraction phase	Surface water and vegetation	• Possible new species identified	*River sand mining to obtain proppant for fracking:* • Same as during exploration phase but on larger scale *Drilling fluid, fracking fluid and wastewater (produced water and flowback) discharge during fracking:* • Various sources of pollutants may impact rivers on a much larger scale than exploration (A) • Increase of sediment and contaminants may impact freshwater organisms physiology or behavior and alter ecological community interactions (A/C) *Infrastructure (Extensive road development, river crossings, extensive wellpad development, wastewater treatment plants)*: • Impacts on surface water and vegetation same as during conventional oil and gas extraction, but on larger scale *Water sourcing from rivers for UOG extraction:* • Same as during exploration phase but on larger scale
Unconventional oil and gas		Groundwater	• Using safer chemicals (e.g., gasses or plant-based oils) • Using green in fracking	• Same as for exploration phase and: • Large scale sourcing of water from local aquifers may induce aquifer connectivity, change groundwater levels, cause contamination and seismic activity (A/C/L) • Shale drilling over large regional areas may cause diffuse contamination (A/C/L) • Surface activities over large regional area contaminate aquifers via surface water-groundwater interaction (A/C/L) • Wastewater produced in large quantities during extraction poses serious challenges if not managed properly (A/C/L) • Poor well integrity may cause leakage of gas or fluids and groundwater contamination, also for CBM (A/C/L) • Large scale extraction of water from CBM causes geology and aquifer deformation, subsidence, decreased baseflow and reduced springflow (A/C/L)
		Seismicity	• Not known	*Increased seismicity:* • Same as during conventional oil and gas extraction but on larger scale
	Post-extraction phase	Surface water (quality) and vegetation	• Risk of surface water contamination lowers	*Drilling fluid, fracking fluid and wastewater (produced water and flowback) discharge during fracking:* • Same as for conventional oil and gas post-extraction phase and: • Not all chemicals used in fracturing fluids are known, therefore unknown chemical impacts are uncertain(A/C/L) • Pollutants may impact rivers (A/C/L) • Possible contamination via groundwater pathway due to interconnected resources (A/C) *Disturbed area:* • Surface water and vegetation impacts same as for conventional oil and gas post-extraction
		Ground-water	• Pollution risk in the area where fracking is ceased, lowers	• Aquifer pollution from deep shale layers may only surface years after a pollution incident (A/CL) • The extent of possible long-term contamination in freshwater aquifers could not be predicted at this stage (A/C/L) • Country/territory not able to rehabilitate contaminated aquifers in complex geology (physically and economically) (A/C/L) • Well abandonment and long-term monitoring may be problematic (A/C/L) • Oil and gas well casing failure and leakage may pose long term legacy issues and lead to inevitable groundwater contamination (A/C/L)
		Seismicity	• Not known	• Same as for conventional oil and gas post-extraction but on larger scale

Table 2 Water-related socio-economic impacts of conventional and unconventional oil and gas extraction.

Socio-economic impacts for oil and gas extraction during exploration, extraction and post-extraction

Activity	*Phase*	*Possible positive impacts*	*Possible negative impacts*
Exploration and extraction phases	Population	• No water-related impacts indicated in literature	• Short- and medium-term population influx place pressure on natural and social environment (e.g., water resources and water & sanitation infrastructure) (A)
	Economic	• Infrastructure development (e.g., roads, water, sanitation)	• "Boom-town" effect": pressure on existing infrastructure and social services (e.g., water and sanitation); pressure on municipal services (i.e., wastewater management) (A) • Decline in tourism potential stemming from land-use changes, degradation of pristine environments, biodiversity loss, and reduced water quality (A/C)
	Agriculture and food security	• No water-related impacts indicated in literature	• Diverting scarce water resources from agriculture to oil and gas interests (A) • Long-term impacts from dust pollution, water shortages and quality on crop production are uncertain (C) • Land-use changes affect availability and productivity of agricultural land (C/L) • Chemicals used in extraction may impact reproductive health of animals (C/L) • Rural livelihoods affected by reduced access to, and availability of, wild food sources (e.g., fish) (A/C) • Damage to agricultural land from oil spills (A/C)
	Health and social well-being	• No water-related impacts indicated in literature	• Naturally occurring radioactive materials from produced water can have health implications (A/C) • Water quality issues may contribute to increased risk of chronic diseases (e.g., cancer and asthma), especially in vulnerable groups (children and elderly) (C/L) • Risk of reproductive health issues uncertain (C/L) • Psychological impacts: perceived health risks, frustration, and anxiety over nuisances such as increased traffic and noise (A/C) • Social conflict: between community members; community and local/national government; community and oil and gas companies (A/C) • Loss of access to cultural sites and rituals (i.e., baptisms in rivers) (A/L) • Increased risk of injury and death (i.e., from accidents and oil spills) (A/C)
Post-extraction phase	Population	• Population decline reduces pressure on fragile natural environments and scarce resources	• No water-related impacts indicated in literature
	Economic	• No water-related impacts indicated in literature	• No water-related impacts indicated in literature
	Agriculture and food security	• No water-related impacts indicated in literature	• Land unsuitable for farming after oil and gas resources are depleted due lingering impacts on soil, and water quality and quantity (L) • Declining food security (A)
	Health and social well-being	• No water-related impacts indicated in literature	• Lingering health issues (e.g., cancer) (L) • Birth defects as a result of exposure to mutagenic chemicals (L)

Box 1 Oil in mangroves.

While not inland waters, mangroves are critical transition zones that link land, freshwater habitats, and the sea. They form a relatively small, but distinctive biome that delivers unique ecosystem services to coastal communities, and that serves as a nursery for many marine species. Oil contamination from ship transportation spillages and accidents during exploitation and pipeline transport, has severely affected these ecosystems (Duke, 2016). Mangroves often occur within large bay areas in tidal areas and river mouths in the tropics and subtropics, where important ports have been and are being constructed. The intense movement of large ships increases the chances of both acute accidental oil spills and smaller oil leaks. Additionally, mangroves are found within several of the world's main hydrocarbon extraction sites, such as the Persian Gulf, the Gulf of Guinea (including the Niger delta), the Caribbean Sea, and the Gulf of Mexico. Mangrove ecosystems are extremely vulnerable to oil contamination, particularly to large acute oil spills, but also to chronic oil contamination incidents. Understanding and distinguishing synergistic acute and chronic responses, as well as the singular effects of contamination, and negative impacts that stifle mangroves, are all essential to predict the ecological consequences of spillages more accurately, and for modeling subsequent impact and recovery.

Over the last few decades, large oil spills in and around the Port of Paranaguá in southern Brazil severely impacted mangroves. In 2001, the oil tanker Norma leaked 392,000 L of naphtha, contaminating 3000 m^2 of the Paranaguá bay, while a leaking Petrobras pipeline released 4000 L of diesel oil into the Caninana stream. The pipeline leak damaged the local fauna and flora (including mangroves) and led to the prohibition of fishing. In 2004, the Vicuña vessel exploded in the port and released millions of liters of oil and methanol into the bay. This contamination severely damaged the environment, while locals whose income depended on fishing, were compromised during fishing prohibitions. In the same year, a train derailing released 4000 L of fuel into the Caninana stream, while a Petrobras truck collision released 30,000 L of oil into the Padre and Pinto rivers, with all these pollutants ultimately reaching the mangroves. All these acute oil spills occurred within only 5 years and affected the same mangrove areas in the Paranaguá, Antonina, and Guaraqueçaba bays of the Paranaguá Estuarine Complex.

Nowhere on earth are the effects of careless oil exploitation in mangrove areas more visible than in the Niger Delta (Nigeria). This ecologically sensitive delta contains the largest section of mangroves in Africa, but is also rich in oil and gas resources (Ayanlade and Howard, 2016). Oil and gas production in this region causes some 300 oil spills a year, with leaking pipes, and toxic waste leaching into groundwater from unlined pits, killing fish and wildlife and making it hard to grow crops (Faber, 2020). The Nigerian government has committed many human rights abuses against people protesting the destruction of the delta by the oil and gas industry (Wong, 2020).

Over the last six decades, over 200 prominent oil contamination incidents were reported to have negatively affected mangroves across the world. Together, these account for at least 5 million tons of oil that have been released upon up to 2 million ha of mangrove, killing or altering over 126,000 ha of mangrove flora (Duke, 2016). With less than 15 million ha of mangrove cover left as of 2020, this renders mangroves as one of the biomes most affected by the oil and gas industry. However, given the lack of reporting, these are probably grave underestimates. Oil spills' effects on mangroves can be measured by calculating the total and relative areas of dead vegetation post oiling. Such data have however only been reported on a relatively small number of incidents. This is mostly due to incomplete or unavailable data on oil spill impacts and a global disparate bias in terms of large regions and countries. The biggest data gap on indirect long-term contamination, is chronic and diluted leaks in or near large ports and extraction platforms and their sublethal effects in terms of complex animal and plant ecological interactions. Abnormal changes in the condition of either plants or animals will affect other organisms and abiotic parameters and conditions. Small and large crustaceans, such as crabs, modulate the availability of resources to other species by changing ecosystem components (Jones et al., 1994), and thus provide many ecosystem services, including burrowing that improves sediment aeration and nutrient turnover and enhances water exchange, among others (Duke, 2001). To redress ineffective oil spill reporting in mangrove ecosystems, Duke (2016) recommends updating operational planning and action standards, highlighting that selective trials during a spill are an opportunity to rehabilitate contaminated mangroves that can guide future clean up responses. Such data must be publicly available.

Box 2 Oilfields in Amazonia.

Oil extraction has been particularly harmful to tropical forests and aquatic ecosystems of the Amazon Basin (Martínez et al., 2007; Yusta-García et al., 2017). In the upper reaches of the Amazon, in Ecuador and Peru, 12.1 million liters of produced water per day, 60 thousand liters of suspended oil per day, and large volumes of toxic mud have been released since 1990 (Martínez et al., 2007; Yusta-García et al., 2017). Instead of pumping the produced water, which contains salts, heavy metals, and other toxins, back into the wells, it was released into the rivers (Kimerling, 2006). The Trans-Ecuadorian pipeline, which connects the main production site of Lago Agrio (Ecuador) with the Pacific Ocean, also leaked approximately 73 billion liters of oil between 1964 and 1993. This represents 1.8 times the volume of the better-known 41-billion liter Exxon Valdez oil spill (Kimerling, 2006; Sebastián and Hurtig, 2004). In 1989, feeder pipelines were leaking 5400 L per day (Sebastián and Hurtig, 2004).

Major oil spills however still occur in this region, such as in the Coca River in 2009, 2013, and especially in 2020, when a 2.5 billion liter spill impacted the Kichwa Indigenous people (Koenig, 2021; Ricci, 2021). These operations also seriously degraded the fisheries in Ecuador's Napo and Coca Rivers, and what locals described as a "splendid" variety of fish in these two major river basins, was essentially destroyed (Kimerling, 2006). Amazonian fish are particularly sensitive to oil spills because many species have evolved adaptations to oxygen-poor water, leading them to come to the surface where they would encounter floating oil (Almeida-Val et al., 1999). These fish include the pirarucu or paiche (*Arapaima* spp.) air-breathing species and specially-adapted gilled species that exploit the oxygen-rich film at the water surface (Val and Almeida-Val, 1999). Salts from produced water also significantly alter regional saline concentrations (Moquet et al., 2014), and act as invisible barriers blocking fish migrations (Kimerling, 2006). The oil is not only toxic to fish (Sadauskas-Henrique et al., 2016) but also reduces the abundance and diversity of aquatic invertebrates, as shown by studies of spills near Manaus, Brazil (Couceiro et al., 2006, 2007). This undermines the base of food chains that support fish populations.

Even though Brazil already suffered significant oil and gas extraction environmental impacts, including from the upstream Ecuadorian and Peruvian operations, it still plans large-scale oil and gas extraction in the "Solimões" region (Brazilian for the Upper Amazon River, upstream of the confluence with the Rio Negro at Manaus) (Consórcio PIATAM/COPPETEC and EPE, 2020). A relatively small extraction site has operated since 1988 in this area at Urucu (purple areas in Fig. 1.1). Expanding these operations within the Solimões region would however affect an area of 740,946 km^2, which is larger than the United States state of California (Fig. 2.1).

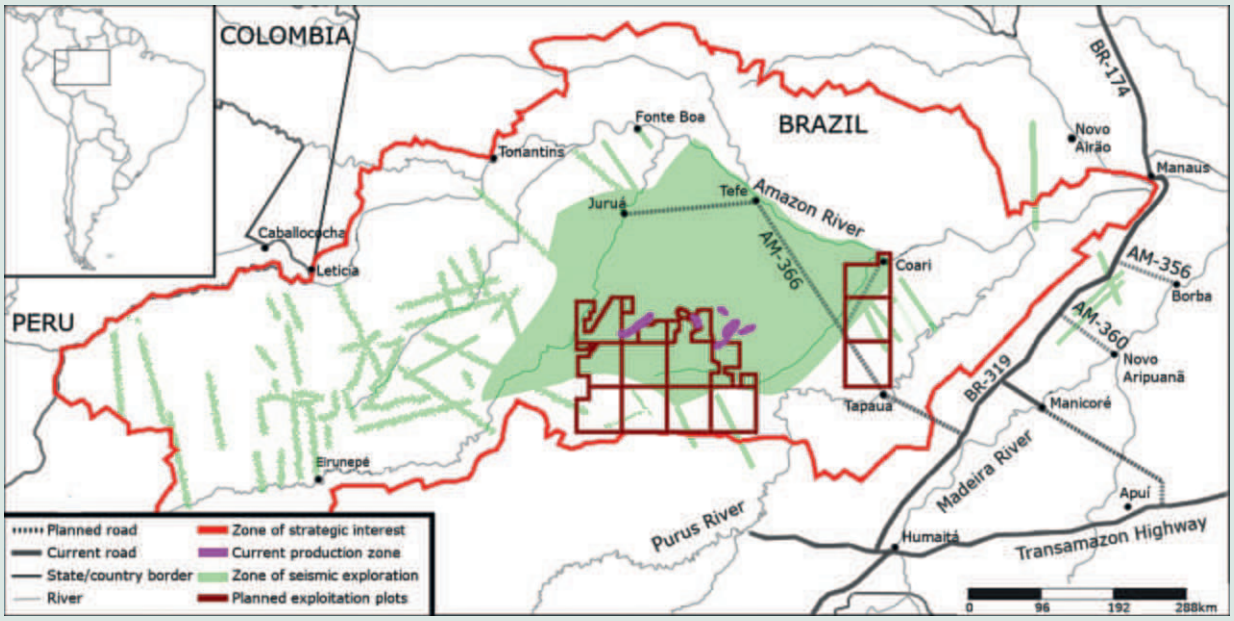

Fig. 2.1 Map of oil and gas drilling blocks in the state of Amazonia, showing the current production zone and the region where seismic surveys have already taken place. In this the 'zone of seismic exploration', around 185,000 km of seismic surveys were performed before 2019 (See Consórcio PIATAM/COPPETEC and EPE, 2020 for detailed map of survey transects). The project's 'zone of strategic interest' is larger than the United States state of California. The controversial BR-319 and the planned AM-366 highways would provide deforesters access to the vast area of intact rainforest west of the Purus River (Fearnside and Graça, 2006). Oil block connections to this road would likely spread deforestation throughout the Trans-Purus region (Fearnside, 2020a). (Image source: M Van Steenberge).

Currently, extraction sites at Urucu have no road access and are treated like oil platforms at sea (the "platform" model). The lack of roads has prevented settlement, land grabbing, and deforestation. With possibly thousands of wells to be drilled in the Solimões expansion project, road access would however be much cheaper. Oil companies will likely pressure the government to connect project areas to major roads, despite this not being part of the official project plan. A connection to the AM-366 highway that will connect the BR-319 (Manaus-Porto Velho) highway to Tefé, Coarí, and Juruá (Fig. 1.1), is most likely.

The first oil extraction rights, located on the planned AM-366 route, have already been sold to Rosneft (Departamento Nacional de Infraestrutura de Transportes (DNIT), 2020), the Russian oil company accused of causing over 10,000 annual oil spills worldwide (The Guardian, 2015). Oil spills and leaks from pipelines connecting wells to central hubs and from there to Coarí via larger pipelines, are an inherent risk. The Solimões project itself could, however, incentivize the AM-366 road construction, where an illegal 'branch' road already exists along the first stretch of the planned route (Fearnside et al., 2020). Such road access would initiate uncontrolled deforestation (Fearnside, 2017) and land grabbing (Ferrante et al., 2021). At risk is Brazil's last major block of intact Amazon forest: the Trans-Purus region between the Purus River and Brazil's border with Peru (Fearnside, 2020a,b). The environmental services of the Trans-Purus forest not only curb global warming and maintain biodiversity, but also maintain water-cycling that supplies rainfall to São Paulo and other major Brazilian population centers and neighboring countries (Fearnside et al., 2020).

Box 3 Different approaches to water resource protection during oil and gas extraction in water-scarce areas of Southern Africa.

There are many similarities between the Namibian Okavango and South African Karoo oil and gas extraction areas—both are water-scarce and in both cases, locals depend extensively on groundwater resources. The Namibian Kavango basin also has the same geology and depositional environment as the South African Karoo basin and is an extension of the South African Karoo Supergroup (Catuneanu et al., 2005; Werner, 2006). The approaches toward managing and protecting the scarce water resources of these two areas, however, differ widely and are discussed below.

Case study 1: Okavango

Reconnaissance Energy Africa (ReconAfrica), a Canadian oil and gas company, holds a license to explore both conventional and unconventional oil and gas over an area of approximately 35,000 km^2 in the northern parts of Namibia and Botswana (Tan, 2021), Fig. 3.1. These areas include the Namibian headwaters of the Okavango delta and the Kavango-Zambezi transfrontier conservation area (KAZA). The KAZA has one of the most diverse ecosystems on the planet, borders three national parks, and covers 11 community conservancy concessions. A world heritage site that lies within ReconAfrica's PEL001 exploration area, Tsodilo Hills, was excluded from their license area in 2021 after intervention by United Nations Educational, Scientific and Cultural Organization (UNESCO) (2021).

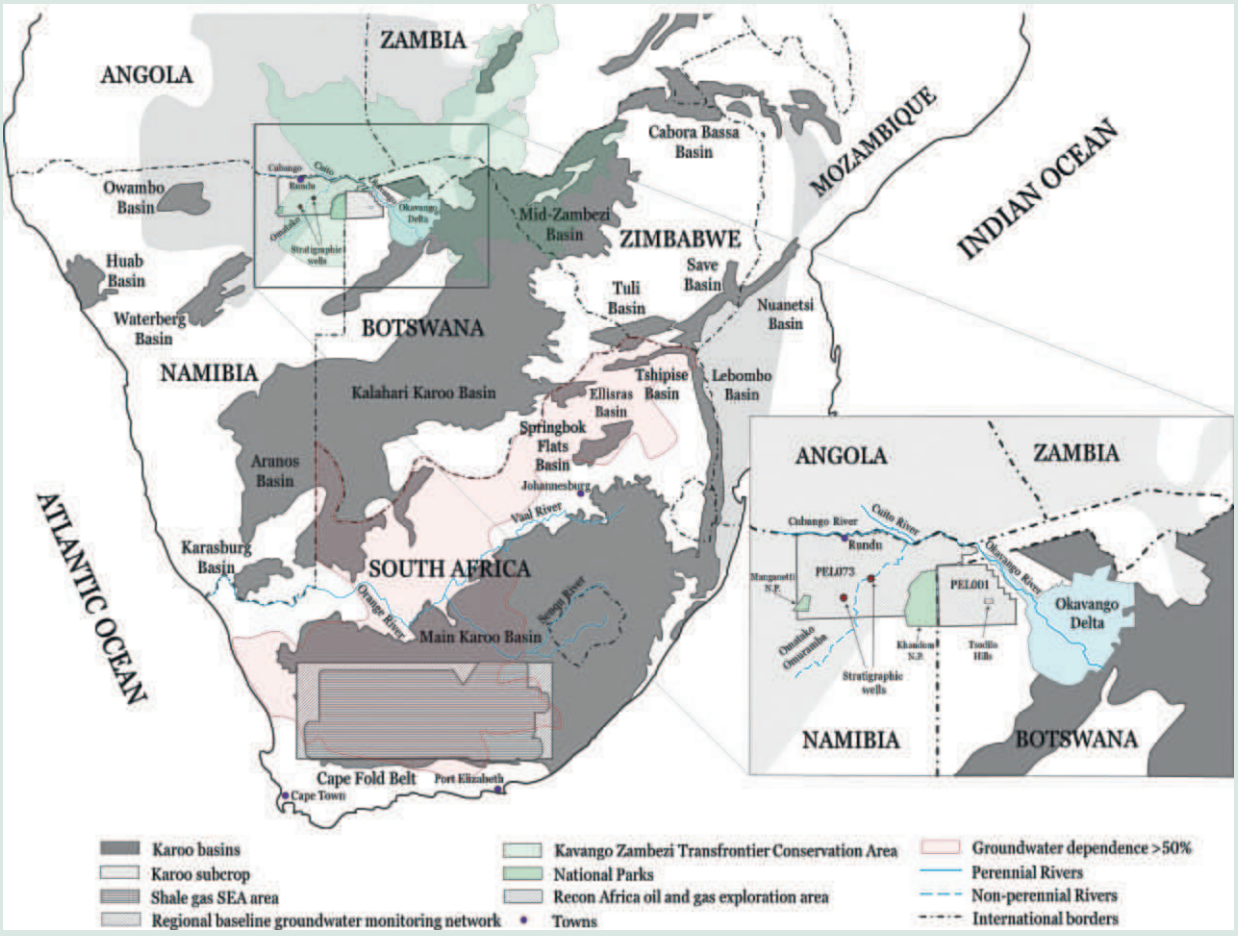

Fig. 3.1 Map of Southern Africa with the South African Karoo and Okavango delta case studies, showing relevant rivers and geological basins (Image source: S Esterhuyse).

Groundwater is especially important in the arid PEL073 ReconAfrica license area in Namibia. Because the Omatako River within PEL073 is ephemeral, rural people rely predominantly on shallow groundwater, especially close to the river (Jones, 2010). Groundwater is used for domestic and livestock supplies to villages, rural communities, and farms (Christelis and Struckmeier, 2011). The boreholes and dug wells that supply water are concentrated, as are the people, along the Omatako river valley.

ReconAfrica has started to drill their first exploratory well within the Omatako river valley in January 2021 (Barbee and Neme, 2021) and reports surfaced that the reserve pit where returned drilling fluids and wastewater is being stored, is not lined (Barbee, 2021). This poses a serious contamination risk to the groundwater resources in the Omatako valley. With a shallow groundwater level of less than 30 m, and with sandy unconfined aquifers into which contaminants can easily migrate, the groundwater in the Omatako valley is especially vulnerable (Christelis and Struckmeier, 2011). Recharge of the groundwater system occurs mainly via the river systems (Jones, 2010). Once aquifers in arid areas are contaminated, it is nearly impossible to clean up, and this contamination, therefore, poses a legacy contamination risk.

Future exploration that may include drilling in the PEL001 license area near the Okavango delta in Botswana, also poses a legacy contamination risk to the delta. The Okavango delta does not have an outlet to the sea, and any contamination that enters the delta will therefore accumulate, as confirmed by a continued increase in the salinity of the water in the delta over time (Oromeng et al., 2020).

Box 3 (Continued)

Both Namibia and Botswana require environmental impact assessments for oil and gas extraction, and public participation as part of the EIAs. There were, however, numerous reports of poor public participation (Esterhuyse, 2020) when ReconAfrica applied for its licenses. ReconAfrica is dismissive of any water impact that may emanate from its activities (Barbee, 2021). The poor management and lax regulation of oil and gas exploration in the Okavango threatens its water resources and should be handled with much more care.

The exploration areas cover a large region of extremely sensitive areas and span across international borders. A strategic environmental assessment should therefore have been performed in addition to the EIAs. A baseline of water resources in the license areas has not been done, nor do proper regulations exist to protect its water resources. The apparent lack of transparency of ReconAfrica in sharing information about its activities (Barbee and Neme, 2021) is also worrying. Without transparency, Botswana and Namibia may not be able to avoid a resource curse, and would not be able to properly manage or monitor the transboundary effects of exploration and extraction activities on the shared water resources.

Case study 2: Fracking in South Africa

Unconventional gas extraction using hydraulic fracturing is seen as a way for South Africa to achieve energy security and can assist the country in meeting its socio-economic development agenda (Ndlovu and Inglesi-Lotz, 2019). In 2011, Shell applied for a shale gas extraction license, covering approximately 180,000 km^2, in the central part of the country in an area known as the Karoo (Fig. 3.1). The mean annual precipitation in the Karoo ranges from 500 mm in the east to less than 100 mm in the west. The arid Karoo is ecologically sensitive and most of its rivers are ephemeral (Esterhuyse et al., 2016a,b). Groundwater is therefore its most important water source, with most agriculture and towns in the central and western Karoo depending on it (Fig. 3.1).

The limited water resources and sensitive landscape limits economic and agricultural activities (Walker et al., 2018). Agricultural activity, supporting around 100,000 people in the area (Oettle et al., 2016; Murcott and Webster, 2020), mostly focuses on livestock farming, including dairy farming and wool and meat production, but also includes other activities such as seed crop production. The Karoo people have low employment levels and are poverty-stricken, with a high dependency on social grants (Redelinghuys, 2016). They cannot mitigate the impacts of water pollution and water scarcity. Karoo towns also experience ongoing issues with service delivery that fuel social and political unrest. Service delivery protests are strongly linked to water access, which is exacerbated by the limited institutional capacity of the poorly functioning municipalities (Atkinson et al., 2016).

Fracking can potentially disrupt the Karoo's natural ecosystem through the use and pollution of scarce water resources, negatively impacting the health and wellbeing of the people and the natural environment. Because of this, a strategic environmental assessment (SEA) for shale gas development has been done in the Shell permit area (Scholes et al., 2016), Fig. 3.1. This SEA highlighted the risk of shale gas development for polluting Karoo groundwater resources, and crucially stated that no additional inland water is available for fracking. Because of this, the Petroleum Agency of South Africa commissioned the development of a regional baseline groundwater monitoring network (Groundwater Division of the Geological Society of South Africa (GWD GSSA), 2021) to assess the baseline groundwater quality and quantity. South Africa is also developing regulations to protect water resources during fracking (Republic of South Africa (RSA), 2021). These management tools will assist in protecting the scarce Karoo water resources, and no UOG extraction licenses are being granted until these management tools are in place.

phase. Given the uneven distribution in oil and gas production and consumption, oil and gas are transported over large distances using tanker trucks, rail, and, most importantly, pipelines (Michel and Fingas, 2016). As many streams and rivers are crossed by roads, freshwater environments are highly susceptible to the impacts of spills from tanker trucks (Laurance et al., 2009). These aquatic ecosystem impacts can extend over long distances from the source and affect fish, crustaceans, reptiles, birds, and mammals. Although pipelines can economically transport enormous volumes of oil over large distances, they come with an inherent risk of oil spills, often resulting in the contamination of surface waters. A review of Canadian oil leaks from pipelines revealed that spills were frequent, variable in scale, and posed a wide range of potential adverse environmental effects. Additionally, pipeline oil spills were difficult to predict, posing challenges to management and policy (Kheraj, 2020). To detect spillages, companies rely on high-tech (automatic monitoring) and low-tech techniques (pipeline walkers, helicopter patrols). In developing nations, however, and in regions with weak governments, relaxed environmental regulation increases the risk of undetected leakage. Pipelines are often targeted during armed conflicts, especially in areas with a rich oil wealth (Le Billon, 2013), and also face significant threats from vandalization and cyber-attacks (Oluwatuyi and Ileri, 2013; Dancy and Dancy, 2017), which increases leakage risks. Because of these risks, the construction of new pipelines, especially through culturally or ecologically sensitive land, is increasingly opposed.

Ecological impact on aquatic communities

The direct impacts of oil and gas extraction on biodiversity and ecosystem services include habitat loss and fragmentation, pollution, changes in water resources and flow regimes, alterations in the structure of freshwater communities (Entrekin et al., 2011a,b; Jones et al., 2015), and changes in wildlife habitat use (O'Rourke and Connolly, 2003) (Table 1, Fig. 2). Although the composition of petroleum varies greatly, crude oil is a mixture of (cyclo)alkanes and (poly) aromatic hydrocarbons (PAHs), with, to a lesser degree, sulfur- and nitrogen-containing hydrocarbons and trace metals. Several PAHs are carcinogenic and/or acutely toxic to aquatic organisms (Echols et al., 2009).

In freshwater environments, oil droplets can attach to suspended matter to form oil-particle aggregates. Even after complete clean-up of an oil spill, these can resuspend in the water column (Zhu et al., 2018). Toxic resuspended oil from oil spills, as well as flowback, produced water, and wastewater can result in wildlife mortality (Etkin, 2011). This toxicity can impact all levels of biological organization (from organism to ecosystem or landscape), reach different spatial scales (from localized to expanded regional impacts), and may continue for years (Azevedo-Santos et al., 2021). At the individual level, potential oil spill impacts include changes in the behavior, morphology, or life history of native species, while at the population level, impacts include changes in the abundance and distribution of native or non-native species. At the community level, oil and gas extraction impacts can cause

extirpations and species extinctions, but more commonly causes changes in species composition and diversity or abundances and interactions. These alterations can cause biotic homogenization and changes in the size and structure of food webs. At the ecosystem level, oil spills can affect and even alter entire river ecosystems. It can directly affect certain ecosystem engineers, e.g. bivalves, due to their high filtration rates, and can change primary productivity from food webs based on macrophytes to food webs based on benthic algae. Furthermore, impacts at the lower levels of biological organization may affect the higher levels, which can lead to a decrease in biodiversity and deterioration of genetic heritage (Gomes et al., 2000).

In addition to the direct impacts, indirect threats of oil and gas exploration can exacerbate the negative impacts on ecosystem functioning and biodiversity loss. Exploratory drilling can open up new areas, leading to the expansion of logging, hunting, and human settlements, as well as the introduction of non-native species (Laurance et al., 2009). These indirect threats pose challenges in tropical forests, as they lead to deforestation, with oilfield access roads providing access to settlers and other actors who invade and clear the forest. In Ecuador, 500 km of roads were built for oil extraction by 1989, leading to 10,000 km^2 of land being claimed by settlers, in addition to the entry of agribusiness, ranching, and logging (Kimerling, 2006). This is a harbinger of one of the dangers of Brazil's massive plans for oil and gas extraction in the western portion of its Amazon region (see Box 2).

Socio-economic impacts

Oil and gas development has profound and often long-lasting impacts on surrounding communities (Table 2). While some socio-economic benefits include increased job opportunities and improvements in infrastructure such as roads, these benefits are often gained at the expense of community cohesion, human health, and wellbeing, and local livelihoods (Appel et al., 2015; Jenkins et al., 2016; Scanlan, 2017). Existing social, political, and economic inequalities further result in an unfair distribution of benefits, risks, and harm associated with these developments. This is referred to as environmental injustice. Negative impacts disproportionately affect vulnerable and marginalized groups and communities that are least able to protect themselves (Inkpen and Moffett, 2011), such as ethnic minorities, indigenous communities, rural communities, the poor, and women. These vulnerabilities are often intersecting (Canfield et al., 2020; Long et al., 2020).

Areas surrounding oil and gas developments experience an influx of people, drawn by the possibilities of employment and economic development. Rapid population increases lead to increased pressure on natural resources such as water and land (Ayanlade and Howard, 2016). Oil and gas extraction furthermore contribute to pollution of air, water, and land, and this pollution has implications for human health and wellbeing. Chemicals used in unconventional oil and gas extraction processes that are released into the environment may gradually contaminate water resources, with the impacts on human health only becoming apparent with time. These chemicals have been linked to the development of cancers, birth defects, miscarriages, and other diseases and much uncertainty remains to what extent unconventional oil and gas extraction contributes to the development of these diseases (Finkel, 2016; Gorski and Schwartz, 2019). In the case of oil spills, surface and groundwater sources are contaminated, killing wildlife and fish and ruining the resource base on which local people depend for subsistence (Faber, 2020).

Poor or indigenous communities often rely on freely available ecosystem services for subsistence. Some 25% of poor rural households' livelihood resources such as firewood, medicinal plants, and food are obtained directly from the environment (UNEP, 2016; FAO, 2018). Additionally, small-scale fisheries are a major source of protein and income for the rural poor (Béné et al., 2009). When local communities lose access to wild food source areas, and when environmental pollution from oil and gas extraction and transportation exacerbate resource scarcity, it affects their food security and income generation. Particularly in water-scarce areas, access to and availability of clean water are critical community concerns. Communities downstream from such developments may experience dropping water levels in rivers, lakes, and wetlands. Falling water levels can disconnect indigenous populations from accessing subsistence lands as they are unable to reach these lands by boat (Scanlan, 2017; Westman and Joly, 2019).

Legacy impacts

Legacy impacts are long-term impacts that span over multiple generations and that are not easy to fix. Oil and gas extraction can have legacy impacts on both surface water and groundwater. On a local scale, leaking oil and gas wells can contaminate groundwater resources, which often cannot be cleaned up easily, if at all (National Research Council (NRC), 2013). This can lead to a permanent loss of the groundwater resource, meaning that communities must rely on other water sources or imported water over the medium-term. Over the long-term, communities may even be displaced because of a loss in livelihoods due to the groundwater supply loss.

On a regional scale, the abandonment of oil and gas wells, or the poor sealing of wells after well decommissioning, may lead to long-term groundwater contamination legacy issues (Australian National University (ANU), 2012). Davies et al. (2014) report that between 1.9% and 75% of wells from different oil and gas extraction areas worldwide, failed, but estimates are that almost all wells would eventually leak and potentially contaminate groundwater due to the mechanical failure of well casings (Bishop, 2011). Apart from contaminating groundwater resources, abandoned oil and gas wells also release methane into groundwater and the atmosphere. In the US alone, the oil and gas industry has abandoned about 3.4 million wells that were used over the past 100 plus years of drilling. These wells emitted an estimated 290 kt of methane into the atmosphere in 2018 alone (Environmental Protection Agency (EPA), 2021). The large number of wells that are drilled to access oil and gas resources, makes the regional legacy impact of leaking wells considerable.

Oil and gas extraction can also have vast impacts on surface water resources. If planned oil and gas drilling in the Okavango catchment contaminates the Okavango delta, it will lead to legacy contamination impacts (see Box 3: Okavango case study).

Similarly, legacy impacts can also be expected if current initiatives for oil exploration will lead to exploitation in the East African Great Lakes. Oil exploration is advanced in Africa's largest freshwater reservoirs, including the rift valley lakes Tanganyika, Malawi, and, lately, Albert, threatening their unique ecosystems and biota (Verheyen et al., 2016). As these are crucial in terms of water, food, and livelihoods for millions of people, an oil spill would markedly affect the health, water supply, and food security of local communities. The remote location of these lakes impedes quick and effective reactions to oil spills and as appropriate infrastructure is currently unavailable, bringing in heavy equipment at the time of a spill would be cumbersome, logistically impossible, or prohibitively expensive. Additionally, several of these lakes have very long flushing times, which means that recovery from an oil spill could take millennia. For Lake Tanganyika, which contains about one-fifth of the world's surface freshwater, the flushing time is approximately 7000 years (Verheyen et al., 2016). Finally, these lakes form the headwaters of some of the continent's largest rivers, including the Congo, the Nile, and the Zambezi. An oil spill in these lakes, which are home to thousands of endemic species, would therefore be a global biodiversity catastrophe. An accident might deal a devastating blow to these ecosystems, which have already been rendered fragile by anthropogenic stressors such as overfishing, deforestation, and global warming.

Long-term legacy impacts are possibly the least studied and understood, because impact monitoring usually ceases soon after oil and gas extraction stopped. This stresses the importance for governments to consider long-term financial planning to address legacy issues while hydrocarbons are still being extracted (National Academies Press (NAP), 2018), by investing some of the funds derived from current production to address potential future environmental issues.

Management of oil and gas extraction

Preventing impacts of oil and gas extraction on water resources is a very important but often neglected aspect of management. The precautionary principle, an international environmental law approach, is important to prevent negative impacts from high-risk activities, especially when considering climate change and increasing future water scarcity. The most salient example of the application of the precautionary principle is the placing of moratoria on fracking, or its outright banning in many countries (Esterhuyse et al., 2019). This principle is also especially important for groundwater resource protection because polluted groundwater resources often cannot be remediated. The precautionary principle should be used in conjunction with risk management tools, such as Environmental Impact Assessments (EIAs), Strategic Environmental Assessments (SEAs), water resource baselines, and the regulation of the oil and gas industry, to minimize negative impacts (see Box 3: South Africa case study).

Whereas EIAs assess the impacts of oil and gas development on a project level, SEAs assess broader potential impacts of plans, policies and programs, including cumulative impacts in a regional context (Esterhuyse, 2018). EIAs and SEAs must be independent to ensure evidence-based decision making that considers and addresses any environmental and societal damage that may ensue from extraction, including national or ethnic conflicts.

Baseline studies provide information on water resources before oil and gas extraction starts. Baseline data on existing water use can ensure that water uses are considered and protected before allocating water resources for extraction, while baseline water quality information alert regulators to contamination events, which can also be used to determine rehabilitation targets (Esterhuyse et al., 2019). Baselines are indispensable for establishing a legal basis for proving contamination, identifying the party responsible for the contamination, or for a company to refute a contamination claim (Esterhuyse et al., 2019).

A very important government tool to minimize impacts on water resources is regulation (Esterhuyse et al., 2019). The most effective regulatory framework includes both 'hard' command-and-control regulations and 'soft' market-based and voluntary regulations that are effectively enforced. Enforceable regulations contain provisions that establish criminal liability for cases where regulations are violated, commonly known as environmental crime. Where regulations are contravened, fines or sanctions can be imposed, for example, in 2021 Shell was ordered to pay over $111 million for water contamination in the Niger Delta (British Broadcasting Corporation (BBC), 2021). Regulations should also require public disclosure of the oil and gas operations. Disclosed data should be stored in publicly accessible databases to allow for independent scientific review of data by government, academia, and the private sector, which will allow for timely and appropriate adaptive management and the amendment of regulations as necessary.

Once contamination has occurred, clean-up and mitigation are required to minimize the negative effects on water resources. Here, the 'polluter pays' (see above example) and 'cradle-to-grave' principles are useful for holding the polluting companies liable, assuming that the polluter can be identified. However, even if companies pay for remediating water resources, the remediation of groundwater pollution (which mostly includes pump-and-treat and in situ bioremediation methods) is often unsuccessful (National Research Council (NRC), 2013), which is why groundwater pollution should be prevented at all costs. Ogoniland in the Niger Delta, home to the third-largest mangrove ecosystem in the world (see Box 1), is one of the most striking examples of groundwater pollution by oil and its lack of remediation success. Here, the groundwater of 69 sites covering around 1000 km^2 was severely contaminated with oil, mostly from leaking pipelines. Several years after these sites were contaminated, and after various clean up attempts, they are nowhere near remediated (UNEP, 2011; Gundlach et al., 2021). Remediation of surface water, which is also not always successful, includes biological, chemical, physical and chemical, thermal and heat, electric and electromagnetic, acoustic, and ultrasonic treatment methods (Ossai et al., 2020).

Establishing protected areas also protects regional sensitive aquatic environments. However, the difficulty in protecting aquatic environments from hydrocarbon extraction and its often significant impact on the livelihoods of riparian residents is globally evident. Numerous incidents worldwide, such as spills from drilling sites, lead to local claims of water pollution and health effects on human communities and their livestock.

Rather than opting for sustainable development strategies, governments often circumvent legal barriers by issuing hydrocarbon exploration and extraction permits in sensitive and even protected areas (see Box 1: Niger Delta and Box 3: Okavango case study). This negatively affects freshwater habitats that are the source of livelihoods for riparian populations and that contribute to sustainable economic development. The problem is most pronounced where governments want to quickly build up their state revenues, while a lack of resources to manage protected areas further compounds the issue. It is also important to note that these protected areas represent only a fraction of the scientifically identified priority biodiversity areas.

To avoid the prioritization of short-term gains over the long-term sustainable livelihoods of people living in oil and gas target areas (La Vina et al., 2010), governments should develop economically and ecologically viable extraction strategies in collaboration with regional stakeholders and scientists throughout the decision-making process. Norway is an example of where civil society influences petroleum governance to ensure sustainable development (Overland, 2018) Community initiatives to conserve natural habitats during hydrocarbon extraction can complement central government initiatives. Decentralized management of sensitive and protected areas is an obvious, if not a more viable solution, given the difficulties that the respective responsible central agencies sometimes face.

Sound environmental principles, such as the development of specific guidelines for public participation, should be incorporated during protected area management planning. Implementation of these principles requires unfettered access to information, including maps, relevant rules and regulations; and results on energy resources within protected areas. Only with these kinds of tools can local communities curb their governmental aspirations of sudden wealth, and prevent discrimination, dispossession, and long-term health problems.

The future of oil and gas extraction

The energy sector is the source of around three-quarters of greenhouse gas emissions (IEA, 2021) and holds the key to averting the worst effects of climate change, which is perhaps the greatest challenge humankind has faced. Climate change and its effects are inextricably linked to water resources (Stephens et al., 2020), leading to sea-level rise, climate extremes with more severe droughts and floods, irreversible effects on aquatic ecology, more water scarcity, and massive economic loss (Betts et al., 2018). Sea-level rise could in turn further endanger mangroves and also lead to coastal freshwater aquifers being intruded by saltwater, further limiting freshwater supplies. To limit such negative effects, the long-term increase in average global temperatures must be limited to 1.5 °C, as required under the international Paris Agreement, by achieving net-zero carbon emissions by 2050 (IEA, 2021).

The path to net-zero emissions by 2050 requires an immediate and massive deployment of all available clean and efficient energy technologies. Reaching net-zero emissions by 2050, with a world economy in 2030 being some 40% larger than today, requires a worldwide increase in energy efficiency, emissions reductions from the energy sector in CO_2, and a drop of 75% in methane emissions from fossil fuel production (IEA, 2021).

Future energy requirements predict that energy demand reaches a plateau from around 2030 onwards and that gas will become increasingly prominent over the coming years (McKinsey, 2021). It is predicted that gas will fuel the energy transition and overtake oil to become one of the world's largest primary energy sources by 2025 (International Energy Administration (IEA), 2019). The European Union sees gas as a critical transition to renewable energy and is of the view that substituting coal and oil with gas could help to reduce carbon emissions (European Commission (EC), 2012, International Renewable Energy Agency (IRENA), 2018). Although large-scale investment in natural gas may help in transitioning from coal and oil to renewables, gas can only temporarily fulfil this role because it still emits CO_2 and CH_4. Over the long-term, natural gas extraction can therefore work against reaching the climate goals (Gürsan and de Gooyert, 2020).

Oil majors are already significantly increasing the share of gas in their portfolios, and despite fossil fuel extraction having to end to avoid catastrophic climate change (IEA, 2021), continued investment in new gas developments is still expected. It is however of the utmost importance that any new oil and gas developments limit negative water resource impacts. Considering climate change (International Panel on Climate Change (IPCC), 2021) and biodiversity loss (Dasgupta, 2021), governments must in the long run limit CO_2 and CH_4 emissions by moving away from fossil fuel extraction, and pursue sustainable engagements with Nature that enhances our wellbeing and that of our descendants.

Glossary

Acid mine drainage Acid mine drainage is mining influenced water with a pH below 5.6, characterized by high proton, (semi-) metal and sulfate concentrations and an elevated mineralization.

Acid rock drainage Acid rock drainage is a low pH water resulting from pyrite oxidation in natural rocks.

Acidithiobacillus thiooxidans *Acidithiobacillus thiooxidans* is a microorganism catalyzing pyrite oxidation by a factor of up to one million. It gains its energy from the oxidation of sulfur.

Atlantic Forest Atlantic Forest is a South American biome, characterized by high biodiversity and endemism.

Barite Barite is a sulfate mineral with the formula $BaSO_4$.

Bootleg workings Bootleg workings are a historic or traditional mining method which extracts the raw material down to shallow depths leaving a bootleg type opening underground.

Category of accident risk Category of accident risk of a dam refers to the aspects of the dam itself that may influence the probability of an accident: project aspects, structure integrity, conservation, operation and maintenance status, and compliance with its Safety Plan.

Cone of depression Cone of depression is the subsoil area that becomes dewatered when mines are pumped.

Decommissioning Decommissioning is the final termination of a mining or processing operation, removing plant and equipment, and disposing wastes.

Digital twins Digital twins are computer simulations of water treatment plants to understand and visualize all relevant processes that would occur in the real plant.

Dry stacking Dry stacking is a process by which dewatering of tailings can be done with the help of vacuum or pressure filters, with the aim of stacking the tailings afterwards.

Efflorescent salts Efflorescent salts are minerals that are formed when mineralized mine water evaporates and leaves back easily water-soluble minerals.

Electrical conductivity Electrical conductivity (EC) is a measure for the potential of a liquid to conduct electricity. In general, the more ions are dissolved in a liquid, the higher this value will be, which is usually measured in mS cm^{-1} or µS cm^{-1}. It is compensated to either 25 ∘C or, more seldom, to 20 ∘C. Because of this characteristic, the electrical conductivity can be used for a quick indication of a mine water's contamination status.

First flush First flush is the fast increase of water constituents after an underground mine is flooded and the subsequent decrease of these constituents' concentrations over time, while fresh water kärchers the mine workings.

Geochemical barrier Geochemical barrier is a subsoil remediation method that uses reactive material in a permeable, vertical layer of various length, depths, and thickness to react with pollutants in flowing groundwater.

 https://doi.org/10.1016/B978-0-12-819166-8.00085-2

Iberian Pyrite Belt Iberian Pyrite Belt is the world's largest single ore district for copper and iron ore stretching from Spain to Portugal.
In-lake-neutralization In-lake-neutralization is an open pit mine water remediation method using various chemicals and gasses applied to the mining influenced water to increase the pH of acidified open pit lakes.
Inundation Inundation is an accidental inflow of water into mine workings, predominantly underground mines, eventually causing the mine to flood.
Karstified Karstified rocks are mainly composed of carbonate minerals that are dissolved by acidic ground water, leaving back caves or sinkholes.
Leptospirillum ferrooxidans *Leptospirillum ferrooxidans* is a microorganism that catalyzes pyrite oxidation by a factor of up to one million. It gains its energy from the oxidation of iron.
Micro-/macrocosm Micro-/macrocosm is a lake remediation method using enclosures of various size installed in open pit lakes and filled with various reactive substrates to inhibit microbial growth and subsequently sulfate reduction and metal precipitation.
Mine pool Mine pool is not a public swimming location underground, but the sum of all the polluted or unpolluted water collected in an underground mine.
Mine water Mine water or mining influenced water (not: mine wastewater, mining impacted water, mining affected water) is all the water in a surface or underground mine or seeping through waste rock. Strictly speaking, the water from the processing plant and the tailings is process water, as it contains human-induced process chemicals.
Mudflow Mudflow is a mass movement that involves an extremely rapid to fast, sometimes surge-like flow of debris, sediments, and sludge. In the presence of substantial amounts of water, the material may become partially or completely liquid.
Ochre Ochre is a collective term for yellow to dark orange iron oxides with a clayey to sandy composition.
Passive treatment Passive treatment is a remediation method for polluted mine water or soil which uses only natural or potential energy, plants, and microorganisms for improving mine water quality.
Process intensification Process intensification is a method to optimize an existing process, instrument, or device such that its use is optimized. The addition of a centrifugal governor to old style steam engines by James Watt is considered a process intensification bringing steam engines to save and reliable use.
Pyrite Pyrite is a sulfide mineral with the formula FeS_2. Though chemically identical to marcasite, it has another crystal structure. When pyrite or marcasite come into contact with water and oxygen, acid mine drainage or acid rock drainage forms.
Reactive wall Reactive wall see geochemical barrier.
Siltation Siltation is often a result of soil erosion or sediment pollution whose particle size is mainly in the silt or clay range. It may result in the pollution of water courses.
SPOT-6/LANDSAT-8 SPOT-6/LANDSAT-8 are satellite systems that are capturing the earth's surface by means of scanners or cameras with various wavelengths.
Tailings Tailings are the fine-grained residues of mineral processing and contain currently uneconomic crushed and milled rock and chemicals from the processing plant. Tailings are stored in sludge ponds, called tailings dams, or are dry stacked in tailings disposal sites.
Tailings dams Tailings dams contain the residues of raw material processing, and the dams are typically built of loose material.
Trophic levels Trophic levels are the different hierarchical levels from primary producers to primary and secondary consumers in a food chain.

Introduction

Selecting suitable case studies for mining influenced surface waters is an easy task because there are so many well-described studies from around the world. However, this does not imply that all mining operations cause pollution in the receiving water bodies or are prone to tailings dam failures—it just means that those that occur are often well studied. The intention behind selecting the following sites as case studies was: to describe and illustrate some important mining influenced rivers/streams; to describe the pollution sources and potential remediation options in these rivers/streams; and, to indicate that irresponsible conduct could cause severe regional, social and environmental effects (Table. 1). In addition, these sites are all located in mining areas of outstanding importance to human's mining history—which will be left to historians and archeologists to document. Besides the case studies presented, here could also be a case study about the Loisach rivulet near Biberwier in Tirol, which once was affected by lead, zinc, and silver mining, but now is a beautiful mountain stream. Or the Sabie River in South Africa could be shown, which is partly fed by abandoned gold mine discharges, and now used as drinking water and for recreational purposes for the town and tourists of Sabie. Moreover, this section could include the Metsämonttu mine in Finland, where natural attenuation and a small constructed aerobic wetland decrease the iron concentrations below the detection limit before the mine water enters a Natura 2000 protected river system. However, images of clean water are less impressive in this context than images of red or orange water—though the Cape Breton Island section shows a clean-water image for Cadegan's Brook, which is an excellent example of successful remediation measures. This section's intention is also to present case studies from which we can learn how to tackle the problems associated with polluted mine water and with the storage of mining residues, such as tailings.

From a large range of possible case studies that can illustrate environmental management of mining, seven have been chosen because of their importance in this context. Yet, all case studies are representative for the many thousands of mining influenced streams, rivers, and lakes around the world.

Cape Breton Island, Canada

Mining influenced water from Cape Breton Island's 1B mine pool is treated by a passive aerobic constructed wetland system. This system substantially improves the water quality in the receiving water course, Cadegan's Brook, and the Atlantic Ocean as the final recipient.

The subsequent discussion about mine water in the 1B mine pool on Cape Breton Island, Nova Scotia (NS), Canada, is based on publications of Amirault et al. (1993), Calder et al. (1993), Forgeron (2007), Frost (1964), Government of Canada (2016), MGI Limited et al. (2003), Moreland (2013), Shea (2008, 2009), and Wolkersdorfer (2011).

Coal mining on Cape Breton Island (Fig. 1) is the oldest of its kind in Northern America and dates to 1685, when French soldiers worked coal seam outcrops in the Sydney/NS area. First commercial coal mining began in 1720, when a coal mine was opened in Cow Bay (Port Morien). In 1999, triggered by a flooding accident, mining ceased for economic reasons. Until then, 45 major underground and undersea coal mines were in operation on Northern industrial Cape Breton Island. They stretched from Big Bras D'Or in the northwest to Port Morien in the southeast.

One of the largest of these underground coal mining operations was around Sydney/NS, with the 1B mine pool holding most of the polluted mine water in 10 individual, interconnected mines. They stretched several kilometers into the Atlantic Ocean, and the mine pool has an estimated volume of 76.8 million m^3. With the № 26 colliery, mine water rebound started in 1985, when the first pump in 1B shaft was shut down. In 1999, the last of these 10 mines, the Phalen Colliery, closed after a controlled flooding, which ended in 2002. Since then, the mine water level is kept below sea level and under the discharge point to the Atlantic Ocean by a sophisticated pumping scheme. Since 2009, the discharged mine water from the Neville Street pumping scheme is treated in a passive mine water treatment system which was expanded in 2016 to treat a larger volume of mine water. Aim of the pumping and treatment scheme is to protect Cadegan's Brook from deteriorating and the Atlantic Ocean from receiving elevated concentrations of potentially toxic metals and sulfate through the 1A outfall. If polluted mine water would enter the Atlantic Ocean, the local lobster fishing would be impaired and an important source of income for Cape Bretoners would cease.

At the time of the flooding accident, two mines were still in operation, and to ensure safe operation, pumping in the 1B shaft was restarted in 1992 to prevent the Phalen Colliery from flooding. Though the water quality was good at initial sampling ([Fe] 0.004 g L^{-1}, pH 7.2, EC 9.1 mS cm^{-1}), it soon deteriorated to unacceptable iron concentrations and electrical conductivities ([Fe] 2.1 g L^{-1}, pH 3.9, EC 48.4 mS cm^{-1}) staining the Atlantic Ocean orange to yellow for a length of several kilometers.

All the mine water that was and is pumped from the Neville Street pumping scheme is discharged into a small stream, Cadegan's Brook, and from there, after a 3 km long course, it drains into Indian Bay (Atlantic Ocean) near Bridgeport. In addition, the main infiltration into the 1B mine pool seems to be connected with this brook, flowing from South to North in the communities of Reserve Mines, Glace Bay, and Dominion. Before the passive mine water treatment system went into operation, all the pumped mine water reached the brook, and consequently the sea. Flow in the brook varies substantially (80–260 L s^{-1}), depending on the precipitation, and in winter it is frozen. Upstream the mine water discharge location, the brook flows through a wetland area which formed above bootleg workings and sinkholes at MacKay's Corner. These bootleg workings are located above the № 5 colliery workings and surface water infiltrates into these mine workings to a degree not known precisely. Infiltration into the abandoned mine workings also appears downstream the mine water treatment plant's discharge, which accounts to approximately 3% of the total flow of Cadegan's Brook.

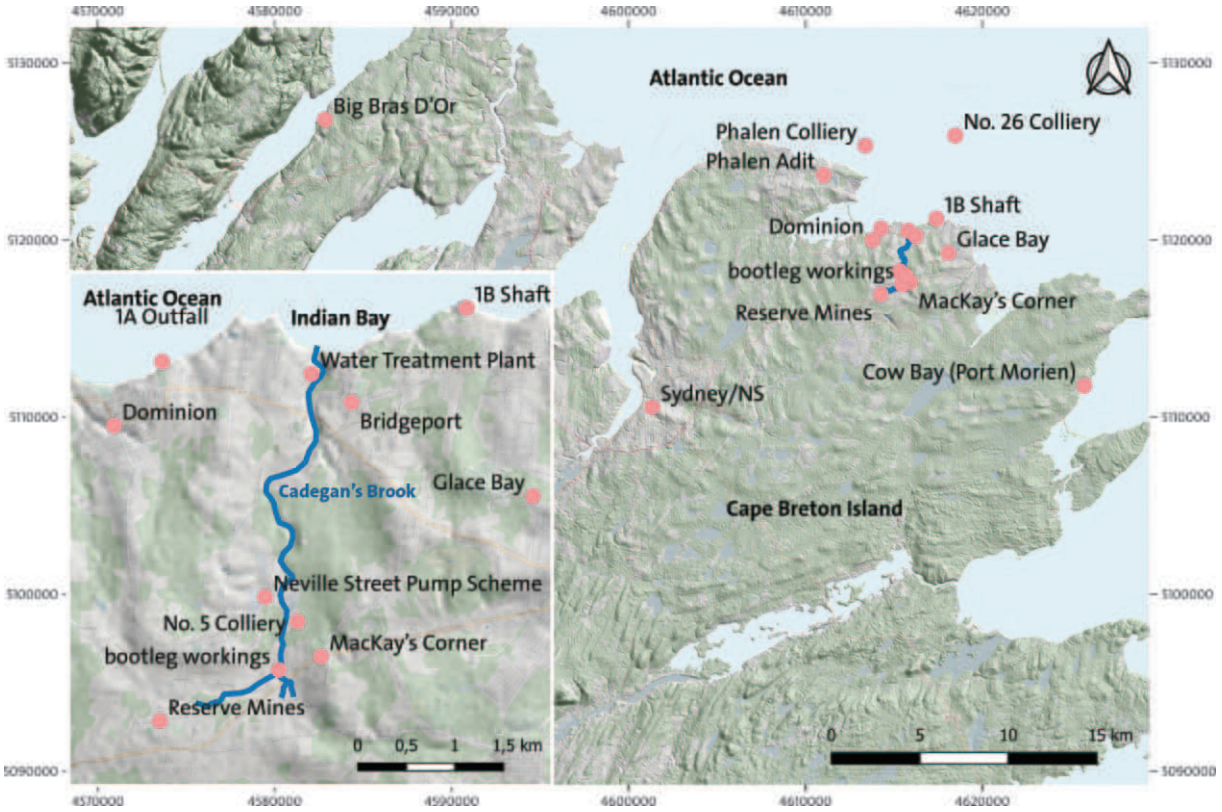

Fig. 1 Details of the Sydney/NS coal mining region. Sources: Open Street Maps community, Nova Scotia (NS) Department of Natural Resources.

In 2003, before the passive water treatment system went into operation, total dissolved solids upstream the discharge locations ranged between 72 and 364 mg L^{-1}, and downstream between 160 and 1400 mg L^{-1} (controlled by the sulfate concentration), while upstream iron concentrations were 0.1–2.5 mg L^{-1}, and downstream concentrations up to 1.7 mg L^{-1}. After the treatment system went into operation, upstream electrical conductivity was about 385 µS cm^{-1} and downstream about 1124 µS cm^{-1} but improved along the course of the brook to 100–200 µS cm^{-1} (2009 and 2011 data). Iron concentrations downstream of the discharge location were in the range of 0.4–0.8 mg L^{-1}. This shows that the brook's chemical water quality improved after the mine water treatment system became operational.

Before the passive treatment system came into operation in 2009, Cadegan's Brook was heavily stained with iron precipitates up to its mouth at Indian Bay. Even after the water quality improved, these precipitates still existed and made the stream bed muddy nearly everywhere. In 2013, four years after the passive mine water treatment system's construction, a benthic macroinvertebrates study was conducted. This study showed that the brook's water quality improved (Fig. 2) and reached acceptable water quality standards, indicating that the mine water remediation scheme was successful.

Río Tinto, Spain

This case study about the Río Tinto River exemplifies how thousands of years of mining results in a unique ecosystem with highly acid water. It also shows that some mining influenced inland waters became so highly polluted that they will very likely never be remediated.

The following discussion for the Spanish and Portuguese Río Tinto River is based on publications by Ariza (1998), Chacon-Baca et al. (2021), Grande et al. (2014), Leblanc et al. (2000), Nieto et al. (2007), Olías et al. (2020), Olías and Nieto (2015), Olías et al. (2004), Ruiz Cánovas et al. (2019), Sainz and Loredo (2005), Salkield (1987), and Torre et al. (2014).

Without question, the 4000 km^2 river basins of the Spanish Río Tinto and Río Odiel in the Iberian Pyrite Belt are the blueprints for mining affected streams *per se* (Fig. 3), but the microbiological inventory of the rivers indicate that already the earliest mines might have found a stream colored in red. Mining in the area dates back 4500 years to the Copper Age and left around 100 km of the Río Tinto polluted with acid mine drainage. In summary, the mass of the pyrite ore in the Iberian Pyrite Belt is estimated to be more than 10 Gt. Most of the ore deposits were mined for zinc, copper, lead, gold, silver and for sulfuric acid production. As the ores were mined in near surface ore bodies, vast quantities of pyritic mining residues exist in the area. This resulted in acid mine drainage with average pH values between 2.2 and 2.5, which directly discharges into the receiving water courses of the Tinto and Odiel rivers. First

Fig. 2 Optically clean Cadegan's Brook water downstream the Dominion water treatment plant. Algae growing on the rocks are indicative of elevated nutrients' concentrations. No visual indication of mining influenced water can be seen. Photograph: Christian Wolkersdorfer.

Fig. 3 Río Tinto at Zalamea la Real (Huelva, Andalucía, España). Source: LBM1948 (Luis Bartolomé Marcos), CC BY-SA 4.0, via Wikimedia Commons.

accounts on the river's pollution date to the year 1556, when priest Diego Delgado noticed that there are neither animals in the water nor do the locals use the water for consumption. Yet, he reports that the water will heal eye diseases when applied for external use. Because of the large amounts of highly acidic and metal enriched water, the rivers comprise dozens of kilometers of red to yellow colored water resulting mainly from the high iron concentration. Thus, the name Río Tinto: the red river. This is also the region where the initially British-German mining house Rio Tinto coined its name, as their mining activities started in the headwaters of the Río Tinto in 1873.

Metal and sulfate concentrations in the Río Tinto decrease along the course of the river and show seasonal fluctuations, which also occur in the Río Odiel. As in other mining affected streams, the metal concentrations and the electrical conductivity increase with decreasing pH values of the water. At the river's mouth, sulfate concentrations are still around 1 g L^{-1} and Fe concentrations around 14 mg L^{-1}, while upstream, sulfate concentrations are in the range of 111–1460 mg L^{-1} and Fe concentrations in the range of 4–316 mg L^{-1}. During rain events, the pollutant load increases, which is an indication of efflorescent salt deposits along the riverbanks and the mining residues being dissolved and flushed into the stream. Depending on the element, 30–98% of the load results from these periods of rain. Geochemical signatures indicate a common source area of the two rivers. Though the headwaters of the streams emanate within the pyrite rich host rocks, the rivers' current conditions are mainly the result of the historic mining activities. Natural acid rock drainage is a very minor contribution to the rivers' acidic conditions.

Though the rivers, as commonly assumed, look inhabited, they host an abundance of extremophile organisms, including algae, fungi, and bacteria. At least 1300 species have been identified and give evidence that the earliest Bronze Age miners might already have found a stream colored in red because of pyrite oxidation by *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans*.

Unfortunately, all efforts to fully remediate the Río Tinto and Odiel areas—though it would be technically feasible and is studied for the Río Odiel—will be without success, as the mass of pyrite is so large that measures to mitigate the abandoned mines or the river will be only short lived. However, for reopening a mine in the Odiel watershed, the regional government, in view of past environmental liabilities, required the mining company to progressively reduce discharge loads to the Río Odiel. A reduction of 30% must be achieved before the third year after exploitation starts, 50% before the sixth year and 100% before the tenth year. Treatment facilities in these two watersheds, be they active or passive, might possibly work *ad infinitum* and will only result in local improvements. When the Spanish government announced that the mouth of the Tinto and Odiel rivers shall be rehabilitated, a group of biologists remarked that the microbial community in the rivers is unique and needs to be protected. This resulted in the whole Río Tinto being announced a protected area by the Andalucían government. A mixture of mining heritage, geo heritage and natural conservation in combination with selected rehabilitation areas might be assumed the best solution for these mining influenced streams.

Lusatia, Germany

After the German Reunification in 1990, it became obvious that the abandoned lignite mines in Lusatia could not be remediated with standard technologies. In a combined effort of the state, universities and consulting companies, process intensification resulted in new technologies to start the remediation of the area. In addition, the post-mining landscape will be converted to a tourist region in future.

The subsequent discussion about open pit lignite mining in Lusatia, Germany, are based on the following publications by Benthaus et al. (2020), Geller et al. (2013), Janneck et al. (2018), Kaden (1997), Luckner and Totsche (2017), Märten (2006), Merkel et al. (2005), Strzodka et al. (2013), Weber et al. (2019), and Wolkersdorfer (2021).

Lignite mined in Lusatia (Lausitz), southeast of Berlin, was the principal energy source of the former German Democratic Republic, with 200 Mt. mined in 1990 and a maximum of 1.2 km^3 of mine water pumped in 1985. A centralized, socialist planning regime prioritized lignite and energy production over environmental protection and left an area of 200,000 km^2 affected by mining, with a groundwater table lowered by up to 100 m and a cone of depression up to 13 km^3. After reunification, priorities changed in the 1990s, and the partly uneconomic opencast lignite mines slowly ceased, leaving only economically feasible mining in operation. Mine closure and a subsequent increase of the groundwater level filled the open pits. Today, remediation in the Lusatia area can be considered one of the world's largest lignite mining remediation projects with nearly 100 pit lakes being managed.

Most of the lignite is found under 20–80 m Quaternary sandy to clayey overburden which had to be dumped, mainly inside the open voids of the pits. As the coal and overburden contains pyrite, the ground and mine water quality substantially deteriorated with lower pH values around 2.5, sulfate concentrations up to 3 g L^{-1}, Fe up to 360 mg L^{-1} and Al up to 40 mg L^{-1}. While the groundwater level rose, the open pit mines (which can be considered windows to the groundwater) flooded, and some water courses suffered from ferrous, acid mine drainage. This, together with elevated sulfate concentrations, affected predominantly the river Spree, which feeds the Unesco Biosphere Reserve Spreewald (designation date 1991) and flows through the German capital Berlin, where it is, among others, used as infiltration water for drinking water production.

To remediate the negative effects of the acidic and mineralized mine water in the open pit lakes, numerous techniques were tested, but standard technologies were not able to tackle the problem reliably. Even using sludges from mine water treatment plants was tested for by-product recovery. Most of the preliminary treatment methods failed because of the very specific conditions in Lusatia. Obstacles for passive technologies incur high costs for the large areas needed, a reduced process control compared with active methods, and the vast volumes of mine water in Lusatia that would have to be treated passively. Nonetheless, less than a dozen passive systems were tested in the Lusatia area. Microcosms ($\approx$20 m^3) and macrocosms ($\approx$4500 m^3) in the lakes were successful only in or near the enclosures itself but could not cope with the whole lake volumes. Active treatment of all the mining influenced water was also not feasible because of the large water volumes. In addition, the mine water does not occur as point sources, but as diffuse flow through the overburden and waste materials to the lakes, streams and groundwater.

Finally, a twofold approach was initiated: (1) developing a lake landscape (Lausitzer Seenland: Lusatian Lake Land) such that it can be managed for touristic and environmental purposes; and (2) improving standard technologies that were not successfully mitigating the negative effects of the acid mine drainage, by optimizing a technology that was adapted from experiences in acid rain mitigation in Scandinavia in the 1970s: in-lake-neutralization. After initial issues with the lime, caustic soda, and limestone distribution in the lakes and finding the appropriate application technology, the remediation company developed a land and vessel-based application of neutralizing agents. During the early phases, it became obvious that in all cases of in-lake-neutralization, monitoring is important. Successful application and calculation of lime or limestone masses is only possible with a full understanding of the geochemical mechanisms in the water columns of the lakes.

So far, in 13 Lusatian lakes, with 4–6 to follow, in-lake-neutralization has been successful (Fig. 4). In all cases, the lakes' acidity substantially decreased while the alkalinity rose. pH values increased to around 7 and Al concentrations decreased to below the detection limit, as in the case of Lake Partwitz. Yet, in-lake-neutralization is not a clear or short-term solution, as it requires regular repetition as long as the pyrite oxidation in the overburden and waste rock persists and the acidic groundwater flows through the lakes.

Western Basin, South Africa

In the Western Basin of the South African Witwatersrand, active mine water treatment and a natural wetland are improving the mine water quality. It is also an example of lengthy discussions by various interest groups with highly variable scientific backgrounds.

The subsequent discussion about mining influenced water in the Western Basin of South Africa's Witwatersrand gold fields are based on publications by Coetzee et al. (2003), Digby Wells and Associates (Pty) Ltd. Co (2012), Frimmel (2019), Hobbs and Cobbing (2007), Liefferink and van Eeden (2010), Robb and Robb (1998), Shapi et al. (2020), Turton (2013), Wolkersdorfer and von Hünefeld-Mugova (2018), and Yibas (2020).

South Africa hosts the largest gold deposit in the world: the Witwatersrand basin, comprising nine gold fields of economic importance and covering an area of 400 km^2. Mining started in 1884 and is still ongoing. Though the production is in a decline since its peak in the 1960s, it is still the location where most gold was mined worldwide. In 2020 this was 53 kt, accounting for 30% of the world's gold production to date. In addition, the gold "reefs" are enriched in uranium, which was produced concurrently to gold in some of the mines, amounting to 75 kt. As most mines did not focus on uranium extraction, a large accumulation of uranium in the remaining and abandoned tailings dams along the current and former gold extraction locations remains. Currently, 270 mining residues such as tailings dams and waste rock piles are known, which—to a smaller or larger degree—contribute to the contamination of surface waters within the whole Witwatersrand basin. Due to the lack of buffering minerals in the tailings material, tailings release substantial amounts of acid, sulfate, (semi-)metals and suspended solids. Since mining in the three largest basins has largely ceased, groundwater is filling the open voids and gradually floods the abandoned mine workings. In June 2002, the first of these basins was fully flooded, and the Western mine pool started to overflow through borehole BH1 and the Black Reef Incline shaft into the receiving water course, the 10 km long Tweelopiespruit rivulet in the Mogale (Krugersdorp) Municipality, which originates at Robinson Lake west of Johannesburg. Though this discharge did not happen unexpectedly, as several experts where aware that this would happen since around 1996, authorities and decision makers reacted with astonishment, and a series of reports, political discussions, scientific papers and decisions began to tackle the negative environmental effects of this acid mine drainage discharge. This discharge of the West Wits Mine was especially problematic in two ways: (i) the Tweelopiespruit flows through the Krugersdorp Game reserve, leading to the Bloubankspruit; and (ii) then flows though the Unesco World heritage area "Fossil Hominid Sites of South Africa" (*vulgo* "Cradle of Humankind"). As the caves are within the dolomites of the Malmani Subgroup, there was concern that the acid mine drainage might dissolve the dolomite and therefore negatively affect the cave's integrity.

Initial monitoring of the 6–9 $m^3\ min^{-1}$ mine water discharge showed the water quality to be extremely poor, as would have been expected shortly after the initial stage of the first flush. Electrical conductivity was around 3.6 mS cm^{-1}, pH 3.4, sulfate 2.5 g L^{-1} and Fe as well as uranium concentrations reached 235 and 0.9 mg L^{-1}, respectively. Unaffected springs in this area would have electrical conductivities around 1 mS cm^{-1}, a pH of 6, sulfate 0.5 g L^{-1} and Fe of 0.1 mg L^{-1}.

On contact with the atmosphere, the mine water quickly oxidizes and hydrolyzes, resulting in a pH decrease downstream of the discharge locations. These processes stained the Tweelopiespruit with thick deposits of ochre and barite, substantially affecting aquatic life and the stream's appearance downstream of the discharge locations. As an operational mine (at that time Harmony

Gold) with a working water treatment facility was close to the discharge points, collection ponds and a pumping scheme to the mine water treatment plant were constructed. There, the acid mine drainage was treated in a neutralization process, which in a modified form is still ongoing today.

Based on numerous expert reports and pressure from the public, NGOS and politicians (sometimes with risk of supporting particular interests), it was decided to keep the water level at an "environmentally critical level" (ECL) of 167 m below surface. This is accomplished by means of a pumping scheme in the № 8 and 9 shafts and upgrading the existing mine water treatment plant to handle a volume stream of 18–22 $m^3\ min^{-1}$. Currently, this scheme, financed by the South African government's tax revenues, is maintained by Sibanye Gold.

Mine water treatment in this plant is a standard neutralization method with aeration, settling, liming and coagulation. From the mine water treatment plant, the mine water is pumped into a large, unlined sludge settling pond, and from there, by gravitational flow, discharged into the Tweelopiespruit. Further, it flows through 1.7 km of natural wetlands before it enters the Krugersdorp Game Reserve (Fig. 5). Though the mine water, after treatment, is still highly mineralized, with electrical conductivities between 3.0 and 3.6 mS cm^{-1}, the pH values in the stream substantially increased to circumneutral conditions. However, maintaining the treatment has been challenged by vandalism to the electricity system, and low maintenance of the plant. Most of the red stain in the Tweelopiespruit has meanwhile been flushed or is covered with gypsum precipitates that build up as long as the treated mine water is oversaturated in regards to gypsum. Additionally, the soils along the Tweelopiespruit still contain elevated concentrations of potentially harmful elements originating from pre- and post-flooding times. Flow in the Tweelopiespruit is highly variable between 3 and 50 $m^3\ min^{-1}$, being a function of pumped mine water and rain events. As the pumping rate in the № 8/9 shafts is not at a constant rate, the mine water table is substantially fluctuating. This causes a large beach in the mine water pool, which constantly causes pyrite oxidation and represents the main source of contaminants for the mine water. In addition, the mine water body is stratified, with a better water quality on top of mine water with a worse quality. Pumping at excessive rates, therefore, decreases the water quality as bad quality water reaches the pumps.

In consequence, though the water quality in the Tweelopiespruit has improved since 2002, water treatment must continue for a long time until the first flush phase is over, and the water table can be kept at a more constant level. Eventually, keeping the mine water level at the ECL in № 8/9 shafts can cease as there might be no immediate danger to the dolomite caves, and mine water with a better quality can be treated and discharged into the Tweelopiespruit. This will result in near natural pH values and a low mineralization, resulting in a recovery of the natural ecosystem.

Kizel Coal Basin, Russia

Russia's Kizel Coal Basin is an example of environmental pollution resulting from a policy that considered economics being more important than environmental protection. It is also an example of some individuals trying to improve the situation, and of a policy change that now tries to remediate the environmental impacts of the past.

For the following discussion about the Russian Kizel Coal Basin in the Ural Mountains, the following English and Russian publications have been used: Berezina et al. (2018), Blinov and Krasilnikova (2019), Imaykin (2014), Khayrulina et al. (2016), Maksimovich et al. (2019), Maksimovich and Pyankov (2018), Maximovich (2008), Maximovich et al. (1995), and Pyankov et al. (2021).

One of the largest areas in the Ural Mountains polluted by acid mine drainage is the Kizel Coal Basin. This coal basin is part of three river basins: the Yayva (with the North Vil'va and the Bol'shoi Kizel tributary), the Kos'va, and the Chusovaya (with the Us'va and the South Vil'va tributaries) basins. All these rivers are tributaries of the Kama river basin, and the area has an average annual rainfall of 800–900 mm. Various coal mines were worked from 1796 until mining terminated in the early 2000s and covered an area of 2000 km^2 with a north–south extension of 100 km and a width of 15–20 km. After mining ceased, the groundwater table in the more than 1000 m deep underground mines rose gradually until the mine water discharged to the surface and into the receiving water courses. These discharge locations have pH values between 2.3 and 4.5 with an average discharge of 15–25 million m^3 and a maximum of 75 million m^3 annually. More than 100 waste rock piles and tailings ponds (50 million m^3 of material) contribute to the pollution with a drainage mine water volume of 32 $m^3\ h^{-1}$. Approximately 90% of this water draining the waste rock and the abandoned mines discharges into the receiving water courses, and in some cases the mineralization is up to 35 g L^{-1}. Currently, there are still 19 mine water discharges and more than 100 waste rock and tailings piles contributing to the pollution load.

Geologically, the Kizel Coal Basin is highly karstified, which resulted in large ingress volumes during the active mining period. It is assumed that annually $\approx$100 million m^3 of acid mine water was discharged into the local streams without any treatment, causing substantial damage to the ecosystems.

Source for the acid mine drainage is the pyrite in the coal seams which reached up to 9%. Its oxidation resulted in highly acidic mine waters with low pH values, and of the 26 ions and elements found with elevated concentrations, 12 show 10–1000 times higher concentrations than the local background. On average, the Bol'shoi River receives annual sulfate loads of 15,300 t, an Fe load of 6000 t, Al of 400 t and Mn 57 t. These mine waters change the type of the natural rivers from HCO_3-Ca to SO_4-HCO_3-Ca when the mineralization is 700–760 mg L^{-1} and SO_4-Fe-Al-Na-Ca in cases where the mineralization goes up to 3–35 g L^{-1}. Many of the receiving water courses are covered by thick layers of precipitates (ochre) and, therefore, cause substantial smothering of stream beds and local biota (Fig. 6). In many locations, acid-tolerant green algae give indication of the low pH values and the high metal and acidity concentrations. In some of these locations, the soil's pH is around 3 and prevents most plants from growing.

Fig. 5 Abandoned flow gaging station at the end of the natural wetland area of the Tweelopiespruit. Corrosion from the initial acid mine drainage and gypsum precipitates from the treated mine water can be seen at the flow gages' outflow. Photograph: Christian Wolkersdorfer.

Fig. 6 Thick ochre precipitates from acid mine water discharging from an abandoned mine in the Kizel Coal Basin. Photograph: Christian Wolkersdorfer.

After the breakdown of the USSR and the closure of many of the mines, it was found relevant to remediate these heavily polluted areas. Using SPOT-6 and LANDSAT-8 satellite data as well as sampling around 200 sites, provided identification of biologically inactive stream sections. Geochemical and GIS (geographical information system) modeling identified the priority locations for environmental protection activities, which will help to decrease the negative effects of the acid mine drainage by about 40%. It is anticipated that the mine water will be treated by means of active and passive mine water treatment systems. First on-site tests showed that some of the acidic soils can be reclaimed with limestone, selected plants, and grass mixtures. By doing so, acidic soils as

well as acid mine water discharges could be successfully remediated. Other remediation methods planned are geochemical barriers (better known as reactive walls), which modify the groundwater's composition before it reaches the rivers. Yet, it will take decades until the severe pollution and damage to the rivers in the Kizel Coal Basin will be remediated and a close to natural condition will be restored.

Mariana and Brumadinho Dams, Brazil

Both the Mariana and Brumadinho tailings dam failures exemplify the importance of reliable measures to contain ore processing residues. They show how ignoring geotechnical principles and state of the art technologies can result in accidents with severe ecological and social negative effects on the surrounding areas and downstream water courses.

Introduction

Brazil holds more than 800 mine tailings dams, of which about 400 are classified into some category of accident risk (Agência Nacional de Mineração (ANM), 2021). Most of these tailings dams are located in Minas Gerais State, which is a metal-rich region and has a long history of land use focused on extensive mining activities (Jacobi et al., 2011; Hatje et al., 2017). This State also holds the largest number of mine tailings dams in Brazil rated as high accident risk (Agência Nacional de Mineração (ANM), 2021), posing a severe potential threat of both social and environmental disaster (Nazareno and Vitule, 2016; Kamino et al., 2020; Azevedo-Santos et al., 2021).

Fundão Dam, Mariana

In November 2015, the Fundão tailings dam broke in the Bento Rodrigues District, Mariana City, Minas Gerais State. About 43 million m^3 of iron mine wastes were released into the Doce River basin. This spill is considered one of the world's largest mining environmental disasters. Individual mud waves reached a height of 10 m, and the tailings deposit layers were between 50 cm and 3 m thick. During the spill, the Bento Rodrigues District was partly buried by the mudflow, and its entire population of approximately 600 people displaced. The mudflow traveled 668 km along the Doce River, before reaching the Atlantic Ocean approximately 15 days after the dam ruptured (Escobar, 2015; Carmo et al., 2017; Fig. 7). This toxic mudflow polluted drinking water and decimated the aquatic fauna of the Doce River, also affecting the soil and flora of floodplain areas (Lambertz and Dergam, 2015; Garcia et al., 2017).

The most striking short-term negative effects caused by the tailings were siltation of entire rivers, changes to channels and river dynamics (i.e., the interactions among flow, sediment transport, and morphology), spread of chemical compounds, and the destruction of terrestrial and aquatic ecosystems (Fernandes et al., 2016; Garcia et al., 2017). This disaster resulted in water contamination and caused the death of entire fish, amphibians, mammals, turtles, birds, and invertebrates populations (Lopes, 2016; Carmo et al., 2017). Long-term effects include increased metal concentrations in the sediment, toxic effects at different trophic levels, metal accumulation in fish muscle tissue along with cytotoxic, genotoxic and mutagenic effects, and in water and sediment (Vergilio et al., 2021). In addition, the tailings led to vegetation loss and damaged several protected areas (Lopes, 2016; Carmo et al., 2017). This severe accident killed 19 people, affected several down-stream municipalities and hundreds of thousands of people (including Krenak and Guarani indigenous tribes), caused the loss of natural and cultural heritage, increased the exposure to toxic elements (mainly arsenic, mercury and lead) and impaired the local economy (Fernandes et al., 2016; Carmo et al., 2017; Valle, 2020; Koppe, 2021).

Fig. 7 The toxic mudflow in the mouth of the Doce River reaching the Atlantic Ocean in Regência, Espírito Santo State. Photograph: Hauley Valim.

This mining disaster is still causing negative ecological and socio-economic effects because adequate tailings removal was either inefficient or not carried out at all. One year after the dam rupture, about 0.17 million m^3 of tailings were cleaned from affected areas, and after 3 years, about 48% were removed (Carmo et al., 2017; Cionek et al., 2019). Yet, the long-term effects of the spillage must be accounted for, and the environmental recovery of areas affected by tailings will take a long time.

This tailings dam failure could have been avoided if proper maintenance of the dam and surrounding areas had been performed. Mine residue dams require constant maintenance, aiming to reduce the likelihood of leaks or dam failures, and minimizing ecological and social damage (Sergeant and Olden, 2020). In addition, multidisciplinary efforts and investments should be periodically dedicated to rigorous inspection, monitoring, and environmental licensing (Cionek et al., 2019). A potential solution to the waste in mine dams could be dry stacking, which causes less environmental impacts compared with current tailings storage (Gomes et al., 2016). Another important strategy in tropical environments should be the construction of tailings ponds and infrastructure resisting large influxes of water (i.e., tropical storms rainfall; Edwards and Laurance, 2015).

Córrego do Feijão Dam, Brumadinho

In January 2019, the B1 Dam at the Córrego do Feijão Mine ruptured in Brumadinho City, Minas Gerais State. This disaster spilled 12 million m^3 of iron mining waste, with 10 m high mud waves, spreading for 10 km and reaching the Paraopeba River, a major tributary of the São Francisco River (Fig. 8).

Shortly after the dam ruptured, the mudflow hit the mining company buildings, as well as hotels and farms in the region, killing more than 270 people (Olden et al., 2019). Severe negative short-term effects on water quality and sediments of the Paraopeba River resulted from this toxic mudflow, including an increase in water turbidity, high metal and nutrient concentrations, increase in iron tolerant bacteria, toxic effects at different trophic levels, and metal accumulation in fish muscle tissue, requiring future studies to monitor the long-term consequences in this river (Thompson et al., 2020; Vergilio et al., 2020). This disaster jeopardized the water supply of cities in the surrounding area and affected fish and bird species (Pereira et al., 2019; Salvador et al., 2020). The spill of the tailings caused a major change in land cover, severe loss of Atlantic Forest vegetation, and impaired agricultural areas (Pereira et al., 2019; Rotta et al., 2020).

Post-disaster actions following the Brumadinho dam rupture were conflicting. A study reported that the mudflow reached the Retiro Baixo Hydroelectric Dam (302 km downstream from the collapsed dam, in the Paraopeba River), while another study reported that the mudflow reached the Três Marias Dam's reservoir (around 330 km from Brumadinho, in São Francisco River; Salvador et al., 2020). In addition, a controversial action was proposed by the Brazilian National Water Agency (Agência Nacional de Águas e Saneamento Básico, ANA), which planned to use the Retiro Baixo Hydroelectric Dam to prevent the spread of mine tailings; however this strategy has been considered ineffective in restricting the environmental and social damage along the tailings' travel path (Hatje et al., 2017; Cionek et al., 2019).

Upstream tailings dams like that in the Córrego do Feijão Mine are cheaper, occupy smaller areas, and require less material for construction than other tailings dams, since new tailings are accumulated on top of previous deposits (Kossoff et al., 2014; Rotta et al., 2020). However, this tailings dam model is considered highly risky, mainly due to the potential of static liquefaction, a process in which solid materials behave like liquids, which can trigger the dam's collapse (Kossoff et al., 2014). Brazil's National

Fig. 8 Mudflow from the collapse of the B1 Dam at Córrego do Feijão Mine, Brumadinho City region, Minas Gerais State, a tailings dam failure that caused severe social and environmental impacts. Photograph: Isis Medeiros.

Mining Agency (Agência Nacional de Mineração, ANM) planned to ban upstream tailings dams after the Córrego do Feijão Dam collapse in Brumadinho (Spring, 2019). The collapse of the Brumadinho Dam was a major global warning of the risks posed by unsafe, rudimentary, and antiquated mining dams (Koppe, 2021). Every mine is unique in terms of its geography, physical setting, or environmental context. Nevertheless, only with science-based safety guidelines and stricter enforcement, can the chances of repeating a disaster like this be minimized (Olden et al., 2019).

Technological improvements, and the future of mine tailings dams

Emerging technologies, while expensive, have some promising alternative solutions, that include approaches such as paste and thickened tailings, tailings reuse, recycling and reprocessing in combination with proactive management in a way to combine the separation of sulfide by flotation and the use of cemented paste backfill as soil support. For instance, novel mine tailings are usually stored above ground or in impermeable plastic casings below the surface, which make them less likely to seep into the ground and contaminate groundwater and adjacent watercourses (Edraki et al., 2014). Alternatively, wetland integrated systems are easy, affordable to build and relatively low maintenance alternatives since they are efficient in regions that do not have too cold winter months.

After these two mine tailing dam disasters, the Brazilian Government has decided to decommission all mines with upstream characteristics similar to the Fundão and Córrego do Feijão Dams. This decommissioning would involve removal of the wastes deposited in the tailings dams, construction of new dams or transportation to preexisting dams to accommodate them, and finally their inactivation. Nevertheless, this change represents a challenge in terms of time, investments and efforts required to do so. Undoubtedly, the environmental impacts and human toll were high for Minas Gerais State, for companies and the regions involved as a whole.

Conclusions

Mining activities and residues such as tailings or mine water can cause substantial negative effects to inland waters. One of the most noticeable and destructive, but fortunately rare accidents, are tailings dam failures which often impair socio-economic balances, along with regional pollution that damages both aquatic and terrestrial ecosystems. Less obvious is the pollution caused by mining influenced water, although iron rich mine water often visually impairs water courses. Solutions to these effects on inland waters and the ecosystem would be mining bans in sensitive regions or more stringent control measures.

All case studies show negative effects on the surrounding environment, sometimes hundreds of kilometers from the mine site. Though some of them can be corrected, some of them will last for a very long or indefinite time. It can be concluded that reliable and sustainable treatment options, state of the art mine residue storage or encapsulation and stringent monitoring, as well as legislative measures and enforcement are necessary for environmentally safe operations.

Knowledge gaps

One of the main knowledge gaps in the mining context is how to prevent environmental pollution or loss of life under all circumstances. Yet, as long as humans are involved in the processes, mistakes, misinterpretation or negligent behavior cannot be fully avoided. Though substantial research has been done after the Aznalcóllar and Baia Mare tailings dam failures (e.g., Hernandez et al., 1999; Macklin et al., 2003), how nature recovers from these types of events still remains unclear and requires further research. It is also not well-known which methods can be most effective to assist the recovery of the freshwater and terrestrial ecosystems that are affected.

More research is needed in sustainable mine water remediation techniques. This is especially relevant when considering the economic cost/benefit of recovery of valuable material from the mine water including the circular economy aspects of mining and the interplay with mine water issues. Treatment options that selectively recover metals or semi-metals would be able to partly assist in the remuneration of the costs incurred. Moreover, digital twins of active and passive mine water treatment systems are not available so far. Finally, artificial intelligence or machine learning is required to optimize mine water management and help in adjusting to future scenarios. Detailed studies into the micro- or small-scale effects of mining influenced water or tailings dam failures on the local or regional economy as well as the social structure are only rarely conducted.

Physical Impacts of Sand Mining in Rivers and Floodplains

C Juez[a] **and MJ Franca**[b], [a]Department of Geoenvironmental Processes, Instituto Pirenaico de Ecología, Consejo Superior de Investigaciones Científicas (IPE-CSIC), Zaragoza, Spain; [b]Karlsruhe Institute of Technology, Karlsruhe, Germany

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Alluvial deposit Material deposited by rivers. It consists of silt, sand and gravel, as well as much organic matter.
Bar skimming Mining method which consists in removing all the material in a sand bar above a reference line.
Braided river River which consists of a network of river channels separated by small, often temporary, islands called braid bars.
Delta Landform created by deposition of sediment that is conveyed by a river as the flow leaves its mouth and enters an ocean, sea, lake or reservoir.
Floodplain Area adjacent to a river, formed mainly of river sediments and subject to flooding.
Mining pit Excavation or cut made at the surface of the ground for the purpose of extracting mineral (e.g., sand).
Mud blanketing River process by which high concentrations of silt and clay may end up covering river landforms.
Nick point Part of a river or channel where there is a sharp change in channel slope.
Pool Deep areas of a river where water runs slow.
Riffle Shallow area of a river where water runs fast and is agitated by rocks, gravel or coarse substrate.
Sand Fragments of rock and soil with a specific grain size in between 1/16 mm and 2 mm. It is thus finer than gravel and coarser than silt.
Sediment regime Term used to refer to the sediment budget (amount, type and timing of sediment inputs, transport, storage and outputs) of the river system as well as the way water and sediment interact to drive river conditions.
Sediment transport capacity Term used to define the maximum load of sediment that a given flow rate can carry. It is referred to as net erosion or deposition, respectively, when the actual sediment load is below or above the transport capacity.
Sediment General term used to refer to mineral particles, which have been created by the weathering of rocks and soils and transported by natural processes, such as water and wind. Sediments include, in order of decreasing size, boulders, gravel, sand and silt. *Particulate matter* is sometimes used as a synonym of *sediment*. However, this is often not considered in the topic of sand mining.

Introduction

Sand is used massively in construction, as well as for other applications such as glass production and electronics manufacturing. As a result, sand mining has become an expanding business due to the rapid population growth. Globally, humans consume up to 25 billion metric tons of sand every year, equivalent to 9 kg per person per day (Koehnken and Rintoul, 2018).

Sand is primarily removed from alluvial deposits (see Fig. 1). This extraction is carried out either from instream mining or from excavation pits in river floodplains. Instream sand mining consists of extracting sand directly from river bed. Removal of bed sediment is normally carried out by two common methods: pit excavation and bar skimming (see Section "River channel" for further details). Excavation pits in river floodplains are in turn defined as dry or wet pits, depending on whether the depth of the excavation crosses the groundwater table (wet pit) or not (dry pit).

Fig. 1 Sand mining activities at Borkena River, Ethiopia (left, center) and a truck of sand extracted from wetlands of Lake Victoria (Uganda) for construction in Kampala. Credit to K. Irvine.

Sediment deposited in alluvial deposits is composed of gravel (diameter from 2 mm to 256 mm), sand (diameter from 1/16 mm to 2 mm) and silt (diameter less than 1/16 mm). Alluvial sediment is particularly desirable in construction because weak materials are eliminated by abrasion and resulting particles are durable, clean of impurities (washed by fresh water) and with irregular shapes that bind well with cement. Gravel is also mined since it is a key mineral used in the construction industry, but not to the same degree as sand. Uses of sand go beyond construction and span multiple manufacturing processes.

Despite the well-known impacts of sand mining on river morphology and sediment transport, this significant environmental problem is mostly ignored by policy makers and, to a large extent, unknown by the general public (Koehnken and Rintoul, 2018). In the following section, we outline the main impacts derived from sand mining.

Role and importance of sediment in fluvial systems

The sediment particles (gravel, sand and silt) are important for ecology, safety, economic and societal functions of rivers. They are drivers of landscape change and ensure a coherent continuum of mineral, chemical and biological components along river valleys. This continuum constitutes the sediment regime or budget in terms of amount, type and timing of sediment inputs, transport, storage and outputs, as well as the way water and sediment interact to determine river conditions (Wohl et al., 2015). Any disturbance of sediment regime is of potential concern as it affects a broad range of river functions and management, primarily: (i) flood control: varying grain size distribution of the river bed results in a change in roughness, which can have notable impacts on measured and estimated water levels; (ii) lotic system: changes in the fluvial sediment supply result in a change in river bed variability and composition which can have positive or negative impacts on the species populating river reaches; (iii) river restoration/rehabilitation activities: the understanding of the sediment transport dynamics of the restoration reach is a crucial factor for successful design of restorative measures; and (iv) hydropower production: changes related to the sediment regime have an impact on the management actions of reservoirs (e.g., reservoir siltation).

River channel

River forms and river processes are deeply affected by changes in sediment regime. Extensive instream mining cause a major disturbance of the sediment regime. As a result of the sediment removal, the natural sediment continuum of the river, along with channel morphology and instream bed forms are altered (Kondolf, 1997).

Instream removal from the channel bed disrupts the river reach sediment balance at the local scale, but the impact can also extend both up and downstream from the point of extraction. Removal of bed sediment is normally carried out by two common methods: pit excavation and bar skimming. The choice of which type of sediment removal that occurs is dependent on the nature of the river channel and the opportunity, or ease, of extraction. In both cases, an imbalance is created between sediment supply and transport capacity due to mining activity that is propagated downstream, upstream or in both directions.

Excavation pits generate local incisions with steep slopes (see Fig. 2). At the upstream edge of such pits, the slope accelerates flow, leading to an increase of shear stress and sediment transport capacity. This area is called the nick point. Each nick point evolves moving upstream due to river erosion to adjust to the base level (Knighton, 1984; Kondolf, 1998). Thus, with a steady flow, a series of nick points can be generated that migrate upstream from the initial bed incision. Excavation pits act as sediment traps for much of the incoming sand supply. Thereby downstream of these pits, there is insufficient sediment load, and the river sediment transport capacity can only be satisfied with the sediments eroded from the bed. River erosion and resulting bed degradation, therefore, occurs upstream and downstream of the pits.

Bar skimming (or scalping) mining consists of removing all the material in a sand bar above a reference line. This widens the river channel and consequently, slows the flow velocity causing upstream sediment supply to be deposited locally in the mining area. Downstream, the flow arrives with a sediment load deficit and compensates by eroding material from the river bed. Ultimately,

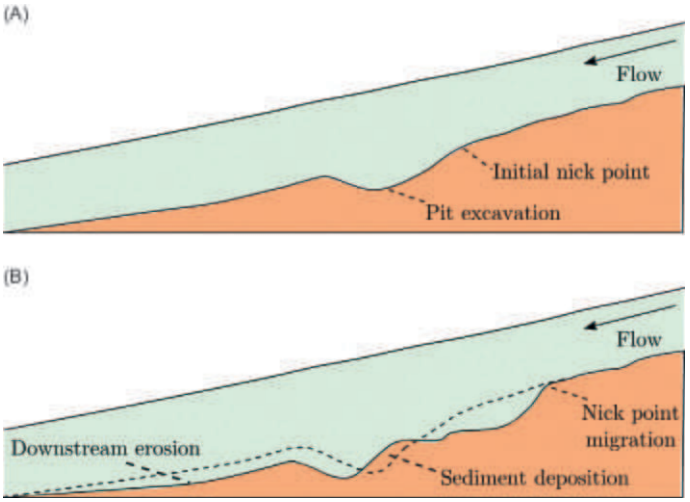

Fig. 2 River bed erosion due to pit excavation for sand mining. (A) Pit excavation causes the formation of a nick point. (B) The continuous shear and sediment transport capacity of the river flow forces the nick point to migrate upstream. The pit is partially filled with incoming sediments. A sediment supply deficit occurs in the downstream part and sediment transport capacity is satisfied with the material eroded from the river bed.

this leads to severe bed incision. In addition, bar skimming causes other problems such as lateral channel instability, bank erosion and bank retreat, abrupt modification of the floodplains, and higher mobility of loosened sediments (Kondolf, 1998).

In braided river systems, the combination of the two river processes derived from sand mining, bed incision and lateral widening, may lead to the formation of a unique deep channel. Former lateral active channels and gravel bars may quickly be colonized by thick vegetation, leading to the formation of stable islands in the former braided area and thereby, supporting the stability of the new river channel layout (Padmalal and Maya, 2014).

River sediment granulometry

Sand mining activities selectively remove medium to very fine sands, which are the ones used in the construction, glass and electronics industries. Over time, the river reach experiences changes in the granulometry characteristics of the sediment material. The river bed at the mining site suffers coarsening as a result of the selective removal of fine particles (Knighton, 1984; Kondolf, 1998; Padmalal and Maya, 2014). This reduces habitat complexity and riffle-pool structures, directly affecting ecosystem structure and function. This can alter ecosystem processes and the prevalence and distribution of vegetation, fish and benthic communities.

The granulometry of the river bars is also affected by sand mining since the natural sediment sorting is abruptly altered and only the larger (cobbles and pebbles) and the finer sediment particles (silt and clay) remain. High concentrations of silt and clay transported downstream may end up covering sand bars (*mud blanketing*), leading to the permanent stabilization of these river forms by fostering vegetative growth.

The process of size-selective mining facilitates the formation of sediment laden plumes of fine material, that travel and deposit downstream, potentially clogging the river bed (and thus, making it unsuitable as habitat for many organisms, see, e.g., Owens et al., 2005) or reducing the channel conveyance (and thus, increasing the risk of flooding, see, e.g., Kemp et al., 2011). Sediment plumes reduce the depth of light penetration in rivers, which in turn reduce algae and aquatic vegetation growth in slower flowing rivers, typically in the downstream reaches.

Floodplains

Excavation of instream pits near floodplains causes the alteration of the natural course of rivers. The continuous removal of sand, systematically enlarges the size of the pits, ultimately reaching the river bank causing collapse. As a result of this, river banks recede and the river channel is widened, modifying the local hydraulic and morphological conditions of the river reach (Juez et al., 2019). The receding of river banks and the widening of river channel causes the lowering of the water level, and eventually the lowering of the groundwater table. This has implications for local human communities who rely on these water resources. A lower groundwater table also has negative implications for the vegetation covering the floodplains, where meadows and trees may dry out, and thereby deprive biota of cover, shade, nursery areas or supply of food. This can have an important effect on the whole floodplain ecology, modulating the production for fish and other animals that use the floodplain as part of their production cycle.

Dry sand mining on floodplains can also impact the natural course of rivers. This mining method consists of excavating deep pits near river channels. The pits may be flooded during high river flows, causing them to be completely eroded, and thereby creating a

permanent alternative river channel. Sometimes, the flooded pit is partially eroded and remains disconnected from the main channel, creating a stagnant water body. Dry sand mining on floodplains may also have an impact on the groundwater table. Pits are pumped dry to guarantee access to the sand resource. Thereby, if the pit is deep enough to intercept the groundwater table, the steady pumping may alter aquifer dynamics (Padmalal and Maya, 2014).

Built infrastructure

As highlighted above, sand mining activities can cause channel degradation up or downstream from the mining activities, resulting in damage to infrastructure. This may include bridge piers being undermined, or buried pipelines, intake structures for dams or irrigation channels becoming exposed. In some parts of South East Asia, numerous irrigation structures and wells used for extracting water for human and animal consumption have been abandoned because of the lowering of the river bed and consequently, of the river water intake level (Padmalal and Maya, 2014). In addition, sand removal at sites close to the sea, facilitates the saline intrusion into freshwater channels, leading to problems of corrosion in the existing infrastructure, and changes to biotic communities.

Water quality

Continuous resuspension of sediments due to removal of instream sand have an impact on river water quality at the mining site and downstream. These sand mining activities lead to an increase of turbidity in the main channel, which can hinder fish visibility, thus impairing visual feeding behavior, and fish spawning by clogging the downstream river reaches, causing zoobenthos scouring (Sternecker et al., 2013; Blettler et al., 2015). Human populations living downstream of the mining site may have to address increasing water treatment costs due to the high concentration of suspended sediment.

Nutrients and other pollutants are often attached to the sediments. Due to the high concentration of sediment in suspension, and consequently, the high concentration of nutrient content, the ecosystem of river reaches located downstream mining sites may be altered by the proliferation of vegetation and other living organisms. For instance, sand excavation process may release large quantities of nutrients from the sediment and promote eutrophication, giving rise to increasing growth of benthic macrophytes and algae, and associated biofilms. When nutrient enrichment from sediment mining affects downstream lakes this can manifest as algal blooms (Zou et al., 2019). Furthermore, alterations in the incoming rate of nutrients attached to the sediments may cause the arrival of invasive species, as new conditions can be more suitable for exotic plants than for native plants (Zou et al., 2019).

Sediments can fix pollutants, reducing their bioavailability, i.e., they become contaminated sediments (SedNet, 2004). During sand mining activities, oil spills and oil leaks from excavation heavy machinery and transportation vehicles, can occur. As a result, these pollutants can be adsorbed by sediments and conveyed downstream by the river (this is especially relevant for hydrophobic pesticides, such as endosulfan, see, e.g., Weber et al., 2010). Contaminated sediments can be transported by the river flow, acting as a potential source of pollution to surface water and groundwater, and need to be handled with special techniques (SedNet, 2004).

Riparian environment

Extensive areas of farmland, timber reserves and natural habitats are lost from riparian-areas due to the excavation of pits for sand mining (Koehnken and Rintoul, 2018). Degraded habitats near rivers result in the drop of number and type of fish, loss of biodiversity and loss of leisure potential. The destruction of the soil profile, leads to heavy impact above of surface water levels, and below the river bed on the groundwater table, resulting in the reduction in biodiversity of both aquatic fauna and flora. The disappearance of natural vegetation and trees near the river banks can increase water temperature (lack of shadows, see, e.g., Ptak et al., 2019) as well as limit the woody debris-supply to the water body, important for instream habitats (Wyżga et al., 2009; Nagayama and Nakamura, 2010). Finally, sand mining requires heavy excavation machinery, transportation vehicles and the construction of routes to the site. These activities generate a lot of noise and other disturbance, expelling away local birds and terrestrial animals (Padmalal and Maya, 2014).

Deltas

Rivers convey sediments from the hill slopes to the low hills and further downstream to lakes, and ultimately to deltas, seas and oceans. From the vast quantity of river sediments supplied to the coast, only a fraction of this material settles in the estuarine environment. Most of the finer material, clay and silt, travels offshore where it eventually deposits. In contrast, most of the sand fraction remains in the coastal areas and is moved by currents and waves, thus delivering material to the deltas and beaches. Sand mining activities may reduce the volume of sediment conveyed by the river and supplied to the river delta and coastal zone (Jordan et al., 2019). Due to this deficit in the sediment supply, deltas can erode and degrade, reducing their capacity as highly productive agricultural areas. Furthermore, deltas and coastal areas play an important role as a natural defensive system against storms and extreme weather events. Degradation of delta areas can lead to an accelerated erosion of dune systems, thereby increasing the risk of devastating flooding events for local communities (Sumi and Hirose, 2009).

Management and mitigation strategies

Important environmental and socio-economic impacts are caused by sand mining activities. Therefore, it is important to protect rivers courses and water resources by following guidelines that regulate and control sand mining activities. To this end, several management and mitigation strategies can minimize the related impacts identified above. In the following we briefly outline these:

- Reinforce national Water Resources Policy to protect the river environment, control illegal sand mining activities and instigate sand auditing initiatives.
- Develop and implement public awareness programs about the potential environmental impacts from increasing demand for sand.
- Introduce a sustainable extraction of river sand policy. Field campaings should be carried out to monitor and assess site specific flow and sediment regimes. It could be possible to determine the volume of sediment that could be sustainably removed within the variability of the sediment load of the river and without jeopardizing the integrity of the river reach (Rempel and Church, 2009).
- To carry out pre-sand and post-sand mining baseline survey at both the local and river basin scale to audit the exact volume of sand removed from the river bed.
- To prohibit sand mining activities during periods of high biotic activity, such as fish migration or fish spawning period.
- To introduce a recycled concrete policy in construction. This strategy could serve to reduce the global demand of sand.
- To replace the sand with other materials for the construction industry. There are currently a number of initiatives which pursue to re-use organic (e.g., walnut shell) and non-organic wastes (e.g., rubber tyres, ashes or plastic waste) as aggregates in concrete production.

Knowledge gaps

Major knowledge gaps relating to impact from, and management of sand mining are:

- Research in rivers where in-stream sand mining is active is required to enhance understanding and quantification of impacts.
- Further exploration of new management and remediation strategies for rivers.
- Research into economic factors that can help local communities to carry out sustainable sand mining activities.
- Technical opportunities to replace the sand with other materials for the construction industry, better recycling for a more circular economy of construction materials, and their economic feasibility under consideration of internalized environmental impacts.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Aggradation Sediment deposition that raises the level of the stream channel or land surface.
Aggregates Granular materials for construction, mostly extracted from marine, river and lake water bodies.
Balanced sediment regime A balance between sediment supply and transport capacity that maintains specific physical processes and forms within the river corridor.
Sustainability The ability of ecosystems to remain diverse and productive; in a physical context, may refer to the ability of a system to continue functioning or providing natural resources.
Terrace (river) A former channel or floodplain surface now elevated above contemporary flood levels as a result of continued deposition on the floodplain or incision by the active channel.
Thalweg The line of lowest elevation within a river; the line of the fastest flow along a river channel.

Introduction

This chapter introduces sediment mining in rivers as a significant environmental issue and highlights pathways to sustainability through integrated river basin management. The chapter presents biophysical impacts of sand mining on rivers in terms of biophysical, ecologic and socio-economic impacts, discusses current management approaches, and highlights the critical aspects that need to be addressed for sustainable sediment extraction. To this aim, an approach adopted within the European Union (EU) is presented, and its transferability to very different contexts discussed.

Sand mining: A global problem

Sand and gravel are an essential resource for ecosystems, and for socio-economic growth. Freshwater aggregates, i.e., granular materials derived from rivers and lakes, are the preferred material, particularly for mixing concrete. Compared with aggregates sourced from the ocean or terrestrial sources, freshwater aggregates are clean, of desirable physical properties, and have low costs of processing and transport. Marine sand has to be processed to remove corrosive sodium salts that can undermine structure stability, although it is commonly used for reclamation. Rounded desert sand has undesirable mechanic properties in a concrete mixture. In all cases, the environmental costs of aggregate mining are rarely internalized and accounted for in relevant decisions on alternative locations or materials. Therefore, such activity is still profitable and widely practiced, especially in growing economies (e.g., Bravard et al., 2013; Hübler and Pothen, 2021; Beiser, 2018), whereas its sustainability is not yet ensured by current regulations (e.g., Bendixen et al., 2021; Torres et al., 2021; Hackney et al., 2021).

The dimensions of the phenomenon and its effects are immense: sand and gravel constitute the highest volume of material extracted worldwide (e.g., UNEP, 2019; Cooper et al., 2018; UN Comtrade, 2020), at a rate by far exceeding the renewal rate (e.g., UNEP, 2014). Extraction of sand is projected to double by 2060 due to the increasing demand (OECD, 2019), with likely severe impacts on ecosystems, and serious implications for sand supply for human activity that pose risks for economic activity and social conflicts (e.g., Hübler and Pothen, 2021; Beiser, 2017).

The problem is complex and needs to be addressed at several levels (UNEP, 2014): (a) reducing consumption and providing incentives for alternatives; (b) reducing the impacts of mining through scientifically based planning; and (c) regulating aggregate extraction from national and international water bodies. For the purposes of this chapter, the last two aspects, related to freshwater sediment mining, are addressed.

Sand mining in rivers

Aggregate mining (commonly referred to as "sand mining") in rivers is the activity by which sediments (gravel and sand deposits) are extracted from river channels, floodplains or terraces (Sear and Archer, 1998; Kondolf, 1994a). Aggregates can also be a side product of mining for precious metals in river sediments (placer mining).

River sediment mining activities can be classified according to locations (river channel, floodplain or terrace) and technique of extraction. Three main mining techniques for (river) in-channel mining and their relation with water table can be identified (e.g., Kondolf, 1994b; Kondolf et al., 2001): (a) dry-pit mining, in ephemeral streams, by e.g., bulldozers; (b) underwater wet-pit mining, by e.g., dredges; (c) bar skimming, by scraping off the top layer from a gravel bar, above water level (Fig. 1). Alluvial sediments are also extracted from adjacent floodplains and older terrace deposits (and from tributary lakes). The extraction of sediments can occur at an industrial scale, with heavy machinery, or as artisanal informal mining, using hand tools. The impacts of both approaches can be comparable, as artisanal mining can involve up to a thousand people working on the same river site concurrently (Cordy et al., 2010).

Often, sediment budgets of rivers are already heavily impacted by human interventions, for example, the trapping of sediment in dams already leads to a downstream reduction in sediment transport. Sediment mining compounds those effects. In natural conditions, rivers often have aggrading reaches, where sediment accumulates temporarily as it moves through a river system (Schmitt et al., 2017). Aggradation can be emphasized by certain management actions, e.g., flow diversions which reduce discharges in rivers or increased sediment supply from land use change and mining. Such anthropic aggradation can create problems for flood protection, navigation, and water infrastructure and sediment removal and subsequent use can be used for temporary mitigation. Similarly, excess sediment accumulated in reservoirs might be suitable for human uses. Lastly, rivers are often incised because of upstream sediment trapping in dams, thus disconnecting the river from its original floodplains. In some cases, artificial lowering of the floodplains (e.g., Dufour and Piégay, 2005) has been used to restore lateral connectivity, while selling the removed material to set-off parts of the costs.

Effects of sediment mining and implications for regulatory frameworks

Historically, sediments have been regarded as an infinite resource to be exploited in order to sustain human activities. As such, they have been reflected inside relevant policies, but only in the last decades have environmental considerations been considered or integrated into regulations. Extraction of sediments has been addressed independently from the different "nature" of the sites of extraction, equating mines and quarries to rivers and considering the effects of mining as localized, leading to the illusion of restoring sites of sand mines in rivers after exploitation (e.g., Kondolf, 1993; 1994b) and, consequently, irreversible damage to river systems. The wide-ranging effects of sediment mining in river channels and in adjacent floodplains are now well acknowledged (e.g., Collins and Dunne, 1990; Kondolf, 1994b, 1997; Rinaldi and Simon, 1998; Ladson and Judd, 2014; Comiti et al., 2011; Comiti and Scorpio, 2020; Wohl et al., 2015; Koehnken et al., 2020).

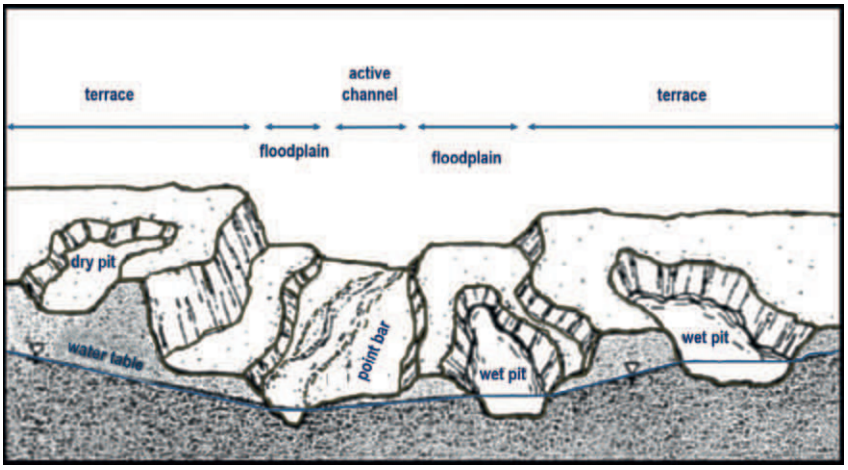

Fig. 1 Diagram of active river channel, floodplain and terraces, and relation between pit elevations and water table. Modified from Kondolf GM (1994a) Environmental planning in regulation and management of instream gravel mining in California. *Landscape and Urban Planning* 29: 185–199.

River mining triggers erosion, incision, and channel instability upstream and downstream of instream mining pits. River mining thus undermines structures, disrupts habitats, and alters hydraulic connections between channels and groundwater and floodplains far beyond the site of the actual mine. These processes also impact other economic sectors, such as tourism, agriculture, water supply and public and private infrastructure (Kondolf, 1997; Cooper et al., 2013). In large rivers, sediment mining can be sufficient to imbalance sediment budgets and eventually affect downstream coasts and river deltas (Schmitt et al., 2017, 2021; Hackney et al., 2020). The effects of sand mining can thus extend to dramatically wider temporal and spatial scales than the mining site, and are amplified if sediment mining occurs in degrading reaches and concurs with other pressures. Indeed, in terms of effects, sand mining can considerably exceed other pressures (e.g., Campana et al., 2014; Comiti et al., 2021—Figs. 2 and 3). Recovery from such effects is based on the capacity to restore a balanced sediment budget (e.g., Kondolf, 1997).

With such severe implications, sediment mining in rivers and lakes should only be allowed if better environmental options are not available or not sufficient to satisfy the demand. If alternatives are unavailable, it should be determined that aggregate mining

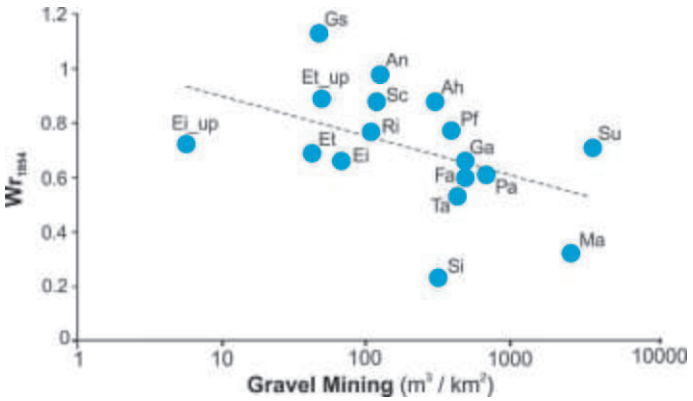

Fig. 2 Channel narrowing since 1954 (Wr_{1954}) in streams (represented as blue points) subject to intensive sediment mining since the 1950s compared with relative gravel mining intensity for some alpine rivers, represented in blue dots. Gravel mining shows clearly a significant negative relationship with the channel width trend. From Comiti F, Scorpio V, Andreoli A and Coviello V (2021) Management of coarse sediment fluxes and morphological dynamics of Alpine rivers: Lessons learned from South Tyrol (Eastern Italian Alps). *Proceedings of the International Symposium on Bedload Management. Interlaken, Switzerland*, 8-10.11.2021 (in publication).

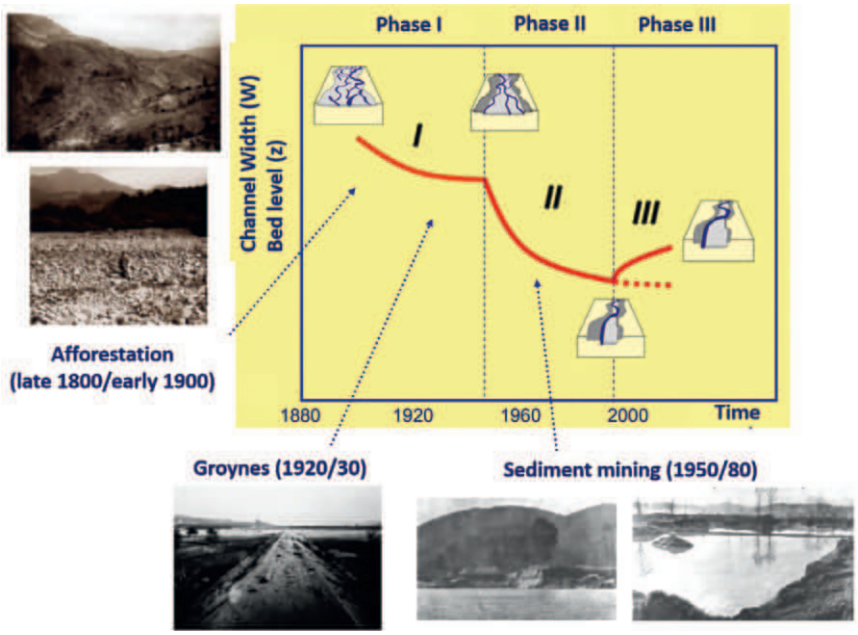

Fig. 3 Evolution of Magra River channel (Italy) in response to the different pressures in the catchment. In Phase II, the effect of sediment mining prevails, exacerbating incision and narrowing. The effect of environmental legislation enforced since the late 1980s is evident at the end of the 1990s, with an inversion of trend characterizing the current period (Phase III). Modified from Rinaldi M, Nardi L and Scozzafava R (2012) Studio del F. Magra e degli affluenti principali dal punto di vista geomorfologico a seguito dell'evento alluvionale del 25/10/2011 e definizione delle azioni e degli interventi di messa in sicurezza. https://www.regione.toscana.it/documents/16409/11270781/Univ_Firenze_Rinaldi_Effetti_Morfol_F_Magra.pdf/1fc79fdc-0923-448f-87ff-8a072fb3a950.

will not cause significant effects on ecosystems and society, such as increasing flood risk. Impairing water supply; or, undermining the stability of infrastructures and navigation. However, verifying such conditions requires: (1) a detailed knowledge of sediment dynamics in the catchment (e.g., Rinaldi et al., 2009, 2015), based on monitored and modeled information, including historic (Box 1); (2) a consistent map of current and future sediment demand per sector (e.g., cement, road bases, land reclamation and coastal protection etc.) and supply sources to meet such demand; and (3) expertise in implementing scientific assessment by relevant public bodies.

Box 1 Aspects recommended to underpin regulations on sediment mining (modified from Rinaldi et al., 2005).

1. Accurate analysis at the catchment and reach scale to understand if a river is aggrading, i.e., if there is a natural surplus of sediment.
2. If aggrading reaches exist: (i) identification of aggrading reaches, based on evolutionary trend of river channel and of the possible points of extraction; (ii) setting extraction rates to be lower than the replenishment rate from upstream (and ideally related to the excess volume that would cause aggradation); (iii) estimation of effects (environmental, socio-economic) of different extraction scenarios based on the demand.
3. Monitoring programs to control the extracted volumes, the modifications to channel sections and the ecological and morphological consequences.
4. Adaptive management, to review the permits based on the monitoring results.

Adopting basin scale approaches to manage aggregate mining

The spatial scale of river processes (catchment to site) and the cumulative impacts of the different socio-economic activities on them, require that sediment mining is addressed in the frame of integrated river basin planning. The benefits of resource extraction from freshwater bodies can then be assessed against the environmental costs of their present and future impacts.

Some regulations on aggregate mining require evaluating cumulative impacts of mining, although not indicating up to which extent (river reach compared with catchment). Other regulations address river mining within the wider context of an integrated catchment management framework, and do thus explicitly require a cumulative impact assessment. The latter is the case of the European Water Framework Directive (WFD; European Parliament and Council, 2000), which is legally binding for all member states of the European Union. The WFD aims to protect European water bodies and promote their sustainable use through successive river basin management planning on six-year cycles for all European basins, and implementation of measures to achieve the "good status" or "good ecological potential" of water bodies as defined in the WFD, except in some well-defined and motivated circumstances (EC, 2009).

The WFD recognizes the fundamental role of sediments and related morphodynamic processes in sustaining habitats and aquatic ecosystems, as well as the socio-economic needs related to sediments (e.g., aggregate supply, flood risk management, navigation) and promotes a risk-based approach to manage them sustainably at the catchment level. According to WFD, human activities potentially downgrading water body's conditions (e.g., water abstraction, river engineering, sediment mining) cannot be allowed unless specific conditions are verified. Sediment mining is not specifically mentioned in the WFD, but it is considered as a significant pressure on water bodies and, as such, it must undergo well-defined assessment procedures (e.g., EC, 2020). Sediment mining has to be managed at the catchment scale and allowed only if it does not undermine the achievement of good status of water bodies or the deterioration of some components. If so, it has to be reliably demonstrated that there is an "overriding public interest" in developing sediment mines (e.g., according to national strategies on aggregate supply) and that better environmental options (e.g., using alternative aggregates from quarries or floodplains) are technically impossible, prohibitively expensive, or having a worse overall environmental consequence (European Commission, 2009, 2018).

The WFD encourages two level assessments, a strategic system-scale assessment and an assessment at project-scales (e.g., European Commission, 2018, 2020). At systems scales (e.g., for international river basins or nationally) other means than mining for achieving the scope (e.g., importing aggregates, using alternative materials) have to be screened and evaluated, internalizing environmental costs of each alternative (e.g., other building materials, imported aggregates). The analysis at the strategic level will identify the national quota for aggregate mining based on the national demand for aggregate (considering for different uses, e.g., cement production, road subbase, industrial products) and screen potential riverine sources for aggregates based on productivity and ecological value. At the project level, alternative projects in the potential river stretches have to be assessed against the criteria whether other means (e.g., mining river terraces, sediment deposits in human-made reservoirs deltas, and quarries) can serve the same purpose with less environmental impacts. This includes also different project designs (e.g., different extraction techniques) which are technically feasible and not disproportionately costly. Once the project is selected, a monitoring program for river conditions has to be implemented and extraction regimes need to be adapted if that is the case. WFD has greatly contributed to prevent or limit in-stream mining in Europe, or corroborated the implementation of preceding environmental legislation addressing sediment mining.

Regulations on sediment mining and sustainable sediment management

No binding international convention regulates river sand mining and related trade, or commits countries to develop and implement sustainable management policies, although indirectly (i.e., conventions on environmental impact assessment in transboundary catchments or on the protection of nature and biodiversity) some protection could be considered to be in place. Outside of the

Europe and North America, or partly Australia, regulatory policies on sediment mining that are effectively implemented are still few, especially in developing countries, where demand for aggregates is very high and mining provides much employment.

Regulatory frameworks that recognize the environmental impacts of sediment mining in rivers and the necessity of a sustainable approach focus on the concept of a balanced sediment budget. The ways this concept is transposed into mining limits can be mainly summarized as follows:

1. *Definition of a "Red line"*, in terms of minimum elevation of the thalweg. Mining is permitted only if the river bed does not incise below this line that is annually re-evaluated on the basis of topographic surveys. Such a criterion is used in several countries but usually expressed as depth below the riverbed, and not as absolute elevation above a datum (e.g., Ministry of Environment and Water of Malaysia, 2009) and thus incision cannot be prevented;
2. *Definition of an annual replenishment rate* (sediment supply from upstream). Mining is permitted if the extraction rate is equal to or less than the replenishment rate. In many countries, extractions are permitted at the replenishment rate, and mostly calculated as a long-term average of annual sediment supply. This criterion is effective in preventing incision only if the actual replenishment rate is calculated based on that year's data (given the high interannual variability) and if the extraction rate allows for supplying the downstream reach (e.g., SEPA, 2012; Malaysia, 2009). River-wide estimation of annual replenishment is often imprecise, due to the assumptions in sediment modeling and measurement (e.g., Kondolf et al., 2001). Site-specific evaluation of the annual deposited sediment, carried out by specific surveys, is far more reliable, especially to define sound extraction rates; and.
3. *Definition of management rules based on empirical studies*. Recognizing the complexity of river systems and the geomorphic processes that shape them, science has developed solid methods to monitor and analyze sediment transport, and approaches to estimate sediment budgets and the effects of mining on sediment transport and, in general, on river systems. Scientifically based monitoring is indispensable to set reliable estimations of sediment yields, rates and effects, and is essential to calibrate models. In facts, numerical models alone cannot provide specific and secure predictions of the effects of certain extraction rates on channel changes and transport rates, as they are limited by the simplifying assumptions on geomorphic processes and the lack of relevant data to feed and calibrate them (e.g., Kondolf et al., 2001). Regulations that are underpinned by such scientific outcomes are still few.

Regulatory frameworks differ in the way how these aspects are translated into binding regulations, and in the capacity to provide effective technical indications, related to the availability of specific research in the relevant areas. Where comprehensive research has been carried out on the effect of river mining in specific catchments (e.g., Europe, North America), strict rules have followed (Koehnken et al., 2020) and in-river mining is prohibited or limited to some specific uses (e.g., flood risk mitigation, river restoration), subject to sustainability criteria (e.g., WFD). An example is provided in Box 2, related to the Scottish regulation on sediment management, which implements and specifies the WFD dictate in terms of guidance and criteria for sediment mining (Scottish Environment Protection Agency, 2010, 2012).

Box 2 General criteria for authorizing extraction of sediments related to some uses. Source: Scottish Environment Protection Agency (2012).

Aggregate extraction for commercial use. Consideration should be given to using aggregate that is not sourced directly from the aquatic environment. May be justified where resource is abundant compared to usage; local habitats are insensitive to such removal; assessment of sediment budget has been made and extraction practices are good. The operator should demonstrate that these conditions have been met and that a sustainable balance can be achieved. Where these conditions are not met, the activity is unlikely to be justified.

Flood management. May be justified in cases where it is demonstrated that sediment accumulation is increasing flood risk and the benefits of removing sediment can be quantified (e.g., using hydraulic and/or sediment transport modeling or other agreed method) and there are no other significantly better environmental options. However, it is likely that sediment will continue to accumulate in problem areas; therefore consideration should be given to longer-term alternatives for flood protection. It is more likely to be justified if part of a catchment flood management strategy. May be difficult to justify if the problem could be resolved by addressing an identifiable root cause of increased flood risk.

In countries where in-stream mining is still a widespread practice, guidelines to achieve sustainable mining may exist, although often poorly implemented. Technically solid national guidelines incorporating geomorphic-based approaches to sustainable mining have been issued, with procedures in place to identify the steps to identify sites, extraction methods, extraction rates and a comprehensive monitoring programme (e.g., Department Irrigation and Drainage, Malaysia, 2009). They are extremely valuable, but unfortunately not compulsory. Federal Guidelines to regulate the entire sediment value chain (from State demand to extraction rates, to trade) have been developed in India (Ministry of Mines, India, 2018). Nevertheless, they are not binding unless States enact them. Moreover, as sand mining controls are devolved to a large number of Districts, sustainable sediment management at the catchment-scale is not possible, as there is no coordination in defining coherent criteria across upstream and downstream districts. In the Mekong, where sand mining rates exceed replenishment rates by far and where natural sediment supply is heavily reduced by upstream dams, countries like Cambodia have banned export of sand, which was mostly exported to countries like Singapore for land reclamation (Kondolf et al., 2018; Bravard et al., 2013). However, enforcement seems patchy, as there is still a major sand trade

between Cambodia and whose sources are poorly traceable. Also, local sand demand is still exceeding supply rates, creating significant impacts on local river channels and the Mekong Delta (Schmitt et al., 2021). In some African countries, regulations have been issued, but the phenomenon is far from being governed. Where governance is lacking, mining is ongoing, as is illegal sand trade.

Promoting sustainable sediment management

Sediments, like water, require river basin governance. This implies agreements and a shared vision among different administrative entities, e.g., countries, in the case of international river basins, or sub-national entities (e.g. Hettiarachchi, 2019; Leal Filho et al., 2021). Yet, basin scale information on sediment dynamics and the effects of sediment mining is often scarce, but it is essential to underpin evaluations through scientific approaches. While numerical models can help to understand the basin scale sediment transport and pinpoint sediment supply rates, source areas, and aggrading reaches (Rinaldi et al., 2009, Schmitt et al., 2016, 2018), reliable evaluations need reliable monitored data as input, especially in complex systems. Given the complexity of sediment dynamics and related uncertainty, precautionary principles have to be applied proportionally to the lack of monitored data, and applications for sediment mining should only be taken into consideration if supported by sufficient monitored data.

Sediment transport and hydraulics are not intuitive matters. The devastating large-scale effects of apparently localized extractions are not commonly understood, and sometimes denied by non-experts and underrated among technicians. Education to increase awareness on such issues both among a wider public and practitioners is indispensable to promote an effective shift to sustainability. Comprehensive cost-benefit analysis and internalization of environmental costs are needed to provide incentives for research on alternative sources of sand and other aggregates.

Water and sediments are basic components of ecosystems and economies. While sediment dynamics and human uses should be analyzed, evaluated and managed at the catchment scale (e.g., Wohl et al., 2015), this is scarcely recognized in national policies and in terms of regional or global conventions. However, there is hope as new initiatives promote sustainable sediment management in international river basins, providing recommendations, technical guidelines for monitoring and management, and education (see. Box 3).

Box 3 Recommendations for sustainable sediment management in international river basins (UNESCO, 2011).

Recommendation 1: Sediment management (quantity and quality) should become a part of all river basin management plans.
Recommendation 2: Encourage soil conservation initiatives, in particular on steep agricultural land.
Recommendation 3: There is a need to work with international agencies such as the ISI in developing a commonly accepted international protocol for measuring erosion, sediment transport and sedimentation in river systems.
Recommendation 4: It is important that efforts should be made to involve the community in sediment control and management and to provide sufficient information on how they can improve river health and contribute to sediment management.
Recommendation 5: Sediment management must be based on a sound understanding of the sediment dynamics of the river basin involved. There is a need to clearly define the sediment budget or balance of a river system and collate available data to identify knowledge gaps and further enhance understanding of sediment issues on a global scale.
Recommendation 6: Sediment management plans should be periodically reviewed to ensure that they are in line with international best-practice.
Recommendation 7: The potential downstream impacts of any river structures and sediment management strategies must be considered.
Recommendation 8: There is a need for investment in capacity building to ensure that water management personnel understand and engage with sediment issues effectively.
Recommendation 9: Further investment in sediment research must be encouraged, particularly in developing countries.
Recommendation 10: There is a need to increase institutional cooperation and collaborate with international partners to share research and experiences.
Recommendation 11: The ISI network should include representatives from all regions of the world (with perhaps one representative who is a key expert in sediment from each of the major sediment-laden river systems of the world).
Recommendation 12: The precautionary principle should be applied in sediment management. The complexity of sediment transport processes and associated uncertainties makes the application of the precautionary principle important to management.

Conclusion/Synthesis (respond to aim)

Aggregates underpin natural systems as well as human-built infrastructure and are the second most extracted global resource after water. Impacts, benefits and alternatives to sediment mining from rivers need to be addressed, managed and governed at the river basin scale and underpinned by a solid knowledge of sediment flows in the catchment.

Most regulatory frameworks are insufficient to sustainably manage sediments (e.g., Kondolf, 1997; Rinaldi et al., 2005; UNEP, 2019). This is also due to the lack of adequate information (Sreebha and Padmalal, 2011) and of any specific international convention regulating sediment mining and trade, particularly in developing economies.

Given the severe implications of sand and aggregates extraction, sediment mining in rivers and lakes should only limited to cases where no less impactful option is available to satisfy a particular demand for sediments (e.g., alternative aggregates/materials for constructions from recycling or lower-impact natural sources, natural flood mitigation strategies), and, if so, where it is not causing significant effects on ecosystems and society.

Evaluation of both conditions require: (i) a detailed knowledge of sediment dynamics and potential supplies in an entire river catchment, based on monitored and modeled information; (ii) consistent information on future sectorial sediment demands (e.g., cement, road bases) and potential alternative sources to meet such demand; and (iii) expertise in implementing scientific assessment approaches for adaptive management of sediment extraction and its impacts and suitable regulatory frameworks—especially in transboundary river basins.

Knowledge gaps

(a) Understand rates of extraction, demands, and their future trajectories.
(b) Quantify impacts of mining on river processes, ecosystems, and livelihoods through modeling and field-based assessments to better quantify and internalize socio-environmental impacts of mining.
(c) Process based quantification of sustainable mining rates through understanding how sediment is generated and moved through a catchment (using local assessments, numerical models, and potentially remotely sensed data) in a modular manner (from basin-scale screening to more local assessments).
(d) Technical opportunities to replace sand in construction with other materials, better recycling for a more circular economy of construction materials, and their economic feasibility under consideration of internalized environmental impacts.

Introduction

Sand and gravel are the most mined resources in the world. They are used mainly for construction, either to make concrete and asphalt or to build reclamation areas (The Economist, 2017). Mining for construction is mainly made in rivers, which puts these at great pressure. The rates of mining are at this moment higher those of natural supply of sediment, and it is estimated that by mid-century the demand will be higher than the supply with serious consequences for price (Bendixen et al., 2019; Sverdrup et al., 2017). Several authors designate sand as new gold (Jappe, 2020). It is thus no surprise that the main regions of the world where sediment mining is observed at the moment are the ones where a boom of urbanization is happening, East Asia, India, and Africa.

Sand and gravel mining for construction can be far away from where it is used, increasing the global footprint of the construction industry. Dubai city is in the proximity of sand-supplied landscapes; however, this sand does not offer the right characteristics for construction forcing Dubai to export sediment from Australia for reclamation works such as the building of artificial islands. Singapore, the world largest importer of sand to support its expansion, buys sediment from neighboring countries but also from Malaysia, Vietnam, and Indonesia (Hall, 2020).

Regulations and restrictions have been put in place by several nations after serious consequences were observed such as islands and beaches disappearances and infrastructures (bridges and building abutments) collapses due to foundation erosion. Many countries in the world regulated or completely blocked the export of mined sediment, which however did not stop the world sand extraction which is now in the hands of criminal gangs and black markets (Jappe, 2020). Sand and gravel extraction can be done, both in daylight and during the night, by a huge variety of methods: through the use of heavy machinery such as dredging boats and suction pumping, to more informal methods such as digging with shovels and bare hands (Bendixen et al., 2019).

Here we provide three examples of sand mining activities in which unregulated or poorly regulated sand mining activities happen or have happened in the past. In the three, mining rates were higher that sediment supply from upstream, causing a sand deficit situation in the rivers, and in the three important consequences are observed in terms of environmental impact, socioeconomic changes and safety. The case studies here presented are: (i) in Indonesia, excessive and unregulated sand mining in the slopes of the Mount Merapi volcano (province of Yogyakarta) are changing the landscape, endangering downstream infrastructures due to erosion and scouring, and changing the local socioeconomic structure; (ii) in Portugal, poorly monitored sand mining activities occurring for a century in river Douro enabled the dramatic collapse of the Hintze Ribeiro bridge which happened in March 2001 and took the lives of 59 persons; and (iii) the excessive sand mining in the heavily human-modified Mekong delta which is one of the main responsible activity for the previewed disappearance of the delta by the end of the century. In each case study, a general description of the sedimentary systems and the mining activities is given, and how the sediment mining activities relate with the observed or anticipated consequences.

The slopes of the Mount Merapi volcano in Indonesia

Climate change and intensive pressure on land use caused an increase on sediment-related disasters in Indonesia in the last years (Surtiari et al., 2017). This is the case of Mount Merapi slopes (province of Yogyakarta), which drains to Progo river which flows into the Indian Ocean. Mount Merapi erupts frequently (Anwar et al., 2017; Gertisser et al., 2012), and a considerable amount of sediments are directly produced by eruptions feeding the volcano slopes. These sediments are responsible for a complex morphological system located between the Mount Merapi volcano and the Indian Ocean, where the river Progo is one of the main features. Downstream, in the coast of the special region of Yogyakarta, these sediments are essential to maintain the barchan dunes, a rare geophysical feature found here.

The activation of the sediments produced by the Mount Merapi volcano by rainfall originate lahar flows, a rapid downhill flow of water and volcanic rock (Lavigne et al., 2000). These have devastating impacts on downstream valleys (Jenkins et al., 2015),

representing the main cause of local secondary hazard (Lavigne et al., 2000; Solikhin et al., 2015). In recent years, safety works including the construction of Sabo dams (Lavigne et al., 2000) decreased considerably the risks against debris flow by retaining the sediments upstream of the valley, and prompting economic development in the region.

The sediment produced by Mount Merapi volcano is an important economic asset, and mining of sand and gravel (Fig. 1), trapped by such protection works as the Sabo dams, became an engine of socioeconomic progress. The sediments are of high quality for construction, making this activity highly lucrative and creating important job opportunities and local incomes (Ikhsan and Fujita, 2012). Infrastructure development was a driver for sand mining activities already in the 1970s. In the 2000s the mining activities intensified after the building of many Sabo dams which trapped the sedimentary material from the Mt. Merapi eruptions that occurred in 1994, 1998, 2006 and 2010. So far, more than 250 Sabo dams of various types have been built around Mt. Merapi.

However, in recent years, the excessive retention of sediment by the protection works and its over-extraction has led to a lack of sediment supply downstream (Gob et al., 2016). Recent records show annual volumes of sediment abstraction from the Mount Merapi slopes of about 4 Mm^3 is similar to the annual production of sediment by the volcano, estimated as 3.9 Mm^3. Legono (2005) refers that the amount of sediment extracted from the Krasak Sabo dam (one of the tributaries of river Progo) in the slopes of Mount Merapi is higher than the upstream supply from recent eruptions. The degradation of the Lower Progo is already happening because of sand mining, estimated as more than 0.10 m/year (Ikhsan et al., 2010).

While the retained sediments are not conveyed downstream to the valleys anymore as they are exploited by mining activities, traditional agriculture practices are now being abandoned in favor of this new economic activity (Ikhsan et al., 2010). Sand mining has an effect on the community's economy, increasing employment opportunities as miners, heavy equipment operators, truck drivers, collectors and sellers of sand. This shift contributes to a sudden change of the local socio-economy which previously was based mainly on local small-scale food production.

Morphological degradation of downstream valleys (with ecological and security consequences) and lack of sediment feeding to coastal areas (essential to maintain barchan dunes, a popular local attraction), result from the lack of natural supply. Excessive river bed degradation, scouring of bridge piers and bank erosion are already observed in the Progo River. The proliferation of sediment mining in the Mount Merapi slopes induces abandonment of agriculture fields which is the basis of local subsistence. Sediments convey nutrients essential for ecology and food production, and reduction of its supply changes downstream habitats and fluvial connectivity.

The slopes of the Mount Merapi are a perfect living lab where a complex nexus between sediment, socio-economy, environment and safety exists. Ikhsan & Fujita (2012) and Legono (2005) illustrate very well the complexity and fragility of this geographic system and how linked geophysical aspects are to local socio-economy, governance, environment and safety. Legono (2005) discusses clearly the need for national and regional policy to regulate the sediment management whilst taking into account all these interdependent aspects.

The Mount Merapi geomorphology system is an intriguing and truly multidisciplinary problem. The sediment management in the Merapi slopes requires an integrated approach which considers the over-retention and exploration of sediments, aspects related to fluvial connectivity and morphology, coastal protection, and to socioeconomic security. Underlying geophysical substratum and the socio-economy of a basin have feedback mechanisms yet to be fully understood.

The bridge Hintze Ribeiro in Portugal

On the night of 4th March 2001, the bridge Hintze Ribeiro in the north of Portugal, constructed in the end of the 19th century, collapsed causing the fall of one bus and three cars and the instant death to its 59 passengers. The accident provoked a political crisis with intensive coverage by national media of death and suffering (Araújo, 2016), and raised skepticism in the capacity the national technical and engineering community.

The bridge, also known as bridge Entre-os-Rios, was located roughly 500 m downstream of the confluence of the river Tâmega with a bend in the River Douro. It was located in the heavily modified valley of the Douro river, about 15 km upstream of the Crestuma-Lever dam in the boundary of its reservoir. Upstream, several major dams impounded the main rivers: Torrão in river Tâmega and Carrapatelo in River Douro are the first dams upstream of the bridge section (Antunes do Carmo, 2014). In Douro, upstream of Carrapatelo, 12 other dams exist in Portuguese and Spanish territory.

The collapse of the bridge Hintze Ribeiro happened with the passage of the fifth consecutive flood wave in the River Douro in a sequence which started on 6th December 2000 (Antunes do Carmo, 2017). All the peak discharges of these five floods were above 8000 m^3/s, and the discharge was kept always above the value of 2000 m^3/s during these 3 months. The permanence of high values of discharge favored sediment movement, not allowing time for the reposition of sediment deposits; furthermore, values of discharge higher than between 2200 and 2600 m^3/s were estimated to be critical for the occurrence of riverbed erosion in this river section (Rocha et al., 2008). As far as it was possible to know, the flood of the Douro river between December 2000 and March 2001 was associated with a return period of more than 100 years (Silva, 2008).

The collapse of the bridge included one pier (the pier P4), two of the adjacent deck slabs and a third contiguous slab (Fig. 2). Pier P4 was in the inner edge of a bend in the river Douro, which is a natural area for sediment deposition; consequently, after the construction of the bridge pier P4 was enveloped by a sand bank, which conferred extra support to its foundation. This sand bank was 4–5 m higher than the normal water surface in the river (Silva, 2008).

After the accident, the position of the collapsed pier, tilted towards upstream, indicating that the collapse happened due to infra-excavation of its foundation (Antunes do Carmo, 2017). In contrast with the other two piers of the bridge which were located in the outer edge of the river bend, P2 and P3, pier P4 were not protected against local scour (Rocha et al., 2008). Several reports prior to the accident say that, although a century-old bridge with some conservation problems, structurally the bridge was generally in good state (Silva, 2008).

Through numerical modeling, the direct influence of hydrodynamics in the collapse of pier P4 was discarded (Rocha et al., 2008). Hence, four mechanisms related to river morphology were identified as possible causes of the accident, alone or combined: temporary riverbed incision due to the floods passage (short-term); local scour of the pier P4 foundation (mid-term, happening regularly in the winter season); morphology alteration due to sand mining activities (long-term); and, channel incision due to sediment supply depletion (long-term).

Extreme floods are not exceptional in the Douro valley, and similar intense floods occurred in February 1979, December 1989 and January 1996. These must have had a similar temporary effect in terms of channel incision, however the state of the riverbed previous to these floods must have been different.

The sand bank which enveloped the pier P4 in the beginning of the 20th century, disappeared completely by local mining activities of the bank itself, and never replenished because of the lack of upstream supply. After having exhausted this sand bar, miners continued the sand extraction along the river and in the reservoir of Crestuma-Lever, upstream and downstream of the bridge location. These mining activities provoked a general incision of the riverbed in the surroundings of the bridge at rates as high as 0.20 m/year (Sousa and Bastos, 2013). From 1913 to 1982 a total incision of the riverbed of 11.5 m was observed in the surroundings of the pier P4 (a rate of 0.17 m/year). Between 1982 and 1989 this incision accelerated and, during this 7 years period, it increased 1.5 m (Rocha et al., 2008). The rate of sand mining exceeded the rate of replenishment due to the natural flux of sediment.

Regarding long-term channel incision, the possibility of lack of sediment supply due to retention in the upstream reservoirs was excluded according to an official report from 2002 by the governmental agency IPTM—Instituto Portuário e dos Transportes Marítimos do Norte (Rocha et al., 2008). However, the section where the bridge of Hintze Ribeiro was located, lack of supply was verified to be caused by upstream sediment extraction.

The main conclusions regarding the causes of the collapse of the bridge Hintze Ribeiro indicate that this was due to a combination of extreme local erosion and riverbed incision provoked by five consecutive flood waves (short-term), acting upon an already incised and altered morphology due to sand mining (long-term). As shown, when the extreme floods in the Douro river occurred between December 2000 and March 2001, the stability of the foundation of pier P4 was already weakened by riverbed incision. The wave of floods provoked an extra debasement of the foundation of about 4 m, which lead to a critical infra-excavation and the consequent collapse of the pier P4 (Antunes do Carmo, 2017; Rocha et al., 2008). This example showed the need for continuous and accurate monitoring of infrastructure which are founded in susceptible riverine environments, and the need to create and enforce regulated sediment mining activities in rivers.

The Mekong delta: Stories of subsidence and coastal erosion

Mekong delta is an important agricultural area for Vietnam, where more than 50% of the national yearly paddy rice harvest is produced (Thuy and Anh, 2015). Nevertheless, its genesis is rather young, as it developed due to a mixture of tectonic processes with an important accumulation of sediment transported by the river Mekong during the last 10,000 years (Tanabe et al., 2003), and an extensive human interference in the last two centuries. The Mekong delta, with an area of about 40,000 km^2, has been heavily modified by human influence from a system of two channels to an intricated system of channels, dykes and floodplains. The actual network of multiple connected channels measures more than 50,000 km (Hung et al., 2012).

Within the last decades, upstream dams in such countries as China, Cambodia and Laos, besides storing water and deviating it from the river for use in local agriculture and water supply, also retain and accumulate sediment in their reservoirs (Räsänen et al., 2017). As direct consequences, the sediment discharge of the Mekong decreases (Räsänen et al., 2017), and the supply available to be transported along the Mekong river substantially decreased (Li et al., 2017). This serious deficit of sediment supply due to upstream retention is exacerbated by sand mining (Fig. 3) which occurs directly in the Mekong river and its tributaries (Brunier et al., 2014; Dastgheib et al., 2016).

The average elevation of the whole delta is roughly 0.8 m above sea level (Minderhoud et al., 2019). The lack of upstream sediment, which is retained or extracted from the river, has serious consequences in the stability and maintenance of the Mekong delta sedimentary system. The lack of upstream supply of sediment disturbs the natural sediment balance in the Mekong channels creating the so-called hungry waters (Kondolf, 1997) which will contribute to channel incision, bank erosion and scouring of bridge piers and endangering of other infrastructures founded in the riverbed.

In addition to the sedimentary factors, other endangerment to the stability of the delta include the loss of the protective mangrove coastal belt (Besset et al., 2019), and progressing coastal erosion (Li et al., 2017). All these factors, which are magnified by climate change induced sea level rise and accelerating subsidence due to groundwater over abstraction, exert a heavy pressure on the delta which is predicted to disappear almost completely by the end of the century (Kondolf et al., 2018).

The long-term sediment yield in the Mekong river was formerly estimated to be between 145 Mt./year (Liu et al., 2013) and 160 Mt./year (Walling, 2009). However, more recent research indicates that the suspended sediment transport is 75% less than assumed previously (Vinh et al., 2016). This may be attributed to more accurate calculation methods but could also be a consequence of sediment trapping by the reservoirs. Mining activities aim at the coarser sediments in the riverine systems; hence, mining activities have an impact mainly in the sediment transported in the form of bedload (near the river bed) rather than the sediments transported in suspension.

In comparison with the sediment transported in suspension, the annual bedload yield was estimated to be less than 1% of the total suspended sediment transported for the period from 1981 to 2014 for the Vietnamese Mekong. Based on these numbers, the total sediment flux (traveling under suspension and as bedload) entering the Lower Mekong Delta can be estimated to be 6.16 ± 2.07 Mt./year which is far less than the sediment extracted by mining activities which was estimated to be between 37 and 62 Mt./year over the similar period. This indicates, therefore, a huge deficit between sediment supply and extraction by mining (Hackney et al., 2020). These amounts of mined sediment agree with the previously published numbers which estimated the instream mining for the Lower Mekong River to be around 55 Mt./year (Bravard et al., 2013). An overview on the sand mining volumes and their respective extraction location is given in Fig. 3.

For 2018, the sand extraction rates by mining were estimated to be 4.64 ± 0.31 Mm^3/year for a 20 km river section along the Tien river (the main northern branch of the Mekong delta in Vietnam). These calculations were based on indirect methods such as bathymetric maps and simulation of local refilling processes. As mining is interrupted during the flooding periods of the wet season, local mining pits were refilled after a few months by the transported sediment and also by the sediment from the collapsing of the pit shoulders; these calculations assumed the possibility of a complete refilling within a period of 6–12 months.

Fig. 3 Sand deposition along the river bank (Tan Hue) of the Mekong. Source: F. Nestmann.

The cumulative amount of sand mining was reported to be 17.77 Mm^3/year for the whole area of the Vietnamese Mekong Delta based on governmental data. However, the authors consider their calculations for the total extracted sand amount as rather conservative, as their observed extraction amount for the Tien Giang province was 0.51 mi m^3 for 2018 while dredging was prohibited for the whole province during that period (Jordan et al., 2019). Those numbers show a considerable disparity, indicating the difficulty of consistent data collection and interpretation. Nevertheless, they all show concerning trends of substantial annual sediment deficits.

The negative impacts of the extensive sand mining in the Mekong delta to the riparian ecology is well documented by several studies focusing on the sediment balance, channel incision, salinity intrusion and river bank destabilization. Research in morphology changes of the two main channels of the delta network, the Mekong and Bassac, showed a mean incision of the channel with around 1.3 m between 1998 and 2008. In parallel, and over the same period, the loss of bedload supply was estimated to be about 90 mi m^3 for the Mekong channel and to be about 110 mi m^3 for the Bassac channel. As both effects showed a weak correlation to hydraulic parameters, they could not be related to the dam induced decreasing discharge of the Mekong (Brunier et al., 2014), but rather to upstream retention and extraction of sediment from the system.

The progressing incision of the river channel due to sand mining increases the relative riverbank height. It was found that this induces seasonal bank instability (Fig. 4) which is a threat to key infrastructure (e.g., bridges) and communities located along the river (Hackney et al., 2020). As sand mining reveals negative effects to the environment, predicting the impacts from sand mining to the river morphology becomes of utmost importance. Recent studies of the Mekong segment in the An Giang province, by means of numerical modeling and bathymetry measurements, show clearly the impact of the mining in altering river morphology (Kim et al., 2020).

The seasonal flooding of the Mekong is essential to the local agriculture, as it conserves floodplain biodiversity and supplies fertile sediments to the agricultural areas in the delta (Vinh et al., 2016). Within the last 20 years (1995 to 2015), a significant decrease of flood frequency and duration could be observed. This may be directly related to the lowering of water levels as effect of intense riverbed mining while the river discharge remained constant over the same period (Park et al., 2020). The river impoundment by dams may be responsible to changes in the hydrological regime as well.

The incision of the river bed has an impact on the intrusion of tidal waves as well, allowing the seawater to move further inland during high tide. This is documented by an increase of salinity in the delta channels (0.2–0.5 PSU/year, Fig. 5) and an increase of the tidal amplitude within the delta (a rate of reduction of 2 cm/year). At the same time, the offshore tidal amplitude increased 1.2–2 mm/year due to climate change induced sea level raise. Both effects could be directly related to bed level incisions (2–3 cm) in response to sediment starvation due to the combined effect of sand mining sediments trapping by the upstream dams (Eslami et al., 2019).

On a concluding note, sand mining along the Vietnamese Mekong river delta already shows its negative impacts in terms of ecology and human life. Extraction rates, allied to retention upstream of dams, are likely to be higher than the natural supply at this moment already. As shown, diversity in the numbers which support these conclusions, means that extra efforts are needed on reliable data collection and further investigation of the sediment balance of the system. However, the actual numbers may even underestimate the situation due to additional unregistered extraction which is not considered in the abovementioned studies. Furthermore, as more dams are already planned in Cambodia and China, the impact of this in the sediment balance is expected to disturb further the sedimentary system by decreasing the sediment supply. Due to its agricultural importance, prompt solutions are needed on the national (restriction of sand mining) as well as on the international (transboundary river management) level to maintain the Mekong Delta for future generations.

Conclusions

The case studies illustrate current and likely future problems with sand mining for river morphology, with important consequences for human safety and river ecology. The three case studies presented have in common a poor or no regulation and monitoring of the mining activity, and highlighted by fact that rates of sediment extraction are higher than the rate of upstream sediment supply. In some cases, the excess sand mining is happening at this moment, with negative consequences which are already observed or are expected to happen in the near future. In another case, the consequences were felt after years of excessive extraction, showing that the recovery of these natural sedimentary systems is long-term. The scale of the problem of excessive sediment extraction is global and often increasing. At the moment this is happening mainly in economically developing societies, where construction and land reclamation is occurring at unprecedent levels. Following the current rhythm of sediment exploitation, by mid-century the demand for sediment for construction will be higher than the supply, which will have negative, and unprecedent, consequences for the morphology of the world's sedimentary systems, as well as for the costs of construction.

Emerging and Less Commonly Recognized Chemical Contaminants: Organic Micropollutants

Fabio Bacci[a] **and Pablo Campo**[b], [a]The Gables, Carrowpeter, Galway, Ireland; [b]Cranfield Water Science Institute, Cranfield University, Cranfield, Bedford, United Kingdom

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Bioaccumulation The increase of concentration of a pollutant in organisms exposed to the substance in the environment. Bioaccumulation effects occur at one trophic level and are governed by the rate of metabolism of the pollutant by the exposed organism. If the metabolic rate is low or negligible the pollutant is poorly broken down and can be adsorbed in the organism's tissue. When the rate of adsorption and storage exceeds the rate of excretion the pollutant accumulates in the organism's tissue. Further, bioaccumulation can be exacerbated if the pollutant has lipophilic (tendency to dissolve in lipids) characteristics.

Biocide A substance designed to eliminate an undesired organism. Biocides include herbicides, fungicides and insecticides. A biocide contains one or more active ingredients, being a chemical, plant extract, pheromone or microorganism that has action against pests or on plants, parts of plants or plant products.

Biomagnification The amplification of concentration of a pollutant in the environment along the food chain. Biomagnification effects occur at successive trophic levels, culminating in elevated concentrations in top predators.

Endocrine disruptor (ED) Exogenous (of external origin) substance with potential to cause adverse health effects of an organism by altering the function of its endocrine system. Adverse effects range from reproductive impairment, immune system decline and developmental and cognitive deficits. Moreover, endocrine disruptors can cause mutagenicity, carcinogenicity and teratogenicity, thus affecting progeny and sub-populations.

Negative removal efficiency The increase in concentration of a chemical substance through wastewater treatment processes. The effect is caused by the breakdown of precursor molecules (e.g., polymers, metabolites or conjugates) into the chemical under investigation, causing an increment between influent concentration and effluent concentration of the substance.

Organic micropollutants Organic (carbon based, either aliphatic or aromatic) chemicals of anthropogenic origins occurring in the environment at trace level concentrations of ppb to ppt, or $\mu g\ L^{-1}$ to $ng\ L^{-1}$, with potential to cause adverse environmental effects and hazard to human health.

Perfluoroalkyl substances Organic (aliphatic, non-cyclical) compounds on which fluorine atoms replace all the hydrogen substituents in the moiety.

Persistent organic pollutant (POP) Organic (carbon based, either aliphatic or aromatic) compound, including its transformation products, with determined characteristics of persistence in the environment, bioaccumulation, potential for long-range environmental dispersion and known adverse effects or toxicity to human health or to the environment.

Personal care product (PCP) Beautification or personal hygiene substance for topical (superficial) application. Cosmetics, perfumes, deodorants, creams and lotions, dental care products, soaps and shampoos are examples of personal care products. Emissions of parabens, a family of preservatives, and the antimicrobial disinfectant triclosan are primarily linked to personal care products.
Pharmaceutical substance A substance containing a pharmaceutically active ingredient providing pharmacological activity or direct effects on disease prevention, treatment or palliation or direct effect in adjusting, restoring or altering physiological functions.
Pseudo-persistence Effect caused by continuous emission, or flux. Numerous organic micropollutants susceptible to degradation in the environment are candidates for pseudo-persistence characteristics. The characteristic is simulated by the ubiquitous presence of a substance in the flux of effluent to the aquatic environment.
Surfactant A substance lessening the surface tension of a liquid, thus enhancing its dispersion by increasing wetting, spreading and penetrating properties. Surfactants are used in detergents, both for household and industrial applications, polymers, paper industry processes and textiles. The principal organic micropollutant deriving from surfactants is nonylphenol.

Introduction

Chemical contaminants are consistently associated with anthropogenic progress. Whether medicinal drugs improving public health, veterinary drugs and agrochemicals fortifying food security or flame retardants minimizing fire hazards, the benefits provided by these chemicals are considerable and phasing out or elimination of some classes of these substances can spark contentious socio-economic arguments.

Concern about the occurrence of micropollutants in water is not recent; in fact, the Commission of the European Communities (1981) began hosting symposia on the theme in the late 1970s. However, with novel chemicals discoveries and advancements in analytics, the defining scope of organic micropollutants has changed considerably. Today, substances characterized as organic micropollutants include perfluorinated compounds (PFCs), biocides, human and veterinary pharmaceuticals, steroid hormones, Personal Care Products (PCPs) and surfactants (Stasinakis and Gatidou, 2019). Organic micropollutants occur in the water column at trace level concentrations of ppb to ppt, or $\mu g\ L^{-1}$ to $ng\ L^{-1}$ range, have the potential to cause adverse environmental effects and can pose a risk to human health. Hazard assessment of organic micropollutants is conventionally characterized by Persistence, Bioaccumulation and Toxicity (PBT) and Endocrine Disrupting (ED) properties (European Chemical Bureau, 2003).

Due to the scale of classes of organic micropollutants and the enormous variety of their applications, this article is merely a digest of the topic. The complexity of this anthropogenic pressure on water resources is perhaps better conveyed by presenting the most common sources of organic micropollutants and their pathways to the aquatic environments. Fig. 1 broadly depicts the main applications of organic micropollutants; it is immediately clear that these substances have extensive socio-economic merits. Nevertheless, their emission to the aquatic environment has ramifications. In addition to the impact of single organic chemicals, the interactions and synergies of mixtures of substances, particularly mixtures of different classes of organic micropollutants, is an ever-increasing concern recurrently addressed in this article. Further, contemporary policy response, invariably grounded on hazard potential, forms another reoccurring theme of the article.

Owning to high chemical stability, lipophilic characteristics and consequent likelihood for biomagnification, PFCs are particularly hazardous chemicals. Recently, the PFC class of per- and polyfluoroalkyl substances (PFAS) has been under significant scrutiny and policy action at European level is imminent (Council of the European Union, 2019). In fact, emphasis on monitoring programs in aquatic environments focusing on one specific class of PFAS, the perfluorooctane sulfonic acid and its salts (PFOS), is intended to inform on the occurrence and persistence at global level (UNEP, 2017). Furthermore, recent EU policy for drinking water, stipulating routine monitoring for PFAS Total and Sum of PFAS (from a list of 20 PFCs) to commence by 12 January 2026, demonstrates the concern with risk to human health posed by this class of organic micropollutants (European Union, 2020).

Pesticides, herbicides and other parasite control substances are another class of organic micropollutants rigorously addressed in world-wide policy. Biocides, for instance the antifouling tributyltin, were among the initial micropollutants addressed by the Commission of the European Communities (1991). Nonetheless, biocides continue to raise concern for both the health of the aquatic environment and human health; in fact, regulatory instruments are periodically reviewed and updated to incorporate findings of systematic investigation programs (Secretariat of the Stockholm Convention, 2018; European Commission, 2020a; Gomez Cortes et al., 2020).

Awareness of the occurrence of pharmaceutical products in aquatic environment, raised by decades of academic research (Daughton, 2016), has finally kindled a response from global institutions for methodical evaluations and assessment to inform future policy responses (Kümmerer, 2019; OECD, 2019). Once again, recent EU policy for drinking water provided for investigations to be concluded and findings disseminated by 12 January 2029 on the potential threat posed by pharmaceuticals in source water (European Union, 2020). Of particular concern are the endocrine disrupting effects of synthetic steroid hormones 17β-estradiol (E2) and 17α-ethinylestradiol (EE2). Both drugs, administered primarily as sex hormones, were two of the only three pharmaceuticals first added to the Priority Substances Directive watch list (European Union, 2013).

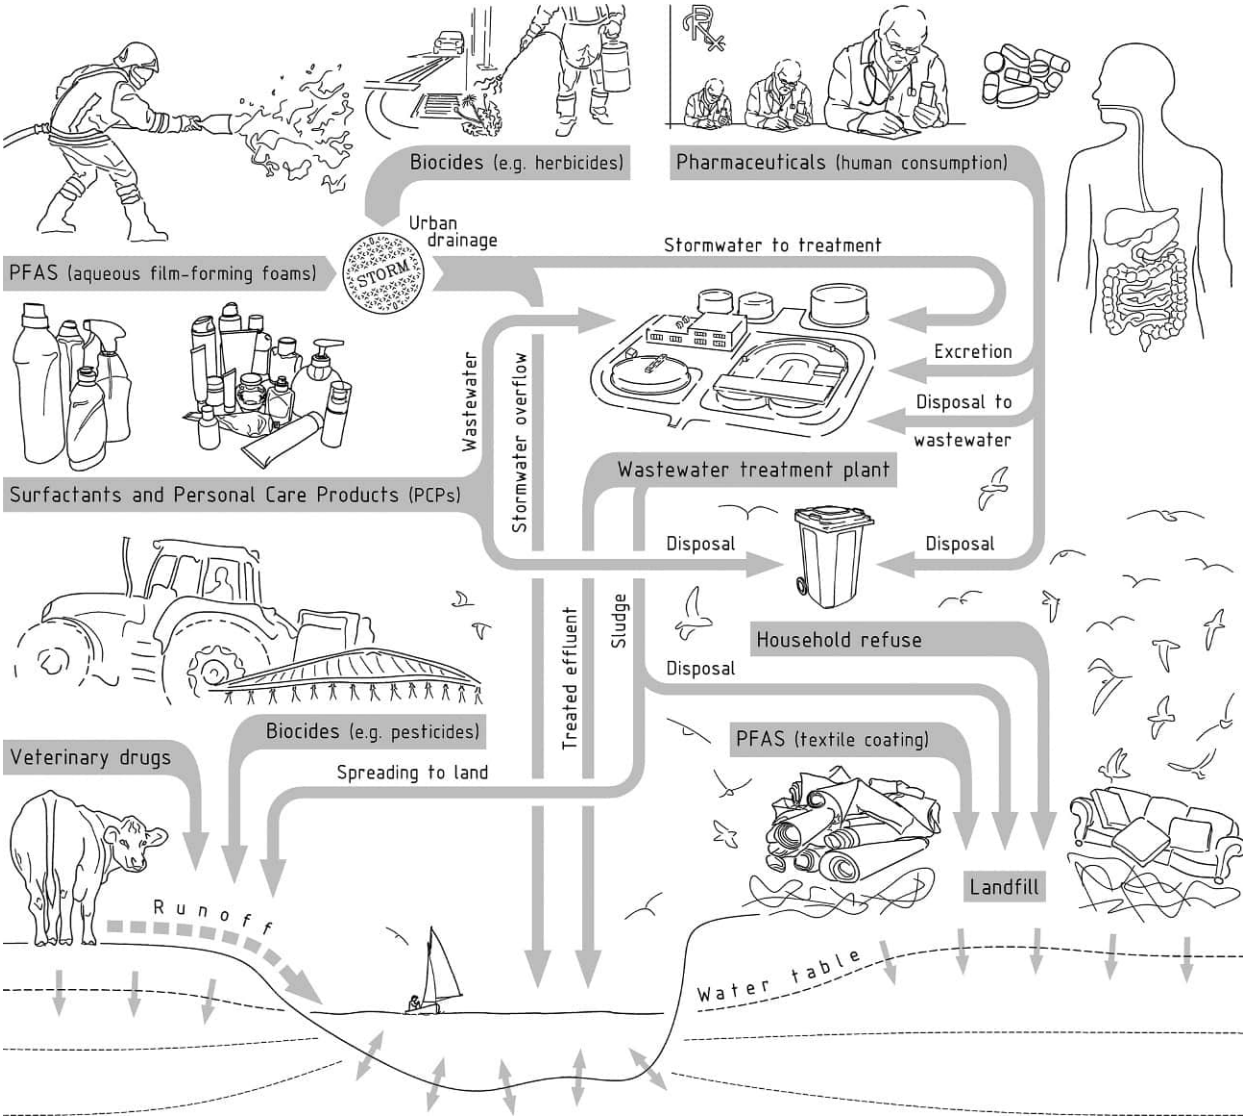

Fig. 1 General pathways of organic micropollutants to the aquatic environment.

Lastly, although surfactants and personal care products remain largely unregulated substances, these are noteworthy organic micropollutants because of their widely reported ED and ubiquity in the aquatic environment.

Biocidal substances

Biocidal substances (e.g., herbicides, fungicides and insecticides) are products designed to eliminate an undesired organism. Among other ingredients, biocides contain at least one active substance. An active substance can be either a chemical, plant extract, pheromone, or microorganism that has action against pests or on plants, parts of plants or plant products (European Commission, 2009). From a chemical point of view, biocides classify as inorganic (e.g., salts and oxides containing copper, lead) and organic (carbon compounds), the latter being more commonly used worldwide. Depending upon the presence of different elements such as chlorine, phosphorus, or nitrogen, and functional groups, organic biocides fall into four families: organophosphates, carbamates, triazines, and phenoxys. Within a given chemical family, biocides show close chemical structures and share similar behaviors when discharged into the environment. Aquatic biocidal pollution mainly results from agricultural and urban applications and its occurrence highly depends on land use, season, and rainfall-runoff events. A brief description of representative biocides of timely importance is provided below.

Glyphosate

Glyphosate or *N*-(phosphonomethyl)glycine is an active substance in commercial formulations for control of broadleaf weeds and grasses worldwide. Glyphosate disrupts the regulation of the synthesis of aromatic amino acids and secondary compounds in plants, fungi and bacteria (Funke et al., 2006). Glyphosate and aminomethyl phosphonic acid (AMPA), its primary transformation product, persist in the environment because of the inert nature of the carbon-phosphorus bond, which causes strong enzyme inhibition and thus hinders further degradation. Glyphosate and AMPA adsorb to clay or organic matter; consequently, both tend to accumulate in soils. Erosion, irrigation and rain events mobilize glyphosate and AMPA, explaining their presence in surface and groundwaters as well as sediments (Van Bruggen et al., 2018). In combination with surfactants (e.g., polyethoxylated tallowamine), glyphosate impacts aquatic fauna at different trophic levels (microalgae, protozoa, mussels, crustaceans, frogs, and fish). Conversely, it poses a low acute toxicity to amphibians, reptile, and mammals. Studies on the chronic exposure of humans to glyphosate provided inconclusive results and more research is needed to determine its safety (Agostini et al., 2020).

MCPA and 2,4-D

Both 4-dichlorophenoxy acetic acid (2,4-D) and 2-methyl-4-chlorophenoxyacetic acid (MCPA) are the most common phenoxy acids applied for post-emergent control of terrestrial and aquatic broadleaf weeds. These acids mimic indoleacetic acid, a growth phytohormone. When sprayed on broadleaf weeds at high concentrations, 2,4-D and MCPA stimulate a rapid, uncontrolled growth leading to tissue death. Because of their high solubility, 2,4-D and MCPA stay in water rather than partitioning to solids, which implies a high environmental mobility and explains the frequent detection of these acids in surface waters and aquifers worldwide (Muszyński et al., 2020). Biodegradation is the main removal mechanism for phenoxy acids in aquatic systems. Nevertheless, lack of microbial acclimatation or oxygen limitations can lead to their persistence, particularly in groundwater. Both 2,4-D and MCPA exert low toxicity toward aquatic fauna (Britt et al., 2003) and no sufficient relationship, at environmentally relevant concentrations, has been found between 2,4-D and MCPA and carcinogenic effects on humans.

Amitrole

Amitrole (3-amino-1,2,4-triazole) is used to control grass and broadleaf weeds. Amitrole accumulates in soils and, because of its high solubility, may leach to surface water and groundwaters as a result of runoff. Microbes in soil, sediments and wastewater processes degrade amitrole under aerobic conditions (European Food Safety Authority, 2014). Owing to its solubility and hydrophilicity, no significant bioaccumulation of amitrole has been reported in animals and humans.

Endosulfan

Endosulfan (6,7,8,9,10,10-hexachloro-1,5,5a,6,9,9a-hexahydro-6,9-methano-2,4,3-benzodioxathiepine-3-oxide) is an organochlorine biocide used for controlling pests and mites by generating neurotoxic effects (i.e., hyperstimulation) (Berntssen et al., 2017). Upon application, receiving soils act as a primary reservoir of endosulfan in the environment; because of its hydrophobic properties, endosulfan has shown high mobility across environmental compartments. Classified as a semi-volatile compound, endosulfan is prone to evaporation; subsequent atmospheric transportation may occur, resulting in wide dispersion and remote deposition from application sites. Endosulfan transfers to water bodies through runoff and favors accumulation onto sediments once in the water column (Weber et al., 2010). Both microbial and abiotic processes transform endosulfan in the environment: bacteria oxidize endosulfan to the respective sulfate, whereas endosulfan diol forms after alkaline hydrolysis. These intermediates exert similar toxic effects on biota and humans. Chronic exposure to endosulfan leads to bioaccumulation in fish; acute exposure results in neurotoxicity (hyperactivity and convulsions) in animals and humans; severe poisoning can lead to organ failure and death.

Per and poly-fluorinated chemicals

Per- and polyfluoroalkyl substances (PFAS) are organic (aliphatic) compounds on which fluorine atoms replace all the hydrogen substituents in the moiety (Fig. 2). The covalent bond between carbon and fluorine provides to the perfluoroalkyl molecules both strong chemical and thermal resistance as well as oil- and water-repellent properties.

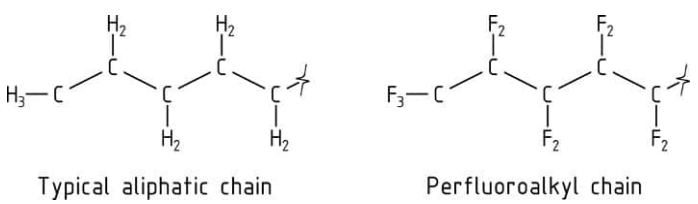

Fig. 2 General difference from aliphatic to perfluoroalkyl chains.

Because of these distinctive features, PFAS have resulted in varying commercial applications such as stain-resistant coatings, water-resistant fabrics, metal plating paints, pesticides, fluoropolymers, greaseproof paper, and aqueous film-forming foams used in firefighting (Alexander et al., 2008). PFAS enter aquatic environments either through direct emissions caused by manufacture, usage, and disposal of commercial products (Fig. 1), or indirect emissions from the breakdown of precursor substances, mainly larger derivatives and polymers both of which include perfluoroalkyl moieties (Prevedouros et al., 2006). While PFAS represent a wide chemical family comprising 268 individual compounds, special attention is paid to long-chain perfluoroalkyl carboxylic or sulfonic acids for regulatory purpose (Buck et al., 2011). Present in the ng L^{-1} level, perfluorooctanoic acid (PFOA) and perfluorooctanesulfonate (PFOS) are the most frequently detected fluorinated substances in ambient water (Arvaniti and Stasinakis, 2015).

Most of the PFAS withstand conventional wastewater treatment processes and effluents can contain PFAS originating from domestic and industrial sources. Furthermore, PFAS can be subject to negative removal efficiency. When comparing influent with final effluent concentrations, several studies have reported increasing concentrations of perfluoroalkyl acids (PFAAs) such as perfluorocarboxylic acids (PFCA) and perfluorosulfonic acids (PFSA) (Arvaniti et al., 2014; Filipovic and Berger, 2015). These concentration increments could be attributed to breakdown of polymers (e.g., such as polyfluoroalkyl phosphoric acid esters, fluorotelomer sulfonic acids, fluorotelomer sulfonates, and fluorotelomer alcohols) which act as PFAS precursors. Coggan et al. (2019) conducted an extensive PFAS sampling campaign across 19 Australian wastewater works. The total concentration of 21 targeted PFAS rose in both aqueous and solid phases through the treatment processes from influent to primary effluent, secondary effluent, final effluent, and recycled water. These concentration increments in treated effluents represents a continuous discharge of short-chain PFAS into receiving waters.

Environmental impact and potential risk to human health

Because of their profuse use, PFAS accumulate in aquatic environments and have consistently been detected in biota and humans. The accumulation of PFAS in both surface water and groundwater can be attributed to the limited removal efficiencies of conventional treatment processes (Kucharzyk et al., 2017). Of particular concern is the PFAS presence in water bodies where abstraction for drinking purposes takes place. Cousins et al. (2016) concluded that PFAS present in groundwater will result in contamination difficult to treat.

In terms of human exposure, the European Food Safety Authority Panel on Contaminants in the Food Chain defined tolerable weekly intakes of 6 and 13 ng kg^{-1} bodyweight for PFOA and PFOS, respectively (Knutsen et al., 2018). For both compounds, the Panel reported higher doses than the recommended intakes across a significant fraction of the population. Rising serum total cholesterol levels (PFOA and PFOS) and attenuation of immune response in children's vaccinations (PFOS) are the critical effects observed in humans.

Pharmaceuticals

Contrasting with other organic micropollutants, pharmaceuticals, at least those used for human therapy, have a number of distinctions preventing stringent regulation of their emission to the environment.

Drug discoveries from the 1950s onward contributed immensely to the well-being of society and significantly increased life expectancy (Rowland et al., 2012). Furthermore, medical progress yielded earlier diagnoses, leading to extended drug therapy regimes aimed at postponing disease onset or prolonging the morbidity period (Fries, 2005). Generally referred as pharmaceuticalisation of society (Conrad, 2005), the gained health improvements came at the cost of global dependence on this class of chemicals along with the interrelated environmental ramifications. Essentially, the human health benefits redeemed by society make the regulation of emission of pharmaceuticals products a highly ethical issue. The solution will require a multifaceted response from source control to end of pipe abatement (Kümmerer, 2019; OECD, 2019; European Commission, 2020b).

Other environmentally relevant aspects unique to pharmaceuticals are the sheer number of Active Pharmaceutical Ingredients (APIs) available from a global list of over 3000 APIs, their intended biological actions and their interactions when administered concurrently. By definition, therapeutic drugs are designed to have a specific biological effect, potentially replicated on organisms populating aquatic environments receiving discharge of pharmaceutical residue.

Lastly, numerous monographs on drug interaction on human patients are routinely consulted to prevent hazardous side effects caused by administration of multiple APIs; yet, knowledge on the consequences of discharging cocktails of drugs to aquatic environments is currently limited. Concerningly, the Joint Research Centre of the European Commission rates the risk of mixtures three orders of magnitude higher than exposure to individual pharmaceuticals, clearly stressing the need for extensive environmental impact research.

Regulation and management

Agencies such as the European Medicine Agency (EMA) and the Food and Drugs Administration (FDA) are responsible for the Environmental Risk Assessment of new drugs for which marketing authorization is sought. However, determinations of these assessments are merely informative and neither agencies can take into consideration adverse environmental ramifications in their decision to approve novel human pharmaceuticals (OECD, 2019). Furthermore, the mandatory submission of environmental risk

Table 1 Timeline of inclusion of pharmaceuticals to the watch list of Priority Substances Directive 2013/39/EC.

Drug class	*Year of inclusion to watch list*			
	2013[a]	*2015*[b]	*2018*[c]	*2020*[d]
NSAID	Diclofenac	Diclofenac		
Estrogens	17α-ethinylestradiol (EE2)	17α-ethinylestradiol (EE2)	17α-ethinylestradiol (EE2)	
	17β-estradiol (E2)	17β-estradiol (E2)	17β-estradiol (E2))	
Macrolide antibacterials		Erythromycin	Erythromycin	
		Clarithromycin	Clarithromycin	
		Azithromycin	Azithromycin	
			Amoxicillin	Amoxicillin
			Ciprofloxacin	Ciprofloxacin
Sulfonamides and trimethoprims				Sulfamethoxazole
				Trimethoprim
Psychoanaleptic antidepressants				Venlafaxine and *O*-desmethylvenlafaxine
Antifungal azole compounds				Clotrimazole
				Fluconazole
				Miconazole

assessments as part of the dossier for marketing authorization applications has only been recently introduced; consequently, for the majority of legacy pharmaceuticals on the market, their potential ecotoxicological impact on receiving environments remains unknown (Kümmerer, 2019). Essentially, emission of human pharmaceuticals to the environment arising from utilization remains unregulated. Nonetheless, recent actions taken by the European Commission clearly demonstrate that future policy will be guided by determinations of monitoring programs. In fact, periodic revisions to the watch list stipulated by the Priority Substance Directive (European Union, 2013; European Commission, 2015, 2018) have seen the addition of numerous pharmaceutical products, particularly antibacterial drugs (Table 1), intended to inform the decision making process.

Market authorization for veterinary drugs constitute another equally important source of emission, albeit access to market for veterinary drugs is more stringent and environmental impacts are taken into consideration in the decision to grant marketing authorizations.

Sources of environmental loading and fate in ambient water

Municipal wastewater treatment plants constitute the primary source of discharge of human pharmaceuticals to aquatic environments (Fig. 1). Administered pharmaceuticals are excreted by patients in various percentages of the original dose either as unchanged parent compounds, metabolites or conjugates (Petrie et al., 2015). Yet another form of emission is the disposal of unused or expired pharmaceuticals into sewers or in household waste (Ruhoy and Daughton, 2008); fortunately, numerous national take-back schemes have been implemented to address the latter form of emission (OECD, 2019). Although healthcare facilities represent another important source of discharge to wastewater, their share of emission constitutes a small fraction of the total environmental loading (OECD, 2019). Veterinary applications are yet another significant, albeit markedly more diffuse, source of pharmaceutical emission (Kümmerer, 2019). The Non-Steroidal Anti-Inflammatory Drug (NSAID) diclofenac, for example, is commonly administered to livestock.

Wastewater treatment efficacy varies considerably among pharmaceuticals, ranging from complete removal to negative removal rates. The latter consist of an increase in concentration of some compounds caused by the action of organisms in biological wastewater treatment. Metabolites and conjugates present in influent streams can undergo deconjugation, converting back to the original parent compound, thus incrementing the concentration between influent and effluent (Evgenidou et al., 2015; Daughton, 2016). Diclofenac is one of the chemicals known to undergo deconjugation in biological wastewater treatment processes (Peake et al., 2015).

Numerous tertiary treatment technologies designed for pharmaceutical removal exist. Processes revolve around filtration, adsorption and oxidation, often used in various combinations. Activated carbon in granular or powdered forms remains a viable choice but innovative solutions, for instance filtration through media loaded with enzymes, are advancing toward commercialization. In fact, Gonzalez-Gil et al. (2020) suggest that enzymatic pathways might provide viable solutions to treat emissions of pharmaceuticals. While wastewater treatment technologies are available, their efficacy varies substantially across the spectrum of physicochemical properties of pharmaceuticals and numerous compounds show recalcitrance to even the most effective solutions.

In general, pharmaceuticals are considered ubiquitous in aquatic environments (Kümmerer, 2019; OECD, 2019). Among the most commonly detected are the antiepileptic carbamazepine, NSAIDs diclofenac and ibuprofen, the antibiotic sulfamethoxazole and the antidepressant fluoxetine. Furthermore, numerous biotic and abiotic transformation products from wastewater treatment processes are known to be persistent in the environment. In the water column, most pharmaceuticals are susceptible to natural degradation mechanisms such as sorption, photolysis and hydrolysis with varying dissipation half-life depending on physicochemical characteristics (Peake et al., 2015). Nevertheless, the unremitting flux of pharmaceuticals in aquatic environments causes a pseudo-persistence effect.

Environmental impact and potential risk to human health

As affirmed by the WHO (2012), risk to human health via ingestion of contaminated drinking water is very low, with concentrations generally 1000-fold lower than minimum therapeutic doses. While assumed to be well within safety exposure limits, trace levels in drinking water are continuously changing according to utilization patterns (Oosterhuis et al., 2013) and variations in national formularies. An important example is the increased treatment of cancer patients with antineoplastic drugs as outpatients, leading to discharge of potent drug residues into municipal wastewater treatment systems that are largely inadequate to remove these chemicals (Mompelat et al., 2009). Consequently, research on the potential ramifications of chronic human exposure to trace levels of pharmaceuticals and their mixtures in drinking water remain a priority.

While outside the context of aquatic environment, the principal case of environmental impact relates to the near extinction (>95%) of the Asian *Gyps* vulture population caused by diclofenac. The NSAID, administered as a veterinary drug, caused liver damage to the scavengers feeding on carcasses of medicated livestock (Arnold et al., 2014; Peake et al., 2015). Within the aquatic environment, the impact of pharmaceutical emissions takes numerous facets. For instance, behavioral change, namely the inhibition to hazard perception, in fish species has been linked to exposure to psychiatric drugs (Arnold et al., 2014; OECD, 2019). Yet, the most acute impact is caused by estrogenic compounds. While endogenous oestrogens are excreted by humans and can also occur naturally in the environment, emissions of synthetic steroid hormones 17β-estradiol (E2) and 17α-ethinylestradiol (EE2), administered as sex-hormones, account for most of the estrogenicity of receiving aquatic environments. Rapid biodegradation (0.2–9 days at 20 °C) transforms E2 to estrogen in the water column whereas EE2 is primarily broken down by photolysis. Nonetheless, both compounds are liable to bioaccumulation and biomagnification (Stasinakis and Gatidou, 2019). Furthermore, the toxicity of these oestrogens expresses in the production of vitellogenin in fish, causing the feminisation of male fish (Peake et al., 2015), where trace concentrations of 5–6 μg L^{-1} are sufficient to cause crashes in fathead minnow's populations (Arnold et al., 2014; OECD, 2019). With the exception of estrogens E2 and EE2, based on the current body of knowledge bioaccumulation in aquatic biota does not appear to be a cause of concern even for the most ubiquitous pharmaceutical substances. With regards to human health, the ED characteristics of EE2 are certainly of concern to the European Commission as the substance will be added to the first watchlist for drinking water by 12 January 2022 for the purpose of informing human health risk assessment (European Union, 2020).

Surfactants and personal care products

Among the environmental contaminants present in cosmetics, personal hygiene products and detergents, the compounds causing most reason for concern are triclosan, nonylphenol and the parabens. Endocrine disrupting characteristics are the primary toxicity hazard across all of these compounds (Stasinakis and Gatidou, 2019).

Both detergents and Personal Care Products (PCPs) reach the aquatic environment primarily through influent to wastewater treatment or disposal to municipal refuse and subsequent landfill (Fig. 1). Analogous to pharmaceuticals, surfactants and PCP, at least where wastewater treatment removal is not completely effective, are prone to the pseudo-persistence effect caused by continuous environmental loading.

Personal care products: Triclosan

Triclosan, an halogenated microbial disinfectant used in PCPs, is designed to permeate cell walls of bacteria and target various cell organs, including synthesis of RNA (Hontela and Habibi, 2013). Wastewater is the main pathway of environmental loading of triclosan; removal rates vary from 50% to 80% by conventional treatment technologies (Petrie et al., 2015). However, disinfection processes can lead to the formation of chlorinated triclosan derivatives, potentially augmenting the antimicrobial and ED characteristics of this universal product (Evgenidou et al., 2015). Another concerning aspect of the environmental fate of triclosan is the degradation by photolysis. Stasinakis and Gatidou (2019) report that this natural degradation process on triclosan can cause

the generation of dioxins, toxic organic compounds with high persistence properties, high bioaccumulation potential along the food chain and substantial human health impact, including carcinogenicity.

Personal care products: Parabens

The parabens, a class of preservatives inhibiting growth of fungi and yeast in cosmetics, are primarily represented by four substances, ethyl-, butyl-, propyl- and methyl-paraben. Petrie et al. (2015) reports presence of all four parabens in wastewater influent streams in the United Kingdom but high removal rates (>80%) by conventional wastewater treatment. The potential impact of parabens to receiving aquatic environments is due to their, albeit weak, ED characteristics. Furthermore, parabens react strongly with chlorine in disinfection processes, forming chlorinated by-products with higher acute toxicity than their ED potential (Evgenidou et al., 2015). Essentially, despite the extensive reliance on parabens for preservation of PCP, paucity of knowledge on their potential impact to chronic exposure prevents accurate risk assessment.

Surfactants: Nonylphenol

Nonylphenol derives from detergents. Alkylphenol ethoxylates, some of the most widely used surfactants, are primarily constituted of nonylphenol ethoxylates. Microbial breakdown of the latter results in the release of nonylphenol (Kennedy et al., 2013; Stasinakis and Gatidou, 2019). Occurrence of nonylphenol in wastewater effluent from activated sludge plants (0–35 $\mu g\ L^{-1}$), as well as river water (3.0 $\mu g\ L^{-1}$) and groundwater (2.0 $\mu g\ L^{-1}$) has been documented for four decades (Commission of the European Communities, 1981). Although nonylphenol is rapidly degraded in the aquatic environment by photolysis (10–15 h half-life), it partitions strongly to sediment (Stasinakis and Gatidou, 2019). Furthermore, because of continuous discharge to wastewater, the substance is subject to pseudo-persistence effects. Bioaccumulation of nonylphenol in mussels (*Mytilus edulis*) has also been known for at least three decades (Commission of the European Communities, 1991). More recent research demonstrated bioaccumulation by freshwater macroalgae (*Cladophora glomerata*) and microalgae (*Chlorella vulgaris*) and consequent biomagnification in fathead minnow and subsequent trophic levels (Sun et al., 2014). Endocrine disruption characteristics are the primary cause of concern relating to nonylphenol (Kennedy et al., 2013; European Union, 2020).

Among the most researched surfactants and PCPs, nonylphenol is the only substance currently regulated in Europe by the Priority Substances Directive, stipulating a maximum allowable concentration of 2.0 $\mu g\ L^{-1}$ for inland surface waters (European Union, 2013). While the WHO proposed the consideration of nonylphenol (at a value of 3.0 $\mu g\ L^{-1}$) as a benchmark substance for ED risk assessment for drinking water, at this time the European Commission opted for the inclusion of the substance to the first watch list of contaminants of emerging concern. The watch list, to be formalized by 12 January 2022, will indicate guidance values for nonylphenol. Furthermore, Member States operating drinking water supplies exceeding the established guidance value will be required to initiate corrective measures (European Union, 2020).

Global regulatory framework

Perhaps the most significant problem in the regulation of emission of organic micropollutants is the sheer number of chemical substances present on the market. Exacerbating the challenge even further, the applications for these substances vary immensely, from endless functions in the case of PFCs to specific utilization for pharmaceutical ingredients. Aiming to achieve unity in responsibility across the planet, Multilateral Environmental Agreements (MEA) offer mechanisms for Parties—generally States or International Organisations—to conform on the regulatory front, particularly important where the fate of micropollutants has transboundary characteristics. These Treaties, brokered under the aegis of the United Nations Environment Programme (UNEP), are widely ratified across the world (Diamond et al., 2015).

Chemical legislation regulating emissions to the environment expands substantially at regional jurisdiction levels. For instance, in Europe, the Priority Substances Directive (European Union, 2013) governs policy action necessary to manage chemical pollution to the environment. Further, on 16 December 2020, the European Parliament adopted a recast of the Drinking Water Directive (European Union, 2020), which formalizes the inclusion of micropollutants to a watch list mechanism aimed at informing further policy decisions. The latter legislation clearly demonstrates the growing concern on emerging chemical pollutants. Nonetheless, this abridged appraisal focuses on global coverage only with particular emphasis on one specific MEA, more pertinent to micropollutants, the Stockholm Convention on Persistent Organic Pollutants (POPs).

Persistent organic pollutants: Original 12 chemicals and recent additions to the Stockholm convention annexes

Growing concerns about environmental and human health risk posed by organic chemicals showing high persistency in the environment, high partitioning to sediment and biota, bioaccumulation and biomagnification, extended range of atmospheric transport and, most importantly, high toxicity warranted the devising of a global response. On 25 May 1995, the UNEP Governing Council (1995) issued Decision 18/32, inviting a series of assessments for 12 POPs to be carried out under the direction of the Intergovernmental Forum on Chemical Safety. The resulting recommendations issued by the Forum led to the adoption of the Stockholm Convention on 23 May 2001. However, in order to enter into force, the Treaty required a minimum of 50 statutory

instruments of ratification, acceptance, approval or accession submitted by Parties to the Convention. On 17 May 2004 the Treaty became legally binding to the Parties and, as at January 2021, the Stockholm Convention had 152 Parties and 184 Signatories.

Undoubtedly, in addition to the socio-economic aspects, the formulation of international conventions necessitates exhaustive assessments of the hazard posed by chemical substances. In the case of the Stockholm Convention, 9 years passed before the Treaty became legally binding, despite the fact that substantial knowledge on the environmental and human health risk was already available for the original 12 POPs. While the lengthy process is necessary to guarantee the effectiveness of these global policies, the delayed action meant that, because of the persistent nature of POPs, legacy emission and accumulation in sediment and biota sinks continued uninterrupted during the legislative period (Hung et al., 2016).

The initial 12 POPs consisted of nine pesticides, two industrial chemicals, one of which is also used as a pesticide, and two incomplete combustion by-products (Table 2). The listing of chemicals is based on a three-tier system: Annex A lists prohibited substances and Annex B stipulates restriction of production and use. Whereas Annex A and Annex B address intentional production, Annex C calls for (i) the formulation of action plans at regional levels to address unintentional production from anthropogenic sources, and (ii) the application of Best Available Techniques (BAT) to abate emissions of these by-products.

Periodical reviews of POPs, conducted by the appointed POP Review Committee, are requested by Parties to the Conventions for listing of new chemicals based on the criteria specified in Annex D. To date, a further 18 chemicals have been added to the list; interestingly, all but one, PFOS and PFOS-F, are listed in Annex A (Table 2). Another criterion of considerable relevance to

Table 2 List of Persistent Organic Pollutants (POPs) under the Stockholm Convention as at January 2021 categorized by usage and Annex listing. Note that substances may be listed under multiple application categories.

	Pesticide by-products	Pesticides	Flame retardants	Insulation coating, plasticisers, solvents and lubricants	Incomplete combustion by-products
Initial 12 (legacy) POPs				HCB	PCDD

micropollutants is stipulated in Part [b] of Annex E, namely the profiling of risk caused by simultaneous exposure to multiple chemicals. As knowledge on toxicological interaction and ED potential of mixtures expands, more micropollutants will be proposed for review.

The Stockholm Convention provided a concerted action to address the global risk posed by legacy POPs. Despite the challenges associated by a Global Monitoring Plan (Magulova and Priceputu, 2016), the second global monitoring report (UNEP, 2017) shows declining environmental concentrations of legacy POPs, a clear demonstration of the success of this MEA.

PFOS and PFOA inclusion in the Stockholm convention annexes

Although not present in the initial set of POPs, flame retardants featured extensively in the subsequent 18 additions to the Stockholm Convention. A total of nine flame retardants were included since 2009, all but one becoming prohibited substances under Annex A (Table 2). Whereas PFOS and PFOS-F were listed in Annex B in 2009 (UNEP, 2009), the decision to add PFOA compounds to Annex A was reached in 2019, albeit with abundant exemptions (UNEP, 2019).

In the context of water pollution, the content of PFOA in firefighting foams is of primary importance. As part of the listing of PFOA, the Convention of the Parties included and addendum stipulating that, no later than 2025, the use of PFOA containing firefighting foams must be restricted to sites providing surface water drainage containment. Another amendment to the Convention relevant to water pollution was implement in 2011. The amendment, addressing the Global Monitoring Plan, called for the establishment of a monitoring program for PFOS in surface water with the aim of informing future evaluations (UNEP, 2011).

Synthesis

The intricacy of sources, applications and pathways of emission of organic micropollutants to the aquatic environment was presented in this article. Due to the wide diversity among organic micropollutants, environmental impacts and the hazard posed to human health vary substantially and are poorly understood for many compounds. Table 3 provides a succinct summary of these

Table 3 Summary of primary sources, pathways of emission, environmental fate and human health hazard for four classes of organic micropollutants.

Class	*Applications and sources*	*Pathways of emission*	*Fate*	*Environmental impact*	*Human health hazard*
PFAS (PFOS and PFOA)	Firefighting (aqueous film-forming foams), flame retardant additives, plasticisers, textile coating (stain-resistant and water-resistant coatings) pesticides, fluoropolymers, greaseproof paper	Dispersal of aqueous film-forming foams via urban drainage to WWT or storm overflow Discharge in WWT treated effluent WWT sludge spreading to land Textile coating is a primary source of legacy emissions	Prone to negative removal efficiency effect Highly persistent in the aquatic environment and resistant to natural degradation processes	Classed as POPs, with numerous potential impacts to receiving aquatic environments. Groundwater contamination difficult to treat	Tolerable weekly intakes of 6 and 13 ng kg^{-1} bodyweight for PFOA and PFOS[a] Serum total cholesterol levels (PFOA and PFOS) and attenuation of immune response in children's vaccinations (PFOS)
Biocides	Diffuse application to land or spot application	Runoff from land and urban areas Urban drainage to WWT or storm overflow Discharge in WWT treated effluent	Persistence and degradation vary, governed by substance physicochemical characteristics	Bioaccumulation and toxicity vary, governed by substance physicochemical characteristics	Toxicity varies, governed by substance physicochemical characteristics. Primary route of exposure through the food chain
Pharmaceuticals	Over the counter sales and prescription of human pharmaceuticals. Veterinary drugs administration to livestock	Discharge to wastewater Disposal of unused medicines to wastewater or landfill Discharge in WWT treated effluent WWT sludge spreading to land Runoff containing animal excreta from medicated livestock	Persistence generally low. Both persistence and degradation governed by substance physicochemical characteristics Subject to pseudo-persistence effect Negative removal efficiency effect known for some compounds	Bioaccumulation and toxicity vary but evidence of widespread impact is lacking. ED impact on fish by estrogenic compounds remains the primary concern	Acute exposure via drinking water unlikely. However, knowledge on effect of chronic exposure to trace concentrations is lacking

Table 3 (Continued)

Class	*Applications and sources*	*Pathways of emission*	*Fate*	*Environmental impact*	*Human health hazard*
Surfactants (nonylphenol)	Detergents, industrial and household applications	Discharge to wastewater WWT sludge spreading to land Disposal to landfill	Rapidly photodegraded (10–15 h half-life) but partitions strongly to sediments[b]. Subject to pseudo-persistence effect	Substantial evidence of bioaccumulation, biomagnification and ED properties. Maximum allowable concentration of 2.0 $\mu g\ L^{-1}$ for inland surface waters[c]	Recommended benchmark substance for ED risk assessment for drinking water by the WHO[d]
PCPs (triclosan and parabens)	Beautification and personal hygiene	Discharge to wastewater WWT sludge spreading to land Disposal to landfill	High removal by conventional WWT. PCPs can generate by-products with greater ED or toxicity potential during disinfection. Triclosan shown potential to generate dioxins by photolysis	ED characteristics. Triclosan bioaccumulates strongly	Potential exposure to triclosan, a possible carcinogen, through the food chain Information on parabens is lacking

Abbreviations: ED, endocrine disruptor; PCP, personal care product; PFAS, Per- and polyfluoroalkyl substances; PFOA, perfluorooctanoic acid, its salts and PFOA-related compounds; PFOS, perfluorooctane sulfonic acid and its salts; POP, persistent organic pollutant; WHO, World Health Organisation; WWT, wastewater treatment.

aspects of organic micropollutants. With the exemption of pharmaceutical products for human and animal utilization, knowledge of the impact on the environment in terms of PBT and ED properties has been well characterized for PFC and biocides and it is relatively well understood for the most common surfactants and PCPs. Largely because of the vast number of pharmaceuticals available on the market and the richness in their chemical structure diversity, knowledge of the potential hazard by trace levels of contamination of drugs to the aquatic environment is severely limited.

However, concern is rapidly shifting from the adverse effect caused by individual substances to potential amplifications of impacts generated by synergies and interactions of mixtures of organic micropollutants. This is a plausible concern warranted by extensive knowledge available on drug interaction. Yet, knowledge on the interactions of hundreds of pharmaceuticals emitted in unison is negligeable and the concern on chemical mixtures in the aquatic environment rightly extends to possible synergies between the various classes of organic micropollutants. Exacerbating the problem further, particularly so for aquatic environments, is the pseudo-persistence effect caused by continuous discharge of trace levels of some micropollutants, namely surfactants, PCPs, pharmaceuticals and short chain PFAS.

Because of these complexities, the problem of organic micropollutants will require an array of multifaceted solutions, among them improving removal technologies, greening chemistry and changing socio-economic models. The progress made by the Stockholm Convention demonstrates that multilateral alliances can provide systematic frameworks to achieve change; nevertheless, command and control currently remains the most viable alternative to address the emission of organic micropollutants.

Glossary

Feeding guild A group of unrelated species that exploit the same environmental resources in a similar manner (e.g., detritivores, benthivores, herbivores, and so on).
Food chain: a linear network of trophic transfer links, within a food web, starting from a producer organism and ending at an apex predator species, detritivore, or decomposer.
Hazard A potential source of danger and/or harm.
Risk The likelihood that harm from a specific hazard will occur, and this is typically assessed by considering both the hazard and exposure to that hazard.
Trophic transfer The process by which constituents, including contaminants, are transferred from one trophic level to another.

Introduction

Micro-sized particles are ubiquitous in all ecosystems and, as a consequence, all living organisms are exposed to such particles. Most of these particles have a natural origin (e.g., spores, pollen, sand, silt or clay), but as a result of human activities, anthropogenic micro-sized particles are also present in the environment (e.g., particulate matter from combustion processes or microplastics) (Ogonowski et al., 2018). The threat of microplastic pollution is only starting to be recognized by the wider public (Henderson and Green, 2020). This contrasts with the public awareness of macroplastic pollution. The presence of plastic litter in the environment has caught the attention of the general public as well as policymakers. The collection of plastic debris on shores and/or in waterbodies by hand or using mechanical implements has demonstrated the extent of macroplastic pollution in the environment, as well as the dangers to wildlife through entanglement or following ingestion. Yet, a more insidious danger relates to the formation of smaller (less than 5 mm) micro- and nano-sized plastics from macroplastic waste.

Plastics are relatively new materials. Commercial production of plastics started in the early 1900s with Bakelite, and global production has increased from 5 million tonnes in the 1950s (Andrady and Neal, 2009) to 368 million tonnes in 2018 (Plastics Europe, 2020), a compound annual growth rate in production of more than 8% (Geyer et al., 2017). Characteristics such as durability, light weight, moldability and low production costs, have rapidly made plastics the key material of the current time (Thompson et al., 2009).

The term "plastic" refers to a range of synthetic materials that are mostly thermoplastic polymers of high molecular weight that can be moulded into films, fibers, filaments and other structures. Examples of commonly encountered plastics are polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinylchloride (PVC), polyethylene terephthalate (PET), and polyester, polyamide, and acrylic (PP&A). These different plastics share similar moldability and durability, but have distinct physicochemical properties,

which will determine their environmental fate and impacts on living organisms (Wang and Wang, 2018). For example, depending on its density a plastic may float or settle in the sediment, and the resulting differences in distribution will determine which organisms are exposed to these plastics. The vast majority of plastics produced are made using fossil fuels, and are not biodegradable (Geyer et al., 2017). They therefore accumulate rather than decompose in the environment unless recycled or incinerated. It has been estimated that if current production and waste management trends continue, roughly 12,000 megatonnes of plastic waste will be in landfills or in the natural environment by 2050 (Geyer et al., 2017).

Notwithstanding the environmental threat posed by macroplastics, a more insidious risk of plastics relates to small plastic particles, referred to as micro- and nanoplastics. The term microplastic was initially used rather loosely to indicate small pieces of plastics found in the natural environment (Thompson et al., 2004). A more advanced definition was proposed by Frias and Nash (2019) who described a microplastic particle as a "synthetic solid particle or polymeric matrix, with regular or irregular shape and with a size ranging from 1 μm to 5 mm, of either primary or secondary manufacturing origin, which is insoluble in water". Plastic particles smaller than 1 μm diameter are referred to as nanoplastics (Koelmans et al., 2019; Triebskorn et al., 2019).

Primary microplastics are those plastics that are manufactured as microparticles. Microbeads present in, for example, cosmetics or personal care products such as toothpaste or facial scrubs are typical primary microplastics. The majority of microbeads (93%) are made from polyethylene (UNEP, 2015). Napper et al. (2015) estimated that up to 94,500 particles can enter the environment per single use of a facial scrub. The use of microbeads in cosmetics is increasingly subject to restrictions in many countries, but it is expected that plastic microbeads, intact and/or after fragmentation into nanoparticles, will still be present in environmental samples for a long time due to their durability.

Secondary microplastics include plastic fragments and fibers, which are released when larger plastic objects disintegrate. The fragmentation of plastics into smaller pieces has been described as a slow process that is caused by exposure to UV light (i.e., photodegradation), heat (Andrady, 2011), wave-action and physical abrasion (Browne et al., 2011), or a combination of these processes. For example, due to wear-and-tear microplastics are released from tyres (Kole et al., 2017) and the artificial grass used in sports pitches (Mahon et al., 2014). Plastics and plastic fragments are highly durable and, depending on their chemical makeup, have been speculated to persist for hundreds of years, although accurate information on persistence is notably lacking (Ward and Reddy, 2020). Plastic microfibers from textiles are particularly common in environmental samples (Browne et al., 2011; Zambrano et al., 2020), including marine (Gago et al., 2018), freshwater (Miller et al., 2017), and indoor or outdoor atmospheric samples (Gasperi et al., 2018; Liu et al., 2019a). Most microfibers are released during washing and drying of textiles by consumers (Browne et al., 2011). The scope for microfiber release is subject to some debate, but it is estimated that a 6 kg wash load may release 700,000 fibers from an acrylic fabric, 500,000 fibers from a polyester fabric and 140,000 fibers from a polyester-cotton blend (Napper and Thompson, 2016). Other authors found in excess of 6 million microfibers per 5 kg wash load (De Falco et al., 2018). The former study referred to fibers between 12 and 18 μm in diameter, and 5–8 mm in length, while the latter considered fibers between 0.3 and 0.5 mm in length. Thus, small (<1 mm) microfibers in particular are generated in very large amounts during the laundry process. To make matters worse, tumble drying can subsequently release even more (three to four times) polyester microfibers than washing (Pirc et al., 2016). Notwithstanding the potential of some wastewater treatment plants to remove high percentages of microplastics, large numbers are likely to pass through filtration systems because of their small size (Horton et al., 2017). Furthermore, those microfibers (and other microplastics) contained within the sludges of wastewater treatment plants may still enter the freshwater environment at a later stage following application of the sludge as a soil improver (Horton et al., 2017). Thus, it is not surprising that microfibers are highly abundant in environmental samples (Browne et al., 2011; Zambrano et al., 2020).

It is now widely accepted that microplastics are widespread in terrestrial, marine and freshwater environments. The knowledge concerning the distribution and fate of microplastics and their impacts on the living organisms is rapidly increasing. However, major knowledge gaps remain, particularly for the freshwater environment. The aim of this chapter is to introduce some of the current understanding concerning micro- and nano-plastics in the freshwater environment, focusing on two key issues: Monitoring of distribution and assessment of biological impacts.

Monitoring microplastic in the freshwater environment

A prerequisite for understanding the ecological impacts of plastics is good quantitative knowledge of the distribution of plastics in the environment. Here we will discuss some of the current microplastic monitoring approaches and their shortfalls, but also the important finding that microplastics are ubiquitous in the natural environment.

The technology to monitor microplastics in the environment is not yet standardized

Notwithstanding a drive to recycle and/or incinerate plastic waste, plastic litter is now pervasive in the environment (Gall and Thompson, 2015). Indeed, plastics are so prevalent that they are now referred to as a stratigraphic indicator for the Anthropocene (Waters et al., 2016). The visible presence of macroplastic waste has become an issue of public and policy concern. Plastics are predominantly of terrestrial origin, and enter the freshwater environment either as diffuse, general litter, or through specific point sources such as wastewater treatment discharges (Horton et al., 2017). In the environment, plastics tend to fragment, resulting in the formation of smaller, secondary plastics, including micro- and nanoplastics. These small plastic particles are now considered ubiquitous in the environment (Rochman, 2018). Indeed, multiple studies have reported the presence of microplastics in air, food

and drinking water samples (Koelmans et al., 2019), as well as in far flung places such as the deep sea (Van Cauwenberghe et al., 2013) and the Arctic (Cózar et al., 2017). Based on their pervasive presence in the freshwater environment, the ability to adsorb other pollutants and the potential to cause negative impacts when ingested by organisms, Wagner et al. (2014) proposed to categorize microplastics as Contaminants of Emerging Concern (CECs) for the freshwater environment.

Actual concentrations of microplastics in the freshwater environment can vary dramatically, depending on factors such as water depth, currents, and wind exposure (Horton et al., 2017). Tens to hundreds of microplastic particles have been found per kg of dry sediment (Horton et al., 2017), while water samples can contain anything between 1×10^{-2} and 1×10^{8} particles per m^3, with highest concentrations found in wastewater treatment effluent (Koelmans et al., 2019). High microplastic concentrations tend to be associated with urbanization (Horton et al., 2017). However, it is likely that a major determinant of the variation in microplastic concentration is the sampling technology. Monitoring of microplastics in the environment is still under development, and standardized monitoring protocols and units of measurement are lacking (Rodrigues et al., 2018; Koelmans et al., 2019). Sampling of microplastics in the water column typically involves the use of filters with mesh sizes varying between 50 μm and 500 μm. Not surprisingly, the abundance of plastics is far greater when filters with a small mesh size are used; however, such filters easily clog up with non-plastic microparticles (Stock et al., 2019; Lindeque et al., 2020). As a consequence, most environmental monitoring studies fail to monitor microplastics in the sub-200 μm range (O'Connor et al., 2020). Thus, information on the presence of nanoplastics in natural environments is substantially lacking.

Surface layer plastics are sampled using a variety of implements, including rotating drum samplers, while sediment samples are taken using grabbers, box or drill corers (Stock et al., 2019). Sample preparation (e.g., the separation of microplastics, water, sediment and organic material) using density and/or electrostatic separation techniques and chemical or enzymatic digestion is followed by characterization of particles using specialized analytical techniques such as Fourier-transform infrared spectroscopy, Raman microscopy, and pyrolysis gas chromatography (Stock et al., 2019). Yet, in practice the determination of polymer identity is often lacking (Li et al., 2018; Koelmans et al., 2019). Identifying the chemical composition of plastic particles is critical from an impact perspective. However, it is also a complex and expensive challenge because the various plastic polymers used in commercial plastics are complemented by additives such as plasticizers, fillers, flame retardants and dyes (Geyer et al., 2017; Rochman et al., 2019). Due to the lack of standardized microplastic measurement and analysis protocols, extreme care is required when interpreting quantitative data on the prevalence of microplastic pollution. Furthermore, data on the perceived ecotoxicological risks associated with microplastics in the freshwater environment should be interpreted against a background of limited information on environmental concentrations and polymer identity (Triebskorn et al., 2019).

Microplastics are ubiquitous in the freshwater environment

Monitoring has, up to now, focused disproportionally on marine plastics. In contrast, studies on the presence of microplastics in freshwaters are relatively scarce. It appears that some of the early studies on microplastics perceived streams and rivers simply as channels that transfer terrestrial plastics to the marine sink, ignoring the vital ecological, economic, cultural, and aesthetic importance of freshwater environments. In sharp contrast, a host of recent studies has revealed that freshwater systems do not just transport plastics from land to marine environments, but are microplastic pollution sinks (Ballent et al., 2016; Wagner and Lambert, 2018), as well as a starting point for the transfer of plastics through food webs (Gouin, 2020) (Fig. 1). Rivers near urban and industrial centers are now considered hotspots of microplastics pollution (Horton et al., 2017), while lakes may act as microplastic sinks (Free et al., 2014). Microplastics can be found on the freshwater surface, in the water column (Lechner et al., 2014; Mani et al., 2015; Miller et al., 2017), and in benthic sediments (Castañeda et al., 2014; Klein et al., 2015; Tan et al., 2016; Pomeroy et al., 2017; Hurley et al., 2018). Polyethylene, polystyrene and polypropylene based plastics are most frequently found in freshwater samples, and this finding is likely to reflect plastic production and use, as well as the actual polymer density. The most common plastic forms observed in freshwater samples are microfibers and fragments, with lesser numbers of films and microbeads (Horton et al., 2017; Hurley et al., 2018; Koelmans et al., 2019). Water samples from rivers and lakes contain both small and medium size microparticles (<1 mm). Yet, the lack of standardized microplastic monitoring protocols, makes quantitative comparisons across different studies using different protocols problematic (Koelmans et al., 2019).

Notwithstanding uncertainties with respect to the quantification of microplastics in the freshwater environment, there is no doubt that such plastics are ubiquitous. Given the rapid progress in the development of monitoring technology, it can reasonably be expected that more accurate quantitative information on microplastics in the freshwater environment will increasingly become available in the coming years. However, major challenges remain with respect to the quantification of nanoplastics and the chemical characterization of nano- and microplastics. Nevertheless, such information is critically needed to inform impact studies and risk assessments.

Effects of microplastics on freshwater organisms

Substantial research efforts are being made to analyze the impacts of microplastics on freshwater organisms. Yet, there is still a lack of consensus regarding the biological effects of micro- and nanoplastics on organisms, and especially ecological communities. Here we consider the uptake by, and presence of microplastics in freshwater organisms, as well as the evidence for impacts on these species.

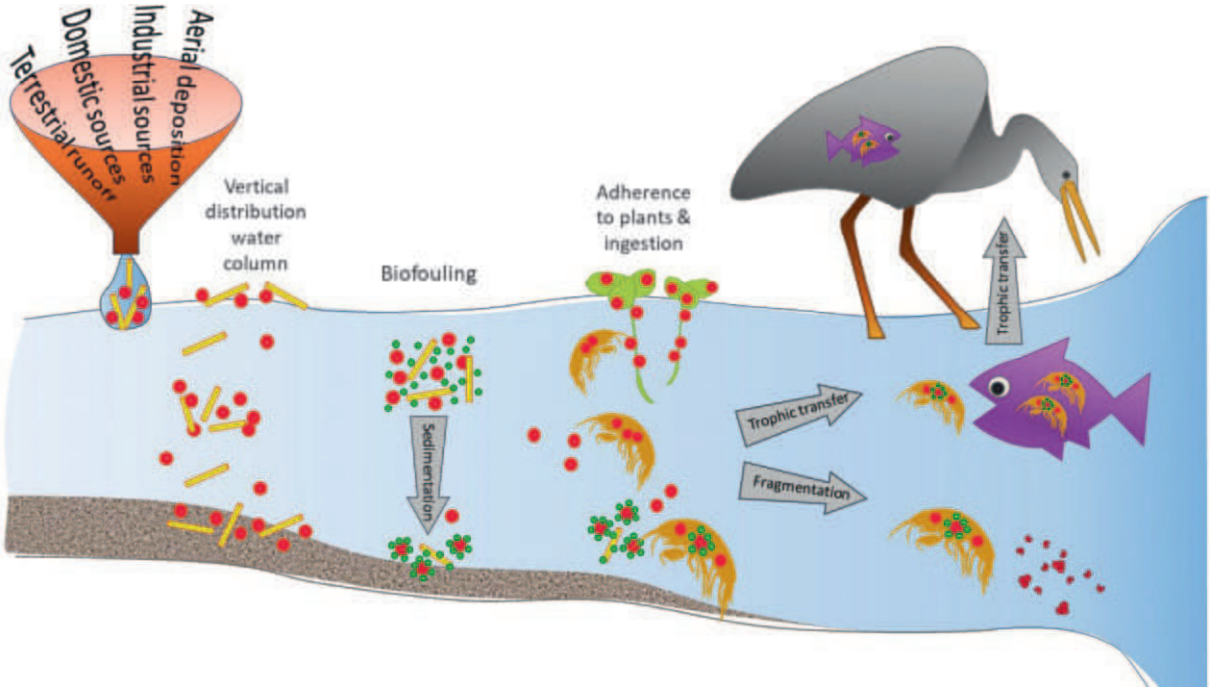

Fig. 1 Conceptual graphic showing key aspects of microplastic pollution in the freshwater environment. Micro- and nanoplastics enter the freshwater environment from a potentially large variety of different terrestrial sources. Depending amongst others on the density of the specific plastic polymer, microplastics float, are suspended in the water column, or settle in the sediment, resulting in a particular vertical distribution that will have consequences for the type of organisms exposed to these plastics. Biofouling of microplastics, and formation of aggregates with organic or inorganic detritus will accelerate sedimentation, but may also increase "accidental" ingestion by various organisms. Ingestion of microplastics may also relate to the adherence of plastics to plants and macroalgae. Once ingested, microplastics may be fragmented into nanoplastics, which are thought to be potentially more hazardous than microplastics. Furthermore, trophic transfer of ingested plastics will result in large numbers of species being exposed to plastics.

Microplastics are found inside organisms

Given the presence of micro- and nanoplastics in the freshwater environment, organisms will unavoidably be exposed to these polymers (Fig. 1). Indeed, microplastics have been identified inside a variety of freshwater organisms. For example, 75% of all sampled bayflies (*Chironomus* spp.) collected in the summer from South African rivers were found to contain microplastics, and this increased to 98% in the winter (Nel et al., 2018). The reported microplastic load varied between 0 and 1.4 particles per mg body weight during the summer, but increased up to 5.04 particles per mg in the winter (Nel et al., 2018). The microplastic load in the bayflies was positively correlated with the microplastic load in the sediment, indicating the lack of an organismal avoidance response. Rather, seasonal flow dynamics were found to be the major determinant of concentrations of microplastics in the sediment, and hence organismal plastic loads. Mayflies (*Baetidae* spp. and *Heptageniidae* spp.) and caddisflies (*Hydropsychidae* spp.) were similarly found to have ingested microplastic particles (Windsor et al., 2019), while Hurley et al. (2017) noted microplastic concentrations of 0.13 particles mg^{-1} body weight in sediment dwelling sludge worms (*Tubifex tubifex*). Microplastic ingestion is not limited to invertebrates. Microplastics have been identified in more than 200 freshwater species (Azevedo-Santos et al., 2021), including species of riverine fish (Collard et al., 2018; McNeish et al., 2018) and amphibians (Azevedo-Santos et al., 2021), in faecal samples of birds (D'Souza et al., 2020) and mammals (Smiroldo et al., 2019), as well as attached to plant surfaces (Mateos-Cárdenas et al., 2019). These data emphasize the apparent lack of a microplastic avoidance response, i.e., once present in the environment, it is likely that all parts of the aquatic food web will be exposed to these particles.

Impacts of microplastics on biota

A pertinent question concerns the effects of plastic particles on organisms. There is currently no consensus regarding the impacts of micro- and nanoplastics on living organisms, although a range of potential effects have been proposed. For example, and depending on attributes such as size and chemical composition (Carbery et al., 2018), ingested plastic particles can cause lacerations, inflammations, and immune responses. Plastics can also accumulate in organisms and interfere with feeding, leading to starvation, although there is currently no evidence for substantial bioaccumulation of microplastics in organisms. Some studies have shown that plastics can cross the gut wall and enter internal tissues (Farrell and Nelson, 2013) and this would be particularly the case for smaller plastics, i.e., nanoplastics. Understanding of the toxicology of nanoplastics is still limited, but cytotoxicity is associated with nanoplastic-induced oxidative stress, protein modification, DNA fragmentation, membrane damage and alterations in gene expression (Kihara et al., 2020).

Thus, plastics may impact on cells, tissues and/or organisms in a number of ways, through direct physical interactions, as vehicles for surface adhering contaminants or through direct toxicity of the plastic and its constituents themselves. Yet, while some studies have revealed negative impacts, others failed to do so. There are several reasons underlying the lack of agreement among studies. Firstly, microplastics comprise a bewildering assortment of different materials with different physicochemical characteristics, including polymer type, size, shape and presence of additives and contaminants (Triebskorn et al., 2019). Additives in particular have received considerable attention. Potentially, toxic effects can be related to additives, such as dyes, UV stabilizers or plasticizers, all of which may leach out of plastics. For example, phthalates are plasticizers that are also endocrine disruptors (Sheikh and Beg, 2017). Furthermore, the physical and chemical properties of micro- and nanoplastics, including their high surface area-to-volume compared with macroplastics, can facilitate adherence of further pollutants. In particular, hydrophobic contaminants can easily adhere to the hydrophobic surfaces of plastics (Hartmann et al., 2017). Marine studies have demonstrated adherence of polyaromatic hydrocarbons (PAHs), and polychlorinated biphenyls (PCBs) to polypropylene and polyethylene pellets (Frias et al., 2010), as well as adherence of cadmium and lead to plastic pellets collected from beaches (Ashton et al., 2010). It has been argued that such adherence results in the creation of a vector for contaminants, with release of pollutants inside organisms as a result of exposure to acidic gut conditions as shown by Batel et al. (2016). Yet, the environmental evidence for such adherence and release processes is not conclusive (Triebskorn et al., 2019). In summary, it appears that micro- and nanoplastics can cause direct, rather generic effects (e.g., lacerations, inflammations, impediments of feed intake) once ingested by organisms. These effects may be complemented by impacts related to the specific type of plastic, used additives, and adhering pollutants. Thus, the question is not whether microplastics are toxic, but rather which plastics are toxic under which environmental conditions (Triebskorn et al., 2019).

At present, the number of toxicological studies quantifying impacts of microplastics on freshwater organisms is limited, particularly in comparison with the extensive knowledge describing impacts of microplastics on marine species (Wegner et al., 2012; Cole et al., 2015). Most studied are impacts of plastics on daphnids, a common freshwater model species for toxicological testing. Acute exposure of the filter feeder *Daphnia magna* to polyethylene microbeads (size 1–100 μm) resulted in immobilization (Rehse et al., 2016), while exposure to polyester microfibers (length 300 μm) negatively impacted *D. magna* survival in the absence of food (Jemec et al., 2016). Acute exposure of *D. pulex* to a high concentration of polystyrene nanoplastics caused mortality with a 48-h median lethal concentration of 77 mg nanoplastic per liter (Liu et al., 2019b). Conversely, exposure of *D. pulex* over three 21-day generations to a more environmentally relevant concentration of polystyrene nanoplastics did not affect survival, although a range of subtle physiological changes were noted (Liu et al., 2020). Apart from concentration, size is a key determinant of toxicity to daphnids. While 50 nm polystyrene nanoplastics are highly toxic for *D. magna* in acute exposure studies, no mortality was caused by 200–500 nm nanoplastics (Frankel et al., 2020). Another important determinant of toxicity is nanoplastic surface structure. Polystyrene nanoparticles with added surface groups (amine- and carboxylate-groups) are less toxic to *D. magna* compared with the non-modified nanoplastics (Lin et al., 2019).

These daphnid studies demonstrate a broad range of biological effects of nano- and microplastics. Older studies were typically performed using pristine (non-weathered) microplastics (>5–10 μm) which are less likely to be taken up in the tissues or cells of exposed organisms, compared with nanoplastics. More recent studies have focused on nanoplastics which can potentially enter cells and tissues through processes ranging from diffusion to endocytosis (Triebskorn et al., 2019), and, therefore, pose a greater threat. By and large, observed effects refer to potential hazards, resulting from short-term (i.e., acute) exposure to an excessively high concentration of pristine plastics under laboratory conditions. In contrast, in the natural environment, exposure of organisms involves two important differences. Firstly, organisms are more likely to be chronically exposed to much lower concentrations of plastics. Secondly, it has been argued that plastics in the natural environment may act as vectors of adhering pollutants already present in the environment. At present, there is an urgent need to improve our understanding of how low concentrations of nanoplastics affect freshwater organisms, as well as their communities. This, in combination with advanced environmental monitoring of plastics, can lead to an informed risk analysis concerning plastics in the environment.

Biota alter microplastics in the freshwater environment

Microplastics can affect a broad range of organisms. However, the reverse is also true, biota can affect microplastic distribution, fate and fragmentation. Here we consider three specific processes: biofouling of plastics by microorganisms, adherence to plant structures and fragmentation by consumer species.

Biofouling of plastics

Depending on specific density, a substantial part of plastic waste entering the aquatic environment will sink and end up in sediments. Relatively dense plastics, such as polystyrene, will sink readily. However, less dense plastics often sink as well because of biofouling by microorganisms, sometimes in combination with larger organisms such as plants, macroalgae and small animals. Kaiser et al. (2017) demonstrated how the formation of a biofilm accelerated sinking of polystyrene and polyethylene microplastics in marine and estuarine waters. Investigating the sedimentation of low-density plastics in a freshwater system, Leiser et al. (2021) observed how phototrophic cyanobacteria (*Chamaesiphon* spp. and *Leptolyngbya* spp.) precipitated calcite while forming biofilms on microplastics, leading to increased sinking of polyethylene particles. Analyses of microplastics isolated from sediment attributed the relative high density to a combination of biofouling and adherence of inorganic minerals (Wu et al., 2020). Apart from increasing

the density, biofilms can secrete sticky polymeric substances which aid in the formation of larger aggregates of microplastic particles with organic and inorganic detritus that alter the density and therefore the distribution of plastics in the environment (Besseling et al., 2017).

Consequences of biofouling are far reaching. The presence of a biofilm, as well as the resulting sedimentation, may shield plastics from UV radiation, slowing down light-dependent fragmentation of macroplastics into micro- and nanoplastics (Gerritse et al., 2020). Furthermore, the altered vertical distribution of particles in the water column will alter the exposure of specific feeding guilds to these particles. It has also been reported that the formation of a biofilm may actually attract organisms that use olfactory and gustatory cues to select feed (Carbery et al., 2018). Thus, biofouling may contribute to feeding by organisms on plastic (Kooi et al., 2017).

Fragmentation of plastics

Plastics in the natural environment are subject to weathering, fragmentation and mineralization, with rates that differ for different types of plastics (Gerritse et al., 2020). Fragmentation results in the formation of smaller particles, i.e., micro- and nanoplastics, and has been largely associated with a combination of mechanical processes, including abrasion, and photodegradation following exposure to UV wavelengths. Recently, the role of biota in fragmentation has been highlighted. Microorganisms such as bacteria and fungi have long been implicated in plastic degradation (Horton et al., 2017), but it was shown that common freshwater invertebrates can also fragment some microplastics (Mateos-Cárdenas et al., 2020; Hasegawa and Nakaoka, 2021). Mateos-Cárdenas et al. (2020) demonstrated the generation and accumulation of polyethylene nanoplastics from microplastics in the digestive tracts of *Gammarus duebeni* following just a few days of plastic exposure (Figs. 1 and 2). Similarly, Hasegawa and Nakaoka (2021) showed that mysids (*Neomysis* spp.) fragment polyethylene microplastics, and that these fragments are ingested by the benthic fish *Myoxocephalus brandti* when it feeds on these crustaceans. Such nanoplastics are perceived as a greater environmental hazard than microplastics, as they can cross into cells and cause adverse effects in microalgae (Besseling et al., 2014), macrophytes

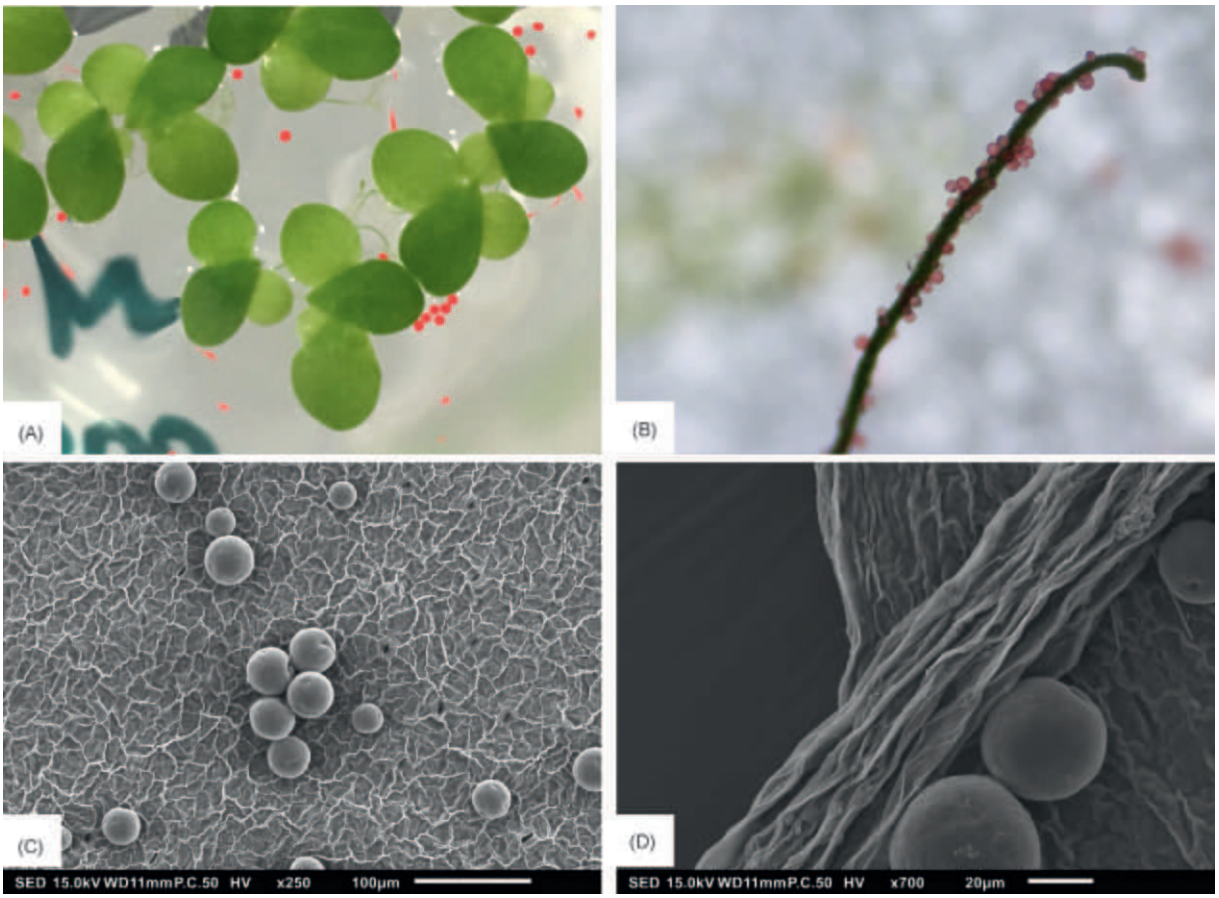

Fig. 2 Adherence of microplastics to plants and microalgae can be a step towards ingestion by herbivores and detritivores. Here, 30 µm diameter brightly stained polyethylene beads are seen to adhere to the duckweed *Lemna minor* (panels A and B, respectively). Using Scanning Electron Microscopy, adherence of 30 µm microplastics to the adaxial surface of the duckweed frond, and to the root can be seen (panel C and D). Size bars are shown for panels C and D. Full details in Mateos-Cárdenas et al. (2019).

(van Weert et al., 2019) and invertebrates (Cui et al., 2017). These discoveries reveal that once larger plastics are allowed to accumulate in the environment, the formation of more hazardous nanoplastics is almost unavoidable due to mechanical, photochemical and biological fragmentation processes. This, in turn, implies that prevention and/or capture of polluting macroplastics is essential to avert formation of micro- and nanoplastics.

Adherence of plastics to aquatic plants

There is a striking lack of studies on the effects of micro- and nanoplastics on freshwater plants and macroalgae. Those studies that explored potential effects did, in general, identify at most minor effects on growth and development. For example, Mateos-Cárdenas et al. (2019) found that exposure of the duckweed *Lemna minor* to polyethylene microbeads did not affect growth, biomass accumulation and photosynthesis. Kalčíková et al. (2017) also found no effects of polyethylene microplastic particles on *Lemna minor* leaf growth and photosynthetic pigments, but reported that sharp-shaped particles caused some root damage. However, a remarkable find was that microbeads were adsorbed to the roots of aquatic duckweed (*Lemna minor*). Mateos-Cárdenas et al. (2019) showed that a single *L. minor* colony can adsorb as many as 125 polyethylene microplastic particles after 72 h exposure (Fig. 3). Similarly, it was found that nanosized plastic particles adsorbed externally to the duckweed *Spirodela polyrhiza*, although no nanoplastics were observed inside plant tissues (Dovidat et al., 2020). However, other studies have shown that nanoplastics can be taken up in the tissues of exposed plants (Ma et al., 2010; Chae and An, 2020).

The mechanisms of microplastic adsorption onto plant surfaces are unclear. It is speculated that absorbance is the result of the affinity of some microplastics for hydrophobic substances (Xia et al., 2020), such as waxy plant cuticles. Irrespective of the mechanism, the relevance of adherence of plastics to plant and algal surfaces is substantial even when they may have no impact on plant health. Plants and algae are at the bottom of the food web, and therefore adsorption of microplastics is directly relevant for trophic transfer of plastics to herbivorous organisms, and further up the food chain, potentially to human consumers.

Trophic mobility of plastics

The transfer of microplastics through the food web is of serious concern and may, among others, result in exposure of human consumers to microplastics. Here we consider some of the evidence that indicates that trophic transfer of microplastics in the freshwater environment is likely to be widespread.

The literature contains ample evidence that microplastics are commonly present inside freshwater macroinvertebrates (Fig. 4) (Windsor et al., 2019; Triebskorn et al., 2019; Li et al., 2020). Micro- and nanoplastics are also present on plant surfaces (Kalčíková et al., 2017; Mateos-Cárdenas et al., 2019). Given that these organisms constitute basal trophic resources, there is a potential risk of transfer of plastics to organisms higher up in the food web by trophic transfer. Indeed, microplastics have been identified in riverine fish (Collard et al., 2018; McNeish et al., 2018) and amphibians (Azevedo-Santos et al., 2021), as well as faecal samples of birds (D'Souza et al., 2020) and mammals (Smiroldo et al., 2019). Hasegawa and Nakaoka (2021) compared microplastic ingestion directly from the water column with ingestion through feed, and concluded that trophic transfer of plastics from mysids to the benthic fish *Myoxocephalus brandti* considerably exceeds direct uptake from the water column. It was concluded that trophic transfer of microplastics is a key exposure route for organisms at higher trophic levels.

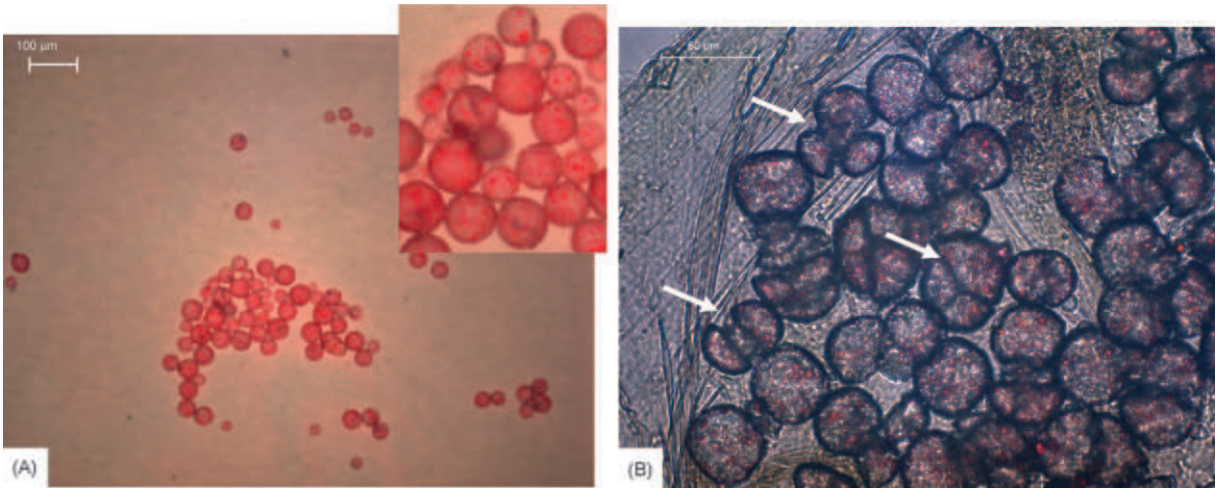

Fig. 3 Ingestion of microplastics by the invertebrate *Gammarus duebeni* can lead to fragmentation, and generation of nano-sized fragments. Here, a suspension of 30 µm diameter stained polyethylene beads are visualized using fluorescent microscopy (panel A). The same microplastics visualized using light microscopy in the gut of *G. duebeni*, display distinct cracks, leading to fragmentation (panel B). Size bars are shown. Full details in Mateos-Cárdenas et al. (2020).

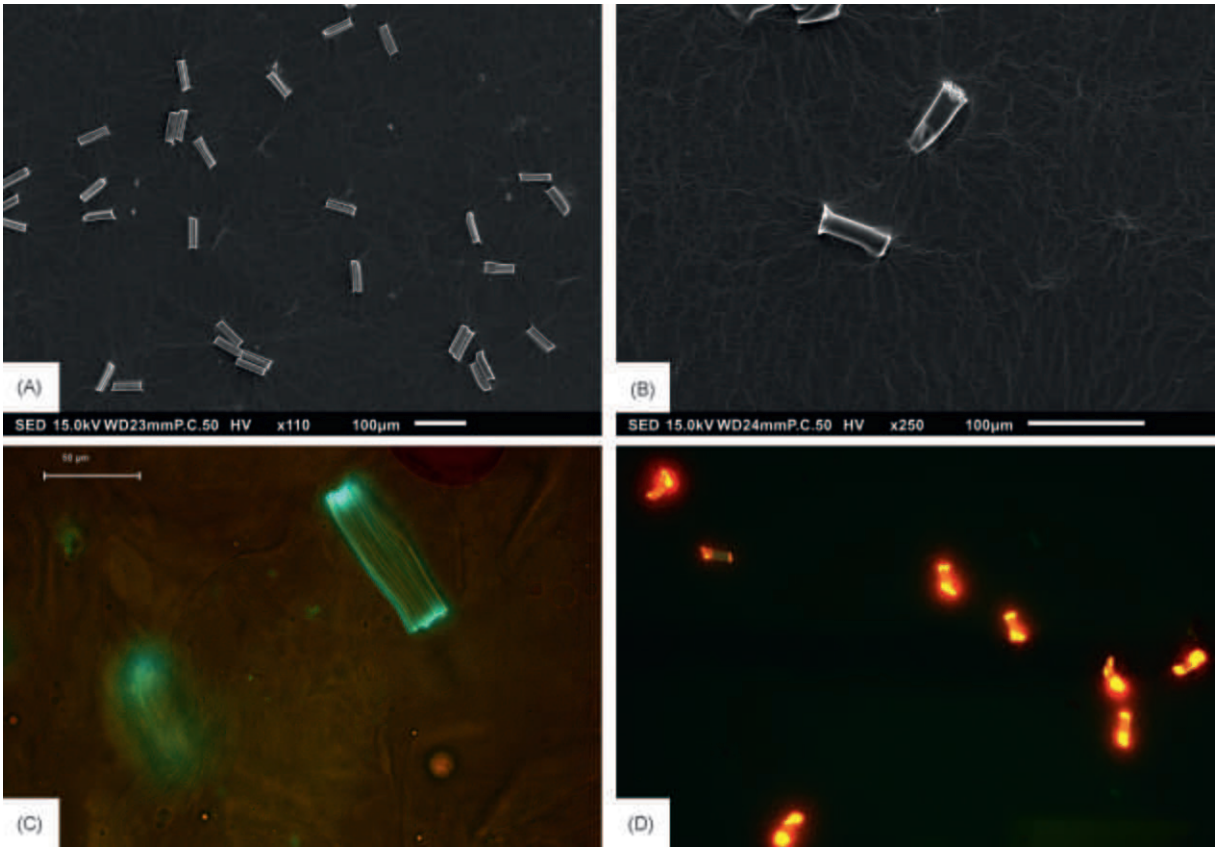

Fig. 4 Plastic microfibers are amongst the most common type of microplastics in the natural environment. Here, short cellulose and polyester fibers are visualized using Scanning Electron Microscopy (panel A and B, respectively). Using fluorescent microscopy, cellulose (panel C) and polyester (panel D) microfibers were also visualized to accumulate in the digestive tract of *G. duebeni*. Size bars are shown in panels A, B, and C. Full details in Mateos-Cárdenas et al. (2021).

The importance of trophic transfer was confirmed by a recent study which demonstrated the ingestion of microplastics by the Eurasian dipper (*Cinclus cinclus*). Modelling indicates that some 200 plastic particles can typically be ingested per day by these birds. Plastics were identified in some 50% of regurgitates and 45% of fecal samples, and concentrations in these samples were positively linked to local environmental concentrations (D'Souza et al., 2020). Plastic uptake by the dipper was directly associated with ingestion of microplastic-containing prey. Indeed, freshwater macroinvertebrates such as gammarids are a key staple of the dipper (Taylor and O'Halloran, 1997), but also for a range of other species such as brown trout *Salmo trutta* (MacNeil et al., 1999), implying that trophic transfer of plastics is likely to be widespread in the freshwater environment.

So far, microplastic trophic transfer studies have predominantly investigated prey-predator interactions, studied either under controlled experimental conditions (Athey et al., 2020; Hasegawa and Nakaoka, 2021) or in the natural environment (Nelms et al., 2018), with less attention to primary producers like plants. Nevertheless, adsorption of microplastics to plant surfaces is of concern given the role of plant biomass as food for herbivores, omnivores and detritivores. A recent study shows quantitative transfer of microplastics from the primary producers *L. minor* to the consumer *G. duebeni* in a model freshwater food chain (Mateos-Cárdenas et al., 2019). The implications of the finding of trophic transfer from *L. minor* to *G. duebeni* go beyond the actual species and are relevant for entire ecosystems. While the trophic transfer of microplastics in freshwater systems remains less well understood than that in marine environments (e.g., Carbery et al., 2018), it can be speculated that such transfer will result in all parts of the aquatic food web being exposed to micro- and nanoplastics.

Conclusion—synthesis

Technology to monitor microplastics in the natural environment is developing rapidly. However, at present there are no agreed standardized monitoring protocols to determine microplastic concentrations and analyze plastic composition, and as a result it is difficult to compare data generated by different research groups. Furthermore, current technology mostly monitors macroplastics, and larger microplastics, but fails to assess the presence of potentially more hazardous nanoplastics in the natural environment. Nevertheless, it is clear that both micro- and nanoplastics are ubiquitous throughout terrestrial, marine and freshwater environments.

Microplastics in the freshwater environment remain insufficiently studied. Yet, it has become evident that freshwater systems are not just a conduit for transport of plastics from terrestrial sources to the marine sink. Rather, freshwater systems themselves are important sinks for plastics, with widely reported observations on the presence of microplastics in the sediment as well as inside freshwater invertebrates, fish, amphibians, birds and mammals, as well as adherence to plant and algal surfaces (Fig. 1). Despite the pervasive presence of microplastics inside freshwater organisms, there is lack of consensus concerning the impacts of micro- and nanoplastics on these organisms. It is likely that nanoplastics are more hazardous than microplastics, while additives (e.g., plasticizers, dyes and UV-stabilizers) and adhering pollutants (e.g., polyaromatic hydrocarbons) further add to their hazard potential. Nevertheless, given the level of uncertainty with respect to actual microplastic concentrations in the environment, it remains unknown to what extent these potential hazards pose a real risk to freshwater species and communities. While there is a strong extent of uncertainty with respect to the impacts of microplastics on freshwater organisms, the opposite is becoming quite clear: Biota can impact on microplastics in the freshwater environment. Biofouling can increase the density of plastics resulting in increased sedimentation. Ingestion by invertebrates may result in fragmentation into smaller plastics, including potentially more hazardous nanoplastics. Adherence to plant surfaces does remove some of the freely suspended plastics from the water column, but may result in increased ingestion by herbivorous species. Indeed, an important finding is the trophic transfer of microplastics throughout the freshwater food web.

In conclusion, once macroplastics are discharged into the aquatic environment, processes such as fragmentation, ingestion and trophic transfer will spread these plastics in the form of micro- and nanoplastics throughout the aquatic food web (Fig. 1). Currently, no effective techniques are available to remove micro- and nanoplastics from the natural environment. Therefore, the emphasis in water management needs to be on prevention of plastic pollution rather than remediation.

Knowledge gaps

- There is a lack of quantitative data on the presence of microplastics in the freshwater environment, and this relates to a lack of standardized protocols for monitoring the presence of plastic particles.
- There is a need to develop novel methods to detect and quantify nano-, and possible even smaller, plastics in the environment.
- The environmental fate of plastics in the freshwater environment, including distribution, transport, sedimentation, fragmentation, ingestion and adsorption, remains to be fully established.
- The hazards, and especially risks, posed by micro- and especially nanoplastics to freshwater species and communities remain unclear.
- The roles of additives and adhering pollutants in microplastic toxicity remain to be fully established.

Constructed Wetlands for Urban Wastewater Treatment: An Overview

Diederik PL Rousseau, Flor Louage, Qintong Wang, and Rui Zhang, Laboratory of Industrial Water and Ecotechnology (LIWET), Department of Green Chemistry and Technology, Ghent University, Kortrijk, Belgium

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Constructed wetland Manmade wetland ecosystems, engineered in such a way that they make optimal use of the biological, physical and chemical processes offered by wetland vegetation, microorganisms and soil/filling media to purify water.
Ecological engineering Design, construction and management of ecosystems that have value to both humans and the environment.
Intensified constructed wetlands CWs with extra engineering features such as active aeration or recirculation or special filling media, typically with the aim of improving treatment efficiency and thus reducing the area needed.
Population or Person Equivalent—PE The water based organic biodegradable pollutant load produced per capita per day. In EU legislation, 1 PE = 60 gBOD/cap/day. Actual numbers vary however based on water and food consumption patterns.
Primary treatment The removal of undissolved particles and preparation for secondary treatment.
Secondary treatment The treatment of waste water, generally through a biological process, to remove the largest part of the biological oxygen demand.
Subsurface flow constructed wetlands CWs where the water flows either vertically or horizontally below the ground surface through a porous medium such as sand or gravel.
Surface flow constructed wetlands CWs where the water flows above the ground surface and where there is direct contact between the water and the atmosphere.
Tertiary treatment Also called 'polishing' or 'advanced treatment'. The treatment of secondary treated wastewater to further improve quality for discharge into the receiving water body.
Urban wastewater Usually a mix of domestic wastewater, stormwater and (possibly already partially treated) artisanal/industrial wastewater.

Introduction and aim of the chapter

Most domestic, industrial and agricultural activities generate wastewater streams which, depending on the specific activity, contain varying concentrations of organic matter, nutrients, inorganic (e.g., heavy metals) and organic (e.g., pesticides, pharmaceutical residues) micropollutants and pathogenic microorganisms. According to estimations from the United Nations (UN Water, 2017), more than 80% of all wastewater generated globally is discharged to the environment without adequate treatment. This threatens not only ecosystem health through phenomena such as oxygen depletion, eutrophication, ecotoxicity, but also threatens human health of those people depending on the water resources where the wastewaters are discharged. In addition, valuable and non-renewable resources such as phosphorus and metals are in this way lost to the environment.

In a reaction to these problems, wastewater treatment technologies were developed from the late 1800s onwards (Lofrano and Brown, 2010). While originally focused on improving hygienic conditions, through time the focus shifted to environmental protection and in recent years to resource recovery, each time posing more stringent demands on effluent quality. Many of the commonly used wastewater treatment technologies are, however, very resource intensive, both during the building phase (construction materials) and during their operational life (energy for pumping and aeration, sludge conditioning chemicals) (Garfí et al., 2017). In the 1960s, German researchers developed a new, resource-extensive technology which was entirely based on the self-purification capacity of nature: constructed wetlands (CWs). CWs are defined as manmade wetland ecosystems, engineered in such a way that they make optimal use of the biological, physical and chemical processes offered by wetland vegetation, microorganisms and soil to purify water. An alternative term is treatment wetlands, to distinguish them from other "constructed" (i.e., artificial) wetlands whose primary purpose is nature restoration rather than water purification.

Apart from wastewater treatment, CWs potentially also offer other ecosystem and circular economy services such as biomass production, wildlife habitat provision, evaporative cooling and even recreational possibilities (Masi et al., 2018). In this way, CWs are a prime example of ecological engineering, a term coined in 1962 by the American ecologist Howard T. Odum, and defined as "design, construction and management of ecosystems that have value to both humans and the environment". Likewise, CWs can be considered as green infrastructure under the umbrella concept of nature-based solutions, which are equally defined as "working with nature to address societal challenges, providing benefits for both human well-being and biodiversity" (Nature-based Solutions Initiative, n.d.).

From their initial conceptualization for domestic wastewater treatment, the use of CWs has been expanding rapidly, and CWs are now being used across the globe, in every possible type of climate (desert to arctic, e.g., Stefanakis et al. (2018) and Yates et al. (2012)), for a wide range of wastewater types, i.e., domestic, urban, industrial and agricultural, and at scales varying from a few m^2 to several km^2. This expansion is chiefly due to the positive balance between investment and operation costs on the one hand, which are typically lower than other wastewater treatment technologies, and the obtained treatment efficiencies on the other hand, which are competitive with other biological treatment technologies, though obviously cannot reach similar quality levels as energy-intensive systems like membrane filtration. The major drawback of CWs—when ignoring other ecosystem services apart from wastewater treatment—is the rather large area they occupy compared with conventional industrial plants. For this reason, CWs are mainly applied in rural and semi-urban areas, although recent developments (see section "Alternative lay-outs") have triggered urban applications as well.

This chapter gives an overview on the use of constructed wetlands for urban wastewater treatment. Urban wastewater consists at least of domestic wastewater, in many cases mixed with (possibly already partially treated) industrial wastewater and/or stormwater runoff (Fig. 1). To this end, the different types of constructed wetlands and their characteristics will be summarized, the most important treatment processes occurring in CWs will be discussed, and the essential criteria for choosing, designing and operating CWs will be listed.

Types of constructed wetlands

Over the years, various types of CWs have been created which, just as their natural counterparts, vary in terms of vegetation, soil, water levels etc. In this chapter only the most widely applied CW types are discussed (Table 1). For a more comprehensive overview, the reader is referred to Fonder and Headley (2013).

Based on the hydrology and vegetation, four main types of CWs are differentiated. The first two are surface flow systems and the last two are mainly subsurface flow systems.

Surface flow (SF), free water surface (FWS) or free-floating macrophyte wetland (FFM)

These CWs have a water level that is set above the substrate, allowing for a larger available water volume than their subsurface CW counterparts where only the pore spaces are available. Aboveground water entails higher risks of odor, insects and contact of wildlife with the wastewater, hence such CWs are more often used for tertiary treatment or polishing. The upper water layers in contact with the atmosphere tend to be aerobic unless they are completely covered by floating macrophytes. Lower water layers tend to be anoxic or anaerobic.

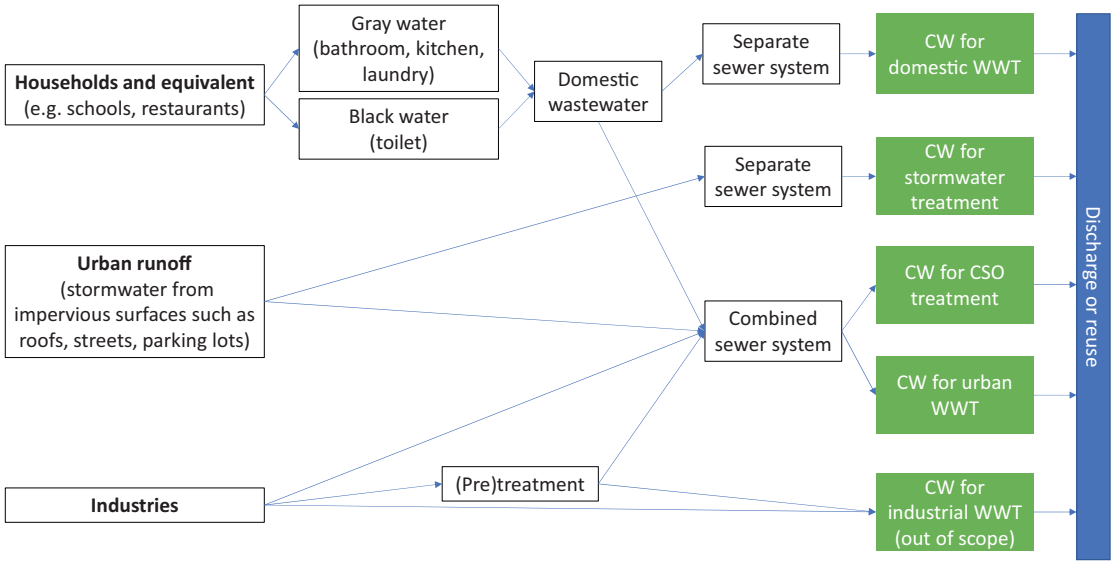

Fig. 1 Concept of urban wastewater (*WWT*, wastewater treatment; *CW*, constructed wetland; *CSO*, combined sewer overflow).

The macrophytes dominating these systems are emergent or free-floating (Table 2). When free-floating macrophytes are used, the recommended minimum water depth is considered 0.8–1.0 m, to prevent roots growing into the sediment and losing the free-floating character (Headley and Tanner, 2012). Emergent macrophytes require lower water depths, in the order of 0.5 m. Apart from the treatment processes discussed in section "Important treatment processes in constructed wetlands", macrophytes also play a role in reducing harmful algal blooms by lowering the amount of sunlight that reaches the water.

Floating emergent macrophyte (FEM) CW or floating CW

Similar to SF CWs, the FEM CWs have a substrate-free upper water column. The main difference is that the macrophytes are anchored in buoyant structures with or without growing media. The FEM CWs are very suitable for stormwater applications because the water level is not constrained so these systems can deal with sudden high inflow rates (Headley and Tanner, 2012). The buoyant structures provide shading, reducing algae growth.

Horizontal subsurface flow (HSSF) CW

Wastewater is fed through the buried inlet zone and flows horizontally through the substrate until it reaches the outlet zone for collection and discharge. The water level is typically regulated with an elbow-like effluent pipe, and is maintained 5–10 cm below the surface. Oxygen transfer is, therefore, restricted, and HSSF CW are typically anoxic or anaerobic environments. The substrate generally consists of porous materials like gravel, sand or soil. HSSF CW are typically planted with emergent plants which are usually herbaceous (Table 2). A rule of thumb for design is 5 m^2 PE^{-1}, when treating domestic wastewater (Vymazal, 2010).

Vertical down flow (VDF) or vertical subsurface (VSSF) CW

Primary treated wastewater is intermittently fed on top of the wetland and migrates down through the substrate. This intermittent feeding enhances oxygen transfer and ensures aerobic conditions. The upper substrate surface consists of fine material to distribute the water. The bottom layer of the substrate consists of coarser material to enhance the draining capacity (Fonder and Headley, 2013). Similar macrophytes as in HSSF are used. A rule of thumb for design when treating domestic wastewater is 1–3 m^2 PE^{-1} (Vymazal, 2010).

A modification where raw (untreated) wastewater instead of primary treated wastewater is fed on a VDF is usually referred to as a French-type CW. These French-type CWs consist in essence of two stages of several parallel VDF CWs, which are operated in a rotational manner, i.e., some beds are loaded while others are resting. The first stage VDF CWs receive raw wastewater and as a result a sludge layer quickly accumulates on top. This sludge layer is biologically very active and enhances treatment efficiency, but on the other hand it also reduces water infiltration rates. During the resting periods, this layer dries out and the accumulated organic matter is being mineralized, thus restoring the infiltration capacity. This results in an overall increase of the sludge layer of only 1–2 cm $year^{-1}$. A second stage VDF CW is needed for further nitrification and carbon removal (Morvannou et al., 2015).

Table 1 Overview of different types of CWs and their main characteristics.

Wetland name and abbreviation	*Water level relative to substrate*	*Flow direction*	*Vegetation type*	*Type of treatment*[d]	*Typical removal efficiencies*	*Scheme*

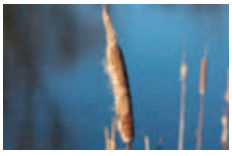
Table 2 Examples of typical species of vegetation used in constructed wetlands.

Classification	*Name*			
Emergent plants—herbaceous	Reed *Phragmites australis*	Bulrush *Typha latifolia*	Papyrus *Cyperus papyrus*	Golden torch *Heliconia psittacorum*
				


Emergent plants—woody	Mangroves *Rhizophoraceae*	Pond cypress *Taxodium distichum*		
				
Floating-leaved plants	Water lilies *Nymphaea*	Water caltrops *Trapa bicornis*		
				
Floating plants	Water hyacinth *Eichhornia crassipes*	Duckweed *Spirodela polyrhiza*	Water lettuce *Pistia stratiotes*	
				

Hybrid wetlands

It is also perfectly possible to combine several of the above-described CW types into one single treatment plant. Such wetlands are then called hybrid wetlands. A popular combination is for instance VDF followed by HSSF CWs because the sequence of aerobic and anoxic conditions allows to optimize nitrogen removal.

Important treatment processes in constructed wetlands

Solids

From an operational point of view, solids (Total Suspended Solids—TSS) in wastewater are a prime concern, especially in subsurface flow CWs, as they can cause clogging of the porous media. CWs therefore rely on a preceding primary treatment step, such as a septic tank or Imhoff tank, to remove most solids. The only exception are the French-type CWs (see section "Types of constructed wetlands") which treat raw wastewater. Any remaining particles are then removed efficiently by CWs (Table 1). In subsurface flow CWs, this mainly happens through filtration, governed not only by the pore characteristics of the porous media, but also by the density and penetration depth of the plant root biomass. In SF CWs, filtration depends mainly on aboveground vegetation density, and is complemented by settling of particles in the slow-flowing water. In both cases, filtration is aided by the "sticky" biofilms that develop on any hard surface in the CWs (porous materials, plant stems and basin walls) which capture suspended solids. Retained materials, if biodegradable in nature, can be hydrolyzed and mineralized by microorganisms and will thus liberate dissolved components (e.g., C, N, P) to the water; non-biodegradable organic matter and inorganic materials will accumulate in the system and will have to be removed eventually to avoid water flow blockage. This is usually needed after 8–10 years (Knowles et al., 2011; Nivala et al., 2012). Protozoans (e.g., ciliates) and metazoans (e.g., worms) also play a role in capturing and processing particles (Decamp and Warren, 1998; Ye et al., 2018).

Dissolved organic matter

Dissolved organic matter (designated as BOD, Biochemical Oxygen Demand or COD, Chemical Oxygen Demand) is mainly processed by the ubiquitous biofilms. Depending on the type of wetland, position within the CW (top vs. bottom, inlet compared with outlet) and loading conditions, these biofilms may be exposed to aerobic, anoxic or even anaerobic conditions, which allows a wide range of concurrent removal processes. Even within one section of biofilm, different redox conditions may exist simultaneously due to the oxygen gradients that are formed. Of particular note here is the concept of root oxygen loss, which concerns oxygen leakage by wetland plant roots as a mechanism to survive the typical anoxic wetland soil environments. Root oxygen loss creates aerobic conditions in the biofilm layers in closest contact with the plant roots. For a while, it was considered that this oxygen supply was sufficient to cover a large part of the oxygen demand (for BOD removal and nitrification), but more recent insights have refuted this idea (Liu et al., 2016).

Biodegradable organic matter can be removed by aerobic or anaerobic respiration, typically leading to high removal efficiencies (Table 1). Notwithstanding, this also results in CO_2 and/or CH_4 greenhouse gas emissions. As the vegetation also fixes atmospheric carbon by photosynthesis, most CWs still act as a net sink for greenhouse gases, and they typically emit less greenhouse gases per unit of BOD or COD removed than conventional wastewater treatment plants (Maucieri et al., 2017).

Nitrogenous compounds

The dominant nitrogenous compounds in urban wastewater are mostly organic nitrogen and NH_4^+. As for organic material, nitrogen cycling is dominated by microbial processes in the biofilm. Microbial nitrogen conversions typically involve ammonification, nitrification and denitrification, although other biological N-conversions such as nitrogen fixation, ANAMMOX and dissimilatory nitrate reduction have also been shown to play a role in CWs (Fig. 2). Only denitrification and ANAMMOX result in nitrogen removal, as the final product N_2 escapes to the atmosphere. All other processes simply convert one form into another. This may still be beneficial as for instance nitrate is less toxic to aquatic life than ammonia. Next to microbial conversions, there are also uptake processes. N-uptake by the microorganisms is insignificant, because N taken up by the bacteria in biofilms is liberated again when the bacteria decay. Plant uptake is more significant, and can be a permanent sink of N when aboveground biomass is harvested and removed from the CW. N removal efficiency by CWs is usually 40–80%, depending on the type and operation of the CW (Table 1). Finally, certain N-compounds can also be adsorbed to the porous media, soil particles or dead organic matter, but this process is typically also insignificant over longer periods as saturation limits are rapidly reached.

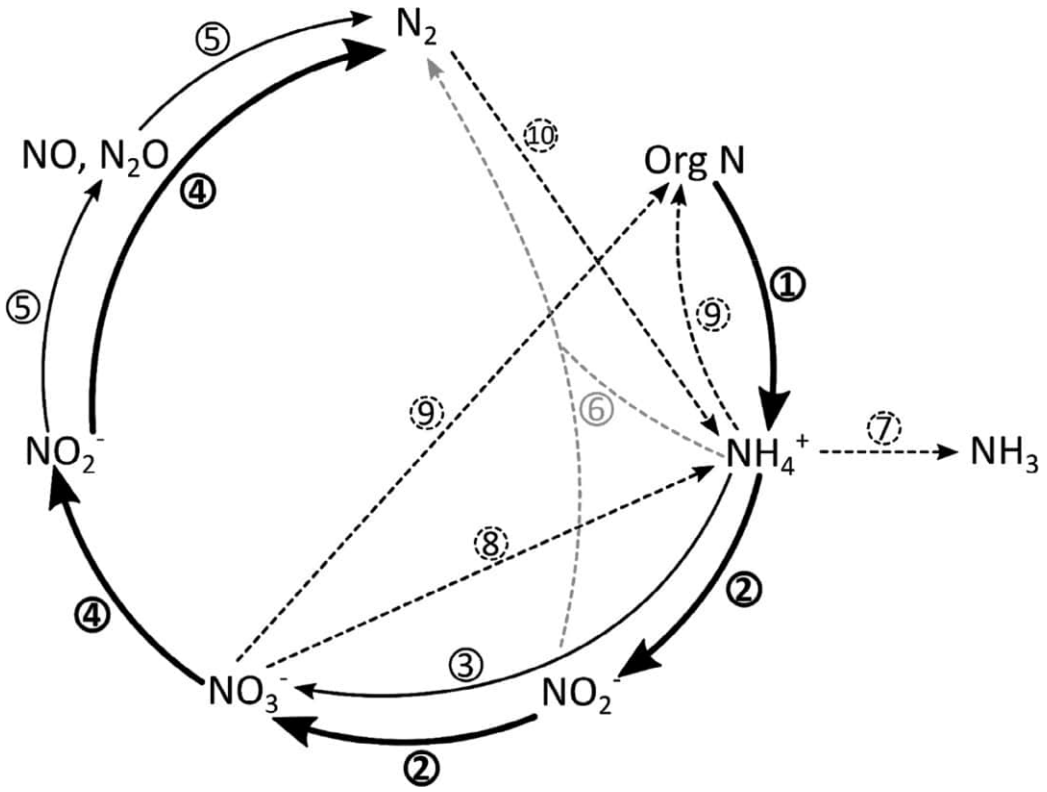


Fig. 2 Nitrogen cycle in constructed wetlands with following processes: 1 ammonification, 2 nitrification, 3 comammox, 4 complete denitrification, 5 partial denitrification, 6 ANAMMOX, 7 volatilization, 8 dissimilatory nitrate reduction, 9 assimilation and 10 nitrogen fixation.

Phosphorus compounds

The main phosphorus removal mechanisms in CWs are typically adsorption and precipitation by porous media (SSF CW) or soil (SF CW). Unfortunately, these are by nature finite processes, limited by the maximal adsorption capacity of the applied material, or the maximal amount of ions liberated that can precipitate phosphates. Both largely depend on the content of iron, calcium and aluminum, as well as on the specific surface (area per volume) of the applied materials. Therefore, recent research aims to apply new substrates that have a high phosphorus removal capacity in CWs (see section "New substrates"). To avoid having to refurbish the entire CW once the substrate is saturated, P-adsorbing materials can also be added as a separate filter behind the CW.

In addition, as for nitrogen, plants also take up P, but the quantity stored in the plant biomass is usually insignificant versus the amount of P delivered to the CW by the urban wastewater, hence this is not an important removal mechanism. Likewise, P-uptake by the bacteria is at best a temporary phenomenon during biofilm development, which very quickly evolves to an equilibrium between uptake and decay.

Pathogens

Pathogens are the main vector for the spread of diseases. In urban wastewater, pathogens mainly include viruses, bacteria, pathogenic protozoa and pathogenic helminths stemming from human and animal feces. Currently, their presence in wastewater is assessed by routine monitoring of indicator microorganisms such as *Escherichia coli* (*E. coli*), total coliforms, fecal coliforms, fecal streptococci and *Clostridium perfringens*. The removal of pathogens in CWs depends on mechanisms which include sedimentation, filtration, adsorption, predation, and natural death (Wu et al., 2016). Sedimentation and filtration in CWs (discussed above) plays a major role in the removal of pathogens. Adsorption of pathogens in CWs is also partially a mechanism of filtration as pathogens are adsorbed by the substrates, plant roots or biofilms and thus trapped in the CWs. Predation is another important process as both protozoans such as ciliates, and metazoans such as nematodes and copepods have been reported to be an important factor in the removal of bacteria. Finally, natural death of pathogens is a complex process that may involve a variety of physical and chemical factors such as pH, oxygen levels etc. The overall pathogen removal capacity is dependent on various factors such as flow pattern, matrix, vegetation and hydraulic retention time. Also, natural factors such as temperature and solar intensity are of importance. Generally, subsurface flow CWs have better capacity than surface flow CWs (Table 1).

Micropollutants

Micropollutants encompass a massive range of organic and inorganic pollutants of anthropogenic origin, whose presence at even very low concentrations (ng to μg/L) in the environment can have negative effects on living organisms. Urban wastewater contains a wide variety of micropollutants including metals, pharmaceuticals and personal care products (PPCPs) and microplastics, which have gradually received attention in CWs.

Adsorption and precipitation are the main physical and chemical processes that stimulate metal retention and removal in CWs. Metals can either be adsorbed by ion exchange, or they can form insoluble compounds through redox reactions. Plants can also play a major role in extracting metals and metabolizing them (Marchand et al., 2010).

CWs also possess the ability to remove some pharmaceuticals and personal care products (PPCPs). As for other wastewater components, the micro-environments formed by microbiological communities in CWs are able to offer different metabolic pathway for their degradation (Ilyas and van Hullebusch, 2020a,b).

The removal and fate of microplastics as a persistent pollutant is also gaining attention in CWs. Current studies indicate that CWs can effectively remove microplastics by filtration, but further research is needed on removal mechanisms and influencing factors (Wang et al., 2020a; Wei et al., 2020).

Alternative lay-outs

The search for smaller area and higher performance CWs in the past decades has led to "intensification" of CWs (Ilyas and Masih, 2017). The tradeoff here is that the low-tech, low-maintenance, low-cost and natural character of traditional CWs is (partially) lost for higher efficiency treatment of wastewater. The recently developed CWs are generally designed to enhance a certain treatment process or as a crossover with other environmental technologies.

Enhanced nitrogen removal by hybrid wetlands and recirculation

Hybrid CWs are a combination of two or more standard CW types with sometimes partial recirculation. The most used hybrid combination is a VDF CW followed by a HSSF CW, where the VDF CW promotes nitrification and the HSSF denitrification (Vymazal, 2013; Ilyas and Masih, 2017). Removal of BOD, COD, TSS and TP are less affected by such hybrid configurations.

In an effluent recirculation system, part of the effluent is returned to the influent zone of the CW. The goal is to improve effluent quality, by making only minor changes to the design of the CW. Nitrate-rich effluent can be denitrified in the presence of fresh carbon-rich wastewater, with a higher hydraulic load promoting less oxygen transfer due to shorter atmospheric contact time. Recirculation can also be used as a strategy to dilute influent with a high toxicity and hence to reduce toxic effects on the (micro) biota of the CW. Recirculation is mainly carried out in subsurface flow CWs and recirculation ratios vary from 0.5 to 2.5. The total CW area can be reduced to 1.1–1.6 m^2 PE^{-1}, depending on the CW type, but the hydraulic conductivity must be taken into account to prevent flooding of the CW (Prost-Boucle and Molle, 2012; Wu et al., 2014, 2015).

Oxygen enhancement

Low oxygen concentrations reduce the removal rate of BOD and COD and inhibit the conversion of ammonium to nitrate. This can be countered by artificial aeration in the form of compressed air addition. The aeration regime must be balanced to allow for anoxic conditions for nitrate removal. Aeration efficiency is still being researched (Rous et al., 2019). Ouellet-Plamondon et al. (2006) found that aeration cannot replace macrophytes, pointing out that macrophytes have more functions in relation to treatment efficiency than only oxygen addition to the root zone. Aeration however leads to additional operation and maintenance costs (Wu et al., 2014; Ilyas and Masih, 2017).

Alternatively, a passive aeration strategy can be applied by designing a two or multiple stage CW. When water travels gravitationally to the next stage, a waterfall is created and oxygen is being dissolved (White, 1995). This waterfall aeration is however limited to a one-time spike of 7–14 mg L^{-1}, depending on environment temperature. Vertical baffles, spanning the whole CW length, can be inserted to promote water mixing and subsequent oxygen transfer. Another passive aeration strategy is to use vertical perforated pipes, that suck in air when water is draining due to negative pressure (Wu et al., 2014).

A tidal flow or FaD CW is considered a separate category of CWs (Table 1), but has recently gained more attention. Tidal flow CWs are batch operated, in contrast to all other standard CW types. A cycle consists of filling, contact phase, draining and resting, where the emphasis lies on the alternation of saturated/unsaturated substrate. This regime pulls in oxygen for nitrification when filling and resting, while anaerobic conditions are reached during the contact phase. The energy requirements for a FaD CW are about half as much as for actively aerated CWs (Austin and Nivala, 2009).

New substrates

Substrates such as gravel, sand and soil have been used for decades in CWs, with the primary functions of supporting macrophyte growth and providing surfaces for microbial growth. Recent research has started to focus more on improvements of substrates for CWs, in areas such as waste material reuse, nutrient removal and prevention of clogging (Wang et al., 2020b). A number of materials that have been tried as newer substrates in CWs include:

I. Zeolites, a group of minerals rich in micro and macro pores, with high sorption capacity of cations such as heavy metals and ammonium. Phosphorus removal is, however, moderate to low. Zeolites are relatively easy to obtain and the price is reasonably low, making them suitable for use in CWs;
II. Woodchips, bark chips or wood shavings are an abundant by-product of the timber industry. The woodchips can be implemented in a CW substrate for better denitrification and thus nitrogen removal, as it acts as a slow-release carbon source;
III. Biochar is produced through pyrolysis of agricultural biomass and is intended as a soil-improving substance. Biochar is similar to activated carbon, but is not specifically activated. Yet, biochar has a large surface area and high sorption capacity, yielding removal of heavy metals and ammonium. Biochar also is a slow-release carbon source, suitable for denitrification;
IV. Oyster shells mainly consist of $CaCO_3$ and have a great potential for phosphorus removal through adsorption and precipitation;
V. Construction wastes consist of bricks, gravel, concrete, fly-ash, etc. Some construction wastes facilitate phosphorus removal, similar to oyster shells; and
VI. Slag is an industrial by-product from the steel industry, with practically no other uses, making it cheap to use. Slag has a high phosphorus sorption capacity, but can leach other metals and can negatively affect macrophyte growing conditions.

Crossover with other environmental technologies

Microbial fuel cell (MFC): MFCs are bioelectrochemical systems that generate current by means of electrochemically active microorganisms as catalysts. In a wastewater MFC, organic substrates present in the wastewater are hydrolyzed and oxidized by bacteria. The electrons are transferred to an anode from where they flow through a conductive material and a resistor to an electron acceptor, such as oxygen, at the cathode (Logan et al., 2006; Rabaey et al., 2007). Such processes require a redox gradient. A CW has aerobic and anoxic zones and is therefore suitable for embedding MFCs (Ji et al., 2021). The technology is still in its infancy and needs more research before upscaling. The power output is low and ranges from a few to several thousands of milliWatts, however the combination of a standard type of CW with an MFC yields better COD and nitrogen removal compared with a standalone CW (Ebrahimi et al., 2021; Gupta et al., 2021). An MFC can also be used as an alarm-like biosensor for detecting high COD influent concentrations, as the voltage of an MFC is correlated with the COD concentration (Corbella et al., 2019).

Green roofs: Green roofs are typically used to reduce stormwater flows by storing rainwater, and in addition provide air filtration, cooling in urban areas and better building insulation. However, they can also be constructed or converted into CWs for treating domestic wastewater (Vo et al., 2019). The design generally consists of a standard type HSSF or VDF CW. Surface flow CWs are not recommended as they are prone to odor nuisances and mosquito growth. The depth of the CW is reduced and lighter substrate material is required to reduce structural load on the roof. The treated water can be reused for flushing toilets or irrigation as this poses less health and safety issues than reuse for other purposes.

Green walls: Green walls or living walls have become popular to improve the aesthetic appearance of buildings and to introduce patches of green in dense urban environments. Similar to green roofs, they also provide some insulation in terms of heat and noise, provide a habitat for insects and can improve air quality by capturing fine dust. Whereas most green walls are maintained with tap water or rainwater and chemical fertilizers, it has also been shown that such systems can treat wastewater (Pradhan et al., 2019). Flipping a CW 90° obviously saves a great deal of space.

A CW project from A-Z

Opting to use CWs for wastewater treatment and consequently designing the system, typically involves several steps (Fig. 3). The decision whether or not to use CWs in a new wastewater treatment project, mainly depends on three criteria:

- Available space: depending on the selected type and climate, conventional CWs require an absolute minimum of 1 m^2 PE^{-1} up to >5 m^2 PE^{-1}. With aerated wetland technology, 0.5–1 m^2 PE^{-1} is possible. If even that amount of space is not available, alternative spaces such as roofs or walls may be used, or other technologies need to be considered.
- Toxicity of the wastewater: like any biological wastewater treatment plant, the bacteria and in the case of CWs also the vegetation can only function within certain ecotoxicological boundaries. If toxicity is an issue, CWs can only be used further down in the treatment train, after having removed most of the toxic substances with other technologies. For urban wastewater, this would rarely be the case.
- Effluent requirements: as discussed above (Table 1). CWs are very effective in removing BOD, COD and TSS, reasonably effective in removing N and pathogens, and rather inefficient in removing phosphorus, unless using special porous media or additional P-removal techniques. Micropollutant removal is highly variable and depends on the individual components. Applying CWs thus depends on the requirements of the receiving water bodies or on the intended reuse purposes.

In a next step, the appropriate type(s) of CWs should be selected. Apart from the treatment performance which varies between types (Table 1), other points of attention are:

- Is a good primary treatment feasible or not? If not, subsurface flow CWs will not be appropriate.
- When applied for secondary treatment, odor and insect nuisance is typically lower in subsurface flow CWs. When using SF CWs, a reasonable distance between CW and nearest houses should be foreseen. For tertiary treatment, this is less a point of attention as concentrations are already much lower.
- Health and safety issues: open water surfaces as in SF CWs promote contact between wastewater and wildlife, and if not properly fenced entail drowning risks.

The next step is then to calculate the required CW area. For VF CWs, this still involves very simple rules of thumbs (e.g., x m^2 PE^{-1}), complemented in several countries with national standards detailing required pretreatment technology, filter depth and filter materials (grain size distribution, different layers) (Dotro et al., 2017). For FWS and HSSF CW, the most widespread design model is the P-k-C^* model. This model takes into account mixing conditions in the wetlands (P), weathering of pollutants (e.g., the phenomenon that bacteria will rapidly degrade easily biodegradable material, but be more slow in degrading more recalcitrant materials) (P), removal rates as affected by temperature (k), and a background concentration (C^*) which considers for instance that due to the decay of plants and microorganisms or due to droppings from wildlife, concentrations in the water never really go down to zero. For aerated wetlands, the design mainly involves a balance between the oxygen demand and the oxygen supply that can be provided through aeration. For a more detailed discussion, see Dotro et al. (2017).

For larger FWS wetlands, and for any HSSF wetland, translating the obtained area to an appropriate LxW further involves hydraulic calculations, in FWS according to a Manning-type equation, and in HSSF wetlands according to the Darcy equation (Dotro et al., 2017). The obtained area can also be split over several cells which gives some flexibility in terms of maintenance.

Most CWs are built with a plastic liner (PE, PP, etc.) to ensure water tightness. Alternatively, basins can be sealed with clay or concrete.

For SSF CW, choosing the correct porous media is essential. This involves firstly considering properties such as grain size distribution, porosity and hydraulic conductivity which will be of importance in the above-mentioned Darcy equation. Secondly, sorption capacity (for N, P, metals, etc.) should be taken into account if relevant. Finally, another important factor is the cost of the material and its transport, which in part depends on local availability.

The final step is to vegetate the wetland. It is highly recommended, and in some cases legally required, to use native plant species. *Phragmites australis* for instance is commonly used in Europe in CWs, but is considered an invasive species in the United States. Next, plants should be selected which can survive in hydric soils and in nutrient-rich conditions, and which preferably form a dense and deep root system. An overview is given by Vymazal (2013). Another potential criterion is the subsequent use of harvested plant materials (e.g., ornamental plants, for roof thatching) which may also influence the selection. From an aesthetic point of view, it may be desirable to select evergreen species, but this is not essential from a treatment point of view as the root systems keep supporting the biofilms also during winter. In temperate and cold climates, it is advised to harvest in spring, just before the plants start growing again. The dead biomass will provide some insulation during winter time, conserving heat inside the CW. In tropical climates, multiple harvests may be possible within 1 year, leading to higher nutrient exports.

Once in operation, a CW requires minimal maintenance. Apart from plant harvesting discussed above, this mainly involves maintenance of pumps, cleaning of water distribution systems, and sludge removal from the primary treatment step when applicable.

Synthesis

Since their conception in the 1960s, CWs have become a standard option for urban wastewater treatment. These manmade wetlands make optimal use of the physical, biological and chemical treatment processes offered by vegetation, (micro)organisms and soil/filling media. In addition, CWs can provide other important ecosystem services such as biomass production, habitat provision and cooling.

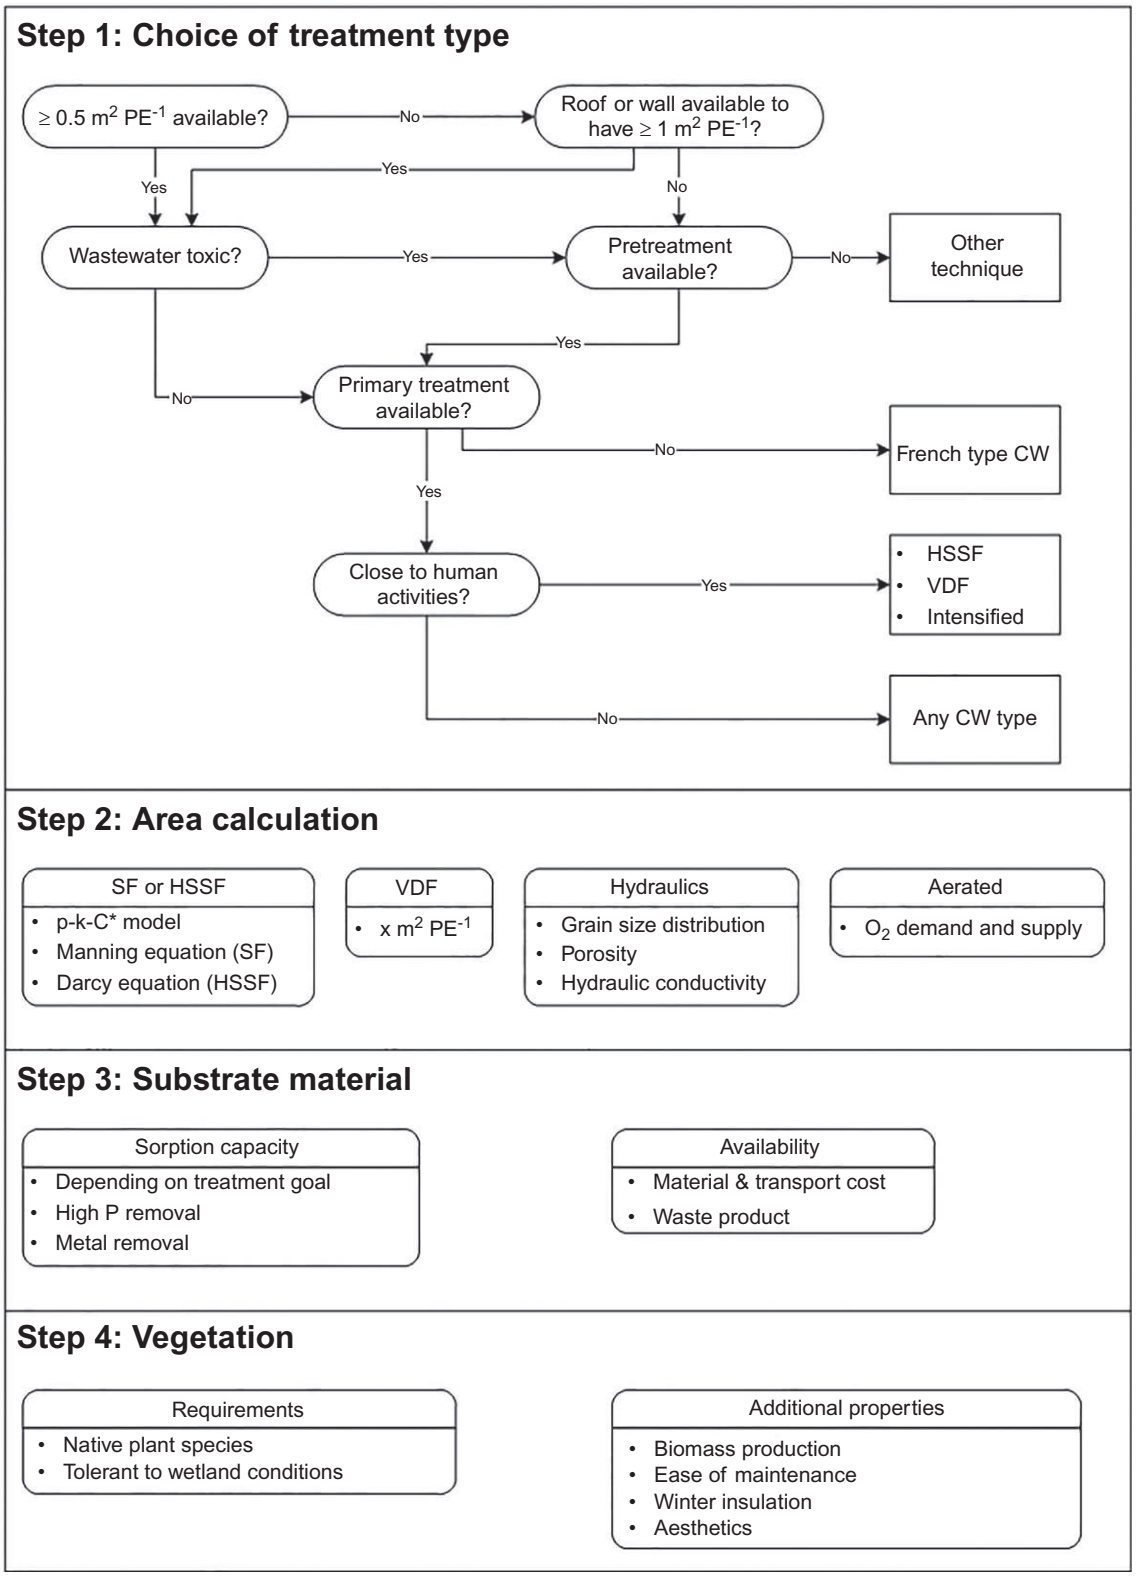

Fig. 3 Flowchart showing the essential steps in selecting and designing constructed wetlands.

The first generations of CWs mainly consisted of surface flow and subsurface flow types with traditional filling media such as gravel, sand and soil. The search for more efficient and less area-demanding technologies has paved the way for intensified wetlands and cross-over technologies, with a higher degree of engineering interventions. Especially in terms of urban wastewater treatment, this has resulted in an increasing application of CWs in more densely populated areas.

Knowledge gaps

- *Modelling*: Process-based models are an essential tool to guide design and operation of wastewater treatment plants. Despite many efforts (e.g., Langergraber et al., 2009; Samsó et al., 2015), CW models have not surpassed the research stage yet and are thus far not available as straightforward tools for consultants and engineers. This is one of the key aspects that hampers further uptake of CWs, unlike for instance the wide-spread activated sludge wastewater treatment systems for which the activated sludge models have become standard tools (Henze et al., 2000).
- *Emerging pollutants*: through time, various groups of emerging pollutants have become the focus of attention. There is a large body of evidence now on for instance the removal of pesticides, pharmaceuticals and personal care products, but researchers have only recently started to tackle other pollutants of concern such microplastics, PFAS (*Per-* and polyfluoroalkyl substances) and metallic nanoparticles.
- *Practical and full-scale applications*: a large majority of research papers on CWs are based on short-term laboratory-scale studies. Although such studies have undeniable merits, they also have many disadvantages such as ignoring meteorological influences, seasonal influences, wastewater variability. Longer-term, pilot-scale or full-scale studies are needed to irrefutably demonstrate the success of new concepts.
- *Ecosystem service valuation and accounting*: CWs, and to a wider extent all nature-based solutions, struggle to valuate and account for the less tangible ecosystem services such as aesthetics, evaporative cooling, air quality improvement, habitat provision etc. Ignoring such benefits when comparing green (nature-based) and grey (non-nature-based) solutions results in distorted cost-benefit analyses often favoring the grey solutions. Standardized methods remain to be developed that take such aspects into account.
- *Circular economy perspective*: It has become a commonplace to consider (urban) wastewater as an interesting resource rather than as a nuisance. Hence, rather than the classic linear approach of collecting—treating—discharging, the circular approach attempts to recover water, nutrients and other components contained in the wastewater, and energy. CWs can surely play a role in this model by delivering for example, effluents suitable for toilet flushing or even irrigation and by producing plant biomass that can serve as biofuel or can be converted into compost or even building materials. As rightfully pointed out by Masi et al. (2018), most research is still aimed at improving the treatment efficiency within a linear approach, and a paradigm shift is needed towards the circular approach.

Glossary

"Black box" concept Studying the system in terms of its inputs and outputs, without detailed consideration of its internal processes.
Agricultural loads/pollution Sediment load caused by soil degradation and erosion, chemical pollution by application of fertilizers and pesticides, discharge from animal farms.
Catchment Geographical area of land within which all precipitation falling and all water flowing in streams drains into a common outlet.
Diffuse pollution Differs from direct pollution originating from point sources since there is no specific point of discharge and hence are more difficult to control. Main pathways are surface runoff, subsurface flow, and soil loss. Agriculture is a key source of diffuse pollution, but urban land, forestry, atmospheric deposition and rural dwellings can also be important sources.
Ecosystem service The resources and benefits that humans derive from an ecosystem directly or indirectly.
Ecotone Transition area between two ecosystems, more specifically also border zones separating different land use types.
Eutrophication Enrichment of water by inorganic nutrients which results in intensive growth of plants (algae, macrophytes).
Interstream divide A terrain that separates drainage basins.
Nutrient load retention Difference between inflow and outflow of nutrients within the system boundary.
Urbanization Increasing proportion of human population living in urban areas.

Introduction

The importance of natural wetlands has been appreciated by numerous cultures throughout history, e.g., the economic basis of the culture of the Marsh Arabs (inhabitants of the Tigris-Euphrates marshlands, Southern Iraq) is based upon the marshes as a natural sustainable resource. Wetlands also received particular interest in terms of its role as a natural "filtering/purification-system" of freshwater in the second half of the 20th century (e.g., Mitsch et al. (1979), and more recently have received attention as engineered semi-natural systems in the treatment of diffuse loads of nutrients originating from agricultural areas (Mitsch, 1992; Vymazal and Dvořáková Březinová, 2018).

Until the 1950s, on a global scale, farming was primarily carried out on smaller, family farm units, as opposed to large monocultural and intensively managed units common today. Previously, therefore, the amount of farming waste produced was smaller and it was more easily assimilated by soil and receiving water bodies (Novotny, 1999). Between 1961 and 2009, however, there was a 12% increase in the extent of cultivated land to 1.6 billion ha (almost the size of Russia), mostly at the expense of wetlands, natural grasslands, and forest,s while, irrigated land increased by about 120% Dubois (2011). Together, these processes have resulted in the loss of about 35% of all natural wetlands (primarily inland wetlands) since the 1970s, mostly due to the encroachment of agricultural, residential and industrial land uses. This worrying trend continues, also affecting extensive areas of internationally renowned wetlands, e.g., the loss of the whole Matogrossense National Park (Brazil), or the oil exploration plans in the Okavango delta (Botswana) (Editorial, 2021). In addition, with the increase of the area under cultivation or intensification of grasslands, the amount of nonpoint (diffuse) pollution of nutrients arriving in surface waters has also increased. This has reached such an extent that in industrialized countries, agriculture has become one of the major sources of nutrient loss to surface waters (Mateo-Sagasta et al., 2018).

Diffuse pollution from agriculture may be defined as pollution without an obvious single point of discharge. Contaminants are indirectly discharged into receiving water bodies and cannot be easily traced back to a single source. Moreover, it may also mask effluents from minor point sources. While the term is not exclusive to loads deriving from agricultural activity and the transformation of land use, agricultural loads (consisting of, among others, phosphorus (P) and nitrogen (N) compounds) may indeed be considered primarily as non-point in origin and diffuse in transport. Since P and N compounds are the primary limiting factor for algal growth (Yang et al., 2008), agricultural diffuse loads are responsible for the eutrophication and degradation of inland surface waters across the globe (Carpenter et al., 1998), e.g., in Europe (Csathó et al., 2007), North America (Daniel et al., 1998), and Asia (Agrawal, 1999; Jiang et al., 2007). In Europe, nutrient run-off from agriculture is a critical obstacle to the achievement of the "good chemical and ecological status" of surface waters required by the Water Framework Directive (EC, 2000; Vymazal et al., 2020).

Retaining such loads and protecting surface waters in a non-urban environment requires complex catchment-wide approaches and should be achieved in the most 'natural way' possible. In this context one of the most effective tools for mitigation of risk of pollution to surface waters are (semi-)constructed wetlands.

This chapter provides an overview of the most important characteristics of (semi-)constructed wetlands in their capacity to retain agricultural diffuse loads from ever reaching inland surface waters. Due to their complex nature, the basics of wetland typology, the design criteria, and their possible location in the landscape (including riparian wetlands) require a multi-faceted discussion. Furthermore, agricultural diffuse loads of nonpoint source-nature, will also be introduced. We do not provide a detailed technical description of the underlying processes operating in wetlands, rather give an overview of the key concept and functionality of wetlands.

Wetlands

Up to date, there is no single scientific definition of what specifically constitutes a wetland (Box 1). Instead, depending on the discipline, there is a range of characterizations of the water bodies that might be defined as "wetlands." Despite this constrain, a commonly agreed characteristic of wetlands is that they are permanently or seasonally saturated by water, with soils distinct from those found in uplands, and whose flora (and fauna) is adapted to saturated conditions (Scholz and Lee, 2005). Wetlands can be found on every continent, with the most recent global area estimated as around 12.1×10^6 km^2 (Davidson et al., 2018). At the same time, there has been a loss of 64–71% in wetland area since 1900, while the total loss since 1700 may be as high as 87% (Davidson, 2014).

Box 1 Wetlands.

The term "wetland" refers to a wide set of primarily aquatic habitats that usually have a number of common features; thus, one route to a comprehensive definition is via the consideration of numerous definitions.

Wetlands represent a transient world existing between two which are easily recognizable, terrestrial and aquatic ecosystems, serving as an interface/ecotone (Holland et al., 1990) between the two, displaying some of the characteristics and depending on both, yet still remaining distinct (Smith et al., 1996; Mitsch and Gosselink, 2011; Scholz and Lee, 2005). It was the Ramsar Convention on Wetlands (1971) that brought the question of wetland conservation into the limelight. It represented a move towards a more specific wetland-definition (Gardner and Davidson, 2011): "areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six meters."

In contrast to fully natural wetlands, which are gravity-fed and have a fully natural vegetation, and thus found at the most natural, low-energy end of the hydrological gradient, constructed wetlands are higher energy water bodies engineered for a given purpose (Box 2). One example would be for treatment of urban or agricultural wastewater (Kadlec, 2009; Vymazal, 2010, 2011). In this instance, the aspect of deliberate construction makes them effective measures in the removal of particulate material and nutrients lost from agriculture and reduction of their transport into water bodies. Despite being constructed, such wetlands operate in a near natural state (Kasak et al., 2018). In relation to this function, eight primary principles of wetland design to control nonpoint source (diffuse) pollution were listed by Mitsch (1992).

Box 2 Ecological Engineering.

This discipline aims to solve environmental problems via the combination of ecology and engineering, designing natural systems using the quantitative approaches of science with technology, in the form of self-designing ecosystems, to generate efficient and cost-effective alternatives to common environmental solutions. Examples might include the restoration, design, and construction of ecosystems, including wetlands, which shall contain all biological components present under natural conditions (Kangas, 2003; Mitsch and Joergensen, 1989).

The system should:

- require minimal maintenance and be developed to maximize the possibility of self-maintenance and self-design;
- utilize natural (renewable) energies;
- be embedded in the natural landscape, and not against it;
- have one major and multiple side-objectives;
- be designed as an ecotone (i.e., include a buffer strip, see Section "Riparian wetlands as buffer strips" for details);
- be given time to develop;
- be designed for function, not for form;
- mimic natural systems rather than being over-engineered.

Typology of wetlands

In the early years, typology of *natural wetlands* was primarily based on their utilization (farmable, marginal and unfarmable). The Ramsar Convention on Wetlands (1971) fundamentally changed this paradigm, placing wetlands into three main categories: marine and coastal wetlands, inland wetlands, and man-made wetlands. These were then further subdivided into 42 wetland types; see e.g., Finlayson (2016). Numerous attempts have been made to refine, standardize and/or modernize this typology to arrive at a more systematic classification and to move away from the current listing of wetlands. The modern classification of wetlands is approached by a range of highly diverse perspectives, and these are also applied at different international, national or regional levels. Even the aims vary, such as comparisons of natural value, or examinations of the functionality of a wetland. Yet, the typology agreed in the Ramsar Convention has remained one of the most frequently used typologies on a global scale.

In contrast to the discussion above, the *categorization of constructed wetlands* (Box 3) is much more straightforward, consisting of two main categories. The first one is based on the type of aquatic plants, commonly known as macrophytes. This would include

BOX 3 (Semi-)constructed wetlands.

Constructed wetlands or treatment wetlands are ecologically engineered artificial wetlands designed to harness the natural processes taking place in wetland vegetation and soils, their associated microbial assemblages and utilize these in the treatment of organic, inorganic and excess nutrient contaminants in surface water, municipal wastewater, domestic sewage, refinery effluents, or landfill leachate.

Semi-constructed wetlands represent a "compromise" between natural and constructed wetlands in terms of their purpose and functioning. They are commonly established on degraded/modified wetlands and/or in areas where the filtering capability of a natural wetland must be enhanced and directed by means of minor construction/modification (Illustration 1). At the same time, semi-natural wetlands may be considered as those which are constructed but do not need any energy input and have a minimum of artificial structures, such as free water surface wetlands. Although this type is fully artificial, again, the level of construction is minimal, and therefore resembles a natural wetland. The extent to which a restored wetland resembles a natural one will ultimately define its success.

Illustration 1 The outflow of the Kis-Balaton Water Protection System to Lake Balaton (Hungary, Europe) with neighboring agricultural fields, marshes, and the wetland ecosystem in the distance. The construction shows the speedway being built crossing the inflow channel of the River Zala to Lake Balaton after passing through the Kis-Balaton Water Protection System (see e.g., Hatvani et al., 2014; Honti et al., 2020; Bhomia et al., 2022). Foto by 'LégiProjekt'.

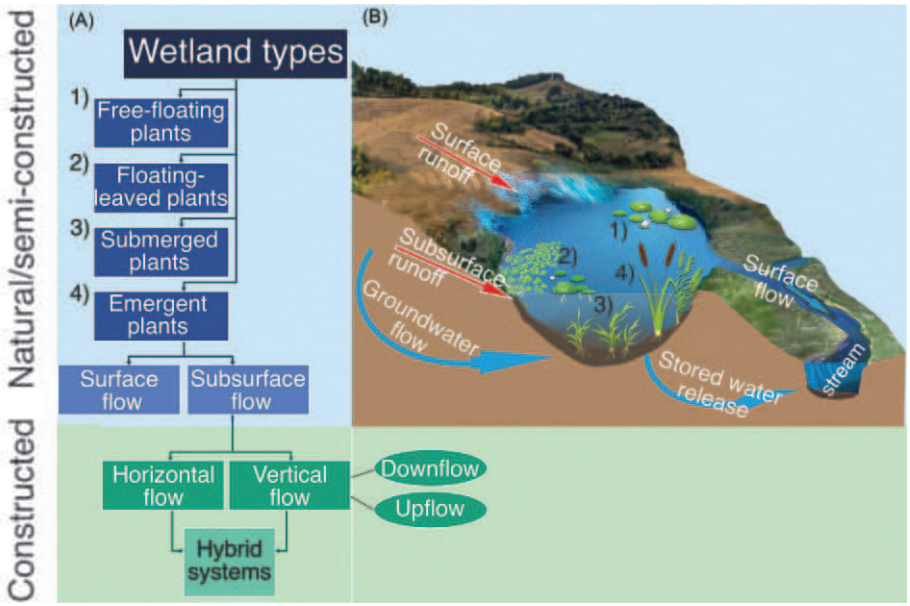

Fig. 1 Types of constructed wetlands after Vymazal (2001) (A), and the illustration of the most basic hydrological fluxes in a semi-constructed wetland (B). Red arrows indicate the direction of loading processes, blue arrows show the primary water flow directions. The numbers in the figure (B) indicate the types of vegetation based on which classification can be done (A).

species normally found growing in wetlands of any kind, either in or on the water, or where soils are flooded or saturated long enough for anaerobic conditions to develop in the root zone. In terms of growth type and morphologies, these may be described as emergent, submergent, floating-leaved, or floating species (Fig. 1A and B).

The second categorization is based on the water flow regime (Fig. 1A: green background). According to the International Water Association (2000), regimes can be subdivided into three basic types of treatment systems in constructed wetlands: free water surface, horizontal subsurface flow, and vertical flow (Fig. 1A) (Kadlec, 2009; Vymazal, 2001).[1] Wetlands with free water surface (FWS) closely resemble natural wetlands. Since semi-constructed wetlands directly exploit the remaining resources of the former natural wetlands, the FWS model reflects most of their characteristics.

Non-point source (diffuse) pollution

Great efforts have been made to handle point source pollution in the past. Unfortunately, the retention and treatment of agricultural diffuse loads has not been so successful. Several factors lie behind this. In the early years (mid-late 20th century) of recognizing and attempting to ameliorate pollution arriving to surface waters, point source pollution had an overwhelming and much more distinguishable effect on receiving waters than diffuse loads. When management measures seemed to fail, or were not as successful as anticipated, greater research effort was expended on diffuse pollution, which is harder to monitor and identify than point sources that are typically discharges of effluent from a pipe.

The main characteristics of diffuse sources of pollution according to Campbell et al. (2005) are those discharged into the receiving surface waters intermittently and in a diffuse manner. These pollutants transit across landscapes—involving complex transport and transformation routes through several media—on a catchment-scale with a spatiotemporally variable volume and concentration depending on the environmental conditions (meteorological, geological and geographical). They involve a variety of sources and pathways (Heathwaite et al., 2005). It is difficult or even impossible to monitor them at their source, due to their non-point nature and any impact assessment is performed rather on a catchment-scale, focusing primarily on nutrients, suspended solids, toxic compounds and pathogens. These, in turn, operate in certain situations superimposed on and/or parallel to point sources, in which case they are practically indistinguishable from them; e.g., Hatvani et al. (2015). The issue is further complicated since these systems may cross administrative divisions such as catchments, sub-national regions or even national borders, making their control even more difficult.

[1]For a more detailed description of the typology, the reader is referred to the Ecology of Wetlands: Classification Systems chapter of the first edition of this encyclopedia Tiner (2009) and the Constructed Wetlands for urban wastewater treatment: an overview chapter in the Human pressures and management of Inland Waters Section of this encyclopedia Rousseau et al. (2022).

Agricultural catchments

Diffuse pollution from agriculture is of different origin: (i) increased soil erosion and soil loss, (ii) chemical pollution by fertilizers and pesticides, (iii) irrigation return flow, and (iv) pollution from animal husbandry (Campbell et al., 2005). In the past there have been attempts to reduce the overall loss of nutrients with

(i) the focused measures taken to reduce point source loads;
(ii) changes in technologies (in fertilizers, sewage handling in wastewater treatment plants, etc.) and policies, e.g., the banning phosphorus from detergents;
(iii) the decline of industry and agricultural production, characteristic in the late 20th century over much of the area of Eastern European countries, e.g., Hatvani et al. (2015); and,
(iv) the implementation of directives such as the Clean Water Act in the US (US Gov, 1948), or the Water Framework Directive in Europe (EC, 2000).

Despite the foregoing, the water quality of surface water bodies remained poor, and still of major global concern; see e.g., Thornton (1999), Carvalho et al. (2019), Malone and Newton (2020). A likely cause of this somewhat paradoxical result is that, while nutrient losses from easily identified point sources have indeed been reduced in many countries, diffuse loads originating from agriculture remain significant.

Given current trends in global population growth, according to the Food and Agriculture Organization (FAO), by 2050 the current output of the food production industry must increase on average by 70% compared with 2011 (Dubois, 2011) to be able to maintain current highly wasteful consumption habits in which approximately one third of produced food is lost (FAO, 2011). Agriculture is the main source of diffuse pollution affecting surface (and subsurface) waters on a catchment-scale. Therefore, any increase in productivity presents a risk to, among others, the quality of surface water ecosystems and ecosystem services. The phenomenon can be viewed both as the loss of substances from agricultural fields and an overuse or misuse of land (Novotny, 1999), or the appearance of these substances as excess in surface waters. The primary impacts will be associated with the enrichment of nutrients derived from fertilizers, applied in agriculture and forestry, which contain phosphorus and/or nitrogen. Furthermore, sediment contamination is likely to increase, and pathogens, pesticides, salts, trace elements, dissolved organic carbon, and substances contributing to the increase in biological oxygen demand are also likely to be arriving in the receiving waters (O'Geen et al., 2010).

The management of diffuse pollution from agricultural areas is necessarily a complex operation requiring catchment-wide approaches (OEDC, 2017). It is in this context that (semi)-constructed wetlands can be efficient tools for mitigation of risk of pollution to surface waters.

Wetlands in the mitigation of agricultural diffuse pollution

Constructed wetlands in agricultural settings are very different from their urban "treatment" counterparts in terms of flow, nutrient composition, etc. Under natural conditions, the inflow rate to wetlands is characterized by a higher degree of variation over seasonal or even diurnal scales. In contrast to constructed treatment wetlands used to treat municipal wastewater, this might be due to localized meteorological events (Gopal, 1999). Not only the flow conditions, but also the composition and concentration of substances in the inflow are different.

Possible location of semi-constructed wetlands in a catchment—general considerations

The location of wetlands, whether on an interstream divide, coastal lowland, in a topographic depression, or on a slope, is a product of historical development and the regulation of surface water within the landscape. For a semi-constructed or constructed wetland to function, it must be self-sustaining. In order to achieve that, it has to be properly embedded in the catchment, because its location in the landscape influences its geographical characteristics, and should be evaluated in this context. Elements such as slope, thickness and permeability of soils, and the hydrogeological properties of the subsurface layers have to be taken into account, since all of these influence surface and subsurface flows of water. The slope of the area where the wetland is located is a key factor. In the case of slopes which have a moderate to steep gradient, similar characteristics will prevail, with any changes ocurring mainly in the flora; however, the steeper the slope, the more the functionality of the buffer strip is shifted towards erosion prevention and P retention from runoff (Stuart et al., 2022).

The question of where a wetland is located within the catchment is important. In the case of upstream wetlands (Fig. 2A), their optimal location coincides with the maximization of particle trapping, placing them close to the sediment resource areas (hot-spots), where the erosion potential is the highest within the catchment. In this way, travel distance is minimized and the likelihood of the wetland receiving intact aggregates, which have greater settling velocities than smaller particles, is higher (O'Geen et al., 2010). If, however, the aim is to maximize the retention of agricultural diffuse loads within the landscape (i.e., collect as much of the effluents as possible), the ultimate receiving water bodies must be located at an elevation relatively lower in the catchment than the contributing upland hot-spots (Fig. 2B–D). The essential point is that, the closer the wetland to the source, the more sediment it retains, while the further downstream it is—and therefore the more extensive the catchment upstream of it—the greater amount of diffuse loads it can retain.

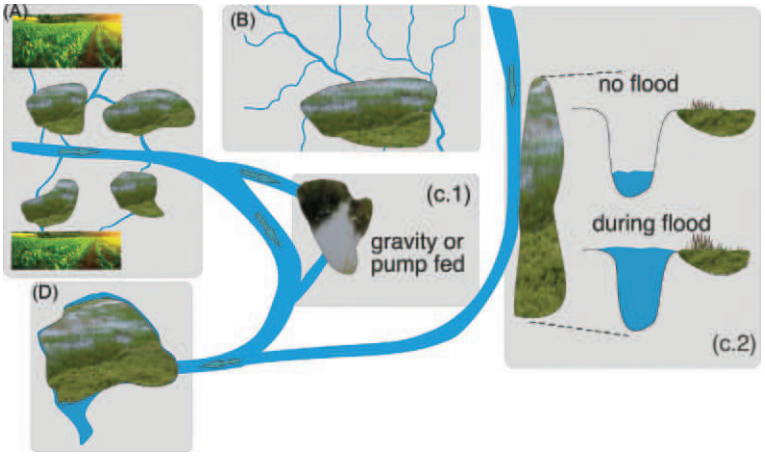

Fig. 2 Possible locations of (semi-)constructed and/or natural wetlands in a landscape for controlling nonpoint source pollution. Upstream (A); isolated wetlands with their own catchment (B); riparian (C) including gravity/pump fed (c.1) and flood fed (c.2); and downstream (D) wetland locations. All of these are illustrated in a catchment of a large river receiving agricultural diffuse loads inspired by Mitsch (1992). The blue arrows indicate the water flow direction.

To evaluate the position and possible functions of wetlands created or restored for compensatory mitigation purposes, the context of the landscape itself should be considered, and that landscape is divided into catchments, by watersheds. Wetland development and/or restoration have to be drawn up with reference to the catchment in order to identify the most appropriate location for mitigation sites (NRC, 2001). Agricultural runoff (surface and/or subsurface) can reach rivers, streams and lakes via different paths across a wetland system depending on its construction and location within the landscape and a catchment (O'Geen et al., 2010). Within a catchment, wetlands can be located: (i) U*pstream*, where numerous relatively smaller wetlands independently intercept waters arriving from smaller water courses/channels before allowing these to reach the main river or stream (Fig. 2A). These, however, are not necessarily located in the streams themselves: one common location is in the restored floodplain (e.g. Fig. 2B). This then constitutes the next location: (ii) *riparian zones*. These run parallel to the river, and serve as an interface between the land and freshwater ecosystems, and thus represent transitional areas. Wetlands in the riparian zone can be further subdivided: (ii/a) pump fed (Fig. 2c.1) or (ii/b) gravity fed (Fig. 2c.2), with the latter having continuous water flow, or flow only during flood events. Lastly, (iii) *downstream* wetlands are characteristic of water courses which are mostly located instream (Fig. 2D), and are among the largest in size and runoff, usually comprising engineered control structures (Mitsch, 1992).

Design criteria and characterization of wetlands adjacent to agricultural areas intended to increase retention efficiency

(Semi-)constructed wetlands

Semi-constructed wetlands are designed to serve a variety of purposes, such as the retention of excess nutrients through the ecosystem services they provide: e.g., contribution to biological habitats and diversity, hydrologic buffering, or water filtration (for details see Section "Ecosystem services"). Their position within a catchment and the landscape involves many considerations (as seen in Section "Possible location of semi-constructed wetlands in a catchment—general considerations"; Fig. 2). Wetlands at the head of stream channels prevent further pollution by exercising their effects before the water enters the mainstream channel. The efficiency of retention is primarily determined by how evenly the arriving water is distributed across the wetland area. Therefore, the most important design parameters of constructed wetlands are (i) area and (ii) hydrologic load, which in turn, affect the (iii) retention time of the water in the system (see Section "Retention of substances" as well).

The minimal area of a wetland ((i) above), will vary between 0.1% and 7% proportionate to the size of its contributing catchment (O'Geen et al., 2010; Mander et al., 2017). If the wetland to catchment ratio is too small, the connectedness problem[2] will arise—see Mander et al. (2017) and Zedler (2003)—excessive loading rates will limit the water and substance retention times, and a significant amount of water will not flow through the wetlands. In contrast, larger wetlands will be highly sensitive to dry periods, due to the increased water surface area.

From a hydrological perspective, flow velocity, volume, seasonality and duration of flow are important factors, and will differ greatly among agricultural catchments. Therefore, all these parameters have to be considered in the design process (O'Geen et al., 2010). Depending on the spatiotemporal distribution of rainfall there is a continuous variation in the water depth, degree of water saturation and the area of the wetland. This spatiotemporal pattern affects the surface area of wetlands, which vegetation is present, the pace and degree of particle settling and resuspension, biodiversity, the redox status of the soil and its mineralogy, and last, but by no means least, the capability of the wetland to remove pollutants (Mitsch and Gosselink, 2011; O'Geen et al., 2010). Fluctuations in floods and dry periods facilitate the aerobic and anaerobic conditions, respectively, which are necessary for wetlands to retain

[2]The connectedness problem deals with the hydrological connectedness of wetlands t the stream network, which is an important factor in their phosphorus and nitrogen removal capacity, see Mander et al. (2017).

their natural functioning as much as possible; e.g., Hatvani et al. (2011). The coming and going of these aerobic and anaerobic conditions facilitates biochemical nutrient removal processes, such as denitrification and the degradation of organic carbon, as well as assisting in the transformation of phosphorus to soluble forms via Eh/pH driven reactions (O'Geen et al., 2010).

As a general principle, to calculate hydrologic loading and hydraulic retention time ((ii) and (iii) above), the flow rate has to be divided by the wetland surface area and the volume, respectively. In general, maximizing the retention time should elevate the degree of pollutant removal, and the removal efficiency correlates negatively with the hydraulic load (Mander et al., 2017). Mitsch and Gosselink (2011) suggested that (ii) hydrologic loading rates should vary between 25 and 50 mm day^{-1}. Although the manipulation of the area of a semi-constructed wetland is necessary to optimize hydraulic loading rate (O'Geen et al., 2010), this is difficult to achieve, since such wetlands can receive highly variable inflow rates originating from potentially vast areas of land in most agricultural settings.

Given that (iii) hydraulic retention time depends on the volume of a water body, the same retention time can be attributed to a wetland small in area, but deep, as to a one which is extensive, but shallow. These, however, will not have the same ecological characteristics, due to the effects of water depth on various key elements of any water body. These include plant habitats, the Secchi depth,[3] particle settling and resuspension rates and perhaps most importantly, depth is negatively correlated with the efficiency of the removal of most pollutants. The shallower the depth, the greater the surface area for a given planned volume in engineered systems, since more plant and microbial biomass can be present. For example, a wetland with a small surface area, but which is deep may have a similar retention time to a more extensive but shallow system, but the latter may well display a higher degree of efficiency in nutrient removal. This is why many studies suggest that depth should range from 15 cm to 50 cm. Thus, areal loading rate is a more accurate criterion then the load per volume (O'Geen et al., 2010).

In the case of a constructed wetland, the ratio of its length to width (as measured along the direction of flow and perpendicular to this) is a critical question in terms of the optimal proportions regarding their effect on removal efficiency (Mander et al., 2017). In order for semi-constructed wetlands to be efficient in load retention these have to be of a width sufficient to ensure the effective trapping of sediment and other particulate materials, and of a length sufficient to ensure an adequate residence time. Some argue that long, narrow wetlands are less efficient at removing contaminants than square or round ones (Scholz et al., 2007; O'Geen et al., 2010). Nevertheless, it is those wetlands with a channel-like surface flow and a length to width ratio of >20:1 that achieve the best water treatment performance (Kadlec and Wallace, 2008). In the meanwhile, in rectangular constructed wetlands, a serpentine flow-path winding along the long axis is the best way to increase hydraulic retention time (Persson et al., 1999).

Besides the abiotic design characteristics discussed above, the type of vegetation that is planted affects the effective area of the wetland, its hydraulic retention time, as well as its light conditions too. The most important task in either restoring, or designing/creating, a wetland is at least to maintain and if possible increase the diversity of flora and fauna. Diversity in terms of plants ensures a low cost, whether this is initial, operational or maintenance, and the efficient operation of any wetland system. For details on the types of vegetation, the reader is referred to Rousseau et al. (2022), and regarding the related processes to Section "Retention of substances".

Riparian wetlands as buffer strips

Riparian zones form an ecotone between anthropogenically disturbed lands and surface waters. These are one of the most effective and widely applied means to the interruption of the movement of diffuse substances from adjacent agricultural areas to surface waters (Stutter et al., 2019). This is because the processes taking place in such zones are fundamentally driven by the channel dynamics, flooding and soil moisture. In addition, and in a similar way to wetlands, these areas filter water originating from intensively managed agricultural land in the vicinity, and polluted flows which arrive by both overland and subsurface routes. They also work to protect the banks against erosion. Furthermore, the shade from the canopy of trees growing in riparian zones helps inhibit the intensive growth of aquatic macrophytes, not to mention improving the microclimate in the adjacent fields (Fig. 3) (Mander et al., 1997). Nowadays the extent of the areas adjacent to intensively cultivated agricultural zones is becoming ever more limited, often reduced to only narrow (sometimes mandatory) strips of vegetation along streams and rivers characteristic of various riparian soil water conditions, and without the prescribed management of this buffer zone between field and water body (Mander et al., 2017; Stutter et al., 2012).

That said, many riparian areas can and do function as wetlands, if the water table has a sufficient spatiotemporal presence for hydromorphic features, characteristic for wetlands to develop in the top 50 cm of the soil profile (Mitsch and Gosselink, 2011). Conversely, only those wetlands which are located along the banks of a stream or river and have at least seasonal connection to them can be rightly regarded as riparian (Fig. 2).

Riparian buffer zones frequently consist of semi-constructed wetlands. It should be borne in mind that a wetland itself can have its own buffer zone(s) (see e.g., Norman (1996)), but in such a case, this will not be riparian rather "just" a buffer zone. In the present case the focus is on semi-constructed wetlands located within the riparian zone of a larger river (Fig. 2C). Specifically, functioning as buffers between the larger river and the intensively managed adjacent agricultural fields, since these have a much higher efficiency in the retention of nutrients from the river than a vegetated buffer strip (Osborne and Kovacic, 1993). Hence, semi-constructed buffer wetlands in riparian zones have become a widely implemented and studied "edge-of-the-field" mitigation measure to provide a physical barrier against nitrogen, phosphorus, and sediment transfer (Stutter et al., 2012).

[3] "The Secchi disk in most countries is a circular white disk 30 cm in diameter that is lowered into a natural body of water by a human observer until it disappears from view. The depth of disappearance is a visual measure of the clarity of the water" Preisendorfer (1986).

The main processes mediating water quality are sediment trapping, denitrification, nutrient uptake, and the sorption of phosphate into soil particles, as is the case in natural wetlands; see review by Vymazal (1995). By example, with regard to P loads—which are typically bound to sediment—a buffer strip 10 m in width can reduce these P loads brought by surface runoff by up to 95%, but again depending on the P forms efficiency can vary; see e.g., Dorioz et al. (2006). Nitrate is more difficult to remove, because it is less likely to adsorbed in the soil and may be removed and/or transformed by soil microbial processes such as denitrification in these zones. Nonetheless, there is about 50% efficiency in its removal in these same buffer strips (Vought et al., 1995); e.g., Fig. 3 circular arrows. Efficiency may, however, vary greatly, as the relationship between pollutant removal and buffer width is nonlinear with wider buffers tend to remove more N (Mayer et al., 2007). To reach a similar level of retention as in the previously mentioned case, in a coastal setting for P, a 250 m width is needed, while for N this figure is only 3.5 m. In any case, generally optimal buffer efficiency occurs at approximately 80% removal (Desbonnet et al., 1995). It should be noted that *there is no "one-size-fits-all solution"* in this regard.

In order to exploit the retention capability of a riparian wetland, its integrated embedding into the landscape is suggested, and as close to the stream as practicable. Moreover, besides engineering and landscape considerations, when wetlands are designed and placed within a catchment, a balance should be reached between the primary drivers of nutrient removal rates (e.g., the hydraulic loading rate and inflow concentration), so the wetland is capable of achieving peak retention capacity of the total transport of nutrients. This balance is, as in many natural systems, delicate, and subject to tipping into imbalance as a result of only small changes in any of its elements. In terms of the likely effects of climate change, loads of N (Jeppesen et al., 2011) and P (Jeppesen et al., 2009) from cultivated areas to surface waters will probably increase, rendering efficient functioning even more important.

Proceeding from the agricultural fields towards the stream, the following sequence is suggested: First, a narrow grass strip at the upland edge of the zone for runoff control and which will retain suspended solids and phosphorus. Next, an area of shrubs and a wider area of primarily deciduous trees; this should be capable of retaining nitrate, providing organic matter and shade under the canopy (Mander et al., 2017). Heading towards the stream, the riparian trees will achieve bigger and more robust growth as the shallow groundwater table (replenished by the stream) approaches approximately the level of the ground surface. The final zone is defined by the saturated condition of the soil, and it is only here that the riparian wetland ecosystem proper can be said to begin, and it is this zone that forms the ultimate "defense against" the excess substances lost from agricultural fields reaching the stream or river Fig. 3).[4]

Retention of substances

In agricultural settings, wetlands serve as filters and transformers of water-quality constituents. In terms of the mass balance, they may function as either sinks or sources, depending on the wetland type, hydrological conditions and the duration and temporal variability of input nutrient flow. The latter may adversely affect both the rates and pathways of removal mechanisms by the transfer of contaminants from one compartment of the system (water column) to another (sediment). Such transfers are the result of a combination of hydrological and biogeochemical processes which control how they are mobilized in an agricultural landscape and subsequently delivered by land or water. Due to the complexity of agricultural landscapes, these processes might as well be difficult to understand and to model (Dupas et al., 2015).

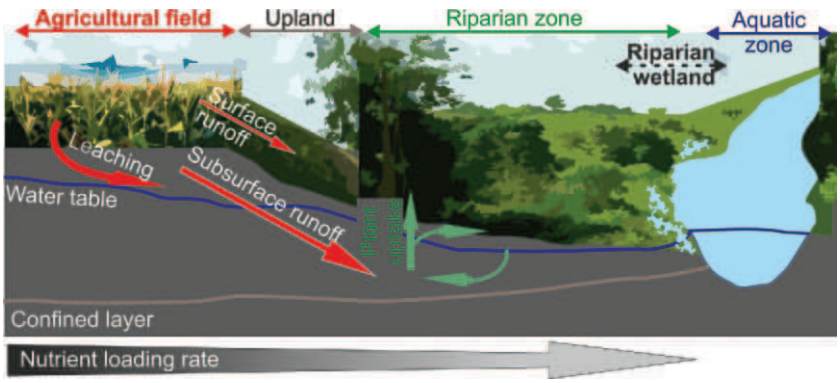

Fig. 3 Cross-section of a riparian zone including a riparian wetland area, showing the primary hydrological fluxes responsible for nutrient transport from agricultural land. The arrowed divisions at the top of the figure indicate the various areas of a (simplified) riparian zone. Red arrows indicate the direction of nutrient loading processes, with the shaded arrow at the bottom indicates the loading rate as it decreases towards the stream, the shading reflecting the intensity of these from dark (higher) to light (lower). Green arrows indicate main processes retaining and reprocessing nutrient loads arriving from the agricultural field.

[4]For a more detailed description of the three-zone structure, the reader is referred to the Constructed Wetlands for urban wastewater treatment: an overview Chapter in the Human pressures and management of Inland Waters Section of this encyclopedia (Stuart et al., 2022).

In constructed wetlands, the removal of contaminants can take place via various mechanisms. These primarily include: the biotic uptake of nutrients, including, in some cases, salts; pesticides and organic matter undergoing microbial degradation; biogeochemical transformations, for example, methanogenesis and denitrification; the sedimentation of substances like phosphorus, pesticides, particulate organic carbon and pathogens, and their subsequent burial; biogeochemical transformations, such as denitrification and methanogenesis; redox transformations, which in turn, affect qualities like solubility, sorption, and even toxicity; pathogen predation; pesticides and organic matter undergoing photodegradation (Zedler, 2003).

Wetland flora is the major element of such a system through which these mechanisms operate for the retention of nutrients. The most essential component in this regard are the micro-biomes in the sediment/soil in the vicinity of the roots. As might be expected, it is most active in the growing season, due to higher rates of microbial activity and macrophyte productivity. An increased plant presence increases the nutrient removal efficiency; though the quantity removed will depend on the choice of plant species used to vegetate the area; for a comprehensive review see Vymazal (2007). Whatever exceptions and caveats might be made, it is possible to make the following general points concerning wetland plants:

- They influence water chemistry in two directions: through their uptake of nutrients, acting as nutrient sinks, and through input, as nutrient pumps transferring compounds from the sediment to the water column (Fig. 3: plant uptake). The relationship of emergent vegetation to contaminant removal is not a simple, straightforward one.While vital in the translocation and transformation of nutrients, the vegetation can only remove these excess materials from the system if the vegetation itself is harvested and removed (or in the case of nitrogen, burned). That said, however, if this is not the case, wetland vegetation can and does still contribute to nutrient removal in a variety of ways, but indirectly: simply by impeding water flow, which in turn, promotes particle settling and the prevention of sediment resuspension, on account of the mere presence of stems and leaves within the water column (Fig. 1B) (Johnston, 1991).
- Wetland plants also perform vital functions in the wetland ecosystem by providing habitat for other taxonomic groups. Apart from the living plants themselves, their litter and stems increase the surface area of the substrate available for microbial attachment, as also for biofilm communities, and these two are in the front line of many transformation processes. What is more, the death and decay of plants recycles P and N to the system, while supplying organic carbon which then plays a central role in many microbial transformations, a key example in the current context being denitrification. Parallel to this, the carbon content of plant litter functions as the energy source for heterotrophic denitrifiers (Brix, 1994).
- Plants also influence hydrologic conditions, like transpiration and water shading; and they also stabilize the banks by modifying currents and sedimentation, as well as mitigating the effects of flooding. In addition, the composition of such vegetation may serve as an indicator of the health of a wetland (Cronk and Fennessy, 2009).
- Wetland plants intercept solar radiation, thus reducing the penetration of UV light into the water column, thereby reducing pathogen attenuation and the process of photodegradation. However, light interception also "shades out" algae, resulting in fewer phytoplankton which, in excessive numbers might cause high biological oxygen demand and hypoxia (O'Geen et al., 2010).

Nutrients: Phosphorus and nitrogen

Looking at the number of influencing factors, the question may arise of what might in fact be expected of semi-constructed / natural wetland systems in terms of their retention of agricultural diffuse loads. The degree of efficiency in nutrient removal of semi-constructed wetlands has been discussed from innumerable angles over recent decades; e.g., Fisher and Acreman (2004), Land et al. (2016). A thorough review of the topic in 2016 looked at more than 200 wetlands (primarily in N America and Europe) which were assessed in 93 different papers (Land et al., 2016). Despite this potentially baffling variety, one general and overarching truth can be established: the greater the amount of nutrients (total phosphorus (TP) and total nitrogen (TN)) received by the wetland, so, proportionately, the greater percentage of that total will the wetland be capable of removing, see e.g., Hatvani et al., 2014. It is, however, important to impose a qualification on this general point: the specific degree of the efficiency of the removal of a given amount of nutrients will vary greatly across different sites depending on factors such as the structure and functioning of the particular wetland, inflow concentration, load variations, hydraulic retention time, the temperature regime (Kadlec and Reddy, 2001), hydraulic efficiency, and the type of wetland in the first place (Land et al., 2016; Kadlec, 2009). It is for this reason that making any comparison or any generalization at all is fraught with difficulty. Taking all of this into account, it is no wonder that there has been widespread confusion over the relationship between nutrient reduction within wetlands and the quantity of nutrient loads arriving in them.

Wetlands play a crucial role in the retention of phosphorus and nitrogen compounds from agricultural fields, thus retaining the degradation and eutrophication of freshwater ecosystems. Temporary storage via plant uptake retains both P and N, while inorganic soil adsorption, and in peatlands, incorporation of organic matter into the peat, both reduce P loads. N, meanwhile, is retained by microbial activity, specifically, its immobilization and storage in the soil as organic N and its conversion to gaseous N-forms (Mander et al., 1997).

Before presenting some figures for removal rates, it is important to note that the removal rates of nutrients loads are commonly expressed either in g m^{-2} $year^{-1}$ or in %, and referred to as *removal efficiency*. (In certain cases, the former is also expressed in kg ha^{-1} $year^{-1}$, which basically gives values one order of magnitude larger). It is also necessary to note that, as a general principle, in wetlands' nutrient retention, the variability of diffuse inflow in terms of its occurrence and concentration is quite problematic. The

more balanced the inflow of nutrients, the more the system can retain (Tanner and Kadlec, 2013). Thus, there is a strong tendency in the numerous reviews of nutrient retention to treat wetland systems as 'black boxes', for which the internal workings are not always explored.

Nevertheless, turning to the figures, it can be stated that in the last 25 years of the 20th century, sustainable removal rates for constructed wetlands were typically 10–40 g N m^{-2} $year^{-1}$ and 0.5–5 g P m^{-2} $year^{-1}$ (Mitsch et al., 2000). These may be compared with figures from a review of the first 20 years of the 21st century, which suggests a wider range for N and P removal from agricultural drainage and runoff by free water surface constructed wetlands: approximately 1 to 1.125 g N m^{-2} $year^{-1}$ (avg. 117.5 g N m^{-2} $year^{-1}$) and approximately 0.2 to 115 g P m^{-2} $year^{-1}$ (avg. 15.7 g P m^{-2} $year^{-1}$) (Vymazal and Dvořáková Březinová, 2018). The most comprehensive study reviewed 203 wetlands of all types (Fig. 1A), with various inflow types (e.g., agricultural runoff, secondary domestic wastewater, etc.). The average removal rates for TN and TP were 184 and 15 g m^{-2} $year^{-1}$, respectively; that is, these were of the same magnitude as in the case of the wetlands discussed previously, or those reviewed by Weisner et al. (2015), although it must be emphasized that these were mostly (about 80%) free water surface wetlands, and about 50% of the wetlands had agricultural runoff inflow (Land et al., 2016). It should also be emphasized that within the bounds of natural variability, the removal efficiency of TN and TP (among others) increases with hydraulic loading rate (mm day^{-1}) and inflow concentration (mg L^{-1}); note that there is a steeper increase in removal rate at concentrations higher than about 20 mg L^{-1} and about 0.5 mg L^{-1}, respectively (Land et al., 2016).

Outlook on retaining pesticides

The number of products registered as pesticides are already in the thousands and in 2017 approximately 4.1 million tons were *reportedly* applied globally (FAO, 2020). These are substances or their mixtures, primarily used to control weeds, pests and pathogens in agriculture to increase crop yields, and used to protect humans from vector-borne diseases (Nicolopoulou-Stamati et al., 2016). Unfortunately, after playing their role in the fields such compounds enter surface and subsurface water bodies primarily via diffuse pollution (see Section "Non-point source (diffuse) pollution"). The mechanisms of this process are as follows: surface runoff and erosion; spray-drift[5]; leaching; drainflow, or as it is sometimes called, preferential flow; various other atmospheric routes, such as deposition and atmospheric transport of soil eroded by the wind (Reichenberger et al., 2007). Although there are various highly important negative aspects of pesticides and their residues, in the present subsection we focus on their presence and more importantly retention via wetland systems from surface waters.

In surface waters pesticide concentrations are primarily related to soil management practices and agriculture, and their most effective control is with the application of edge-of-field and riparian buffer strips (see Section "Riparian wetlands as buffer strips"), vegetated ditches (which may replace the grass strip of a riparian buffer strip), and constructed wetlands. However, removal efficiency varies across different pesticides, grouped based on the chemical basis of their compounds between approximately 25% (triazinone) to approximately 100% (e.g., organochloride, organophosphate), or based on the pesticides' physicochemical parameters (Vymazal and Březinová, 2015). It is a common characteristic, however, that removal efficiency increases with retention time in all cases, although not in a linear fashion. Depending on whether the environment is aerobic or anaerobic, the following processes will be operating in pesticide mitigation: hydrolysis, photolysis, sedimentation, adsorption, microbial degradation or plant uptake. However, the extent and intensity of these processes will depend on local conditions, making an a priori decision regarding the importance of any one of them difficult. One thing does appear to be definite, and that is the evidence that the presence of vegetation enhances pesticide retention: as one study found, plant uptake and sorption of systemic herbicides could reach up to 80% in some cases (Vymazal and Březinová, 2015). This however raises the question, how much of these pesticides will be accumulated in the sediments, or their residues over time?

Although there are trends emerging to reduce the use of pesticides, this might lead to a serious drop in crop yields. Therefore, new approaches and technologies, and a change in paradigm are needed, especially in the view of the aforementioned ever greater need for produced food (see Section "Introduction") (Chen and Wong, 2016).

Ecological considerations

Ecosystem services

In the first decades of the 21st century the global monetary value of ecosystem services provided by wetlands reached almost Int$50 trillion a year (Davidson et al., 2018). In terms of Green infrastructure, then, it is clear that constructed wetlands in a catchment and riparian buffer zones (including when a buffer zone comprises the wetland) are important and valuable elements of such infrastructure in intensively farmed landscapes (Mander et al., 2017). While for centuries constructed and restored wetlands had played a crucial role in improving wildlife habitats in agricultural settings, with the rise of awareness of the problems of pollution and the importance of environmental protection in the 1970s, they came to be recognized as zones capable of efficiently retaining diffuse pollution from agricultural areas arriving to freshwater rivers and lakes. Indeed, since then, wetlands have come to be seen as the 'kidneys' (although with a limited capacity) of the hydrological cycle, providing a wide variety of ecosystem services working in

[5]Spray drift can occur during the application of plant protection products. It is defined as the transfer of small spray droplets by wind from the target area due to poor calibration or application practices.

favor of the mitigation of agricultural diffuse loads. These wetlands act as biodiversity hot-spots by providing shade, wind buffering, protection from floods and a habitat for birds, thus sustaining the natural functioning of the wetland. In the meanwhile, these factors can only enhance their functioning as carbon sinks. Completing and complementing these defenses and protections, wetlands support the formation of fertile soils, thus helping further in decreasing nutrient and sediment loss from agricultural areas.

The foregoing does not, however, exhaust the ways in which wetland ecosystem services are beneficial. Wetlands act as areas of flood protection, and are a valuable resource in terms of drought resistance. They support grazing and aquaculture and they provide raw materials such as timber, peat and firewood. Wetlands are also a source of drinking water for livestock. Last, but not least, wetlands have an aesthetic and cultural value as well (Zedler, 2003). When the extent and/or functioning of wetlands is degraded for the benefit of the extension of agriculture or urbanization, all of the above-mentioned services are also degraded, or even completely lost. However, at sites where farming is not profitable, the restoration of former wetlands could revitalize these ecosystem services, via rethinking existing landscape-design models and attuning them to agricultural landscapes (Zedler, 2003).

A practical demonstration of the potential ecological and economic value of wetland restoration is the case of the Nakivubo wetland system in Kampala (Uganda, Africa), which has been used as part of the nutrient management by Kampala and reducing loads to Lake Victoria. This wetland system is hemmed in by urban and agricultural land, and runs from the central industrial district of Kampala, entering Lake Victoria. About one third of its original area has been used for agriculture and further part for industry and housing in the past decades (Emerton et al., 1999). The interesting part in the case study—from the perspective of this chapter—is that there has been a detailed estimation of the overall costs of the restoration and its benefits in ecosystem services. The capital cost of the project alone was Int$53 million, approximately 20% of which was used to handle nonpoint source pollution and focused on wetland rehabilitation; measures to control agricultural activity comprised <0.1% of the total budget. Even in the case of the worst estimates, the internal rate of return over a period of 15 years was projected to be 4% per year, reaching up to 34% in the best-case scenario (Turpie et al., 2017).

This case study emphasizes the importance of integrating wetland values into land use and development decisions, and provides examples of the estimated economic value of important wetland 'goods' and services. However, the proportionately low level of planned expenditure designated for the handling of related agricultural problems seems to be associated with the lower priority historically given to such phenomena (see Section "Non-point source (diffuse) pollution").

Eutrophication and trophic state

The process of eutrophication in any wetland is not essentially different from other water bodies. Natural or anthropogenic input/load of inorganic elements, primarily phosphorus and nitrogen among many others (Naeem et al., 2014), can lead to internal enrichment of nutrients in the system. The resulting excessive growth of macrophytes or algae enhancing primary productivity, net accumulation and decomposition of organic matter differ little from symptoms in shallow lakes (Scheffer, 2013). Although there is still a controversy about the role and magnitude of nitrogen and phosphorus in limiting the productivity of aquatic ecosystems. Nitrogen is often the most limiting element in flooded soils of wetlands and not phosphorus. Soil microbial biomass, however, reacts positively to phosphorus enrichment. Consequently, internal phosphorus loading from the sediment/flooded soil regulates the eutrophic status of wetlands particularly at low or reduced external loading (Sánchez-Carrillo et al., 2011). All processes associated with eutrophication will be intensified by climate warming, reinforced weather variability, population growth, changes in land use and agricultural pollution (Dokulil and Teubner, 2011; Dokulil, 2014) with severe effects on biodiversity of macrophytes and freshwater algae (Dokulil, 2003, 2017).

One of the main direct effects of discharge of the anthropogenically-driven excess nutrients into aquatic ecosystems from agricultural runoff is the dramatic shift towards less desirable trophic status, which represents the most widespread challenge to water quality globally. The oxygen depletion and algal blooms caused by this process lead to the serious degradation of freshwater biodiversity, ecosystem services and water quality. A cause for concern is that examples of the adverse effects of algae blooms on shallow lakes have been, and continue to be, reported all over the world, for example: in Asia (Qin et al., 2007); North America (López-López et al., 2016; Oberholster et al., 2006); Europe (Hatvani et al., 2020); South America (Oliveira and Machado, 2013) and Africa (Muli, 1996). Furthermore, it appears that the nutrient (and especially P) enrichment of surface waters is reaching such levels that it will be extremely difficult to reverse, or even that it is no longer possible (Carpenter and Bennett, 2011). The timescale in which this problem is unfolding is measured in generations: it has taken a whole generation to recognize the gravity of agricultural diffuse loads arriving to surface waters, and it will most likely take another to resolve its impacts (Withers et al., 2014).

Conclusion/synthesis

This chapter gives an overview on the most important characteristics of (semi-) constructed wetlands in retaining agricultural diffuse loads from inland surface waters. The basics of their typology and possible location in the landscape, and most important design criteria are discussed while keeping the focus on nutrient retention.

The preservation of water bodies of all sorts for future generations is a global need. At first it may seem that the satisfaction of human demands, the provision of enough food for the ever-growing human population, stands in opposition to the necessity of mitigating the negative effects of expanding agricultural production. This is not, however, an either/or choice, but rather a problem of finding nature-based solutions capable of meeting both the socio-economic and environmental challenges.

Wetlands of all kinds in the right position in the landscape and the catchment are one of the most capable tools of handling catchment-scale pollution from agricultural areas. (Semi-)constructed wetlands in this context can be a "compromise" between natural and constructed wetlands in terms of their purpose and functioning, while not requiring any energy input (unlike constructed ones) and have a minimum of artificial structures. Semi-constructed wetlands are designed to serve a variety of purposes, such as the retention of excess nutrients, pesticides, etc. through the ecosystem services they provide, e.g., contribution to biological habitats and diversity, hydrologic buffering, or water filtration.

It is, however, strongly preferable to preserve and protect existing wetlands rather than to let them degrade and then create artificial wetlands. It has taken decades to recognize and begin to understand the complex nature of agricultural diffuse pollution and its adverse effects in continental waters. It will take considerably global, and collaborative, effort across multiple sectors to mitigate these negative changes. With cross-disciplinary research and good policies made in due time, conserved and semi-constructed wetlands can play an important role as nature-based solutions in reducing transport and mitigating impact of inland agricultural diffuse pollutant loads.

Knowledge gaps

- There remains major *uncertainty* about the retention of certain substances (*material fluxes*) by wetlands, despite many experiences and strong knowledge of the underlying processes. In our review, we did not cover in detail heavy metals (Matagi et al., 1998) and, other micropollutants related to agricultural origin (e.g. livestock farming), such as the removal of pharmaceuticals, e.g. antibiotics (Liu et al., 2019).
- *Lifespan of wetlands*: one of the main benefits of natural systems compared to artificial treatment is their long lifespan. However, in this review the question is not discussed, how does efficiency and functionality change over time? Furthermore, how will natural wetlands respond to changing external loading and/or changing climatic conditions (Honti et al., 2020)? There is quite a lot of uncertainty, for example regarding sediment accumulation, changes in the wetland ecosystem, and decreasing adsorption capacity (Dugan and Dugan, 1990).
- *Legislative issues*: the management of natural wetlands raises legal issues (Smardon, 2009), for example, harmonization with agricultural regulations (Shine and De Klemm, 1999). Property rights need to be clarified: who is the owner and who is responsible for the maintenance of wetlands? More general, a main question is how farmers may be persuaded (and supported) to establish a wetland on their land? This can be achieved through the proper application of subsidies.

Important case studies

- Case study chapter of the same Book Section (under planning); leading author Rupesh Bhomia.
- Kis-Balaton Water Protection System (Hungary, Europe; adjacent to Lake Balaton) (Hatvani et al., 2014; Honti et al., 2020; Rupesh Bhomia et al., 2022).
- Nakivubo wetland system in Kampala (Uganda, Africa; adjacent to Lake Victoria) (Emerton et al., 1999; Turpie et al., 2017).
- Heavy metal retention by constructed wetlands (case study) (Vymazal and Březinová, 2016).
- Case study on the mitigatind diffuse loads with a field wetland (Ockenden et al., 2012).
- Case study on how low nutrient removal efficiency can be from agricultural diffuse loads (Kasak et al., 2018).

Glossary

Biomass The mass of animals and plants within a habitat measured at a given time.
Emergy The amount of energy that was consumed in direct and indirect transformations to make a product or service.
Eutrophication Enrichment of water by inorganic nutrients which results in intensive growth of plants (algae, macrophytes).
Heavy metals Metalliferous elements and their derivatives including zinc, lead, copper, iron, mercury, cadmium, cobalt, manganese and nickel.
Input output analysis The statistical assessment and visualization of the difference between inflow and outflow nutrient fluxes within the system boundary.; see Box 1 for further details.
Medium Soil, gravel or other material used in a constructed wetland in which to grow plants and support micro-organisms; also known as support matrix.
Nutrient load retention Difference between inflow and outflow nutrient fluxes within the system boundary.

 https://doi.org/10.1016/B978-0-12-819166-8.00150-X

Nutrients These are essential for the survival of an organism. In aquatic environments, nitrogen (N) and phosphorus (P) are key nutrients that affect the growth rate of plants. Although N and P are vital in natural systems, they are also fertilizer components. These nutrients leave the landscape as stormwater runoff (urban and agricultural) and harm natural areas by promoting algae growth and an overabundance of non-native plants disrupting food sources and habitats used by native wildlife.
Population equivalent (PE) Amount of degradable matter (expressed as BOD or something other) or volume of wastewater produced per capita (1 pe <150 LD^{-1} <0.15 m^3 D^{-1}).
Primary treatment Physical separation of solids, usually by settlement, before secondary biological sewage treatment.
Secondary treatment First biological stage of treatment for sewage.
Tertiary treatment Treatment following the biological stage of treatment for sewage, which may incorporate removal of nitrate and removal of surplus suspended solids.

Introduction

Wetlands are used as cost-effective nature-based solutions that provide environmental and socio-economic benefits to people locally and regionally. However, increased demand for, and exploitation of, wetland ecosystem services have placed stress on wetlands worldwide (Zedler and Kercher, 2005; Mitsch and Gosselink, 2011; Hatvani et al., 2022). Wetlands have often been treated in ways that results in pressures such as pollution, eutrophication, overexploitation of resources, and introduction of alien species. In a natural water body (lakes, ponds, wetlands), phosphorus (P) and nitrogen (N) compounds are primary limiting factors for algal growth (Yang et al., 2008), and addition of P and N through agricultural diffuse loads have been primarily responsible for eutrophication and degradation of inland surface waters across the globe (Carpenter et al., 1998), e.g., in Europe (Csathó et al., 2007), N. America (Daniel et al., 1998), and Asia (Jiang et al., 2007; Agrawal, 1999).

While more attention is needed to conserve wetlands and prevent rapid disappearance of existing natural wetlands, this chapter is aimed to highlight the role of wetlands as natural solutions to improve the quality of water which has been deteriorated due to anthropogenic activities. By availing natural biogeochemical processes, constructed wetlands have been widely used to remove excessive nutrients and other pollutants and improve water quality before it is discharged downstream (Langergraber et al., 2019; Rousseau et al., 2022).

Constructed wetlands (CW) utilized specifically for water treatment benefits serve as buffers in the catchment to retain nutrients, sediments, and contaminants (Kadlec and Wallace, 2009; Callaway et al., 2012; DeLaune et al., 2013, 2018; Bhomia et al., 2015; Morris et al., 2016; Qualls and Heyvaert, 2017). These CWs are designed to take advantage of many of the same biogeochemical processes that occur in natural wetlands, but do so within a more controlled manner. Constructed wetlands are used for reduction of nutrient loads in surface runoff to protect downstream ecosystems. Impacts from excess nutrient availability are known to degrade the natural balance of aquatic ecosystems (Smith, 2003; Verhoeven et al., 2006), hence CWs are specifically designed and strategically positioned on the landscape to transform and assimilate excess nutrients (Solano et al., 2004; Vymazal, 2007; Hatvani et al., 2022). Given their ability to 'treat' water, constructed wetlands specifically created for water quality enhancement are referred to as 'treatment wetlands'.

Constructed and semi-constructed wetlands are used to manage point and nonpoint sources of water pollution, including stormwater runoff (e.g., Rizzo et al., 2020; Sharma et al., 2021), domestic wastewater (e.g., Stefanakis et al., 2014; Auvinen et al., 2016), and agricultural wastewater (e.g., Hatvani et al., 2022). Constructed wetlands are mechanically simple, require low energy inputs, and generally have low operational and management costs. Additionally, wetlands can be designed across a broad realm of operational scales ranging in size from smaller units capable of treating wastewaters from a single household to large systems covering many hectares and treating high volumes of agricultural or stormwater runoff (Chen et al., 2009). These constructed treatment wetlands offer relatively natural and sustainable solutions to the more technological and resource intensive options for improving water quality and can operate for a long period of time.

This chapter provides four case studies where constructed (and semi-constructed) wetlands have been employed to reduce pollutants (and nutrients) originating from both point and non-point sources from having an impact on downstream waterbodies. These case studies not only highlights the successful utilization of natural biogeochemical processes for pollutant abatement but also demonstrates how constructed wetlands led also to significant improvement in our knowledge and understanding of these biological systems. These examples also indicate the wide acceptance of treatment wetlands as a functional ecological solution to effluent treatment across broad range of operational parameters. The first case study focuses on Florida Everglades (United States) which represents a semi-tropical system where constructed wetlands play a crucial role in ecological restoration of Everglades. The second case study focusses on Lake Balaton (Hungary), the largest shallow freshwater lake in Central Europe, and the important service these wetlands provides in reducing excessive nutrients to downstream ecosystems. The third case study provides details of a constructed wetland close to the capital city of New Delhi (India) treating effluent from domestic and small scale industrial/commercial units to generate treated water for irrigation. The fourth and last case study is based on a hybrid constructed wetland for decentralized treatment of municipal wastewater in De Pinte (Belgium) as an alternative to a large-scale conventional wastewater treatment plant.

Case study 1

The Everglades: Background

The Everglades system can be defined as the watershed beginning at the Kissimmee Chain of Lakes in central Florida, running south through Lake Okeechobee, the Everglades Agricultural Area, Water Conservation Areas, the ridges and sloughs of South Florida, the Shark River Slough, and ending at Florida Bay (Fig. 1). The Everglades system also includes the Caloosahatchee River and the St. Lucie Canal, flowing west and east, respectively from Lake Okeechobee.

Historically, distinct wet and dry seasons brought varying rain throughout the year, and annual fluctuations in rainfall overtime contributed to the ever-changing landscape of the Everglades, but the system remained oligotrophic in absence of any significant external inputs of nutrients. Interconnected small and large wetlands, the unique ridge and slough system, and limestone bedrock worked in concert with the volatile weather patterns and provided ideal conditions for water storage. Though slow moving for much of the year, water flowed through this landscape creating near perfect habitat for wetland populations of migrating birds, as well as terrestrial and marine wildlife.

This system was never a static ecosystem, but the rate of ecological and landscape change dramatically increased over the past 125 years. Drivers of these changes were from a set of predominately natural sources to a complex interplay of anthropogenic sources. This transformation of the historic Everglades was accelerated by an unprecedented input of phosphorus (P) as a byproduct of agricultural and urban development during mid-twentieth century (Richardson, 2010). The impacts due to excessive P influx have been widely documented for the greater Everglades ecosystem (Noe et al., 2001; Reddy et al., 1999). These impacts include reduced productivity of submerged plants and benthic periphyton, depletion of dissolved oxygen in the water, and changes in invertebrate and vertebrate community structure (Smith et al., 2009). The most conspicuous change in the Everglades has been the expansion of monotypic stands of cattail (*Typha* spp.) that displaced the indigenous sawgrass community (*Cladium jamaicense Crantz*) (Daoust and Childers, 2004).

Phosphorus is included in fertilizers and feed supplements to meet the requirement of agricultural crops and livestock and enable continued high yields, but unutilized P is lost from the agricultural fields or livestock feed lots. Because P in all its various forms is non-volatile, it follows hydrologic pathways and often gets concentrated in wetlands and inland water bodies after being introduced in the environment (Reddy et al., 1999). This excessive P in the Everglades system has been responsible for disrupting historical natural balance and unwanted impacts on flora and fauna of the system. In the past two decades much effort has gone into restoring the Everglades to its original hydrologic flow and ecological condition (Chimney, 2020).

Everglades restoration

Restoration of the Everglades is currently underway, with the aim to improve water quality, quantity, timing, and flow for both human needs and ecological integrity. Restoration efforts are steered by plans outlined in the Comprehensive Everglades

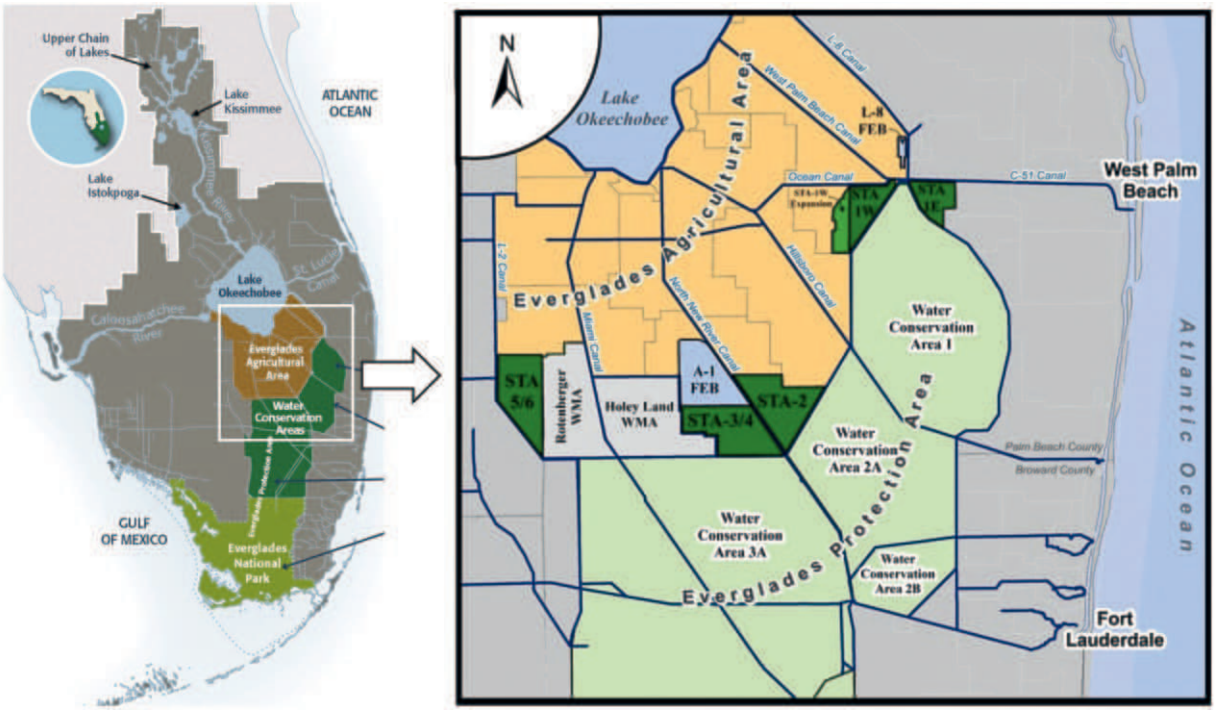

Fig. 1 Everglades ecosystem and location of six treatment wetlands intercepting agricultural and stormwater runoff originating from Everglades Agricultural Area. Map source: South Florida Water Management District.

Restoration Plan. A major component of this plan, water quality improvement, includes reduction of P inputs by implementing best management practices in the Everglades agriculture area (Diaz et al., 2005; Rice et al., 2002) and subsequent treatment of agricultural drainage waters (ADW) running off farmlands. A network of constructed treatment wetlands established to intercept ADW and stormwater runoff forms a crucial component of the Comprehensive Everglades Restoration Plan.

These constructed wetlands referred to as the Everglades stormwater treatment areas (STAs) are designed to reduce total P (TP) concentrations in surface runoff to reduce risk to receiving ecosystems. Six STAs (Fig. 1) with different sizes and configurations with a combined treatment area of 23,000 ha have been in operation for different time periods. The strategic location of these STAs has allowed them to retain over 2882 tons of P between WY1993 (Water Year 1993: May 1992–April 1993) and WY2020 (Chimney, 2020) which has resulted in a considerable load reduction of P to the Everglades. The overall outflow flow-weighted mean total P concentration from these treatment wetlands during this period has been 31 μg/L (Chimney, 2020) (Fig. 2). Although some of this retained P is in the vegetation and thriving biota (birds, fishes and alligators), a significant proportion of removed P is accumulated in soils and stored in both organic and inorganic forms (Reddy et al., 2020).

Complexity of STA operations

Although the STAs have sequestered a substantial amount of P during their operational history, they are known to exhibit variable treatment performance in terms of P removal efficiency over time (Chen et al., 2015). The spatio-temporal variability in STA treatment performance has been attributed to factors such as antecedent land use, vegetation condition and species composition, nutrient and hydraulic loading, hydraulic residence time, hydroperiod, soil characteristics and P content, flow way topography and configuration, extreme weather events, construction activities and regional operations (Germain and Pietro, 2011).

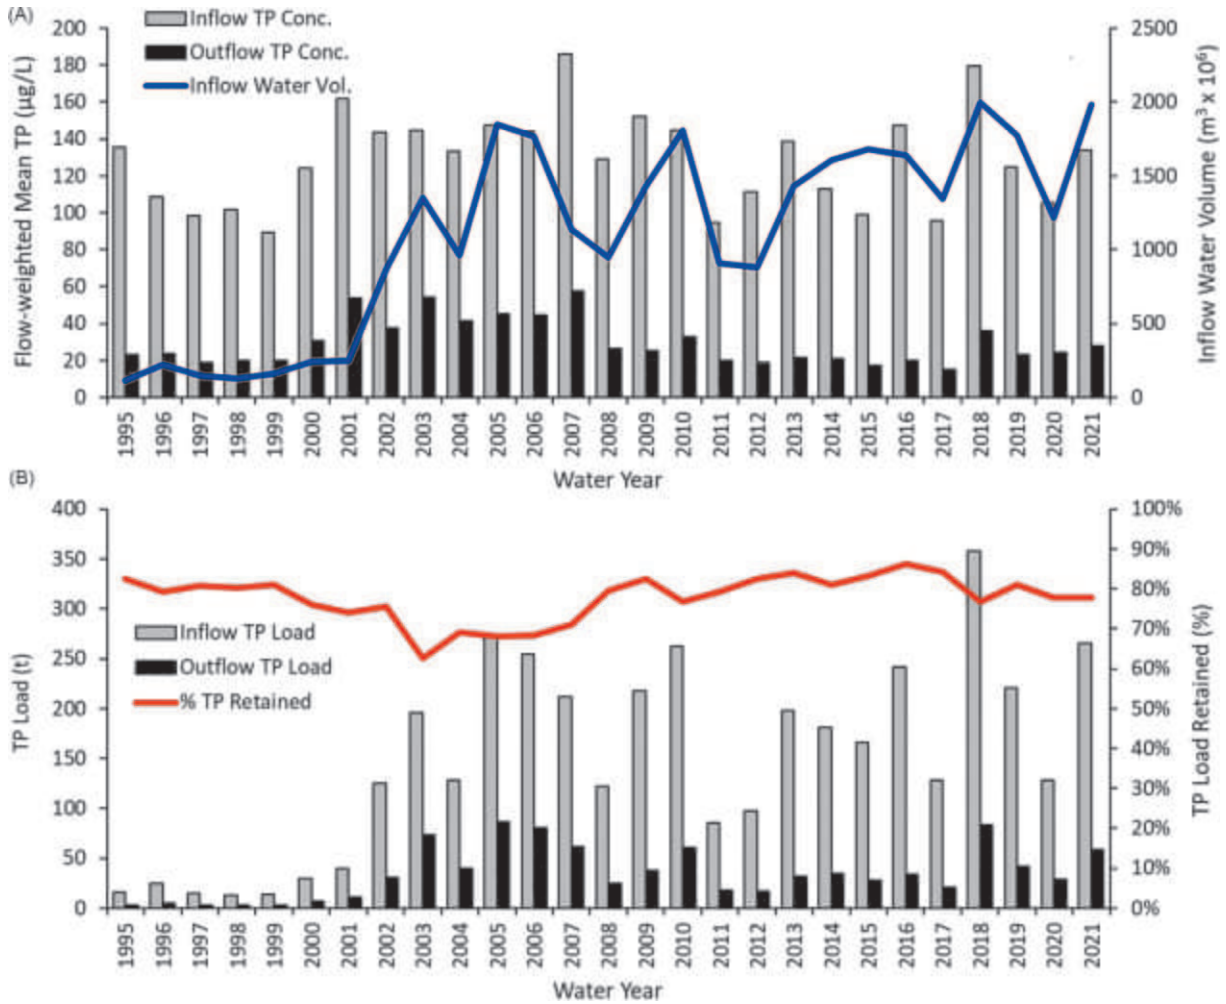

Fig. 2 Period of record time series of water quality enhancement (phosphorus removal by Everglades Stormwater areas. (A) Annual inflow and outflow flow weighted mean total P concentrations with corresponding inflow water volumes. (B) Annual inflow and outflow total P loads with percent total P load retained in the system (Chimney, 2020).

Performance of the STAs for regulatory compliance is quantified by measuring hydrologic parameters, i.e., volume and chemical characteristics of inflow and outflow waters to and from STAs. This approach, however, overlooks the complex biogeochemical processes that regulate P removal from the water column and controls the stability of sequestered P pools in the STAs. With continued STA operation, P removed from the water column accumulates as recently accreted soil and contributes to the incremental enrichment of the surficial layer of soil, potentially leading to the saturation of internal P storage compartments. Recently accreted soils (RAS) share an active interface with floc (unconsolidated detritus that is deposited on the consolidated wetland surface layer) and the overlying water column, and depending on the existing biogeochemical factors, nutrient concentrations in the RAS layer could potentially influence STA TP outflows (White et al., 2006; Bhomia, 2013). Therefore, an understanding of the complex processes that regulate long-term sustainable P removal in the STAs is desired for effective management and for meeting Everglades restoration goals.

Future outlook

The Everglades STAs are unique because of their large size and low target outflow TP concentrations (~13–19 μg/L). The general range of inflow P concentrations in many other treatment wetlands are 1–2 orders of magnitude greater than the STAs. The large expanse of STAs, past land use (agricultural farm or historic wetland), extreme weather events (e.g., droughts, storms), and suspension of operations due to nesting of migratory bird species, are only a few examples of the complex challenges encountered during the management of the STAs. The status of STA operational phases (start-up, routine operation, or recovery) and management activities (e.g., drawdown, cell rehabilitation, vegetation conversion and control) also influence outflow P concentrations from the STAs. For STAs to meet the desired outflow TP concentrations, it is important to understand the chemical composition and stability of accreted soil and implement sustainable management strategies for long-term performance of STAs. In addition, P storage, transformation, and transport are linked to cycling of other associated elements including C, N, K, and S. All these cycles are mutually dependent on each other and ultimately influence stability of stored P in soils and export of P into surface water. These interactions among key elemental cycles need further study and proper assessment before new management strategies are planned and implemented. Each of these factors has some bearing on the overall treatment performance of the STAs, and detailed understanding of the fate and transformation of sequestered P in STA soils may help in adaptive management to optimize STA efficiency.

Case study 2

The Kis-Balaton water protection system—Background

The Kis-Balaton Water Protection System (KBWPS) is a semi-constructed wetland (for a definition, see Hatvani et al., 2022) constructed on the remains of a once fully natural wetland—Kis-Balaton—to retain the nutrient loads brought to Lake Balaton by the River Zala (Fig. 3). The Zala accounts for about 50% of Lake Balaton's water and ~40% of its nutrient input (Hatvani et al., 2014). Lake Balaton is the largest shallow freshwater lake in Europe (surface area = 596 km^2), with an average water depth of 3.2 m, and its catchment extends over an area about 10 times that of its surface (~5180 km^2; Somlyódy and van Straten, 1986). Besides its role in the protection of water quality, the KBWPS is a protected nature conservation and NATURA 2000 area and has been under the de-jure protection of the Ramsar Convention since 1979 (Convention on Wetlands, 1971).

Brief history of the Kis-Balaton Wetland and the KBWPS

Prior to the 18th century, the area where the KBWPS is now located formed a part of the water body of Lake Balaton (Fig. 3A). However, due to deforestation, river control measures (primarily the regulation of the River Zala), and erosion, excess sediment was delivered to the western basin of the lake, resulting in the separation of the area and the formation of the Kis-Balaton Wetland (Erdélyi, 1963). It was first mentioned in historical documents as a separate water body in 1805 (Lovász and Baranyai, 2019; Lotz, 1988). In the 19th century, the River Zala was further regulated, and the wetland areas were drained to create arable land. Simultaneously, the water level of Lake Balaton was regulated (resulting in a drop in water level of 2–2.5 m by the mid-19th century) to protect the then-newly built railways. Thus, by the turn of the 20th century, the River Zala entered lake Balaton directly in its westernmost basin bringing nutrient-rich sediment to the lake without the KBW filtering or retaining it. Over the course of the 20th century, with increased agricultural activity, the growth of towns, and the rise of modern tourism with its concomitant expansion of the built environment expanding urbanization (the number of holiday homes along the shores quadrupled between 1920 and 1960), deterioration of Balaton's water quality continued (Hatvani et al., 2014; Somlyódy et al., 1983). Comprehensive measures to halt and reverse these negative trends were taken (details in Section "Construction and current setup of the KBWPS" and Hatvani et al. (2020) and Istvánovics et al. (2007) alongside the plans to reverse the adverse effects of agriculture and urbanization on the lower reaches of the Zala through the restoration of the former wetland in the form of the Kis-Balaton Water Protection System (Tátrai et al., 2000).

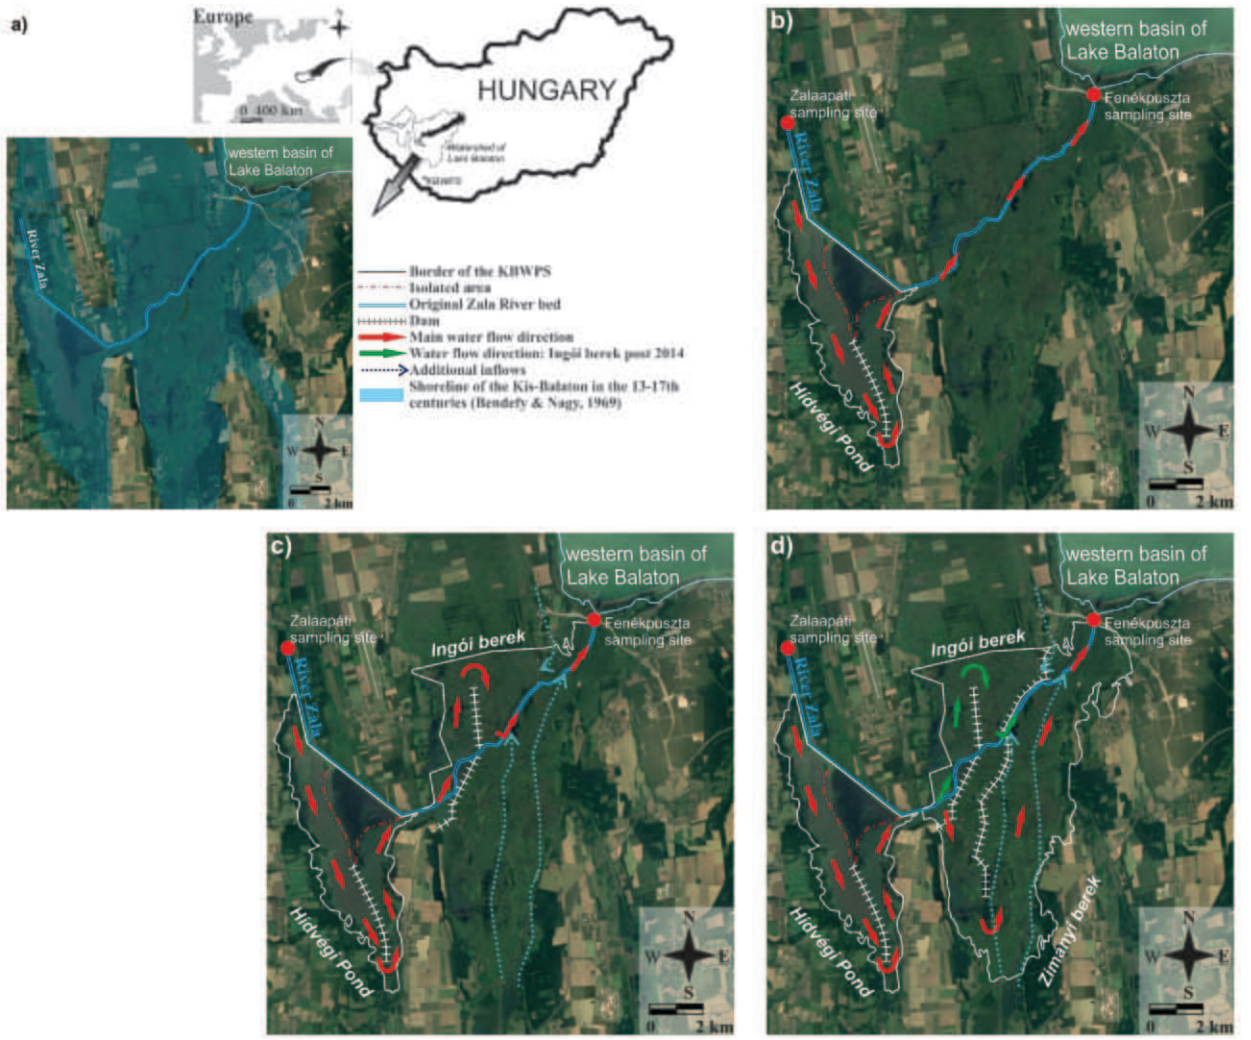

Fig. 3 Location and historical changes in the structure of the Kis-Balaton Water Protection System. (A) Pre-18th century catchment; (B) inundated 1985–1992 state of Phase I (Hídvégi Pond); (C) partial completion of Phase II (Ingói-berek inundated) (1992–2014); and (D) the current state of the system (post-2015). The names in italics indicate geographic names of different areas of the system; the area of former Kis-Balaton Wetland was drawn based on Bendefy and Nagy (1969); illustrative map based on Hatvani et al. (2017); basemap: Google map imagery taken on 14 August, 2021.

Restoration of the wetland

Construction and current setup of the KBWPS

The original plan (from 1976) was (i) to remove nutrients—primarily P—already in the KBWPS area using macrophytes before the nutrients ever entered Lake Balaton (Tátrai et al., 2000) and (ii) to move the eutrophication processes upstream of Lake Balaton into the reservoir(s) of the KBWPS to prevent further deterioration in water quality, with the aim that by 2005–2010, a return to the trophic conditions typical of the early 1960s would be achieved (Istvánovics et al., 2007). We now know that this was approximated in the mid-2010s (Hatvani et al., 2020).

The construction of the KBWPS was planned in two phases. The area of Phase I was formerly grassland and partially forested, that was inundated in 1985 (the 18 km^2 Hídvégi Pond; Fig. 3B). However, instead of becoming a wetland populated by macrophytes, became an algae dominated pond. Phase II (total area 51 km^2) was partially inundated (Ingói-berek: 16 km^2) at the end of 1992 (Fig. 3C), and became an area covered by macrophytes, predominantly reeds/reed-beds. The remaining area (Zimányi-berek: ~35 km^2) was inundated in 2014, when a new operating approach was introduced and the main water flow direction was changed, so that loads no longer affected the Ingói-berek on a daily basis (Fig. 3D); it only receives water for natural protection purposes from the Zala. The system is operated utilizing multi-directional water management options that can be adapted to ecological, water quality and water quantity conditions.

Operation and management of the system

The operation of the system is maintained by 26 engineered structures (e.g., sluices, dams (Fig. 3), pumping stations) per multiple parallel requirements of the policies of the General Directorate of Water Management, the Ministry of Interior, and the National Park governing water quality and other aspects. Thus, the water level in the system is dynamically managed to mimic natural water level in the areas to maintain wetland habitats (Kovács et al., 2010; Hatvani et al., 2017), to keep up with the recreational use-needs of Lake Balaton, both in terms of quality and quantity (Istvánovics et al., 2007; Kutics, 2019) and provide for other economic needs (e.g., inland water pumping). Because of several adverse changes made in the system over the decades, it difficult to compare its functioning to other semi-constructed wetlands on a decadal timescale.

Retention capacity

In natural (and semi-natural) systems, retention is influenced by many factors; see e.g., Dupas et al. (2015), Zedler (2003), Hatvani et al. (2022). Uncertainties regarding the KBWPS are, therefore, not surprising, especially due to the numerous interventions this system has been subjected to over time. In order to improve water quality and achieve good ecological status, as prescribed by Water Framework Directive (EC, 2000), and support the oligotrophication of Lake Balaton, phosphorus retention is crucial (Tátrai et al., 2000; Istvánovics et al., 2007). Thus, the storage of P has the highest importance in the KBWPS, both in the short-term (uptake and release by vegetation, microorganisms, periphyton and detritus) and long-term (deposition in soil and accretion of organic matter; Reddy et al., 1999).

The retention capacity of the system can be viewed from two perspectives. In the first, if only the input from catchment of River Zala into KBWPS is considered (Zalaapáti sampling site) (Fig. 4A), and in the second, if full input to KBWPS is estimated including the system's direct catchments between Zalaapáti and Fenékpuszta (Figs. 3 and 4B). The former accounts for about 60% of the total load arriving to Lake Balaton, important in long-term historical comparisons with the literature, while the latter is of practical significance for achieving management objectives (Nyuduvizig, 2020).

Prior to the inundation of Phase I (1985), an excess amount of P left the area of former Kis-Balaton Wetland into Lake Balaton (Fig. 4A: blue ellipse), while after being inundated in 1985, the Hídvégi Pond removed about 50% of the external P loads annually (Fig. 4A: yellow ellipse) up to 1991. However, after the reduction of external loads from the Zala catchment, the TP retention efficiency highly decreased (Hatvani et al., 2014); Fig. 4A: green ellipse). Between 1981 and 1990 an annual average of ~92 t of TP load arrived into the KBWPS, while this value dropped to only ~42 t in the 1990s (Hatvani et al., 2014).

At the turn of 1990s, Hungarian agriculture and heavy industry were thoroughly restructured following political and economic changes, and high state subsidies to mineral fertilizers were withdrawn, and this ran parallel to a drastic reduction in fertilizer usage (Hatvani et al., 2015). These changes contributed to the significant reduction in diffuse pollution arriving in the system. Continuing the load reduction measures, in the late 1990s additional nutrient removal was implemented, i.e., phosphorus removal began at wastewater treatment plants in the Balaton region, resulting in reduced TP inputs to Lake Balaton compared to the 1980s (Somlyódy, 1998) (Figs. 4B and 5). This reduction was not, however, as great as anticipated, due to the increased contribution of internal loading as a response to the reduction in external loads (Clement et al., 1998; Sas, 1990). This resulted in decreased retention (Fig. 4A: green ellipse). It is understood that if input decreases, rate of retention (%) does not decrease proportionately, but to a much greater degree. In the years following 2010, the TP input to the KBWPS reached its lowest, thus its retention efficiency further decreased (Fig. 4A: red ellipse). Nevertheless, taking the system and the input to Lake Balaton as a whole, this was not a major issue because of the already low inputs (<20 t TP a^{-1}) to the KBWPS, and outputs to Lake Balaton (<7 t TP a^{-1}), equivalent to a calculated annual average TP input of approximately 0.13 mg/L and 0.003 mg/L annual average TP output from the KBWPS for 2010–2019.

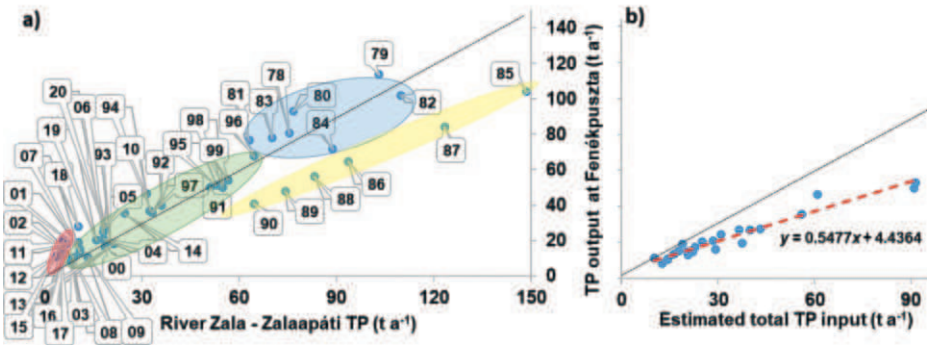

Fig. 4 Total phosphorus input-output graph of the KBWPS. Input from the upstream catchment of the River Zala (Zalaapáti sampling site; see Fig. 1) and output to Lake Balaton at Fenékpuszta sampling site (1978–2020; for locations see Fig. 1), updated from Hatvani et al. (2014). (A) Calculated TP input-output between the upstream and direct catchment of the KBWPS and Lake Balaton at Fenékpuszta (1998–2020). The ellipses with different colors indicate the arbitrarily chosen clusters of years. The years themselves are marked as data labels next to the points. (B) The red dashed line is the linear regression between input and output. The dashed 1:1 line represents the points along which the same amount of TP is entering KBWPS as leaving it; for details see Box 1. Data: Nyuduvizig (2020).

Box 1

Input-output analysis in water quality protection explores the mass of substances entering and leaving a system, revealing systems capacity to retain or transform a given proportion of these substances. In some cases, larger mass leaves a system then being added', this additional amount is due to internal loadings, e.g., when phosphorous is released from the sediment of the given water body. In its most typical visualization, a graph is presented on which the output values are scattered along the ordinate and the input amounts along the ordinate. Therefore, if a 1:1 line is drawn, the values above it will indicate excess output, and the ones below it will indicate retention. See Fig. 4 and e.g., Chen et al. (2009).

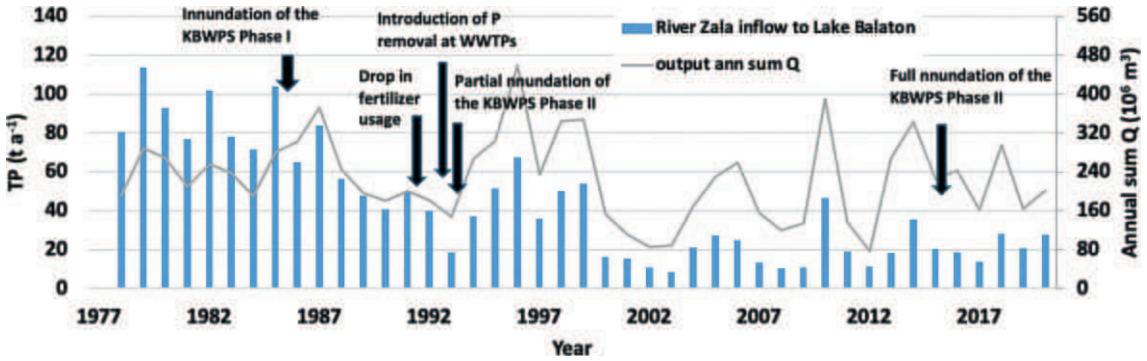

Fig. 5 Annual TP loads and volume of water arriving in Lake Balaton from the KBWPS at Fenékpuszta (Fig. 1B–D) between 1978 and 2020. The historical milestones of the system are indicated above the graphs.

Considering entire inflow and outflow data (available after 1998), it is visible that if input increases, the amount of output (t nutrient per year) from the system increases in a way which is close to linear ($r_{\text{calculated input - output load}}$ (23) = 0.94, $p < .00001$), while overall the system is working efficiently (Fig. 4B). The total load carried by the River Zala directly into Lake Balaton has changed dramatically, with the inter-annual variation depending to a significant degree on the rate of flow ($r_{\text{TP—Q outflow}}$ (41) = 0.60, $p = .000034$) (Fig. 5). Examining the overall operation of the system, P retention is smaller than originally anticipated (Tátrai et al., 2000), but always positive on an annual basis, except for 2 years during last two decades (Fig. 4B). The system, therefore, fulfills its function in protecting the water quality of Lake Balaton.

Given that abiotic processes controlling P retention are dominated by sediment sorption and chemical precipitation (see e.g., Hatvani et al. (2022), Vymazal (2007)), if external P loads are low, wetlands may export P instead of retaining it. This is significantly different from wetlands which are constructed as buffers or for the treatment of domestic or industrial waste waters, since in such systems the concentration ranges of nutrients and organic matter are several orders of magnitude higher; e.g., He et al. (2007). As a result, these do not lend themselves readily to comparison with those treating surface waters (low P levels) (Hatvani et al., 2014). As the KBWPS's retention capacity is strongly influenced by inflow concentrations, the P resuspension from the sediment of the system depends to a great extent on the current water levels and the amount of sediment brought by the river, again influencing the retention capacity of the system. Thus, any changes in the Zala catchment (Fig. 5) will affect its efficiency (Hatvani et al., 2014; Clement et al., 1998). Nevertheless, proper maintenance (e.g., dredging and vegetation removal) and operation are of paramount importance to the retention of P and then its removal from the sediment of the KBWPS.

Future outlook

In conjunction with other measures, the KBWPS can be considered a success story in ameliorating the water quality of Lake Balaton, a process leading to changes in the trophic state and the restructuring of the lake's ecosystem (Istvánovics et al., 2007). The construction of the KBWPS was an important measure—albeit not the only one taken—to facilitate these oligotrophization processes. However, in addition to its major role in diminishing the loads carried by the Zala River through natural filtration, the KBWPS has also proven capable of thoroughly modifying river load conditions in its role as a pre-reservoir system. As such, the water governance and water level management of the system is of great importance because of its multiple habitats with different ecological needs.

In future, the most important task will be to apply research concerning the operational experience and monitoring studies of the KBWPS. Solutions continue to be sought for the optimization of the operation of the KBWPS in the interests of the economically and ecologically efficient regeneration of the system, and ensuring good water quality of Lake Balaton. In the long term it is anticipated that the experience gained, and conclusions drawn from the monitoring at KBWPS can serve as a basis for construction of other living waters and reservoirs, and for addressing any operational difficulties (Lovász et al., 2020). In comparison with international case studies the "story" of the KBWPS once again underlines that such semi-constructed wetland systems can only be successful in retaining external nutrient loads if continuous monitoring and event-specific operation is maintained, the focus being on the achievement of a close to natural state.

Case study 3

Indian Agricultural Research Institute Wastewater Treatment System: Background

The Indian Agricultural Research Institute (IARI)- a micro-watershed located at the heart of the National Capital Territory (NCT)—Delhi (India) comprises about 290-ha ground water-irrigated farm area and a network of storm water drains, responsible for annually discharging about 700 ha-m (or 20-Million Liters per Day, MLD) of wastewaters (besides storm waters) received from the domestic and small scale industrial/commercial units located within IARI micro-watershed and its adjoining areas. The untreated urban wastewater stream (originating from nearby residential colonies—Krishi Kunj and Loha Mandi) used to pass through IARI farm area to into the Loha Mandi drain—a branch of the main Najafgarh (storm water) drain of the NCT-Delhi, which discharges runoff and domestic/industrial effluents from the entire Delhi catchment area into the Yamuna River.

Detailed physical and chemical analysis of this wastewater stream showed that it was associated with extensive inter-seasonal turbidity of 200 to 1000 NTU and increased biological oxygen demand (BOD) from 230 to 730 mg/L, along with elevated nutrients (0.1–12 mg/L nitrates; 3–28 mg/L phosphates, 11–99 mg/L sulphates) and heavy metals (0.1–1.3 mg/L nickel, 1.5–2.3 mg/L chromium, 0.41–23.60 mg/L iron and 0.31–4.65 mg/L zinc). As a result, the wastewater (apart from being a habitat for mosquito breeding and a source of offensive smell) contributed to the extensive soil and groundwater degradation in the farm area (Fig. 6A). A detailed analysis of total soil heavy metal pollution load at the local farm site indicated 1.23 times more than permissible level(PL) of copper (Actual value: 122 mg/kg, PL: 100 mg/kg), 1.57 times more zinc (Actual value: 393 mg/kg, PL: 250 mg/kg), 4.3 times more nickel (Actual value: 42.8 mg/kg; PL: 20 mg/kg) and about 11.5 times more chromium (Actual value: 252 mg/kg; PL: 100 mg/kg), as per international agricultural soil standards (Alloway, 1990).

The agricultural activity within the IARI micro-watershed had been experiencing an annual irrigation water deficit of about 101.5 ha-m (or 2.78 MLD), while wastewater was passing through this system as it was unfit for use. Hence against the backdrop of an acute water shortage in the farm area on one hand and the availability of an appreciable quantity of urban wastewaters that could be treated, recycled, and re-used for safe farm irrigations on the other hand; a need to utilize and operationalize low-cost energy efficient constructed wetland at the project site was felt.

Implementation process

The first step in designing appropriate wastewater treatment system at the proposed farm site, with 1.42 ha land area was to obtain detailed temporal information on the quantity and quality of the wastewaters and assess their impact on the soil and ground water quality at the site (2010–2011). The land and water quality information were used to design a unique decentralized urban wastewater treatment facility (during February–March 2011), based on the optimized hydraulic loading rates (HLR) and hydraulic retention times (HRT), for effective remediation and safe re-use of about 2.2 MLD wastewaters at the site. The developed wastewater treatment facility (Figs. 6B and 7) comprised two wastewater collection wells and one grit chamber (for reducing unintentional solid's spill-over due to any upstream processes) besides three treatment beds and one treated water collection tank, along with a conduit for bypassing excess flows. The construction of the optimized design began in September 2011 and was completed by 2013 after observing satisfactory performance of the first treatment cell. To make the whole treatment process energy intensive, a complete gravity flow of the wastewater, from the grit chamber to each of the treatment beds and thereafter up to the treated water collection tank was ensured.

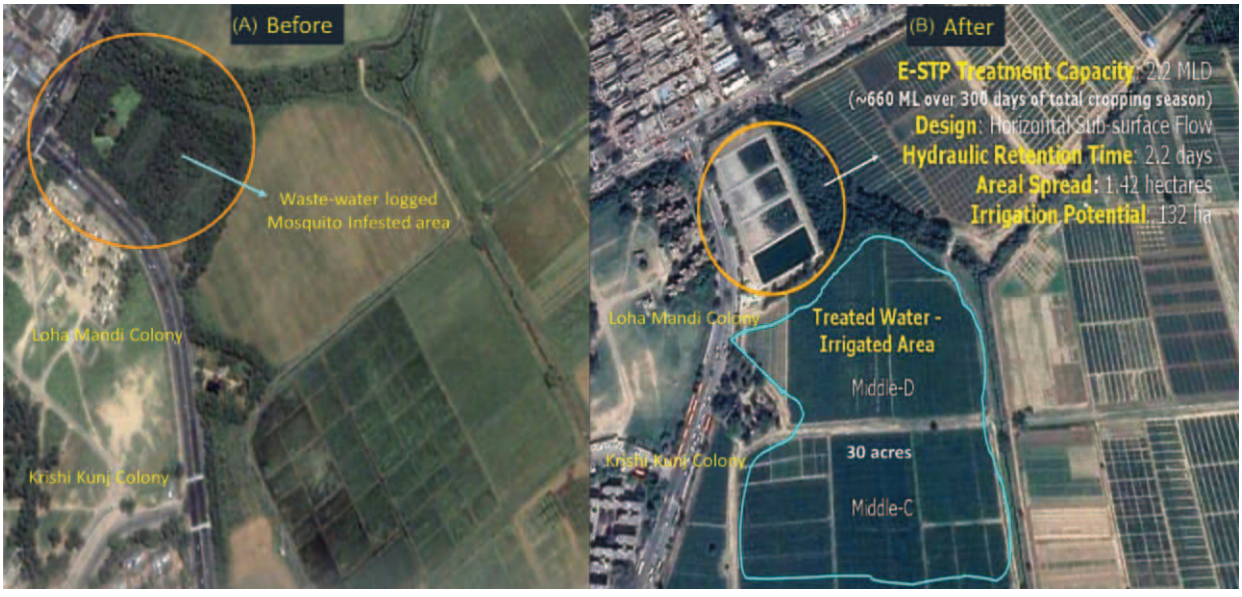

Fig. 6 Satellite view of the project site (A) before and (B) after implementation of the wastewater treatment technology.

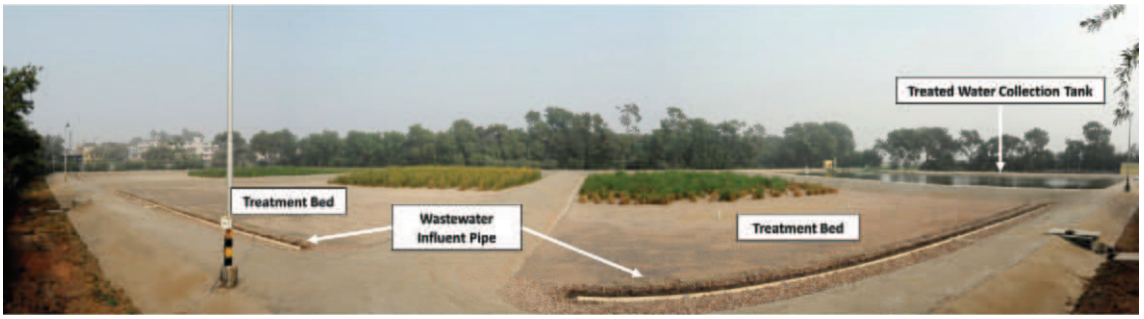

Fig. 7 Panoramic view of eco-friendly wastewater treatment facility at Indian Agricultural Research Institute farm.

The treatment process works on the Plant—Microbe—Media interactions and thus utilizes natural biogeochemical processes triggered by the emergent vegetation (*Typha latifolia*), planted at design depth and inter-spacing on the appropriately sized stratified-media and the native microbial assemblages present in the influent wastewaters. Unlike the conventional subsurface flow wetland systems, wherein clogging is the major operational and maintenance issue, the proposed technology solution took care of the system clogging by completely eliminating the incorporation of any sand/soil in the treatment beds and ensuring intermittent uniform sheet-distribution of the influent wastewaters over the entire treatment zone through the use of multi-perforated influent discharge pipes.

Hence, with the wastewater moving at design depth and flow rate through the root-zone of the planted emergent vegetation and its interaction with the native micro-organisms and the planting media, various organic/inorganic pollutants and heavy metals in the wastewater got adsorbed, transformed, sequestered, and thus removed from the influent—wastewaters. The treated water was finally collected in a 2 m deep treated water collection tank, from where it is being regularly pumped into the irrigation network of the Indian Agricultural Research Institute farm, through a riser and a set of hydrants. The system is in operation since September 2012 and is regularly monitored for its nutrient and metal reduction efficiencies.

Treatment efficiency and impact

Monitoring of long-term pollutant reduction efficiency of the facility has shown that it is capable of yielding treated wastewaters with 97.62% reduction in turbidity, 99.9% lower pathogen loads, 83.6% reduction in BOD levels, 39.5–87.9% reduction in heavy metals and 38.5–53.5% reduction in phosphate and nitrate concentrations (Table 1).

The treated wastewaters were used for aquaculture as an alternative business model, in collaboration with the Regional Research Centre, ICAR-CIFA, Kolkata and ICAR-Central Institute of Freshwater Aquaculture, Bhubaneswar. As a part of this intervention, 2315 *Pangas pungas* fish fry of 5 g each were stocked in the treated sewage water pond of 0.3 ha area. Regular monitoring of pond ecology and water quality revealed its moderate natural productivity (GPP: 340–425 mg C/m^3/h and NPP: 150–350 mg C/m^3/h), high DO (8.8–14.2 mg/L), low BOD (<30 ppm) and normal pH (7.2). In such condition, fish growth was recorded in the range of 200–300 g (from an initial 5.0 g), over 3.5 months of culture and with 80% survival. The pond was harvested with an exceptional fish catch of about 580 kg in 3.5 months (equivalent to 4 tons/ha/9 months). Noteworthy feature of this intervention was that this could be achieved through just 115 kg of supplementary feed, which is below 50% of the normal feed requirement. It was further observed that the heavy metals (viz. Cu: 0.09–0.14 ppm, Fe: 0.97–1.1 ppm; Mn: 0.13–0.17 ppm; Zn: 0.54–0.68 ppm; Ni: 0.38–0.42 ppm; Pb: 0.10–0.44 ppm) as recorded from fish muscle (Table 2, Kaur, 2020) were completely within designated safe limits, from the point of view of both fish growth and consumer health.

Ecological efficiency and sustainability

Emergy analysis, a comprehensive environmental accounting technique (Odum II, 1996), was applied in terms of several Emergy indices (Table 3; Kaur, 2020) for comparing the ecological efficiency and sustainability of the developed solution vs. a comparable conventional sewage treatment plant (STP). The analysis showed that the implemented solution utilizes 27 times more renewable resources than a conventional STP and is, thus, 1500 times more sustainable (as evident from Emergy Sustainability Index in Table 3). The implemented solution was in fact found to cause about 31 times lesser environmental stress (as evident from the environment loading ratio in Table 3), than a comparable conventional Sewage treatment plant.

Economic considerations

In terms of standard cost-accounting, as per 2011–2012 cost estimates, the implemented solution was found to be associated with about 76,300 USD per MLD of capital expenditure (CAPEX), with civil works and media demanding (80–90%), electrical works demanding (8–15%) and purchase/incorporation of appropriate vegetation demanding the remaining (2–5%) of the total capital requirement. The operational and maintenance expenditure (OPEX) on the implemented solution, on the other hand, was

Table 3 Ecological efficiency and sustainability of proposed initiative compared with conventional STP.

Emergy Indices	*Implemented Solution*	*Conventional STP*
Emergy Yield Ratio	0.70	0.01
Environment Loading Ratio	1.37	42.19
Renewable Percentage	0.54	0.02
Emergy Sustainability Index	0.51	0.00034

evaluated to be around 0.85 US cents per Kiloliter (KL) that primarily constituted expenditure on energy of around 0.35 cents, for pumping and incorporating 1-KL wastewaters into the treatment beds of the facility, and on unskilled manpower, of about 0.49 cents.

Comparison of the implemented solution with a comparable conventional wastewater treatment technology thus revealed that the developed solution is associated with zero-chemical application and zero energy demand for treatment, besides having no skilled manpower requirement. Hence the implemented technology was observed to be associated with about 50–65% reduced treatment costs than the conventional wastewater treatment technologies.

Revenue generation potential

The vegetation planted in the treatment beds of the fully operational wastewater treatment facility could be harvested (once every 3–4 months) to annually yield about 30 tons of dry biomass. The harvested biomass could be either sold to the local particle board manufacturing units (@USD 28 per ton, as dry biomass) or be transformed into the (termite- and water—proof) particle boards (16,000 sq. ft. per annum @USD 0.168/sq. ft.) or the energy-pellets (24,000 kg @USD 0.112/kg) thereby demonstrating an annual revenue generation potential of around USD 2688 through the *Cash from Trash* wastewater treatment intervention.

Conclusions

The proposed initiative was able to generate good-quality local surface water resource of about 660 million liters per annum and led to avoidance of applying contaminated drain waters (@ USD 25,900 per annum) for meeting irrigation water demand of IARI farmland. The initiative could thus, in addition to resulting in an annual saving of about USD 25,900 and bridging the annual gap (of 520 ML) in the irrigation water supply and demand of the IARI farmland, could also lead to effective urban wastewater management and sanitation (including reduction in offensive smell and mosquito breeding areas). In fact, the project site that used to be completely unapproachable (Fig. 6A) got transformed into an eco-park (Figs. 6B and 7) after the establishment of this constructed treatment wetland.

Case study 4

Zevergem waste-water treatment plant: Background

Flanders is a densely populated region in Belgium with 487 inhabitants km^{-2} and a total area of 13,625 km^2. Yet, only 85.5% of all household wastewater is treated. This is largely due to the fragmented spatial planning (StatBel, 2020; VMM, 2021) which makes it not always economically feasible for smaller communities or single homes to connect to large centralized wastewater treatment plants. Constructed wetlands (CW) for wastewater treatment generally meet discharge standards, are cost effective and require low maintenance. In 2014, there were 338 constructed wetlands in use in Flanders, designed as systems for $\leq$2500 person equivalent (PE) (Auvinen et al., 2016).

One of those systems is the constructed wetland from the village of Zevergem, which is part of the municipality of De Pinte. The system was designed for 750 PE and has been in operation since, 2000. The municipal wastewater first receives primary treatment in a simple settling tank. Secondary treatment is accomplished by a hybrid system comprised of two vertical down flow constructed wetlands (VSSF = vertical subsurface flow) followed by two horizontal subsurface flow (HSSF) constructed wetlands, each in parallel (Fig. 8). The CWs are planted with *Phragmites australis*. No tertiary treatment is applied, and the treated water is discharged in the Toutefaisbeek, a small brook, which leads to the river Scheldt.

Removal of organic matter and nutrients

Flemish discharge standards for urban wastewater treatment plants state that every parameter given in Table 4 should be lower than the concentration limit and should have a minimal reduction percentage relative to the incoming wastewater. Analysis results (Flemish Environment Agency, geoloket.vmm.be) show that for biological oxygen demand (BOD), chemical oxygen demand (COD) and total suspended solids (TSS), respectively, 99.5%, 99% and 99% of samples ($n \geq 215$, data available since 2002) meet the discharge standards (Fig. 9).

Discharge limits for other water quality parameters such as nutrients are yet nonexistent for small-scale wastewater treatment plants (<2000 PE) in Flanders. Notwithstanding, more parameters than required are being monitored and give insight on nitrogen and phosphorus removal.

The largest part of total N enters and exits the system as ammonium. Ammonium removal requires aerobic conditions for nitrification, but as Fig. 10 shows, ammonium effluent concentrations are generally high. It can be concluded that oxygen transfer to the system is not sufficient for nitrogen removal. The VSSF should be the main supplier of oxygen but is in this case not able to provide sufficient oxygen for complete nitrification. In addition, nitrate requires anoxic conditions and a carbon source for denitrification. Denitrification is clearly happening as 90% of effluent NO_3^--values are below 7 mg N L^{-1}, which leads to the conclusion that the HSSF can remove nitrate well in the current setting.

Phosphorus removal is very low (Fig. 11), because the main removal mechanisms are precipitation and adsorption. The substrate of a CW quickly becomes saturated with phosphorus compounds over time, and P-removal therefore ceases.

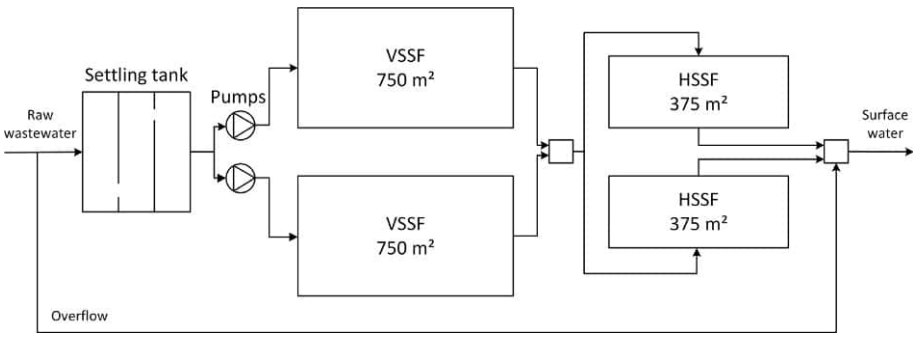

Fig. 8 Process scheme of the constructed wetland in Zevergem. [VSSF, vertical subsurface flow; HSSF, horizontal subsurface flow].

Table 4 Flemish discharge limits for urban wastewater treatment plants, receiving wastewater from agglomerations smaller than 2000 population equivalent (PE).

Parameter	*Concentration limit (mg/L)*	*Minimal reduction percentage (%)*

Removal of micropollutants

Metals

Apart from organic matter and nutrients, municipal wastewater typically also contains micropollutants. The treatment system in Zevergem has been monitored also in that respect, looking at metals and at microplastics.

In 2004, the system was studied in detail in terms of metal removal and metal accumulation (Lesage et al., 2007). Al, Cd, Cr, Cu, Fe, Mn, Ni and Zn were measured in the influent and effluent, in the sediment and in the macrophytes (Table 5). Sediment was defined here as everything that was not roots or gravel (i.e., organic and inorganic matter accumulated on the wetland and in the pore spaces).

Only Cu and Zn were encountered in the influent of the system in concentrations above the detection limit. The removal of Zn and Cu by the CW was 72% and at least 64% respectively. Notwithstanding, other metals were also retained in the wetlands, as proven by elevated concentrations especially in sediments and to a much lesser extent also in plants. Indeed, uptake of metals by *P. australis* aboveground biomass was found to be very low, which was also confirmed by many other studies. A mass balance indicated that *P. australis* was responsible for less than 2% of Cu and Zn removal from the influent, the largest amounts were thus retained in the sediment.

The Cd, Cu, Pb and Zn concentrations in the sediment decreased along the treatment path, being highest in the VSSF and lowest at the end of the HSSF. The other sampled metals were highest in the HSSF inlet area, except for Mn, which was highest at the HSSF outlet. An explanation for this behavior was found in the redox conditions. A sludge layer had formed on top of the VSSF wetland and flooding was observed during the monitoring period. These events indicate low oxygen transfer and consequently anaerobic and reducing conditions inside the VSSF, which are not desirable. Reducing conditions can increase the mobility of Al, Cr, Fe, Mn and Ni, allowing them to enter the second stage HSSF CW. There the metals encounter oxidizing conditions around the roots of *P. australis* (root oxygen loss) and this in turn leads to metal precipitation. However, the most important conclusion of the study was that all metals remained far below any threshold level for soil pollution and soil remediation.

Microplastics

In 2020–2021, the inflows and outflows of the different unit processes have been monitored for microplastics (MP) (Wang et al., in preparation). The system in Zevergem removed 96% of all MPs entering the system, thereby reducing the MPs concentration in the raw wastewater of 15.0 particles L^{-1} to 0.6 particles L^{-1} in the final effluent (Fig. 12). The primary treatment removed more than 50% of all MPs, and the CWs removed another 91% of the microplastics that were still left after the primary treatment.

Table 5 Estimation of the yearly metal mass removal from *P. australis* in the CW system in Zevergem (mg m^{-2} y^{-1}).

	Cd	*Cu*	*Pb*	*Zn*	*Cr*	*Ni*	*Al*	*Fe*	*Mn*
VSSF	0.014	7.5	0.44	90	0.6	0.91	9.4	64	91
HSSF	0.038	2.9	0.36	30	0.57	0.57	8.7	42	58

Data from Lesage E et al. (2007).

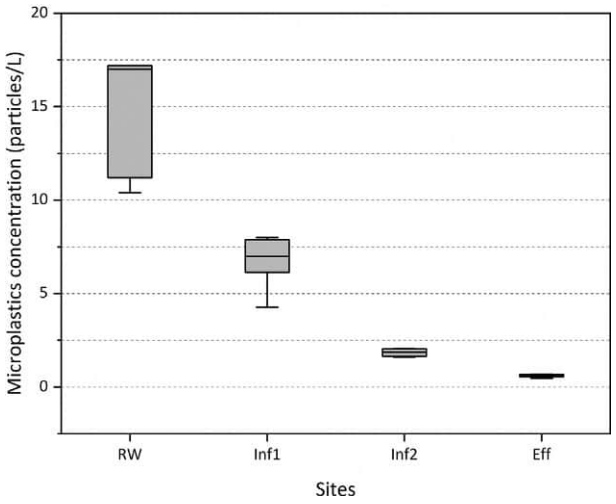

Fig. 12 Microplastics concentration (particles/L) from different sites in the Zevergem CW.

Future outlook

The CW at Zevergem is a perfect example of a good functioning wastewater treatment solution for a small community (750 PE). All discharge limits are met with averages of >99%. However, it should be noted that this configuration of VSSF-HSSF is not capable of protecting sensitive water courses from eutrophication, as nutrient removal is rather low. Additional solutions are needed in that case, such as "intensification" of the wetlands (Rousseau et al., 2022). Micropollutants such as metals and microplastics are retained as well and end up mostly in the sediments. Their accumulation should be assessed on a case-by-case base to verify whether or not any toxic threshold levels are reached.

Summary and conclusions

Constructed and semi-constructed wetlands have played an important role in offering simple and cost-effective solutions for wastewater treatment worldwide. These systems are effective in treating a wide variety of pollutants and have been utilized to treat both point and non-point sources of pollution. The four case studies discussed here demonstrates functional constructed wetlands employed for treating agricultural drainage waters and stormwater runoff, domestic wastewater and semi-industrial effluent as well as municipal waste waters. These constructed treatment wetlands offer natural and sustainable solutions in comparison to the more technological and resource intensive options and are known to also provide some economic benefits on top of ecological services.

The examples included in this chapter highlights marked improvement in our understanding of these biological systems and growing experience in operating, managing and running these systems across a broad range of climatic and operational parameters strengthens their wide acceptance as a functional ecological solution to effluent treatment around the world. As a special case of inland wetlands, constructed wetlands have played an important role in human society, and we have greatly benefitted from their functional roles either by treating our waste waters, or reducing harmful pollutants, or offering a habitat for biodiversity.

Glossary

Age at sexual maturity The expected age that fish of a given species will be able to reproduce.
Aquaculture Farmed fish.
Capture fisheries Wild harvest of fish from the natural environment, rather than farmed or produced through breeding methods controlled by humans.
Fecundity Ability to produce offspring and/or the quantity of eggs or off-spring an individual fish will produce either in a single breeding period or over their life.
Fermented fish products Fish that is preserved using the technique of fermentation, which is a method that makes fish muscle more acidic and thus prevents microbials from making the fish spoil.
Fin-fish Fish with fins and tail as opposed to shellfish.
Fishery production The amount of fish that is present in the waterbody being fished, roughly equivalent to the fish resource availability.
Gillnet A type of fishing gear made of fine cord (e.g. string or nylon) tied together to create a mesh of squares that form a net. The net is hung vertically in the water column with weights at the bottom and floats and the top. Fish are caught by their opercula and heads as they try to swim through. The space between squares can vary to allow capture of smaller or larger fish.
Harvest The quantity of fish that is gathered by one or more fishers.
Indiscriminate fishery A fishery in which no particular fish or species are specifically targeted, and all species and individuals are harvested, as opposed to fisheries in which only selected individuals (sizes) or species are harvested through specific gears used or by throwing back individuals that are not targeted.
Inland aquatic ecosystems Any environment that is inside land borders having no or low salinity. They include some brackish estuarine areas and a variety of natural (streams, rivers, floodplains, lakes, swamps, etc.) and manmade (reservoirs, rice fields, irrigation canals, etc.) inland water bodies.
Landed Brought on land to be processed or sold.
Landing sites Areas where fish can be brought to land. They are often associated with the first sale of fish from fishers to the middle-men or processing institutions. They can vary from well-established formal docks or ports, where fish are brought to shore in large numbers to small mud banks where fish are sold locally.
Middle-men Middle-men generally do not buy for their own consumption or processing but will sell the fish onto another buyer.

 https://doi.org/10.1016/B978-0-12-819166-8.00189-4

Post-harvest production The use of fish once extracted from the water body to make fish products, ranging from dried fish to fish sauces.
Quota A set amount allocated to an individual or group.
Seine net A type of fishing gear made of a fine mesh that is used to encircle fish so that they cannot escape. The mesh size can vary to allow capture of smaller or larger fish.
Subsistence fishery The capture of low quantities of fish with the primary purpose of feeding an individual, family or group. It can also include harvests large enough to sell locally in order to buy other staples. The primary purpose of the fishing activity is not for sale and the fish does not formally enter the market. Almost exclusively small-scale (using simple technology and of limited amount).
Sustainability/sustainable catch limits See panel.

Introduction

Inland fisheries rely on both wild capture and cultured fish resources from a variety of water bodies, including rivers, streams, lakes, wetlands, rice-fields, reservoirs, and natural or man-made ponds. Inland fisheries are an important resource for communities the world over (Lynch et al., 2017). Many poor communities are especially reliant on them to provide food, nutrition, employment and income (Funge-Smith and Bennett, 2019). In some places, inland fisheries supplement other primary livelihoods, in others they are the only regular source of protein and income available (Martin et al., 2013).

In this chapter the inland fisheries livelihoods are described through a series of case studies taken from different perspectives around the globe. They illustrate how important inland fisheries are to people for a variety of livelihoods and discuss how with improved management a resource that is heavily exploited has the potential to be sustained into the future.

Livelihoods

Livelihoods supported by inland fisheries can be diverse. They not only encompass subsistence, recreational, commercial, and aquaculture fisheries (Cooke et al., 2016a,b), but also extend to a myriad of post-harvest production and trade opportunities provided by the fishery (Zelasney et al., 2020). While subsistence fishing is often considered synonymous with inland fisheries, and poor communities in developing nations frequently rely on them as their only livelihood option (Cooke et al., 2016b; Smith et al., 2005), inland aquatic ecosystems also support important post-harvest livelihoods (Allison and Horemans, 2006). Market traders, middle-men, and aquarium traders, among others, rely on fresh inland fish to provide them with income and employment. Livelihoods are also supported along the value chain of post-harvest production. As fresh inland fish are processed into dried, smoked, or fermented fish products, employment options for packaging, processing, transporting and selling arise (Fig. 1). Similarly, inland fish are increasingly supporting an expanding canned and fish sauce industry (Loring et al., 2019).

Exploitation of inland resources and sustainability

As in marine environments, fish resources in inland waters are hidden under water and thus hard to quantify (Welcomme, 2011). They are often also characterized by high species diversity (Darwall et al., 2009), high mobility (Deinet et al., 2020) and seasonality (Winemiller and Jepsen, 1998). These innate challenges of inland fish for managing and regulating harvests are compounded by the following specific characteristics of inland fisheries. Although some inland fisheries target a handful of species, or individual fishers within the fishery might be somewhat selective (e.g. snakehead, trout), in the majority of inland environments wild capture will include most species, which will be harvested indiscriminately (McCann et al., 2016). This makes it extremely difficult to monitor species-specific harvests and set associated quotas. Inland fisheries are largely dominated by numerous small-scale operators, so fish may be taken directly to a fisher's household, landed at commercially operated landing sites (Fig. 2), or taken directly abroad through inland waterways (Fluet-Chouinard et al., 2018). These diverse landing options, again, make it hard to monitor what catch is being withdrawn and to set limits. Consequently, defining resource availability by estimating production, setting sustainable catch limits, and regulating harvests is challenging.

Historically, marine harvest has largely been regulated at the species level, with catch limits being calculated based on models of sustainability (Hilborn, 2004; Kinzey and Punt, 2009). These models generally incorporate life-history characteristics (e.g. fecundity, age at sexual maturity) that indicate how often the harvested fish will be replenished by reproduction, combined with reasonably accurate estimates of the amount of fish being removed from the system (Sissenwine and Shepherd, 1987). These models calculate exploitation levels that should enable the stock to replenish, while allowing regular harvest; generating, what is known as, a maximum sustainable yield (MSY) (Fig. 3). These models require fairly accurate predictions of the productivity of the fishery and reasonably precise estimates of the on-going levels of exploitation (Funge-Smith and Bennett, 2019). However, in biodiverse inland fisheries, obtaining accurate life-history information on numerous species, while keeping track of the fish being caught and landed at a variety of sites, makes using these models to calculate an MSY virtually impossible (Lorenzen et al., 2016). More recently, models have been developed specifically for data-limited fisheries (Walsh et al., 2018). Models use a range of alternative approaches as surrogates for detailed life-history and catch statistics. Some use size-based approaches, others use indicator-based systems, with the aim of determining harvest levels that can be expected to be sustained (De Graaf et al., 2015; Lorenzen et al., 2016; Kindong et al., 2019; Mildenberger et al., 2021). However, the accuracy of these approaches is also limited (Chrysafi and Kuparinen, 2016).

Increasing human populations and the accessibility of inland fisheries resources has led some people to assume that inland fisheries are being over-exploited and suggest that inland fisheries livelihoods are just not sustainable. However, on-going global efforts to improve management and overcome or circumvent some of the challenges of monitoring and managing fisheries, bring hope to the many peoples who rely on these resources, and who often have no viable alternatives.

Fig. 2 (A) A medium-sized operator carries his fish to the landing site in a basket for sale to middle men, (B) small-scale operators land small fish, (C) a large-scale operator lands containers full of fish for sale, (D) fish are sorted and weighed for sale by commercial middlemen. Fig. 3 Illustration of Maximum Sustainable yields (MSY). Maximum Sustainable yield is derived from estimates of population biomass of fish or the amount of fish (in number or weight) that can be produced by the system given the biology of the fish and the environmental conditions, and the fishing pressure or amount of fish being removed by fishers. The purpose is to understand the system well enough to have accurate estimates of the quantity of fish being produced, and to have an accurate estimate of how much fish is being harvested, to define an amount that can be removed while allowing the fish to reproduce and replace the individuals that have been removed by fishing or that die from other causes. This is called the maximum sustainable yield or the maximum amount of fish that can be removed without resulting in a net reduction in total fish availability. The number of individuals that can be taken without compromising the ability of a species to replace the individuals taken through reproduction is dependent on the biology of the individual species (the number of individuals that are produced, the number that will survive to be reproductive, the number of years before the individuals will be reproductively capable). These characteristics can be highly variable from species to species making it challenging to define values of sustainable harvest in biodiverse systems. The number of individuals harvested of each species is often not recorded when fishing behavior is indiscriminate, compounding the challenge for setting and adhering to maximum yields.

Case studies

Case studies are presented here from across the globe, showing how local fishermen and fishing communities are working with governments to combat some of the challenges of inland fisheries livelihoods. From the Murray-Darling basin in Southern Australia, where environmental performance indicators are being used to overcome the challenge of stock assessments, to the Mekong River in South-east Asia, where widespread community-managed fish conservation zones are being endorsed by the government to provide a network for migratory fish. Along Costa Rica's Di Crí river, communities are combining traditional knowledge with science to improve fisheries management, while in the Midwest territories of North America, Tribes are working with state governments to rehabilitate the walleye (*Sander vitreus)* fishery. Finally, in Lake Victoria in East Africa, rights-based fisheries options are being explored to overcome the challenges of open-access over-exploitation, and local fishers are exploring opportunities to enhance profits without increasing fishing pressure by exploring product enhancement techniques, while at the same time exploring alternative livelihood options. Building on local knowledge combined with evidence-based management and strong support from the government, local fishers and communities are working together to overcome some of the challenges facing fishery-based livelihoods in inland waters.

Case study: The south Australian Lakes and Coorong fishery

The Lakes and Coorong Fishery (LCF) is a small-scale, semi-artisanal commercial fishery that operates at the terminus of Australia's longest river system, the Murray-Darling Basin (MDB) (Fig. 4). The Lower Lakes and Coorong region is recognized as a Wetland of International Importance under the Ramsar Convention due to its unique ecological character and is a place of significant cultural value, particularly to the local indigenous people, the Ngarrindjeri (Phillips and Muller, 2006).

In operation since 1846, the LCF is a multi-species, multi-method fishery, primarily targeting finfish in freshwater and estuarine habitats (Olsen and Evans, 1991). The fishery is a regionally important source of fresh fish and employment. The average annual catch for 2016–2021 was ~1700 t, with a gross value of ~AU$11.5 M/year, supporting a fleet of 36 licensed vessels, and directly employing ~70 skippers and crew (EconSearch, 2019; Earl and Bailleul, 2021). Like many small-scale fisheries, the LCF is characterized by 'sole-operator' local fishers that use small vessels and basic methods, primarily gillnets of varying mesh size. As mandated by regulations, all gillnets are 50 m long, and each vessel has a daily entitlement of up to 100 gillnets.

Different species are targeted in freshwater and estuarine waters. In freshwaters, golden perch (*Macquaria ambigua ambigua*), bony herring (*Nematalosa erebi*) and non-native common carp (*Cyprinus carpio*) are key species. Whereas, mulloway (*Argyrosomus japonicus*), yelloweye mullet (*Aldrichetta forsteri*), greenback flounder (*Rhombosolea tapirina*) and black bream (*Acanthopagrus butcheri*) comprise the majority of the estuarine harvest. With the exception of common carp and bony herring, which are primarily supplied as bait to local commercial crustacean fisheries, catches support high-value domestic human consumption markets (Ferguson et al., 2018). The Ngarrindjeri way of life is inextricably linked with the fishes of the Lower Lakes and Coorong region, several of which represent Ngarrindjeri *njartis* (totems – friends) and have provided important food sources for thousands of years (Berndt et al., 1993). More recently, several species, notably mulloway, form the basis of an important recreational fishery (Ferguson et al., 2018). Total harvest by indigenous and recreational sectors is unquantified but is an important consideration for management of the LCF and the environment.

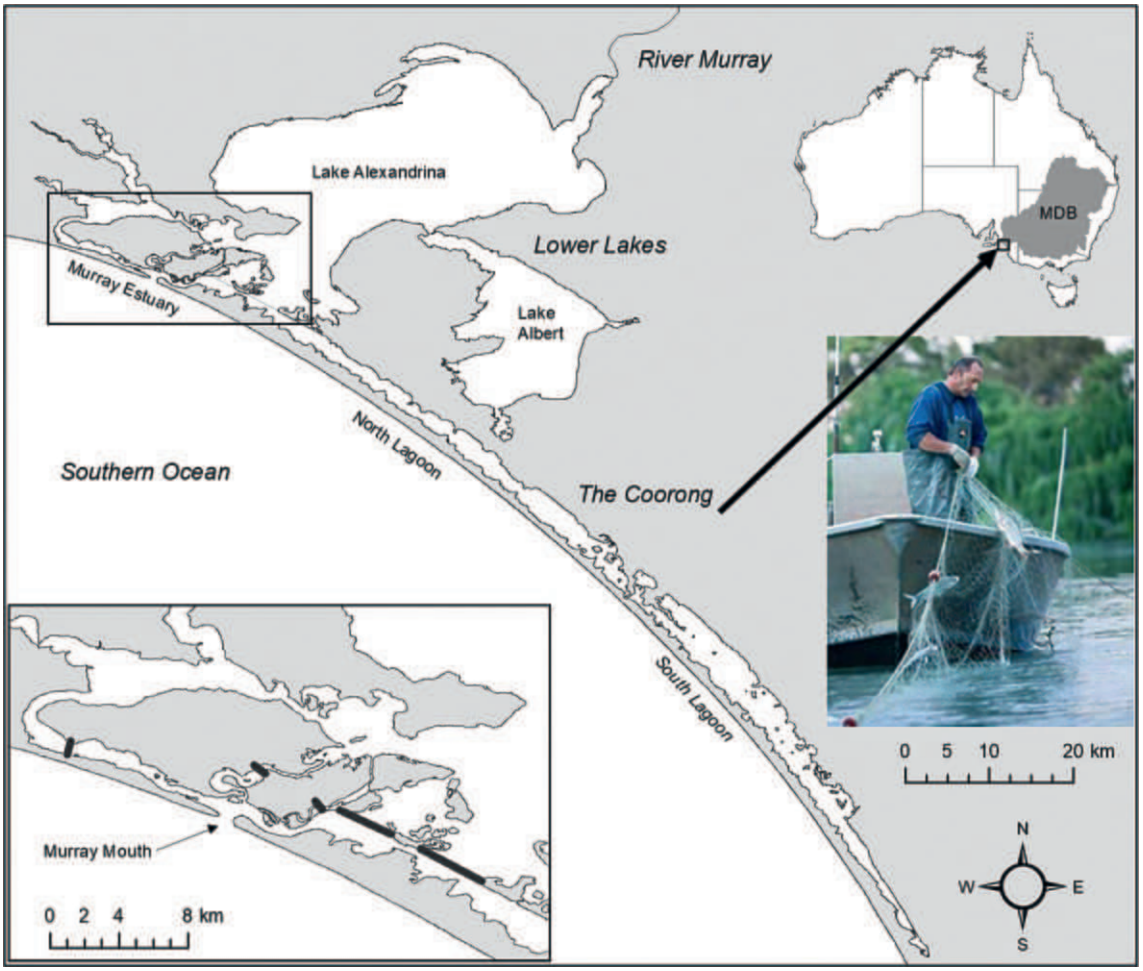

Fig. 4 Map of the Coorong (Murray Estuary, North Lagoon and Southern Lagoon) and Lower Lakes (Lakes Alexandrina and Albert) at the terminus of the Murray-Darling Basin (MDB), southern Australia. Inset shows the Murray Estuary, highlighting the Murray Mouth and the five tidal barrages (dark thick lines) that separate freshwater (Lower Lakes) and estuarine (Coorong) environments of the region. Insert LCF Fisher. Photo credit: Randy Larcombe, Southern Fishermen's Association.

A critical aspect of the LCF is the influence of river flow on target species abundance. The MDB is known as Australia's food bowl, supporting 70% of the country's irrigated agriculture (ABS/ABARE/BRS, 2009). Consequently, end-of-system freshwater flow is on average approximately only a third of its natural potential, while a series of tidal barrages separate freshwater and estuarine environments of the LCF. These changes have resulted in disruption to population dynamics and historic declines in species critical to the LCF (Bice et al., 2018). The ecological value of the region and legislative responsibility associated with the Ramsar convention and the *Murray-Darling Basin Plan* have recently prompted considerable management action to promote ecosystem rehabilitation. This has involved the delivery of environmental flows that seek, in part, to promote connectivity, and salinity regimes that support ecologically and commercially important fish species (Bice et al., 2018). Thus, there is a nexus between environmental and fishery management that is critical to the production and sustainability of the LCF.

Fisheries management for the LCF has been gradually established since the 1970s, including a minimum legal length for most target species, as well as input controls that include limited entry (restrictions in the time or seasonal access), gear restrictions (only specified types of fishing gears can be used), and spatial closures (some locations are off-bounds for fishing permanently or seasonally) (Ferguson et al., 2018). A compliance program, with cost-recovery through commercial fishery license fees, is in place to educate fishers, deter opportunistic and financially motivated fishery-related crimes and enforce the rules and regulations.

In 2015, a review of the fisheries management arrangements for the LCF exposed several operational shortfalls. This included a lack of quantitative indicators and defined management responses to varying environmental conditions; no limit reference point that defined an unacceptable risk of fishing pressure; and no formal mechanism to control the level of exploitation should any reference point be approached (Knuckey et al., 2015). This led to the development of a harvest strategy for finfish and the introduction of specific output controls in the form of a total allowable commercial gillnet effort (TACE) for the freshwater and estuarine fishery. In the absence of quantitative stock assessments, often infeasible for multi-species fisheries (Newman et al., 2018),

the harvest strategy aims to manage the sustainable harvest of target species relative to the condition of the environment within which the fishery operates using environmental performance indicators (e.g. lake water levels) as surrogate metrics for fishable biomass (Knuckey et al., 2015). The harvest strategy could, however, be improved for key species by integrating biological performance indicators, such as population age structure, to inform on the influence of fishing pressure, environmental variability and demographic processes (i.e. recruitment and movement) on stock status. Consideration of trends in commercial fishery catch and effort statistics for key species (e.g. standardized catch rates) may also improve the capacity for effective management at the species level. Such integration will strengthen the sustainability of the LCF and contribute to maintaining the rich cultural, ecological and social values of the Lower Lakes and Coorong into the future.

Case study: Community-based fisheries management at Kengmai rapids on the Mekong River in northern Lao PDR

The Mekong River is the largest river in Southeast Asia and flows through six countries from its headwaters in the Tibetan Plateau to the Mekong Delta in Vietnam. At Kengmai Rapids, there is a 5-km section of the Mekong River in northern Lao People's Democratic Republic (Lao PDR) that is bordered by the villages of Donsok, Phalath, Donmen, and Houayla (Fig. 5). The principal livelihood practiced by over 90% of the people is farming for rice and other agricultural products. Fishing is primarily opportunistic for household consumption, with the largest number of full or part-time fishers found in Houayla. Fishing is typically conducted by men from wooden boats, primarily using gillnets, cast nets, hook and line, and traps. Women participate in fish processing activities, such as drying and fermenting. The catch is diverse, with key species consisting of catfishes (e.g., *Bagarius yarrelli*., *Clarias* spp., *Hemibagrus* spp., *Micronema* spp., *Pangasius* spp.) and cyprinids (e.g., *Cyclocheilichthys* spp., *Hypsibarbus* spp., *Morulius chrysophekadion*, *Mystacoleucus* spp.).

The fishery is largely indiscriminate with the notable exceptions of the critically endangered Jullien's golden carp (*Probarbus jullieni*) and the endangered thick-lipped barb (*Probarbus labeamajor*). Historically, the villages would target these species when the fish congregate to spawn at sand bars and rapids during the dry season (December–February). The fish splash at the surface during their spawning displays, making them vulnerable to fishing activity. *Probarbus* are economically prized and are sold to fish traders. As a result of overfishing and loss of habitat, these highly migratory fish have declined significantly in number and size.

Based on interviews with local communities in 2014, Kengmai Rapids was identified as a potential *Probarbus* spawning habitat and proposed as the location for a community-managed protected area. Villages in Lao PDR are authorized to set their own

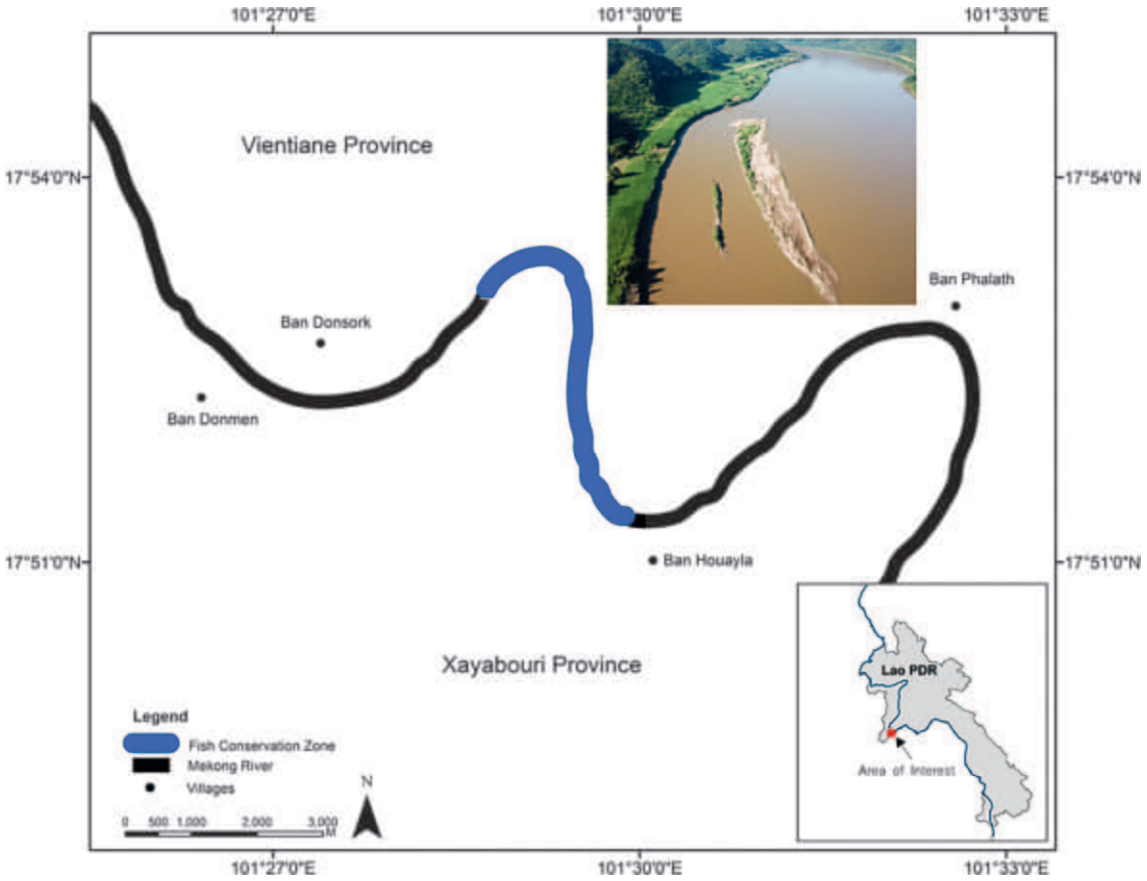

Fig. 5 Map of communities at Kengmai Rapids, Lao PDR. Courtesy of Erin Loury, FISHBIO.

regulations for fisheries management under the Lao fisheries law. In 2015, the four villages formally established a community-managed Fish Conservation Zone (FCZ) at Kengmai Rapids, one of over 1300 such FCZs recognized by the Lao government. The Kengmai Rapids FCZ supports biodiversity conservation, local livelihoods and food security by protecting spawning *Probarbus* and key breeding and feeding habitats for other species. Enforcement of the FCZ regulations also addresses the threat from destructive dynamite and electrofishing. Fish sampling surveys have documented juvenile *Probarbus* inside the FCZ, confirming the importance of the location as a spawning and rearing area.

The FCZ prohibits all fishing along a 5-km stretch of the Mekong River, and represents one of the largest freshwater protected areas on the mainstem Mekong in Lao PDR. Although the size of the area presents logistical challenges for patrolling and enforcement, the villages share responsibility for enforcing the FCZ regulations, and communities are generally supportive of the FCZ. Illegal fishing does still occur in the area; however, communities believe that the FCZ has helped increase compliance with regulations and decrease the extent of illegal and destructive practices. Given adequate support, local communities are able to effectively manage fish resources to both sustain food security and to conserve freshwater biodiversity. Government recognition of FCZs is a major contributing factor that has enabled this model to be adopted by communities throughout Lao PDR. Although dam construction on the Mekong River threatens the habitat and the migratory fishes protected by the Kengmai Rapids FCZ, increased coordination of community enforcement at FCZs across Lao PDR could help support a network of refuges for aquatic biodiversity at a landscape scale, while providing resilience to local fisheries.

Case study: Fisheries in the indigenous territory of Rey Curré, Costa Rica

Rey Curré is an indigenous territory (10,600 ha) in the Puntarenas province of Costa Rica, inhabited by the Bruncaj people. The territory is located close to Costa Rica's largest (160 km) river, the Térraba river, known locally as Dí Crí, meaning big water (Fig. 6). The river flows 50 km from the center of Rey Curré downstream toward the Pacific Ocean, passing through the Térraba-Sierpe wetlands RAMSAR site, the largest mangrove system in the country.

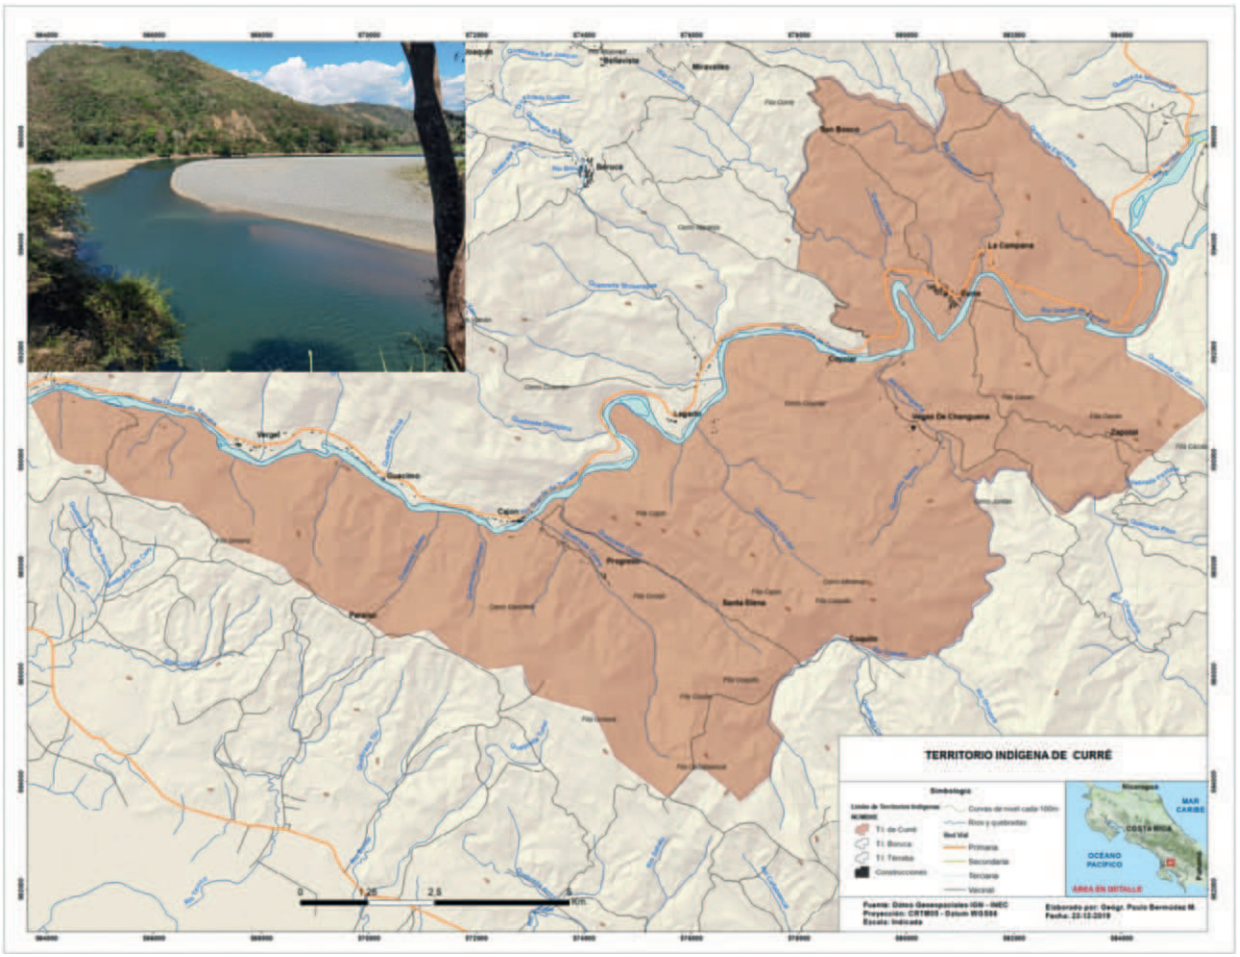

Fig. 6 Fishing communities in Rey Curré. Courtesy of Eva Salas, FISHBIO.

The inland fishery provides an important source of protein for these low-income communities and has historically been important to the culture of Rey Curré and nearby indigenous territories. In particular, the Di Crí river is considered a sacred place, of spiritual, recreational and cultural value. The multispecies subsistence fishery is largely shore-based and is most active during the dry season. Although the most common and abundant catch is machaca (*Brycon beherae*), the diverse fishery includes various shrimp species, especially *Macrobrachium* spp. and maruchas (*Atya spp*), as well as coastal fish species, such as snooks (Centropomidae), grunts (Haemulidae) and snappers (Lutjanidae).

The only legal fishing gear in Costa Rican inland waters is the hook and line, but other gears, such as cast nets, gillnets, seine nets, and spear guns are also frequently used, because regulations are rarely enforced. Of even greater concern is the use of poisons for harvesting shrimp. Although there is work in progress to establish additional local management, as well as an interest in establishing freshwater protected areas, there are currently no other regulations, such as size, season or species restrictions, and no freshwater protected areas. The lack of regulations and increasing fishing pressure have prompted local fears that the fishery is being over-exploited. Local ecological knowledge surveys suggest that shrimp in particular, are being over harvested as a result of the use of poisons.

Despite providing an important source of local protein and a pressing need for improved fishery management, inland fisheries are not a national priority, due to the greater economic importance of marine fisheries. As a result of this lack of attention, there is insufficient funding available for patrolling and other management needs, including establishing the critical regulations and other interventions to enhance the fishery and the environment.

Pineapple crops, deforestation and climate change are making conditions drier and threatening downstream ecosystems, such as the wetlands of the Terraba-Sierpe, affecting the whole watershed and having far-reaching consequences for fish health, productivity and life-history. To protect and manage their valuable resources, Rey Curré and the neighboring territories of Boruca and Térraba need more support. Through the development of local management plans led by local communities and informed by science, there are opportunities to combine traditional knowledge with western science to guide management and conservation goals that will help restore the river, protect its species, and unite the communities around the same goals.

Acknowledgements

We want to thank Daniel Leiva of the Instancia de Consulta, and over 40 people of the territory that have shared fishery information. The information used to build the profile of Rey Curré comes from the collective knowledge of over 40 people of the territory that have participated in FISHBIO project workshops, and it was validated by José Rigoberto Leiva, the current president of Rey Curré's Asociación de Desarrollo Integral (ADI Curré).

Case study: Co-management of fisheries in the ceded territories of the upper Midwest, USA

Harvest of *Ogaa* (Walleye; *Sander vitreus*) is an essential subsistence and cultural activity among the Ojibwe Tribes of the northern glaciated region of the states, now known as Wisconsin, Michigan, and Minnesota in the United States of America. During the early spring when *Ogaa* are spawning in nearshore areas (BIA, 1991), harvesters spear or net *Ogaa* and share the harvest with members of their extended families, elders, and throughout the community. These fish form an important part of ceremonies and community feasts. Harvest season brings the tribal community together and provides sustenance for the coming months.

Ogaa also contribute to the sportfishing economy of the midwestern region (BIA, 1991). It rates as one of the most popular fish targeted by anglers for recreation and harvest, and draws tourists to the region throughout most of the year. As the most abundant predator in most of the lakes and rivers in the region, *Ogaa* is also important ecologically.

In the mid-1800s, Ojibwe ceded large tracts of land to the USA in a series of treaties (Fig. 7) in which tribes reserved the right to hunt, fish, and gather on the lands. In Wisconsin and Minnesota, Tribes regulate their harvests according to court mandates. Although not formalized in Michigan, Tribes in these territories have set up similar systems to regulate harvest. The Great Lakes Indian Fish and Wildlife Commission (GLIFWC) is a tribal natural resource agency that was formed by, and assists, its 11 member Ojibwe Tribes in implementing the federal court orders and intergovernmental arrangements governing treaty rights. In these systems, Tribes and GLIFWC work with the State Department of Natural Resources (DNR) to co-manage and set annual quotas in accordance with the best available population data for individual lakes (Hansen et al., 1991, 2015; Schmalz et al., 2011). These decisions are made based on science generated by all partners and traditional knowledge held by the Tribes. The available annual harvest is allocated between tribal subsistence fisheries and state-regulated angling fisheries, implicitly based on the method of harvest (i.e. Wisconsin Lakes, Staggs et al., 1990), or explicitly (i.e. Mille Lacs Lake, MN) based on an agreement between the parties (Schmalz et al., 2011). In all territories, the goal of the Tribes is to allow walleye populations to be sustained and provide harvest opportunities for current members and for the next seven generations.

Despite these goals and careful consideration, *Ogaa* are declining in many of these waters. Habitat destruction, invasive species, continued harvest of declining populations (Embke et al., 2019), and climate change pose major threats to walleye populations in this region (Hansen et al., 2017). Extra coordination between Tribes, States, and others will be required to rehabilitate declining stocks and protect resilient populations. In some lakes where *Ogaa* populations are declining, Tribes are working with state agencies and nongovernmental organizations to create and implement rehabilitation plans. These plans have primarily focused on resisting fish community transformations that may be caused by ecosystem change, but recent discussions have included accepting or directing these transformations. Typically harvest reductions, stocking, and frequent population monitoring are the main tools used for rehabilitation. More recently, plans have attempted to account for climate change when projecting fish populations

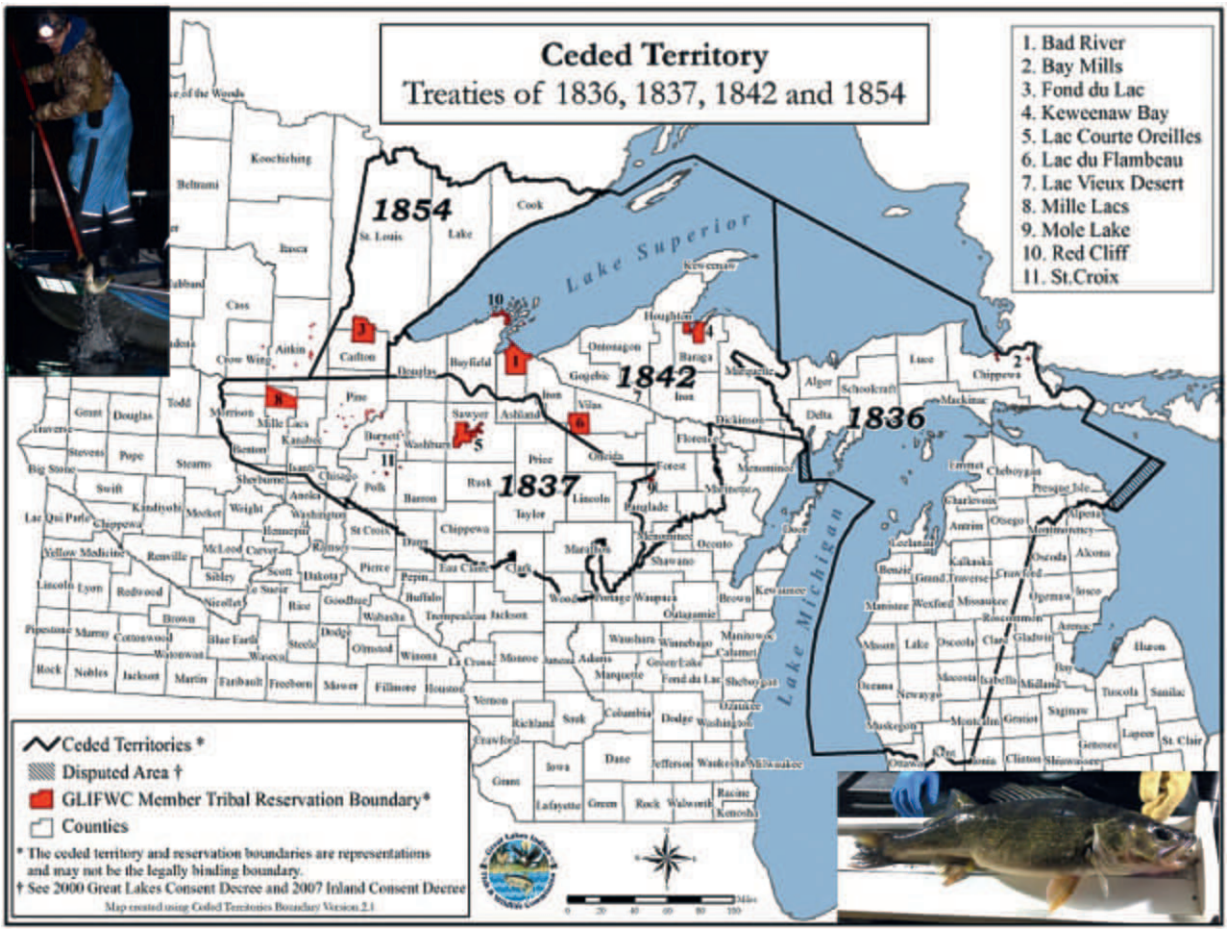

Fig. 7 Map of the Ceded Territories in the Upper Midwest, USA. Image credit: Great Lakes Indian Fish & Wildlife Commission.

(e.g. Hansen et al., 2017), evaluating future habitat, and implementing potential mitigation efforts, such as those proposed in the Midwest Glacial Lakes Partnership Conservation Plan, 2019.

Overall, *Ogaa* remain an important species for subsistence harvest and recreational angling in the Ceded Territories of the Upper Midwest. Additional protection and rehabilitation efforts will be required to ensure that fisheries livelihoods can be sustained in the area for the long term.

Ann McCammon-Soltis provided valuable edits to earlier versions of this case study. Dara Unglaube supplied us with the map of the Ceded Territories in the Upper Midwest.

Case study: Human pressure and management of Lake Victoria resource use

Lake Victoria (2°3′S 33°4′E) is the largest (about 68,800 km^2) inland tropical lake. The main lake is shared between Kenya (6% of coastline), Uganda (43%) and Tanzania (51%) with a catchment that extends to Burundi and Rwanda (Fig. 8). The Lake Victoria Basin supports the lives of about 51 million inhabitants with more than 500 persons per km^2, which makes it one of the most densely populated basins globally (Kimani et al., 2018a). The fishery is estimated to directly employ about 200,000 fishers, and 700,000 people along the value chain, while supporting the livelihoods of 3–4 million people (Mkumbo and Marshall, 2015).

Since the 1950s, the fishery has transformed from a multispecies, native fishery to focus on three species of commercial importance: *Lates niloticus* (Nile perch), *Oreochromis niloticus* (Nile tilapia) and *Rastrineobola argentea* (Dagaa or Omena). The Nile perch, together with four Tilapiines: *O. niloticus* (L), *O. leucosticus* (Trewavas), *Coptodon rendalli* (Boulenger) and *Coptodon zillii* (Gervais) were introduced in the 1950s and 1960s (Powell, 2020). The introduction of these exotic fish species placed endemic cichlids in grave danger of extinction and is thought to have led to the explosion of Nile perch population (although there is some debate) and a dramatic decrease in the species diversity and fish biomass in the lake (Marshall, 2018; Downing et al., 2013). Nile perch has been credited with the disappearance of more than 200 species of haplochromine cichlids, one of the most biodiverse and locally adapted Tribe of cichlids, and the decline of other native species (Nyamweya et al., 2016).

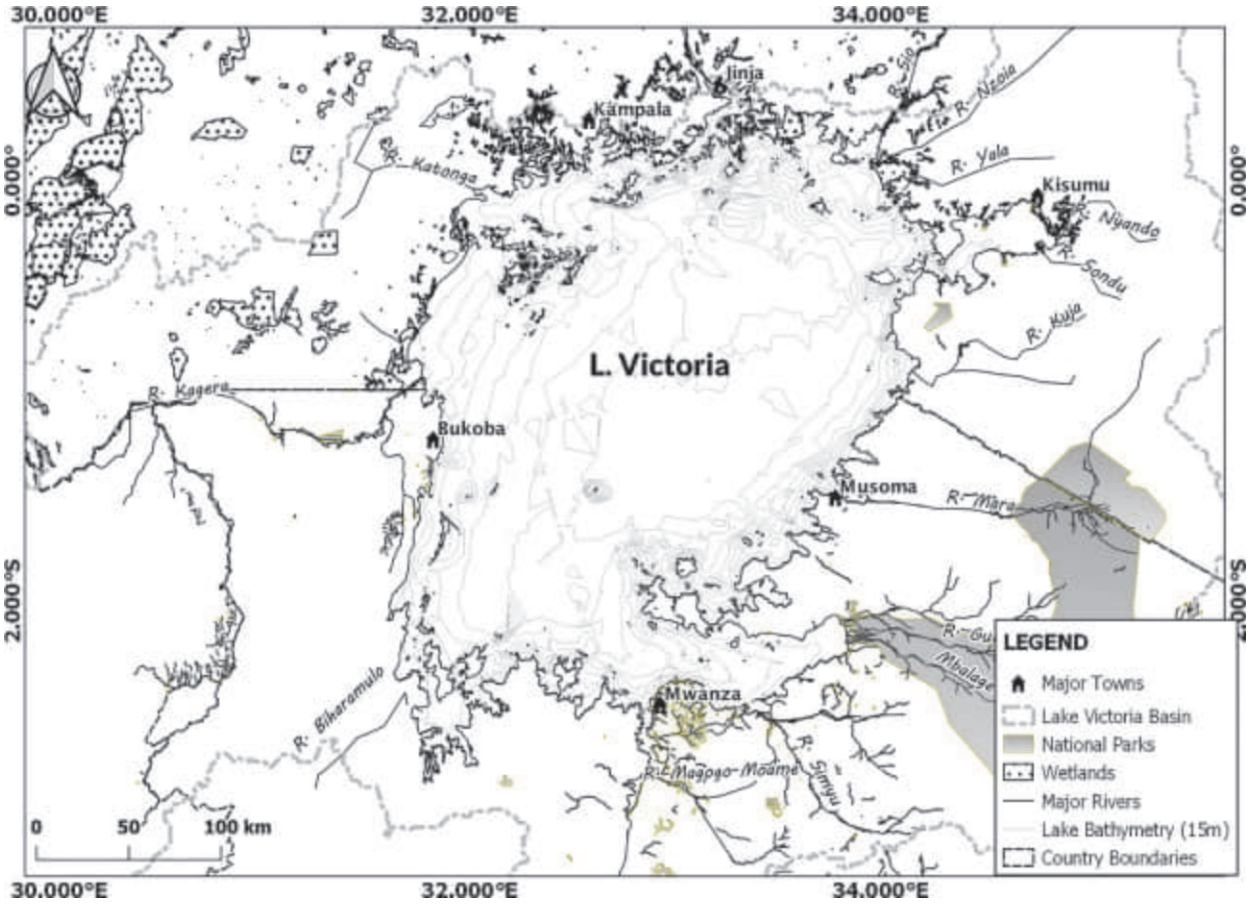

Fig. 8 Lake Vitoria Fisheries with major rivers, towns and other natural resources. Image credit Christopher Aura.

While Nile perch decimated native biodiversity, it has also expanded commercial opportunities within the lake, with international exports of Nile perch reaching Europe and the Middle East (Odongkara et al., 2005). The lake provides a blended artisanal-commercial fishery, which is largely traditional in terms of fishing methods and vessels, but supports a large Nile perch fish export industry, coupled with substantial domestic trade in many endemic species. Fisheries production from Lake Victoria increased tenfold from 1980 to 2016 (98,250 tons in 1980 to 918,000 tons in 2016) (Aura et al., 2020). About 1 million metric tons of fish are harvested annually from Lake Victoria, generating >840 million US$ at the beach and > 300 million US$ in exports (van Zwieten et al., 2016; Aura et al., 2020). Further processing and marketing of the catch is valued at US$ 60 million. However, the fishery has recorded a steady decline in fish harvests since the year 2000, and continues to exhibit this trend, provoking fears that the lake is being over-harvested and requires better management to support sustainable harvests (Nyamweya et al., 2020). Aside from the transformation of the aquatic food web, the Lake Victoria region has experienced an accelerated rate of population growth, land cover change, and ecosystem change, which has put increasing pressure on the fishery, challenging its sustainability (Ongore et al., 2018).

The lake is co-managed by local associations (Beach Management Units, BMUs), national management and research institutions and regional institutions consisting of Lake Victoria Fisheries Organization (LVFO), the East African Community (EAC), and the Lake Victoria Basin Commission (LVBC); with several international, regional and national regulations, policies and laws also guiding the exploitation and management of fisheries resources (Aura et al., 2019). The BMUs are intended to bring together everyone involved in fisheries, in particular fishers, boat owners, traders, processors, boat builders, net menders, and others - to work together with the government in an attempt to manage the fisheries resources more holistically. Despite the extensive co-management efforts, there have been many challenges, including Uganda suspending its BMU activity (Etiegni et al., 2020) and Lake Victoria largely continues to operate as an open-access system (Nunan, 2010). This poses a serious challenge to managing fishing effort sustainably. Exploration of rights-based fisheries to delimit local fishing areas as an alternative to open-access, and being more cognizant of community priorities, biases and limitations, could improve the existing co-management (Edward et al., 2011; Mgaya and Mahongo, 2017). Increased investment in Monitoring Control and Surveillance (MCS) and identifying ways of determining sustainable fishing effort for the Lake, would also be beneficial.

Options for expanding livelihood opportunities within the fishery are few. However, with improved management and regulation, cage culture, which integrates fisheries knowledge with entrepreneurship skills could be a particularly attractive option,

increasing productivity and offering employment (Kizza et al., 2009; Aura et al., 2018). Expansion of trading opportunities in the local and international markets through post-harvest production has the potential to enhance the value of the same catch, helping to reduce fishing pressure. With appropriate technology and investment, trade in fish products and aquatic plants could also offer a viable alternative. Nile perch swim bladder (fish maw), which is largely exported to China through Hong Kong fetches a higher price than fish itself. Fish maw are used as a source of collagen, proteins and nutrients, which are believed to improve skin tissues and tone and promote healing of weak lungs and kidneys (Kimani et al., 2018b). If the Nile perch maw trade is formalized and optimized, it could improve the socio-economic benefits for the region. Careful exploration of the potential use of selected endemic and small indigenous species like Dagaa by the animal feed industries, could ease pressure on the preferred Nile tilapia food-fish, but they play a critical role in local food security and thus should be approached with caution (Matsuishi et al., 2006).

Unrestricted fisheries have few entry demands and a rather quick repayment period, providing significant advantages over many livelihood alternatives (e.g., farming) (Edward et al., 2011). Nevertheless, Lake Victoria's 7000 km shoreline provides great potential for fisheries tourism and a fledgling hospitality industry (McCarthy, 2004; Hamilton, 2016). The shoreline and the lake could also offer unique and unexploited recreational opportunities like sport fishing, boat racing, and wind surfing in the expansive open waters, snorkeling and diving in aquatic diversity hotspots, and holidaying in its many exotic islands. Fish, plants and other local resources could also be turned into souvenirs and sold to the tourists. Invasive aquatic weeds, such as the water hyacinth, which have gained much attention for their undesirable socio-ecological impacts could, for example, be used for energy production; to make mats and furniture; for fish feeds; for biodegradable paper; and to produce charcoal (Ongore et al., 2018). With declining fisheries, fishers are being forced to consider alternatives and finding livelihood opportunities outside the fishery is becoming essential to ensure the sustainability of the Lake Victoria ecosystem and its resources.

Conclusions

While coasts offer many marine fishery landing opportunities, inland waters are integrated into the landscape as wetlands, ponds, agri-fisheries, and networks of rivers and streams, all offering the possibility to bring fish on land. Thus, the challenge of monitoring and regulating exploitation with so many opportunities, becomes insurmountable. Inland fisheries, more so than marine, must rely on the integrity and interest of fishers to harvest sustainably in order for exploitation of inland resources to remain a viable livelihood option. Inland fishers, fishing communities and governments around the world are working together to make fishing practices more sustainable and to ensure that inland fisheries remain a feasible livelihood in the future.

Implications of Climate Change for Freshwater Fisheries

Seán Kelly, James Barry, and Fiona L Kelly, Inland Fisheries Ireland, Dublin, Ireland

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Adaptive capacity The capacity of a species to adapt to changing environmental conditions, such as increased temperature. This can involve behavioral, physiological, morphological and phenological change.
Critical thermal maxima/minima Thermal endpoint following a constant change in water temperature at which a loss of equilibrium occurs. Used to assess the tolerance of fish species and populations to upper and lower temperature extremes.
Degree-days The accumulated thermal units, measured as mean daily temperature, experienced by a fish over time (e.g. a fish held for 1 day at 10 °C and a fish held for 2 days at 5 °C have both experienced 10 degree-days).
Diadromous Species that migrate between marine and freshwater habitats.
Eurytherm Species that can function over a wide temperature range.
Freshwater fish A fish species that spends all or part of its life-cycle in freshwater bodies, such as lakes or rivers.
Inland fisheries Includes all types of fisheries (artisanal, subsistence, recreational and commercial) in freshwater and brackish waterbodies.
Lentic Still or slow-moving freshwater habitat (lakes, reservoirs, ponds, floodplains).
Lotic Fast-flowing freshwater habitat (rivers and streams).
Potamodromous Species that migrate within freshwater habitats (e.g. between rivers and lakes).
Riparian zone A transitional interface between aquatic and terrestrial environments, characterized by a zone of vegetation bordering water bodies.
Stenotherm Species that typically can only function over a narrower temperature range.

Introduction - climate change as a threat for freshwater fish

The diversity and widespread distribution of *freshwater fishes* illustrates an extraordinary adaptability to a range of environmental conditions, from small mountain streams to vast lowland river basins and from shallow ponds to the world's deepest lakes. Even the natural range of a single fish species may be spread across a considerable climatic gradient. For example, the native distributions of the American eel (*Anguilla rostrata*) and European eel (*Anguilla anguilla*) cover drainage basins that occur along latitudinal extremes on western and eastern Atlantic coastlines. Throughout the long evolutionary history of freshwater fish they have experienced, and have successfully adapted to, shifts in climatic and environmental conditions. Recent and rapidly changing human-influenced climate change is a novel form of climatic variability that fish populations have not experienced previously. Substantial increases in atmospheric greenhouse gases over the past two centuries have occurred due to human activities (IPCC, 2021) and the primary relevance to freshwater fisheries involves changes to the temperature and precipitation climatology at the Earth's surface.

Additional factors, often arising through complex feedback loops, involve increased frequency, duration, and intensity of episodic and extreme climatic events such as storms, floods, heatwaves, and droughts. The need to understand climate-induced changes in freshwater fish habitat and resulting ecological consequences is clear - half of all current freshwater fish species are predicted to be potentially at risk of climate-induced extinctions in the coming century (Manjarrés-Hernández et al., 2021) and over a third of species may have over a half of their current geographic range exposed to climatic extremes (Barbarossa et al., 2021).

The aim of this chapter is to provide a general overview of predicted climate-induced impacts on freshwater fish species, their habitats and fisheries and to review potential ecological consequences. Specific *lentic* and *lotic* responses to climate change pertinent to fish populations are discussed. Furthermore, the unequal vulnerability of individual fish species and inland fisheries to climate change is considered, which depends not only on the magnitude of change occurring across a species' natural range but also on each species' biological tolerance and capacity to adapt. The emerging threat of climate change for freshwater fish and their habitats is much more formidable combined with multiple additional existing and emergent stressors, with direct climate change effects potentially accentuating existing pressures faced by fish populations. While an exhaustive account of human impacts on freshwater fish is beyond the scope of this article, the potential for climatic and other specific anthropogenic environmental pressures to interact and create compounding stressors is considered. The chapter is concluded by highlighting some important knowledge gaps and potential mitigation strategies aimed at increasing the resilience of freshwater fish to climate change.

Climate change effects on freshwater fish environments

Thermal habitat

At a global scale, the net outcome of excess radiative energy being trapped in the atmosphere due to increased greenhouse gas concentrations is an increase in heat uptake in inland waters through modification of the surface energy budget (Vanderkelen et al., 2020). This will inevitably lead to thermal regimes in lakes and rivers worldwide becoming warmer on average, which has major ecological consequences for fish.

As obligate ectotherms, the body temperature of almost all fish is dictated by the surrounding water temperature (Haesemeyer, 2020). Therefore, the ambient temperature affects various physiological processes such as blood circulation, respiration, hormonal activity, the immune system, and behavior. It also affects movement, reproduction, growth, and life span. Unable to thermoregulate to any significant degree through internal physiological processes, fish must inhabit thermal environments that allow them to maintain a body temperature necessary for physiological and metabolic functioning.

Individual fish species have evolved a set of critical upper and lower thermal limits that allows them to adapt to their environment (see Section "Vulnerability and resiliency of freshwater fish to climate change"). Thermal tolerances within each species can be further categorized, as different life-stages (adults, juveniles, spawning adults and developing embryos) generally have a different set of critical thermal limits (Dahlke et al., 2020). Spawning adults and the developing egg stage are the least thermally tolerant, with a much narrower set of thermal limits compared with juveniles and adults during the growth stage (e.g. Elliott and Elliott, 2010). Therefore, reproductive phases potentially represent a thermal bottleneck in the life stage of freshwater fish and could be the most important determinant for whether a temperature increase in their native habitat will be tolerable. In this regard, temperature increases during the spawning season and subsequent incubation period are of particular concern. The rudimentary cardio-respiratory system, and inability to produce heat shock proteins in response to direct heat stress, leaves the egg stage at highest risk for warming-related mortality. Furthermore, development at the egg stage is highly temperature dependent and warmer average temperatures during the developmental stage cause *degree-days* to be accumulated at a more rapid pace. This can cause the overall developmental time (in degree-days but not necessarily in calendar days) to be longer, depleting the yolk sac and resulting in smaller, poorer conditioned fry upon hatching (Mari et al., 2021). Total incubation length in calendar days however may still be shorter at warmer temperatures as the increased number of degree-days are accumulated more rapidly. This could lead many species to undergo shifts in timing of reproductive life-history events, with spawning and hatching events in spring and summer spawning species likely to occur earlier in the year. In addition, changes in hatching phenology could lead to possible timing mismatches between emergence of fry and peak food availability (e.g. Jonsson and Setzer, 2015).

The global distribution of freshwater fish across climatic gradients reflects the thermal tolerances of individual species. Fish living in warm tropical rivers and lakes (e.g. cichlids) have a relatively high 'critical thermal maximum' while fish in northern temperate and polar environments (e.g. salmonids) have a 'lower critical thermal minimum', allowing them to tolerate cold, ice-covered waters. *Stenothermal* species (e.g. Arctic charr, (*Salvelinus alpinus*)) have a narrow thermal tolerance limit, while 'eurythermal' species can tolerate a wider range of water temperatures and generally illustrate a wide latitudinal distribution reflecting this (e.g. freshwater eels in the genus *Anguilla* (Froese and Pauly, 2000). However, stenothermal species may be able to exploit extreme freshwater habitat types uninhabitable to most other species (Klemetsen et al., 2003). Furthermore, while fish can survive within a sublethal temperature range bounded by their upper and lower critical limits, each species is defined typically by an optimal temperature range for growth (Elliott and Elliott, 2010). This optimal range is even narrower than the critical thermal range and fish exposed to warmer temperatures outside of this optimal range may cease to grow efficiently, primarily due to more energy being invested into cellular repair related to heat damage. This decreases energy allotment for somatic growth (e.g. muscle, skeletal, organ) and reproductive growth as well as activity, which inevitably leads to reduced feeding. Thus, given the critical role of water temperature

in shaping the ecology and contemporary global distribution of freshwater fish, climate-induced warming could necessitate range shifts and change the overall extent of species' distributions (Comte et al., 2013). The different critical thermal limits and thermal optima of freshwater fish could also lead to a competitive edge for warm-adapted species, which could alter fish species assemblages in river and lake ecosystems.

Freshwater heatwaves are projected to become an increasingly common, longer-lasting phenomenon over the coming century (Woolway et al., 2021). This will greatly increase the risk of fish die-offs and major fish kills (Till et al., 2019). If the water temperature exceeds the critical thermal maxima of fish in river or lake environments, physiological functioning ceases and mortality follows. While fish kills due to extreme heat events have always occurred, the increased risk associated with ongoing climate change is related to the frequency and intensity of such heat events. The specific thermal response of rivers and their fish populations to heatwaves strongly depends on factors such as altitude (e.g. rivers fed by snowmelt may show a damped thermal response (Piccolroaz et al., 2018)). Shading from catchment features and riparian cover may alleviate heatwave conditions (Garner et al., 2017). Physical factors that govern the severity of heatwave events in lakes and wetlands may include morphometry, as large shallow bodies with a high surface area to volume ratio are more exposed to direct atmospheric heating across their surface and have a reduced capacity to store cool subsurface water, leaving less suitable thermal habitat for fish to occupy.

Dissolved oxygen depletion

Along with direct thermal stress, one of the most important consequences of increased water temperature for fish is the effect on dissolved oxygen. The solubility of oxygen in water decreases with temperature. For most fish, dissolved oxygen is fundamental for controlling elements of behavior, growth and reproductive functioning (Claireaux and Chabot, 2016). A scenario combining lower dissolved oxygen and warmer water temperatures represents a dire combination for fish, as increased temperature elevates metabolic rate and oxygen consumption. This combination has the potential to severely reduce growth rate and reproductive potential. Alarmingly, evidence of a global decline in dissolved oxygen in freshwater ecosystems as a response to climate change is beginning to emerge (Jane et al., 2021). However, as the oxygen budget in lotic and lentic systems depends upon additional biogeochemical processes, land-use and catchment-scale factors play a key role in determining rates of aquatic oxygen consumption in freshwater environments (Jenny et al., 2016). In systems that receive large quantities of organic matter input, oxygen consumption through respiration is likely to be high, and when superimposed on lower dissolved oxygen solubility due to warming, there is a greater deoxygenation risk compared with systems that have a net positive production of oxygen. In addition, physical limnology plays an important role in determining the areal extent of deoxygenation (see Section "Lakes").

Climate change effects on specific freshwater fish habitat

Rivers and streams

In addition to the direct warming effects discussed above, climate-induced changes in precipitation and evaporation will also impact lotic environments by modifying hydrologic regimes. For riverine fish species, current velocity is a major environmental variable that exerts considerable influence over habitat selection and availability (Maddock, 1999). The energetic cost of holding in-stream position and swimming against currents can vary dramatically depending upon the velocity and resulting drag forces associated with river flow. River flow also mediates predator-prey interactions and food availability (Turschwell et al., 2019) and provides a supply of oxygen-rich water to developing embryos in spawning sites.

Decreased precipitation and increased evaporation associated with climate change could lead to decreased river water levels and reduced current velocities, also accentuated by other water user demands. Regions most acutely at risk include arid and tropical regions during the dry season, where increased drought intensity, frequency and duration during the 20th century has been attributed to anthropogenic climate change (Chiang et al., 2021). Many tropical river basins may experience significant habitat loss and fragmentation owing to reduced hydrological connectivity associated with low flows and water levels (e.g. Pettit et al., 2017). This will create a reduction in wetted area and a decrease in suitable fish habitat. Furthermore, drastically decreased flow velocities tend to create homogeneous river flows, as turbulent, heterogenous flow created by fast river flow interacting with instream bed features and channel morphology decreases. While the role of turbulence in riverine fish ecology is complex, turbulent patches, and hydraulic variability in general, benefit fish bioenergetics (Tullos and Walter, 2015). Shallow, turbulent riffle zones, an important source of invertebrate prey items, may undergo partial drying during prolonged periods of low flow. Lower water levels could lead to increased competition for pools, mainly during concurrent warming phases. If decreased flow occurs during spawning season, shallow gravel spawning sites may become partially or entirely desiccated.

In addition to periods of decreased river flow, episodic periods of increased rainfall intensity and duration may cause extreme flood events, with several geographic regions (e.g. southeast Asia) anticipated to experience larger peak flows (Dankers et al., 2014). Fast current velocities typically invoke a high energetic demand for riverine fish and this could particularly have an impact on overwintering juvenile fish attempting to minimize energy loss during a period of low food intake (Finstad et al., 2004). Higher flows in combination with warmer temperatures may invoke a high metabolic cost and result in decreased body condition and overall survival.

Another cause for concern in relation to hydrologic change and fish ecology is not necessarily change in mean annual discharge, but rather changes in how discharge is distributed over the course of the year (e.g. Bunn and Arthington, 2002). The freshwater fish

groups most likely to be affected by this are the *diadromous* and *potamodromous* species. Rivers provide the necessary migration routes for fluvial-adfluvial, fluvial-lacustrine and fluvial-marine migrations that characterize the life cycles of some of the most ecologically and economically important freshwater fish, including the salmonids, eels and sturgeons. However, migratory freshwater fish populations have declined by an estimated 76% on average since the 1970s (Deinet et al., 2020). Climate-induced alteration of flows has the potential to impede migration if adverse flow conditions coincide with migration timing. The phenology of migration is a complicated process depending upon remote-scale cues (e.g. conditions in marine feeding grounds and antecedent freshwater conditions during the growth phase) and local-scale cues (e.g. water temperature, timing of adequate water flow, daylight hours and lunar phase) (Carr-Harris et al., 2018). Widespread declines in diadromous Atlantic and Pacific salmon (*Salmo salar* and *Oncorhynchus* spp.) have coincided with the changing climate, and multiple climate change threats in conjunction with existing pressures have been identified in the marine and freshwater life stages of salmon (Thorstad et al., 2021). Changing hydrological regimes and increasing temperatures have led to concern that phenological mismatches may occur between migrating salmonid smolts and favorable survival conditions as fish move into the marine environment (Kennedy and Crozier, 2010). For example, the direct effects of climate and local-scale river conditions on salmonid migration timing were apparent during the 2020 smolt migration downstream from the Erriff river system, Ireland's National Salmonid Index Catchment (Fig. 1). Such adverse flow conditions during the annual migratory phase can decrease migration success and highlight the heightened sensitivity of diadromous fish to changing climatic conditions.

Lakes

The summer warming response of lakes to climate change has been well documented (e.g. O'Reilly et al., 2015). For lake and potamodromous fish ecology in temperate regions, a key period for feeding and growth occurs from spring through summer, when high primary productivity fuels the lake food web. Warming lake temperatures and changes in the stratification regime may negate some of the bioenergetic benefits of lake productivity (Fig. 2). Warm surface summer lake temperatures can restrict suitable fish thermal habitat. Like rivers, cool spots associated with groundwater seeps may become prime thermal refugia for fish, although groundwater levels may also decrease in some regions (Wu et al., 2020). For many cold-preferring fish, the deep, cooler hypolimnion can provide an escape from excessively warm surface water (Morrissey-McCaffrey et al., 2019). However, one effect of increased length and intensity of stratification is a depletion of hypolimnetic oxygen. The longer the stratification duration, the greater the severity of oxygen depletion and the stronger the stratification (i.e. the greater the temperature difference between surface and bottom waters) the more limited the rates of deep-water ventilation.

Nutrient enrichment can exacerbate the problem of deoxygenation as excessive primary production leads to heightened oxygen consumption (Müller et al., 2019). Lake fish could be faced with a contraction of habitat – warm unhabitable conditions at the surface and deoxygenated water near the bottom (Fig. 2). In addition, wind-driven upwelling of low oxygen deep water into shallower nearshore oxygenated areas may occur, which can effectively compress usable fish habitat even further (e.g. Kelly et al., 2018).

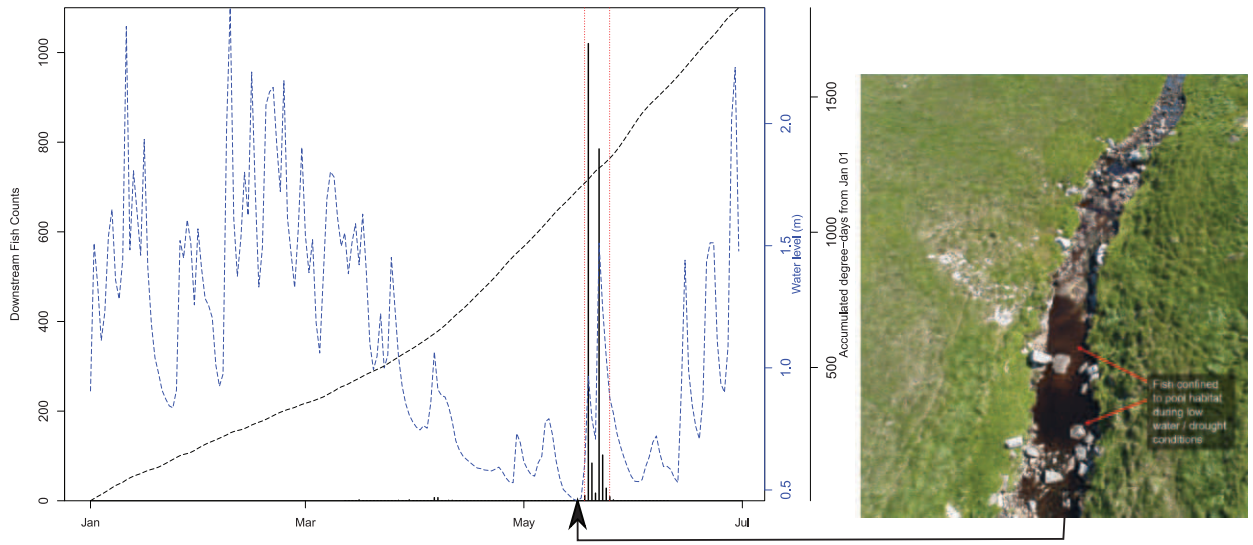

Fig. 1 (A) Timeseries showing the importance of climatic cues for the seaward migration of Sea trout (*Salmo trutta*) from the Erriff river (Ireland). Trout normally enter seawater during the spring period, with onset of migration mainly triggered by temperature accumulation (black dashed line) and photoperiod (daylength). However, a prolonged dry period without rainfall from April to May meant that extremely low river levels (blue dashed line) held up migrating smolts and 98% of the migration (black vertical bars) occurred within a narrow five-day window following rainfall. (B) Fish are confined to river pools during such low water conditions, which can increase predation risk and lead to a phenological mismatch between timing of outmigration from freshwater and optimal coastal conditions (Unpublished data, Inland Fisheries Ireland).

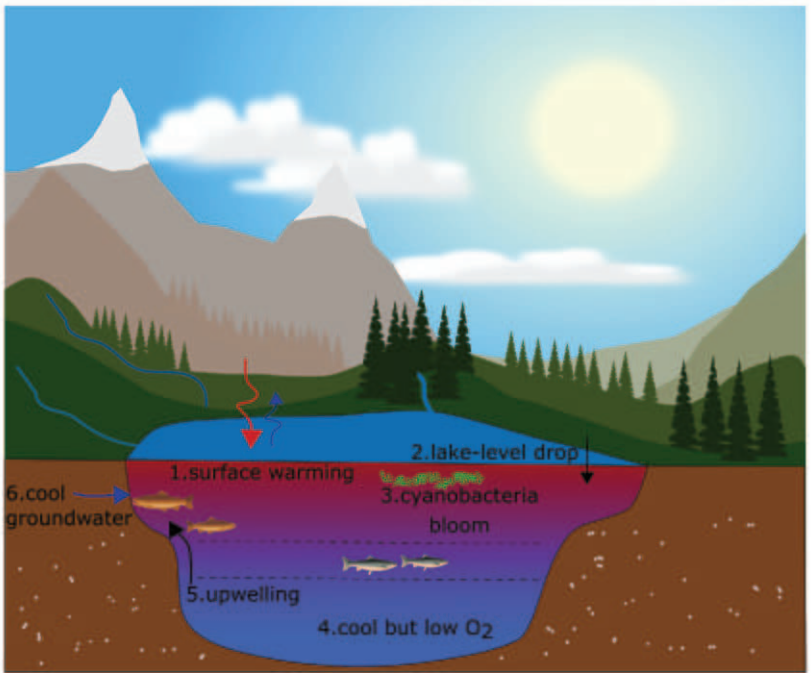

Fig. 2 Some examples of a typical lake response to summer climate warming relevant to fish ecology. 1. Excessive near-surface warming will avert many fish species away from this zone entirely; 2. Decreased river inflows, low rainfall and high evaporative cooling leads to reduced lake volume; 3. Warm conditions and stable thermal stratification during calm wind conditions, favors formation of cyanobacterial blooms; 4. Long periods of stable stratification prevent ventilation of lake bottom water – fish habitat contracts if cooler, deep water deoxygenates; 5. Upwelling events may pump deoxygenated deep water into shallower nearshore zones; 6. Sites of cool groundwater inflow become increasingly important as thermal refugia.

While the direct effects of climate change on tropical lakes and their fish populations is understudied compared to temperate lakes, climate-mediated changes in physical limnology and deep-water deoxygenation may be most severe in such ecosystems. In many large, deep tropical lakes, intensified surface warming experienced at low latitudes reduces the extent of vertical mixing not just during a seasonal stratified period but often year-round. This can result in decreased algal productivity in the nutrient-depleted sunlit surface zone (Verburg and Hecky, 2009) and a contraction in oxygenated benthic habitat in nearshore zones (Cohen et al., 2016), both of which have the capacity to negatively impact fishery productivity.

Prolonged periods of warm, stratified lake conditions are also conducive to the formation of algal blooms. When wind forcing is also weak, suppressed water column turbulence and upwelling of nutrient-rich hypolimnetic water favors cyanobacterial blooms owing to their competitive advantage in these conditions (O'Neil et al., 2012). However, cyanobacteria-dominant phytoplankton blooms can be unfavorable for fish as they provide a poor food source for most zooplankton grazers and may also lead to the accumulation of toxins in fish tissues (Flores et al., 2018).

For lake-spawning fish, the role of water temperature, water level, oxygen concentration and current speeds at spawning sites are all important components of spawning success. Warmer temperatures at lake spawning sites are projected for many lakes (Kelly et al., 2020), which are likely to impede subsequent embryo survival and fry condition (Farmer et al., 2015). Furthermore, warmer temperatures and siltation related to phosphorus loading can have a compounding effect, significantly reducing rates of embryonic survival (Mari et al., 2021). Wind-swept shoreline habitats are critical for lake spawning success as they provide a flow of oxygen-rich water and may disturb predators on fish eggs; in contrast, excessive current speeds may cause a loss of eggs and wash-out of spawning sites entirely (Callaghan et al., 2016). Climate-mediated changes in wind speed could affect current dynamics in some lakes, although the precise mechanisms are complex and depend upon lake characteristics (fetch and shoreline sheltering). Increased frequency of winter-time storm events related to climate change may negatively impact lake spawning sites for example.

Reductions in the thickness and extent of lake ice, and timing of ice onset and break-up, are pertinent signals of climate warming in boreal and polar lakes (Sharma et al., 2019). Potential effects on fish ecology include reduced anadromy rates (with a longer ice-free season potentially encouraging freshwater residency (Reist et al., 2006)) and a shorter winter torpor phase (Curry et al., 2005). The effects of winter warming for fish in high latitude lakes are complex, as overwintering fish are faced with low winter productivity and food abundance, minimal under-ice light conditions and very cold temperatures, which often results in high winter mortality and overall poor body condition (Amundsen and Knudsen, 2009). Thus, an increase in temperature, and a decrease in ice cover duration and thickness, may aid fish survival initially. However, longer-term adverse impacts may be that these lakes eventually become hospitable to non-cold stenothermic fish species (e.g. Hein et al., 2012). This could mean that extreme cold-adapted species such as Arctic Charr, that previously persisted in isolation in the northernmost lakes on Earth, could face competition from existing competitors or new interloping species such as pike or trout (e.g. Svenning et al., 2021), should corridors to range expansion become available (Connor et al., 2019).

Wetlands and floodplains

In many regions, wetland and floodplain ecosystems provide valuable natural fish habitat, yet are highly vulnerable to changes in rainfall patterns and increasing temperatures. Yet, relative to rivers and lakes in ***temperate*** regions, monitoring of thermal and hydrological dynamics, and especially long-term temperature timeseries, are lacking for floodplain ecosystems (Hamilton, 2010).

Sufficient water depth is necessary to sustain wetland fisheries, which support a critical and highly productive component of natural fishery resources in regions such as southern Asia (e.g. Sarkar et al., 2020), south-eastern United States (e.g. Hupp, 2000), central and southern Africa (e.g. Mosepele et al., 2009) and South America (Junk et al., 2011). High water during the wet season creates vast river floodplains and leaves behind floodplain lakes during subsequent lower water stages, which provide critical nursery habitat for juvenile fish. Owing to their intrinsic seasonal fluctuations in water level, many floodplain ecosystems depend upon low and predictable inter-annual variation in seasonal water cycles. Thus, a future climate scenario with a reduction in rainfall and high evaporation due to warmer, drier atmospheric conditions could reduce the extent and connectivity of floodplain lakes and lead to a decline in fish species abundance. An increase in the length of the dry season may be further exacerbated by a decrease in the amount of rainfall during the wet season. An extreme drought in the Brazilian Amazon in 2005 led to isolation of floodplain lakes and large reductions in wetted area, causing mass fish kills and a reduction in the abundance of economically valuable species (Freitas et al., 2013).

In addition, river floodplain waters typically experience the highest temperatures in tropical freshwater systems (Hamilton, 2010). This is related to their shallow, slow-flowing nature and occurrence at low elevations, exposing them to intense daytime atmospheric heating. Water temperatures may remain elevated above 30 °C year-round in tropical floodplain lakes (e.g. de Melo and Huszar, 2000). A decrease in water level due to drier, warmer atmospheric conditions could escalate daytime water heating for resident fish, as shallower floodplains concentrate heat accumulation from direct solar radiation over a smaller volume of water. An additional concern in many tropical basins and their floodplain ecosystems relates to large-scale changes in terrestrial vegetation associated with climate-induced changes in hydroclimate and the severity and intensity of wildfires (e.g. Flores and Holmgren, 2021). This could have profound effects on hydrological and thermal regimes in floodplains, given the role of floodplain forests in regional precipitation dynamics and their provision of canopy cover from direct solar heating.

Vulnerability and resilience of freshwater fish and inland fisheries to climate change

Vulnerability and resilience of freshwater fish to climate change

The impacts of climate change will not affect all freshwater fish equally – some species will experience more severe impacts and some species will be more resilient to changes compared with others. This will depend ultimately upon the severity of climatic changes that occur within the geographical range of individual species, as well as their phenotypic and genetic response to rapidly changing environmental conditions. Consider the foremost example of climate-induced changes relevant to freshwater fish discussed thus far - increased water temperatures. Each freshwater fish species has evolved a physiological capacity to acclimatize to a specific range of water temperatures, that typically correspond with their contemporary thermal habitat. The upper limit of species' thermal tolerance range and the 'adaptive capacity' of their response to warming environmental temperatures differs between species. These are largely constrained by evolutionary conservatism of ancestral traits as well as the degree to which environmental conditions fluctuate across their current geographic range.

Owing to the naturally fragmented landscape of freshwater ecosystems and the abundance of unnatural barriers and waterway modification, behavioral adaptation to changing environmental conditions may be difficult, as dispersal and range shift opportunities are often severely limited (Woodward et al., 2010). Some behavioral adaptations that may alleviate direct effects of warming include migrating to cooler waters, groundwater-fed streams or deep, stratified lentic waters. Diadromous species may be able to move along coastlines and colonize watersheds characterized by cooler thermal regimes. Landscape features unique to each watershed, such as large amounts of riparian and topographical shading of direct sunlight or a large proportion of wetlands and lakes can increase the availability of thermal refugia. In this regard, euryhaline migratory fish that display straying behavior in their selection of spawning rivers rather than homing to their natal stream of origin may have greater innate behavioral flexibility for adapting to climate change. Phenological adaptation, such as modifying timing of key life-history events such as spawning or migration, may be an especially important resiliency strategy in freshwater fish. Climate change may alter seasonal timing and dynamics (e.g. later onset of cold-season, early onset of warm-season) and in many fish such as salmonids, phenological traits have a high degree of heritability, implying that they may be a likely source of evolutionary adaptation to changing environmental cues (Manhard et al., 2017). Both Atlantic (Kennedy and Crozier, 2010) and Pacific (Kovach et al., 2015) salmonid populations have shown indication of earlier seaward migration timing, consistent with springtime warming trends.

Perhaps most vulnerable to the direct effects of warming are obligate freshwater resident fishes, especially populations that reside permanently within a single lake and have little or no potential to colonize other lentic or lotic ecosystems. Tragically, many such vulnerable 'land-locked' species are often endemic, such as the cichlid species of the African Great Lakes (Nyboer et al., 2019). The loss of such endemic species would represent a substantial loss of total global freshwater fish biodiversity. For riverine fish, moving upstream to higher altitude, cooler streams is one viable behavioral modification although dams and other barriers to dispersal may severely limit such range shifts (Woodward et al., 2010). Thus, physiological adaptation to warmer temperatures is a critical consideration when assessing the capacity of fish species to adapt to climate warming.

How well individual fish species can adapt physiologically to increasingly warmer temperatures will depend upon their thermal tolerance range, capacity to acclimatize and how close they currently live to their critical thermal maximum. For example, tropical fish inhabiting lakes and rivers at low, warm latitudes are typically more heat-tolerant and have higher critical thermal maxima compared with fish species at colder latitudes. In contrast, fish at temperate and polar latitudes experience a larger thermal range, with greater seasonal variation and, although not as heat tolerant as tropical fish, very often the warmest annual water temperatures they experience are much higher than their upper thermal limits. As tropical freshwater fish species are generally closer to their critical thermal maxima under contemporary climatic conditions (Comte and Olden, 2017), they may have reduced physiological scope for continually buffering against ongoing temperature increases, leaving little opportunity to adapt. Thus, despite the magnitude of climate-induced warming being greater toward the poles (Stuecker et al., 2018), and tropical fish having a higher warm tolerance compared with high latitude fish, populations near the tropics may be more acutely vulnerable to climate warming. The same dynamic can also be illustrated within a single species complex (Fig. 3). Peripheral populations near the latitudinal limit of a species natural geographic distribution routinely survive in, and have adapted to, warmer temperatures compared with other populations of the same species. Nevertheless, they may also be the most vulnerable to climate change, given that they are already close to their upper physiological thermal limit. This is likely, given that upper thermal limits among populations of the same

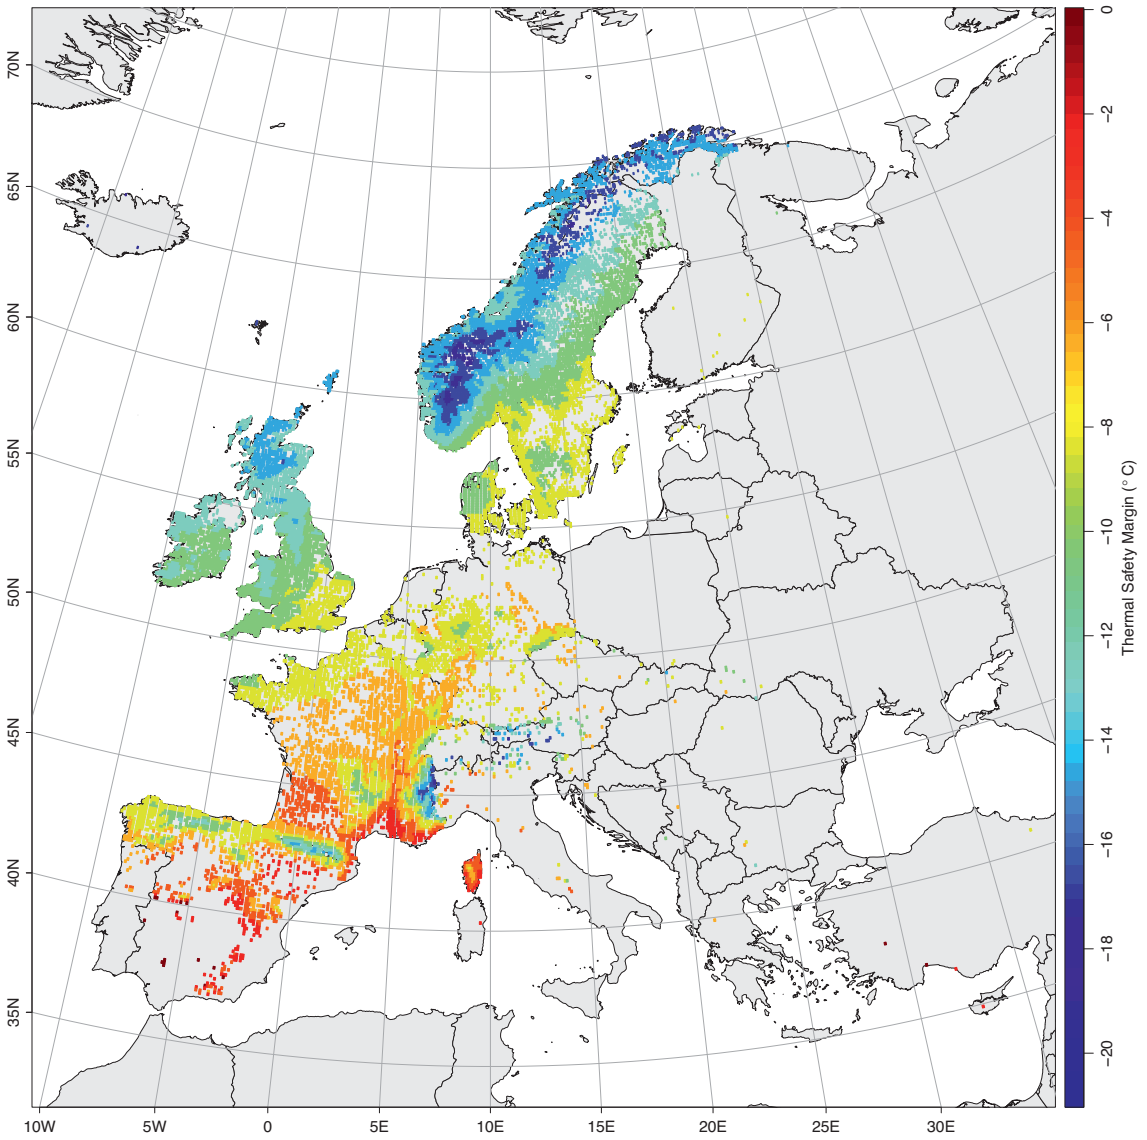

Fig. 3 Vulnerability to warming among Brown trout (*Salmo trutta*) populations across its native European range. Thermal safety margin represents the difference between mean July stream temperature for the 30-year climate period 1991–2020 and the critical thermal maximum of trout (estimated as 28 °C, Elliott and Elliott, 2010). Southern peripheral populations in low-elevation regions seemingly have minimal buffering capacity to tolerate continued warming (Unpublished data, Inland Fisheries Ireland). Species occurrences, which are incomplete, were obtained from www.gbif.org and matched with temperature data from the ERA5-Land reanalysis product (Muñoz-Sabater et al., 2021). Surface temperatures were converted to stream temperature in each 0.1° grid cell following (Punzet et al., 2012).

species, and between closely related species, seem to be a highly conserved trait compared with lower thermal limits (Bennett et al., 2021). A similar, comparatively understudied, set of evolutionary and environmental determinants are also likely to dictate how resilient specific fish species and sub-populations are to other climate-induced impacts, such as flow regime and dissolved oxygen concentrations, making climate-induced extinctions, range shifts and future distributions of freshwater fish especially difficult to predict.

Vulnerability and resilience of inland fisheries to climate change

Given profound effects on freshwater fish species and their habitats, climate change will likely have outcomes for inland fisheries on every continent, particularly those that are already heavily impacted by non-climatic pressures. Many inland fisheries throughout the world provide a range of important ecosystem services to human populations including food and livelihoods. In many such populations, inland fisheries provide the primary or secondary source of income and fish provides critical nutritional security (e.g. African Great Lakes, Lower Mekong Basin, Peruvian, Brazilian Amazon) (FAO, 2020). In 2018 it was estimated that the world's inland fisheries had an estimated value of $26 billion (USD), but the value could be as high as $35 billion (USD) (Funge-Smith, 2018; FAO, 2020). Their significance varies worldwide and is highest in Asia (66%) and Africa (25%). In contrast, the value of recreational fisheries worldwide is higher and has been estimated to be more than $64 billion (USD) (Funge-Smith, 2018).

Inland fisheries most at risk occur in areas that experience water stress and competition for water resources (Seggel and De Young, 2016). Several regions and countries that are highly dependent on inland fisheries including central and western Africa, north-western South America and tropical Asia have been identified as most vulnerable to potential climate change impacts (Allison et al., 2009). Fisheries that already experience severe threats from anthropogenic and natural environmental pressures from agriculture (e.g. irrigation), urbanization, industry and damming are likely to be most affected.

It is crucial to identify those at risk and to prioritize conservation measures and maximize resilience of threatened fisheries sectors. Through altered growth rates and inter-species competition, climate change could cause an increase or decrease in productivity and in biodiversity, which will affect harvests in a fishery or region (Harrod, 2015). Fishers may gain access to new fisheries or lose access to traditional ones, efficiency of fishing gear may change and become ineffective, and additional pressures from contaminants or parasites may mean that fish are unsuitable for sale. Fishers living in or close to poverty are likely to be particularly vulnerable because they may be unable to adapt to the changes caused by climate change. Additionally, extreme weather events such as storms and floods may damage gear, risk lives, and restrict fishery operations.

It is estimated that 20% of recreationally-targeted fish species (including diadromous fishes) are vulnerable to climate change, with a higher proportion of recreationally targeted freshwater species at risk from climate change compared with marine species (Nyboer et al., 2021). Furthermore, 72% of freshwater fishes and 33% of diadromous fishes have no conservation measures in place, despite their high vulnerability and cultural value. Clearly, a multi-faceted approach toward managing recreational inland fisheries in the context of climate change is required that links together climate impacts, vulnerable species and angling behavior toward targeted or prized recreational species.

Interaction between climate change and additional environmental stressors

The threat of climate change for freshwater fish is magnified given the array of pre-existing and emerging environmental stressors. Of particular concern is the potential for direct climate change effects to interact with additional anthropogenic stressors faced by species and populations (Staudt et al., 2013). This phenomenon is difficult to identify and predict for freshwater fisheries. As outlined so far in this chapter, multiple pathways exist for climate change to impact fish and their habitats, and inland waterways are generally rife with additional environmental stressors for fish including habitat modification and fragmentation, pollution and non-native species introductions. Much of the challenge associated with understanding these interactions relates to the dimensionality - a single climate impact may interact with one or many additional climatic or environmental stressors simultaneously. Multiple stressors may co-occur and have an additive effect, or they may act synergistically whereby the combined effects have a compounding impact. Future climate change may invoke increasing demands on water resources, or alter land-use practices that further intensify direct climate impacts on fish habitat (e.g. increased water abstractions during drought).

An integral aspect of assessing climatic vulnerability of specific fish populations is identifying concurrent stressors that decrease resiliency to climatic changes. Given the site-specific nature of non-climatic pressures and interaction with climate change, Fig. 4 conceptualizes some examples of a direct climate change effect on freshwater fish habitat with associated impacts and potential adaptations, while highlighting potential interaction pathways with additional anthropogenic factors that may exacerbate the situation for freshwater fish populations.

Adaptation and mitigation

Understanding the factors through which climate change can affect freshwater fish species and subpopulations, and the fisheries they support, will aid enormously with adaptation and mitigation strategies aimed at increasing the resiliency of climatically vulnerable fish populations. While the most ambitious mitigation strategy is to reduce greenhouse gas emissions sufficiently on a global scale, local strategies to decrease climate vulnerability of freshwater fish populations and inland fisheries can represent a pragmatic approach.

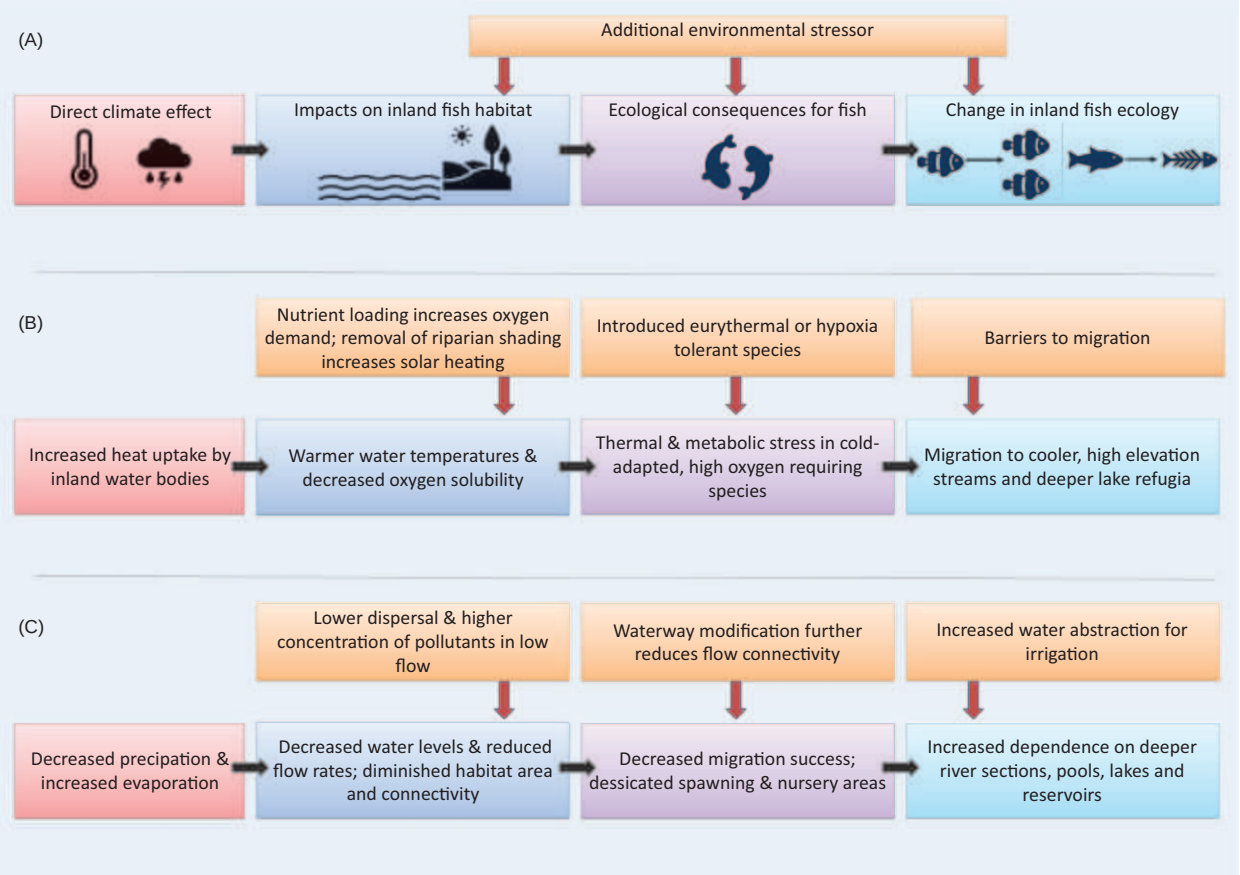

Fig. 4 (A) Conceptualization of the pathways through which a direct climate effect and additional anthropogenic or environmental stressors may impact freshwater fish. Additional stressors may have an interactive effect with a climate stressor by simultaneously impacting fish habitat, intensifying ecological consequences of climate-induced habitat changes or compromising the capacity of affected species to overcome the climate impact. A single climate change effect may also interact with other climate change effects and the interaction between a climate effect and an additional environmental stressor can work both ways (i.e. the climate change impact can intensify a pre-existing environmental stressor). Example of this simplified multi-pressure conceptualization for (B) water temperature increases and (C) decreased precipitation and increased evaporation rates associated with climate change.

Fish species and their habitats

Management and mitigation measures need to follow an ecosystem-based approach toward conserving overall biodiversity and should not focus solely on fish species of interest (capture fisheries). Potential approaches include:

- Mitigation strategies to decrease thermal vulnerability include: ensuring riparian cover is maintained or increased along sun-exposed shallow streams; improving both longitudinal and lateral river connectivity; restoring pools which act as a thermal refuge for fish species in modified channels; and tighter regulation surrounding introductions of non-native species adapted to warmer temperatures in sensitive regions.
- Mitigation strategies to protect against climate-induced flow alterations (droughts and floods) include minimizing extensive channel modification that directly intensifies flow-related stress and ensuring suitable flow regimes resilient to climate impacts are reconstructed in heavily modified rivers.
- To alleviate climate-induced deoxygenation it is imperative that good water quality is maintained, and poor water quality improved, in sensitive habitats and during warm spells with low water conditions.
- Identifying populations (e.g. peripheral; isolated), species (e.g. cold-water-adapted; migratory), regions (e.g. with severe warming projections) and local habitats (e.g. shallow lakes; low-lying unshaded streams) that are most vulnerable to warmer water temperatures could facilitate a focusing of fishery management practices.

Inland fisheries ecosystem services

Vulnerability of inland fisheries to climate change can be reduced through adaptive strategies that allow for management of unexpected results and to exploit any positive opportunities that may arise. It is important that governments worldwide understand the anticipated risks of climate change for inland fisheries and attempt to identify vulnerable systems through:

- Incorporating adaptive strategies for the inland fisheries sector into climate adaptation policies to ensure sustainability.
- Fish biologists, fishery managers and fishery scientists need to consider climate change in their activities, policies and future management. For example, a review of ethics of angling practices during warm periods or the closing of heavily impacted fisheries to conserve stocks may be required for many recreational fisheries.
- Measures could include diversification of livelihoods for the most vulnerable fisheries and fishers, management of stocks in response to projected climate change impacts and catch declines, advances in technology and planning for vulnerable areas.

Such mitigation strategies must be supported by evidence-based research to maximize their efficacy. There is a need for investment in science education strategies for fishers, fishery managers and the public encompassing climate-related impacts.

Conclusion and knowledge gaps

Given the multiple climate effects, interaction pathways with additional stressors and nuanced response of freshwater fish populations and inland fisheries to combined climatic and environmental changes, there are considerable requirements for further research to address critical questions. The future status of freshwater fish will largely depend upon how climatic, environmental, biological and socio-economic factors integrate. Some prospective avenues for further research include:

- Assessing the linkage between past climate dynamics and historical changes in freshwater fish abundance and distributions, which if understood will provide insight into how future fish populations will respond to specific climate projections.
- Disentangling the compounding effects of direct climate change and additional anthropogenic stressors such as introduced non-native species, water quality decline and habitat modification and fragmentation. There is a need to understand explicitly how multiple stressors interact and which specific combinations generate additive impacts or compounding impacts.
- Identifying proposed or conceivable alterations to land-use and water resource management related to climate adaptation strategies that could jeopardize freshwater fish populations.
- Understanding the resilience of different fish species and populations to changing climatic and hydrologic conditions. This would facilitate identification of the most acutely vulnerable populations.
- Informed by each of the prior suggestions, use of coupled climate-fish habitat models, that consider biological and ecological dynamics as well as inland fishery management practices where necessary. Applications could allow for robust predictions on the future status of freshwater fish abundance and distribution and allow adoption of guided management strategies.

This article has outlined some of the general pathways through which climate change can affect riverine and lake fish, and consequently global inland fisheries. Climate change consequences will be unique to individual species and their subpopulations and specific to their local environment. The immense ecological, economical and societal value of freshwater fish and inland fisheries demands that monitoring and research programs dedicated to sensing their vulnerability to climatic and environmental change are implemented and continued. By neglecting this component of freshwater fish conservation, we invite irreversible biodiversity loss and the continued decline of one the world's most imperiled vertebrate groups.

Glossary

Algal bloom The rapid and excessive growth of microscopic, unicellular algae that produce toxins; often as a consequence of eutrophication (the excessive richness of nutrients in a body of water, often as a result of run-off).
Anerobic Without air.
Bioaccumulate To collect or become concentrated in the tissues of organisms.
Evidence-based limits Restrictions or maximum quantities of a given resource (e.g. fish) based on some scientific evidence or knowledge to verify the reasonableness of the limit.
Harvest regulations A series of instructions or restrictions associated with the amount of fish that can be removed; often linked to specific time periods and associated with permits or quota.
Licensing schemes A fishery system regulated by the use of a permit or license for a vessel, gear or fishing activity to allow its use. Often associated with a particular timeframe, season or location.
Precautionary principal In the absence of sufficient information to make an evidence-based informed decision the least consequential action should be followed to reduce harms (for example, to the environment or organisms) but the lack of information should not lead to inaction.
Psychosocial balance Maintaining an equilibrium between mental health and social interaction.
Quota-based management Management linked to setting limits of fish catch and allocating them among individuals or groups who are given or can purchase a portion of the total available catch.
Resource stewards Individuals who often voluntarily advocate for particular resources (e.g., fish), ensuring their sustainability.
Rights-based approaches Based on the principle that everyone has the right to participate in decisions, these approaches focus on trying to establish an equity among the holders of rights to the resource.
Sediment transport Movement of particles (including sand and silt) in the water flow that helps distribute nutrients through the aquatic ecosystem.
Smelt Small silvery food fish, usually consumed whole or with the head removed.
Sustainability/sustainable fishery The ability of a system or fishery to have a certain quantity of individuals withdrawn while retaining the capacity of the remaining individuals to reproduce and replenish stocks (fish numbers).

Introduction

The importance of inland fisheries for food security and livelihoods is often overlooked because of the higher profile of marine fisheries (Funge-Smith and Bennett, 2019). While the contribution of inland fisheries to global commercial fish production may be overshadowed by marine outputs, inland fish play an important role in sustaining local and small-scale operations, providing valuable recreational opportunities, and contributing to global biodiversity (Lynch et al., 2017). Importantly, inland fish support the food security and livelihoods of some of the most vulnerable communities (Cooke et al., 2016). Freshwaters form a network of connected ecosystems that weave their way among terrestrial landscapes from icy mountain streams, through vast turbulent rivers to seasonally flooded wetlands and brackish estuaries. Inland aquatic environments are also extremely diverse, ranging from tiny streams, brooks, ponds, reservoirs, and canals to large lakes, floodplains, wetlands, inland seas, and vast rivers. They even include the mosaic habitats found in estuaries and rice fields, with fish thriving in almost all of these environments (Moyle and Leidy, 1992). Their accessibility and connectivity, however, make them vulnerable to diverse threats from pollution to infrastructure development; the impacts of which can often be detected many miles downstream (Reid et al., 2019). Despite their importance for nature and humans, rapid development continues to threaten freshwater ecosystems and the fisheries resources that rely on them (Youn et al., 2014).

This chapter covers important but often overlooked aspects of inland aquatic ecosystems and highlights their major contributions to livelihoods and food security. It comprises five case studies:

Case Study 1: Inland Recreational Fisheries
Case Study 2: Rights in Inland Fisheries
Case Study 3: Threats to Inland Capture Fisheries: Hydropower, Mining, Agriculture, and Aquaculture
Case Study 4: Welfare Considerations of Aquaculture and Fisheries
Case Study 5: Freshwater Elasmobranchs.

Case study 1: Inland recreational fisheries

From flyfishing for rainbow trout in the headwater streams of the Pacific northwest, to ice fishing for smelt in lakes on the Korean Peninsula, to catching tigerfish in the Zambezi River of south-central Africa, inland recreational fisheries span the globe and represent diverse intersections between humans and freshwater ecosystems (Cooke et al., 2016; Funge-Smith and Bennett, 2019). Recreational fishing is defined by the Food and Agriculture Organization (FAO) of the United Nations (UN) as the "fishing of aquatic animals (mainly fish) that doesn't constitute the individual's primary resource to meet basic nutrition needs and are not generally sold or otherwise traded on export, domestic or black markets." (FAO, 2012). Recreational fishers mostly use rod and reel (i.e., angling), although other gear such as nets are also commonly used in some regions (Arlinghaus et al., 2007; Arlinghaus and Cooke, 2009). While recreational fishing can certainly be consumptive, catch and release is common, with release rates exceeding 95% for some species (Fayram, 2003). The reasons people engage in recreational fishing is as diverse as the fish targeted, and spans beyond the desire to catch and/or harvest fish (Fedler and Ditton, 1994). Many people derive satisfaction from spending time in nature, and/or fishing with friends and family, and therefore benefit from increases in wellbeing because of recreational fishing (Hunt and McManus, 2016; Wheeler et al., 2020).

Recreational inland fisheries are most common in developed countries where there is disposable income, which can be devoted to leisure and fishing for fun (Arlinghaus et al., 2021). Yet, there is also evidence that at some point during the development cycle, interest in recreational fishing declines as recreational fishing is supplanted by conservation values (Arlinghaus et al., 2021). It is estimated that, on average, around 10% of the human population engages in recreational fishing, although participation rates are highly variable around the world (Arlinghaus et al., 2015). Inland recreational fisheries generate a variety of benefits, including economic returns from fees for example, in the tens of billions of USD (Lynch et al., 2016), psychosocial balance (Hunt and McManus, 2016; Wheeler et al., 2020), and nutritional security (Cooke et al., 2018). In most developed countries, recreational fishing is intensively managed through harvest regulations and licensing schemes (Arlinghaus and Cooke, 2009). By contrast, recreational fisheries in developing countries frequently have no active monitoring or management and are often ignored and undervalued (Bower et al., 2020). Recreational anglers can be important resource stewards. Not only do many anglers offset their environmental impacts through conservation-minded actions on the water, but many also actively engage in directly managing, and protecting water resources and aquatic environments, or they contribute their voice to advocacy for aquatic species or habitats at risk (Granek et al., 2008).

While recreational fisheries are of socio-economic importance and can foster conservation-minded actions directed at aquatic ecosystems, recreational fishing can also have negative impacts on the sustainability of resources and the environment. Recreational fishing has been implicated in the collapse of some inland fish populations in Canada (Post et al., 2002) for several reasons. For one, overfishing can occur if systems are not adequately monitored. Even when release rates are high, fishing mortality can occur in the form of release mortality (Bartholomew and Bohnsack, 2005). Secondly, many non-native fish have been introduced by recreational fishers or managers to enhance fishing opportunities with negative consequences for native biodiversity (Gozlan et al., 2010; Mickle and Higgs, 2018). In addition, recreational fisheries can lead to other undesirable consequences, such as disturbances from boat noise (Whitfield and Becker, 2014), trampling of habitats while wading (O'Toole et al., 2009), and the entanglement or hooking of non-target species (e.g. birds and turtles; Lloret et al., 2020). Fortunately, most of these issues can be addressed through regulation and encouragement of responsible fishing behavior (Cooke et al., 2019). Moving forward, there is much potential for recreational fisheries to be conducted in a responsible and sustainable manner that connects people to freshwater ecosystems. Climate change will require the sector to adapt, as fish, freshwater ecosystems, and anglers experience additional external pressures (Holder et al., 2020). Nonetheless, there is evidence that inland recreational fisheries can be resilient or adapt if managers and fishers are proactive (Jeanson et al., 2021). For example, simple changes in angler behavior (e.g., following best practices for handling and releasing fish) will reduce the negative impacts of climate change on fishing mortality. Recreational fisheries create opportunities for interactions with freshwater organisms, increasing awareness of the value of freshwater ecosystems, enhancing respect for the environment and encouraging people to be more active advocates for, and stewards of, freshwater ecosystems.

Case study 2: Rights in inland fisheries

Recognizing the need to secure equality in access and withdrawal rights for fishers has lagged well behind securing rights and tenure on land (Ruddle et al., 1992). Capture fisheries have historically been an open-access resource throughout the world (Arthur, 2020). The ease of access and challenges for control and regulation have meant, that in large areas of the globe, open-access rights to fishing have prevailed, despite recognition of their issues. This has resulted in several problems, including fishing industry over-capacity, challenges in monitoring and control of exploitation, negative environmental impacts, inequities in access to resources, and insecure tenure rights. In some regions, licenses for commercial operations have been granted to improve control over the fishery and harvest, but has generally exacerbated over-fishing, inequality, conflict, and food insecurity (Arthur, 2020).

Determining how to define access rights that are equitable is not an easy challenge to resolve. Further, the ecological implications of establishing property rights have historically not always been positive (Brubaker, 1997). Increasingly, rights-based approaches have been explored to reduce food insecurity and reduce stakeholder conflicts.

Some guidelines to help improve equity in fishery rights have been outlined by the FAO (e.g. Small-Scale Fisheries Guidelines (FAO, 2015) or the Rome declaration (FAO and MSU, 2016)), but challenges remain for the best ways to implement them in diverse global fisheries, which are already showing signs of over-exploitation. Adopting rights-based approaches has been suggested by FAO and others, to be an equitable solution for meeting combined objectives for conservation, food security and livelihoods (FAO, 2015; Allison et al., 2012; Willmann et al., 2017a,b). Rights-based approaches have been adopted in many countries in an effort to

increase equity, however, enforcement and implementation are often lacking, limiting the opportunities for the benefits of rights-based approaches to be realized (Willmann et al., 2017a,b).

The conditions for access and removal of fish need to be clearly defined, evidence-based limits need to be set, and fishers need to agree and commit to access agreements. While rights-based approaches can help to allocate resources more fairly, the existence of multiple fishing rights holders in a single waterbody (in contrast to ownership by the State) and high mobility of fish resources, complicate the situation. Such circumstances disincentivize investment in management of resources because investment by one rights-holder is just as likely to support the harvest of another rights-holder. The use of quota-based management and resource sharing can help to distribute access and withdrawal rights equitably (Bellanger et al., 2019; Bradley et al., 2019). For example, the Japanese catch-share system has a long history of equitable catch-sharing success (McIlwain, 2013). However, careful management of quotas and restriction of quota transfers, are needed to prevent aggregation of quotas by large industry resulting in the exclusion of smaller operators (Delaney, 2015).

By ensuring access and rights to withdraw, manage and protect fisheries, people in communities reliant on fisheries can retain greater ownership and responsibility for the fishery. As a result, they can implement approaches that help them to respond to sustainability needs, increasing fishing pressure, development, and climate change. Co-operative management and regimes that build trust among collectives have the potential to improve equity in fishery rights. However, caution must be taken to avoid pitfalls experienced when cooperatives become too big and commercial operations start to dominate, reducing equity for smaller operators.

Case study 3: Threats to capture fisheries

Many of the exploited populations of inland fisheries can be found in floodplains and seasonal waterbodies. The geographic conditions associated with inland capture fisheries, subject them to a variety of threats, including hydropower development and agriculture, mining and aquaculture. The inherent restrictions of freshwater ecosystems, i.e., being constrained by land, being widely distributed, having a relatively small volume of water that is subject to climatic conditions (e.g., flood and drought), and being forced to follow a path through human-dominated landscapes, make inland aquatic organisms extremely vulnerable to habitat changes (Compagno and Cook, 1995). Inland capture fisheries provide important contributions to food and nutrition security, especially in developing regions, where there are often few livelihood alternatives. The following examples describe a cross-section of industrial developments that are increasingly threatening the viability of inland capture fisheries and the communities that rely upon them for nutrition and food security, and commercial and livelihood opportunities.

Example 1: Hydropower development

The impact of hydropower development on fish has garnered a lot of recent attention, especially regarding large and highly migratory species found in the Amazon, Columbia, Congo, Nile, and Mekong rivers (Winemiller et al., 2016; Jager et al., 2001). Hydropower dams block fish movement, change hydrology and water flows, disrupt seasonal patterns on which fish rely for behavioral cues, and block the movement of sediments, thus preventing the distribution of nutrients (Clarke et al., 2008). These impacts are being felt to a greater or lesser degree in watersheds the world over (Wu et al., 2019). In developed regions, many dams are being removed and waterways are being opened up (Ding et al., 2019), with both positive and negative impacts on the ecosystem and fish (Bednarek, 2001). In developing nations, sustainable development makes hydropower (a renewable energy source) a very attractive option (Fearnside, 2014). Recent attention to the problem of dams for fish has seen the development of tools and approaches to help mitigate impacts, including moving dams into less vulnerable locations (Opperman et al., 2019), managing flows for fish (Sabo et al., 2017), helping fish circumnavigate dams through alternative tributaries (Schmitt et al., 2019), or developing fish passages (Schilt, 2007).

Example 2: Mining and mercury

Mercury contamination is one of the main reasons that caution is advised for consumption of large quantities of fish. Mercury 'bioaccumulates' in the tissues of fish (Johnsson et al., 2005), and when the fish are eaten can rapidly lead to mercury poisoning (Ha et al., 2017). The mining industry, especially artisanal miners, use mercury in the extraction process, leading to the leaching of mercury into the environment (Veiga et al., 2006). Mercury is also a bi-product of coal-fired power generation (Kuiken and Stadler, 2003). Aside from the human health impacts, mercury poisoning also leads to neurological conditions (Morcillo et al., 2017) and reproductive problems in fish (Scheuhammer et al., 2015; Crump and Trudeau, 2009). Increased awareness of the impacts and research investigations have led to the use of mercury alternatives in industry, improved waste treatment, the development of guidelines and regulation for reducing leeching into the environment, and recommendations for consumers to reduce their intake of some high-risk species (EPA-FDA, 2021). Mercury in fish tissues and waterways is still problematic (Kolipinski et al., 2020; Evers and Sunderland, 2019; Wang et al., 2004) and further investigations are required to determine effective ways to reduce or remove mercury from fish tissues and waterbodies (Jezierska and Witeska, 2006; Cuvin-Aralar and Furness, 1991).

Example 3: Agriculture

The impacts of agriculture on fisheries are often considered to be quite localized but agriculture can have extreme and far-reaching consequences (Blann et al., 2009). The modified landscape leads to changes in drainage and hydrologic dynamics, transforming the structure and function of stream and wetland ecosystems and impeding connectivity, limiting access to key habitats, disrupting nutrient cycling, and interfering with sediment transport (Carpenter et al., 2011). The consequent changes to nutrient transport, and quantity and configuration of waterflows, can both directly and indirectly affect fish and their behavior (Bunn and Arthington, 2002).

The impacts of agricultural development in flood plains and wetlands can also reach far beyond the floodplains and inland waters. Pesticides and fertilizers, used to enhance crops both in the floodplain and in the watershed beyond, are often directly toxic for fish (Klemick and Lichtenberg, 2008). Chemicals, such as phosphorus found in runoff from agriculture, can also indirectly impact fish by transforming the nutrient and trophic dynamics of the aquatic ecosystem. The increased availability of phosphorus can lead to over-production of aquatic microorganisms, such as cyanobacterial algae. The increased production of algae (or algal bloom) reduces the availability of oxygen in the water below concentrations tolerated by fish. Some cyanobacteria algae also release toxins into the water that have a poisonous effect on fish. Sudden low oxygen levels combined with high levels of toxins in the water can result in mass fish die-offs (Paerl et al., 2001).

Transformations in the floodplain and conversion of wetlands from flooded forest and submerged vegetation can remove important habitats. Wetlands are frequently drained, so that land can be 'reclaimed' for property or agricultural development, with barriers erected to prevent flooding. Conversely, barriers might be erected to retain water for rice crops or water might be diverted to irrigate other crops, consequently reducing natural flows, preventing fish passage, and limiting access to important habitats.

Recently, positive interactions between farming and fisheries have increased. In the floodplains of South-east and South Asia, complementary management of rice-field fisheries has led to mutual benefits for the farmers and fishers (Freed et al., 2020). In lieu of pesticides and fertilizers, farmers help retain access passages for fish to breed and feed in their rice-fields. The fish then contribute important fertilizing nutrients in their feces and feed on agricultural pests. The fish grow and develop in the rice-fields and are then harvested as the waters recede (Ahmed and Garnett, 2011). Such examples can serve as a positive model for finding complementary management solutions in a variety of inland aquatic ecosystems.

Example 4: Aquaculture

Negative environmental impacts of aquaculture are well-documented (Fernandes et al., 2001), but most of them occur in marine environments where the majority of aquaculture occurs. Recent development of inland aquaculture in both developed (Gooley et al., 2000) and developing regions (Musinguzi et al., 2019), has given rise to many of these same impacts in inland waters (Telfer et al., 2009; Beveridge and Phillips, 1993). Typically, aquaculture uses substances that can become pollutants, for example phosphorus and nitrogen, which are used in feeds and chemical maintenance of aquaculture ponds. These chemicals when released into the environment can result in algal blooms by over-stimulating algal growth. As well as depleting the oxygen concentrations below the tolerance of fish, some algae (e.g. cyanobacteria) also release toxins into the water, which can be toxic to fish (Brooks et al., 2016; Herath and Satoh, 2015). Other impacts include the release of non-native species, e.g., Tilapia, that outcompete natives for resources; and selective breeding that can contaminate the natural gene pool (Ansah et al., 2014; Canonico et al., 2005).

As well as the above more obvious environmental concerns, increasing harvest of small fish from inland waters to feed the growing marine aquaculture industry (Edwards et al., 2004) is putting additional pressure on the inland capture fishery (Nunoo et al., 2009). Although there are now more feed options available, the aquaculture industry still relies heavily on small "feed fish" from capture fisheries to supply farmed fish with vital nutrient inputs (Tacon and Metian, 2008). Both whole fish and fish processed into fishmeal, that are fed to the farmed fish rely on low value "trash fish," harvested from the wild (Goldburg and Naylor, 2005). In developing countries, in particular, where small fish species are often an essential source of protein and nutrients (Allan, 2004), the rerouting of these fish from human consumption to feeding the farmed fish, has a negative impact on food and nutrition security (Belton and Thilsted, 2014; Tacon and Metian, 2009). Small individuals of larger species are also harvested and sold to the aquaculture industry as 'trash-fish,' often removing the young-of-the-year and constraining production of commercially important species (Huntington and Hasan, 2009).

Case study 4: Welfare considerations of aquaculture and fisheries

The methods used in fisheries that result in the death of fish are some of the harshest and often thoughtless of all methods used in animal production. Although sentience of fish is still debated (e.g., Kristopher et al., 2004; Rose et al., 2014) the awareness and consciousness of some fish including elasmobranchs, that lack nociceptors (or pain receptors) is increasingly being documented (Brown, 2015). The difference in the way that fish apparently experience pain has led to the generally dispassionate way that harvest of fish in fisheries is handled, and a lack of consideration of the need to use more humane methods (Fernö et al., 2020). Irrespective of the reality, the precautionary principal dictates that we should give the benefit of the doubt to fish and assume that they are suffering when death is prolonged or dramatic, or when experimental procedures require invasive procedures (JWD, 2016; Cooke et al., 2013a,b; Browman et al., 2019).

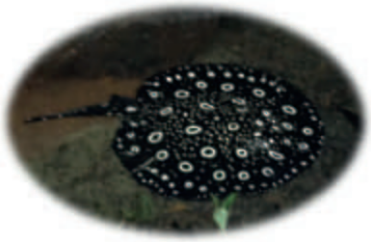
In experimental work, increasingly more humane methods are being adopted, such as the use of clove oils and other temporary sedatives for the capture, killing or tagging of experimental animals (Cooke et al., 2013a,b). In captive and aquarium contexts, the care and welfare needs of fish are increasingly being considered. But fisheries lag behind. Aquaculture ponds are essentially large industrial aquaria where the objective is to harvest and sell the fish for food rather than for display. However, the conditions in which they are kept in fish farms, and the process by which they are killed, presents a stark contrast to aquarium conditions. Of greatest welfare concern is the prevalence of diseases and over-crowding that result in negative welfare conditions (Barreto et al., 2021). Even more extreme, the conditions experienced by fish in the mass hauls of global capture fisheries, during which fish experience prolonged death by suffocation, crushing, decompression, asphyxiation, or exsanguination (bleeding to death), make the sometimes-unpleasant conditions and harvest practices used in aquaculture seem benign (Breen et al., 2020). While the capture techniques of recreational fisheries, are often considered more humane, they can also present welfare concerns for fish. Recently increased attention and an increased understanding of fish experiences have led researchers and anglers to consider the welfare and physiological experiences of fish more carefully (Cooke et al., 2013a,b). It is also worth noting that, improvement in the management of wild populations, where behavioral and physiological indicators suggest that welfare can vary depending on environmental and ecological factors, such as turbidity and predation risk, could also be beneficial (Freeling and Connell, 2021).

As recently noted by Lugert et al. (2020) "Lack of knowledge does not justify a lack of action." Irrespective of whether fish are sentient and feel pain or not, we have a responsibility to consider their welfare. The regulations and concern for inland aquatic organisms lag well behind that of terrestrial animals, despite the much greater harvest of individuals and use across industries. Increasing awareness and a sense of connection to wildlife, felt by recreational anglers, has led to welfare improvements in the capture techniques being used in recreational fisheries. Recognition of the benefits to the product quality and individual survival, of addressing welfare for fish sold as ornamentals, has led to improvements in conditions in the aquarium trade, such as preventing over-crowding, providing enrichments, and keeping the water clean (Stevens, 2019). Aquaculture and capture fisheries could benefit from more humane capture techniques and better holding conditions (e.g. water quality and enrichments), increasingly being used due to recognition of fish welfare in recreational fisheries and the aquarium trade, respectively. Recreational anglers may in fact, be particularly inclined to advocate for improved welfare consideration of inland fish (Cooke et al., 2013a,b), and may lead the way in drawing greater attention to the need for improved methods used for the harvest of fish by fisheries.

Case study 5: Freshwater elasmobranchs

Freshwater elasmobranchs are often overlooked when considering inland aquatic biodiversity, likely because the vast majority of cartilaginous fish species are associated with coastal and high seas marine environments. They are, however, particularly vulnerable and will need careful management to protect key habitats that support their life-cycles in order to persist. Freshwater elasmobranchs or stenohaline species (those that have a low tolerance for changes in salinity), have successfully adapted to freshwater environments and have developed the ability to complete their life cycles in streams, rivers, and lakes without depending on marine waters.

There are also species of freshwater elasmobranchs found in rivers, lakes and estuaries that conduct only part of their life cycle in fresh or brackish waters (euryhaline). These species can tolerate low salinity levels (<32 psu) during brief incursions, up to several months, in freshwater or during specific life development stages (mainly pupping and juvenile development). It is estimated that at least 171 species (15%) of elasmobranchs inhabit areas with reduced salinity (Martin, 2005).



The stenohaline elasmobranch species belong mainly to a group of stingrays (Potamotrygoninae). This chondrichthyan lineage, mainly of sharks and rays, successfully colonized South American freshwater environments. The subfamily Potamotrygoninae, or Neotropical Freshwater Stingrays, comprises 39 described species (Last et al., 2016; Roberts, 2020; Loboda et al., 2021), distributed in the main water basins and sub-basins of South America. Most potamotrygonin species are endemic to a single basin, sometimes even to a single river, which contrasts to bony-fish species, that are widely distributed in multiple watersheds (Lasso et al., 2016). Known as 'river jewels,' some species have attractive and striking dorsal color patterns that make them a target for the ornamental trade. This trade threatens the conservation and sustainability of the group (Araújo et al., 2004).

Stenohaline chondrichthyan ray species are also found in other freshwater ecosystems around the world. Two species, Smooth Stingray (*Fontitrygon gaurouensis*) and Thorny Stingray (*F. ukpam*) are present in West Africa. Another six species, Roughback Whipray (*Fluvitrygon kittipongi*), Marbled Whipray (*F. oxyrhynchus*), White-edge Whipray (*F. signifer*), Mekong Stingray (*Hemitrygon laosensis*), Chindwin Cowtail Ray (*Makararaja chindwinensis*), and the Giant Freshwater Whipray (*Urogymnus polylepis*) are found in various water bodies of Southeast Asia. While most of the stenohaline chondrichthyan species are rays, there are also sharks from the genus *Glyphis* that exclusively inhabit freshwater habitats in Australia, Papua New Guinea, India and Myanmar.

Several other ray species including, *Hypanus* spp., *Fontitrygon colarensis, F. geijskesi, and Styracura* spp., are euryhaline and depend on inland waters to complete their life cycle, using estuarine habitats as a nursery and for pupping. Several euryhaline shark species can also be found in estuaries and inland waters around the world, while many other sharks are classified as marginal species, tolerating the lower salinities found in estuaries but not venturing into true freshwater environments (Martin, 2005). Six species of sawfish from the Pristidae family, five in the genus *Pristis* and one in the genus *Anoxypristis*, and three species of requiem shark, two from the genus *Glyphis* and one Carcharhinus are also euryhaline. Among them the iconic Bull Shark (*Carcharhinus leucas*) has been recorded worldwide making extensive migrations hundreds of kilometers inland through rivers in Africa, Asia, Australia, and the Americas (Gaussman, 2018), including an infamous migration 80 km up the Mississippi River (Shell and Gardner, 2021) and even more extraordinary, sightings 4000 km up the Amazon River (Thorson, 1972). This is, however, not the rule for most species that generally occupy more restricted habitats.

The freshwater elasmobranchs face several threats from fisheries, including uncontrolled harvest for consumption, and for the aquarium trade, particularly of several species of South American freshwater stingray in the family Potamotrygonidae. They are also threatened by bycatch, especially by the use of trawling operations (Araújo et al., 2004). Some countries are now applying species quotas, but most of the harvest and the market is unregulated. Recreational fishing is a particular concern for the large-bodied species found in South America (*Potamotrygon brachyura*) and Southeast Asia (*Urogymnus polylepis*), where they are targeted for their prestige and often mishandled (Vidthayanon et al., 2016). Due to accidents, mainly with stingrays, elasmobranchs have a reputation for being dangerous. As a result, mainly to avoid conflicts in tourist areas (Rosa et al., 2010), "negative fishing" has developed, which targets elasmobranch species with the aim of eliminating them in some areas (Araújo et al., 2004).

Freshwater elasmobranchs are subject to a number of threats, with the constraints of freshwater ecosystems making them even more vulnerable to environmental changes (Compagno and Cook, 1995). For example, the life cycles of inland elasmobranchs are closely tied to cycles of droughts and floods (Charvet-Almeida et al., 2005). Across the globe climate change is altering the hydrology of inland aquatic ecosystems, disrupting these seasonal dynamics and interfering with fish lifecycles. They are also threatened by pollution from a number of sources, including mining, sewage discharge, agricultural or industrial runoff (Carpenter et al., 2011), as well as by damming and silting. Damming of the upper Paraná River (Brazil), for example, has altered the distribution of freshwater stingray species in the Paraná Basin providing favorable conditions for some species in the genus Potamotrygon to become invasive (Garrone-Neto et al., 2014). These impacts are heightened by rising human populations and their predilection to concentrate along freshwater bodies (Martin, 2005). Most of the freshwater elasmobranch species are concentrated in tropical regions, which face strong human population growth and habitat degradation (Bradshaw et al., 2009).

The management and protection of important nursery and pupping habitats is important to ensure their persistence, particularly of elasmobranch species that are dependent on these environments.

Developing management strategies for freshwater elasmobranchs is essential but challenging. Like many other elasmobranchs, freshwater elasmobranchs are typical K-strategists with low fertility, late maturity, and long lifespans, making them more susceptible to exploitation (Charvet-Almeida et al., 2005). The restrictions created by their life history characteristics, combined with the constraints of freshwater environments, make them particularly vulnerable species, for which careful management is required. Currently, there are very few conservation measures in place to protect them. There is an optional recommendation for Potamotrygoninae species to be listed on the CITES Appendix III, which is a list of species recognizing them as being of some conservation concern (CITES, n.d.). However, most agreements are at the national level (e.g., ornamental trade export quotas), and the risk of

extinction for most species has not yet been evaluated. A lack of basic biological knowledge for most freshwater elasmobranchs has been an obstacle for developing effective assessments and management strategies (Martin, 2005). Thus, filling knowledge gaps and ensuring that socio-economic considerations are included, will be essential for developing adequate strategies. To preserve elasmobranch species in their natural environments, careful and coordinated management will be needed both globally in the form of legislation controlling trade, and locally to ensure that interventions address their specific context.

Future research needs

While much is understood about the needs for sustainable fish harvest (Hilborn, 2011), critical knowledge gaps remain, impeding sustainable fisheries management by limiting the potential for setting effective regulations (Funge-Smith and Bennett, 2019). Both an improved understanding of inland aquatic ecosystems, and greater knowledge of the ecology of particular fish species, are needed to identify management strategies that will lead to sustainable harvests, and that can address the various challenges outlined in this chapter (Cooke et al., 2021). Inland fish life-histories are closely tied to environmental conditions (Bergerot et al., 2015; Mims and Olden, 2013) and as such, are especially vulnerable to climate changes (Myers et al., 2017). Expanding the knowledge base, through research and monitoring that targets these critical knowledge gaps (Loury et al., 2021), can help equip managers and fishers with the necessary tools to improve management and respond to climate change (Myers et al., 2017). Understanding fish welfare and how we can improve their quality of life, also requires greater emphasis on research. Through targeted welfare studies of fish behavior and physiology, it is possible to increase awareness and understanding of fish sentience, capacity for pain and critical thinking. By gaining a better understanding of the impacts of threats to inland fisheries, outlined in this chapter, fisheries managers can improve management approaches and adapt to changing conditions. Particular research priorities for the future include understanding climate change impacts on hydrology, filling critical knowledge gaps in fish ecology, improving our understanding of fish welfare and cognition, and investigating the links between fishing practices and resource sustainability.

Conclusions

Inland aquatic ecosystems are diverse and widespread. They provide key habitats to a high diversity of aquatic organisms and sustain the livelihoods of many human communities around the globe (Funge-Smith and Bennett, 2019). Their integration into the landscape makes them vital for ecosystem function and at the same time extremely vulnerable to increasing threats from development and agriculture (Reid et al., 2019). The fisheries that they sustain are at the same time biodiverse and important for supporting food security, livelihoods and recreation (Funge-Smith and Bennett, 2019). Some freshwater fish species are highly attractive and sought after, making them very important to the aquarium trade (Stevens, 2019). The effective management of fisheries is increasingly important as human populations continue to increase and demands on the fisheries and the ecosystems they rely on grow more numerous and diverse (Youn et al., 2014). Consideration of the welfare of individual fish in a growing industry, and recognition of the benefits that ensure care is taken when handling them, is a recent development in fisheries (Breen et al., 2020), one that builds on centuries of awareness that the well-being of animals is of moral and practical concern.

A diverse set of case studies has been presented, describing a range of themes within freshwater fisheries. While representing various perspectives, they are all areas that have been overlooked to some degree. A common theme identified in the case studies is the need for effective management, which, in many cases, requires addressing critical knowledge gaps. Together the case studies highlight that changes to the way we consider fish, and approach and manage fisheries are needed to ensure that recreational fisheries, rights of fishers, and elasmobranch species can be sustained in the face of diverse threats.

Glossary

Alien species See "non-native species."

Colonization pressure The number of species introduced to a given location (Lockwood et al., 2009). Colonization pressure should be discriminated from "propagule pressure" (see below).

Impact A change or effect of a non-native species on either the environment (i.e., biodiversity) or socio-economics in the broad sense (i.e., including culture, religion, human health, safety, livelihoods and other aspects of human well-being), whether positive or negative (Jeschke et al., 2014).

Introduction pathways The processes and mechanisms behind the human-mediated introduction of non-native species from one geographic location to another (Hulme et al., 2008). These introductions can be either intended by humans or unintentional.

Invasion process See "invasive species."

Invasive species Species that have successfully completed the invasion process, i.e., they have: (i) been intentionally or unintentionally transported by human action from their native range to a new range; (ii) been released there or escaped into the wild; (iii) have established one or more self-sustaining populations; and (iv) have spread substantially beyond their point(s) of release or escape (Blackburn et al., 2011; Jeschke et al., 2013, see also Fig. 1). The stages i and ii of the process are jointly called "introduction," and an alternative name for the invasion process is the "introduction-naturalization-invasion continuum" (Richardson and Pyšek, 2012). Synonyms of invasive species are "invasive alien species" or "invasive non-native species."

Naturalized species Species that have reached the third stage of the invasion process, i.e., they have: (i) been intentionally or unintentionally transported by human action from their native range to a new range; (ii) been released there or escaped into the wild; and (iii) have established one or more self-sustaining populations (Blackburn et al., 2011, see also Fig. 1).

Non-native species Species that have been intentionally or unintentionally transported by human action from their native range to a new range (Blackburn et al., 2011). Non-native species are also called "alien species," "exotic species" or "non-indigenous species." Therefore, non-native species are not necessarily invasive, but invasive species as defined above are always non-native.

Phenotypic plasticity The ability of a genotype to have variable phenotypes in different environments. Phenotypic plasticity is widespread, but the degree of plasticity varies among species and genotypes (DeWitt and Scheiner, 2004; Engel et al., 2011; Jeschke and Heger, 2018).

Propagule pressure A composite measure of introduction effort consisting of: (i) the frequency of introduction events (propagule frequency or number); (ii) the number of individuals or propagules introduced per introduction event (propagule size); and (iii) the type of individuals (life stage, genotype, phenotype) introduced per introduction even (propagule composition) (Lockwood et al., 2005; Simberloff, 2009; Ricciardi et al., 2013; Jeschke and Heger, 2018). Propagule pressure should be discriminated from "colonization pressure" (see above). While propagule pressure refers to the number of introduced individuals or propagules of the same species, colonization pressure considers the number of introduced species.

Species distribution models (SDMs) Empirical models that are developed on the basis of niche theory by fitting the relationship between observed species distributions and environmental variables with a wide range of statistical algorithms and machine-learning methods to understand the drivers of biodiversity patterns and forecast species distributions across space and time (Guisan and Thuiller, 2005), e.g., in the context of climate change.

Introduction to the topic

Biological invasions have been a research topic for a long time, and even the probably most famous biologist of all times, Charles Darwin, thought and wrote about them back in the 19th century (Darwin, 1859; Ludsin and Wolfe, 2001; Cadotte, 2006). However, neither Darwin nor other influential researchers before the 20th century *focused* their investigations on biological invasions. After World War II, Charles Elton published *The ecology of invasions by animals and plants* (Elton, 1958), which laid the foundation for the discipline of invasion biology. Yet it took until the 1990s that this discipline really started to rise. Research on biological invasions has intensified rapidly since then, indicated by the strong increase in the number of relevant publications (Richardson and Pyšek, 2008; Enders et al., 2019). The number and impacts of non-native species translocated across the globe have seen a similar rise (Seebens et al., 2017, Pyšek et al., 2020).

Biological invasions are thus an important component of how ecological communities form and are being formed in the Anthropocene (Crutzen, 2002; Waters et al., 2016). While investigating invasions, we learn a lot about biotic interactions, community and evolutionary dynamics, dispersal and species distributions (Sax et al., 2005). In addition, it is a highly interdisciplinary research topic related to socio-ecological systems, the values of nature and its contributions to people. Therefore, biological invasions not only unify efforts from various ecological and related disciplines, but also from other natural sciences, economics and social sciences.

An important concept in this research field is the invasion process which consists of the consecutive stages that invasive species go through: transport, release/escape, establishment and spread (Fig. 1, Glossary, Blackburn et al., 2011; Jeschke et al., 2013). This definition also specifies what invasion biologists mean when talking or writing about "non-native", "alien" or "invasive" species: the latter are only those species that reached the final stage of the process, while "non-native" (or "alien"; these are synonyms) species are all those that completed at least the first stage (Fig. 1, Glossary and Blackburn et al., 2011). In other words, invasive species are a subgroup of non-native species.

The invasion process also guides the structure of the current chapter which consists of two main sections. The first main section focuses on the stages transport and release/escape, which are frequently summarized as "introduction". This section outlines (1a) historical dynamics of species introductions and (1b) how pathways of species introductions can be categorized and analyzed. The second main section focuses on the establishment and spread of non-native species, featuring (2a) major hypotheses about non-native species, which largely focus on their establishment and spread; and (2b) species distribution models, which are an

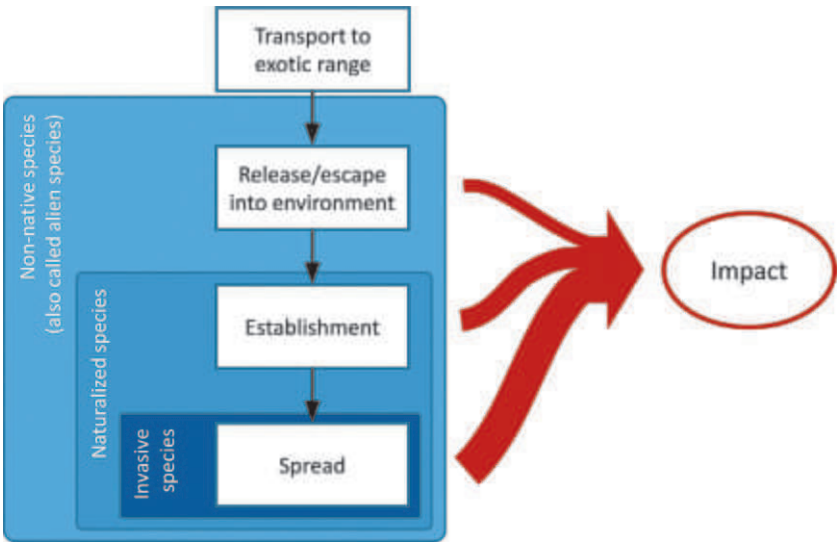

Fig. 1 The invasion process consists of four consecutive stages (indicated by rectangular boxes; see Blackburn et al., 2011 and Jeschke et al., 2013). Only those non-native species that reached the final stage (spread) are termed "invasive species." The first two stages of the process are sometimes summarized as "introduction." "Impact" itself is not considered a stage of the invasion process, as non-native species can have impacts at any stage. Impact magnitude typically increases as non-native species progress through the invasion process (indicated by increasingly thicker red arrows).

important and widely used tool to predict where non-native species are able to establish themselves and spread. The present chapter is complemented by two other chapters on biological invasions in this encyclopedia, which outline the impact and management of non-native species and feature case studies, respectively.

Introductions of non-native species

Historical dynamics of species introductions

The introduction (i.e., transport and escape/release, cf. Fig. 1) of non-native species by humans has a very long history, spanning hundreds to thousands of years. Indications of early non-native species introductions exist from all over the world, including for example during the time of the Pharaohs in ancient Egypt and within areas in Central America 3000 years ago (Sanchéz, 1997; Janick, 2007), by the Polynesians in the Pacific region, the Greeks and Romans in the Mediterranean and the Han dynasty in China (di Castri, 1989; Cox and Banack, 1991; Keller, 1994; Sanchéz, 1997). However, nearly all of these cases represent terrestrial species, with the vast majority being agricultural or ornamental plant species (see the following section for details on introduction pathways). An exception represents the well documented introductions of ornamental fishes in China, where for instance common carp (*Cyprinus carpio*) have been raised and dispersed already 1000–2000 years ago (Ma et al., 2003).

Overall, reports of freshwater species introductions are largely lacking from before 1500 and are still low before 1800 (Fig. 2). Outside China, a few reports of early introductions of freshwater species exist for the 16th century. In most cases, these were introductions of fishes, such as common carp introduced to the United Kingdom (Jackson and Grey, 2013) or common bream (*Abramis brama*) to Ireland (O'Flynn et al., 2014). Integrating the First Records Database (Seebens et al., 2017) with habitat types of species obtained from WoRMS Editorial Board (2020) revealed that the earliest introduction of a non-native freshwater plant species was recorded for European water-plantain (*Alisma plantago-aquatica*), which was found in 1672 in the USA (Pyšek et al., 2015). Among invertebrates, one of the few early records denote the introduction of the zebra mussel (*Dreissena polymorpha*), which was already recorded in 1619 as being introduced to North America from Europe or Central Asia, and is now widespread and abundant in large parts of the United States and Canada (Mangiante et al., 2018).

After 1800, the total number of non-native freshwater species shows a clear rising trend until today (Fig. 2). According to the First Records Database, a total of 645 non-native freshwater species have been introduced worldwide until 2010. As the time of first detection is not available for most introduction events, many species are lacking from this database and the true number of non-native freshwater species is likely much higher. For example, a comparison of non-native species occurrences reported in the online database FishBase (Froese and Pauly, 2019) and the First Records Database revealed that for most regions of the world the proportion of entries with available dates of first record is often below 50% (Seebens et al., 2021). For less investigated taxonomic groups such as invertebrates, the proportion is certainly even lower. While the absolute numbers of introduced non-native species must be higher, sensitivity analyzes revealed that the trends are robust (Seebens et al., 2018).

The overall rise in the number of non-native freshwater species has been consistently reported from all over the world, across habitats such as lakes and rivers, and across a large range of taxonomic groups (Cowie, 1998; Kumar, 2000; Ricciardi, 2001; Roll et al., 2009; Hussner et al., 2010; Jackson and Grey, 2013; Rabitsch and Nehring, 2017; Mangiante et al., 2018; Muñoz-Mas and García-Berthou, 2020). Although comprehensive analyzes of long-term trends of non-native freshwater species are still missing at the global scale, the consistency of reported trends across taxonomic groups, habitats and regions indicates that similar trends can also be expected for less investigated taxa and regions.

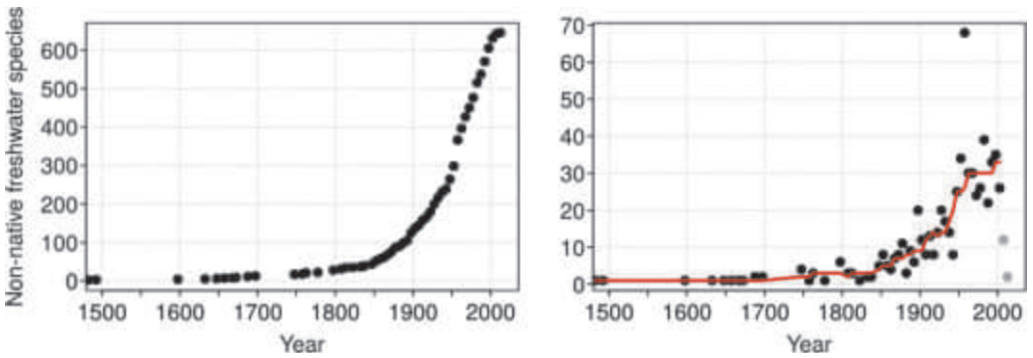

Fig. 2 Temporal development of the number of non-native freshwater species globally shown as total numbers (left panel) and the number of new non-native species per five-year interval (right panel). The red line indicates the overall trend calculated as a running median until 2005. Records after 2005 (grey dots) are prone to time lags in detection and recording, and were thus not considered for the trend calculation. Available from https://www.marinespecies.org at VLIZ. (Accessed 10 October 2020). https://doi.org/10.14284/170.

In addition to increases in total numbers, also the rate of new records per time has risen continuously (Fig. 2; Ricciardi, 2001, Jackson and Grey, 2013, Muñoz-Mas and García-Berthou, 2020). This rise may indicate an acceleration of introductions, although such dynamics may also result from increased sampling intensity (Costello and Solow, 2003; Belmaker et al., 2009). A few studies reported declines in rates of new non-native species records in most recent years (i.e., after 2005), which is also apparent in Fig. 2 (grey dots). However, it has been repeatedly concluded that such apparently declining trends in recent years are most likely a consequence of delays in detection and reporting of new non-native species rather than the reflection of true trends (Seebens et al., 2017, Mangiante et al., 2018, Muñoz-Mas and García-Berthou, 2020).

Within the coming decades, the observed rise in the number of non-native freshwater species is very likely to continue for two reasons: First, numbers of non-native species consistently increased during the last decades for nearly all taxonomic groups and regions without signs of saturation (Seebens et al., 2017). As there are no indications for upcoming major policy changes to mitigate further introductions, it seems unlikely that trends will change distinctly in the near future. Second, drivers of introduction and establishment of non-native freshwater species are expected to increase likewise. For instance, the intensity of shipping, tourism or fishing, but also the number of pets and the interconnectivity among freshwater systems through canals—which are all pathways of introduction (see above and Cowie, 1998, Ricciardi, 2001, Galil et al., 2007, Jackson and Grey, 2013)—are expected to increase. If dynamics continue as observed during the last decades, further increases in the number of new non-native species in inland waters are very likely. Indeed, such increases are predicted to occur until 2050, although the dynamics may vary among taxonomic groups (Seebens et al., 2021): While a clear increase is predicted for non-native freshwater plants, introductions of non-native freshwater arthropods are predicted to slow down, which can be partly attributed to the depletion of source pools (Liebhold et al., 2017). Finally, climate change will increasingly affect the establishment and spatial distribution of non-native freshwater species in manifold ways (e.g., Bellard et al., 2013, 2018).

Introduction pathways of non-native species

Non-native species can be introduced from one geographic location to another, intentionally or unintentionally, by various processes and mechanisms which are called introduction pathways. As mentioned above, "introduction" refers to the first two stages of the invasion process, namely "transport" and "escape/release" (Fig. 1). To make the large variety of pathways easier to grasp and more effectively manageable, efforts have been made to standardize pathway terminology and categorization. Based on foundational work by Hulme et al. (2008), the Convention on Biological Diversity proposed a unified pathway categorization (CBD, 2014; IUCN, 2017; Table 1) which differentiates between three general mechanisms (importation as or with a commodity, arrival via a transport vector, natural spread from a neighboring region where the species is alien) and six main pathway categories: Release in nature; Escape from confinement; Transport—Contaminant; Transport—Stowaway; Corridor; and Unaided. Each of these main pathways comprises several subcategories (Table 1; Faulkner et al., 2020; Pergl et al., 2020 discuss potential improvements to this standard scheme). The categories Release and Escape relate to the intentional transportation of non-native species outside of their native range, whereas the other categories describe unintentional transportation.

The relevance of many introduction pathways is linked directly to the strong increase in global trade and transport in the last centuries. Differences in their importance relative to each other, however, can be seen when considering different habitat types and taxonomic groups. Combined pathway data from two major IAS databases, IUCN's Global Invasive Species Database (GISD) and the DAISIE European Invasive Alien Species Gateway, show that the pathway Escape is responsible for most introductions of freshwater species (Fig. 3A, modified from Saul et al., 2017). For instance, many species of fish, crustaceans and mollusks were transported outside of their native areas for aquaculture and escaped from the respective facilities into the wild. Freshwater species used in aquarium trade or for ornamental purposes (animals as well as plants) often escape with or without their owner's knowledge (Keller et al., 2011; Fig. 3B). Release is the second most important pathway in freshwater habitats, comprising such widespread activities as stocking of fish and crustaceans as a means to improve commercial and recreational fisheries or introductions for biocontrol (e.g., mosquitofish *Gambusia* spp. for mosquito control, or herbivorous weevils to control aquatic invaders like water hyacinth *Eichhornia crassipes* and giant salvinia *Salvinia molesta*). The pooled pathway category "Transport— Contaminant & Stowaway" (a differentiation between the two individual transport categories is not possible with sufficient certainty in the global dataset from Saul et al., 2017) comes third, with contaminated bait and stowaways in angling/fishing equipment, ballast water and "hitchhikers" on ship or boat hulls (hull fouling) being of particular relevance for freshwater introductions. Finally, many freshwater introductions have been facilitated through the creation of canals (pathway Corridor), such as the Rhine-Main-Danube canal in Europe, which is effectively connecting the Black Sea with the North Sea, or the Chicago Sanitary and Ship Canal in North America connecting the Great Lakes with the Mississippi River. The Corridor pathway is particularly important for introductions of freshwater invertebrates (Fig. 3B).

The prevalence of pathways for species introductions may change over time due to changes in human activities, such as trade, tourism or fashion (see e.g., Ricciardi, 2006; Hulme et al., 2008; Essl et al., 2015; Pagnucco et al., 2015). Likewise, the relative importance of pathways varies among freshwater systems of different regions. For example, the proportions of pathways responsible for freshwater introductions in Europe (see e.g., Gherardi et al., 2009; Nunes et al., 2015) align well with the overall pattern found in the combined dataset described above. By contrast, in the Laurentian Great Lake basin in North America, one of the world's most invaded freshwater system, until recently ballast water (pathway Transport—Contaminant) was the overwhelmingly dominant pathway (Ricciardi, 2006; Pagnucco et al., 2015). In South Africa, important introduction pathways of freshwater fish are related to stocking for sport fishing and food (pathway Release) as well as aquaculture and aquarium trade (pathway Escape) (Richardson et al., 2003).

Table 1 CBD pathway categorization (CBD, 2014; IUCN, 2017).

Mechanism	*Category*	*Subcategory*
Importation as or with a commodity	Release in nature	Biological control
		Erosion control/dune stabilization
		Fishery in the wild
		Hunting in the wild
		Landscape/flora/fauna "improvement"
		Introduction for conservation purposes
		Release in nature for use
		Other intentional release
	Escape from confinement	Agriculture
		Aquaculture/mariculture
		Botanical garden/zoo/aquaria
		Pet/aquarium/terrarium species
		Farmed animals
		Forestry
		Fur farms
		Horticulture
		Ornamental purpose (not horticulture)
		Research and ex-situ breeding
		Live food & live bait
		Other escape from confinement
	Transport—Contaminant	Contaminant nursery material
		Contaminated bait
		Food contaminant
		Contaminant on animals
		Parasites on animals
		Contaminant on plants
		Parasites on plants
		Seed contaminant
		Timber trade
		Transportation of habitat material
Arrival via a transport vector	Transport—Stowaway	Angling/fishing equipment
		Container/bulk
		Hitchhikers in or on airplane
		Hitchhikers on ship/boat
		Machinery/equipment
		People & their luggage/equipment
		Organic packing material
		Ship/boat ballast water
		Ship/boat hull fouling
		Vehicles
		Other means of transport
Spread	Corridor	Interconnected waterways/basins/seas
		Tunnels & land bridges
	Unaided	Natural dispersal across borders
		(from an area to which the species was introduced by human mediation)

The categories Release and Escape relate to the intentional transportation of non-native species outside of their native range, whereas the other categories relate to unintentional transportation.

Establishment and spread of non-native species: Hypotheses and models about invasion success

While the previous section focused on the first two stages of the invasion process, stages three and four refer to establishment and spread. These two stages have received more attention in invasion biology than the early stages, particularly in the 20th and early 21st century. For example, the SCOPE program in the 1980s formulated the following central research questions for biological invasions, which have remained highly influential for the field until today: "What are the characteristics of a successful invader species? What characteristics determine the susceptibility to invasions of a natural ecosystem? How successful are attempts to predict in a quantitative manner the outcome of a particular introduction, or the effect of an invading organism on ecosystem structure and function? What particular implications are there for the management and conservation of natural or semi-natural ecosystems?" (pp. 8–9 in Huenneke, 1988).

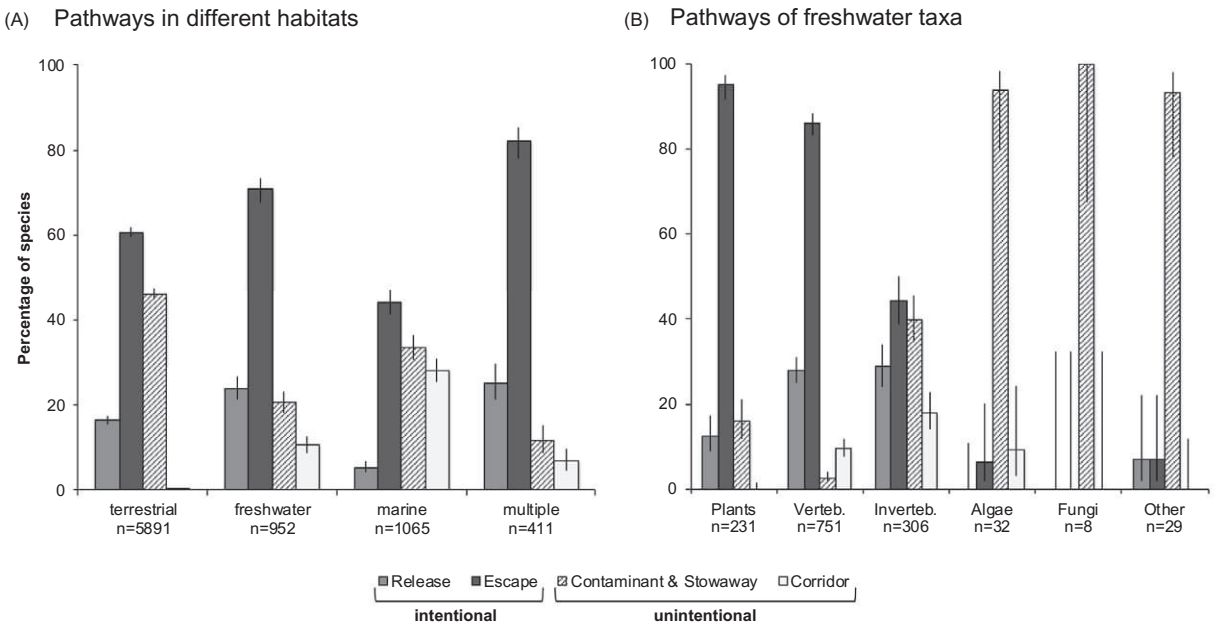

Fig. 3 Main introduction pathways recorded in a large dataset that combines global data from GISD/IASPMR with European data from DAISIE, comparing among (A) different habitat types (8319 spp.) and (B) different taxonomic groups of freshwater species (1357 spp.). Species in (B) include those that occur in freshwater alongside other habitat types (part of "multiple" in (A)). The pathways Transport—Contaminant and Transport—Stowaway were pooled ("Contaminant & Stowaway") since their differentiation was not possible with sufficient certainty for many of the species in the dataset. The sum of pathway proportions is larger than 100% for each habitat and taxonomic group since species can be introduced via more than one pathway. Error bars indicate 95% Wilson confidence intervals; (B) uses the combined dataset provided therein. Strongly modified from a previous publication by the authors who own the copyright: Saul W-C, Roy HE, Booy O, Carnevali L, Chen H-J, Genovesi P, Harrower CA, Hulme PE, Pagad S, Pergl J and Jeschke JM (2017) Assessing patterns in introduction pathways of alien species by linking major invasion databases. *Journal of Applied Ecology* 54: 657–669.

These questions largely focus on invasion success (i.e., which factors are responsible that invasive species have completed the invasion process?), emphasizing the relevance of identifying the characteristics of invasive species and invaded ecosystems. It could be argued that in order to answer these questions, the complete invasion process should be considered, including the first stages. However, the importance of considering the role of humans in the introduction of non-native species to improve our understanding on the invasion success has only become clear to the field in the 2000s. In this decade, Richardson (2004; see also Richardson and Pyšek, 2008) declared understanding propagule pressure, and generally the role of the early stages of the invasion process, as the new frontier in invasion biology. Taking into account propagule pressure, a composite measure of (human-driven) introduction effort (see Glossary for details), has been eye-opening: it turned out that it is often more important for the success of non-native species than the biological characteristics of these species or the ecosystems to which they were introduced (reviewed in e.g., Simberloff, 2009, Keller et al., 2011).

The following sub-sections focus on invasion success of non-native species, particularly their establishment and spread, from two different perspectives: The first one highlights major hypotheses in the field of invasion biology about the reasons for invasion success (or failure); and the second sub-section outlines species distribution models (SDMs), which are widely used for predicting where non-native species are able to establish and spread.

Major hypotheses on the invasion success of non-native species

Major hypotheses of a research field are typically a rich source of knowledge reflecting the combined conceptual understanding of the field. In a thriving discipline such as invasion biology, it is quite challenging to get and keep on overview of existing hypotheses. In their review "Fifty years of invasion ecology—the legacy of Charles Elton", Richardson and Pyšek (2008) wrote: "The literature on invasion ecology contains a growing number of theories and generalizations, with much duplication, redundancy and reinventing of the wheel. There is a need to distill the fundamental issues from the different theories, while realizing that invasions are context specific summarizing the state of the field" (p. 166). Only a year later, Catford et al. (2009) tackled exactly this issue by publishing their seminal paper "Reducing redundancy in invasion ecology by integrating hypotheses into a single theoretical framework."

More recently, the first author of this article teamed up with Martin Enders, Tina Heger and colleagues to create interactive conceptual maps of invasion biology by constructing zoomable networks of common invasion hypotheses (Jeschke, 2014; Enders

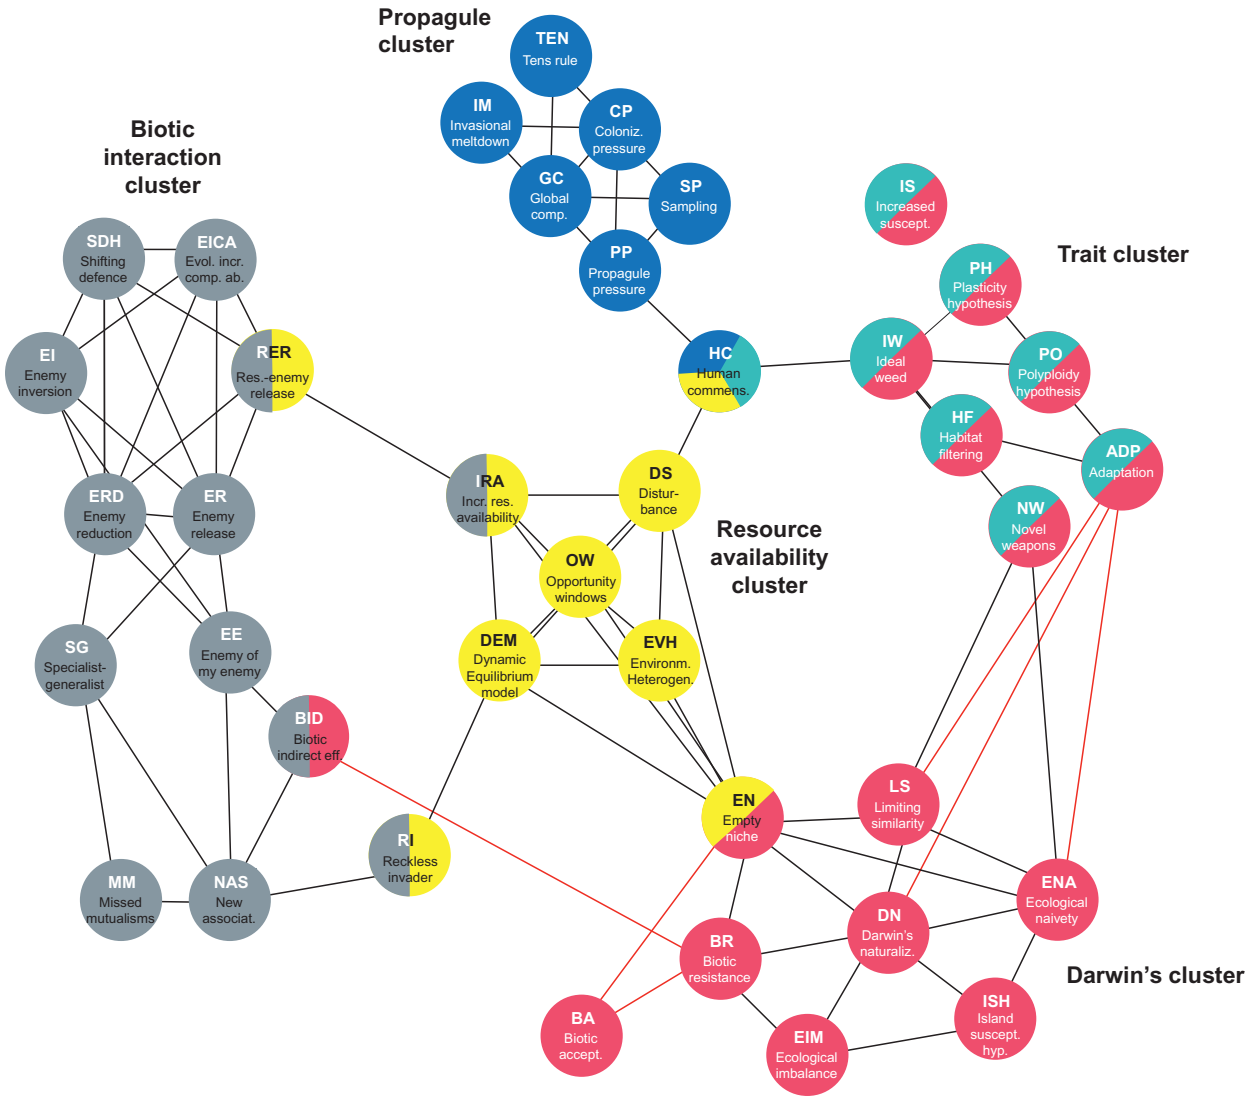

Fig. 4 Hypothesis network consisting of 39 invasion hypotheses grouped in five topical clusters. The color of each hypothesis illustrates to which cluster it belongs. Multi-color hypotheses belong to more than one cluster—they conceptually connect clusters. A black line connecting two hypotheses indicates that they are logically similar, whereas a red line indicates contradictory hypotheses. More information on each hypothesis is provided at https://hi-knowledge.org and in: Enders M, Havemann F, Ruland F, Bernard-Verdier M, Catford JA, Gómez-Aparicio L, Haider S, Heger T, Kueffer C, Kühn I, Meyerson LA, Musseau C, Novoa A, Ricciardi A, Sagouis A, Schittko C, Strayer DL, Vilà M, Essl F, Hulme PE, van Kleunen M, Kumschick S, Lockwood JL, Mabey AL, McGeoch M, Palma E, Pyšek P, Saul W-C, Yannelli FA and Jeschke JM (2020) A conceptual map of invasion biology: integrating hypotheses into a consensus network. *Global Ecology and Biogeography* 29: 978–991.

et al., 2018, 2019, 2020; Jeschke and Heger, 2018). These conceptual maps provide a visual overview of existing key hypotheses of the field as well as how they are related to each other, and are freely available online at https://hi-knowledge.org. Taking the most recent conceptual map (Enders et al., 2020), 39 invasion hypotheses are connected in five topical clusters that each represent a different perspective on biological invasions (Fig. 4).

Specifically, the propagule cluster includes hypotheses that highlight the role of humans and the importance of propagule and colonization pressure (Lockwood et al., 2009) for invasion success. The best known hypothesis in this cluster (according to a survey performed by Enders et al., 2018) is the propagule pressure hypothesis which posits that non-native species with a high propagule pressure have a higher invasion success than non-native species with a low propagule pressure (Lockwood et al., 2005; Jeschke and Heger, 2018). It is one of the best supported hypotheses in the field. More than 80% of the studies addressing this hypothesis reported evidence in its support (Jeschke and Heger, 2018). Another hypothesis in this cluster is the tens rule, which says that about 10% of species will pass from one stage of the invasion process to the next. For example, if 100 species have been introduced to an exotic range, the tens rule predicts that 10 of these species will establish themselves and 1 species will spread. According to Jeschke

and Heger (2018), the overall percentage of species passing from one stage of the invasion process to the next was 38% ($n = 66$ studies), thus almost four times more than predicted. For freshwater species, this percentage was even 54% ($n = 5$) which is significantly higher than the 34% observed for terrestrial species ($n = 52$). Thus for freshwater species, about five times more species pass from one invasion stage to the next one than predicted by the tens rule. On the other side, the sample size for freshwater species was low, so more studies are needed to allow for a more robust conclusion.

The resource-availability cluster includes hypotheses on the characteristics of ecosystems into which non-native species were introduced. One well-known hypothesis in this cluster is the disturbance hypothesis, which posits that the invasion success of non-native species is higher in disturbed than undisturbed ecosystems (Elton, 1958; Hobbs and Huenneke, 1992; Jeschke and Heger, 2018; Enders et al., 2020). "Disturbance" can be measured in different ways, but empirical support for the disturbance hypothesis is high across almost all disturbance measures, having an overall level of support of about 60% of the studies addressing it (Jeschke and Heger, 2018). As for other invasion hypotheses, though, most studies addressing the disturbance hypothesis were done in terrestrial systems; in this case, only 4% of all studies focused on fresh waters (Jeschke and Heger, 2018).

Darwin's cluster includes the oldest major invasion hypothesis, Darwin's naturalization hypothesis, which states that the invasion success of non-native species is higher in areas that are poor in closely related species than in areas that are rich in closely related species (Darwin, 1859; Daehler, 2001; Schaefer et al., 2011; Jeschke and Heger, 2018; Enders et al., 2020). This hypothesis is well supported by evidence if phylogenetic distance is measured between the non-native species and the phylogenetically closest native species (phylogenetic nearest neighbor distance), whereas it is poorly supported if a taxonomic measure is used (non-membership in the same genus or family; Jeschke and Heger, 2018). Other hypotheses in this cluster also focus on eco-evolutionary factors to explain the invasion success (or failure) and impacts (or lack thereof) of non-native species. Specifically, the ecological naivety hypothesis posits that the invasion success and impact of non-native species on biodiversity is influenced by the eco-evolutionary experience of the resident community. Thus, invasion success and impacts are particularly high if no phylogenetically or functionally similar species exist in the resident community (Diamond and Case, 1986; Ricciardi and Atkinson, 2004; Saul and Jeschke, 2015; Enders et al., 2020). Another hypothesis in this cluster is the biotic resistance hypothesis, which posits that an ecosystem with high biodiversity is more resistant against non-native species than an ecosystem with lower biodiversity (Elton, 1958; Levine and D'Antonio 1999; Jeschke and Heger, 2018, Enders et al., 2020). This hypothesis is also known as diversity-invasibility hypothesis and is poorly supported by empirical evidence, particularly if "resistance" is implied simply from the number of non-native species in an ecosystem: if resistance is high, there should be few non-native species in the ecosystem, whereas if it is low, there should be many. If the biodiversity of ecosystems is measured as the number of native species in a system, a simple test of the resistance hypothesis is if the number of native and non-native species found in comparable ecosystems are negatively related to each other: such a negative correlation would be expected based on this hypothesis, as a high biodiversity (i.e., many native species) is predicted to result in high resistance (i.e., few non-native species). However, most studies testing this relationship did not find this pattern, which led to the formulation of the acceptance hypothesis (Stohlgren et al., 2006; Enders et al., 2020), which predicts the opposite pattern and is also included in Darwin's cluster.

The trait cluster is nested in Darwin's cluster and includes hypotheses with a focus on species characteristics. In particular, the ideal weed hypothesis posits that the invasion success of a non-native species depends on its specific traits (e.g., life-history traits) (Baker, 1965; Rejmánek and Richardson, 1996; Enders et al., 2020). The plasticity hypothesis states that a particular characteristic of non-native species, phenotypic plasticity, often makes them successful invaders (Richards et al., 2006; Jeschke and Heger, 2018; Enders et al., 2020). This hypothesis has been empirically supported by more than 60% of the studies addressing it, similar to the propagule pressure and disturbance hypotheses and, therefore, is among the best supported invasion hypotheses (Jeschke and Heger, 2018).

Finally, the biotic interaction cluster features hypotheses that emphasize the importance of species interactions for invasion success. A central hypothesis in this cluster is the enemy release hypothesis, which says that the absence of enemies in the exotic range is a cause of invasion success (Keane and Crawley, 2002; Heger and Jeschke, 2014; Jeschke and Heger, 2018; Enders et al., 2020). According to the survey by Enders et al. (2018), this is altogether the best known invasion hypothesis. Its empirical support is mixed, though: while invaders indeed seem to be frequently released from their enemies, they rarely showed an enhanced performance if released from enemies (Heger and Jeschke, 2014; Jeschke and Heger, 2018; Ryo et al., 2020).

Predicting establishment and spread of non-native species using species distribution models (SDMs)

Much research has been devoted to accurately predicting the potential distributions of non-native species in exotic ranges, for example to design cost-effective strategies for managing invasions (Vander Zanden and Olden, 2008; Bellard et al., 2013; Liu et al., 2019). Species distribution models (SDMs) have emerged as one of the most promising and popular tools to forecast the invasion risks of non-native species and the vulnerability of recipient ecosystems (Jeschke and Strayer, 2008; Liu et al., 2020a). The development of SDMs is based on the realized ecological niche, which defines the set of environmental conditions occupied by species in nature as a consequence of negative biotic interactions and dispersal limitations (rather than the fundamental niche, i.e., the set of environmental conditions that species can in principle occupy based on their physiological tolerance). Specifically, SDMs are first developed with statistical or machine-learning algorithms using the observed data of species distributions and environmental predictors to delineate the conditions in which species can survive (Guisan and Thuiller, 2005; Liu et al., 2020a). Models are then applied to new environmental layers to predict habitat suitability for species in new geographic ranges and/or within certain

time frames (Yates et al., 2018). Recent years have seen a proliferation of data on species distributions and environmental factors, and a rapid development of modeling algorithms, greatly facilitating the application of SDMs to forecast invasion risks of non-native species (Guisan and Thuiller, 2005; Werkowska et al., 2017).

For non-native species in inland waters, many studies have employed SDMs to anticipate their potential establishment and spread at global (e.g., Larson and Olden, 2012), national (e.g., Liu et al., 2019) and local (e.g., Vander Zanden and Olden, 2008) scales. Bellard et al. (2013) predicted the global distributions of 100 of the worst invaders (i.e., invasive species that are very successful and have a high impact) and found that range size would increase by 12% for aquatic plants and by 59% for aquatic invertebrates under upcoming climates.

To better predict species distributions, considerable efforts have been made for improving the predictive performance of SDMs (Guisan and Thuiller, 2005; Qiao et al., 2015; Werkowska et al., 2017). A recent synthesis documented that the predictability of SDMs in new ranges was positively correlated with the number of presence points used for developing models, but negatively with the number of predictors (Liu et al., 2020a). Therefore, selecting appropriate presence and predictor data is a key step to improve model performance in exotic ranges (Liu et al., 2020a). Developing SDMs should also account for the physiological characters of focal species, as species-environment relationships are remarkably different among functional groups (Yates et al., 2018; Norberg et al., 2019). Previous studies reported that distributions of species with larger body size, lower dispersal capacity or smaller range size could be predicted with greater accuracy (Soininen and Luoto, 2014). Huang et al. (2016) evaluated model performance for 16 freshwater fish species in the eastern USA and found a higher performance for species endemic in cool waters and species with small population sizes. Biotic interactions are another important factor, because the distributions of species are strongly shaped by their interactions with other species (e.g., competition and predation; Guisan and Thuiller, 2005, Yates et al., 2018). Also, biotic interactions regulating species distributions in the native range are often absent in the exotic range, yet biotic interactions are not considered in most SDM studies (Guisan and Thuiller, 2005; Jeschke and Strayer, 2008). In addition, better model performance has been found for non-native species with shorter residence times and for species introduced both intentionally and unintentionally (Liu et al., 2020a). Given the substantial heterogeneity in the ways of species being introduced, it is necessary to integrate the history and intentionality of species introductions into SDMs.

Several sources of uncertainty underlie the prediction of spatial distributions for non-native species (Jeschke and Strayer, 2008). One key premise of applying SDMs is that species should be in equilibrium with the environment (i.e., present in all suitable conditions and absent in all unsuitable conditions, Guisan and Thuiller, 2005). But this premise is often violated by non-native species, as it takes time until a non-native species is more or less in equilibrium with its exotic environment (Václavík and Meentemeyer, 2012). For example, Prussian carp (*Carassius gibelio*) showed an eightfold expansion of its range from 2000 to 2014 in Canada, and will likely continue to spread into the United States (Docherty et al., 2017). There are no signs yet that this species has reached equilibrium, and its expansion is further facilitated by additional human introductions and artificial waterways. For non-native species in a non-equilibrium state, many introduced populations might be observed in sink habitats (i.e., environmental conditions under which species can survive, but cannot maintain a population; Jeschke and Strayer, 2008, Liu et al., 2020b), reducing the performance of SDMs to predict species distributions in their exotic range (Zhu et al., 2014). Another key premise is that species do not or only slowly change their niche (i.e., niche conservatism), so that they can occupy similar environmental conditions in new regions and time periods (Liu et al., 2020b). However, non-native species may actually rapidly change their realized niches in exotic ranges due to new biotic interactions, dispersal limitations or rapid evolution (Guisan et al., 2014; Liu et al., 2020b). Changes in the realized niche have, for example, been reported for eastern mosquitofish *Gambusia holbrooki* introduced to Europe (Strubbe et al., 2015) and for freshwater invertebrates introduced to New Zealand (Torres et al., 2018). Niche changes cause SDMs to incorrectly assess species-environment relationships, leading to decreased reliability of predicted distributions (Liu et al., 2020a). A deteriorating effect of niche change on model performance has been found for multiple taxonomic groups, such as plants (Petitpierre et al., 2017) and vertebrates (Strubbe et al., 2015). Despite being rarely investigated for freshwater species, such an effect has been found for freshwater fishes in Brazil (Frederico et al., 2019) and crayfish in the United States (Morehouse and Tobler, 2013). Incorporating equilibrium status and niche changes into SDMs can be an effective way to increase model performance for non-native species (Pearman et al., 2008; Václavík and Meentemeyer, 2012).

Conclusions

Although classic studies about non-native species exist, the modern discipline of invasion biology did not emerge before the 1990s. An important conceptual strength that the discipline has developed over time is the invasion process, which consists of the consecutive stages that invasive species go through: transport, release/escape, establishment and spread. Research on biological invasions in the 1990s focused mainly on establishment and spread, and thus on those stages that are not as strongly connected to human actions as species transport and release/escape. This initial focus is unsurprising, as invasion biology emerged as an ecological subdiscipline and first focused on interactions between species and their environment without usually considering humans as an explicit part of this environment. Until today, most hypotheses in the field focus on establishment and spread, and do not put a strong focus on the role of humans. Since the 21st century, however, humans and their actions have become increasingly recognized as important to the field. Introduction pathways of non-native species are now more frequently studied, including their past and potential future dynamics. Similarly, propagule and colonization pressure, that is the number of individuals and species being globally translocated by humans, either intentionally or unintentionally, have become key concepts. These are also

empirically well supported, in contrast to some classic hypotheses that have received relatively little empirical support. The trend of the discipline to increasingly incorporate humans and their actions needs to continue in order to allow for a better understanding of biological invasions in the Anthropocene (cf. Kueffer, 2017; Archibald et al., 2020). Indeed, the importance of factors not classically investigated by biologists and ecologists has been predicted to further rise in the future, particularly transport, climate change and socio-economic change (Essl et al., 2020). Forecasting future distributions of non-native species has also become a stronger research focus, for which species distribution models (SDMs) are frequently applied. Novel synthesis tools that, for example, apply interactive visualization techniques to allow researchers and other stakeholders to get and keep an overview of the field's vast and further growing literature are becoming increasingly important as well (cf. Jeschke et al., 2020). Finally, there is a rise in research effort on the impacts and management of non-native species, which is the focus of the second chapter on biological invasions in this encyclopedia.

Knowledge gaps

- Information about biological invasions is strongly biased spatially towards large economies, temporally towards very recent data and taxonomically towards vertebrates and plants. Thus, large knowledge gaps exist, particularly for invertebrates in the aquatic realm in the global South (Pyšek et al., 2008; Jeschke et al., 2012; Bellard and Jeschke, 2016). There is a similar research bias in the application of species distribution models (SDMs), which also have mainly been applied in terrestrial systems (Soininen and Luoto, 2014; Liu et al., 2020a).
- There is a lack of general hypotheses about species introduction pathways.
- Our capacity to differentiate between pathways of primary introduction (e.g., intercontinental introductions to major ports) and of subsequent secondary introduction (e.g., intracontinental transport to smaller towns or natural spread of introduced species) needs to be increased to use limited management resources more efficiently. In particular, information about unaided introductions, i.e., secondary natural dispersal across borders, is very incomplete.
- Pathway information is still often scattered across databases that utilize disparate terminology and pathway categorisations. Databases need to be harmonized to exploit the full potential of accumulating pathway data.
- The influence of non-equilibrium status and niche changes on the performance of SDMs is not yet understood.
- We currently do not know to which degree the performance of SDMs can be improved by considering biotic interactions or the physiological characteristics and introduction history of the focal non-native species.

Acknowledgments

We thank Ken Irvine for the invitation to contribute this article. His comments on the chapter and those of Thomas Mehner and an anonymous reviewer are also highly appreciated. HS, JMJ and WCS acknowledge support by the Belmont-Forum-BiodivERsA project AlienScenarios through the national funder German Federal Ministry of Education and Research (BMBF; grants 01LC1807A and 01LC1807B). CL was sponsored by the PRIME program of the German Academic Exchange Service (DAAD) with funds from the BMBF. This chapter is a contribution of the Invasion Dynamics Network (InDyNet).

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Alien species See 'non-native species.'

EICAT Short for Environmental Impact Classification for Alien Taxa, a standardized system to assess biodiversity impacts of non-native species (Blackburn et al., 2014; Hawkins et al., 2015) that has been adopted by the International Union for Conservation of Nature (IUCN, 2020a, b).

Impact A change or effect of a non-native species on either the environment (i.e. biodiversity) or socio-economics in the broad sense (i.e. including culture, religion, human health, safety, livelihoods and other aspects of human well-being), whether positive or negative (Jeschke et al., 2014).

Introduction pathways The processes and mechanisms behind the human-mediated transportation and introduction of non-native species from one geographic location to another (Hulme et al., 2008). These introductions can be either intended by humans or unintentional.

Invasion process See 'invasive species.'

Invasion syndrome A combination of pathways, alien species traits and characteristics of the recipient ecosystem that collectively result in predictable dynamics and impacts, and that can be managed effectively using specific policy and management actions (Novoa et al., 2020).

Invasive species Species that have successfully completed the invasion process, i.e. they have: (i) been intentionally or unintentionally transported by human action from their native range to a new range; (ii) been released there or escaped into the wild; (iii) have established one or more self-sustaining populations; and (iv) have spread substantially beyond their point(s) of release or escape (Blackburn et al., 2011; Jeschke et al., 2013). Synonyms of invasive species are 'invasive alien species' or 'invasive non-native species.'

Management of biological invasions Actions that reduce the presence, abundance or impact of non-native species. These actions may: (1) prevent a non-native species from entering a new area (prevention and captive management); (2) if introduced, may remove it before it becomes widely established (eradication); and (3) if it becomes widely established, may limit its impact by reducing spread and abundance (long-term management). Management may also include actions that reduce impact without affecting the presence or abundance of non-native species. These actions include: (4) impact adaptation; and (5) environmental restoration after species removal (Robertson et al., 2020).

Non-native species Species that have been intentionally or unintentionally transported by human action from their native range to a new range (Blackburn et al., 2011). Non-native species are also called 'alien species,' 'exotic species' or 'non-indigenous species.' Therefore, non-native species are not necessarily invasive, but invasive species as defined above are always non-native.

SEICAT Short for Socio-Economic Impact Classification for Alien Taxa, a standardized system to assess socio-economic impacts of non-native species (Bacher et al., 2018) that complements EICAT (which focuses on environmental impacts, see above).

Introduction to the topic

Biological invasions are a key stressor of biodiversity (IPBES, 2019; Pyšek et al., 2020) and have important impacts on socio-economics in a broad sense (including culture, religion, human health, safety, livelihoods and other aspects of human well-being) (Pyšek et al., 2020). There is often confusion about what is meant by 'impact' in the context of biological invasions, which is why we start the main part of this chapter with an outline of the different meanings of this term. We also outline how impacts of non-native species can be categorized and assessed, using the IUCN EICAT scheme as an example (which assesses biodiversity impacts; Blackburn et al., 2014; Hawkins et al., 2015; IUCN, 2020a, b), together with the associated SEICAT scheme (which assesses socio-economic impacts; Bacher et al., 2018). A key benefit of such schemes is that they help identify non-native species that have particularly severe impacts in order to prioritize management actions. The management of non-native species is the second focus of this chapter. We provide a detailed description of a management framework and each of its components.

This chapter is complementary to two other chapters on biological invasions in this encyclopedia. These give a general introduction to biological invasions with a focus on their introduction, establishment and spread, and feature case studies of freshwater invaders, respectively.

Defining the impact of non-native species

As for many other key terms in ecology and related disciplines, the term 'impact' is widely used in the context of biological invasions, and often with quite different meanings. This is unsurprising, as an array of people with various backgrounds and perspectives are interested in invader impacts. Often, the definition of impact is not explicitly provided, which can make interpretation difficult. Unclear terminology hampers the progress of science, the growth of knowledge and the translation of scientific findings into practical applications (Jeschke et al., 2019), for example to manage the impacts of non-native species.

What are the different meanings of 'impact' in the context of biological invasions? Fig. 1 (modified from Jeschke et al., 2014) gives an overview. First, some authors only consider unidirectional effects, focusing on either the negative or positive consequences of the presence of non-native species. In contrast, others consider bidirectional effects, i.e. both negative and positive consequences. The IUCN EICAT scheme outlined below is an example of a framework that only considers unidirectional effects, in this case negative effects on the environment (Blackburn et al., 2014; Hawkins et al., 2015; IUCN, 2020a, b). A complementary scheme that also considers positive effects on the environment is currently in preparation.

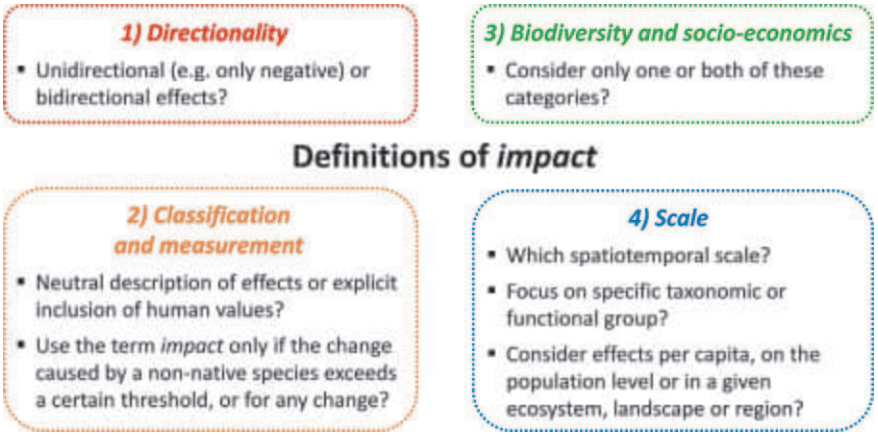

Fig. 1 To clearly define *impact* in the context of biological invasions, several questions need to be addressed. These fall into four categories: (1) directionality, (2) classification and measurement, (3) biodiversity and socio-economics and (4) scale. Modified from Jeschke JM, Bacher S, Blackburn TM, Dick JTA, Essl F, Evans T, Gaertner M, Hulme PE, Kühn I, Mrugała A, Pergl J, Pyšek P, Rabitsch W, Ricciardi A, Richardson DM, Sendek A, Vilà M, Winter M, and Kumschick S (2014) Defining the impact of non-native species. *Conservation Biology* 28: 1188–1194.

Second, some authors aim to define and measure the impacts of non-native species in a way that excludes human values as far as possible. In contrast, others intentionally and explicitly include human values. The former typically focus on measures such as absolute or relative changes caused by non-native species (e.g. percentage decrease in the population size of a native species). They aim to describe changes caused by non-native species, but not to evaluate if they are desirable ('good') or undesirable ('bad') from a certain perspective or for different stakeholders. Other authors explicitly aim for such an evaluation (cf. Bartz et al., 2010). Indeed, different stakeholders often have contradictory perspectives on the impacts of non-native species. For example, while anglers often consider it desirable to have the opportunity to catch exotic fish species in their local water bodies, conservationists are concerned about the detrimental impacts that these fishes can have on native species (see e.g. the rainbow trout (*Oncorhynchus mykiss*) conflict, Woodford et al., 2016). When discussing the classification and measurement of impacts caused by non-native species, an important aspect is the extent of the impact. That is, whether the change caused by a non-native species needs to exceed a certain threshold to be called an 'impact' or whether any change (including a very small one, as long as it is detectable) is sufficient.

Third, some authors focus on biodiversity impacts of non-native species (e.g. Blackburn et al., 2014 when developing the EICAT scheme), others on socio-economic impacts (e.g. Bacher et al., 2018 when developing the SEICAT scheme, and see the next section for details about these schemes). Included in this second group are impacts that can be monetized (i.e. they are quantifiable in euros, dollars or other financial currencies; e.g. Pimentel et al., 2005; Lovell et al., 2006; Diagne et al., 2020). Regulations on biological invasions also focus on different types of impacts. For instance, the EU Regulation 1143/2014 (EU, 2014) concentrates on biodiversity impacts of non-native species, which is why the list of 'Invasive Alien Species of Union concern' (EU, 2016, 2017, 2019) is mainly composed of species with such impacts (still, socio-economic impacts are not completely ignored by this regulation).

Fourth and finally, the scale used to define the impacts of non-native species can also vary. Spatial scale can range from local to global. The EICAT scheme, for instance, is typically applied at the global level, but it can also be applied at continental, national, regional or local levels. Regarding the temporal scale, relatively few studies about biological invasions have a mid- to long-term perspective, while the majority of studies cover short timespans (Strayer et al., 2006). Further, some authors focus on certain taxonomic or functional groups. Traditionally, the field of invasion biology has a strong focus on terrestrial species, mainly plants and, to a lesser degree, vertebrates and invertebrates, whereas aquatic species are only considered in a relatively small number of studies (Pyšek et al., 2008; Jeschke et al., 2012; Jeschke and Heger, 2018). Finally, some authors refer to per-capita impact, others to impacts of a non-native species' population or in a given ecosystem, landscape or larger geographic or political region, such as a county or country. According to Parker et al.'s (1999) widely used impact equation, the total impact of a given non-native species in a geographic region is the product of its range size, its average population density and its per-capita impact. However, a linear relationship between impact and population density cannot usually be expected (Thiele et al., 2010; Strayer, 2020).

Assessing the impact of non-native species

The environmental and socio-economic impacts of non-native species can be severe. For example, they have caused native species extinctions (Blackburn et al., 2019) and threaten human livelihoods in developing countries by adversely affecting agricultural production and hence food security (Perrings, 2005). Unfortunately, comprehensive data on biological invasions is often lacking, making it difficult to identify their causes and consequences, and the non-native species we should prioritize for management (Kumschick et al., 2015; Hoffmann and Courchamp, 2016; Wilson et al., 2016). A current challenge for invasion science is to find ways to quantify and categorize the impacts of non-native species in a standardized manner, to support comparisons across geographic regions, habitats and taxonomic groups (Nentwig et al., 2010). To this end, numerous schemes have been developed (see e.g. González-Moreno et al., 2019; Vimercati et al., 2020). We highlight two of them here, the Environmental Impact Classification for Alien Taxa (EICAT) (Blackburn et al., 2014; Hawkins et al., 2015; IUCN, 2020a, b) and the Socio-Economic Impact Classification for Alien Taxa (SEICAT) (Bacher et al., 2018) (Fig. 2).

Environmental impact classification for alien taxa (EICAT)

The main aim of EICAT is to enable research scientists and other stakeholders to identify variation in the severity and type of environmental impacts caused by different non-native species. EICAT facilitates clear comparisons regarding the severity and type of these impacts occurring in different regions of the world and caused by different taxonomic groups of non-native species. Following published guidelines (IUCN, 2020a, b), semi-quantitative impact descriptions are used to allocate a non-native species to one of five impact categories, depending on the most severe documented impacts it has caused. The categories are: Minimal Concern (MC – meaning that while the non-native species interacts with a native species, it causes no discernible impacts); Minor (MN – the non-native species causes impacts that affected the performance of individual native species); Moderate (MO – the non-native species causes declining populations of one or more native species); Major (MR – the non-native species causes native species extirpations that would be reversible if the non-native species was removed); and Massive (MV – the non-native species causes irreversible native species extinctions).

Each non-native species is also categorized by the type of impacts it causes according to 12 mechanisms: (1) competition, (2) predation, (3) hybridization, (4) transmission of disease, (5) parasitism, (6) poisoning/toxicity, (7) bio-fouling or other direct physical disturbance, (8) grazing/herbivory/browsing, (9, 10, 11) chemical, physical, or structural impact on ecosystem, and (12) indirect impacts through interactions with other species.

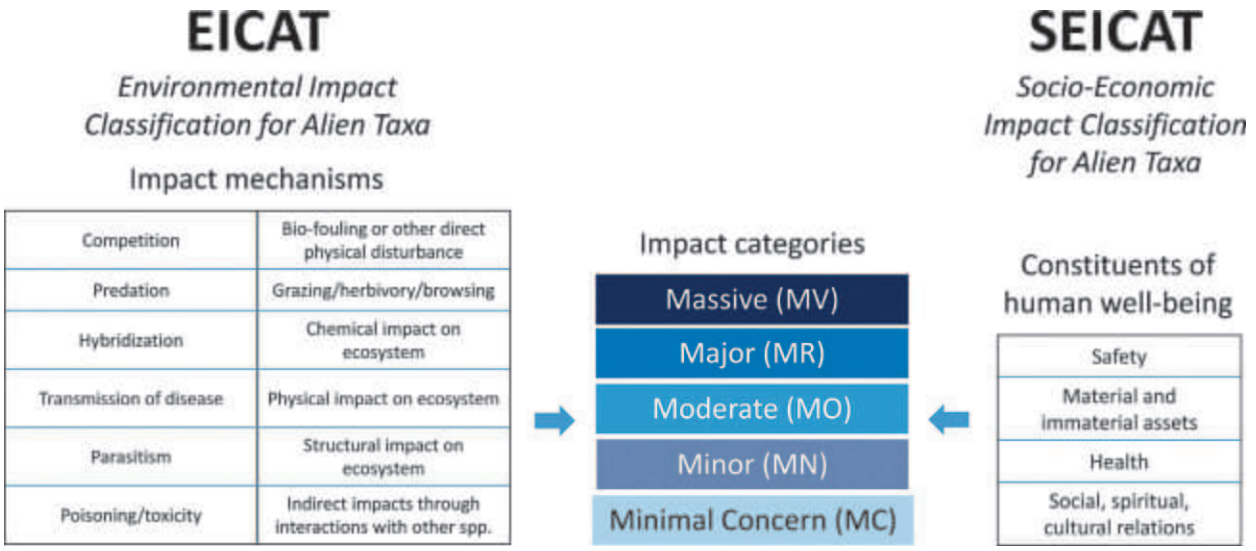

Fig. 2 The EICAT and SEICAT impact classification schemes focus on environmental and socio-economic impacts, respectively. Both schemes can be used to classify non-native species according to the severity of their impacts into one of five impact categories, from Minimal concern (MC) to Massive (MV). EICAT thereby discriminates 12 impact mechanisms, while SEICAT considers four constituents of human well-being and how these are affected by non-native species. See main text for details and references.

EICAT was adopted by the IUCN in 2020 as its formal method for categorizing and assessing the impacts of non-native species. It has been applied to various taxonomic groups including non-native birds (Evans et al., 2016), amphibians (Kumschick et al., 2017), fishes (Galanidi et al., 2018), gastropods (Kesner and Kumschick, 2018) and bamboos (Canavan et al., 2019). Data from EICAT assessments have been used to identify the characteristics of non-native bird species that have the most severe impacts (Evans et al., 2018a) and the characteristics of native bird species that make them vulnerable to the impacts of non-native bird species (Evans et al., 2021). EICAT assessments have also been used to identify the factors that influence why we have impact data for some non-native bird species (Evans et al., 2018b) and for some regions of the world (Evans and Blackburn, 2020), but not others. EICAT may therefore be used to direct research to identify impacts associated with data-deficient species and regions.

Socio-economic impact classification for alien taxa (SEICAT)

SEICAT has been developed analogously to EICAT to provide a standardized method for categorizing and assessing the wide-ranging socio-economic impacts caused by non-native species. It is based on the capability approach from welfare economics and uses changes in human activities that result from the impacts of non-native species to assess the severity of these impacts. SEICAT enables direct comparisons to be made regarding the severity of impacts to human well-being occurring in different regions of the world and caused by different taxonomic groups of non-native species.

As with EICAT, a series of impact descriptions are used to allocate a non-native species to one of five impact categories, depending on the most severe documented impacts it has caused. The categories are: Minimal Concern (MC – meaning that the impacts caused by a non-native species do not affect human well-being); Minor (MN – the non-native species causes impacts that make it difficult for people to participate in their normal activities and individuals suffer in at least one constituent of human well-being (e.g. security, material assets, health)); Moderate (MO – the non-native species causes impacts that result in a reduction in the size of an activity, with fewer people participating in it (e.g. the partial abandonment of an activity)); Major (MR – the non-native species causes impacts that result in the local disappearance of an activity from all or part of an area it has invaded (e.g. people switch to other activities), but this impact is considered to be reversible if the non-native species is controlled or removed); and Massive (MV – the non-native species causes impacts that result in the local disappearance of an activity, and this change is likely to persist for at least a decade, even if the non-native species is controlled or removed).

Unlike EICAT, SECIAT does not include a standardized set of impact mechanisms through which to categorize the types of impacts caused by a non-native species. Instead, these are determined during the SEICAT assessment by the assessor, taking into account different constituents of human well-being (based on MEA, 2005). These include safety (e.g. personal safety, secure resource access, security from disasters), material and immaterial assets (adequate livelihoods, sufficient food, shelter, access to goods), health (strength, feeling well, access to clean air and water) and social, spiritual and cultural relations (social, spiritual and cultural practice, mutual respect, friendship). For example, a SEICAT assessment undertaken for non-native birds (Evans et al., 2020) identified impacts to human safety (resulting from bird strikes with aircraft), livelihoods (through impacts to agriculture such as damage to soft fruit crops), and social and cultural assets (for example through the fouling of sports pitches and recreational facilities). Aside from non-native birds, SEICAT assessments have so far been undertaken for amphibians (Bacher et al., 2018), gastropods (Kesner and Kumschick, 2018) and fishes (Galanidi et al., 2018).

Freshwater invaders on high-impact lists

Several lists have been produced that identify non-native species with particularly high known impacts. We focus on two of these lists here – one at the global level, the other specific to continental European level; highlighting the freshwater invaders included in both.

At the global level, a well-known list of high-impact invaders has been compiled by IUCN's Invasive Species Specialist Group (ISSG). This list is called '100 of the World's Worst Invasive Alien Species' and is accessible online at the Global Invasive Species Database (GISD): http://www.iucngisd.org/gisd/100_worst.php. Importantly and as the name implies, this list does not claim to include *the* 100 worst invasive species. Instead, it includes 100 invasive species that are *among* the worst. Rather than following a particular impact assessment, the ISSG selected species for this list based on the following criteria: "their serious impact on biological diversity and/or human activities, and their illustration of important issues surrounding biological invasion. To ensure the inclusion of a wide variety of examples, only one species from each genus was selected" (quote from above-given website, accessed 17 October 2020). The list was first compiled in 2000 and updated in 2004 and 2013. Of the 100 species in this list, 24 can be considered freshwater species (including those that partly live in fresh waters, e.g. amphibians) (Table 1). Once more invasive species have been assessed with the new IUCN EICAT standard, the IUCN list of high-impact invaders might be updated again.

At the continental level, we highlight the EU list of 'Invasive Alien Species of Union concern': https://ec.europa.eu/environment/nature/invasivealien/list/index_en.htm (EU, 2016, 2017, 2019). This list relates to EU Regulation 1143/2014 (EU, 2014) which focuses on the biodiversity impacts of non-native species. As such, these species have been listed from a conservation perspective. The European Commission and EU member states can propose species to be listed. These proposals are supported by scientific risk assessments, which are reviewed by the Scientific Forum established under the regulation. Final decisions on the listing of species

Table 1 Freshwater species included in IUCN's list '100 of the World's Worst Invasive Alien Species' and the EU list of 'Invasive Alien Species of Union concern' (which currently includes 66 species altogether).

100 of the World's Worst Invasive Alien Species	*Invasive Alien Species of European Union concern*
Vertebrates	
Clarias batrachus (walking catfish)	*Alopochen aegyptiacus* (Egyptian goose)
Cyprinus carpio (common carp)	*Lepomis gibbosus* (pumpkinseed)
Eleutherodactylus coqui (common coquí)	***Lithobates catesbeianus* (American bullfrog)**
Gambusia affinis (western mosquitofish)	***Myocastor coypus* (coypu, nutria)**
Lates niloticus (Nile perch)	*Ondatra zibethicus* (muskrat)
***Lithobates catesbeianus* (American bullfrog)**	*Oxyura jamaicensis* (ruddy duck)
Micropterus salmoides (largemouth bass)	*Perccottus glenii* (Amur sleeper)
***Myocastor coypus* (coypu, nutria)**	*Plotosus lineatus* (striped eel catfish)
Oncorhynchus mykiss (rainbow trout)	*Pseudorasbora parva* (stone moroko)
Oreochromis mossambicus (Mozambique tilapia)	***Trachemys scripta* (red-eared, yellow-bellied and Cumberland sliders)**
Rhinella marina (cane toad)	
Salmo trutta (brown trout)	
***Trachemys scripta elegans* (red-eared slider)**	
Invertebrates	
Aedes albopictus (Asian tiger mosquito)	***Eriocheir sinensis* (Chinese mitten crab)**
Anopheles quadrimaculatus (malaria mosquito)	*Faxonius limosus* (spiny-cheek crayfish)
Carcinus maenas (European green crab)	*Orconectes virilis* (virile crayfish)
Cercopagis pengoi (fishhook waterflea)	*Pacifastacus leniusculus* (signal crayfish)
Dreissena polymorpha (zebra mussel)	*Procambarus clarkii* (red swamp crayfish)
***Eriocheir sinensis* (Chinese mitten crab)**	*Procambarus virginalis* (marbled crayfish)
Pomacea canaliculata (golden apple snail)	
Plants	
***Eichhornia crassipes* (water hyacinth)**	*Alternanthera philoxeroides* (Alligator weed)
***Salvinia molesta* (giant salvinia)**	*Cabomba caroliniana* (Carolina fanwort)
Other taxonomic groups	***Eichhornia crassipes* (water hyacinth)**
Aphanomyces astaci (crayfish plague pathogen)	*Elodea nuttallii* (Nuttall's waterweed)
Batrachochytrium dendrobatidis (amphibian chytrid fungus)	*Gymnocoronis spilanthoides* (Senegal tea plant)
	Hydrocotyle ranunculoides (floating pennywort)
	Lagarosiphon major (curly waterweed)
	Ludwigia grandiflora (water primrose)
	Ludwigia peploides (floating primrose-willow)
	Myriophyllum aquaticum (parrot's feather)
	Myriophyllum heterophyllum (broadleaf watermilfoil)
	***Salvinia molesta* (giant salvinia)**

Six freshwater species (highlighted in bold) are included in both lists.

are political, being made by the European Commission and the IAS Committee, which includes representatives from all EU member states. This list is of high practical importance, as the listed species are the focus of management actions in the EU member states. The list focuses on the EU as a whole, and species can only be listed if they are non-native to the entire EU region. This means that, for example, Ponto-Caspian invaders such as the round goby (*Neogobius melanostomus*) cannot be included (such species could be listed as invasive alien species of regional concern). The list was first published in 2016 and included 37 species (EU, 2016); the first update in 2017 added 12 species (EU, 2017) and the second update in 2019 added another 17 species (EU, 2019). Given it is a dynamic list, the number of species it includes will continue to vary over time. Of the 66 currently listed species, 28 (42%) can be considered freshwater species (Table 1). This is a strikingly high number, as freshwater invaders are much less frequently researched than terrestrial ones (Pyšek et al., 2008; Jeschke et al., 2012; Jeschke and Heger, 2018).

Management of non-native species

Framework for the management of non-native species

As a species enters, establishes and spreads within a new environment, the opportunities and objectives of management change. Our main focus here is on active management – actions taken that directly influence the presence or abundance of the focal non-native species. Active management can help achieve the following specific goals: (1) it may prevent a non-native species from entering a new area; (2) if the species is introduced, active management may remove it before it becomes widely established; and (3) if it becomes widely established, active management may limit its impact by reducing spread and abundance. Robertson et al. (2020) provide a framework for the management of non-native species, based on changing species status during the invasion process, and the different forms of management that apply to each stage (Fig. 3). Management may also include actions that reduce impact without affecting the presence or abundance of the focal non-native species, in particular through (4) impact adaptation or (5) environmental restoration after species removal. Finally, we also outline how identifying invasion syndromes (see Glossary) may improve the future management of non-native species.

A range of supporting methods are widely used to guide active management, but do not in themselves involve any form of intervention. These include informing the public and raising awareness (Eiswerth et al., 2011); early detection and monitoring (Trebitz et al., 2017); risk analysis, which includes risk assessment (Mandrak and Cudmore, 2015), risk management (Booy et al., 2017) and risk communication (Verbrugge et al., 2014); contingency planning (Wittenberg and Cock, 2005); and analysis of costs (Oreska and Aldridge, 2011). All of these support active management and help ensure that it is well targeted, feasible and cost-effective.

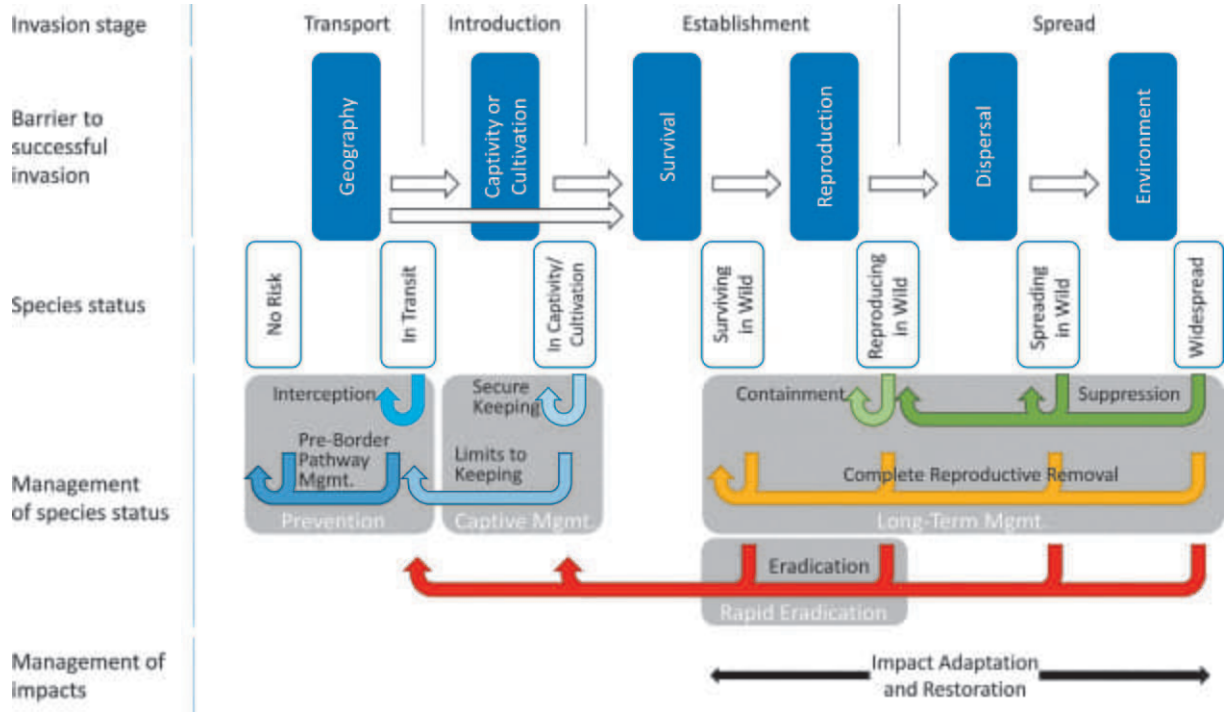

Fig. 3 Framework of the possible management actions during a biological invasion (Robertson et al., 2020). The barriers to successful invasion described by Blackburn et al. (2011) are represented by blue bars. The descriptions of species status associated with the barriers are presented as white boxes. The different forms of management and their associated changes in species status are represented by colored arrows. Four groups of related management actions are represented by grey boxes with white labels.

Some regions, particularly in the Southern Hemisphere, have well developed systems to apply the full range of management options. The New Zealand archipelago has the largest number of established non-native plants compared with other islands (Hulme, 2020). As such, New Zealand is a global leader in tackling plant invasions through stringent biosecurity measures. New Zealand's intended appropriate level of protection is strict compared with that of most other developed countries and operates pre-border control with a 'guilty until proven innocent' approach (Brenton-Rule et al., 2016). Investment in invader management in New Zealand, Australia and South Africa is highly prioritized. In New Zealand, this is supported by legislation (Biosecurity Act 1993, http://www.legislation.govt.nz/act/public/1993/0095/latest/DLM314623.html), particularly for aquatic non-native species, which are generally understudied (Champion, 2018). In South Africa, efforts to manage and regulate invasions began in the 19th century, leading to a wealth of knowledge on the management of non-native species (van Wilgen et al., 2020). In the following sections, we review the different forms of management.

Prevention

Preventing the introduction of non-native species is usually considered a preferable option in management, as the costs for doing so are often significantly lower than those for eradication and long-term control measures necessary once a species is established and spreading. The focus lies on pre-border pathway management, i.e. on reducing the uptake of non-native species and their transport, as well as on the interception of individuals when they first enter a country or other area of interest (Robertson et al., 2020). Successful prevention of non-native species introductions thus critically depends on identifying the relevant introduction pathways. Subsequent to the identification of relevant pathways, these need to be prioritized (e.g. according to the total number of species introduced by each pathway) to maximize management effectiveness in view of the generally limited available resources. Following this approach, management may target pathways shared by several non-native species or shared attributes of different pathways (Hulme et al., 2008).

Pathway identification and prioritization is increasingly integrated into international goals of biodiversity conservation, such as Aichi Target 9 (CBD, 2010), as well as in invasion policy, such as EU regulation No 1143/2014 on invasive alien species (EU, 2014; Rabitsch et al., 2018). In this context, a working collaboration and coordination between countries (especially when they have shared borders) and/or with private companies (e.g. when non-native species of economic interest need to be managed) is another challenge for successful management. Furthermore, pathways and their prioritization need to be regularly updated, as the importance of introduction pathways changes over time, for example due to changes in trade activities (Ricciardi, 2006; Hulme et al., 2008; Essl et al., 2015; Pagnucco et al., 2015).

Despite increasing efforts, our knowledge about the specific pathways used by different non-native species (and about potential regional differences) is still incomplete. This is especially true in regard to unaided introductions, i.e. the secondary natural dispersal of non-native species across borders (e.g. Saul et al., 2017), which may be of particular importance for freshwater species using the large number and extent of continental waterways. So far, shipping ballast water has been identified as a major pathway for the transport of aquatic species (Werschkun et al., 2014), which is why international agreements have introduced measures to reduce the risks of invasive species transport by this route (i.e. pre-border management; Tsolaki and Diamadopoulos, 2010). For the interception of individuals of non-native species, many countries rely on processes of inspection on entry, but this faces many challenges. It mostly applies to formal imports, yet the growth of international online trade has led to alternative routes of entry for species such as aquatic weeds (Kay and Hoyle, 2001). Further, given the diversity of aquatic species and their often cryptic nature, identification can be challenging, although modern genetic barcoding offers a potential solution in some circumstances (Collins et al., 2012).

Captive management

Species may be introduced to an area but held in captivity or under controlled conditions without free-living populations. Such captive populations, however, can provide a route of entry to the wild. With regard to inland waters, this applies especially to species occurring in garden ponds, in aquaria or aquaculture. Two forms of management are available to reduce the risk of these captive species establishing free-living populations in the wild: (1) limits to keeping, and (2) secure keeping. Keeping of a species may be limited by way of legislation. For example, all species listed as Invasive Alien Species of Union concern under EU regulation (EU, 2014) are prohibited from being kept, bred, transported, sold, used or exchanged, allowed to reproduce, to be grown or cultivated, or released into the environment (EU, 2014). Secure keeping, on the other hand, involves intensified measures to reduce the risk that captive species may escape control and establish in the wild. This may include increased biosecurity (e.g. quarantine) and licensing approaches.

Despite the potential use of captive management, escapes from captivity remain an important introduction pathway for freshwater invaders. They include accidental and intentional escapes of species from the aquarium trade (Padilla and Williams, 2004; Magalhães et al., 2017; Banha et al., 2019) and the aquaculture trade (the farming of fish, shellfish and aquatic plants), which is considered a key vector for aquatic invasive species worldwide (Naylor et al., 2001). Here, biosecurity measures exist that aim to protect managed or cultured populations of aquatic species, as well as the wider environment, from disease and pests (Hine et al., 2012), but ensuring their effectiveness can be challenging as there are a wide range of species cultured under a variety of conditions (regarding e.g. containment, intensity of practice, type of management) (Subasinghe, 2005). The main introduction pathways by aquaculture activities are escape via effluent water, inappropriate management and rupture or overflow of ponds after floods

(Forneck et al., 2016). In freshwater systems, which feature high levels of connectivity between water bodies, this leads to the repeated spread of invaders. For example, Nile tilapia (*Oreochromis niloticus*) originating from fish aquaculture in Brazil are now widespread and established from North to South America. This invasive species changes community structure, reduces abundance of planktonic microcrustaceans, lowers water transparency, and increases the abundance of microalgae (Vitule et al., 2009). Aquaculture is a very efficient way of producing proteins for human consumption, and the rapid expansion of this sector warrants special care to avoid the spread of even more invasive species.

Eradication

If an invasive species has established itself in a new environment, then eradication is a favored option. Eradication has been defined as the complete and permanent removal of all wild populations from a defined area by a time-limited campaign (Bomford and O'Brien, 1995). The objective of this approach is clear – complete and permanent removal – but care is needed to define the area involved. Scale is also a significant challenge for the use of this approach. This can be particularly difficult in aquatic environments. Connectivity among water bodies and the flow of water through landscapes increases opportunities for species dispersal, thereby increasing the area of invasion to be addressed. This creates unique challenges for the control and management of aquatic invaders. Detection of non-native species in aquatic habitats is also difficult due to lack of visibility, and control options are often limited. Successful eradication of aquatic species has mainly been achieved at small spatial scales, predominantly in ponds and lakes. Examples include the eradication of the invasive fish species top-mouth gudgeon (*Pseudorasbora parva)* from small fishing lakes (Britton et al., 2008) and of the invasive aquatic plant giant salvinia (*Salvinia molesta)* from ponds in South Carolina, USA (Mack and Lonsdale, 2002). In both cases was the invasive species detected soon after arrival, established in a small area and was removed prior to further spread into neighboring river systems.

Eradication in aquatic habitats often involves extreme measures such as chemical spraying and water draining. In order to remove signal crayfish (*Pacifastacus leniusculus*) from five small water bodies in the North Esk catchment, Scotland, biocide treatment was applied to both the aquatic and adjacent terrestrial habitats. Prior to treatment, through flow was stopped and fish had to be removed, followed by lengthy biomonitoring to test water-quality conditions (Peay et al., 2006). Eradications from open river systems are scarcer, although work in Norway has included the eradication of the salmonid parasite *Gyrodactylus salaris* from entire river systems by treatment with rotenone to temporarily remove their fish hosts (Sandodden et al., 2018). Many documented success stories of eradication within aquatic environments have targeted non-discrete invader populations, and would be better described as complete reproductive removal, as they will need ongoing management to maintain the areas as clear of the species (Robertson et al., 2020). While eradication of some species may be possible in small enclosed water bodies, the feasibility and cost change rapidly as the size of the water body increases, and become particularly challenging in open water systems. Risk management methods are available to help assess and prioritize cases where eradication may or may not be feasible (Booy et al., 2017). As a consequence, considering eradication in aquatic systems is often focused on a rapid response, detecting and removing the species before it has had a chance to spread (Vander Zanden et al., 2010).

Long-term management

If a non-native species has established and eradication is not feasible, then the population will remain and has the potential to spread. In this case, the objective of management is typically driven by the need to reduce the impacts of the species and will require continued management inputs for the foreseeable future. Long-term management of this sort includes three different management approaches: (1) complete reproductive removal; (2) containment; and (3) suppression.

Complete reproductive removal aims to eliminate the entire reproductive population of a species from the area of interest. This management method has similarities to eradication, but requires an on-going effort to maintain the area in the face of dormant life stages such as seeds, or the continued influx of new individuals from neighboring areas. If not, there remains the risk of re-invasion, further reproduction or the remaining presence of non-breeding forms. Examples of this approach include the removal of semi-aquatic American mink (*Neovison vison*) from a large area in Northern Scotland. Although mink populations remain in neighboring areas, ongoing management aims to prevent the re-establishment of breeding mink populations in the cleared area (Bryce et al., 2011). The ruddy duck (*Oxyura jamaicensis*) has been removed as a breeding species from the United Kingdom, and work is ongoing in neighboring countries to remove the species from Europe (Robertson et al., 2015). However, until eradication is complete at a continental scale, ongoing management is required to prevent the species from re-establishing.

Containment includes measures to limit the spread of a reproducing population. This approach includes any action aimed at creating barriers that minimize the risk of an invader population to disperse and spread beyond the invaded area (EU, 2014). Networks of connected inland waters offer opportunities for species spread, and methods to assess the risks and routes of spread are used to prioritize action (Vander Zanden and Olden, 2008). This can be particularly important when new developments such as canals (Leuven et al., 2009) or bulk water transfer (Gallardo and Aldridge, 2018) allow spread between previously isolated catchments. Management can include methods to reduce the risks of local spread through the movement of boats or equipment (Anderson et al., 2015), or the construction of barriers to limit species spread (Lavis et al., 2003; Robinson et al., 2019).

Suppression includes measures to reduce the distribution or abundance of a population within the area of interest. Suppression is a widely used form of management, and its objectives are typically defined in terms of the degree of suppression or the reduction of impact needed to meet socio-economic or conservation goals (e.g. Pinto et al., 2005). There is a large literature describing

management methods to control different aquatic invasive species including the trapping or shooting of animals (Roy et al., 2015; Robertson et al., 2015), cutting of vegetation (Kettenring and Adams, 2011), excavation and dredging of the substrate, water-level manipulation and desiccation (Coughlan et al., 2018), use of toxins or other chemicals (Christie et al., 2003), biological control (Hill et al., 2020), jets of water or steam (Coughlan et al., 2020) or genetic methods to reduce reproduction of the target species (Twohey et al., 2003). Detailed accounts and reviews are available that describe the options for managing different taxa, including aquatic plants (Hussner et al., 2017), crayfish (Manfrin et al., 2019) and fish (Donaldson and Cooke, 2016).

Suppression of impacts often requires balancing the costs of management with the benefits in terms of reduced impacts. Understanding the form of the relationship between effort and benefit is important to rationalize the choices inherent in long-term management (Norbury et al., 2015). However, as biological systems contain great complexity and uncertainty, adaptive management (Williams, 2011) can be of particular benefit in these circumstances. Adaptive management systems learn through management, applying a sequence of predicting the effects of management based on the best available data, implementing management, monitoring the effects, reviewing the results and updating future predictions based on improved understanding. This approach has particular value for guiding rational management given the uncertainties inherent in natural systems.

Impact adaptation (managing impacts without directly intervening with the invader)

The examples above describe the different forms of direct intervention to manage non-native species. However, in many situations the management objective is to reduce impacts, and this can also be achieved without direct intervention with the respective species. Examples include responding to increased erosion risk by mechanically stabilizing habitats (Bendoricchio et al., 2000), altering human behavior to adapt to the presence of the invasive species (Havel et al., 2015) or compensating landowners for damage caused (Panzacchi et al., 2007).

Restoration

Restoration is the management of the environment following its degradation, for example due to an invasive species. Related terms describing different forms and intensities of management include regeneration, revegetation, replacement, rehabilitation and remediation of a habitat favoring native communities (van Andel and Aronson, 2012). Definitions include 'restoring ecosystems following the removal of invasive species' (van Wilgen et al., 2014) or to 'restore or rehabilitate degraded areas to their proper ecological function [. . .] after invasive species removal' (USDA, 2004).

Restoration of freshwater habitats can be particularly challenging, as they are typically highly connected (river catchments), heavily impacted by humans and difficult to monitor, as most changes occur below the water surface. There are a limited number of successful restoration examples of invaded freshwater habitats (Havel et al., 2015). When restoration efforts are successful, the benefits can be tangible. For example, water hyacinth (*Eichornia crassipes*) is an aquatic plant that can form dense floating mats on the surface of water bodies. These mats alter processes of respiration and primary production, with flow-on effects to food webs; they also reduce connectivity between adjacent water bodies (Perna et al., 2012). Restoration of the heavily invaded Burdekin River floodplain, Australia, following removal of water hyacinth, led to improved water quality and increased connectivity between adjacent lagoons. This resulted in the re-establishment of many native fish populations (Perna et al., 2012).

A lack of funding often prevents the long-term monitoring of restoration sites following the removal of non-native species (Geist and Hawkins, 2016). However, without monitoring it is difficult to deduce the efficacy and longevity of restoration practices in freshwater systems. The Working for Water program was established in South Africa in 1995. In coordination with local communities, the scheme aims to remove invasive species in order to restore water supplies (Binns et al., 2001). Ongoing monitoring and treatments are carried out to maintain restoration sites, which also provides employment opportunities for local communities. Plant invaders in riparian zones can use significantly more water than native species: clearing 25,000 m^2 of invasive trees from river banks within the Western Cape, South Africa, led to an increase in streamflow of an estimated 30,480 l of water per day (Binns et al., 2001), illustrating the links between restoring invaded sites and livelihoods.

Thus, targeted approaches can aid in the success of restoration practices. Restoration projects should also be properly monitored to assess success, thus enabling adaptive management and learning for the future from both successful and unsuccessful restorations (Janssen et al., 2007).

Invasion syndromes

The management framework presented above greatly helps to determine the appropriate management response to individual cases of invasion. Novoa et al. (2020) argue that for being able to deal with the continuously growing number of non-native species, we need to determine groups of invasion events for which similar management goals and responses apply. They propose to delineate invasion syndromes by identifying congruence among invasions regarding the introduction pathways used, the traits of the non-native species, the characteristics of the area of introduction and the invasion outcomes. The expectation is that congruence in these aspects will also lead to congruence in the set of response options that are suitable for managing the respective invasions. By identifying a species as a member of an invasion syndrome, we would know which management measures are likely to be most effective without having to consider a multitude of case-specific details first. Thus, we can act faster and with a higher probability of success, based on sharing of management lessons learnt from previous invasion events. Novoa et al. (2020) describe introduced

piscivorous freshwater fish as an example for a freshwater invasion syndrome. They are often introduced intentionally (e.g. for enhancing fisheries) and primarily invade connected inland waters. Impacts include hybridization with native species, introduction of disease and extirpations of native species by direct predation. The management of invasive freshwater fish turns out to be challenging: they are difficult to eradicate once established, and conflicting values of stakeholders may interfere (see above, e.g. the rainbow trout (*Oncorhynchus mykiss*) conflict, Woodford et al., 2016). Therefore, active management may in this case focus on prevention and long-term management.

Summary

The impact of non-native species has been defined in different ways and from different perspectives. It is therefore important to be aware of the various possible meanings of 'impact' in the context of biological invasions. Similarly, numerous schemes have been developed to assess the impacts of non-native species The EICAT scheme for assessing environmental impacts has recently been adopted as an IUCN standard (Blackburn et al., 2014; Hawkins et al., 2015; IUCN, 2020a, b), and the SEICAT scheme can be analogously used to assess the socio-economic impacts of non-native species (Bacher et al., 2018). These and other schemes have been widely applied, yet freshwater species have been under-assessed when compared with terrestrial species. There are numerous lists of high-impact invasive species, some are legally binding (e.g. the European Union list of 'Invasive Alien Species of Union concern'), while others are not (e.g. the IUCN list of '100 of the World's Worst Invasive Alien Species'). Freshwater species that often appear on high-impact lists include the coypu (*Myocastor coypu*), American bullfrog (*Lithobates catesbeianus*), red-eared slider (*Trachemys scripta elegans*), Chinese mitten crab (*Eriocheir sinensis*), water hyacinth (*Eichhornia crassipes*) and giant salvinia (*Salvinia molesta*).

As for impact, the terminology referring to the management of non-native species is often confusing. However, a standard framework has recently been developed which we outlined above (Robertson et al., 2020). This framework aligns with the invasion process and its consecutive stages (see Glossary and Blackburn et al., 2011). It includes various management actions that either actively target the focal non-native species (prevention, captive management, eradication and long-term management) or reduce impact without affecting the presence or abundance of the focal non-native species (impact adaptation and restoration). Invasion syndromes (Novoa et al., 2020) may be an efficient way of dealing with the continuously growing number of non-native species.

Different stakeholders are involved in the impact and management of non-native species: impact assessment is mainly done by researchers; decisions which species should be listed on legally binding lists of high-impact invaders are mainly made by policy makers; decisions which invaders should be targeted by which management actions are mainly made by national, regional and local authorities; and on-the-ground management is mainly carried out by paid practitioners and unpaid volunteers. All stakeholders have an important role and collaboration is recommended. However, there are often conflicts, and a lack of understanding and communication between stakeholders can hamper effective research, decision-making and management (e.g. Heger et al., 2013; Matzek et al., 2015). Platforms and networks such as the RISCC Network in the Northeast USA (www.risccnetwork.org) are important for bringing stakeholders together and improving mutual understanding.

Knowledge gaps

- Freshwater invasive species are known for their high potential to have strong harmful impacts (see e.g. Vilà et al., 2010 and the EU list of Invasive Alien Species of Union Concern, which includes a high proportion of freshwater invaders, see Table 1), yet only few studies in invasion biology focus on freshwater habitats (Pyšek et al., 2008; Jeschke et al., 2012; Jeschke and Heger, 2018).
- Knowledge about the mid- to long-term impacts of non-native species is critical, yet the majority of studies about biological invasions only cover short timespans (Strayer et al., 2006; Pergl et al., 2020).
- Evidence that is available for those few freshwater invaders that have been investigated in a high number of systems and for longer time periods suggests that their population dynamics and impacts can be highly variable and context-dependent (see e.g. Strayer et al., 2019 for zebra and quagga mussels, *Dreissena polymorpha* and *D. rostriformis*). Better understanding this context-dependency is critical.
- The standardized EICAT and SEICAT schemes for assessing negative impacts of non-native species on biodiversity and socio-economics (as outlined above) do not yet have parallel schemes for assessing positive impacts of non-native species. Such schemes are currently being developed. Schemes assessing positive impacts of non-native species are generally rare compared to those assessing negative impacts (Vimercati et al., 2020). Once they are available, careful evaluation is needed how non-native species with both positive and negative impacts should be managed.
- Since escapes from captivity remain an important introduction pathway for freshwater invaders, more effective ways for captive management need to be found, taking into account the wide range of species cultured under a variety of conditions.
- The number of successful eradications in freshwater systems remain limited. As experience grows and further methods are developed, there is a need to increase the number and scale of eradication programs.

- For many established invasive species, long-term management will be crucial to reduce their impacts. There is a need to develop new and more cost-effective methods of reducing impacts, together with recording and sharing information on costs and best practice.
- Restoration of invaded freshwater habitats is difficult and relies on long-term monitoring which is often limited by lack of funding. Clear restoration targets and assessment of success can aid progression towards better restorations in the future.
- More invasion syndromes (Novoa et al., 2020) have yet to be identified and existing ones need to be refined, so that their full potential for a more effective management can be exploited.

Acknowledgments

We thank Ken Irvine for the invitation to contribute this chapter. His comments on the chapter and those of Thomas Mehner and an anonymous reviewer are highly appreciated as well. JMJ and WCS acknowledge support by the Belmont-Forum-BiodivERsA project InvasiBES through the national funder German Federal Ministry of Education and Research (BMBF; grant 01LC1803A). TE was supported by the Alexander von Humboldt Foundation. This chapter is a contribution of the Invasion Dynamics Network (InDyNet).

Glossary

Alien species See 'non-native species.'

Impact A change or effect of a non-native species on either the environment (i.e. biodiversity) or socio-economics in the broad sense (i.e. including culture, religion, human health, safety, livelihoods and other aspects of human well-being), whether positive or negative (Jeschke et al., 2014).

Introduction pathways The processes and mechanisms behind the human-mediated transportation and introduction of non-native species from one geographic location to another. They can be either intended by humans or unintentional (Hulme et al., 2008).

Invasive species Species that have successfully completed the invasion process, i.e. they have: (i) been intentionally or unintentionally transported by human action from their native range to a new range; (ii) been released there or escaped into the wild; (iii) have established one or more self-sustaining populations; and (iv) have spread substantially beyond their point(s) of release or escape (Blackburn et al., 2011; Jeschke et al., 2013). Synonyms of invasive species are 'invasive alien species' or 'invasive non-native species.'

Management of biological invasions Actions that reduce the presence, abundance or impact of non-native species. These actions may: (1) prevent a non-native species from entering a new area (prevention and captive management); (2) if introduced, may remove it before it becomes widely established (eradication); and (3) if it becomes widely established, may limit its impact by reducing spread and abundance (long-term management). Management may also include actions that reduce impact without affecting the presence or abundance of non-native species. These actions include: (4) impact adaptation; and (5) environmental restoration after species removal (Robertson et al., 2020).

Non-native species Species that have been intentionally or unintentionally transported by human action from their native range to a new range. Non-native species are also called 'alien species,' 'exotic species' or 'non-indigenous species' (Blackburn et al., 2011). Therefore, non-native species are not necessarily invasive, but invasive species as defined above are always non-native.

Introduction to the topic

Biological invasions are a major research focus of ecologists, conservation biologists and scientists in related fields. This is particularly true for terrestrial invaders, but increasingly also for freshwater species. Comparing studies in freshwater and terrestrial habitats suggests that non-native freshwater species have both particularly high invasion success and particularly high impacts in their exotic ranges (Vilà et al., 2010; Jeschke and Heger, 2018). Thus, research insights are clearly needed to allow for a better understanding and more effective management of freshwater invasive species.

This chapter builds on and complements the two previous chapters on biological invasions in this encyclopedia, which focused on (i) the introduction, establishment and spread of non-native species, and (ii) on their impact and management. In the current chapter, case studies of invasive species in different taxonomic groups are featured. The compilation we present here cannot be exhaustive, as that would need an encyclopedia in itself.

We highlight taxonomic groups that either (1) include particularly well-known freshwater invaders (bivalves; crustaceans, here with a focus on crayfish; and fish) or (2) are often overlooked when it comes to freshwater invaders, as they are mainly investigated in terrestrial habitats (plants and mammals). For each taxonomic group, we provide a brief general introduction to their biology and ecology. We also give examples of invasive species within each taxon, particularly high-impact invaders, and indicate where on the globe they are invasive. The main introduction pathways are outlined as well, including a brief description of major events in the taxonomic group's invasion history, and the main ecological and socio-economic impacts. Finally, we describe possible management actions.

Aquatic plants

Aquatic plants (macrophytes) are important components of freshwater ecosystems, affecting diverse ecosystem functions and services (Hilt et al., 2017). Many aquatic macrophyte species have a high invasion potential due to their high propagule pressure, rapid growth, wide environmental tolerance, high phenotypic plasticity and ability to produce allelopathic compounds (Riis et al., 2010; Heidbüchel et al., 2020; Hussner et al., 2021). Biological interactions such as competition, mutual facilitation, invasional meltdown and novel weapons can also be crucial for their invasion success (e.g. Fleming and Dibble, 2015; Wegner et al., 2019). Climate change is expected to result in a range expansion of macrophytes from warmer climates into formerly cooler regions. In general, global warming and habitat disturbance by hydrological and trophic alterations can accelerate the invasion success of non-native aquatic macrophytes. In contrast, the presence of native vegetation can decrease the establishment success of non-native macrophytes (Petruzzella et al., 2018).

Ornamental trade is considered to be the main introduction pathway for invasive aquatic plants (Maki and Galatowitsch, 2004; Peres et al., 2018; Hill et al., 2020). Most traded aquatic plant species are characterized by a low sensitivity to mechanical and handling damage, easy propagation and the ability to grow under a large variety of environmental conditions; traits that are related to their invasiveness in freshwater ecosystems (Azan et al., 2015). Once introduced into a new region, invasive macrophytes spread via sexual and asexual propagules (i.e. stem fragments and tubers or turions; Hussner et al., 2021). Within connected water bodies, these propagules are usually transported by water movement (Heidbüchel et al., 2016, 2020). Overland transport to new water bodies can occur through attachment to water sport equipment (Johnstone et al., 1985; Bruckerhoff et al., 2015) or animals (Van Leeuwen, 2018).

Once established, non-native aquatic plants often rapidly grow and spread, and can cause various significant ecological and socio-economic impacts. Ecosystem functions and services can be hampered, such as fishing, boating and diving, and the aesthetic values of infested waters can be reduced (Janssen et al., 2021). A well-known example is the invasion of the free-floating water hyacinth (*Eichhornia crassipes*, Fig. 1A) into Lake Victoria (Africa). It directly and indirectly affected 30 million people through the

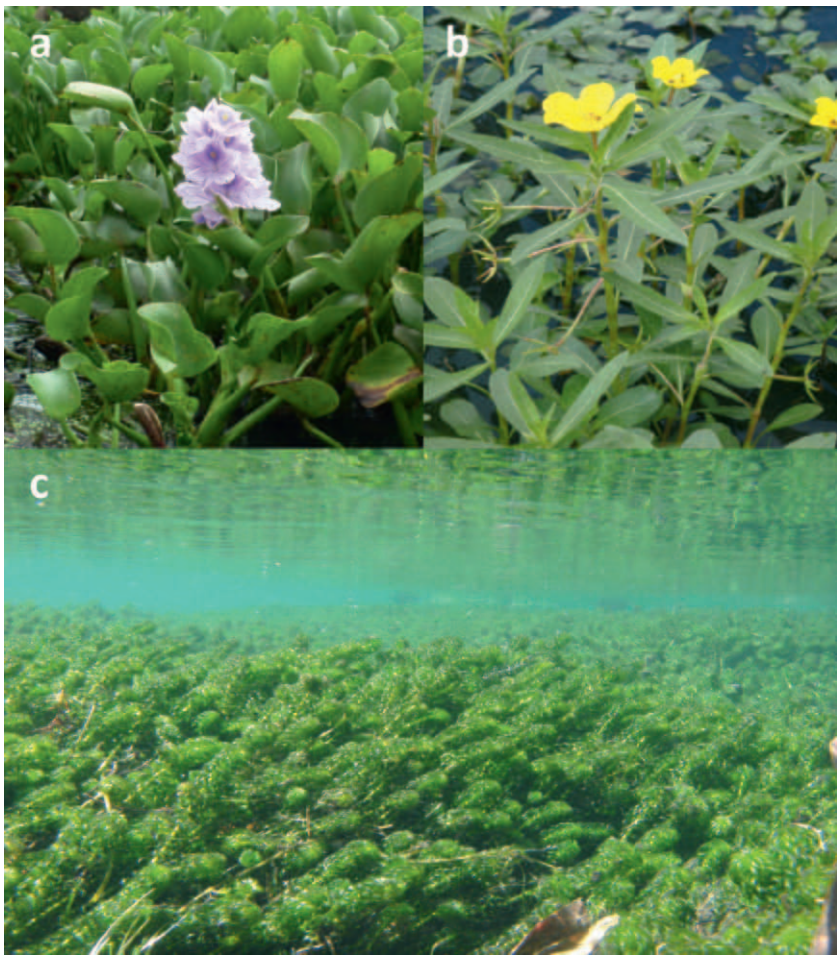

Fig. 1 Three types of invasive aquatic plants: (A) free-floating *Eichhornia crassipes* (water hyacinth), (B) sediment rooted, emerged and floating-leaved *Ludwigia grandiflora* (water primrose) and (C) submerged rooted *Lagarosiphon major* (curly waterweed). Photos: Andreas Hussner.

loss of fisheries, water supply and transport, environmental health and power generation (Aloo et al., 2013). Invasive macrophytes are recognized as a major biodiversity threat. They can change the structure and composition of native macrophyte, zooplankton (Stiers and Triest, 2017), macroinvertebrate (Houston and Duivenvoorden, 2002) and fish communities (Carniatto et al., 2013). Invasive macrophytes can grow in dense mats that limit water flow and light penetration, cause hypoxia or anoxia in the water column and alter nutrient cycling (Urban et al., 2006; Thomaz et al., 2015), productivity and food-web dynamics. Dense stands of invasive macrophytes can trigger stable stratification events and can be involved in a change in the metabolism of ecosystems, resulting in a net nutrient release towards the water column, concurrently with a net increase in carbon emission towards the atmosphere, as recently demonstrated for large infestations of *Lagarosiphon major* (Fig. 1C) and *Egeria densa* in France (Ribaudo et al., 2018). On the other hand, non-native macrophytes can also provide habitat to animals or remove nitrogen from inland waters (Strayer et al., 2003; Tall et al., 2011). Overall, current knowledge on the impacts of non-native macrophytes is restricted to a few species (e.g. Table 1).

The most effective management action against invasive macrophytes is preventing their introduction (Hussner et al., 2017). Trading bans are a major tool and should be based on Pest Risk Assessment scorings of plant characteristics, such as habitat versatility, competitive ability, reproductive output, dispersal mechanisms and the range of potential impacts. The Aquatic Weed Risk Assessment Model (AWRAM, Champion and Clayton, 2000) has been successfully established in New Zealand and Australia (see Table 1 for AWRAM scores of invasive macrophytes in New Zealand and the USA) to guide the import control and management of invasive and potentially invasive macrophytes. Early detection and rapid response increase the likelihood of eradication of invasive macrophytes. Maintenance of invasive macrophyte stands, however, often only come into play after a species has spread and causes nuisance, or if eradication measures have failed (Hussner et al., 2017; Simberloff, 2021). The eradication and management of invasive macrophytes comprise a range of biological, chemical and mechanical control methods that are either applied alone or in combination, and which must be tailored towards the focal species and habitat characteristics (Hussner et al., 2017).

Table 1 Status (native or non-native) and classification of invasiveness of 21 selected macrophyte species in the USA (www.plants.usda.gov; Gordon et al., 2012), South Africa (Coetzee et al., 2011; Hill et al., 2020), China (Wu and Ding, 2019) and New Zealand (Champion and Clayton, 2001); additional information was taken from CABI (2020).

	Species	*USA*	*South Africa*	*China*	*New Zealand*	*EU*

Invasiveness is based on the Aquatic Weed Risk Assessment score (in parenthesis for the USA and New Zealand; maximum score = 100) and for the EU on the List of Invasive Alien Species of Union concern (EU, 2016, 2017, 2019).

Adapted from Hussner A, Stiers I, Verhofstad M, Bakker ES, Grutters B, Haury J, Van Valkenburg J, Brundu G, Newman J, Clayton J, Anderson L, and Hofstra D (2017) Management and control methods of invasive alien freshwater aquatic plants: A review. *Aquatic Botany* 136: 112–137.

Bivalves

Although just a few of the world's ca. 1200 species of freshwater bivalves have become invasive, they include some of the world's most widespread, well known, and problematic invaders. The five selected species discussed here come from four widely divergent groups of bivalves, and so have different origins, affinities, biological characteristics and histories of spread. Specifically, two species of Dreissenidae, the zebra mussel (*Dreissena polymorpha*, Fig. 2A) and the quagga mussel (*Dreissena bugensis*), have spread widely from their native ranges in the Black, Caspian and Aral Sea basins. Both are now common and widespread in Europe and North America. Dreissenids have separate sexes, free-swimming planktonic larvae that live for a few weeks and sessile adults that live for 1–10 years (Nalepa and Schloesser, 2014). The golden mussel *Limnoperna fortunei* (Mytilidae, Fig. 2B) is native to south China and perhaps elsewhere in southeastern Asia. It has spread widely elsewhere in Asia and in South America. Its life cycle and general biology are broadly similar to the dreissenids (Boltovskoy, 2015). The Asian clam *Corbicula* (Cyrenidae, Fig. 2C), native to East Asia, is now common and widespread in the Americas and Europe, and recently appeared in Morocco (Crespo et al., 2015). The taxonomy of *Corbicula* is poorly understood, and perhaps two to four species of *Corbicula* are spreading around the world (Lydeard and Cummings, 2019). Most invasive populations of *Corbicula* apparently consist of hermaphrodites reproducing asexually by androgenesis (in which only male nuclear DNA is inherited; Pigneur et al., 2012). Adults typically live for 1–5 years. Finally, the Chinese pond mussel *Sinanodonta woodiana* (Fig. 2D) is a pearly mussel (Unionidae) native to East Asia that is now common and widespread across Europe. Non-native populations have also established outside its native range in Asia, and in Central America and the USA (from which it was apparently eradicated). Larvae of the Chinese pond mussel are parasites on fish. Following this parasitic phase, the burrowing juvenile and adult live in sediments, and may live for 10–15 years (Cummings, 2011).

Invasive bivalves spread through a combination of long-distance leaps across continents and drainage basins via human activities, plus short-distance spread within drainage basins via both natural and human-aided means (see references cited in the previous paragraph). The main human-aided introduction pathways depend on the biology of each species. For species with free-living larvae (all of the species treated here except the Chinese pond mussel), the movement of ship ballast water between continents has been of primary importance. The larvae or small juveniles and adults of these species are also readily transported on recreational boats. The chief pathway for the Chinese pond mussel was the transport of infested carps in aquaculture. The Chinese pond mussel and *Corbicula* are sold as 'biofilters' in the aquarium and water-garden trade.

Most long-distance leaps in freshwater bivalve distributions occurred since 1900, reflecting large increases in intercontinental trade. Zebra mussels spread westward across Europe beginning in 1825 with the opening of new canals, and both zebra and quagga mussels appeared in North America in the 1980s via ballast water introductions. The golden mussel moved into new areas of Asia between 1965 and 1990, and was first seen in South America in 1991. *Corbicula* appeared in western North America in 1924, in the

eastern and central United States in the 1950s, and in South America and Europe in the 1970s. The Chinese pond mussel came into Europe in the 1960s. All of these bivalves are spreading so rapidly that the ranges given here will soon be out of date. Future range expansions will probably include spread into continents and drainage basins not yet occupied, as well as range-filling within already-occupied regions (e.g. Strayer, 2010; Gama et al., 2017; Petsch et al., 2021).

The impacts of invasive bivalves stem from three major mechanisms: (1) removal of phytoplankton and consequent effects on the food web; (2) fouling of human-made structures and animals; and (3) habitat engineering by shell-building (Strayer, 2009, 2010; Higgins and Vander Zanden, 2010; Nalepa and Schloesser, 2014; Sousa et al., 2014; Boltovskoy, 2015). *Sinanodonta* also competes for fish hosts with native unionid mussels (Donrovich et al., 2017). All of the bivalves discussed here feed on phytoplankton and other small particles in the water column. Because they often form dense populations, their feeding can substantially reduce phytoplankton populations, often by 50% or more. Bivalve-caused losses of phytoplankton have led to strong impacts on freshwater ecosystems, including increased water clarity, increased concentrations of soluble nitrogen and phosphorus, declines in zooplankton, native bivalves and suspension-feeders in general, increased growth and coverage of aquatic plants, and changes in fish abundance, growth and distribution. *Dreissena* and *Limnoperna* attach to hard surfaces, including shells of living native bivalves, a process called 'fouling.' They and *Corbicula* block pipes and other water infrastructure, leading to problems for power plants, water intakes and irrigation systems (Nakano and Strayer, 2014). Fouling by *Dreissena* has extirpated or greatly reduced many populations of unionid mussels (Lucy et al., 2014). Finally, both the shells of living bivalves and their empty shells, which may persist for decades after death, change the physical character of aquatic habitats, affecting both their value as habitat for other animals and exchanges of materials between the sediments and water column. Large windrows of shells and decaying animals on beaches may reduce their recreational value.

It is easier and more cost-effective to prevent new invasions by freshwater bivalves than to manage established populations. New invasions can be reduced by managing the vectors that carry bivalves from place to place. For example, regulations, public education and application of better practices can prevent movement of larvae in ballast water, live wells and bait buckets, or of older animals on boat hulls and trailers; it can stop sale of living bivalves in the pet and water-garden trade, reduce deliberate releases of living bivalves into lakes for food or to 'clean up the water' and reduce transport of *Sinanodonta* in contaminated aquaculture stock.

Options are fewer once a bivalve population is established. If the control area is small or isolated, it may be feasible to apply molluscicides (e.g. the bacterial toxin Zequanox® for dreissenids, or potassium chloride) to locally eradicate the bivalve (Fernald and Watson, 2014; Whitledge et al., 2015). In some cases, bivalves may be killed by installing benthic barriers or draining the body of water. In closed settings (e.g. water intakes, power plants), bivalve fouling can be managed using screening, antifouling coatings, chlorine, polyquaternary ammonium compounds, heat, dewatering or mechanical scraping (Mackie and Claudi, 2009; Nalepa and Schloesser, 2014). Because of concerns about feasibility, cost and harmful side-effects, post-establishment control is used widely only in closed settings and not in open waters. If it is not possible to control or eradicate the population of the invasive bivalve itself, it may be possible to reduce some of its harmful effects. For example, imperiled native bivalves can be moved into uninfested waters or propagated in hatcheries or zoos, nuisance aquatic plants that flourish in the newly clearer waters can be cut and oxygen-depleted waters can be aerated. These options have rarely been pursued.

Crayfish

Freshwater crayfish are a diverse group of decapod crustaceans in temperate and subtropical regions that can be found in lotic, lentic and terrestrial habitats. They are native to all continents except continental Africa (seven species occur in Madagascar) and Antarctica. Over 660 species have been described, with hotspots of diversity in the south-eastern USA (>400 species) and south-eastern Australia (>170 species) (Crandall and De Grave, 2017). Many crayfish species, including invasive ones, are able to construct burrows that ensure their survival during droughts (Reynolds et al., 2013). They are 'ecosystem engineers' (see Jones et al., 1994, 2010) that can fundamentally alter the structure and functioning of aquatic ecosystems. As generalist omnivores, crayfish also influence the rates and pathways of nutrient and energy flows (Reynolds et al., 2013).

The economic significance of freshwater crayfish led to their successful introductions around the world (Hobbs et al., 1989; Kouba et al., 2014; Madzivanzira et al., 2021). Their tolerance to a broad range of environmental conditions and high fecundity predisposed them to establish and spread in new ranges (Hobbs and Lodge, 2010; Lodge et al., 2012; Twardochleb et al., 2013). Freshwater crayfish have been traded for direct consumption, aquaculture and stocking for centuries, with documented translocations dating back to the 18th century (Hobbs et al., 1989). More recent introductions are also related to the pet trade and the use of crayfish as fish bait (Souty-Grosset et al., 2006; Oficialdegui et al., 2020; Madzivanzira et al., 2021). As a result, Europe currently harbors the highest number of non-native crayfish species of North American and Australian origin (Kouba et al., 2014), and all crayfish species occurring in continental Africa are of foreign origin (Madzivanzira et al., 2021). North American crayfish species are most frequently introduced, particularly the genera *Faxonius, Pacifastacus* and *Procambarus*. For example, the originally North American red swamp crayfish (*Procambarus clarkii*, Fig. 3A) is now the most widely introduced crayfish species worldwide (Loureiro et al., 2015; shown for Europe in Fig. 3D). Due to its high growth rate and commercial value, it has become established all over the USA (far beyond its native range), in Europe, South America, Africa and Asia (Hobbs et al., 1989; Loureiro et al., 2015; Oficialdegui et al., 2020).

More recently, introductions of *P. clarkii* and many other freshwater crayfish were linked to the pet trade, specifically aquarium releases and garden-pond escapes (Peay, 2009; Patoka et al., 2014; Faulkes, 2015). For more than a decade, trade in ornamental

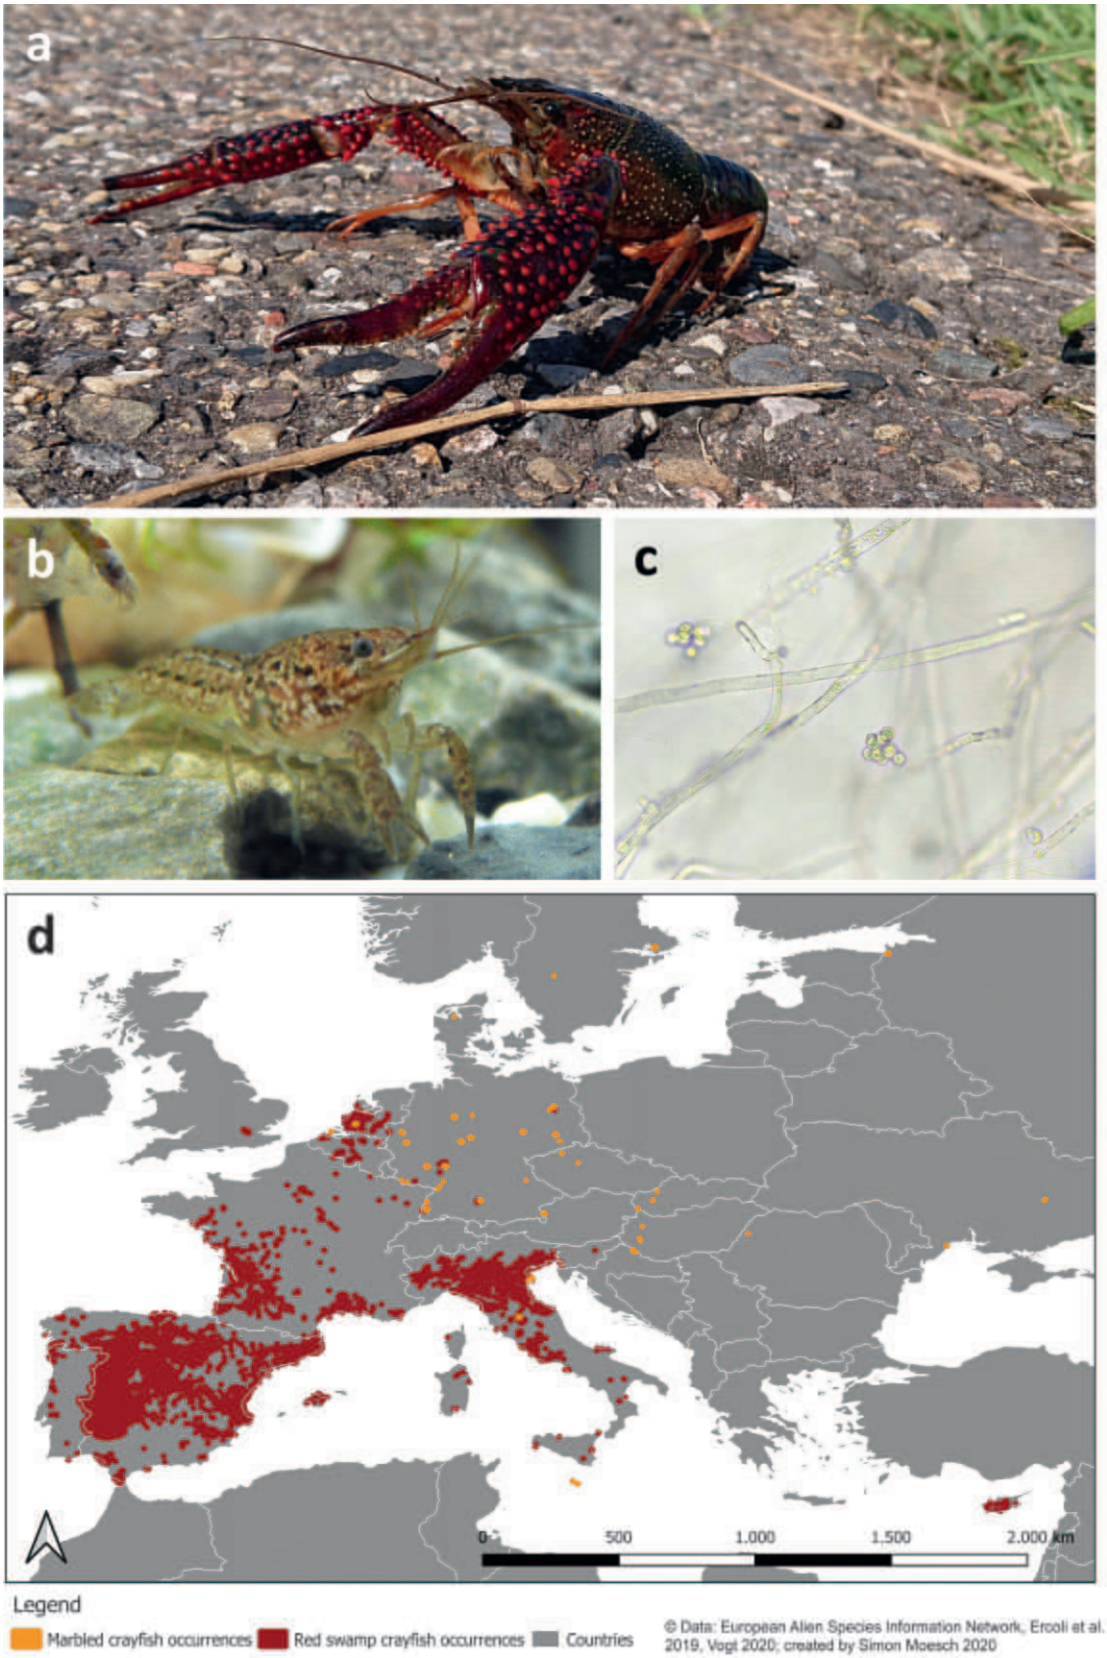

Fig. 3 The invasive (A) red swamp crayfish (*Procambarus clarkii*) and (B) marbled crayfish (*Procambarus virginalis*) can both transmit the (C) crayfish plague pathogen (*Aphanomyces astaci*) and occur in (D) many European countries (see the main text for other occurrences on the globe). Photos A–C by Bram Koese.

crayfish has acted as the most prominent introduction pathway of these crustaceans in Europe (Peay, 2009), including the marbled crayfish (*Procambarus virginalis*, Fig. 3B), the only known parthenogenetic crayfish, which appeared in the German pet trade in the mid-1990s (Scholtz et al., 2003). Due to the fact that a single individual is able to establish a population, this species has high potential to become a widespread invader. In fact, it has already managed to establish populations in many European countries (Fig. 3D, Ercoli et al., 2019; Vogt, 2020 and references therein) and to spread rapidly across Madagascar (Andriantsoa et al., 2020).

The socio-economic benefits through stocking and aquaculture are the main reasons for most crayfish introductions. However, introduced crayfish can cause negative ecological and socio-economic impacts that often surpass these benefits (Lodge et al., 2012; Twardochleb et al., 2013). For example, non-native crayfish can interfere with fisheries by damaging fishing gear, scavenging on caught fish, competing with fish and negatively affecting their recruitment. As prominent burrowers, they may increase bank erosion and siltation of waterways as well as damage earth dams and irrigation canals that may lead to drying of the rice fields (Lodge et al., 2012; Madzivanzira et al., 2021). They can also substantially alter freshwater food webs by negatively affecting the biomass and abundance of macrophytes, invertebrates, fish and amphibians (Twardochleb et al., 2013). Moreover, many native crayfish are threatened through competition and predation, which often leads to their replacement and disappearance from water catchments.

Non-native crayfish may also act as vectors of harmful pathogens, parasites and epibionts. The most infamous example is the crayfish plague pathogen (*Aphanomyces astaci*, Fig. 3C; Souty-Grosset et al., 2006). It was introduced to Europe in the mid-19th century and since then has caused severe declines of European crayfish populations (Alderman, 1996) that led to its inclusion among '100 of the World's Worst Invasive Alien Species' (http://www.iucngisd.org/gisd/100_worst.php). North American crayfish exhibit higher resistance to this pathogen, but act as asymptomatic carriers. Therefore, their global spread threatens crayfish species outside of North America, for which infection with this pathogen is usually lethal (Svoboda et al., 2017). The relation between North American crayfish and the formerly 'mysterious' disease in Europe wasonly discovered after the introductions of North American crayfish to compensate for the loss of European stocks. Beyond Europe, *A. astaci* caused mass mortalities of *Cambaroides japonicus,* endemic to Japan (Martín-Torrijos et al., 2018), and of the Australian *Cherax quadricarinatus,* farmed in Taiwan (Hsieh et al., 2016). The pathogen was also introduced to Brazil and Indonesia with infected *P. clarkii* (Peiró et al., 2016; Putra et al., 2018).

The growing concern about negative impacts caused by non-native crayfish species led to restrictions on their import and use. In the European Union, five non-native crayfish species (including *P. clarkii* and *P. virginalis*) are included in the List of Invasive Alien Species of Union concern that prohibits import, breeding, commercial production and keeping of these species (EU 2016, 2017, 2019). However, the regulations differ across countries in Europe as a whole and in other continents, which often hinders successful control of introduced species Souty-Grosset et al., 2016). Populations of non-native crayfish can be eradicated or controlled through physical measures (intensive trapping, draining of ponds, construction of barriers), chemicals (use of biocides) and biological measures (e.g. predators) (Gherardi et al., 2001; Manfrin et al., 2019). Complete eradication of crayfish populations is, however, rarely feasible. Prevention of their introduction is, therefore, typically more cost-effective and environmentally more desirable (Gherardi et al., 2001).

Fish

More than 34,000 species of fish live in marine and inland waters worldwide. Fish can be found in most freshwater systems including wetlands, ponds, lakes, streams, rivers and estuaries in which they occupy a wide range of ecological niches and trophic positions.

Fish are among the organisms most commonly introduced outside their native range (Gozlan et al., 2010). In particular, the Salmonidae family (charr, salmon and trout) includes some of the most widely introduced species (Cucherousset and Olden, 2011), including the rainbow trout (*Oncorhynchus mykiss*) and brown trout (*Salmo trutta*) which are both listed among '100 of the World's Worst Invasive Alien Species' (http://www.iucngisd.org/gisd/100_worst.php) (Fig. 4). These two species, originally from western North America and Eurasia/northern Africa, respectively, have been widely introduced and are considered as global invaders. Centrarchidae (sunfishes, black basses) are native to North America, but can now be found in most other continents in vegetated lakes, ponds and rivers. The Poeciliidae (mosquitofish, guppy) are among the most frequently introduced fish species. This family originally comes from the southeastern USA, southeastern South America and Africa. An important invader in this

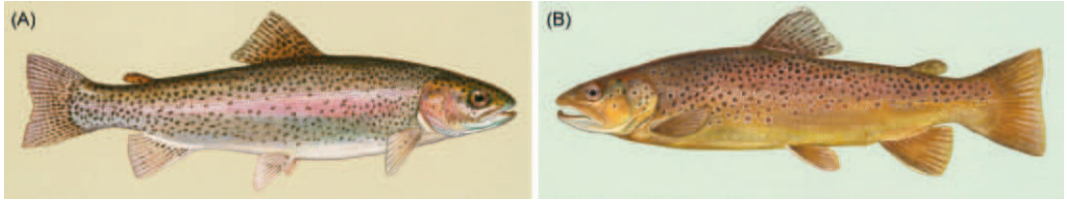

Fig. 4 The (A) rainbow trout (*Oncorhynchus mykiss*) is native to western North America and has been introduced to many areas worldwide including Europe where the (B) brown trout (*Salmo trutta*) is native, which has in turn been introduced to North America and elsewhere. This species pair is thus an interesting example of a crosswise introduction. Both species are also included in the IUCN's list of '100 of the World's Worst Invasive Alien Species.' Illustrations: Duane Raver, U.S. Fish and Wildlife Service.

family is the mosquitofish (*Gambusia affinis*) which is also included in the list of '100 of the World's Worst Invasive Alien Species.' It has been introduced around the world, starting early last century as a biological control agent for mosquitoes, and is now established in Europe, Asia, Australasia, South America, North America and Africa. While introductions have vastly increased the spatial distribution of many fish species, they are usually restricted to the type of ecosystem they are adapted to, such as well oxygenated fast-flowing waters for Salmonidae. On the contrary, more generalist species dwelling in both lotic and lentic, pristine or disturbed ecosystems develop and expand without further human intervention. It is also interesting to note that beyond the spatial extent that some species reached because of human activities, some species such as *Cyprinus carpio* (common carp) from the Cyprinidae family (carps, tenchs) were introduced to natural ecosystems centuries or even millennia ago (Balon, 1995; Ma et al., 2003). For species that were introduced such a long time ago, it depends on the time period that is considered to still call a species non-native. For example, if using the threshold of 1492 or 1500, carp would be called native in many countries where they were historically introduced (cf. Essl et al., 2018).

Non-native fish species have been introduced worldwide through human activities, either intentionally or unintentionally. To enhance aquaculture production and performance of commercial fisheries, invasive fish such as the Nile perch (*Lates niloticus*) have been stocked in artificial and natural ecosystems for centuries, and still are (Gozlan et al., 2010). Besides pisciculture, invasive fish are still stocked to support angling. This is true for piscivorous fish that are of angling interest due to their flesh or their combativity, and for fish species that these predators forage (e.g. threadfin shad or smelt) (Devries and Stein, 1990). During the second half of the 20th century, modern human activities created new introduction pathways. For instance, biocontrol became a strong motive for invasive fish introductions, either for controlling phytoplankton, macrophytes or mosquitos. Another example is the release of ornamental fish (Padilla and Williams, 2004).

Non-native fish species can have deleterious effects at all levels of biological organization from genetics to ecosystem functioning, including individual, population and community levels (Cucherousset and Olden, 2011). Hybridization with invasive species is a major threat, as native populations can be replaced by hybrids, which is particularly concerning when the native populations are rare and vulnerable. For example, the Mediterranean trout (*Salmo cettii*) in Central Italy (Splendiani et al., 2019) and the marble trout (*Salmo marmoratus*) in the Po and Soča basins (Crivelli et al., 2006) have been partly replaced in their native ranges by hybrids with introduced brown trout. Non-native fish species induce predator-avoiding adaptive mechanisms in native prey species that affect their morphology, behavior or life-history traits (Cucherousset and Olden, 2011). Such adaptations can in turn affect native predators' success and diet. Invasive fishes can severely impact native fishes through direct and indirect competition for space and food, or through transmitting pathogens (Spikmans et al., 2020). At the community level, invasive fish species can change community structure and composition, for example through extinction of resident species. One of the best-known examples is the introduction of Nile perch (*Lates niloticus*) to Lake Victoria (Africa) in the 1960s to improve fisheries production, which happened despite contrary advice from scientists and other experts (Marshall, 2018). This species caused the demise of more than 500 endemic fish species in the lake (Marshall, 2018). Introductions of invasive fish species can cause trophic cascades with severe effects at multiple levels of the food web, modifying nutrient cycles and cross-ecosystem interactions across a large landscape. The introduction of the lake trout (*Salvelinus namaycush*) in the Yellowstone Lake (USA) resulted in the addition of a new predator preying upon the native planktivorous cutthroat trout (*Oncorhynchus clarkii bouvieri*). The decline of the native trout led to changes in plankton communities, a decline in chlorophyll *a* concentration and alteration of nitrogen dynamics. Indirectly, the introduction of lake trout had far-reaching consequences, affecting neighboring ecosystems and other taxa such as predatory birds and mammals, as the loss of migrating spawning native cutthroat trout in tributary streams modified the cross-ecosystem interactions and therefore terrestrial food webs (Koel et al., 2019).

Invasive fish species have not only ecological impacts but also socio-economic ones, as they can strongly affect local fisheries and ecosystem services provided by freshwater ecosystems to human societies. For example, the Great Lakes invasion by the sea lamprey (*Petromyzon marinus*) led to an economic catastrophe after severe losses of highly valuable species in the region (Siefkies, 2017). By using their suction-cup mouth, rasping tongue and pointy teeth, parasitic sea lamprey feed on the blood and other vital fluids of their fish hosts. Native fish in the Great Lakes did not coevolve with this large and prolific parasite, thus many of them declined sharply since its arrival.

To minimize the harmful impacts of invasive fish species, diverse management strategies are used: prevention, early detection, rapid response and eradication, and control methods for reducing invasive populations. For example, the invasive common carp was successfully removed from a reservoir in South Africa using rotenone, and the removal was followed by an improvement of the water quality and recovery of invertebrates and zooplankton communities (Dalu et al., 2020). However, this successful removal is an exception, as most attempts to remove invasive fish fail or have unexpected effects. Removal attempts also incur high environmental and financial costs which might exceed the focal invader's impacts. In addition, such management actions may face opposition, as anglers and other interest groups often value the presence of exotic fish, even if they have detrimental impacts on resident species (e.g. McIntosh et al., 2012). The general public can also oppose management against invasive fish species, particularly piscivores which are charismatic for many people (see Jarić et al., 2020 for a general treatment on the role of species charisma in biological invasions). New technologies, such as environmental DNA metabarcoding, are promising to allow for better monitoring, early detection and thus rapid response against invasive fish (and other invasive aquatic) species (Hinlo et al., 2017). Such rapid responses are less costly for the environment and the taxpayer, and they also face less opposition from the public.

Mammals

There are about 6500 known species of mammals (Mammal Diversity Database, 2020). This group includes high-impact invaders such as rats (*Rattus* spp.), cats (*Felis catus*) and pigs (*Sus scrofa*) (cf. Bellard et al., 2016, http://www.iucngisd.org/gisd/100_worst.php). Since most mammals are terrestrial, this section is structured with a focus on five selected invasive mammal species (three from the order Rodentia, two from the order Carnivora) that are often found in or around inland waters.

Beavers (Fig. 5A) are semi-aquatic rodents whose dam-building activities alter freshwater systems; they are therefore 'ecosystem engineers' (Jones et al., 1994, 2010; Rosell et al., 2005). North American beavers (*Castor canadensis*) are native to the USA and Canada where they are official state symbols (Jernelöv, 2017). Eurasian beavers (*Castor fiber*) were almost hunted to extinction in the 19th century (Sjöberg et al., 2011), but were successfully reintroduced in Bavaria (Germany) in 1966 (Schwab and Schmidbauer, 2003), Hungary in 1996 (Bajomi, 2011) and the UK in 2009 (Stringer and Gaywood, 2016). In Finland, 17 Eurasian beavers from

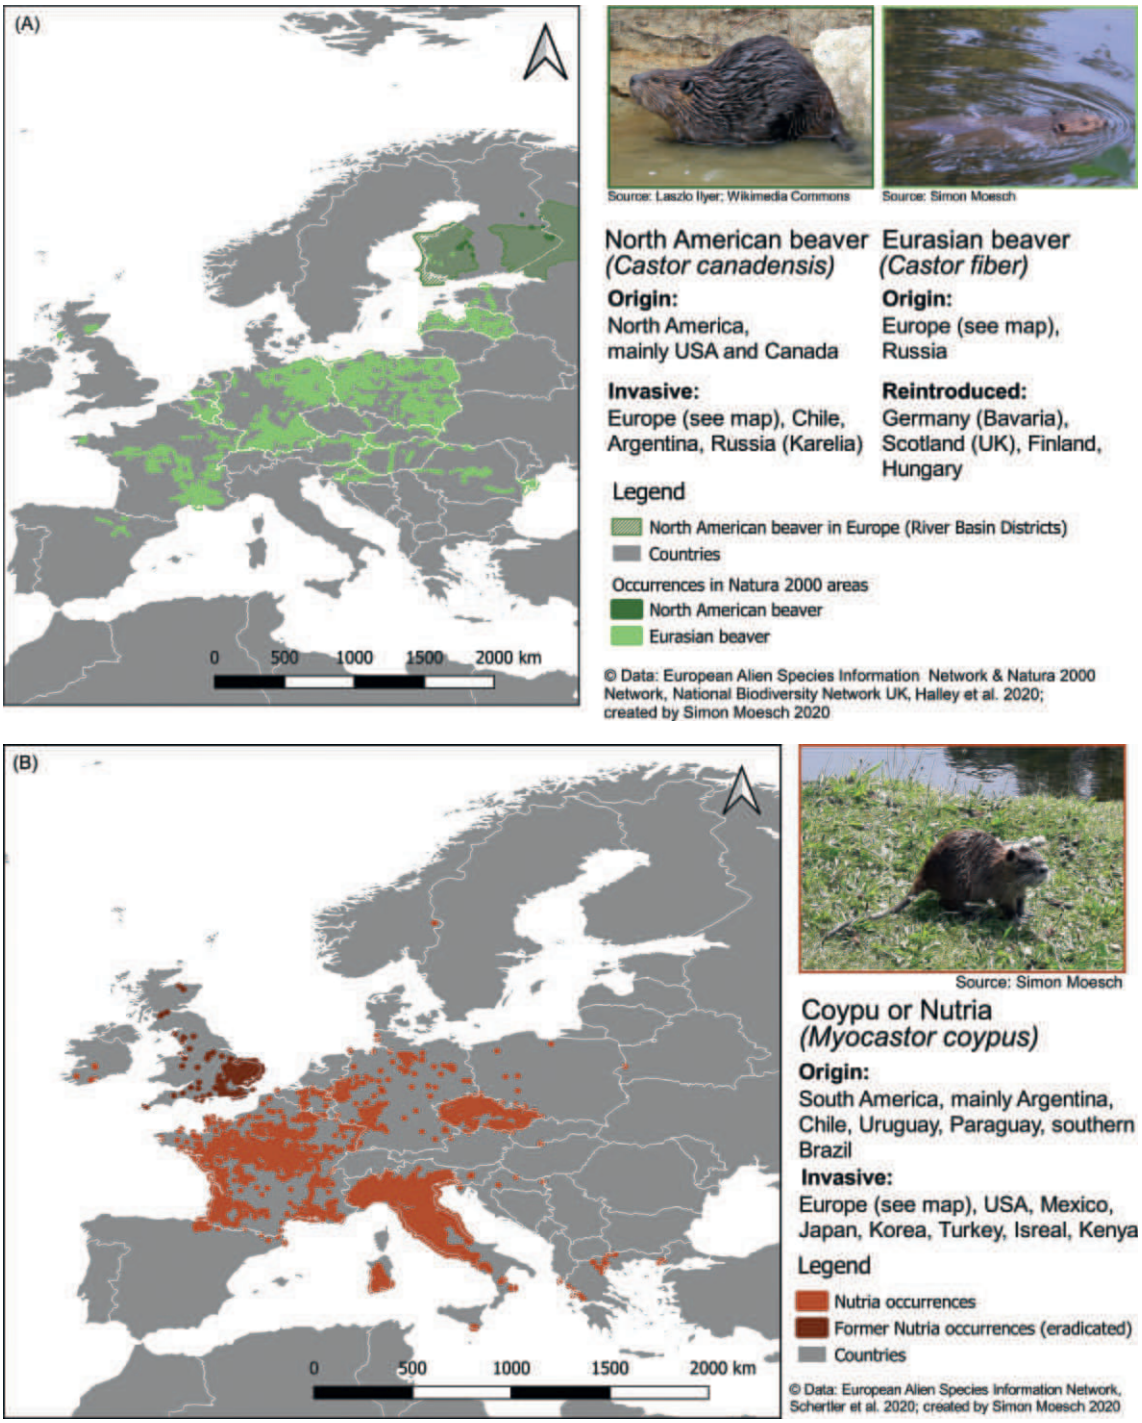

Fig. 5 European occurrences of (A) North American and Eurasian beavers (*Castor canadensis*, *Castor fiber*), (B) the coypu or nutria (*Myocastor coypus*), (C) muskrat (*Ondatra zibethicus*), (D) American mink (*Neovison vison*) and (E) raccoon (*Procyon lotor*).

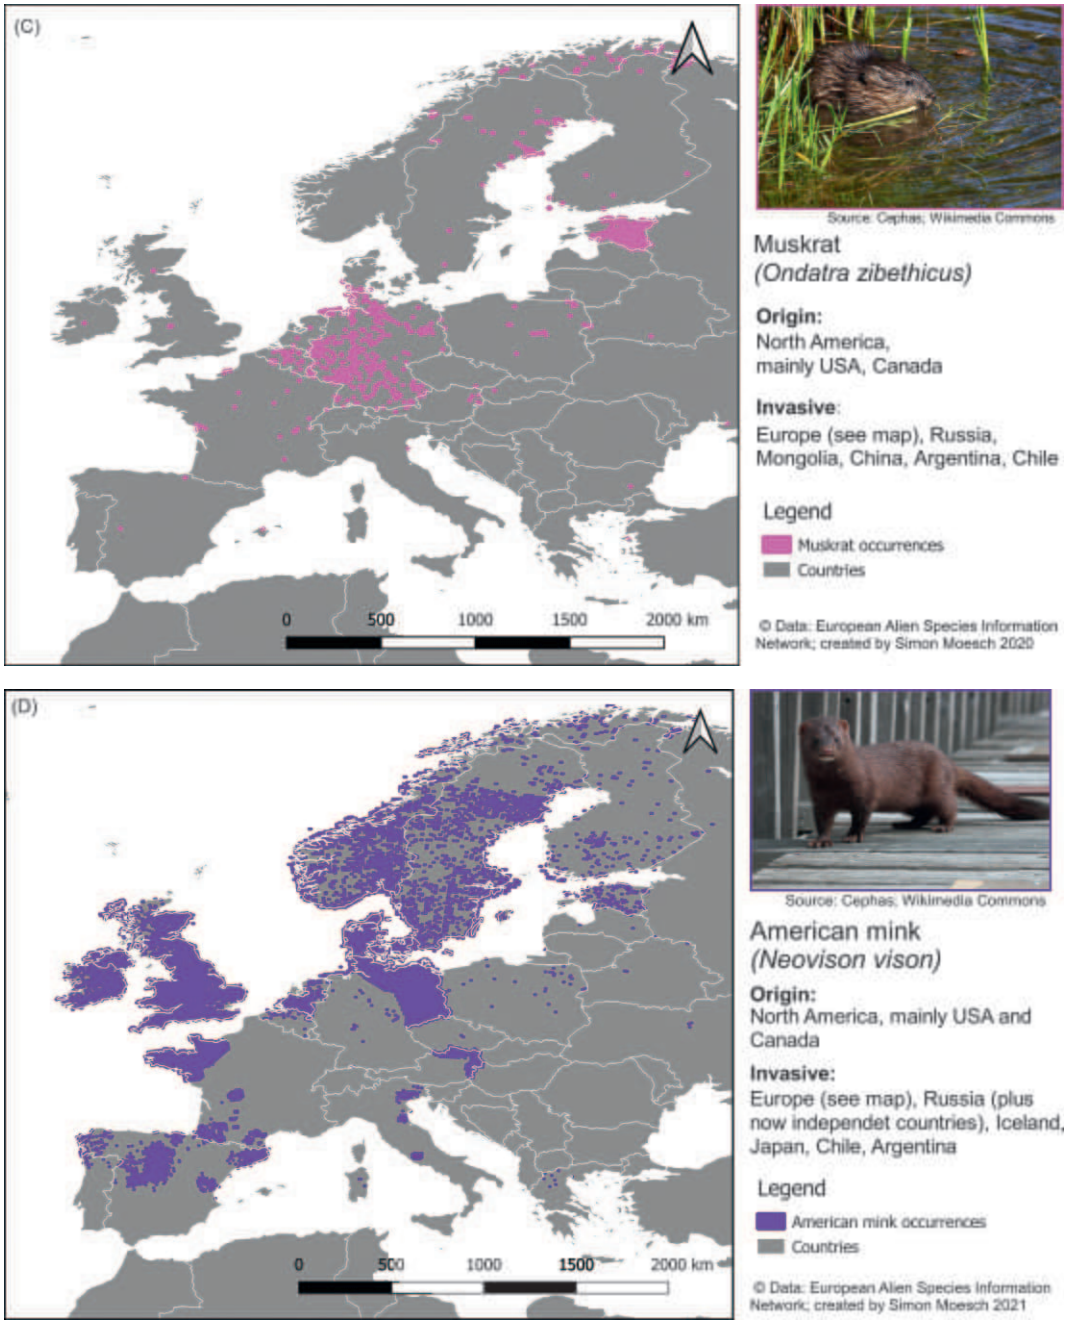

Fig. 5—cont'd

(Continued)

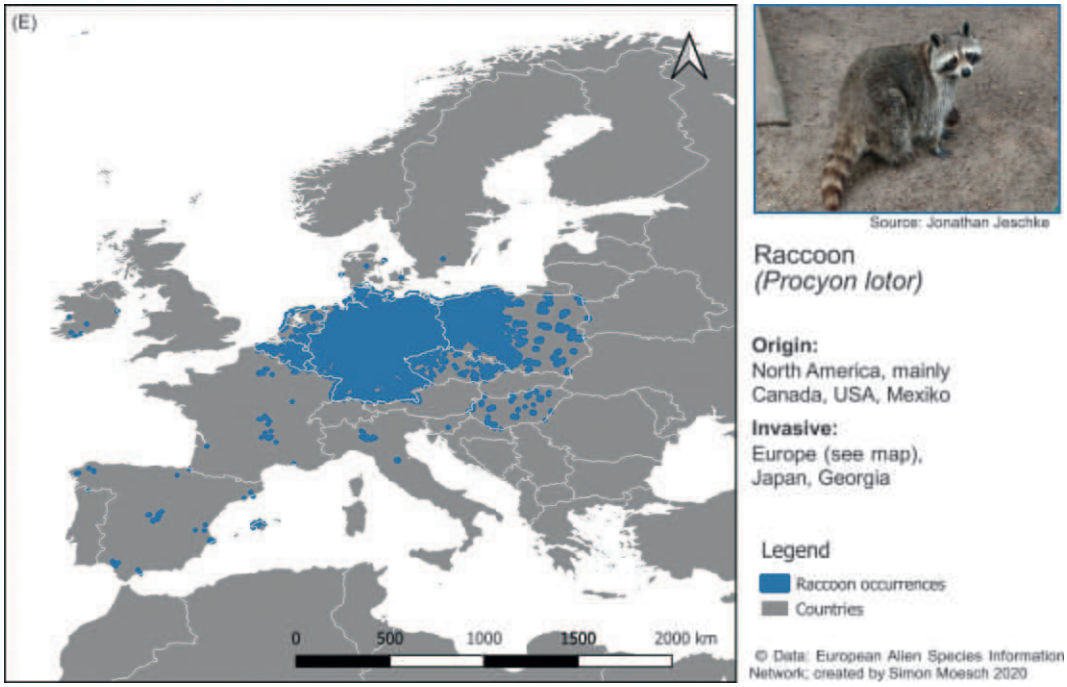

Fig. 5—cont'd

Norway and seven North American beavers from the USA were reintroduced at around 1930 (Härkönen, 1999a). Until 1973, North American and Eurasian beavers were often believed to be the same species until chromosome counts showed a difference (Parker et al., 2012). North American beavers are spreading faster in Europe than Eurasian beavers (Halley et al., 2021). In South America, 25 pairs of North American beavers from Manitoba (Canada) were introduced in 1946 to Tierra del Fuego by the Secretary of the Navy of Argentina to enrich the community and for fur trading (Pietrek and Fasola, 2014). Since then, they have vastly altered the ecosystem there (Anderson et al., 2009; Henn et al., 2016), caused the establishment of non-native plants (Martínez Pastur et al., 2006) and are beneficial for native but also non-native fish species (Malmierca et al., 2011). Beaver impacts include those on agriculture through flooding and erosion due to dam building and burrowing into flood banks, on forestry through tree damage, on fishery due to beaver dams being migration barriers and raising water temperatures, and on infrastructure due to dam failure (Butler and Malanson, 1994; Härkönen, 1999b; Collen and Gibson, 2000; Müller-Schwarze, 2011). To reduce such impacts, invasive North American beavers are now being hunted and trapped in both South America and Europe (Worth, 2014; Brommer et al., 2017).

The coypu, which is alternatively called nutria (*Myocastor coypus*, Fig. 5B), is also a semi-aquatic rodent and often mistaken for a beaver or muskrat (see below). It is native to South America and was introduced to Europe in the 19th century for fur farming where individuals escaped confinement and established wild populations (Carter and Leonard, 2002; Schertler et al., 2020). Other invasive populations exist in the USA, Mexico, Japan, Korea, Kenya and the Middle East (Bertolino et al., 2012). The coypu is widely recognized as a high-impact invader. It is on the lists of '100 of the World's Worst Invasive Alien Species' (http://www.iucngisd.org/gisd/100_worst.php) and 'Invasive Alien Species of Union concern' (EU, 2016). Specifically, the coypu is responsible for the loss of freshwater marshes through the 'eat-out effect' where aboveground biomass is washed away due to root foraging (Linscombe and Kinler, 1997; Carter et al., 1999). It threatens various species, e.g. hygrophilic plants (Prigioni et al., 2005) and freshwater mussels (Stemmer, 2017), reduces water quality in urban areas (Nehring et al., 2015), and its burrowing reduces dam stability (Reinhardt et al., 2003; Nehring et al., 2015). Due to successful eradication programs, the UK and the Chesapeake Bay (USA) are now believed to be coypu-free (Kil et al., 2015). Eradication programs only work where re-immigration is impossible (Robertson et al., 2017). Therefore, successful management requires cost-benefit analysis plus long-term measures at the local (e.g. fencing off waterways) and national level (e.g. hunting, water-level adjustment) (Gethöffer and Siebert, 2020).

The final semi-aquatic rodent highlighted here is the muskrat (*Ondatra zibethicus*). This species is native to North America and invasive in Europe (Fig. 5C), Asia (Russia, Mongolia, China) and South America (Argentina, Chile) (Skyrienė and Paulauskas, 2012). It is listed as Invasive Alien Species of Union concern (EU, 2017) and its successful invasion in Eurasia resulted from multiple releases at numerous sites (Danell, 1996; Skyrienė and Paulauskas, 2012). Muskrats damage watercourse embankments through burrowing and forage on crops (Bayoumi and Meguid, 2011; Skyrienė and Paulauskas, 2012). They also alter aquatic plant communities (Smirnov and Tretyakov, 1998) and negatively affect freshwater mussels (Zahner-Meike and Hanson, 2001). Trapping is currently the most effective management action to control the spread of muskrats (Bos et al., 2019).

The American mink (*Neovison vison*, Fig. 5D) is a high-impact invader from the family of Mustelidae within the order Carnivora (Genovesi et al., 2012). A semi-aquatic generalist predator native to North America, this species is now invasive in Europe, Asia and South America (Reid et al., 2016). Mink were trapped in North America for commercial fur trade since the 17th century (Spraakman and Wilkie, 2000). Starting in the late 1920s when populations declined and trapping was less profitable, large numbers were transported to Europe to be released (Heptner et al., 1967) and kept in fur farms (Macdonald and Harrington, 2003). Many individuals escaped or were released from farms in years of bad business, so that by 1969 the American mink was naturalized in at least 16 European countries (Bonesi and Palazon, 2007). High propagule pressure and multiple introductions increase fitness and resilience of mink populations in Europe (Bevanger and Henriksen, 1995). The spread is ongoing (e.g. Brzeziński et al., 2019), as are impacts on native species such as the European mink (*Mustela lutreola*, Macdonald et al., 2017), the water vole (*Arvicola amphibius*, Defra, 2005) and waterfowl (Dunstone, 1993; Magnusdottir et al., 2012). American mink can also be infected with SARS-CoV-2 and can infect humans with it, and infected mink have been found both on farms and in the wild (Oude Munnink et al., 2021, https://promedmail.org/promed-post/?id=8015608). Controlling mink populations by hunting and trapping is costly (Stefansson et al., 2016), which is why programs of complete eradication are discussed (see e.g. Martin and Lea, 2020 for the UK).

Finally, the raccoon (*Procyon lotor*) is a medium-sized, nocturnal and omnivorous mammal from the family Procyonidae, order Carnivora, that is recognizable by its grey fur, bushy tail and 'bandit's mask' fur pattern around the eyes (Hohmann et al., 2001). It is native to North America and invasive in Europe and Asia (Fig. 5E, Zeveloff, 2002; Ikeda et al., 2004; Salgado, 2018). Its introduction in Japan resulted from zoo escapes in 1962 (Ikeda et al., 2004) and releases and escapes of pets promoted through a children's book and its TV adaptation (Clark, 2015). Hence, the raccoon is another good example of an invasive species that benefited from its charisma (Jarić et al., 2020). In Europe, raccoons can be traced back to releases in the 1930s in Germany and are now found especially in urban regions such as Kassel, Hamburg, Frankfurt, Berlin, Madrid, Milan and Prague (Jernelöv, 2017). Raccoons are known for inspecting food in water (Zeveloff, 2002) and are frequently found in the vicinity of inland waters. They are listed as an Invasive Alien Species of Union concern (EU, 2016), and negative influences on e.g. breeding birds (García et al., 2012; Tolkmitt et al., 2012), crayfish and salamanders have been recognized (Ikeda et al., 2004). They have significant socio-economic impacts, particularly due to their high abundance in cities: raccoons damage attics and gardens, and are potential transmitters of diseases (Michler, 2004). Management actions include trapping, hunting, fencing off areas, making buildings inaccessible and raising public awareness about raccoon impacts (Suzuki and Ikeda, 2020, https://neobiota.bfn.de/unionsliste/art-19-management.html). As the raccoon population tripled in Europe since 1980, long-term management strategies are needed (Salgado, 2018).

Conclusions

Invasive freshwater species can be found in many taxonomic groups, some of which were featured here. An exhaustive overview of freshwater invaders could not be provided in this chapter, and examples of other important taxonomic groups are snails, e.g. *Cipangopaludina chinensis* (Chinese mystery snail), *Pomacea canaliculata* (golden apple snail) and *Potamopyrgus antipodarum* (New Zealand mud snail); crustaceans other than crayfish, e.g. the waterfleas *Cercopagis pengoi* and *Daphnia lumholtzi*, or the Chinese mitten crab (*Eriocheir sinensis*); insects, e.g. the mosquito species *Aedes albopictus* (Asian tiger mosquito), *Aedes japonicas* (Asian bush mosquito) and *Anopheles quadrimaculatus* (common malaria mosquito); amphibians, e.g. *Lithobates catesbeianus* (American bullfrog) and *Rhinella marina* (cane toad); reptiles, e.g. *Python bivittatus* (Burmese python) and *Trachemys scripta* (red-eared, yellow-bellied and Cumberland sliders); birds, e.g. *Alopochen aegyptiacus* (Egyptian goose), *Branta canadensis* (Canada goose) and *Oxyura jamaicensis* (ruddy duck); and different taxonomic groups of pathogens, e.g. chytrids (for example, *Batrachochytrium dendrobatidis* and *Batrachochytrium salamandrivorans* affecting amphibians).

This list and the whole chapter illustrate the huge variety of freshwater invaders that can now be found across the globe. They are being either intentionally or unintentionally introduced through different pathways, have various impacts and can be managed in multiple ways, but more research is clearly needed to better understand their ecology and impacts in order to improve current policy and management practices.

Knowledge gaps

- Compared with terrestrial invasive species, relatively little is known about freshwater invaders.
- Current knowledge on invasive macrophyte impacts is particularly restricted and focused on a few species.
- We do not fully understand how the alteration of habitat properties could facilitate or limit the establishment and spread of invasive species.
- Estimates of the economic impacts of freshwater invaders are scarce, incomplete and imprecise.
- We still need to identify the strategies that are most effective in raising awareness of the impacts of freshwater invaders, so that introduction rates of invaders are reduced and management efforts improved.
- The interplay between invasive species and other biodiversity drivers (such as habitat change, climate change, pollution, overexploitation artificial light at night etc.) is still poorly understood, as most studies focus on one of these factors only (Mazor et al., 2018).

Acknowledgments

We thank Ken Irvine for the invitation to contribute this chapter. His comments and those of Thomas Mehner and an anonymous reviewer are also highly appreciated. We acknowledge financial support from the Federal Agency for Nature Conservation (FKZ: 3519892014) to AH, the Alexander von Humboldt Foundation to AM, the German Federal Ministry of Education and Research (BMBF) within the Collaborative Project 'Bridging in Biodiversity Science - BIBS' (funding number 01LC1501A-H) to CLM and the German Research Foundation (DFG–FZT 118, 202548816) within iDiv to AS. This chapter is a contribution of the Invasion Dynamics Network (InDyNet).

Moving Towards Water Sensitive Cities: A Planning Framework, Underlying Principles, and Technologies—Case Study Kunshan Sponge City

Junyu Zhang[a], **Dafang Fu**[b], **and Chris Zevenbergen**[a], [a]IHE Delft Institute for Water Education, Delft, Netherlands; [b]Southeast University, Nanjing, China

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Ken Irvine, Debbie Chapman and Stuart Warner.

Glossary

Blue infrastructure Refers to water elements, like rivers, canals, ponds, wetlands, floodplains, can be used to connect the benefits of green and gray infrastructure.

Cultural eutrophication The impact of an increase in the concentration of phosphorus, nitrogen, and other plant nutrients in an aquatic ecosystem due to human activities. Water blooms, or great concentrations of algae and microscopic organisms, often develop on the surface, preventing the light penetration and oxygen absorption necessary for underwater life. Eutrophic waters are often murky and may support fewer large animals, such as fish and birds, than non-eutrophic waters.

Detention and retention Detention and retention are two conventional methods to manage pluvial and/or fluvial flooding. Retention systems are designed to always have water in it and detention systems only detain the water during rainy periods or flood events. Retention systems usually capture water from its original path and release it for other usages (e.g., supplementing groundwater, stormwater utilization). Detention systems usually capture water from its original path and release it into the same path (e.g., to the drainage network, to the canals).

Green infrastructure Is the strategic use of networks of natural lands, working landscapes, and other open spaces to conserve ecosystem values and functions and provide associated benefits to human populations (Benedict and McMahon, 2006; Gartner et al., 2013), which are generally decentralized. The 2013 European Commission (2013) defines GI as a "strategically planned network of natural and semi-natural areas with other environmental features designed and managed to deliver a wide range of ecosystem services."

Gray infrastructure Refers to the human-engineered infrastructure for water resources such as water and wastewater treatment plants, pipelines, and reservoirs, which is generally a centralized approach for water management.

Livable city Is conceptualized as a city which is "safe, attractive, socially cohesive and inclusive, and environmentally sustainable."

Nature-based solution Interventions (technologies and designs) which are inspired, supported by, or copied from nature to address the ecological, social, and economic challenges our society are facing in a sustainable way.

Polder area Tract of lowland reclaimed from a body of water, often the sea or main rivers, by the construction of dikes roughly parallel to the shoreline, followed by drainage of the area between the dikes and the natural waterbody (Britannica, 2015).
Sponge City An emerging approach developed in China which refers to a city that functions like a sponge to absorb, store, and purify rainwater and to release water for replenishing ground water or reuse when necessary, now and in future. Hence, it aims to alleviate waterlogging, water resource shortages, and improves the ecological environment and biodiversity in cities by absorbing, capturing utilizing rainwater. Similar concepts developed outside China include low-impact development (North America), nature-based solutions (European Union), and water sensitive urban design (Australia).

Introduction

Globally, cities are increasingly under pressure as they have to adapt to rapidly changing environmental conditions as well as to socio-economic development. Cities are vulnerable to water- related hazards such as flooding, water pollution and droughts. As the intensity and frequency of extreme weather events increase due to climate change, cities need to embrace integrated and decentralized urban water management approaches. These challenges are particularly felt in "yesterday's cities" that require transformation of the existing urban fabric to ensure a city is created that is more sustainable, livable and disaster resilient.

Blue-green infrastructure (BGI) is advocated as one of the key solutions for resolving water and environmental-related challenges and is particularly relevant for cities. However, mainstreaming BGI in urban redevelopment projects is still constrained. While current upscaling efforts of pilot projects are important steps towards broader implementation, in many cities BGI projects still have limited impact due to their small size and scattered distribution (Albert et al., 2021). BGIs ultimate focus is on residents' health and well-being and on reducing the city's environmental impact. A sustainable urban water system is a prerequisite to achieve these objectives.

China is experiencing unprecedented urban expansion and growth in wealth since the 1980s. In 2020, about 64% of the total population in China lives in cities, which is higher than the global average of 55%. Many cities in China are experiencing regular flooding and severe pollution of urban waterbodies. China is currently making the transition towards Sponge Cities enforced by a new vision coined as "ecological civilization" (Gare, 2020). Laid down in the Chinese constitution in 2018, the vision of "ecological civilization construction" has become the major ideological principle for environmental and climate policy action at different levels of government and across policy sectors in China. This vision is driving the uptake of BGI projects in urban and infrastructure planning of new built-up areas and in redevelopment programs of the existing urban fabric.

In 2014, China adopted a National Policy referred to as the Sponge Cities Program. In line with other emerging concepts of holistic urban water management (Fletcher et al., 2014), the Chinese concept of Sponge Cities calls for an integrative approach acknowledging that the urban water system is a dynamic part of a larger water catchment. Only recently, China has shifted its emphasis from traditional gray infrastructure towards blue-green and blue-green-gray infrastructure to improve the capacity of cities to capture, convey and purify urban water.

In these cities, BGI is currently being implemented at a rapid pace to replace and/or upgrade existing gray infrastructure with the objective to expand capacity and increase resilience. At the same time there is a growing recognition that BGI solutions are conditional to improve the livability of cities. This shift in focus from largely mono-functional to multi-functional approaches is also reflected in the planning, design and engineering process of urban water infrastructure in many other countries (Wong, 2006; Gersonius et al., 2012; Zevenbergen et al., 2018). It is increasingly recognized that the process of BGI uptake requires engagement of a broad range of disciplines, such as architecture, landscape design, planning, ecology, engineering and social science (Wong, 2006; Fletcher et al., 2014).

As part of the Sponge Cities Program, numerous BGI projects in the first batch of 30 'pilot cities' across the country have been implemented and are currently being monitored (Li et al., 2017; Jiang et al., 2017; Chan et al., 2018). One of these pilot cities is Kunshan, a low-lying city located in China's Jiangsu Province. A typical hydrological feature of Kunshan is its location in a low-lying polder area. Polder cities can be found in many regions across the globe, particularly in deltas. Typical examples of polder cities are Rotterdam (The Netherlands), Surabaya (Indonesia) and Bangkok (Thailand) (Hooimeijer, 2011). They are prone to flooding, experiencing subsidence and their surface waters generally have a poor water quality. Indeed, Kunshan experienced frequent flooding in the past and suffered from severe water pollution.

Kunshan is one of the vanguard sponge cities of China. In 2015, the city has launched its "Kunshan Sponge City Implementation Plan." An area of 23 km^2 was designated to be transformed into a Sponge City area which was accomplished in 2018. In that same year, the city launched a follow-up program referred to as "Kunshan Sponge City Special Plan," which targets the transformation of the remainder 80% of the urbanized area (233 km^2) into a Sponge City by 2030.

In this chapter, the underlying principles, methodologies and technologies of this new sponge city program will be given, which eventually aims to result in the transformation of Kunshan into a water sensitive city referred to as a Sponge City. A selection of projects which have already been implemented under this program will be presented.

Sponge cities program and technologies

The Sponge City program aims to restore the city's capacity to infiltrate, detain, store, purify, drain, and utilize rainwater and regulate the water cycle as much as possible to mimic the natural hydrological cycle. To achieve these objectives, three types of interventions (referred to as Sponge Cities Technologies (SPTs)) are being proposed (Li et al., 2017): (i) implementation of BGI to effectively retain and store peak run off and to purify rainwater (regular rainfall), (ii) upgrading of the existing (gray) infrastructure to collect, transport and discharge rainwater, and (iii) (re)introduction of natural waterbodies and deployment of multifunctional storage facilities and underground tunnels to deal with extreme events (to cope with excess run off beyond the design standard). China's ambition is to transform 80% of the urban areas of Chinese cities into a sponge city to absorb, retain and reuse 70% of rainwater by 2030.

An overview of the various BGI technologies and their application in China is shown in Fig. 1 and Table 1. These technologies are also used in many other countries across the globe (Balmforth, 2006; Woods-Ballard et al., 2007; Hoyer and Al, 2011). Their effectiveness depends on several factors, such as the prevailing climatological and geophysical conditions.

An expanding polder city: Example of Kunshan

Development of polder cities

In China, the first polders were mostly formed in coastal zones and lower river catchments for agricultural and flood protection. This can be traced back to the Pre-Qin Period (before 221 B.C.), whereas in Europe the first polders date back to the 11th century. The oldest extant polder is the Achtermeer polder in the Netherlands (from 1533). Urban settlements and villages expanded rapidly in polder areas resulting in densely populated areas over the past decades (Su and Luo, 2019). Due to their manmade nature, they have a unique water system comprising embankments (or dikes), canals, pumps, sluices and sewer systems to provide flood protection (dikes) drainage. The drainage system removes surplus rain and seepage water, and is made up of a network of field drains. These field drains are connected to the main drainage system and an outlet structure to evacuate the water from the area (Schultz, 1983). Hence, typical features of a polder city are: (i) controlled high water levels which may fluctuate depending on the season through groundwater extraction and/or surface water discharge; (ii) a hydrological regime and water table which are independent from their surrounding environment; and (iii) soil subsidence due to continuous groundwater extraction (Segeren, 1983).

Before the onset of the economic growth and urbanization in the 1980s and 1990s, the pollutants discharged from agricultural runoff and domestic wastewater to the aquatic environment were limited and counterbalanced by the self-purification capacity of the receiving waterbodies in the polder (Fig. 2).

Translated and modified from Ministry of Housing and Urban-Rural Development of the People's Republic of China: 'Technical Guideline for Sponge City Construction (Trial)', 2014.

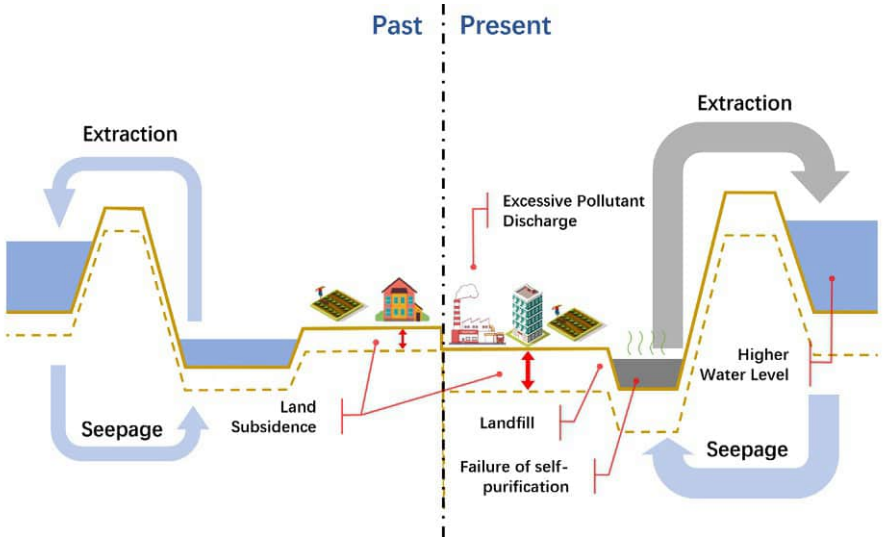

Fig. 2 Cross section of the polder system before and after urbanization showing its impact on water quality (population growth and industrial development led to excessive pollution), water quantity (expansion of the city led to landfill of channels), and regional vulnerability (global climate change led to an increase of the water level outside the polder, resulting in an increase of the seepage, extraction and land subsidence rate).

The rapid process of urbanization leads to competing land use claims to accommodate residential, industrial, and commercial development, and associated water demands and subsequent pressures on water circulation and storage. In polder cities, the total area of land available for urbanization is physically constrained by the surrounding embankments, canals and other open waterbodies. Moreover, continued land reclamation by landfilling has transformed these waterbodies into dry land to allow expansion of the urban areas. This in turn has led to an intensification of the hydrological cycle. A sharp reduction of farmland and grassland areas leads to an increase of the surface runoff coefficient and runoff volume. Meanwhile, increasing pollution loads from urbanization and industrial activities are discharged into water systems without any prior treatment (Jeon et al., 2006; Gagrani et al., 2013; Yadav et al., 2019), with impact on the quality of life of the citizens and aquatic ecosystem health (Huang et al., 2016).

These land-use changes often lead to more frequent urban waterlogging and even to severe pluvial flooding after heavy rainfall events when the volume of floodwater exceeds the capacity of the existing infrastructure. The floodwater is eventually discharged into the water system of the polder. This floodwater is often contaminated with nitrogen and phosphorus from domestic sewage, industrial wastewater, and surface runoff. In order to prevent further deterioration of the water quality, more water from outside the polder is pumped into the water system of the polder to reduce the concentration of the pollutants. In addition, continuous surface water and groundwater extraction to remove seepage water often leads to land subsidence and salinity intrusion.

The planning framework and underlying principles

The planning framework used in the Kunshan Sponge City program is based on three general principles which have been derived from water management practices developed in the Netherlands (see Chen et al., 2021). This framework is used in the selection, final design and engineering of the individual SPT interventions of the program. These principles are:

(i) Interventions should mimic natural processes as much as possible. By introducing BGI, the capacity of the city to deal with water stress such as drought, flood and water pollution will increase. BGI can also provide important additional ecosystem services and socio-cultural benefits and enhance the adaptability of the water system to future (uncertain) changes in climate and land use.

(ii) Interventions should foster or contribute to the preservation or restoration of the indigenous (man-made) water system. In many cases these systems do not exist anymore in modern cities as the huge demand for land has resulted in landfilling of indigenous canals and detention ponds to allow these landfilled areas to be used for urban development. These indigenous water systems have evolved over many decades and even centuries. They function well and sustainably under the prevailing (slow changing) geophysical and climatological conditions. In this context the indigenous water system refers to the polder water system before urbanization and offers important directions to better manage current water challenges.

(iii) Interventions should contribute to the overall performance of the city. Hence, these interventions should not be conceived as isolated, ad hoc interventions, but as ones that are interacting and impacting the urban water system as a whole. Applying this principle to manage stormwater sustainably results in an intervention which is not shifting its problem to a neighboring area. Adopting this principle requires a strategic, integrated approach at the city-scale and is based on an understanding of the function of the water system.

The last two principles are also reflected in the so called "Layer Approach," used in landscape planning and management. The Layer Approach provides guidance to identify, select, prioritize, plan and design interventions based on their impact on the water system and on the opportunities of an intervention arising from the dynamics (end-of-life cycle) of and interdependencies (incl. synergies) among the various components of the urban landscape. These components consist of: (i) surface and subsurface infrastructure; (ii) other engineered elements of the urban fabric such as buildings and public spaces; and (iii) the top and deeper soil layer; and (iv) the natural water system. The Layer Approach originates from the shearing layers concept of Duffy (1992) used in architecture and later adopted by van Schaick and Klaasen (2011) in landscape planning. This approach recognizes that buildings and landscapes can be conceived as a multi-layered system. Each layer of the system accommodates a collection of components with specific temporal features. The components of each layer have a confined and distinct time window. The performance and functions of each layer change over time, but at different rates depending on the substitution rate of the components. Components with the highest substitution rate and thus the highest adaptability are found in the upper layer, while components with the lowest substitution rate are confined to the bottom layer. When the Layer Approach is applied to the context of the polders of Kunshan, three distinct layers based on their dynamics can be defined (Fig. 3):

1. *The Occupation Layer*—This layer hosts the buildings, public spaces and all SPT (above ground) interventions. The lifetime of the components is between 10 to max 20 years.
2. *The Network Layer*—This layer consists of road infrastructure, an underground urban drainage system and other infrastructure such as bridges and pipes with lifetimes between 20 and 50 years. The capacity to adapt to changing conditions (such as driven by densification) of this layer is lower than of the Occupation Layer.

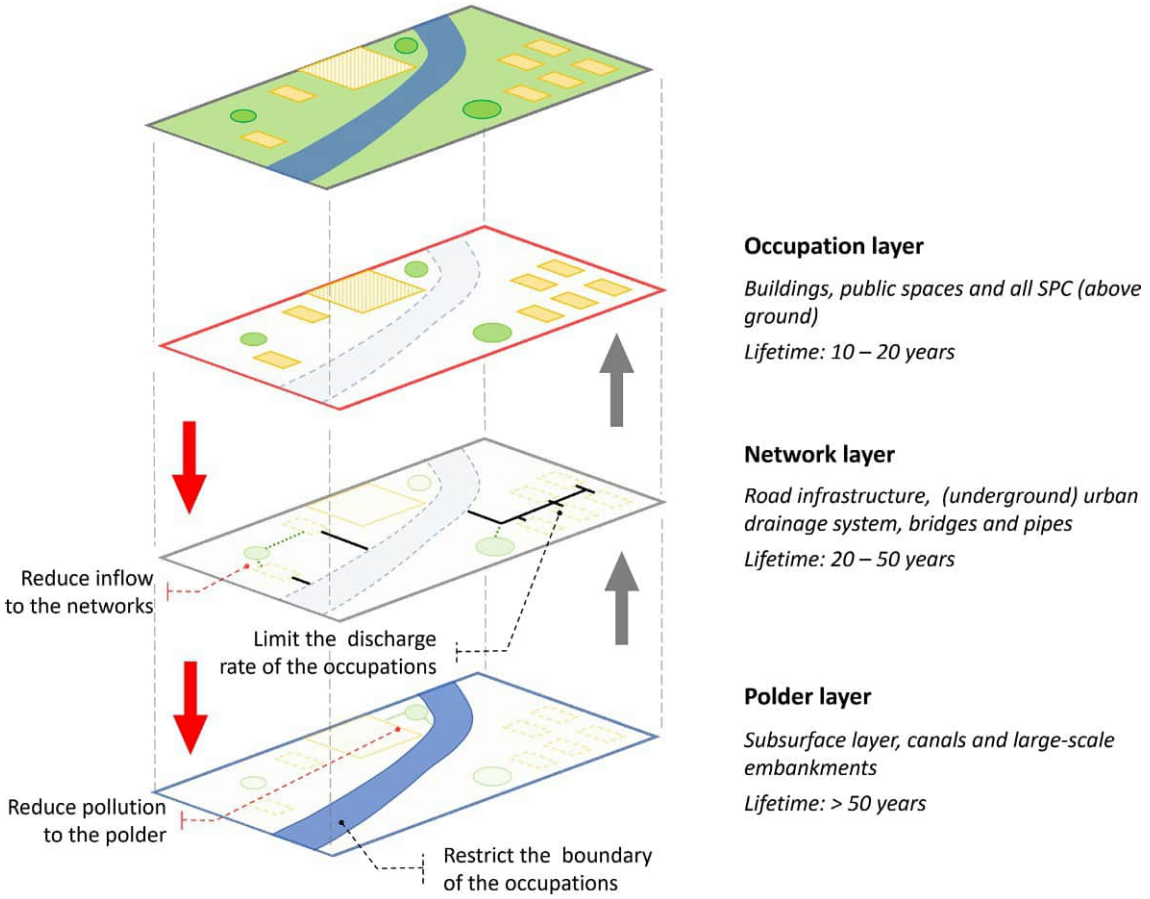

Fig. 3 The Layer approach for sponge polder management. The gray arrows indicate the hierarchy between the three layers based on the dynamics of the components of each layer. The Polder Layer with the lowest rate of change imposes restrictions on the Network Layer situated above, which in turn, imposes restrictions on the Occupation Layer. The SPT interventions are confined to the Occupation Layer. The red arrows indicate the potential impacts ranging from adverse to highly positive (synergies) of an intervention taken at the Occupation Layer on the layers below. The selection, design, and engineering of SPT interventions should be based on the opportunities that arise from the differences in dynamics (gray arrow) between the three layers, and the synergies (red arrow) of interventions on the Polder Layer and Network Layer.

3. *The Polder Layer*—This layer comprises the subsurface layer and the long lifetime man-made structures typically associated with the polder system, including large scale embankments and canals. These components have lifetimes of more than 50 years. The indigenous water system of the polder is part of this layer.

The visualization of the Polder System in layers reveals the inter-connections and the hierarchy between the layers. For example, replacing a (subsurface) drainage system to expand its capacity in the Network Layer is opportune when it has reached its end of lifetime. As these gray infrastructure systems have lifetimes of 40–50 years, in many cities they will not be replaced in the coming decade(s). Expanding their capacity by adding BGI in the Occupation Layer to the existing gray systems is an alternative option to increase the capacity but at much lower cost. Moreover, introducing BGI is an opportunity to bring additional benefits to the area. Hence, the strength of the Layer Approach is that it provides guidance in prioritizing SPT interventions (which occur in the Occupation Layer) based on restrictions imposed by the dynamics of the components in the Network and Polder Layer. At the same time, understanding and mapping the rate of change of components in the Network and even in the Polder layer will provide crucial information for strategic (longer term) planning as it will assist in identifying opportunities to intervene and synergies across the three layers.

The process steps

The overall design process of transformation is depicted in Fig. 4. Each step of the process has a specific emphasis and objective.

Step 1. System analysis

A comprehensive assessment of the water quality and quantity is conducted at polder level to establish a detailed understanding of hydrology and environmental quality, and the challenges for implementing the plans. The assessment focused on the main aspects of pollution and flooding.

To understand the challenges related to pollution, an assessment of the water quality and potential pollution sources are carried out with the aim to identify the dominant sources of pollution (e.g., farmland, industries.). Attention is also paid to pollutants in runoff which could also contaminate waterbodies in the polder. A series of control measures at the source are then implemented to reduce pollution. To assess the flood risk (stormwater), flood maps will be developed. Based on these maps, areas vulnerable to flooding will be identified to assist in the selection and location of SPT interventions in step 2.

Step 2. SPT interventions

Based on the results of the water quality and quantity assessment of step 1, SPT interventions in the occupation layer are identified and prioritized for the whole polder system Only those measures were selected which provided multiple benefits: notably flood risk reduction (reduced waterlogging) and emission reduction of contaminants to the inland waterbodies (see also Table 1). Principle (i) (mimic natural processes) is the guiding principle in this step.

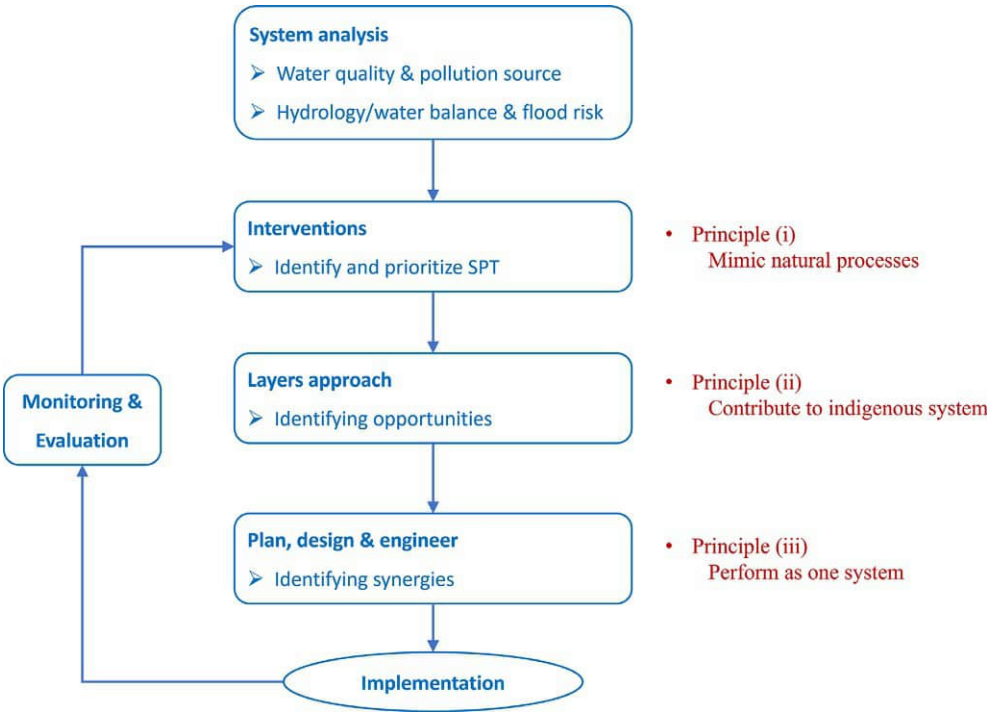

Fig. 4 The process steps of Kunshan's Sponge City Special Plan.

Step 3. Layers approach

In step 3, the selection, customization and planning of the candidate interventions are further elaborated and defined based on an understanding of the interactions and water flows among the three layers. Opportunities of when and where to intervene are identified by mapping the remaining lifetime of each component of an individual system (largely involving buildings and gray infrastructure in the occupation and network layer, respectively). Based on this information, candidate SPT interventions are selected which could coexist with, or adaptively replace these components. Principle (ii) (contribute to the indigenous system) is the guiding principle in this step.

For example, the allocation of a new bioretention cell (Occupation Layer) is constrained by other buildings in the area (Occupation Layer). The maximum depth of the cell is subject to the depth of the underground systems such as pipe networks or metros (Network Layer), as well as the water level of the nearby canals (Polder Layer). In return, the implementation of a bioretention cell could enlarge the flood protection capacity of an outdated drainage network (Network Layer), or reduce contaminant discharged into the canals (Polder Layer). In this case, opportunities will be identified to offer choices such as small new bioretention cell with preservation of the outdated drainage network, large new bioretention cell with dismantling of the drainage network. . .

Step 4. Plan, design and engineer

For the design and customization (engineering) of SPT interventions, and in particular, for a cluster of facilities in the large-scale polder cities, much attention is paid to the social/environmental functions they provide and the risk of failure, in case of exceedance of the design standard of an individual facility.

To achieve that, synergies between individual SPT interventions or different layers are identified (e.g., the conventional pumping system in the outlet of a constructed wetland could contribute to the discharge capacity of the receiving canal, the connection of nearby detention facilities could help to balance the load during flood events). Depending on the results of the assessments, adjustments of the design are made to increase the robustness of the final design. Such robustness refers here to the capacity of the design to deal with failure in case the design standard of an individual SPT intervention of the design is exceeded. If failure of an individual SPT intervention will have a minimum impact on the total performance of the design, as other interventions will take over the burden resulting from failure of that individual SPT intervention, the design is considered to be robust. This iterative process eventually results in a blend of SPT interventions contributing to a blue-green and gray infrastructure network servicing a relatively large area (>5 km^2). Principle (iii) (perform as one system) is the guiding principle in this step.

Step 5. Monitoring and evaluation

After implementation of the interventions, a monitoring scheme is set up to assess and evaluate the performance of individual interventions as well as of the polder system. These insights are required to optimize the maintenance and operation schemes.

An expanding polder city: Application in the design of Kunshan

Kunshan, a city in China's Jiangsu Province, is located in a low-lying polder landscape. These polders have been reclaimed in the 7th century and onwards. Throughout the centuries farmers managed to adapt their agricultural system to soil subsidence and occasional flooding. In the past decades the original rural landscape transformed into an urban landscape (Fig. 5). The rapid urban development of the polders around the city of Kunshan started in the 1980s. This resulted in the creation of the present-day Kunshan polder city (928 km^2) which consists of 51% rural area and 32% urban area. The city expansion developed on a paddy soil which is drained by means of a network of indigenous drainage channels interconnected to the neighboring canals and lakes (17%). By the 2000s, nearly half of the canals became black and odorous, seriously impacting the residents' health.

In addition, to human-induced soil subsidence, an increase of the impervious area has led to a further reduction of the water retention capacity. As a result, less rainwater is detained or retained in periods of excessive rainfall. If this trend will continue (following a business as unusual scenario), Kunshan will experience more frequent inundations.

"Kunshan Sponge City Special Plan"

After the implementation and evaluation of the first batch of pilot projects (2015–2018), which largely consists of isolated, small-scale (SPT) interventions, the Kunshan government adopted a comprehensive, integrated approach for the second batch of projects in a new Sponge City planning program (the Kunshan Sponge City Special Plan). This new program, launched in 2018, aims to address both the water challenges Kunshan is currently facing as well as the poor living conditions in the city. In order to accomplish this ambition, BGI is envisioned as a mechanism to foster urban regeneration: the full range of BGI benefits needs to be considered both at the level of a single intervention as well as the polder system as a whole. This requires that these benefits have to be understood, valued, and used in the planning, design and engineering process of the program. A new integrated planning framework and institutional arrangements have been adopted to identify these benefits arising from the interactions between multiple spatial scales, and cross-departmental cooperation between policy domains and sectoral planning processes, such as transportation (road infrastructure) and water resource management, respectively (Jiang et al., 2018).

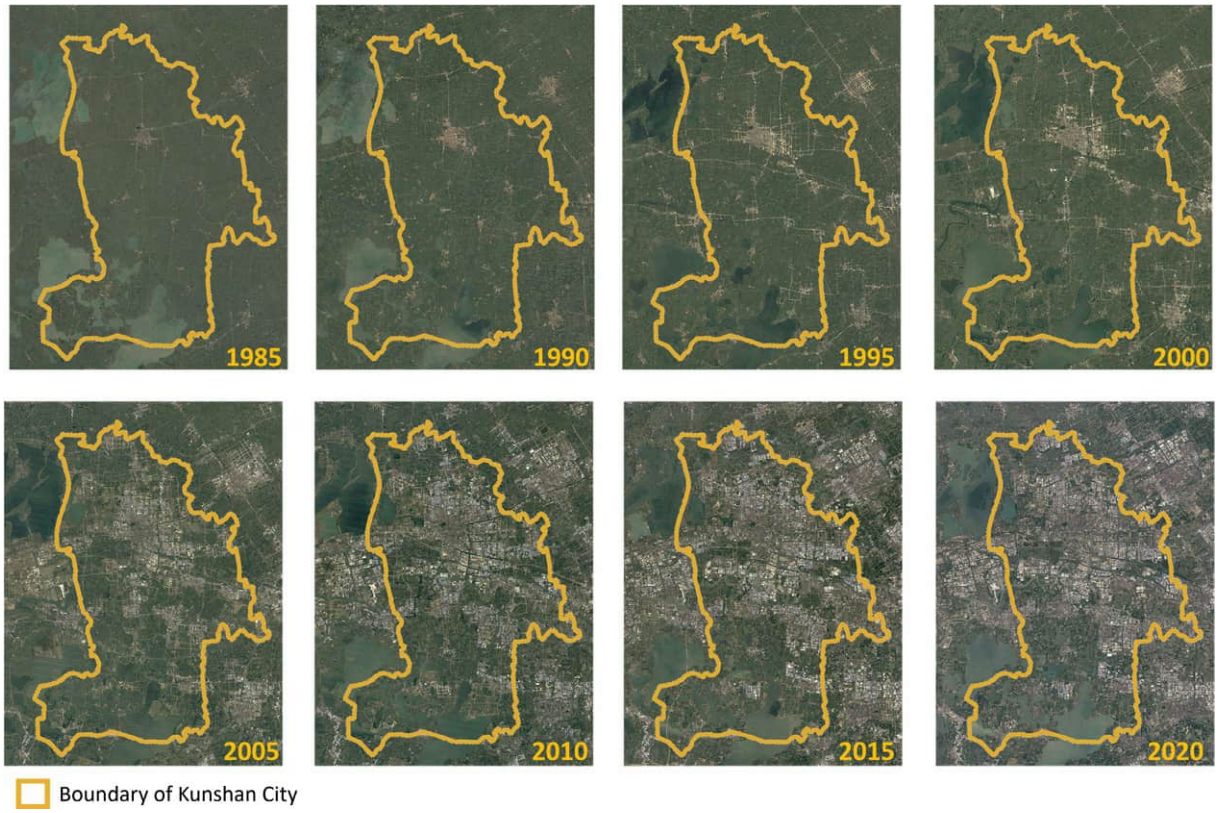

Fig. 5 Change of land use in Kunshan (1985–2020). The city originally consisted of polders used for farming. In the last 25 years, rapid development has significantly changed its land use, and consequently its water quality and flood protection capacity. Based on the remote sensing data from Kunshan government.

Table 2 Annual average water quality of some monitored canals in Kunshan (2017).

	Ammonia-N[a] *(mg L^{-1})*	*Phosphate-P (mg L^{-1})*
1#	9.77	0.78
2#	4.23	0.47
3#	4.92	0.26
4#	5.26	0.54
5#	6.08	0.32
6#	13.36	1.35
7#	18.1	2.29
Class III	1.0	0.2
Class V	2.0	0.4

Only Ammonia-N and Phosphate-P were reported as they were the dominant excessive pollutants.
[a]There is no requirement for nitrate-N or total nitrogen in the standard for surface water not serving as water sources, because the testing result of nitrate-N or total nitrogen is sensitive to nitrate-N which could bring large uncertainties in the assessment.

Implementing Kunshan's Sponge City Special Plan

Step 1. System analysis

The water quality of Kunshan was evaluated using monitoring data since early 2017. Hundreds of canals were identified as" black and odorous rivers" according to China's national Environmental Quality Standards for Surface Water (Table 2). In this standard, Class III is the minimum requirement for surface water which is accessible to citizens (e.g., swimming, fishery, or serving as water sources) and Class V is the minimum requirement for surface water to be utilized in cities (e.g., irrigation, inaccessible waterscape). The monitoring data indicate that the excessive pollutants in Kunshan comprising ammonia-N and phosphate-P originate predominantly from combined sewage system and agricultural runoff.

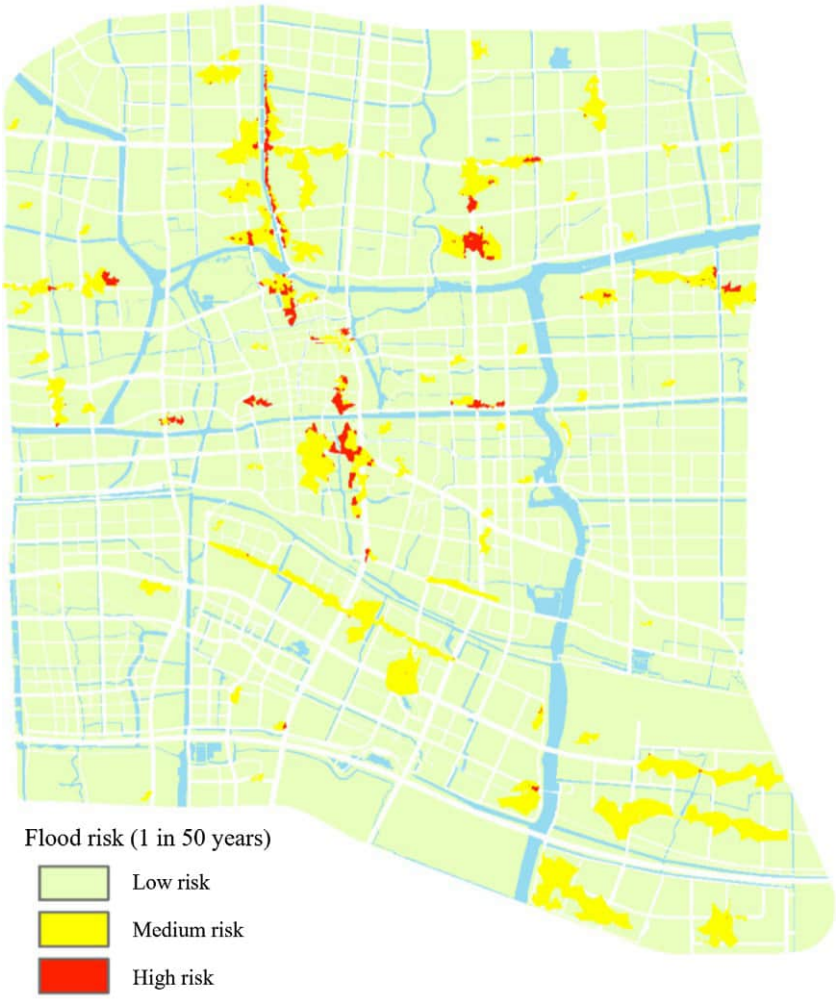

Fig. 6 Flood risk map of the city center of Kunshan indicating areas at risk in a situation after extreme rainfall (50-year rainfall event). Reproduced with permission from Stormwater system planning of Kunshan City.

Hydrological modelling was carried out to assess the extent and depth of flooding resulting from extreme rainfall events (one in 50-year rainfall event) of Kunshan. The results reveal a scattered distribution of highly localized inundated areas across the city. The total flooded area comprises 1.9%, with different flood depths (15–29 cm, 47%; 30–49 cm, 50%; $\geq$50 cm, 3%). A flood risk map was constructed using these data in combination with an assessment of the flood duration and potential loss (see Fig. 6).

Step 2. SPT interventions

SPT interventions which have been selected in step 2 are constructed wetlands, detention plazas and bioswales (Table 1).

Constructed wetlands are artificial wetlands to treat sewage, greywater, stormwater runoff and industrial wastewater. All water flows through a settling basin (where large particles settle), a treating basin (where biological processes take place) and a drainage basin. The treatment basin is the dominant section of the wetland. In this section different water velocities and dissolved oxygen in the basin enable natural purification and mimic natural processes to foster various kinds bio-chemical processes such as micro-biome or biocenosis in the same infrastructure facility. Other water sources than stormwater, such as river water or treated water from wastewater treatment plants, have been considered in the wetland designs to assure permanent saturation of the system. Constructed wetlands provide multiple benefits: runoff mitigation and purification on rainy days, improve local water environment and micro-climate on non-rainy days. Typical examples of constructed wetlands in Kunshan are depicted in Fig. 7.

Detention plazas are designed to retain/store stormwater rather than provide water quality improvement. They are usually constructed in new land development projects in residential or commercial areas, providing flood protection capacity as well as a social function.

Typical design allows large flow of water to enter but limits the outflow by having small openings at the lowest point of the structure. The size of the opening is determined by the capacity of underground and downstream culverts to handle the release of the contained water (Dykehouse and Edmunds, 2010). Typical examples of detention plazas in Kunshan are depicted in Fig. 8.

Fig. 7 Constructed wetlands in Kunshan: (left) a constructed wetland in industrial park; (right) a roadside wetland landscape.

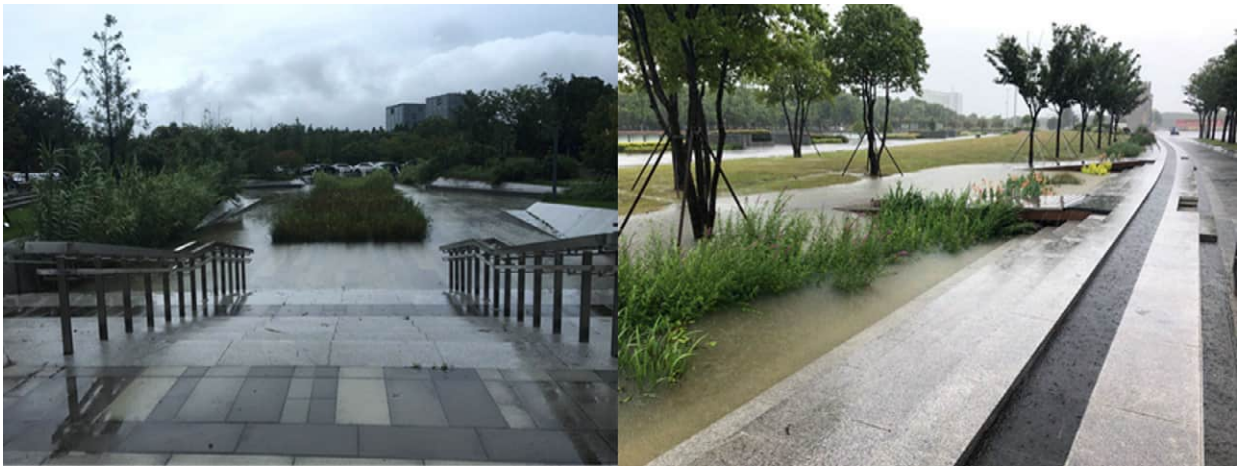

Fig. 8 A detention plaza in Kunshan: (left) plaza during normal days; (right) plaza during rainfall events.

*Bioswale*s consist of a ditch with vegetation and a porous bottom. They can be regarded as a smaller and decentralized version of the bioretention cell with a limited pollution removal capacity. Stormwater (from roofs and roads) does not flow into sewers but instead is directed into the bioswale. As bioswales are much smaller in size than bioretention cells and wetlands, they fit more easily into most of the existing green spaces than the other SPT technologies. Typical examples of bioswales in Kunshan are depicted in Fig. 9.

Step 3. Layers approach

After selecting the candidate SPT interventions, opportunities are identified to integrate these interventions into the design of the existing system. An example project is the upgrading of the existing combined sewage system (CSS) of Kunshan. In 2016, 94 communities in Kunshan's downtown area used CSS (Fig. 10). The capacity of the CSS system could no longer meet the needs of the growing population and accommodate the volumes of stormwater during extreme rainfall. To expand its capacity and separate the drainage network from the existing CSS, the SPT interventions comprised a stepwise and opportunity driven approach (Fig. 11). This involved short, medium and long-term initiatives. In the short-term, highly permeable pavement (roads, public spaces) were deployed to allow direct infiltration of stormwater to the natural water system and detention of runoff in above ground facilities such as plazas, bioswales, constructed wetlands. In the medium term, large scale (gray infrastructure) interventions such as underground water storage facilities will be implemented when components of the existing CSS infrastructure have reached their end of life (Xi, 2020). In the long-term, this will result in the total replacement of the existing CSS system to deliver sufficient capacity, to treat domestic wastewater in non-rainy days for the growing population.

Fig. 9 Bioswales in Kunshan: (left) a bioswale in a closed housing district; (right) a bioswale in public space.

Reproduced with permission from Xi F (2020) A multi-layered approach to rapid transitioning of high- density Chinese urban areas to water sensitive neighbourhoods in Kunshan. Unpublished master's thesis, IHE Delft Institution for Water Education, Delft, Netherlands.

Step 4. Plan, design and engineer

Based upon the timeline of implementation of the interventions, in this step the design process is used to appraise the synergies among SPT interventions and the robustness of the resulting system. Via an iterative process the final design (and engineering) is delivered. One typical example of this step comprises a large-scale blue-green and gray infrastructure network (covering 10 ha which equals the surface area of 14 standard soccer fields), the Qingsong Wetland Park project in Kunshan. This project consists of a collection of SPT interventions to support urban agriculture targeting to maximize synergies resulting from an integrated design. In China, and many other countries, the potential of urban agriculture to provide fresh food, generate employment, enhance livability and recycle of urban wastewater are increasingly recognized. Only in recent years, urban agriculture has been acknowledged and promoted as a new generation of BGI to play a role in strengthening cities' resilience to climate change. The Qingsong project aims to introduce a new, urban agricultural function into one of Kunshan's urban redevelopment programs. The programs serve at least two objectives: (i) to comply with the Sponge Cities requirements to enhance pollutants removal and water retention while maintaining its original land use function such as basic farmland and green space; and (ii) to enhance the livability and attractiveness of the redeveloped urban area for its citizens.

In Figs. 12 and 13, the layout of the project is given together with impressions of its multiple functions. An important design criterion for the park is its capacity to remove nitrogen from the surrounding surface waters (canals).

There are three SPT interventions and three city components which have been integrated to create synergies between the individual parts in this project (see Fig. 14). The CSS in the residential area was connected to the farmland to prevent excessive ammonia and phosphate pollution of the canal. The farmland was designed as a bioretention cell with extra submerged layers to store nutrients from either fertilization or CSS discharging while maintaining its agricultural function. Wetland A detain stormwater from Road & Highway as well as overflow from Farmland, and release irrigation water for Farmland when needed. The water in the canal was pumped into Wetland A and B from the west and north side while the treated water was released into the canal from the south side.

Fig. 12 Layout of the Qingsong Wetland Park, Kunshan.

Fig. 13 Qingsong Wetland Park: (Left) Harvesting paddy rice field; (Middle) information provided to visitors; (Right) monitoring of the wetland system.

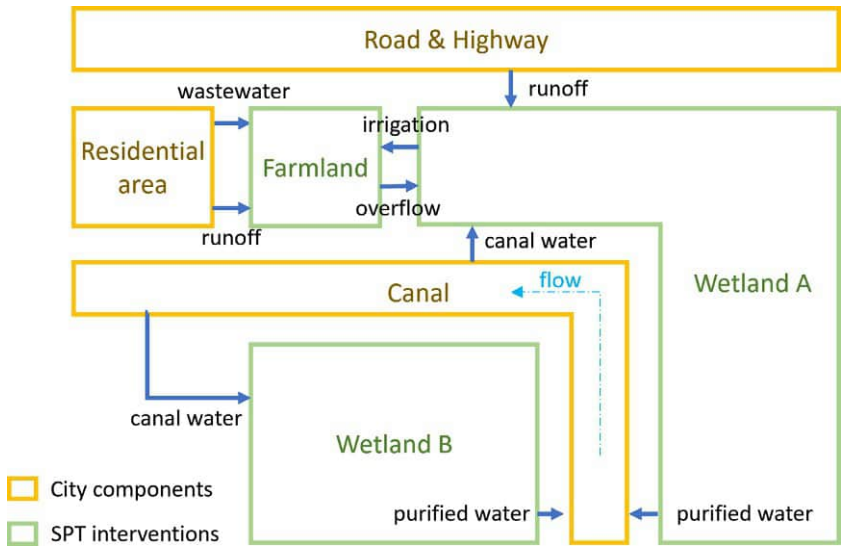

Fig. 14 Synergistical design in the Qingsong Wetland Park.

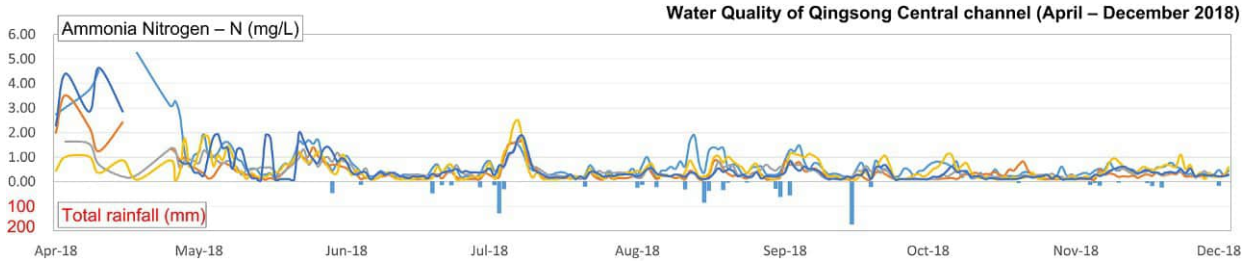

Fig. 15 Monitoring data for total rainfall and ammonia nitrogen in April 2017–December 2017 (the starting period of sponge city transformation). The transformation significantly reduces the nitrogen concentration in the river. Rainfall events could cause the increase of nitrogen in the river due to the runoff from farmland, road, etc.

When failure occurs in any part of the project, the design of the park always assures that the receiving waters are being well detained and treated. E.g., Wetland A is designed to treat domestic wastewater and retain runoff from the residential area when the farmland area fails; Wetland A and B will function as a substitution when one of the two fails; When the CSS leaks into the canal, Wetland B will partially treat and retain the wastewater; Runoff water from the roads and highway will always take a D-tour through the residential area of the farmland before it is arriving in Wetland A.

Through continuous circulation, the contaminants that originally are being discharged into the canal are captured and utilized by the farmland and/or degraded by the wetland, resulting in a gradual improvement of the water quality of the canal system in the polder. In particular, the citizens are benefiting from the park as many of them engage in the urban farming activities of the park of which its environment is gradually improving.

Step 5. Monitoring and evaluation

An example of the results of the monitoring is given in Fig. 15. Total rainfall and ammonia and nitrogen concentrations of surface water are given, which illustrate the effect of the Qingsong Wetland Park on the water quality (starting from April 2018 (before implementation) to December 2018 (after implementation)). The concentration and its fluctuation of these components gradually decrease over time to a stable level.

Conclusions

Cities both in the developed and developing world are facing complex challenges associated with urban growth, aging infrastructure, and degraded environments, exacerbated by climate change. Urban planning is urgently required to address these challenges and to transform cities into livable and resilient cities. Water is playing a pivotal and steering role in this transformation process. It calls for a broad, integrated approach to urban water infrastructure planning as our current urban water related challenges cannot be resolved in isolation. This will require to have in place the capacities at the various governmental institutions and stakeholders to work together. To capturing the multiple benefits of blue-green infrastructure as well as the interdependencies over the entire water infrastructure system comprising water supply, storm water runoff drainage, sewerage wastewater management.

Current practice tends to focus on individual (sectoral) projects and specific neighborhoods of the city, often resulting in (institutional) fragmentation and disconnected activities neglecting synergies and lacking consideration for wider societal benefits from human-nature relations. It also may lead to a sectoral approach which forgoes the opportunity to make the link with other domains (such as sustainable energy and circular economy).

The aim of the Sponge City concept is to address both the current water challenges, such as a poor water quality, floods and droughts, and to improve the livability of cities. In China, an ambitious program has been launched to accelerate this transformation process towards a water sensitive or sponge city. BGI technologies are a crucial component in this program to foster this transformation to become a Sponge City. The polder city Kunshan is one of the frontrunner cities in this program. Kunshan is following an integrated, strategic approach which is stepwise and opportunity-driven, with short, medium and long-term interventions that are planned, designed and engineered using the Layer Approach. This approach fosters to maximize synergies between the different interventions and to seize opportunities that arise from autonomous urban renewal activities outside the water domain in the city.

Most of the technologies to build a sponge city are already widely available, but they lack a historical track record (on their long-term performance, operation and maintenance) and are often not embedded in an integrated plan. Cities in other regions of the world can benefit from the experiences of Kunshan, which is now building that evidence base through its Sponge City program and application of various SPT technologies following a dynamic-based planning approach.

Knowledge gaps

Knowledge on Sponge City performance is still limited, because of a lack of understanding on the functioning of BGI under different conditions and their long-term behavior as they age. Moreover, it is a challenge to design a meaningful monitoring program and to select key performance indicators for monitoring.

Nevertheless, local stakeholder involvement and alignment is generally more important for BGI than for gray infrastructure. However, stakeholders' expertise, knowledge and perspectives are still underutilized. The way to effectively involve stakeholders in the Sponge City program is still a challenge and requires further study.

Acknowledgments

We thank Ken Irvine for the invitation to contribute this chapter. His comments on the chapter and those of an anonymous reviewer are also highly appreciated.

Section Introduction: Societal Values and Other Human Dimensions in the Science and Management of Inland Waters: For Whom? By Whom?

Catherine M Febria[a] and Gail Krantzberg[b], [a]Great Lakes Institute for Environmental Research and Department of Integrative Biology, University of Windsor, Windsor, ON, Canada; [b]W Booth School of Engineering Practice and Technology, McMaster University, Hamilton, ON, Canada

Glossary

Biocultural dimensions As defined by the Convention on Biological Diversity (2018), this term broadly links biological diversity with cultural dimensions, reflecting a holistic approach of many Indigenous peoples and local communities.
Human dimensions The broad range of ways that humans are in relationship with fresh water, and particularly as they relate to the science and management of inland freshwater ecosystems at a range of scales.
Societal values One example of human dimensions as they relate to inland freshwater, referring to how local communities and society place priority over an attribute of fresh water. This can include cultural, recreational, fishery, ecosystem provisioning, etc., and can elicit or necessitate efforts to place value on aspects of fresh water.
Socio-ecological system Linked social and ecological units as one system of study or management.

Introduction

The link between humans and freshwater is inextricable. Humans are drivers of degradation and critical to ensuring a more sustainable freshwater future. Freshwater is so widely recognized as being vital to human life and societal well-being that many Indigenous and local cultures have a common saying: Water is life. Despite being responsible for the degradation and stress placed on inland freshwater ecosystems, humans play a central role in the study, stewardship and management of freshwater. As drivers of the Anthropocene (Lewis and Maslin, 2015), humans are also critical in reversing further declines in biodiversity and ecosystem functioning to ensure planetary sustainability for future generations (Bennett et al., 2016). Unfortunately, the intentional inclusion of human dimensions in freshwater science and especially policy- and management-relevant science is not yet commonplace. In the current 'code red' state of emergency when it comes to climate change (IPCC, 2021), it is almost impossible to imagine that the science and management of inland waters can proceed without accelerated efforts to incorporate societal values and other human dimensions related to fresh water.

Freshwater biodiversity has been in crisis globally (Dudgeon, 2010; Dudgeon et al., 2006; Jenny et al., 2020; Reid et al., 2019) which intersects with threats to human water security (Vorosmarty et al., 2010). Thus, freshwater and human dimensions are inextricable. Human dimensions refer to the multiplicity of ways in which society interacts with and benefits from a relationship with water. The term is inherently diverse in scope, nature, geography and thus necessitate a pluralistic view and set of approaches when dealing with incorporation in science-based pursuits and management. One of the more common operational frameworks for linking humans and ecosystems is the *ecosystem services* concept which provided a way to encode economically valuable services provided by freshwater alongside other societal benefits (e.g., health and well-being) (Millenium Ecosystem Assessment, 2005). For freshwater specifically, there is a growing global recognition that water is a finite human resource that must be managed to address economic, social, environmental and basic needs of society. This has necessitated strategic partnerships at a range of scales, including across multiple nations (e.g., European Union's Water Framework Directive) (European Commission, 2000) and increasing awareness of the

importance of different knowledge systems (Ban et al., 2018; Whaanga et al., 2018). Thus, societal values are highly variable, context-dependent that can inform how water is prioritized in and across communities (e.g., recreation, culture, biodiversity, etc.) but also in practically assessing preferences through exercises in valuation (e.g., economic) (Tadaki et al., 2017). While examples of human dimensions are varied across inland ecosystems and contexts, considerable progress has been made in better understanding how to gather, harness and amplify societal values in research and management. It is not our intention to capture all of the examples in this chapter but to provide a broad overview on recent work and highlight the opportunities that are on the horizon.

Looking back

Along the same vein, looking to the future requires an effort to consider what has been done to date. As one example, the aim of the 1st Edition of the Encyclopedia of Inland Waters (2009) was to bring together the most recent and comprehensive overview of knowledge for scientists to study and manage? inland freshwater ecosystems. Additionally, the resource was developed to provide critical information for water-related decision-makers to effectively manage and protect inland ecosystems for future generations. The initial offering covered the suite of physical, biological and ecological attributes of inland ecosystems globally across all levels of taxa and across ecosystems. Notably, human dimensions were featured in an analysis of water as a human resource (Dudgeon, 2010; Reid et al., 2019), in terms of water ecosystem services (Limburg, 2009), relationship to human health (McNinch et al., 2009), agriculture (Jones and Downing, 2009), aquaculture (Boyd, 2009), aesthetic values (Corrigan et al., 2009), management (Cardoso et al., 2009), bioassessment (Norris and Barbour, 2009), to name a few. Varied human dimensions were also woven across chapters that were geographical in focus.

For further context, we explored and broadly quantified the growing literature that explores inland ecosystems and some human dimension (Supplementary Material 1 in the online version at https://doi.org/10.1016/B978-0-12-819166-8.00216-4). More than 100,000 peer-reviewed publications have appeared with direct use of inland freshwater ecosystems alongside social dimensions (Fig. 1). These offerings have more than doubled in the last decade since the publication of the 1st edition.

Current examples integrating human dimensions in science

Collaborations between science and management have been incredibly fruitful but still have a far way to go to successfully restoring inland waters globally as coupled environmental and human dimensions are rarely assessed (Padowski et al., 2015).

Inland fisheries have been a classic motivation for collaboration between science and management. Lynch et al. (in press) provide a global overview of inland fisheries and provide examples for nine societal services provided by inland waters. From livelihoods to subsistence income, food and nutrition, recreational, cultural, economic and ecosystem provisioning services, they are all under threat due to human-induced pressures. Despite case studies globally showing how science and management have

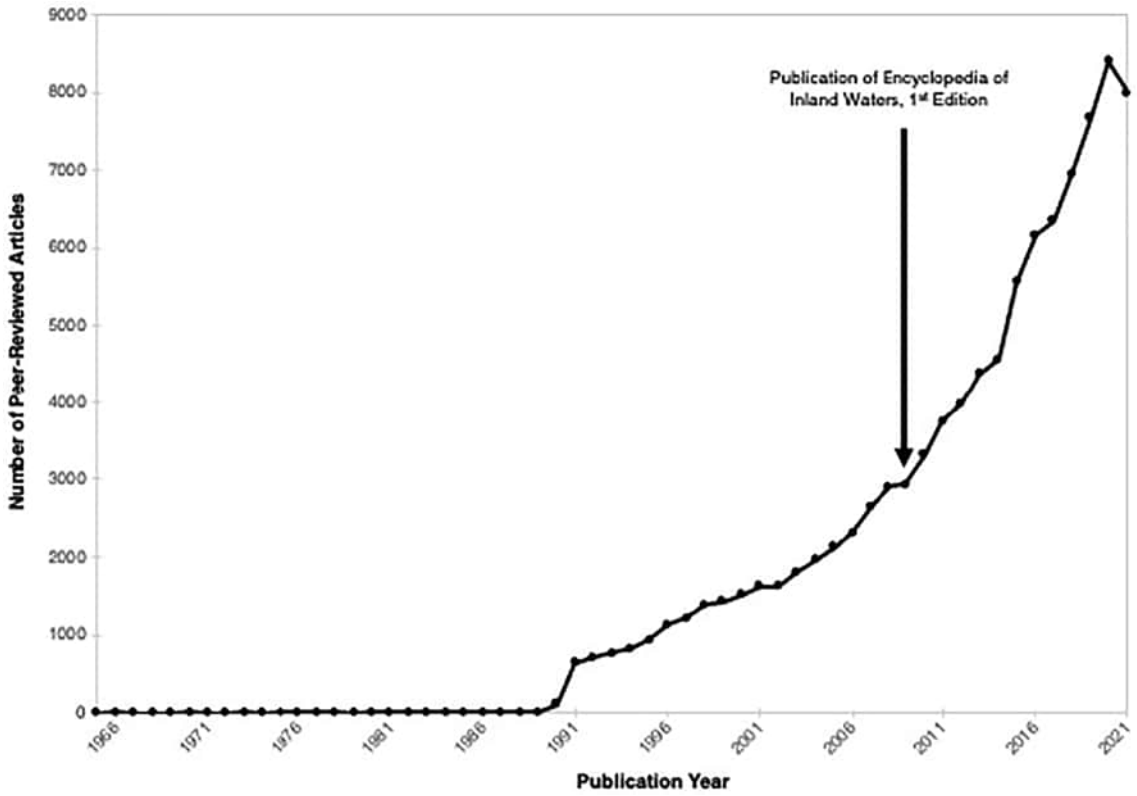

Fig. 1 Published peer-reviewed articles over time since 1965 covering societal dimensions of inland, freshwater ecosystems globally. See Supplementary Material 1 for broad search terms employed and thematic analysis.

come together to support local needs and interests, there are many gaps to be filled to ensure that the incredible biodiversity found in inland systems can be sustainably stewarded and managed.

Situated at the science-management nexus is the protection of inland waterways through the restoration of land-water/aquatic-terrestrial interface via the implementation of riparian buffers at range of scales. Stokes and Smidt (in press) applied a land cover change analysis of riparian buffers in the United States to illustrate the diverse values and support further valuation of riparian zones in decision-making. Their analysis confirms the importance of considering transitional aquatic habitats (e.g., wetlands) as well as terrestrial species in riparian buffers as part of the science required to advance management in the United States but likely also globally. Krantzberg (in press) catalogues the intense efforts of communities and governments of all orders place on restoration of ecosystem function to achieve desired human and non-human uses of the Great Lakes basin geographic Areas of Concern.

To illustrate the diverse set of values placed on inland waters, we look to the Global South where societal implications to effective science and management are essential for addressing multiple stressors and supporting livelihoods at a range of complex and interacting scales. Obiero et al. (in press) provide an overview of the challenges and opportunities facing Kenya, a riparian country in the African Great Lakes basin. Top of mind is the harnessing of societal dimensions to enhance sustainable management of inland resources for current and future generations. An emphasis on the blue economy, or economic activities linked to the sustainable use of freshwater, has the potential to offer the most significant contribution to Kenya's economic growth. To balance the societal dimensions with ecological challenges and opportunities, a driver-pressure-state-impact-response (DPSIR) framework is offered to bring Kenya into the future in a people-centered, equitable and just way.

Centering human dimensions—For whom?

It is critical that those engaged in scientific research on inland waters—especially the next generation of leaders—understand the social or governance structures that connect research with management and practice to anticipate, integrate and co-design work that can be implemented more rapidly. Farhad and Baird (in press) draw on resilience principles and perspectives to illustrate the role that governance places on inland systems. Invoking socio-ecological systems thinking, the authors describe how freshwater management and governance can incorporate attributes to ensure good outcomes when resilience principles are incorporated. Resilience as an ecological concept should be familiar to most scientific undertakings; however, translated to social realms, it becomes clear that decision-making can be more effectively supported when social dimensions are intentionally incorporated.

This theme is echoed in Johns' offering and consideration of how societal values are reflected in public policy (Johns in press). Drawing on rich case studies from the North American/Laurentian Great Lakes system, the author illustrates how conflicts in values can be addressed using alternative approaches. A key example in Canada and other countries is the values shared by Indigenous communities, the original stewards of water resources prior to European colonization and settlement of North America. Contrasting current and Indigenous laws, this offering illustrates the interconnectedness of water as a guiding principle or new water ethic. Underpinning this is that water is a basic human right, which despite offering an alternative path for water valuation, remains an ongoing challenge. Other alternatives, such as re-framing values placed on built environments, and economic mechanisms to support sustainable water management are discussed using the North American/Laurentian Great Lakes as a regional example (Krantzberg in press). Efforts in the Laurentian Great Lakes are built upon decades of an Ecosystem approach (Alsip et al., 2021; Hartig et al., 1998), which has offered a collaborative governance framework for considering the interrelationships between the Great Lakes ecosystem and various actors around the basin. Building on decades of efforts focused on Areas of Concern (AOC) and remedial action plans (RAPs), much insight is offered by Krantzberg (in press) (Krantzberg, 2018) on how this approach may offer a path for the management of inland waters elsewhere.

More broadly, legal and institutional frameworks vary within and across nations that share boundary waters. In the Global South, Achieng et al. (in press) examine how cross-nation watershed management in Africa might be approached to engage national and regional social and biophysical elements. Finding common ground within a shared watershed, the biodiversity and values found therein, the authors provide examples for how a more decentralized approach may facilitate greater engagement at the local level in more effective watershed management.

Given the varied examples across the globe, Nagabhatla et al. (in press) offer a framework for addressing societal values through the general idea of 'Valuing Water' as a multifaceted effort to operationalize terms and concepts for the benefit of multiple actors, from research to policy and stakeholders involved in water decisions. A key motivation for valuing water is to enable and accelerate change to ensure that the UN Sustainable Development Goals (SDGs) can be achieved. Reframing water values is their proposed solution, and drawing on examples globally, they highlight the importance of pluralistic approaches to valuing water through economic and non-economic lenses to facilitate more equitable access to the management of water.

Centering human dimensions—By whom?

Notions of just, equitable and fair access to, distribution of and research on inland fresh water are a common theme in this thematic section and the growing body of literature. Not often discussed is the human dimension of those engaging in research, management and stewardship of inland waters, i.e., who is conducting this work?

In this thematic section, Penaluna and Arismendi (in press) pull the curtain back on those engaging in published work related to fisheries. Focusing on the period of time just prior to the publication of the 1st edition of this Encyclopedia (i.e., 2006–2020), the authors examined the gap in women vs. men in fisheries. The trends observed in this global analysis confer similar patterns found at national and sub-regional scales: women are consistently disproportionately represented in publications, are cited less than men, which all contribute to a lack of recruitment and retention in research-related and leadership positions. Given the central role than

women play in water stewardship globally, the authors make visible a 'productivity' vs. 'impact' gap in fisheries and highlight the need for a systemic shift in how we value women and non-binary individuals who engage in fisheries work.

We acknowledge that the global community of researchers and decision-makers are in a period of incredible flux. At the time of writing, the global COVID-19 pandemic—which took hold in March 2020—continues to exert prolonged stress on society. When it comes to the inland research and management community, the impacts are most deeply felt by historically underrepresented groups, notably women, early-career, Black, Indigenous and People of Colour (BIPOC). Despite a lengthy period of invitations and interactions with potential authors, many invitations were declined or remained unanswered. Our analyses of publications (Fig. 1) provide reveal a levelling off in 2020–2021, likely due to widespread disruptions due to the pandemic. Societal impacts are multi-fold, particularly when we consider countries of the Global South where freshwater is already a limited resource. Women often play central roles in terms of local scale water stewardship. Early reports suggest a magnification of inequity when it comes to women and water because of the pandemic (Parry and Gordon, 2021; Stoler et al., 2020). Moreover, women in the research community are also experiencing inequities due to intersecting, underrepresented identities in academia that include parenthood (Gewin, 2020; Kramer, 2020). As we continue to navigate a multitude of stressors, there are opportunities to re-think, re-frame and rebuild opportunities to support a richer, more inclusive and impactful global freshwater community (Fulweiler et al., 2021; Gewin, 2020; Nocco et al., 2021).

Looking forward and moving towards connectedness

Inland waters have long been recognized as being hotspots of biodiversity (Dudgeon et al., 2006), inextricably connected to their surrounding catchment (i.e., the stream and its valley) (Hynes, 1975) however in practice local management units often focus on land or water separately. Multiple efforts have promoted more integrated social-ecological systems approaches to water restoration or management (Naiman, 2013; Ostrom, 2009). Falkenmark (2004) suggested that moving beyond land-water dichotomies in freshwater management was essential to achieving global targets for global freshwater sustainability. In particular, balancing local-scale with catchment-scale efforts. In the recent decade, growing efforts have sought to move beyond freshwater units alone but connectivity with terrestrial units, the interface or ecotone in between, and as discussed in this thematic section, human perspectives and dimensions.

Consideration of human dimensions and how they may be more effectively incorporated in freshwater research and management have long been pursued, discussed and conceptualized (Fig. 2). Moving forward, it seems essential that intentional engagement of human dimensions must be incorporated from the start both conceptually (e.g., socio-ecological systems) (Naiman, 2013; Ostrom, 2009; Parsons et al., 2016), by engaging and maximizing diverse knowledge systems (Febria et al., 2022; Suding et al., 2015), and operationally through engagement and partnership as part of a larger process of knowledge co-production (Ban et al., 2018; Norström et al., 2020).

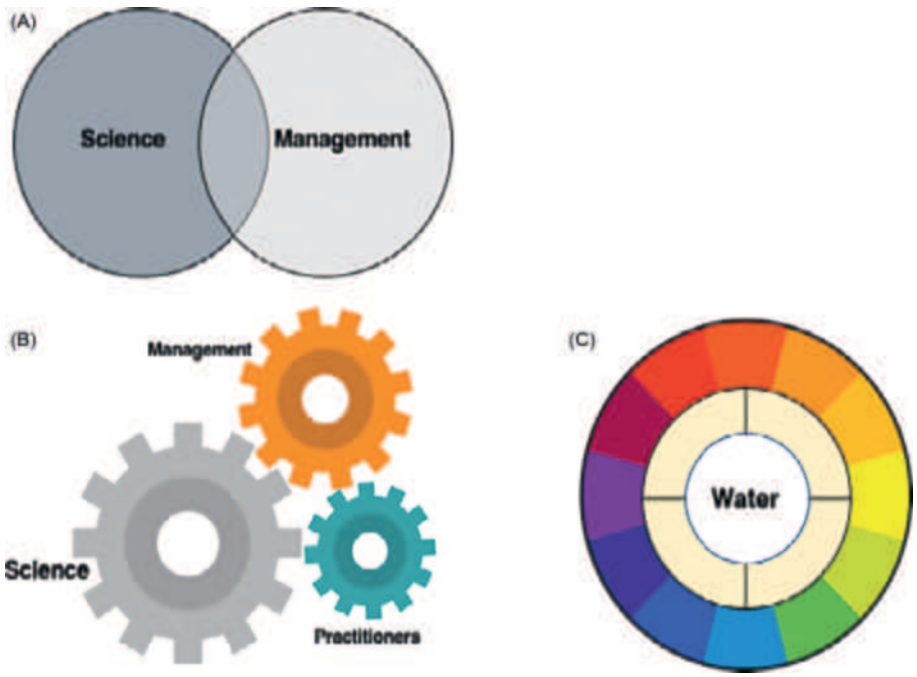

Fig. 2 Conceptual shift in approach in inland freshwater science and management from (A) to (B) that attempt to recognize complementary components leading to more innovative outcomes, or (C) more pluralistic, inclusive and holistic approaches that engage human dimensions, Indigenous and local knowledge systems, values and ways of knowing.

Ko au te awa, ko te awa ko au (I am the River and the River is me)—Māori proverb

There are increasing examples of change in the ways that inland research and management is taking place globally. Notably, growing awareness of a connectedness with nature, and the inseparability of society and nature has been best exemplified by greater amplification of Indigenous knowledge systems alongside western science-led efforts in various examples globally (Ban et al., 2018; Collier, 2017; Rayne et al., 2020; Reid et al., 2021; Suding et al., 2015). For example, in Aotearoa New Zealand, the Whanganui River was recently granted legal person status, a first for rivers globally. Empowering Indigenous communities as the guardians of the river offers a framework for connecting the river from mountains to the sea, its' tributaries and catchment into a more holistic, integrated view of the river as a living ancestor. Similar efforts are underfoot elsewhere, such as the Ganges River (India), the Magpie River (Canada) and to varying extents in South America (Ecuador, Bolivia).

Knowledge gaps

To effectively bridge science with human dimensions, the offerings presented here and across the literature demonstrate how the approach is shifting towards a more innovative knowledge co-creation process (Hallett et al., 2017; Krantzberg, 2018; Norström et al., 2020), including the prioritization of collaborations, partnerships and workforce training. Outcomes of collaborative co-design of research and management can lead to shared benefits/co-benefits and enrichened trust-based collaborations in governance and decision-making at a range of scales (Alsip et al., 2021; Febria et al., 2020, 2022). Therefore, this thematic section provides rich and varied examples such as locally-implemented river restoration and riparian planting (Stokes et al. 2022), watershed management (Achieng et al. 2022), to legal and social mechanisms (Lynch et al. 2022; Johns 2022). As important is how different sectors of society in this work (Penualuna and Arismendi 2022). Thus, evidence is building towards more equitable, inclusive and just approaches to research and management of inland waters, the advancement, operationalization and testing of frameworks that can be tailored to societal values and systems, that will be truly impactful if they can address and alleviate existing disparities and inequities in inland water research and management.

Conclusions

Now is the time to consider the plurality of connections between inland ecosystems and humans. In related efforts, such as biodiversity conservation, it has become clear that efforts to achieve sustainability at local to global scales must consider new approaches to co-produce knowledge and co-innovate science-based innovations to improve management and sustainability. Notably, a more just and inclusive approach in these efforts—which also centers Indigenous and local knowledge systems—alongside western science may also help to address apparent cultural and gender-based gaps in the inland freshwater science and management work thus far. Reflecting on the decade in between the first and second offering of this holistic and comprehensive resource, the sheer number of efforts that span disciplines, ecosystem and geographical scales have increased. We anticipate that the decade ahead will reflect the growing awareness and importance of linking science, management and human dimensions as the status quo approach for the benefit of future generations.

Great Lakes Revitalization and Renewal

Gail Krantzberg, W Booth School of Engineering Practice and Technology, McMaster University, Hamilton, ON, Canada

This contribution is a compilation of publications that I co-authored on large lakes, and particularly, Great Lakes resilience and restoration. It consists of sections adapted from published works. The reference list includes literature cited herein as well as other relevant readings.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Editor in Chief Klement Tockner.

Glossary

Area of Concern Locations within the *Great Lakes* identified as having experienced high levels of environmental harm.
Beneficial uses A change in the chemical, physical or biological integrity of the Great Lakes system sufficient to cause significant environmental degradation.
Ecosystem services The transformation of a set of natural assets (soil, plants and animals, air and water) into things that we value as humans.
Eutrophication Excessive richness of nutrients in a lake or other body of water, frequently due to runoff from the land, which causes a dense growth of plant life and death of animal life from lack of oxygen.
GLWQA The Great Lakes Water Quality Agreement (GLWQA) is a commitment between the United States and Canada to restore and protect the waters of the Great Lakes.
Invasive species An organism that causes ecological or economic harm in a new environment where it is not native.
Microplastics Extremely small pieces of plastic debris in the environment resulting from the disposal and breakdown of consumer products and industrial waste.
Regeneration Restored to a better state.
Revival An improvement in the condition or strength of something, here, ecosystems and communities.
Stressors Physical, chemical, and biological constraints on the productivity of species and on the development of *ecosystems*.

Introduction

Fresh waters are the most valuable natural reserves on Earth. Lakes provide ecosystem services not only to humans, but also on broader scales: provisioning, regulating, supporting and cultural integrity (Table 1). Large lakes provide drinking water to hundreds of millions of people, a crucial matter considering that the drinking water insecurity faced by many populations might even be reinforced with the potential increase in drought due to a changing climate. Food harvested from large lakes is also of cultural and economic importance, and includes fish, invertebrates such as crayfish, and aquatic plants. Large lakes also provide important shipping corridors for trade, as is the case with the Laurentian Great Lakes. Regulating services—benefits obtained by regulating ecosystem processes—provided by large lakes include safe harbors (protection from storms), erosion and sedimentation regulation, water storage, hydroelectric power generation potential, water quality regulation, and waste assimilation. In terms of non-material benefits or societal services, large lakes offer extraordinary aesthetic experiences (viewscapes), recreational (boating, fishing, beach use) and tourist opportunities, and places of spiritual interludes that humans value immeasurably (Jenny et al., 2020). The variability in ecosystem services provided by large lakes depends on their underlying ecology and the current state of their environment that is closely connected to the surrounding watershed (de Groot et al., 2012).

Table. 1 List of services provided by large lakes, and specific examples of services.

	Ecosystem services	*Examples*
1	Provisioning services	Food, drinking water, industrial water and hydroelectricity, water for navigation, genetic resources, medicinal resources
2	Regulating services	Water flow regulation, local climate regulation, water quality regulation, regulation of natural risks, transfers or sequestration of elements . . .
3	Supporting services	Habitats for nursery and reproduction (plant and animal), maintenance of aquatic fauna and flora from micro-organisms to macro-organisms, sustain migratory species and wildlife, hot spots of biodiversity
4	Cultural services	Aesthetics, recreation, inspiration for culture and art, spiritual experience, cognitive and scientific development

Most of these services are provided by lakes of all sizes and are not restricted to large lakes. However, large lakes represent 90% of the total lake surface area and hence contribute the major portion of these services.

Modified from de Groot R, Brander L, van der Ploeg S, Costanza R, Bernard F, Braat L, Christie M, Crossman N, Ghermandi A, Hein L, Hussain S, Kumar P, McVittie A, Portela R, Rodriguez LC, ten Brink P, van Beukering P (2012). Global estimates of the value of ecosystems and their services in monetary units. *Ecosystem Services* 1: 50–61. https://doi.org/10.1016/j.ecoser.2012.07.005.

Degradation of lake ecosystems is evident worldwide, threatening the functioning of these ecosystems and the essential services they provide at a global scale (Fig. 1, Keeler et al., 2012). Future threats to large lakes include the overexploitation of resources, inputs of excess nutrients and harmful algal blooms, changing climate, overfishing, species invasions, infectious diseases, expanding hydropower, acidification, contaminants, emerging contaminants, engineered nanomaterials, microplastic pollution, and cumulative stressors.

Past alteration of large lakes is also reducing their capability to resist new threats, and degradation of water quality will continue because of the cumulative impact of ongoing local pressures, synergies among stressors, and the imposition of global stressors (climate, volatile compounds, and invasive species). Even in regions that successfully combatted environmental degradation such as eutrophication, new threats are emerging, with consequences for large lakes and their ecosystem services that are difficult to fully predict. These impacts are altering large lake ecosystems and services in unprecedented ways, causing widespread concern among freshwater scientists.

Long-term ecosystem services of large lakes: Their role for humanity

The contribution of lakes to human assets and to the regulation of nutrient and biological cycles is particularly important to society. Over the last centuries, societal awareness and value of provisioning, regulating or cultural ecosystem services (Table 1) provided by large lakes have shifted, often in response to a growing human population and after those services were degraded. Large lakes provide critically important benefits to all people (Table 2), and they need increasing care and attention to meet the growing demands for their ecosystem services at a time of increasing threats of ecosystem degradation.

Large lakes are sentinels of local human pressure, pollution and ecological impacts, particularly large lakes, which integrate the impacts of human activities on land use, mass fluxes, pollutant transfers and management interventions. Large lakes therefore provide evidence of socio-ecological resilience, and an integrative measure of the humanity's willingness to protect and sustain the surrounding environment (Jenny et al., 2020). Many of large lakes are transboundary, necessitating international policy frameworks. Several examples of international policy frameworks and programs geared toward large lakes are described in Table 3.

Major disturbances and threats

Stressors can change physical and chemical conditions in a lake to enhance or limit plant and animal growth, alter hormone function, operate as toxic element by increasing mortality, or change the behavior and seasonal timing of plant and animal development. In addition to the direct effects, stressors can operate indirectly through prey, predation, competition and non-trophic interactions, resulting in profound impacts on water quality and ecosystem services (Fig. 4). The most widespread stressors with strong impacts on human society and a description of the main impacts are summarized below.

– Increased nutrient loading as a result of human activities results in eutrophication. Cultural eutrophication is historically associated with an oversupply of phosphorus (P) (Carpenter, 2008; Carpenter et al., 2018; Schindler, 1977, 2012). Most common symptoms of cultural eutrophication also include changes in species composition, decrease in water transparency, anoxia and biodiversity loss (Carpenter, 2005). Adverse impacts include the development of cyanobacterial blooms. Consequently, eutrophication impairs ecosystem services such as fishing, water supply, and recreation. In Lake Erie, external loading of nutrients has become a more significant threat, particularly due to increased delivery of soluble reactive phosphorus delivery from nonpoint sources via tributaries (Jarvie et al., 2017). Since the 1950s, excess nutrient concentrations of nitrogen and phosphorus

Table 2 List of services provided by large lakes, related lake properties in each service class, and specific examples of services.

	Services related to observation and warning	*Related characteristics*	*Examples*
1	Earth system integrators	Lake area, volume, depth lakeshore length; lake:watershed; position within fluvial systems, and Earth system, sensitivity to climate variability	Climate and atmospheric regulation (local and regional), mitigation (buffer) of water volumes and quality and hydric-pollutions transfer to the sea: storage of particulates matters, bio-geochemical reactors (erosion, carbon circulation, water-storage), mostly equivalent to "regulating services"
2	Natural laboratories	Depth, age, origin, morphology, basin/lake ratio; water renewal time, salinity, chemistry, microbiology, endemism, species colonization	Lake system functioning, basic processes (water chemistry interface, chemotrophic microbiota, speciation, paleo-limnology, ecological responses to natural or anthropogenic perturbations, etc.)
3	Sentinels of global and local changes	Length of hydrological, thermal, chemical and ecological records; position within biomes; paleo-limnological records	Surveillance of climate and human impacts on biota, habitat, physics and geochemical cycles
4	Natural archives of human history	Riparian population, drinking water supply, other irreplaceable economic resources; documented historical records; evidence of past/present spiritual value, land cover and uses	Anthropocene, witness of human history, interaction of human with nature, changes in how humans value lakes, but also land ecosystems

have been changing the trophic state of Lake Erie's ecosystem, leading to reduced water quality and shifting environmental structures and functions within the lake ecosystem (Steffen et al., 2014). Eutrophication coupled with climate change appear to be resulting in cyanobacteria blooms, including dominance by *Microcystis* spp. (Steffen et al., 2014; Brittain et al., 2000; Chaffin and Bridgeman, 2014; Rinta-Kanto et al., 2005). Phosphorus has been considered the primary driver of the biological productivity of freshwater ecosystems (Schindler, 1974, 1977), however, the precise nutrient regime that favors toxigenic, non-nitrogen fixing cyanobacteria is complicated and needs to be better understood (Carey et al., 2012). Several studies suggest that nitrogen chemistry may shape the biological diversity of the system (e.g., Wilhelm et al., 2003). Still, the vast majority of nutrient management plans target the reduction of phosphorus loads into the watersheds of Lake Erie, not nitrogen loads (United States Environmental Protection Agency, 2015, 2017). As such, management measures are still ineffective and inadequate in mitigating the resurgence of cyanobacterial blooms of *Microcystis* (Gobler et al., 2016; Harke et al., 2016).

- Climate change is considered to be one of the most important challenges facing humanity today (Feulner, 2017; IPCC, 2018). Responses of lakes to climate change are well documented with increases in surface water temperature and water masses stability (O'Reilly et al., 2015; Schneider and Hook, 2010), loss of ice cover (Magnuson et al., 1990; Sharma et al., 2019), alterations in distribution of freshwater fishes, or decrease in deep-water oxygen concentrations (Zhang et al., 2020). The largest lakes in the world are most vulnerable to losing ice cover (Sharma et al., 2019) and are warming at the fastest rates, even as high as 1.0 °C per decade (O'Reilly et al., 2015; Schneider and Hook, 2010). Further, climate change interactions with additional stressors can lead to ecological surprises (Christensen et al., 2016). For example, changes in precipitation levels and increased potential evaporation rates have contributed to some lakes experiencing historically low water levels, whereas others are facing high water levels because of increasing runoff (Rodell et al., 2018; Wurtsbaugh et al., 2019), contributing to alterations in water quantity, water quality, and consequently water scarcity (Vörösmarty et al., 2000).
- Littoral shoreline modification is a direct consequence of the development of human societies. Human settlement on the coast, nutrients and pollutants inputs, creation of harbors and beaches strongly influence local shorelines habitats, which represent the engines of lake biodiversity (Schmieder, 2004; Vadeboncoeur et al., 2011). Shoreline transformations modify the physical impact of waves and littoral slopes, and create sheltered areas with higher nutrient accumulation, enhancing the development of phytoplankton do the detriment of macrophyte communities (Weisner et al., 1997). This affects habitats for fishes and macroinvertebrates, and can disrupt the trophic relationships of the whole ecosystem.
- Invasive species have drastically altered large lake ecosystems, resulting in significant economic losses to society. Dreissenid mussels have changed nutrient pathways in the Laurentian Great Lakes (Hecky et al., 2004), altering benthic invertebrate and plankton communities (Madenjian et al., 2015) and leading to population changes felt by the commercial fishery (Fera et al., 2015, 2017). The threat from invasive species will likely be exacerbated as climate change pushes species boundaries to new areas. Further, transoceanic shipping networks (such as in the Laurentian Great Lakes, Holeck et al., 2004) combined with ship ballast represent an open door to invasive species if not managed aggressively.

Table 3 Examples of some international and national frameworks to manage large lakes.

Programs	*Year*	*Countries/lakes*	*Description*
International/multi-national			
Global Lake Temperature Collaboration (GLTC)	2010	15 countries in the world	Working group that analyzed global lake water temperature records
Laurentian Great Lakes Coastal Wetland Monitoring Program		USA, Canada	Assess coastal wetlands (Cooper et al., 2018; Uzarski et al., 2017)
Cooperative Science and Monitoring Initiative (CSMI)		USA, Canada—Laurentian GL	CSMI coordinates research activities and focuses resources on a few key issues (Foley et al., 2009)
EU Water Framework Directive (WFD)	2000	European Union countries	Legislative framework for assessing and protecting ecological status of all aquatic ecosystems (Directive 2000/60/EC; WFD, n.d.)
The Great Lakes Water Quality Agreement (GLWQA)	1972, 2012	USA and Canada	Commitment to restore and maintain the integrity of the Laurentian GL waters
Global Lake Ecological Observatory Network (GLEON)		34 countries on 6 continents	Network that conducts innovative science by sharing and interpreting long-term or/and high-resolution sensor data
Commission Internationale pour la Protection des Eaux du Léman (CIPEL)	1963	Switzerland and France	Commission responsible for monitoring the quality of the water in Lake Geneva, in the Rhône and in their tributaries
International Commission for the Protection of Lake Constance (IGKB)	1959	Germany, Austria, Switzerland and Liechtenstein	Observation, recommendation for coordinated preventive measures, and discussion of planned utilization of the lake
Long-Term Ecological Research (LTER)—e.g., North Temperate Lakes (NTL)	1980	Many countries world-wide	Studying ecological processes over extended temporal and spatial scales
The Great Lakes Basin Compact (GLC)	1955	Eight US states and Ontario and Quebec, Canada	Enable transboundary cooperation on lake management
National/domestic			
US Clean Water Act (CWA)	1972	USA	Primarily, regulating discharges of pollutants into the waters
Canada Ontario Agreement (COA)		Canada	Restore, protect, conserve Laurentian Great Lakes water quality and ecosystem health
Water Pollution Prevention and Control (WPPC)		China	Water management to ensure emergency and back-up water resources are available in cities
Single large lake policies			
Aral Sea Wetland Restoration Project (ASWRP)		Aral Sea	Ecosystem rehabilitation via creation of artificial ponds and wetlands in the delta, and dry bed
Aral Sea Program	1995	Aral Sea	Restoring the Aral Sea to its former level
Convention on the Legal Status of the Caspian Sea	2018	Caspian Sea	How to divide up the potentially huge oil and gas resources
Framework Convention for the Protection of the Marine Environment of the Caspian Sea	2006	Caspian Sea	Protection of the Caspian environment from all sources of pollution
Lake Victoria Environmental Management Program (LVEMP)	2011	Lake Victoria, Africa	Tackle environmental challenges of lake basin over the long-term and improve welfare of inhabitants that depend on its resources
Canada-Ontario Lake Erie Action Plan, Under Large Lakes Protection Act	2018	Lake Erie	Reducing P loads to the western and central basins of Lake Erie by 40% by 2025
Convention on the Sustainable Management of Lake Tanganyika	2003	Lake Tanganyika	Objective to ensure the protection and conservation of the biological diversity and the sustainable use of the natural resources

The story of sea lamprey (*Petromyzon marinus*) in the Laurentian Great Lakes is a rare example of the successful, ecosystem-scale control of an invasive aquatic vertebrate. The sea lamprey, native to the Atlantic Ocean, was first recorded in Lake Ontario in 1835 and, after improvements to the Welland Canal, spread throughout the remaining Laurentian Great Lakes by the 1920s–30s (Christie and Goddard, 2003). This species invasion was catastrophic both ecologically and economically, decimating lake trout stocks and other native species and contributing to the collapse of commercial fisheries (Siefkes et al., 2013). Sea lamprey adults are parasitic, attaching to a fish host with their suction cup mouth, using a rasping tongue to pierce the host's flesh, and feeding on blood and body fluids. A breakthrough was made in the 1950s, when it was discovered that a compound, 3-trifluoromethyl-4′-nitrophenol (TFM), could selectively kill sea lamprey larvae (Applegate et al., 1957). The treatment of Great Lakes' tributaries with TFM is the cornerstone of an extensive binational, science-based control program administered by the Great Lakes Fishery Commission. Sea

lamprey populations have been suppressed by as much as approximately 90% compared to pre-control levels (Heinrich et al., 2003; Smith and Tibbles, 1980), resulting in the recovery of key fish populations and the restoration of the 7-billion-dollar recreational fishery (Siefkes et al., 2013). The sea lamprey example highlights the success of a science-based invasive species control program, but is also a cautionary tale for the importance of preventing exotic species introductions in the first place to avoid costly control programs to mitigate negative effects.

New challenges and future threats to large lakes

Ecosystem health and ecosystem services provided by large lakes are vulnerable to emerging threats such as microplastics, micropollutants, and the cumulative effects of threats including climate change, eutrophication, over-harvesting, and invasive species. Among contaminants, microplastics are an emerging issue for freshwaters, but studies of microplastics in freshwaters are still rare, fragmented and include little quantitative data (Mani et al., 2015; Helm, 2020). Emerging threats and the challenges associated with cumulative effects of multiple stressors in large lakes follow.

- Microplastics: Since the start of plastics mass production in the 1940s, microplastic contamination of aquatic environments has been a growing problem. Microplastics can be ingested by organisms, accumulate in specific tissues, and be transported along the food chains. Moreover, they sorb and transfer chemicals and persistent, bioaccumulative substances into the food web (Krantzberg, 2020; Eerkes-Medrano et al., 2015). As these polymers are highly resistant to degradation, quantities of microplastics in aquatic environments will most likely continue to increase over time (Galloway and Lewis, 2016).

  Although marine microplastic research remains at the forefront, in recent years researchers, recognizing the comparative lack of studies on microplastics in freshwater environments, have begun to address this field as a matter of priority (Horton et al., 2017). Tributaries and point source effluents have been identified as major pathways for microplastics of terrestrial sources (Mani et al., 2015). Recent research now shows large lakes also contain microplastic pollution, with the highest concentrations in heavily urbanized regions, such as Toronto (Canada) and Detroit (USA) (Eriksen et al., 2013). For example, Castañeda et al. (2014) found that a liter of sediment from the St. Lawrence River contained up to 1000 spherical microplastics—on par with the world's most polluted marine sediments. Plans to combat and curtail plastic debris pollution (i.e., by reducing debris input, but also tracking and removal efforts) in large lakes will come at a significant economic cost, likely in excess of $400 million annually (Driedger et al., 2015).

- Micropollutants: Micropollutants, including heavy metals, pesticides, pharmaceuticals, and cosmetics pose significant threats for aquatic ecosystems (Blair et al., 2013; Codling et al., 2018; Metcalfe et al., 2019; Schwarzenbach et al., 2006). Endocrine-disrupting compounds mimic natural hormones and interfere with the endocrine systems of animals and humans. Pharmaceuticals and personal care products are discharged into surface waters as they are not degraded by wastewater treatment plants (Kümmerer, 2008).

Micropollutants can affect the survival and behavior of aquatic species, alter the reproductive system of aquatic organisms, and promote the development of resistant bacterial strains representing a health risk to humans (Uslu, 2012). In the future, increasing human populations will exacerbate the release of micropollutants to aquatic systems. This is particularly true for large lakes as their huge catchments make them the final sink of pollution. Regulation of the release of micropollutants is essential (Uslu, 2012). This suggests that regional and international cooperation must be forged to ensure lake water quality.

Summary on threats and management of large lakes

The demands of a growing global population with rapidly changing consumption patterns for food, mobility and energy are exerting ever-increasing pressure on the Earth's ecosystems and their life-supporting services. In combination with climate change, these changes raise concerns about current large lakes ecological status and the services they can provide. In addition, increasing threats to large lakes include the overexploitation of resources (water and food), inputs of excess nutrients and contaminants, reduction of habitats, species introduction or invasion, and cumulative stressors.

Restoration efforts can achieve success. Complete restoration to historic condition or pristine condition is hard to achieve, sometimes it even fails, but the Remedial Action Plan (RAP) examples below show that the regeneration of ecosystem function is attainable. The RAP process is a method to determine restoration targets to recognize the recovery of self-functioning freshwater ecosystems. Establishing systems for efficient management may be expensive but the future cost of inaction may be too high.

Plans to combat and curtail emerging threats, such as plastic debris pollution in large lakes, will come at significant economic cost (Driedger et al., 2015). The large costs associated with conservation efforts are legitimate concerns by the citizens who bear those costs, and who need to understand the pertinence and sustainability of such programs. Further, decisions about long-term strategies will have to be supported by future generations. As such, lake managers need to consider if these strategies can be supported in the future, at what cost, and be able to demonstrate the costs and social, cultural, economic and ecological implications from temporal or permanent interruptions in ecosystem services due to inadequate investment in policies and programs for large lake monitoring, restoration, and protection.

A deeper look into the Laurentian Great Lakes

The Great Lakes and other lakes and rivers in the Basin provide drinking water to tens of millions of people. On both sides of the border, the Basin supports multibillion-dollar manufacturing, service, tourism and outdoor recreation industries as well as strong maritime transportation systems and diversified agricultural sectors. It provides the foundation for trade between Canada and the United States, equaling 50% of Canada's annual trade with the United States. Each year, the Great Lakes region contributes $180 billion to Canada-US trade. In 2012, the Great Lakes region had a combined GDP of $5.2 trillion among the two provinces and eight states (ECCC (Environment and Climate Change Canada), 2016).

Unfortunately, degradation of environmental quality directly damages the viability and vigor of the region. The reliance of the economy on a healthy Great Lakes Basin Ecosystem is unequivocal and the imperative to restore ecosystem health is clear. To strive for a sustainable future, social and ecological and economic interests must be integrated. As Costanza (1992) asserts, sustainability can be defined as a balanced relationship between the dynamic human economic systems and the dynamic, but generally slower-changing ecological systems in which: (1) human life can continue indefinitely; (2) people can flourish, (3) cultures can develop, but within bounds such that human activities do not destroy the diversity, complexity, and function of the ecological life-support system.

As consumerism and industrial production are on the rise, non-renewable and renewable natural resources are being used more frequently in order to satisfy human desires. As described by deBoer and Krantzberg (2013)

> Robert Hennigan (1970) at the Thirteenth Conference on Great Lakes Research expressed that there is a requirement for understanding and reform of the Great Lakes institutional ecosystem to establish an attainable and workable system for effective water management. Incorporation of the action elements of persuasion and education, legal action and economic incentives were noted as being particularly necessary for the success of this system.

This prophetic insight still holds and calls on stakeholders to regard the water management issue as an integrated governance challenge and not a compilation of programs and policies applied reactively to address insults to the system.

Binational accords and events

> The United States of America and His Majesty the King of the United Kingdom of Great Britain and Ireland and of the British Dominions beyond the Seas, Emperor of India, being equally desirous to prevent disputes regarding the use of boundary waters and to settle all questions which are now pending between the United States and the Dominion of Canada involving the rights, obligations, or interests of either in relation to the other or to the inhabitants of the other, along their common frontier, and to make provision for the adjustment and settlement of all such questions as may hereafter arise, have resolved to conclude a treaty in furtherance of these ends, and for that purpose have appointed as their respective plenipotentiaries
>
> BWT (Boundary Waters Treaty) (1909)

The 1909 Boundary Waters Treaty stated that "boundary waters and water flowing across the boundary shall not be polluted on either side to the injury of health or property on the other." The Treaty created the International Joint Commission to prevent and resolve disputes over the use of boundary waters and to deal with boundary tensions between the two nations.

A 1966 detailed investigation of pollution problems in Lakes Erie and Ontario and the St. Lawrence River resulted in an in-depth report on water quality and the recommendation for an international lower lakes clean-up effort focused on the role of phosphorus in eutrophication. The report resulted in the signing of the Great Lakes Water Quality Agreement in 1972. The Agreement coordinated an international clean-up effort to enhance the water quality of the Great Lakes. The International Joint Commission became actively involved in analyzing and disseminating information. The Commission advised both governments on effectiveness of programs and provided water quality updates.

In 1978, the Canadian and US governments reviewed the Agreement of 1972 and revised it to re-affirm the commitment of each country to restore and maintain the chemical, physical and biological integrity of the Great Lakes Basin Ecosystem. Even more comprehensive than the original agreement, the 1978 Great Lakes Water Quality Agreement placed greater emphasis on toxic substance management, dredging and shipping regulations, and continuation of the phosphorus control program started in 1972.

The Great Lakes Water Quality Board (the principal policy advisors to the IJC), in its 1977 Annual report, listed the problem geographic locations, described the nature of the problem, identified dischargers of substances that were probably causing the problem, and commented on progress toward compliance with jurisdictional enforcement programs. The report also described remedial programs in the drainage basin of each problem area and progress toward meeting boundary water quality objectives. The Board developed a procedure for data assessment and identification of Areas of Concern. The unique experiment in place-based remediation and protection called for in the 1987 Protocol emerged directly from recommendations of the WQB (Water Quality Board, 1985; Krantzberg et al., 2006).

In 1987, a Protocol was signed amending the 1978 Agreement. The amendments were aimed at strengthening the programs, practices and technology described in the 1978 Agreement and to increase accountability for their implementation. Timetables were set for implementation of specific programs. New annexes address atmospheric deposition of toxic pollutants, contaminated sediment, groundwater, and nonpoint sources of pollution. Annexes were also added to incorporate the development and implementation of Remedial Action Plans for Areas of Concern and Lakewide management plans to control critical pollutants.

In 1985, the Water Quality Board reported that a clear manner to measure progress in AOC implement or how to remove one from the AOC list (delisting) was absent. The Water Quality Board created a process for AOC development and implementation with categories that identify the status of the information database, ongoing programs to fill in information gaps, and the extent of remedial efforts directed at to addressing specific use impairments. Hartig and Thomas (1988) pointed out early in the program establishment that the development of RAPs represents a challenging departure from most historical pollution control efforts, where separate programs for regulation of municipal and industrial discharge, urban runoff, and agriculture runoff were implemented without considering overlapping responsibilities or whether they would be adequate to restore beneficial uses. This new process will thus call upon the talents available in a wide array of programs far beyond those traditionally associated with water pollution control, including the involvement of local communities and a wide range of agencies at all government levels. All programs, agencies, and communities affecting an Area of Concern must come together to work on common goals and objectives in the RAP.

The location of the geographic Areas of Concern is present in Fig. 4. Originally, the Province of Ontario had 17 AOCs, the State of Michigan had 14 AOCs, the State of Wisconsin had 4 AOCs, St. Louis River/Bay is the only Area of Concern in Minnesota, Waukegan Harbor is the only AOC in Illinois, Ohio had 4 AOCs, The Grand Calumet River/Indiana Harbor is the only AOC in Indiana, and New York had 6 AOCs.

Annex 1 in the Great Lakes Water Quality Agreement 2012 Protocol identifies 14 beneficial use impairments and initiated programs to restore these uses to the Great Lakes. These are:

(i) restrictions on fish and wildlife consumption;
(ii) tainting of fish and wildlife flavor;
(iii) degradation of fish wildlife populations;
(iv) fish tumors or other deformities;
(v) bird or animal deformities or reproduction problems;
(vi) degradation of benthos;
(vii) restrictions on dredging activities;
(viii) eutrophication or undesirable algae;
(ix) restrictions on drinking water consumption, or taste and odor problems
(x) beach closings;
(xi) degradation of aesthetics;
(xii) added costs to agriculture or industry;
(xiii) degradation of phytoplankton and zooplankton populations; and
(xiv) loss of fish and wildlife habitat (GLWQA, Canada and the United States, 1987).

As Krantzberg et al. (2006) described, the Agreement calls for the federal governments, in cooperation with state and provincial governments, to ensure the public is consulted throughout the development and implementation of the RAPs. Despite organizational and fiscal resource hurdles, several RAPs are being applied and as a result, there are notable advances in remediation and prevention programs. Essential elements that characterize successful initiatives include true participatory decision making, a clearly articulated and shared vision, and focused and deliberate leadership (Krantzberg, 2003).

Vallentyne and Beeton (1988) instructed that an "Ecosystem approach" means an integrated set of policies and managerial practices that relate people to "ecosystems" of which they are part-rather than to external resources or environments with which they interact. The identifying characteristics include: synthesis (integrated knowledge); a holistic perspective interrelating systems at different levels of integration; and actions that are ecological, anticipatory, and ethical in respect of other systems of Nature.

Adopting an ecosystem approach would require three changes: reframing the planning problem, creating an integrative knowledge base, and institutionalizing multi-stakeholder participation in decision making (Kellog, 1998). RAPs were a departure from water quality remediation plans to a watershed-based management context that would consider a broad array of human actions that affect water and ecosystem quality. Ecosystem-based action plans address remedial actions to restore degraded conditions, and would also inquire into the human dimensions that consider changing human behaviors that enable long term functionality and sustainability of the ecosystem. Discovering such methods necessitated an integrative understanding of the watershed's bio-chemical-physical functions and their susceptibility to anthropogenic stresses.

Hartig (1997) points out that there is no single best way to implement an ecosystem approach, since each defined AOCs involves a distinct physicochemical and biological factors, stakeholders, institutional frameworks, regulatory complexity and more. An implementation framework that is guided by eight criteria should include:

- stakeholder involvement;
- leadership;
- information and interpretation;
- action planning within a strategic framework;
- human resource development;
- results and indicators;
- review and feedback; and
- stakeholder satisfaction

The experiment in collaboration aimed at aquatic ecosystem health, as Sproule-Jones (2002) asserted, provided an innovative approach in which resource users, regulators, and those in an interest in regenerating resilience for the local ecosystem can collaborate toward a common purpose. They promise to empower local stakeholders to determine their own solutions to ecological degradation, and open new venues for collaboration.

With the assistance of governments, residents in most AOCs formed an advisory council/committee to work with federal/state/provincial technical and scientific experts. Citizen advisory committees were used as the focal point of public involvement for RAPs in 75% of the Areas of Concern. Known in various jurisdictions as public advisory committees (PACs), basin committees, or stakeholder groups, the IJC contends that such mechanisms are the key to implementing the ecosystem approach in remedial action planning. In citizen advisory committees, diverse interests come to the same table to participate in the planning process in an interactive manner, advising the planning agency throughout the preparation of the RAP. These committees typically have or had representatives from diverse community sectors, including, agriculture, business and industry, citizens-at-large, community groups, conservation and environment, education, fisheries, health, labor, municipal governments, native peoples, shipping, tourism and recreation (Landre and Knuth, 1993).

Engaging stakeholder groups in the plan design minimizes the risk of future polarization (Samy et al., 2003). Advisory Committee participants possess unique knowledge and represent the interests of their particular stakeholder groups. A key premise is that community residents poses important knowledge, and can provide an informed perspective of the social impacts of the decisions (Harris et al., 2003). The importance of involving communities in the management of water resources was one of the strongest and most consistent messages coming forward from an international conference in interjurisdictional water programs (Managing Shared Waters, 2002). Important is recognizing the value of traditional knowledge and the local public's anecdotal and experiential intellect. Best practices in public engagement processes use plain language to communicate clearly, are supported by commitments in institutional programs and policies, demonstrate early and often how the public input will be used, include mechanisms to resolve disputes, provide the community with access to technical experts, celebrate successes to nurture momentum and train community leaders thereby building capacity to sustain progress.

Jetoo et al. (2015) note that governance can be difficult to define as it is used in a multitude of different ways. While different interpretations abound, most agree that the basic characteristic of governance is the migration of power from the central state up into supranational institutions, horizontally to non-state actors, and down to sub-national levels of government and non-state actors. The collective objective is to work with governments and develop a plan to revitalize ecosystem health and implement the plan to achieve agreed-upon targets that indicate when beneficial uses are restored (Krantzberg, 2006).

Central to the successful deployment of the RAP process is clear accountability for active interventions. This is best accomplished through the open sharing of information, clear and unambiguous definition of stressors and problems (including the identification of indicators to be used in measuring when the desired state for a beneficial use is reached), agreement on the priority actions required, and the identification of who is responsible for taking what action. From this foundation, Hartig and Zarull (1992) clearly delineate the responsible institutions and individuals can be held accountable for progress.

The first stage for each Remedial Action Plan is to identify environmental problems, impaired beneficial uses, and their probable causes. The second stage is to develop a recommended set of remedial actions and preventative initiatives to improve environmental quality in support of the beneficial uses. Targets are set by which RAP practitioners can recognize that they have met their goals surrounding beneficial uses. In some AOCs, the targets set science-based and quantitative, wherever possible. In other cases, general statements guide the practitioners, making it difficult to recognize when success has been achieved.

Major successes include Collingwood Harbour, Severn Sound, and Wheatley Harbour in Ontario, Deer Lake, White Lakes, Presque Isle Bay and Oswego River in the United States, where conditions have improved to the point that these locations are no longer considered to be Areas of Concern. Spanish Harbour Jackfish Harbour in Ontario are now recognized as in a stage of recovery due to completion of all selected remedial actions, while monitoring continues to measure recovery of beneficial uses.

The Parties have completed all remedial actions at five other AOCs: Nipigon Bay in Canada; and Sheboygan River (Wisconsin), Waukegan Harbor (Illinois), Ashtabula River (Ohio), and St. Clair River (Michigan) in the United States. With remedial work completed, these five AOCs are now being monitored to determine when the beneficial use impairments have been fully addressed and delisting can occur (Progress Report of the Parties, 2016).

According to the Progress Report of the Parties (2016) improvements in Canadian AOCs include a total of 65 impairments of beneficial uses of the environment have been eliminated, with 81 impairments remaining. In 2015 construction began on the largest contaminated sediment remediation project ever undertaken in a Canadian AOC. Through a public-private partnership, the project will clean up 700,000 m^3 of severely contaminated sediment in the Hamilton Harbour AOC. Fig. 1 shows a summary of actions taken to date.

Other accomplishments in Canadian AOCs during the 2013–2016 period include improvements to approximately 4 km of shoreline habitat and approximately, 180 ha of coastal wetlands and fish spawning grounds; investments of approximately $562 million in upgrades to municipal wastewater treatment plants to significantly reduce nutrients, suspended solids and pollutants.

The US Environmental Protection Agency estimates that management actions will be completed at nine more AOCs by 2019. This pace of AOC restoration is attributed to the Great Lakes Restoration Initiative, where federal agencies have been able to apply over $650 million in GLRI funding to finance remedial action plan implementation. Fig. 2 shows a summary of actions taken to date.

The location of all the AOC are described in Fig. 3, while Fig. 4 demonstrations the process used by the International Joint Commission to monitor the progress of Canada and the United States in RAP implementation. Figs. 5 and 6 provide case studies in RAP achievements and successes.

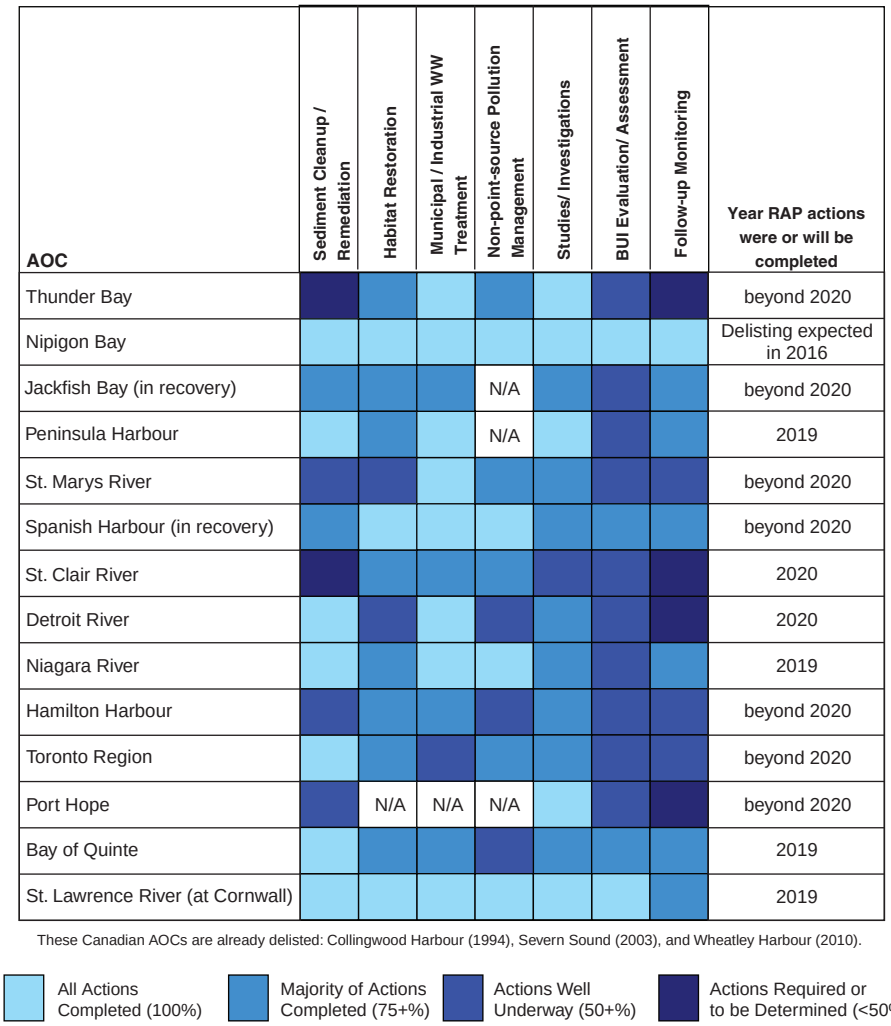

Fig. 1 Status of actions in Canada AOCs. From Progress Report of the Parties (2016) Pursuant to the Canada-United States Great Lakes Water Quality Agreement.

Working in the trenches of ecosystem-based watershed management is a challenging puzzle requiring a marathoner's discipline and perseverance. Yet the people in the 43 Great Lakes AOCs had a strong incentive to come together to clean up their communities over the past few decades. By studying their efforts, we can learn about the approaches that worked and did not work. We also can see how these efforts have paid off in the form of preventing pollution, restoring habitat for fish and wildlife, cleaning up contaminated sediment, and creating vibrant waterfronts that connect people to the water. The successes illustrated in the 10 case studies below demonstrate approaches that other waterfront communities can consider in shaping their own collaborative efforts.

Committing for the long run

It took nearly two centuries to reach the state of pollution found in the AOCs in 1985. Restoring these spots is no quick task either, considering the time it takes to build trust among stakeholders, reach agreement on problems, identify and select remedial and preventive actions, and secure funding for implementation, especially given all the competing interests for funding.

Initially, progress was slow because of the need to reach agreement on the severity and geographic extent of the problems identified in 1985; employ an ecosystem approach and involve stakeholders; align management programs; and secure commitments for implementation. Other factors included limited federal, state, and provincial funding for RAPs (Krantzberg, 2003; Botts and Muldoon, 2005), decline in the effectiveness of International Joint Commission oversight (Botts and Muldoon, 2005), and a governmental "reluctance" to accept responsibility for fulfilling obligations under the Great Lakes Water Quality Agreement (General Accounting Office (GAO), 2003, 2009). Funding commitments are an important component of the RAP program successes. Funding uncertainties in both the United States and Canada jeopardize continued progress in these important programs.

As of 2020, seven AOCs have been delisted, two have been designated as Areas of Concern in Recovery (i.e., an area where, based on community and government consensus, all scientifically feasible and economically reasonable actions have been implemented and additional time is required for the environment to recover), and six have implemented all remedial actions deemed necessary for use restoration. In addition, 75 of 146 known use impairments identified in Canadian AOCs and 73 of 255 in the United States have been eliminated. Successful RAPs have been cleanup- and prevention-driven; made existing programs and statutes work;

AOC	State	Sediment Remediation	Habitat Restoration	Hydrologic Controls/Diversions	Safe Drinking Water Provided	Engineering Design	Studies/Investigations	Other Regulatory Action	BUI Evaluation/ Assessment	Year all remediation and restoration actions were or will be completed

established priorities on a local basis and worked to elevate those priorities within state, provincial, and federal governments; ensured strong community-based planning processes; streamlined decision making for use restoration; and been affirming processes (Hartig, 1997).

Engaging and empowering the community

RAPs called for involving the public through use of an ecosystem approach that accounts for the interrelationships among water, air, land, and all living things, including humans, and involves all user groups in managing their communities' waterways (Vallentyne and Beeton, 1988; Hartig and Vallentyne, 1989). RAPs challenged governments and other stakeholders to transform management (McLaughlin and Krantzberg, 2018).

This commitment to an ecosystem approach and stakeholder involvement led to the establishment of a variety of institutional structures, including public advisory councils or committees (PACs), stakeholder groups, basin committees, and others. Beeker et al. (1991) identified that structuring the process to create a sense of ownership of the RAP by participants, who were the very businesses, state and local agencies, and citizens who would have to carry out the recommendations, was a critical factor in RAP acceptance by all involved. Essential elements that characterize successful initiatives include true participatory decision making, a clearly articulated and shared vision, and focused and deliberate leadership (Krantzberg, 2003).

Fig. 3 Location and status of the Areas of Concern (Progress Report of the Parties, 2016).

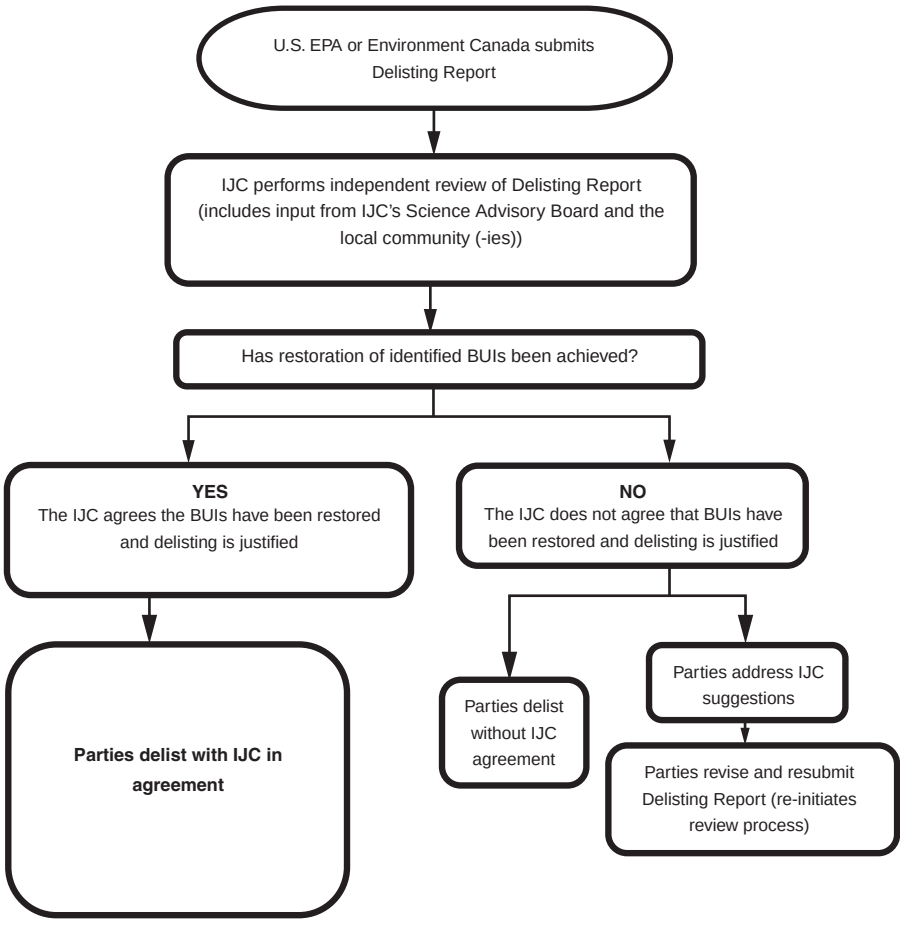

Fig. 4 A generalized process for review of RAP reports by the commission (International Joint Commission, 2003).

Randle Reef Sediment Remediation Project

Remediation is now underway at Randle Reef. The Randle Reef sediment remediation project involves constructing a 6.2 hectare engineered containment facility (ECF) on top of a portion of the most contaminated sediment, then dredging and placing the remaining contaminated sediment in the facility. The facility will be made of double steel sheet pile walls with the outer walls being driven to depths of up to 24 metres into the underlying sediment. The inner and outer walls will be sealed creating an impermeable barrier. The sediment will then be covered by a multi-layered environmental cap.

Skyway and Woodward Wastewater Treatment Plant Upgrades

Skyway (Burlington) and Woodward (Hamilton) WWTPs are currently undergoing major upgrades to improve treatment performance. At Woodward WWTP, phase 1 is now nearing completion. Future treatment process after phase 2 work is complete will employ additional methods to improve performance and reduce loadings that reach the Harbour through the effluent discharged to the Red Hill Creek.

Windermere Basin Restoration

In the summer of 2013, federal, provincial and Hamilton officials celebrated the completion of the $20.6-million rehabilitation of Windermere Basin, a 25 hectare plot of reclaimed industrial land. The purpose of the development project was to conduct restoration of the local ecosystem and provide natural wildlife areas and parklands for passive recreational use.

The project served several important environmental, social, and economic purposes. Windermere Basin:

- Enhances the Dundas Wastewater Treatment Plant's disinfection system to remove chlorine in the plant's sewage
- Increases Hamilton Harbour's visual appeal, while improving the fish and wildlife's habitat
- Creates an open body into a 13 hectare healthy Great Lakes coastal wetland that will benefit local fish and wildlife.
- Is a home to a variety of plants and animals, while offering community-based recreational opportunities.

Walleye Stocking

To create a balanced ecosystem, the presence of top predators is a necessity. In recent years, the Ministry of Natural Resources has annually stocked Hamilton Harbour with young walleye to help boost populations. In 2012, 100,000 young fish were introduced into the Harbour, followed by 10,000 in 2013, 950,000 in 2014, and another 50,000 in 2015. Along with improved water quality, the survival and eventual reproduction of walleye in Hamilton Harbour is a sign of a regenerating ecosystem.

Improvements to Public Access

With public access now restored to 28% of the Harbour shoreline, people are returning to Hamilton Harbour to enjoy recreational activities from cycling and strolling, to picnicking, sightseeing and dining. Future efforts aim to restore public access to 35% of the Harbour

A key concept in RAP processes has been accountability for action. This accountability is established through open sharing of information, clear definition of problems and causes, agreement on remedial and preventive actions needed, and identification of who is responsible for taking actions. From this foundation, the responsible institutions and individuals can be held accountable for progress. Indeed, increasing accountability was one RAP tenet identified in the 1987 Protocol to the Great Lakes Water Quality Agreement (Canada and the United States, 1987).

Cleaning up the legacy of toxic substances in sediment

Over many decades, toxic substances like heavy metals and organochlorine compounds were released into waterways and eventually accumulated in high concentrations in river, harbor, and embayment sediment. This buildup of toxic substances contributed to health advisories on fish, impacts on invertebrate life living in sediment, loss of habitat, restrictions on dredging activities, and more. Clearly, contaminated sediment was a major problem, yet there were no comprehensive federal, state, or provincial programs to address it. Dredging for navigational purposes was the primary means for addressing this problem at that time. Governments and RAP groups quickly discovered that the severity and geographic extent of the contaminated sediment problem was not well understood, nor was the relative importance of contaminated sediment in causing specific use impairments. In addition, stakeholders lacked a basis for determining how much sediment to clean up and what environmental/ecological improvements to expect over time.

Participatory decision-making works in the case of Presque Isle Bay for a number of reasons. First, is the relationships built over the years between the Public Advisory Council (PAC) and Pennsylvania Department of environmental Protection (PADEP) and the shared commitment to restoring the bay. That commitment is evidenced by the fact that many of the original PAC members continue to participate today nearly two decades after the bay became an AOC. Second, the citizens took ownership and exercised leadership in the decision to list the bay as an AOC. Third, both sides recognize the value of the other and appreciate the tools available to each; the PADEP understands the importance of public support and the PAC knows that government agencies are required to take or prevented from taking action due to laws, regulations, or agreements they implement. Fourth is the diversity of the PAC membership. Balancing of economic and environmental needs occurred around the PAC table as members of both communities worked hand-in-hand with regulators as part of the decision-making process. The composition of the PAC itself provided the opportunities to integrate the different yet dependent goals of economic prosperity and environmental restoration in the RAP process. While not always in agreement nor able to be equally balances, PAC members considered both perspectives. A willingness of members to compromise after being heard and the assurance of their role in decision-making prevented either perspective from bringing the RAP process to a standstill. Presque Isle Bay is a healthier ecosystem today as a direct result of the leadership and support of the community through the Coalition, Council, and PAC, as well as the vision and willingness to act exhibited by the local and state governments.

Fig. 6 Presque Isle Bay: participatory decision making. Source: Boughton (2012).

Governments, research scientists, and RAP groups had to figure out how to make decisions (e.g., on the severity and geographic extent of sediment contamination, on whether or not to remediate, on what techniques to use) and how to get the money to remediate sediment, if necessary. In many respects, both the Canadian and US contaminated sediment assessment and remediation programs came out of the RAP program.

To effectively address contaminated sediment at Canadian AOCs, the Canada-Ontario Agreement on Great Lakes Water Quality and Ecosystem Health's Sediment Assessment Decision-Making Framework was created in the early 1990s. This was a step-by-step guidance for an ecosystem approach to assess the risk of contaminated sediment. There have been nine Canadian AOCs where active remediation has been completed and the sites restored; however, additional work is still required at some AOCs where multiple sites require remediation. Remediation is currently ongoing or in the planning stages in three AOCs. One of those sites is Randle Reef in Hamilton Harbour, the largest Canadian contaminated sediment site in the Great Lakes. Remediation there is expected to cost approximately $139 million (Canadian). When completed, it is expected that water quality will improve, current restrictions on navigation will be removed, and economic returns will be generated through the creation of valuable port lands. Peninsula Harbour, a mercury- and PCB-contaminated site in Canadian waters of Lake Superior, was remediated in 2012 with the placement of the first thin layer cap. Four additional AOCs will likely continue with controlling contaminants at their source and leaving contaminated sediment in place and allowing clean sediment, over time, to effectively bury contaminated sediment; a process called monitored natural recovery.

In the United States, the US Environmental Protection Agency created the Assessment and Remediation of Contaminated Sediment (ARCS) Program in the early 1990s to measure sediment contamination at chosen sites, recommend approaches both to evaluate the effects of these contaminants on aquatic life and to assess risks to wildlife and human health posed by the contaminants, and test technologies that could be used to clean up contaminated sediment. Although the ARCS program significantly added to the scientific understanding of sediment assessment and remediation techniques, federal and state enforcement programs were primarily responsible for progress in remediating contaminated sediment in AOCs. The sediment remediation funding shortfall was then filled by the Great Lakes Legacy Act and GLRI. In total, between 2004 and 2017, US federal, state, and other partners have completed 46 contaminated sediment remediation projects in US AOCs, resulting in the remediation of more than 6.6 million cubic meters of contaminated sediment at a cost of $1 billion (US) (Tuchman et al., 2018).

Fish and wildlife habitat

Loss of fish and wildlife habitat is a common problem in most AOCs. Prior to the onset of RAPs, it was often said that "habitat had no home." Responsibility for habitat was fragmented among many stakeholders. RAPs made habitat a priority and challenged management agencies to address it explicitly. Restoration of fish and wildlife habitat had to be addressed in a systematic and

comprehensive fashion, which was particularly challenging in urban AOCs. In many cases, RAPs helped make sure that habitat was an integral part of community master plans. Early involvement of habitat experts in project planning and partnerships was essential to habitat project success.

As a result of this focus, considerable habitat rehabilitation has been undertaken in AOCs. For example, early efforts in the late 1980s and 1990s focused on the scientific assessment of "loss of fish and wildlife habitat" and its causes through RAP development. Later efforts focused on restoration options and determining how much habitat was enough to remove it as a use impairment. In general, limited habitat restoration occurred in US AOCs until the GLRI provided significant resources. Between 2011 and March 2018, more than $280 million (US) from the GLRI alone was spent on habitat restoration in US AOCs, with many projects still in the design phase (Hartig et al., 2018b). These substantial financial resources clearly accelerated habitat restoration in US AOCs.

In Canada, restoration of fish and wildlife habitat in AOCs has been a priority since the onset of RAPs. The development and implementation of Natural Heritage strategies to conserve biodiversity, as well as fish and wildlife management plans, were pioneered in AOCs. The RAP program also developed, demonstrated, and evaluated habitat restoration techniques. Since 1989, more than $500 million (Canadian) has been spent on habitat restoration in Canadian AOCs (Hartig et al., 2018a).

Restoring fish and wildlife habitat was an essential component of RAPs in each of the 10 case studies, with more than $129 million (Canadian) and more than $176 million (US) spent thus far.

Concluding remarks

Margerum and Robinson (2015) advised that partnerships operating at the organizational level require networks that support the flow of information and decisions across agencies. While such efforts predict improved better decision making, long-term efficiencies and better outcomes, there are high transaction costs, and the benefits are often not accrued until the long term. They point out that this necessitates that leaders be willing to make long-term investments and that organizations understand the need to change their culture and reward structures to support partnerships. For RAPs this is a difficult challenge if current pressures were aimed at short-term results, individual performance measures, and a focus on core organizational goals rather than collective management to attain shared goals.

Hall et al. (2006) provide an evaluation of the strengths the RAP processes. To achieve the goal of restoring environmental health requires "a dynamic process that relies heavily on research and monitoring to direct remediation efforts. Three principle means of coordinating this research and monitoring include: research and monitoring workshops; a monitoring catalogue outlining both government and nongovernment initiatives; and an annual report written by a local community group. These tools increase the effectiveness of remedial actions by: (i) improving stakeholders' ability to track trends; (ii) allowing program decision-makers to utilize adaptive management techniques to continuously modify programs based on new results; (iii) integrating interdisciplinary fields, and (iv) increasing accountability."

Together, pollution prevention, habitat restoration, contaminated sediment remediation, and other remedial and preventive actions have been a springboard for local communities to convert areas that were once a detriment to economic growth into valuable waterfront economic assets. Indeed, cleanup of AOCs is an integral and essential part of waterfront community revitalization. Good examples of where AOC cleanup has led to improved public waterfront access, followed by revitalization, include Buffalo River, Collingwood Harbour, Cuyahoga River, Detroit River, Hamilton Harbour, Muskegon Lake, River Raisin, Severn Sound, St. Louis River, and Toronto and Region. These communities are literally transforming former polluted rivers and harbors in the industrial heartland into healthier and more attractive waterfront destinations for businesses, recreation, and tourism. In many respects, this process of cleaning up AOCs, improving public access to these waters, and revitalizing waterfronts is like place making, a process that engages stakeholders in efforts to improve the quality of a public place and the lives of all who live in the community. The goal is to create a sense of place, defined as an authentic personal attachment or belonging to a particular place. Once people acquire a sense of place, this can lead to caring about their place and developing a stewardship ethic.

During the second industrial revolution, waterfronts of most communities evolved to support transportation, industry, and commerce. As such, these communities made rivers and harbors their back doors, and AOCs were no exception. In contrast, waterfronts today are viewed as magical places where the water meets the land and draws people to the shore for enjoyment and livelihood. Simply put, we have come to recognize the need to look at the water and not away from it. Experience has shown that creating waterfront vistas, reintroducing watershed residents to river history and geography, establishing unique conservation places linked by greenways and blueways (i.e., canoe and kayak trails), promoting ecotourism, and championing green developments founded on a "sense of place" help people see how they are part of an ecosystem and not separate from it. People must come to understand that what they do to their ecosystem, they do to themselves. This helps create a psychological connection that brings people to see that water is part of their life and culture. This connection also can lead to development of a stewardship ethic that builds the political base for watershed preservation and sustainability.

The Great Lakes basin ecosystem is home to 107 million people and 51 million jobs, accounts for more than 50% of all US/Canadian bilateral border trade and supports shipping of over 200 million tons of cargo annually. If it were its own country, it would have a gross domestic product of $6 trillion (US), making it the third biggest economy in the world (Desjardins, 2017).

AOCs can be considered microcosms of human impacts on the Great Lakes. After human settlement along the shores of the Great Lakes and their tributaries, these areas became centers of trade and commerce, followed by development of industry and agriculture that powered economic growth in the region. Use and abuse of these waters to power the region's mining, lumber, pulp and paper,

steel, automotive, chemical, energy, ship building, and grain industries reached a zenith in the 1960s when birds like bald eagles and peregrine falcons experienced reproductive failure because of pesticides like DDT, massive algal blooms resulted in Time magazine declaring Lake Erie dead, and indiscriminate discharge of oil and petroleum products resulted in the burning of the Buffalo, Cuyahoga, and Rouge rivers. The resulting public outcry spurred the environmental movement that led to establishment of Earth Day in 1970 and the passage of the Canada Water Act in 1970, the US Clean Water Act in 1972, the Canada-US Great Lakes Water Quality Agreement in 1972, and the US Endangered Species Act in 1973.

We continue today to clean up legacy pollution in AOCs. The development and implementation of RAPs using an ecosystem approach has opened the door to seeing how cleanup and restoration of AOCs can help catalyze waterfront revitalization. Linkages must be better established between cleanup and restoration efforts in AOCs and community revitalization efforts. Greater effort must be placed on bringing these two activities (i.e., cleanup/restoration and revitalization) into alignment and making sure that they are complementary and reinforcing to achieve a synergy for sustainable redevelopment with its substantial economic and social benefits.

Considerable evidence shows that people are willing to pay to locate in areas of high ecosystem quality (Anderson et al., 2009). People place a high value on the Great Lakes and are willing to pay a premium to live in coastal communities. Cleaning up AOCs not only improves ecosystem services (i.e., the benefits we receive from healthy ecosystems and natural resources) and makes these cities more desirable places to live, but helps businesses attract and retain employees.

The AOC designation has contributed to a negative perception of communities living in and near them. For many, the AOC designation was perceived as a "black eye" for their reputation. Cleaning up AOCs not only improves ecosystem services but can help change how communities are perceived.

The development and implementation of RAPs using an ecosystem approach has opened the door to seeing how cleanup and restoration of AOCs can help catalyze waterfront revitalization.

Where successful, RAPs clearly embrace the ecosystem approach. Here, the ecosystem approach is based on the man-in-system concept rather than a system-external-to-man concept (https://www.ijc.org/en/what/glwqa-history), where the ecosystem is composed of the interacting elements of water, air, land and living organisms including man. While there are several variants of the ecosystem approach, most share a focus on the responsiveness of ecological systems to natural and human activities, and a readiness to strike a programmatic compromise between detailed understanding and more comprehensive holistic meaning. This flexible pragmatism is perhaps the most productive feature for addressing Great Lakes environmental problems. Place-based types of restoration initiatives like RAPs are an unprecedented collaboration of international significant (Krantzberg, 1997).

Creative, distributed governance mechanisms and new institutional arrangements are needed (Krantzberg, 2003) to stimulate and sustain advances in the clean up local waterways, raise public awareness of individuals' responsibilities, unite a community around a shared purpose and need, and make the Lakes Great.

Glossary

Alluvial Pertaining to the deposition of sediment (e.g., clay, silt, sand, gravel) material by running water.
Ecosystem services The many and varied direct and indirect benefits obtained from ecosystems. Also, ecological contributions to human well-being. The four major categories are: provisioning, regulating, cultural and supporting services.
Emergent herbaceous wetlands A classification of vegetation characterized by herbaceous plants rooted below the surface of the water and either standing erect above the water or growing at the surface.
Floodplain The area of land, typically flat, adjacent to a river or stream, from its banks to bluff lines or valley edge.
Headwaters The initial source, or beginning location, of the water in a river. Typically, first, second, and third order streams.
Herbaceous Relating to vascular plants with non-woody stems, including grasses, sedges, rushes, and ferns.
Inland waters Freshwater aquatic ecosystems, including lakes, ponds, rivers, streams, creeks, springs, canals, reservoirs, and wetlands.
Lotic Moving, flowing or running waters, including rivers, streams, channels, creeks, and springs. Antonym is *lentic*, pertaining to low or standing waters, including lakes, ponds, swamps and marshes.
Riparian buffer The (vegetated) area near or adjacent to a stream or waterway. May be used synonymously as *stream buffer*, *riverine corridor*, or *stream corridor*.
Riparian Of, or relating to, the transitional area between aquatic and upland habitats. Frequently used broadly to describe the banks or areas surrounding a natural water area. Sometimes used interchangeably with *riverine*.
River Continuum Concept A framework describing the physical and biological gradients and longitudinal dynamics from headwaters to mouth.
Stream order A measure of the relative size of streams that assigns numerical delineations (1 through 12) according to the location of a stream segment relative to a watershed network. Streams are classified based on their number of tributaries. As such, larger orders correspond to increasing river size: first, second, and third order streams are typically considered *streams;* fourth, fifth, and sixth order streams are considered *medium streams*; and those seventh order and above are typically considered *rivers*.
Stream First to third order classification on the Strahler system for stream ordering.

Introduction

Rivers and streams cover less than 0.5% of the world's surface, yet they provide some of the most essential services for human existence, provisioning, and development (Downing et al., 2012; Allen and Pavelsky, 2018). High demand for the limited supplies of freshwater makes these ecosystems especially vulnerable to human pressures (Vörösmarty et al., 2010). Nearly 80% of the rivers important for water security and 65% of their habitat critical for biodiversity are threatened by multiple stressors from human activities including agricultural runoff, irrigation, pollution, invasive species, livestock grazing, and riparian degradation (Vörösmarty et al., 2010).

Riparian zones, at the transitional interface of terrestrial and aquatic ecosystems, encompass the low water areas of the stream channel through the surrounding upland terrestrial landscape (Naiman and Décamps, 1997). They represent a small proportion of landscape area but are more biologically diverse and productive than adjacent areas. With the majority (⅞) of the world's population living within 3 km of a river (Kummu et al., 2011) and human activities highly concentrated along rivers, riparian zones face disproportionately greater effects of human pressures on river landscapes (Naiman and Décamps, 1997).

Within riparian zones, riparian buffers are the vegetated areas most proximate to water (i.e., the areas buffering the waterway). Natural, vegetated riparian buffers provide key ecological functions, including bank stabilization, decreased erosion, flood buffering, sediment and nutrient filtration, shading and temperature moderation, and climate regulation. Buffers also provide important social services, including: (1) improved well-being from greenspaces, greenways and cultural sites along rivers; (2) improved air and water quality for human health; (3) enhanced recreational opportunities from high species richness and diversity; and (4) soil fertility and nutrient-rich soils for agriculture (Jones, 2008; Fig. 1). For example, riparian buffers support floral and faunal diversity important for human recreation, including many species of birds and ungulates (Naiman et al., 1993). Over half of adults in the U.S. hunt, fish, birdwatch or photograph wildlife, making riparian zones recreational hotspots (Jones, 2008). Proximity to riparian zones has also been shown to generate price premiums of up to 26% for residential properties adjacent to, or within, riparian zones (Jones, 2008). In Spain, approximately 4.3 million visitors enjoy riverine areas within national parks annually, and increasing numbers of urban residents are attracted to the country's river beaches and natural springs for recreational use (Gutiérrez and Alonso, 2013). In Canada, the riparian ecosystem services of just three rivers are estimated to provide 6000 Canadian dollars per hectare (Buffin-Bélanger et al., 2015). Elsewhere, riparian areas provide important intrinsic social and cultural services, including value as sacred sites or waterholes, windbreaks and hunting grounds, and in discovering a sense of place (Goldstein and DellaSala, 2020; Riis et al., 2020).

Collectively, riparian zones have considerable value to both human and natural systems (Fig. 2). Riparian buffers further serve as valuable protection for waterways from outside influences (e.g., nutrient loading). Buffers are most effective when they are contiguous along waterways and thus are often recommended as priority over broader, fragmented riparian zones (Fischer and Fischenich, 2000). Yet, by the turn of the century, the majority of riparian areas were reported to have been degraded or converted for human use; in some case studies, riparian vegetation had declined by as much as 95% (National Research Council, 2002). This is important when considering the entirety of a watershed because headwater streams have the greatest land-area ratio and are more susceptible to non-point source pollution as they are dominated by overland water flow (National Research Council, 2002). Headwater areas also have more influence on water quality than wider, downstream areas (Alexander et al., 2007). For example, removing forested buffers in smaller stream orders (i.e., size of the stream) will have a greater impact on increased water temperature than in larger rivers, where only part of the river is shaded. As such, riparian zones relative to the stream order can provide valuable opportunities for environmental management.

In the U.S., 2.65 million stream segments result in riparian areas accounting for less than 5% of total land area (National Research Council, 2002). Despite their small percentage of total land area, riparian zones are extremely important to overall

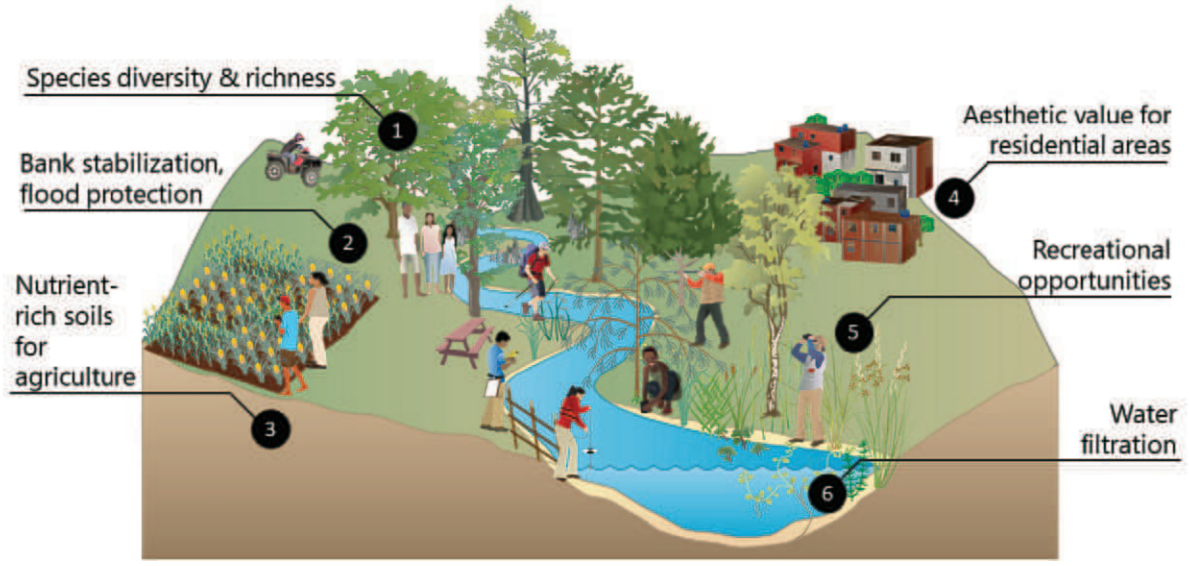

Fig. 1 Socio-economic values and uses of riparian zones: (1) species richness and diversity; (2) bank stabilization and flood control; (3) nutrient-rich soil for agricultural activities; (4) aesthetic benefits for residential properties; (5) recreational opportunities, including birdwatching, hunting, biking, and hiking (shown above); and (6) water filtration for improved water quality.

ecosystem function. Research is needed to understand which attributes of riparian buffers drive how people value them (Young, 2016), and historical land use trends can further be analyzed to help advance future decision-making. This chapter aims to provide a foundation for future analysis and understanding by presenting a snapshot of land cover change within riparian zone buffers classified by stream order and land cover classification. We use the U.S. from 2001 to 2020 as a case study to: (1) explore the basics of riparian zones, (2) identify trends in riparian zone land cover, (3) contribute an observational evaluation of how the U.S. has prioritized riparian zones during the 21st century, (4) provide examples of societal values placed on them and their protections, and (5) identify research gaps and needs.

Stream orders within a watershed

When water falls on the land surface, typically in the form of precipitation, some of the water drains along the land surface. As water moves along the land surface, it will flow from a location of high energy to a location of low energy; this most often results in water flowing downhill. As water flows downhill, it will establish preferential flow paths based on the path of least resistance, which ultimately results in the formation of channels for streams and rivers. As channels converge and form larger channels, the drainage pattern of water flowing across the landscape most often becomes dendritic (i.e., having a branching pattern similar to that of a tree). This is also referred to as a fractal pattern, where the drainage pattern remains the same at all spatial scales (i.e., small channels converge to form larger channels, just like larger channels converge to form even larger channels). This drainage pattern forms within a watershed, which is a topographical boundary where all surface water drainage within that boundary will exit the boundary through a single outlet (often the largest channel within the watershed as it captures all the flow).

Channels within a watershed are often a place of interest for researchers, as their surface water and channel morphology can serve as valuable indicators for the overall quality and characteristics of the watershed. There are multiple methods for classifying these

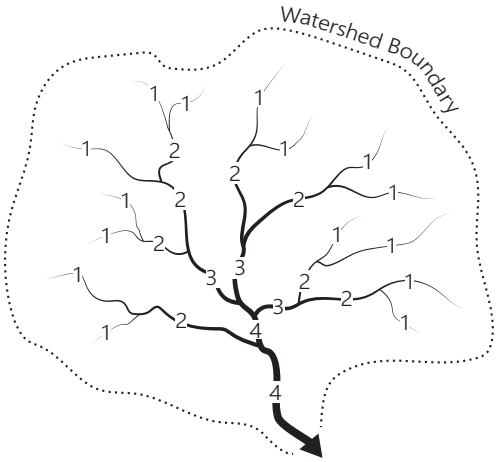

Fig. 3 Strahler stream ordering for a conceptual watershed, where stream order increases at the convergence of two segments of the same number.

channels (i.e., streams), but one of the most common is the Strahler order. The Strahler order starts with the headwaters as the first order (i.e., these are the smallest streams; the start of surface water flow). When two first order streams converge, they form a second order stream. Thereafter, whenever two streams of the same order converge, their downstream channel becomes the next higher stream order. If two streams converge of different stream orders, the highest order remains the same for the downstream channel. An example of Strahler stream ordering is available in Fig. 3, where the watershed outlet is a fourth order stream.

The U.S. has an extensive drainage network, where large mountain ranges throughout the country form the boundaries of the largest of watersheds. For example, the largest U.S. watershed is the Mississippi River watershed, where its largest channel is a 9th order stream at its outlet (Lehner and Grill, 2013; some sources have this listed as a 10th order stream; e.g., Hill et al., 2011). Bounded by the Rocky Mountains in the west and the Appalachian Mountains in the east, the Mississippi River watershed is nearly 3.2 million km^2 (Gassman and Secchi, 2006). Large stream orders (e.g., >6) are typically classified as rivers, where increasing stream number also reflects a likely increasing discharge and river power. For reference, the Amazon River is the only 12th order river in the world and has a watershed covering over 7 million km^2. Like anywhere else in the world, U.S. waterways can be divided into many smaller watersheds and subsequently many smaller stream orders (Fig. 4; Lehner and Grill, 2013). Globally, approximately 35% of all stream area is 5th order and smaller streams (Downing et al., 2012).

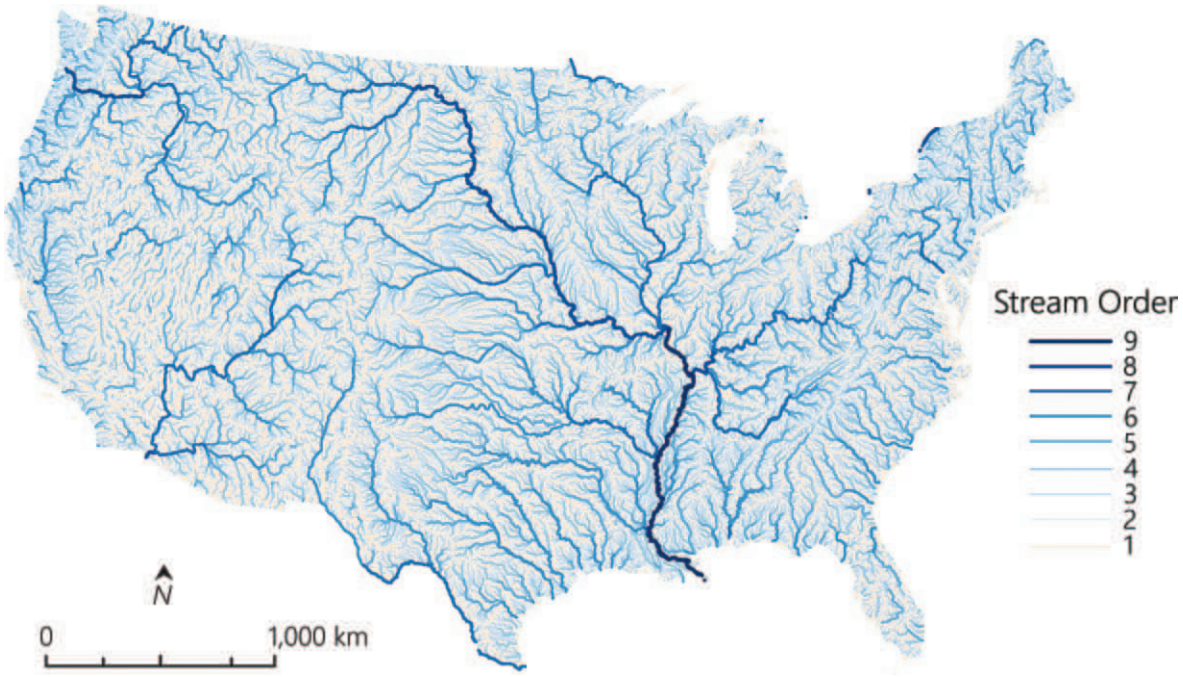

Fig. 4 U.S. streams and rivers classified by Strahler stream order (Lehner and Grill, 2013).

Land cover classifications

As water drains across the land surface, it interacts with many different land covers (e.g., urban, agriculture, forest, etc.). These land cover interactions are incredibly important for ecosystems and environmental management as draining water can inherently pick up artifacts like excess nutrients or pollutants from some of these land surfaces (e.g., urban; McGrane, 2016), while across other land surfaces (e.g., forest; Anbumozhi et al., 2005), artifacts may be removed or reduced. Likewise, different land covers (e.g., forest, grassland) generate unique environmental signals (e.g., reduced water temperatures, increased sediment load) that also have ecosystem impacts (Jones et al., 2010). Across the U.S., land cover has been divided into 8 predominant land cover classifications through the National Land Cover Database (NLCD; Homer et al., 2020). These include: (1) open water/ice, (2) developed (i.e., urban), (3) barren, (4) forest, (5) shrub/scrub, (6) grassland/herbaceous, (7) agriculture, and (8) wetlands. Each classification typically has a sub-classification that is more specific to the localized land cover. For example, forest as a classification can be subcategorized into deciduous, evergreen, or mixed. The contiguous U.S. can be summarized into 16 predominant subcategories (Fig. 5).

Riparian buffers

Riparian zones are the interfaces between waterways and adjacent lands. Riparian buffers are then often referred to as an undisrupted (i.e., vegetated) gap between a waterway and a predominant human land use (i.e., disrupted), such as a farm or urban area. Also common are buffer sequences which define the succession of vegetation within a buffer zone. For example, a common buffer sequence may consist of heavy vegetation along a waterway followed by a decrease in vegetated density away from the stream or river. An undisturbed forest, managed forest, grassland sequence is common for riparian zone management. Regardless of the sequence or vegetation, the purpose of a riparian buffer is to shelter the waterway from adjacent land use impacts while also supporting other ecosystem services, such as reduced water temperatures from the shade of a forest canopy along the stream channel. As a result, riparian buffers are often used to manage for a desirable ecosystem service; buffer sizes do not all have to be the same to achieve each service (Table 1).

The reality of human-induced land transformation is that riparian zones are often targeted for their high economic value, and historically, buffer zones have not always been respected. For example, most cities that have developed along waterways have urbanized the entirety of the buffer zone, even to the point of installing seawalls (i.e., developing right up to the water's edge). This historically has been a balance of risk versus opportunity, where development within a buffer zone opened access for trade or other economic opportunities, including crop cultivation within fertile floodplains, where the risk included the negative impacts from flood events. Human engineering has allowed for many opportunities to outweigh the flood risk, and many riparian buffers have been eliminated as a result. In recent years, the economic value of a riparian buffer has become more recognized as water quality has degraded and ecosystem services have been lost (Young, 2016). In response, there have been growing initiatives in the U.S. to protect or restore riparian buffers. For example, the Conservation Reserve Program through the United States Department of Agriculture has provided payments to landowners who have taken agricultural land out of production in riparian zones and have even subsidized landowners who have worked to establish or restore buffer zones (Sullivan et al., 2004). Similarly, financial incentives proved motivational for New Zealand farmers to install riparian fencing, for Madagascan governments to make payments for ecosystem services in critical riparian corridor areas, and for South African programs (e.g., Working for Water) to create jobs for invasive species removal and catchment protection (González et al., 2017; Wendland et al., 2010; Turpie et al., 2008). But even with these initiatives, riparian zones remain a frequently exploited region for human activities. Examples of riparian zones with varying buffer types are displayed in Fig. 6, where Panel A captures an urbanized riparian zone, Panel B an agricultural riparian zone, Panel C a forested riparian zone, and Panel D a riparian zone of wetlands.

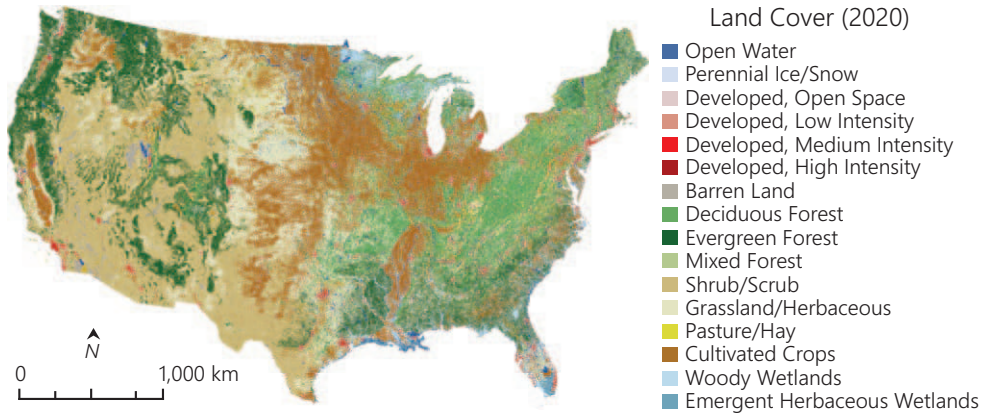

Fig. 5 U.S. land cover for the year 2020. Modified from the 2020 Cropland Data Layer; USDA (2021) *USDA National Agricultural Statistics Service Cropland Data Layer*. Washington, DC: USDA-NASS.

Table 1 Examples of recommended riparian buffer widths by ecosystem service type. Derived from Jontos (2004) and Lind et al. (2019).

Ecosystem service or management goal	*Recommended buffer width (m)*
Detrital input	3–10
Water quality protection	5–30
Sediment removal	9
Stream stabilization	10–20
Nitrogen or phosphorus reduction	11
Shading, temperature regulation	21
Floral diversity	24
Flood attenuation	20–150
Bird diversity	144
Riparian habitat	30–500+

GIS analysis of riparian buffers

GIS analysis

A Geographic Information System (GIS) is a computer system that can display, manipulate, and analyze geographically based data. To analyze land cover within riparian zones, both the location of a stream and its adjacent land cover must be available and spatially aligned in GIS. Several databases exist for these types of geospatial data and are freely available for download. For example, we used the National Land Cover Database (NLCD) for 2001 land cover (Dewitz, 2019; Homer et al., 2020), an NLCD-summarized version of the Cropland Data Layer (CDL) for 2020 land cover (see Fig. 5; USDA, 2021), and HydroRIVERS v1.0 (Lehner and Grill, 2013) for U.S. streams and rivers. The streams and river data are a set of lines that represent the centerline of the stream and do not represent the width of the stream channel. We found a 1:100 ratio of Strahler stream order to centerline buffer size (meters) extracted a relatively consistent area (i.e., buffer zone) of land cover along the banks of streams and rivers (e.g., we used a 500-m flowline buffer for a 5th order stream; Fig. 7). We then calculated the percent change between extracted land cover from our 2001 and 2020 datasets.

Using big data

The term "big data" is typically used when referring to data files or data volumes that are so large that they are either labor or technology limited. In other words, these data require unique processing techniques that eliminate the human labor necessary to process them or higher capacity computing technologies that can handle extremely large data. For example, the 2001 and 2020 land cover datasets for the contiguous U.S. each include almost 9 billion pixels at 30 × 30-m resolution. Likewise, the HydroRIVERS flowlines data include over 400,000 unique streams. Trying to process land cover change stream-by-stream would be prohibitively time-intensive for an individual to complete by hand and attempting to process these data as a group can overwhelm the technological capacities of smaller PCs. Big data users often use both a higher performing computer and scripting language (e.g., Python) to automate computer tasks. Here, we used Python to work with ArcGIS to: (1) extract flowlines by stream order from the HydroRIVERS file, (2) create a representative buffer around those extracted flowlines, and (3) extract land cover data from the 2001 and 2020 datasets. The final data outputs of these automated processes were then stored into spreadsheets (MS Excel) for analysis.

Riparian land cover change (2001 – 2020)

The results of the land cover change analysis are available in Table 2, where the percent change was calculated using Eq. (1):

$$\%Change = \frac{LC_{2020} - LC_{2001}}{LC_{2001}} x\ 100 \quad (1)$$

where LC_{2020} are the extracted data from the 2020 land cover dataset and LC_{2001} are the extracted data from the 2001 land cover dataset.

Table 2 shows land cover change by stream order, where positive numbers suggest the addition of a land cover classification (i.e., more of that land cover), and negative numbers represent the subtraction of a land cover (i.e., less of that land cover). There are several general trends across all stream orders.

(1) Developed open space has decreased through time. Typically, urbanization patterns follow an inside-out development trend, where highest intensity is in the middle and the lowest intensity on the outside (Balk et al., 2018). Over time, the urban hub becomes more intensely developed, and new urbanization sprawls away from the urban hub in the form of open or low intensity development. Since developed open space has decreased from 2001 to 2020, this trend suggests urban sprawl has slowed within riparian zones.

The notion that new urbanization has stalled in riparian zones is further supported by (2) low intensity development that has remained fairly stable throughout this time period.

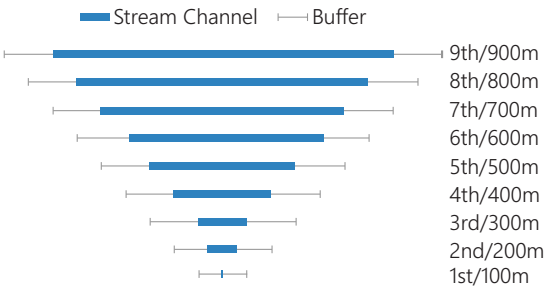

Fig. 7 Increased stream order and buffer size capture a relatively consistent width of adjacent riparian land cover.

Table 2 Land cover change in U.S. riparian zones by stream order, where change is the percent gain or loss of land area by land cover classification between 2001 and 2020.

% Change (2001–2020)									
Land Cover	*Stream Order*								
	1	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*
Developed, Open Space	–10.8	–13.5	–17.4	–19.5	–19.6	–22.4	–21.7	–26.8	–20.2

Contrarily, (3) medium and high intensity development have largely increased in riparian zones from 2001 to 2020. This trend suggests urbanization is still occurring within riparian zones, but it is from the densification of pre-existing urban areas instead of the expansion of new urban land.

(4) Barren land has greatly decreased. Barren land is where very little vegetation exists in a natural (i.e., non-urban) setting like a beach or desert. But barren land can also be classified as places that have been clear cut or drained and are awaiting a new land cover transformation. For example, barren land can also represent a clear-cut forest that is expected to become cultivated or a drained wetland that is expected to become developed. Since there is less barren land, there is less space along waterways that remains bare. This trend suggests these bare spaces have become more vegetated or have been converted into wetlands, since new urbanization was not greatly observed over the same time period (trends 1 and 2).

(5) Forests, scrublands, and grasslands have observed mixed land cover transition, where most notably deciduous forests have declined, and mixed forests have greatly increased. This trend may suggest deciduous forests have become more mixed or that deciduous forests have been removed in some areas. Regardless, forested riparian zones will make for an interesting future research trajectory given their impacts on ecosystem services and varying land cover trends. The increases in scrub and grasslands may also support the vegetation of barren land (trend 4).

(6) Agricultural land has greatly declined in riparian zones as cultivated and harvested areas were taken out of production. This trend may also contribute to the increase in grassland and forest as agricultural land is converted into other land classifications.

(7) Wetlands have increased in riparian zones which may have previously been agricultural land, barren land, or even forested land. One explanation is that floodplains have become more respected, so draining of the landscape through tiles or other engineering has decreased, and previously dry lands have been transitioned to wetlands. Likewise, there are U.S. policies that require new urbanization to also establish wetlands to offset the negative impacts of urbanization (Coker et al., 2018), so as urbanization increases throughout the country, more wetlands are likely to appear. A contrasting explanation is that increases in urbanization or urban density (both inside and outside of riparian zones) alongside changing weather patterns have made flood events more variable and common (Miller and Hutchins, 2017; Feng et al., 2021), which may result in increased wetland areas alongside waterways as floodplains become more frequently inundated.

Synthesis and conclusion

Observed patterns of riparian zones

Collectively, land cover trends suggest urban sprawl has been reduced in riparian zones, and the overall vegetation of riparian zones has increased. Likewise, intensively managed agricultural lands have also been reduced and likely replaced with less-intensive vegetated land cover (e.g., grasslands, forest) in riparian zones. From these trends, it appears the value of riparian buffers is becoming increasingly recognized in ecosystem management. However, many riparian zones remain heavily altered as evidenced by urban areas established on the banks of many waterways and agricultural lands encroaching on waterways due to the fertile soils of floodplains.

Urbanization intensity also increased the greatest in the lowest stream orders, which suggests there is an increase in human interference in headwater streams, which can be observed throughout the entirety of a watershed. It is not difficult to view satellite imagery and find many examples of limited, fragmented, or absent riparian zone buffers, and these areas certainly carry an ecological footprint that can be readily observed downstream (e.g., Novoa et al., 2018).

Future implications for riparian zones

The riparian landscape is becoming an increasingly interesting component to ecosystem management. There are clear land cover trends that document both their protection and degradation. Most urban areas within riparian zones are virtually locked in place, so their impacts will remain a foreseeable issue. Agricultural trends within riparian zones appear to be the most fluid in the 21st century, as they can easily be converted to alternate land covers. Likewise, the changes in wetland and forested environments within riparian zones should also keep attention moving forward. In terms of research and subsequent environmental management, there are several interesting questions based on the results of this chapter:

1. Why are wetlands increasing in riparian zones, and what are their impacts on human and natural systems?
2. Why are forests becoming more mixed in riparian zones, and how will this impact human and natural systems?
3. To what extent do riparian buffers need to be protected or restored to offset the inevitable impacts of increasingly dense urban areas along U.S. waterways?
4. Thinking globally, to what extent can this analysis offer insights to contexts elsewhere? What other societal dimensions may need to be considered in other contexts?

The approach described in this chapter can be applied to any geographic location globally to assess riparian changes at multiple spatial scales and across sociopolitical boundaries. It can also illuminate the global diversity of societal values of riparian areas and assist in tracking changes over time by providing a baseline metric of present and past land use.

Conclusion

Riparian zones are critically important for the overall sustainability of human and natural systems, yet these areas remain heavily degraded by human interactions. Some of this degradation is inevitable and is unlikely to change in the future, but this is largely restricted to fixed land cover like major urban areas. The rest of riparian zones can be managed and improved in a way that maximizes their ecosystem services. From 2001 to 2020, U.S. riparian zones did document more vegetation, less urban sprawl, and increased wetlands within riparian zones.

These changes suggest the value of riparian zones is influencing decision-making and environmental management during the 21st century. Going forward, there remain many important research gaps that can be addressed to help establish a thriving balance of human and natural systems within riparian zones in the U.S. and beyond. Globally, the vulnerability of riparian zones to climate impacts, biological invasions, agricultural intensification, and urbanization elevates the importance of riparian conservation and management efforts (Capon et al., 2013). Such efforts are especially needed in biomes and regions with disproportionately high riparian degradation (e.g., tropics, González et al., 2017). Consideration of the social, cultural, economic, and ecological values and services of riparian zones, including those highlighted here, will be necessary for the long-term sustainable management and restoration of local, regional, and global riparian areas.

This article was reviewed for the Encyclopedia of Inland Waters, Second Edition by Section Editors Catherine Febria and Gail Krantzberg.

Introduction

Kenya is an emerging economy with socio-economically important inland and marine water resources that underpin the livelihoods of millions of people. The country is endowed with plenty of aquatic resources providing numerous ecological goods and services to the national economy yet classified as a lower-middle-income country (United Nations, 2019) with a rapidly growing population of over 50 million (World Bank, 2019). Kenya launched a long-term development blueprint in 2008 envisioning that by the year 2030, she will transform into a "newly-industrializing, middle-income country providing a high quality of life to all its citizens in a clean and secure environment anchored by improved services in its social, political and economic pillars." The Third Medium Term Plan (MTP III) 2018–2022 of the Vision identified the Blue Economy—including utilizing marine and freshwater fisheries resources as one of the priority sectors with a high potential to spur inclusive economic growth and development (Government of Kenya, 2018a).

Kenya has a total area of about 582,646 km^2 (square kilometers), of which 11,230 km^2 (1.9%) is covered by inland waters, while 14,300 km^2 (2.5%) is covered by territorial marine waters (NEMA, 2021). Its freshwater resources are represented by lakes, rivers, swamps, springs as well as dams, water pans and groundwater. While its territorial marine ecosystems include seagrass, mangroves, coral and river delta, and a coastline of 640 km on the Western Indian Ocean, in addition to a further 200 nautical miles Exclusive Economic Zone (EEZ). However, Kenya is a water-scarce country, with a per capita water availability of 647 cubic meters (m^3), well below the global benchmark of 1000 m^3 per capita, indicating chronic water scarcity (Government of Kenya, 2018b). The country is a chronically water scarce country with one lowest natural water replenishment rate in the world (Puzyreva and Roy, 2018). The inland waters are located in five major drainage basins (Lake Victoria, Rift Valley, Ewaso Ng'iro, Tana River and Athi River) originating from five main water towers—Cherangani Hills, Mount Kenya, Mount Elgon, the Mau Forest Complex and the Aberdares Ranges—which are the principal suppliers of water. The water towers are currently under heavy fragmentation and degraded due to human activities such as encroachment for settlement, conversion into agricultural lands owing to population pressure, grey infrastructural development and weak implementation of environmental policies (World Bank, 2019).

Presently, Kenya's aquatic resources are under immense and increasing pressure from human-related activities including rapid population growth, unsustainable agriculture, a proliferation of tourist facilities with unsustainable effluent management, deforestation and habitat degradation, water pollution, overexploitation of water resources, declining capture fishery, and the introduction of invasive non-native species (NEMA, 2021; Obiero et al., 2020; Sayer et al., 2018) with future risk from proposed dam construction, large scale irrigation and climate change. While the ecosystem faces many threats, including those in the present and those predicted for the future, the aquatic ecosystems can be resilient if management efforts focus on balancing competing user

needs. This chapter reviews the status of Kenyan inland and marine waters, major stressors and threats facing their ecological integrity and key recommendations that can be harnessed to help meet Kenya's Vision 2030 targets and sustainable development goals (SDGs).

Inland freshwater resources in Kenya

Kenya is endowed with a vast network of freshwater aquatic resources comprising lakes, rivers, dams/reservoirs, and streams. The surface water resources are distributed within five drainage basins (Fig. 1; Achieng et al., 2021): the Tana (21.7%), Athi (11.5%), Ewaso Ng'iro (36%), Rift Valley (22.7%), and Lake Victoria Basin (8%), with the highest surface water resource distribution in Lake Victoria Basin 11,672 (10^6 m^3) and lowest in Ewaso Ng'iro Basin 339 (10^6 m^3). Its groundwater resource range between 116 (10^6 m^3) and 87 (10^6 m^3) for Lake Victoria and Athi River Basin respectively (Table 1). The Lake Victoria Basin receives the highest average annual rainfall (1368 mm) while Ewaso Ng'iro receives the lowest average annual rainfall. Table 1 shows Kenya's surface and groundwater resources distribution and water abstraction levels of the five drainage basins.

Lake Victoria Basin

The Lake Victoria Basin (LVB) covers about 8% of the total area of Kenya but accounts for over 54% of the national freshwater resources (MEMR, 2012). The Kagera River which originates from Rwanda and Burundi is the largest inflow, contributing up to 33% of the surface inflow into the lake. The main inflows from the Kenyan catchment include the Sio, Nzoia, Yala, Nyando, Sondu-Miriu, North Awach, South Awach and Gucha-Migori rivers. The other major rivers are Bukora and Katonga which originate in Uganda; while the Mori, Simiyu, Grumeti, Mbalageti, Magogo-Moame, and other small streams originate from Tanzania (LVBC, 2007).

The lake basin plays major ecological, social and economic roles in the East African Community (EAC). Its drainage basin consists of rivers, streams and wetlands and supports a human population of over 42 million (Awange, 2020) by providing a variety of economic and development opportunities, including fisheries, tourism, transportation, hydropower production and trans-boundary conservation (Obiero et al., 2015). The lake is one of the most productive freshwater fisheries in the world, with an annual fish catch of 1 million tons of fish and a fishery carrying capacity of 200 million metric tons (Kimani et al., 2018; Onyango et al. 2021). The lake's fisheries support approximately 4 million people with household incomes and meet the annual fish consumption needs of almost 22 million people in the region (Onyango et al., 2021). Given the unique and diverse nature of freshwater species within the basin, the dependence of rural communities and regional economies on these species, and the high levels of threat, there is a clear need for a stronger focus on the conservation of freshwater biodiversity (Sayer et al., 2018).

Rift Valley Basin

This basin covers an area of about 130,452 km^2 and consists of a number of hydrologically closed basins. It encompasses the basins discharging into Lake Turkana in the North through the Turkwel and Kerio rivers and those draining into Lake Natron in the south through the Ewaso Ng'iro South River. The smaller lakes such as Baringo, Bogoria, Nakuru, Elementaita, Naivasha and Magadi also form individual basins (Fig. 2). In the past decade, the Great Rift Valley lakes of Kenya have recently experienced significant increases in their water levels, negatively impacting the local communities (Githaiga et al., 2021; Herrnegger et al., 2021). The increases in lake levels and consequent inundations of the riparian areas have had significant negative impacts on the local communities, since homes, schools, hospitals, roads, but also the basis for the local economy such as agricultural areas or tourism infrastructure like hotels have been submerged and rendered unusable (Githaiga et al., 2021).

Athi River Basin

The Athi Basin has an area of 66,559 km^2 and borders Tanzania to the south, the Indian Ocean coastline to the east, the Tana Basin to the north and the Rift Valley Basin to the west (NEMA, 2011). The Athi River is the main river in the Athi Basin, draining about 57% (38,170 km^2) of the basin. Although the Athi Basin only covers about 11% of Kenya's land surface area, it has high economic activity, houses a quarter of the country's population, and hosts the two largest cities in Kenya viz. Nairobi and Mombasa (Aurecon AMEI Limited, 2020). The total population of the Athi Basin is 13.43 million, which is equivalent to a population density of 202 persons/km^2. Water plays a key role in the Athi Basin and is of critical importance for economic development in the two major urban hubs of Nairobi and Mombasa. Water security is essential for industries, health, tourism and for supporting an improved standard of living. It is estimated that 63% of the urban population in the basin receives piped water provided by Water Service Providers, while 20% are dependent on unimproved water sources. The remaining 17% are supplied from groundwater, which includes protected and unimproved sources (Aurecon AMEI Limited, 2020).

Tana River Basin

The Tana River Basin covers 22% of the country's total landmass and is home to 18% of the country's population (van Beukering and De Moel, 2015). It contributes over 50% of Kenya's river discharge to the Western Indian Ocean. The basin drains the eastern slopes of the Aberdares range, the southern slopes of Mount Kenya and the Nyambene hills before discharging into the Indian Ocean through the Tana River (NEMA, 2011). Ecosystems in the Tana River Basin including forests, arid and semiarid lands, mountain vegetation, freshwaters and wetlands, marine and coastal areas and agrosystems provide a range of ecosystem services vital for human wellbeing such as drinking water, hydro-electric power, fisheries, agriculture and biodiversity (van Beukering and De Moel, 2015). Like the Athi River Basin, the River Tana basin drains an area that is highly populated and urbanized with the Upper Tana River Basin hosting over 5.3 million people (TNC, 2015). In addition, Tana River is a major source of hydropower and has an estimated installed capacity of 480 Mega Watts (MW) out of its total estimated potential of 960 MW. For example, the basin supplies 80% of the drinking water for Kenya's capital, Nairobi. The Tana River is the country's primary source of hydroelectric power produced from five dams along the river (i.e., 70% of Kenya's hydroelectric power and 38% of Kenya power supply). Fisheries and agriculture in the basin provide a major source of food and employment for the estimated 7 million residents living in the greater basin area and other parts of the country. One of the basin's important ecosystems is the Tana Delta at the coast. This biodiversity hotspot is home to several endangered species and was designated as a Ramsar site in the year 2012—a recognized wetland of global importance (TNC, 2015).

Ewaso Ng'iro basin

The Ewaso Ng'iro North River basin covers an area of 209,000 km^2. It is found in the Northern part of Kenya and drains the northern slopes of the Aberdares Range and Mount Kenya (NEMA, 2011). It represents a typical tropical highland-lowland system characterized by humid to semi-humid conditions in the relatively small upper reaches and semi-arid to arid conditions on the plateau and in the vast lower parts of the basin (Kiteme, 2020). As a result of these conditions, the most limiting factor for human activities and development in more than 90% of the basin is water, with precipitation below the agriculturally critical 600 mm annually. In the past five decades, the Ewaso Ng'iro North basin underwent drastic socio-economic transition (Providoli et al., 2019). Large-scale ranching, immigrating small-scale farmers and recently established large-scale horticultural enterprises transformed the upper basin from its original pastoralists land use system, which still prevails in large parts of the lower basin. This transition has led to a steep increase in population densities, which in combination with the new land use systems dramatically increased the pressure on water resources, in particular on river water (Providoli et al., 2019; Kiteme, 2020).

Lacustrine ecosystems

Freshwater resources, including rivers, lakes and wetlands in Kenya are widely distributed among the five main drainage basins. The lakes provide diverse habitats ranging from the freshwater lakes of Victoria, Naivasha and Baringo to the semi-saline Lake Turkana and the alkaline lakes of Magadi, Elmentaita, Nakuru and Bogoria (Table 2). Despite their small sizes, the alkaline lakes are known for their rich biodiversity that includes bird species (both residents and migrants). The alkaline lakes also provide unique feeding habitats for East Africa's famous lesser flamingos while the freshwater lakes support important fisheries and agriculture. The semi-alkaline Lake Turkana is the world's largest permanent desert lake situated in a hydrologically closed basin that sustains indigenous fisheries, including some endemic species (Ojwang et al., 2016). Five lakes within the Rift Valley drainage basin are recognized as Wetlands of International Importance (Ramsar Sites: Table 2), and all are Important Bird Areas, with several being within UNESCO-listed World Heritage Sites (MEMR, 2012).

Riverine ecosystems

Kenya is endowed with major river systems including Athi, Tana, Nzoia, Mara, Yala, Nyando, Sondu, Kuja, Turkwel, Kerio and Ewaso Ng'iro (Table 3 and Fig. 3). Four major rivers namely Gucha-Migori, Nyando, Nzoia and Tana, discharge over 1000 m^3/day (MEMR, 2012); other rivers with a significant perennial flow are Mara, Sondu and Yala. The Tana River is Kenya's longest river and originates from two of Kenya's major water towers: Mt. Kenya and the Aberdares. River Tana measures approximately 1050 km in length and has an average width of 39.3 m, a mean depth of 2.5 m and an average flow rate of 41.98 m^3/s. Its mean annual

Table 2 Characteristics of major Kenya lakes.

Name	*River(s) draining into the lake(s)*	*Surface area (km^2)*	*Maximum depth*	*Altitude (m amsl)*	*Water quality*
1. Lakes with special categories (Ramsar sites or World Heritage Sites)					
Lake Nakuru (Ramsar/World Heritage Site)	Njoro, Makalla, Ngosur, Lamudhiak, Enderit	49	4.5	1754	45% saline (pH 10.5)
Lake Elementaita	Waseges-Sandai, Loboi, Emsos and Mogun	18	1.9	1670	40% saline (pH 9.4)
Lake Baringo (Ramsar)	Pekerra, Molo, Ndoo, Toigibe	168	8	1000	Fresh
Lake Bogoria (Ramsar/World Heritage Site)	Waseges-Sandai, Loboi, Emsos and Mogun	42.5	8.5	990	35% saline (pH 9.8–10.3)
Lake Naivasha	Malewa, Gilgil, Karati	156	7	1884	Fresh
2. Transboundary Lakes					
Lake Victoria	Nyando, Yala, Sondu, Kibis, Kija, Mara, Sio (Kenya)	68,800	84	1134	Fresh
Lake Turkana	Turkwel (Kenya), Kerio (Kenya), Omo (Ethiopia)	7560	114	360	Brackish
Lake Jipe	Umi	28	2	705	Fresh
Lake Chala	Underground seepage	6	90	880	Fresh
Lake Magadi	Ewaso Kedong	105	0.5	579	Saline pH 10.5)
3. Other lakes					
Lake Kamnarok	Kerio	1	Shallow	1064	Fresh
Lake Ol Bolossat	Ewaso Ngi'ro North	43	Shallow	2340	Fresh
Lake Amboseli	Namanga	–	Shallow	1150	Fresh
Lake Kanyaboli	Yala	15	3	1140	Fresh

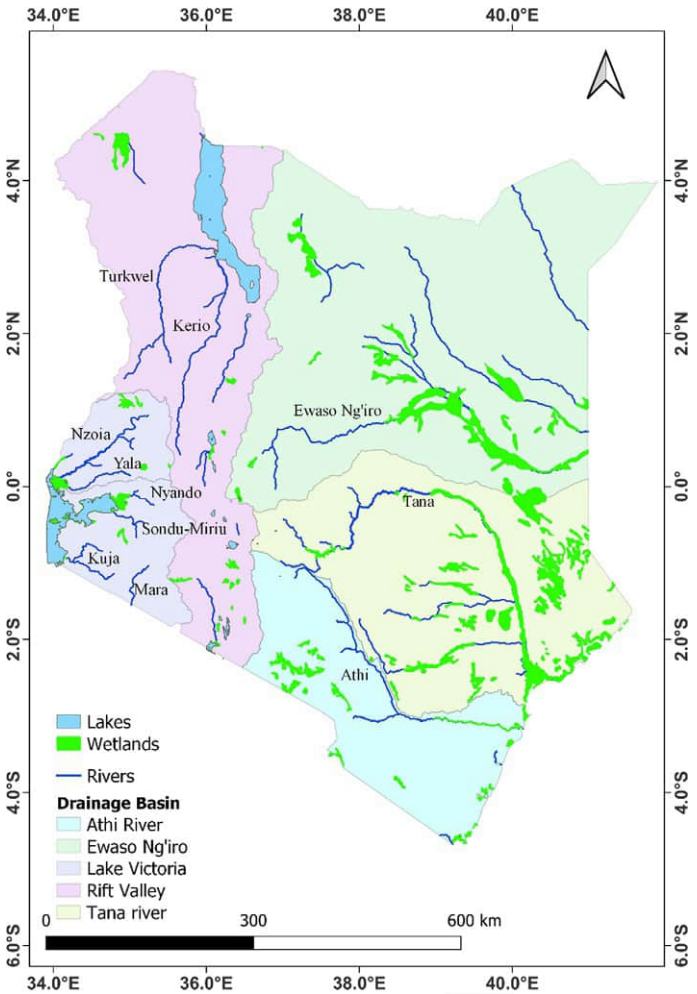

Fig. 3 Major rivers in Kenya.

discharge at Garissa is 5 billion cubic meters (BCM) (NEMA, 2011). The Athi River measures approximately 591 km and has an average width of 44.76 m, an average depth of 0.29 m and an average flow rate of 6.76 m^3/s. The Kerio River is the main river in the Rift Valley basin with a total length of 354 km. It has an average width of about 5.7 m, a mean depth of 0.21 m and the mean flow is 4.47m^3/s (NEMA, 2011).

A recent biodiversity report by World Wide Fund for Nature (WWF) in the Mara River basin identified 473 native freshwater species including four mammals, 88 waterbirds, 126 freshwater associated birds, four reptiles, 20 amphibians, 40 fishes, 50 invertebrate species and 141 vascular plants (Pringle et al., 2020). At least 10 species—equivalent to 2% of total species—are on the International Union for Conservation of Nature list of threatened species. Three—the Ningu (*Labeo victorianus*), Singida (*Oreochromis esculentus*) and Victoria tilapia (*Oreochromis variabilis*)—are "critically endangered," threatened by the introduction of non-native fish such as the Nile perch (*Lates niloticus*) (Pringle et al., 2020).

Wetland ecosystems

Kenya's wetlands are biologically productive ecosystems, rich, diverse and provide multiple goods and servises, and are critical for water purification and storage, support biodiversity, flow regulation, and flood control (Box 1; World Bank, 2019). The Kenya Environmental Management and Coordination (Wetlands, Riverbanks, Lakeshores and Sea Shores Management) Regulations 2009 define wetlands as "areas permanently or seasonally flooded by water where plants and animals have become adapted; and include swamps, areas of marsh, peatland, mountain bogs, banks of rivers, vegetation, areas of impeded drainage or brackish, salt or alkaline; including areas of marine water the depth of which at low tide does not exceed six meters". This definition includes swamps, marshes, bogs, shallow lakes, ox-bow lakes, dams, river meanders and floodplains, as well as riverbanks, lakeshores and seashores where wetland plants grow. The definition also covers marine and intertidal wetlands such as deltas, estuaries, mudflats, mangroves, salt marshes, seagrass beds and shallow reefs (MEMR, 2012).

Even though the exact extent of Kenya's wetlands is unknown owing to lack of comprehensive wetland inventory, they are estimated to occupy around 3–4%, which is approximately 14,000 km^2 of Kenya's landmass which can temporarily grow to 6% during the rainy seasons (NEMA, 2011). The Ramsar classification of wetland types contains three broad categories: inland; marine and coastal; and human-made. These are then sub-divided into 42 types (Fig. 4). Owing to Kenya's diverse climate and topography, the country is home to six wetland types: riverine; lacustrine; palustrine; estuarine; marine; and constructed wetlands. Inland freshwater wetlands cover approximately 2,641,690 ha which far outstrips the area covered by marine and coastal wetlands at 96,100 ha (MEMR, 2012). Five sites in the country have been designated as Wetlands of International Importance (Ramsar Sites) including lakes (Nakuru, Naivasha, Bogoria, Baringo and Elementaita) that are part of the Great Rift Valley system. All these lakes are important in regulating local climate, nutrient cycling, habitat for various aquatic and terrestrial species including bird, particularly renowned for their large flamingo populations and several other ecosystem servises (Box 2). As such, they are frequently visited by ornithologists, making them an important component of the tourist circuit.

Box 1 Importance of wetlands in Kenya.

Kenya is endowed with rich and diverse wetlands crucial for the provision of multiple ecosystem goods and services, beneficial to its citizens, economy and associated ecosystems. Ecologically, wetlands form the unique interface between water and land that supports a distinctive community of plants, including floating lilies and sedges, and animals including frogs, fish and turtles (MEWNR, 2015). Wetlands buffer the effects of floods, reduce erosion control, capture carbon, filter out and decontaminate pollutants and toxins, recycle nutrients and stabilize stream banks and shorelines. Wetlands store excess water and act as buffers against drought for wildlife, farmers and herders. Wetlands also provide an abundance of plant and animal produce for humans, including food, water, medicine, and material for handicrafts, furniture and construction. In recent decades wetlands have become important in irrigated farming, commercial fishing, paludiculture, carbon sequestration, flood control, wildlife conservation, tourism and recreation. Wetlands are key assets in sustainable development, poverty alleviation and the improvement of livelihoods. For instance, from horticulture alone, Lake Naivasha contributes over Kshs 5.3 billion (approximately US$ 63 million) per year while over 30,000 people derive their livelihoods from this important wetland ecosystem (MEMR, 2012). Oduor et al. (2015) revealed that Nyando Wetlands yield a flow of economic benefits from consumptive goods and services estimated at US$ 1.5 billion (US$ 62,500 ha^{-1} $year^{-1}$) with a present value of US$ 75.5 billion at a 2% discount rate. As a result, the reclamation of the wetlands would imply high economic benefits to the government and local communities. Therefore, there is a justified need to maintain the biological diversity and productivity, and to permit the wise use of Kenya's wetland resources, through development and implementation of focused management actions, and conduct regular reviews to address emerging issues in line with the changing context of the environment in the wider wetland landscape (Wetlands International, 2020).

Box 2 Importance of lakes and rivers.

Kenya's lakes and rivers contain some 20 billion cubic meters of water—which plays a critical role in local climate (MEWNR, 2015). They capture nutrients and sediments eroded from the land and so sustain a highly productive and diverse assemblage of plants and animals. Freshwater habitats support unique and specialized species, several endemics and many rare or threatened species. Lakes and rivers are important stepping stones for Palearctic migratory birds, flamingoes and shorebirds. They also supply the bulk of the water that drives the Kenyan economy, from farming and ranching to industry, commerce and settlement. Freshwater fisheries have, until recently, been dominated by traditional and artisanal fishing communities but now sustain commercial fisheries in Lake Victoria and Lake Turkana. Rivers also produce hydroelectric power, filter and provide clean water for human settlement and, together with lakes, provide transport routes for commerce and a range of amenities that attract tourists, outdoor and water-sports enthusiasts.

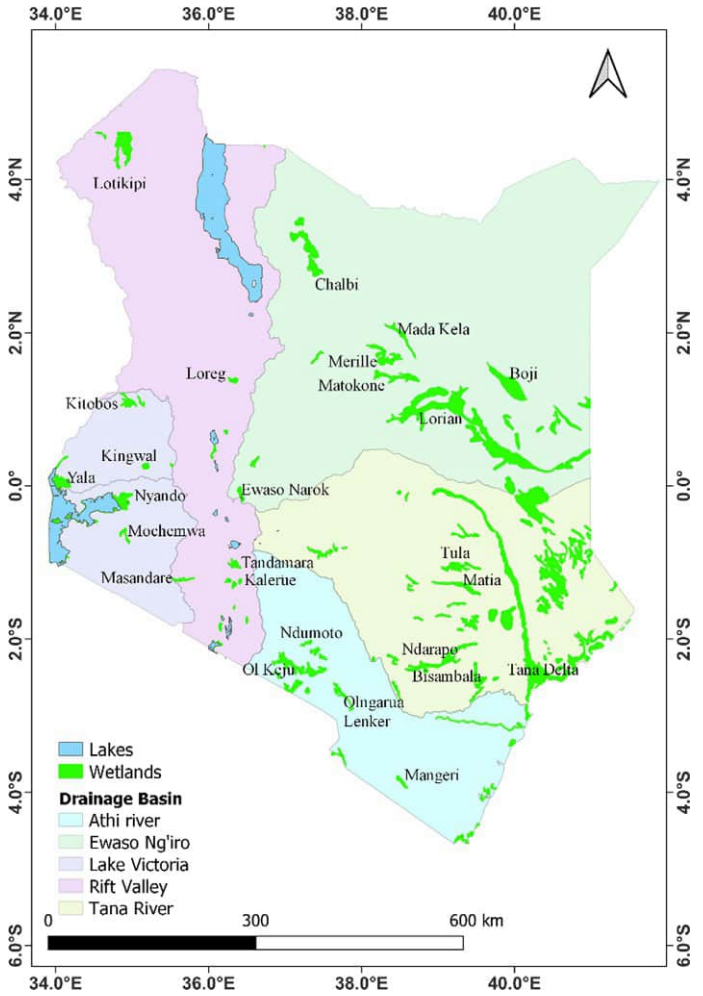

Fig. 4 Map showing the main wetlands in Kenya.

The Tana River Delta is an unprotected wetland on the Kenyan coast. The Delta, a designated Key Biodiversity Area (KBA), covers 127,000 km^2 and is Kenya's largest wetland. The Tana River Delta is also a designated Ramsar site—a recognized wetland of global importance. The Mara basin (65% of which is in Kenya and 35% in Tanzania) covers 13,750 km^2 and is home to the highest density of large herbivores on Earth (Pringle et al., 2020). The area is known globally for the annual wildebeest and zebra migration, which brings in millions of dollars in tourism.

Coastal and marine ecosystems

Kenya enjoys a marine coastline of about 640 km giving a total area of territorial waters of 9700 km^2 while the EEZ is 142,400 km^2 (Rasowo et al., 2020). The coastal region is endowed with rich natural resources that play a critical role in fostering economic development. Such resources include beaches for recreation, fisheries resources, mangrove forests and cultural diversity. Table 4 contains an overview of Kenya's coastline and marine resources including mangroves (Fig. 5A) and other coastal forests, seagrass beds (Fig. 5B), sand dunes and sandy beaches and coral reefs.

Blue economy

The World Bank defined the "blue economy" (BE) as "the sustainable use of ocean resources for economic growth, improved livelihoods, and jobs while preserving the health of ocean ecosystem" (World Bank, 2017, p.6). In the global context, the blue economy concept integrates the economic exploitation and sustainable conservation of renewable and non-renewable marine resources (UNECA, 2016). The BE sector fits within the framework of the United Nations (UN) 2030 Agenda and embraces all the sustainable development goals (SDGs) given its inclusive nature (World Bank, 2017). Kenyan has domesticated the BE concept, which is now the eighth priority sector in the Economic Pillar under the Third Medium Term Plan (MTP III) of the Kenya Vision 2030 (Third Medium Term Plan 2018–2022). The BE in Kenya encompasses activities that explore, develop and use the ocean's resources and space and protect the ocean's ecosystems. It incorporates traditional maritime industries e.g., fisheries, coastal tourism, energy and mineral production, boat building, shipping and ports as well as new and developing industries such as blue carbon (carbon stored in mangroves, seagrass and saltmarsh ecosystems, aquaculture products, marine renewable energy (i.e., wind, wave and tidal energy), bio-products (pharmaceutical and agrichemicals), and desalination.

Table 4 Kenya's coastal resources at a glance.

Coastal resource	*Description and key characteristics*
Coastal forests and mangroves	• Mangroves and coastal forests of Kenya characterize the low lying inter-tidal areas and system of low ridges between 100 and 300 m in altitude (Fig. 5) • The forests have a canopy span of up to 7 m, covering about 139,000 ha and with lowland forest patches, woodlands, bushlands and thickets • The main forests in the coastal area include Arabuko Sokoke (41,000 ha) and the Shimba Hills system (19,260 ha). Others are smaller patches ranging from 10 to 2000 ha and mainly consist of the "Kaya," sacred forests of the Mijikenda communities • Mangrove forests occur along the coast in the intertidal area between the land and the sea. The total area of mangroves in Kenya has been estimated at between 53,000–61,000 ha. It is estimated that 10,310 ha of mangrove forests have been lost due to conversion to other land uses, overexploitation and pollution • There are nine mangrove species found along the East African coast. All these occur in Kenya although the dominant ones are *Rhizophora mucronata* and *Ceriops tagal*. Other rarer species include *Heritiera littoralis and Xylocarpus moluccensis*
Seagrasses	• Seagrasses occur in extensive beds that cover the largest proportion of shallow reef slopes and form an important habitat for many species living in them and adjacent systems • Twelve seagrass species are found in Kenya. *Thalassondendron ciliatum*, which forms monospecific stands, is the dominant one. Its canopy structure provides habitats for small and juvenile fish and invertebrates • Other common seagrass species found in the country are *Halophila ovalis*, *Halophila minor, Halophila stipulacea, Halodule uninervis, Halodule wrightii, Syringodium isoetifolium, Cymodocea rotundata, C. serrulata, Thalassia hemprichii, Zostera capensis,* and *Enhalus acoroides* • Seagrass meadows are composed of submerged flowering plants that colonize shallow marine waters. The meadows settle sediment loads in the tidal zone, buffer the coastline from ocean currents, absorb suspended nutrients and sequester nitrogen. They also offer food and shelter for invertebrates and fish and are important to the subsistence, commercial and sport-fishing industry off the coast
Coral reefs	• Coral reefs are the ocean's richest ecosystems in terms of biodiversity and productivity. Kenya's reefs are particularly productive ecosystems rich in corals, sponges, sea ferns, algae, seagrasses, phytoplankton, and an extraordinary variety of invertebrates ranging from burrowing worms and bristle worms to jellyfish, anemones, shrimps, lobsters, crabs, starfish, sea urchins, sea cumbers, giant clams, bivalves, conches, sea hares, squids and octopuses

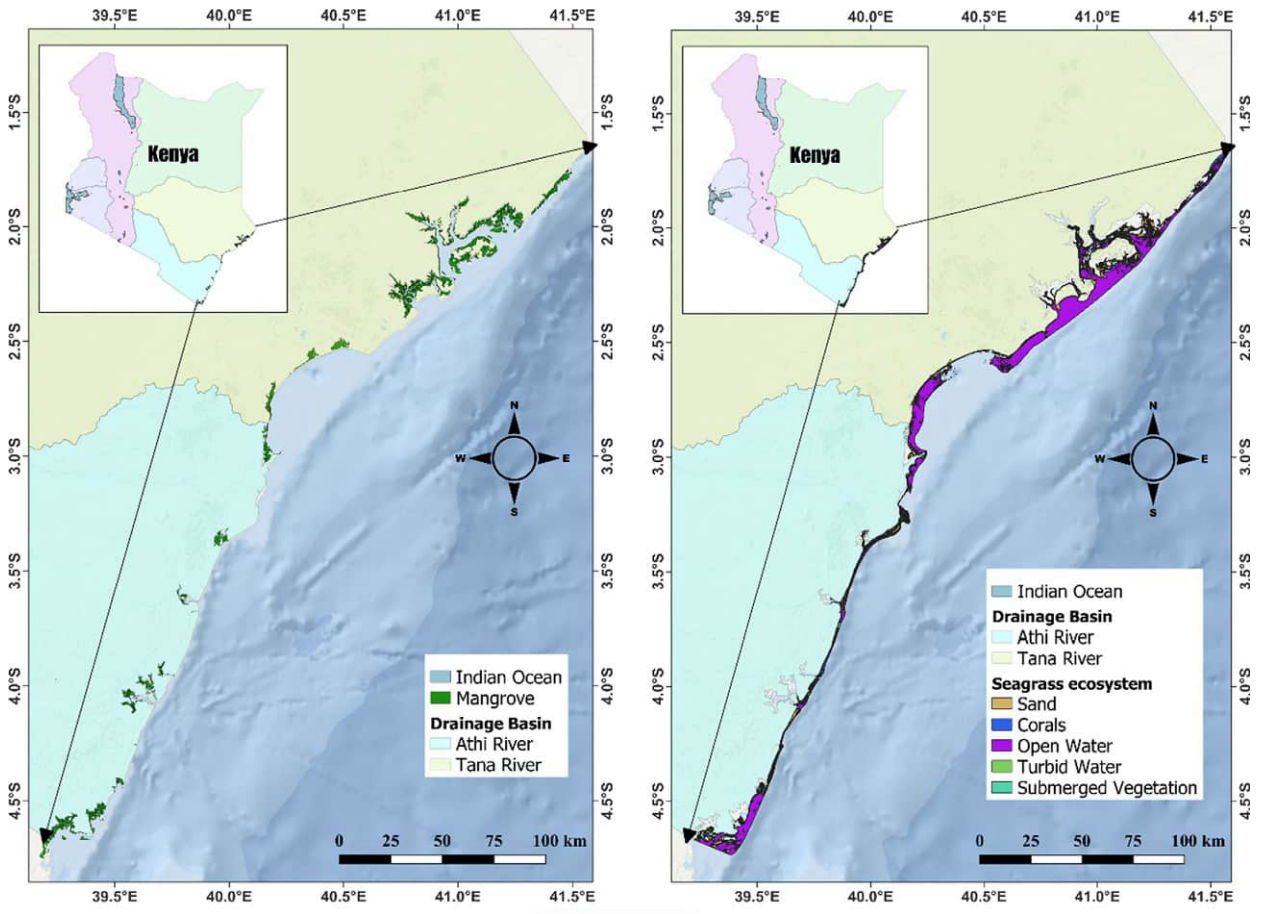

Fig. 5 Mangrove (A) and Seagrass (B) ecosystems.

Box 3 Blue Economy sector in Kenya.

The blue economy has significant value to Kenya's economy. The blue economy refers to economic activities linked to the sustainable use and economic development of all aquatic environments including oceans, seas, coasts, lakes, rivers, reservoirs, dams and underground water. Kenya's blue economy is worth about US$4.4 billion every year (World Bank, 2019). This is roughly 5.5% of gross domestic product (GDP) of which US$4.1 billion is dependent on the tourism sector (UNDP, 2018). Fisheries is another important component of the blue economy which contributes 0.8% to the country's GDP, with the inland fisheries making up about 80%, aquaculture (15%) and marine fisheries about 5% of the total national fisheries production. Close to 80% of Kenya's imports and 20% of exports are transported via sea routes. The Kenya National Bureau of Statistics (KNBS) Economic Survey estimates marine fishing had an annual fish potential of 350,000 metric tons worth over Kshs. 90 billion yet the country only harvested a paltry 25,656 metric tons worth Ksh3.3 billion in 2020 (KNBS, 2021).

The Blue Economy sector is poised to make a significant contribution to Kenya's economic growth (Box 3). In recognition of the importance of this sector to fuel Kenya's economic growth, the Kenyan Government recently allocated Kshs. 2 billion to turn around the Blue Economy sector (Ogello et al., 2021). Despite the high-level attention towards the exploitation of the BE sector in Kenya, the full economic potential of marine resources has not been exploited, yet Kenya has a maritime territory of 230,000 km^2 and a distance of 200 nautical miles offshore. Therefore, the development of Kenya's Blue Economy is expected to offer massive opportunities for sustainable growth in several traditional and emerging economic sectors.

Fisheries and aquaculture

Kenya's fishery sector can be divided into five sub-sectors: freshwater fishery, aquaculture, coastal marine capture fishery, offshore pelagic fishery and the EEZ fishery. Wild-caught fisheries play a central role in Kenya's culture, economy and food supply chain, and were valued at US$ 440 million in 2018 (Kimani et al., 2018). Overall, the fisheries sector supports about 1.2 million people working as fishers, traders, processors, suppliers and merchants of fishing accessories (Kenya Fisheries Service, 2016). The country's total fish production in 2020 is estimated at 149,678 metric tons worth US$ 256 million (Kshs. 25.6 billion) (KNBS, 2021).

The fisheries potential of Kenya's inland waters, mainly from commercial fishing is estimated between 150,000 to 300,000 metric tonnes (MT). Production from wild-caught fisheries has stagnated and declined over the past decade (Kenya Fisheries Service, 2016). Over the last 5 years, fish production from freshwater sources remained the major source of fish landed accounting for over 80% of the total fish output (Table 5). Fish output from marine sources contributed a relatively small share mainly due to inadequate technology necessary for fishing in deep waters (KNBS, 2021). Aquaculture is regarded as an alternative to bridging the widening gap between fish demand and its supply in Kenya (Obiero et al., 2019). As the industry has evolved and grown, new and promising early-stage investment opportunities to enhance sustainable aquaculture practices among young people have emerged. These have included enhanced sensing and monitoring technologies for waste pollutants; improved farm management; yield enhancement; disease control monitoring and inputs; alternative protein and feed sources (insect-based e.g., black soldier fly larvae, plant-based e.g., soy and algae), and developments in aquaculture infrastructure technologies (Munguti et al., 2021).

Table 5 Quantity (in metric tonnes) of fish production in Kenya from 2016 to 2020.

Year	*2016*	*2017*	*2018*	*2019*	*2020*

Although Kenya's fisheries are of strategic value given the role of the sector in supporting livelihoods and contributing to food security, the resources are grossly underreported and undervalued in official statistics (Schubert et al., 2021; Onyango et al., 2021). Building on previous literature to reconstruct Kenya's marine fisheries data from 1950 (Le Manach et al., 2016; McAlpine, 2019), a new study by Schubert et al. (2021) reconstructed the freshwater catches in the country, disaggregated by major water bodies, fishing sector, taxon and reporting status. The study revealed that the total reconstructed catches in Kenya from 1950 to 2017 were 32% higher than the catches reported by the FAO on behalf of Kenya. This under-reporting was due to unmonitored water bodies, incomplete time series for monitored water bodies, and the under-representation in the officially reported data of both the catches taken with illegal gears, as well as locally consumed catches from the non-commercial subsistence sector (Schubert et al., 2021). In addition, the study showed that the subsistence fisheries sector accounted for 71% of unreported catches, compared with 29% for artisanal sector catches (small-scale, commercial), suggesting that non-commercial catches for direct local consumption are substantially under-represented in nationally reported statistics and should receive greater attention to support sustainable food security in Kenya (Onyango et al., 2021).

Major threats and challenges to water resource management in Kenya

Kenya's rich and diverse inland and marine ecosystems are under multiple threats and challenges. The Drivers-Pressure-State-Impact and Response (DPSIR) framework has been widely applied globally in assessing, addressing and communicating with regard to environmental problems (Troian et al., 2021). This framework provides a nexus between the causes of environmental problems and the resultant pressures, associated impacts and responses needed to resolve and manage specific environmental issues and challenges. This conceptual framework is used to understand, synthesize and visualize the cause-effect interactions of the threats and challenges facing water resources and to develop potential actions for improving the implementation of sustainable water resource conservation and management interventions in the country (Fig. 6). These threats vary in their severity of impacts and consequences as well as proposed mitigation measures as summarized in Table 6.

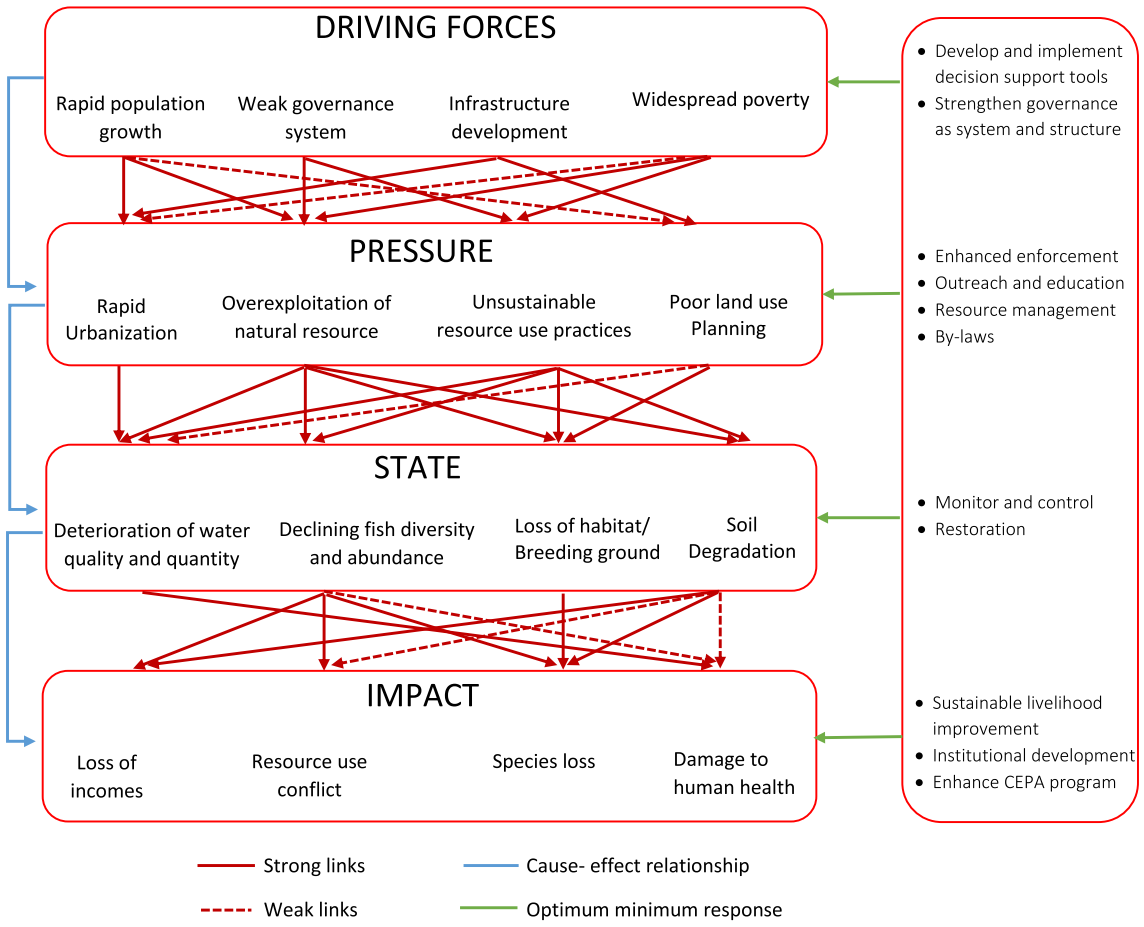

Fig. 6 Drivers-Pressure-State-Impact and Response (DPSIR) summary model of inland and marine water challenges in Kenya. Adapted from Wetlands International (2020) *Transboundary Wetland Management Plan for the Sio-Siteko Wetland Between the Republic of Kenya and the Republic of Uganda 2020–2030*. Wetlands International, Wetlands Across Borders Project, June 2020.

Table 6 Major threats and their causes, impacts, and consequences for water resources in Kenya.

Major threats and causes	*Impacts*	*Consequences*
Social drivers		
• Rapid population growth • Rural-urban migration • Infrastructural developments • Extreme poverty • Lack of education and awareness • Community alienation and marginalization	• Loss of system productivity • Resource use conflicts • Habitat fragmentation • Loss of biomass • Reduced boundaries and ecosystems • Fragmented river systems, inhibiting species movements	• Loss of revenue • Loss of livelihoods • Increased poverty • Loss of aesthetic value of resources
Environmental drivers		
• Climate change and extreme climate events • Catchment degradation due to poor agricultural practices • Urban and industrial Pollution • Extreme water level changes • Shoreline erosion and changes • Unsustainable land use management	• Increased erosion and sedimentation • More severe droughts and floods • Drying of rivers • Increased disease incidences • Coral bleaching • Reduced landscape vegetation	• Increased temperature, shifts in precipitation patterns and increase in the frequency of floods and droughts • Loss of land and property bordering water bodies • Loss of tourism opportunities • Loss of biotic integrity • Species extinctions
Ecological drivers		
• Harmful algal blooms • Eutrophication • Invasive species • Anoxia	• Biodiversity loss • Decline in aquatic species and extinction • Deteriorating of water quality and quantity • Reduced species growth, survival and reproduction	• Alteration of species size, range, phenology and survival • Loss of biotic integrity • Loss of revenue • Massive fish kills • Increased poverty
Ecosystem goods and services		
• Over abstraction of water resources • Degradation of resources • Overexploitation of fisheries resources • Unregulated harvesting of inland and marine water products	• Decline in harvestable resources • Loss of aesthetic value • Increased deforestation • Deteriorating water quantity and quality	• Decline in harvestable resources • Decreased revenue • Increased resource use conflicts • Increased poverty
Governance issues		
• Multiple and overlapping institutional mandates • Weak institutional linkages • Limited consultation of stakeholders • Inequitable resource access and control • Unilateral (often top down) decision-making • Weak monitoring, control and surveillance (MCS) • Inadequate capacity and resources at the local level to effectively manage resources	• Unsuitable exploitation of living resources • Undervaluation of ecosystem services • Limited ability to think beyond immediate needs • Diminishing livelihoods	• Decline in harvestable resources • Decreased revenue • Increased resource use conflicts • Increased poverty • Loss of aesthetic value

Modified from NEMA (2011) Freshwater, Coastal and Marine Resources. In: *Kenya: State of Environment and Outlook 2010* (pp. 124–169). National Environment Management Authority.

Key recommendations for sustainable management of inland and marine water resources

1. *Conserve, sustainably manage, restore, and remediate degraded ecosystems*: (i) consolidate and restore protected areas, landscapes, and watersheds for maximizing multiple ecosystem services; (ii) reduce deforestation rates to zero in the next decade and halt the degradation of terrestrial and aquatic ecosystems; (iii) reafforestation to improve and restore the forest cover within the gazetted areas and encourage tree plantation in uncultivated land; and (iv) implement systems to monitor, evaluate, incentivize, and hold stakeholders accountable for restoration and remediation measures.
2. *People empowerment and good governance*: (i) implement transparency and inclusive devolved governance system to improve terrestrial and aquatic resource management and strengthen human and terrestrial land and property rights; (ii) engage indigenous people and local riparian communities in planning and policy-making processes to promote their political representation at all levels of water resource governance; (iii) recognize different indigenous technical knowledge systems and promote intercultural education and information sharing through dialogs and coordinated fora where all actors convene and ventilate as well as share concerns, perspectives and ideas.

3. *Invest in a sustainable fisheries and aquaculture, lake and flowing rivers bioeconomy*: (i) invest in education, science, research, technology, and innovation; (ii) create fiscal and financial incentives to engage the private sector and multilateral institutions in innovation and sustainable fisheries and aquaculture value chains; (iii) sustainable intensification of existing aquaculture systems for increasing accessibility of aquatic foods, based on scaling of proven but infrequently adopted interventions; (iv) promote green job creation and capacity building; (v) invest in rural, urban, and peri-urban sustainable infrastructure.
4. *Expand sustainable land management interventions*: (i) diversify alternative livelihoods through climate-smart agriculture technologies, innovations and management practices; (ii) invest in sustainable land management interventions to reduce the impacts of pressures on water and land and contribute to improving food and nutrition security.
5. *Enhance compliance with environmental policies to reduce pollution and improve environmental health*: (i) strengthen environmental accountability mechanisms for industry players especially the manufacturing sector; (ii) invest in staffing and training to ensure that suitably trained government staff are dedicated to compliance are available to provide oversight on water related projects regardless of the source of funding; (iii) raise public awareness through campaigns to facilitate culture change and nationwide appreciation of the importance of environmental health for water resources.
6. *Mobilize financing and foster partnerships for water resource conservation, restoration, and sustainable development*: the current market economy and policy conditions favor deforestation over conservation or restoration. The scale of Kenya's blue economy, and the challenges it faces, call for ambitious, large-scale international finance development, and private and public financial partnerships to promote and sustain restoration, conservation, management, the development of sustainable value chains, payments for ecosystem services schemes, and investment in education, science, technology, and innovation.

Conclusion

Water is a primary life-giving resource in Kenya and across the globe. Its availability is an essential component in socioeconomic development and poverty reduction. In the face of a changing climate, rapid population growth, growing urbanization, increased deforestation and ecosystem degradation, and overexploitation of resources, water resources in Kenya could soon reach a tipping point beyond which sustainable utilization is impossible. The continuous expansion of uncontrolled agriculture, environmental degradation and extractive industries threatens freshwater and marine biodiversity. Addressing these emerging and persistent threats demands comprehensive water resource management and planning, coupled with extensive investment in climate-resilient water infrastructure. Improving the management and utilization of Kenya's rich and diverse aquatics resources will boost both growth and development in key sectors of the blue economy, such as fisheries, tourism, wave and wind energy production and bioprospecting. To safeguard the ecological integrity of freshwater and marine resources in Kenya, it is not only necessary to cease loss and degradation, but also to restore and remediate terrestrial and aquatic ecosystems. These efforts must be transboundary and support the development and implementation of landscape-level initiatives that help maintain connectivity and the health of freshwater ecosystems, ecological functions, and conserve and restore the heterogeneous biomes and their biodiversity while improving livelihoods and generating new economic activities.

Glossary

Catchment area The area of land bounded by watersheds draining into a river, basin or an ocean.
Conservation The care and management of a resource so that the resource maintains its ability to fulfill its functions and provide goods and services for present and future generations.
Drainage basin An area of land drained by a river and its tributaries (river system). It includes water found in the water table and surface run-off.
Ecosystem A geographic area consisting of all the organisms, as well as the non-living components of the environment with which the organisms interact, such as air, soil, water, and sunlight.
Headwater Watershed Upstream area that drains low-order streams to the main river channel.
Invasive species Non-native (or alien) species to the ecosystem under consideration and whose introduction causes or is likely to cause economic or environmental harm or harm to human health.
Land use Characterization of land based on human activities commonly practiced in a region (geographical area).
Sustainable management Present use of the environment or natural resources which does not compromise the ability to use the same by future generations or degrade the carrying capacity of supporting ecosystems.
Terminus Watershed The discharge or outflow area that drains the river system into a basin or an ocean.
Watershed An area of land that drains all the streams and rainfall to a common outlet.

Introduction

Watersheds are biophysical systems defining the land surface that drains water and waterborne sediments, nutrients, and chemical constituents in a stream channel, river, lake, or ocean specified by topographic boundaries (Brooks et al., 2012). They are the systems used to study the biogeochemical and hydrologic cycles in a region and make inference on the impact of human activities on terrestrial and aquatic ecosystem processes, structure and function. They support diverse lifeforms and are important habitats for both terrestrial and aquatic species.

Watersheds are described and mapped according to their position in the landscape, whereby, the catchment at the upper-most and unbranched streams are called headwater watersheds while at the river-outflow point are called the terminus watersheds (Duan et al., 2018). Depending on the stream size, they can be described as first order, second order or n-th order watershed. Consequently, large watersheds are a collection of many small watersheds, and every sub-catchment within a river basin is considered a watershed. The sub-catchments form local sites for river influences, socio-economic activities and anthropogenic influences that arise from various drivers of ecosystem change.

There are two categories of drivers of ecosystem change in watersheds; indirect and direct drivers. Indirect drivers include socio-economic and demographic factors affecting resource utilization, technological factors resulting in environmental degradation and cultural and government influences that affect values and decision framework on governance. In contrast, direct drivers impact on ecosystem processes and include pollution, resource exploitation, invasive species, and climate change and land-use effects among others. Major direct drivers of ecosystem change such as land-use are inextricably linked with indirect drivers. For instance, land cover conversion for agricultural use through deforestation can be linked to socio-economic and demographic

Table 1 Socioeconomic and environmental impact of land use change.

Land use change	*Socioeconomic impact*
Conversion of farmland and forests to urban development	Reduced land for food, timber, local agricultural economy, open space and environmental amenities
Agriculture and deforestation	Soil erosion, salinization, desertification, and other soil degradations hence reduced soil quality and agricultural productivity
Urban development	Organization of society, encroached rural communities, income segregation and economic disparities among communities
Land use regulations curbing development	Hinder function of market forces

Land use change	*Environmental impacts*
Agricultural run-off	Water pollution
Draining wetlands for crop production	Biodiversity loss, water diversion
Intensive farming and deforestation	Soil erosion, salinization, desertification, and other soil degradations
Deforestation	Greenhouse effect, destroys habitats that support biodiversity, affects the hydrological cycle and increases soil erosion, runoff, flooding and landslides
Urban development	Air pollution, water pollution, and urban runoff and flooding
	Habitat destruction, fragmentation, and alteration, biodiversity decline and species extinctions

Modified from Wu J (2008) Land use changes: Economic, Social, and Environmental Impacts. *Choices, Agricultural and Applied Economic Association* 23(4): 6–10, https://www.choicesmagazine.org/magazine/article.php?article=49.

changes, urbanization or settlements associated with technological developments, and change in the management of ecosystem or spatial configuration of the ecosystem affected by cultural and government influences. In this regard, land use change is a contributor to global societal challenges such as food security, climate change and biodiversity loss.

Even though land use change is necessary and essential for economic development and social progress, its socioeconomic and environmental impacts are evident (Table 1). In the last six decades, it has affected approximately a third of the global land area, especially, through deforestation and agricultural expansion in the tropics (Mwangi et al., 2015; Winkler et al., 2021). Land use is an important driver of hydrological and ecological changes (Lin et al., 2015) and has caused shrinking and fragmentation of watershed resources and modification of their natural landscapes (Rogger et al., 2017) thus impacting catchment run-off, drought and flooding. Land management practices have major influence on watershed resources including water, soil, air, nutrients, plants, and animals (Wu, 2008), with worrying trends in the developing countries (Xiong et al., 2017) where weak governance of natural resources (Arthur, 2014) and challenges with implementation of policy, institutional and legal framework are escalated by increasing population and overdependence on natural resource as primary source of livelihood.

Strengthening policy, institutional and legal frameworks and implementation of good governance for watershed resource serve as precondition for the successful watershed management and interventions especially in developing countries. This requires understanding of the hydrological basins at the watershed scale and their intersection with local populations through informed studies. We therefore review and analyze watersheds in Kenya with regards to human activities, drivers of ecosystem change, legal, policy and institutional frameworks and map land-use systems at national scale to depict the rich values of these ecosystems, their need for sustainable management and lessons to learn from a developing country grappling with conflicts between resource use demands and conservation.

Kenyan drainage basins

Kenya has five major drainage basins that water the whole country, namely, Lake Victoria, Athi, Tana, Rift Valley and Ewaso Ng'iro/Nyiro (Fig. 1), covering 8%, 11.5%, 21.7%, 22.7%, and 36% of the country, respectively (Seegers et al., 2003; Nyingi et al., 2013). They describe and depict a variety of watershed characteristics. Their headwater watersheds originate from tropical and montane rainforests in central and western parts of the country and flow eastwards to the Indian Ocean, northwards to Lake Turkana and south west into Lake Victoria (Fig. 2A). Their midstream are endowed with national parks, national reserves and conservancies teaming with terrestrial and aquatic biodiversity, while the terminus watersheds or river-outflow points that discharge into transboundary lakes or the ocean (Fig. 2B). These natural assets play a critical role in the achievement of socio-economic and ecological development in the country. They are exceptional geographical features, rich in biodiversity and endemic terrestrial and aquatic species supported by various habitats; from montane and afro-alpine highlands, forests, grasslands, rangelands to lakes, rivers, wetlands and marine environments that provide a wide variety of niches for many different species (Western et al., 2015). Like many tropical ecosystems, they are ecologically rich and with evidence of complex biotic interactions (Western et al., 2015) with fascinating theories (time, climate stability, spatial heterogeneity, competition, predation and productivity hypotheses) explaining these exclusive reservoirs of much of the world's biodiversity (Pianka, 1966; Sodhi et al., 2010; Schemske and Mittelbach, 2017).

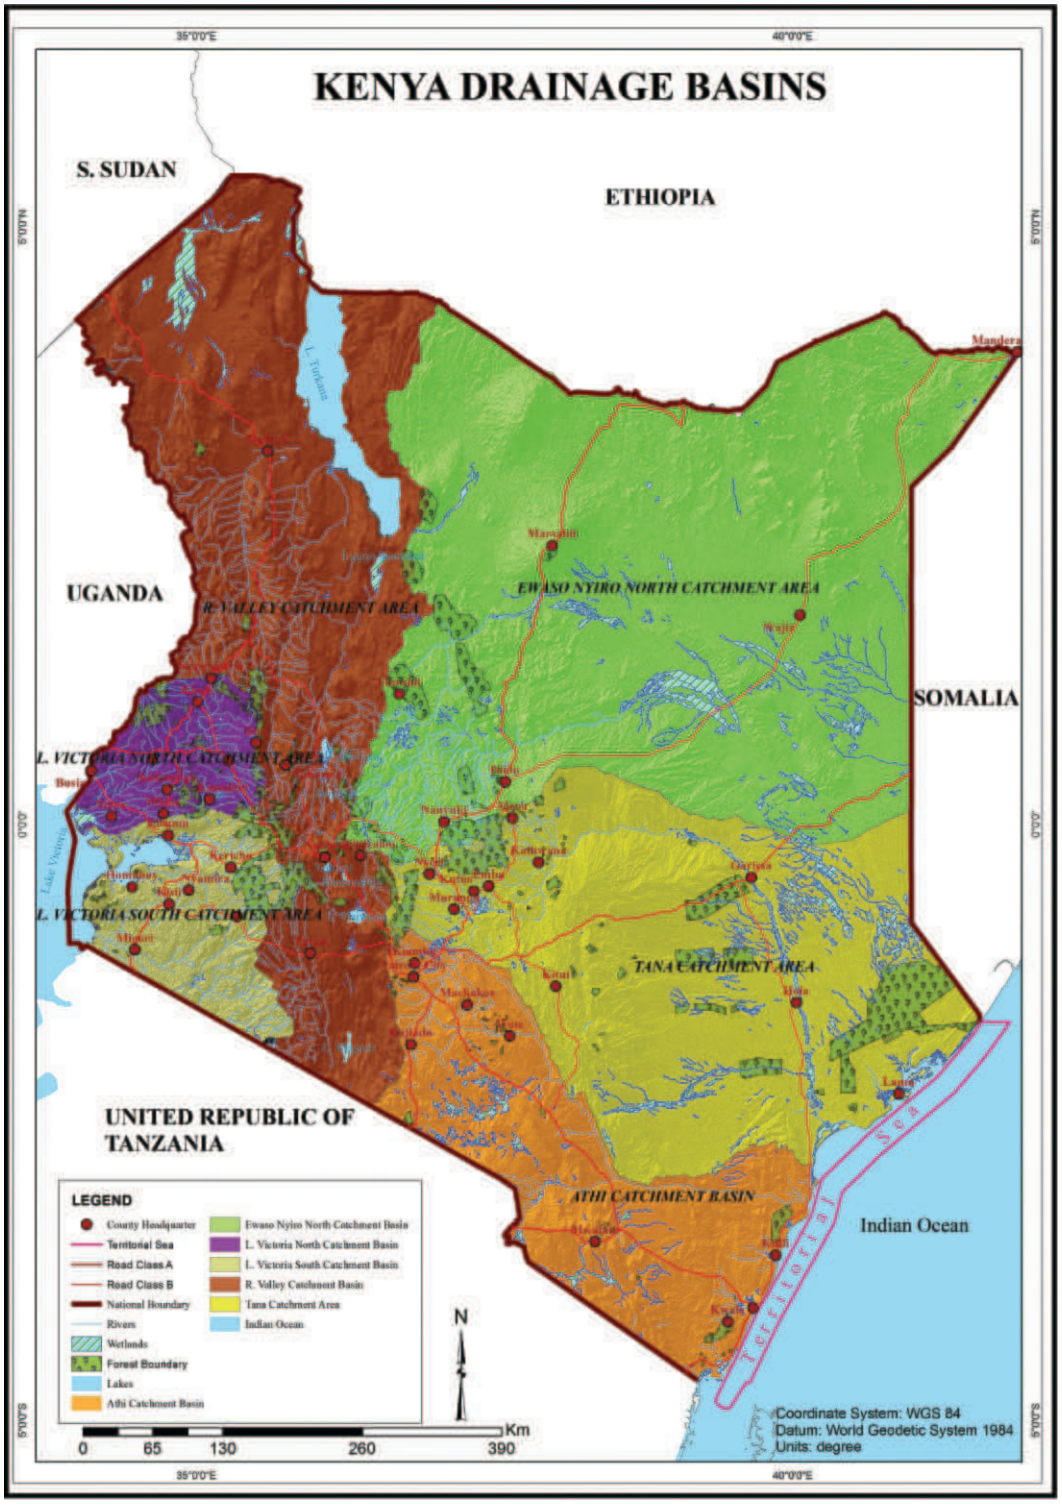

Fig. 1 Kenya's Drainage basins.

The five drainage basins differ in their environmental and socioeconomic characteristics and benefits. Ewaso Ng'iro (Fig. 2A) exhibits physical, socioeconomic and ecological diversities with high temporal and spatial variability in rainfall and has one of the steepest ecological gradients in water flow regime and temperature variations in East Africa (Kiteme et al., 2019; Providoli et al., 2019). A small fraction of the basin at the slopes and foot of Mount Kenya receives constant, periodic and reliable rainfall with fertile land for agriculture, but the rest of the basin is arid and semi-arid land with seasonal river flow and frequented by drought. Tana and Athi basins originate from Mount Kenya and Aberdare forests with fertile agricultural land at the headwaters. Athi stretches

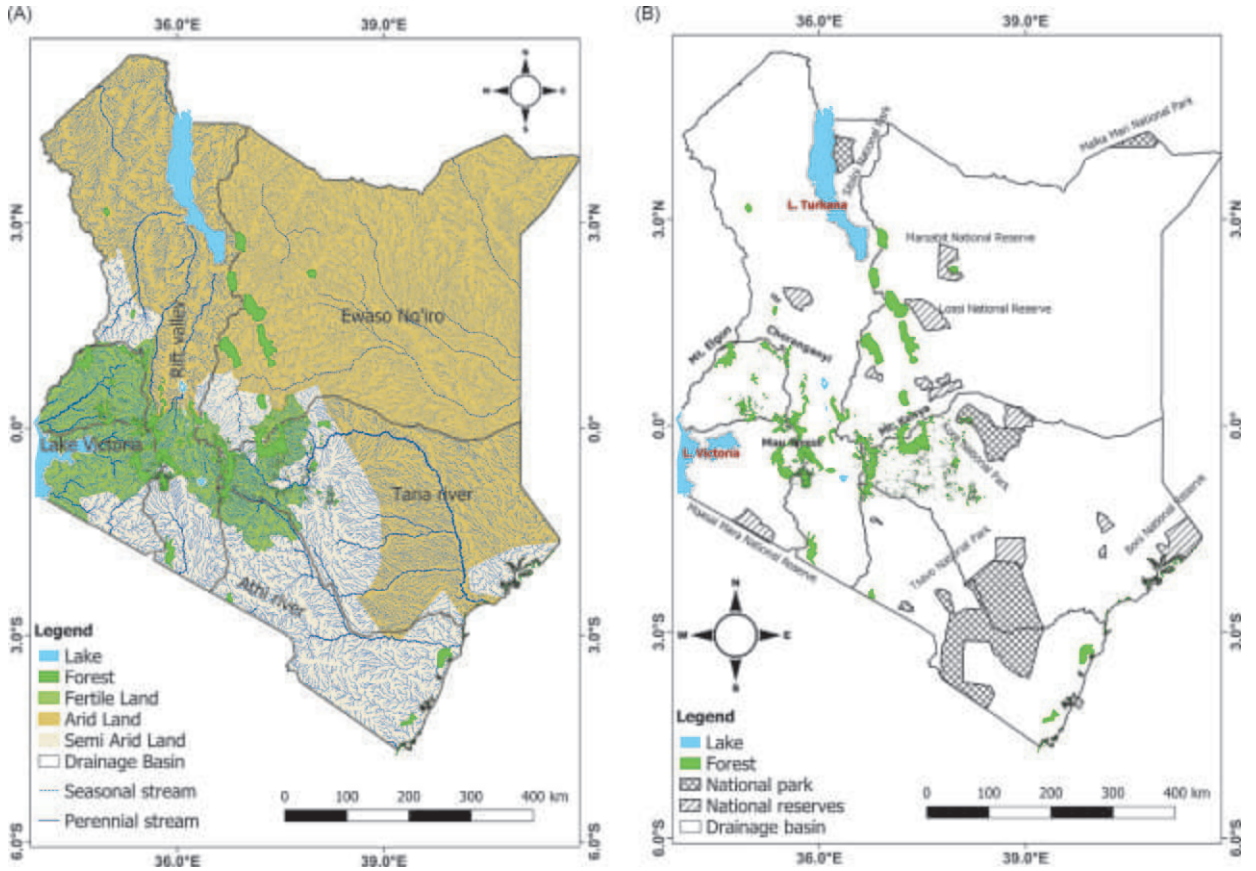

Fig. 2 Kenya landscape (A) land cover and (B) protected areas.

through semi-arid land into the ocean while Tana basin traverses both semi-arid and arid land (Fig. 2A). The two basins not only host over 40% of the Kenyan population with major dams and irrigation schemes (Langat et al., 2019), but also largest protected areas such as national parks and reserves in the plains (Fig. 2B), dominated by grassland (Tamooh et al., 2014; Marwick et al., 2018). The Rift valley basin exhibits high temporal and spatial variability in rainfall. Its headwaters originate from the Cheranganyi, Mau and Aberdare forests with fertile agricultural land and extends northwards into arid land before draining into Lake Turkana and southwards through semi-arid land into Lake Natron (Fig. 2A). The basin attracts birdwatchers due to the string of alkaline lakes which attracts flamingos, pelicans, and many other species. Lastly, the Kenyan side of the Lake Victoria drainage basin stretches through fertile agricultural land into the second largest freshwater lake globally, except the mid-stream of Mara River basin which is a semi-arid area bordering Tanzania and within the Maasai Mara National Reserve. The headwaters of Lake Victoria basin originate from Mount Elgon, Kakamega, Cheranganyi and Mau Forests (Fig. 2A). The region is considered as the food basket for the country since it is very productive, but also is a densely populated basin, with more than 500 persons per square kilometer (World Bank, 2016; Sayer et al., 2018; Olaka et al., 2019).

Land use in Kenyan watersheds

The headwaters through terminus watersheds for the five drainage basins have experienced fundamental environmental and ecological changes especially due to change in land use and land cover (Krhoda, 2006; MEMR, 2012a, b) with majority of the land being pastoral in the semi-arid zones and agricultural in the humid zones (UNEP, 2009). Average land area under cultivation has increased over the last decades as a result of clearing forests, farming in marginal lands and conversion of humid rangeland to farmlands causing an increase in competing land uses including forestry and wildlife conservation, new cultivation methods and cropping systems as well as the introduction of irrigation schemes, sedentary farming and livestock management (UNEP, 2009). Competing land uses is compounded by the fact that over 89% of the country is Arid and Semi-Arid Land (ASAL) occupied by roughly 38% of the country's population (Republic of Kenya, 2012; Bedelian et al., 2019), while the remaining 11% being non-arid land occupied by more than half (62%) of the country's population, and mostly under agricultural activities. The country depends on agriculture as its primary source of income; consequently, direct and indirect contribution of agriculture accounts for 51% of Kenya's GDP, 60% of employment and 65% of exports (Birch, 2018; World Bank Group, 2018). Agriculture also supports about 80% of Kenyan population (UNEP, 2009).

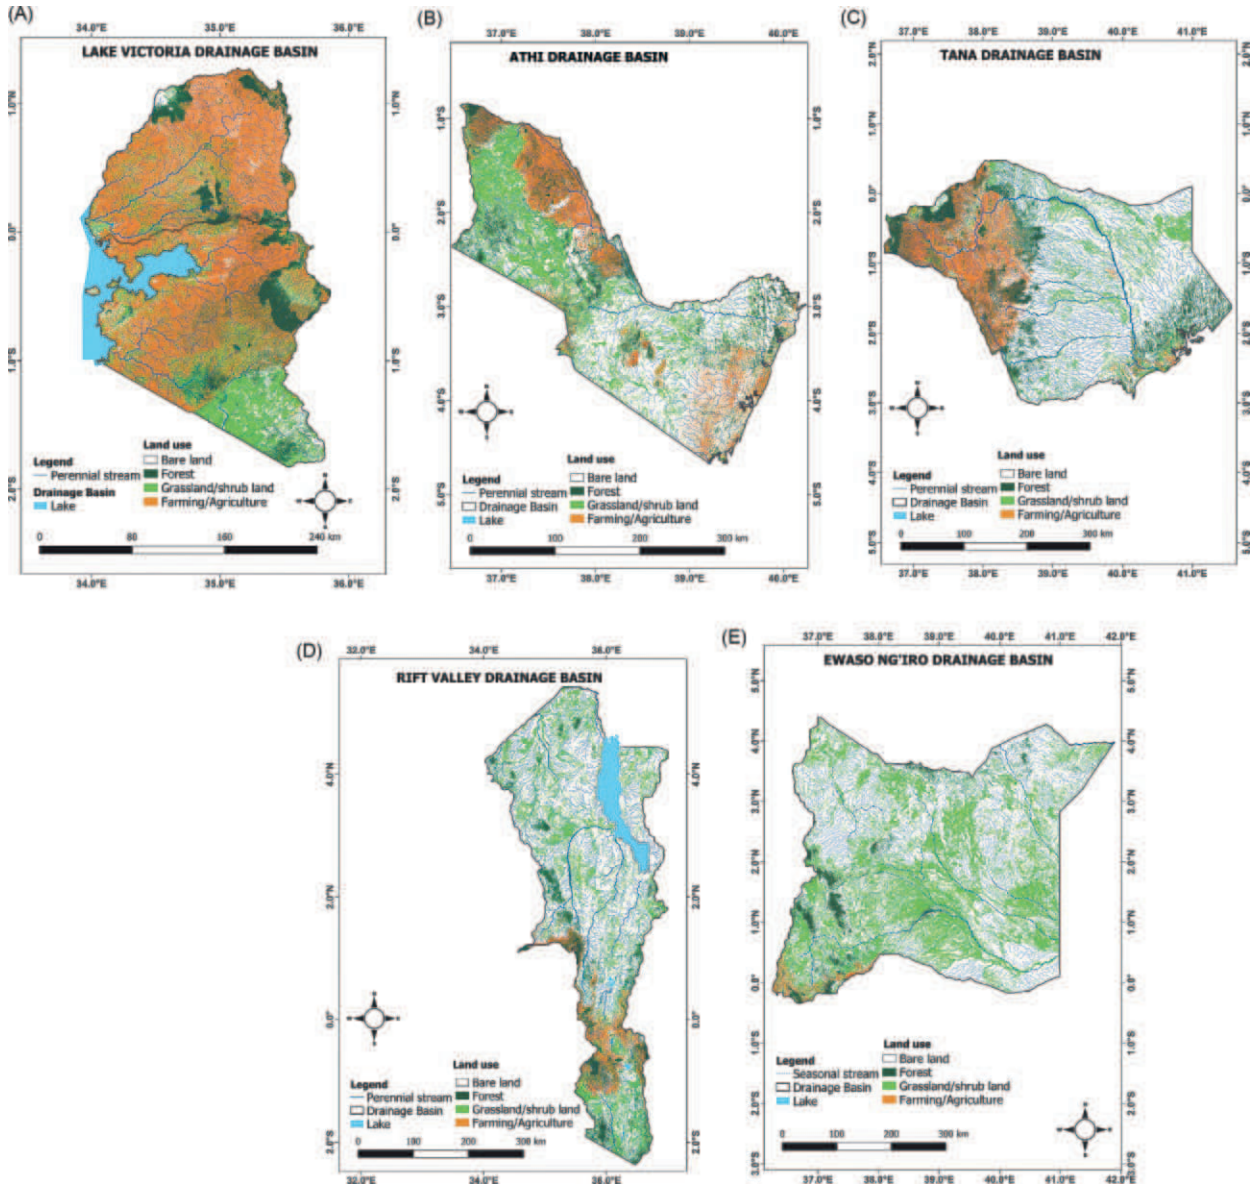

Fig. 3 Agricultural land use patterns at Kenyan drainage basins (A) Lake Victoria, (B) Athi river, (C) Tana river (D) Rift valley and (E) Ewaso Ng'iro.

Most of the agricultural production (subsistence and commercial) is concentrated at the headwater watersheds of the five drainage basins (Fig. 3) thus impacting downstream water availability for different uses. Agricultural production ranges from small- and medium-scale cultivations to mechanized large-scale cultivation systems, characterized by the high use of fertilizers, pesticides and herbicides, as well as supplementary irrigation. Agricultural activities are mostly concentrated (i) throughout the Lake Victoria basin (Lake Victoria Basin Commission and GRID-Arendal, 2017; Achieng et al., 2021) with the largest proportion of agricultural activities (Fig. 3A), (ii) at the upper and mid reaches of Athi and Tana basin (Kauffman et al., 2014; Langat et al., 2019) with considerable proportion of agricultural land use (Fig. 3B and C) and (iii) upper Rift Valley (Kuiper and Greiner, 2021) and Ewaso Ng'iro basins (Lanari et al., 2018) with the least proportion of agricultural practice (Fig. 3D and E). Athi and Tana basins also have many irrigation schemes and major hydropower stations resulting in competing water demand and scarcity (Langat et al., 2019) while Rift Valley and Ewaso Ng'iro basins are largely bare arid land with seasonal rivers (Fig. 3D and E).

Impact of land use and drivers of ecosystem change

Kenya has seen rapidly growing populations over the last six decades, from 10.9 million in 1969 to 47.6 million in 2019. The population is youthful (75.1%), largely rural (68.9%) and depends on natural resources for livelihoods (KNBS, 2019). Majority of

the population lives within the non-arid land and around the forests at the drainage basins, consequently impacting on land use and causing pressure on watershed resources (Table 2). At the headwaters and forested land, deforestation, forest degradation and encroachment are driven by (i) agricultural extension subject to population pressure, rural poverty, and limited alternative sources of income, (ii) excision, resulting from poor governance, political interference, and weak institutional capacity to protect forested land, (iii) wood extraction for commercial logging and extraction of forest products for subsistence and income, (iv) livestock grazing, and (v) infrastructural development (Ongugo et al., 2014; Achieng et al., 2017).

Drivers of land use change at the midstream to terminus watersheds vary with the drainage basins but range from settlements, urbanization, damming and hydropower production, pastoralism, mining, conversion of wetlands into farmlands (Table 2) and a multitude of other emerging demands on watershed resources (Mulinge et al., 2016) which has led to water crisis of unprecedented scale at the arid land and downstream of the basins (Wamuyu, 2014; Schilling et al., 2012; Providoli et al., 2019). Furthermore, increased competition and conflicts between different user groups, namely large-scale commercial farms, smallholders, pastoralists, large-scale ranchers, and wildlife conservation among others, result in water scarcity, degradation, human encroachment, illegal abstraction and overexploitation of watershed resources (Table 3). Consequently, the amounts of land in the agriculturally productive highlands and the productivity of these lands are declining due to growing populations and other socio-economic variables (poverty, knowledge, attitudes and perceptions, culture and gender imperatives).

Transboundary issues are also growing in importance since all of the drainage basins are shared resource with neighboring countries such as Ethiopia, Somalia, Tanzania and Uganda. Catchment activities in one country impact on resources in another. In most of the region, rapidly evolving socio-economic dynamics are propelling demand upstream, which in turn is threatening downstream supplies. The impacts and potential remedies are even more complex when watershed resources are shared internationally. A major complexity faced at the basins is that watershed management and governance processes take place at different spatio-temporal scales and societal levels which involve a multitude of actors. The societies in these regions have to find sustainable sub-basin management solutions; however, the decisions they make impact on others far away. Connection between social and institutional development, the available information base, legal requirements and policy development processes should be smoothly weaved to support each other for informed decision-making and effective action in the watersheds.

Policy, legal and institutional framework

Implementation of good governance for watershed resources serves as a precondition for the successful watershed management and interventions. In Kenya, the promulgation of a new constitution in the year 2010, anchored on sustainable development, rule of law, and protection of ecologically sensitive areas and devolution of power and resources, led to review and alignments of laws and policies, as well as creation of new institutions and structures for watershed governance. The Constitution established two levels of Governments: National and Counties with clear functions though with mutual interactions and intergovernmental structures to ensure smooth operations and dispute resolution between the two levels of Governments. Devolution aims to facilitate the involvement of stakeholders and enhance public participation at different levels of the watershed and sharing of resources (including power) in relation to natural resources management, especially at the grassroots-level. Thus, in Kenya, Natural resources management function is therefore a concurrent jurisdiction between National and County Governments as espoused in the Fourth Schedule of the Constitution as well as Articles 6(1) and Article 185 (2) & 186 (1) for County and National Governments respectively. The two-tier governmental functional boundary is also provided in Article 187 (2) of the Constitution of Kenya 2010.

Government Ministries in watershed management include Ministries in charge of Water, Sanitation and irrigation; Agriculture, Livestock, Fisheries and Cooperatives; Wildlife and Tourism; Environment and Forestry (that hosts Climate Change Directorate); and Petroleum and Mining operating at national level, among others (Table 4). All these sectors are mirrored (replicated) at the county-level, and require capacity strengthening by the National Government (human, financial and technological capacity) for their proper functioning, in line with function Number 32 of the National Government under the Constitution. It is also important to note that within each of these line ministries, there are a number of Semi-Autonomous Government Agencies (SAGAs) and independent Constitutional Commissions and offices that work closely with the ministries in discharging the relevant natural resources management and development mandates.

Other institutions, especially State cooperations such as Kenya Forest Service, Kenya Wildlife Service, Kenya Water Towers Agency, National Environment Management Authority and Kenya Fisheries Service as well as National Land Commission are also involved and have a major stake in conservation, development, and sustainable management of the terrestrial and aquatic resource in the watersheds (Mwangi et al., 2015) from the National to the Community level. For instance, the institutional framework for Water Sector under Water Act 2016 is shown in Fig. 4 (Puzyreva and Roy, 2018).

However, governance in watershed management still faces major challenges including data sharing, overlapping functions and responsibilities between or among state cooperations, inadequate funds for cutting-edge research to inform policies and regulations, or limited skilled personnel and shortage of essential facilities. Other challenges include perennial conflicts among different communities, especially pastoralists in drylands experiencing little rainfall and water shortage, and change in land cover in agriculturally productive land. The drainage basins also traverse many county governments that exhibit physical, socioeconomic and ecological diversities hence varying watershed management (priorities as well as conflicts) at community level within a watershed.

Table 2 Major land use and drivers of ecosystem change at the drainage basins.

Basin and Basin area (sq. km.)	*Major land use*	*Pressure*	*Impact*
Lake Victoria North 32,384 sq. km. Lake Victoria South 18,613 sq. km.	Fishing, large-scale farming, Mining, harvesting papyrus reeds, brick making, forestry, pastoralism, conservation, national reserve, tourism and recreation, irrigation, power production/energy, water supply, national reserve, artisanal products	• Inappropriate land use and overutilization • Conversion of wetlands to agricultural land • Unsustainable exploitation of resources • Land subdivision and fragmentation	• Pollution • Loss of land cover • Invasive species • Reduced water quantity and quality • Loss of biodiversity • Flooding • Reduced fisheries
Rift Valley 138,459 sq. km.	Conservation, mining, fishing, forestry, pastoralism, energy- geo and hydropower, ranching, irrigation, tourism and recreation,	• Urbanization • Inappropriate land use • Conversion of land for agriculture • Unsustainable exploitation of resources • Increased demand for resources • Land subdivision and fragmentation	• Pollution • Soil erosion/siltation • Loss of land/forest cover • Overgrazing • Reduced quantity and quality of water
Ewaso Ng'iro 213,731 sq. km.	Large scale commercial farms, pastoralism, ranching, wildlife conservancies, oil and gas exploration, forestry, grazing, water supply, fish farming, tourism	• Inappropriate land use • Overutilization of water • Conversion of land to agriculture • Overstocking of livestock • Settlements • Loss of catchment forests • Increased demand for resources • Reduced water levels • Land subdivision and fragmentation	• Pollution • Soil erosion/siltation • Overgrazing • Reduced water volume
Tana 120,925 sq. km.	Large scale farming, conservation, irrigation, pastoralism, mining-sand, fishing, quarrying, forestry, hydropower generation, recreation, water supply	• Inappropriate land use • Overutilization of water • Conversion of land to agriculture • Overstocking of livestock • Settlements • Loss of catchment forests • Increased demand for resources • Reduced water levels • Land subdivision and fragmentation • Damming	• Pollution • Soil erosion/siltation • Overgrazing • Reduced water volume • Loss of critical habitats and species • Reduced hydrological capacity • Increased river salinity as a result of damming • Reduced fisheries production
Athi 67,337 sq. km	Wildlife conservation area (Nairobi National Park Amboseli, Tsavo East and Tsao West, Shimba Hills), industrial use, farming (subsistence and commercial), pastoralism, livestock ranching, limestone, fishing, forestry, energy-wind and thermal water supply, natural conservation and recreation, irrigation, sand harvesting, dry season grazing, cultural and spiritual use, watering points for livestock, wastewater treatment, fishing	• Over-exploitation of surface and groundwater resources • Wetland resource degradation • Unregulated diversions of river channels • Catchment degradation due to overgrazing and sand harvesting • Land use changes for settlement and agriculture • Climate change and variability	• Acute water scarcity due to high water demand • Limited ground water recharge • Changing river regime • Pollution of water resources from industrial effluents, and agricultural and domestic waste

Modified from MEMR (2012a) *Kenya Wetlands Atlas*. Nairobi, Kenya: Ministry of Environment and Mineral Resources, https://na.unep.net/siouxfalls/publications/Kenya_Wetlands.pdf.

Watershed governance

Legal and institutional frameworks play a key role in sustaining environmental goods and services at the watershed scale. They act as both carrot and the stick for effective governance, especially in enhancing natural resources stewardship. While polices are tied to politics, having strong policies does not necessarily translate into sustainable watershed resources management, if (political) goodwill is lacking at national and subnational (county and ward) levels. Goodwill fosters effective implementation and ensures resourcing for specific actions for green growth, resilient economies and ecosystems. Equally, policies and legislative regimes that give birth to strong institutions to regulate human behavior on ecosystems and watershed resource use and interactions, are key to sustainable development. This is core in setting good governance principles relating to sustainable watershed resources use, equity and equality, rule of law, access to and control of resource as well as conflict management.

Table 3 Water management challenges in Kenyan drainage basins.

Drainage basin	*Primary challenges*
Athi	Acute water scarcity due to demand exceeding availability
	Pollution of water resources from agro-industries and waste disposal
	Catchment degradation due to overgrazing and sand harvesting
	Over-exploitation of surface and ground water resources.
Ewaso Ng'iro	Acute water scarcity due to demand exceeding availability
	High salinity of groundwater in certain areas underlain by basement rocks and colluvial deposits
	Catchment degradation due to overgrazing, poor farming practices and encroachment into wetland areas.
Lake Victoria	Degradation of water resources from both point and non-point sources of pollution
	Catchment degradation through soil erosion, siltation, landslides, deforestation, destruction of springs and human encroachment into the watershed
	Depletion of water resources through planting of exotic trees
	Frequent flooding along the shores of Lake Victoria.
Rift Valley	Degradation of water resources from both point and non-point sources of pollution
	Illegal abstractions and over-exploitation
	Quarrying and mining along river banks
	Human encroachment into and destruction of the watershed.
Tana	Acute water scarcity
	Degradation of water resources from both point and non-point sources of pollution
	Catchment degradation in Mount Kenya and the Aberdare Range slopes, soil erosion and overgrazing in the lower parts of the region
	Human encroachment into the watershed
	High salinity of ground water (due to salt water intrusion) in the lower Tana due to over-exploitation
	Increased water resource demand owing to urbanization and industrialization.

Modified from MEMR (2012a) *Kenya Wetlands Atlas*. Nairobi, Kenya: Ministry of Environment and Mineral Resources, https://na.unep.net/siouxfalls/publications/Kenya_Wetlands.pdf.

Local community participation and involvement in sustainable utilization of resources within watersheds are also very important, especially where the resource is the primary source of income and food (livelihood). Conflicts between resource use demands and conservation are evident due to rare alternative source of livelihoods. Community participation and involvement enables local people to identify and prioritize their environmental problems accurately, ensure efficient resource allocation, promote greater respect for decisions made with local inputs such as rules for resource use, allow for easier monitoring of resource use and give marginalized and vulnerable groups greater influence on local policy (Larson, 2003).

Understanding of hydrological basins at the watershed scale and their intersection with local populations for effective conservation and management of the landscapes and the natural resources is extremely important. This is only possible with well formulated studies on the landscape with integration across disciplines and involving the community within the watershed as well as the incorporation of technological advancements into watershed management. Cutting-edge research to inform governance is currently weak due to limited skilled human resource in the region. Very few studies exist on assessment, monitoring, mapping and modeling of these ecosystems to correlate them with the socioeconomic and geo-political imperatives to establish impacts and ecological changes. This disconnect and lack of intersection analysis, is possibly the genesis of all the challenges in Kenyan watersheds. Natural resources including watersheds are still managed with the traditional 'conservationist' approaches, giving little attention to social, economic and political dimensions – the key good governance ingredients - in land-based resources management and development.

Conclusion

Kenyan watersheds are rich ecosystems supporting diverse aquatic and terrestrial communities. The fertile lands flourish with human population practicing subsistence and commercial agriculture while, the arid and semi-arid land is populated with pastoralists and wildlife. Change in land cover, especially due to agriculture and deforestation are the major socioeconomic and environmental drivers of ecosystem degradation. Their impacts on the watershed include pollution, soil erosion, siltation, loss of land cover, reduced water quality and quantity, reduced hydrological capacity, acute water scarcity, biodiversity loss and loss of critical habitat among others. Despite the established policies, legal and institutional instruments and infrastructure, with improved governance in watershed resource due to decentralized government and devolution that facilitates the involvement of stakeholders and enhances public participation at different levels of the watershed management; skilled human resource and cutting-edge research are still imperative in understanding the hydrological basins at the watershed scale and their intersection with local populations for their effective conservation and management.

Table 4 Policy, legal framework and institutions involved in watershed governance in Kenya.

Policy	*Legal Framework*	*Governance on Water Catchment*	*Institution*
	The Constitution of Kenya 2010	The supreme law that guides human development, environmental and land-resources management and conservation in the Country. It facilitates justice and entrenches the protection of human rights (in all forms including social, cultural, environmental and political) for purposes of achieving ecologically sensitive development and use of natural resources	Government of Kenya (GoK)
Forest Policy 1968; Forest Policy 2020	The Forest Act 2016	This law guides and coordinates actions toward development and sustainable management, including conservation and rational utilization of all forest resources for the socio-economic development of the country areas.	Ministry of Environment and Forestry/Forest Service (KFS)
Water Policy Sessional Paper I of 1999; Sessional Paper No 1 of 2021	Water Act 2016	Provides the legal and institutional framework as well as action plan for coordinating sub-sectors in water resources development and management	Ministry of Water & Sanitation and Irrigation
Several (draft) policies	Agriculture Act (Cap 318; rev 2012)	Seeks to promote and maintain a stable agriculture, and guide conservation of soil and its fertility and to stimulate the development of agricultural land in accordance with the accepted practices of good land management and good husbandry.	Ministry of Agriculture, Livestock, Fisheries & Co-operatives
The National Wildlife Policy 2020	Wildlife Conservation and Management Act 2013	This guides the country toward securing a healthy and resilient wildlife, Kenya's heritage, by providing efficient and effective policy, legal and institutional framework for the conservation and management of Kenya's wildlife resources	Ministry of Environment and Forestry
		framework for the conservation and management of Kenya's wildlife resources including habitats/ecosystems	Kenya Wildlife Service (KWS)
	County Governments Act No 17 of 2012	Specifies the functions, powers and responsibilities of, and that guide, County Governments in service delivery including those that relate to natural resources/watershed management	County Governments
Sessional Paper No 7 of 2016 on Mining and Mineral policy	Mining Act 2016	Vests mineral resources under the custodianship of the National Government and guides all mineral operations and development in all land categories such as parks and forest reserves in Kenya	Ministry of Petroleum & Mining
	Regional Development Authority Acts	Facilitates basin-based regional planning, socio-economic and ecologically resilient development	Regional Development Authorities
Session Paper 6 of 1999	EMCA Act No. 8 of 1999 (amended in 2015)	This is the motherboard/main framework law that guides and co-ordinates activities related to the management and conservation of the environment including natural resources such as wetlands and riparian lands	Ministry of Environment and Forestry/ National Environmental Management Authority
	Fisheries Management and Development Act No 35 of 2016	Promotes and coordinates activities relating to conservation, management and development of fisheries and other aquatic resources to enhance the livelihood of communities' dependent on fishing. It establishes the Kenya Fisheries Services	Ministry of Agriculture Livestock, Fisheries & Co-operatives
Sessional Paper No 3 of 2009 on the National Land Policy	Land Act No. 6 of 2012 (rev 2016); National Land Commission Act No 5 of 2012 (rev 2015); Community land Act No 27 of 2016 and Land Registration Act No 3 of 2012	These are the main laws governing land in Kenya that foster the realization of sustainable land and natural resources management and administration including the protection of ecological sensitive areas such as wetlands, riparian lands, water catchment areas, forests and biodiversity hotspots.	Ministry of Lands and Physical Planning and the National Land Commission
